similar to the database UF. If the RfD/RfC is based on animal data, a factor of 3 is often applied if either a prenatal toxicity study or a two-generation reproduction study is missing, or a factor of 10 may be applied if both are missing (Dourson et al., 1996). Dourson et al. (1992) examined the use of the database UF by analyzing ratios of NOAELs for chronic dog, rat, and mouse studies and reproductive and developmental toxicity studies in rats. They concluded that reproductive and developmental toxicity studies provide useful information for establishing the lowest NOAEL, and if one or more bioassays are missing, a factor should be used to address this scientific uncertainty in deriving a chronic RfD.

If data from the available toxicology studies raise suspicions of developmental toxicity and signal the need for developmental data on specific organ systems (e.g., detailed nervous system, immune system, carcinogenesis, or endocrine system), then the database factor should take into account whether or not these data are available and used in the assessment and their potential to affect the POD for the particular duration RfD or RfC under development.

If the RfD/RfC is based on human data, a similar assessment regarding the completeness of the database is necessary. Information on life stages and organ systems may come from either animal or human studies. If data on specific life stages or organ systems are unavailable or limited data suggest that availability of more extensive data might decrease the POD, this should be taken into account in assigning a database UF. For example, depending on the database and what is known about the chemical, the lack of a two-generation animal reproductive toxicity study might be considered a deficiency even if the reference value is based on human data. In any case, the size of the database factor to be applied will depend on other information in the database and on how much impact the missing data may have on determining the toxicity of a chemical and, consequently, the POD.

4.4.5.6. *Subchronic-to-Chronic-Duration UF*

As indicated earlier, a duration adjustment currently in use is the application of a UF when only a subchronic duration study is available to develop a chronic reference value such as the RfC or the RfD (U.S. EPA, 1994). A default value of 10 for this UF is applied to the NOAEL/LOAEL or BMDL/BMCL from the subchronic study on the assumption that effects from a given compound in a subchronic study occur at a 10-fold higher concentration than in a corresponding (but absent) chronic study. This factor would be applied subsequent to the adjustment of the exposures from intermittent to continuous, as above.

The specific use of a UF applied to a subchronic study in the derivation of a chronic reference value is reasonable. Some work has been published on this aspect of extrapolation (Lewis et al., 1990; Pieters et al., 1998). Guidance for replacement of the default factor of 10 by

CSAFs may be forthcoming. It would be appropriate to incorporate such data into applicable assessments. In the current practice, this factor is applied when a chronic reference value is derived from a database in which the critical study is of subchronic duration. No chronic reference value is derived if neither a subchronic nor chronic study is available. The application of a UF to less-than-subchronic studies is not part of the current practice, but further exploration of this issue may be appropriate. For short-term and longer-term reference values, the application of a UF analogous to the subchronic-to-chronic duration UF also needs to be explored, as there may be situations in which data are available and applicable but they are from studies in which the dosing period is considerably shorter than that for the reference value being derived.

4.4.5.7. *Modifying Factor (MF)*

A clear definition of intended usage for an MF is lacking. The only comments located about the MF are in the RfC methodology (U.S. EPA, 1994), and they indicate that the MF is intended to account for scientific uncertainties in the study or database that are not explicitly treated by other UFs. It is further stated that use of the factor depends principally on professional judgment and assessment. Some example applications are also given, such as accounting for small sample size or for poor exposure characterization in the principal study. The definition in the IRIS glossary gives similar examples.

The description of the database UF shows substantial similarity to that of the MF. Text on the database UF indicates that this factor attempts to recognize that without a comprehensive array of endpoints there is uncertainty as to whether all possible toxicologic endpoints at the various life stages are adequately addressed. Without this information, uncertainty remains as to whether the critical effect chosen for RfD or RfC derivation is either the most sensitive or the most appropriate. There are only seven cases in IRIS for which an MF has been applied: RfDs for chromium III, chromium VI, nitrite, 1,1-biphenyl, and manganese and RfCs for methyl ethyl ketone and acetonitrile. The rationale for these varies considerably but in all cases appeared to be for reasons that could be considered under other UFs.

Recent developments in the IRIS process include the obligation for risk characterization within the assessments. A central aspect of risk characterization includes discussing confidence and uncertainties in the quality of data used and the “clarity, transparency, consistency and reasonableness” of the assessment (U.S. EPA, 2000b). Within the risk characterization, the assessor has a pathway provided to discuss and analyze all aspects of uncertainty about the database, including the adequacy or limitations of the database, directly in the assessment.

The Panel considers the purpose of the MF to be sufficiently subsumed in the general database UF. The Panel also notes that the risk characterization section of assessments may be used to provide a full and complete characterization of all uncertainty, including any residual uncertainty that may not be addressed by the other UFs. In view of these factors, the Panel recommends that use of the MF be discontinued.

4.4.6. Future Directions

4.4.6.1. *Chemical-Specific Adjustment Factors (CSAFs)*

There is growing support for the use of CSAFs in place of DAFs (see Section 4.4.3.), and this will provide an incentive to fill existing data gaps (Murray and Andersen, 2001; Meek, 2001; Meek et al., 2001; Bogdanffy et al., 2001). Additional chemical-specific data permit the replacement of components of interspecies or inter-individual variation with data-derived values in the context of the traditional default framework as developed by Renwick (1993) and revised by IPCS (1994). The following is a brief discussion of available methodologies that promote the use of CSAFs in risk assessment.

Renwick (1993) described the use of toxicokinetic and toxicodynamic data as a means of replacing the traditional 10-fold safety factors for human sensitivity and experimental animal-to-human extrapolation in developing acceptable daily intakes. His data-derived approach assigns default values for both toxicokinetic and toxicodynamic differences within each traditional 10-fold safety factor. Specifically, Renwick proposed dividing both the interspecies and the inter-individual UFs into a factor of 2.5 for toxicodynamics and a factor of 4.0 for toxicokinetics. IPCS (1994) has adopted the data-derived approach initially proposed by Renwick (1993), with a slight modification in the UF for inter-individual variation (3.16 for toxicodynamics and 3.16 for toxicokinetics). IPCS has used this approach in several of its recent risk assessments (e.g., IPCS, 1998), and EPA is proposing a similar approach for boron (U.S. EPA, 2001b).

IPCS has developed a draft guidance document (IPCS, 2001) to assist risk assessors in the use of experimental data in deriving CSAFs for interspecies differences and human variability in dose/concentration response assessment. CSAFs have been adopted because they better describe the nature of the refinement to the usual default approach.

For several years, EPA used a more qualitative approach to modify the usual 10-fold default values (Dourson et al., 1996). Recently, it has used a data-derived approach as one of the methods to derive a UF for boron (U.S. EPA, 2001b).

EPA has not yet established guidance for the use of chemical-specific data for deriving UFs, but the division of UFs into toxicodynamic and toxicokinetic components is in the RfC methodology (U.S. EPA, 1994). EPA's assessments of data assume a division of both

interspecies and intraspecies UFs into toxicokinetic and toxicodynamic components that have assigned default values of 3.16 ($10^{0.5}$) each. The Agency will develop its own guidance for the use of CSAFs in risk assessment, based on some of the available methodologies (e.g., IPCS).

The Technical Panel would like to caution the user that for many substances there are relatively few data available to serve as an adequate basis to replace defaults for interspecies differences and human variability with more informative CSAFs. Currently, relevant data for consideration are often restricted to the component of uncertainty related to interspecies differences in toxicokinetics. Although there are fewer relevant data with which to address the other four components namely—interspecies (animal-to-human) differences in toxicodynamics, intraspecies (human) variability in toxicokinetics, intraspecies (human) variability in toxicodynamics, and adequacy of the database—it is anticipated that availability of such information will be needed to apply CSAFs. Specifically, the data-derived CSAF approach for any single substance is necessarily determined principally by the availability of relevant data. The extent of data available is, in turn, often a function of the economic importance of the substance, and this is frequently related to the extent of potential human exposure.

4.4.6.2. *Probabilistic Approaches*

Another approach to quantifying uncertainty in RfD or RfC derivation when data are not sufficient to develop a chemical-specific or biologically based dose-response model is probabilistic analysis. When the available data are sufficient to meaningfully characterize the distributions of interest, a probabilistic approach would provide results as a distribution rather than as a single measure for the dose/concentration-response. For example, distributions could be used for inputs into a toxicokinetic model to derive a distribution of internal dose metrics. Also, the approaches described in the draft IPCS guidance document (IPCS, 2001) are amenable to probabilistic analysis.

Probabilistic analysis for human health assessments generally has been confined to the exposure variables. In deriving human health toxicity reference values, inter-individual variability in toxicokinetics and toxicodynamics is usually represented with a UF because data are insufficient to support a more quantitative representation of these sources of inter-individual variability. Several studies have been published addressing the use of probabilistic data for health assessments (Baird et al., 1996; Maull et al., 1997; Slob and Pieters, 1998; Swartout et al., 1998; Brand et al., 1999; Gaylor and Kodell, 2000; Evans et al., 2001). The Technical Panel recommends that the Agency further evaluate approaches such as probabilistic analysis for characterizing variability and uncertainty in toxicity reference values.

4.4.7. Summary of Key Points from the Case Studies

Two case studies were developed to illustrate many of the recommendations in this report. The studies are for two hypothetical chemicals: Inhalate, a synthetic halogenated aliphatic alkene, and Luteinate, a new pesticide that acts via the neuroendocrine system.

The available database on Inhalate was considered adequate for deriving inhalation reference values for all four durations of exposure (acute, short-term, longer-term, and chronic). Very little is known about the mode of action for Inhalate except for the tumorigenic effects in liver, which are thought to be produced as a result of prolonged cytotoxicity caused by oxidative metabolism. Thus, a nonlinear mode of action is assumed for Inhalate carcinogenesis, and a chronic reference value is derived that takes into account these effects along with others seen after chronic exposure. Acute, short-term, longer-term, and chronic reference values were derived for Inhalate. This case study illustrates the use of a variety of types of data from toxicity testing studies in deriving a set of inhalation reference values, including carcinogenic effects assumed to have a nonlinear dose-response.

Luteinate belongs to a class of chemicals known to work through a neuroendocrine mode of action. In order to ascertain its potency and confirm a similar mode of action, a number of short-term studies were conducted, followed by testing in more traditional toxicology studies to establish its long-term effects and dose response relationships. The data were considered adequate to derive oral reference values for all four durations of exposure. This case study provides an example of the usefulness of mode-of-action information in establishing the short- and long-term effects of Luteinate on relevant target organ systems at different life stages. Such information enables the development of a targeted robust data set for use in establishing reference values for various durations of exposure.

A detailed summary of the case studies is provided in Appendix B. Several key points are described here that demonstrate the use of the proposed framework outlined in this chapter. First, the data are reviewed and characterized on the basis of the hazard and dose-response information, including consideration of the weight-of-evidence factors discussed in Section 4.3.2, above. A narrative statement is used to describe the extent of the database for each chemical as well as the gaps in information that would make the database more robust. Dosimetric adjustments were made to derive HECs in the case of Inhalate. For Luteinate, adjustments for oral exposure were made on a BW^{1} basis and do not incorporate the $BW^{3/4}$ scaling factor or other DAF, as further work is needed on the harmonization of approaches for deriving of oral and dermal HEDs.

The data are presented both in tabular form and in graphical form as an exposure response array to provide a visualization of the data applicable to each duration of exposure.

Then, the reference values are derived by considering all of the relevant data for each duration reference value, weighing the evidence in the database, developing sample values on the basis of various endpoints considered for each duration, and selecting a final reference value for each duration on the basis of an evaluation of each of the relevant endpoints rather than on a single critical study and critical effect.

The approaches illustrated by the case studies showing derivation of multiple-duration reference values are not without precedent. Several offices within EPA, as well as ATSDR and the AEGL committee, derive multiple duration values for various purposes (see review in Chapter 2). The derivation of sample reference values in selecting the final reference value also is not a new idea. For example, EPA's assessment for methylmercury included the derivation of sample RfDs from prospective longitudinal studies of the effects of in utero exposure to methylmercury (Table 4-4) in deriving a chronic RfD (U.S. EPA, 2001d).

Sample RfDs were derived from a number of neuropsychological endpoints from two studies in which an association was observed (New Zealand and the Faroe Islands) as well as an integrative analysis of those studies plus a study in the Seychelles Islands in which no association between in utero methylmercury exposure and deficits in neuropsychological function were reported. The sample RfDs converged on 0.1 μg/kg/day, providing strong support for the appropriateness of this value. This RfD is not a developmental RfD per se, and its use is not restricted to pregnancy or developmental periods. The RfD, derived from an overall evaluation of the database, is applicable to lifetime daily exposure for all populations, including sensitive subgroups.

In a recently released health assessment document on 1,3-butadiene (U.S. EPA, 2002d), sample RfCs were derived for determining the chronic RfC.

Table 4-4. BMDLs, ingested dose, and RfDs for various endpoints from the Faroe Islands, New Zealand, and the NRC integrative analysis

Test[b]	BMDL[a] (ppb mercury cord blood)	Ingested dose[b] (µg/kg/day)	RfD[c] (µg/kg/day)

[a] $BMDL_{05}$s from NRC (2000), Tables 7-4, 7-5, 7-6. Hair mercury was converted to blood mercury using a 250:1 ratio and an assumption of equivalent maternal and cord levels.
[b] Calculated using a one-compartment model.
[c] Calculated using an UF of 10.
[d] There was significant co-exposure to PCBs in the Faroe Islands study, with PCB cord tissue concentrations available for about half of the whole cohort. Analyses were performed adjusted for PCBs (half the cohort) as well as unadjusted for PCBs in those individuals in the lowest PCB tertile (i.e., one-sixth of the whole cohort).

BNT = Boston Naming Test; CPT = Continuous Performance Test; CVLT = California Verbal Learning Test; MCCPP = McCarthy Perceived Performance; MCMT = McCarthy Motor Test.

5. RECOMMENDATIONS

A number of recommendations have been made in other parts of this report. This chapter summarizes those recommendations, based on the Technical Panel's review of the RfD and RfC process. The Technical Panel assumes that it will be possible to implement some of the recommendations in the near future, given adequate resources and personnel, whereas others will require additional effort. In particular, testing strategies are needed that consider toxicokinetic and mode of action information early in the process, as well as when to implement new testing guidelines in the process of developing a data package on a particular chemical. OPPTS, together with scientists in other parts of the Agency, will consider the recommendations to develop additional or alternative testing guidelines as part of the Harmonized Health Effects Test Guidelines (870 Series).

As part of its deliberations, the Technical Panel considered the recommendations of the Toxicology Working Group of the 10X Task Force (U.S. EPA, 1999b, and Appendix A). The Technical Panel endorses those recommendations and extends and expands them to deal with a broader view of life stages, timing and duration of exposure, and evaluation of endpoints, both structural and functional. The recommendations are presented here in the order of the chapters in which they appear. Further discussion of the specific recommendations can be found in the earlier chapters.

Chapter 2

The Technical Panel concurred with the recommendation of the 10X Task Force that reference values should be derived, where possible, for acute, short-term, and longer-term as well as chronic exposures for oral, dermal, and inhalation routes and that they be included in the IRIS database for use by EPA programs, where applicable. The definitions for duration should be standardized but left flexible so they can be adjusted depending on the exposure situation of concern.

Chapter 3

The Technical Panel reviewed and evaluated current testing guidelines and testing approaches as a follow-up to its recommendation in Chapter 2 concerning the derivation of less-than-lifetime reference values. This review was undertaken to determine what information is currently gathered with regard to life stage assessment, endpoint assessment, route and duration of exposure, and latency to response. The intent of this review is not to suggest that additional

testing be conducted for each and every chemical in order to fill in the information gaps identified for those organ systems evaluated. Nor is it suggested that the alternative testing protocols discussed in this chapter be conducted for every chemical or become part of current toxicology testing requirements or that these alternative protocols are the only options available. Rather, it is the goal of this document to provide a basis for the development of innovative alternative testing approaches and the use of such data in risk assessment. The recommendations include:

- Develop a strategy for alternative approaches to toxicity testing, with guidance on how and when to use existing and newly recommended guidelines.

- Develop guidelines or guideline study protocols that will provide more systematic information on toxicokinetics and toxicodynamics (i.e., mechanism or mode of action), including at different life stages.

- Develop protocols for acute and short-term studies that provide more comprehensive data for setting reference values.

- Modify existing guideline study protocols to provide more comprehensive coverage of life stages for both exposure and outcomes.

- Collect more information from less-than-lifetime exposures to evaluate latency to effect and reversibility of effect.

- Develop guidelines or guideline study protocols to assess immunotoxicity, carcinogenicity, and cardiovascular toxicity at different life stages.

- Explore the feasibility of setting dermal reference values for direct toxicity at the portal of entry, including sensitization.

Chapter 4

The Technical Panel discussed a number of modifications to the existing framework for reference value derivation, both for the current chronic reference values (RfD and RfC) and for the acute, short-term, and longer-term reference values. In addition, two case studies that

illustrate many of these concepts are summarized in Chapter 4 and discussed in detail in Appendix B. The recommendations for improvement and expansion of the existing approaches are aimed at taking a broader approach to the characterization of the entire database and what impact that will have on the dose-response assessment and risk characterization of a chemical. Included are recommendations for setting several less-than-lifetime reference values, broader characterization of the database instead of using a checklist of a minimum set of studies for setting a reference value, using an exposure-response array and carrying appropriate and relevant endpoints through the derivation of sample reference values before deciding which endpoint(s) to use for the POD, and deriving reference values in a way that is protective of all relevant endpoints rather than setting reference values on particular endpoints (e.g., the RfD_{DT}) but using a process that facilitates the evaluation of risk to particular subgroups for specific program office needs, including cumulative risk assessment.

The specific recommendations follow:

1. Include the acute, short-term, longer-term, and chronic reference values derived on the basis of the recommendations in this report in IRIS after appropriate internal, external, and consensus review.

2. Use consistent definitions for the duration of exposure in deriving acute, short-term, longer-term, and chronic reference values.

3. Use the revised definition for reference values shown in Chapter 4. This definition is aimed at clarifying that the approach to reference values discussed here is intended for risk assessments for any type of health effect known or assumed to be produced through a nonlinear and/or threshold mode of action (which may include U-shaped or other nonmonotonic dose-response curves as well as thresholds). Thus, the term “noncancer” has been removed from the definition in the spirit of overall harmonization of risk assessment approaches for human health effects because it has been recommended that health effects no longer be categorized as “cancer” or “noncancer” for the purposes of hazard characterization and dose-response analysis. This change denotes the move toward defining approaches for low-dose estimation or extrapolation based on mode of action.

The term “deleterious” has been replaced with the term “adverse,” because the latter is more commonly used and understood in data evaluation and selection of endpoints for setting reference values. The parenthetical statement in the current RfD and RfC definitions, “with uncertainty spanning perhaps an order of magnitude,” has been removed from the proposed revision of the definition for reference value, and it is recommended that issues of uncertainty/variability be discussed qualitatively as part of the weight of evidence and characterization of the database.

4. For consistency in the designation of various duration reference values, the Panel recommends that the terminology for reference values be standardized; this standardized terminology should reflect both duration and route of exposure. Consistent terminology recommendations for reference values are proposed in this report, but additional suggestions are welcome.

5. The Technical Panel recommends that endpoint-specific reference values per se not be developed, including the RfD_{DT}, which was originally proposed in *Guidelines for Developmental Toxicity Risk Assessment* (U.S. EPA, 1991). Rather, a sample reference value should be calculated for each relevant and appropriate endpoint and these should then be considered in the derivation of various duration reference values. The reference values should be derived to be protective of all types of effects for a given duration of exposure.

6. An expanded approach to the evaluation of studies and characterization of the extent of the database as a whole is recommended; in particular, several factors are discussed that should be considered in a weight-of-evidence approach for characterizing hazard for the population as a whole as well as for potentially sensitive subpopulations. Those considerations for assessing level of concern raised by the Toxicology Working Group of the 10X Task Force (U.S. EPA, 1999b) have been incorporated into this approach.

7. A narrative approach rather than a confidence ranking of high, medium, or low should be used in describing the extent of the database. The extremes for the extent of the database (i.e., minimal or robust) are defined in Chapter 4. The narrative approach is intended to emphasize the types of data available (both human and animal) as well as research needed to fill the data gaps that could improve the derivation of reference

values, and it should encourage the use of a wider range of information in deriving reference values, taking into consideration the life stages evaluated; the issues of timing, duration, and route of exposure; the types and extent of endpoint assessment (i.e., structure and function); and the potential for latent effects and/or reversibility of responses.

8. Duration adjustment procedures to continuous exposures for inhalation developmental toxicity studies should be done in the same way as for other health endpoints.

9. Additional consideration of the HEC and HED derivation methodology is needed to confirm or assess the relevance for all population subgroups (particularly children).

10. An exposure-response array should be used as a visual display of all relevant endpoints and durations of exposure, as shown in the case studies. This type of array can be used to evaluate the range of exposure-response data for different durations of exposure in order to determine the range of numerical values available for each route and duration reference value.

11. The POD should be selected on the basis of an evaluation of all appropriate and relevant endpoints carried through to sample reference value derivation, with selection of the limiting value(s) as the final step, rather than on a single “critical study” and “critical effect.”

12. It is imperative that the IRIS documentation contain a justification for the individual factors selected for each chemical or assessment, because rigid application of UFs could lead to an illogical set of reference values. Although default factors of 10 are recommended, with 3 used in place of half-power values (i.e., $10^{0.5}$) when occurring singly, the exact value of the UF chosen should depend on the quality of the studies available, the extent of the database, and scientific judgment. Sound scientific judgment should be used in the application of UFs to derive reference values that are applied to the value chosen for the POD derived from the available database (BMDL, NOAEL, or LOAEL).

13. The Technical Panel recommends that if there is uncertainty in more than four areas of extrapolation, it is unlikely that the database is sufficient to derive a reference value. Even when there is uncertainty in four areas, the database should be carefully evaluated to determine whether the derivation of a reference value is appropriate. In addition, the Technical Panel recommends limiting the total UF applied to a chronic reference value for any particular chemical to 3000. This maximum of 3000 applies only to the UFs and does not include the various adjustment factors discussed in Chapter 4.

14. The intraspecies UF is applied to account for variations in susceptibility within the human population (interhuman variability) and the possibility (given a lack of relevant data) that the database available is not representative of the dose/exposure-response relationship in the subgroups of the human population that are most sensitive to the health hazards of the chemical being assessed. As the reference concentration/dose is defined to be applicable to "susceptible subgroups," this UF was established to account for uncertainty in that regard. In general, the Technical Panel reaffirms the importance of this UF, recommending that reduction of the intraspecies UF from a default of 10 be considered only if data are sufficiently representative of the exposure/dose-response data for the most susceptible subpopulation(s).

At the other extreme, a 10-fold factor may sometimes be too small because of factors that can influence large differences in susceptibility, such as genetic polymorphisms. The Technical Panel urges the development of data to support the selection of the appropriate size of this factor, but it recognizes that often there are insufficient data to support a factor other than the default.

15. The Technical Panel urges continued research and evaluation of the similarities and differences between the general population and sensitive subpopulations in their responses to particular agents, particularly children and the elderly. From such evaluations, the protectiveness of the 10-fold default factor can continue to be assessed.

16. Given that several UFs can be used to deal with data deficiencies as part of the current reference value process, and given that these are assumed to overlap to some extent, the Technical Panel agrees with the 10X Task Force Toxicology Working Group (U.S. EPA, 1999b) that the current interspecies, intraspecies, and database deficiency UFs, if appropriately applied using the approaches recommended in this review, will be

adequate in most cases to cover concerns and uncertainties about children's health risks. Any residual concerns about toxicity and/or exposure can be dealt with in risk characterization/risk management (e.g., by retention of all or part of the FQPA safety factor for pesticides).

17. The Panel considers the purpose of the MF to be sufficiently subsumed in the general database UF. Therefore, the Panel recommends that use of the MF be discontinued.

18. EPA has not yet established guidance for the use of specific data to replace UFs (i.e., CSAFs), but the division of the interspecies UF into toxicodynamic and toxicokinetic components is in the RfC methodology (U.S. EPA, 1994) and may apply to the intraspecies UF as well. The Agency is encouraged to develop its own guidance, based on some of the available methodologies (e.g., IPCS).

The following issues were discussed by the Technical Panel but were considered more appropriate for discussion and recommendation by other panels/committees:

1. There have been inconsistencies in the use of BMD modeling approaches to deriving RfDs and RfCs currently in IRIS. The Technical Panel was unable to fully evaluate these issues or to reach agreement about any recommendation for change to current methodology and recommends that they be considered further by the Agency. The Technical Panel also recommends that factors such as the response rates at the BMD or NOAEL, the power of the study, and slope of the dose-response curve be included in the description of the database, where possible, as part of risk characterization.

2. The Technical Panel recommends harmonization of the approaches for HEC and HED derivation for all types of health effects. Development of the appropriate adjustment procedure is referred to the Harmonization Framework Technical Panel.

3. The Technical Panel recommends that the Agency further evaluate approaches such as probabilistic analysis for characterizing variability and uncertainty in toxicity reference values.

4. The Technical Panel recommends further evaluation of appropriate adjustment of doses for duration of exposure. The method derived from ten Berge et al. (1986) is raised as a possibility for acute exposures on the basis of its recommendation in the ARE methodology. Duration adjustment for short-term and longer-term reference values analogous to the subchronic-to-chronic duration UF for chronic reference values is raised in the case study and should be explored further.

APPENDIX A: ISSUES RAISED BY THE 10X TASK FORCE

A number of issues were raised by the 10X Task Force[1] in its discussions of the requirements for protecting children's health and application of an additional 10X safety factor, as mandated by the 1996 FQPA. The Task Force felt that these issues, which include the following, should be discussed on a broader Agency-wide basis as well as with the outside community for both pesticides and other agents.

1. *Appropriate application of the database modifying factor for additional required developmental and adult toxicity studies.* It appears from the data available that the default intraspecies 10-fold uncertainty factor may be adequate in the majority of cases for protecting children's health. However, when data specific to children's health are missing or inadequate for a particular agent, application of the database modifying factor in addition to the intraspecies variability factor may be sufficient to account for the possibility that children may be significantly more sensitive than adults. This issue needs further examination.

2. *How to account for the level of concern in the RfD/RfC process.* Criteria for assessing the level of concern for children's health were developed by the Toxicology Working Group of the 10X Task Force and include factors such as (a) human data on pre- and postnatal toxicity; (b) pre- and postnatal toxicity in animal studies, including effects of a different or similar type as those in adults; (c) dose-response nature of the experimental animal data, including the dose-related incidence of response, relative potency of response, slope of the dose-response curve when the margin of exposure is small, and how well the NOAEL or BMD is defined; and (d) relevance of the experimental animal data to humans, including toxicokinetics, similarity of the biological response, and knowledge of the mechanism of action. For each of these areas, criteria are given for estimating a level of concern for children's health as high, moderate, or low. The level of concern may be taken into account in the uncertainty and modifying factors applied to the RfD, although there is currently no formal process for doing so.

---

[1]See 10X Task Force documents: *Toxicology Data Requirements for Assessing Risks of Pesticide Exposure to Children's Health* (U.S. EPA, 1999b) and *Exposure Requirements for Assessing Risks from Pesticide Exposure to Children's Health* (U.S. EPA, 1999c).

3. As indicated in the toxicology document appended to the Task Force report, *the current default recommended for using developmental toxicity data for different duration reference values is to apply most endpoints for all durations*. This is because it is assumed that most endpoints of developmental toxicity can be caused by a single exposure. If, however, developmental effects are more sensitive than those seen after longer-term exposures, then even the chronic RfD/RfC should be based on such effects to reduce the risk of potential greater sensitivity in children. Because the standard studies currently conducted for developmental toxicity involve repeated exposures, data are not often available on which endpoints may be induced by acute, subacute, subchronic, or chronic dosing regimens and, therefore, on which should be used in setting various duration reference values. Further consideration of the appropriate application of developmental toxicity endpoints to various duration reference values is recommended. As part of this recommendation, an in-depth review of the HED document on Hazard Identification—Toxicology Endpoint Selection System, should be undertaken.

4. *Appropriate setting of intermediate RfDs/RfCs for pesticides and other agents.* The focus of the RfD and the RfC has been on chronic exposure reference values. Acute RfDs are also set for pesticides, and intermediate reference values are set for residential exposures as well as for drinking water. Data on developmental toxicity will often be a greater factor in calculating the acute and intermediate reference values, and exposures to children are more often of this type as well. Consideration should be given to setting intermediate reference values for environmental agents. In addition, the question of whether or when to set RfDs/RfCs specific for children should be considered.

5. *Appropriate adjustment of the NOAEL or the BMD from inhalation exposure studies for extrapolation of developmental toxicity data using less-than-continuous exposure to a continuous-exposure scenario.* Currently, NOAELs/BMDs from inhalation exposure studies other than those for developmental toxicity using, for example, a 6-hr/day exposure regimen, are adjusted to a continuous (24 hr/day) exposure for calculating RfDs/RfCs. The developmental toxicity risk assessment guidelines (U.S. EPA, 1991) recommended against making this adjustment because it was assumed that there was a threshold above which exposure would have to occur before an effect would result. This recommendation needs to be reconsidered, along with the adjustment of NOAELS/BMDs in general.

Several improvements in testing approaches were also proposed for consideration in the 10X Task Force report as a way to improve the assessment of potential risks to children. The Technical Panel was asked to consider the need for such tests, when they should be required, and interpretation of the data for risk assessment purposes. The improvements to be considered include

- pharmacokinetics that include data from different developmental stages, perhaps done in a tiered approach as suggested in Kimmel and Francis (1990);

- direct dosing of neonates, especially when early exposure is of concern, because this is the time when differences in metabolic capability are greatest;

- perinatal carcinogenesis studies and appropriate triggers for when they should be required;

- developmental immunotoxicity testing and appropriate triggers; and

- advanced DNT testing, in particular, cognitive testing that is more similar to that used in humans.

An additional issue was how to make exposure assessments compatible with the dose-response assessment. For example, how should the appropriate durations of exposure be determined for toxic endpoints of concern? Should standard exposure durations be used?

APPENDIX B: CASE STUDIES—EVALUATING AND SELECTING HEALTH ENDPOINTS FOR DERIVING REFERENCE VALUES

Two case studies were developed by the Technical Panel to illustrate many of the points discussed in this report. The first case study is of a hypothetical volatile chemical for which limited data are available and little information is known about the mode of action except that there is support for a nonlinear mode of action for cancer.

The second case study is of a hypothetical endocrine disruptor for which the mode of action is known or assumed from other chemicals in the same class. This case study is used to illustrate in part how the information on mode of action can inform a more focused collection of data as well as the interpretation of the data and its use in risk assessment.

In both case studies, NOAELs and LOAELs rather than BMDLs or BMCLs are used to derive reference values, in large part because the data are fictitious and were not developed to the point that they could be readily modeled. However, the Technical Panel strongly encourages the use of dose-response modeling and calculation of BMDLs or BMCLs for selection of the POD to be used as the basis for deriving reference values.

CASE STUDY 1: INHALATE

Inhalate, a synthetic halogenated aliphatic alkene, is a nonflammable volatile liquid at room temperature. The chemical enters the air through its industrial and commercial use, primarily as a solvent. It is also found in surface and ground water and soil upon disposal. The most important route of human exposure is inhalation of the chemical in the ambient and indoor air, although there is a lower possibility of ingestion through contaminated drinking water. Because of its high volatility, dermal exposure to the chemical is expected to be minimal.

This case study illustrates the use of single or multiple health endpoints for deriving reference values for different durations of exposure following inhalation exposure. It also illustrates the harmonized approach for all effects (including cancer) that are known or assumed to be produced through a nonlinear or threshold mode of action. For the purpose of illustration, results of key studies are summarized in Table B-1, including dose-response data for different health endpoints relevant to different durations of exposure via inhalation exposure. Although oral data for this chemical were available, a brief description is included here only to show the consistency with which effects were seen after either inhalation or oral exposure.

SUMMARY OF HEALTH EFFECTS INFORMATION

Absorption, Distribution, Metabolism, and Elimination

There is very little information on the absorption and distribution of Inhalate in humans and laboratory animals following oral, inhalation, or dermal exposure. However, similar effects are seen by oral and inhalation exposures, suggesting that Inhalate or its metabolites reach their target sites after absorption from either exposure route. Available in vitro metabolic studies indicate that Inhalate is extensively metabolized in target tissues including the liver and kidney of rats and mice. Limited in vitro studies with human tissues show a similar pattern of metabolism. As discussed below, much of Inhalate-induced toxicity appears to be due to its metabolites. These metabolites have been detected in the urine of rats and mice following inhalation and oral exposure to the parent chemical.

Postulated Mode of Action

No information is available on mode of action except for the carcinogenicity of Inhalate. The carcinogenic effects of Inhalate in rodent liver are attributed to oxidative metabolism-mediated cytotoxicity in the target organ. The oxidative metabolism produces highly tissue-reactive metabolites that lead to tissue injury and cell death. The persistent cell proliferation

Table B-1. Summary results of major inhalation exposure studies on Inhalate

Species	Sex	Exposure duration and frequency	Concentrations (mg/m^3)	LOAEL/ NOAEL (mg/m^3)	HEC [a] (mg/m^3)	Responses
Human	M/F	2 hrs	4, 40, 400	40/4	40/4, 2-hr	Headache, dizziness, incoordination, drowsiness, anesthesia at 2000 mg/m^3
		Accidental exposure	NA	NA	-	Narcosis, proteinuria, hematuria
		6 hrs/day for 7 days (clinical exposure)[b]	10, 20, 100, 150	20/10	4/2	Headache, dizziness, incoordination, drowsiness

GD = gestation day

presumably would lead to higher probabilities of cell mutation and subsequent cancer. Liver tumors were produced only at dose levels that resulted in repeated or sustained cytotoxicity and regenerative cell proliferation. This postulated mode of action is further supported by the observation in specialized studies that neither the cytotoxicity nor cell proliferation occurred in the CYP2E1 null mouse or in the wild type treated with a P450 inhibitor at the same exposure. The weight of the evidence indicates that a mutagenic mode of action via DNA reactivity is not a significant component of Inhalate-induced liver tumors in rats and mice. There are no data indicating that the mode of action observed in rodents is not also likely to apply to humans.

Nervous System

Inhalate has been found to elicit dose-dependent clinical signs of CNS effects in adult humans following acute inhalation exposure and accidental ingestion. CNS symptoms have been reported in several studies of occupational exposure of workers to Inhalate. Dose-dependent clinical signs of CNS effects have been observed in adult rats and mice exposed to Inhalate by inhalation following different duration of exposures. There are limited data indicating that prenatal exposure to Inhalate adversely affects the developing nervous system in rats and mice (see Growth and Development below). There are no data on the ability of Inhalate to affect the nervous system at other life stages (e.g., during the fetal period, infancy, childhood, or old age). The mechanism of action for the CNS effects has not been clearly established, but it is believed to be related to effects of the parent compound on lipid and fatty acid composition of the membranes.

Inhalation Exposure

Several reports available in the open literature indicate dose-dependent clinical signs of CNS symptoms in adults exposed acutely and subacutely via inhalation to Inhalate. Males and females exposed acutely to high concentrations (40–400 mg/m^3 for 2 hours) showed dose-dependent effects, including headache, dizziness, incoordination, drowsiness, and anesthesia. No effect was reported following acute exposure to 4 mg/m^3. Similar effects were observed in adult human volunteers at lower concentrations (10, 20, 100, 150 mg/m^3) for 6 hours per day for up to 7 days, with a NOAEL of 10 mg/m^3. An acute accidental exposure of a small group of workers to an unknown (presumably high) concentration resulted in narcosis.

Long-term and chronic neurotoxic effects have been reported in several studies of occupational exposure of workers to Inhalate in different industries. Exposure data were not provided in these reports; however, it can be presumed that these workers were exposed to a

daily TWA exposure of 56 mg/m^3. Subjective neurological symptoms, including dizziness and forgetfulness, were consistently reported across studies. No other information on possible neurological effects was collected in these studies.

Concentration-dependent clinical signs of neurological effects, including hyperactivity, ataxia, hypoactivity, and finally loss of consciousness, have also been reported in adult rats and mice following acute (13, 24, 50 mg/m^3 for 4 hours) and short-term inhalation exposure (50,100, 200 mg/m^3 6 hrs/day for 2 weeks) to Inhalate at high concentration. Similar effects were observed in rats exposed at 39 and 88 mg/m^3 and in mice at 50 and 100 mg/m^3 for 13 weeks. The subchronic NOAELs for rats and mice were 22 and 28 mg/m^3, respectively.

Chronic exposure to Inhalate at lower concentrations resulted in less serious clinical signs of CNS effects in rats (22 or 44 mg/m^3) and mice (28 or 56 mg/m^3). The chronic NOAELs for rats and mice in these studies were both 11 mg/m^3. It should be noted that neurological endpoints examined in these animal studies are limited to clinical signs and histopathology. In a special study, changes in fatty acid composition of the brain were observed in rats exposed at 30 mg/m^3 (the only tested concentration) for 90 days.

Pregnant rats were exposed by inhalation to Inhalate at 0, 10, or 90 mg/m^3 for 6 hrs/day on days 7–13 of gestation. Decreased motor activity was observed in 21- or 60-day-old pups from dams exposed to 90 mg/m^3. A NOAEL of 10 mg/m^3 for developmental neurotoxicity was identified in this study.

Oral Exposure

Acute neurological effects in adult humans after ingestion of Inhalate are similar to those seen after inhalation. Accidental exposure to approximately 6–8 mL (or about 100 mg/kg/day) resulted in narcotic effects. Neural tube defects and eye anomalies were reported in studies of offspring of residents exposed to drinking water contaminated with Inhalate and other solvents. Exposure levels were not determined in this study.

Single oral gavage administration of Inhalate to adult rats (1000 mg/kg) caused ataxia. Ataxia was also observed in pregnant rats treated by gavage at 900 mg/kg on gestation days (GDs) 6–19. No CNS effects were reported in a chronic oral gavage study in rats and mice at 50, 100, or 300 mg/kg/day. However, neurological endpoints examined in these studies were limited to clinical signs and histopathology.

In a study that investigated the effect of Inhalate on the developing nervous system, male mouse pups were treated by gavage at 50 or 300 mg/kg/day for 7 days (postnatal days [PNDs]

10–17). Hyperactivity was reported in animals during adulthood at the high dose. No studies with exposure throughout development (prenatal and postnatal) were available.

Liver

Two reports provided suggestive evidence of liver effects in workers exposed to Inhalate in different industries. Inhalate has been shown to induce dose-dependent liver toxicity in adult rats and mice following subchronic and chronic exposure by inhalation and oral gavage. Liver tumors were also observed in chronic studies of rats and mice. Available data support the conclusion that liver tumors were produced only at dose levels that resulted in repeated or sustained cytotoxicity and regenerative cell proliferation. Inhalate carcinogenic effects in rodent liver are attributed to oxidative metabolism-mediated cytotoxicity in the target organ. The oxidative metabolism produces highly tissue-reactive metabolites that lead to tissue injury and cell death. The persistent cell proliferation presumably would lead to higher probabilities of cell mutation and subsequent cancer.

This postulated mode of action is further supported by the observation in specialized studies that neither the cytotoxicity nor cell proliferation occurred in the CYP2E1 null mouse or in the wild type treated with a P450 inhibitor at the same exposure. The weight of the evidence indicates that a mutagenic mode of action via DNA reactivity is not a significant component of Inhalate-induced liver tumors in rats and mice. No data exist indicating that the mode of action observed in rodents is not also likely to apply to humans. There are no data that provide any insights into possible differential sensitivity across life stages.

Inhalation Exposure

One study reported changes in serum levels of liver enzymes in workers exposed to the chemical at a daily TWA exposure concentration of about 56 mg/m^3 over an 8-hour work shift. These workers, however, did not exhibit any clinical symptoms of liver dysfunction.

Dose-related liver effects (liver hypertrophy, vacuolization of hepatocytes, necrosis) have been observed in mice following subchronic exposure (13 weeks) to Inhalate at 50 or 100 mg/m^3, with a NOAEL of 28 mg/m^3. Dose-related liver toxicity and hepatocellular carcinomas were also found in mice following chronic exposure at 28 and 56 mg/m^3. The NOAEL for liver toxicity in mice in this chronic study was 11 mg/m^3.

Rats showed similar liver responses but at higher exposure concentrations following subchronic exposure (39 or 88 mg/m^3), with a NOAEL of 22 mg/m^3. Liver toxicity and hepatocellular carcinomas were also observed at 22 or 44 mg/m^3 in a chronic study in rats. The

NOAEL for liver effects in rats was 11 mg/m^3. It should be noted that liver effects examined in these subchronic and chronic studies were limited to clinical chemistry, morphology, and histopathology.

Oral Exposure

Liver effects were observed in mice and rats treated subchronically (100, 300, 500 mg/kg/day) or chronically (50, 100, 300 mg/kg/day) with Inhalate via oral gavage and were similar to those seen after inhalation exposure. Mice showed more severe effects than did rats. Dose-related hepatocellular carcinomas were also found in treated mice in a chronic study.

Kidney

Available human and animal studies indicate that Inhalate also has the potential to cause renal toxicity in adults. The mechanisms for the development of kidney effects in humans and animals are not known. No data were available to evaluate the effects of Inhalate at life stages other than in adults (i.e., during development or old age).

Inhalation Exposure

Symptoms of renal dysfunction (proteinuria, hematuria) have been associated with accidental human exposure to anesthetic concentrations of Inhalate. Subtle or no renal effects were reported in workers exposed chronically. Increased urinary levels of lysozyme and beta-glucuronidase suggestive of mild renal tubular damage have been observed in workers exposed for an average of 15 years to a daily TWA concentration of 56 mg/m^3.

Dose-related renal toxicity (cytomegaly, toxic nephrosis of tubular epithelial cells in the inner renal cortex) was induced in rats (39, 88 mg/m^3) and mice (50, 100 mg/m^3) exposed to Inhalate for 13 weeks. Subchronic NOAELs for renal effects in rats and mice were 22 mg/m^3 and 28 mg/m^3, respectively. Similar renal effects were observed in a chronic study in rats (22, 44 mg/m^3) and mice (28, 56 mg/m^3). Chronic NOAELs for renal effects in rats and mice were both 11 mg/m^3.

Oral Exposure

Dose-related toxic nephropathy characterized by degenerative changes in the proximal convoluted tubules and necrosis of the tubular epithelium were found in rats and mice treated with Inhalate via oral gavage for 90 days at 100, 300, or 500 mg/kg/day and for 2 years at 50,

100, or 300 mg/kg/day. Subchronic and chronic NOAELs for renal effects in rats and mice were at 100 and 50 mg/kg/day, respectively.

Growth and Development

Available studies in humans and animals indicate that Inhalate has the potential to cause developmental effects by inhalation and oral ingestion. Limitations of human studies could not resolve whether the observed developmental effects were causally related to the chemical or were a result of chance or bias. However, the epidemiologic findings are supported by animal studies with exposure to Inhalate by inhalation and oral gavage that show that the developing nervous system is the most sensitive target in rats and mice.

Inhalation Exposure

Epidemiologic studies of women occupationally exposed to Inhalate and other related solvents have reported elevated risk of spontaneous abortion and cardiac anomalies in their offspring. Due to limitations of these studies, an exposure-response could not be established. No other health endpoints were investigated in these studies.

Pregnant rats were exposed by inhalation to Inhalate at 0, 10, or 90 mg/m^3 for 6 hrs/day on days 7–13 of gestation. Decreased motor activity was observed in 21- and 60-day-old pups from dams exposed to 90 mg/m^3. A NOAEL of 10 mg/m^3 for developmental effects was identified in this study. No studies included exposure throughout gestation and lactation to determine effects at other developmental stages. Data from a two-generation reproduction study indicated a reduction in litter size and survival of offspring in rats exposure to Inhalate at 100 mg/m^3, a concentration that also resulted in sedation and renal effects. No effects were reported at 28 mg/m^3.

Oral Exposure

Neural tube defects and eye anomalies have been reported in studies of residents exposed to drinking water contaminated with Inhalate and other solvents. Exposure levels were not determined in this study.

An increased incidence of micro/anophthalmia were observed in the offspring of rats treated with Inhalate by gavage at 900 mg/kg/day on GDs 6–19. In a study that investigated the effect of Inhalate on the developing nervous system, male mouse pups were treated by gavage with Inhalate at 50 or 300 mg/kg/day for 7 days (age 10–17 days). Hyperactivity was reported in animals during adulthood at the high dose. No effects were found at the low dose. No studies

included exposure throughout gestation and lactation to determine effects at other developmental stages.

Reproductive System

Available studies in humans and animals suggest that Inhalate may have the potential to cause reproductive effects. The underlying mechanism of action for potential reproductive effects is not known.

Inhalation Exposure

There is suggestive evidence of spontaneous abortion and menstrual disorders among women occupationally exposed to Inhalate. However, no definitive conclusions can be made because of the limitations associated with these studies.

Reduced litter size and reduced survival of offspring were reported in rats exposed to Inhalate at 100 mg/m^3 in a two-generation reproduction inhalation study; this concentration also resulted in sedation and renal effects. No effects were identified at 28 mg/m^3. The protocol used, however, was not the most recent one, in which reproductive development (e.g., timing of puberty or anogenital distance) and adult reproductive function (semen quality, estrous cyclicity) are evaluated, nor were organ weights measured. No effects on the reproductive system were noted in any other studies.

Oral Exposure

No information is available on the potential reproductive effects of Inhalate in animals via oral exposure.

SELECTION OF HEALTH ENDPOINTS AND DERIVATION OF REFERENCE VALUES

Narrative Description of the Extent of the Database

No information is available on possible modes of action except for liver carcinogenic effects in rats and mice. In this case, the mode of action is attributed to oxidative metabolism-mediated cytotoxicity and persistent cell proliferation in the liver. Persistent regenerative cell proliferation presumably would lead to higher probabilities of cell mutation and subsequent cancer. No data exist to indicate that the mode of action observed in rodents is not also likely to apply to humans. Pharmacokinetic data indicate that Inhalate is extensively metabolized and that much of its toxicity is due to the metabolites.

The database for inhalation exposure is limited but adequate for deriving reference values. Some human data on acute, short-term, and longer-term exposures are available, although the range of endpoints evaluated and the dose-response information for different durations of exposure are limited. The animal data include acute, short-term, longer-term, and chronic studies with exposures beginning in young adult animals. The acute and short-term data are limited to clinical signs of morbidity and mortality, whereas the longer-term and chronic studies include some histopathology as well.

A developmental neurotoxicity (DNT) study was conducted in rats with prenatal exposure limited to GDs 7–13 (as opposed to more extensive exposure throughout a major part of CNS development, e.g., GD 6 to PND 11 or 20 in the standard DNT study testing protocol). No other studies of prenatal or postnatal developmental toxicity were done except for evaluations of survival and growth in a two-generation reproduction study in rats. However, the protocol used was one in which reproductive development (e.g., timing of puberty or anogenital distance) and adult reproductive function (semen quality, estrous cyclicity) were not evaluated, nor were organ weights measured. No studies were conducted that considered issues related to the toxicity of the agent in old age, either from earlier exposures or from exposures in aged animals.

The database for oral exposure is much more limited than the database for inhalation exposure, with acute accidental ingestion data in humans at a single, high-dose level resulting in narcosis and chronic drinking water exposure (no dose information) associated with an increase in birth defects. The animal data are likewise very limited, with a single-dose acute toxicity study in rats in which clinical signs of morbidity and mortality were evaluated and subchronic (90-day) and chronic toxicity data in rats and mice indicating effects similar to those seen with inhalation exposure. Prenatal developmental toxicity data were available in rats following exposure on GDs 6–19, and an evaluation of adult neurotoxicity was conducted in mice following developmental exposure on PNDs 10–17. No other developmental toxicity data, and no information on reproductive toxicity or adult neurotoxicity were available. No studies were conducted that considered issues related to the toxicity of the agent in old age, either from earlier exposures or from exposures in aged animals.

Exposure-Response Array

In addition to displaying the data in tabular form (Table B-1), an exposure-response array can be a useful way of visually displaying the data (see Figures B-1 through B-4) to show what data are available for each duration of exposure. The data shown in the graphs are the human equivalent concentrations (HECs) based on the dosimetric adjustments discussed in Chapter 4 of

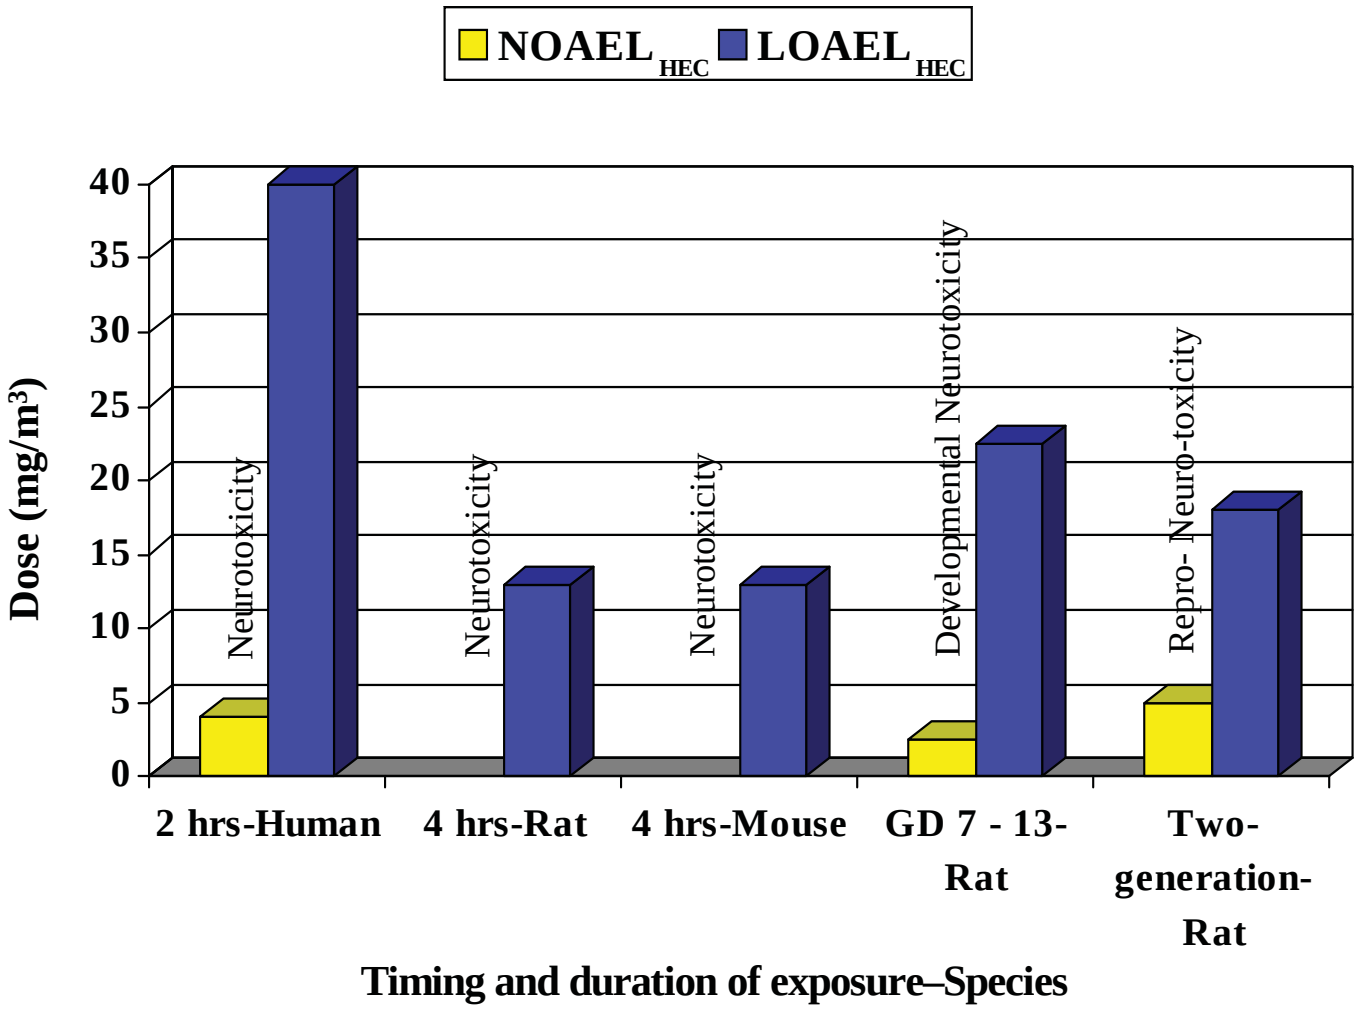

Figure B-1. Exposure-response array of data considered for the Inhalate acute reference value.

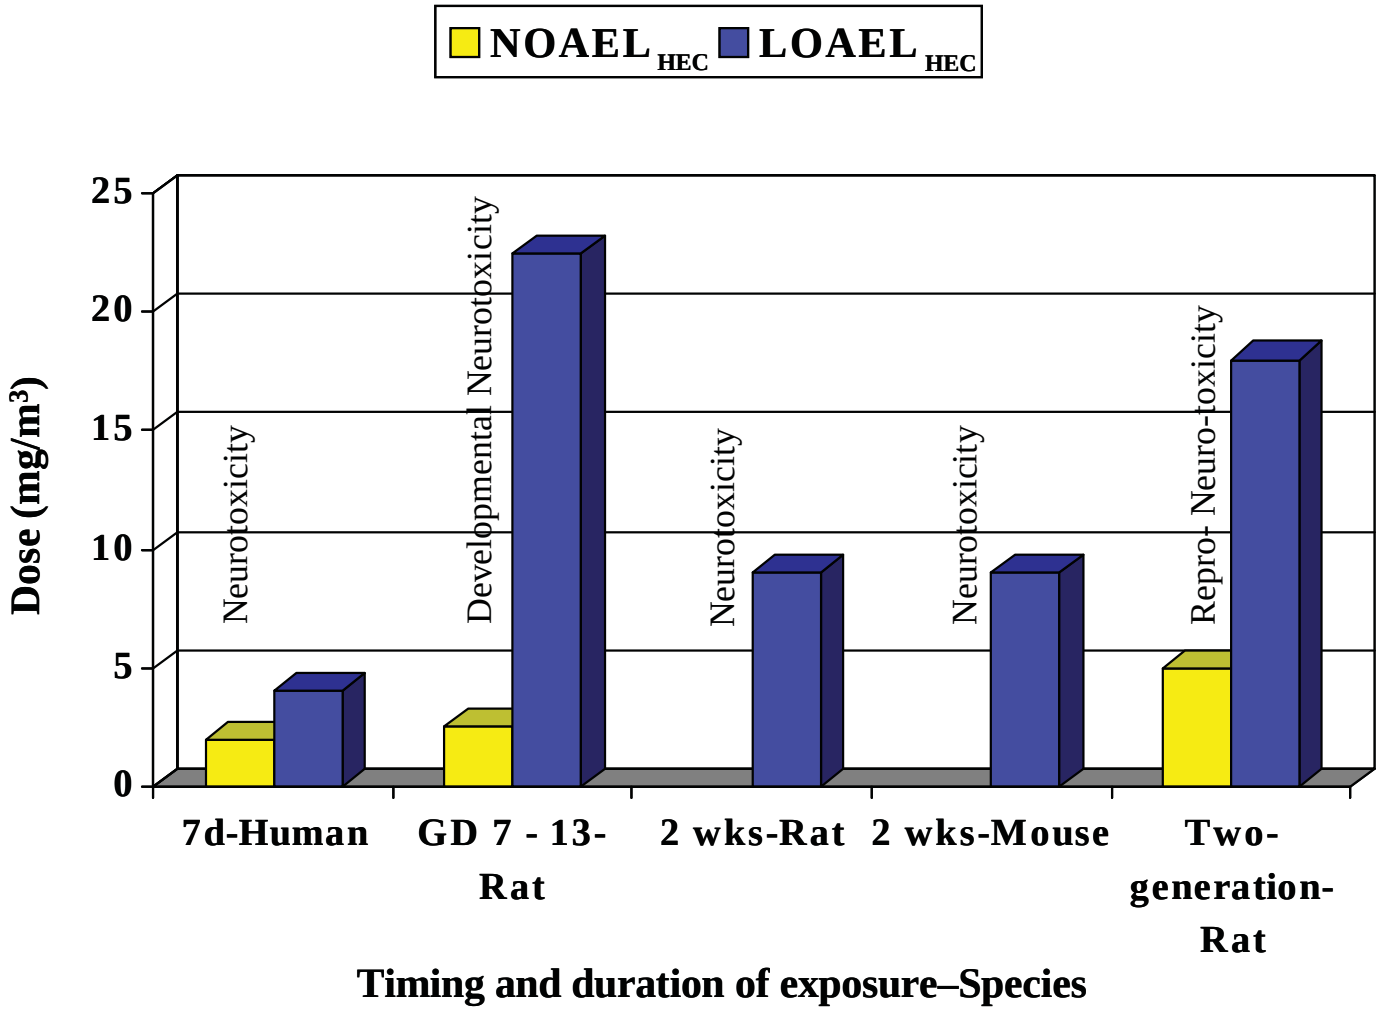

Figure B-2. Exposure-response array of data considered for the Inhalate short-term reference value.

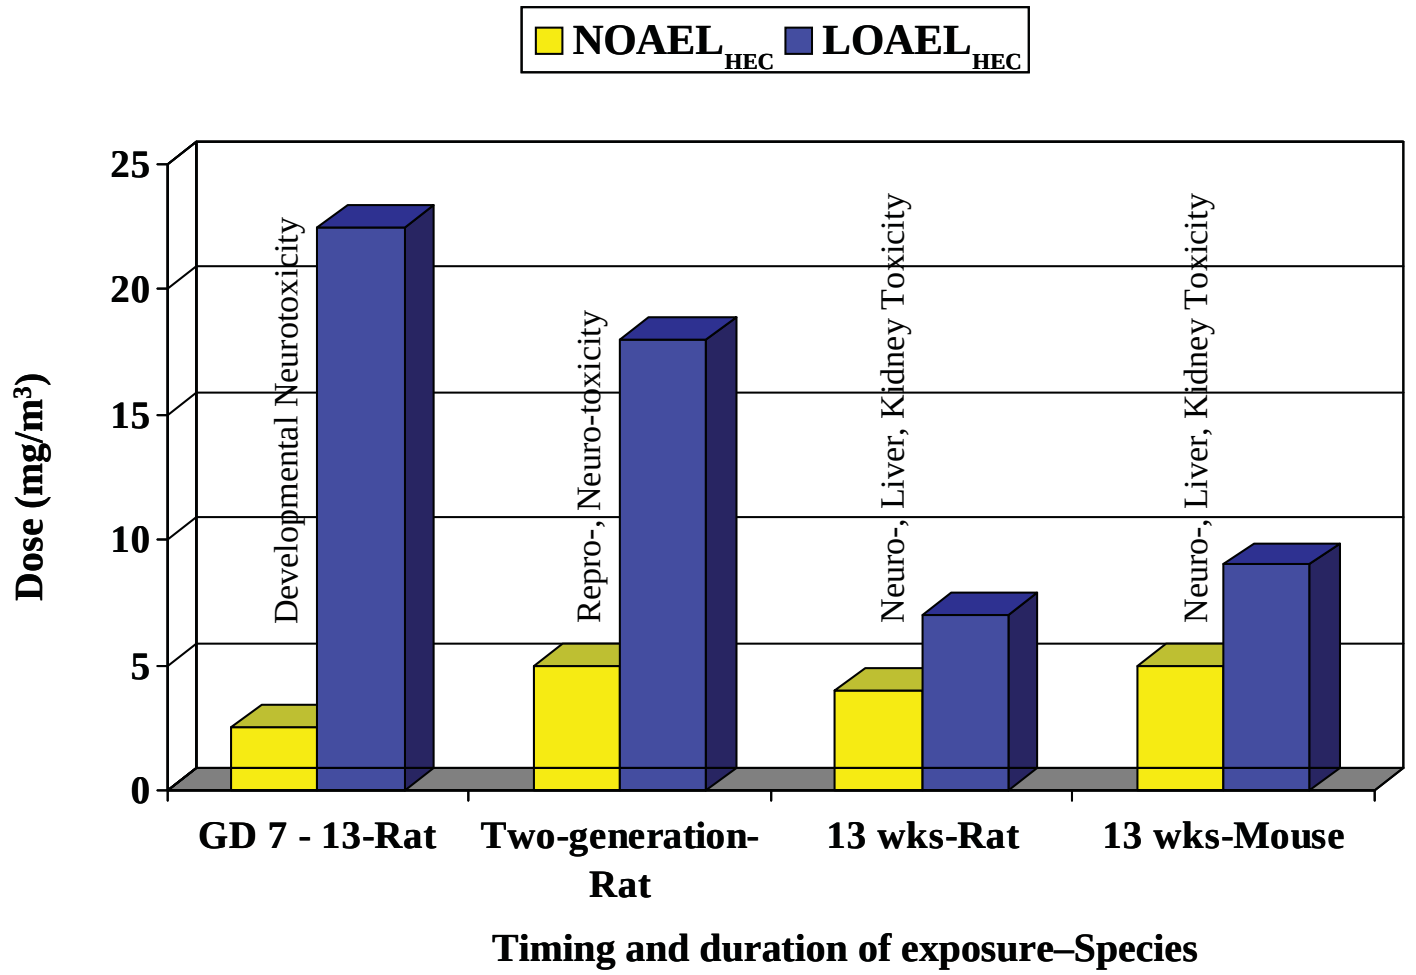

Figure B-3. Exposure-response array of data considered for the Inhalate longer-term reference value.

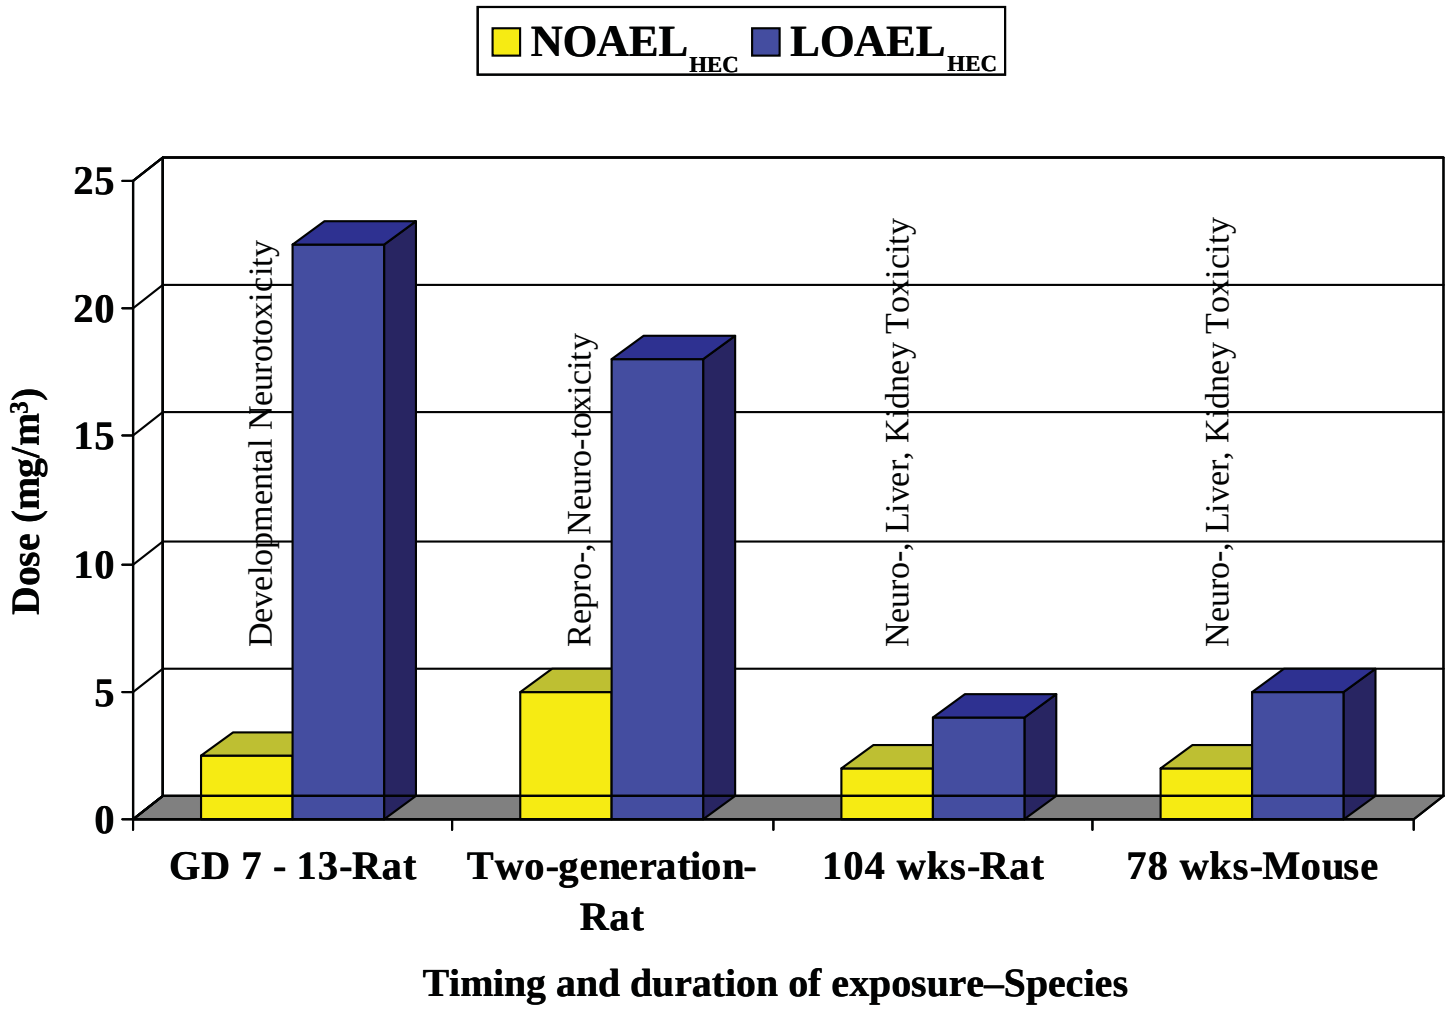

Figure B-4. Exposure-response array of data considered for the Inhalate chronic reference value.

this report, including dosimetric adjustment of the developmental toxicity data in the same manner as for other types of toxicity data, as recommended in U.S. EPA (1994) and Chapter 4.

No toxicokinetic model is available for Inhalate, so adjustments to the applied concentrations for dose adjustments and calculation of the HEC in this case study were done using the default procedures discussed in U.S. EPA (1994) and Chapter 4 of this document. As the effects observed are systemic, with no indications of portal-of-entry effects, the specific default procedures are based on the vapors of Inhalate being a category 3 gas. The principal parameter for interspecies extrapolation of category 3 gases, the blood:gas (air) partition coefficient ($H_{b/g}$), is unknown for both humans and animals and assumed to be 1. Therefore, the dosimetric adjustment factor (DAF) (see Chapter 4, Section 4.4.3) applied to the duration adjusted concentrations is 1, such that the duration adjusted values then become the HECs.

Duration adjustment was accomplished by factoring the exposure concentration (in mg/m^3) by 6/24 (for hours of exposure) and, where applicable, by 5/7 for the number of days per week exposed. As noted in Chapter 4, Section 4.4.2.1, duration adjustments were not made to acute (i.e., less than 24-hr) single exposures.

Uncertainty Factors (UFs)

An interspecies UF (A in Table B-2) of $10^{1/2}$ was applied in all cases to animal studies because the dosimetric adjustment procedures applied to Inhalate are considered to address the toxicokinetics portion of this UF, leaving the rest of the UF to cover interspecies toxicodynamics (U.S. EPA, 1994). An intraspecies UF (H in Table B-2) of 10 was applied in all cases because the data did not allow the estimation of within-human variability and the most sensitive life stage and/or susceptible subpopulation was not clearly identified in the database.

A LOAEL-to-NOAEL UF (L in Table B-2) was applied to the human data for neurotoxicity for the longer-term and chronic reference values because only a LOAEL was identified in the data for those two durations of exposure. A subchronic-to-chronic (duration) UF (S in Table B-2) was not applied, as there were data available for the appropriate duration of exposure in each case. For the longer-term and chronic reference values, a duration UF was not applied to the data from the developmental toxicity study, as this is not the usual practice when considering these data for longer-term and chronic exposures. However, as noted in the report (Chapter 4, Section 4.4.5.6), the application of a UF analogous to the subchronic-to-chronic-duration UF should be explored, as there may be situations in which data are available and applicable but they are from studies in which the dosing period is considerably shorter than that for the reference value being derived.

Table B-2. Derivation of reference values for Inhalate—inhalation exposure

Reference value duration	Exposure duration	HEC (mg/m^3)	Species	Type of effect[a]	Uncertainty factors[b]						Reference value (ppm)[c]

[a] NT = neurotoxicity; DNT = developmental neurotoxicity; RT = reproductive toxicity; LT = liver toxicity; KT = kidney toxicity

[b] A = animal-to-human (interspecies); H = inter-individual (intraspecies); L = LOAEL-to-NOAEL; S = subchronic-to-chronic duration; D = database deficiency

[c] Sample = reference value based on that particular endpoint, species, duration; Final = reference value for the entire database for a particular duration of exposure.

[d] L indicates that this value is the HEC based on the LOAEL.

[e] A duration UF was not applied to the data from the developmental neurotoxicity study for either the longer-term or chronic reference value; however, the adjustment should be considered when extrapolating from shorter to longer durations of exposure.

GD = gestation day

A database UF of $10^{1/2}$ was applied in all cases because there were data indicating that one of the main target organs for Inhalate was the nervous system, that there was neurotoxicity in adults (humans and animals), and that there were some data on developmental neurotoxicity, but with exposure limited to only a portion of the developmental period. In addition, there was no study in which pregnancy outcomes were evaluated (i.e., fetal survival, growth, and structural development) except for a possible association with spontaneous abortion and cardiac anomalies in occupationally exposed workers. These data gaps were not considered likely to reduce the NOAEL by more than a factor of 3 because there were some data on developmental exposures from a two-generation reproductive toxicity study. There were no reports of effects on fertility or reproduction per se, except for a possible association with menstrual disturbances in occupationally exposed workers.

Acute Inhalation Exposure

Results of available studies indicate that acute inhalation exposure to Inhalate can result in neurotoxic effects in human adults with a $LOAEL_{HEC}$ of 40 mg/m^3 and a $NOAEL_{HEC}$ of 4 mg/m^3 in a 2-hour exposure. Animal studies also show that Inhalate has the potential to cause neurotoxicity in adults with a $LOAEL_{HEC}$ of 13 mg/m^3 in a 4-hr exposure, and developmental neurotoxicity and other reproductive effects with $LOAEL_{HEC}$s of 22.5 mg/m^3 and 18 mg/m^3 and $NOAEL_{HEC}$s of 2.5 mg/m^3 and 5 mg/m^3, respectively.

Default UFs of $10^{1/2}$ (animal-to-human extrapolation), 10 (inter-individual differences), and $10^{1/2}$ (database deficiencies: no adequate prenatal developmental toxicity studies in two species, no adequate developmental neurotoxicity study) were applied to all the $NOAEL_{HEC}$s to derive sample reference values. In addition, a UF of 10 (LOAEL to NOAEL) was applied to the 4-hr rat and mouse $LOAEL_{HEC}$s. Human and animal studies indicate that the nervous system is vulnerable to Inhalate exposure. Although the sample reference values for the 4-hr adult rat and mouse exposures were lower than that based on the developmental neurotoxicity study, the values were within a similar range and the sample reference value for developmental neurotoxicity had less overall uncertainty. Therefore, the resultant reference value chosen for acute inhalation exposure is 0.03 mg/m^3 (Table B-2).

Short-term Inhalation Exposure

The reference value for short-term inhalation exposure is based on the human data $NOAEL_{HEC}$s of 2 mg/m^3 as well as the animal developmental neurotoxicity NOAEL of 2.5 mg/m^3 and

reproductive toxicity NOAEL of 5 mg/m^3 ($LOAEL_{HEC}$s of 4 mg/m^3, 22.5 mg/m^3, and 18 mg/m^3, respectively). In addition, the 14 day exposures of rats and mice resulted in a $LOAEL_{HEC}$ of 9 mg/m^3. For the human $NOAEL_{HEC}$ of 2 mg/m^3, applying a 10-fold default UF for intraspecies uncertainty and variability and a $10^{1/2}$-fold UF for database deficiencies results in a sample reference value for short-term inhalation exposure of 0.07 mg/m^3. Sample reference values based on animal data include default factors of $10^{1/2}$ (interspecies), 10 (intraspecies) and $10^{1/2}$ (database deficiencies) applied to the $NOAEL_{HEC}$s for developmental neurotoxicity and reproductive toxicity (2.5 and 5 mg/m^3, respectively) and result in sample reference values of 0.03 and 0.05 mg/m^3. An additional factor of 10 (LOAEL to NOAEL) applied to the adult neurotoxicity data in rats and mice results in a sample reference value of 0.01 mg/m^3. Given the close range of values and the lower overall uncertainty in the sample reference value for developmental neurotoxicity than that for adult neurotoxicity, the final reference value of 0.03 mg/m^3 is chosen (Table B-2).

Longer-term Inhalation Exposure

Subchronic and chronic inhalation exposure to Inhalate can result in multiple health effects. Available studies demonstrate neurotoxicity in adult humans. However, dose-response information is not available, and the presumed LOAEL (20 mg/m^3) for neurotoxicity in humans is somewhat higher than the HECs for other health endpoints (developmental, reproductive, liver, and renal effects) observed in animal studies, where the $LOAEL_{HEC}$s range from 7 mg/m^3 to 22.5 mg/m^3 and the $NOAEL_{HEC}$s range from 2.5 mg/m^3 to 5 mg/m^3. Dose-response data for these health endpoints in animal studies can be used as the basis for deriving a longer-term inhalation reference value for Inhalate.

UFs of $10^{1/2}$ (interspecies), 10 (intraspecies), and $10^{1/2}$ (database deficiencies) were applied to $NOAEL_{HEC}$s for the various endpoints in deriving sample reference values. If an additional factor of 3 were applied to the rat developmental toxicity data to account for the marked difference in exposure duration in the study itself (7 days of exposure: GDs 7–13) versus the duration covered by this reference value (up to 10% of the life span), a longer-term sample reference value of 0.01 mg/m^3 would result. Without this additional factor, the sample reference value from the developmental toxicity study was still the lowest value (0.03 mg/m^3), although all values from the animal studies were in a similar range (0.03–0.05).

The final reference value chosen was 0.03 mg/m^3 to be protective of the developing individual as well as adults (Table B-2). Whether an additional factor should be applied to the developmental toxicity data or to other data of much shorter duration should be explored further.

Chronic Inhalation Exposure

For the chronic inhalation reference value, the $LOAEL_{HEC}$s range from 4 mg/m^3 to18 mg/m^3 and the $NOAEL_{HEC}$s range from 2 mg/m^3 to 5 mg/m^3. UFs of $10^{1/2}$ (interspecies), 10 (intraspecies), and $10^{1/2}$ (database deficiencies) applied to the chronic exposure $NOAEL_{HEC}$s for neurotoxicity and liver, kidney, and reproductive toxicity data result in sample reference values of 0.02–0.05 mg/m^3 (Table B-2). Applying these UFs to the $NOAEL_{HEC}$ of 2.5 mg/m^3 for developmental toxicity yields a sample reference value of 0.03 mg/m^3, which falls within the range of chronic study-based values. If, contrary to current practice, an additional 3- or 10-fold UF for subchronic to chronic duration were applied to the developmental $NOAEL_{HEC}$, the sample reference value would be 0.01 or 0.003. As mentioned in Section 4.4.5.6, this issue may need further exploration. In this example, several endpoints result in a sample chronic inhalation reference value of 0.02 mg/m^3, the value chosen for the chronic inhalation reference value.

With regard to the liver effects of Inhalate, the $NOAEL_{HEC}$s and reference values for liver histopathology were the same as for the tumorigenic effects; thus, the reference value based on liver toxicity should be protective of the carcinogenic effects of Inhalate.

Overall Evaluation of Reference Values

The reference values for Inhalate were similar across all durations of exposure. This is because the same data were used as the basis for the acute, short-term, and longer-term reference value, that is, the effects on developmental neurotoxicity. Although there were human data appropriate for consideration for all four durations of exposure, the endpoints examined in these studies or reports were limited and were not indicative of effects on the developing nervous system. To be protective of developmental life stages, it was considered appropriate to base the reference values on the developmental neurotoxic effects, for which the sample reference value was slightly lower than for other endpoints. For the chronic reference value, a number of sample reference values, including that for the carcinogenic effects of Inhalate, were clustered in the same range, at 0.02 mg/m^3, slightly lower than that for developmental neurotoxicity. In this case, it was considered appropriate to use this lower reference value to be protective of all potential effects for lifetime exposures.

CASE STUDY 2: LUTEINATE

INTRODUCTION

Luteinate is a new pesticide that was developed for use as an herbicide. Environmental fate studies have shown that it will persist in soils and will therefore likely to move into ground and surface water. The general population may be exposed to Luteinate through consumption of food and drinking water.

Luteinate belongs to a class of pesticides for which the neuroendocrine mode of action is known. It was designed to be less potent than other members of the class. In order to ascertain its potency, a number of short-term studies were first conducted; they confirmed a similar mode of action and the fact that Luteinate was less potent. Following this, Luteinate was tested in more traditional toxicology studies to establish its long-term effects and dose-response relationships.

This case study provides an example of the usefulness of mode of action information in establishing the short- and long-term effects of Luteinate on relevant target organ systems at different life stages. Such information enables the development of a targeted robust data set for use in establishing reference values for various durations of exposure.

Postulated Mode of Action

Other members of this class of pesticides have been shown to act on the hypothalamic-pituitary-ovarian axis. These pesticides affect the hypothalamus, leading to a decreased secretion of hypothalamic norepinephrine (NE). Decreased NE levels result in decreased release of gonadotropin releasing hormone (GnRH) from the hypothalamus. GnRH is the hormone responsible for inducing the pituitary gland to release luteinizing hormone (LH). Thus, the decrease in GnRH leads to a suppression of the pituitary LH release. These compounds also decrease the neurotransmitter dopamine, which in turn leads to a decrease in pituitary prolactin.

Decreased LH and prolactin levels have the potential to impact several organ systems at different life stages. In humans, there are robust pulses of the LH surge in the fetus and prior to birth. The LH pulsatility continues with diminishing amplitude during the early months of postnatal life, and then LH secretion becomes barely detectable during much of the first decade of postnatal life. Around the age of 10, there is the reemergence or re-awaking of LH pulses while sleeping.

The natural progression from prepubertal to postpubertal status is dependent on the normal function of the hypothalamic-pituitary-gonadal axis. Likewise, many of the same hypothalamic mechanisms that control pituitary function and the pituitary hormones themselves

(especially LH and prolactin) play a key role in pubertal development. In the adult, ovulation is dependent on sufficient LH levels. Therefore, this class of pesticides impacts critical reproductive processes, including puberty, ovarian cyclicity, pregnancy, and lactation (milk quality/production). Given the role of NE and dopamine in the development of the CNS, this class of pesticides may also affect the developing CNS; however, relevant toxicology studies have not yet been conducted. In addition, suppression of prolactin during the early postnatal period in rodents may lead to prostate inflammation in male offspring.

This class of pesticides has also been shown to lead to mammary tumors in Sprague-Dawley (SD) rats but not in other strains of rats or mice. Mammary tumors result from the prolonged decrease in serum LH, which leads to a cessation of ovulation and eventually causes the ovarian follicles to continue to secret estradiol. In concert with prolactin, estrogen acts on the mammary gland and leads to the formation of mammary tumors. However, the induction of the tumors has been shown to be due to unique features of the reproductive aging process in Sprague-Dawley rats; because humans do not age in the same manner, this mode of action is unlikely to be operative in humans.

SUMMARY OF HEALTH EFFECTS INFORMATION

Studies with other pesticides in this chemical class have found negligible differences in response (with the exception of the induction of mammary tumors in SD rats) among various strains of rats and between rats and mice. Therefore, all studies on Luteinate were conducted on SD rats.

Luteinate exposure results in a spectrum of effects that are related to decreases in serum LH and decreases in prolactin. The toxicology studies are summarized below in the context of the specific effects associated with either decreases in LH or prolactin. In addition, the effect levels for specific toxicological endpoints are summarized in Table B-3. It is important to note that as the spectrum of effects are mechanistically related to decreases in serum LH or prolactin, there is great similarity in the doses that affect LH and prolactin levels and those that cause the related effects.

Absorption, Distribution, Metabolism, and Elimination

Studies in adult rats have shown that Luteinate is rapidly absorbed following oral exposure. It is not metabolized and is eliminated in the urine. No other information is available. The toxicokinetic profiles of other pesticides in this chemical class have not been extensively examined either.

Table B-3. Summary of endpoints and effect levels for rat studies of Luteinate

Response	Exposure period	Dose levels (mg/kg/day)	NOAEL/LOAEL (mg/kg/day)
Decreased LH	Pregnant females: GDs 1–8	 50, 100, 200	 100/200
	PNDs 22–41	25, 50, 100	50/100
	Adults: 3 days 28 days 6 months	 50, 100, 200 40, 80, 160 4, 8, 16	 100/200 40/80 4/8
	Two-generation reproduction study: 10 weeks - F0 13 weeks - F1[a]	 5, 10, 25, 50 5, 10, 25, 50	 5/10 5/10
Disruption of estrous cyclicity	PND 22-41	25, 50, 100	50/100
	Adults: 28 days 6 months	 40, 80, 160 4, 8, 16	 40/80 4/8
	Two-generation reproduction study: 10 weeks - F0 13 weeks - F1[a]	 5, 10, 25, 50 5, 10, 25, 50	 5/10 5/10
Altered pregnancy maintenance	Pregnant females: GDs 1–8 GDs 6–10 GDs 1–20	 50, 100, 200 100, 200, 400 50, 100, 200	 100/200 200/400 100/200
	Two-generation reproduction study: 11–13 weeks - F0 14–16 weeks - F1[a]	 5, 10, 25, 50 5, 10, 25, 50	 5/10 5/10
Delayed parturition	Pregnant females: GDs 6–10	 100, 200, 400	 100/200
	Two-generation reproduction study: 14 weeks - F0 17 weeks - F1[a]	 5, 10, 25, 50 5, 10, 25, 50	 5/10 5/10
Delayed vaginal opening	PNDs 22–41	25, 50, 100	50/100
	Two-generation reproduction study: 4–5 weeks - F1[a]	 5, 10, 25, 50	 25/50
Delayed preputial separation	PND 23–53	25, 50, 100	50/100
	Two-generation reproduction study: 6–7 weeks - F1[a]	 5, 10, 25, 50	 25/50

Table B-3. Summary of endpoints and effect levels for rat studies of Luteinate (continued)

Response	Exposure period	Dose levels (mg/kg/day)	NOAEL/LOAEL (mg/kg/day)
Attenuation of prolactin release	Lactating females: PNDs 1–4	 25, 50, 100	 25/50
	Adults: 3 days 28 days 6 months	 50, 100, 200 40, 80, 160 4, 8, 16	 100/200 40/80 4/8
	Two-generation reproduction study: 10 weeks - F0 13 weeks - F1[a]	 5, 10, 25, 50 5, 10, 25, 50	 5/10 5/10
Increased prostatitis in offspring	PNDs 1–4	25, 50, 100	25/50
	Adults: 28 days 6 months	 40, 80, 160 4, 8, 16	 >200/NA[b] >160/NA[b]
	Two-generation reproduction study: 16 weeks - F0 16 weeks - F1[a]	 5, 10, 25, 50 5, 10, 25, 50	 >50/NA[b] 5/10
Reduced weight of seminal vesicles and ventral prostate	PNDs 23–53	25, 50, 100	50/100
	Adults: 28 days 6 months	 40, 80, 160 4, 8, 16	 >200/NA[b] >160/NA[b]
	Two-generation reproduction study: 16 weeks - F1[a]	 5, 10, 25, 50	 5/10
Fetus: Delayed ossification Reduced fetal weight	 GDs 1–20 GDs 1–20	 50, 100, 200 50, 100, 200	 100/200 >200/NA[b]

[a] F1 exposures are indicated for the duration of postnatal exposure, but it is assumed that 3 weeks of prenatal exposure also occurred.

[b] When no effect on a particular endpoint was noted in a study, the NOAEL is indicated as > the highest dose, and the LOAEL as NA (not applicable).

Decreased LH Surge and Related Effects

Exposure to Luteinate resulted in a significant decrease in serum LH that was dependent on the dose and duration of exposure. In a 3-day gavage study of SD male and female rats exposed to levels of 0, 50, 100, and 200 mg/kg/day, there were significant decreases in serum LH at 200 mg/kg/day. Serum LH was significantly reduced at doses of 80 mg/kg/day and above in a 28-day study and at doses of 8 mg/kg/day and above in a 6-month study of SD rats. Levels in the latter study were similar to those observed in the F0 rats in a two-generation reproductive toxicity study in which significant decreases in serum LH were observed at doses of 10 mg/kg/day and higher following 10 weeks of exposure.

Serum LH was also measured in pregnant dams exposed to doses of 0, 50, 100, and 200 mg/kg/day on GDs 1–8 and was significantly reduced at 200 mg/kg/day. Exposure of weanling SD rats on PNDs 22–41 to doses of 0, 25, 50, and 100 mg/kg/day of Luteinate resulted in a significant decrease in serum LH at 100 mg/kg/day. In a two-generation reproductive toxicity study, serum LH was measured in the F1 generation prior to mating (13 weeks postnatal exposure) and was significantly reduced at doses of 10 mg/kg/day and higher.

Disruption of Estrous Cyclicity

In the adult female, ovulation is dependent on sufficient levels of LH. Because exposure to Luteinate suppresses LH, it would be anticipated to also disrupt the normal estrous cycle. Estrous cyclicity was abnormal in SD rats exposed to 80 mg/kg/day for 28 days and 8 mg/kg/day for 6 months. In the two-generation reproductive toxicity study, estrous cyclicity was abnormal in the F0 females exposed to 10 mg/kg/day for 10 weeks and in the F1 females exposed to 10 mg/kg/day for 13 weeks postnatally (as well as prenatally). In addition, exposure of weanlings to 100 mg/kg/day on PNDs 22–41 resulted in abnormal estrous cycles.

Pregnancy

Altered LH levels also impact the ability of the female to maintain pregnancy as well as the timing of parturition. Thus, in a variety of exposure scenarios, an increase in pre- and postimplantation loss was observed. Implantation was affected following exposure to 200 mg/kg/day on GDs 1–8 or 1–20 and after exposure to 400 mg/kg/day on GDs 6–10. Parturition was delayed following exposure to 200 mg/kg/day and above on GDs 6–10. In the two-generation reproductive toxicity study, there was an increase in pre- and postimplantation loss and a delay in parturition in the F0 and F1 females at doses of 10 mg/kg/day and higher.

Sexual Maturation

At the time of puberty, the CNS and pituitary respond to increased concentrations of estradiol in a positive feedback fashion culminating in the first LH surge. Thus, exposure to Luteinate would likely impact sexual maturation. Vaginal opening was delayed in female SD rats following exposure to 100 mg/kg/day on PNDs 22–41 and preputial separation was delayed in males exposed to 100 mg/kg/day on PNDs 23–53. In the two-generation reproductive toxicity study, vaginal opening was delayed in the F1 females exposed to 50 mg/kg/day and preputial separation was delayed in the F1 males exposed to 50 mg/kg/day.

Decreased Prolactin and Related Effects

Prolactin levels were significantly decreased in adult SD rats following exposure to 200 mg/kg/day of Luteinate for 3 days, to 80 mg/kg/day for 28 days, and to 8 mg/kg/day for 6 months. In a study in which lactating dams were exposed during PNDs 1–4, prolactin levels were reduced at doses of 50 mg/kg/day. In the two-generation reproductive toxicity study, prolactin levels were reduced in the F0 and F1 animals at doses of 10 mg/kg/day.

Prostatitis

As a consequence of the reduced prolactin levels, an increased incidence of prostatitis was observed in males following maternal exposure to 50 mg/kg/day during lactation days 1–4, and in the F1 males exposed to 10 mg/kg/day and higher. Prostatitis was not observed in males exposed during adulthood only (i.e., F0 males, males in 28-day and 6-month studies).

Organ Weights

In males exposed to doses of 100 mg/kg/day Luteinate during PNDs 23–53, there was a decrease in absolute and relative weights of the seminal vesicles and ventral prostate. This was also observed in the F1 males exposed to doses of 10 mg/kg/day or greater at the time of terminal sacrifice following mating. Histopathological examination revealed no lesions in either study. No organ weight changes or histopathological lesions were noted in any of the other studies.

Effects Unrelated to LH or Prolactin

A prenatal developmental toxicity study was conducted in which pregnant SD rats were exposed to doses of 0, 50, 100, or 200 mg/kg/day Luteinate on GDs 1–20. In addition to the increase in implantation loss noted above, there was an increase in delayed ossification at 200

mg/kg/day but no effect on fetal body weight. It is unlikely that this effect is related to LH levels. However, the mode of action is unknown.

SELECTION OF HEALTH ENDPOINTS AND DERIVATION OF REFERENCE VALUES

Narrative Description of the Extent of the Database

The database for oral exposure is quite robust and is adequate for deriving reference values. Because the mode of action was known for other pesticides in this chemical class, it was possible to study known targets during relevant life stages. Luteinate was shown to interfere with the pituitary-hypothalamic axis, resulting in a decrease in serum LH and prolactin. The decrease was shown to be dependent on dose and duration of exposure. Normal LH levels are known to be required for ovulation, maintenance of pregnancy, timing of parturition, and sexual maturation. Similarly, decreases in prolactin can lead to prostatitis and effects on the male reproductive organs. Each of these events were examined in several short-term studies as well as in traditional prenatal developmental toxicity studies and a two-generation reproductive toxicity study.

An acute toxicity study of Luteinate was not conducted. However, information was available on serum LH and prolactin levels from other short-term exposures that was informative for acute exposures. The database as a whole demonstrates that there is a clear dose-duration relationship for Luteinate on serum LH levels. Serum LH levels were reduced following a 3-day exposure in adult rats and in pregnant rats on GDs 1–8 at doses of 200 mg/kg/day; longer exposures to weanlings on PNDs 22–41 or to adults for 28 days required a dose of 100 or 80 mg/kg/day, respectively. The effective dose of 10 mg/kg/day was still lower following 10 to 13 weeks exposure. Therefore, it is unlikely that serum LH levels and related effects would occur at doses less than 200 mg/kg/day following an acute exposure, but higher doses may actually be necessary.

The situation is less clear for the decrease in prolactin and related effects. Prolactin levels were reduced following a 3-day exposure to adult rats at 200 mg/kg/day and following exposure to lactating dams at 50 mg/kg/day. A 28-day exposure to adult rats resulted in decreased prolactin levels at 80 mg/kg/day, whereas 10 mg/kg/day was an effective dose at 10 to 13 weeks of exposure. Thus, although there is a clear dose-duration relationship between the 4- and 10-week periods, the relationship is less clear for durations of less than 28 days. However, it is unlikely that serum prolactin levels and related effects would have NOAELs less than 25 mg/kg/day following an acute exposure.

Knowledge about the effect of Luteinate on serum LH and prolactin levels from these other studies was considered in conjunction with the prenatal developmental toxicity study for deriving the acute reference value. It is assumed that effects resulting from developmental exposures (both prenatal and postnatal) may be the result of a single exposure. Therefore, the fetal and offspring effects resulting from exposures during gestation and postnatally to the time of sexual maturation were also considered for the acute reference value. Data from the two-generation study were not considered because there were always shorter-term studies showing effects at higher doses. Taken as a whole, the lack of an acute toxicity study was not considered to be a major data gap for Luteinate.

A chronic study of Luteinate was not conducted. However, serum LH was decreased at 10 mg/kg/day in the F0 and F1 animals in the two-generation reproductive toxicity study and at 8 mg/kg/day in the 6-month study. Because there is essentially no change in the effective dose levels following 13 weeks of exposure and 6 months of exposure, it is unlikely that a longer exposure period would substantially lower the effective dose. Thus, the lack of a chronic study was not considered a major database deficiency. Although there is no knowledge of the effects of continued LH and prolactin suppression on reproductive aging, this is probably a qualitative, rather than a quantitative data gap. It is known from chronic bioassays of other pesticides in this chemical class that lifetime exposure results in mammary tumors in SD rats, but this mode of action is unlikely to be operative in humans due to differences in the aging process. Thus, this was not considered to be a data gap for Luteinate.

A developmental neurotoxicity study was not conducted. Given that Luteinate interferes with two neuroreceptors, norepinephrine and dopamine, the potential for developmental neurotoxicity exists. Thus, the lack of knowledge regarding the developing nervous system is considered to be a data gap.

Exposure-Response Array

In addition to the display in tabular form (Table B-3), the data considered useful for deriving each reference value were displayed in an exposure-response array. The arrays for acute, short-term, longer-term, and chronic exposures are shown in Figures B-5 through B-8, respectively. Although data on delayed ossification were considered in deriving the longer-term and chronic reference values, the data were not included in Figures B-7 and B-8 because the doses were substantially higher than those for all other endpoints, and inclusion would have altered the y-axis substantially. Figure B-9 is a composite of the NOAELs for each endpoint

with each exposure duration. In addition, the NOAELs for each relevant endpoint, the uncertainty factors (UFs), and the sample and final reference values are shown in Table B-4.

Uncertainty Factors

An interspecies UF (A in Table B-4) of 10 was applied in all cases because the data were insufficient to characterize toxicokinetic and toxicodynamic differences between rodents and humans. An intraspecies UF (H in Table B-4) of 10 was applied in all cases because the data did not allow the estimation of human variability. A UF for LOAEL to NOAEL (L in Table B-4) was not applied because the NOAEL was known for each exposure duration. A subchronic-to-chronic UF (S in Table B-4) was not applied because there were data available for each exposure duration. A database UF of $10^{1/2}$ was applied in all cases because there are concerns for the potential developmental neurotoxicity of Luteinate and there were no available data.

A database UF of $10^{1/2}$ (rather than a UF of 10) was applied on basis of the observation that for other pesticides in this chemical class, the doses that result in a decrease in norephinephrine and dopamine are very similar to the doses that lead to decreases in serum LH. Therefore, it is likely that any developmental neurotoxicity effects would be observed at similar doses. Because the effects of Luteinate on serum LH levels have been well characterized, additional developmental neurotoxicity information is unlikely to dramatically affect the reference values. However, a UF of $10^{1/2}$ was retained to reflect underlying uncertainties of this data gap.

Acute Exposure

For the derivation of the acute reference value, a standard prenatal developmental toxicity study provided information on the effects of Luteinate on fetal ossification in the absence of an effect on fetal weight. There was no information on serum LH or prolactin and related effects following an acute exposure. As described above in the discussion of the extent of the database, it is unlikely that the NOAEL for serum LH levels and related effects would be less than 100 mg/kg/day following an acute exposure, and it could be higher. Similarly, it is unlikely that the NOAEL for serum prolactin levels and related effects would be less than 25 mg/kg/day following an acute exposure. The effects on sexual maturation occurred at a dose of 100 mg/kg/day (NOAEL of 50 mg/kg/day) and effects on ossification occurred at a dose of 200 mg/kg/day (NOAEL of 100 mg/kg/day).

Thus, derivation of the acute reference value based on these endpoints would also be protective of effects on serum LH and related effects, but may not cover effects on prolactin and

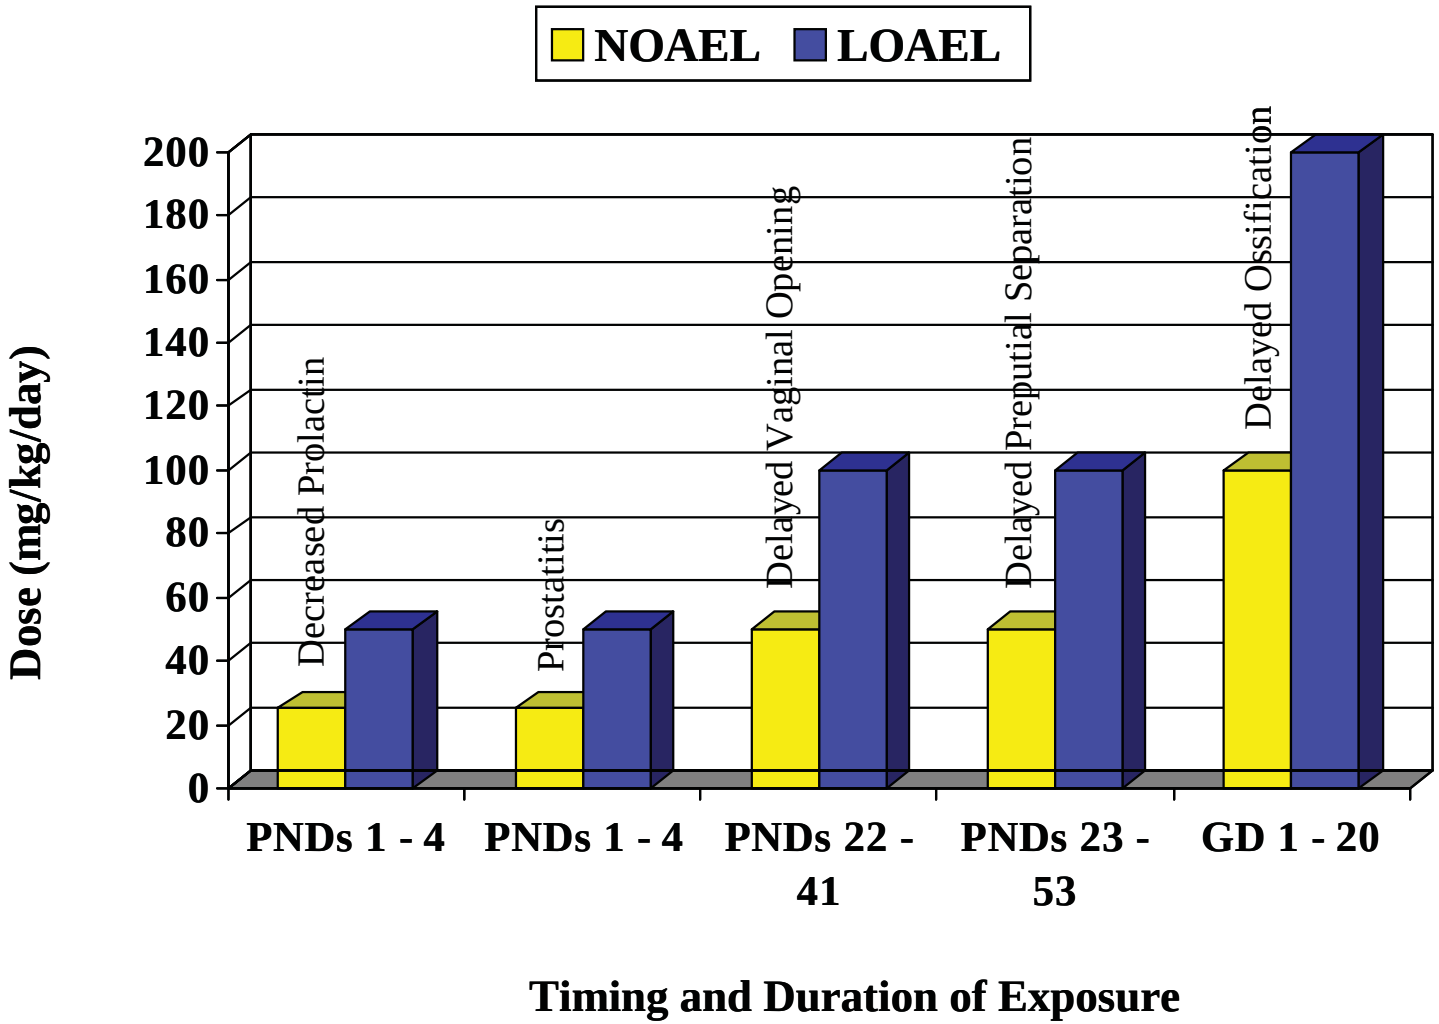

Figure B-5. Exposure-response array of data considered for the Luteinate acute reference value.

related effects. For this reason, the NOAEL of 25 mg/kg/day for prolactin and related effects following a 4-day developmental (neonatal) exposure was used as the basis for the acute reference value, with the assumption that a single exposure during a critical period of development would be sufficient to produce these effects.

Although a single-exposure LOAEL, particularly for the reduction in prolactin and increase in prostatitis (which showed a dependence on exposure duration in adults), might be slightly higher than the 4-day LOAEL, lack of data on this endpoint from a single-day exposure leads us to rely on the 4-day value during what appears to be a particularly sensitive time in the early postnatal period. Effects on prolactin (and therefore dopamine) also indicate a concern for developmental neurotoxicity (Figure B-5). Because there is a strong relationship between the data gaps of the acute toxicity study and the developmental neurotoxicity study, a database UF of $10^{1/2}$ was applied. In addition, UFs of 10 for interspecies and intraspecies uncertainty/variability were applied. The resulting reference value was 0.08 mg/kg/day.

Short-term Exposure

A variety of endpoints were examined for calculating the short-term reference value. Information was available on serum LH from the 3-day and 28-day adult studies as well as the study in which pregnant dams were exposed on GDs 1–8. Information on estrous cyclicity was available from the 28-day study in adult rats and in the study in which female weanlings were exposed on PNDs 22–41. Information on pregnancy maintenance was available from studies in which pregnant dams were exposed on GDs 1–8, 6–10, and 1–20, and information on parturition was available for exposures on GDs 6–10.

Information on sexual maturation in females was available from the study in which female weanlings were exposed on PNDs 22–41, and information on sexual maturation in males was available from the study in which weanling male rats were exposed on PNDs 23–53. In addition, information on sexual maturation from the two-generation reproductive toxicity study was also considered relevant. The latter study also provided information on the effects of Luteinate on the seminal vesicles and ventral prostate. Information on prolactin was available from the 28-day study in adults and the study in which lactating dams were exposed on PNDs 1–4; information on prostatitis was also available from the latter study (Figure B-6).

Interspecies and intraspecies UFs of 10 were applied to each of these endpoints (Table B-4). For the entire database available for short-term exposure, a database UF of $10^{1/2}$ was applied in the derivation of the final reference value for the lack of a developmental neurotoxicity study. The resulting reference values ranged from 0.08 to 0.67 mg/kg/day, and the final reference value was 0.08 mg/kg/day.

Longer-term Exposure

For derivation of the longer-term reference value, the databases available for the acute and shorter-term exposures were considered. In addition, the two-generation reproductive toxicity study provided information following longer exposures for serum LH, estrous cyclicity, pregnancy maintenance, parturition, prolactin, and prostatitis (Fig. B-7). Interspecies and intraspecies UFs of 10 were applied to each of these endpoints (Table B-4). The resulting sample reference values were 0.33 mg/kg/day, based on delayed ossification and 0.08 mg/kg/day, based on sexual maturation; all the other endpoints yielded a value of 0.02 mg/kg/day. The latter was chosen as the final value for the longer-term reference value.

Chronic Exposure

Information from all of the exposure scenarios described above was considered in deriving the chronic reference value. In addition, information on serum LH and estrous cyclicity was available from the 6-month study in adult rats. For endpoints where there was a clear exposure-dose-effect relationship, only information from studies of the longest exposure period was included in Table B-4 and Figure B-8. As noted above, decreases in serum LH were observed at 8 mg/kg/day in the 6-month study and at 10 mg/kg/day in the two-generation reproductive toxicity study; the NOAELs were 4 and 5 mg/kg/day, respectively. Estrous cyclicity was affected at these same dose levels in the two studies. The NOAEL for all other endpoints in the two-generation reproductive toxicity study was also 5 mg/kg/day.

Given the similarity in effect levels in the two studies, it is unlikely that longer exposures would alter the effect level. For this reason, although there is no information on the effect of Luteinate on reproductive aging, this is considered to be a qualitative gap in hazard identification, but was not considered to be a database deficiency for the purposes of deriving a chronic reference value. UFs of 10 for interspecies and intraspecies variability and uncertainty were applied to each of these endpoints (Table B-4). The reference values ranged from 0.01 to 0.02 mg/kg/day, and 0.01 mg/kg/day was chosen as the final value.

GLOSSARY

NOTE*: The following terms are used in this document. To the extent possible, definitions were taken from other EPA sources, e.g., IRIS, the Children's Health Research Strategy, the RfC Methodology. In some cases, the definitions have been revised from the originals in IRIS for the sake of clarity or to be consistent with usage in this document. Those terms and definitions that are changed and/or newly proposed in this document to be added to IRIS are shown in italics and the definition(s) they are proposed to replace are indicated in brackets. A number of other terms are included in the IRIS glossary that are not listed here, simply because they were not used in this document.*

Acute Exposure: One dose or multiple doses of short duration spanning less than or equal to 24 hours. [Current IRIS definition.]

Acute Exposure*: Exposure by the oral, dermal, or inhalation route for 24 hours or less.* [Proposed definition to replace the current Acute Exposure definition on IRIS.]

Adverse Effect: A biochemical change, functional impairment, or pathologic lesion that affects the performance of the whole organism or reduces an organism's ability to respond to an additional environmental challenge.

Benchmark Dose (BMD) or Concentration (BMC): A statistical lower confidence limit on the dose that produces a predetermined change in response rate of an adverse effect (called the benchmark response or BMR) compared to background. [current IRIS definition]

Benchmark Dose (BMD) or Concentration (BMC): *A dose or concentration that produces a predetermined change in response rate of an adverse effect (called the benchmark response or BMR) compared to background.* [Proposed definition to replace the current definition on IRIS.]

BMDL or BMCL: *A statistical lower confidence limit on the dose or concentration at the BMD or BMC, respectively.* [A new definition to be added to IRIS.]

Benchmark Response (BMR): An adverse effect used to define a benchmark dose from which an RfD (or RfC) can be developed. The change in response rate over background of the BMR is usually in the range of 5 to 10%, which is the limit of responses typically observed in well-conducted animal experiments.

Bioassay: An assay for determining the potency (or concentration) of a substance that causes a biological change in experimental animals.

Bioavailability: The degree to which a substance becomes available to the target tissue after administration or exposure.

Biologically Based Dose Response (BBDR) model: A predictive tool used to estimate potential human health risks by describing and quantifying the key steps in the cellular, tissue, and organismal responses as a result of chemical exposure. [Current IRIS definition.]

Biologically Based Dose Response (BBDR) Model: *A predictive model that describes biological processes at the cellular and molecular level linking the target organ dose to the adverse effect.* [Proposed definition to replace the current definition on IRIS.]

Blood-to-air Partition Coefficient: A ratio of a chemical's concentration between blood and air when at equilibrium.

Chronic Exposure: Multiple exposures occurring over an extended period of time or a significant fraction of the animal's or the individual's lifetime. [Current IRIS definition.]

Chronic Exposure*: Repeated exposure by the oral, dermal, or inhalation route for more than approximately 10% of the life span in humans (more than approximately 90 days to 2 years in typically used laboratory animal species).* [Proposed definition to replace the current definition for Chronic Exposure on IRIS.]

Chronic Study: A toxicity study designed to measure the (toxic) effects of chronic exposure to a chemical.

Critical Effect: The first adverse effect, or its known precursor, that occurs to the most sensitive species as the dose rate of an agent increases.

Critical Study: The study that contributes most significantly to the qualitative and quantitative assessment of risk; also called Principal Study.

Developmental Toxicity: Adverse effects on the developing organism that may result from exposure prior to conception (either parent), during prenatal development, or postnatally until the time of sexual maturation. The major manifestations of developmental toxicity include death of the developing organism, structural abnormality, altered growth, and functional deficiency.

Dose*: The amount of a substance available for interactions with metabolic processes or biologically significant receptors after crossing the outer boundary of an organism. The* ***potential dose*** *is the amount ingested, inhaled, or applied to the skin. The* ***applied dose*** *is the amount presented to an absorption barrier and available for absorption (although not necessarily having yet crossed the outer boundary of the organism). The* ***absorbed dose*** *is the amount crossing a specific absorption barrier (e.g., the exchange boundaries of the skin, lung, and digestive tract) through uptake processes.* ***Internal dose*** *is a more general term denoting the amount absorbed without respect to specific absorption barriers or exchange boundaries. The amount of the chemical available for interaction by any particular organ or cell is termed*

*the **delivered** or **biologically effective dose** for that organ or cell.* [New definition proposed to be added to IRIS.]

Dose-Response Assessment: A determination of the relationship between the magnitude of an administered, applied, or internal dose and a specific biological response. Response can be expressed as measured or observed incidence, percent response in groups of subjects (or populations), or as the probability of occurrence within a population. [Current IRIS definition.]

Dose-Response Assessment: *A determination of the relationship between the magnitude of an administered, applied, or internal dose and a specific biological response. Response can be expressed as measured or observed incidence or change in level of response, percent response in groups of subjects (or populations), or the probability of occurrence or change in level of response within a population.* [Proposed definition to replace the current definition on IRIS.]

Dose-Response Relationship: The relationship between a quantified exposure (dose) and the proportion of subjects demonstrating specific, biological changes (response). [Current IRIS definition.]

Dose-Response Relationship: *The relationship between a quantified exposure (dose) and the proportion of subjects demonstrating specific biological changes in incidence or in degree of change (response).* [Proposed definition to replace the current definition on IRIS.]

Endpoint: An observable or measurable biological event or chemical concentration (e.g., metabolite concentration in a target tissue) used as an index of an effect of a chemical exposure.

Epidemiology: The study of disease patterns in human populations. [Current IRIS definition.]

Epidemiology: *The study of the distribution and determinants of health-related states or events in specified populations and the application of this study to the control of health problems.* [Proposed definition to replace the current definition on IRIS.]

Exposure: Contact made between a chemical, physical, or biological agent and the outer boundary of an organism. Exposure is quantified as the amount of an agent available at the exchange boundaries of the organism (e.g., skin, lungs, gut).

Exposure Assessment: An identification and evaluation of the human population exposed to a toxic agent, describing its composition and size, as well as the type, magnitude, frequency, route, and duration of exposure.

Exposure Pathway: The physical course an environmental agent takes from the source to the individual exposed.

Extrapolation, Low Dose: An estimate of the response at a point below the range of the experimental data, generally through the use of a mathematical model.

Hazard: A potential source of harm.

Hazard Assessment: The process of determining whether exposure to an agent can cause an increase in the incidence of a particular adverse health effect (e.g., cancer, birth defect) and whether the adverse health effect is likely to occur in humans.

Hazard Characterization*: A description of the potential adverse health effects attributable to a specific environmental agent, the mechanisms by which agents exert their toxic effects, and the associated dose, route, duration, and timing of exposure.* [New definition proposed to be added to IRIS]

Human Equivalent Concentration (HEC): The human concentration (for inhalation exposure) of an agent that is believed to induce the same magnitude of toxic effect as the experimental animal species concentration. This adjustment may incorporate toxicokinetic information on the particular agent, if available, or use a default procedure.

Human Equivalent Dose (HED): The human dose (for other than the inhalation routes of exposure) of an agent that is believed to induce the same magnitude of toxic effect as the experimental animal species dose. This adjustment may incorporate toxicokinetic information on the particular agent, if available, or use a default procedure, such as assuming that daily oral doses experienced for a lifetime are proportional to body weight raised to the 0.75 power.

Incidence: The number of new cases of a disease that develop within a specified population over a specified period of time.

Incidence Rate: The ratio of new cases within a population to the total population at risk given a specified period of time.

Latency Period: The time between exposure to an agent and manifestation or detection of a health effect of interest.

Linear Dose Response: A pattern of frequency or severity of biological response that varies proportionately with the amount of dose of an agent. [Current IRIS definition.]

Linear Dose Response: *A pattern of frequency or severity of biological response that varies directly with the amount of dose of an agent. This linear relationship holds only at low doses in the range of extrapolation.* [Proposed definition to replace the current definition on IRIS.]

Longer-term Exposure: *Repeated exposure by the oral, dermal, or inhalation route for more than 30 days, up to approximately 10% of the life span in humans (more than 30 days up to*

approximately 90 days in typically used laboratory animal species). [Proposed new definition to be used relative to the Longer-term Reference Value. Similar to the current definition for Subchronic Exposure. Because subchronic exposure studies will continue to be used in risk assessment, the latter term should be retained as well but replaced with the definition for Longer-term Exposure.]

Lowest-Observed-Adverse-Effect Level (LOAEL): The lowest exposure level at which there are statistically or biologically significant increases in frequency or severity of adverse effects between the exposed population and its appropriate control group. Also referred to as lowest-effect level (LEL). [Current IRIS and RfC Methodology definition.]

Lowest-Observed-Adverse-Effect Level (LOAEL): *The lowest exposure level at which there are biologically significant increases in frequency or severity of adverse effects between the exposed population and its appropriate control group.* [Proposed to replace the current definition in IRIS and the RfC methodology, U.S. EPA, 1994]

Margin of Exposure (MOE): The LED10 or other point of departure divided by the actual or projected environmental exposure of interest.

Mechanism of Action: The complete sequence of biological events that must occur to produce the toxic effect.

Mode of Action (MOA): A less-detailed description of the mechanism of action in which some but not all of the sequence of biological events leading to a toxic effect is known.

Modifying Factor (MF): A factor used in derivation of a reference dose or reference concentration. The magnitude of the MF reflects the scientific uncertainties of the study and database not explicitly treated with standard uncertainty factors (e.g., the completeness of the overall database). A MF is greater than zero and less than or equal to 10, and the default value for the MF is1. [Current definition in IRIS; this report recommends that its use be discontinued.]

No-Observed-Adverse-Effect Level (NOAEL): The highest exposure level at which there are no statistically or biologically significant increases in the frequency or severity of adverse effect between the exposed population and its appropriate control; some effects may be produced at this level, but they are not considered adverse, nor precursors to adverse effects. [Current IRIS and RfC Methodology definition.]

No-Observed-Adverse-Effect Level (NOAEL): *The highest exposure level at which there are no biologically significant increases in the frequency or severity of adverse effect between the exposed population and its appropriate control; some effects may be produced at this level, but they are not considered adverse or precursors to adverse effects.* [Proposed to replace the current definition in IRIS and the RfC methodology, U.S. EPA, 1994.]

Nonlinear Dose Response: A pattern of frequency or severity of biological response that does not vary proportionately with the amount of dose of an agent. When mode of action information indicates that responses may not follow a linear pattern below the dose range of the observed data, non-linear methods for determining risk at low dose may be justified. [Current IRIS definition.]

Nonlinear Dose Response: *A pattern of frequency or severity of biological response that does not vary directly with the amount of dose of an agent. When mode of action information indicates that responses may fall more rapidly than dose below the range of the observed data, nonlinear methods for determining risk at low dose may be justified.* [Proposed definition to replace the current definition on IRIS.]

Physiologically Based Pharmacokinetic (PBPK) Model: Physiologically based compartmental model used to characterize pharmacokinetic behavior of a chemical. Available data on blood flow rates, and metabolic and other processes which the chemical undergoes within each compartment are used to construct a mass-balance framework for the PBPK model. [Current IRIS definition.]

Physiologically Based Pharmacokinetic (PBPK) Model: *A model that estimates the dose to a target tissue or organ by taking into account the rate of absorption into the body, distribution among target organs and tissues, metabolism, and excretion.* [Proposed definition to replace the current definition on IRIS.]

Point of Departure: The dose-response point that marks the beginning of a low-dose extrapolation. This point is most often the upper bound on an observed incidence or on an estimated incidence from a dose-response model. [Current IRIS definition.]

Point of Departure: *The dose-response point that marks the beginning of a low-dose extrapolation. This point can be the lower bound on dose for an estimated incidence or a change in response level from a dose-response model (BMD), or a NOAEL or LOAEL for an observed incidence, or change in level of response.* [Proposed definition to replace the current definition on IRIS.]

Ppb: A unit of measure expressed as parts per billion. Equivalent to 1×10^{-9}.

Ppm: A unit of measure expressed as parts per million. Equivalent to 1×10^{-6}.

Prevalence: The proportion of disease cases that exist within a population at a specific point in time relative to the number of individuals within that population at the same point in time.

Reference Concentration (RfC): An estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a

lifetime. It can be derived from a NOAEL, LOAEL, or benchmark concentration, with uncertainty factors generally applied to reflect limitations of the data used. Generally used in EPA's noncancer health assessments. [Current IRIS definition.]

Reference Dose (RfD): An estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. It can be derived from a NOAEL, LOAEL, or benchmark dose, with uncertainty factors generally applied to reflect limitations of the data used. Generally used in EPA's noncancer health assessments. [Current IRIS definition.]

Reference Value (RfV): *An estimate of an exposure for [a given duration] to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse effects over a lifetime. It is derived from a BMDL, a NOAEL, a LOAEL, or another suitable point of departure, with uncertainty/variability factors applied to reflect limitations of the data used.* [Durations include acute, short-term, longer-term, and chronic and are defined individually in this glossary. This definition is proposed to replace those for the Reference Dose (RfD) and Reference Concentration (RfC). A subscript would be used with the RfV to denote route and duration, e.g., RfV_{AO} for the Acute Oral Reference Value.]

Regional Deposited Dose (RDD): The deposited dose of particles calculated for a respiratory tract region of interest (r) as related to an observed toxicity. For respiratory effects of particles, the deposited dose is adjusted for ventilatory volumes and the surface area of the respiratory region affected (mg/min-sq. cm). For extrarespiratory effects of particles, the deposited dose in the total respiratory system is adjusted for ventilatory volumes and body weight (mg/min-kg).

Regional Deposited Dose Ratio (RDDR): The ratio of the regional deposited dose calculated for a given exposure in the animal species of interest to the regional deposited dose of the same exposure in a human. This ratio is used to adjust the exposure-effect level for interspecies dosimetric differences to derive a human equivalent concentration for particles.

Regional Gas Dose: The gas dose calculated for the region of interest as related to the observed effect for respiratory effects. The deposited dose is adjusted for ventilatory volumes and the surface area of the respiratory region affected (mg/min-sq.cm).

Regional Gas Dose Ratio (RGDR): The ratio of the regional gas dose calculated for a given exposure in the animal species of interest to the regional gas dose of the same exposure in humans. This ratio is used to adjust the exposure effect level for interspecies dosimetric differences to derive a human equivalent concentration for gases with respiratory effects.

Risk (in the context of human health): The probability of injury, disease, or death from exposure to a chemical agent or a mixture of chemicals. In quantitative terms, risk is expressed in values ranging from zero (representing the certainty that harm will not occur) to one

(representing the certainty that harm will occur). The following are examples of how risk is expressed within IRIS: E-4 or 10-4 = a risk of 1/10,000; E-5 or 10-5 = 1/100,000; E-6 or 10-6 = 1/1,000,000. Similarly, 1.3 E-3 or 1.3 x 10-3 = a risk of 1.3/1,000=1/770; 8 E-3 or 8 x 10-3 = a risk of 1/125 and 1.2 E-5 or 1.2 x 10-5 = a risk of 1/83,000. [Current IRIS definition.]

Risk: *The probability of adverse effects resulting from exposure to an environmental agent or mixture of agents.* [Proposed definition to replace the current definition on IRIS.]

Risk Characterization*: The integration of information on hazard, exposure, and dose-response to provide an estimate of the likelihood that any of the identified adverse effects will occur in exposed people.* [New definition proposed to be added to IRIS.]

Risk Assessment (in the context of human health): The determination of potential adverse health effects from exposure to chemicals, including both quantitative and qualitative expressions of risk. The process of risk assessment involves four major steps: hazard identification, dose-response assessment, exposure assessment, and risk characterization. [Current IRIS definition.]

Risk Assessment: *The evaluation of scientific information on the hazardous properties of environmental agents (hazard characterization), the dose-response relationship (dose-response assessment), and the extent of human exposure to those agents (exposure assessment). The product of the risk assessment is a statement regarding the probability that populations or individuals so exposed will be harmed and to what degree (risk characterization).* [Proposed definition to replace the current definition on IRIS.]

Short-term Exposure: Multiple or continuous exposure to an agent for a short period of time, usually one week. [Current IRIS definition.]

Short-term Exposure: *Repeated exposure by the oral, dermal, or inhalation route for more than 24 hours, up to 30 days.* [Proposed definition to replace the current definition for Short-term Exposure on IRIS.]

Statistical Significance: The probability that a result [sic] likely to be due to chance alone. By convention, a difference between two groups is usually considered statistically significant if chance could explain it only 5% of the time or less. Study design considerations may influence the a priori choice of a different statistical significance level. [Current IRIS definition.]

Statistical Significance: *The probability that a result is not likely to be due to chance alone. By convention, a difference between two groups is usually considered statistically significant if chance could explain it only 5% of the time or less. Study design considerations may influence the a priori choice of a different level of statistical significance.* [Proposed definition to replace the current definition on IRIS.]

Subchronic Exposure: Exposure to a substance spanning approximately 10% of the lifetime of an organism. [See note for Longer-term Exposure.]

Subchronic Study: A toxicity study designed to measure effects from subchronic exposure to a chemical.

Supporting Studies: Studies that contain information useful for providing insight and support for conclusions.

Susceptible Subgroups*: May refer to life stages, for example, children or the elderly, or to other segments of the population, for example, asthmatics or the immune-compromised, but are likely to be somewhat chemical-specific and may not be consistently defined in all cases.* [New definition proposed to be added to IRIS.]

Susceptibility*: Increased likelihood of an adverse effect, often discussed in terms of relationship to a factor that can be used to describe a human subpopulation (e.g., life stage, demographic feature, or genetic characteristic).* [New definition proposed to be added to IRIS.]

Systemic Effects or Systemic Toxicity: Toxic effects as a result of absorption and distribution of a toxicant to a site distant from its entry point, at which point effects are produced. Not all chemicals that produce systemic effects cause the same degree of toxicity in all organs. [Current IRIS definition.]

Systemic Effects or Systemic Toxicity: *Toxic effects as a result of absorption and distribution of a toxicant to a site distant from its entry point.* [Proposed definition to replace the current definition on IRIS.]

Target Organ: The biological organ(s) most adversely affected by exposure to a chemical substance. [Current IRIS definition.]

Target Organ: *The biological organ(s) most adversely affected by exposure to a chemical or physical agent.* [Proposed definition to replace the current definition on IRIS.]

Threshold: The dose or exposure below which no deleterious effect is expected to occur.

Toxicity: The degree to which a chemical substance elicits a deleterious or adverse effect upon the biological system of an organism exposed to the substance over a designated time period. [Current IRIS definition.]

Toxicity: *Deleterious or adverse biological effects elicited by a chemical, physical, or biological agent.* [Proposed definition to replace the current definition on IRIS.]

Toxicodynamics*: The determination and quantification of the sequence of events at the cellular and molecular levels leading to a toxic response to an environmental agent (also called pharmacodynamics).* [New definition proposed to be added to IRIS.]

Toxicokinetics*: The determination and quantification of the time course of absorption, distribution, biotransformation, and excretion of chemicals (also called pharmacokinetics).* [New definition proposed to be added to IRIS.]

Toxicology: The study of harmful interactions between chemicals and biological systems. [current IRIS definition]

Toxicology: *The study of harmful interactions between chemical, physical, or biological agents and biological systems.* [Proposed definition to replace the current definition on IRIS.]

Toxic Substance: A chemical substance or agent which may cause an adverse effect or effects to biological systems. [Current IRIS definition.]

Toxic Substance: *A chemical, physical, or biological agent that may cause an adverse effect or effects to biological systems*. [Proposed definition to replace the current definition on IRIS.]

Uncertainty*: Uncertainty occurs because of a lack of knowledge. It is not the same as variability. For example, a risk assessor may be very certain that different people drink different amounts of water but may be uncertain about how much variability there is in water intakes within the population. Uncertainty can often be reduced by collecting more and better data, whereas variability is an inherent property of the population being evaluated. Variability can be better characterized with more data but it cannot be reduced or eliminated. Efforts to clearly distinguish between variability and uncertainty are important for both risk assessment and risk characterization.* [New definition proposed to be added to IRIS.]

Uncertainty Factor (UF): One of several, generally 10-fold, factors used in operationally deriving the RfD and RfC from experimental data. UFs are intended to account for (1) variation in sensitivity among the members of the human population, i.e., interhuman or intraspecies variability; (2) the uncertainty in extrapolating animal data to humans, i.e., interspecies variability; (3) the uncertainty in extrapolating from data obtained in a study with less-than-lifetime exposure to lifetime exposure, i.e., extrapolating from subchronic to chronic exposure; (4) the uncertainty in extrapolating from a LOAEL rather than from a NOAEL; and (5) the uncertainty associated with extrapolation from animal data when the data base is incomplete. [current IRIS definition]

Uncertainty/Variability Factors (UFs): *One of several, generally 10-fold, default factors used in operationally deriving the RfD and RfC from experimental data. The factors are intended to account for (1) variation in sensitivity among the members of the human population (i.e., inter-individual variability); (2) uncertainty in extrapolating animal data to humans (i.e.,*

interspecies uncertainty); (3) uncertainty in extrapolating from data obtained in a study with less-than-lifetime exposure to lifetime exposure (i.e., extrapolating from subchronic to chronic exposure); (4) uncertainty in extrapolating from a LOAEL rather than from a NOAEL; and (5) uncertainty associated with extrapolation when the database is incomplete. [Proposed definition to replace the current one for Uncertainty Factor on IRIS.]

***Variability**: Variability refers to true heterogeneity or diversity. For example, among a population that drinks water from the same source and with the same contaminant concentration, the risks from consuming the water may vary. This may be due to differences in exposure (i.e., different people drinking different amounts of water and having different body weights, different exposure frequencies, and different exposure durations) as well as differences in response (e.g., genetic differences in resistance to a chemical dose). Those inherent differences are referred to as variability. Differences among individuals in a population are referred to as inter-individual variability; differences for one individual over time is referred to as intra-individual variability.* [New definition proposed to be added to IRIS.]

CONTENTS

CONTENTS (continued)

LIST OF TABLES

LIST OF FIGURES

LIST OF ABBREVIATIONS

ADME	absorption, distribution, metabolism, excretion
Agency	U.S. Environmental Protection Agency
AOP	adverse outcome pathway
AUC	area under the curve (optional subscripts $_{A}$ = animal AUC value; $_{gen}$ = general human population AUC value; $_{sens}$ = sensitive human population AUC value)
AUC_A	animal AUC value (AUC value produced in animals at or near the animal point of departure)
AUC_{gen}	general human population AUC value (area under the concentration-time curve at a fixed external dose at a measure of central tendency in the entire or general human population)
AUC_{sens}	sensitive human population AUC value (area under the concentration-time curve at a fixed external dose at a percentile of interest for the sensitive human population or representing sensitive individuals among the entire human population)
BBDR	biologically based dose-response
$BMDL_x$	lower confidence bound on benchmark dose corresponding to an *x*% increase in response
$BW^{¾}$	body weight raised to the ¾ power
CF	composite factor
Cl	clearance (optional subscripts $_{A}$ = animal Cl value; $_{H}$ = human Cl value; $_{gen}$ = general human population Cl value; $_{sens}$ = sensitive human population Cl value; $_{hep}$ = hepatic Cl value; $_{int}$ = intrinsic Cl value)
Cl_A	animal Cl value
Cl_H	human Cl value
Cl_{gen}	general human population Cl value (at a measure of central tendency in the entire or general human population)
Cl_{sens}	sensitive human population Cl value (at a percentile of interest in the sensitive human population or representing sensitive individuals among the entire human population)
Cl_{hep}	hepatic Cl value
Cl_{int}	intrinsic Cl value
C_{max}	maximum concentration (optional subscripts $_{gen}$ = general human population C_{max} value; $_{sens}$ = sensitive human population C_{max} value)
$C_{max\ gen}$	general human population C_{max} value (at a fixed external dose at a measure of central tendency in the entire or general human population)
$C_{max\ sens}$	sensitive human population C_{max} value (at a fixed external dose at a percentile of interest in the sensitive human population or representing sensitive individuals among the entire human population)
CSAF	chemical-specific adjustment factor

LIST OF ABBREVIATIONS (continued)

D_A	animal external dose (administered or external dose in the test animal species that leads to a level of a toxicologically relevant dose metric at or near the point of departure)
D_H	human external dose (administered or external dose at the central tendency in the general human population that leads to the same level of the same dose metric identified in the test animal species)
DDEF	data-derived extrapolation factor
DNA	deoxyribonucleic acid
EF	extrapolation factor (optional subscripts $_A$ = interspecies/animal to human; $_H$ = intraspecies/within human variability; $_D$ = toxicodynamic component; $_K$ = toxicokinetic component)
EF_{AD}	interspecies toxicodynamic EF
EF_{AK}	interspecies toxicokinetic EF
EF_{HD}	intraspecies toxicodynamic EF
EF_{HK}	intraspecies toxicokinetic EF
EPA	U.S. Environmental Protection Agency
HEC	human equivalent concentration
HED	human equivalent dose
IOM	Institute of Medicine
IPCS	International Programme on Chemical Safety
IRIS	Integrated Risk Information System
K_m	Michaelis constant, substrate concentration at rate of ½ V_{max}
MOA	mode of action
NRC	National Research Council
PBPK	physiologically based pharmacokinetic
POD	point of departure
RfC	reference concentration
RfD	reference dose
TD	toxicodynamic
TK	toxicokinetic
UF	uncertainty factor (optional subscripts $_A$ = interspecies/animal to human; $_H$ = intraspecies/within human variability)
UF_A	interspecies UF
UF_H	intraspecies UF
U.S. EPA	U.S. Environmental Protection Agency
V_{max}	theoretical maximal initial velocity
WHO	World Health Organization

EXECUTIVE SUMMARY

The mission of the U.S. Environmental Protection Agency ("EPA" or "Agency") is to protect human health and the environment. The statutes under which EPA functions require the Agency to identify substances in the environment that may elicit a response, and determine the potential for harmful effects from exposure to those substances. Risk assessment is an analytical process routinely used by EPA to inform decisions on managing risks to human health and the environment (U.S. EPA, 2012). Because no risk assessment is definitive, uncertainties must be handled in a manner that is both consistent with EPA's policies and responsive to the needs of decision makers (U.S. EPA, 2004a). It is a common practice to resort to default assumptions (including values) to allow the assessment to proceed when data are limited. This document is consistent with the recommendations in *Science and Decisions: Advancing Risk Assessment* (NRC, 2009) as it describes the process for developing scientifically supportable values to account for inter- and intraspecies extrapolation.

Among the default values most commonly used in human health risk assessment are those used to extrapolate toxicity data derived from animal models to humans and those that account for human variability. This document provides guidance to risk assessors who are well versed in chemical dosimetry and/or studies of tissue responses on methods used to account for the differences between the model species and the average human (interspecies variation), and for variation in the human population (intraspecies variation). Moving from the established default values for inter- and intraspecies extrapolation to empirically derived values addresses the recommendations in *Science and Decisions: Advancing Risk Assessment* (NRC, 2009) to "…continue and expand use of the best, most current science to support and revise default assumptions." The Institute of Medicine (IOM) report *Environmental Decisions in the Face of Uncertainty* concluded "… if enough scientific information exists about the differences in the metabolism or mode of action of a chemical in animals versus in humans, then scientifically derived extrapolation factors can be used rather than the defaults." The IOM report goes on to say about data-derived values, "If those factors more accurately reflect the differences between animals and humans than default adjustment factors, the use of such data-derived extrapolation factors would decrease the uncertainty in the risk assessment" (IOM, 2013).

The goals of data-derived extrapolation factors (DDEFs) are to maximize the use of available data and improve the scientific support for a risk assessment. A DDEF approach is an accepted approach for deriving reference concentrations (RfCs), reference doses (RfDs), or counterpart values and is consistent with existing Agency guidance. This guidance presents the Agency's approach to identifying, justifying, and employing quantitatively useful data to develop nondefault values for inter- and intraspecies extrapolation. Moreover, this guidance will

aid risk assessors and researchers in identifying data gaps and developing informative experiments to yield quantitatively valuable data.

DDEF values are applicable in the derivation of RfCs and RfDs, or other relevant values or metrics (e.g., hazard index, margins of exposure). This guidance describes the process for identifying pertinent data useful for quantifying inter- and intraspecies differences to serve as the basis for empirically determined DDEFs. When using DDEFs, inter- and intraspecies extrapolation factors are divided into two components representing toxicokinetic (TK; amount of agent reaching the target tissue) variability and toxicodynamic (TD; dose at which the target tissue responds to the agent) variability. Key considerations include identifying an adverse health outcome, a measurable biological event associated with that adverse health outcome, and the concentration of the toxicant associated with the development of the biological event. Interspecies TK variability is quantified based on the external exposure that produces the same tissue concentration in animals and in humans. Intraspecies TK variability is defined as differences in tissue concentration attained from the same human external exposure (dose). TD variability is quantified on the basis of differences in the tissue or *in vitro* concentration that produce the same response between animals and humans or among humans.

1. INTRODUCTION

1.1. BACKGROUND

Risk assessment is an analytical process used by the U.S. Environmental Protection Agency ("EPA" or "Agency") to inform decisions on managing risks to human health and the environment (U.S. EPA, 2012). No risk assessment can reflect risk with absolute certainty, so it is important that uncertainties be accounted for in a predictable, scientifically defensible manner that is both consistent with EPA's policies and responsive to the needs of decision makers (U.S. EPA, 2004a). The risk assessment process involves decreasing uncertainty in estimates whenever possible, defining uncertainty and variability in estimates, and quantifying the uncertainty when feasible. In deriving reference concentrations (RfCs) and reference doses (RfDs), the Agency has historically used default uncertainty factors (UFs) to compensate for a lack of information (U.S. EPA, 2002b). As science has advanced, however, there has been a growing effort to increase reliance on available data to modify the values for these UFs (IPCS, 2005). The default UFs were developed to address data gaps in the development of RfDs and RfCs, but when appropriate data are available for an assessment, those data are given precedence over standard default values (U.S. EPA, 2004a). This guidance describes an approach for identifying and using pertinent information for developing data-derived extrapolation factors (DDEFs) for the purposes of developing RfDs, RfCs, or related metrics/approaches (e.g., hazard index, margin of exposure).

It is common to use default values and processes in risk assessments to compensate for the absence of data. EPA uses the definition of default assumption articulated by the National Research Council (NRC): "the option chosen on the basis of risk assessment policy that appears to be the best choice in the absence of data to the contrary" (NRC, 1983). In its report *Science and Judgment in Risk Assessment* (NRC, 1994), the NRC supported EPA's use of defaults as a reasonable way to consider uncertainty. The report stated that EPA should have principles for choosing default options and for judging when and how to depart from them. Specifically, the report recognized that EPA uses default assumptions (e.g., UF) and indicated that criteria for their use should be clearly articulated in situations in which "the chemical and/or site-specific data are unavailable." In the report *Science and Decisions: Advancing Risk Assessment* (NRC, 2009), the NRC recommended that "EPA should develop clear, general standards for the level of evidence needed to justify the use of alternative assumptions in place of defaults." The current document is responsive to the recommendations in *Science and Decisions: Advancing Risk Assessment* because it describes the process for developing scientifically supportable values to account for inter- and intraspecies extrapolation.

While risk assessors have generally tried to make maximum use of available data, the shift away from standard default assumptions as the starting point in risk assessment was formalized as EPA science policy with the publication of the 2005 *Guidelines for Carcinogen Risk Assessment* [or "*Cancer Guidelines*"; (U.S. EPA, 2005)]. The *Cancer Guidelines* state "these cancer guidelines view a critical analysis of all of the available information…as the starting point from which a default option may be invoked if needed to address uncertainty or the absence of critical information." Applying the available and sufficient data to avoid default UF values will improve the scientific basis of risk assessments when data are sufficient for refining UFs (IOM, 2013). In cases where data are not sufficient and default approaches are used, hazard and risk characterizations will be improved because data needs can be more clearly articulated and potentially met in the future (Bogdanffy et al., 2001; Meek, 2001; Meek et al., 2001; Murray and Andersen, 2001).

Extrapolation is most scientifically robust when data are first evaluated before using defaults. However, with a multitude of types of data, analyses, and risk assessments, as well as the diversity of needs of decision makers, it is neither possible nor desirable to specify step-by-step criteria for decisions to invoke a default option. Some risk assessments may be limited by constraints of data, time, and/or resources. Other risk assessments may require only screening-level evaluations; in these cases, the risk assessor may be more likely to resort to one or more default assumptions. On the other hand, risk assessments used to support significant risk management decisions will often benefit from a more comprehensive approach. In general, the level of effort applied in a particular assessment should be related to the needs of decision makers, as determined through planning and scoping for that assessment (U.S. EPA, 2014).

1.2. PURPOSE AND SCOPE

Efforts by the United States and international communities have improved the scientific basis for human health risk assessments by increasing the use of mechanistic and kinetic data. For example, the *Cancer Guidelines* (U.S. EPA, 2005) emphasize the use of mode-of-action (MOA) information in characterizing potential health effects of exposure to environmental agents. International efforts, including those by the International Life Sciences Institute and the World Health Organization (WHO)'s International Programme on Chemical Safety (IPCS), have developed frameworks for evaluating animal data to determine the human relevance of described MOAs (Boobis et al., 2008; Seed et al., 2005; Sonich-Mullin et al., 2001).[2] These documents

[2]Use of the term adverse outcome pathway (AOP) has become common. AOPs and MOAs are similar in that they identify an initiating event and the important biological steps associated with different levels of biological organization leading to an adverse health outcome.

guide the qualitative and quantitative evaluation of the relevance of a particular animal MOA in humans and discuss the use of *in vivo* and *in vitro* data when considering animal-to-human extrapolation. The 2005 *Cancer Guidelines* (U.S. EPA, 2005) and other documents such as IPCS's chemical-specific adjustment factors (CSAFs) guidance (IPCS, 2005), the *Methods for Derivation of Inhalation Reference Concentrations and Application of Inhalation Dosimetry* (U.S. EPA, 1994), and *An Examination of EPA Risk Assessment Principles and Practices: Staff Paper Prepared for the U.S. EPA by Members of the Risk Assessment Task Force* (U.S. EPA, 2004a) also encourage the use of sophisticated models like physiologically based pharmacokinetic (PBPK) and biologically based dose-response (BBDR) models in interspecies extrapolation.

This guidance deals specifically with the development and use of DDEFs in the calculation of RfDs, RfCs, and other relevant approaches (e.g., margin of exposure) to assessing risk. The goal of DDEFs is to maximize the use of available data and improve the scientific support for a risk assessment. The processes described herein have benefited from ongoing discussions in the scientific community regarding the need to refine the default 10-fold UFs historically used in deriving safety estimates (e.g., RfDs, minimal risk levels, and acceptable daily intakes). Finalized in 2005 (IPCS, 2005), the WHO CSAF guidance describes approaches for using data to refine inter- and intraspecies default UFs. *Guidance for Applying Quantitative Data to Develop Data-Derived Extrapolation Factors for Interspecies and Intraspecies Extrapolation* is based largely on analyses by Renwick (1993, 1991) and Renwick and Lazarus (1998), which describe a data-derived approach that assigns values for toxicokinetic (TK) and toxicodynamic (TD) differences as components within an established 10 × 10 framework for inter- and intraspecies extrapolation. DDEFs are similar in concept to the CSAFs in that the factors for interspecies and intraspecies extrapolation are subdivided into TK and TD components, and kinetic and mechanistic data are used to derive refined inter- or intraspecies extrapolation factors.

LINKING TOXICOKINETICS AND TOXICODYNAMICS

Interactions between the toxicologically active chemical moiety and the cellular receptor are responsible for producing an adverse response. Therefore, this guidance presents a single methodology to quantify differences in target tissue concentrations of toxicants (toxicokinetics) and differences in target tissue responses to toxicants (toxicodynamics) to avoid reliance on default values for inter- and intraspecies uncertainty factors when data are available.

The Appendix to this document contains case study examples taken from EPA's Integrated Risk Information System (IRIS) and from EPA Program Office records. These case studies present the application of principles contained in this document to data and modeling studies for actual chemicals and should serve as instructional aides.

Issues related to the derivation and use of DDEFs to avoid default UFs for intraspecies (human) variability and interspecies variability are the focus of this guidance document. Thus, concepts beyond the scope of this guidance are not discussed in detail here; they include approaches for selecting critical effects, establishing key events in an MOA analysis,[3] deriving points of departure (PODs), performing benchmark dose analysis, and developing and evaluating PBPK and BBDR models. In addition, no discussion is included on factors that have been used for other areas of uncertainty or variability (e.g., duration, database deficiencies, or lack of a no-observed-adverse-effect level).[4]

Finally, this document is written for toxicologists and risk assessors, and the methods described here should be conducted by or in conjunction with scientists with the appropriate level of expertise.

[3]MOA refers to a series of key, determinant, and necessary interactions between the toxicant and its molecular target(s) that lead to the toxic response. Refer to Section 2.3 for further information on use of MOAs in developing DDEFs.

[4]The Food Quality Protection Act mandates the use of a presumptive 10-fold factor in risk assessments performed for establishing pesticide tolerances as part of pesticide registration for the protection of infants and children in addition to inter- and intraspecies factors. This factor can only be modified based upon reliable data.

2. TECHNICAL CONCEPTS AND PRINCIPLES FOR DATA-DERIVED EXTRAPOLATION FACTORS

2.1. BACKGROUND

EPA has developed several methodologies to guide and refine the approach to estimate reference values for human exposures. This approach comprises several steps that include inter- and intraspecies extrapolation, in which UFs based on default assumptions may be required to account for inherent uncertainties and variability (U.S. EPA, 2011, 2002b; Bogdanffy and Jarabek, 1995; U.S. EPA, 1994; 1993, see Figure 1). This guidance describes an approach to performing inter- and intraspecies extrapolations based on the use of the best available science

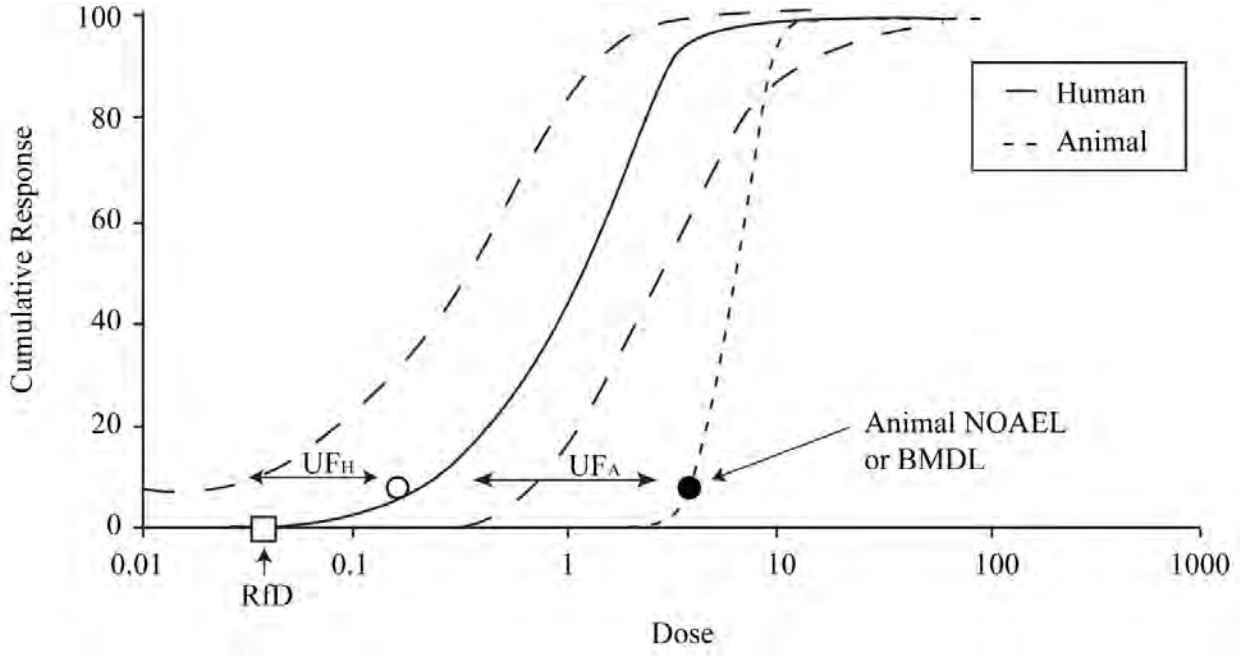

Figure 1. Derivation of reference dose/reference concentration using uncertainty factors. This figure depicts the extrapolation of the dose-response relationship between and among species. The POD (filled circle) for the animal dose-response relationship (dotted line) is extrapolated to humans (solid line) through application of the interspecies uncertainty factor (UF_A), which is "applied to account for the extrapolation of laboratory animal data to humans, and it generally is presumed to include both TK and TD aspects." Here, per long-standing guidance, the dose at the animal POD associated with a predetermined level of response is extrapolated using UF_A to a measure of dose assumed to represent the same level of response (open circle) for a central tendency member of the general human population (solid line) (U.S. EPA, 1993). Dashed lines surrounding the solid line represent confidence bounds for human variability. Note that while the dose is extrapolated to other values, the response level remains fixed both between animals and humans, as well as within the human population.

and data. The rationale for choosing an extrapolation factor value should be presented transparently, include a full discussion of the perceived strengths and limitations of the data and describe the impact of science policy considerations include relevant science policy choices or implications

In the context of the methodologies for the derivation of RfDs, RfCs, and other relevant metrics, DDEFs are intended to address, as needed, inter- and intraspecies extrapolation of the POD from experimental data to an estimate for the sensitive human population or life stage. DDEFs are developed from data on inter- or intraspecies differences. DDEFs may consider both TK and TD properties. These factors can be derived for a single agent or chemical, for a class of chemicals with shared chemical or toxicological properties, or for a group of chemicals that share a mode or mechanism of action or TK characteristics. As described below, DDEFs can be calculated using sophisticated TD or TK models or can be calculated as ratios using key kinetic or dynamic data. With regard to interspecies extrapolation, EPA currently recognizes a hierarchy of approaches ranging from the preferred approach using PBPK modeling (U.S. EPA, 2011, 2006a, 1994) to default approaches when data do not support a more chemical-specific approach. "The intraspecies uncertainty factor (UF_H) is applied to account for variations in susceptibility within the human population (interhuman variability) and the possibility (given a lack of relevant data) that the database available is not representative of the dose/exposure-response relationship in the groups of the human population that are most sensitive to the health hazards of the chemical being assessed" (U.S. EPA, 2002b). The default value for UF_H is 10-fold; the default value for interspecies uncertainty factor (UF_A) is apportioned into a TD component valued at one-half order of magnitude and a TK component addressed via default inhalation dosimetry methods (U.S. EPA, 1994) or body-weight scaling for orally encountered compounds (U.S. EPA, 2011). DDEFs fall within this hierarchical range of approaches.

CHEMICAL-SPECIFIC DATA

When deriving an RfD/RfC from animal data, and in the absence of information to the contrary, humans are assumed to be more sensitive to the toxic effect of chemicals than are test animal species. Humans also demonstrate population variability in response. These differences in sensitivity between species and among humans are captured in two uncertainty factors: interspecies (UF_A) and intraspecies (UF_H), respectively (U.S. EPA, 2002b). The default values for these UFs are based on our understanding and interpretation of data for a limited number of chemicals. With data relevant to the chemical of interest, DDEF may be used instead of the default values, thus increasing the confidence in the assessment.

Avoiding default assumptions with DDEFs begins with an evaluation of the strengths of the available data. Using *in vitro* data in risk assessment, as advocated in *Toxicity Testing in the 21st Century* (NRC, 2007), offers some distinct advantages over *in vivo* studies. While data derived in whole animal bioassays offer some value in deriving DDEF values, the data are accompanied by limitations. Given that humans and test animal species may differ in terms of

both dosimetry and innate sensitivity, response data from whole animal bioassays offer little opportunity to separate the TK and TD components of uncertainty. *In vitro* systems offer some advantages in that the influence of TK can be well controlled and response data can be well characterized, largely due to the avoidance of experimental constraints (e.g., less restrictive constraints on resources in areas like the number of doses/concentrations for testing). *In vitro* systems also offer some distinct advantages in studying both metabolism and response development in the human species because the ethical considerations of exposure are substantially lessened. Regardless, *in vitro* data require interpretation in the context of the intact mammalian system. For example, when *in vitro* data are derived from preparations representing only a fraction of the total biology of the cell (e.g., microsomal protein), care should be taken to ensure that the measured TD event (e.g., protein binding) or TK outcome (e.g., formation of an/the active metabolite) accurately reflects the biology of the *in vivo* effect. Regardless of the system evaluated (*in vitro* or *in vivo*), determinations regarding the strengths of the relevant data require careful consideration and characterization.

2.1.1. Uncertainty Factors Compared to Data-Derived Extrapolation Factors

DDEF values are not UFs, *per se*. UFs incorporate both extrapolation components that address variability (heterogeneity between species or within a population) and components that address uncertainty (i.e., lack of knowledge); (U.S. EPA, 2002b; Dourson et al., 1996; Dourson and Stara, 1983), whereas DDEFs focus on variability. Additionally, interspecies and intraspecies UFs are values based on general assumptions, whereas data-derived values are empirically determined based on chemical-specific data.

Thus, DDEF values are more precise and accurate than default UF values, but the values for the DDEF components may sometimes be similar to default values for UFs. Regardless of any similarity to default UF values, developing a DDEF quantifies variability and reduces uncertainty, carrying with it a change in nomenclature (IOM, 2013).

UNCERTAINTY AND VARIABILITY EXPLAINED

Variability refers to true heterogeneity or diversity. This may be due to differences in exposure as well as differences in response. Those inherent differences are referred to as variability. Differences among individuals in a population are referred to as interindividual variability, while differences for one individual over time are referred to as intraindividual variability. DDEF values quantify variability on the basis of chemical specific information.

Uncertainty occurs because of lack of knowledge. It is not the same as variability. Uncertainty can often be reduced by collecting more and better data, while variability is an inherent property of the population being evaluated. Variability can be better characterized with more data but cannot be eliminated. Efforts to clearly distinguish between variability and uncertainty are important for both risk assessment and risk characterization.

Source: U.S. EPA (2002b).

Evaluation of the sources and magnitude of uncertainty accompanying DDEF values is informative (U.S. EPA, 2005, 2001c, 1997a, b), and quantitative uncertainty analyses may be undertaken, but such analyses are not presented in this guidance. When quantitative approaches are not feasible, qualitative uncertainty analyses may be developed. Furthermore, as discussed in the 2005 *Cancer Guidelines*, "a default option may be invoked if needed to address uncertainty or the absence of critical information."

The use of human response data for the critical effect obviates the need for a $UF_{A.}$ The richness of a human data set may offer additional potential to develop DDEF values for interindividual variability. It may prove difficult to separate the contributions of TK and TD in these data sets without additional data and/or models.

RESPONSE DATA IN HUMANS

For some chemicals, the available data describing adverse effects in humans are suitable for dose-response analysis. When the POD is derived from studies with humans, the need for a UF_A is obviated, and the value for UF_A is set to 1.

The capability to develop a DDEF value depends on the availability and suitability of experimental data and/or predictions from reliable models (see Section 2.2.5). Once data sets are evaluated to justify their basis for a quantitative reliance, three primary sets of information are required to develop a DDEF value:

≠ Sufficient information on the MOA, such as understanding of the major steps leading from exposure to adverse outcome, including identification of the toxicologically active chemical species;

≠ Identification of the target tissues or organs; and

≠ Availability of information to determine whether an instantaneous (i.e., maximum concentration [C_{max}]) or a time-normalized (i.e., clearance [Cl] or area-under-the-curve, [AUC]) measure of exposure is the more appropriate basis for tissue response.

2.1.2. Sensitivity and Susceptibility in the Context of Data-Derived Extrapolation Factors

For the purpose of this DDEF guidance, the terms susceptibility and sensitivity are used interchangeably and defined as an increased response to a given exposure. [Note the term *susceptible* is also used to describe *sensitive* or *vulnerable* populations or life stages. These terms have varying definitions within EPA documents and are used interchangeably. No convention for use of the terms sensitivity, susceptibility, or vulnerably is widely accepted (U.S. EPA, 2004a). The term, vulnerability, is not used in this document.] Susceptibility in the human population may be due to life stage, health status or disease state, genetic disposition, exposure, or other factors. Therefore, with respect to intraspecies variability, it is important to consider the

factors that lead some individuals or groups to be more sensitive than others. Humans respond differently to chemical exposures based on several factors that can be exogenous and/or intrinsic. Exogenous factors relate to exposure conditions such as chemical concentration/external dose, media, pathway, or duration. Physiological, anatomical, and biochemical parameters are intrinsic factors that may also be the basis for differential susceptibility among the population and at different life stages. Intrinsic factors can mediate sensitivity by influencing the target tissue concentrations of the chemical inside the body (TK; see Section 3.3.1.1) or by modulating an increased responsiveness of the tissues to the toxicologically active chemical species (TD; see Section 4.3.1.1). For some chemicals, data may be sufficient to identify one or more sensitive populations or life stages.

Life stage is a key consideration in susceptibility. Developing organisms (e.g., fetus, infant) can be more sensitive for several reasons, some of which include a higher body mass-adjusted exposure and the potential for increased sensitivity of rapidly growing tissues. Critical windows of development, and therefore windows of sensitivity, occur at different times for various tissues, organs, and systems; therefore, considering susceptibility to more than one critical effect may require consideration of more than one life stage. The aged may also represent a sensitive life stage.

Toxicity (response) data from the sensitive life stage may be used directly to identify the POD. In other cases, TK or TD data may be used in derivation of DDEFs to extrapolate POD values, for example from the average adult to the sensitive life stage. Because every human being goes through developmental life stages, sensitive life stages are not a population *per se*, but sensitive life stages do need to be considered explicitly in the risk assessment when sufficient data are available. For purposes of this guidance, life stages are considered among the multiple potentially sensitive populations.

With respect to TK, sensitivity is the result of higher tissue concentrations being attained at a fixed dose. Elevated tissue concentrations may be the result of an increased distribution to tissues or a decreased elimination from tissues. Regarding measures of tissue concentrations, maximum concentration (C_{max}) and AUC are suitable measures, and sensitive individuals or sensitive populations will be those at or near the upper tail of the population distribution. With respect to measures of the removal of toxicant, measures of Cl are suitable, and sensitive individuals or sensitive populations will be at the lower tail of the population distribution. Sensitive individuals or sensitive populations will be those in which a predetermined level of response will be reached at lower tissue (or *in vitro*) concentrations. A quantification of DDEF values based on measures obtained from those deemed sensitive and those representing the generally responsive portion of the population are described later (TK in Section 3.3.2.2; TD in Section 4.3.2.2).

The development and evaluation of experimental data and models describing TK and TD are likely to lead to an improved understanding of population sensitivities and thus population variability, as well provide a means for quantitation. Understanding population sensitivity and characterization of population variability will improve the scientific basis for human health risk assessment.

2.2. DERIVING AND APPLYING DATA-DERIVED EXTRAPOLATION FACTORS

The foundation of DDEFs is the concept that the toxicity of a particular agent is due to a combination of both TK and TD factors, and that those factors can be quantified in animals and humans. For purposes of this guidance, TK is defined as the determination and quantification of the time course and dose dependency of absorption, distribution, metabolism, and excretion (ADME) of chemicals (sometimes referred to as pharmacokinetics) of the chemical agent, while TD is defined as the determination and quantification of the sequence of events at the cellular and molecular levels leading to a toxic response. TK and TD share a common point—each is concerned with the concentration of the toxicologically active chemical species in the target tissue. As such, it can be difficult to establish a clear separation between TK and TD because the processes leading to biological responses include aspects of both—including interactions between TK and TD processes.

SUBDIVIDING UF_A AND UF_H

The response to toxicants is based broadly on two functions: target tissue exposure (i.e., TK) and innate sensitivity to the insult that modulates the type and severity of the response (i.e., TD). Thus, both UF_A and UF_H have been divided into TK and TD components. This distinction was described in the RfC guidance for inhaled substances (U.S. EPA, 1994). The subdivision of UF_H has been applied in several assessments described in Appendix A. The subdivision of the UFs provides the framework for the quantitative inclusion of TK and TD data sets in inter- and intraspecies extrapolation.

Extrapolation from animals to humans and within the human population can be accomplished by one of several approaches ranging from the use of sophisticated BBDR models to the calculation of relatively simple ratios using TK or TD data describing critical factors in inter- or intraspecies extrapolation. The following text describes the approaches for calculating the different DDEF values. In the absence of data for performing sophisticated modeling or for deriving DDEF values, default approaches for toxicokinetics are used, but no such approaches for toxicodynamics are yet available.

Four DDEFs can be calculated given sufficient information. Two extrapolation factors are for interspecies extrapolation from animal data to humans (EF_A): (1) extrapolation factor covering interspecies toxicokinetics (EF_{AK}) is calculated to account for TK variability, while (2) extrapolation factor covering interspecies toxicodynamics (EF_{AD}) accounts for TD variability. Likewise, there are two extrapolation factors dealing with variability within the human population (EF_H): (1) extrapolation factor covering intraspecies toxicokinetics (EF_{HK}) for TK and

(2) extrapolation factor covering intraspecies toxicodynamics (EF_{HD}) for TD. Table 1 provides example equations for calculating these DDEFs. Section 3 describes how to calculate and when to use TK factors for interspecies (see Section 3.2) and intraspecies (see Section 3.3) extrapolation. Section 4 describes how to calculate and when to use TD factors for both interspecies (see Section 4.2) and intraspecies (see Section 4.3) extrapolations. Section 5 describes how to combine EF_{AK}, EF_{AD}, EF_{HK}, and EF_{HD} into the composite UF.

Table 1. Example equations used to derive data-derived extrapolation factors

Extrapolation	Toxicokinetics (Section 3)	Toxicodynamics (Section 4)
Animal to human (interspecies)	$EF_{AK} = \frac{D_A}{D_H}$	$EF_{AD} = \frac{Concentration_A}{Concentration_H}$
Within human (intraspecies)	$EF_{HK} = \frac{AUC_{sens}}{AUC_{gen}}$	$EF_{HD} = \frac{Concentration_{gen}}{Concentration_{sens}}$

EF_{AK} = interspecies TK extrapolation factor.
D_A = animal external dose (administered or external dose in the test animal species that leads to a level of a toxicologically relevant dose metric at or near the POD).
D_H = human external dose (administered or external dose at the central tendency in the general human population that leads to the same level of the same dose metric identified in the test animal species).
EF_{AD} = interspecies TD extrapolation factor.
$Concentration_A$ = animal concentration (concentration of the agent in the tissue or *in vitro* in the test animal species corresponding to a level of response near the animal POD).
$Concentration_H$ = human concentration (concentration of the agent in the tissue or *in vitro* in the human corresponding to a level of response near the animal POD).
EF_{HK} = intraspecies TK extrapolation factor.
AUC_{gen} = general human population AUC value (area under the concentration-time curve at a fixed external dose at a measure of central tendency in the entire or general human population).
AUC_{sens} = sensitive human population AUC value (area under the concentration-time curve at a fixed external dose at a percentile of interest for the sensitive human population or representing sensitive individuals among the entire human population).
EF_{HD} = intraspecies TD extrapolation factor.
$Concentration_{gen}$ = general human population concentration (concentration producing the response corresponding to the POD at a measure of central tendency in the general human population).
$Concentration_{sens}$ = sensitive human population concentration (concentration producing the response corresponding to the POD at a percentile of interest for the sensitive human population or representing sensitive individuals among the entire human population).

The benefit of DDEFs is that they maximize the use of available data and improve the overall scientific support for a risk assessment. Figure 2 provides a flowchart of the decision process for the extrapolation used in deriving DDEFs. As described in more detail in Sections 3 and 4, it is important for the human health hazard and/or risk characterizations to include

thorough and transparent discussions of methods and data used to support extrapolation approaches.

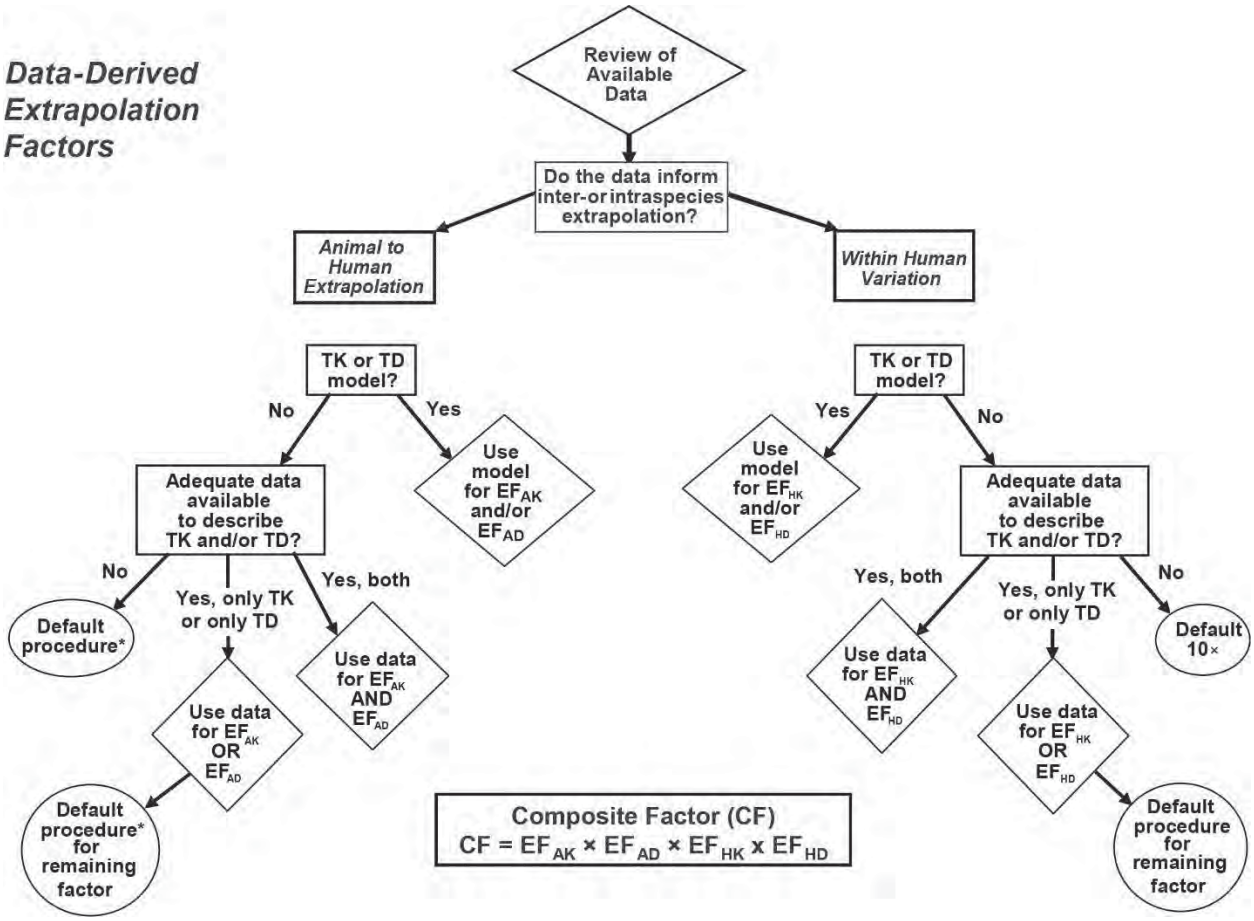

Figure 2. Decision process for data-derived extrapolation factors. The availability of an adequate TK or TD model is considered first, followed by analysis of the availability of adequate data to describe the TK and/or the TD of the chemical. With the availability of an adequate model or data, data-derived extrapolation factors for intraspecies (EF_{AK}, EF_{AD}) and interspecies extrapolation (EF_{HK}, EF_{HD}) are developed. In the absence of an adequate model or data, default factors are used.

*For interspecies extrapolation, the default procedure is ¾ body-weight scaling for RfD (U.S. EPA, 2011) and the RfC method (U.S. EPA, 1994) for inhalation to derive a human equivalent dose (HED) and human equivalent concentration (HEC), respectively. When these methods are used in deriving the RfD and RfC, the default interspecies UF is then reduced to a value of 3. The composite factor (CF) accounts for inter- and intraspecies extrapolation and can comprise default or DDEF values for the four extrapolation factor components.

2.2.1. TK and TD Models

TK and TD data and/or models represent the preferred approach to intra- and/or interspecies extrapolation. Models vary in level of complexity from classical compartmental and simple statistical response models to physiologically realistic models of TK and TD processes, up to and including BBDR models. These models provide a quantitative description of the biological processes involved in the TK and/or MOA of chemical(s). In these TK and TD models, some measure of the internal dose is related to the external dose and response, respectively. When available, BBDR models combine TK and TD modeling, using the measure of internal dose or dose metric to link the TK and TD aspects of the modeling approach (see discussion in Section 4.2.2.2).

TK modeling is the process of developing a mathematical description of ADME in a living organism. Two common types of TK models are (1) data-based noncompartmental or compartmental models and (2) PBPK models. Data-based models, also known as classical models, mathematically describe the temporal change in chemical concentration in blood, tissue, or excreta of the species for which the data were generated. The classical models often treat the body as a single homogenous or multicompartment system with elimination occurring in a specific compartment; the characteristics of the compartments (number, volume, etc.) are hypothetical in that they are chosen for the purpose of describing the data rather than based *a priori* on the physiological characteristics of the organism or the biological attributes of the response. Due to these characteristics, classical models are used for interpolation [i.e., within the range of doses, dose route, and species in which the data were generated (Renwick, 1994)].

PBPK models differ from classical compartmental models in that they are composed of compartments with realistic tissue volumes that are linked by blood flow. Other parameters used in these models account for chemical-specific characteristics that can be independently measured in both humans and laboratory animals (usually using *in vitro* techniques); these chemical-specific parameters include tissue solubility (i.e., partition coefficients), binding, and metabolism. These models are used to simulate the relationship between applied (administered) dose and internal dose at the target tissue. PBPK models require more data to develop compared to classical compartmental models, but they are advantageous because they can be used for extrapolation [i.e., across dose range, among animal species, between routes of exposure, and across exposure scenarios (U.S. EPA, 2006a; Krishnan and Andersen, 1994)].

TD models can be developed when sufficient data exist to both ascertain the MOA and to quantitatively support model parameters that represent rates and other quantities associated with key precursor events in the MOA. A BBDR model describes biological processes at the cellular and molecular levels in such a way as to link target tissue dose with adverse effect; in practice, BBDR models are often described as a combined TK/TD model. These models may be used for

extrapolation. However, with an adequate understanding of the nature of the response and sufficient empirical data describing the dose-response function in relevant species or populations, a fully developed TD model may not be required to develop a DDEF.

2.2.2. Use of Ratios to Calculate Data-Derived Extrapolation Factor

In the absence of sufficient data to develop a robust TK or TD model, the risk assessor need not necessarily use default approaches and UFs. DDEFs can be calculated as ratios using data from key studies evaluating TK or TD profiles or properties of a particular chemical. Some example equations for calculating DDEFs were provided in Table 1 and are described in more detail in Sections 3 (TK) and 4 (TD).

TARGET TISSUE CONCENTRATIONS IN DDEF CALCULATIONS

DDEF values are based on an understanding of target tissue concentrations, rather than relying solely on external concentrations or effective doses. For TK (see Section 3), interspecies differences are calculated as differences in external (administered) dose resulting in the same target tissue concentration, and intraspecies differences are calculated as differences in internal concentrations resulting from the same external dose or exposure. TD differences (see Section 4) are calculated as differences in target tissue concentrations resulting in the same response level.

In general, *interspecies* extrapolation involves calculating a ratio of animal data (for a kinetic or dynamic parameter) to human data for a kinetic or dynamic parameter. Similarly, for *intraspecies* extrapolation from the general (average) human population to the sensitive population, a ratio is calculated using data from the sensitive population and that for the central tendency of the general population. Data to derive the TK factors may come from *in vivo* or *in vitro* studies. For TD, in general, interspecies extrapolation may have its basis in data from *in vivo* studies but may often be accomplished with *in vitro* data in a relevant tissue. When adequate data on toxic effects are available in humans, these data may be considered when identifying a POD, eliminating the need for the interspecies extrapolation. Otherwise, the human information can be used to inform an interspecies factor when the POD is derived from animals, allowing a quantitation of UF_A components, rather than relying on default values.

SENSITIVITY

In the absence of data to the contrary, it is assumed that humans will exhibit response in the same tissues as in test species. When humans are more toxicodynamically sensitive than animals, humans will demonstrate the same level of response, but at lower tissue concentrations. If the same dose results in higher observed or predicted AUC or C_{max} values, or lower clearance values in humans than in animals, then humans are more (toxicokinetically) sensitive and EF_{AK} will be greater than 1.

Intraspecies susceptibility may be based on differences in TK or TD. Sensitive populations will demonstrate higher tissue concentrations at the same dose (TK), or the same type and level of response at lower tissue concentrations (TD).

For interspecies extrapolation, it is preferred that the ratio be based on data at or near the POD. When sufficient data are available, interspecies DDEF values should be calculated for a

range of doses near the POD because the shape of the dose-response curve can vary among species. Metabolism and kinetic properties can vary across doses, particularly in the higher dose ranges; thus, developing multiple estimates of DDEF values at or near the POD helps avoid potential uncertainty in the DDEF estimate that may be introduced by nonlinearity in kinetic properties. Moreover, evaluating a range of PODs takes into account the dependence of the DDEFs on the POD selected. One way to address this is to calculate interspecies DDEF values at multiple doses in the range of the POD to demonstrate the stability of the DDEF value. Likewise, when the POD is expressed with a confidence bound, some effort can be taken to include this range of POD values when developing DDEF values. The interspecies DDEF values should be derived using an estimate of central tendency, such as the mean, median, or mode, depending on the characteristics of the data. In contrast, when calculating intraspecies DDEF values, the ratio includes a measure of central tendency of the general population and percentiles of the distribution representing those potentially sensitive (see Section 2.1.2). As the needs of risk managers and decision makers vary, it is recommended that the risk assessor consult with the risk manager or decision maker to determine the risk assessment objectives (U.S. EPA, 2014). A range of percentiles may be useful and thus evaluated and their corresponding DDEFs be reported in the human health hazard and risk characterizations.

DATA FROM SENSITIVE POPULATIONS

The POD may be determined in test animals, in the general human population, or in susceptible human populations. For some well-studied chemicals (e.g., nitrate, fluoride), dose-response data from the sensitive human population may be available. When these data are sufficient to identify a POD in the sensitive population, the issue of human variability has been addressed and the need to apply an intraspecies uncertainty factor (UF_H) is obviated—UF_H is set to a value of 1.

AREA UNDER THE CURVE, CLEARANCE, AND HALF LIFE

Area under the curve (AUC = (μg/ml) × hr) is related to total dose; clearance (Cl = ml/min per kg body weight) is independent of dose and inversely related to AUC. Half-life is not an acceptable basis for DDEF calculation because it is related to neither body weight nor volume of distribution. When clearance decreases, AUC values increase; when clearance increases, AUC values decrease. When a chemical does not induce or inhibit its own metabolism or clearance, AUC or clearance values after a single dose, when extrapolated to infinity, may prove a suitable alternative basis for DDEF calculation.

TK ratios (for either interspecies or intraspecies extrapolation) are informed by the MOA and are based on the relevant dose metric, such as AUC and the C_{max}.[5] Other metrics (e.g., AUC above a threshold) may be used if supported by the data or if relevant for a particular chemical or MOA. For toxicants that bind covalently or cause irreversible damage, especially as a consequence of subchronic or chronic exposure, an integrated measure

[5]Clearance can be used to calculate this ratio when it can be assumed or demonstrated that the relevant dose metric is the AUC or concentration at steady state.

of dose over time such as AUC is preferable (O'Flaherty, 1989). In the case of effects occurring as a consequence of acute exposure or when toxicity is related to exceeding an internal concentration threshold, C_{max} may be more appropriate (Barton, 2005; Boyes et al., 2005). When data on chemical-specific AUC, C_{max}, or Cl are not available, a chemical-related physiological parameter (e.g., renal glomerular filtration rate) that is critical to the onset of toxicity or to the MOA may be used.

2.2.3. Default Methods for the Derivation of Reference Concentrations, Reference Doses, and Other Relevant Metrics

In accordance with the hierarchy of approaches, when available agent-specific data are supportive of DDEF derivation from use of models or from ratios, a data-derived approach is preferred over using the default RfC approach or ¾ body-weight scaling. When deriving reference values (or counterpart values) from an animal POD in the absence of applicable TK and/or TD data in animals and humans, a default uncertainty factor value is applied unless it can be concluded that the test species is equally or more susceptible than humans (U.S. EPA (2002b).

The default approach for the inhalation exposure route (i.e., RfC) involves applying both a categorical dosimetric adjustment factor to account for species differences in tissue exposure (i.e., TK) and a residual UF of a value of one-half order of magnitude, that is generally described as covering TD (U.S. EPA, 1994). The dosimetric adjustments are based on the following:

- ≠ Anatomical and physiological differences between species
- ≠ Physical differences between particles and gases
- ≠ Whether the toxic effect(s) are portal-of-entry or systemic in nature

For the oral exposure route, the default approach for interspecies extrapolation involves scaling the applied dose, according to body weight to the ¾ power ($BW^{3/4}$), and applying a UF of one-half order of magnitude to account for residual uncertainty (U.S. EPA, 2011).

After default adjustment between species, the residual UF associated with either route (oral or inhalation) has a default value of one-half order of magnitude, which may be modified based on available data (U.S. EPA, 2011, 1994).

2.2.4. Qualitative Considerations

Although in some cases data may be insufficient for a quantitative estimate of a DDEF, there may still be information to support a UF different from the default. For example, there may be qualitative evidence based on an MOA that humans are less sensitive than animals or that

certain groups are more sensitive than the central tendency of the general population. In these cases, where only qualitative data are available, a thorough weight-of-evidence analysis can be considered with the hazard characterization to discuss the derivation of the DDEF along with associated uncertainties in the available database.

2.2.5. Information Quality

Before conducting a DDEF analysis, it is recommended that the risk assessor perform a critical evaluation of all data that may be used to support the development of DDEFs. As an important step in the process, it is advised that data providing qualitative support for the MOA and choice of dose metric, as well as data used in the quantitative derivation of the DDEF itself, be examined. Documentation of the types of literature and data evaluated and a summary of the strengths and weaknesses of data sets should be provided. This will instill confidence in the selection of data chosen as the basis for DDEF derivation, as well as provide an increased understanding of the rationale for any dismissed data. Supporting studies can be evaluated using EPA guidance documents, including the 2005 *Cancer Guidelines*, as well as earlier guidelines specific to neurotoxic, reproductive, and developmental endpoints (U.S. EPA, 2005, 1998, 1996, 1991). In addition, general principles outlined in the EPA information quality guidelines are consulted when critically evaluating data used to support the development and application of DDEF values (U.S. EPA, 2002a).

Use of secondary data sources is one area for particular consideration. Examples of secondary data sources include compilations of pharmacokinetic parameters (e.g., Brown et al., 1997) and studies cited and summarized in toxicity profiles and review articles. In general, for principal and supporting studies used directly in the derivation of DDEF values, a review of the original literature is recommended. In the case of critical assumptions and data, contradictory results from different studies are best resolved by reviewing the original publications.

Quantitative TK and TD data used in the DDEF-derivation process require particular attention to the appropriateness of the study design, the analytical methodology used, and the statistical analysis of the data. Consideration of appropriate study design extends beyond simply verifying that the methods used were adequate for the goals of the study; it also encompasses consideration of the relevancy of the animal or *in vitro* test system used to derive the DDEF for the endpoint of concern. Relevance can be assessed in both qualitative and quantitative terms. For example, if there is a lack of concordance (i.e., a particular TK or TD process relevant to the endpoint does not occur in the test system), or if physiologically unrealistic conditions are used, or different tissue or cell types are evaluated, then the relevancy of the data may be uncertain. Particular considerations relevant to the use of *in vitro* data are discussed below. Another important factor in terms of relevancy is to consider whether the TK or TD response represents a

uniquely sensitive tissue, process, or population. This decision is a critical determinant in evaluating the use of data to describe intraspecies variability.

2.3. MODE OF ACTION

Information on MOA is important in DDEF derivation, even when a complete understanding of the mechanism is not available. DDEFs for both TK and TD are endpoint driven—that is, they are considered in the context of the toxic endpoints most relevant for purposes of the risk assessment. Understanding the MOA(s) for the agent(s) of interest ensures that the TK or TD parameter used to derive the DDEF will be causally related to the adverse outcome of interest. The key events in MOA are likely to identify important metabolite(s) and can aid in identifying potential life-stage susceptibility, sensitive population groups, and/or species differences. Moreover, data on key events may be used directly to estimate EF_{AK} or EF_{AD}.

In the 2005 *Cancer Guidelines*, EPA describes the MOA evaluation as the critical information that defines the conditions under which a toxicant causes its effect, the relevance of animal data for hazard identification, and the most appropriate approach to low-dose extrapolation. The 2005 *Cancer Guidelines* also presents a framework for evaluating data in support of an MOA determination. Major components of this framework include a description of the hypothesized MOA and a discussion of the experimental support for the hypothesized MOA based on modified Hill criteria (U.S. EPA, 2005) for demonstrating associations in human studies.

The MOA is defined as a sequence of key events and processes, starting with the interaction of an agent with a cell, proceeding through functional and anatomical changes, and resulting in toxicity. A key event is an empirically observable precursor step that is itself a necessary element of the MOA or is a biologically based marker for such an element. MOA is contrasted with "mechanism of action," which implies a more detailed understanding and description of events, often at the molecular level, than is meant by MOA (U.S. EPA, 2005). As a result of the 2007 NRC report on *Toxicity Testing in the 21st Century* (NRC, 2007), the concept of the adverse outcome pathway (AOP) has been introduced (Ankley et al., 2010). An AOP links a molecular initiating event, or mechanism of action, to progressive levels of biological organization at the individual or population level. As such, this framework is conceptually similar to, but in some cases may be more comprehensive than, MOA and would be particularly useful for derivation of DDEFs.

2.4. USE OF *IN VITRO* DATA

In vitro assays play an important role in defining DDEFs; however, care must be taken to avoid taking isolated findings out of context. Consideration of interspecies differences in ADME is essential because the dose to the target tissue in any given exposure scenario is a balance among multiple and competing ADME processes. Thus, it is recommended that *in vitro* data not be used for quantitative purposes unless interpreted in the context of the intact system. Among the questions to be considered when applying *in vitro* data to DDEFs are the following:

- ≠ Was the toxicologically active form of the agent studied?
- ≠ How directly was the measured response linked to the adverse effect?
- ≠ Are the biological samples used in the assays derived from equivalent organs, tissues, cell types, age, stage of development, and sex of the animals/humans in which the target organ toxicity was identified?
- ≠ What is the range of variability (e.g., diverse human populations and life stages) that the biological materials cover?[6]
- ≠ If the effect occurs or can be measured in several tissues, is the studied tissue or tissue preparation an appropriate surrogate? Or, in situations where the effect is not localized, is the effect consistent across tissues?
- ≠ Does the design of the study allow for statistically valid comparisons based on such factors as replicate and sample size?
- ≠ Was chemical uptake considered when the chemical was applied to the samples so as to give comparable intracellular concentrations across tissues?
- ≠ Were similar tissues or samples evaluated across species?
- ≠ Do the concentrations in the *in vitro* studies allow for comparison with *in vivo* conditions?

All of these issues affect the utility of applying *in vitro* data for risk assessment. A clear discussion of these points helps clarify the appropriateness of the information used for deriving DDEFs.

[6]Quality (purity, viability, donor demographics) of the samples is of particular concern with biological materials derived from human organ donors.

2.5. MULTIPLE POTENTIAL CRITICAL EFFECTS

For some toxicants, multiple adverse effects may be identified during hazard identification; these may occur at similar doses or exposures and may be the result of a common similar, a dissimilar, or an unknown MOA. It is also possible that the uncertainty and/or variability associated with the TK and/or TD of each of the several adverse effects may differ, resulting in different DDEFs or the retention of default values for UFs, which may lead to differences in dose extrapolation and different reference values. One explanation is that risk assessors may be more certain about inter- and intraspecies differences for one effect versus another. For that reason, the results generated for the multiple responding tissues/organs can be presented for comparison (e.g., in a table that is accompanied by a discussion of the methods used), particularly if multiple MOAs are operational or unknown. It is important not to mix DDEFs derived for one tissue or one MOA with DDEFs (or default UFs) derived from a different tissue unless they can be justified on the basis of the biology of the insult. For example, DDEF values for kidney effects may not apply to liver effects due to innate differences in physiology and biochemistry of the tissues.

DDEF VALUES AND CRITICAL EFFECTS

The PODs for multiple potential critical effects should be combined with their respective default UF or DDEF values to produce an array of potential reference values.

3. DATA-DERIVED EXTRAPOLATION FACTORS BASED ON TOXICOKINETICS

3.1. GENERAL CONSIDERATIONS

TK is concerned with the ADME of chemicals, with an emphasis on the exposure of the biologically active chemical species to the target tissue of interest. Data on tissue concentrations of toxicants or clearance rates of toxicant removal serve as the basis for deriving DDEF values for TK components. This section provides a discussion of factors common to the derivation of both inter- and intraspecies values to account for TK variability. Given the UF_A and intraspecies uncertainty factor (UF_H) framework for uncertainty and extrapolation, there are three generally identifiable points bounding inter- and intraspecies extrapolation: (1) the animal model, (2) the general human population, and (3) sensitive populations or life stages. When a sensitive population(s) or life stage(s) has been identified, and when TK data in animals and the sensitive population(s) are available, these data may be employed to develop a DDEF value for TK that combines both inter- and intraspecies extrapolation. In this case, the DDEF value represents both EF_{AK} and EF_{HK}. Since this situation is not common, this section addresses inter- and intraspecies extrapolations separately.

Data on the quantitative TK differences between animals and humans are used for EF_{AK}. TK differences among the human population are used for the EF_{HK}. Thus, the factor EF_{AK} accounts for extrapolation from laboratory animals to the general human population. EF_{HK} accounts for the variation due to TK in the exposure associated with the critical effect between the human population group represented by the dose-response assessment and sensitive human individuals or populations. Developing a DDEF for TK requires knowledge about the relationship between external dose and internal (target tissue) concentrations. This information can come from studies in which tissue concentrations are measured or predicted, in which both types of data are recorded, or from adequate TK models, which expand the range of confidence from that of the empirical observations. TK models, especially PBPK models, represent an important tool through which *in vitro* observations can be interpreted in the context of the intact system. As such, they represent an advantageous means to evaluate the impact of studies (especially those using human tissues) conducted *in vitro*.

The TK portion of each factor (EF_{AK}, EF_{HK}) is combined with the corresponding TD factors to assemble the composite UF (see Section 5). When the data are not sufficient to derive a DDEF for TK, other approaches can be considered for EF_{AK} or EF_{HK}. For example, the RfC approach (U.S. EPA, 1994) describes default procedures for interspecies extrapolation for inhaled substances. Some important questions to address for TK include:

- What is/are the critical effect(s) and POD being used for this assessment?
- Has the toxicologically active chemical moiety been identified?
- What is the MOA, AOP, or mechanism for that toxicity? Have the key events been identified and quantified? Do these key events identify important metabolic steps?
- Are the processes of ADME of the chemical well characterized? If dose-response data are from an animal model, do animals and humans metabolize the chemical(s) in a similar way (qualitatively and quantitatively)?
- Are there data in human populations describing variation in important kinetic parameter values for this chemical(s)? Have sensitive populations and/or life stages been identified? Are the data for these sensitive populations adequate for quantitative analyses?

TK data may be developed empirically or through compartmental or physiologically based TK models. It is recommended that these data, models, and approaches be evaluated for their appropriateness (IPCS, 2010; U.S. EPA, 2006a). For each critical effect identified for a particular agent, separate DDEF analyses are conducted for EF_{AK} and EF_{HK}. As such, data for multiple sensitive tissues/endpoints can be evaluated, concentrating on those effects that demonstrate response levels near the POD for the critical effect.

3.1.1. Dose Metric

Dose metric is a measure of the internal dose of a chemical agent. A dose metric associated with the health outcome of interest is most useful when it describes target tissue exposure in terms of the toxic chemical moiety (parent or metabolite) and is expressed in appropriate time-normalized terms. The choice of the dose metric is an important component in TK extrapolations. This choice depends on whether toxicity is best ascribed to a transient tissue exposure or a cumulative dose to the target tissue. For a given chemical, the appropriate dose metric will also be determined by, and can vary with, the MOA, duration of exposure, and the adverse effect of concern (U.S. EPA, 2006a). Selection of an appropriate dose metric based on specific endpoints involves several elements including:

DOSE METRIC

Dose metric is a measure of the tissue concentration of the toxicologically active chemical species that reflects a time-normalized (i.e., AUC) or instantaneous (i.e., C_{max}) measure of concentration. Dose metric values may also include measures of chemical flux or clearance. In some cases, dose metrics may be expressed in direct physiological units like glomerular filtration. (See the boron and compounds case study in Appendix A to this document.)

≠ Duration of exposure and effect;

≠ Identification of the active chemical moiety;

≠ Selection of the organ or tissue group in which some measure of internal dose is desired; and

≠ Selection of the measure of exposure that best correlates with toxicity.

SELECTION OF THE APPROPRIATE DOSE METRIC

Dose metrics will differ with respect to the toxicological response of interest. While clearance values for some agents may be used to describe internal exposures, clearance may not be the dose metric most closely associated with the toxicological response of interest. Rather, the toxicological response may be mediated by the interaction of the toxicologically active chemical form with the receptors in the target tissue of interest, better represented by C_{max} or AUC values.

For example, the acute central nervous system effects of halogenated solvents may relate to C_{max} values for the parent compound in the brain, while chronically observed nephrotoxicity may best relate to averaged tissue concentrations of a metabolite or the rate at which metabolites are formed.

Whether an adverse effect is a consequence of an acute or chronic exposure impacts the choice of dose metric. For acute, reversible effects (e.g., sensory irritation, narcosis), a measure of instantaneous or peak tissue exposure such as C_{max} may be the most appropriate dose metric (Boyes et al., 2005; Alarie, 1973). For chronic effects, in the absence of MOA information to the contrary, it is generally assumed that some integrated cumulative measure of tissue exposure to the active toxicant is the most appropriate dose metric (e.g., AUC). Alternative choices, such as amount of chemical or rate of metabolite production, can be used as appropriate for a particular agent or MOA (U.S. EPA, 2006a). For example, there may be a case where a temporally large influx of active chemical to a target site in a relatively short period of time (peak exposure) is observed. In this case, a less commonly used metric, such as time above a critical concentration, may be more appropriate. It is recommended that the assessor provide the data and rationale in support of a particular dose metric.

Clearance, while not often considered a dose metric, can be used in DDEF derivation. Clearance is mathematically inversely related to AUC (i.e., AUC = dose/clearance); thus, differences in clearance values can be used in the calculation of ratios. When metabolism represents the primary or sole clearance mechanism, either of two clearance models may be applicable. The first, intrinsic clearance (Cl_{int}), has been used for interspecies scaling of administered doses in drug development (Houston and Carlile, 1997) and is applicable at doses that do not result in metabolic saturation. Cl_{int} is calculated as a ratio of the theoretical maximal initial velocity of the reaction to the Michaelis constant (V_{max}/K_m) and is in units of volume of the substrate cleared per unit time, where K_m is the substrate concentration driving the reaction rate at one-half V_{max}. The Cl_{int} can be extrapolated to the whole body with knowledge of protein binding and the recovery of the protein or cellular or subcellular fraction used in the *in vitro* investigations (Carlile et al., 1997).

INTRINSIC CLEARANCE

Cl_{int} is often calculated for therapeutics (as V_{max}/K_m). While it is a valuable measurement for purposes of comparing agents, it is not suitable for derivation of DDEFs. Measures of intrinsic clearance do not take into account the constraints of the intact system (e.g., partitioning into tissues, blood flow), which can limit metabolic clearance.

The second clearance model is hepatic clearance (Cl_{hep}), which is also based on V_{max}/K_m measurements but includes a substrate delivery term whose value is governed by hepatic blood flow. These measures of clearance differ in that Cl_{int} is not bounded by hepatic blood flow, but Cl_{hep} cannot exceed hepatic blood flow. While metabolic rate constants (V_{max} and K_m) derived from *in vitro* data can also be scaled up and incorporated into PBPK models, the use of the hepatic clearance model is a simpler approach when an appropriate PBPK model is unavailable. Classical, compartmental TK analyses and measures of clearance of the parent compound are best suited for conditions where metabolism represents a detoxication process, when substrate concentration is less than the K_m value, and when metabolism represents the major clearance mechanism.

Whether toxicity is attributable to a parent chemical, a metabolite, or some combination of metabolites is a critical consideration. The active chemical moiety can be identified through studies in which the toxicities induced by the parent chemical and metabolite(s) are compared or from the results of studies using enzyme inhibitors and/or inducers. *In vitro* studies can also be quite useful in this regard under appropriate conditions (see Sections 2.4 and 3.1.3). Quantifying differences in dosimetry can be difficult when metabolic pathways become complex (e.g., where competition among pathways may be concentration dependent). If the metabolic pathway bifurcates and the identity of the bioactive metabolite(s) is unknown or unquantifiable, determination of the appropriate dose metric can be highly uncertain.

The target organ or tissue group is the preferred site in which estimates of internal dose (tissue concentration) are generated. In practice, this information may be unavailable in the absence of an appropriate PBPK model. It may be necessary to use absorbed dose of the parent chemical as a surrogate measure of internal dose. Another surrogate dose metric is the measured concentration of the parent chemical or active metabolite in circulating blood if the relationship between target tissue concentration and blood concentration is known or can be reliably inferred from experimental data. Some data have demonstrated that blood:air partition coefficient values may vary appreciably among species but that tissue:air (e.g., liver:air) partition coefficients are similar among mammalian species (Thomas, 1975). It seems reasonable to use the cross-species similarity as the primary determinant of diffusion from blood into tissues as a justification to rely on concentrations of the toxicant in blood as a surrogate for tissue concentrations. However, when local tissue bioactivation may determine the toxic response, special care should be used when developing DDEF values on the basis of blood concentrations. Those issues

notwithstanding, measurements of internal dose in circulating blood (IPCS, 2005) may be used as the basis for DDEF derivation under either of the following conditions:

≠ When evaluating interspecies differences, the distribution from blood to target (critical) tissues is shown to be or can be assumed to be the same between animals and humans.

≠ When evaluating intraspecies differences, the distribution from blood to sensitive (critical) tissues is shown to be or can be assumed to be the same in segments of the human population representing those generally responsive and potentially sensitive human populations.

Confidence in model predictions is enhanced when predictions can be compared directly to observed data. However, few human data sets exist that describe concentrations of toxicants in solid tissues. Blood, however, is much more readily obtained, and so the ability to compare predictions of blood to observations is more readily accomplished. This situation results in a higher level of confidence in modeled blood concentrations compared to solid tissue concentrations. Since the partitioning of the active chemical from blood into systemic target tissues may be governed more by physicochemical properties than by biological processes, communication of the understanding of these processes will increase confidence in predictions of solid tissue concentrations. This difference in confidence in predictions may be considered another basis for relying on data describing the concentration and variability of the biologically active metabolite in the central compartment.[7] For example, the ratio of blood lipid to tissue lipid concentrations may be a key determinant in the diffusion of lipophilic compounds out of blood; however, differences in tissue lipid composition between species may be fairly small compared to differences in blood flow and metabolic activity.

3.1.2. Dose Selection

Because variability in internal dosimetry may be a function of dose, the selection of the external exposure (inhaled concentration or orally ingested dose) is important. In some cases, there may be nonlinearities between the external dose and the dose metric. That is, increasing or decreasing doses may not produce proportional increases or decreases in the dose metric. In this instance, the dose selected for the DDEF derivation will impact the magnitude of EF_{AK} or EF_{HK}. Using a dose at or near the POD alleviates some concerns regarding nonlinearities in

[7]The central compartment is defined as blood, plasma, or serum in the systemic circulation. All tissues except those representing the portal of entry are defined as peripheral compartments.

metabolism. This situation is especially true for interspecies extrapolation, where the basis for DDEF calculation is the dose metric. The human equivalent concentration (HEC) or human equivalent dose (HED) is defined as the human exposure producing the same level of the dose metric as attained in the animal at the POD. Alternatively, data that show a linear relationship between external dose and internal dose metrics will lessen this dependence of dose on the estimation of EF_{AK} or EF_{HK}; thus, doses that may be higher or lower than the POD for the critical effect can be used in the calculation.

3.1.3. *In Vitro* Data

Due to ethical and practical constraints, some studies with humans are not possible—especially with chemicals already known to be toxic. *In vitro* study designs offer excellent opportunities to assess the toxicity of an agent, especially when the need to isolate TK from TD is a concern. However, it is important when deriving EF_{AK} and EF_{HK} to consider interspecies differences in ADME. *In vitro* data can be used for quantitative purposes only when interpreted in the context of the intact system, as discussed in Section 2.4. Care must be taken to avoid taking isolated findings out of context.

IN VITRO CAVEATS

When investigating toxicodynamic events, *in vitro* experiments offer the opportunity to control for TK influences; concentrations of the toxicant can be well controlled. Results of *in vitro* toxicokinetic/metabolism studies should be used only when interpreted in the context of the intact system. Samples used *in vitro* should closely represent the species/population of interest, and the measured response should be one well associated with the critical effect.

3.2. INTERSPECIES TOXICOKINETIC EXTRAPOLATION

This section provides a discussion of the quantitative differences in the TK between animals and humans that are used to compute EF_{AK}. In this process, TK differences between species are characterized as the ratio of applied (administered) doses in the test species and in humans (if human data or models are available) that result in the same level of the internal dose metric (see Figure 3). Values for the dose metric may be calculated from the external doses actually used in the dose-response evaluations, or by normalizing the dose metric to account for administered dose (e.g., correcting AUC for each species by dividing the AUC by the external dose) when the relationship between the values for the dose metric and the applied dose are linear in the range of extrapolation. Predictions of dose metrics from verified TK models are often acceptable. Illustrative case studies are included in Appendix A.

3.2.1. Considerations for Interspecies Toxicokinetic Extrapolation Factor

TK differences between animals and humans are evaluated for the selected critical effect and for effects arising near the POD for the presumed critical effect. This analysis includes

consideration of MOA, identification of the active chemical agent for this particular effect, and determination of the appropriate dose metric. Selection of the dose metric is based on a weight-of-evidence approach emphasizing both qualitative and quantitative evidence. An important part of this process is evaluating concordance of metabolic processes between the animal model and humans. An additional consideration is whether the kinetic data are from a "typical" or average adult animal as opposed to an animal model system that may be unusually sensitive for a particular effect (e.g., metabolic knockout).

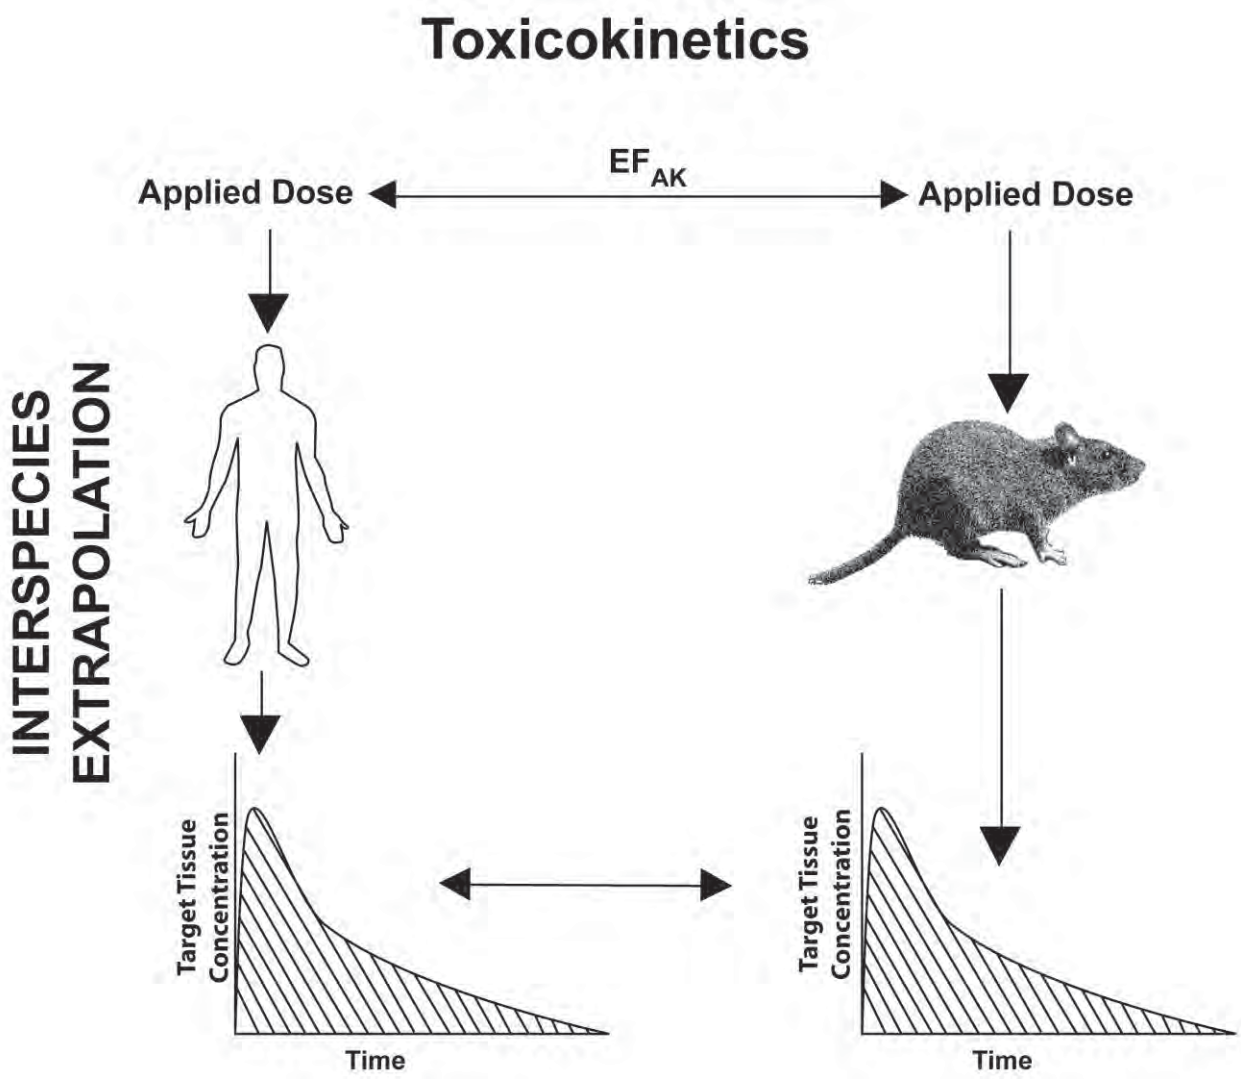

Figure 3. Interspecies toxicokinetics. In keeping with the principles established in earlier Agency guidance, which addressed inhaled toxicants (U.S. EPA, 1994), interspecies differences in TK are defined as differences in the external dose producing the same level of the dose metric in the target tissue of interest in test animals.

When animal data come from a group or from individuals expressing a condition known to be useful in identifying a sensitive human population or life stage, and when the corresponding population group in humans is determined to be the sensitive population, the extrapolation can be conducted between the sensitive animal and sensitive human. In this case, these data may cover both inter- and intraspecies extrapolation, and so represent both EF_{AK} and $EF_{HK,}$ respectively. However, it is recommended that a full weight-of-evidence evaluation be conducted. Using this example, if there are no data in the developing human, but data are available in the adult human, then the data-derived interspecies extrapolation would be from the more sensitive animal (e.g., sensitive life stage) to the general human population; intraspecies extrapolation would require default assumptions.

Furthermore, it is important to assess the relationship of externally applied dose to internal dose metric over the entire range of dose levels used in the critical study. Careful attention should be paid both to measures of central tendency and to variability, particularly in the range of concentrations or doses close to the point of inflection (where the shape or slope of the dose-response curve changes) because of potential nonlinearities in metabolism.

3.2.2. Computation

For interspecies TK extrapolation, the goal is to determine differences in dosimetry between animals and humans. For interspecies extrapolation, toxicokinetically equivalent exposures are determined by fixing the internal dose (level of the dose metric at or near the POD) and determining the ratio of external (applied) dose that results in the same level of the dose metric in animals and humans. This approach is consistent with that in the RfC guidance for inhaled toxicants (U.S. EPA, 1994).

3.2.2.1. *Use of Toxicokinetic Models*

A PBPK (or other TK) model provides the most biologically appropriate approach for evaluating interspecies TK extrapolation. The model is subjected to evaluation as previously described (IPCS, 2010; U.S. EPA, 2006a). The model can be used in different ways, depending on the model and the circumstances. In some cases, the TK model may be used directly to perform interspecies extrapolation (i.e., to derive a human equivalent concentration or dose that includes TK considerations). The use of a PBPK model would obviate the need for EF_{AK}. In other cases, the TK model may be used to derive EF_{AK}.

3.2.2.2. *Use of Ratios*

When AUC or concentration at steady state is the relevant dose metric, and if animal and human data or TK models are available, EF_{AK} is derived using a ratio of external or applied

doses producing the same AUC value. This is accomplished by identifying doses associated with the AUC value produced in animals at or near the animal POD (AUC_A) (see eq 1 and Figure 4). The human dose that produces the same AUC_A value is the toxicokinetically equivalent dose. In these cases, differences between the animal and the human dose producing the same AUC value in each species define the EF_{AK}.

$$AUC = Dose \div Clearance \quad (1)$$

$$AUC_A = D_A \div Cl_A = D_H \div Cl_H$$

where,

D_A = animal external dose (administered or external dose to the test animal species that leads to a level of a toxicologically relevant dose metric at or near the POD)

Cl_A = animal clearance value

D_H = human external dose (administered or external dose to the central tendency in the general human population that leads to the same level of the same dose metric identified in the test animal species)

ClH = human clearance value

Using these data, EF_{AK} is calculated according to eq 2.

$$EF_{AK} = \frac{D_A}{D_H} \text{ OR } \frac{Cl_A}{Cl_H} \quad (2)$$

where,

D_A = animal external dose (administered or external dose to the test animal species that leads to a level of a toxicologically relevant dose metric at or near the POD)

D_H = human external dose (administered or external dose to the central tendency in the general human population that leads to the same level of the same dose metric identified in the test animal species)

ClA = animal clearance value

Cl_H = human clearance value

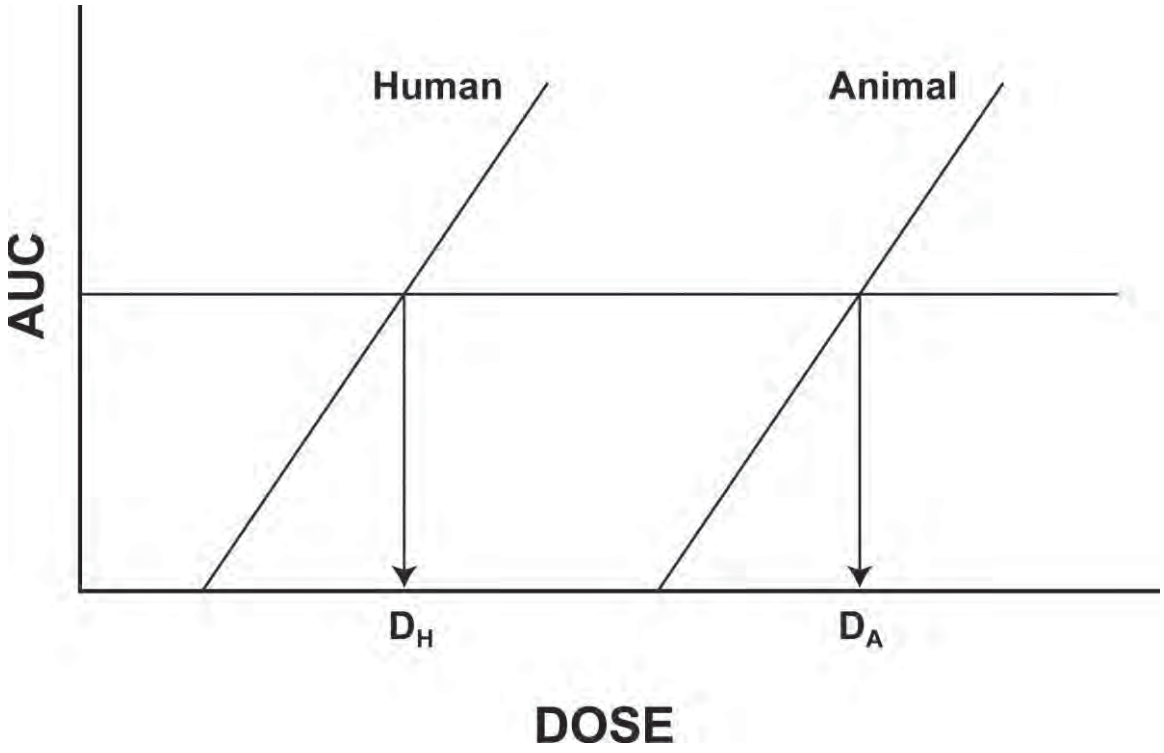

Figure 4. The conceptual relationship between dose and dose metric in animals and humans. Here, AUC is the appropriate dose metric, and the relationship between dose and AUC is determined in animals and in humans. This method can be used to develop a human equivalent dose or concentration, or in the calculation of EF_{AK}. Calculation of EF_{AK} requires knowledge of applied D_A and D_H that produce the AUC value determined in animals at the point of departure (i.e., AUC_A).

Using AUC as an example, the value for the dose metric would be AUC_A, which is the AUC value determined in animals at the POD. Thus, in this example, eq 2 can be conceptualized as

$$EF_{AK} = \frac{D_A \text{ producing } AUC_A}{D_H \text{ producing } AUC_A} \quad (3)$$

where,

D_A = animal external dose (administered or external dose to the test animal species that leads to a level of a toxicologically relevant dose metric at or near the POD)

AUC_A = area-under-the-curve value produced in animals at or near the animal POD

D_H = human external dose (administered or external dose to the central tendency in the general human population that leads to the same level of the same dose metric identified in the test animal species)

This is graphically presented in Figure 4.

Because clearance values are the mathematical reciprocal of internal dose (i.e., AUC), they may also be used to calculate a DDEF value, with the human clearance value in the denominator. Calculations using C_{max} are developed in a manner similar to that for AUC. When the dose is lower in humans than animals at the same AUC or C_{max} value, the developed DDEF will be greater than 1, demonstrating that humans are more sensitive than animals.

3.2.3. Relationship to Other EPA Guidance

The development and use of data for model predictions for tissue dosimetry to serve as the basis for quantitative, interspecies extrapolation via DDEFs is consistent with existing EPA policy (U.S. EPA, 2006a, 2002b). EPA's inhalation RfC methodology presents a continuum of approaches from rudimentary knowledge to biologically based dose-response models (U.S. EPA, 2012, 1994). The RfC methodology describes default approaches for dosimetric adjustment of animal exposure concentrations based on categorical descriptions of target tissue and target tissue concentrations in test species and humans. The first is for reactive (Category 1) gases and inhaled particles that damage portal-of-entry (respiratory tract) tissues, and the second is for gases that are absorbed and produce toxicity in tissues bathed by circulating blood (Category 3 gases). For Category 1 gases, toxicity information identifies the affected region of the respiratory tract, and species differences in the regional respiratory tract surface area and airflow (respiratory rate) serve as the basis to quantify species differences in dosimetry. For Category 3 gases, species differences in the solubility of the compound in blood (the blood:air partition coefficient) serve as the basis upon which to quantify species differences in dosimetry. The default interspecies extrapolation approach for deriving an oral RfD is dose scaling by the ratio of species' body weights raised to the ¾ power (human BW:animal BW)$^{3/4}$ (U.S. EPA, 2011). These guidance documents indicate that their approaches are default dosimetric adjustments, to be superseded when more detailed information on tissue dosimetry can be developed. The

subject of this DDEF guidance is the development and interpretation of quantitative TK data for the purpose of developing nondefault values for inter- and intraspecies uncertainty/extrapolation.

3.2.4. Conclusions for Interspecies Toxicokinetic Extrapolation Factor

Mathematically, EF_{AK} is the ratio of the external animal dose (at or near the POD) to the external human dose expected to result in the same level of the dose metric. This situation is mathematically analogous to developing the HEC or the HED.[8] If possible, EF_{AK} values should be calculated for multiple organs/effects. For a given organ or effect, the same level of the dose metric at the animal POD should be used for TK analyses conducted in test animals and humans. The quantitatively determined DDEF values for EF_{AK} will be less than 1 if the level of the dose metric at the animal POD is attained at a higher dose in humans than in animals (indicating that humans are less toxicokinetically sensitive).

EF_{AK} CAN BE LESS THAN 1

For EF_{AK}, central tendency estimates of doses or exposures producing the same measure of target tissue exposure in animals and humans are used. Lower sensitivity in humans compared to animals is demonstrated by lower AUC or C_{max} values, or higher clearance values in humans than in animals at the same exposure. In these instances, the calculated value of EF_{AK} will be less than 1.

Confidence in EF_{AK} is increased when decisions and calculations are well documented. This narrative includes descriptions of toxicity data identifying the target tissue, chemical species, MOA, and species concordance of effects. Data describing the TK, the metabolism of the compound, and the relationship between external dose and dose metric are also summarized. Data that show a linear relationship between external dose and internal dose metrics can be specifically reiterated in this description, which will indicate generalizability of the EF_{AK} value to doses that may be higher or lower than those used in DDEF calculation. Because animal-to-human differences in target tissue concentrations may not be consistent for all responding tissues or organs, a comparison of POD and DDEF values from multiple affected organs will increase confidence in the extent to which the developed DDEF value sufficiently addresses the toxic action of the assessed chemical. Results can be presented in tabular form for ease of comparison across endpoints.

3.3. INTRASPECIES TOXICOKINETIC EXTRAPOLATION FACTOR

When toxicity data defining the POD are developed in test animals, the established framework for UFs includes an initial extrapolation to the human population, then an

[8]If an HED or HEC value is developed, the residual one-half order of magnitude in the value for UF_A encompasses TD, as well as any residual uncertainty in the derived HEC or HED value.

extrapolation to account for human intraspecies or interindividual variation. The purpose of these analyses is to characterize the variation of TK among the human population, the quantitation of which will help avoid the application of default UFs. From a TK standpoint, among humans experiencing the same *external* dose, sensitivity is due to higher target tissue concentrations of the toxicant in the sensitive population or group relative to the rest of the general human population. As with interspecies extrapolation, the DDEF values may be compared to default UF values. This comparison is conducted to aid policy decisions and risk communication after the adequacy of the underlying data have been confirmed (a data quality evaluation). Characterization of the available data includes considering how completely the sensitive population has been identified and its sensitivity described (as opposed to assumed) (U.S. EPA, 2002b). The selection of a bimodal- or unimodal-based analysis will be a function of the available data. It is important to document the available information and related statistical analysis and/or assumptions that serve as the basis for selecting a unimodal or a bimodal distribution of sensitivity. The extent to which this description has been done will inform decisions regarding the application of DDEF analyses.

Sensitivity may reside in an identifiable population (e.g., distinct life stage or genetic polymorphism) or may be less distinctly distributed among humans (e.g., differences in the levels of an endogenously expressed enzyme). As described in more detail below, extrapolation among the human species is accomplished by either of two options (or both): (1) evaluating human interindividual variability among the entire human population or (2) explicit identification of the potentially sensitive population(s) for TK analysis. Differences in the scope/intent of the risk assessment and the availability of data to identify a given population or group as sensitive (e.g., the aged, those with genetic polymorphisms) may limit application of the second option. This section provides a discussion of the quantitative differences in TK among humans for intraspecies extrapolation (i.e., EF_{HK}).

Although it is important to acknowledge the complex factors that contribute to human variability, for sake of simplicity, the entire human population can be distinguished as those who are sensitive and others that make up the general population. This is an important distinction, influencing the choice of computational methods. A bimodal analysis (segregating the entire population into the general and the sensitive populations) is used when sensitive individuals can be identified on the basis of physiological, biochemical, or life-stage attributes and grouped into a distinct population. A unimodal analysis is used when sensitive individuals cannot be identified *a priori* on the basis of physiological, biochemical, or life-stage attributes. Regardless of the analysis type, it should be based on a sufficiently large and diverse population data set, including adequate sampling of potentially sensitive populations and life stages.

3.3.1. Considerations for Intraspecies Toxicokinetic Extrapolation Factor

3.3.1.1. *Sensitive Populations*

This section presents the process of considering the TK of an agent among the human population. For some chemicals, data may be sufficient to identify one or more sensitive populations but insufficient for other chemicals. Sensitivity in the human population may be due to life stage, health status or disease state, genetic disposition, and other factors (also see Section 2.1.2). Critical windows of development, and therefore "windows of susceptibility," occur at different times for various tissues, organs, and systems; therefore, considering sensitivity to more than one critical effect may require consideration of more than one life stage. As discussed in more detail below, distributional analysis of response data can be conducted to identify points for use in quantitation. In completing the analysis, it is important to describe the relationship between the dose metric and the toxicity endpoint(s) of concern (e.g., critical effect or key event). The intraspecies extrapolation step is intended to account for differences between the central tendency of the entire population and the sensitive portion of the population (unimodal analysis) or between the central tendency of the general population and some point in the distribution of the population of sensitive individuals (see bimodal analysis; Section 3.3). Considering sensitivity to more than one critical effect may require consideration of more than one potentially sensitive population.

From a TK standpoint, among humans experiencing the same *external* dose, sensitivity is due to higher target tissue concentrations of the toxicant in the sensitive population relative to the rest of the human population. Higher tissue concentrations can be demonstrated as higher AUC or C_{max} values, or by lower Cl values. Thus, when assessing sensitivity, values in the upper tail of the distribution (e.g., 95th, 97.5th, 99th percentiles) of values for AUC and C_{max} values are considered, while values in the lower tail of the distribution (e.g., 1st, 2.5th, 5th) of values for Cl are considered. The examples demonstrated in this section use AUC or C_{max} as the dose metric. Equation 4, discussed in Section 3.3.2.2, demonstrates the mathematical approach to quantitation of EF_{HK} based on AUC, C_{max}, or Cl. For AUC and C_{max} values, EF_{HK} is computed as the ratio of an internal dose metric attained in the sensitive population to that observed at or near the central tendency in the general human population exposed to the same external dose or concentration. Illustrative examples are included in Appendix A.

Sensitivity may be due to increased tissue exposure at a given dose (TK) or to increased responsiveness to a given tissue concentration (TD; see also Section 4.3.1.1). With an adequate description of the population variability of biochemical, physiological, and anatomical variability, a distributional analysis of the dose metric can confirm that TK variability influences sensitivity. If the dose metric is segregated into distinct groups and the supposed sensitive population has a higher level of the dose metric (e.g., AUC or C_{max}) than the rest of the

population (see Figure 5, left panel), these results would confirm that sensitivity may be at least partially influenced by TK. However, if the dose metric demonstrates a uniform distribution (see Figure 5, right panel) and sensitive individuals are distributed among the entire population distribution, such results would suggest that TK variability may have little influence on sensitivity. Ideally, data will be complete enough to enable more than point estimates among the populations. As discussed in more detail below, distributional analysis of response data should be conducted to identify points for use in quantitation. In completing the analysis, it is important to describe the relationship between the dose metric and the toxicity endpoint of concern (e.g., critical effect or key event). A sufficiently large and diverse population data set must be used to ensure that it includes an adequate sampling of potentially sensitive populations and life stages.

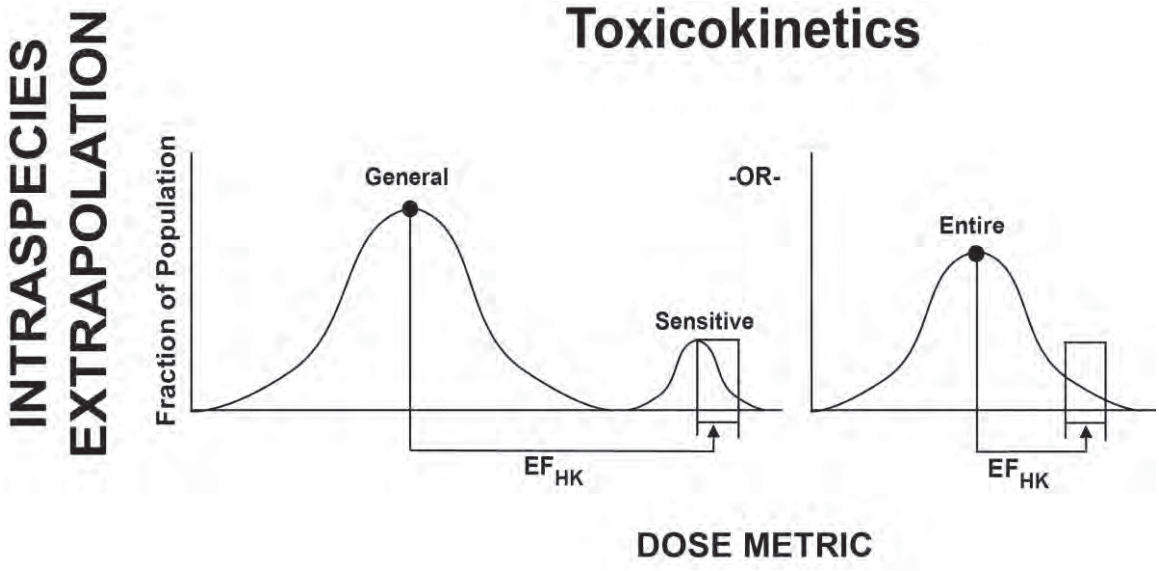

Figure 5. Intraspecies toxicokinetics. Dose metric values may be distributed among the human population in a bi- (or multi-) modal or a unimodal fashion. Even when an identifiable population is presumed or demonstrated to be sensitive on the basis of exposure, the distribution of dose metric values may be unimodal. Differences in distribution type affect quantitative methods as described in the text. EF_{HK} is computed on the basis of differences in dose metric attained at the same external dose. This figure demonstrates analysis of AUC and C_{max} data.

3.3.1.2. *Target Tissues*

When responses are observed in several organs at or near the POD for the most sensitive effect, a comparison of EF_{HK} values developed for those tissues is informative. However, the selection of a target organ for calculating human variability other than the one serving as the

basis for animal-to-human extrapolation is best accompanied with a justification. Development of candidate DDEF values should be undertaken in a manner analogous to the development of candidate RfD or RfC values per EPA (U.S. EPA, 2002b). The extrapolation approach is generally most consistent when the same tissue or organ is used for each phase of the extrapolation procedure.

3.3.1.3. *Dose-Response*

Because variability in internal dosimetry may be a function of dose, the selection of the external exposure (e.g., inhaled concentration or orally ingested dose) is important for use in estimating intraspecies differences in dosimetry. When the POD is derived in animals, several options exist for interspecies extrapolation, depending on the availability of suitable animal and human data describing TK and/or TD. In the TK part of the interspecies extrapolation step, the animal POD is extrapolated to produce a toxicokinetically equivalent human dose or concentration. In some instances, interspecies extrapolation may also include a separate, technical treatment of TD. Also, interspecies adjustment may be completed by the default value for UF_A, or the POD may be defined from dose-response studies in humans. Regardless of whether the default UF is applied or DDEF value is computed to complete *interspecies extrapolation*, it is the external dose (mg/kg-day) or concentration (mg/m^3) reflecting this adjustment that is most appropriate for application in determining human *intraspecies* TK variability.

The basis for comparison of *human variability* is at the level of the internal dose metric rather than the external dose. This choice for the level of comparison is consistent with the principle that it is the target tissue dose that drives the toxic response, not an external (applied) dose. Placing the comparison at the level of the target tissue dose (dose metric, internal dose) forces the assumption of TK linearity to maintain consistency with the established approach of applying UFs to external doses. Thus, it is important that the relationship between internal and external doses be well characterized to ensure TK linearity (the proportionality of the ratio of external dose to dose metric across some range of doses or exposures). While nonlinearities may become evident at substantially different human exposures (e.g., between the interspecies-adjusted POD and the resulting RfD or RfC), the prime point for comparison is the range of doses (or concentrations) immediately surrounding the interspecies-adjusted POD. Because EF_{HK} and preceding DDEF values will be used to extrapolate external doses, it is recommended that TK linearity be tested by documenting a consistent ratio of external doses and dose metric values in a range of exposures bounded by the value of EF_{HK}.

Nonlinearities in TK frequently arise due to metabolism, and are addressed on a case-by-case basis. Several circumstances may account for nonlinearities. When a chemical is

metabolized by a single enzyme and the concentration is below the K_m, the metabolic rate is essentially defined by V_{max}/K_m—metabolism is essentially first order. When concentrations become saturating, further increases in concentration do not result in increased metabolism. When metabolism represents a bioactivation process, no further increase in toxicity due to a bioactivated metabolite is anticipated. However, if metabolism represents a detoxication process, then a disproportionate increase in toxicity from the accumulation of the toxic parent chemical may be predicted. However, increasing concentrations of the chemical may recruit additional enzymes with a lower affinity, and these enzymes may be responsible for the production of detoxicated or bioactivated metabolites. Nonlinearities represent special cases, and when identified, are seldom evident over narrow ranges of concentrations. This DDEF guidance is concerned with the factors governing inter- and intraspecies extrapolation. When nonlinearities become evident in the range of doses pertinent to these dose extrapolation steps, they are considered on a case-by-case basis. Consideration of nonlinearities that are evident across broader ranges of concentrations (e.g., animal POD versus RfD values) are beyond the scope of this guidance.

Specific differences among humans, particularly those demonstrated *in vitro* (i.e., intrinsic clearance), are most reliably used when they are translated into differences in dosimetry based on the anatomical and physiological constraints imposed by the intact system (whole animals). This approach may include evaluations of multiple different doses.

3.3.2. Computation

For intraspecies TK extrapolation, differences in dosimetry are characterized for the human population by comparison of central tendency TK data for the sensitive population to measures of the general population or the entire population (see Section 3.3.1.1, Figure 5). The comparisons are among differences in internal dosimetry (or target site dose, dose metric) resulting from the same external exposure. To address human variability, some attention is devoted to documenting the reasons for the assumption of sensitivity among any population anticipated *a priori* to be sensitive (generating a bimodal analysis, which involves the general and sensitive populations). In the absence of a specifically identifiable population as sensitive, or when the analysis of TK among humans includes a separate population presumed to be sensitive fails to result in distinguishable distributions of the dose metric, a unimodal type analysis should be conducted. In this instance, comparisons of the dose metric between the central tendency and defined percentiles of the entire population distribution (upper percentiles for C_{max} and AUC; lower percentiles for clearance) can be made. Regardless of the distribution type, the presentation of multiple values/points in the tail of the distribution will better enable risk communication and management decisions.

3.3.2.1. *Use of Toxicokinetic Models*

A PBPK or other TK model provides the most biologically appropriate approach for evaluating intraspecies TK extrapolation. When a model is available and has been properly evaluated (IPCS, 2010; U.S. EPA, 2006a). It can be used in different ways depending on the model and the circumstances. There are several potential applications of TK models for sensitivity among humans. Some examples include the identification of the POD in a test animal species and a subsequent two-step process to perform a TK extrapolation to account for inter- and intraspecies differences. This case is the typical scenario, and in it, the initial extrapolation is from the animal POD value to a value representing the central tendency in the human population. If TK data or a reliable TK model exists that can be used to examine dosimetry in the segment of the human population deemed sensitive, then the second extrapolation step to account for human variability is undertaken to define differences in tissue concentrations between the central tendency of the general population and those in the sensitive population or in the sensitive portion of the population. For example, the DDEF value for EF_{HK} is determined as the ratio $Concentration_{sens}$:$Concentration_{gen}$.

A second circumstance is exemplified when the POD is identified in the generally responsive (e.g., 70-kg adult human male), obviating the need for interspecies extrapolation and requiring an extrapolation to account for sensitivity among humans. In this case, the data or the model used to identify the dose metric near the central tendency of the general (overall) human population and in the segment of the population representing sensitivity/susceptibility will be examined. However, when the POD is determined in the portion of the human population that is sensitive, deriving UFs or DDEF values for inter- or intraspecies extrapolation is unnecessary.

3.3.2.2. *Use of Ratios*

In addition to predictive models, EF_{HK} can be derived using a ratio (see eq 4). The value for the dose metric employed as the central-tendency measure in humans (e.g., area under the concentration-time curve at a fixed external dose at a measure of central tendency in the entire or general human population [AUC_{gen}]) would be that level of the dose metric identified from studies with animals and further extrapolated to account for interspecies TD differences, or from studies in humans. The value for the dose metric in sensitive populations or at a percentile of the entire population (e.g., area under the concentration-time curve at a fixed external dose at a percentile of interest for the sensitive human population or representing sensitive individuals among the entire human population [AUC_{sens}]) should be determined from empirical data or pharmacokinetic modeling.

$$EF_{HK} = \frac{AUC_{sens}}{AUC_{gen}} \text{ OR } \frac{C_{max\ sens}}{C_{max\ gen}} \text{ OR } \frac{Cl_{gen}}{Cl_{sens}} \quad (4)$$

where,

EF_{HK} = intraspecies TK extrapolation factor

AUC_{gen} = general human population AUC value (area under the concentration-time curve at a fixed external dose at a measure of central tendency in the entire or general human population)

AUC_{sens} = sensitive human population AUC value (area under the concentration-time curve at a fixed external dose at a percentile of interest for the sensitive population or representing sensitive individuals in the entire human population)

$C_{max\ gen}$ = general human population maximum concentration value (at a fixed external dose at the central tendency in the entire or the general human population)

$C_{max\ sens}$ = sensitive human population maximum concentration value (at a fixed external dose at a percentile of interest for the sensitive population or representing sensitive individuals in the entire human population)

Cl_{gen} = general human population clearance value (at a measure of central tendency in the entire or general human population)

Cl_{sens} = sensitive human population clearance value (at a percentile of interest in the sensitive human population or representing sensitive individuals among the entire human population)

3.3.3. Conclusions for Intraspecies Toxicokinetic Extrapolation Factor

EF_{HK} is a comparison of dose metrics resulting from the same external dose across the human population(s). When using an empirical ratio, EF_{HK} is the ratio of the dose metric value at a percentile of the distribution intended to represent the sensitive population or individuals and the dose metric value at a central-tendency measure of the general or the entire population. By quantitatively, EF_{HK} cannot be less than 1.

The dose selected for quantifying human interindividual variance may have an impact on the magnitude of variability (the DDEF value). When the POD is identified in a test species, the dose adjusted from the animal POD to account for all components of UF_A is the preferred dose for quantitation of human variability. If the POD is identified in humans not deemed to represent a human population, then human variability should be characterized at that dose. DDEF values should be calculated for multiple organs/effects when multiple tissues respond near the POD for

the most sensitive tissue (the critical effect). The consistency of DDEF values should be evaluated over a range of doses surrounding the POD to increase the level of confidence. DDEF values should be developed for each of the candidate tissues or effects, combined with POD values for each candidate tissue or effect, and clearly communicated. To ensure transparency, associated documentation should describe the mathematical method employed, the type of distribution and percentile(s) of interest, the rationale for choosing percentiles of interest, the dose metrics (e.g., AUC of parent compound in kidney), and the target tissues for which EF_{HK} values are developed. Confidence in the extrapolation is improved when distribution types are justified or explained.

4. DATA-DERIVED EXTRAPOLATION FACTORS BASED ON TOXICODYNAMICS

4.1. GENERAL CONSIDERATIONS

TD describes the critical interaction of the toxicologically active chemical moiety with the target site and the ensuing sequence of events leading to toxicity. Data that describe the dose-response relationship serve as the basis for deriving extrapolation factors for TD components. This section provides a discussion of factors common to inter- and intraspecies extrapolation for TD. In contrast to TK, which focuses on *differences in internal dosimetry,* TD differences are quantified as *differences in concentration*[9] *producing the same level of response* between test animals and humans, as well as among humans. TD evaluations may include multiple response levels, critical effects, key events, or analytical methods. Developing a DDEF for TD requires knowledge about the relationship between an event measured *in vitro* or *in vivo* (e.g., receptor binding) and the end result (critical effect). Doses or concentrations producing the measured event can be obtained *in vitro* or *in vivo* in the tissue of interest or a suitable surrogate. TD models, the most complex of which may be represented by BBDR models, are an important tool through which predictions may be made to extend the range of empirical observations. Comparisons between animals and humans or to quantify human interindividual differences are made on the basis of doses or concentrations that produce the same level of the same measured response.

Quantitative differences between animals and humans are used for EF_{AD}, whereas differences in sensitivity within the human population are used for EF_{HD}. Thus, EF_{AD} is used to extrapolate findings in laboratory animals to the general human population, and EF_{HD} is used to extrapolate to sensitive human populations. The TD components (EF_{AD}, EF_{HD}) are combined with the corresponding TK components to develop the composite factor.

In rare cases, when a sensitive population or life stage has been identified, TD data in animals and the sensitive population (if available) may be employed to develop a DDEF value that combines both inter- and intraspecies TD extrapolation. In this case, the DDEF value derived represents both EF_{AD} and EF_{HD}. Because this is expected to be a rare situation, this section will address extrapolations separately.

Although a complete mechanistic understanding is not required, derivation of a DDEF for TD relies on some understanding of an MOA for the critical effect(s) identified for risk

[9]When using a biologically based dose-response model, differences may be quantified as the ratio of dose metrics in respective species or population groups producing the same level of the response. However, DDEF values for TD may also be quantified as the ratio of *in vitro* concentrations producing the same level of the response.

assessment. As for all DDEF derivations, adequate and appropriate data are essential. Important issues to address include the following:

≠ What are the critical effect(s) and POD(s) being used in this assessment? If more than one, each should be considered in this process.

≠ What is the MOA, AOP, or mechanism(s) for that toxicity? Have the key events been identified? How are they measured?

≠ Is the MOA, AOP, or mechanism(s) in the animal model relevant to humans (qualitatively and/or quantitatively)?

≠ For interspecies extrapolation, are there sufficient data on the key events amenable to modeling such that a uniform measure of response in animals and humans can be derived? If not, do the available data points include a response level that is sufficiently similar in animals and humans?

≠ For intraspecies extrapolation, are there adequate data in human populations that describe population variation in response as a function of internal dose metric? Do the available data identify sensitive population(s)? Can the degree of this sensitivity be adequately estimated?

4.1.1. Mode of Action

TD extrapolation should be endpoint driven (considered in the context of the critical effect). For clarity, the choice of critical effect is justified, when possible, based on findings of response in exposed humans (U.S. EPA, 1994). Understanding MOA for the agent(s) of interest ensures that the TD responses (the biological events) used to derive the DDEF are relevant to the adverse health outcome of interest. These responses could include receptor affinity, enzyme inhibition, and molecular changes, among others. Repair of deoxyribonucleic acid (DNA) or tissue damage, biological thresholds, residual function, and other processes that could contribute to the shape of the dose-response curve and effects are considered. Experimental systems and measured responses in each species should be the same or comparable for both inter- and intraspecies extrapolation.

4.1.2. Relating Response to Dose or Concentration

TD data may be developed from the results of *in vivo* or *in vitro* studies. In some cases, *in vivo* data may be used, but care should be taken to control for the influence of TK. If there are existing human data measuring the response, then those data can be used to derive the POD,

thereby removing the need for the UF_A. Likewise, data from the most sensitive human population, if available, could be used for the risk assessment and a UF_H may not be needed.

Care should be taken to ensure that kinetic factors do not confound the interpretation of response data. Comparisons based on an internal dose metric are preferred over external dose; that is, the internal concentration producing the level of response (rather than applied dose or concentration) is preferred so that TD response may be distinguished from TK influences. Tissue-specific metabolism could also influence the actual target tissue concentrations and must be considered. Blood levels are an acceptable measure of internal dose when it can be shown that they are proportional to concentrations of toxicologically active chemical moieties in the target tissue or biological preparation.

When using *in vitro* systems, the response measured should be representative of the toxicity; that is, the measured endpoint should be consistent with or comparable to the critical effect or key event observed *in vivo* (if known). In cases where the measured response *in vitro* is known to differ from that observed *in vivo*, it is important to describe the potential impact of these differences on the final DDEF. For the sake of transparency when using *in vitro* data, the comparability of chemical uptake between animal and human tissues or preparations is addressed. Among the factors considered when presenting *in vitro* results are data describing metabolism of the test chemical by the *in vitro* system used.

4.1.3. Range of Doses or Concentrations

The relationship between the doses, tissue concentrations, and/or *in vitro* concentrations used to derive the DDEF, and those attained in the toxicity studies from which the POD is derived, can be characterized to improve transparency of the assessment. Optimally, the concentrations used in studies of the critical effect(s) include the concentration at the POD. The need for quantitative data is important because the variability in the response may change with increasing or decreasing dose or concentration. Doses and/or tissue concentrations may also be compared to those expected from environmental exposure; this comparison is part of the consideration of overall relevance of the test system.

4.2. INTERSPECIES TOXICODYNAMIC EXTRAPOLATION FACTOR

This section provides information for calculating TD differences between species (EF_{AD}). These are characterized as the ratio of the concentrations (concentrations used *in vitro* or the level of the dose metric) in animals and humans producing the *same level of response*. Note that the level of comparison is at a fixed response level, and it is not a comparison of responses produced by the same concentration (see Figure 6). Illustrative examples are included in Appendix A.

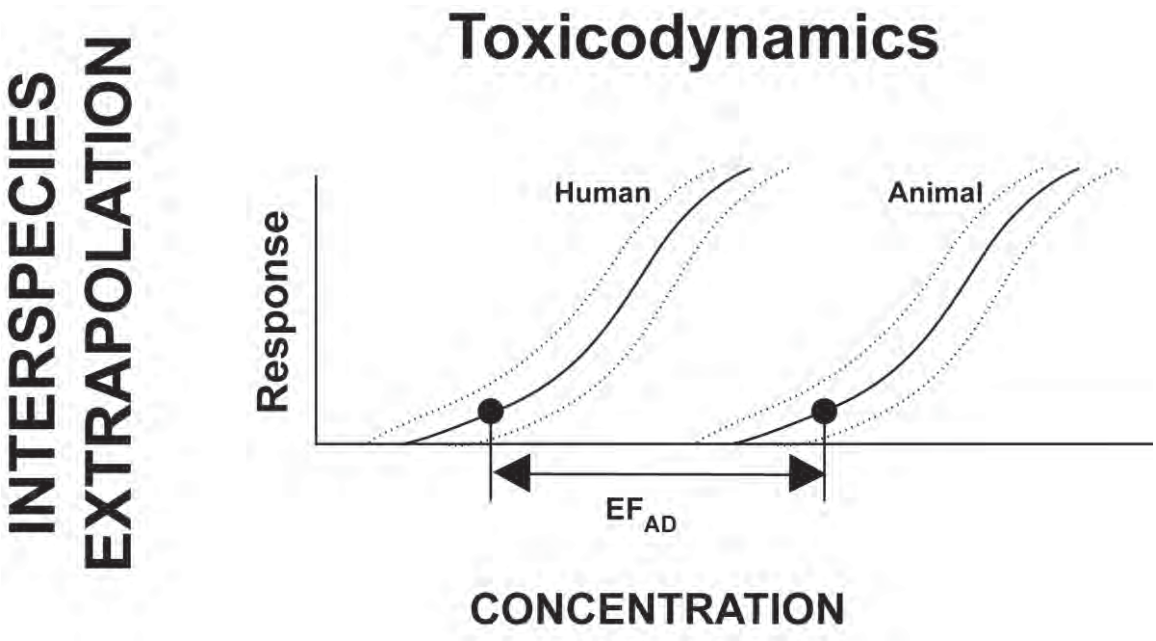

Figure 6. Interspecies toxicodynamics. The TD difference between test animals and humans is calculated from concentration-response relationships determined in test systems or animals generally representative of the respective species. The comparison is made for concentrations producing the same level of response, and comparisons are made using values representing the central tendency. Dashed lines represent variability.

4.2.1. Considerations for Interspecies Toxicodynamic Extrapolation Factor

4.2.1.1. *Mode of Action*

Endpoint(s) must be chosen for which to derive the EF_{AD}, and the endpoint(s) should be the actual critical effect or a key event in the MOA or AOP. For each endpoint evaluated, it is determined whether the data are from an animal typical of the responding species/strain/sex/life stage, as opposed to an animal model system that may be unusually sensitive for a particular effect. Characterization of the test animal might be important in transgenic animals and in animal models used to study specific human diseases (e.g., spontaneously hypertensive rats). Animal models and the MOA(s) based on them are best evaluated for human relevance (Meek et al., 2003), as has been done for forestomach tumors (Proctor et al., 2007).

4.2.1.2. *Target Tissues*

Data from the target tissues are preferred but not always available for human tissue. Where there are data from the molecular targets in both species, but the data are not from the critical target organ, the data can be used provided there is sufficient justification that one tissue

is an appropriate surrogate for another. For example, a target enzyme may be present in several tissues, including blood; however, blood is easily obtained from humans, but tissue from the target organ is not. Studies may show that the effect on this target enzyme in blood correlates very well and is entirely predictive of the effect in the target organ, and that the enzyme structure, function, and chemical affinity are the same regardless of tissue. Such information would be necessary to justify comparisons of chemical effects in the blood enzyme in both humans and laboratory animals.

4.2.1.3. *Dose-Response*

The choice of response level to use for comparison depends on several factors:

- ≠ Completeness of dose-response data,
- ≠ Shape of the dose-response curves, and
- ≠ Understanding of the effect along the toxicity pathway at that response level.

The magnitude of EF_{AD} may be a function of the response level chosen for extrapolation. Confidence is increased when the response level employed for EF_{AD} calculation approximates the response level at the POD and when the ratio of doses producing the same response level in animals and humans is similar over a range of doses. When data are available to describe the full dose-response curve, evaluating the shape of the dose curves for animals and humans can provide important information. If the shapes of the curves are different, then the magnitude of EF_{AD} will depend on the response level selected. Note that concentrations causing greater magnitudes of effect may also produce nonspecific cellular changes that could confound the comparisons.

4.2.1.4. *In vitro Data*

When using data from *in vitro* systems, the activity of the parent chemical and/or metabolites, as well as the extent of metabolism of the compound by the *in vitro* system, should be known. The *in vitro* assay should measure a response that can be linked to the toxic outcome, and the assays should employ the same (responding) tissues from the *in vivo* test animal species/strain/sex/life stage and from humans. Experimental systems should be as closely matched as possible, and the concentrations of toxicant *in vitro* should be compared to tissue concentrations (the dose metric) at the POD. See Section 2.4 for other general considerations.

4.2.2. Computation

4.2.2.1. *Use of Ratios*

When TD models are not available, EF_{AD} can be calculated as a ratio describing the relationship between the tissue concentrations producing a set response in human tissues compared to animal tissues, preferably at or near the response level at the POD. For example, "*x* response level" may be a 10% response if the effective dose producing a 10% response rate or lower confidence bound on benchmark dose corresponding to a 10% increase in response ($BMDL_{10}$ value) is used. The EF_{AD} value would be calculated as follows:

$$EF_{AD} = \frac{\text{Concentration}_{\text{A-}x\text{ response level}}}{\text{Concentration}_{\text{H-}x\text{ response level}}} \quad (5)$$

where,

EF_{AD} = factor for interspecies extrapolation covering TD

$\text{Concentration}_{\text{A}-x\text{ response level}}$ = concentration of the agent at the tissue in the animal resulting in an *x*% response

$\text{Concentration}_{\text{H}-x\text{ response level}}$ = concentration of the agent at the tissue in the human resulting in an *x*% response, where *x* is the same response value as in animals

To evaluate the extent to which the shape of the dose-response curve varies between animals and humans, and thus impacts the magnitude of EF_{AD}, a range of response levels should be evaluated (e.g., in cases where the dose-response data are extrapolated to derive levels for the POD). The rationale and implications for choosing the point for extrapolation should also be presented.

4.2.2.2. *Biologically Based Dose-Response Models*

A BBDR model often provides the most robust approach for evaluating interspecies extrapolation. These models are typically expansions of PBPK models (addressing TK) extended to include TD. By including both TK and TD components, BBDR models provide a linkage between external (applied) dose and biological response. Such models incorporate data from key events allowing direct estimation of adverse health outcome. In cases where the ultimate biological effect modeled in the BBDR model (e.g., DNA binding of the toxicant) is not the adverse health outcome of interest (e.g., tumor development), additional considerations are

needed. Perhaps the most important among these is the quantitative relationship between the modeled biological effect and the adverse health outcome. In keeping with principles established herein and elsewhere in Agency guidance, several points are important when evaluating a BBDR model for quantitative reliance. Fundamentally, the TK components of the model must be evaluated according to established principles (U.S. EPA, 2006a). TD components of the model should be evaluated according to principles established in this section. Because BBRD models translate exposure to response (without necessarily separating out TK from TD influences), they may be used to complete species extrapolation without developing distinct values for EF_{AK} and EF_{AD}. Alternatively, this human exposure may be identified as the HEC (for inhaled toxicants) or an HED (for orally encountered toxicants).

4.2.3. Conclusions for Interspecies Toxicodynamic Extrapolation Factor

Mathematically, EF_{AD} will be the ratio of the concentrations or dose metric values resulting in the same level of response in both the test species and human. DDEF values may be calculated for multiple PODs and organs/effects, but the response levels used for quantitation should be the same in animals and humans. Confidence in the value (knowing whether the DDEF value can vary depending on the response level) is improved when EF_{AD} values developed from multiple points on the concentration-response curve are comparable; the shape/slope of the curves may also influence these values. Quantitatively, EF_{AD} can be less than 1 if the data show humans are less sensitive than test species.

Preferably a summary of all conclusions and their scientific support are provided. Data describing the dose-response of the compound in animals and humans can be specifically reiterated in the summary. Finally, the summary also indicates the extent to which the EF_{AD} value can be generalized to doses that may be higher or lower than those used in its calculation.

4.3. INTRASPECIES TOXICODYNAMIC EXTRAPOLATION FACTOR

This section provides information for calculating TD variability within the human population. EF_{HD} is calculated as the ratio of concentrations or dose metric values producing the same level of the response at or near the central tendency in the general (nonsensitive) or the entire population to concentrations of the dose metric observed/predicted in the sensitive population or sensitive portion of the entire. From a TD standpoint, sensitivity is based on attaining a given level of response at a lower concentration of toxicant. For this evaluation, multiple response levels, critical effects (or key events), analytical methods, or sensitive populations may be considered.

4.3.1. Considerations for Intraspecies Toxicodynamic Extrapolation Factor

4.3.1.1. *Sensitive Populations*

Sensitivity in the human population may be due to life stage, health status or disease state, genetic disposition, or other factors as discussed in Section 2.1.2. Critical windows of development, and therefore windows of sensitivity, occur at different times for various tissues, organs, and systems. Considering sensitivity to more than one critical effect may require consideration of more than one life stage. Data to address differential sensitivities in dynamic response are becoming more available with advances in the science (IOM, 2013). For example, population variation, such as genetic polymorphisms, is an expanding area of study. The increased availability and application of newer technologies, such as omics and high through-put, will benefit the derivation of DDEFs in general, and EF_{HD} in particular. A data-derived EF_{HD} is feasible if human data are of sufficient quality, the data address aspects of the critical effect consistent with that identified from applicable human or animal studies, studies have been conducted in the segment(s) of the population deemed sensitive, and/or a sufficiently large and diverse sample set is available.

For quality purposes, data should be sufficient to enable at least a rudimentary understanding of the distribution of values. As presented in Section 3.3.1.1, sensitivity may be distributed among the entire population or segregated into an identifiable sensitive population, dictating a unimodal or bimodal distribution, respectively, with their inherent DDEF quantitative procedures. As discussed in more detail below, distributional analysis of response data may be conducted to identify points for use in DDEF quantitation. The relationship between the measured response and the toxicity endpoint of concern (e.g., critical effect or key event) should be described, whether determined *in vivo* or *in vitro*.

4.3.1.2. *Target Tissues*

For calculation of EF_{HD}, data for multiple responding tissues can be evaluated and multiple DDEFs can be derived. It is particularly important to evaluate those tissues that demonstrate response at doses or concentrations near that for the critical effect.

4.3.1.3. *In vitro Data*

Given the constraints on generation of human response data *in vivo*, *in vitro* studies offer an alternative. Samples selected for *in vitro* investigation should represent the central tendency of the human population as well as sensitive populations or life stages (see Section 2.4 for other general considerations). It is important that the *in vitro* assay measure a response that can be linked to the toxic outcome, and also that the assays employ the same (responding) tissues or

suitable surrogates for the tissues identified in the *in vivo* test animal species/strain/sex/life stage and from humans. Finally, experimental systems for each segment of the human population should be as similar as possible, and the concentrations of the toxicant *in vitro* be compared to tissue concentrations (the dose metric) at the POD.

4.3.2. Computation

For intraspecies TD extrapolation, differences in response are characterized for the human population by comparison of the TD data (doses or concentrations producing the same level of response) for the central tendency of the populations to the sensitive population or segment of the population. For quantitation, data on the critical response(s) are derived from a population that includes sensitive populations. Because the data available to define potentially sensitive populations from which to derive quantitative differences could be viewed in different ways, a statistical analysis may be helpful to determine distribution type (see Figure 7), which include:

≠ A unimodal distribution where the sensitive population represents the tail of the distribution because the sensitive individuals cannot be separated from the remainder of the human population; a sufficiently large and diverse population data set must be used to ensure that it includes an adequate sampling of potentially sensitive populations and life stages.

≠ A bimodal (or multimodal) distribution where the sensitive populations have been identified or suggested.

4.3.2.1. *Use of TD Models*

In the absence of *in vivo* response data in the sensitive human population, a BBDR or other TD model provides the best approach for evaluating intraspecies TD extrapolation. When sufficient data are available, these TD models can be structured and used to include differences in MOA components that may be life-stage dependent or influenced by other conditions potentially conferring increased sensitivity, such as genetic polymorphisms. Specific to EF_{HD}, it is critical that the model parameter(s) conferring increased sensitivity be well documented. When an appropriate model is available, it can be used in different ways depending on the model. In some cases, the TD model may directly account for interindividual variation and/or include data from the sensitive population, thus eliminating the need for EF_{HD}. In other cases, the TD model may be used to derive EF_{HD}.

4.3.2.2. *Use of Ratios*

When TD models are not available and populations can be identified as sensitive, then the ratio approach may be used. EF_{HD} is defined as the ratio between the concentrations producing the same level of response at the central tendency of the general population and a specified percentile of the distribution in the sensitive populations and/or life stages. EF_{HD} is calculated using eq 6 and described in Figure 7.

$$EF_{HD} \cong \frac{Concentration_{gen}}{Concentration_{sens}} \quad (6)$$

where,

EF_{HD} = factor for intraspecies extrapolation covering TD

$Concentration_{gen}$ = concentration producing the response corresponding to the POD at a measure of central tendency in the entire or the general human population

$Concentration_{sens}$ = concentration producing the response corresponding to the POD at a percentile of interest for the sensitive human population

When sensitivity among the population exhibits a unimodal distribution, EF_{HD} is the ratio of the concentration that elicits a level of response at the central tendency of the entire distribution to the concentration that elicits the same level of response at a lower sensitive percentile of the distribution. It is important to define and justify the point(s) in the distribution representing sensitivity; a sufficiently large and diverse population data set must be used to ensure that it includes an adequate sampling of potentially sensitive populations and life stages.

When sensitivity among the population exhibits a bimodal (or multimodal) distribution, the DDEF is determined in a similar manner, using the concentrations that elicit the specified level of response at the central tendency of the general population and in the lower tail of the sensitive population. The values selected to describe the sensitive population are defined and presented. The selection of the response level and the percentile of the distribution used to describe the potentially sensitive populations is an important issue. A justification for selection of the response level and percentile for sensitive population should be provided.

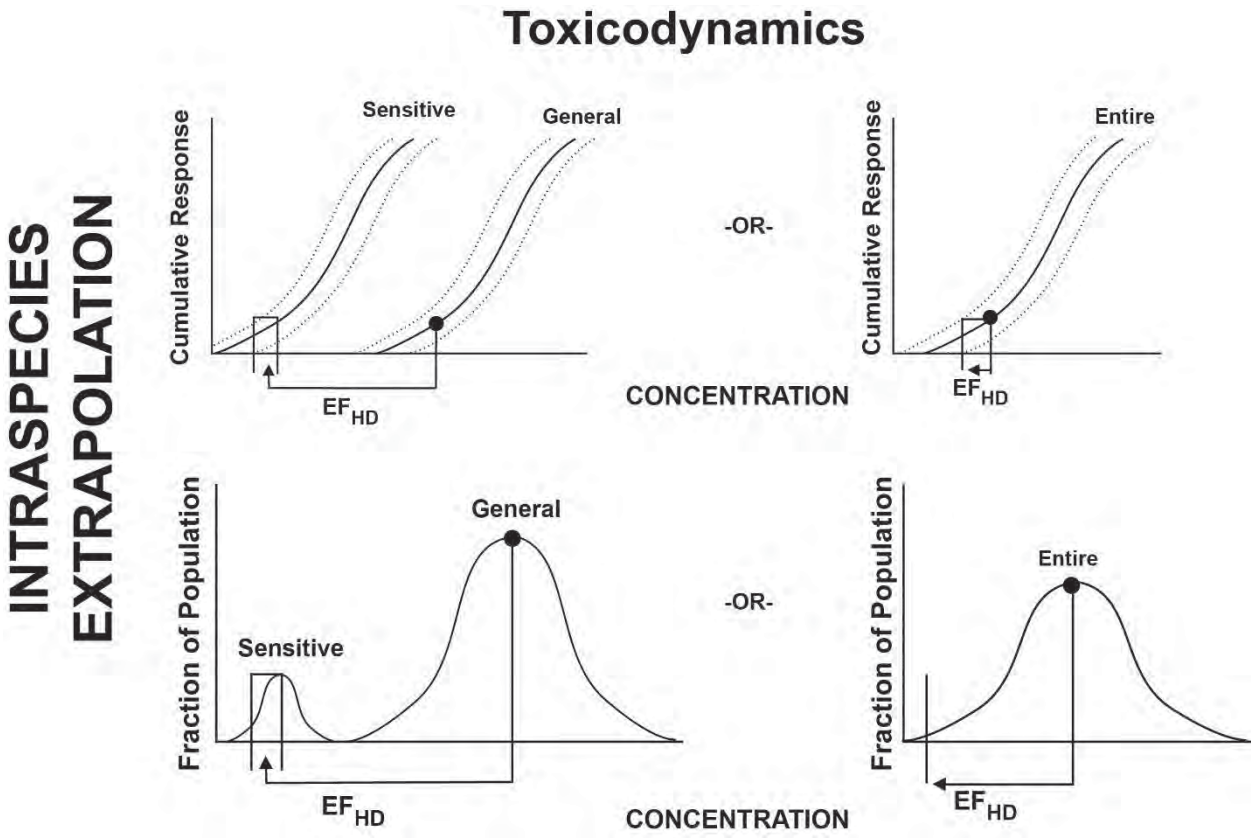

Figure 7. Intraspecies toxicodynamics. Sensitivity may be distributed among the human population in a bi- (or multi-) modal or a unimodal fashion. Even when an identifiable population may be presumed or demonstrated to be sensitive, the distribution of dose metric values may be unimodal. Differences in distribution type affect quantitative methods. TD differences are quantified on the basis of differences in concentration producing the same level of the observed response.

4.3.3. Conclusions for Intraspecies Toxicodynamic Extrapolation Factor

A BBDR or other TD model provides the most biologically appropriate approach for developing an EF_{HD} value. When using empirical ratios, EF_{HD} is the ratio of the concentration producing the specified level of response in sensitive populations to the concentration of the toxicant producing the same level of response at the central tendency of the general or the entire human population. Increased confidence in EF_{HD} is developed when the range of concentrations

INTRASPECIES EXTRAPOLATION OF RESPONSE

For the toxicodynamics component of EF_{HD}, the relationship between the response measured *in vitro* and the response observed *in vivo* should be presented, and EF_{HD} is calculated as the ratio of concentrations producing the same level of the response in the respective population groups—general or entire to sensitive population groups.

used to determine EF_{HD} is comparable to target tissue concentrations at or near the human POD (the animal POD adjusted by the value of the UF_A). Quantitatively, EF_{HD} cannot be less than 1.

The risk assessor describes all choices and rationales, including the use of multiple response levels, critical effects (or key events), analytical methods, or data from sensitive populations and/or life stage. The conclusions include a clearly worded description of the mathematical method(s) employed and a presentation of the relationship between the measured response and toxicity (i.e., critical effects or key events). This description should clearly identify and provide the justification for the selection of data and points in the distribution(s) representing sensitive groups. Attention should be paid to characterizing the distribution type employed for analysis; uncertainty in the choice of distribution type can be reduced by presenting DDEF values resulting from multiple distribution types.

5. CALCULATION OF THE DATA-DERIVED EXTRAPOLATION FACTOR

The composite factor is calculated after the appropriate DDEF values for inter- and intraspecies differences in TK and TD have been derived. The composite factor is calculated by multiplying the specific factor values (default and/or DDEFs), as shown in eq 7. This computation is entirely analogous to calculating composite UFs when using the 10× defaults for UF_A and UF_H. The composite DDEF may be less or greater than 100.

$$CF = EF_{AK} \times EF_{AD} \times EF_{HK} \times EF_{HD} \quad (7)$$

where,

CF = composite factor

EF_{AK} = interspecies TK extrapolation factor

EF_{AD} = interspecies TD extrapolation factor

EF_{HK} = intraspecies TK extrapolation factor

EF_{HD} = intraspecies TD extrapolation factor

In practice, data may only be available to develop a DDEF for one component of extrapolation or another (e.g., data for EF_{AK} but not EF_{AD}). In these situations, the remaining extrapolation is done by an appropriate default procedure. When default values are used, DDEFs and default values (i.e., UFs) are used in combination. Often this default will be one-half order of magnitude UF—as described in the Agency's RfC methodology (U.S. EPA, 1994). When data are not available to develop DDEFs for either component of inter- or intraspecies extrapolation, the default approach (e.g., $BW^{3/4}$ scaling for interspecies extrapolation for oral RfDs, RfC default for interspecies extrapolation for RfCs, or application of UFs) is employed (U.S. EPA, 2011).

Finally, the composite factor provides the total magnitude of the factor. The values derived for each of the components and the resulting extrapolations should be clearly reported and characterized. The relationship of each of these doses or concentrations to the POD should be presented.

DISCLAIMER

This document has been reviewed in accordance with U.S. Environmental Protection Agency policy and approved for publication. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

LIST OF ABBREVIATIONS

AChE	acetylcholinesterase
AML	amount of metabolite in the liver
AUC	area under the curve
BAA	2-butoxyacetic acid
BMD	benchmark dose
BMD_x	benchmark dose corresponding to an *x*% increase in response
BMDL	benchmark dose lower bound (i.e., lower confidence bound on benchmark dose)
$BMDL_x$	lower confidence bound on benchmark dose corresponding to an *x*% increase in response
BMR	benchmark response
CMG	common mechanism group
CRA	cumulative risk assessment
DAF	dosimetric adjustment factor
DDEF	data-derived extrapolation factor
DMA	dimethyl arsenic acid
EF	extrapolation factor (optional subscripts $_A$ = interspecies/animal-to-human; $_H$ = intraspecies/within human variability; $_D$ = toxicodynamic component; $_K$ = toxicokinetic component)
EF_{AD}	interspecies toxicodynamic EF
EF_{AK}	interspecies toxicokinetic EF
EF_{HK}	intraspecies toxicokinetic EF
EGBE	ethylene glycol monobutyl ether
EPA	U.S. Environmental Protection Agency
GFR	glomerular filtration rate
HED	human equivalent dose
IRIS	Integrated Risk Information System
LC_{50}	lethal concentration for 50% of the population
LOAEL	lowest-observed-adverse-effect level
MCV	mean corpuscular volume
MeHg	methylmercury
MOA	mode of action
MOE	margin of exposure
NMC	N-methyl carbamate
NOAEL	no-observed-adverse-effect level
OPP	Office of Pesticide Programs
PBPK	physiologically based pharmacokinetic
POD	point of departure
RBC	red blood cell
RED	registration eligibility decision
RfD	reference dose
RPF	relative potency factor
SD	standard deviation(s)
TD	toxicodynamic
TK	toxicokinetic

LIST OF ABBREVIATIONS (continued)

UF	uncertainty factor (optional subscripts $_A$ = interspecies/animal to human; $_H$ = intraspecies/within human variability; $_D$ = toxicodynamic component; $_K$ = toxicokinetic component)
UF_A	interspecies UF
UF_H	intraspecies UF
UF_{AD}	interspecies UF for the TD component
UF_{HD}	intraspecies UF for the TD component
UF_{AK}	interspecies UF for the TK component
UF_{HK}	intraspecies UF for the TK component
VC	vinyl chloride

APPENDIX A.
CASE STUDIES TO ACCOMPANY
DATA-DERIVED EXTRAPOLATION FACTOR GUIDANCE

This document is an Appendix to the document *Guidance for Applying Quantitative Data to Develop Data-Derived Extrapolation Factors for Interspecies and Intraspecies Extrapolation*. It presents examples where the availability of data for given chemicals support the derivation of nondefault values for components of uncertainty factors (UFs). Each of the chemicals examined has an existing Integrated Risk Information System (IRIS) file and/or U.S. Environmental Protection Agency (EPA) Program Office risk assessment, although the derivation of data-derived extrapolation factors (DDEFs) contained in these examples may not be found in the those documents. The intent of this case study document is to present examples that instruct the calculation of DDEF values; reference values derived in these case studies should not be used in place of values found in IRIS or Program Office risk assessments.

A consistent format, shown below, has been developed and applied to the case studies. However, different components of case studies are more extensively described for some chemicals than for others. Differences are due to chemical-specific data sets, which may be more informative for some areas than others.

1. Summary
   This section communicates the current assessment(s) (e.g., IRIS, Provisional Peer Reviewed Toxicity Values, Registration Eligibility Decision (RED), premanufacture notice/existing chemical, International Programme on Chemical Safety) and reference values. It includes the individual and composite UFs, and indicates how the DDEF was applied.

2. Hazard Identification and Dose-Response
   This section lists the key studies, identifying the principal study and critical effects including supplemental studies that might help to inform the decision. Methods used to characterize the dose-response relationship and models or data describing response as a function of internal (target tissue) concentration are described. Also included is information on the mode/mechanism of action. The section is not intended to be a compendium of data; rather it should communicate the information necessary to serve as a basis for the case study.

3. Basis for Data-Derived Extrapolation Factor
   This section provides the rationale for developing a DDEF rather than relying on default values. Models or data available for evaluation, the basis for selection of DDEF method, and the connection between the measure of dose and adverse effect are described.

4. Data-Derived Extrapolation Factor Derivation
   This section presents the computation of the DDEF value so that the reader can follow the derivation. Comparisons to other possible values for the UF component are presented.

The case studies illustrate different principles described in the main document. Table A-1 provides a summary of the principles illustrated in each. Note that the Agency does not yet have experience with deriving a DDEF for intraspecies extrapolation with regard to the toxicodynamic (TD) component. As such, no case study for that component is provided here.

Table A-1. Data-derived extrapolation factor case study chemicals and issues

DDEF	Chemical	Other principles or issues
Extrapolation Factor (EF) for the Interspecies/Animal-to-Human (A) Toxicokinetic Component (K) (EF_{AK})[a]	Ethylene glycol monobutyl ether	Choice among dose metrics, physiologically based pharmacokinetic modeling, benchmark dose applied to internal, not external, doses
	Vinyl chloride	Mode-of-action analysis to identify dose metric; internal dose of reactive metabolite in liver chosen as basis for toxicokinetic equivalency between species
EF for the Interspecies/Animal-to-Human (A) Toxicodynamic Component (D) (EF_{AD})	Ethylene glycol monobutyl ether	*In vivo* toxicity evaluations to identify effects to quantify in both species *in vitro*
	Dimethyl arsenic acid	Mode of action analysis, use of *in vitro* data, use of genomics data
	N-methyl carbamate pesticides	Application of a DDEF to a common mechanism group of chemicals, use of DDEF approach to identify data gaps
EF for the Intraspecies/Within Human Variability (H) Toxicokinetic Component (K) (EF_{HK})	Boron	Clearance mechanism identified, surrogate measures of clearance employed for quantitation
	Methylmercury	Toxicokinetic model developed using human data from dietary exposures, choice of dose metric from among several surrogates

[a]The IRIS Assessments for these chemicals calculate a human equivalent dose—based on the results from physiologically based pharmacokinetic modeling. This document guides the development of a DDEF that results in the same human external dose when adjusted for interspecies differences in dosimetry. The DDEF concept applied to interspecies differences in dosimetry makes explicit the magnitude of species differences, whereas methods that calculate a human equivalent dose or human equivalent concentration do not make that calculation explicit.

A.1. INTERSPECIES EXTRAPOLATION FACTOR FOR TOXICOKINETICS

A.1.1. Ethylene Glycol Monobutyl Ether—Interspecies Extrapolation Factor for Toxicokinetics Case Study

A.1.1.1. *Summary*

Ethylene glycol monobutyl ether (EGBE; also known as 2-butoxy ethanol) has an established reference dose (RfD) of 0.1 mg/kg-day in EPA's IRIS database (U.S. EPA, 2010b). This value is based on a human equivalent dose (HED) developed from the results of a chronic inhalation study (NTP, 2000). Internal doses resulting in hemosiderin deposition in liver were extrapolated via physiologically based pharmacokinetic (PBPK) modeling to identify the HED.

As described below, the IRIS RfD is based on a PBPK modeling approach that identified an HED of 1.4 mg/kg-day. To this value, a combined UF of 10 was applied, which comprised a UF value of 10 for variation in sensitivity within the human population/intraspecies UF (UF_H), a value of 1 for the interspecies UF for the toxicokinetic (TK) component (UF_{AK}) (based on application of a PBPK model), and a value of 1 for interspecies toxicodynamic uncertainty factor (UF_{AD}) on the basis of quantified differences in red blood cell (RBC) sensitivity defined *in vitro* [as discussed in the EGBE interspecies/animal-to-human extrapolation factor (EF) for the toxicodynamic (TD) component (EF_{AD}) case study presented later in this appendix].

A.1.1.2. *Hazard Identification and Dose-Response*

No chronic-duration oral studies are currently available for EGBE; there are only two subchronic-duration, 91-day drinking water studies in rats and mice (Dieter, 1993) and a chronic inhalation study in rats and mice (NTP, 2000). Based on a comparison of no-observed-adverse-effect levels (NOAELs) and lowest-observed-adverse-effect level (LOAELs) for hematologic and liver effects, rats are clearly more sensitive than mice. Hematologic and hepatocellular changes were noted in both sexes of rats. Hemosiderin accumulation in liver of male rats, a consequence of hemolysis, was chosen as the critical effect. Hemolysis in humans has been demonstrated to result in hemosiderin accumulation in the liver, and acute exposure to EGBE has been shown to produce hematological changes in humans (U.S. EPA, 2010b).

In the 2010 IRIS assessment, PBPK modeling was used to convert each of the inhalation exposures to levels of internal dose, and this measure of dose was combined with response levels. A benchmark dose (BMD) analysis revealed the lower confidence bound on benchmark dose (BMDL) corresponding to a 10% increase in response ($BMDL_{10}$) value, which was chosen as the point of departure (POD). The $BMDL_{10}$ value (expressed as internal dose) was 133 μmol butoxy acetic acid/liter-hour; this was used as the starting point in the development of the IRIS RfD for hemosiderin deposition in male rat liver (NTP, 2000). In the IRIS assessment, the

dose-response relationship was developed by combining PBPK modeling with BMD analysis as shown in Figure A-1.

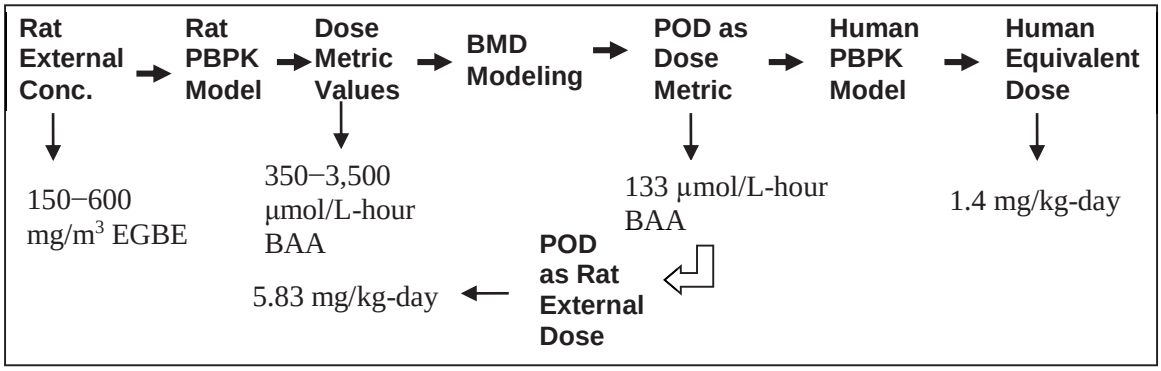

Figure A-1. Analysis approach for developing the human equivalent dose (HED) with values shown.

A.1.1.3. *Basis for Data-Derived Extrapolation Factor*

Area under the curve (AUC) values for the EGBE metabolite 2-butoxyacetic acid (BAA) in arterial blood of male rats following oral exposure were estimated using the PBPK model of Corley et al. (1994) as modified by Corley et al. (1997). BAA levels, rather than EGBE levels, were deemed appropriate measures of exposure based on the findings of Carpenter et al. (1956), who demonstrated *in vitro* that concentrations of 0.1% BAA induced hemolysis; whereas, hemolysis was not induced by EGBE until concentrations of approximately 2.5% were reached. PBPK modeling was used to translate each of the external concentrations to levels of the dose metric, AUC.

Next, BMD modeling was applied to the results of the PBPK modeling. The results of this analysis indicated that an AUC value of 133 µmol/L-hour BAA in arterial blood is the $BMDL_{10}$ for increased hemosiderin deposition in the liver in male rats.

The AUC value for BAA of 133 µmol/L-hour in arterial blood was chosen as the POD for interspecies extrapolation. Next, a human PBPK model was employed to translate this level of the dose metric to an HED of 1.4 mg/kg-day.

A.1.1.4. *Data-Derived Extrapolation Factor Derivation*

The PBPK modeling approach described above was used as the basis for the development of the DDEF. In addition to the data presented in the IRIS file, the rat PBPK model was run to identify that an external dose of 5.83 mg/kg-day in rats would produce this $BMDL_{10}$

concentration (133 μmol/L-hour) of the BAA metabolite (Dr. Richard Corley, personal communication, 2010). The human PBPK model was run to identify the external dose that produced the same level of the dose metric (133 μmol/L-hour); this value of the dose metric was produced by an external dose of 1.4 mg/kg-day in humans. The AUC dose metric was used as the basis for human equivalence.

An alternative approach for deriving the DDEF illustrated in this case study would be to use the ratio of rat-to-human external doses derived from the PBPK model to derive an interspecies toxicokinetic extrapolation factor (EF_{AK}; see eq 1, Section 3.2.2.2.). Using the data described above, a comparison of the external doses would yield an EF_{AK} value of 5.83 mg/kg-day ÷ 1.4 mg/kg-day = 4.2. The 4.2-fold DDEF would replace the default UF_{AK} threefold factor.

Applying the EF_{AK} 4.2-fold[10] to the rat external dose (5.83 mg/kg-day) yields an HED of 1.4 mg/kg-day. This HED is identical to that derived in the IRIS assessment (U.S. EPA, 2010b).

The above methods can also be compared to the default methodology that is based on body-weight scaling (U.S. EPA, 2011). Using a study-specific female rat body weight of 0.188 kg and a default human body weight of 70 kg, these values would result in a default dosimetric adjustment factor (DAF) = $(0.188 \div 70)^{1/4}$ = 0.23. The DAF is multiplied by the animal external dose (5.83 mg/kg-day) to yield an HED of 1.3 mg/kg-day. The reciprocal of the 0.23 DAF is 4.3. When using body weight to ¾ power scaling, the accompanying reduced default interspecies UF is threefold. In this case study, the body-weight scaling default approach yields a similar RfD as the data-derived approaches described above. However, the DDEF approach makes use of quantitative TK data for EGBE and uses the TK/TD framework, which preserves the option also to rely on quantitative TD information.

A.1.2. Vinyl Chloride—Interspecies Extrapolation Factor for Toxicokinetics Case Study

A.1.2.1. *Summary*

Vinyl chloride (VC) has an established oral RfD of 3×10^{-3} (0.003) mg/kg-day in the current IRIS file (U.S. EPA, 2000a). The POD for liver toxicity is a NOAEL value of 0.13 mg/kg-day from a chronic feeding study in male Wistar rats. PBPK modeling was used to develop an HED of 0.09 mg/kg-day, making the UF_{AK} unnecessary. The composite UF of 30 comprises a UF of 3 to cover TD differences between species and a default value of 10 for intraspecies variability. Species differences in dosimetry were determined on the basis of external doses required to produce the same level of the toxicologically active metabolite in the critical organ (liver). This case study demonstrates the application of data to inform EF_{AK}.

A.1.2.2. *Hazard Identification and Dose-Response*

The liver was selected as the critical target organ of VC in humans and experimental animals. Strong epidemiological evidence exists for liver effects in humans. Studies involving workers in the polyvinyl chloride plastics industry from several countries have demonstrated a significant relationship between VC inhalation exposure and liver cancer. While limited evidence may suggest a risk for other, nonliver tumors (e.g., leukemia, brain, lung, pancreas, mammary), “vinylchloride is not likely to be associated strongly with cancers other than liver in humans” (U.S. EPA, 2000a). Other noncancer effects noted in epidemiologic investigations include impaired liver function and biochemical and histological evidence of liver damage and focal hepatocellular hyperplasia. Pulmonary function appeared unimpaired, and no solid evidence of teratogenicity in humans has been identified.

Limited data are available for inhalation studies in animals. Data are available from a 12-month inhalation study, which supports the liver as the critical organ. Bi et al. (1985) exposed Wistar rats to 0, 10, 100, or 3000 ppm VC for 6 hours/day, 6 days/week. Cellular alterations, degeneration, and necrosis were observed in the seminiferous tubules of the testes, with a NOAEL in the 10-ppm exposure group. This same exposure was the LOAEL for liver effects, characterized only as liver weight changes.

Like the inhalation results, studies conducted via the oral route identify the liver as the critical target organ. Til et al. (1991; 1983) reported the results of two-year rodent bioassays with VC in feed. Groups of 100 or 50 male and female Wistar rats were exposed to 0, 0.014, 0.13, or 1.3 mg/kg-day in feed for only 4 hours/day to minimize volatilization. The VC content of feed was measured before and after feeding to control for volatilization. Multiple hepatic effects were noted, including several that were deemed neoplastic or preneoplastic. The pathologists were able to delineate and determine incidences for two effects not thought to represent neoplastic or preneoplastic changes. Liver cell polymorphisms and proliferative bile duct epithelium cysts served as the basis for identifying the liver as the critical target tissue for noncancer effects in the chronic bioassay. These same changes were observed in a second study, but the doses employed in that study (Feron et al., 1981) were higher than those employed by Til and coworkers. Because of a lack of confidence in the outcome from a BMD modeling approach based on external dose, a traditional (i.e., NOAEL) approach to dose-response evaluation for events not associated with carcinogenicity was used. The POD for species extrapolation was the NOAEL of 0.13 mg/kg-day for liver cell polymorphisms and bile duct cysts.

The initial process in the mode of action (MOA) appears to be the formation of reactive and short-lived metabolites that achieve only low steady-state concentrations. These metabolites are thought to be responsible for the toxic effects of VC (Bolt, 1978). Experiments that manipulated the longevity of cytochrome P450-derived metabolites demonstrated an inverse relationship between metabolite longevity and protein and nucleotide binding (Guengerich et al., 1981). Thus, the metabolism of VC to reactive intermediates was demonstrated to be a critical determinant of toxicity. Because of the short-lived nature of the metabolite(s), a measure of their concentration in the target tissue (liver, the site of their formation) was deemed the appropriate dose metric for quantitative application. This concept and approach has also been applied to methylene chloride (Andersen et al., 1987) and chloroform (ILSI, 1997).

A.1.2.3. *Basis for Data-Derived Extrapolation Factor*

The liver was determined to be the target organ, and evidence indicated that the formation of a reactive metabolite was likely responsible for the toxicity of VC. BMD modeling of external doses failed. Because of this, the POD for extrapolation was determined as the study

NOAEL for liver effects, 0.13 mg/kg-day. Consistent with the guidance for reference concentration derivation, PBPK modeling of the formation of the active metabolite in liver was used as the basis for determining an HED. PBPK models were developed for rats and humans and used to extrapolate dosimetry between species (Clewell et al., 1995b; Clewell et al., 1995a); the models were subjected to an external peer review and deemed sufficient for quantitative reliance. The NOAEL dose (0.13 mg/kg-day) was converted into the dose metric for VC—the amount of metabolite in the liver (AML), with units of concentration (mg/L) of liver.

A.1.2.4. *Data-Derived Extrapolation Factor Derivation*

Importantly for dose extrapolation, these models demonstrated a linear relationship between applied dose and the dose metric (i.e., AML) up to doses approximating 25 mg/kg-day. This allowed linear interpolation to be used to identify levels of external doses associated with specific amounts of the internal dose, rather than specific iterations via PBPK modeling. The rat NOAEL dose of 0.13 mg/kg-day produced AML at a value of 3.0 mg/L (see Figure A-2). This level of internal exposure in the 70-kg human was determined to result from a drinking water exposure of 0.09 mg/kg-day (the HED). Thus, doses of 0.13 mg/kg-day and 0.09 mg/kg-day in the rat and human, respectively, are toxicokinetically equivalent.

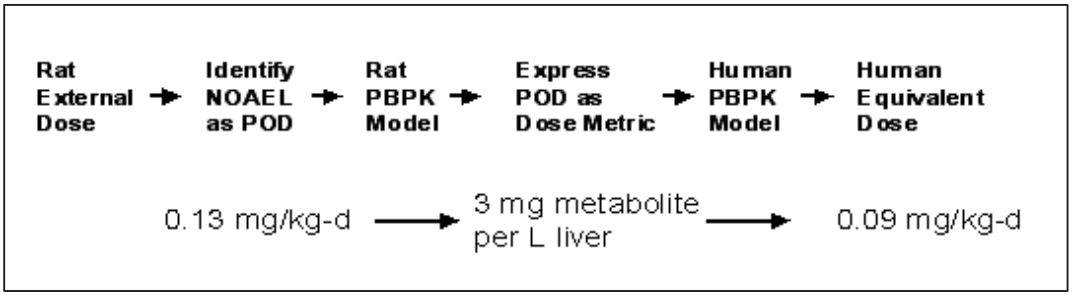

Figure A-2. Schematic for dose extrapolation for vinyl chloride. The POD was defined as the external dose in the rat, with PBPK modeling of the rat. PBPK modeling of the dose metric translated dose from units of applied dose to units of tissue concentration, representing the dose metric. PBPK modeling in the human identified the HED, the dose producing the same level of the dose metric in the rat study at the POD.

The IRIS file for VC used the HED as the POD to which UFs are to be applied. An alternative approach illustrated in this case study to deriving the DDEF for interspecies TK differences would be to use the ratio of rat and human external doses resulting in the same level of target tissue exposure at the POD.

Using the data described above, a DDEF value for EF_{AK} of 0.13 ÷ 0.09 = 1.44 is indicated. Combined with the default value of 3 for TD, a DDEF for EF_{AK} would be 3 × 1.44 = 4.32, in place of the default value of 10. By applying the DDEF calculated above (4.32-fold) and the default value of 10 for UF_H to the animal NOAEL (0.13 mg/kg-day), the RfD is 0.13 mg/kg-day ÷ 43.2 = 0.003 mg/kg-day. This is the same value that was calculated for the IRIS assessment, which was expressed as the HED/UF, or 0.09 mg/kg-day/30 (U.S. EPA, 2000a).

The above methods can also be compared to the default methodology that is based on body-weight scaling (U.S. EPA, 2011). Using a default value of 0.462 kg for adult Wistar rats (U.S. EPA, 1988) and applying the body-weight scaling approach described in *Recommended Use of Body Weight $^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose* (U.S. EPA, 2011) to the NOAEL of 0.13 mg/kg-day, an HED can be calculated as:

$$0.13 \text{ mg/kg-day} \times 0.462 \text{ kg} = 0.060 \text{ mg}$$

$$0.06 \text{ mg} \times (70 \text{ kg} \div 0.462 \text{ kg})^{3/4} =$$

$$0.06 \text{ mg} \times 43.19 = 2.59 \text{ mg}$$

$$2.59 \text{ mg} \div 70 \text{ kg} = 0.037 \text{ mg/kg-day} \qquad \text{(A-1)}$$

In this case study, the body-weight scaling default approach yields a slightly lower POD value than the data-derived approaches described above. Furthermore, this approach makes use of quantitative data on VC.

A.2. INTERSPECIES EXTRAPOLATION FACTOR FOR TOXICODYNAMICS

A.2.1. Ethylene Glycol Monobutyl Ether—Interspecies Extrapolation Factor for Toxicodynamics Case Study

A.2.1.1. *Summary*

As noted in Section A.1.1.1, EGBE has an established RfD of 0.1 mg/kg-day in EPA's IRIS database (U.S. EPA, 2010b). This value is based on the results of a subchronic-duration drinking water study in mice and rats where increases in Kupffer cell hemosiderin content secondary to hemolysis were determined to be the critical effect. Derivation of the HED of 1.4 mg/kg-day is detailed in the EGBE TK case study in Section A.1.1 and in the IRIS file for EGBE (U.S. EPA, 2010b).

The IRIS RfD is based on a PBPK modeling approach that identified an HED of 1.4 mg/kg-day. UFs were applied to this POD value to derive the RfD. A total UF of 10 was applied to this HED to derive the RfD. A default value of 10 was used to account for variation in sensitivity within the UF_H. The interspecies UF (UF_A) was reduced to 1 on the basis of dosimetry adjustments to account for TK (discussed case study A.1.1, for EGBE TK). EF_{AD} was also reduced to a value of 1, because studies indicate that humans may be significantly less sensitive than rats to the hematological effects of EGBE. *In this case study, however, issues associated with EGBE TD are described and an alternative approach to DDEF derivation based on the use of in vitro data are described.*

A.2.1.2. *Hazard Identification and Dose-Response*

Based on extensive review of the literature, hematologic effects appear to be the most sensitive of the adverse effects observed in laboratory animals exposed to EGBE. Hematologic effects (e.g., hemoglobinuria) have also been documented in worker populations exposed to technical grade EGBE (Cellosolve™) and following ingestion of cleaning products containing EGBE (U.S. EPA, 2010b).

Key events in the proposed MOA in RBCs leading to increases in hemoglobin accumulation in Kupffer cells include:

≠ Oxidative metabolism to BAA

≠ RBC swelling and lysis (probably preceded by an increase in osmotic fragility and loss of deformability)

≠ Decreased RBC count, hemoglobin, and hematocrit, and in response, increased production of immature RBCs (reticulocytes) by the bone marrow

Carpenter et al. (1956) incubated RBCs from rats, mice, rabbits, monkeys, dogs, humans, and guinea pigs with 0.1% BAA. Results demonstrating maximum time without hemolysis were 35−40, 40−45, 60−90, 103−120, 80−120, 147−268, and 360 minutes, respectively. These data indicate that guinea pigs and humans are more resistant and that rats and mice may be more sensitive to the hemolytic effects of BAA. Studies with Cellosolve and BAA demonstrated that RBCs were much more sensitive to BAA than to Cellosolve. These results led Carpenter et al. (1956) to speculate that the BAA metabolite of Cellosolve was responsible for hemolysis.

In a direct comparison of the effects of BAA on rat and human RBCs, Udden and Patton (1994) devised a study using filtration, phase contrast light microscopy, and routine hematologic methods. RBCs were obtained from healthy adults via venipuncture and from 9- to 11-week-old male Fischer 344 rats via cardiac puncture. Rat RBCs were incubated with 0.2 and 2.0 mM BAA; human RBCs were incubated with only 2.0 mM BAA. Rat RBC demonstrated 30% hemolysis after incubation with 2.0 mM BAA for 4 hours, and 4% hemolysis after incubation with 0.2 mM BAA for 6 hours or longer. The 4% measure was "mild," and the data were not shown. Incubation of human RBC with 2.0 mM BAA for 4 hours resulted in no increase in hemolysis over the background (control) level of 1%. Histologic evaluations of rat, but not human, RBC preparations postexposure demonstrated RBC "ghosts," which are cell membranes from lysed cells. These incubation conditions resulted in increases in mean corpuscular volume (MCV) in rat RBCs incubated with 0.2 mM BAA, but not human RBCs incubated with 2.0 mM BAA. The increase in MCV indicates RBC swelling, an event that leads to fragility.

Finally, these investigators examined the deformability of RBCs by pumping them through a narrow-diameter filter and monitoring an increase in inflow pressure. The results were presented graphically, as pressure versus time plots. The logic behind this study was that RBCs normally can deform to pass through tight spaces (like capillaries). However, RBCs in which swelling has been induced and in which other mechanisms may have been activated that can lead to increased membrane rigidity, will not pass through the membrane, resulting in an increase in inflow pressure. Rat RBCs demonstrated a nearly doubled pressure in rat RBCs incubated with 0.2 mM BAA for 4 hours, and a roughly tripled pressure when incubated with 2.0 mM BAA for 4 hours compared to controls. In contrast, pressure differences between human RBCs incubated in the absence of BAA and in the presence of 2.0 mM BAA for 4 hours were not distinguishable. Udden and Patton (1994) indicated that their findings that human RBCs were less sensitive *in vitro* to the hemolytic effects of BAA were consistent with multiple other findings. In a follow-up study, Udden (2002) demonstrated again that human RBCs were less susceptible to the

effects of BAA than RBCs from rats. Whereas rat RBCs demonstrated alterations including deformability and changes in MCV at 0.05 mM, human RBCs did not demonstrate changes in MCV at concentrations below 10 mM—a difference of 200-fold.

Ghanayem and Sullivan (1993) also performed a species comparison of BAA-induced RBC effects *in vitro*. An advantage of this study is that it applied a pairwise statistical design to determine the effect of treatment over control. Male Fischer 344 rats 15 weeks of age were used, and human blood was drawn from adult male donors. BAA (2.0 mM incubated up to 4 hours) produced only slight, but not statistically significant, alterations of hematological parameters: hematocrit was increased 2−4% and MCV was increased less than 4% above vehicle controls. The authors concluded that their results demonstrated that humans were "minimally sensitive" to the *in vitro* effects of BAA. In comparison, RBCs from rats were deemed "relatively susceptible" to the effects of BAA. A graphic presentation of data demonstrated that in rats, MCV and hematocrit were increased nearly 60% when exposed to 2.0 mM BAA.

Udden (2002) compared the subhemolytic and hemolytic effects of BAA in rat and human RBCs. RBC deformability, density, MCV, count, osmotic fragility, and hemolysis were measured following a 4-hour exposure. Alterations were noted in loss of deformability, but at concentrations that were 150-fold higher in rat RBCs than in human RBCs (0.05 mM vs. 7.5 mM). A larger species difference in response was noted in comparing effect levels for increases in MCV—these differences approximated 200-fold, with rat RBCs responding at 0.05 mM and human RBCs demonstrating alterations of MCV at 10 mM. Changes in osmotic fragility were similar.

A.2.1.3. *Basis for Data-Derived Extrapolation Factor*

Several data sets are available in which the responsiveness of rat and human blood at 2.0 mM can be compared. *However, comparison of effect data for TD is most appropriately accomplished by comparing the different concentrations resulting in the same response.*

Hemolytic effects were observed in rat RBCs exposed to BAA at concentrations as low as 0.05 mM. In contrast, similar hemolytic effects were observed in human blood exposed to 10 mM BAA. The IRIS file indicates that humans may be much less sensitive than rats to the hematologic effects of EGBE, and for this reason a value of 1 was selected for the UF_{AD}.

A.2.1.4. *Data-Derived Extrapolation Factor Derivation*

One potential approach would be to derive an adjustment factor of 0.005 for UF_{AD} (0.05 mM/10 mM = 0.005). This approach requires the assumption that the TD differences observed *in vitro* would be approximated *in vivo*. Uncertainty about this issue prompted EPA to

take a different approach. In the IRIS assessment (U.S. EPA, 2010b), the UF value for UF_{AD} was established at 1.

Regarding TD, *in vivo* (Carpenter et al., 1956) and *in vitro* (Udden, 2002; Udden and Patton, 1994; Udden, 1994; Ghanayem and Sullivan, 1993) studies indicate that humans may be significantly less sensitive than rats to the hematological effects of EGBE. For this reason, a value of 1 was selected for the TD portion of the UF_A.

A.2.2. Dimethyl Arsenic Acid—Interspecies Extrapolation Factor for Toxicodynamics Case Study

A.2.2.1. *Summary*

Dimethyl arsenic acid (DMA), also known as cacodylic acid, is an herbicide used on primarily cotton and turf. DMA is also a urinary metabolite in most mammals, including humans, following direct exposure to inorganic arsenic. The Office of Pesticide Programs (OPP), in collaboration with National Health and Environmental Effects Research Laboratory scientists, developed a nonlinear MOA assessment for DMA for the development of rat bladder tumors (U.S. EPA, 2006b). The MOA and dose-response assessments were developed using the MOA (Sonich-Mullin et al., 2001) and Human Relevance (Boobis et al., 2006) Frameworks. The information provided by the MOA analysis also provides the basis for the chronic RfD and

the respective UFs in the RED for cacodylic acid. Instead of the default 10-fold factor to extrapolation from animal to human, OPP has reduced the TD component of UF_A (EF_{AD}) to a value of 1. This case study describes the determination of the one-half order of magnitude (threefold) factor, which was used to account for TD differences between animals and humans. The default value of 10 for UF_H was also applied leading to a composite factor of 30.

A.2.2.2. *Hazard Identification and Dose-Response*

In rat carcinogenicity studies, oral exposure to DMA^V leads to bladder tumors. The overall weight of the evidence provides convincing support for a nonlinear MOA for DMA^V-induced carcinogenesis in rodents. The key events include:

- ≠ Reductive metabolism of DMA^V to DMA^{III}.
- ≠ DMA^{III} causes urothelial cytotoxicity. Regenerative cell proliferation then ensues in order to replace dead urothelial cells. The amount of cell killing is a function of the severity of the cytotoxicity, which is related to the amount of DMA^{III} present. The amount of DMA^{III} is dependent on the conversion of DMA^V to DMA^{III}.
- ≠ Sustained cytotoxicity leads to regenerative cell proliferation, which in turn, ultimately leads to hyperplasia and bladder tumors.

To obtain a tumor via the proliferation/replication genetic error process, induced cell proliferation needs to be persistent. There is convincing experimental evidence to indicate that this is the case for the rat bladder. There is a clear association of DMA^V treatment and cell killing/regenerative proliferation and bladder tumors. The amount of proliferation would be a function of the amount of cell killing since the tissue will undergo regenerative proliferation in response to cell killing. As the severity of cytotoxicity increases with increasing levels of DMA^V (DMA^{III}), regenerative proliferation is the rate limiting step for tumor formation, even though the product is chromosome mutations. Thus, a tumor dose-response curve would be influenced by the induced cell proliferation curve, even though chromosomal mutations may be an output. DMA^V-induced tumors would be produced only at treatment durations and dose levels that result in significant cell killing and regenerative cell proliferation in the urothelium of the bladder. Experimental data are available to support the coincidence of key events at similar concentration levels. The levels of DMA^{III} in the urine of rats treated with 100-ppm DMA^V range from 0.5−5.0 μM. The lethal concentration for 50% of the population (LC_{50}) values for DMA^{III} in rat and human urinary epithelial cells *in vitro* are 0.5−0.8 μM. A significant increase in chromosome aberrations occurs in human lymphocytes *in vitro* at about 1.35 μM DMA^{III}. At

100 ppm, there is significant cell killing and regenerative proliferation in female rat bladders. It appears that chromosomal mutations, cytotoxicity, and cell proliferation can potentially occur concurrently at 100-ppm DMA^V, which is the tumorigenic dose in female rats via diet.

Among the several key events, all of which are necessary for tumor formation, cell proliferation has been used for deriving a POD because it is needed for increasing the likelihood of chromosome mutation formation and for the perpetuation of genetic errors, as well as for hyperplasia. A $BMDL_{10}$ value (0.43 mg/kg bw/day) is the basis for the POD in deriving an RfD or a margin of exposure (MOE). This approach is considered public health protective because a $BMDL_{10}$ of 0.43 mg/kg bw/day is approximately an order of magnitude lower than the dose (~0.7 mg/kg bw/day or 10 ppm) that resulted in a 1.5-fold statistically nonsignificant increase in cell proliferation after 10 weeks of exposure to DMA^V and about two orders of magnitude lower than the dose (~9.4 mg/kg bw/day) resulting in neoplasia in the feeding studies.

A.2.2.3. *Basis for Data-Derived Extrapolation Factor*

In the 2006 DMA risk assessment (U.S. EPA, 2006b), instead of the default 10-fold factor to extrapolate from animal to human, the OPP reduced the TD component to 1. A factor of 3 was used to account for interspecies differences in TK. UF_{AD} was reduced to 1 given that, at a similar dose at the target site (i.e., bladder urothelial), humans and rats are expected to respond pharmacodynamically similar. This case is built on a combination of information:

≠ Chemical-specific *in vitro* data from Cohen et al. (2002) which show that human and rat cells respond similarly to exposure to DMA^{III}—the LC_{50} values for cytotoxicity in human and rat epithelial cells were very similar (0.8 μM and 0.5 μM, respectively).

≠ There is microarray support (Sen et al., 2005). Qualitatively the genes that are upregulated in human urinary bladder epithelial cells (UROtsa) are similar to those upregulated in rat urinary bladder epithelial cells (MYP3) exposed to DMA^V *in vitro*. In this study, the rat cell line was quantitatively more sensitive compared to the human cell line.

≠ General information on the development and function of the bladder along with incidence of bladder tumors in human populations qualitatively supports the animal MOA in humans.

There are known pharmacokinetic differences between rats and humans. These pharmacokinetic differences include sequestration of DMA^{III} by rat hemoglobin, which results in a longer retention time in the rat compared to humans or mice, and the increased urinary output of trimethylarsine oxide in rats compared to humans. Because of uncertainties regarding

quantifying the tissue dose in humans using rat data, and in the absence of a fully developed PBPK model at the time of the risk assessment, an EF_A of 3 was applied. Pharmacokinetic analyses indicate that, for similar chronic low-level exposures, rats would take longer to achieve steady-state concentrations of DMA^V and metabolites in target tissue compared to humans, and that for a given exposure target tissue, concentrations would be elevated for a longer time after exposure ceased in the rat because rat hemoglobin acts as a slow-release storage depot. Note that the half-life in the rat for DMA^V appears to correlate with erythrocyte half-life, indicating that the binding to hemoglobin is not readily reversible. There are, however, uncertainties regarding the quantitative differences between rats and humans that prevent further reduction of the UF_A.

A.2.2.4. *Data-Derived Extrapolation Factor Derivation*

A value of 1 was developed for EF_{AD} based on the rationale above in combination with the animal MOA and implementation of the Human Relevance Framework. Together, the weight of the evidence provides a strong case for TD equivalence between rats and humans. A factor of 3 was used to account for interspecies differences in TK. The default value of 10 for UF_H was also applied, leading to a composite factor of 30.

A.2.3. N-methyl Carbamate Pesticides—Interspecies Extrapolation Factor for Toxicodynamics Case Study

A.2.3.1. *Summary*

OPP released its revised cumulative risk assessment (CRA) for the N-methyl carbamates (NMCs) in 2007 (U.S. EPA, 2007). As required under the Food Quality Protection Act (FQPA) (FQPA, 1996), a CRA incorporates exposures from multiple pathways (i.e., food, drinking water, and residential/nonoccupational exposure to pesticides in air, or on soil, grass, and indoor surfaces) for those chemicals with a common mechanism of toxicity (FQPA, 1996). This CRA began with the identification of a group of chemicals, called a common mechanism group (CMG), which induces a common toxic effect by a common mechanism of toxicity. The NMCs were considered to be a CMG due to their common inhibitory actions on acetylcholinesterase (AChE), an enzyme that is normally required for ending cholinergic transmission in the nervous system.

This case study describes a sensitivity analysis conducted in the risk characterization phase of the revised CRA using a DDEF approach. TD equivalence for animal-to-human extrapolation ($EF_{AD} = 1$) was assumed for several chemicals for which human data were not available.

A.2.3.2. *Hazard Identification and Dose-Response*

The NMCs were established as a CMG by EPA in 2001 (U.S. EPA, 2001a) based on their similar structural characteristics and shared ability to inhibit AChE by carbamylation of the serine hydroxyl group located in the active site of the enzyme. When AChE is inhibited, acetylcholine accumulates and results in cholinergic toxicity, due to continuous stimulation of cholinergic receptors throughout the central and peripheral nervous systems that innervate virtually every organ in the body. An important aspect of NMC toxicity is the rapid nature of the onset and recovery of effects; following maximal inhibition of cholinesterase (typically between 15 and 45 minutes), recovery occurs rapidly (minutes to hours).

Inhibition of AChE is considered the first and critical step in the toxicity of NMCs. Human health monitoring has capitalized on the availability of blood cholinesterase measurements, and these have been widely accepted as a marker of exposure. However, since the brain may be considered more as the critical target site, data on inhibition of brain AChE are obviously only available using laboratory animals. Brain AChE data have been widely used as a POD for risk assessment.

EPA used the relative potency factor (RPF) method to determine the combined risk associated with exposure to NMCs. Briefly, the RPF approach uses an index chemical as the

point of reference for comparing the toxicity of the NMC pesticides. RPFs are calculated as the ratio of the toxic potency of a given chemical to that of the index chemical and are used to convert exposures of all chemicals in the group into exposure equivalents of the index chemical. Because of high-quality dose-response data for all routes of exposure, as well as high-quality time-to-recovery data, EPA selected oxamyl as the index chemical for standardizing the toxic potencies and calculating RPFs for each NMC pesticide.

A.2.3.3. ***Basis for a Data-Derived Extrapolation Factor***

In the single chemical assessments for most NMCs, a default value of 10 for animal-to-human/intraspecies extrapolation factor (EF_H) was used. For three NMCs (aldicarb, methomyl, and oxamyl), however, studies in human subjects were determined by EPA to be ethically and scientifically acceptable for use in risk assessment, after considering the advice of the Human Studies Review Board. These studies were used to derive the chemical-specific EF_A for these three chemicals. Table A-2 summarizes the dose-response and time-course modeling data for critical rat and human studies for these three NMCs.

Table A-2. N-methyl carbamate cumulative risk assessment: interspecies/animal-to-human extrapolation factors and corresponding rat and human BMD_{10}s and $BMDL_{10}$s

	Rat						Human			
	Brain			RBC			RBC			
Chemical	BMD_{10} (mg/kg)	$BMDL_{10}$ (mg/kg)	Half-life (hr)	BMD_{10} (mg/kg)	$BMDL_{10}$ (mg/kg)	Half-life (hr)	BMD_{10} (mg/kg)	$BMDL_{10}$ (mg/kg)	Half-life (hr)	UF_A
Aldicarb	F = 0.048 M = 0.056	F = 0.035 M = 0.035	1.5	0.031	0.020	1.1	0.016	0.013	1.7	2
Methomyl	0.486	0.331	1.0	0.204	0.112	0.8	0.040	0.028	1.6	5
Oxamyl	F = 0.145 M = 0.185	F = 0.111 M = 0.143	0.9	0.278	0.158	0.8	0.083	0.068	2.4	3

With regard to the EF_{AK}, NMCs have similar metabolic profiles across species. NMCs do not require activation; the parent compound is an active AChE inhibitor. Although some metabolites of NMCs have been shown to be active as well, none have been shown to be more potent than the parent chemical. Thus, metabolism is considered to be a detoxification process. As such, species differences in tissue dosimetry are likely correlated with differences in body weight to the ¾ power (U.S. EPA, 2011).

The mechanism of toxic action of NMCs is reproducible across a range of species, including rodents and humans. In addition, the AChE enzyme in humans and rats has similar function and structure. See reviews by Radić and Taylor (2006) and Sultatos (2006). The half-life to recovery values[11] for rats and humans provided in Table A-2 range from approximately 1 to 2 hours and demonstrate the similarity of the half-lives of the two species. Based on this information, given a similar dose or concentration at the target site, it is likely that human and rat AChE would respond similarly. This understanding can inform the interspecies DDEF (EF_{AD}).

A.2.3.4. *Data-Derived Extrapolation Factor Derivation*

For the CRA, toxic potencies for the NMCs were determined using brain AChE inhibition measured at peak inhibition following gavage exposures in rats. The Agency used an exponential dose-time-response model to develop BMD estimates at a level estimated to result in 10% brain cholinesterase inhibition (i.e., a BMD or BMD_{10}) to estimate RPF. Ratios comparing doses (administered) that produce the same magnitude of effect may then be derived. Using the data in Table A-2, and dividing the $BMD_{10\text{-rat}}$ by the $BMD_{10\text{-human}}$ for RBC cholinesterase inhibition:

$$\text{Aldicarb: } 0.031 \div 0.016 = 1.9 \approx 2 \quad \text{(A-2)}$$

$$\text{Methomyl: } 0.204 \div 0.040 = 5.1 \approx 5 \quad \text{(A-3)}$$

$$\text{Oxamyl: } 0.278 \div 0.083 = 3.3 \approx 3 \quad \text{(A-4)}$$

This analysis showed that the ratio of the BMDs for rat/human ranges from 2 to 5 for these NMCs. This range would tend to support the DDEF approach described here to reduce the standard interspecies factor value from 10 to 3. The concentration of toxicant at the active site *in vivo* is controlled by TK processes. The available data described the TD processes (enzyme regeneration) and indicated that rats and humans were very similar in this area. The remaining threefold (default) value for UF_A addresses species differences in TK.

[11]Recovery half-life differs from elimination half-life. While elimination half-life is not an acceptable basis for calculation of a DDEF for *toxicokinetic* components, enzyme regeneration measurements (the subject of the present analysis) are also expressed in half-life values. This usage refers to regeneration of enzymatic activity or *de novo* synthesis of additional enzyme (protein). In this instance, "half-life" measures are an adequate basis for derivation of DDEF values for *toxicodynamic* events.

It may be possible to use *in vitro* studies using human and rat tissues and human and rat AChE to test this hypothesis. In other words, it may be possible to use *in vitro* studies to demonstrate TD equivalence between rats and humans. If these data were available and they showed TD equivalence, the Agency could reduce the interspecies factor for those NMCs to a value of 3 without human toxicity studies. Due to the lack of these *in vitro* studies, the Agency does not believe it appropriate at this time to refine the standard for EF_A of 10 further. Instead, the Agency has used the DDEF approach as a sensitivity analysis in its risk characterization.

In this sensitivity analysis, the interspecies factor was reduced from 10 to 3 based on the assumption of TD equivalence for carbaryl, carbofuran, and formetanate HCl. These three NMCs were identified since they were shown in the CRA to contribute a large portion of the estimated human exposure to the cumulative risk to this group. The results of this sensitivity analysis for the food exposure assessment are shown below in Table A-3. The Agency has used a probabilistic approach to the food exposure assessment. The estimated exposures of the NMC as a group (i.e., oxamyl equivalents) and the MOE at the 99.9th percentile are shown here. The target MOE is 10 or higher for EF_H. The table compared the MOEs when using the standard UF to those obtained with the modified UF_A.

Table A-3. Sensitivity analyses N-methyl carbamate cumulative food assessment: Data-derived extrapolation factor approach for interspecies uncertainty factors

Age group		Estimated exposure at the 99.9th percentile (mg/kg oxamyl equivalents)	MOE at the 99.9th percentile	Percentile at which target of 10 is reached
Baseline CRA	Children 1−2	0.0229	7.9	99.848th
	Children 3−5	0.0209	8.6	99.870th
DDEF approach for interspecies UF	Children 1−2	0.0183	9.8	99.896th
	Children 3−5	0.0171	10.5	N/A

Review of this table shows that:

≠ Using the standard interspecies factor of 10 for all NMCs without human data, the (baseline) MOEs at the 99.9th percentile of exposure are less than 10 for children 1−2 and 3−5 years of age. Furthermore, MOEs reach the target of 10 at the 99.848th and 99.870th percentiles of exposures.

≠ When considering an alternative approach to the interspecies factor that assumes a value of 3 for carbaryl, carbofuran, and formetanate HCl, the MOEs at 99.9th percentile of exposure increase to 9.8 and 10.5 for children 1−2 and 3−5 years of age, respectively—a 20% increase in MOEs. The exposure for the younger age group reaches the target MOE of 10 at the 99.896th percentile of exposures.

This sensitivity analysis suggests that additional data could provide a substantial improvement in the refinement of the CRA.

A.3. INTRASPECIES EXPTRAPOLATION FACTOR FOR TOXICOKINETICS

A.3.1. Boron and Compounds—Intraspecies Extrapolation Factor for Toxicokinetics Case Study

A.3.1.1. *Summary*

In the EPA IRIS summary file for Boron and Compounds (U.S. EPA, 2004b), an RfD value of 2×10^{-1} mg/kg-day has been developed based on the critical developmental effect of decreased fetal weights (U.S. EPA, 2004b). The POD for the derivation of this value is the $BMDL_{05}$ value of 10.3 mg/kg-day. The $BMDL_{05}$ is based on the combined results of two separate studies chosen for the derivation of the RfD (Price et al., 1996; Price et al., 1994; Heindel et al., 1992). Using data from rats (Vaziri et al., 2001) and humans (Pahl et al., 2001), a mathematical model was applied to the EF_{AK} to address interspecies TK. The EF_{AK} was calculated to be 3.3. An intraspecies toxicokinetic extrapolation factor (EF_{HK}) of 2.0 was estimated from three studies (Sturgiss et al., 1996; Krutzén et al., 1992; Dunlop, 1981), using glomerular filtration rate (GFR) as a surrogate for boron clearance. The remaining uncertainty in the RfD derivation was from TD. Interspecies and intraspecies TD uncertainty were each assigned the default value of one-half order of magnitude (3.16). The product of all the adjustment and subfactors served as the total adjustment factor of 66. The RfD was derived by dividing the $BMDL_{05}$ of 10.3 mg/kg-day by the adjustment factor and rounding to one digit. This case study demonstrates the use of data to develop an EF_{HK}. Specifically, it demonstrates how a value of 2.0 for EF_{HK} was identified from three studies (Sturgiss et al., 1996; Krutzén et al., 1992; Dunlop, 1981), using GFR as a surrogate for boron clearance.

A.3.1.2. *Hazard Identification and Dose-Response*

Oral animal studies have identified the testes and the developing fetus as the two most sensitive targets of boron toxicity in multiple species (U.S. EPA, 2004b). Testicular effects include reduced organ weight and organ-to-body weight ratio, atrophy, degeneration of the spermatogenic epithelium, impaired spermatogenesis, reduced fertility, and sterility. The mechanism of action for boron's effect on the testes is not known, but the available data suggest an effect on Sertoli cells. Developmental effects following oral exposure to boron have been reported in mice, rabbits, and rats, and include high prenatal mortality, reduced fetal body weight, and malformations and variations of the eyes, central nervous system, cardiovascular system, and axial skeleton. Similarities in the NOAEL values for the reproductive toxicity studies and quality control issues complicated the choosing of testicular effects as the critical effect.

Developmental effects (decreased fetal weights) are considered the critical effect and serve to identify the sensitive population—the fetus of the pregnant female. The studies by Price et al. (1996; 1994), Heindel et al. (1992), and NTP (1990) in rats were chosen as critical developmental studies because they were well-conducted studies of a sensitive endpoint that identified both a NOAEL and LOAEL. Rats were more sensitive than mice and rabbits, which were also studied for developmental toxicity.

The POD was determined by BMD modeling. BMD evaluation of multiple developmental endpoints identified decreased fetal body weight as the most suitable endpoint. Two studies (Price et al., 1996; Price et al., 1994; Heindel et al., 1992) provided data on fetal body weight, and the results were combined for BMD evaluation. The benchmark response (BMR) level for mean fetal weight was chosen to be the $BMDL_{05}$ value of 10.3 mg/kg-day.

No data are available to identify an MOA, but boron is absorbed, distributed, and eliminated unchanged in urine. It is not metabolized, so some measure of exposure to the parent compound should serve as the basis for dose (exposure) expression.

A.3.1.3. *Basis for Data-Derived Extrapolation Factor*

Following administration, boron is rapidly absorbed and distributed throughout the body. It distributes with total body water; concentrations in all tissues examined were similar. Bone and fat tissues represent outliers—boron seems to accumulate in bone and the low water content of adipose tissue reduces boron distribution to fat.

Given the relatively uniform distribution of boron to the tissues and that the majority of the compound is excreted quickly, the likelihood for sequestration of boron by a given tissue is minimal. Although there are no direct measurements of fetal boron concentrations, boron concentrations in the fetus should be the same as in the mother because boron is freely diffusible across biological membranes and will rapidly and evenly equilibrate in all body water compartments. As the boron RfD is based on developmental effects observed in rats, the most relevant kinetic data are those pertaining to pregnant rats and pregnant humans. Given the difficulty in obtaining tissue boron concentrations in the developing fetus, data on plasma boron in these species were considered; however, data were insufficient to compare plasma boron in rats and humans at the same exposure levels. Therefore, boron clearance is used as an estimator of internal dose. Again, complications of the availability of data on boron clearance in a large enough population sufficient to support reliable estimates of variability were identified.

Since boron is not metabolized, clearance from blood and tissues is via urinary elimination. Boron is a small, uncharged molecule, and data indicate a lack of protein binding. Evidence from human dialysis studies indicates clearance is via passive diffusion. These (and other) data identify passive renal mechanisms as those most governing boron clearance. Because

the molecular and physical attributes of boron were consistent with those for agents eliminated by glomerular filtration and because boron clearance correlated with measures of glomerular filtration in some studies, variability of GFR was deemed an acceptable surrogate for variability of boron clearance among pregnant women. Table A-4 lists several studies that have characterized the variability of GFR among pregnant humans. The application of these data describing variance of GFR among pregnant humans serves as the basis for estimating human intraspecies differences in internal exposure.

Table A-4. Measures of glomerular filtration rate variability among pregnant women

Study	Mean GFR (mL/min)	Standard Deviation
Dunlop	150.5[a]	17.6
Krutzen	195[b]	32
Sturgiss	138.9[c]	26.1

[a]Serially averaged observations across three time periods (16, 26, and 36 weeks) for 25 pregnant women.

[b]Third-trimester values for 13 pregnant women.

[c]Serially averaged observations across two time periods (early and late pregnancy) for 21 pregnant women (basal index plus basal control individuals).

A.3.1.4. *Data-Derived Extrapolation Factor Derivation*

For the assessment of intraspecies TK variability, GFR is used as a surrogate for boron clearance. Although the study of Pahl et al. (2001) provides an estimate of boron clearance variability in pregnant women, the data are judged to be inadequate for this purpose. As boron clearance is largely a function of GFR, GFR is considered to be an appropriate surrogate and there is a larger, more certain database on GFR and its variability among humans than on boron clearance. Thus, the GFR database is used to estimate boron clearance variability. Because the measured boron clearances in the rat and human kinetic studies were less than GFR, tubular reabsorption could be contributing to the variability of boron clearance. Variability in these factors, however, is judged to be minor in comparison to the variability in GFR.

GFR data have been used previously in the context of the boron RfD by Dourson et al. (1998), who proposed the ratio of the mean GFR to the GFR value two standard deviations (SDs) below the general population mean (mean ÷ [mean − 2 SD]) as the metric for the EF_{HK}. This

approach is referred to as the sigma method, which is a common term used for statistical methods using multiple SDs to establish "acceptable" lower bounds.

For the derivation of EF_{HK}, for reasons described here, the sigma method is modified by using 3 SD as the reduction factor for establishing the lower bound (i.e., mean GFR − 3 SD). The basic formula modified from Dourson et al. (1998) for EF_{HK} is:

$$GFR_{AVG}{}^{EFHK} = GFR_{AVG} - 3\ SD_{GFR} \qquad \text{(A-5)}$$

where GFR_{AVG} and SD_{GFR} are the mean and SD of the GFR (mL/minute) for the general healthy population of pregnant women. The use of 3 SD rather than 2 SD (as in Dourson et al., 1998) is based on a statistical analysis of the published GFR data, with more consideration being given to the full range of GFR values likely to be found in the population of pregnant women. In the aggregate, the data suggest that a lower bound GFR 2 SD below the mean does not provide adequate coverage of the susceptible subpopulation (those pregnant women experiencing or predisposed to preeclampsia who have lower GFR values). While no conclusive information exists from controlled-dose studies in humans, it may be possible that the variability in boron clearance might be greater than GFR variability, but this is not expected. The uncertainty surrounding this possibility is low. Therefore, EF_{HK} must also account for any residual uncertainty in using GFR as a surrogate.

The three studies listed in Table A-4 (Sturgiss et al., 1996; Krutzén et al., 1992; Dunlop, 1981) were found to address GFR variability in pregnant women. Dunlop (1981) assessed GFR for 25 women at 3 different time points during pregnancy (16, 26, and 36 weeks) and again after delivery. In this study, GFR was measured as inulin clearance and the overall average and SD was 150.5 and 17.6 mL/minute, respectively. Sturgiss et al. (1996) performed a similar assessment of GFR (also using inulin clearance) for 21 women in early (12−19 weeks) and late (30−35 weeks) pregnancy and again at 15−25 weeks postpartum and found a mean GFR of 138.9 mL/minute with an SD of 26.1 mL/minute. Krutzén et al. (1992) evaluated GFR during pregnancy for 4 different groups of women (13 normal healthy women, 16 diabetic women, 8 hypertensive women, and 12 women diagnosed with preeclampsia) by using iohexol clearance in the second and third trimester and again 6−12 months postpartum. Krutzén et al. (1992) reported the third trimester mean GFR and SD for the healthy women as 195 and 32 mL/minute, respectively. In general, the GFR values reported in this study are much higher than those reported by Sturgiss et al. (1996) and Dunlop (1981). The reason for this discrepancy is not known. The GFRs from these studies and the results of the sigma method value calculations for EF_{HK} are shown in Table A-5.

Table A-5. Sigma-method value calculation for intraspecies toxicokinetic extrapolation factor[a]

Study	Mean GFR (SD) (mL/min)	Mean GFR − (3 SD)	Sigma-Method Value
Dunlop	150.5 (17.6)[b]	97.7	1.54
Krutzen	195 (32)[c]	99	1.97
Sturgiss	138.9 (26.1)[d]	60.6	2.29
Averages	161.5	85.8	1.93

[a]Mean GFR ÷ (Mean GFR − 3 SD).

[b]Serially averaged observations across 3 time periods (16, 26, and 36 weeks) for 25 pregnant women.

[c]Third-trimester values for 13 pregnant women.

[d]Serially averaged observations across two time periods (early and late pregnancy) for 21 pregnant women (basal index plus basal control individuals).

Considering the Krutzén et al. (1992) results in the context of the sigma method, a reduction of 2 SD from the healthy population mean to establish the lower bound (which results in a GFR slightly higher than the mean of the preeclamptic GFR) would appear to be insufficient for adequate coverage of the susceptible population. Thus, the use of 3 SD below the healthy GFR mean gives coverage in the sensitive subpopulation to about 1 SD below the mean preeclamptic GFR.

As no single study is considered to be definitive for assessment of population GFR variability, EF_{HK} is determined from the average of the individual sigma-method values for each of the three studies. The mean GFR and SD values in Table A-5 are based on average GFR across the entire gestational period, except for the Krutzén et al. (1992) estimate, which was for the third trimester only. The average sigma-method value from the three studies is 1.93. Considering a small residual uncertainty in the use of GFR as a surrogate for boron clearance, the average sigma-method value of 1.93 is rounded upward to 2.0 and established as the value for EF_{HK}.

By virtue of their lower GFR, pregnant women diagnosed with preeclampsia are considered to be a sensitive subpopulation, at least toxicokinetically. TD sensitivity is presumably independent of TK sensitivity. The onset of preeclampsia generally occurs after week 20 of pregnancy and is characterized by acute hypertension, often accompanied by edema and proteinuria. Women with preeclampsia are at increased risk for premature separation of the placenta from the uterus and acute renal failure, among other adverse health effects. The fetus may become hypoxic and is at increased risk of low birth weight or perinatal death.

The approximately twofold intraspecies variability factor derived from 3 SDs below the mean of three studies for pregnancy GFR (mean = 161.5 mL/minute; mean − 3 SD = 85.8) is considered preferable for providing adequate coverage to women predisposed to adverse birth outcomes due to renal complications. Therefore, the default value of 3.16 for intraspecies UF for the TK component (UF_{HK}) was obviated by a DDEF of 2.0.

A.3.2. Methylmercury—Intraspecies Extrapolation Factor for Toxicokinetics Case Study

A.3.2.1. *Summary*

This case study presents information derived from the *Water Quality Criterion for the Protection of Human Health: Methylmercury* (U.S. EPA, 2001d) and the IRIS entry for methylmercury (MeHg) (U.S. EPA, 2001b). MeHg has an RfD of 1×10^{-4} mg/kg-day in EPA's IRIS database (U.S. EPA, 2001b). No Toxicological Review is available for MeHg, but the underlying data and interpretations are published in the *Water Quality Criterion for the Protection of Human Health: Methylmercury* (U.S. EPA, 2001d).

Multiple RfDs were calculated from $BMDL_{05}$ values for various endpoints reported in three epidemiological studies measuring neurobehavioral deficits in children exposed *in utero*. Composite UFs of 10 were used in all calculations. This included a default threefold factor for human TD variability and uncertainty and a threefold factor for human TK variability and uncertainty. This latter EF_{HK} was based on published analyses of human TK data.

A.3.2.2. *Hazard Identification and Dose-Response*

MeHg can produce a variety of toxicities depending on the dose. These range from seizures and death to subtle neurobehavioral changes in humans exposed *in utero*. The choices of studies, critical effects, model, and POD were informed by an NRC advisory report and a subsequent review by an independent scientific panel (U.S. EPA, 2000b).

Mercury is methylated in soils and sediments by microorganisms and is bioaccumulated through aquatic food webs. It can reach relatively high concentrations (1 ppm or more) in predatory fish and sea mammals consumed by humans and wildlife. MeHg is absorbed readily from the human gut and is transported through the body, crossing both the blood/brain and placental barriers. Human studies from environmental exposures (fish and seafood consumption) were available and served to define the POD. Neurobehavioral effects were observed in two studies of children exposed *in utero* from maternal consumption of seafood [Faroe Islands and New Zealand; (U.S. EPA, 2001d)]. The Faroe Islands study was a longitudinal study of about 900 mother-infant pairs (Grandjean et al., 1997). The main independent variable was cord-blood mercury; maternal hair mercury was also measured as was child hair mercury. At 7 years of age, children were tested on a variety of tasks designed to assess function in specific behavioral domains. In the New Zealand study (Kjellstrom et al., 1989; Kjellstrom et al., 1986), increased maternal hair mercury was associated with decreased scores on standard intelligence quotient tests in 6-year-old children. No effects were reported in a third such study in the Seychelles Islands, but these data were also included in the modeling (NRC, 2000).

No MOA for MeHg has been established.

Test responses of children in three large studies discussed above (Faroe Islands, Seychelles, and New Zealand) were coupled with measured or calculated MeHg cord-blood concentrations for the dose-response analysis. BMD analysis was applied to the results from multiple individual neurobehavioral tests (e.g., Boston Naming Test, Continuous Performance Test, and California Verbal Learning Test). Data were modeled using a *K*-power model with $K \geq 1$; $K = 1$ generally giving the best fit. These data were continuous in exposure and effect. An abnormal response was defined as one falling into the lowest 5% of test responses ($P_0 = 0.05$). The BMR was set at 0.05, based on the NRC committee's advice that the combination of BMR and P_0 were within the observed range of responses and were, in fact, typical for these types of measurements (NRC, 2000). $BMDL_{05}$ values of 46 to 79 ppb MeHg in fetal cord blood were chosen as the points of departure for RfD calculation.

There is a correlation between maternal-blood mercury concentrations and fetal-blood mercury concentrations. A review of results from 21 studies demonstrated that the ratio of concentrations (fetal:maternal) is typically higher than 1, with overall mean values supporting a ratio close to 1.7. Based on the advice of an NRC panel, EPA (U.S. EPA, 2001b) chose not to make a numerical adjustment between cord-blood and maternal-blood mercury in calculating the RfD. The relationship between cord-blood and maternal-blood mercury was instead discussed as an area of variability and uncertainty during UF derivation.

Twenty-four RfDs were calculated using various $BMDL_{05}$ values but with the same dose conversion and a composite UF of 10. These calculations resulted in one RfD = 0.2 μg/kg bw/day, three RfD = 0.05 μg/kg bw/day, and twenty RfD = 0.1 μg/kg bw/day (or 1×10^{-4} mg/kg-day).

A.3.2.3. *Basis for Data-Derived Extrapolation Factor*

A PBPK model and a one-compartment model for pregnant women were used to examine the relationship between ingested doses of MeHg and maternal blood levels. To estimate human intraspecies variability (of MeHg concentrations in maternal blood to ingested MeHg dose), the most deterministic (sensitive) parameters of the TK model were identified and varied. Model results demonstrated that external doses required to produce maternal-blood concentrations of 1 ppm varied up to threefold. This value (3) served as a nondefault value for EF_{HK}; the TD component of the intraspecies UF (UF_{HD}) was left at a default value of 3 and the overall intraspecies UF value was 10.

A.3.2.4. *Data-Derived Extrapolation Factor Derivation*

Multiple measures of MeHg exposure are available from several human studies. For MeHg, hair and blood are considered more appropriate than urine, particularly for longer term exposure. The toxicity evaluated was induced during gestation, at a time when MeHg exposure to the developing brain of the fetus is through the placental blood supply. Thus, MeHg originated from the maternal blood circulation. Both a PBPK model and a one-compartment model were used to assess variables in fetal MeHg exposure. Independent of model type, ability to estimate maternal hair concentrations required at least two more parameters (blood-to-hair transfer and hair growth rate) than was required to estimate maternal blood concentrations. In addition, because EPA set cord-blood concentrations to equal maternal-blood concentrations, the model was able to predict fetal cord blood concentrations with less uncertainty than maternal hair concentrations. Largely for these reasons, blood MeHg concentrations were selected as the most appropriate dose metric.

EPA characterized human TK variability as differences in external (ingested) doses of MeHg that resulted in the same concentration of MeHg in maternal blood. The concentration selected for analysis was one that was relevant to the $BMDL_{05}$ for the neurobehavioral effects—namely 1 ppm. This concentration is about 12 to 20 times higher than the concentrations serving as the POD, but the choice was based in part on increasing model uncertainty when predicting concentrations lower than 1 ppm. An evaluation of the uncertainty and variability in model parameters was conducted in three studies (Swartout and Rice, 2000; Clewell et al., 1999; Stern, 1997) to identify the extent to which the external (ingested) dose might vary when compared to a fixed maternal hair or blood concentration.

Results from the Stern (1997) analysis were available in the original publication, whereas specific predictions of values at given percentiles for the Swartout and Rice (2000) and Clewell et al. (1999) studies required additional model exercises by the original authors; these analyses were published by NRC (2000). All data used in the models were from human studies. The analysis demonstrated the ratio of external (ingested) doses (in µg/kg-day) that resulted in the same blood concentration. The value of 3 was selected to represent the TK portion of the intraspecies extrapolation. This value was at or above the estimates from all three analyses for the comparison of the dose at the 50th percentile of the distribution to the dose at the 1st percentile of the distribution. The selected value of 3 thus encompassed the difference across these percentiles of the distribution. Because the dose at the 1st percentile of the distribution is lower than the dose at the 50th percentile of the distribution, the ratio has a value greater than 1.0.

Table A-6 presents the ratios developed (external dose at the 50th percentile/external dose at the 1st percentile) for each of the three studies. Considering TK variability as described

by the ratio of external doses at the specified percentiles of the distribution, values for blood and hair ranged from 1.7 to 3.3. Maximum values were 3.3 and 3.0 for hair and blood, respectively. EPA's IRIS entry for MeHg states, "Using maternal blood as the starting point, the consolidated range from the three analyses is 1.7 to 3.0." This is consistent with EPA's Water Quality Criterion document (U.S. EPA, 2001d). On this basis, a value of 3 was chosen to represent the TK portion of intraspecies variability. As no data were available to address intraspecies differences in susceptibility (TD), this portion of the UF was left at the default value of 3. Together these values for the components of UF_H combine to equal a value of 10, which was characterized as a "hybrid" value, comprising values based on default methodology and on data.

Table A-6. Comparison of results from three analyses of the intraspecies variability in the ingested dose of methylmercury corresponding to a given maternal-hair or blood mercury concentration

Study	Maternal medium	50th Percentile[a] (µg/kg-day)	50th Percentile/ 5th percentile[b]	50th Percentile/ 1st percentile[c]
Stern (1997)	Hair	0.03–0.05[d] (mean = 0.04)	1.8–2.4 (mean = 2.1)	2.3–3.3 (mean = 2.7)
	Blood	0.01	1.5–2.2 (mean = 1.8)	1.7–3.0 (mean = 2.4)
Swartout and Rice (2000)	Hair	0.08	2.2	Data not reported
	Blood[e]	0.02	2.1	2.8
Clewell et al. (1999)	Hair	0.08	1.5	1.8
	Blood[f]	0.07	1.4	1.7

[a]Predicted 50th percentile of the ingested dose of MeHg that corresponds to 1 ppm Hg in hair or 1 ppb in blood.
[b]Ratio of 50th percentile of ingested dose of MeHg that corresponds to 1 ppm Hg in hair or 1 ppb in blood to the 5th percentile.
[c]Ratio of 50th percentile of ingested dose of MeHg that corresponds to 1 ppm Hg in hair or 1 ppb in blood to the 1st percentile.
[d]Range reflects minimum and maximum values among eight alternative analyses.
[e]Data from J. Swartout, U.S. EPA, personal communication; June 9, 2000.
[f]Data from H.J. Clewell, ICF Consulting, personal communication; April 19, 2000 as cited in NRC (2000).

1. INTRODUCTION

1.1. PURPOSE AND SCOPE OF THE GUIDELINES

These guidelines revise and replace the U.S. Environmental Protection Agency's (EPA's, or the Agency's) *Guidelines for Carcinogen Risk Assessment*, published in 51 FR 33992, September 24, 1986 (U.S. EPA, 1986a) and the 1999 interim final guidelines (U.S. EPA, 1999a; see U.S. EPA 2001b). They provide EPA staff with guidance for developing and using risk assessments. They also provide basic information to the public about the Agency's risk assessment methods.

These cancer guidelines are used with other risk assessment guidelines, such as the *Guidelines for Mutagenicity Risk Assessment* (U.S. EPA, 1986b) and the *Guidelines for Exposure Assessment* (U.S. EPA, 1992a). Consideration of other Agency guidance documents is also important in assessing cancer risks where procedures for evaluating specific target organ effects have been developed (e.g., assessment of thyroid follicular cell tumors, U.S. EPA, 1998a). All of EPA's guidelines should be consulted when conducting a risk assessment in order to ensure that information from studies on carcinogenesis and other health effects are considered together in the overall characterization of risk. This is particularly true in the case in which a precursor effect for a tumor is also a precursor or endpoint of other health effects or when there is a concern for a particular susceptible life-stage for which the Agency has developed guidance, for example, *Guidelines for Developmental Toxicity Risk Assessment* (U.S. EPA, 1991a). The developmental guidelines discuss hazards to children that may result from exposures during preconception and prenatal or postnatal development to sexual maturity. Similar guidelines exist for reproductive toxicant risk assessments (U.S. EPA, 1996a) and for neurotoxicity risk assessment (U.S. EPA, 1998b). The overall characterization of risk is conducted within the context of broader policies and guidance such as Executive Order 13045, "Protection of Children From Environmental Health Risks and Safety Risks"(Executive Order 13045, 1997) which is the primary directive to federal agencies and departments to identify and assess environmental health risks and safety risks that may disproportionately affect children.

The cancer guidelines encourage both consistency in the procedures that support scientific components of Agency decision making and flexibility to allow incorporation of innovations and contemporaneous scientific concepts. In balancing these goals, the Agency relies on established scientific peer review processes (U.S. EPA, 2000a; OMB 2004). The cancer guidelines incorporate basic principles and science policies based on evaluation of the currently available information. The Agency intends to revise these cancer guidelines when substantial changes are necessary. As more information about carcinogenesis develops, the need may arise to make appropriate changes in risk assessment guidance. In the interim, the Agency intends to issue special reports, after appropriate peer review, to supplement and update guidance on single topics (e.g., U.S. EPA, 1991b). One such guidance document, *Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens* ("Supplemental Guidance"), was developed in conjunction with these cancer guidelines (U.S. EPA., 2005). Because both the methodology and the data in the Supplemental Guidance (see Section 1.3.6) are expected to evolve more rapidly than the issues addressed in these cancer guidelines, the two were developed as separate documents. The Supplemental Guidance, however, as well as any other relevant (including subsequent) guidance documents, should be considered along with these cancer guidelines as risk assessments for carcinogens are generated. The use of supplemental guidance, such as the Supplemental Guidance for Assessing Cancer Susceptibility from Early-life Exposure to Carcinogens, has the advantage of allowing the Supplemental Guidance to be modified as more data become available. Thus, the consideration of new, peer-reviewed scientific understanding and data in an assessment can always be consistent with the purposes of these cancer guidelines.

These cancer guidelines are intended as guidance only. They do not establish any substantive "rules" under the Administrative Procedure Act or any other law and have no binding effect on EPA or any regulated entity, but instead represent a non-binding statement of policy. EPA believes that the cancer guidelines represent a sound and up-to-date approach to cancer risk assessment, and the cancer guidelines enhance the application of the best available science in EPA's risk assessments. However, EPA cancer risk assessments may be conducted differently than envisioned in the cancer guidelines for many reasons, including (but not limited to) new

information, new scientific understanding, or new science policy judgment. The science of risk assessment continues to develop rapidly, and specific components of the cancer guidelines may become outdated or may otherwise require modification in individual settings. Use of the cancer guidelines in future risk assessments will be based on decisions by EPA that the approaches are suitable and appropriate in the context of those particular risk assessments. These judgments will be tested through peer review, and risk assessments will be modified to use different approaches if appropriate.

1.2. ORGANIZATION AND APPLICATION OF THE CANCER GUIDELINES

1.2.1. Organization

Publications by the Office of Science and Technology (OSTP, 1985) and the National Research Council (NRC) (NRC, 1983, 1994) provide information and general principles about risk assessment. Risk assessment uses available scientific information on the properties of an agent[1] and its effects in biological systems to provide an evaluation of the potential for harm as a consequence of environmental exposure. The 1983 and 1994 NRC documents organize risk assessment information into four areas: hazard identification, dose-response assessment, exposure assessment, and risk characterization. This structure appears in these cancer guidelines, with additional emphasis placed on characterization of evidence and conclusions in each area of the assessment. In particular, the cancer guidelines adopt the approach of the NRC's 1994 report in adding a dimension of characterization to the hazard identification step: an evaluation of the conditions under which its expression is anticipated. Risk assessment questions addressed in these cancer guidelines are as follows.

- For hazard—Can the identified agent present a carcinogenic hazard to humans and, if so, under what circumstances?

- For dose response—At what levels of exposure might effects occur?

[1] The term “agent” refers generally to any chemical substance, mixture, or physical or biological entity being assessed, unless otherwise noted (See Section 1.2.2 for a note on radiation.).

- For exposure—What are the conditions of human exposure?

- For risk—What is the character of the risk? How well do data support conclusions about the nature and extent of the risk from various exposures?

The risk characterization process first summarizes findings on hazard, dose response, and exposure characterizations and then develops an integrative analysis of the whole risk case. It ends in the writing of a technical risk characterization. Other documents, such as summaries for the risk managers and the public, reflecting the key points of the risk characterization are usually written. A summary for managers is a presentation for those who may or may not be familiar with the scientific details of cancer assessment. It also provides information for other interested readers. The initial steps in the risk characterization process are to make building blocks in the form of characterizations of the assessments of hazard, dose response, and exposure. The individual assessments and characterizations are then integrated to arrive at risk estimates for exposure scenarios of interest. As part of the characterization process, explicit evaluations are made of the hazard and risk potential for susceptible lifestages, including children (U.S. EPA, 1995, 2000b).

The 1994 NRC document also explicitly called attention to the role of the risk assessment process in identifying scientific uncertainties that, if addressed, could serve to reduce their uncertainty in future iterations of the risk assessment. NRC recommended that when the Agency "reports estimates of risk to decisions-makers and the public, it should present not only point estimates of risk, but also the sources and magnitudes of uncertainty associated with these estimates" (p. 15). Thus, the identified uncertainties serve as a feedback loop to the research community and decisionmakers, specifying areas and types of information that would be particularly useful.

There are several reasons for individually characterizing the hazard, dose response, and exposure assessments. One is that they are often done by different people than those who do the integrative analyses. The second is that there is very often a lapse of time between the conduct of hazard and dose-response analyses and the conduct of exposure assessment and integrative

analysis. Thus, it is important to capture characterizations of assessments as the assessments are done to avoid the need to go back and reconstruct them. Finally, frequently a single hazard assessment is used by several programs for several different exposure scenarios. There may be one or several documents involved. "Integrative analysis" is a generic term; and many documents that have other titles may contain integrative analyses. In the following sections, the elements of these characterizations are discussed.

1.2.2. Application

The cancer guidelines apply within the framework of policies provided by applicable EPA statutes and do not alter such policies.

- The cancer guidelines cover the assessment of available data. They do not imply that one kind of data or another is prerequisite for regulatory action concerning any agent. It is important that, when evaluating and considering the use of any data, EPA analysts incorporate the basic standards of quality, as defined by the EPA Information Quality Guidelines (U.S. EPA, 2002a see Appendix B) and other Agency guidance on data quality such as the EPA Quality Manual for Environmental Programs (U.S. EPA, 2000e), as well as *OMB Guidelines for Ensuring and Maximizing the Quality, Utility, and Integrity of Information Disseminated by Federal Agencies* (OMB, 2002). It is very important that all analyses consider the basic standards of quality, including objectivity, utility, and integrity. A summary of the factors and considerations generally used by the Agency when evaluating and considering the use of scientific and technical information is contained in EPA's *A Summary of General Assessment Factors for Evaluating the Quality of Scientific and Technical Information* (U.S. EPA, 2003).

- Risk management applies directives in statutes, which may require consideration of potential risk or solely hazard or exposure potential, along with social, economic, technical, and other factors in decision making. Risk assessments may be used to support

decisions, but in order to maintain their integrity as decision-making tools, they are not influenced by consideration of the social or economic consequences of regulatory action.

The assessment of risk from radiation sources is informed by the continuing examination of human data by the National Academy of Sciences/NRC in its series of numbered reports: "Biological Effects of Ionizing Radiation." Although some of the general principles of these cancer guidelines may also apply to radiation risk assessments, some of the details of their risk assessment procedures may not, as they are most focused on other kinds of agents. Therefore, these cancer guidelines are not intended to provide the primary source of, or guidance for, the Agency's evaluation of the carcinogenic risks of radiation.

Not every EPA assessment has the same scope or depth, a factor recognized by the National Academy of Sciences (NRC, 1996). For example, EPA's Information Quality Guidelines (U.S. EPA, 2002a, see Appendix B) discuss influential information that "will have or does have a clear and substantial impact ... on important public policies or private sector decisions ... that should adhere to a rigorous standard of quality." It is often difficult to know *a priori* how the results of a risk assessment are likely to be used by the Agency. Some risk assessments may be used by Agency economists and policy analysts, and the necessary information for such analyses, as discussed in detail later in this document, should be included when practicable (U.S. EPA, 2002a). On the other hand, Agency staff often conduct screening-level assessments for priority setting or separate assessments of hazard or exposure for ranking purposes or to decide whether to invest resources in collecting data for a full assessment. Moreover, a given assessment of hazard and dose response may be used with more than one exposure assessment that may be conducted separately and at different times as the need arises in studying environmental problems related to various exposure media. The cancer guidelines apply to these various situations in appropriate detail, given the scope and depth of the particular assessment. For example, a screening assessment may be based almost entirely on structure-activity relationships (SARs) and default options, when other data are not readily available. When more data and resources are readily available, assessments can use a critical analysis of all of the available data as the starting point of the risk assessment. Under these conditions, default

options would only be used to address uncertainties or the absence of critical data. Default options are inferences based on general scientific knowledge of the phenomena in question and are also matters of policy concerning the appropriate way to bridge uncertainties that concern potential risk to human health.

These cancer guidelines do not suggest that all of the kinds of data covered here will need to be available or used for either assessment or decision making. The level of detail of an assessment is a matter of Agency management discretion regarding applicable decision-making needs. The Agency generally presumes that key cancer information (e.g., assessments contained in the Agency's Integrated risk Information System) is "influential information" as defined by the EPA Information Quality Guidelines and "highly influential" as defined by OMB's Information Quality Bulletin for Peer Review (OMB 2004).

1.3. KEY FEATURES OF THE CANCER GUIDELINES

1.3.1. Critical Analysis of Available Information as the Starting Point for Evaluation

As an increasing understanding of carcinogenesis is becoming available, these cancer guidelines adopt a view of default options that is consistent with EPA's mission to protect human health while adhering to the tenets of sound science. Rather than viewing default options as the starting point from which departures may be justified by new scientific information, these cancer guidelines view a critical analysis of all of the available information that is relevant to assessing the carcinogenic risk as the starting point from which a default option may be invoked if needed to address uncertainty or the absence of critical information. Preference is given to using information that has been peer reviewed, e.g., reported in peer-reviewed scientific journals. The primary goal of EPA actions is protection of human health; accordingly, as an Agency policy, risk assessment procedures, including default options that are used in the absence of scientific data to the contrary, should be health protective (U.S. EPA, 1999b).

Use of health protective risk assessment procedures as described in these cancer guidelines means that estimates, while uncertain, are more likely to overstate than understate hazard and/or risk. NRC (1994) reaffirmed the use of default options as "a reasonable way to cope with uncertainty about the choice of appropriate models or theory" (p. 104). NRC saw the

need to treat uncertainty in a predictable way that is "scientifically defensible, consistent with the agency's statutory mission, and responsive to the needs of decision-makers" (p. 86). The extent of health protection provided to the public ultimately depends upon what risk managers decide is the appropriate course of regulatory action. When risk assessments are performed using only one set of procedures, it may be difficult for risk managers to determine how much health protectiveness is built into a particular hazard determination or risk characterization. When there are alternative procedures having significant biological support, the Agency encourages assessments to be performed using these alternative procedures, if feasible, in order to shed light on the uncertainties in the assessment, recognizing that the Agency may decide to give greater weight to one set of procedures than another in a specific assessment or management decision.

Encouraging risk assessors to be receptive to new scientific information, NRC discussed the need for departures from default options when a "sufficient showing" is made. It called on EPA to articulate clearly its criteria for a departure so that decisions to depart from default options would be "scientifically credible and receive public acceptance" (p. 91). It was concerned that *ad hoc* departures would undercut the scientific credibility of a risk assessment. NRC envisioned that principles for choosing and departing from default options would balance several objectives, including "protecting the public health, ensuring scientific validity, minimizing serious errors in estimating risks, maximizing incentives for research, creating an orderly and predictable process, and fostering openness and trustworthiness" (p. 81).

Appendices N-1 and N-2 of NRC (1994) discussed two competing standards for choosing default options articulated by members of the committee. One suggested approach would evaluate a departure in terms of whether "it is scientifically plausible" and whether it "tends to protect public health in the face of scientific uncertainty" (p. 601). An alternative approach "emphasizes scientific plausibility with regard to the use of alternative models" (p. 631). Reaching no consensus on a single approach, NRC recognized that developing criteria for departures is an EPA policy matter.

The basis for invoking a default option depends on the circumstances. Generally, if a gap in basic understanding exists or if agent-specific information is missing, a default option may be used. If agent-specific information is present but critical analysis reveals inadequacies, a default

option may also be used. If critical analysis of agent-specific information is consistent with one or more biologically based models as well as with the default option, the alternative models and the default option are both carried through the assessment and characterized for the risk manager. In this case, the default model not only fits the data, but also serves as a benchmark for comparison with other analyses. This case also highlights the importance of extensive experimentation to support a conclusion about mode of action, including addressing the issue of whether alternative modes of action are also plausible. Section 2.4 provides a framework for critical analysis of mode of action information to address the extent to which the available information supports the hypothesized mode of action, whether alternative modes of action are also plausible, and whether there is confidence that the same inferences can be extended to populations and lifestages that are not represented among the experimental data.

Generally, cancer risk decisions strive to be "scientifically defensible, consistent with the agency's statutory mission, and responsive to the needs of decision-makers" (NRC, 1994). Scientific defensibility would be evaluated through use of EPA's Science Advisory Board, EPA's Office of Pesticide Programs' Scientific Advisory Panel, or other independent expert peer review panels to determine whether a consensus among scientific experts exists. Consistency with the Agency's statutory mission would consider whether the risk assessment overall supports EPA's mission to protect human health and safeguard the natural environment. Responsiveness to the needs of decisionmakers would take into account pragmatic considerations such as the nature of the decision; the required depth of analysis; the utility, time, and cost of generating new scientific data; and the time, personnel, and resources allotted to the risk assessment.

With a multitude of types of data, analyses, and risk assessments, as well as the diversity of needs of decisionmakers, it is neither possible nor desirable to specify step-by-step criteria for decisions to invoke a default option. A discussion of major default options appears in the Appendix. Screening-level assessments may more readily use default parameters, even worst-case assumptions, that would not be appropriate in a full-scale assessment. On the other hand, significant risk management decisions will often benefit from a more comprehensive assessment, including alternative risk models having significant biological support. To the extent practicable, such assessments should provide central estimates of potential risks in conjunction with lower

and upper bounds (e.g., confidence limits) and a clear statement of the uncertainty associated with these estimates.

In the absence of sufficient data or understanding to develop of a robust, biologically based model, an appropriate policy choice is to have a single preferred curve-fitting model for each type of data set. Many different curve-fitting models have been developed, and those that fit the observed data reasonably well may lead to several-fold differences in estimated risk at the lower end of the observed range. In addition, goodness-of-fit to the experimental observations is not by itself an effective means of discriminating among models that adequately fit the data (OSTP, 1985). To provide some measure of consistency across different carcinogen assessments, EPA uses a standard curve-fitting procedure for tumor incidence data. Assessments that include a different approach should provide an adequate justification and compare their results with those from the standard procedure. Application of models to data should be conducted in an open and transparent manner.

1.3.2. Mode of Action

The use of mode of action[2] in the assessment of potential carcinogens is a main focus of these cancer guidelines. This area of emphasis arose because of the significant scientific advances that have developed concerning the causes of cancer induction. Elucidation of a mode of action for a particular cancer response in animals or humans is a data-rich determination. Significant information should be developed to ensure that a scientifically justifiable mode of action underlies the process leading to cancer at a given site. In the absence of sufficiently, scientifically justifiable mode of action information, EPA generally takes public health-protective, default positions regarding the interpretation of toxicologic and epidemiologic data:

[2] The term *"mode of action"* is defined as a sequence of key events and processes, starting with interaction of an agent with a cell, proceeding through operational and anatomical changes, and resulting in cancer formation. A *"key event"* is an empirically observable precursor step that is itself a necessary element of the mode of action or is a biologically based marker for such an element. Mode of action is contrasted with "*mechanism of action*," which implies a more detailed understanding and description of events, often at the molecular level, than is meant by mode of action. The toxicokinetic processes that lead to formation or distribution of the active agent to the target tissue are considered in estimating dose but are not part of the mode of action as the term is used here. There are many examples of possible modes of carcinogenic action, such as mutagenicity, mitogenesis, inhibition of cell death, cytotoxicity with reparative cell proliferation, and immune suppression.

animal tumor findings are judged to be relevant to humans, and cancer risks are assumed to conform with low dose linearity.

Understanding of mode of action can be a key to identifying processes that may cause chemical exposures to differentially affect a particular population segment or lifestage. Some modes of action are anticipated to be mutagenic and are assessed with a linear approach. This is the mode of action of radiation and several other agents that are known carcinogens. Other modes of action may be modeled with either linear or nonlinear[3] approaches after a rigorous analysis of available data under the guidance provided in the framework for mode of action analysis (see Section 2.4.3).

1.3.3. Weight of Evidence Narrative

The cancer guidelines emphasize the importance of weighing all of the evidence in reaching conclusions about the human carcinogenic potential of agents. This is accomplished in a single integrative step after assessing all of the individual lines of evidence, which is in contrast to the step-wise approach in the 1986 cancer guidelines. Evidence considered includes tumor findings, or lack thereof, in humans and laboratory animals; an agent's chemical and physical properties; its structure-activity relationships (SARs) as compared with other carcinogenic agents; and studies addressing potential carcinogenic processes and mode(s) of action, either *in vivo* or *in vitro*. Data from epidemiologic studies are generally preferred for characterizing human cancer hazard and risk. However, all of the information discussed above could provide valuable insights into the possible mode(s) of action and likelihood of human cancer hazard and risk. The cancer guidelines recognize the growing sophistication of research methods,

[3]The term "*nonlinear*" is used here in a narrower sense than its usual meaning in the field of mathematical modeling. In these cancer guidelines, the term "*nonlinear*" refers to threshold models (which show no response over a range of low doses that include zero) and some nonthreshold models (e.g., a quadractic model, which shows some response at all doses above zero). In these cancer guidelines, a nonlinear model is one whose slope is zero at (and perhaps above) a dose of zero. A *low-dose-linear* model is one whose slope is greater than zero at a dose of zero. A low-dose-linear model approximates a straight line only at very low doses; at higher doses near the observed data, a low-dose-linear model can display curvature. The term "*low-dose-linear*" is often abbreviated "linear," although a low-dose-linear model is not linear at all doses. Use of nonlinear approaches does not imply a biological threshold dose below which the response is zero. Estimating thresholds can be problematic; for example, a response that is not statistically significant can be consistent with a small risk that falls below an experiment's power of detection.

particularly in their ability to reveal the modes of action of carcinogenic agents at cellular and subcellular levels as well as toxicokinetic processes.

Weighing of the evidence includes addressing not only the likelihood of human carcinogenic effects of the agent but also the conditions under which such effects may be expressed, to the extent that these are revealed in the toxicological and other biologically important features of the agent.

The weight of evidence narrative to characterize hazard summarizes the results of the hazard assessment and provides a conclusion with regard to human carcinogenic potential. The narrative explains the kinds of evidence available and how they fit together in drawing conclusions, and it points out significant issues/strengths/limitations of the data and conclusions. Because the narrative also summarizes the mode of action information, it sets the stage for the discussion of the rationale underlying a recommended approach to dose-response assessment.

In order to provide some measure of clarity and consistency in an otherwise free-form, narrative characterization, standard descriptors are used as part of the hazard narrative to express the conclusion regarding the weight of evidence for carcinogenic hazard potential. There are five recommended standard hazard descriptors: "*Carcinogenic to Humans*," "*Likely to Be Carcinogenic to Humans*," "*Suggestive Evidence of Carcinogenic Potential*," "*Inadequate Information to Assess Carcinogenic Potential*," and "*Not Likely to Be Carcinogenic to Humans*." Each standard descriptor may be applicable to a wide variety of data sets and weights of evidence and is presented only in the context of a weight of evidence narrative. Furthermore, as described in Section 2.5 of these cancer guidelines, more than one conclusion may be reached for an agent.

1.3.4. Dose-response Assessment

Dose-response assessment evaluates potential risks to humans at particular exposure levels. The approach to dose-response assessment for a particular agent is based on the conclusion reached as to its potential mode(s) of action for each tumor type. Because an agent may induce multiple tumor types, the dose-response assessment includes an analysis of all tumor types, followed by an overall synthesis that includes a characterization of the risk estimates across tumor types, the strength of the mode of action information of each tumor type, and the

anticipated relevance of each tumor type to humans, including susceptible populations and lifestages (e.g., childhood).

Dose-response assessment for each tumor type is performed in two steps: assessment of observed data to derive a point of departure (POD),[4] followed by extrapolation to lower exposures to the extent that is necessary. Data from epidemiologic studies, of sufficient quality, are generally preferred for estimating risks. When animal studies are the basis of the analysis, the estimation of a human-equivalent dose should utilize toxicokinetic data to inform cross-species dose scaling if appropriate and if adequate data are available. Otherwise, default procedures should be applied. For oral dose, based on current science, an appropriate default option is to scale daily applied doses experienced for a lifetime in proportion to body weight raised to the 3/4 power (U.S. EPA, 1992b). For inhalation dose, based on current science, an appropriate default methodology estimates respiratory deposition of particles and gases and estimates internal doses of gases with different absorption characteristics. When toxicokinetic modeling (see Section 3.1.2) is used without toxicodynamic modeling (see Section 3.2.2), the dose-response assessment develops and supports an approach for addressing toxicodynamic equivalence, perhaps by retaining some of the cross-species scaling factor (see Section 3.1.3). Guidance is also provided for adjustment of dose from adults to children (see Section 4.3.1).

Response data on effects of the agent on carcinogenic processes are analyzed (nontumor data) in addition to data on tumor incidence. If appropriate, the analyses of data on tumor incidence and on precursor effects may be used in combination. To the extent the relationship between precursor effects and tumor incidence are known, precursor data may be used to estimate a dose-response function below the observable tumor data. Study of the dose-response function for effects believed to be part of the carcinogenic process influenced by the agent may also assist in evaluating the relationship of exposure and response in the range of observation and at exposure levels below the range of observation.

[4] A "*point of departure*" (POD) marks the beginning of extrapolation to lower doses. The POD is an estimated dose (usually expressed in human-equivalent terms) near the lower end of the observed range, without significant extrapolation to lower doses.

The first step of dose-response assessment is evaluation within the range of observation. Approaches to analysis of the range of observation of epidemiologic studies are determined by the type of study and how dose and response are measured in the study. In the absence of adequate human data for dose-response analysis, animal data are generally used. If there are sufficient quantitative data and adequate understanding of the carcinogenic process, a biologically based model may be developed to relate dose and response data on an agent-specific basis. Otherwise, as a default procedure, a standard model can be used to curve-fit the data.

The POD for extrapolating the relationship to environmental exposure levels of interest, when the latter are outside the range of observed data, is generally the lower 95% confidence limit on the lowest dose level that can be supported for modeling by the data. SAB (1997) suggested that, "it may be appropriate to emphasize lower statistical bounds in screening analyses and in activities designed to develop an appropriate human exposure value, since such activities require accounting for various types of uncertainties and a lower bound on the central estimate is a scientifically-based approach accounting for the uncertainty in the true value of the ED_{10} [or central estimate]." However, the consensus of the SAB (1997) was that, "both point estimates and statistical bounds can be useful in different circumstances, and recommended that the Agency routinely calculate and present the point estimate of the ED_{10} [or central estimate] and the corresponding upper and lower 95% statistical bounds." For example, it may be appropriate to emphasize the central estimate in activities that involve formal uncertainty analysis that are required by OMB Circular A-4 (OMB, 2003) as well as ranking agents as to their carcinogenic hazard. Thus, risk assessors should calculate, to the extent practicable, and present the central estimate and the corresponding upper and lower statistical bounds (such as confidence limits) to inform decisionmakers.

The second step of dose-response assessment is extrapolation to lower dose levels, if needed. This extrapolation is based on extension of a biologically based model if supported by substantial data (see Section 3.3.2). Otherwise, default approaches can be applied that are consistent with current understanding of mode(s) of action of the agent, including approaches that assume linearity or nonlinearity of the dose-response relationship, or both. A default approach for linearity extends a straight line from the POD to zero dose/zero response (see

Section 3.3.3). The linear approach is used when: (1) there is an absence of sufficient information on modes of action or (2) the mode of action information indicates that the dose-response curve at low dose is or is expected to be linear. Where alternative approaches have significant biological support, and no scientific consensus favors a single approach, an assessment may present results using alternative approaches. A nonlinear approach can be used to develop a reference dose or a reference concentration (see Section 3.3.4).

1.3.5. Susceptible Populations and Lifestages

An important use of mode of action information is to identify susceptible populations and lifestages. It is rare to have epidemiologic studies or animal bioassays conducted in susceptible individuals. This information need can be filled by identifying the key events of the mode of action and then identifying risk factors, such as differences due to genetic polymorphisms, disease, altered organ function, lifestyle, and lifestage, that can augment these key events. To do this, the information about the key precursor events is reviewed to identify particular populations or lifestages that can be particularly susceptible to their occurrence (see Section 2.4.3.4). Any information suggesting quantitative differences between populations or lifestages is flagged for consideration in the dose-response assessment (see Section 3.5 and U.S. EPA 2002b).

1.3.6. Evaluating Risks from Childhood Exposures

NRC (1994) recommended that "EPA should assess risks to infants and children whenever it appears that their risks might be greater than those of adults." Executive Order 13045 (1997) requires that "each Federal Agency shall make it a high priority to identify and assess environmental health and safety risks that may disproportionately affect children, and shall ensure that their policies, programs, and standards address disproportionate risks that result from environmental health risks or safety risks." In assessing risks to children, EPA considers both effects manifest during childhood and early-life exposures that can contribute to effects at any time later in life.

These cancer guidelines view childhood as a sequence of lifestages rather than viewing children as a subpopulation, the distinction being that a subpopulation refers to a portion of the

population, whereas a lifestage is inclusive of the entire population. Exposures that are of concern extend from conception through adolescence and also include pre-conception exposures of both parents. These cancer guidelines use the term "childhood" in this more inclusive sense.

Rarely are there studies that directly evaluate risks following early-life exposure. Epidemiologic studies of early-life exposure to environmental agents are seldom available. Standard animal bioassays generally begin dosing after the animals are several weeks old, when many organ systems are mature. This could lead to an understatement of risk, because an accepted concept in the science of carcinogenesis is that young animals are usually more susceptible to the carcinogenic activity of a chemical than are mature animals (McConnell, 1992).

At this time, there is some evidence of higher cancer risks following early-life exposure. For radiation carcinogenesis, data indicate that risks for several forms of cancer are highest following childhood exposure (NRC, 1990; Miller, 1995; U.S. EPA, 1999c). These human results are supported by the few animal bioassays that include perinatal (prenatal or early postnatal) exposure. Perinatal exposure to some agents can induce higher incidences of the tumors seen in standard bioassays; some examples include vinyl chloride (Maltoni et al., 1981), diethylnitrosamine (Peto et al., 1984), benzidine, DDT, dieldrin, and safrole (Vesselinovitch et al., 1979). Moreover, perinatal exposure to some agents, including vinyl chloride (Maltoni et al., 1981) and saccharin (Cohen, 1995; Whysner and Williams, 1996), can induce different tumors that are not seen in standard bioassays. Surveys comparing perinatal carcinogenesis bioassays with standard bioassays for a limited number of chemicals (McConnell, 1992; U.S. EPA, 1996b) have concluded that

- the same tumor sites are usually observed following either perinatal or adult exposure, and

- perinatal exposure in conjunction with adult exposure usually increases the incidence of tumors or reduces the latent period before tumors are observed.

The risk attributable to early-life exposure often appears modest compared with the risk from lifetime exposure, but it can be about 10-fold higher than the risk from an exposure of similar duration occurring later in life (Ginsberg, 2003). Further research is warranted to investigate the extent to which these findings apply to specific agents, chemical classes, and modes of action or in general.

These empirical results are consistent with current understanding of the biological processes involved in carcinogenesis, which leads to a reasonable expectation that children can be more susceptible to many carcinogenic agents (Anderson et al., 2000; Birnbaum and Fenton, 2003; Ginsberg, 2003; Miller et al., 2002; Scheuplein et al., 2002). Some aspects potentially leading to childhood susceptibility are listed below.

- Differences in the capacity to metabolize and clear chemicals can result in larger or smaller internal doses of the active agent(s).

- More frequent cell division during development can result in enhanced expression of mutations due to the reduced time available for repair of DNA lesions (Slikker et al., 2004).

- Some embryonic cells, such as brain cells, lack key DNA repair enzymes.

- More frequent cell division during development can result in clonal expansion of cells with mutations from prior unrepaired DNA damage (Slikker et al., 2004).

- Some components of the immune system are not fully functional during development (Holladay and Smialowicz, 2000; Holsapple et al., 2003).

- Hormonal systems operate at different levels during different lifestages.

- Induction of developmental abnormalities can result in a predisposition to carcinogenic effects later in life (Anderson et al., 2000; Birnbaum and Fenton, 2003; Fenton and Davis, 2002).

To evaluate risks from early-life exposure, these cancer guidelines emphasize the role of toxicokinetic information to estimate levels of the active agent in children and toxicodynamic information to identify whether any key events of the mode of action are of increased concern early in life. Developmental toxicity studies can provide information on critical periods of exposure for particular targets of toxicity.

An approach to assessing risks from early-life exposure is presented in Figure 1-1. In the hazard assessment, when there are mode of action data, the assessment considers whether these data have special relevance during childhood, considering the various aspects of development listed above. Examples of such data include toxicokinetics that predict a sufficiently large internal dose in children or a mode of action where a key precursor event is more likely to occur during childhood. There is no recommended default to settle the question of whether tumors arising through a mode of action are relevant during childhood; and adequate understanding the mode of action implies that there are sufficient data (on either the specific agent or the general mode of action) to form a confident conclusion about relevance during childhood (see Section 2.4.3.4).

In the dose-response assessment, the potential for susceptibility during childhood warrants explicit consideration in each assessment. These cancer guidelines encourage developing separate risk estimates for children according to a tiered approach that considers what pertinent data are available (see Section 3.5). Childhood may be a susceptible period; moreover, exposures during childhood generally are not equivalent to exposures at other times and may be treated differently from exposures occurring later in life (see Section 3.5). In addition, adjustment of unit risk estimates may be warranted when used to estimate risks from childhood exposure (see Section 4.4).

At this time, several limitations preclude a full assessment of children's risk. There are no generally used testing protocols to identify potential environmental causes of cancers that are

unique to children, including several forms of childhood cancer and cancers that develop from parental exposures, and cases where developmental exposure may alter susceptibility to carcinogen exposure in the adult (Birnbaum and Fenton, 2003). Dose-response assessment is limited by an inability to observe how developmental exposure can modify incidence and latency and an inability to estimate the ultimate tumor response resulting from induced susceptibility to later carcinogen exposures.

To partially address the limitations identified above, EPA developed in conjunction with these cancer guidelines, *Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens* ("Supplemental Guidance"). The Supplemental Guidance addresses a number of issues pertaining to cancer risks associated with early-life exposures generally, but provides specific guidance on procedures for adjusting cancer potency estimates only for carcinogens acting through a mutagenic mode of action. This Supplemental Guidance recommends, for such chemicals when no chemical-specific data exist, a default approach using estimates from chronic studies (i.e., cancer slope factors) with appropriate modifications to address the potential for differential risk of early-lifestage exposure.

The Agency considered both the advantages and disadvantages to extending the recommended, age dependent adjustment factors for carcinogenic potency to carcinogenic agents for which the mode of action remains unknown. EPA decided to recommend these factors only for carcinogens acting through a mutagenic mode of action based on a combination of analysis of available data and long-standing science policy positions which govern the Agency's overall approach to carcinogen risk assessment. In general, the Agency prefers to rely on analyses of data, rather than general defaults. When data are available for a sensitive lifestage, they would be used directly to evaluate risks for that chemical and that lifestage on a case-by-case basis. In the case of nonmutagenic carcinogens, when the mode of action is unknown, the data were judged by EPA to be too limited and the modes of action too diverse to use this as a category for which a general default adjustment factor approach can be applied. In this situation, a linear low-dose extrapolation methodology (without further adjustment) is recommended. It is the Agency's long-standing science policy position that use of the linear low-dose extrapolation approach

provides adequate public health conservatism in the absence of chemical-specific data indicating differential early-life sensitivity or when the mode of action is not mutagenic.

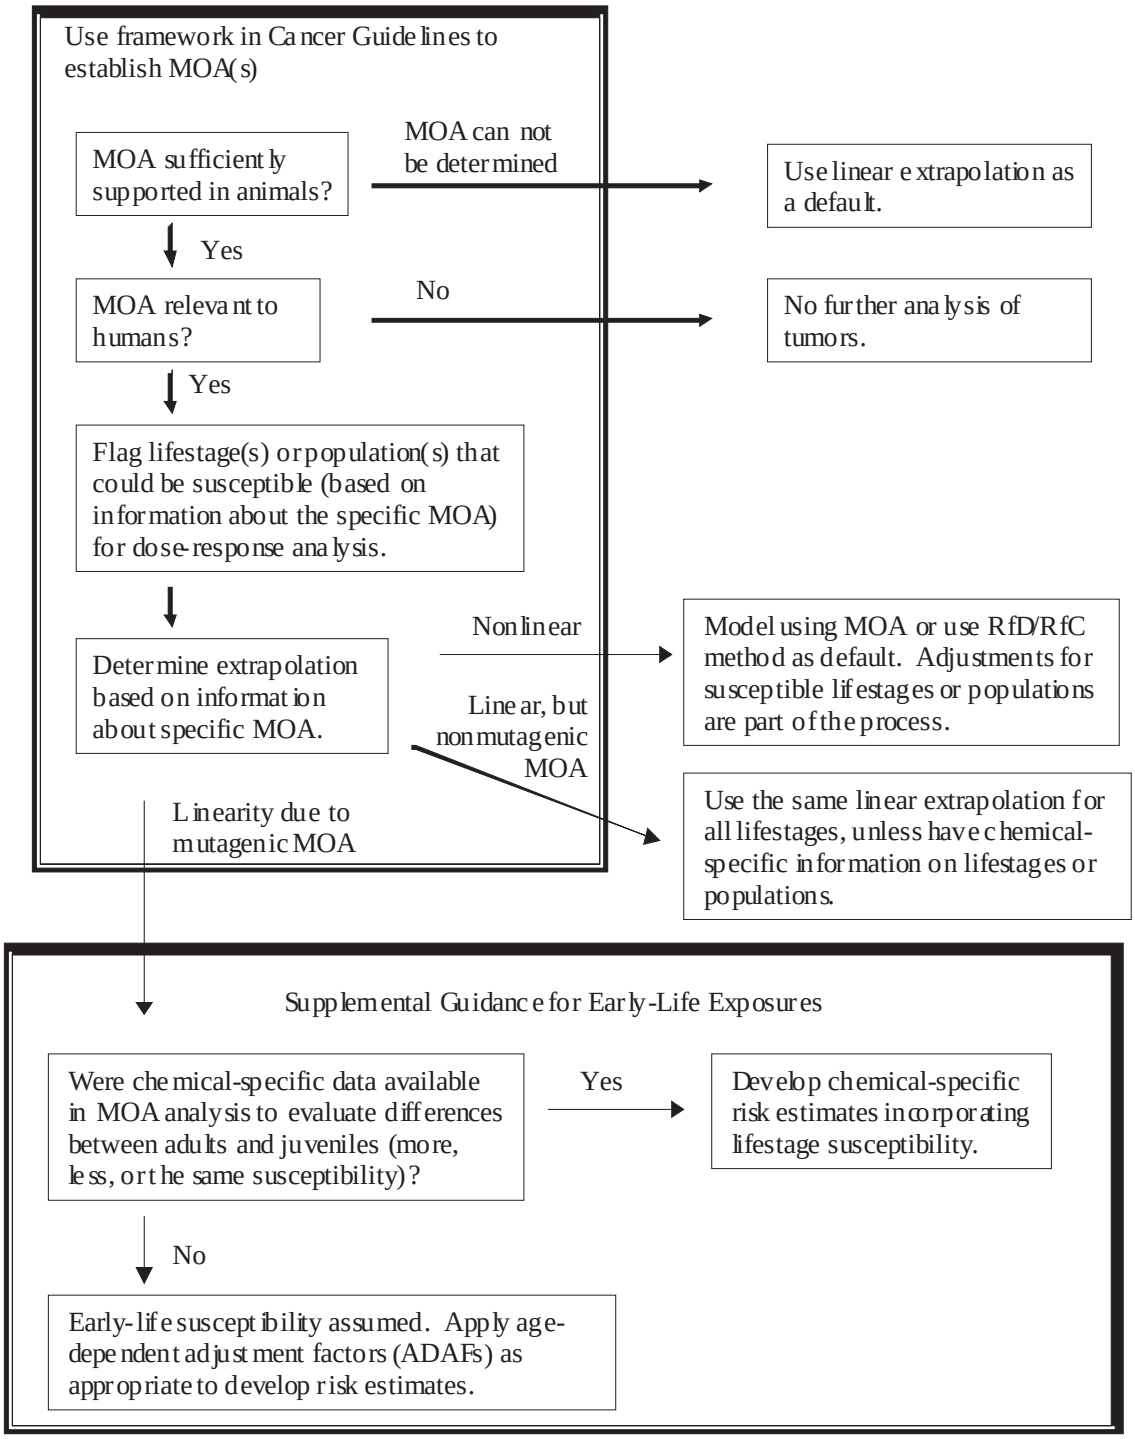
The Agency expects to produce additional supplemental guidance for other modes of action, as data from new research and toxicity testing indicate it is warranted. EPA intends to focus its research, and work collaboratively with its federal partners, to improve understanding of the implications of early life exposure to carcinogens. Development of guidance for estrogenic agents and chemicals acting through other processes resulting in endocrine disruption and subsequent carcinogenesis, for example, might be a reasonable priority in light of the human experience with diethylstilbesterol and the existing early life animal studies. It is worth noting that each mode of action for endocrine disruption will probably require separate analysis.

As the Agency examines additional carcinogenic agents, the age groupings may differ from those recommended for assessing cancer risks from early-life exposure to chemicals with a mutagenic mode of action. Puberty and its associated biological changes, for example, involve many biological processes that could lead to changes in sensitivity to the effects of some carcinogens, depending on their mode of action. The Agency is interested in identifying lifestages that may be particularly sensitive or refractory for carcinogenesis, and believes that the mode of action framework described in these cancer guidelines is an appropriate mechanism for elucidating these lifestages. For each additional mode of action evaluated, the various age groupings determined to be at differential risk may differ from those proposed in the Supplemental Guidance. For example, the age groupings selected for the age-dependent adjustments for carcinogens acting through a mutagenic mode of action were initially selected based on the available data, i.e., for the laboratory animal age range representative of birth to < 2 years in humans. More limited data and information on human biology were used to determine a science-informed policy regarding 2 to < 16 years. Data were not available to refine the latter age group. If more data become available regarding carcinogens with a mutagenic mode of action, consideration may be given to further refinement of these age groups.

1.3.7. Emphasis on Characterization

The cancer guidelines emphasize the importance of a clear and useful characterization narrative that summarizes the analyses of hazard, dose-response, and exposure assessment. These characterizations summarize the assessments to explain the extent and weight of evidence, major points of interpretation and rationale for their selection, strengths and weaknesses of the evidence and the analysis, and discuss alternative conclusions and uncertainties that deserve serious consideration (U.S. EPA, 2000b). They serve as starting materials for the overall risk characterization process that completes the risk assessment.

Figure 1-1. Flow chart for early-life risk assessment using mode of action framework.



2. HAZARD ASSESSMENT

2.1. OVERVIEW OF HAZARD ASSESSMENT AND CHARACTERIZATION

2.1.1. Analyses of Data

The purpose of hazard assessment is to review and evaluate data pertinent to two questions: (1) whether an agent may pose a carcinogenic hazard to human beings, and (2) under what circumstances an identified hazard may be expressed (NRC, 1994). Hazard assessment involves analyses of a variety of data that may range from observations of tumor responses to analysis of structure-activity relationships (SARs). The purpose of the assessment is not simply to assemble these separate evaluations; its purpose is to construct a total analysis examining what the biological data reveal as a whole about carcinogenic effects and mode of action of the agent, and their implications for human hazard and dose-response evaluation. Conclusions are drawn from weight-of-evidence evaluations based on the combined strength and coherence of inferences appropriately drawn from all of the available information. To the extent that data permit, hazard assessment addresses the question of mode of action of an agent as both an initial step in identifying human hazard potential and as a component in considering appropriate approaches to dose-response assessment.

The topics in this chapter include analysis of tumor data, both human and animal, and analysis of other key information about properties and effects that relate to carcinogenic potential. The chapter addresses how information can be used to evaluate potential modes of action. It also provides guidance on performing a weight of evidence evaluation.

2.1.2. Presentation of Results

Presentation of the results of hazard assessment should be informed by Agency guidance as discussed in Section 2.6. The results are presented in a technical hazard characterization that serves as a support to later risk characterization. It includes:

- a summary of the evaluations of hazard data,
- the rationales for its conclusions, and

- an explanation of the significant strengths or limitations of the conclusions.

Another presentation feature is the use of a weight of evidence narrative that includes both a conclusion about the weight of evidence of carcinogenic potential and a summary of the data on which the conclusion rests. This narrative is a brief summary that *in toto* replaces the alphanumerical classification system used in EPA's 1986 cancer guidelines (U.S. EPA, 1986a).

2.2. ANALYSIS OF TUMOR DATA

Evidence of carcinogenicity comes from finding tumor increases in humans or laboratory animals exposed to a given agent or from finding tumors following exposure to structural analogues to the compound under review. The significance of observed or anticipated tumor effects is evaluated in reference to all the other key data on the agent. This section contains guidance for analyzing human and animal studies to decide whether there is an association between exposure to an agent or a structural analogue and occurrence of tumors. Note that the use of the term "tumor" in these cancer guidelines is defined as malignant neoplasms or a combination of malignant and corresponding benign neoplasms.

Observation of only benign neoplasia may or may not have significance for evaluation under these cancer guidelines. Benign tumors that are not observed to progress to malignancy are assessed on a case-by-case basis. There is a range of possibilities for their overall significance. They may deserve attention because they are serious health problems even though they are not malignant; for instance, benign tumors may be a health risk because of their effect on the function of a target tissue such as the brain. They may be significant indicators of the need for further testing of an agent if they are observed in a short- term test protocol, or such an observation may add to the overall weight of evidence if the same agent causes malignancies in a long-term study. Knowledge of the mode of action associated with a benign tumor response may aid in the interpretation of other tumor responses associated with the same agent. In other cases, observation of a benign tumor response alone may have no significant health hazard implications when other sources of evidence show no suggestion of carcinogenicity.

2.2.1. Human Data

Human data may come from epidemiologic studies or case reports. (Clinical human studies, which involve intentional exposures to substances, may provide toxicokinetic data, but generally not data on carcinogenicity.) The most common sources of human data for cancer risk assessment are epidemiologic investigations. Epidemiology is the study of the distribution of disease in human populations and the factors that may influence that distribution. The goals of cancer epidemiology are to identify distribution of cancer risk and determine the extent to which the risk can be attributed causally to specific exposures to exogenous or endogenous factors (see Centers for Disease Control and Prevention [CDC, 2004]). Epidemiologic data are extremely valuable in risk assessment because they provide direct evidence on whether a substance is likely to produce cancer in humans, thereby avoiding issues such as: species-to-species inference, extrapolation to exposures relevant to people, effects of concomitant exposures due to lifestyles. Thus, epidemiologic studies typically evaluate agents under more relevant conditions. When human data of high quality and adequate statistical power are available, they are generally preferable over animal data and should be given greater weight in hazard characterization and dose-response assessment, although both can be used.

Null results from epidemiologic studies alone generally do not prove the absence of carcinogenic effects because such results can arise either from an agent being truly not carcinogenic or from other factors such as: inadequate statistical power, inadequate study design, imprecise estimates, or confounding factors. Moreover, null results from a well-designed and well-conducted epidemiologic study that contains usable exposure data can help to define upper limits for the estimated dose of concern for human exposure in cases where the overall weight of the evidence indicates that the agent is potentially carcinogenic in humans. Furthermore, data from a well designed and well conducted epidemiologic study that does not show positive results, in conjunction with compelling mechanistic information, can lend support to a conclusion that animal responses may not be predictive of a human cancer hazard.

Epidemiology can also complement experimental evidence in corroborating or clarifying the carcinogenic potential of the agent in question. For example, epidemiologic studies that show elevated cancer risk for tumor sites corresponding to those at which laboratory animals

experience increased tumor incidence can strengthen the weight of evidence of human carcinogenicity. Furthermore, biochemical or molecular epidemiology may help improve understanding of the mechanisms of human carcinogenesis.

2.2.1.1. *Assessment of Evidence of Carcinogenicity from Human Data*

All studies that are considered to be of acceptable quality, whether yielding positive or null results, or even suggesting protective carcinogenic effects, should be considered in assessing the totality of the human evidence. Conclusions about the overall evidence for carcinogenicity from available studies in humans should be summarized along with a discussion of uncertainties and gaps in knowledge. Conclusions regarding the strength of the evidence for positive or negative associations observed, as well as evidence supporting judgments of causality, should be clearly described. In assessing the human data within the overall weight of evidence, determination about the strength of the epidemiologic evidence should clearly identify the degree to which the observed associations may be explained by other factors, including bias or confounding.

Characteristics that are generally desirable in epidemiologic studies include (1) clear articulation of study objectives or hypothesis; (2) proper selection and characterization of comparison groups (exposed and unexposed groups or case and control groups); (3) adequate characterization of exposure; (4) sufficient length of follow-up for disease occurrence; (5) valid ascertainment of the causes of cancer morbidity and mortality; (6) proper consideration of bias and confounding factors; (7) adequate sample size to detect an effect; (8) clear, well-documented, and appropriate methodology for data collection and analysis; (9) adequate response rate and methodology for handling missing data; and (10) complete and clear documentation of results. No single criterion determines the overall adequacy of a study. Practical and resource constraints may limit the ability to address all of these characteristics in a study. The risk assessor is encouraged to consider how the limitations of the available studies might influence the conclusions. While positive biases may be due, for example, to a healthy worker effect, it is also important to consider negative biases, for example, workers who may leave the workforce due to illness caused either by high exposures to the agent or to effects of confounders such as smoking.

The following discussions highlight the major factors included in an analysis of epidemiologic studies.

2.2.1.2. *Types of Studies*

The major types of cancer epidemiologic study designs used for examining environmental causes of cancer are analytical studies and descriptive studies. Each study type has well-known strengths and weaknesses that affect interpretation of results, as summarized below (Lilienfeld and Lilienfeld, 1979; Mausner and Kramer, 1985; Kelsey et al., 1996; Rothman and Greenland, 1998).

Analytical epidemiologic studies, which include case-control and cohort designs, are generally relied on for identifying a causal association between human exposure and adverse health effects. In case-control studies, groups of individuals with (cases) and without (controls) a particular disease are identified and compared to determine differences in exposure. In cohort studies, a group of "exposed" and "nonexposed" individuals are identified and studied over time to determine differences in disease occurrence. Cohort studies can be performed either prospectively or retrospectively from historical records. The type of study chosen may depend on the hypothesis to be evaluated. For example, case-control studies may be more appropriate for rare cancers while cohort studies may be more appropriate for more commonly occurring cancers.

On the other hand, descriptive epidemiologic studies examine symptom or disease rates among populations in relation to personal characteristics such as age, gender, race, and temporal or environmental conditions. Descriptive studies are most frequently used to generate hypotheses about exposure factors, but subsequent analytical designs are necessary to infer causality. For example, cross-sectional designs might be used to compare the prevalence of cancer between areas near and far from a Superfund site. However, in studies where exposure and disease information applies only to the current conditions, it is not possible to infer that the exposure actually *caused* the disease. Therefore, these studies are used to identify patterns or trends in disease occurrence over time or in different geographical locations, but typical

limitations in the characterization of populations in these studies make it difficult to infer the causal agent or degree of exposure.

Case reports describe a particular effect in an individual or group of individuals who were exposed to a substance. These reports are often anecdotal or highly selective in nature and generally are of limited use for hazard assessment. Specifically, cancer causality can rarely be inferred from case reports alone. Investigative follow-up may or may not accompany such reports. For cancer, the most common types of case series are associated with occupational and childhood exposures. Case reports can be particularly valuable for identifying unique features, such as an association with an uncommon tumor (e.g., inhalation of vinyl chloride and hepatic angiosarcoma in workers or ingestion of diethylstilbestrol by mothers and clear-cell carcinoma of the vagina in offspring).

2.2.1.3. ***Exposure Issues***.

For epidemiologic data to be useful in determining whether there is an association between health effects and exposure to an agent, there should be adequate characterization of exposure information. In general, greater weight should be given to studies with more precise and specific exposure estimates.

Questions to address about exposure are: What can one reliably conclude about the exposure parameters including (but not limited to) the level, duration, route, and frequency of exposure of individuals in one population as compared with another? How sensitive are study results to uncertainties in these parameters?

Actual exposure measurements are not available for many retrospective studies. Therefore, surrogates are often used to reconstruct exposure parameters. These may involve attributing exposures to job classifications in a workplace or to broader occupational or geographic groupings. Use of surrogates carries a potential for misclassification, i.e., individuals may be placed in an incorrect exposure group. Misclassification generally leads to reduced ability of a study to detect differences between study and referent populations.

When either current or historical monitoring data are available, the exposure evaluation includes consideration of the error bounds of the monitoring and analytic methods and whether

the data are from routine or accidental exposures. The potential for misclassification and for measurement errors is amenable to both qualitative and quantitative analysis. These are essential analyses for judging a study's results, because exposure estimation is the most critical part of a retrospective study.

2.2.1.4. *Biological Markers*.

Biological markers potentially offer excellent measures of exposure (Hulka and Margolin, 1992; Peto and Darby, 1994). In some cases, molecular or cellular effects (e.g., DNA or protein adducts, mutation, chromosomal aberrations, levels of thyroid-stimulating hormone) can be measured in blood, body fluids, cells, and tissues to serve as biomarkers of exposure in humans and animals (Callemen et al., 1978; Birner et al., 1990). As such, they can act as an internal surrogate measure of chemical dose, representing, as appropriate, either recent exposure (e.g., serum concentration) or accumulated exposure over some period (e.g., hemoglobin adducts). Validated markers of exposure such as alkylated hemoglobin from exposure to ethylene oxide (Van Sittert et al., 1985) or urinary arsenic (Enterline et al., 1987) can improve estimates of dose over the relevant time periods for the markers. Markers closely identified with effects promise to greatly increase the ability of studies to distinguish real effects from bias at low levels of relative risk between populations (Taylor et al., 1994; Biggs et al., 1993) and to resolve problems of confounding risk factors. However, when using molecular or cellular effects as biomarkers of exposure, since many of these changes are often not specific to just one type of exposure, it is important to be aware that changes may be due to exposures unrelated to the exposure of interest and attention must be paid to controlling for potential confounders.

Biochemical or molecular epidemiologic studies may use biological markers of effect as indicators of disease or its precursors. The application of techniques for measuring cellular and molecular alterations due to exposure to specific environmental agents may allow conclusions to be drawn about the mechanisms of carcinogenesis (see section 2.4 for more information on this topic).

2.2.1.5. ***Confounding Factors***.

Control for potential confounding factors is an important consideration in the evaluation of the design and in the analysis of observational epidemiologic studies. A confounder is a variable that is related to both the health outcome of concern (cancer) and exposure. Common examples include age, socioeconomic status, smoking habits, and diet. For instance, if older people are more likely to be exposed to a given contaminant as well as more likely to have cancer because of their age, age is considered a confounder. Adjustment for potentially confounding factors (from a statistical as contrasted with an epidemiologic point of view) can occur either in the design of the study (e.g., individual or group matching on critical factors) or in the statistical analysis of the results (stratification or direct or indirect adjustment). Direct adjustment in the statistical analysis may not be possible owing to the presentation of the data or because needed information was not collected during the study. In this case, indirect comparisons may be possible. For example, in the absence of data on smoking status among individuals in the study population, an examination of the possible contribution of cigarette smoking to increased lung cancer risk may be based on information from other sources, such as the American Cancer Society's longitudinal studies (Hammand, 1966; Garfinkel and Silverberg, 1991). The effectiveness of adjustments contributes to the ability to draw inferences from a study.

Different studies involving exposure to an agent may have different confounding factors. If consistent increases in cancer risk are observed across a collection of studies with different confounding factors, the inference that the agent under investigation was the etiologic factor is strengthened.

There may also be instances where the agent of interest is a risk factor in conjunction with another agent. For instance, interaction as well as effect-measure modification are sometimes construed to be confounding, but they are different than confounding. Interaction is described as a situation in which two or more risk factors modify the effect of each other with regard to the occurrence of a given effect. This phenomenon is sometimes described as effect-measure modification or heterogeneity of effect (Szklo and Nieto, 2000). Effect-measure modification refers to variation in the magnitude of measure exposure effect across levels of another variable (Rothman and Greenland, 1998). The variable across which the effect measure varies and is

called an *effect modifier* (e.g., hepatitis virus B and aflatoxin in hepatic cancer). Interaction, on the other hand, means effect of the exposure on the outcome differs, depending on the presence of another variable (the effect modifier). When the effect of the exposure of interest is accentuated by another variable, it is said to be synergistic interaction. Synergistic interaction can be additive (e.g., hepatitis virus B and aflatoxin in hepatic cancer) or multiplicative (e.g., asbestos and smoking in lung cancer). If the effect of exposure is diminished or eliminated by another variable, it said to be antagonistic interaction (e.g., intake of vitamin E and lower occurrence of lung cancer).

2.2.1.6. ***Statistical Considerations***.

The analysis should apply appropriate statistical methods to ascertain whether the observed association between exposure and effects would be expected by chance. A description of the method or methods used should include the reasons for their selection. Statistical analyses of the bias, confounding, and interaction are part of addressing the significance of an association and the power of a study to detect an effect.

The analysis augments examination of the results for the whole population with exploration of the results for groups with comparatively greater exposure or time since first exposure. This may support identifying an association or establishing a dose-response trend. When studies show no association, such exploration may apply to determining an upper limit on potential human risk for consideration alongside results of animal tumor effects studies.

2.2.1.6.1. ***Likelihood of observing an effect***. The power of a study – the likelihood of observing an effect if one exists – increases with sample size, i.e., the number of subjects studied from a population. (For example, a quadrupling of a background rate in the 1 per 10,000 range would require more subjects who have experienced greater or longer exposure or lengthier follow-up, than a doubling of a background rate in the 1 per 100 range.) If the size of the effect is expected to be very small at low doses, higher doses or longer durations of exposure may be needed to have an appreciable likelihood of observing an effect with a given sample size. Because of the often long latency period in cancer development, the likelihood of observing an effect also

depends on whether adequate time has elapsed since exposure began for effects to occur. Since the design of the study and the choice of analysis, as well as the design level of certainty in the results and the magnitude of response in an unexposed population also affect the likelihood of observing an effect, it is important to carefully interpret the absence of an observed effect. A unique feature that can be ascribed to the effects of a particular agent (such as a tumor type that is seen only rarely in the absence of the agent) can increase sensitivity by permitting separation of bias and confounding factors from real effects. Similarly, a biomarker particular to the agent can permit these distinctions. Statistical re-analyses of data, particularly an examination of different exposure indices, can give insight into potential exposure-response relationships. These are all factors to explore in statistical analysis of the data.

2.2.1.6.2. ***Sampling and other bias issues.*** When comparing cases and controls or exposed and non-exposed populations, it would be preferable for the two populations to differ only in exposure to the agent in question. Because this is seldom the case, it is important to identify sources of sampling and other potential biases inherent in a study design or data collection methods.

Bias is a systematic error. In epidemiologic studies, bias can occur in the selection of cases and controls or exposed and non-exposed populations, as well as the follow up of the groups, or the classification of disease or exposure. The size of the risks observed can be affected by noncomparability between populations of factors such as general health, diet, lifestyle, or geographic location; differences in the way case and control individuals recall past events; differences in data collection that result in unequal ascertainment of health effects in the populations; and unequal follow-up of individuals (Rothman and Greenland, 1998). Other factors worth consideration can be inherent in the available cohorts, e.g., use of occupational studies (the healthy worker effect), absence of one sex, or limitations in sample size for one or more ethnicities.

The mere presence of biases does not invalidate a study, but should be reflected in the judgment of its strengths or weaknesses. Acceptance of studies for assessment depends on identifying their sources of bias and the possible effects on study results.

2.2.1.6.3. ***Combining statistical evidence across studies***. Meta-analysis is a means of integrating the results of multiple studies of similar health effects and risk factors. This technique is particularly useful when various studies yield varying degrees of risk or even conflicting associations (negative and positive). It is intended to introduce consistency and comprehensiveness into what otherwise might be a more subjective review of the literature. The value of such an analysis is dependent upon a systematic review of the literature that uses transparent criteria of inclusion and exclusion. In interpreting such analyses, it is important to consider the effects of differences in study quality, as well as the effect of publication bias. Meta-analysis may not be advantageous in some circumstances. These include when the relationship between exposure and disease is obvious from the individual studies; when there are only a few studies of the key health outcomes; when there is insufficient information from available studies related to disease, risk estimate, or exposure classification to insure comparability; or when there are substantial confounding or other biases that cannot be adjusted for in the analysis (Blair et al., 1995; Greenland, 1987; Peto, 1992).

2.2.1.7. ***Evidence for Causality***

Determining whether an observed association (risk) is causal rather than spurious involves consideration of a number of factors. Sir Bradford Hill (Hill, 1965) developed a set of guidelines for evaluating epidemiologic associations that can be used in conjunction with the discussion of causality such as the 2004 Surgeon General's report on smoking (CDC, 2004) and in other documents (e.g., Rothman and Greenland 1998; IPCS, 1999) . The critical assessment of epidemiologic evidence is conceptually based upon consideration of salient aspects of the evidence of associations so as to reach fundamental judgments as to the likely causal significance of the observed associations. In so doing, it is appropriate to draw from those aspects initially presented in Hill's classic monograph (Hill, 1965) and widely used by the scientific community in conducting such evidence-based reviews. A number of these aspects are judged to be particularly salient in evaluating the body of evidence available in this review, including the aspects described by Hill as strength, experiment, consistency, plausibility, and coherence. Other aspects identified by Hill, including temporality and biological gradient, are also relevant and

considered here (e.g., in characterizing lag structures and concentration-response relationships), but are more directly addressed in the design and analyses of the individual epidemiologic studies included in this assessment. As discussed below, these salient aspects are interrelated and considered throughout the evaluation of the epidemiologic evidence generally reflected in the integrative synthesis of the mode of action framework.

The general evaluation of the strength of the epidemiological evidence reflects consideration not only of the magnitude of reported effects estimates and their statistical significance, but also of the precision of the effects estimates and the robustness of the effects associations. Consideration of the robustness of the associations takes into account a number of factors, including in particular the impact of alternative models and model specifications and potential confounding factors, as well issues related to the consequences of measurement error. Consideration of the consistency of the effects associations involves looking across the results of studies conducted by different investigators in different places and times. Particular weight may be given, consistent with Hill's views, to the presence of "similar results reached in quite different ways, e.g., prospectively and retrospectively" (Hill, 1965). Looking beyond the epidemiological evidence, evaluation of the biological plausibility of the associations observed in epidemiologic studies reflects consideration of both exposure-related factors and toxicological evidence relevant to identification of potential modes of action (MOAs). Similarly, consideration of the coherence of health effects associations reported in the epidemiologic literature reflects broad consideration of information pertaining to the nature of the biological markers evaluated in toxicologic and epidemiologic studies.

In identifying these aspects as being particularly salient in this assessment, it is also important to recognize that no one aspect is either necessary or sufficient for drawing inferences of causality. As Hill (1965) emphasized:

> "None of my nine viewpoints can bring indisputable evidence for or against the cause-and-effect hypothesis and none can be required as *a sine qua non*. What they can do, with greater or less strength, is to help us to make up our minds on the fundamental question — is there any other way of explaining the set of facts

> before us, is there any other answer equally, or more, likely than cause and effect?"

While these aspects frame considerations weighed in assessing the epidemiologic evidence, they do not lend themselves to being considered in terms of simple formulas or hard-and-fast rules of evidence leading to answers about causality (Hill, 1965). One, for example, cannot simply count up the numbers of studies reporting statistically significant results or statistically non-significant results for carcinogenesis and related MOAs and reach credible conclusions about the relative strength of the evidence and the likelihood of causality. Rather, these important considerations are taken into account throughout the assessment with a goal of producing an objective appraisal of the evidence (informed by peer and public comment and advice), which includes the weighing of alternative views on controversial issues. Thus, although these guidelines have become known as "causal criteria," it is important to note that they cannot be used as a strictly quantitative checklist. Rather, these "criteria" should be used to determine the strength of the evidence for concluding causality. In particular, the absence of one or more of the "criteria" does not automatically exclude a study from consideration (e.g., see discussion in CDC, 2004). The list below has been adapted from Hill's guidelines as an aid in judging causality.

(a) Consistency of the observed association. An inference of causality is strengthened when a pattern of elevated risks is observed across several independent studies. The reproducibility of findings constitutes one of the strongest arguments for causality. If there are discordant results among investigations, possible reasons such as differences in exposure, confounding factors, and the power of the study are considered.

(b) Strength of the observed association. The finding of large, precise risks increases confidence that the association is not likely due to chance, bias, or other factors. A modest risk, however, does not preclude a causal association and may reflect a lower level of exposure, an agent of lower potency, or a common disease with a high background level.

(c) Specificity of the observed association. As originally intended, this refers to increased inference of causality if one cause is associated with a single effect or disease (Hill, 1965). Based on our current understanding that many agents cause cancer at multiple sites, and

many cancers have multiple causes, this is now considered one of the weaker guidelines for causality. Thus, although the presence of specificity may support causality, its absence does not exclude it.

(d) Temporal relationship of the observed association. A causal interpretation is strengthened when exposure is known to precede development of the disease. Because a latent period of up to 20 years or longer is often associated with cancer development in adults, the study should consider whether exposures occurred sufficiently long ago to produce an effect at the time the cancer is assessed. This is among the strongest criteria for an inference of causality.

(e) Biological gradient (exposure-response relationship). A clear exposure-response relationship (e.g., increasing effects associated with greater exposure) strongly suggests cause and effect, especially when such relationships are also observed for duration of exposure (e.g., increasing effects observed following longer exposure times). There are many possible reasons that an epidemiologic study may fail to detect an exposure-response relationship. For example, an analysis that included decreasing exposures due to improved technology that is combined with higher prior exposure in an initial analysis can require a segmented analysis to apportion exposure. Other reasons for failure to detect a relationship may include a small range of exposures. Thus, the absence of an exposure-response relationship does not exclude a causal relationship.

(f) Biological plausibility. An inference of causality tends to be strengthened by consistency with data from experimental studies or other sources demonstrating plausible biological mechanisms. A lack of mechanistic data, however, is not a reason to reject causality.

(g) Coherence. An inference of causality may be strengthened by other lines of evidence that support a cause-and-effect interpretation of the association. Information is considered from animal bioassays, toxicokinetic studies, and short-term studies. The absence of other lines of evidence, however, is not a reason to reject causality.

(h) Experimental evidence (from human populations). Experimental evidence is seldom available from human populations and exists only when conditions of human exposure have occurred to create a “natural experiment” at different levels of exposure. Strong evidence

for causality can be provided when a change in exposure brings about a change in disease frequency, for example, the decrease in the risk of lung cancer that follows cessation of smoking.

(i) Analogy. SARs and information on the agent's structural analogues can provide insight into whether an association is causal. Similarly, information on mode of action for a chemical, as one of many structural analogues, can inform decisions regarding likely causality.

2.2.2. Animal Data

Various whole-animal test systems are currently used or are under development for evaluating potential carcinogenicity. Cancer studies involving chronic exposure for most of the lifespan of an animal are generally accepted for evaluation of tumor effects (Tomatis et al., 1989; Rall, 1991; Allen et al., 1988; but see Ames and Gold, 1990). Other studies of special design are useful for observing formation of preneoplastic lesions or tumors or investigating specific modes of action. Their applicability is determined on a case-by-case basis.

2.2.2.1. *Long-term Carcinogenicity Studies*

The objective of long-term carcinogenesis bioassays is to determine the potential carcinogenic hazard and dose-response relationships of the test agent. Carcinogenicity rodent studies are designed to examine the production of tumors as well as preneoplastic lesions and other indications of chronic toxicity that may provide evidence of treatment-related effects and insights into the way the test agent produces tumors. Current standardized carcinogenicity studies in rodents test at least 50 animals per sex per dose group in each of three treatment groups and in a concurrent control group, usually for 18 to 24 months, depending on the rodent species tested (OECD, 1981; U.S. EPA, 1998c). The high dose in long-term studies is generally selected to provide the maximum ability to detect treatment-related carcinogenic effects while not compromising the outcome of the study through excessive toxicity or inducing inappropriate toxicokinetics (e.g., overwhelming absorption or detoxification mechanisms). The purpose of two or more lower doses is to provide some information on the shape of the dose-response curve. Similar protocols have been and continue to be used by many laboratories worldwide.

All available studies of tumor effects in whole animals should be considered, at least preliminarily. The analysis should discard studies judged to be wholly inadequate in protocol, conduct, or results. Criteria for the technical adequacy of animal carcinogenicity studies have been published and should be used as guidance to judge the acceptability of individual studies (e.g., NTP, 1984; OSTP, 1985; Chhabra et al., 1990). As these criteria, in whole or in part, may be updated by the National Toxicology Program (NTP) and others, the analyst should consult the appropriate sources to determine both the current standards as well as those that were contemporaneous with the study. Care should be taken to include studies that provide some evidence bearing on carcinogenicity or that help interpret effects noted in other studies, even if these studies have some limitations of protocol or conduct. Such limited, but not wholly inadequate, studies can contribute as their deficiencies permit. The findings of long-term rodent bioassays should be interpreted in conjunction with results of prechronic studies along with toxicokinetic studies and other pertinent information, if available. Evaluation of tumor effects takes into consideration both biological and statistical significance of the findings (Haseman, 1984, 1985, 1990, 1995). The following sections highlight the major issues in the evaluation of long-term carcinogenicity studies.

2.2.2.1.1. ***Dosing issues***. Among the many criteria for technical adequacy of animal carcinogenicity studies is the appropriateness of dose selection. The selection of doses for chronic bioassays is based on scientific judgments and sound toxicologic principles. Dose selection should be made on the basis of relevant toxicologic information from prechronic, mechanistic, and toxicokinetic and mechanistic studies. A scientific rationale for dose selection should be clearly articulated (e.g., NTP, 1984; ILSI, 1997). How well the dose selection is made is evaluated after the completion of the bioassay.

Interpretation of carcinogenicity study results is profoundly affected by study exposure conditions, especially by inappropriate dose selection. This is particularly important in studies that do not show positive results for carcinogenicity, because failure to use a sufficiently high dose reduces the sensitivity of the studies. A lack of tumorigenic responses at exposure levels that cause significant impairment of animal survival may also not be acceptable. In addition,

overt toxicity or qualitatively altered toxicokinetics due to excessively high doses may result in tumor effects that are secondary to the toxicity rather than directly attributable to the agent.

With regard to the appropriateness of the high dose, an adequate high dose would generally be one that produces some toxic effects without unduly affecting mortality from effects other than cancer or producing significant adverse effects on the nutrition and health of the test animals (OECD, 1981; NRC, 1993a). If the test agent does not appear to cause any specific target organ toxicity or perturbation of physiological function, an adequate high dose can be specified in terms of a percentage reduction of body weight gain over the lifespan of the animals. The high dose would generally be considered inadequate if neither toxicity nor change in weight gain is observed. On the other hand, significant increases in mortality from effects other than cancer generally indicate that an adequate high dose has been exceeded.

Other signs of treatment-related toxicity associated with an excessive high dose may include (a) significant reduction of body weight gain (e.g., greater than 10%), (b) significant increases in abnormal behavioral and clinical signs, (c) significant changes in hematology or clinical chemistry, (d) saturation of absorption and detoxification mechanisms, or (e) marked changes in organ weight, morphology, and histopathology. It should be noted that practical upper limits have been established to avoid the use of excessively high doses in long-term carcinogenicity studies of environmental chemicals (e.g., 5% of the test substance in the feed for dietary studies or 1 g/kg body weight for oral gavage studies [OECD, 1981]).

For dietary studies, weight gain reductions should be evaluated as to whether there is a palatability problem or an issue with food efficiency; certainly, the latter is a toxic manifestation. In the case of inhalation studies with respirable particles, evidence of impairment of normal clearance of particles from the lung should be considered along with other signs of toxicity to the respiratory airways to determine whether the high exposure concentration has been appropriately selected (U.S. EPA, 2001a). For dermal studies, evidence of skin irritation may indicate that an adequate high dose has been reached (U.S. EPA, 1989).

In order to obtain the most relevant information from a long-term carcinogenicity study, it is important to maximize exposure conditions to the test material. At the same time, caution is appropriate in using excessive high-dose levels that would confound the interpretation of study

results to humans. The middle and lowest doses should be selected to characterize the shape of the dose-response curve as much as possible. It is important that the doses be adequately spaced so that the study can provide relevant dose-response data for assessing human hazard and risk. If the testing of potential carcinogenicity is being combined with an evaluation of noncancer chronic toxicity, the study should be designed to include one dose in addition to the control(s) that is not expected to elicit adverse effects.

There are several possible outcomes regarding the study interpretation of the significance and relevance of tumorigenic effects associated with exposure or dose levels below, at, or above an adequate high dose. The general guidance is given here; for each case, the information at hand should be evaluated and a rationale should be given for the position taken.

- *Adequately high dose.* If an adequately high dose has been used, tumor effects are judged positive or negative depending on the presence or absence of significant tumor incidence increases, respectively.

- *Excessively high dose.* If toxicity or mortality is excessive at the high dose, interpretation depends on whether or not tumors are found.

  – Studies that show tumor effects only at excessive doses may be compromised and may or may not carry weight, depending on the interpretation in the context of other study results and other lines of evidence. Results of such studies, however, are generally not considered suitable for dose-response extrapolation if it is determined that the mode(s) of action underlying the tumorigenic responses at high doses is not operative at lower doses.

  – Studies that show tumors at lower doses, even though the high dose is excessive and may be discounted, should be evaluated on their own merits.

- If a study does not show an increase in tumor incidence at a toxic high dose and appropriately spaced lower doses are used without such toxicity or tumors, the study is generally judged as negative for carcinogenicity.

- *Inadequately high dose*. Studies of inadequate sensitivity where an adequately high dose has not been reached may be used to bound the dose range where carcinogenic effects might be expected.

2.2.2.1.2. ***Statistical considerations***. The main aim of statistical evaluation is to determine whether exposure to the test agent is associated with an increase of tumor development. Statistical analysis of a long-term study should be performed for each tumor type separately. The incidence of benign and malignant lesions of the same cell type, usually within a single tissue or organ, are considered separately but may be combined when scientifically defensible (McConnell et al., 1986).

Trend tests and pairwise comparison tests are the recommended tests for determining whether chance, rather than a treatment-related effect, is a plausible explanation for an apparent increase in tumor incidence. A trend test such as the Cochran-Armitage test (Snedecor and Cochran, 1967) asks whether the results in all dose groups together increase as dose increases. A pairwise comparison test such as the Fisher exact test (Fisher, 1950) asks whether an incidence in one dose group is increased over that of the control group. By convention, for both tests a statistically significant comparison is one for which p is less than 0.05 that the increased incidence is due to chance. Significance in either kind of test is sufficient to reject the hypothesis that chance accounts for the result.

A statistically significant response may or may not be biologically significant and vice versa. The selection of a significance level is a policy choice based on a trade-off between the risks of false positives and false negatives. A result with a significance level of greater or less than 5% (the most common significance level) is examined to see if the result confirms other scientific information. When the assessment departs from a simple 5% level, this should be

highlighted in the risk characterization. A two-tailed test or a one-tailed test can be used. In either case a rationale is provided.

Statistical power can affect the likelihood that a statistically significant result could reasonably be expected. This is especially important in studies or dose groups with small sample sizes or low dose rates. Reporting the statistical power can be useful for comparing and reconciling positive and negative results from different studies.

Considerations of multiple comparisons should also be taken into account. Haseman (1983) analyzed typical animal bioassays that tested both sexes of two species and concluded that, because of multiple comparisons, a single tumor increase for a species-sex-site combination that is statistically significant at the 1% level for common tumors or 5% for rare tumors corresponds to a 7–8% significance level for the study as a whole. Therefore, animal bioassays presenting only one significant result that falls short of the 1% level for a common tumor should be treated with caution.

2.2.2.1.3. ***Concurrent and historical controls*****.** The standard for determining statistical significance of tumor incidence comes from a comparison of tumors in dosed animals with those in concurrent control animals. Additional insights about both statistical and biological significance can come from an examination of historical control data (Tarone, 1982; Haseman, 1995). Historical control data can add to the analysis, particularly by enabling identification of uncommon tumor types or high spontaneous incidence of a tumor in a given animal strain. Identification of common or uncommon situations prompts further thought about the meaning of the response in the current study in context with other observations in animal studies and with other evidence about the carcinogenic potential of the agent. These other sources of information may reinforce or weaken the significance given to the response in the hazard assessment. Caution should be exercised in simply looking at the ranges of historical responses, because the range ignores differences in survival of animals among studies and is related to the number of studies in the database.

In analyzing results for uncommon tumors in a treated group that are not statistically significant in comparison with concurrent controls, the analyst may be informed by the

experience of historical controls to conclude that the result is in fact unlikely to be due to chance. However, caution should be used in interpreting results. In analyzing results for common tumors, a different set of considerations comes into play. Generally speaking, statistically significant increases in tumors should not be discounted simply because incidence rates in the treated groups are within the range of historical controls or because incidence rates in the concurrent controls are somewhat lower than average. Random assignment of animals to groups and proper statistical procedures provide assurance that statistically significant results are unlikely to be due to chance alone. However, caution should be used in interpreting results that are barely statistically significant or in which incidence rates in concurrent controls are unusually low in comparison with historical controls.

In cases where there may be reason to discount the biological relevance to humans of increases in common animal tumors, such considerations should be weighed on their own merits and clearly distinguished from statistical concerns.

When historical control data are used, the discussion should address several issues that affect comparability of historical and concurrent control data, such as genetic drift in the laboratory strains, differences in pathology examination at different times and in different laboratories (e.g., in criteria for evaluating lesions; variations in the techniques for the preparation or reading of tissue samples among laboratories), and comparability of animals from different suppliers. The most relevant historical data come from the same laboratory and the same supplier and are gathered within 2 or 3 years one way or the other of the study under review; other data should be used only with extreme caution.

2.2.2.1.4. ***Assessment of evidence of carcinogenicity from long-term animal studies***. In general, observation of tumors under different circumstances lends support to the significance of the findings for animal carcinogenicity. Significance is generally increased by the observation of more of the factors listed below. For a factor such as malignancy, the severity of the observed pathology can also affect the significance. The following observations add significance to the tumor findings:

- uncommon tumor types;
- tumors at multiple sites;
- tumors by more than one route of administration;
- tumors in multiple species, strains, or both sexes;
- progression of lesions from preneoplastic to benign to malignant;
- reduced latency of neoplastic lesions;
- metastases;
- unusual magnitude of tumor response;
- proportion of malignant tumors; and
- dose-related increases.

In these cancer guidelines, tumors observed in animals are generally assumed to indicate that an agent may produce tumors in humans. Mode of action may help inform this assumption on a chemical-specific basis. Moreover, the absence of tumors in well-conducted, long-term animal studies in at least two species provides reasonable assurance that an agent may not be a carcinogenic concern for humans.

2.2.2.1.5. ***Site concordance*****.** Site concordance of tumor effects between animals and humans should be considered in each case. Thus far, there is evidence that growth control mechanisms at the level of the cell are homologous among mammals, but there is no evidence that these mechanisms are site concordant. Moreover, agents observed to produce tumors in both humans and animals have produced tumors either at the same site (e.g., vinyl chloride) or different sites (e.g., benzene) (NRC, 1994). Hence, site concordance is not always assumed between animals and humans. On the other hand, certain modes of action with consequences for particular tissue sites (e.g., disruption of thyroid function) may lead to an anticipation of site concordance.

2.2.2.2. ***Perinatal Carcinogenicity Studies***

The objective of perinatal carcinogenesis studies is to determine the carcinogenic potential and dose-response relationships of the test agent in the developing organism. Some

investigators have hypothesized that the age of initial exposure to a chemical carcinogen may influence the carcinogenic response (Vesselinovitch et al., 1979; Rice, 1979; McConnell, 1992). Current standardized long-term carcinogenesis bioassays generally begin dosing animals at 6–8 weeks of age and continue dosing for the lifespan of the animal (18–24 months). This protocol has been modified in some cases to investigate the potential of the test agent to induce transplacental carcinogenesis or to investigate the potential differences following perinatal and adult exposures, but currently there is not a standardized protocol for testing agents for carcinogenic effects following prenatal or early postnatal exposure.

Several cancer bioassay studies have compared adult and perinatal exposures (see McConnell, 1992; U.S. EPA, 1996b). A review of these studies reveals that perinatal exposure rarely identifies carcinogens that are not found in standard animal bioassays. Exposure that is perinatal can increase the incidence of a given type of tumor. The increase may reflect an increased length of exposure and a higher dose for the developing organism relative to the adult or an increase in susceptibility in some cases. Additionally, exposure that is perinatal through adulthood sometimes reduces the latency period for tumors to develop in the growing organism (U.S. EPA, 1996b). EPA evaluates the usefulness of perinatal studies on an agent-by-agent basis (e.g., U.S. EPA, 1997a, b).

Perinatal study data analysis generally follows the principles discussed above for evaluating other long-term carcinogenicity studies. When differences in responses between perinatal animals and adult animals suggest an increased susceptibility of perinatal or postnatal animals, such as the ones below, a separate evaluation of the response should be prepared:

- a difference in dose-response relationship,
- the presence of different tumor types,
- an earlier onset of tumors, or
- an increase in the incidence of tumors.

2.2.2.3. *Other Studies*

Intermediate-term and acute dosing studies often use protocols that screen for carcinogenic or preneoplastic effects, sometimes in a single tissue. Some protocols involve the development of various proliferative lesions, such as foci of alteration in the liver (Goldsworthy et al., 1986). Others use tumor endpoints, such as the induction of lung adenomas in the sensitive strain A mouse (Maronpot et al., 1986) or tumor induction in initiation-promotion studies using various organs such as the bladder, intestine, liver, lung, mammary gland, and thyroid (Ito et al., 1992). In these tests, the selected tissue rather than the whole animal is, in a sense, the test system. Important information concerning the steps in the carcinogenic process and mode of action can be obtained from "start/stop" experiments. In these protocols, an agent is given for a period of time to induce particular lesions or effects and then stopped in order to evaluate the progression or reversibility of processes (Todd, 1986; Marsman and Popp, 1994).

Assays in genetically engineered rodents may provide insight into the chemical and gene interactions involved in carcinogenesis (Tennant et al., 1995). These mechanistically based approaches involve activated oncogenes that are introduced (transgenic) or tumor suppressor genes that are deleted (knocked out). If appropriate genes are selected, not only may these systems provide information on mechanisms, but the rodents typically show tumor development earlier than in the standard bioassay. Transgenic mutagenesis assays also represent a mechanistic approach for assessing the mutagenic properties of agents as well as developing quantitative linkages between exposure, internal dose, and mutation related to tumor induction (Morrison and Ashby, 1994; Sisk et al., 1994; Hayward et al., 1995).

The support that these studies give to a determination of carcinogenicity rests on their contribution to the consistency of other evidence about an agent. For instance, benzoyl peroxide has promoter activity on the skin, but the overall evidence may be less supportive (Kraus et al., 1995). These studies also may contribute information about mode of action. It is important to recognize the limitations of these experimental protocols, such as short duration, limited histology, lack of complete development of tumors, or experimental manipulation of the carcinogenic process, that may limit their contribution to the overall assessment. Generally, their results are appropriate as aids in the interpretation of other toxicological evidence (e.g., rodent

chronic bioassays), especially regarding potential modes of action. On the basis of currently available information, it is unlikely that any of these assays, which are conducted for 6 months with 15 animals per group, will replace all chronic bioassays for hazard identification (Spalding et al., 2000; Gulezian et al., 2000; ILSI, 2001).

2.2.3. Structural Analogue Data

For some chemical classes, there is significant available information, largely from rodent bioassays, on the carcinogenicity of analogues. Analogue effects are instructive in investigating carcinogenic potential of an agent as well as in identifying potential target organs, exposures associated with effects, and potential functional class effects or modes of action. All appropriate studies should be included and analyzed, whether indicative of a positive effect or not. Evaluation includes tests in various animal species, strains, and sexes; with different routes of administration; and at various doses, as data are available. Confidence in conclusions is a function of how similar the analogues are to the agent under review in structure, metabolism, and biological activity. It is important to consider this confidence to ensure a balanced position.

2.3. ANALYSIS OF OTHER KEY DATA

The physical, chemical, and structural properties of an agent, as well as data on endpoints that are thought to be critical elements of the carcinogenic process, provide valuable insights into the likelihood of human cancer risk. The following sections provide guidance for analyses of these data.

2.3.1. Physicochemical Properties

Physicochemical properties affect an agent’s absorption, tissue distribution (bioavailability), biotransformation, and degradation in the body and are important determinants of hazard potential (and dose-response analysis). Properties that should be analyzed include, but are not limited to, molecular weight, size, and shape; valence state; physical state (gas, liquid, solid); water or lipid solubility, which can influence retention and tissue distribution; and potential for chemical degradation or stabilization in the body.

An agent's potential for chemical reaction with cellular components, particularly with DNA and proteins, is also important. The agent's molecular size and shape, electrophilicity, and charge distribution are considered in order to decide whether they would facilitate such reactions.

2.3.2. Structure-Activity Relationships (SARs)

SAR analyses and models can be used to predict molecular properties, surrogate biological endpoints, and carcinogenicity (see, e.g., Richard, 1998a, b; Richard and Williams, 2002; Contrera et al., 2003). Overall, these analyses provide valuable initial information on agents, they may strengthen or weaken concern, and they are part of the weight of evidence.

Currently, SAR analysis is most useful for chemicals and metabolites that are believed to initiate carcinogenesis through covalent interaction with DNA (i.e., DNA-reactive, mutagenic, electrophilic, or proelectrophilic chemicals) (Ashby and Tennant, 1991). For organic chemicals, the predictive capability of SAR analysis combined with other toxicity information has been demonstrated (Ashby and Tennant, 1994). The following parameters are useful in comparing an agent to its structural analogues and congeners that produce tumors and affect related biological processes such as receptor binding and activation, mutagenicity, and general toxicity (Woo and Arcos, 1989):

- nature and reactivity of the electrophilic moiety or moieties present;
- potential to form electrophilic reactive intermediate(s) through chemical, photochemical, or metabolic activation;
- contribution of the carrier molecule to which the electrophilic moiety(ies) is attached;
- physicochemical properties (e.g., physical state, solubility, octanol/water partition coefficient, half-life in aqueous solution);

- structural and substructural features (e.g., electronic, stearic, molecular geometric);
- metabolic pattern (e.g., metabolic pathways and activation and detoxification ratio); and
- possible exposure route(s) of the agent.

Suitable SAR analysis of non-DNA-reactive chemicals and of DNA-reactive chemicals that do not appear to bind covalently to DNA should be based on knowledge or postulation of the probable mode(s) of action of closely related carcinogenic structural analogues (e.g., receptor mediated, cytotoxicity related). Examination of the physicochemical and biochemical properties of the agent may then provide the rest of the information needed in order to make an assessment of the likelihood of the agent's activity by that mode of action.

2.3.3. Comparative Metabolism and Toxicokinetics

Studies of the absorption, distribution, biotransformation, and excretion of agents permit comparisons among species to assist in determining the implications of animal responses for human hazard assessment, supporting identification of active metabolites, identifying changes in distribution and metabolic pathway or pathways over a dose range, and making comparisons among different routes of exposure.

If extensive data are available (e.g., blood/tissue partition coefficients and pertinent physiological parameters of the species of interest), physiologically based toxicokinetic models can be constructed to assist in a determination of tissue dosimetry, species-to-species extrapolation of dose, and route-to-route extrapolation (Conolly and Andersen, 1991; see Section 3.1.2). If sufficient data are not available, it may be assumed as a default that toxicokinetic and metabolic processes are qualitatively comparable among species. Discussion of appropriate procedures for quantitative, interspecies comparisons appears in Chapter 3.

The *qualitative* question of whether an agent is absorbed by a particular route of exposure is important for weight of evidence classification, discussed in Section 2.5. Decisions about

whether route of exposure is a limiting factor on expression of any hazard, e.g., absorption does not occur by a specified route, are generally based on studies in which effects of the agent or its structural analogues have been observed by different routes, on physical-chemical properties, or on toxicokinetics studies.

Adequate metabolism and toxicokinetic data can be applied toward the following, as data permit. Confidence in conclusions is enhanced when *in vivo* data are available.

- *Identifying metabolites and reactive intermediates of metabolism and determining whether one or more of these intermediates is likely to be responsible for the observed effects*. Information on the reactive intermediates focuses on SAR analysis, analysis of potential modes of action, and estimation of internal dose in dose-response assessment (D'Souza et al., 1987; Krewski et al., 1987).

- *Identifying and comparing the relative activities of metabolic pathways in animals and in humans, and at different ages*. This analysis can provide insights for extrapolating results of animal studies to humans.

- *Describing anticipated distribution within the body and possibly identifying target organs*. Use of water solubility, molecular weight, and structure analysis can support qualitative inferences about anticipated distribution and excretion. In addition, describing whether the agent or metabolite of concern will be excreted rapidly or slowly or whether it will be stored in a particular tissue or tissues to be mobilized later can identify issues in comparing species and formulating dose-response assessment approaches.

- *Identifying changes in toxicokinetics and metabolic pathways with increases in dose*. These changes may result in important differences between high and low dose levels in disposition of the agent or generation of its active forms. These

studies play an important role in providing a rationale for dose selection in carcinogenicity studies.

- *Identifying and comparing metabolic process differences by age, sex, or other characteristic so that susceptible subpopulations can be recognized*. For example, metabolic capacity with respect to P450 enzymes in newborn children is extremely limited compared to that in adults, so that a carcinogenic metabolite formed through P450 activity will have limited effect in the young, whereas a carcinogenic agent deactivated through P450 activity will result in increased susceptibility of this lifestage (Cresteil, 1998). A variety of changes in toxicokinetics and physiology occur from the fetal stage to post-weaning to young child. Any of these changes may make a difference for risk (Renwick, 1998).

- *Determining bioavailability via different routes of exposure by analyzing uptake processes under various exposure conditions*. This analysis supports identification of hazards for untested routes. In addition, use of physicochemical data (e.g., octanol-water partition coefficient information) can support an inference about the likelihood of dermal absorption (Flynn, 1990).

Attempts should be made in all of these areas to clarify and describe as much as possible the variability to be expected because of differences in species, sex, age, and route of exposure. The analysis takes into account the presence of subpopulations of individuals who are particularly vulnerable to the effects of an agent because of toxicokinetic or metabolic differences (genetically or environmentally determined) (Bois et al., 1995) and is a special emphasis for assessment of risks to children.

2.3.4. Toxicological and Clinical Findings

Toxicological findings in experimental animals and clinical observations in humans are important resources for the cancer hazard assessment. Such findings provide information on

physiological effects and effects on enzymes, hormones, and other important macromolecules as well as on target organs for toxicity. For example, given that the cancer process represents defects in processes such as terminal differentiation, growth control, and cell death, developmental studies of agents may provide an understanding of the activity of an agent that carries over to cancer assessment. Toxicity studies in animals by different routes of administration support comparison of absorption and metabolism by those routes. Data on human variability in standard clinical tests may also provide insight into the range of human susceptibility and the common mechanisms of agents that affect the tested parameters.

2.3.5. Events Relevant to Mode of Carcinogenic Action

Knowledge of the biochemical and biological changes that precede tumor development (which include, but are not limited to, mutagenesis, increased cell proliferation, inhibition of programmed cell death, and receptor activation) may provide important insight for determining whether a cancer hazard exists and may help inform appropriate consideration of the dose-response relationship below the range of observable tumor response. Because cancer can result from a series of genetic alterations in the genes that control cell growth, division, and differentiation (Vogelstein et al., 1988; Hanahan and Weinberg, 2000; Kinzler and Vogelstein, 2002), the ability of an agent to affect genotype (and hence gene products) or gene expression is of obvious importance in evaluating its influence on the carcinogenic process. Initial and key questions to examine are: Does the agent (or its metabolite) interact directly with DNA, leading to mutations that bring about changes in gene products or gene expression? Does the agent bring about effects on gene expression via other nondirect DNA interaction processes?

Furthermore, carcinogenesis involves a complex series and interplay of events that alter the signals a cell receives from its extracellular environment, thereby promoting uncontrolled growth. Many, but not all, mutagens are carcinogens, and some, but not all, agents that induce cell proliferation lead to tumor development. Thus, understanding the range of key steps in the carcinogenic process upon which an agent might act is essential for evaluating its mode of action. Determination of carcinogens that are operating by a mutagenic mode of action, for example, entails evaluation of *in vivo* or *in vitro* short-term testing results for genetic endpoints, metabolic

profiles, physicochemical properties, and structure-activity relationship (SAR) analyses in a weight-of-evidence approach (Dearfield et al., 1991; U.S. EPA, 1986b; Waters et al., 1999). Key data for a mutagenic mode of action may be evidence that the carcinogen or a metabolite is DNA-reactive and/or has the ability to bind to DNA. Also, mutagenic carcinogens usually produce positive effects in multiple test systems for different genetic endpoints, particularly gene mutations and structural chromosome aberrations, and in tests performed *in vivo* which generally are supported by positive tests *in vitro*. Additionally, carcinogens may be identified as operating via a mutagenic mode of action if they have similar properties and SAR to mutagenic carcinogens. Endpoints that provide insight into an agent's ability to alter gene products and gene expression, together with other features of an agent's potential mode of carcinogenic action, are discussed below.

2.3.5.1. *Direct DNA-Reactive Effects*

It is well known that many carcinogens are electrophiles that interact with DNA, resulting in DNA adducts and breakage (referred to in these cancer guidelines as direct DNA effects). Usually during the process of DNA replication, these DNA lesions can be converted into and fixed as mutations and chromosomal alterations that then may initiate and otherwise contribute to the carcinogenic process (Shelby and Zeiger, 1990; Tinwell and Ashby, 1991; IARC, 1999). Thus, studies of mutations and other genetic lesions continue to inform the assessment of potential human cancer hazard and in the understanding of an agent's mode of carcinogenic action.

EPA has published testing guidelines for detecting the ability of an agent to damage DNA and produce mutations and chromosomal alterations (as discussed in Dearfield et al., 1991). Briefly, standard tests for gene mutations in bacteria and mammalian cells *in vitro* and *in vivo* and for structural chromosomal aberrations *in vitro* and *in vivo* are important examples of relevant methods. New molecular approaches, such as mouse mutations and cancer transgenic models, are providing a means to examine mutation at tissue sites where the tumor response is observed (Heddle and Swiger, 1996; Tennant et al., 1999). Additionally, continued improvements in fluorescent-based chromosome staining methods (fluorescent *in situ*

hybridization [FISH]) will allow the detection of specific chromosomal abnormalities in relevant target tissues (Tucker and Preston, 1998).

Endpoints indicative of DNA damage but not measures of mutation *per se*, such as DNA adducts or strand breakage, may be detected in relevant target tissues and thus contribute to evaluating an agent's mutagenic potential. Evidence of chemical-specific DNA adducts (e.g., reactions at oxygen sites in DNA bases or with ring nitrogens of guanine and adenine) provides information on a mutagen's ability to directly interact with DNA (La and Swenberg, 1996). Some planar molecules (e.g., 9-aminoacridine) intercalate between base pairs of DNA, which results in a physical distortion in DNA that may lead to mutations when DNA replicates. As discussed below, some carcinogens do not interact directly with DNA, but they can produce increases in endogenous levels of DNA adducts (e.g., 8-hydroxyguanine) by indirect mechanisms.

2.3.5.2. *Indirect DNA Effects or Other Effects on Genes/Gene Expression*

Although some carcinogens may result in an elevation of mutations or cytogenetic anomalies, as detected in standard assays, they may do so by indirect mechanisms. These effects may be brought about by chemical-cell interactions rather than by the chemical (or its metabolite) directly interacting with DNA. An increase in mutations might be due to cytotoxic exposures causing regenerative proliferation or to mitogenic influences (Cohen and Ellwein, 1990). Increased cell division may elevate mutation by clonal expansion of initiated cells or by increasing the number of genetic errors by rapid cell division and reduced time for DNA repair. Some agents might result in an elevation of mutations by interfering with the enzymes involved in DNA repair and recombination (Barrett and Lee, 1992). Damage to certain critical DNA repair genes or other genes (e.g., the p53 gene) may result in genomic instability, which predisposes cells to further genetic alterations and increases the probability of neoplastic progression (Harris and Hollstein, 1993; Levine et al., 1994; Rouse and Jackson, 2002). Likewise, DNA repair processes may be saturated at certain doses of a chemical, leading to an elevation of genetic alterations.

The initiation of programmed cell death (apoptosis) can potentially be blocked by an agent, thereby permitting replication of cells carrying genetic errors that would normally be removed from the proliferative pool. At certain doses an agent may also generate reactive oxygen species that produce oxidative damage to DNA and other macromolecules (Chang et al. 1988; Kehrer, 1993; Clayson et al., 1994). The role of cellular alterations that are attributable to oxidative damage in tumorigenesis (e.g., 8-hydroxyguanine) is currently unclear.

Several carcinogens have been shown to induce aneuploidy (the loss or gain of chromosomes) (Barrett, 1992; Gibson et al., 1995). Aneuploidy can result in the loss of heterozygosity or genomic instability (Cavenee et al., 1986; Fearon and Vogelstein, 1990). Agents that cause aneuploidy typically interfere with the normal process of chromosome segregation by interacting with non-DNA targets such as the proteins needed for chromosome segregation and chromosome movement. Whether this chromosome imbalance is the cause or the effect of tumorigenesis is not clear. Thus, it is important to understand if the agent induces aneuploidy as a key early event in the carcinogenic process.

It is possible for an agent to alter gene expression by transcriptional, translational, or post-translational modifications. For example, perturbation of DNA methylation patterns may cause effects that contribute to carcinogenesis (Jones, 1986; Holliday, 1987; Goodman and Counts, 1993; Chuang et al., 1996; Baylin and Bestor, 2002). Overexpression of genes by DNA amplification has been observed in certain tumors (Vainio et al., 1992). Mechanisms of altering gene expression may involve cellular reprogramming through hormonal or receptor-mediated mechanisms (Barrett, 1992; Ashby et al., 1994).

Both cell proliferation and programmed cell death can be part of the maintenance of homeostasis in many normal tissues, and alterations in the level or rate of either can be important elements of the carcinogenic process. The balance between the two can directly affect the survival and growth of initiated cells as well as preneoplastic and tumor cell populations (i.e., increase in cell proliferation or decrease in cell death) (Moolgavkar, 1986; Cohen and Ellwein, 1990, 1991; Cohen et al., 1991; Bellamy et al., 1995). Thus, measurements of these events can contribute to the weight of the evidence for cancer hazard prediction and to mode of action

understanding. In studies of proliferative effects, distinctions should be made between mitogenesis and regenerative proliferation (Cohen and Ellwein, 1990, 1991; Cohen et al., 1991).

In applying information from studies on cell proliferation and apoptosis to risk assessment, it is important to identify the tissues and target cells involved, to measure effects in both normal and neoplastic tissue, to distinguish between apoptosis and necrosis, and to determine the dose that affects these processes. Gap-junctional intercellular communication is believed to play a role in tissue and organ development and in the maintenance of a normal cellular phenotype within tissues. A growing body of evidence suggests that chemical interference with gap-junctional intercellular communication is a contributing factor in tumor development (Swierenga and Yamasaki, 1992; Yamasaki, 1995).

2.3.5.3. *Precursor Events and Biomarker Information*

Most testing schemes for mutagenicity and other short-term assays were designed for hazard identification purposes; thus, these assays are generally conducted using acute exposures. For data on "precursor steps" to be useful in informing the dose-response curve for tumor induction below the level of observation, it is often useful for data to come from *in vivo* studies and from studies where exposure is repeated or given over an extended period of time. Although consistency of results across different assays and animal models provides a stronger basis for drawing conclusions, it is desirable to have data on the precursor event in the same target organ, sex, animal strain, and species as the tumor data. In evaluating an agent's mode of action, it is usually not sufficient to determine that some event commences upon dosing. It is important to understand whether it is a necessary event that plays a key role in the process that leads to tumor development versus an effect of the cancer process itself or simply an associated event.

Various endpoints can serve as biological markers of effects in biological systems or samples. These may help identify doses at which elements of the carcinogenic process are operating; aid in interspecies extrapolations when data are available from both experimental animal and human cells; and under certain circumstances, provide insights into the possible shape of the dose-response curve below levels where tumor incidences are observed (e.g., Choy, 1993).

Genetic and other findings (such as changes in proto-oncogenes and tumor suppressor genes in preneoplastic and neoplastic tissue or, possibly, measures of endocrine disruption) can indicate the potential for disease and, as such, serve as biomarkers of effect. They, too, can be used in different ways.

- The spectrum of genetic changes in proliferative lesions and tumors following chemical administration to experimental animals can be determined and compared with that in spontaneous tumors in control animals, in animals exposed to other agents of varying structural and functional activities, and in persons exposed to the agent under study.

- Biomarkers of effect and/or precursors may help to identify subpopulations of individuals who may be at an elevated risk for a certain cancer or exposure to a certain agent, e.g., cytochrome P450 2D6/debrisoquine sensitivity for lung cancer (Caporaso et al., 1989) or inherited colon cancer syndromes (Kinzler et al., 1991; Peltomäki et al., 1993).

- As with biomarkers of exposure, it may be justified in some cases to use biomarkers of effect and/or precursors for dose-response assessment or to provide insight into the potential shape of the dose-response curve at doses below those at which tumors are induced experimentally.

In applying biomarker data to cancer assessment an assessment should consider:

- analytical methodology,
- routes of exposure,
- exposure to mixtures,
- time after exposure,
- sensitivity and specificity of biomarkers, and
- dose-response relationships.

2.3.5.4. *Judging Data*

Criteria that are generally applicable for judging the adequacy of mechanistically based data include:

- mechanistic relevance of the data to carcinogenicity,
- number of studies of each endpoint,
- consistency of results in different test systems and different species,
- similar dose-response relationships for tumor and mode of action-related effects,
- conduct of the tests in accordance with generally accepted protocols, and
- degree of consensus and general acceptance among scientists regarding interpretation of the significance and specificity of the tests.

Although important information can be gained from *in vitro* test systems, a higher level of confidence is generally given to data that are derived from *in vivo* systems, particularly those results that show a site concordance with the tumor data.

It is important to remember that when judging and considering the use of any data, the basic standard of quality, as defined by the EPA Information Quality Guidelines, should be satisfied.

2.4. MODE OF ACTION—GENERAL CONSIDERATIONS AND FRAMEWORK FOR ANALYSIS

2.4.1. General Considerations

The interaction between the biology of the organism and the chemical properties of the agent determine whether there is an adverse effect. Thus, mode of action analysis is based on physical, chemical, and biological information that helps to explain key events in an agent's influence on development of tumors. The entire range of information developed in the assessment is reviewed to arrive at a reasoned judgment. An agent may work by more than one mode of action, both at different sites and at the same tumor site. Thus the mode of action and human relevance cannot necessarily be generalized to other toxic endpoints or tissues or cell types without additional analyses (IPCS, 1999; Meek et al., 2003). At least some information

bearing on mode of action (e.g., SAR, screening tests for mutagenicity) is present for most agents undergoing assessment of carcinogenicity, even though certainty about exact molecular mechanisms may be rare.

Information for mode of action analysis generally includes tumor data in humans and animals and among structural analogues, as well as the other key data. The more complete the data package and the generic knowledge about a given mode of action, the more confidence one has and the more one can rely on assessment of available data rather than reverting to default options to address the absence of information on mode of action. Reasoned judgments are generally based on a data-rich source of chemical, chemical class, and tumor type-specific information. Many times there will be conflicting data and gaps in the information base; it is important to carefully evaluate these uncertainties before reaching any conclusion.

In making decisions about potential modes of action and the relevance of animal tumor findings to humans (Ashby et al., 1990; Ashby and Tennant, 1991; Tennant, 1993; IPCS 1999; Sonich-Mullin et al., 2001; Meek et al., 2003), very often the results of chronic animal studies may give important clues. Some of the important factors to review include:

- tumor types, for example, those responsive to endocrine influence or those produced by DNA-reactive carcinogens;

- number of studies and of tumor sites, sexes, and species affected or unaffected in those studies and if the data present a coherent story;

- similarity of metabolic activation and detoxification for a specific chemical between humans and tested species;

- influence of route of exposure on the spectrum of tumors and whether they occur at point of exposure or systemic sites;

- effect of high dose exposures on the target organ or systemic toxicity that may not reflect typical physiological conditions, for example, urinary chemical changes associated with stone formation, effects on immune surveillance;

- presence of proliferative lesions, for example, hepatic foci, or hyperplasia;

- effect of dose and time on the progression of lesions from preneoplastic to benign tumors, then to malignant;

- ratio of malignant to benign tumors as a function of dose and time;

- time of appearance of tumors after commencing exposure;

- development of tumors that invade locally or systemically, or lead to death;

- tumors at organ sites with high or low background historical incidence in laboratory animals;

- biomarkers in tumor cells, both induced and spontaneous, for example, DNA or protein adducts, mutation spectra, chromosome changes, oncogene activation; and/or

- shape of the dose-response curve in the range of tumor observation, for example, linear versus nonlinear.

Some of the myriad ways in which information from chronic animal studies influences mode of action judgments include, but are not limited to, the following:

- multisite and multispecies tumor effects that are often associated with mutagenic agents;

- tumors restricted to one sex or species suggesting an influence restricted to gender, strain, or species;

- late onset of tumors that are primarily benign, are at sites with a high historical background incidence, or show reversal of lesions on cessation of exposure suggesting a growth-promoting mode of action;

- the possibility that an agent acting differently in different tissues; or

- the possibility that has more than one mode of action in a single tissue.

Simple knowledge of sites of tumor increase in rodent studies can give preliminary clues as to mode of action. Experience at the National Toxicology Program (NTP) indicates that substances that are DNA reactive and that produce gene mutations may be unique in producing tumors in certain anatomical sites, whereas tumors at other sites may arise from both mutagenic or nonmutagenic influences (Ashby and Tennant, 1991; Huff et al., 1991).

The types of data and their influence on judgments regarding mode of action are expected to evolve, both as science advances and as the risk assessment community gains more experience with these analyses. This section contains a framework for evaluating hypothesized mode(s) of action. This framework has similarities to and differences with the concepts presented in other MOA frameworks (e.g., IPCS, 1999; Sonich-Mullin et al., 2001; Meek et al., 2003). Differences are often due to the context of the use for the framework. For example, the Meek et al. (2003) presents a stand-alone document for addressing mode of action issues; thus, it recommends that conclusions concerning MOA be rendered separately. In these cancer guidelines, however, they are incorporated into the context of all of the data regarding weight of the evidence for carcinogenicity.

2.4.2. Evaluating an Hypothesized Mode of Action

2.4.2.1. *Peer Review*

In reaching conclusions, the question of "general acceptance" of a mode of action should be tested as part of the independent peer review that EPA obtains for its assessment and conclusions. In some cases the mode of action may already have been established by development of a large body of research information and characterization of the phenomenon over time. In some cases there will have been development of an Agency policy (e.g., mode of action involving alpha-2u-globulin in the male rat [U.S. EPA, 1991b]) or a series of previous assessments in which both the mode of action and its applicability to particular cases has been explored. If so, the assessment and its peer review can focus on the evidence that a particular agent acts in this mode. The peer review should also evaluate the strengths and weaknesses of competing modes of action.

In other cases, the mode of action may not have previously been the subject of an Agency document. If so, the data to support both the mode of action and the associated activity of the agent should undergo EPA assessment and subsequent peer review.

2.4.2.2. *Use of the Framework*

The framework supports a full analysis of mode of action information, but it can also be used as a screen to decide whether sufficient information is available to evaluate or whether the data gaps are too substantial to justify further analysis. Mode of action conclusions are used to address the question of human relevance of animal tumor responses, to address differences in anticipated response among humans, such as between children and adults or men and women; and as the basis of decisions about the anticipated shape of the dose-response relationship. Guidance on the latter appears in Section 3.

This framework is intended to provide an analytical approach for evaluating the mode of action. It is neither a checklist nor a list of required criteria. As the type and amount of information will depend on the mode of action postulated, scientific judgment is important to determine if the weight of evidence is sufficient.

2.4.3. Framework for Evaluating Each Hypothesized Carcinogenic Mode of Action

This framework is intended to be an analytic tool for judging whether available data support a mode of carcinogenic action hypothesized for an agent. It is based upon considerations for causality in epidemiologic investigations originally articulated by Hill (1965) but later modified by others and extended to experimental studies. The original Hill criteria were applied to epidemiologic data, whereas this framework is applied to a much wider assortment of experimental data, so it retains the basic principles of Hill but is much modified in content.

The modified Hill criteria can be useful for organizing thinking about aspects of causation, and they are consistent with the scientific method of developing hypotheses and testing those hypotheses experimentally. During analysis by EPA, and as guidance for peer review, a key question is whether the data to support a mode of action meet the standards generally applied in experimental biology regarding inference of causation.

All pertinent studies are reviewed in analyzing a mode of action, and an overall weighing of evidence is performed, laying out the strengths, weaknesses, and uncertainties of the case as well as potential alternative positions and rationales. Identifying data gaps and research needs is also part of the assessment.

To evaluate whether an hypothesized mode of action is operative, an analysis starts with an outline of the scientific findings regarding the hypothesized key events leading to cancer, and then weighing information to determine whether there is a causal relationship between these events and cancer formation, i.e., that the effects are critical for induction of tumors. It is not generally expected that the complete sequence will be known at the molecular level. Instead, empirical observations made at different levels of biological organization—biochemical, cellular, physiological, tissue, organ, and system—are analyzed.

Several important points should be considered when working with the framework:

- The topics listed for analysis should *not* be regarded as a checklist of necessary "proofs." The judgment of whether an hypothesized mode of action is supported by available data takes account of the analysis as a whole.

- The framework provides a structure for organizing the facts upon which conclusions as to mode of action rest. The purpose of using the framework is to make analysis transparent and to allow the reader to understand the facts and reasoning behind a conclusion.

- The framework does not dictate an answer. The weight of evidence that is sufficient to support a decision about a mode of action may be less or more, depending on the purpose of the analysis, for example, screening, research needs identification, or full risk assessment. To make the reasoning transparent, the purpose of the analysis should be made apparent to the reader.

- Toxicokinetic studies may contribute to mode of action analysis by contributing to identifying the active form(s) of an agent that is central to the mode of action. Apart from contributing in this way, toxicokinetics studies may reveal effects of saturation of metabolic processes. These may not be considered key events in a mode of action, but they are given separate consideration in assessing dose metrics and potential nonlinearity of the dose-response relationship.

- Generally, “sufficient” support is a matter of scientific judgment in the context of the requirements of the decisionmaker or in the context of science policy guidance regarding a certain mode of action.

- Even when an hypothesized mode of action is supported for a described response in a specific tissue, it may not explain other tumor responses observed, which should get separate consideration in hazard and dose-response assessment.

For each tumor site being evaluated, the mode of action analysis should begin with a description of the relevant data and key events that may be associated with an hypothesized mode of action and its sequence of key events (see Section 2.4.3.1). This can be followed by a

discussion of various aspects of the experimental support for hypothesized mode(s) of action in animals and humans (see Section 2.4.3.2). The possibility of other modes of action also should be considered and discussed (see Section 2.4.3.3); if there is evidence for more than one mode of action, each should receive a separate analysis. Conclusions about each hypothesized mode of action should address whether the mode of action is supported in animals and is relevant to humans and which populations or lifestages can be particularly susceptible (see Section 2.4.3.4). In a risk assessment document, the analysis of an hypothesized mode of action can be presented before or with the characterization of an agent's potential hazard to humans.

2.4.3.1. *Description of the Hypothesized Mode of Action*

Summary description of the hypothesized mode of action. For each tumor site, the mode of action analysis begins with a description of the hypothesized mode of action and its sequence of key events. If there is evidence for more than one mode of action, each receives a separate analysis.

Identification of key events. In order to judge how well data support involvement of a key event in carcinogenic processes, the experimental definition of the event or events should be clear and reproducible. To support an association, experiments should define and measure an event consistently.

- Can a list of events be identified that are key to the carcinogenic process?

- Are the events well defined?

Pertinent observations may include, but are not limited to, receptor-ligand changes, cytotoxicity, cell cycle effects, increased cell growth, organ weight differences, histological changes, hormone or other protein perturbations, or DNA and chromosome effects.

2.4.3.2. *Discussion of the Experimental Support for the Hypothesized Mode of Action*

The experimental support for the hypothesized mode of action should be discussed from several viewpoints patterned after the Hill criteria (see Section 2.2.1.7). For illustration, the explanation of each topic includes typical questions to be addressed to the available empirical data and experimental observations anticipated to be pertinent. The latter will vary from case to case. For a particular mode of action, certain observations may be established as essential in practice or policy, for example, measures of thyroid hormone levels in supporting thyroid hormone elevation as a key event in carcinogenesis.

Strength, consistency, specificity of association. A statistically significant association between events and a tumor response observed in well-conducted studies is generally supportive of causation. Consistent observations in a number of such studies with differing experimental designs increase that support, because different designs may reduce unknown biases. Studies showing "recovery," i.e, absence or reduction of carcinogenicity when the event is blocked or diminished, are particularly useful tests of the association. Specificity of the association, without evidence of other modes of action, strengthens a causal conclusion. A lack of strength, consistency, and specificity of association weakens the causal conclusions for a particular mode of action.

- What is the level of statistical and biological significance for each event and for cancer?

- Do independent studies and different experimental hypothesis-testing approaches produce the same associations?

- Does the agent produce effects other than those hypothesized?

- Is the key event associated with precursor lesions?

Pertinent observations include tumor response associated with events (site of action logically relates to event[s]), precursor lesions associated with events, initiation-promotion studies, and stop/recovery studies.

Dose-response concordance. If a key event and tumor endpoints increase with dose such that the key events forecast the appearance of tumors at a later time or higher dose, a causal association can be strengthened. Dose-response associations of the key event with other precursor events can add further strength. Difficulty arises when an event is not causal but accompanies the process generally. For example, if tumors and the hypothesized precursor both increase with dose, the two responses will be correlated regardless of whether a causal relationship exists. This is similar to the issue of confounding in epidemiologic studies. Dose-response studies coupled with mechanistic studies can assist in clarifying these relationships.

- What are the correlations among doses producing events and cancer?

Pertinent observations include, but are not limited to, 2-year bioassay observation of lesions correlated with observations of hormone changes and the same lesions in shorter term studies or in interim sacrifice.

Temporal relationship. If an event is shown to be causally linked to tumorigenesis, it will precede tumor appearance. An event may also be observed contemporaneously or after tumor appearance; these observations may add to the strength of association but not to the temporal association.

- What is the ordering of events that underlie the carcinogenic process?

- Is this ordering consistent among independent studies?

Pertinent observations include studies of varying duration observing the temporal sequence of events and development of tumors.

Biological plausibility and coherence. It is important that the hypothesized mode of action and the events that are part of it be based on contemporaneous understanding of the biology of cancer to be accepted. If the body of information under scrutiny is consistent with other examples (including structurally related agents) for which the hypothesized mode of action is accepted, the case is strengthened. Because some modes of action can be anticipated to evoke effects other than cancer, the available toxicity database on noncancer effects, for example, reproductive effects of certain hormonal disturbances, can contribute to this evaluation.

- Is the mode of action consistent with what is known about carcinogenesis in general and for the case specifically?

- Are carcinogenic effects and events consistent across structural analogues?

- Is the database on the agent internally consistent in supporting the purported mode of action, including relevant noncancer toxicities?

Pertinent observations include the scientific basis for considering an hypothesized mode of action generally, given the contemporaneous state of knowledge of carcinogenic processes; previous examples of data sets showing the mode of action; data sets on analogues; and coherence of data in this case from cancer and noncancer toxicity studies.

2.4.3.3. *Consideration of the Possibility of Other Modes of Action*

The possible involvement of more than one mode of action at the tumor site should be considered. Pertinent observations that are not consistent with the hypothesized mode of action can suggest the possibility of other modes of action. Some pertinent observations can be consistent with more than one mode of action. Furthermore, different modes of action can operate in different dose ranges; for example, an agent can act predominantly through cytotoxicity at high doses and through mutagenicity at lower doses where cytotoxicity may not occur.

If there is evidence for more than one mode of action, each should receive a separate analysis. There may be an uneven level of experimental support for the different modes of action. Sometimes this can reflect disproportionate resources spent on investigating one particular mode of action and not the validity or relative importance of the other possible modes of action. Ultimately, however, the information on all of the modes of action should be integrated to better understand how and when each mode acts, and which mode(s) may be of interest for exposure levels relevant to human exposures of interest.

2.4.3.4. *Conclusions About the Hypothesized Mode of Action*

Conclusions about the hypothesized mode of action should address the issues listed below. For those agents for which the mode of action is considered useful for the risk assessment, the weight of the evidence concerning mode of action in animals as well as its relevance for humans would be incorporated into the weight of evidence narrative (Section 2.5).

(a) Is the hypothesized mode of action sufficiently supported in the test animals? Associations observed between key events and tumors may or may not support an inference of causation. The conclusion that the agent causes one or more key events that results in tumors is strengthened as more aspects of causation are satisfied and weakened as fewer are satisfied. Consistent results in different experiments that test the hypothesized mode of action build support for that mode of action. Replicating results in a similar experiment does not generally meaningfully strengthen the original evidence, and discordant results generally weaken that support. Experimental challenge to the hypothesized mode of action, where interrupting the sequence of key events suppresses the tumor response or enhancement of key events increases the tumor response, creates very strong support for the mode of action.

(b) Is the hypothesized mode of action relevant to humans? If an hypothesized mode of action is sufficiently supported in the test animals, the sequence of key precursor events should be reviewed to identify critical similarities and differences between the test animals and humans. The question of concordance can be complicated by cross-species differences in toxicokinetics or

toxicodynamics. For example, the active agent can be formed through different metabolic pathways in animals and humans. Any information suggesting quantitative differences between animals and humans is flagged for consideration in the dose-response assessment. This includes the potential for different internal doses of the active agent or for differential occurrence of a key precursor event.

"Relevance" of a potential mode of action is considered in the context of characterization of hazard, not level of risk. Anticipated levels of human exposure are not used to determine whether the hypothesized mode of action is relevant to humans. Exposure information is integrated into the overall risk characterization.

The question of relevance considers all populations and lifestages. It is possible that the conditions under which a mode of action operates exist primarily in a particular population or lifestage, for example, in those with a pre-existing hormonal imbalance. Other populations or lifestages may not be analogous to the test animals, in which case the question of relevance would be decided by inference.

Special attention should be paid to whether tumors can arise from childhood exposure, considering various aspects of development during these lifestages. Because the studies that support a mode of action are typically conducted in mature animals, conclusions about relevance during childhood generally rely on inference. There is currently no standard Agency position regarding the issue of whether tumors arising through the hypothesized mode of action are relevant during childhood; understanding the mode of action implies that there are sufficient data (on either the specific agent or the general mode of action) to form a confident conclusion about relevance during childhood.

(c) Which populations or lifestages can be particularly susceptible to the hypothesized mode of action? If an hypothesized mode of action is judged relevant to humans, information about the key precursor event(s) is reviewed to identify populations or lifestages that might reasonably expected to be particularly susceptible to their occurrence. Although agent-specific data would provide the strongest indication of susceptibility, this review may also rely on general knowledge about the precursor events and characteristics of individuals susceptible to these

events. Any information suggesting quantitative differences between populations or lifestages should be flagged for consideration in the dose-response assessment (see Section 3.5). This includes the potential for a higher internal dose of the active agent or for an increased occurrence of a key precursor event. Quantitative differences may result in separate risk estimates for susceptible populations or lifestages.

The possibility that childhood is a susceptible period for exposure should be explicitly addressed. Generic understanding of the mode of action can be used to gauge childhood susceptibility, and this determination can be refined through analysis of agent-specific data.

2.4.4 Evolution with Experience

Several groups have proposed or incorporated mode of action into their risk assessments (see, e.g., U.S. EPA , 1991b; Sonich-Mullin et al., 2001; Meek et al., 2003). As the frameworks and mandates under which these evaluations were produced differ, the specific procedures described in and conclusions drawn may also differ. Nevertheless, the number of case studies from all venues remains limited. More experience with differing modes of action are expected to highlight and illustrate the strengths and limitations of the general framework proposed in these cancer guidelines. Moreover, additional toxicological techniques may expand or change scientific judgments regarding which information is useful for mode of action determinations. As warranted, additional guidance may be proposed as experience is gained and/or as toxicological knowledge advances.

2.5. WEIGHT OF EVIDENCE NARRATIVE

The *weight of evidence narrative* is a short summary (one to two pages) that explains an agent's human carcinogenic potential and the conditions that characterize its expression. It should be sufficiently complete to be able to stand alone, highlighting the key issues and decisions that were the basis for the evaluation of the agent’s potential hazard. It should be sufficiently clear and transparent to be useful to risk managers and non-expert readers. It may be useful to summarize all of the significant components and conclusions in the first paragraph of the narrative and to explain complex issues in more depth in the rest of the narrative.

The weight of the evidence should be presented as a narrative laying out the complexity of information that is essential to understanding the hazard and its dependence on the quality, quantity, and type(s) of data available, as well as the circumstances of exposure or the traits of an exposed population that may be required for expression of cancer. For example, the narrative can clearly state to what extent the determination was based on data from human exposure, from animal experiments, from some combination of the two, or from other data. Similarly, information on mode of action can specify to what extent the data are from *in vivo* or *in vitro* exposures or based on similarities to other chemicals. The extent to which an agent's mode of action occurs only on reaching a minimum dose or a minimum duration should also be presented. A hazard might also be expressed disproportionately in individuals possessing a specific gene; such characterizations may follow from a better understanding of the human genome. Furthermore, route of exposure should be used to qualify a hazard if, for example, an agent is not absorbed by some routes. Similarly, a hazard can be attributable to exposures during a susceptible lifestage on the basis of our understanding of human development.

The weight of evidence-of-evidence narrative should highlight:

- the quality and quantity of the data;
- all key decisions and the basis for these major decisions; and
- any data, analyses, or assumptions that are unusual for or new to EPA.

To capture this complexity, a weight of evidence narrative generally includes

- conclusions about human carcinogenic potential (choice of descriptor(s), described below),

- a summary of the key evidence supporting these conclusions (for each descriptor used), including information on the type(s) of data (human and/or animal, *in vivo* and/or *in vitro*) used to support the conclusion(s),

- available information on the epidemiologic or experimental conditions that characterize expression of carcinogenicity (e.g., if carcinogenicity is possible only by one exposure route or only above a certain human exposure level),

- a summary of potential modes of action and how they reinforce the conclusions,

- indications of any susceptible populations or lifestages, when available, and

- a summary of the key default options invoked when the available information is inconclusive.

To provide some measure of clarity and consistency in an otherwise free-form narrative, the weight of evidence descriptors are included in the first sentence of the narrative. Choosing a descriptor is a matter of judgment and cannot be reduced to a formula. Each descriptor may be applicable to a wide variety of potential data sets and weights of evidence. These descriptors and narratives are intended to permit sufficient flexibility to accommodate new scientific understanding and new testing methods as they are developed and accepted by the scientific community and the public. Descriptors represent points along a continuum of evidence; consequently, there are gradations and borderline cases that are clarified by the full narrative. Descriptors, as well as an introductory paragraph, are a short summary of the complete narrative that preserves the complexity that is an essential part of the hazard characterization. **Users of these cancer guidelines and of the risk assessments that result from the use of these cancer guidelines should consider the entire range of information included in the narrative rather than focusing simply on the descriptor.**

In borderline cases, the narrative explains the case for choosing one descriptor and discusses the arguments for considering but not choosing another. For example, between "suggestive" and "likely" or between "suggestive" and "inadequate," the explanation clearly communicates the information needed to consider appropriately the agent's carcinogenic potential in subsequent decisions.

Multiple descriptors can be used for a single agent, for example, when carcinogenesis is dose- or route-dependent. For example, if an agent causes point-of-contact tumors by one exposure route but adequate testing is negative by another route, then the agent could be described as likely to be carcinogenic by the first route but not likely to be carcinogenic by the second. Another example is when the mode of action is sufficiently understood to conclude that a key event in tumor development would not occur below a certain dose range. In this case, the agent could be described as likely to be carcinogenic above a certain dose range but not likely to be carcinogenic below that range.

Descriptors can be selected for an agent that has not been tested in a cancer bioassay if sufficient other information, e.g., toxicokinetic and mode of action information, is available to make a strong, convincing, and logical case through scientific inference. For example, if an agent is one of a well-defined class of agents that are understood to operate through a common mode of action and if that agent has the same mode of action, then in the narrative the untested agent would have the same descriptor as the class. Another example is when an untested agent's effects are understood to be caused by a human metabolite, in which case in the narrative the untested agent could have the same descriptor as the metabolite. As new testing methods are developed and used, assessments may increasingly be based on inferences from toxicokinetic and mode of action information in the absence of tumor studies in animals or humans.

When a well-studied agent produces tumors only at a point of initial contact, the descriptor generally applies only to the exposure route producing tumors unless the mode of action is relevant to other routes. The rationale for this conclusion would be explained in the narrative.

When tumors occur at a site other than the point of initial contact, the descriptor generally applies to all exposure routes that have not been adequately tested at sufficient doses. An

exception occurs when there is convincing information, e.g., toxicokinetic data that absorption does not occur by another route.

When the response differs qualitatively as well as quantitatively with dose, this information should be part of the characterization of the hazard. In some cases reaching a certain dose range can be a precondition for effects to occur, as when cancer is secondary to another toxic effect that appears only above a certain dose. In other cases exposure duration can be a precondition for hazard if effects occur only after exposure is sustained for a certain duration. These considerations differ from the issues of relative absorption or potency at different dose levels because they may represent a discontinuity in a dose-response function.

When multiple bioassays are inconclusive, mode of action data are likely to hold the key to resolution of the more appropriate descriptor. When bioassays are few, further bioassays to replicate a study's results or to investigate the potential for effects in another sex, strain, or species may be useful.

When there are few pertinent data, the descriptor makes a statement about the database, for example, “Inadequate Information to Assess Carcinogenic Potential,” or a database that provides “Suggestive Evidence of Carcinogenic Potential.” With more information, the descriptor expresses a conclusion about the agent’s carcinogenic potential to humans. If the conclusion is positive, the agent could be described as “Likely to Be Carcinogenic to Humans” or, with strong evidence, “Carcinogenic to Humans.” If the conclusion is negative, the agent could be described as “Not Likely to Be Carcinogenic to Humans.”

Although the term “likely” can have a probabilistic connotation in other contexts, its use as a weight of evidence descriptor does not correspond to a quantifiable probability of whether the chemical is carcinogenic. This is because the data that support cancer assessments generally are not suitable for numerical calculations of the probability that an agent is a carcinogen. Other health agencies have expressed a comparable weight of evidence using terms such as “Reasonably Anticipated to Be a Human Carcinogen” (NTP) or “Probably Carcinogenic to Humans” (International Agency for Research on Cancer).

The following descriptors can be used as an introduction to the weight of evidence narrative. The examples presented in the discussion of the descriptors are illustrative. The

examples are neither a checklist nor a limitation for the descriptor. The complete weight of evidence narrative, rather than the descriptor alone, provides the conclusions and the basis for them.

"Carcinogenic to Humans"

This descriptor indicates strong evidence of human carcinogenicity. It covers different combinations of evidence.

- This descriptor is appropriate when there is convincing epidemiologic evidence of a causal association between human exposure and cancer.

- Exceptionally, this descriptor may be equally appropriate with a lesser weight of epidemiologic evidence that is strengthened by other lines of evidence. It can be used when all of the following conditions are met: (a) there is strong evidence of an association between human exposure and either cancer or the key precursor events of the agent's mode of action but not enough for a causal association, and (b) there is extensive evidence of carcinogenicity in animals, and (c) the mode(s) of carcinogenic action and associated key precursor events have been identified in animals, and (d) there is strong evidence that the key precursor events that precede the cancer response in animals are anticipated to occur in humans and progress to tumors, based on available biological information. In this case, the narrative includes a summary of both the experimental and epidemiologic information on mode of action and also an indication of the relative weight that each source of information carries, e.g., based on human information, based on limited human and extensive animal experiments.

"Likely to Be Carcinogenic to Humans"

This descriptor is appropriate when the weight of the evidence is adequate to demonstrate carcinogenic potential to humans but does not reach the weight of evidence for the descriptor

"Carcinogenic to Humans." Adequate evidence consistent with this descriptor covers a broad spectrum. As stated previously, the use of the term "likely" as a weight of evidence descriptor does not correspond to a quantifiable probability. The examples below are meant to represent the broad range of data combinations that are covered by this descriptor; they are illustrative and provide neither a checklist nor a limitation for the data that might support use of this descriptor. Moreover, additional information, e.g., on mode of action, might change the choice of descriptor for the illustrated examples. Supporting data for this descriptor may include:

- an agent demonstrating a plausible (but not definitively causal) association between human exposure and cancer, in most cases with some supporting biological, experimental evidence, though not necessarily carcinogenicity data from animal experiments;

- an agent that has tested positive in animal experiments in more than one species, sex, strain, site, or exposure route, with or without evidence of carcinogenicity in humans;

- a positive tumor study that raises additional biological concerns beyond that of a statistically significant result, for example, a high degree of malignancy, or an early age at onset;

- a rare animal tumor response in a single experiment that is assumed to be relevant to humans; or

- a positive tumor study that is strengthened by other lines of evidence, for example, either plausible (but not definitively causal) association between human exposure and cancer or evidence that the agent or an important metabolite causes events generally known to be associated with tumor formation (such as DNA reactivity or effects on cell growth control) likely to be related to the tumor response in this case.

"Suggestive Evidence of Carcinogenic Potential"

This descriptor of the database is appropriate when the weight of evidence is suggestive of carcinogenicity; a concern for potential carcinogenic effects in humans is raised, but the data are judged not sufficient for a stronger conclusion. This descriptor covers a spectrum of evidence associated with varying levels of concern for carcinogenicity, ranging from a positive cancer result in the only study on an agent to a single positive cancer result in an extensive database that includes negative studies in other species. Depending on the extent of the database, additional studies may or may not provide further insights. Some examples include:

- a small, and possibly not statistically significant, increase in tumor incidence observed in a single animal or human study that does not reach the weight of evidence for the descriptor "Likely to Be Carcinogenic to Humans." The study generally would not be contradicted by other studies of equal quality in the same population group or experimental system (see discussions of *conflicting evidence* and *differing results*, below);

- a small increase in a tumor with a high background rate in that sex and strain, when there is some but insufficient evidence that the observed tumors may be due to intrinsic factors that cause background tumors and not due to the agent being assessed. (When there is a high background rate of a specific tumor in animals of a particular sex and strain, then there may be biological factors operating independently of the agent being assessed that could be responsible for the development of the observed tumors.) In this case, the reasons for determining that the tumors are not due to the agent are explained;

- evidence of a positive response in a study whose power, design, or conduct limits the ability to draw a confident conclusion (but does not make the study fatally

flawed), but where the carcinogenic potential is strengthened by other lines of evidence (such as structure-activity relationships); or

- a statistically significant increase at one dose only, but no significant response at the other doses and no overall trend.

"Inadequate Information to Assess Carcinogenic Potential"

This descriptor of the database is appropriate when available data are judged inadequate for applying one of the other descriptors. Additional studies generally would be expected to provide further insights. Some examples include:

- little or no pertinent information;

- conflicting evidence, that is, some studies provide evidence of carcinogenicity but other studies of equal quality in the same sex and strain are negative. *Differing results*, that is, positive results in some studies and negative results in one or more different experimental systems, do not constitute *conflicting evidence*, as the term is used here. Depending on the overall weight of evidence, differing results can be considered either suggestive evidence or likely evidence; or

- negative results that are not sufficiently robust for the descriptor, "Not Likely to Be Carcinogenic to Humans."

"Not Likely to Be Carcinogenic to Humans"

This descriptor is appropriate when the available data are considered robust for deciding that there is no basis for human hazard concern. In some instances, there can be positive results in experimental animals when there is strong, consistent evidence that each mode of action in experimental animals does not operate in humans. In other cases, there can be convincing

evidence in both humans and animals that the agent is not carcinogenic. The judgment may be based on data such as:

- animal evidence that demonstrates lack of carcinogenic effect in both sexes in well-designed and well-conducted studies in at least two appropriate animal species (in the absence of other animal or human data suggesting a potential for cancer effects),

- convincing and extensive experimental evidence showing that the only carcinogenic effects observed in animals are not relevant to humans,

- convincing evidence that carcinogenic effects are not likely by a particular exposure route (see Section 2.3), or

- convincing evidence that carcinogenic effects are not likely below a defined dose range.

A descriptor of “not likely” applies only to the circumstances supported by the data. For example, an agent may be “Not Likely to Be Carcinogenic” by one route but not necessarily by another. In those cases that have positive animal experiment(s) but the results are judged to be not relevant to humans, the narrative discusses why the results are not relevant.

Multiple Descriptors

More than one descriptor can be used when an agent's effects differ by dose or exposure route. For example, an agent may be “Carcinogenic to Humans” by one exposure route but “Not Likely to Be Carcinogenic” by a route by which it is not absorbed. Also, an agent could be “Likely to Be Carcinogenic” above a specified dose but “Not Likely to Be Carcinogenic” below that dose because a key event in tumor formation does not occur below that dose.

2.6. HAZARD CHARACTERIZATION

The *hazard characterization* contains the hazard information needed for a full risk characterization (U.S. EPA, 2000b). It presents the results of the hazard assessment and explains how the weight of evidence conclusion was reached. The hazard characterization summarizes, in plain language, conclusions about the agent's potential effects, whether they can be expected to depend qualitatively on the circumstances of exposure, and if anyone can be expected to be especially susceptible. It discusses the extent to which these conclusions are supported by data or are the result of default options invoked because the data are inconclusive. It explains how complex cases with differing results in different studies were resolved. The hazard characterization highlights the major issues addressed in the hazard assessment and discusses alternative interpretations of the data and the degree to which they are supportable scientifically and are consistent with EPA guidelines.

When the conclusion is supported by mode of action information, the hazard characterization also provides a clear summary of the mode of action conclusions (see Section 2.4.3.4), including the completeness of the data, the strengths and limitations of the inferences made, the potential for other modes of action, and the implications of the mode of action for selecting viable approaches to the dose-response assessment. The hazard characterization also discusses the extent to which mode of action information is available to address the potential for disproportionate risks in specific populations or lifestages or the potential for enhanced risks on the basis of interactions with other agents or stressors, if anticipated.

Topics that can be addressed in a hazard characterization include:

- summary of the results of the hazard assessment;

- identification of any likely susceptible populations and lifestages, especially attending to children, infants, and fetuses;

- conclusions about the agent's mode of action, and implications for selecting approaches to the dose-response assessment;

- identification of the available lines of evidence (e.g., animal bioassays, epidemiologic studies, toxicokinetic information, mode of action studies, and information about structural analogues or metabolites), highlighting data quality and coherence of results from different lines of evidence; and

- strengths and limitations of the hazard assessment, highlighting significant issues in interpreting the data, alternative interpretations that are considered equally plausible, critical data gaps, and default options invoked when the available information is inconclusive.

3. DOSE-RESPONSE ASSESSMENT

Dose-response assessment estimates potential risks to humans at exposure levels of interest. Dose-response assessments are useful in many applications: estimating risk at different exposure levels, estimating the risk reduction for different decision options, estimating the risk remaining after an action is taken, providing the risk information needed for benefit-cost analyses of different decision options, comparing risks across different agents or health effects, and setting research priorities. The purpose of the assessment should consider the quality of the data available, which will vary from case to case.

A dose-response analysis is generally developed from each study that reports quantitative data on dose and response. Alternative measures of dose are available for analyzing human and animal studies (see Section 3.1). A two-step approach distinguishes analysis of the dose-response data from inferences made about lower doses. The first step is an analysis of dose and response in the range of observation of the experimental or epidemiologic studies (see Section 3.2). Modeling is encouraged to incorporate a wide range of experimental data into the dose-response assessment (see Sections 3.1.2, 3.2.1, 3.2.2, 3.2.3). The modeling yields a point of departure (POD) near the lower end of the observed range, without significant extrapolation to lower doses (see Sections 3.2.4, 3.2.5). The second step is extrapolation to lower doses (see Section 3.3). The extrapolation approach considers what is known about the agent's mode of action (see Section 3.3.1). Both linear and nonlinear approaches are available (see Sections 3.3.3, 3.3.4). When multiple estimates can be developed, the strengths and weaknesses of each are presented. In some cases, they may be combined in a way that best represents human cancer risk (see Section 3.3.5). Special consideration is given to describing dose-response differences attributable to different human exposure scenarios (see Section 3.4) and to susceptible populations and lifestages (see Section 3.5). It is important to discuss significant uncertainties encountered in the analysis (see Section 3.6) and to characterize other important aspects of the dose-response assessment (see Section 3.7).

The scope, depth, and use of a dose-response assessment vary in different circumstances. Although the quality of dose-response data is not necessarily related to the weight of evidence

descriptor, dose-response assessments are generally completed for agents considered "Carcinogenic to Humans" and "Likely to Be Carcinogenic to Humans." When there is suggestive evidence, the Agency generally would not attempt a dose-response assessment, as the nature of the data generally would not support one; however, when the evidence includes a well-conducted study, quantitative analyses may be useful for some purposes, for example, providing a sense of the magnitude and uncertainty of potential risks, ranking potential hazards, or setting research priorities. In each case, the rationale for the quantitative analysis is explained, considering the uncertainty in the data and the suggestive nature of the weight of evidence. These analyses generally would not be considered Agency consensus estimates. Dose-response assessments are generally not done when there is inadequate evidence, although calculating a bounding estimate from an epidemiologic or experimental study that does not show positive results can indicate the study's level of sensitivity and capacity to detect risk levels of concern.

Cancer is a collection of several diseases that develop through cell and tissue changes over time. Dose-response assessment procedures based on tumor incidence have seldom taken into account the effects of key precursor events within the whole biological process due to lack of empirical data and understanding about these events. In this discussion, response data include measures of key precursor events considered integral to the carcinogenic process in addition to tumor incidence. These responses may include changes in DNA, chromosomes, or other key macromolecules; effects on growth signal transduction, including induction of hormonal changes; or physiological or toxic effects that include proliferative events diagnosed as precancerous but not pathology that is judged to be cancer. Analysis of such responses may be done along with that of tumor incidence to enhance the tumor dose-response analysis. If dose-response analysis of nontumor key events is more informative about the carcinogenic process for an agent, it can be used in lieu of, or in conjunction with, tumor incidence analysis for the overall dose-response assessment.

As understanding of mode of action improves and new types of data become available, dose-response assessment will continue to evolve. These cancer guidelines encourage the development and application of new methods that improve dose-response assessment by reflecting new scientific understanding and new sources of information.

3.1. ANALYSIS OF DOSE

For each effect observed, dose-response assessment should begin by determining an appropriate *dose metric*. Several dose metrics have been used, e.g., delivered dose, body burden, and area under the curve, and others may be appropriate depending on the data and mode of action.

Selection of an appropriate dose metric considers what data are available and what is known about the agent's mode of action at the target site, and uncertainties involved in estimation and application of alternative metrics. The dose metric specifies:

- the agent measured, preferably the active agent (administered agent or a metabolite);
- proximity to the target site (exposure concentration, potential dose, internal dose, or delivered dose,[5] reflecting increasing proximity); and

- the time component of the effective dose (cumulative dose, average dose, peak dose, or body burden).

Analyses can be based on estimates of animal dose metrics or human dose metrics. The assessment should describe the approach used to select a dose metric and the reasons for this approach. The final analysis, however, should determine a human equivalent dose metric. This facilitates comparing results from different datasets and effects by using human equivalent dose/concentrations as common metrics. When appropriate, it may be necessary to convert dose metrics across exposure routes. When route-to-route extrapolations are made, the underlying data, algorithms, and assumptions are clearly described.

---

[5] *Exposure* is contact of an agent with the outer boundary of an organism. *Exposure concentration* is the concentration of a chemical in its transport or carrier medium at the point of contact. *Dose* is the amount of a substance available for interaction with metabolic processes or biologically significant receptors after crossing the outer boundary of an organism. *Potential dose* is the amount ingested, inhaled, or applied to the skin. *Applied dose* is the amount of a substance presented to an absorption barrier and available for absorption (although not necessarily having yet crossed the outer boundary of the organism). *Absorbed dose* is the amount crossing a specific absorption barrier (e.g., the exchange boundaries of skin, lung, and digestive tract) through uptake processes. *Internal dose* is a more general term, used without respect to specific absorption barriers or exchange boundaries. *Delivered dose* is the amount of the chemical available for interaction by any particular organ or cell (U.S. EPA, 1992a).

Timing of exposure can also be important. When there is a susceptible lifestage, doses during the susceptible period are not equivalent to doses at other times, and they would be analyzed separately.

3.1.1. Standardizing Different Experimental Exposure Regimens

Complex exposure or dosing regimens are often present in experimental and epidemiologic studies. The resulting internal dose depends on many variables, including concentration, duration, frequency of administration, and duration of recovery periods between administrations. Internal dose also depends on variables that are intrinsic to the exposed individual, such as lifestage and rates of metabolism and clearance. To facilitate comparing results from different study designs and to make inferences about human exposures, a summary estimate of the dose metric, whether the administered dose or inhalation exposure concentration or an internal metric, may be derived for a complex exposure regimen.

Toxicokinetic modeling is the preferred approach for estimating dose metrics from exposure. Toxicokinetic models generally describe the relationship between exposure and measures of internal dose over time. More complex models can reflect sources of intrinsic variation, such as polymorphisms in metabolism and clearance rates. When a robust model is not available, or when the purpose of the assessment does not warrant developing a model, simpler approaches may be used.

For chronic exposure studies, the cumulative exposure or dose administered often is expressed as an average over the duration of the study, as one consistent dose metric. This approach implies that a higher dose administered over a short duration is equivalent to a commensurately lower dose administered over a longer duration. Uncertainty usually increases as the duration becomes shorter relative to the averaging duration or the intermittent doses become more intense than the averaged dose. Moreover, doses during any specific susceptible or refractory period would not be equivalent to doses at other times. For these reasons, cumulative exposure or potential dose may be replaced by a more appropriate dose metric when indicated by the data.

For mode of action studies, the dose metric should be calculated over a duration that reflects the time to occurrence of the key precursor effects. Mode of action studies are often of limited duration, as the precursors can be observed after less-than-chronic exposures. When the experimental exposure regimen is specified on a weekly basis (for example, 4 hours a day, 5 days a week), the daily exposure may be averaged over the week, where appropriate.

Doses in studies at the cellular or molecular level can be difficult to relate to organ- or organism-level dose metrics. Toxicokinetic modeling can sometimes be used to relate doses at the cellular or molecular level to doses or exposures at higher levels of organization.

3.1.2. Toxicokinetic Data and Modeling

In the absence of chemical-specific data, physiologically based toxicokinetic modeling is potentially the most comprehensive way to account for biological processes that determine internal dose. Physiologically based models commonly describe blood flow between physiological compartments and simulate the relationship between applied dose and internal dose. Toxicokinetic models generally need data on absorption, distribution, metabolism, and elimination of the administered agent and its metabolites.

Additionally, in the case of inhalation exposures, models can explicitly characterize the geometry of the respiratory tract and the airflow through it, as well as the interaction of this airflow with the entrained particles or fibers and gases (Kimbell et al., 2001; Subramaniam et al., 2003). Because of large interspecies differences in airway morphometry such models can be particularly useful in interspecies extrapolations. When employed, however, the potential for large inter-individual differences in airway morphometry, are considered to ensure that the models provide information representative of human populations.

Toxicokinetic models can improve dose-response assessment by revealing and describing nonlinear relationships between applied and internal dose. Nonlinearity observed in a dose-response curve often can be attributed to toxicokinetics (Hoel et al., 1983; Gaylor et al., 1994), involving, for example, saturation or induction of enzymatic processes at high doses. In some cases, toxicokinetic processes tend to become linear at sufficiently low doses (Hattis, 1990).

A discussion of confidence should accompany the presentation of model results and include consideration of model validation and sensitivity analysis, stressing the predictive performance of the model and whether the model is sufficient to support decision-making. Quantitative uncertainty analysis is important for evaluating the performance of a model, whether the model is based primarily on default assumptions or chemical-specific data. The uncertainty analysis covers questions of *model uncertainty* (e.g., Is the model based on the appropriate biology and how does that affect estimates of dose metrics?) and *parameter uncertainty* (e.g., Do the data support unbiased and stable estimates of the model parameters?). When a delivered dose measure is used in animal-to-human extrapolation, the assessment discusses the confidence of the target tissue and its toxicodynamics being the same in both species (see Section 3.6). Toxicokinetic modeling results may be presented alone as the preferred method of estimating human equivalent exposures or doses, or these results may be presented in parallel with default procedures (see Section 3.1.3), depending on the confidence in the modeling.

3.1.3. Cross-species Scaling Procedures

Standard cross-species scaling procedures are available when the data are not sufficient to support a toxicokinetic model or when the purpose of the assessment does not warrant developing one. The aim is to define exposure levels for humans and animals that are expected to produce the same degree of effect (U.S. EPA, 1992b), taking into account differences in scale between test animals and humans, such as size and lifespan.

3.1.3.1. Oral Exposures

For oral exposures, administered doses should be scaled from animals to humans on the basis of equivalence of $mg/kg^{3/4}$-d (milligrams of the agent normalized by the 3/4 power of body weight per day) (U.S. EPA, 1992b). The 3/4 power is consistent with current science, including empirical data that allow comparison of potencies in humans and animals, and it is also supported by analysis of the allometric variation of key physiological parameters across mammalian species. It is generally more appropriate at low doses, where sources of nonlinearity such as saturation of enzyme activity are less likely to occur. This scaling is intended as an

unbiased estimate rather than a conservative one. Equating exposure concentrations in food or water is an alternative version of the same approach, because daily intakes of food or water are approximately proportional to the 3/4 power of body weight.

The aim of these cross-species scaling procedures is to estimate administered doses in animals and humans that result in equal lifetime risks. It is useful to recognize two components of this equivalence: *toxicokinetic equivalence*, which determines administered doses in animals and humans that yield equal tissue doses, and *toxicodynamic equivalence*, which determines tissue doses in animals and humans that yield equal lifetime risks (U.S. EPA, 1992b). Toxicokinetic modeling (see Section 3.1.2) addresses factors associated with toxicokinetic equivalence, and toxicodynamic modeling (see Section 3.2.2) addresses factors associated with toxicodynamic equivalence. When toxicokinetic modeling is used without toxicodynamic modeling, the dose-response assessment develops and supports an approach for addressing toxicodynamic equivalence, perhaps by retaining some of the cross-species scaling factor (e.g., using the square root of the cross-species scaling factor or using a factor of 3 to cover toxicodynamic differences between animals and humans, as is currently done in deriving inhalation reference concentrations [U.S. EPA, 1994]).

When assessing risks from childhood exposure, the $mg/kg^{3/4}$-d scaling factor does not use the child's body weight (U.S. EPA, 1992b). This reflects several uncertainties in extrapolating risks to children:

- The data supporting the $mg/kg^{3/4}$-d scaling factor were derived for differences across species and may not apply as well to differently sized individuals of the same species or to different lifestages.

- In addition to metabolic differences, there are also important toxicodynamic differences; for example, children have faster rates of cell division than do adults, so scaling across different lifestages and species simultaneously may be particularly uncertain.

3.1.3.2. Inhalation Exposures

For inhalation exposures experimental exposure concentrations are replaced with human equivalent concentrations calculated using EPA's methods for deriving inhalation reference concentrations (U.S. EPA, 1994), which give preference to the use of toxicokinetic modeling. When toxicokinetic models are unavailable, default dosimetry models are employed to extrapolate from experimental exposure concentrations to human equivalent concentrations. When toxicokinetic modeling or dosimetry modeling is used without toxicodynamic modeling, the dose-response assessment develops and supports an approach for addressing toxicodynamic equivalence.

The default dosimetry models typically involve the use of species-specific physiologic and anatomic factors relevant to the form of the agent (e.g., particle or gas) and categorized with regard to whether the response occurs either locally (i.e., within the respiratory tract) or remotely. For example, current default models (U.S. EPA, 1994) use parameters such as:

- inhalation rate and surface area of the affected part of the respiratory tract for gases eliciting the response locally,

- blood:gas partition coefficients for remote acting gases,

- fractional deposition with inhalation rate and surface area of the affected part of the respiratory tract for particles eliciting the response locally, and

- fractional deposition with inhalation rate and body weight for particles eliciting the response remotely.

The current default values for some parameters used in the default models (e.g., breathing rate and respiratory tract surface area) are based on data from adults (U.S. EPA, 1994). The human respiratory system passes through several distinct stages of maturation and growth during the first several years of life and into adolescence (Pinkerton and Joad, 2000), during which

characteristics important to disposition of inhaled toxicants may vary. Children and adults breathing the same concentration of an agent may receive different doses to the body or lungs (U.S. EPA, 2002b). Consequently, it may be appropriate to evaluate the default models by considering physiologic and anatomic factors representative of early lifestages, for example through the substitution of child-specific parameters (U.S. EPA, 2002b). Such evaluation uses the default model and dosimetric adjustment in use at the time of the assessment coupled with the best understanding of child-specific parameters at that time (e.g., drawn from the scientific literature). This analysis is undertaken with caution: (1) because of the correlations between activity level, breathing rate, respiratory tract dimensions, and body weight and (2) to avoid the possibility of mismatching the type of agent (gas or particle) and its site of response (within the respiratory tract or remote from the respiratory tract) with the relevant dosimetry factors in use at the time of the assessment. Analyses of children's inhalation dosimetry are also considered when using model structures beyond the default models (e.g., physiologically based toxicokinetic models).

When using dosimetry modeling, the comparison of human-equivalent concentrations for different lifestages (e.g., for an adult and a child) can indicate whether it is important to carry both concentrations forward in the dose-response assessment or whether a verbal characterization of any findings will suffice.

3.1.4. Route Extrapolation

In certain situations, an assessment based on studies of one exposure route may be applied to another exposure route. Route-to-route extrapolation has both qualitative and quantitative aspects. For the qualitative aspect, the assessor should weigh the degree to which positive results by one exposure route support a judgment that similar results would be expected by another route. In general, confidence in making such a judgment is strengthened when tumors are observed at a site distant from the portal of entry and when absorption is similar through both routes. In the absence of contrary data, a qualitative default option can be used: if the agent is absorbed through an exposure route to give an internal dose, it may be carcinogenic by that route.

When a qualitative extrapolation can be supported, quantitative extrapolation may still be problematic due to the absence of adequate data. The differences in biological processes among routes of exposure (oral, inhalation, dermal) can be great because of, for example, first-pass effects and different results from different exposure patterns. There is no generally applicable method for accounting for these differences in uptake processes in a quantitative route-to-route extrapolation of dose-response data in the absence of good data on the agent of interest. Therefore, route-to-route extrapolation of dose data relies on a case-by-case analysis of available data. When good data on the agent itself are limited, an extrapolation analysis can be based on expectations from physical and chemical properties of the agent, properties and route-specific data on structurally analogous compounds, or *in vitro* or *in vivo* uptake data on the agent.

Route-to-route uptake models may be applied if model parameters are suitable for the compound of interest. Such models are currently considered interim methods; further model development and validation is awaiting the development of more extensive data. For screening or hazard ranking, route-to-route extrapolation may be based on assumed quantitative comparability as a default, as long as it is reasonable to assume absorption by compared routes. When route-to-route extrapolation is used, the assessor’s degree of confidence in both the qualitative and quantitative extrapolation is discussed in the assessment and highlighted in the dose-response characterization.

Toxicokinetic modeling can be used to compare results of studies by different exposure routes. Results can also be compared on the basis of internal dose for effects distant from the point of contact.

Route extrapolation can be used to understand how internal dose and subsequent effects depend on exposure route. If testing by different exposure routes is available, the observation of similar or dissimilar internal doses can be important in determining whether and what conclusions can be made concerning the dose-response function(s) for different routes of exposure.

3.2. ANALYSIS IN THE RANGE OF OBSERVATION

The principle underlying these cancer guidelines is to use approaches that include as much information as possible. Quantitative information about key precursor events can be used to develop a toxicodynamic model. Alternatively, such information can be fitted by empirical models to extend the dose-response analysis of tumor incidence to lower doses and response levels. The analysis in the range of observation is used to establish a POD near the lower end of the observed range (see Section 3.3).

3.2.1. Epidemiologic Studies

Ideally, epidemiologic data would be used to select the dose-response function for human exposures. Because epidemiologic data are usually limited and many models may fit the data (Samet et al.,1998), other factors may influence model choice. For epidemiologic studies, including those with grouped data, analysis by linear models in the range of observation is generally appropriate unless the fit is poor. The relatively small exposure range observed in many epidemiologic studies, for example, makes it difficult to discern the shape of the exposure- or dose-response curve. Exposure misclassification and errors in exposure estimation also obscure the shape of the dose-response curve. When these errors are unsystematic or random, the result is frequently to bias the risk estimates toward zero. When a linear model fits poorly, more flexible models that allow for low-dose linearity, for example, a linear-quadratic model or a Hill model (Murrell et al., 1998), are often considered next.

Analysis of epidemiologic studies depends on the type of study and quality of the data, particularly the availability of quantitative measures of exposure. The objective is to develop a dose-response curve that estimates the incidence of cancer attributable to the dose (as estimated from the exposure) to the agent. In some cases, e.g., tobacco smoke or occupational exposures, the data are in the range of the exposures of interest. In other cases, as with data from animal experiments, information from the observable range is extrapolated to exposures of interest.

Analysis of effects raises additional issues:

- Many studies collect information from death certificates, which leads to estimates of mortality rather than incidence. Because survival rates vary for different cancers, the analysis may be improved by adjusting mortality figures to reflect the relationship between incidence and mortality.

- Epidemiologic studies, by their nature, are limited in the extent to which they can control for effects due to exposures from other agents. In some cases, the agent can have discernible interactive effects with another agent, making it possible to estimate the contribution of each agent as a risk factor for the effects of the other. For example, competing risks in a study population can limit the observed occurrence of cancer, while additive effects may lead to an increase occurrence of cancer. In the case of rates not already so adjusted, the analysis can be improved by correcting for competing or additive risks that are not similar in exposed and comparison groups.

- Comparison groups that are not free from exposure to the agent can bias the risk estimates toward zero. The analysis can be improved by considering background exposures in the exposed and comparison groups.

- The latent period for most cancers implies that exposures immediately preceding the detection of a tumor would be less likely to have contributed to its development and, therefore, may count less in the analysis. Study subjects who were first exposed near the end of the study may not have had adequate time since exposure for cancer to develop; therefore, analysis of their data may be similar to analysis of data for those who were not exposed. However, for carcinogens that act on multiple stages of the carcinogenic process, especially the later stages, all periods of exposure. including recent exposures, may be important.

Some study designs can yield only a partial characterization of the overall hazard and therefore risk as, for example, in studies that: (1) investigate only one effect (typical of many

case-control studies), (2) include only one population segment (e.g., male workers or workers of one socioeconomic class), or (3) include only one lifestage (e.g., childhood leukemia following maternal exposure to contaminated drinking water). To obtain a more complete characterization that includes risks of other cancers, estimates from these studies can be supplemented with estimates from other studies that investigated other cancers, population segments, or lifestages (see Section 3.5).

When several studies are available for dose-response analysis, *meta-analysis* can provide a systematic approach to weighing positive studies and those studies that do not show positive results, and calculating an overall risk estimate with greater precision. Issues considered include the comparability of studies, heterogeneity across studies, and the potential for a single large study to dominate the analysis. Confidence in a meta-analysis is increased when it considers study quality, including definition of the study population and comparison group, measurement of exposure, potential for exposure misclassification, adequacy of follow-up period, and analysis of confounders (see Section 2.2.1.3).

3.2.2. Toxicodynamic ("Biologically Based") Modeling

Toxicodynamic modeling can be used when there are sufficient data to ascertain the mode of action (see Section 2.4) and quantitatively support model parameters that represent rates and other quantities associated with the key precursor events of the mode of action. Toxicodynamic modeling is potentially the most comprehensive way to account for the biological processes involved in a response. Such models seek to reflect the sequence of key precursor events that lead to cancer. Toxicodynamic models can contribute to dose-response assessment by revealing and describing nonlinear relationships between internal dose and cancer response. Such models may provide a useful approach for analysis in the range of observation, provided the purpose of the assessment justifies the effort involved.

If a new model is developed for a specific agent, extensive data on the agent are important for identifying the form of the model, estimating its parameters, and building confidence in its results. Conformance to the observed tumor incidence data alone does not establish a model's validity, as a model can be designed with a sufficiently large number of parameters so as to fit

any given dataset. Peer review, including both an examination of the scientific basis supporting the model and an independent evaluation of the model's performance, is an essential part of evaluating the new model.

If a standard model already exists for the agent's mode of action, the model can be adapted for the agent by using agent-specific data to estimate the model's parameters. An example is the two-stage clonal expansion model developed by Moolgavkar and Knudson (1981) and Chen and Farland (1991). These models continue to be improved as more information becomes available.

It is possible for different models to provide equivalent fits to the observed data but to diverge substantially in their projections at lower doses. When model parameters are estimated from tumor incidence data, it is often the case that different combinations of parameter estimates can yield similar results in the observed range. For this reason, critical parameters (e.g., mutation rates and cell birth and death rates) are estimated from laboratory studies and not by curve-fitting to tumor incidence data (Portier, 1987). This approach reduces model uncertainty (see Section 3.6) and ensures that the model does not give answers that are biologically unrealistic. This approach also provides a robustness of results, where the results are not likely to change substantially if fitted to slightly different data.

Toxicodynamic modeling can provide insight into the relationship between tumors and key precursor events. For example, a model that includes cell proliferation can be used to explore the extent to which small increases in the cell proliferation rate can lead to large lifetime tumor incidences (Gaylor and Zheng, 1996). In this way, toxicodynamic modeling can be used to select and characterize an appropriate precursor response level (see Section 3.2.2, 3.2.5).

3.2.3. Empirical Modeling (“Curve Fitting”)

When a toxicodynamic model is not available or when the purpose of the assessment does not warrant developing such a model, empirical modeling (sometimes called “curve fitting”) should be used in the range of observation. A model can be fitted to data on either tumor incidence or a key precursor event. Goodness-of-fit to the experimental observations is not by itself an effective means of discriminating among models that adequately fit the data (OSTP,

1985). Many different curve-fitting models have been developed, and those that fit the observed data reasonably well may lead to several-fold differences in estimated risk at the lower end of the observed range. Another problem occurs when a multitude of alternatives are presented without sufficient context to make a reasoned judgment about the alternatives. This form of model uncertainty reflects primarily the availability of different computer models and not biological information about the agent being assessed or about carcinogenesis in general. In cases where curve-fitting models are used because the data are not adequate to support a toxicodynamic model, there generally would be no biological basis to choose among alternative curve-fitting models. However, in situations where there are alternative models with significant biological support, the decisionmaker can be informed by the presentation of these alternatives along with their strengths and uncertainties.

Quantitative data on precursors can be used in conjunction with, or in lieu of, data on tumor incidence to extend the dose-response curve to lower doses. Caution is used with rates of molecular events such as mutation or cell proliferation or signal transduction. Such rates can be difficult to relate to cell or tissue changes overall. The timing of observations of these phenomena, as well as the cell type involved, is linked to other precursor events to ensure that the measurement is truly a key event (Section 2.4).

For incidence data on either tumors or a precursor, an established empirical procedure is used to provide objectivity and consistency among assessments. The procedure models incidence, corrected for background, as an increasing function of dose. The models are sufficiently flexible in the observed range to fit linear and nonlinear datasets. Additional judgments and perhaps alternative analyses are used when the procedure fails to yield reliable results. For example, when a model's fit is poor, the highest dose is often omitted in cases where it is judged that the highest dose reflects competing toxicity that is more relevant at high doses than at lower doses. Another example is when there are large differences in survival across dose groups; here, models that includes time-to-tumor or time-to-event information may be useful.

For continuous data on key precursor effects, empirical models can be chosen on the basis of the structure of the data. The rationale for the choice of model, the alternatives

considered and rejected, and a discussion of model uncertainty are included in the dose-response characterization.

3.2.4. Point of Departure (POD)

For each tumor response, a POD from the observed data should be estimated to mark the beginning of extrapolation to lower doses. The POD is an estimated dose (expressed in human-equivalent terms) near the lower end of the observed range without significant extrapolation to lower doses.

The POD is used as the starting point for subsequent extrapolations and analyses. For linear extrapolation, the POD is used to calculate a *slope factor* (see Section 3.3.3), and for nonlinear extrapolation the POD is used in the calculation of a *reference dose* or *reference concentration* (see Section 3.3.4). In a risk characterization, the POD is part of the determination of a *margin of exposure* (see Section 5.4). With appropriate adjustments, it can also be used as the basis for *hazard rankings* that compare different agents or health effects.

The lowest POD is used that is adequately supported by the data. If the POD is above some data points, it can fail to reflect the shape of the dose-response curve at the lowest doses and can introduce bias into subsequent extrapolations (see Figure 3-1). On the other hand, if the POD is far below all observed data points, it can introduce model uncertainty and parameter uncertainty (see Section 3.6) that increase with the distance between the data and the POD. Use of a POD at the lowest level supported by the data seeks to balance these considerations. It uses information from the model(s) a small distance below the observed range rather than discarding this information and using extrapolation procedures in a range where the model(s) can provide some useful information. Statistical tests involving the ratio of the central estimate and its lower bound (i.e., ED_{xx}/LED_{xx}) can be useful for evaluating how well the data support a model's estimates at a particular response level. (Note that the ability to model at a particular response level is not the same as the study's ability to identify an increase at that response level as statistically significant.)

The POD for extrapolating the relationship to environmental exposure levels of interest, when the latter are outside the range of observed data, is generally the lower 95% confidence

limit on the lowest dose level that can be supported for modeling by the data. SAB (1997) suggested that, "it may be appropriate to emphasize lower statistical bounds in screening analyses and in activities designed to develop an appropriate human exposure value, since such activities require accounting for various types of uncertainties and a lower bound on the central estimate is a scientifically-based approach accounting for the uncertainty in the true value of the ED_{10} [or central estimate]." However, the consensus of the SAB (1997) was that, "both point estimates and statistical bounds can be useful in different circumstances, and recommended that the Agency routinely calculate and present the point estimate of the ED_{10} [or central estimate] and the corresponding upper and lower 95% statistical bounds." For example, it may be appropriate to emphasize the central estimate in activities that involve formal uncertainty analysis that are required by OMB Circular A-4 (OMB, 2003) as well as ranking agents as to their carcinogenic hazard. Thus, risk assessors should calculate, to the extent practicable, and present the central estimate and the corresponding upper and lower statistical bounds (such as confidence limits) to inform decisionmakers.

When tumor data are used, a POD is obtained from the modeled tumor incidences. Conventional cancer bioassays, with approximately 50 animals per group, generally can support modeling down to an increased incidence of 1–10%; epidemiologic studies, with larger sample sizes, below 1%. Various models commonly used for carcinogens yield similar estimates of the POD at response levels as low as 1% (Krewski and Van Ryzin, 1981; Gaylor et al., 1994). Consequently, response levels at or below 10% can often be used as the POD. As a modeling convention, the lower bound on the doses associated with standard response levels of 1, 5, and 10% can be analyzed, presented, and considered. For making comparisons at doses within the observed range, the ED_{10} and LED_{10} are also reported and can be used, with appropriate adjustments, in hazard rankings that compare different agents or health effects (U.S. EPA, 2002c). A *no-observed-adverse-effect level* (NOAEL) generally is not used for assessing the potential for carcinogenic response when one or more models can be fitted to the data.

When good quality precursor data are available and are clearly tied to the mode of action of the compound of interest, models that include both tumors and their precursors may be advantageous for deriving a POD. Such models can provide insight into quantitative

relationships between tumors and precursors (see Section 3.2.2), possibly suggesting the precursor response level that is associated with a particular tumor response level. The goal is to use precursor data to extend the observed range below what can be observed in tumor studies. EPA is continuing to examine this issue and anticipates that findings and conclusions may result in supplemental guidance to these cancer guidelines. If the precursor data are drawn from small samples or if the quantitative relationship between tumors and precursors is not well defined, then the tumor data will provide a more reliable POD. Precursor effects may or may not be biologically adverse in themselves; the intent is to consider not only tumors but also damage that can lead to subsequent tumor development by the agent. Analysis of continuous data may differ from discrete data; Murrell et al. (1998) discuss alternative approaches to deriving a POD from continuous data.

3.2.5. Characterizing the POD: The POD Narrative

As a single-point summary of a single dose-response curve, the POD alone does not convey all the critical information present in the data from which it is derived. To convey a measure of uncertainty, the POD should be presented as a central estimate with upper and lower bounds. A POD narrative summarizes other important features of the database and the POD that are important to account for in low-dose extrapolations or other analyses.

(a) Nature of the response. Is the POD based on tumors or a precursor? If on tumors, does the POD measure incidence or mortality? Is it a lifetime measure or was the study terminated early? The relationships between precursors and tumors, incidence and mortality, and lifetime and early-termination results vary from case to case. Modeling can provide quantitative insight into these relationships, for example, linking a change in a precursor response to a tumor incidence (see Section 3.2.2). This can aid in evaluating the significance of the response at the POD and adjusting different PODs to make them comparable.

(b) Level of the response. What level of response is associated with the POD, for example, 1% cancer risk, 10% cancer risk, or 10% change in a precursor measure?

(c) Nature of the study population. Is the POD based on humans or animals? How large is the effective sample size? Is the study group representative of the general population, of healthy adult workers, or of a susceptible group? Are both sexes represented? Did exposure occur during a susceptible lifestage?

(d) Slope of the dose-response curve at the POD. How does response change as dose is reduced below the POD? A steep slope indicates that risk decreases rapidly as dose decreases. On the other hand, a steep slope also indicates that errors in an exposure assessment can lead to large errors in estimating risk. Both aspects of the slope are important. The slope also indicates whether dose-response curves for different effects are likely to cross below the POD. For example, in the ED_{01} study where 2-acetylaminofluorene caused bladder carcinomas and liver carcinomas in mice (Littlefield et al., 1980), the dose-response curves for these tumors cross between 10% and 1% response (see Figure 3-2). This crossing, which can be inferred from the slopes of the curves at a 10% response, shows how considering the slope can lead to better inferences about the predominant effects expected at lower doses. Mode of action data can also be useful; quantitative information about key precursor events can be used to describe how risk decreases as dose decreases below the POD.

(e) Relationship of the POD with other cancers. How does the POD for this cancer relate to PODs for other cancers observed in the database? For example, a POD based on male workers would not reflect the implications of mammary tumors in female rats or mice.

(f) Extent of the overall cancer database. Have potential cancer responses been adequately studied (e.g., were all tissues examined), or is the database limited to particular effects, population segments, or lifestages? Do the mode of action data suggest a potential for cancers not observed in the database (e.g., disruption of particular endocrine pathways leading to related cancers)?

3.2.6. Relative Potency Factors

Relative potency factors (of which toxicity equivalence factors are a special case) can be used for a well-defined class of agents that operate through a common mode of action for the same toxic endpoint. A complete dose-response assessment is conducted for one well-studied member of the class that serves as the *index chemical* for the class. The other members of the class are tied to the index chemical by relative potency factors that are based on characteristics such as relative toxicological outcomes, relative metabolic rates, relative absorption rates, quantitative SARs, or receptor binding characteristics (U.S. EPA, 2000c). Examples of this approach are the *toxicity equivalence factors* for dioxin-like compounds and the relative potency factors for some carcinogenic polycyclic aromatic hydrocarbons. Whenever practicable, toxicity equivalence factors should be validated and accompanied by quantitative uncertainty analysis.

3.3. EXTRAPOLATION TO LOWER DOSES

The purpose of low-dose extrapolation is to provide as much information as possible about risk in the range of doses below the observed data. The most versatile forms of low-dose extrapolation are dose-response models that characterize risk as a probability over a range of environmental exposure levels. These risk probabilities allow estimates of the risk reduction under different decision options and estimates of the risk remaining after an action is taken and provide the risk information needed for benefit-cost analyses of different decision options.

When a dose-response model is not developed for lower doses, another form of low-dose extrapolation is a safety assessment that characterizes the safety of one lower dose, with no explicit characterization of risks above or below that dose. Although this type of extrapolation may be adequate for evaluation of some decision options, it may not be adequate for other purposes (e.g., benefit-cost analyses) that require a quantitative characterization of risks across a range of doses. At this time, safety assessment is the default approach for tumors that arise through a nonlinear mode of action; however, EPA continues to explore methods for quantifying dose-response relationships over a range of environmental exposure levels for tumors that arise through a nonlinear mode of action (U.S. EPA, 2002c). EPA program offices that need this more

explicit dose-response information may develop and apply methods that are informed by the methods described in these cancer guidelines.

3.3.1. Choosing an Extrapolation Approach

The approach for extrapolation below the observed data considers the understanding of the agent's mode of action at each tumor site (see Section 2.4). Mode of action information can suggest the likely shape of the dose-response curve at lower doses. The extent of inter-individual variation is also considered, with greater variation spreading the response over a wider range of doses.

Linear extrapolation should be used when there are MOA data to indicate that the dose-response curve is expected to have a linear component below the POD. Agents that are generally considered to be linear in this region include:

- agents that are DNA-reactive and have direct mutagenic activity, or

- agents for which human exposures or body burdens are high and near doses associated with key precursor events in the carcinogenic process, so that background exposures to this and other agents operating through a common mode of action are in the increasing, approximately linear, portion of the dose-response curve.

When the weight of evidence evaluation of all available data are insufficient to establish the mode of action for a tumor site and when scientifically plausible based on the available data, linear extrapolation is used as a default approach, because linear extrapolation generally is considered to be a health-protective approach. Nonlinear approaches generally should not be used in cases where the mode of action has not been ascertained. Where alternative approaches with significant biological support are available for the same tumor response and no scientific consensus favors a single approach, an assessment may present results based on more than one approach.

A *nonlinear approach* should be selected when there are sufficient data to ascertain the mode of action and conclude that it is not linear at low doses and the agent does not demonstrate mutagenic or other activity consistent with linearity at low doses. Special attention is important when the data support a nonlinear mode of action but there is also a suggestion of mutagenicity. Depending on the strength of the suggestion of mutagenicity, the assessment may justify a conclusion that mutagenicity is not operative at low doses and focus on a nonlinear approach, or alternatively, the assessment may use both linear and nonlinear approaches.

Both linear and nonlinear approaches may be used when there are multiple modes of action. If there are multiple tumor sites, one with a linear and another with a nonlinear mode of action, then the corresponding approach is used at each site. If there are multiple modes of action at a single tumor site, one linear and another nonlinear, then both approaches are used to decouple and consider the respective contributions of each mode of action in different dose ranges. For example, an agent can act predominantly through cytotoxicity at high doses and through mutagenicity at lower doses where cytotoxicity does not occur. Modeling to a low response level can be useful for estimating the response at doses where the high-dose mode of action would be less important.

3.3.2. Extrapolation Using a Toxicodynamic Model

The preferred approach is to develop a toxicodynamic model of the agent's mode of action and use that model for extrapolation to lower doses (see Section 3.2.2). The extent of extrapolation is governed by an analysis of *model uncertainty*, where alternative models that fit similarly in the observed range can diverge below that range (see Section 3.6). Substantial divergence is likely when model parameters are estimated from tumor incidence data, so that different combinations of parameter estimates yield similar fits in the observed range but have different implications at lower doses. An analysis of model uncertainty can be used to determine the range where extrapolation using the toxicodynamic model is supported and where further extrapolation would be based on either a linear or a nonlinear default, as appropriate (see Sections 3.3.3, 3.3.4).

3.3.3. Extrapolation Using a Low-dose, Linear Model

Linear extrapolation should be used in two distinct circumstances: (1) when there are data to indicate that the dose-response curve has a linear component below the POD, or (2) as a default for a tumor site where the mode of action is not established (see Section 3.3.1). For linear extrapolation, a line should be drawn from the POD to the origin, corrected for background. This implies a proportional (linear) relationship between risk and dose at low doses. (Note that the dose-response curve generally is not linear at higher doses.)

The slope of this line, known as the *slope factor*, is an upper-bound estimate of risk per increment of dose that can be used to estimate risk probabilities for different exposure levels. The slope factor is equal to $0.01/LED_{01}$ if the LED_{01} is used as the POD.

Unit risk estimates express the slope in terms of μg/L drinking water or $\mu g/m^3$ or ppm air. In general, the drinking water unit risk is derived by converting a slope factor from units of mg/kg-d to units of μg/L, whereas an inhalation unit risk is developed directly from a dose-response analysis using equivalent human concentrations already expressed in units of $\mu g/m^3$. Unit risk estimates often assume a standard intake rate (L/day drinking water or m^3/day air) and body weight (kg), which may need to be reconciled with the exposure factors for the population of interest in an exposure assessment (see Section 4.4). Alternatively, when the slope factor for inhalation is in units of ppm, it may sometimes be termed the inhalation unit risk. Although unit risks have not been calculated in the past for dermal exposures, both exposures that are absorbed into the systemic circulation and those that remain in contact with the skin are also important.

Risk-specific doses are derived from the slope factor or unit risk to estimate the dose associated with a specific risk level, for example, a one-in-a-million increased lifetime risk.

3.3.4. Nonlinear Extrapolation to Lower Doses

A nonlinear extrapolation method can be used for cases with sufficient data to ascertain the mode of action and to conclude that it is not linear at low doses but with not enough data to support a toxicodynamic model that may be either nonlinear or linear at low doses. Nonlinear extrapolation having a significant biological support may be presented in addition to a linear approach when the available data and a weight of evidence evaluation support a nonlinear

approach, but the data are not strong enough to ascertain the mode of action applying the Agency's mode of action framework. If the mode of action and other information can support chemical-specific modeling at low doses, it is preferable to default procedures.

For cases where the tumors arise through a nonlinear mode of action, an oral *reference dose* or an inhalation *reference concentration*, or both, should be developed in accordance with EPA's established practice for developing such values, taking into consideration the factors summarized in the characterization of the POD (see Section 3.2.5). This approach expands the past focus of such reference values (previously reserved for effects other than cancer) to include carcinogenic effects determined to have a nonlinear mode of action. As with other health effects of concern, it is important to put cancer in perspective with the overall health impact of an exposure by comparing reference value calculations for cancer with those for other health effects.

For effects other than cancer, reference values have been described as being based on the assumption of biological thresholds. The Agency's more current guidelines for these effects (U.S. EPA, 1996a, 1998b), however, do not use this assumption, citing the difficulty of empirically distinguishing a true threshold from a dose-response curve that is nonlinear at low doses.

Economic and policy analysts need to know how the probability of cancer varies at exposures above the reference value and whether, and to what extent, there are health benefits from reducing exposures below the reference value. The risk assessment community is working to develop better methods to provide more useful information to economic and policy analysts.

3.3.5. Comparing and Combining Multiple Extrapolations

When multiple estimates can be developed, all datasets should be considered and a judgment made about how best to represent the human cancer risk. Some options for presenting results include:

- adding risk estimates derived from different tumor sites (NRC, 1994),

- combining data from different datasets in a joint analysis (Putzrath and Ginevan, 1991; Stiteler et al., 1993; Vater et al., 1993),

- combining responses that operate through a common mode of action,

- representing the overall response in each experiment by counting animals with any tumor showing a statistically significant increase,

- presenting a range of results from multiple datasets (in this case, the dose-response assessment includes guidance on how to choose an appropriate value from the range),

- choosing a single dataset if it can be justified as most representative of the overall response in humans, or

- a combination of these options.

Cross-comparison of estimates from human and animal studies can provide a valuable risk perspective.

- Calculating an animal-derived slope factor and using it to estimate the risk expected in a human study can provide information with which to evaluate the human study design, for example, adequacy of exposure level and sample size.

- Calculating an upper-bound slope factor from a human study that does not show positive results but that has good exposure information, and comparing it to an animal-derived slope factor can indicate whether the animal and humans studies are consistent.

3.4. EXTRAPOLATION TO DIFFERENT HUMAN EXPOSURE SCENARIOS

As described in the previous cancer guidelines, special problems arise when the human exposure situation of concern suggests exposure regimens, e.g., route and dosing schedule, that are substantially different from those used in the relevant animal studies. Unless there is evidence to the contrary in a particular case, the cumulative dose received over a lifetime, expressed as average daily exposure prorated over a lifetime, is recommended as an appropriate measure of exposure to a carcinogen. That is, the assumption is made that a high dose of a carcinogen received over a short period of time is equivalent to a corresponding low dose spread over a lifetime. This approach becomes more problematical as the exposures in question become more intense but less frequent, especially when there is evidence that the agent has shown dose-rate effects (U.S. EPA 1986a).

Accordingly, *for lifetime human exposure scenarios* that involve intermittent or varying levels of exposure, the prevailing practice has been to assess exposure by calculating a *lifetime average daily exposure or dose* (U.S. EPA, 1992a).

For less-than-lifetime human exposure scenarios, too, the lifetime average daily exposure or dose has often been used. The use of these lifetime average exposure metrics was adopted with low-dose linear cancer assessments in mind. The lifetime averaging implies that less-than-lifetime exposure is associated with a linearly proportional reduction of the lifetime risk, regardless of when exposures occur. Such averaging may be problematic in some situations. This can be illustrated using both the multistage model and the two-stage clonal expansion model that predict that short-duration risks are not necessarily proportional to exposure duration and can depend on the nature of the carcinogen and the timing of exposure (Goddard et al., 1995; Murdoch et al., 1992). These examples indicate some circumstances in which use of a lifetime average daily dose (LADD) would underestimate cancer risk by two- to fivefold, and others in which it might overestimate risk (Murdoch et al., 1992). Thus, averaging over the duration of a lifestage or a critical window of exposure may be appropriate. As methodological research focuses on new approaches for estimating risks from less-than-lifetime exposures, methods and defaults can be expected to change.

This highlights the importance for each dose-response assessment to critically evaluate all information pertaining to less-than-lifetime exposure. For example, detailed stop-exposure studies can provide information about the relationship between exposure duration, precursor effects, potential for reversibility, and tumor development. Toxicokinetic modeling can investigate differences in internal dose between short-term and long-term exposure or between intermittent and constant exposure. Persistence in the body can be useful in explaining long-term effects resulting from shorter-term exposures.

For nonlinear cancer analyses, it may be appropriate to assess exposure by calculating a *daily dose* that is averaged over the exposure duration for the study (see Section 3.1.1). For example, when the analysis is based on precursor effects that result from less than a lifetime exposure, that exposure period may be used. This reflects an expectation that the precursor effects on which the analysis is based can result from less-than-lifetime exposure, bringing consistency to the methods used for dose-response assessment and exposure assessment in such cases. The dose-response assessment can provide a recommendation to exposure assessors about the averaging time that is appropriate to the mode of action and to the exposure duration of the scenario.

3.5. EXTRAPOLATION TO SUSCEPTIBLE POPULATIONS AND LIFESTAGES

The dose-response assessment strives to derive separate estimates for susceptible populations and lifestages so that these risks can be explicitly characterized. For a susceptible population, higher risks can be expected from exposures anytime during life, but this applies to only a portion of the general population (e.g., those bearing a particular genetic susceptibility). In contrast, for a susceptible lifestage, higher risks can be expected from exposures during only a portion of a lifetime, but everyone in the population may pass through those lifestages. Effects of exposures during a susceptible period are not equivalent to effects of exposures at other times; consequently, it is useful to estimate the risk attributable to exposures during each period.

Depending on the data available, a tiered approach should be used to address susceptible populations and lifestages.

- When there is an epidemiologic study or an animal bioassay that reports quantitative results for susceptible individuals, the data should be analyzed to provide a separate risk estimate for those who are susceptible. If susceptibility pertains to a lifestage, it is useful to characterize the portion of the lifetime risk that can be attributed to the susceptible lifestage.

- When there are data on some risk-related parameters that allow comparison of the general population and susceptible individuals, the data should be analyzed with an eye toward adjusting the general population estimate for susceptible individuals. This analysis can range from toxicokinetic modeling that uses parameter values representative of susceptible individuals to more simply adjusting a general population estimate to reflect differences in important rate-governing parameters. Care is taken to not make parameter adjustments in isolation, as the appropriate adjustment can depend on the interactions of several parameters; for example, the ratio of metabolic activation and clearance rates can be more appropriate than the activation rate alone (U.S. EPA, 1992b).
- In the absence of such agent-specific data, there is some general information to indicate that childhood can be a susceptible lifestage for exposure to some carcinogens (U.S. EPA, 2005); this warrants explicit consideration in each assessment. The potential for susceptibility from early-life exposure is expected to vary among specific agents and chemical classes. In addition, the concern that the dose-averaging generally used for assessing less-than-lifetime exposure is more likely to understate than overstate risk (see Section 3.4) contributes to the suggestion that alternative approaches be considered for assessing risks from less-than-lifetime exposure that occurs during childhood. Accompanying these cancer guidelines is the Supplemental Guidance that the Agency will use to assess risks from early-life exposure to potential carcinogens (U.S. EPA, 2005). The Supplemental Guidance may be updated to reflect new data and new understanding that may become available in the future.

3.6. UNCERTAINTY

The NRC (1983, 1994, 1996, 2002) has repeatedly advised that proper characterization of uncertainty is essential in risk assessment. An assessment that omits or underestimates uncertainty can leave decisionmakers with a false sense of confidence in estimates of risk. On the other hand, a high level of uncertainty does not imply that a risk assessment or a risk management action should be delayed (NRC, 2002). Uncertainty in dose-response assessment can be classified as either *model uncertainty* or *parameter uncertainty*. A related concept, *human variation*, is discussed below. Assessments should discuss the significant uncertainties encountered in the analysis, distinguishing, if possible, between model uncertainty, parameter uncertainty, and human variation. Origins of these uncertainties can span a range, from a single causal thread supported by sparse data, to abundant information that presents multiple possible conclusions or that does not coalesce. As described in Section 2.6 and in Section 5.1, all contributing features should be noted.

Model uncertainty refers to a lack of knowledge needed to determine which is the correct scientific theory on which to base a model. In risk assessment, model uncertainty is reflected in alternative choices for model structure, dose metrics, and extrapolation approaches. Other sources of model uncertainty concern whether surrogate data are appropriate, for example, using data on adults to make inferences about children. The full extent of model uncertainty usually cannot be quantified; a partial characterization can be obtained by comparing the results of alternative models. Model uncertainty is expressed through comparison of separate analyses from each model, coupled with a subjective probability statement, where feasible and appropriate, of the likelihood that each model might be correct (NRC, 1994).

Some aspects of model uncertainty that should be addressed in an assessment include the use of animal models as a surrogate for humans, the influence of cross-species differences in metabolism and physiology, the use of effects observed at high doses as an indicator of the potential for effects at lower doses, the effect of using linear or nonlinear extrapolation to estimate risks, the use of using small samples and subgroups to make inferences about entire human populations or subpopulations with differential susceptibilities, and the use of

experimental exposure regimens to make inferences about different human exposure scenarios (NRC, 2002).

Toxicokinetic and toxicodynamic models are generally premised on *site concordance* across species, modeling, for example, the relationship between administered dose and liver tissue concentrations to predict increased incidences of liver cancer. This relationship, which can be observed in animals, is typically only inferred for humans. There are, however, numerous examples of an agent causing different cancers in different species. The assessment should discuss the relevant data that bear on this form of model uncertainty.

Parameter uncertainty refers to a lack of knowledge about the values of a model's parameters. This leads to a distribution of values for each parameter. Common sources of parameter uncertainty include random measurement errors, systematic measurement errors, use of surrogate data instead of direct measurements, misclassification of exposure status, random sampling errors, and use of an unrepresentative sample. Most types of parameter uncertainty can be quantified by statistical analysis.

Human variation refers to person-to-person differences in biological susceptibility or in exposure. Although both human variation and uncertainty can be characterized as ranges or distributions, they are fundamentally different concepts. Uncertainty can be reduced by further research that supports a model or improves a parameter estimate, but human variation is a reality that can be better characterized, but not reduced, by further research. Fields other than risk assessment use “variation” or “variability” to mean dispersion about a central value, including measurement errors and other random errors that risk assessors address as uncertainty.

Probabilistic risk assessment, informed by expert judgment, has been used in exposure assessment to estimate human variation and uncertainty in lifetime average daily exposure concentration or dose. Probabilistic methods can be used in this exposure assessment application because the pertinent variables (for example, concentration, intake rate, exposure duration, and body weight) have been identified, their distributions can be observed, and the formula for combining the variables to estimate the lifetime average daily dose is well defined (see U.S. EPA, 1992a). Similarly, probabilistic methods can be applied in dose-response assessment when there is an understanding of the important parameters and their relationships, such as

identification of the key determinants of human variation (for example, metabolic polymorphisms, hormone levels, and cell replication rates), observation of the distributions of these variables, and valid models for combining these variables. With appropriate data and expert judgment, formal approaches to probabilistic risk assessment can be applied to provide insight into the overall extent and dominant sources of human variation and uncertainty. In doing this, it is important to note that analyses that omit or underestimate some principal sources of variation or uncertainty could provide a misleadingly narrow description of the true extent of variation and uncertainty and give decisionmakers a false sense of confidence in estimates of risk. Specification of joint probability distributions is appropriate when variables are not independent of each other. In each case, the assessment should carefully consider the questions of uncertainty and human variation and discuss the extent to which there are data to address them.

Probabilistic risk assessment has also been used in dose-response assessment to determine and distinguish the degree of uncertainty and variability in toxicokinetic and toxicodynamic modeling. Although this field is less advanced that probabilistic exposure assessment, progress is being made and these cancer guidelines are flexible enough to accommodate continuing advances in these approaches.

Advances in uncertainty analysis are expected as the field develops. The cancer guidelines are intended to be flexible enough to incorporate additional approaches for characterizing uncertainty that have less commonly been used by regulatory agencies. In all scientific and engineering fields, data and research limitations often limit the application of established methods. A dearth of data is a particular problem when quantifying the *probability distribution* of model outputs. In many of these scientific and engineering disciplines, researchers have used rigorous expert elicitation methods to overcome the lack of peer-reviewed methods and data. Although expert elicitation has not been widely used in environmental risk assessment, several studies have applied this methodology as a tool for understanding quantitative risk. For example, expert elicitation has been used in chemical risk assessment and its associated uncertainty (e.g., Richmond, 1981; Renn, 1999; Florig et al., 2001; Morgan et al., 2001; Willis et al., 2004), components of risk assessment such as hazard assessment and dose-response

evaluation (e.g., Hawkins and Graham 1988; Jelovsek et al., 1990; Evans et al., 1994; IEc, 2004; U.S. EPA 2004) and exposure assessment (e.g., Whitfield and Wallsten, 1989; Hawkins and Evans, 1989; Winkler et al., 1995; Stiber et al., 1999; Walker et al., 2001, 2003; Van Der Fels-Klerx et al., 2002), and for evaluating other types of risks (e.g., North and Merkhofer, 1976; Fos and McLin, 1990). These cancer guidelines are flexible enough to accommodate the use of expert elicitation to characterize cancer risks, as a complement to the methods presented in the cancer guidelines. According to NRC (NRC, 2002), the rigorous use of expert elicitation for the analyses of risks is considered to be quality science.

3.7. DOSE-RESPONSE CHARACTERIZATION

A *dose-response characterization* extracts the dose-response information needed in a full risk characterization (U.S. EPA, 2000b), including:

- presentation of the recommended estimates (slope factors, reference doses, reference concentrations) and alternatives with significant biological support,
- a summary of the data supporting these estimates,
- a summary and explanation of the modeling approaches used,
- a description of any special features such as the development and consolidation of multiple estimates as detailed in Section 3.3.5,
- the POD narrative (see Section 3.2.5),
- a summary of the key defaults invoked,
- identification of susceptible populations or lifestages and quantification of their differential susceptibility, and

- a discussion of the strengths and limitations of the dose-response assessment, highlighting significant issues in developing risk estimates, alternative approaches considered equally plausible, and how these issues were resolved.

All estimates should be accompanied by the weight of evidence descriptor and its narrative (see Section 2.5) to convey a sense of the qualitative uncertainty about whether the agent may or may not be carcinogenic.

Slope factors generally represent an upper bound on the average risk in a population or the risk for a randomly selected individual but not the risk for a highly susceptible individual or group. Some individuals face a higher risk and some face a lower risk. The use of upper bounds generally is considered to be a health-protective approach for covering the risk to susceptible individuals, although the calculation of upper bounds is not based on susceptibility data. Similarly, exposure during some lifestages can contribute more or less to the total lifetime risk than do similar exposures at other times. The dose-response assessment characterizes, to the extent possible, the extent of these variations.

Depending on the supporting data and modeling approach, a slope factor can have a mix of traits that tend to either estimate, overestimate, or underestimate risk.

Some examples of traits that tend to overestimate risk include the following.

- The slope factor is derived from data on a highly susceptible animal strain.

- Linear extrapolation is used as a default and extends over several orders of magnitude.

- The largest of several slope factors is chosen.

Some examples of traits that tend to underestimate risk include the following.

- Several tumor types were observed, but the slope factor is based on a subset of them.

- The study design does not include exposure during a susceptible lifestage, for example, perinatal exposure.

- The study population is of less-than-average susceptibility, for example, healthy adult workers.

- There is random exposure misclassification or random exposure measurement error in the study from which the slope factor is derived.

Some examples of traits that inherently neither overestimate nor underestimate risk include the following.

- The slope factor is derived from data in humans or in an animal strain that responds like humans.

- Linear extrapolation is appropriate for the agent’s mode of action.

- Environmental exposures are close to the observed data.

- Several slope factors for the same tumor are averaged or a slope factor is derived from pooled data from several studies.

- The slope factor is derived from the only suitable study.

4. EXPOSURE ASSESSMENT

Exposure assessment is the determination (qualitative and quantitative) of the magnitude, frequency, and duration of exposure and internal dose (U.S. EPA, 1992a). This section provides a brief overview of exposure assessment principles, with an emphasis on issues related to carcinogenic risk assessment. The information presented here should be used in conjunction with other guidance documents, including *Guidelines for Exposure Assessment* (U.S. EPA, 1992a), *Science Policy Council Handbook: Risk Characterization* (U.S. EPA, 2000b), *Exposure Factors Handbook* (U.S. EPA, 1997c), the 1997 *Policy for Use of Probabilistic Analysis in Risk Assessments* (U.S. EPA, 1997d), and the 1997 *Guiding Principles for Monte Carlo Analysis* (U.S. EPA, 1997e). In addition, program-specific guidelines for exposure assessment should be consulted.

Exposure assessment generally consists of four major steps: defining the assessment questions, selecting or developing the conceptual and mathematical models, collecting data or selecting and evaluating available data, and exposure characterization. Each of these steps is briefly described below.

4.1. DEFINING THE ASSESSMENT QUESTIONS

In providing a clear and unambiguous statement of the purpose and scope of the exposure assessment (U.S. EPA, 1997e), consider the following.

- The management objectives of the assessment will determine whether deterministic screening level analyses are adequate or whether full probabilistic exposure characterization is needed.

- Identify and include all important sources (e.g., pesticide applications), pathways (e.g., food or water), and routes (e.g., ingestion, inhalation, and dermal) of exposure in the assessment. If a particular source, pathway, or route is omitted, a clear and transparent explanation should be provided.

- Separate analyses should be conducted for each definable subgroup within the population of interest. In particular, subpopulations or lifestages that are believed to be highly exposed or susceptible to a particular health effect should be studied. These include people with certain diseases or genetic susceptibilities and others whose behavior or physiology may lead to higher exposure or susceptibility. Consider the following examples:

  — Physiological differences between men and women (e.g., body weight and inhalation rate) may lead to important differences in exposures. See, for example, the discussion in *Exposure Factors Handbook* (U.S. EPA, 1997c, Appendix 1A).

  — Pregnant and lactating women may have exposures that differ from the general population (e.g., slightly higher water consumption) (U.S. EPA, 1997c). Further, exposure to pregnant women may result in exposure to the developing fetus (NRC, 1993b).

  — Children consume more food per body weight than do adults while consuming fewer types of foods, i.e., have a more limited diet (ILSI, 1992; NRC, 1993b; U.S. EPA, 1997c). In addition, children engage in crawling and mouthing (i.e., putting hands and objects in the mouth) behaviors, which can increase their exposures.

  — The elderly and disabled may have important differences in their exposures due to a more sedentary lifestyle (U.S. EPA, 1997c). In addition, the health status of this group may affect their susceptibility to the detrimental effects of exposure.

For further guidance, see *Guidelines for Exposure Assessment* (U.S. EPA, 1992a, § 3).

4.2. SELECTING OR DEVELOPING THE CONCEPTUAL AND MATHEMATICAL MODELS

Carcinogen risk assessment models have generally been based on the premise that risk is proportional to cumulative lifetime dose. For lifetime human exposure scenarios, therefore, the exposure metric used for carcinogenic risk assessment has been the lifetime average daily dose (LADD) or, in the case of inhalation exposure, the lifetime average exposure concentration. These metrics are typically used in conjunction with the corresponding slope factor to calculate individual excess cancer risk. The LADD is typically an estimate of the daily intake of a carcinogenic agent throughout the entire life of an individual, while the lifetime average exposure concentration is the corresponding estimate of average exposure concentration for the carcinogenic agent over the entire life of an individual. Depending on the objectives of the assessment, the LADD or lifetime average exposure concentration may be calculated deterministically (using point estimates for each factor to derive a point estimate of the exposure) or stochastically (using probability distributions to represent each factor and such techniques as Monte Carlo analysis to derive a distribution of the LADD) (U.S. EPA, 1997e). Stochastic analyses may help to identify certain population segments or lifestages that are highly exposed and may need to be assessed as a special subgroup. For further guidance, see *Guidelines for Exposure Assessment* (U.S. EPA, 1992a, § 5.3.5.2). As methodological research focuses on new approaches for estimating risks from less-than-lifetime exposures, methods and defaults can be expected to change.

There may be cases where the mode of action indicates that dose rates are important in the carcinogenic process. In these cases, short-term, less-than-lifetime exposure estimates may be more appropriate than the LADD for risk assessment. This may be the case when a nonlinear dose-response approach is used (see Section 3.3.4).

4.3. COLLECTING DATA OR SELECTING AND EVALUATING AVAILABLE DATA

After the assessment questions have been defined and the conceptual and mathematical models have been developed, it is important to compile and evaluate existing data or, if necessary, to collect new data. Depending on the exposure scenario under consideration, data on

a wide variety of exposure factors may be needed. EPA's *Exposure Factors Handbook* (U.S. EPA, 1997c) contains a large compilation of exposure data, with some analysis and recommendations. Some of these data are organized by age groups to assist with assessing such subgroups as children. See, for example, *Exposure Factors Handbook* (U.S. EPA, 1997c, Volume 1, Chapter 3). When using these existing data, it is important to evaluate the quality of the data and the extent to which the data are representative of the population under consideration. EPA's (U.S. EPA, 2000d) and OMB's (OMB 2002) guidance on information quality, as well as program-specific guidances can provide further assistance for evaluating existing data.

When existing data fail to provide an adequate surrogate for the needs of a particular assessment, it is important to collect new data. Such data collection efforts should be guided by the references listed above (e.g., *Guidance for Data Quality Assessment* and program-specific guidance). Once again, subpopulations or lifestages of concern are an important consideration in any data collection effort.

4.3.1. Adjusting Unit Risks for Highly Exposed Populations and Lifestages

Unit risk estimates that have been developed in the dose-response assessment often assumed standard adult intake rates. When an exposure assessment focuses on a population or lifestage with differential exposure, good exposure assessment practice would replace the standard intake rates with values representative of the exposed population. Small changes in exposure assessments can be approximated by using linearly proportional adjustments of exposure parameters, but a more accurate integrative analysis may require an analysis stratified by exposure duration (see Section 5.1) .

> *For example*, to adjust the drinking water unit risk for an active population that drinks 4 L/day (instead of 2 L/day), multiply the unit risk by 2.

Because children drink more water relative to their body weight than do adults (U.S. EPA, 2002d), adjustments to unit risk estimates are warranted whenever they are applied in an assessment of childhood exposure.

> *For example*, to adjust the drinking water unit risk for a 9-kg infant who drinks 1 L/day (instead of a 70-kg adult who drinks 2 L/day), multiply the unit risk by [(1 L/day) / (9 kg)] / [(2 L/day) / (70 kg)] = 3.9.

Inhalation dosimetry is employed to derive the human equivalent exposure concentrations on which inhalation unit risks, and reference concentrations, are based (U.S. EPA, 1994). As described previously (see Sections 3.1.2, 3.1.3), different dosimetry methods may be employed depending on the availability of relevant data and chemical-specific characteristics of the pollutant. Consideration of lifestage-particular physiological characteristics in the dosimetry analysis may result in a refinement to the human equivalent concentration (HEC) to insure relevance in risk assessment across lifestages, or might conceivably conclude with multiple HECs, and corresponding inhalation unit risk values (e.g., separate for childhood and adulthood).

The dose-response assessment discusses the key sources of uncertainty in estimating dosimetry, including any related to lifestage. Review of this discussion and of the dosimetric analysis performed in deriving the HEC and resultant unit risk will assist in the appropriate application of inhalation unit risk values to exposure across lifestages.

4.4. EXPOSURE CHARACTERIZATION

The exposure characterization is a technical characterization that presents the assessment results and supports the risk characterization. It provides a statement of the purpose, scope, and approach used in the assessment, identifying the exposure scenarios and population subgroups covered. It provides estimates of the magnitude, frequency, duration, and distribution of exposures among members of the exposed population as the data permit. It identifies and compares the contribution of different sources, pathways, and routes of exposure. In particular, a

qualitative discussion of the strengths and limitations (uncertainties) of the data and models are presented.

The discussion of uncertainties is a critical component of the exposure characterization. Uncertainties can arise out of problems with the conceptual and mathematical models. Uncertainties can also arise from poor data quality and data that are not quite representative of the population or scenario of interest. Consider the following examples of uncertainties.

- National data (i.e., data collected to represent the entire U.S. population) may not be representative of exposures occurring within a regional or local population.

- Use of short-term data to infer chronic, lifetime exposures should be done with caution. Use of short-term data to estimate long-term exposures has the tendency to underestimate the number of people exposed while overestimating the exposure levels experienced by those in the upper end (i.e., above the 90^{th} percentile) of the exposure distribution. For further guidance, refer to *Guidelines for Exposure Assessment* (U.S. EPA, 1992a, § 5.3.1).

- Children's behavior, including their more limited diet, may lead to relatively high but intermittent exposures. This pattern of exposure, "one that gradually declines over the developmental period and which remains relatively constant thereafter" is not accounted for in the LADD model (ILSI, 1992). Further, the physiological characteristics of children may lead to important differences in exposure. Some of these differences can be accounted for in the LADD model. For further guidance, see *Guidelines for Exposure Assessment* (U.S. EPA, 1992a, § 5.3.5.2).

Overall, the exposure characterization should provide a full description of the sources, pathways, and routes of exposure. The characterization also should include a full description of the populations assessed. In particular, highly exposed or susceptible subpopulation or lifestage should be discussed. For further guidance on the exposure characterization, consult *Guidelines*

for Exposure Assessment (U.S. EPA, 1992a), the *Policy and Guidance for Risk Characterization* (U.S. EPA, 2000b,1995) and EPA's *Rule Writer's Guide to Executive Order 13045* (especially Attachment C: Technical Support for Risk Assessors—Suggestions for Characterizing Risks to Children [U.S. EPA, 1998d]).

5. RISK CHARACTERIZATION

5.1. PURPOSE

EPA has developed general guidance on risk characterization for use in its risk assessment activities. The core of EPA's risk characterization policy (U.S. EPA, 2000b, 1995) includes the following.

> Each risk assessment prepared in support of decision making at EPA should include a risk characterization that follows the principles and reflects the values outlined in this policy. A risk characterization should be prepared in a manner that is clear, transparent, reasonable, and consistent with other risk characterizations of similar scope prepared across programs in the Agency. Further, discussion of risk in all EPA reports, presentations, decision packages, and other documents should be substantively consistent with the risk characterization. The nature of the risk characterization will depend upon the information available, the regulatory application of the risk information, and the resources (including time) available. In all cases, however, the assessment should identify and discuss all the major issues associated with determining the nature and extent of the risk and provide commentary on any constraints limiting fuller exposition.

Risk characterization should be carried out in accordance with the EPA (U.S. EPA, 2002a) and OMB (2002) information quality guidelines. EPA's risk characterization handbook (U.S. EPA, 2000b) provides detailed guidance to Agency staff. The discussion below does not attempt to duplicate this material, but it summarizes its applicability to carcinogen risk assessment.

The risk characterization includes a summary for the risk manager in a nontechnical discussion that minimizes the use of technical terms. It is an appraisal of the science that informs the risk manager in public health decisions, as do other decision-making analyses of economic,

social, or technology issues. It also serves the needs of other interested readers. The summary is an information resource for preparing risk communication information, but being somewhat more technical than desired for communication with the general public, is not itself the usual vehicle for communication with every audience.

The risk characterization also brings together the assessments of hazard, dose response, and exposure to make risk estimates for the exposure scenarios of interest. This analysis that follows the summary is generally much more extensive. It typically will identify exposure scenarios of interest in decision making and present risk analyses associated with them. Some of the analyses may concern scenarios in several media; others may examine, for example, only drinking water risks. As these cancer guidelines allow different hazard characterizations and different potencies for specified conditions, e.g., exposure level, route of exposure, or lifestage, some of the integrative analyses may need to be stratified to accommodate the appropriate combinations of parameters across relevant exposure durations.

In constructing high end estimates of risk, the assessor should bear in mind that the high-end risk is a plausible estimate of the risk for those persons at the upper end of the risk distribution (U.S. EPA, 1992a). The intent of this approach is to convey an estimate of risk in the upper range of the distribution, but to avoid estimates that are beyond the true distribution. Overly conservative assumptions, when combined, can lead to unrealistic estimates of risk. This means that when constructing estimates from a series of factors (e.g., emissions, exposure, and unit risk estimates) not all factors should be set to values that maximize exposure, dose, or effect, since this will almost always lead to an estimate that is above the 99th-percentile confidence level and may be of limited use to decisionmakers. This is particularly problematic when using unbounded lognormal factor distributions.

While it is an appropriate aim to assure protection of health and the environment in the face of scientific uncertainty, common sense, reasonable applications of assumptions and policy, and transparency are essential to avoid unrealistically high estimates. It is also important to inform risk managers of the final distribution of risk estimates (U.S. EPA, 2000b; 1995). Otherwise, risk management decisions may be made on varying levels of conservatism, leading

to misplaced risk priorities and potentially higher overall risks. (Nichols and Zeckhauser,1986; Zeckhauser and Viscusi,1990).

The risk characterization presents an integrated and balanced picture of the analysis of the hazard, dose-response, and exposure. The risk analyst should provide summaries of the evidence and results and describe the quality of available data and the degree of confidence to be placed in the risk estimates. Important features include the constraints of available data and the state of knowledge, significant scientific issues, and significant science and science policy choices that were made when alternative interpretations of data exist (U.S. EPA, 1995, 2000b). Choices made about using data or default options in the assessment are explicitly discussed in the course of analysis, and if a choice is a significant issue, it is highlighted in the summary. In situations where there are alternative approaches for a risk assessment that have significant biological support, the decisionmaker can be informed by the presentation of these alternatives along with their strengths and uncertainties.

5.2. APPLICATION

Risk characterization is a necessary part of generating any Agency report on risk, whether the report is preliminary — to support allocation of resources toward further study — or comprehensive — to support regulatory decisions. In the former case, the detail and sophistication of the characterization are appropriately small in scale; in the latter case, appropriately extensive. Even if a document covers only parts of a risk assessment (hazard and dose-response analyses, for instance), the results of these are characterized.

Risk assessment is an iterative process that grows in depth and scope in stages from screening for priority making to preliminary estimation to fuller examination in support of complex regulatory decision making. Default options may be used at any stage, but they are predominant at screening stages and are used less as more data are gathered and incorporated at later stages. Various provisions in EPA-administered statutes require decisions based on differing findings for which differing degrees of analysis are appropriate. There are close to 30 provisions within the major statutes that require decisions based on risk, hazard, or exposure assessment. For example, Agency review of pre-manufacture notices under Section 5 of the Toxic Substances

Control Act relies on screening analyses, whereas requirements for industry testing under Section 4 of that Act rely on preliminary analyses of risk or simply of exposure. In comparison, air quality criteria under the Clean Air Act rest on a rich data collection and are required by statute to undergo periodic reassessment. There are provisions that require ranking of hazards of numerous pollutants — which may be addressed through a screening level of analysis — and other provisions for which a full assessment of risk is more appropriate.

Given this range in the scope and depth of analyses, not all risk characterizations can or should be equal in coverage or depth. The risk assessor should carefully decide which issues in a particular assessment are important to present, choosing those that are noteworthy in their impact on results. For example, health effect assessments typically rely on animal data because human data are rarely available. The objective of characterization of the use of animal data is not to recount generic issues about interpreting and using animal data; Agency guidance documents cover these issues. Rather, the objective is to highlight any significant issues that arose within the particular assessment being characterized and inform the reader about significant uncertainties that affect conclusions.

5.3. PRESENTATION OF THE RISK CHARACTERIZATION SUMMARY

The presentation is a nontechnical discussion of important conclusions, issues, and uncertainties that uses the hazard, dose response, exposure, and integrative analyses for technical support. The primary technical supports within the risk assessment are the hazard characterization, dose-response characterization, and exposure characterization described in these cancer guidelines. The risk characterization is derived from these. The presentation should fulfill the aims outlined in the purpose section above.

5.4. CONTENT OF THE RISK CHARACTERIZATION SUMMARY

Specific guidance on hazard, dose-response, and exposure characterization appears in previous sections. Overall, the risk characterization routinely includes the following, capturing the important items covered in hazard, dose response, and exposure characterization:

- primary conclusions about hazard, dose response, and exposure, including alternatives with significant biological support;

- nature of key supporting information and analytic methods;

- risk estimates and their attendant uncertainties, including key uses of default options when data are missing or uncertain.

  — With linear extrapolations, risk below the POD is typically approximated by multiplying the slope factor by an estimate of exposure, i.e., Risk = Slope Factor x Exposure. For exposure levels above the POD, the dose-response model is used instead of this approximation.

  — With nonlinear extrapolations, the method of risk assessment depends on the procedure used. If a nonlinear dose-response function has been determined, it can be used with the expected exposure to estimate a risk. If an RfD or RfC was calculated, the hazard can be expressed as a *hazard quotient* (HQ), defined as the ratio of an exposure estimate over the reference dose (RfD) or reference concentration (RfC), i.e., HQ = Exposure / (RfD or RfC). From the hazard quotient, it can generally be inferred whether the nonlinear mode of action is relevant at the environmental exposure level in question;

- statement of the extent of extrapolation of risk estimates from observed data to exposure levels of interest and its implications for certainty or uncertainty in quantifying risk. The extent of extrapolation can be expressed as a *margin of exposure* (MOE), defined as the ratio of the POD over an exposure estimate (MOE = POD / Exposure);

.

- significant strengths and limitations of the data and analyses, including any major peer review issues;

- appropriate comparison with similar EPA risk analyses or common risks with which people may be familiar; and

- comparison with all appropriate assessments of the same problem by others.

It is often difficult to know *a priori* when or how different results of a cancer risk assessment are likely to be used by Agency economists, policy analysts, and decisionmakers, so it is important that the resulting characterizations include the necessary information for these analyses to the extent practicable. OMB and EPA guidelines for benefit-cost analysis require expected or central estimates of risk and information on the uncertainty of the estimate when it is possible or practicable. The extent of the uncertainty information needed for analysis depends, in part, on the scale of the policy being considered, with formal quantitative analysis of uncertainty being required in some cases.[6] OMB Circular A-4 (OMB, 2003) emphasizes that agencies "should try to provide some estimate of the probability distribution of regulatory benefits and costs." These OMB guidelines note, "Whenever it is possible to characterize quantitatively the probability distribution, some estimates of expected value ... must be provided in addition to ranges, variances, specified low-end and high-end percentile estimates, and other characteristics of the distribution." The risk characterization should therefore include, where practicable, expected or central estimates of risk, as well as upper and lower bounds, e.g., confidence limits, based on the POD, if not a full characterization of uncertainty of the risk. As discussed in EPA's *Guidelines for Ensuring and Maximizing the Quality, Objectivity, Utility, and Integrity of Information Disseminated by the Environmental Protection Agency* (Appendix B), statutory mandates, such as the Safe Drinking Water Act, the Food Quality Protection Act, and the Clean

6 Specifically, OMB guidelines state: "For rules that exceed the $1 billion annual [economic effects] threshold, a formal quantitative analysis of uncertainty is required. For rules with annual benefits and/or costs in the range from 100 million to $1 billion, you should seek to use more rigorous approaches with higher consequence rules" (OMB, 2003, page 158)

Air Act, call for the Agency to generate specific kinds of risk information, and thus these updated cancer assessment guidelines should be read in conjunction with the Agency's statutory mandates regarding risk assessment.

APPENDIX A: MAJOR DEFAULT OPTIONS

This discussion covers the major default options commonly employed when data are missing or sufficiently uncertain in a cancer risk assessment, as adopted in these cancer guidelines. These options are predominantly inferences that help use the data observed under empirical conditions in order to estimate events and outcomes under environmental conditions. Several inferential issues arise when effects seen in a subpopulation of humans or animals are used to infer potential effects in the population of environmentally exposed humans. Several more inferential issues arise in extrapolating the exposure-effect relationship observed empirically to lower-exposure environmental conditions. The following issues cover the major default areas.

- Is the presence or absence of effects observed in a human population predictive of effects in another exposed human population?

- Is the presence or absence of effects observed in an animal population predictive of effects in exposed humans?

- How do metabolic pathways relate across species and among different age groups and between sexes in humans?

- How do toxicokinetic processes relate across species and among different age groups and between sexes in humans?

- What is the relationship between the observed dose-response relationship to the relationship at lower doses?

Is the Presence or Absence of Effects Observed in a Human Population Predictive of Effects in Another Exposed Human Population?

When cancer effects in exposed humans are attributed to exposure to an agent, the default option is that the resulting data are predictive of cancer in any other exposed human population. Most studies investigating cancer outcomes in humans from exposure to agents are often studies of occupationally exposed humans. By sex, age, and general health, workers may not be representative of the general population exposed environmentally to the same agents. In such studies there is no opportunity to observe subpopulations who are likely to be under represented, such as fetuses, infants and children, women, or people in poor health, who may respond differently from healthy workers. Therefore, it is understood that this option could still underestimate the response of certain human subpopulations (NRC, 1993b, 1994).

When cancer effects are not found in an exposed human population, this information by itself is not generally sufficient to conclude that the agent poses no carcinogenic hazard to this or other populations of potentially exposed humans, including susceptible subpopulations or lifestages. This is because epidemiologic studies often have low power to detect and attribute responses and typically evaluate cancer potential in a restricted population (e.g., by age, healthy workers). The topic of susceptibility and variation is addressed further in the discussion below of quantitative default options about dose-response relationships. Well-conducted studies that fail to detect a statistically significant positive association, however, may have value and should be judged on their merits, including population size, duration of the study, the quality of the exposure characterization and measures of outcome, and the magnitude and duration of the exposure.

There is not yet enough knowledge to form a basis for any generally applicable qualitative or quantitative inference to compensate for the gap in knowledge concerning other populations. In these cancer guidelines, this problem is left to analysis in individual cases, to be attended to with further general guidance as future research and information allow. When information on a susceptible subpopulation or lifestage exists, it will be used. For example, an agent such as diethylstilbestrol (DES) causes a rare form of vaginal cancer (clear-cell adenocarcinoma) (Herbst

et al., 1971) in about 1 per 1000 of adult women whose mothers were exposed during pregnancy (Hatch et al., 1998).

Is the Presence or Absence of Effects Observed in an Animal Population Predictive of Effects in Exposed Humans? *The default option is that positive effects in animal cancer studies indicate that the agent under study can have carcinogenic potential in humans.* Thus, if no adequate human or mode of action data are present, positive effects in animal cancer studies are a basis for assessing the carcinogenic hazard to humans. This option is a public health-protective policy, and it is both appropriate and necessary, given that we do not test for carcinogenicity in humans. The option is supported by the fact that nearly all of the agents known to cause cancer in humans are carcinogenic in animals in tests that have adequate protocols (IARC, 1994; Tomatis et al., 1989; Huff, 1994). Moreover, almost one-third of human carcinogens were identified subsequent to animal testing (Huff, 1993). Further support is provided by research on the molecular biology of cancer processes, which has shown that the mechanisms of control of cell growth and differentiation are remarkably homologous among species and highly conserved in evolution. Nevertheless, the same research tools that have enabled recognition of the nature and commonality of cancer processes at the molecular level also have the power to reveal differences and instances in which animal responses are not relevant to humans (Lijinsky, 1993; U.S. EPA, 1991b). Under these cancer guidelines, available mode of action information is studied for its implications in both hazard and dose-response assessment and its ability to obviate default options.

There may be instances in which the use of an animal model would identify a hazard in animals that is not truly a hazard in humans (e.g., the alpha-2u-globulin association with renal neoplasia in male rats [U.S. EPA, 1991b]). The extent to which animal studies may yield false positive indications for humans is a matter of scientific debate. To demonstrate that a response in animals is not relevant to any human situation, adequate data to assess the relevancy issue are important.

In general, while effects seen at the highest dose tested are assumed to be appropriate for assessment, it is necessary that the experimental conditions be scrutinized. Animal studies

are conducted at high doses in order to provide statistical power, the highest dose being one that is minimally toxic (maximum tolerated dose or MTD). Consequently, the question often arises of whether a carcinogenic effect at the highest dose may be a consequence of cell killing with compensatory cell replication or of general physiological disruption rather than inherent carcinogenicity of the tested agent. There is little doubt that this may happen in some cases, but skepticism exists among some scientists that it is a pervasive problem (Ames and Gold, 1990; Melnick et al., 1993; Barrett, 1993). If adequate data demonstrate that the effects are solely the result of excessive toxicity rather than carcinogenicity of the tested agent *per se*, then the effects may be regarded as not appropriate to include in assessment of the potential for human carcinogenicity of the agent. This is a matter of expert judgment, with consideration given to all of the data available about the agent, including effects in other toxicity studies, structure-activity relationships, and effects on growth control and differentiation.

When cancer effects are not found in well-conducted animal cancer studies in two or more appropriate species and other information does not support the carcinogenic potential of the agent, these data provide a basis for concluding that the agent is not likely to possess human carcinogenic potential, in the absence of human data to the contrary. This default option about lack of cancer effects has limitations. It is recognized that animal studies (and epidemiologic studies as well) have very low power to detect cancer effects. Detection of a 10% tumor incidence is generally the limit of power with standard protocols for animal studies (with the exception of rare tumors that are virtually markers for a particular agent, e.g., angiosarcoma caused by vinyl chloride). In some situations, the tested animal species may not be predictive of effects in humans; for example, arsenic shows only minimal or no effect in animals, whereas it is clearly positive in humans. Therefore, it is important to consider other information as well; absence of mutagenic activity or absence of carcinogenic activity among structural analogues can increase the confidence that negative results in animal studies indicate a lack of human hazard.

Another limitation is that standard animal study protocols are not yet available for effectively studying perinatal effects. The potential for effects on the very young generally should be considered separately. Under existing Agency policy (U.S. EPA, 1997a, b), perinatal studies

accomplished by modification of existing adult bioassay protocols are important in special circumstances.

Target organ concordance is not a prerequisite for evaluating the implications of animal study results for humans. Target organs of carcinogenesis for agents that cause cancer in both animals and humans are most often concordant at one or more sites (Tomatis et al., 1989; Huff, 1994). However, concordance by site is not uniform. The mechanisms of control of cell growth and differentiation are concordant among species, but there are marked differences among species in the way control is managed in various tissues. For example, in humans, mutations of the tumor suppressor genes p53 and retinoblastoma are frequently observed genetic changes in tumors. These tumor-suppressor genes are also observed to be operating in some rodent tissues, but other growth control mechanisms predominate in other rodent tissues. Thus, an animal response may be due to changes in a control that are relevant to humans but appear in animals in a different way.

However, it is appropriate under these cancer guidelines to consider the influences of route of exposure, metabolism, and, particularly, some modes of action that may either support or not support target organ concordance between animals and humans. When data allow, these influences are considered in deciding whether agent-, species-, or organ-specific situations are appropriate to use in preference to this default assumption (NRC, 1994). In contrast, use of toxicokinetic modeling inherently assumes site concordance, as these models are used to estimate delivered dose to a particular tissue or organ in humans on the basis of the same tissue or organ from animal data.

The default is to include benign tumors observed in animal studies in the assessment of animal tumor incidence, if such tumors have the capacity to progress to the malignancies with which they are associated. This default is consistent with the approach of the National Toxicology Program and the International Agency for Research on Cancer and is more protective of public health than not including benign tumors in the assessment; benign and malignant tumors are treated as representative of related responses to the test agent (McConnell et al., 1986), which is scientifically appropriate. Nonetheless, in assessing findings from animal studies, a greater proportion of malignancy is weighed more heavily than is a response with a

greater proportion of benign tumors. Greater frequency of malignancy of a particular tumor type in comparison with other tumor responses observed in an animal study is also a factor to be considered in selecting the response to be used in dose-response assessment.

Benign tumors that are not observed to progress to malignancy are assessed on a case-by-case basis. There is a range of possibilities for the overall significance of benign tumors. They may deserve attention because they are serious health problems even though they are not malignant; for instance, benign tumors may be a health risk because of their effect on the function of a target tissue, such as the brain. They may be significant indicators of the need for further testing of an agent if they are observed in a short-term test protocol, or such an observation may add to the overall weight of evidence if the same agent causes malignancies in a long-term study. Knowledge of the mode of action associated with a benign tumor response may aid in the interpretation of other tumor responses associated with the same agent.

How Do Metabolic Pathways Relate Across Species and Among Different Age Groups and Between Sexes in Humans?

The default option is that there is a similarity of the basic pathways of metabolism and the occurrence of metabolites in tissues in regard to the species-to-species extrapolation of cancer hazard and risk. If comparative metabolism studies were to show no similarity between the tested species and humans and a metabolite(s) was the active form, there would be less support for an inference that the animal response(s) relates to humans. In other cases, parameters of metabolism may vary quantitatively between species; this becomes a factor in deciding on an appropriate human-equivalent dose based on animal studies, optimally in the context of a toxicokinetic model. Although the basic pathways are assumed to be the same among humans, the presence of polymorphisms in the general population and factors such as the maturation of the pathways in infants should be considered. The active form of an agent may be present to differing degrees, or it may be completely absent, which may result in greater or lesser risk for subpopulations.

How Do Toxicokinetic Processes Relate Across Species and Among Different Age Groups and Between Sexes in Humans?

A major issue is how to estimate human-equivalent doses in extrapolating from animal studies. *As a default for oral exposure, a human equivalent dose for adults is estimated from data on another species by an adjustment of animal applied oral dose by a scaling factor based on body weight to the 3/4 power. The same factor is used for children because it is slightly more protective than using children's body weight (see Section 3.1.3).* This adjustment factor is used because it represents scaling of metabolic rate across animals of different size. Because the factor adjusts for a parameter that can be improved on and brought into more sophisticated toxicokinetic modeling when such data become available, they are usually preferable to the default option.

For inhalation exposure, a human equivalent dose for adults is estimated by default methodologies that provide estimates of lung deposition and internal dose (U.S. EPA, 1994). The methodologies can be refined to more sophisticated forms with data on toxicokinetic and metabolic parameters of the specific agent. This default option, like the one for oral exposure, is selected in part because it lays a foundation for incorporating better data. The use of information to improve dose estimation from applied to internal to delivered dose is encouraged, including use of toxicokinetic modeling instead of any default, where data are available.

There are important differences between infants, adults, and older adults in the processes of absorption, distribution, and elimination; for example, infants tend to absorb metals through the gut more rapidly and more efficiently than do older children or adults (Calabrese, 1986). Renal elimination is also not as efficient in infants. Although these processes reach adult competency at about the time of weaning, they may have important implications, particularly when the dose-response relationship for an agent is considered to be nonlinear and there is an exposure scenario disproportionately affecting infants, because in these cases the magnitude of dose is more pertinent than the usual approach in linear extrapolation of averaging dose across a lifetime. Efficiency of intestinal absorption in older adults tends to be generally less overall for most chemicals. Another notable difference is that, post-weaning (about 1 year), children have a

higher metabolic rate than do adults (Renwick, 1998), and they may toxify or detoxify agents at a correspondingly higher rate.

For a route-to-route exposure extrapolation, *the default option is that an agent that causes internal tumors by one route of exposure will be carcinogenic by another route if it is absorbed by the second route to give an internal dose.* This is a qualitative option and is considered to be public-health protective. The rationale is that for internal tumors an internal dose is significant no matter what the route of exposure. Additionally, the metabolism of the agent will be qualitatively the same for an internal dose. The issue of quantitative extrapolation of the dose-response relationship from one route to another is addressed case by case. Quantitative extrapolation is complicated by considerations such as first-pass metabolism.

What Is the Correlation of the Observed Dose-Response Relationship to the Relationship at Lower Doses?

If sufficient data are available, a biologically based model for both the observed range and extrapolation below that range may be used. Although no standard biologically based models are in existence, an agent-specific model may be developed if extensive data exist in a particular case and the purpose of the assessment justifies the investment of the resources needed. *The default procedure for the observed range of data when a biologically based model is not used is to use a curve-fitting model for incidence data.*

In the absence of data supporting a biologically based model for extrapolation outside of the observed range, the choice of approach is based on the view of mode of action of the agent arrived at in the hazard assessment. If more than one approach (e.g., both a nonlinear and linear approach) are supported by the data, they should be used and presented to the decisionmaker.

A linear extrapolation approach is used when the mode of action information is supportive of linearity or mode of action is not understood. The linear approach is used when a view of the mode of action indicates a linear response, for example, when a conclusion is made that an agent directly causes alterations in DNA, a kind of interaction that not only theoretically requires one reaction but also is likely to be additive to ongoing, spontaneous gene mutation. Other kinds of activity may have linear implications, for example, linear rate-limiting steps

would also support a linear procedure. The linear approach is to draw a straight line between a point of departure from observed data, generally as a default, an LED chosen to be representative of the lower end of the observed range, and the origin (zero incremental dose, zero incremental response). This approach is generally considered to be public-health protective.

The linear default is thought to generally provide an upper-bound calculation of potential risk at low doses, for example, a 1/100,000 to 1/1,000,000 risk. This upper bound is thought to be public-health protective at low doses for the range of human variation, considering the typical Agency target range for risk management of 1/1,000,000 to 1/10,000, although it may not completely be so (Bois et al., 1995) if pre-existing disease or genetic constitution place a percentage of the population at greater risk from exposure to carcinogens. The question of what may be the actual variation in human susceptibility is one that was discussed in general in the NRC (1994) report, as well as the NRC report on pesticides in children and infants (NRC, 1993b). NRC has recommended research on the question, and EPA and other agencies are conducting such research. Given the current state of knowledge, EPA will assume that the linear default procedure adequately accounts for human variation unless there is case-specific information for a given agent or mode of action that indicates a particularly susceptible subpopulation or lifestage, in which case the special information will be used.

When adequate data on mode of action provide sufficient evidence to support a nonlinear mode of action for the general population and/or any subpopulations of concern, a different approach — a reference dose/reference concentration that assumes that nonlinearity – is used. The POD is again generally an BMDL when incidence data are modeled. A sufficient basis to support this nonlinear procedure is likely to include data on responses that are key events integral to the carcinogenic process. This means that the POD may be based on these precursor response data, for example, hormone levels or mitogenic effects rather than tumor incidence data.

When the mode of action information indicates that the dose-response function may be adequately described by both a linear and a nonlinear approach, then the results of both the linear and the nonlinear analyses are presented. An assessment may use both linear and nonlinear approaches if different responses are thought to result from different modes of action or a response appears to be very different at high and low doses due to influence of separate

modes of action. The results may be needed for assessment of combined risk from agents that have common modes of action.

Absent data to the contrary, the default assumption is that the cumulative dose received over a lifetime, expressed as a lifetime average daily dose or lifetime average daily exposure, is an appropriate measure of dose or exposure. This assumes that a high dose of such an agent received over a shorter period of time is equivalent to a low dose spread over a lifetime. This is thought to be a relatively public-health-protective option and has some empirical support (Monro, 1992). A counter example, i.e., effects of short-term, high exposure levels that result in subsequent cancer development, is treatment of cancer patients with certain chemotherapeutic agents. When sufficient information is available to support a different approach, it can be used. For example, short-term exposure estimates (several days to several months) may be more appropriate than the lifetime average daily dose. In these cases, both agent concentration and duration are likely to be important, because such effects may be reversible at cessation of very short-term exposures.

LIST OF FIGURES

PREFACE

U.S. Environmental Protection Agency (EPA or the Agency) cancer risk assessments may be conducted differently than envisioned in this Supplemental Guidance for many reasons including, for example, new information, new scientific understanding, or different science policy judgment. The practice of risk assessment with respect to accounting for early-life exposures to toxicants continues to develop, and specific components of this Supplemental Guidance may become outdated or may otherwise require modification in individual settings. It is EPA's intent to use, to the extent practicable and consistent with Agency statutes and regulations, the best available science in its risk assessments and regulatory actions, and this Supplemental Guidance is not intended to provide any substantive or procedural obstacle in achieving that goal. Therefore, the Supplemental Guidance has no binding effect on EPA or on any regulated entity. Where EPA does use the approaches in the Supplemental Guidance in developing risk assessments, it will be because EPA has decided in the context of that risk assessment that the approaches from the Supplemental Guidance are suitable and appropriate. This judgment will be tested through peer review, and the risk assessment will be modified to use different approaches if appropriate.

This Supplemental Guidance is intended for guidance only. It does not establish any substantive "rules" under the Administrative Procedure Act or any other law and has no binding effect on EPA or any regulated entity, but instead represents a non-binding statement of policy.

The Supplemental Guidance addresses a number of issues pertaining to cancer risks associated with early-life exposures generally, but provides specific guidance on potency adjustment only for carcinogens acting through a mutagenic mode of action. This guidance recommends for such chemicals, a default approach using estimates from chronic studies (i.e., cancer slope factors) with appropriate modifications to address the potential for differential risk of early-lifestage exposure. Default adjustment factors are meant to be used only when no chemical-specific data are available to assess directly cancer susceptibility from early-life exposure to a carcinogen acting through a mutagenic mode of action.

The Agency considered both the advantages and disadvantages of extending the recommended, age dependent adjustment factors for carcinogenic potency to carcinogenic agents for which the mode of action remains unknown. EPA recommends these factors only for carcinogens acting through a mutagenic mode of action based on a combination of analysis of available data and long-standing science policy positions that set out the Agency's overall approach to carcinogen risk assessment, e.g., the use of a linear, no threshold extrapolation procedure in the absence of data in order to be health protective. In general, the Agency prefers

to rely on analyses of data rather than on general defaults. When data are available for a susceptible lifestage, they should be used directly to evaluate risks for that chemical and that lifestage on a case-by-case basis. In the case of nonmutagenic carcinogens, when the mode of action is unknown, the data were judged by EPA to be too limited and the modes of action too diverse to use this as a category for which a general default adjustment factor approach can be applied. In this situation per the Agency's *Guidelines for Carcinogen Risk Assessment*, a linear low-dose extrapolation methodology is recommended. It is the Agency's long-standing science policy position that use of the linear low-dose extrapolation approach (without further adjustment) provides adequate public health conservatism in the absence of chemical-specific data indicating differential early-life susceptibility or when the mode of action is not mutagenicity.

The Agency expects to produce additional supplemental guidance for other modes of action, as data from new research and toxicity testing indicate it is warranted. EPA intends to focus its research, and to work collaboratively with its federal partners, to improve understanding of the implications of early life exposure to carcinogens. Development of guidance for estrogenic agents and chemicals acting through other processes resulting in endocrine disruption and subsequent carcinogenesis, for example, might be a reasonable priority in light of the human experience with diethylstilbesterol and the existing early-life animal studies. It is worth noting that each mode of action for endocrine disruption will probably require separate analysis.

As the Agency examines additional carcinogenic agents, the age groupings may differ from those recommended for assessing cancer risks from early-life exposure to chemicals with a mutagenic mode of action. Puberty and its associated biological changes, for example, involve many biological processes that could lead to changes in susceptibility to the effects of some carcinogens, depending on their mode of action. The Agency is interested in identifying lifestages that may be particularly sensitive or refractory for carcinogenesis, and believes that the mode of action framework described in the Agency's *Guidelines for Carcinogen Risk Assessment* is an appropriate mechanism for elucidating these lifestages. For each additional mode of action evaluated, the various age groupings determined to be at differential risk may differ from those described in this Supplemental Guidance. For example, the age groupings selected for the age-dependent adjustments were initially selected based on the available data, i.e., for the laboratory animal age range representative of birth to < 2 years in humans. More limited data and information on human biology are being used to determine a science-informed policy regarding 2 to < 16 years. Data were not available to refine the latter age group. If more data become available regarding carcinogens with a mutagenic mode of action, consideration may be given to further refinement of these age groups.

Access to data and other information relating to the Cancer Guidelines (U.S. EPA, 2005) and this Supplemental Guidance will be through EPA's Risk Assessment Forum website, under Publications, Guidelines, Guidelines for Cancer Risk Assessment. The URL is http://www.epa.gov/cancerguidelines. The data and results of analyses are available in spreadsheets.

1. INTRODUCTION

Cancer risk to children in the context of the U.S. Environmental Protection Agency's cancer guidelines (U.S. EPA, 2005) includes both early-life exposures that may result in the occurrence of cancer during childhood and early-life exposures that may contribute to cancers later in life. The National Research Council (NRC, 1994) recommended that "EPA should assess risks to infants and children whenever it appears that their risks might be greater than those of adults." This document focuses on cancer risks from early-life exposure compared with those from exposures occurring later in life. Evaluating childhood cancer and childhood exposures resulting in cancer later in life are related, but separable, issues.

Historically, the focus on cancer has been as a disease associated with aging, resulting from extended exposure duration with prolonged latency periods before the cancers appear. Because much of cancer epidemiology addresses occupational exposures and because rodent cancer studies are designed to last approximately a lifetime (two years) beginning after sexual maturity, the cancer database used by EPA and other agencies for risk assessment focuses on adults. However, extensive literature demonstrates that exposures early in life (i.e., transplacental or *in utero*, early postnatal, lactational) in animals can result in the development of cancer (reviewed in Toth, 1968; Della Porta and Terracini, 1969; Druckery, 1973; Rice, 1979; Vesselinovitch et al., 1979; Rice and Ward, 1982; Vesselovitch et al., 1983; Anderson et al., 2000). Thus, one element in extending analyses to children is to evaluate the extent to which exposures early in life would alter the incidence of cancers observed later in life, compared with the incidence observed with adult-only exposures (Anderson et al., 2000; NRC, 1993).

The causes of cancer encompass a variety of possible risk factors, including genetic predisposition (Tomlinson et al., 1997), diet, lifestyle, associations with congenital malformations (Bosland, 1996), and exposure to biological and physical agents and chemicals in the environment. In some cases, tumors in adults and children have been compared (Anderson et al., 2000; Ginsberg et al., 2002). Children and adults generally develop the same spectrum of tumors when they have inherited gene and chromosomal mutations, such as Li-Fraumeni syndrome (Birch et al., 1998). With ionizing radiation, which operates through a mutagenic mode of action, both the young and the old develop many of the same tumors, with the difference being that children are more susceptible for a number of tumor types (NRC, 1990; U.S. EPA, 1994; UNSCEAR, 2000). Studies with anticancer drugs (cytotoxic and immunosuppressive) demonstrate a similar spectrum of tumors (Hale et al., 1999; Kushner et al., 1998; Larson et al., 1996; Nyandoto et al., 1998). Various viral infections, such as Epstein Barr and hepatitis B, lead to lymphoma and liver cancer, respectively, in both age groups (Lindahl et

al., 1974; Mahoney, 1999). These observations in humans indicate that the mode of action for these agents would be the same or similar for adults and children.

Although there are similarities between childhood and adult tumors, significant differences are also known to exist (Grufferman, 1998; Israel, 1995). Tumors of childhood generally consist more of embryonic cell tumors, while adults have more carcinomas. Leukemias, brain and other nervous system tumors, lymphomas (lymph node cancers), bone cancers, soft tissue sarcomas, kidney cancers, eye cancers, and adrenal gland cancers are the most common cancers of children, while skin, prostate, breast, lung, and colorectal cancers are the most common in adults (Ries et al., 1999; U. S. Cancer Statistics Working Group, 2002). Some tumors are unique to the young, including several with well established genetic bases, such as tumors of the kidney (Wilms' tumor) or eye (retinoblastoma) (Anderson et al., 2000; Israel, 1995).

The relative rarity in the incidence of childhood cancers and a lack of animal testing guidelines with perinatal[1] exposure impede a full assessment of children's cancer risks from exposure to chemicals in the environment. Unequivocal evidence of childhood cancer in humans occurring from chemical exposures is limited (Anderson et al., 2000). Established risk factors for the development of childhood cancer include radiation and certain pharmaceutical agents used in chemotherapy (Reise, 1999). There is some evidence in humans for adult tumors resulting from perinatal exposure. Pharmacological use of diethylstilbesterol (DES) during pregnancy to prevent miscarriages induced clear cell adenocarcinoma of the vagina in a few daughters exposed *in utero* though this tumor was not observed in exposed mothers (Hatch et al., 1998; Robboy et al., 1984; Vessey, 1989). In addition to the limited human data, there are examples of transplacental carcinogens in animal studies, such as recent studies with nickel and arsenic (Diwan et al., 1992; Waalkes et al., 2003), as well as studies suggesting that altered development can affect later susceptibility[2] to cancer induced by exposure to other chemicals (Anderson et al., 2000; Birnbaum and Fenton, 2003).

Infrequently, perinatal exposure in animals has been shown to induce tumors of different types than those observed with adult exposures. Studies with saccharin (Cohen et al., 1995; Whysner and Williams, 1996; IARC, 1999) and ascorbate (Cohen et al., 1998; Cohen et al., 1995; NTP, 1983) found cancer when exposures were initiated in the perinatal period. In

[1] Perinatal is defined as the time around birth and may include both prenatal (prior to birth) and postnatal (after birth) periods.

[2] Susceptibility is defined here as an increased likelihood of an adverse effect, often discussed in terms of relationship to a factor that can be used to describe a human subpopulation (e.g., lifestage, demographic feature, or genetic characteristic). The terms "susceptibility" and "sensitivity" are used with a variety of definitions in published literature making it essential that readers are aware of these differences in terminology across documents.

contrast, studies submitted to the Food and Drug Administration of approximately a dozen other food additives and colorings that were not adult carcinogens did not indicate cancer, even when perinatal exposures occurred (U.S. EPA, 1996). When observed, the differences between childhood and adult cancers suggest the importance of evaluating the impacts of maternal exposures during pregnancy as well as exposures to children (Anderson et al., 2000). The effects of maternal exposures and transplacental carcinogens require separate evaluation and are not quantitatively evaluated in the analysis presented below.

The limited human information described briefly above is supported by a number of animal bioassays that include both perinatal and adult exposures to chemicals. Standard animal bioassays generally begin dosing after the animals are 6-8 weeks old, when many organs and systems are almost fully developed, though substantial growth in body size continues thereafter (as more fully discussed in Hattis et al., 2005). The literature can be divided roughly into three types of exposure scenarios: those that include *repeated* exposures for the early postnatal to juvenile period, as compared with chronic later-life dosing; *lifetime* (i.e., combined perinatal and adult) exposure as compared with chronic later-life dosing; and those that include more *acute* exposures, such as a single intraperitoneal (ip) or subcutaneous injection, for both early-life and later-life dosing. In the early-life exposure studies that are available, perinatal exposure usually induces higher incidence of tumors later in life than the incidence seen in standard bioassays where adult animals only were exposed; some examples include diethylnitrosamine (DEN) (Peto et al., 1984), benzidine (Vesselinovitch et al., 1979), DDT (Vesselinovitch et al., 1979), and polybrominated biphenyls (PCBs) (Chhabra et al., 1993a). Reviews comparing early-life carcinogenesis bioassays with standard bioassays for a limited number of chemicals (McConnell, 1992; Miller et al., 2002; U.S. EPA, 1996) have concluded:

- The same tumor sites usually are observed following either perinatal or adult exposure.
- Perinatal exposure in conjunction with adult exposure usually increases the incidence of tumor bearing animals or reduces the latent period before tumors are observed.

There is limited evidence to inform the mode(s) of action leading to differences in tumor type and tumor incidence following early-life exposure and exposure later in life. Differences in the capacity to metabolize and clear chemicals at different ages can result in larger or smaller internal doses of the active agent(s), either increasing or decreasing risk (Ginsberg et al., 2002; Renwick, 1998). There is reason to surmise that some chemicals with a mutagenic mode of action, which would be expected to cause irreversible changes to DNA, would exhibit a greater effect in early-life versus later-life exposure. Several studies have shown increased susceptibility

of weanling animals to the formation of DNA adducts following exposure to vinyl chloride (Laib et al., 1989; Morinello et al., 2002a; Morinello et al., 2002b). Additionally, even though not used quantitatively in the analyses in this document, a recent analysis of *in vivo* transplacental micronucleus assays indicated that fetal tissues generally are more sensitive than maternal tissues for induction of micronuclei from mutagenic chemicals (Hayashi et al., 2000), providing qualitative support for the early-life susceptibility. Similarly, the neonatal mouse model for carcinogenesis, which uses two doses prior to weaning followed by observation of tumors at one year, shows carcinogenic responses for mutagenic agents (Flammang et al., 1997; McClain et al., 2001). These results are consistent with the current understanding of biological processes involved in carcinogenesis, which leads to a reasonable expectation that children can be more susceptible to carcinogenic agents than adults (Anderson et al., 2000; Birnbaum and Fenton, 2003; Ginsberg, 2003; Miller et al., 2002; Scheuplein et al., 2002). Some aspects potentially leading to childhood susceptibility include the following issues.

- More frequent cell division during development can result in enhanced fixation of mutations due to the reduced time available for repair of DNA lesions and clonal expansion of mutant cells gives a larger population of mutants (Slikker et al, 2004).
- Some embryonic cells, such as brain cells, lack key DNA repair enzymes.
- Some components of the immune system are not fully functional during development (Holladay and Smialowicz, 2000; Holsapple et al., 2003).
- Hormonal systems operate at different levels during different lifestages (Anderson et al., 2000).
- Induction of developmental abnormalities can result in a predisposition to carcinogenic effects later in life (Anderson et al., 2000; Birnbaum and Fenton, 2003; Fenton and Davis, 2002).

The methodology that has been generally used by the U.S. EPA to estimate cancer risk associated with oral exposures relies on estimation of the lifetime average daily dose, which can account for differences between adults and children with respect to exposure factors such as eating habits and body weight. However, susceptibility differences with respect to early lifestages are not taken into consideration because cancer slope factors[3] are based upon effects

[3] Cancer slope factor – An upper bound estimate of the increased cancer risk from a lifetime exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per unit exposure (e.g., mg/kg-day or ug/m^3), is generally reserved for use in the low-dose region of the dose-response relationship. It is often the statistical upper bound on the potency and therefore the risk. “Upper bound” in this context is a plausible

observed following exposures to adult humans or sexually mature animals. Since a much larger database exists for chemicals inducing cancer in adult humans or sexually mature animals, it is necessary to determine whether adjustment of such adult-based cancer slope factors would be appropriate when assessing cancer risks associated with exposures early in life. The analysis undertaken here addresses this issue, focusing upon studies that define the potential duration and degree of increased susceptibility that may arise from childhood, defined as early-life (typically postnatal and juvenile animal) exposures. Some of these analyses, along with a more complete description of the procedures used, have been published (Barton et al., 2005). The analysis presented in this Supplemental Guidance and in the published article form the basis for developing Supplemental Guidance for evaluating cancer susceptibility associated with early-life exposures.

upper limit to the true probability.

2. PROCEDURES

This section describes the steps taken to assess potential susceptibility to early-life exposure to carcinogenic compounds compared with adult and whole-life exposure. The readily available literature was reviewed to identify animal studies that compared tumor incidence between early-life and adult-only exposures or between early-life-and-adult and adult-only exposures. Studies were categorized by length of exposure; those studies with quantitative information to estimate tumor incidence over time for early-life and adult exposures were identified. These studies provided the basis for quantitatively estimating the difference in susceptibility between early-life and adult exposures, as described below. Finally, summaries of available human data for radiation exposure were reviewed in the context of tumor incidence from early-life versus later-in-life exposure.

2.1. DATA SOURCES FOR ANIMAL STUDIES

Studies in the literature included in this analysis are those that report tumor response from experiments that included both early-life and adult exposure as separate experimental groups. Initial studies for consideration were identified through review articles and a search of the National Toxicology Program (NTP) database. Reviews of the literature regarding cancer susceptibility from early-life exposure in animals include McConnell (1992), Ginsberg (2003), Anderson et al. (2000), Miller et al. (2002) and U.S. EPA (1996). A literature search was conducted utilizing key words and MeSH headings (Medline) from studies identified in the available reviews. The list of chemicals included in this analysis for quantitative evaluation is shown in Table 1a and 1b.

Abstracts or papers were reviewed to determine if a study provided information that could be used for quantitative analysis. The criteria used to decide if a study could be included in the quantitative analysis were:

- Exposure groups at different post-natal ages in the same study or same laboratory, if not concurrent (to control for a large number of potential cross-laboratory experimental variables including pathological examinations),

- Same strain/species (to eliminate strain-specific responses confounding age-dependent responses),

- Approximately the same dose within the limits of diets and drinking water intakes that obviously can vary with age (to eliminate dose-dependent responses confounding age-dependent responses),

- Similar latency period following exposures of different ages (to control for confounding latency period for tumor expression with age-dependent responses), arising from sacrifice at >1 year for all groups exposed at different ages, where early-life exposure can occur up to about 7 weeks. Variations of around 10 to 20% in latency period are acceptable,

- Postnatal exposure for juvenile rats and mice at ages younger than the standard 6 to 8 week start for bioassays; prenatal (*in utero*) exposures are not part of the current analysis. Studies that have postnatal exposure were included (without adjustment) even if they also involved prenatal exposure,

- "Adult" rats and mice exposure beginning at approximately 6 to 8 weeks old or older, i.e. comparable to the age at initiation of a standard cancer bioassay (McConnell, 1992). Studies with animals only at young ages do not provide appropriate comparisons to evaluate age-dependency of response (e.g., the many neonatal mouse cancer studies). Studies in other species were used a supporting evidence, because they are relatively rare and the determination of the appropriate comparison ages across species is not simple, and

- Number of affected animals and total number of animals examined are available or reasonably reconstructed for control, young, and adult groups (i.e., studies reporting only percent response or not including a control group would be excluded unless a reasonable estimate of historical background for the strain was obtainable).

Tables 2 and 3 include information on the methods and results from the animal studies identified in Table 1b. Pertinent information on species, sex, dosing regimen, and tumor incidence is given. Additionally, the "Notes" column includes general information about the relationship between tumor incidence, animal age at first dosing, and sex. The data in Tables 2 and 3 were used for the calculations, described below, for estimating potentially increased cancer risk from early-life exposure.

The available literature includes a wide range of exposure scenarios. This range is due in part to the lack of a defined protocol for early-life testing and the difficulty of standardizing and administering doses preweaning. As noted previously, the literature can be divided roughly into three types of exposure scenarios: those that include repeated exposures for the early postnatal to juvenile period, as compared with chronic later-life dosing; lifetime (i.e., combined perinatal and adult) exposure as compared with chronic later-life dosing; and those that include more acute exposures, such as a single intraperitoneal (ip) or subcutaneous injection, for both early-life and later-life dosing. Table 2 includes the studies that had early postnatal to juvenile exposures, adult chronic exposures, and lifetime exposures. Table 3 includes studies with acute exposures. A discussion of the implications of the different exposure scenarios is included in Section 3.

Studies were identified for more than 50 chemicals not included in Tables 2 and 3 that demonstrated carcinogenesis following perinatal exposure, but did not directly compare exposures at different ages. A large number of studies address *in utero* exposures only. More than 100 chemicals (with both negative and positive findings) have been studied in the neonatal mouse assay, but this assay does not have a comparable adult exposure (Flammang et al., 1997; McClain et al., 2001; Fujii, 1991). Studies across laboratories often varied in their use of animal strains (e.g., for AZT studies, Diwan et al., 1999 used CD-1 mice, while NTP, 1999 used $B6C3F_1$ mice). Studies of tamoxifen use two Wistar-derived strains and had very different periods for tumor expression, i.e., sacrifice at 20 months for adult-exposed rats and natural death up to 35 months for juvenile-exposed rats, with uterine tumors observed in animals dying after 22 months (Carthew et al., 2000; Carthew et al., 1996; Carthew et al., 1995). Due to these factors, the chemicals that belong to this group were not evaluated quantitatively. In addition, there were studies assessing radiation in animals (Covelli et al., 1984; Di et al., 1990; Sasaki et al., 1978). The radiation data were not analyzed in depth, in part because there are recognized differences in toxicokinetics and toxicodynamics between radiation and chemicals with a mutagenic mode of action for carcinogenesis. Even though the data on A-bomb survivors provide information for many different cancer sites in humans with a single exposure involving all ages, a number of national and international committees of experts have analyzed and modeled these data to develop risk estimates for various specific applications. Furthermore, lack of uniformity regarding radiation doses, gestational age at exposure, and the animal strains used make it difficult to make comparisons across studies (Preston et al., 2000).

2.2. EVALUATING THE MODE OF ACTION OF CARCINOGENS

Evaluation of the mode of action of a carcinogen was based upon a weight-of-evidence approach. Multiple modes of action are associated with the chemicals in this database, but a number are associated with mutagenicity (i.e., benzo(a)pyrene, benzidine, dibenzanthracene, diethylnitrosamine, dimethylbenz(a)anthracene, dimethylnitrosamine, ethylnitrosourea, 3-methylcholanthrene, methylnitrosourea, safrole, urethane, and vinyl chloride). Determination of carcinogens that are operating by a mutagenic mode of action entails evaluation of short-term testing results for genetic endpoints, metabolic profiles, physicochemical properties, and structure-activity relationship (SAR) analyses in a weight-of-evidence approach (Dearfield et al., 1991; U.S. EPA, 1986, 1991; Waters et al., 1999), as has been done for several chemicals (e.g., Dearfield et al., 1999; McCarroll et al., 2002; U.S. EPA, 2000a). Key data for a mutagenic mode of action may be evidence that the carcinogen or a metabolite is DNA reactive and/or has the ability to bind to DNA. Also, such carcinogens usually produce positive effects in multiple test

systems for different genetic endpoints, particularly gene mutations and structural chromosome aberrations, and in tests performed *in vivo* which generally are supported by positive tests *in vitro*. Additionally, carcinogens may be identified as operating via a mutagenic mode of action if they have similar properties and SAR to established mutagenic mode of action.

2.3. QUANTITATIVE METHODS

To estimate the potential difference in susceptibility between early-life and adult exposure, we calculated the estimated ratio of the cancer potency from early-life exposure compared to the estimated cancer potency from adult exposure. The cancer potency was estimated from a one-hit model, or a restricted form of the Weibull model, which is commonly used to estimate cumulative incidence for tumor onset. The general form of the equation is:

P(dose) = 1-[1-P(0)]exp(-cancer potency*dose)

The ratio of juvenile to adult cancer potencies were calculated by fitting this model to the data for each age group. The model fit depended upon the design of the experiment that generated the data. Two designs should be handled separately: experiments in which animals are exposed either as juveniles or as adults (with either a single or multiple dose in each period), and experiments in which exposure begins either in the juvenile or in the adult period, but once begun, continues through life.

For the first case, the model equations are:

$$P_A = P_0 + (1 - P_0)(1 - \mathrm{e}^{-m_A \delta_A}) \qquad (1)$$
$$P_J = P_0 + (1 - P_0)\left(1 - \mathrm{e}^{-m_A \mathrm{e}^{\lambda} \delta_J}\right)$$

where:

subscripts *A* and *J* refer to the adult and juvenile period, respectively,
λ is the natural logarithm of the juvenile:adult cancer potency ratio,
P_0 is the fraction of control animals with the particular tumor type being modeled,
P_x is the fraction of animals exposed in age period *x* with the tumor,
m_A is the rate of accumulation of "hits" per unit of time for adults, i.e., the cancer potency, and
δ_x is the duration or number of exposures during age period *x*.

For a substantial number of data sets (acute exposures), $\delta_J = \delta_A = 1$. We are interested in

determining λ, which is the logarithm of the estimated ratio of juvenile to adult cancer potencies, a measure of potential susceptibility for early-life exposure.

For the second kind of design, the model equations should take into account that exposures that were initiated in the juvenile period continue through the adult period. The model equations for the fraction of animals exposed only as adults with tumors in this design are the same as in the first design, but the fraction of animals whose first exposure occurred in the juvenile period is:

$$P_J = P_0 + (1 + P_0)\left(1 - e^{-m_A e^{\lambda}(\delta_J - \delta_A) - m_A \delta_A}\right) \quad (2)$$

All symbols in (eq. 2) have the same interpretation as their counterparts in (eq. 1), but now δ_J includes the duration of exposure during the juvenile period as well as the subsequent adult period.

Parameters in these models were estimated using Bayesian methods (see, for example, Carlin and Louis, 2000), and all inferences about the ratios were based on the marginal posterior distribution of λ. Some of these analyses, including a more complete description of the procedures (including the potential effect of alternative Bayesian priors that have been examined) have been published (Barton et al., 2005). The data for estimating each ratio were in the form of numbers of animals tested and number affected for each of control, juvenile-exposed, and adult-exposed animals, and duration of exposure for each of the juvenile-exposed and adult-exposed groups. A few data sets had separate control groups for the juvenile-exposed and adult-exposed groups, and equations 1 and 2 were modified accordingly. The likelihood for the parameters in the model was the product of three (or four, if there were two control groups) binomial probabilities: for the number of animals with tumors in the control group(s), for the juvenile-exposed group, and for the adult-exposed group. The prior for P_0 (the fraction of control animals with a particular tumor) was right triangular (right angle at the origin), based on the assumption that control incidences should be relatively low. (The base of the distribution is one, as P_0 can not exceed one. As this is a probability distribution, the area of the triangle is one. Therefore, its height at the origin must be 2.) The effect of exposure in adults is quantified by the extra risk, Q, where the probability that an animal has a tumor is $P_0 + (1 - P_0)Q$. So, from equations 1, $Q = 1 - e^{-m_A \delta_A}$, Q was given a uniform prior on the interval (0,1), reflecting total ignorance about the extra risk of adult exposure. Finally, the prior for λ was Gaussian with mean 0 (corresponding to a median or geometric mean ratio of one) and standard deviation 3. The prior for the log ratio of juvenile to adult cancer potency has some influence over the posterior estimates for the ratio of juvenile to adult potency. The magnitude of that influence depends on

the amount of support in the data for different values of the log ratio. The prior also effectively downweights extremely large or small values for the juvenile to adult potency ratio. Three priors for the standard deviation were evaluated (Barton et al., 2005, see Appendix), with the intent of finding the largest prior, i.e., one that would contain the least informative assumption for the prior. A standard deviation of 9 was tried, but some of the intervals would not converge. A standard deviation of 3 worked well, allowed ratio estimates to be derived, with all of the data of interest. An intermediate value of 6 was also examined to ascertain if a less informative prior could be used. While the intervals converged, a sensitivity analysis showed that this value for the standard deviation resulted in sufficient down-weighting of the ratios with limited information that these data would not influence the result. This was considered an unreasonable bias, so a standard deviation of 3 was used for the further analyses. A further discussion of these analyses can be found in Barton et al. (2005).

The posterior distribution for the unknown parameters in these models is the product of the likelihood from the data and the priors (the "unnormalized" prior), divided by a normalization constant that is the integral of the unnormalized prior over the ranges of all the parameters. This normalization constant was computed using numerical integration, as were posterior means and variances and marginal posterior quantiles for the log-ratio λ. All numerical computations were carried out in the R statistical programming language (version 1.8.1; R Development Core Team, 2003).

This method produced a posterior mean ratio of the early-life to adult cancer potency, which is an estimate of the potential susceptibility of early-life exposure to carcinogens. If the ratio was greater than one, this indicated that the experiment found that there was greater susceptibility from early-life exposure. If the ratio was less than one, this indicated that the experiment found that there was less susceptibility from early-life exposure. Summaries of the individual ratios from each of the dose groups from the different experiments for different groupings were also calculated (for example for all acute exposures of chemicals that are carcinogenic by a mutagenic mode of action). The summary ratios were constructed from the individual ratios within a group, by variance-weighting the means of each ratio. The individual, posterior means were weighted by using reciprocals of their posterior variance. This weighting procedure is commonly used because it gives greater weight to those studies for which the variances, i.e., the uncertainties, are smaller. Because the ratios were calculated as log ratios (see eq. 1), exponentiating the resulting inverse-variance-weighted mean yielded inverse-variance-weighted geometric means of ratios.

2.4. IONIZING RADIATION

A supporting role was assigned to the available human radiation data, where cancer incidence in adults who were children at the time of the atomic bomb (A-bomb) exposure was compared with cancer incidence in adults who were older at the time of exposure. Although there are recognized differences in toxicokinetics and toxicodynamics between radiation and chemical carcinogens with a mutagenic mode of action, the data on A-bomb survivors provide information for many different cancer sites in humans with a single exposure involving all ages. In addition to the richness of the data, a number of national and international committees of experts have analyzed and modeled these data to develop risk estimates for various specific applications.

The report of the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR, 2000, with Scientific Annexes) lists more than 80 studies, in addition to the reports of the Japanese A-bomb survivors, in which at least one type of cancer was measured in humans who were exposed either intentionally or accidentally to some form of ionizing radiation. However only the A-bomb survivor reports have relevant information on incidence of early-life exposures. One of the more recent papers cited in the UNSCEAR report, by Thompson et al. (1994), contains detailed data on the incidence of 21 different cancers in 37,270 exposed A-bomb survivors (42,702 unexposed). Also, EPA has used data from the A-bomb survivors to develop age-specific relative risk coefficients using various methods for transporting the risk from the Japanese population to the U.S. population (U.S. EPA, 1994). It is beyond the scope of this effort to present all of the radiation data or a discussion of the various analyses and modeling efforts. Rather, information relevant to comparing cancer risks from juvenile versus adult exposure from UNSCEAR (2000) and U.S. EPA (1994; 1999) is presented as representative findings to determine whether the radiation data are similar qualitatively to the chemical findings. More detailed data on the A-bomb survivors can be found in Delongchamp et al. (1997) and Preston et al. (2000).

As previously noted, several studies have assessed radiation in animal studies (Covelli et al., 1984; Di et al., 1990; Sasaki et al., 1978). However, lack of uniformity regarding radiation doses, gestational age at exposure, and the animal strains used make it difficult to compare the experimental data on cancer induction after prenatal irradiation (Preston et al., 2000).

3. RESULTS

3.1. QUALITATIVE EVALUATION OF THE DATABASE

The question addressed in this analysis was whether, and how, available quantitative scientific data could inform risk assessment policy choices for adjusting cancer slope factors when they are used in the assessment of cancer risk from childhood exposure. Cancer slope factors are, with few exceptions, based on adult human epidemiology or standard chronic adult rodent bioassays, which do not address the impacts of early-life exposures. Thus, the critical data are either human epidemiological data on childhood exposures resulting in adult cancer or research studies with rodents involving early postnatal exposures. The major human data available are from radiation exposures (studies summarized in Tables 9-11), with very limited data available for humans exposed during childhood to chemicals (reviewed in Anderson et al., 2000; Miller et al., 2002).

A review of the literature identified several hundred references reporting more than 50 chemicals that have been shown to be able to cause cancer following perinatal exposure (Table 1a) (reviewed in Toth, 1968; Della Porta and Terracini, 1969; Druckery, 1973, Rice, 1979; Vesselinovitch et al., 1979; Rice and Ward, 1982; Vesselovitch et al.; 1983; Fujii, 1991; Anderson et al., 2000). Studies (or groups of studies from a single laboratory on a given chemical) that directly provided quantitative data on carcinogenesis following early postnatal exposures and adult exposures to chemicals in animals were identified for 18 chemicals, listed in Table 1b, 2, and 3. Of the identified studies, there were 11 chemicals involving repeated exposures during early postnatal and adult lifestages (Table 1b) and 8 chemicals using acute exposures (typically single doses) at different ages (Table 1b). Some of the studies evaluated single tissues or organs for tumors (e.g., only liver), while others evaluated multiple tissues and organs (Tables 2 and 3). Mice, rats, or both species and sometimes multiple strains were tested. These studies serve as the basis for the quantitative analyses presented later in the results.

In addition to the studies identified in Table 1b, studies were identified with early postnatal and early-life exposures that were evaluated qualitatively but not quantitatively. Some of these studies are notable and provide important supporting information. Two recent studies used transgenic mouse models for human tumors. Increased multiplicity of colon tumors was observed following earlier versus later azoxymethane exposures (Paulsen et al., 2003). Shortened mammary tumor latency following estradiol exposure occurred when exposures occurred between 8 and 18 weeks as opposed to earlier or later, which is generally consistent with the incidence results analyzed for DMBA (Yang et al., 2003). Several notable examples exist of developmental windows leading to cancer susceptibilities that were not observable in

adults. Several potent estrogenic chemicals including DES, tamoxifen, and genistein produce uterine tumors with early postnatal exposures of mice, though there also appear to be strain-dependent differences in the tumor sites in adult mice (Gass et al., 1964; Greenman et al., 1990; Newbold et al., 1990, 1997, 1998, 2001). Developmental susceptibilities are believed to play a key role in effects observed with saccharin (Cohen et al., 1995; Whysner and Williams, 1996) and ascorbate (Cohen et al., 1998; NTP, 1983), with bladder tumors arising when early-life exposures occurred. Studies with several species, including rat, mouse, and opossum, indicate that nervous systems tumors associated with exposures to ENU and several other chemicals appear to be highly dependent upon exposures occurring within certain windows, particularly prenatal ones (Rice, 1979; Rice and Ward, 1982; Jurgelski et al., 1979).

Analyses of the difference in cancer risk from exposures during different lifetime periods ideally should address both the period of potential susceptibility and the magnitude of the susceptibility. Available studies used a variety of study designs (see Tables 2 and 3), which can be valuable because they provide different information (Figure 1). However, variations in study design can result in a lack of comparability across chemicals, and can limit information on the consistency of effects with different chemicals acting through different modes of action. The acute dosing (largely single dose) studies (Table 3) are valuable because they involve identical exposures with explicitly defined doses and time periods demonstrating that differential tumor incidences arise exclusively from age-dependent susceptibility. These studies address both the period and magnitude of susceptibility. They were not as appropriate for quantitative adjustments for the cancer potency estimates because of their limitations, including that most used subcutaneous or ip injection that historically have not been considered quantitatively relevant routes of environmental exposure for human cancer risk assessment by EPA, and that these routes of exposure are expected to have only partial or a complete absence of first pass metabolism that is likely to affect potency estimates.

The repeated dosing studies with exposures during early postnatal or adult lifetime provide useful information on the relative impact of repeated exposures at different lifestages and may be more likely to have exposure occur during a window of susceptibility, if there is one. One notable difference in study designs was that studies with repeated early postnatal exposure were included in the analysis even if they also involved earlier maternal and/or prenatal exposure, while studies addressing only prenatal exposure were not otherwise a part of this analysis. Another notable difference among studies involved the tissues that were evaluated for tumors: some studies focused on a single tissue, particularly liver, while others evaluated multiple tissues.

Comparisons within a single repeated dosing study may have limitations for evaluating

differential susceptibility because exposures to the chemical can differ during the different lifestages, particularly when dietary or drinking water exposures are involved. A notable example is the PCB study (Chhabra et al., 1993a), in which mobilization of such lipid-soluble chemicals into mother's milk would be expected to result in infants receiving much larger exposures than other lifestages. While lactational transfer is just as relevant to human nursing offspring, this difference in exposure obscures the extent to which the early lifestage is quantitatively more susceptible (i.e., part of the increased early-life cancer risk arises from higher exposure than during the adult period). Maternal metabolism of compounds such as diphenylhydantoin (DPH) (Chhabra et al., 1993b) also may result in lower exposure during lactation, potentially underestimating the early-lifestage risk, if the parent compound is the active form of the chemical. Similar issues exist due to normal age-dependent changes in food and water consumption. Ascribing differential effects observed in animal studies solely to lifestage susceptibility must be done carefully as there may also be differences in the exposures. There are substantial and clear benefits, therefore, from experimental consistency when comparisons are made directly within a study (e.g., same species and strain, consistent pathological evaluation).

One issue to note is the rationale for the organization of the available data. It was observed that the results across a broad range of chemicals with a variety of modes of action were somewhat variable. Therefore, consistent with the approach of the EPA cancer guidelines (U.S. EPA, 2005), an approach based on mode of action appeared to be a common framework for analysis. Variability in lifestage-dependent susceptibility and susceptibility across a range of modes of action was further supported by theoretical analyses using multistage and two-stage models of carcinogenesis (Goddard and Krewski, 1995; Murdoch et al., 1992).

3.2. QUANTITATIVE EVALUATION OF THE DATABASE

As described in the Section 2.3, the potential difference in susceptibility between early-life and adult exposure was calculated as the estimated ratio of cancer potency from early-life exposure over the cancer potency from adult exposure. Tables 4-7 present the results of the quantitative analysis using the studies that were determined qualitatively to have appropriate study designs (Tables 2 and 3) containing sufficient information to analyze. Based on the studies available, the calculations were organized into four tables: (1) compounds acting through a primarily mutagenic mode of action, where the compound was administered by a chronic dosing regimen to adults and repeated dosing in the early postnatal period (Table 4); (2) compounds acting through a primarily nonmutagenic mode of action, where the compound was administered by a chronic dosing regimen to adults and repeated dosing in the early postnatal period (Table 5);

(3) compounds acting through a primarily mutagenic mode of action, where the compounds were administered by an acute dosing regimen (Table 6); and (4) compounds acting primarily through either a mutagenic or nonmutagenic mode of action with chronic adult dosing and repeated early postnatal dosing (Table 7). In these tables, the 2.5% and 97.5% are percentiles of the posterior distribution. For a Bayesian distribution, these percentiles function in a manner similar to the 95% confidence limits for other types of statistical analyses. The results are discussed below, followed by a description of results from analyses of studies of humans exposed to radiation.

3.2.1. Carcinogens with a Mutagenic Mode of Action

The most informative database on early-lifestage susceptibility exists for chemicals with a well-accepted mutagenic mode of action (e.g., diethylnitrosamine, vinyl chloride). This database includes both single-dose studies and repeated-dose studies involving periods of postnatal and/or chronic exposure. These studies help define the periods of increased vulnerability and the magnitude of the susceptibility. The acute dosing studies demonstrate that the age-dependent responses are not due to differences in exposure, because these studies explicitly control the exposure.

3.2.1.1. *Early Postnatal, Juvenile, and Adult Repeated Dosing Studies of Chemicals with a Mutagenic Mode of Action*

Studies comparing repeated dosing for early-life, adult, or lifetime exposures exist for six carcinogens with a mutagenic mode of action [benzidine, diethylnitrosamine (DEN), 3-methylcholanthrene, safrole, urethane, and vinyl chloride]; DEN also had acute dosing studies. Lifetime (i.e., combined juvenile and adult) compared to adult exposure studies were analyzed for DEN, safrole, and urethane, while studies comparing juvenile with adult exposures were analyzed for benzidine, 3-methylcholanthrene, safrole, and vinyl chloride. These chemicals all require metabolic activation to the active carcinogenic form. Analysis of the tumors arising per unit time of exposure found that juvenile exposures with each chemical could be more effective than adult exposures were at inducing tumors (Tables 4 and 7; Figure 2, a graphic representation of the posterior, unweighted geometric means and their 95% confidence intervals, for the ratios of juvenile to adult cancer potency for carcinogens acting through a mutagenic mode of action). The weighted geometric mean for repeat and lifetime exposures is 10.4; for acute exposures the weighted geometric mean value is 1.5. For benzidine and safrole, there was a notable sex difference, with high liver tumor incidence observed for early postnatal exposures of male, but not female, mice. For both the acute and the repeated/lifetime data, the 95th percentile of the individual, unweighted geometric means is above 10 (Figure 2).

This analysis focused upon the duration of exposure as a surrogate for dose, essentially assuming that the doses animals received during the different periods of these studies were similar. This assumption is a limitation of the analysis because these studies involved exposures via lactation (i.e., dosing the mother prior to weaning), drinking water, diet, or inhalation, which have the potential to deliver different doses at different lifestages. However, the range of the magnitudes of the tumor incidence ratios of juvenile to adult exposures is similar (Table 8) for the repeated dosing studies (0.12 – 111, weighted geometric mean 10.5, 42% of ratios greater than 1), lifetime dosing studies (0.18 – 79, weighted geometric mean 8.7, 67% of ratios greater than 1), and acute dosing studies (0.01 – 178, weighted geometric mean 1.5, 55% of ratios greater than 1), suggesting that these differences in dosing are not the sole determinant of the increased incidence of early tumors, i.e., uncertainty and variability remain. Because these comparisons include different chemicals with different tissue specificities, it may be informative to consider liver as a target organ affected by all of these chemicals. The range of the magnitudes of the liver tumor incidence ratios of juvenile to adult exposures is similar for the repeated dosing studies (0.12 – 111, weighted geometric mean 41.8, 86% of ratios greater than 1, Table 4), lifetime dosing studies (0.47 – 79, weighted geometric mean 14.9, 80% of ratios greater than 1, Table 7), and acute dosing studies (0.1 – 40, weighted geometric mean 8.1, 77% of ratios greater than 1, Table 8). Thus, the repeated dose studies support the concept that early-lifestage exposure to carcinogenic chemicals with a mutagenic mode of action would lead to an increased tumor incidence compared with adult exposures of a similar duration and dose.

3.2.1.2. *Acute Dosing Studies of Chemicals with a Mutagenic Mode of Action*

Acute dosing studies are available for eight carcinogens with a mutagenic mode of action that were administered to mice or rats [benzo[a]pyrene (BaP), dibenzanthracene (DBA), Diethylnitrosamine (DEN), dimethylbenzanthracene (DMBA), dimethylnitrosamine (DMN), ethylnitrosourea (ENU), methylnitrosourea (NMU), and urethane (also known as ethyl carbamate)] (Table 1b). Except for ENU and NMU, these compounds require metabolic activation to their active carcinogenic forms. These acute dosing studies generally compared a single exposure during the first few weeks of life with the identical or similar exposure in young adult animals (Tables 3 and 6). Many of these studies compared exposures during the preweaning period (i.e., approximately day 21 for rats and mice) with effects around week 6, which is approximately the age at which typical chronic bioassays begin dosing animals. These studies largely were by subcutaneous or ip injection, which historically have not been considered quantitatively relevant routes of environmental exposure for human cancer risk assessment by EPA. For purposes of comparing age-dependent susceptibilities to tumor development, these

data are highly relevant. The injection route typically alters the pharmacokinetic time courses of the parent compound and the metabolites compared with oral or other exposures due to altered kinetics of absorption and metabolism. However, for these compounds and the systemic organ effects observed, there are several pharmacokinetic reasons to believe that the age-dependent trends would be similar with other routes of exposure. These compounds are expected to be reasonably well absorbed orally, comparable with injection routes, and largely require metabolic activation, so partial or complete absence of first pass metabolism in the injection studies would be similar to or underestimate metabolic activation when compared with oral exposure.

The early exposures often resulted in higher incidence of tumors than later exposures, with increased early susceptibilities up to 178-fold (unweighted ratios in Table 6 range from 0.011 to 178, with a weighted geometric mean of 1.5, and 55% of ratios greater than 1, Figure 2, Table 8). Examples of the general age-dependent decline in susceptibility of tumor response include BaP (liver tumors), DEN (liver tumors), ENU (liver and nervous system tumors), and urethane (liver and lung tumors). While generally the Day 1 and Day 15 time points were higher than later time points, in several cases similar tumor incidence was observed at both these early times (e.g., ENU-induced kidney tumors, Tables 6 and 8).

While the degree of susceptibility generally declines during the early postnatal period through puberty into early adulthood, there are exceptions due perhaps to pubertal periods of tissue development (e.g., mammary tissues) or very early development of xenobiotic metabolizing enzymes. One such exception was the increased incidence of mammary tumors in 5-8 week old rats given DMBA, compared with older or younger rats (Meranze et al., 1969; Russo et al., 1979). Meranze et al. (1969) reported 8% mammary tumors following a single dose of DMBA at less than two weeks, 56% if given once to animals between 5 and 8 weeks old, and 15% when given once to 26 week old rats. Thus, a ratio of 7.1 is obtained when comparing susceptibilities of 5–8 week and 26-week-old rats (Table 6) compared to a ratio of 0.2 when comparing the exposure at 2 weeks versus 26 weeks. A similar effect was observed by Russo et al. (1979); see Table 3. This observation corresponds well with pubertal development of the mammary tissue, with ovarian function commencing between 3 and 4 weeks (after the < 2 week time point in the Meranze et al., 1969 study), and mammary ductal growth and branching occurring such that it is approximately two-thirds complete by week 5, consistent with the 5–8 week susceptible period of Meranze et al. (Silberstein, 2001). While this differs from the general trend previously discussed, it indicates susceptibility later in the juvenile period rather than earlier. Another example of deviation from the general trend toward an age-dependent decline is DEN-induced lung tumors that were somewhat lower in incidence following exposure on day 1 than observed for the day 15 or day 42 exposures (Vesselinovitch et al., 1975) (Tables 3 and 6).

There are substantial differences in the early-life susceptibility of different tissues observed in the acute studies (Table 8). It should be noted that the target tissues vary with chemical, so the number of chemicals for which data are available varies for each tissue. Several tissues have weighted geometric mean ratios of greater than 1 including kidney, leukemia, liver, lymph, mammary, nerve, reticular tissue, thymic lymphoma, and uterus/vagina. Some of these, such as the nerve and mammary tumors, appear to have a very specific window of susceptibility, as noted above, and the ratios were much higher if the exposure occurred during this window. Tissues with weighted mean ratios less than 1 include forestomach, harderian gland, ovaries, and thyroid. Lung has a weighted geometric mean of 1. Many of the studies produced very high lung tumor responses regardless of age, so the results are difficult to interpret, as illustrated by the dose-response data with urethane in Rogers (1951) in which the increased early susceptibility is only apparent when the dose is low. The large numbers of studies with high lung tumor responses at all ages contribute to the differences in the weighted geometric means for the acute and for the repeated dosing studies.

Overall, the acute dosing studies support the concept that early-lifestage exposure to carcinogenic chemicals with a mutagenic mode of action would lead to an increased incidence of tumors compared with adult exposures of a similar dose and duration. These studies generally use the same dose and duration at all ages, and thus do not have the type of issues discussed for the repeated dosing studies. On the other hand, the acute dosing studies have limitations that were sufficient to decide that they should not be included in the quantitative adjustment of cancer potency. First, as mentioned in the previous paragraph, the large number of studies of lung tumors with almost 100% response observed at all doses and all ages would significantly bias the median ratio toward unity for a reason based on study design rather than biology. Second, cancer potency estimates are usually derived from chronic exposures. Therefore, any adjustment to those potencies should be, if possible, from similar exposures. Third, most exposures of concern to the Agency are from repeated or chronic exposures rather than acute exposures. Finally, many of the acute studies used ip exposures, which is not the usual route of exposure for environmental chemicals. Thus, the repeated and lifetime studies are more appropriate for the purpose of this analysis.

3.2.2. Carcinogens With Modes of Action Other Than Mutagenicity

Studies comparing tumors observed at the same sites following early postnatal and chronic adult exposures in a single protocol were available for six chemicals that do not act through a mutagenic mode of action [amitrole, dichlorodiphenyltrichloroethane (DDT), dieldrin, ethylene thiourea (ETU), diphenylhydantoin (DPH), polybrominated biphenyls (PBB)] (Table 5).

These chemicals cause tumors through several different, not necessarily well defined, modes of action. For example, thyroid hormone disruption by ETU causes thyroid tumors; some PBBs act through aryl hydrocarbon (Ah) receptors, while others are phenobarbital-like pleiotrophic inducers of liver enzymes and liver tumors. Three of these studies evaluated only mouse liver tumors (amitrole, DDT, dieldrin), while the other three evaluated a large number of tissues in both mice and rats (ETU, DPH, PBB). These studies generally included a combined perinatal and adult exposure as well as the separate perinatal or adult-only groups. It should be noted that no acute perinatal dosing studies of carcinogenesis were identified for these agents; such protocols are generally considered largely non-responsive for modes of action other than mutagenicity and potent estrogenicity (e.g., DES).

For five chemicals (amitrole, DDT, dieldrin, PBB and DPH), the same tumors were observed from early and/or adult exposures, though the studies for amitrole, DDT, and dieldrin only evaluates the animals for liver tumors. With ETU, no tumors in mice or rats were observed following perinatal exposure alone (except a small, not-statistically-significant increase in male rat thyroid tumors), while thyroid tumors were observed in adult rats and thyroid, liver, and pituitary tumors in adult mice. Analysis of the incidence of tumors per time of exposure shows early-lifestage susceptibilities. The range of the magnitudes of the tumor incidence ratios of juvenile to adult exposures is similar for the repeated dosing studies (0.06–13.3, weighted geometric mean 2.2, 27% of ratios greater than 1, Tables 5 and 8) and lifetime dosing studies (0.15–36, weighted geometric mean 3.4, 21% of ratios greater than 1, Tables 7 and 8). These ranges and means are similar to those for chemicals with a mutagenic mode of action, though the means and maximums are somewhat lower. Again, liver tumors are common to these chemicals. The range of the magnitudes of liver tumor incidence ratios of juvenile to adult exposures also is similar for the repeated dosing studies (0.06–13.3, weighted geometric mean 2.6, 43% of ratios greater than 1, Tables 5 and 8) and lifetime dosing studies (0.15–36, weighted geometric mean 5.8, 33% of ratios greater than 1, Tables 7 and 8).

The major factor that complicates the interpretation of the results is that these studies, except with DDT and dieldrin, involved dietary feeding initially to the mother, which potentially could increase or decrease the dose received by the pups. Due to the maternal dosing during pregnancy and lactation, the extent to which offspring received similar doses during different early and adult lifestages is particularly uncertain for DPH, ETU, and PBBs. Oral gavage doses in young animals were selected to approximate the average daily dose in adult dietary studies based on standard estimates of feed consumption in the studies with DDT and dieldrin, while the amitrole study involved dietary feeding postnatally to the mother so the young were dosed via lactation. In addition, DDT, dieldrin, and some PBBs are more persistent in the body than are

most chemicals, leading to a prolonged exposure even following limited dosing. Thus, these studies provide evidence that early lifestages can be more susceptible to exposures to chemicals causing cancer through a variety of modes of action other than mutagenicity. However, the studies with ethylene thiourea, which acts via thyroid disruption, indicate that this is not necessarily the case for all modes of action.

3.2.3. Ionizing Radiation

As mentioned previously, the UNSCEAR, Annex I (2000) includes information derived from a wide range of both intentional (generally diagnostic or therapeutic medical) and accidental radiation exposures. Only information derived from the Japanese population (referred to as the Life Span Study in the UNSCEAR Annex I) is presented here. A statistically significant excess cancer mortality associated with radiation has been found among the bomb survivors for the following types of cancer: esophagus, stomach, colon, liver, lung, bone and connective tissue, skin, breast, urinary tract, and leukemia. Tables 9 and 10 are extracted from the tables in UNSCEAR, Annex I. The excess relative risk (ERR) is the increased cancer rate relative to an unexposed population; an ERR of 1 corresponds to a doubling of the cancer rate. Because of the low numbers of cancers in individual sites within narrow age groups, the ERRs for the various solid tumors and leukemia were presented only as less than or greater than 20 years of age at the time of exposure. The larger number of thyroid tumors enable a more detailed breakout shown in Table 10. Most sites show greater risks in the younger than in the older ages.

The U.S. EPA (1994) document presents a methodology for estimation of cancer risks in the U.S. population due to low-LET (linear energy transfer) radiation exposures using data from the Atomic Bomb Survivor Study (ABSS) as well as from selected medical exposures. The report developed mortality risk coefficients using several models that took into account age and gender dependence of dosimetry, radiogenic risk, and competing causes of death as well as transporting of risks across populations. The risk projections were updated using more recent vital statistics in a report that also included an uncertainty analysis (U.S. EPA, 1999). Details of the derivation of these coefficients are available at http://www.epa.gov/radiation/docs/rad_risk.pdf .

Table 11 contains the calculated age-specific risk coefficients derived from the application of the various models to the ABSS data. For most of the sites in the table, the risk coefficients are higher in the earlier age groups; liver, bone, skin, and kidney coefficients are age-independent and only esophageal cancer coefficients increase with increasing age. Also of note is that the coefficients generally are higher for females. Similar to the information from the UNSCEAR (2000) Annex, most sites show greater risks in the younger ages than the older ages.

However, a comparison of the two tables seems to show reversal of risks for some sites as a function of age at exposure. While the high sampling variability in the epidemiological data for some ages may contribute to this apparent reversal, the choice of risk models and associated parameters also is a factor.

4. DISCUSSION

The challenge for this analysis was how to use the existing, but limited, scientific database on early postnatal and juvenile exposures to carcinogens to inform a science policy decision on whether, and if so how, to assess the risk from childhood exposures to chemicals for which we have evidence of carcinogenicity only in adult humans or sexually mature laboratory animals. The database overall is of limited size (particularly compared with the number of chemicals that have been studied in adult occupational epidemiological studies or chronic bioassays). The majority of the human data involves exposures to ionizing radiation or DES (Anderson et al., 2000). More than 50 chemicals have been demonstrated to cause cancer following perinatal exposures in animals (without adult exposures), but only a subset of the chemicals have comparative studies across ages. The comparative experimental studies used 18 chemicals, 12 of which had mutagenic modes of action and 6 of which had data from repeated or lifetime exposures. Other analyses of similar data have found similar results (Hattis et al. 2005), but have focused on other aspects of the data, e.g., gender differences.

Previously published or internal U.S. EPA analyses have concluded that the standard animal bioassay protocols usually do not miss chemicals that would have been identified as carcinogens if perinatal exposures had been undertaken (McConnell, 1992; Miller et al., 2002; U.S. EPA, 1996). Given the increased complexity and costs of chronic bioassays with perinatal exposures, a limited number of such studies have been performed. However, these are the studies that largely constitute the available database for this analysis. In addition to the chronic bioassays with perinatal exposures, there are studies with acute dosing at different lifestages and a large number of studies with perinatal exposures without a directly comparative adult study.

Two other kinds of information can contribute toward developing a scientifically informed policy: theoretical analyses and analyses of stop studies.[4] Theoretical analyses suggest that the differential susceptibility would depend in part on the mode of action (i.e., at what step in the cancer process(s) the chemical was acting) and that the use of the average daily exposure prorated over a lifetime may underestimate or overestimate the cancer risk when exposures are time-dependent (Goddard and Krewski, 1995; Murdoch et al., 1992). Evidence for old-age-dependent promotion of basophilic foci in rats by peroxisome proliferators appears to provide a concrete example consistent with these theoretical analyses (Cattley et al., 1991; Kraupp-Grasl et al., 1991). The stop studies performed by the National Toxicology Program began exposure at the standard post-weaning age, but stopped exposure after varying periods of months. Other groups of animals were exposed for a full two years; all animals were evaluated

[4] Stop studies are studies in which exposure is halted after a predetermined period.

for tumors at the end of two years regardless of the duration of exposure (Halmes et al., 2000). Related data also are available from the stop studies with vinyl chloride (Drew et al., 1983). Analysis by Halmes et al. (2000) showed that, for six of the eleven chemicals and half the tumor sites, the assumption that the cancer risk would be equal when the product of concentration and time (i.e., C x T) was constant was incorrect, and usually underestimated risk, as more of the risk came from the beginning of the exposure rather than the end. This dependence of risk on both duration and intensity of exposure did not appear to be correlated with mutagenicity. It should be noted that these stop studies all involved exposures early in the life of the animal (as opposed to a limited number of cancer studies that looked at later periods of life; e.g., Drew et al., 1983), but the extent to which the differences in tumor outcome result from increased susceptibility in these early periods or the extended period for expression of the cancer cannot be evaluated. These stop studies also used doses as high as or higher than the highest dose used in the two-year exposure. This latter factor clearly had a significant effect for two chemicals, causing tumors at higher doses that were not observed at lower doses. These results suggest that pharmacokinetic or other dose-rate dependencies can make the effects of exposures at high doses different from those exposures at lower doses. While not directly informative about early childhood exposures, these studies provide a perspective on the common cancer risk assessment practice of averaging exposures over a lifetime, especially those that include earlier lifestages. Thus, alternative methods for estimating risks from short-term exposures during childhood should be considered.

Information on different lifestage susceptibilities to cancer risks for humans exists for ionizing radiation. The effects of chemical mutagens at different lifestages on cancer induction are derived from laboratory animal studies. While the induction of cancer by ionizing radiation and the induction of cancer by chemical mutagens are not identical processes, both involve direct damage to DNA as critical causal steps in the process. In both cases, the impacts of early exposure can be greater than the impacts of later exposures, probably due to some combination of early-lifestage susceptibility and the longer periods for observation of effects. As indicated in Tables 9 and 10, A-bomb survivors exhibited different lifestage dependencies at different tumor sites, though the total radiation-related incidence of tumors showed a general slow decline with age at exposure. However, as previously noted, there are apparent differences at some sites between the two tables. In addition to the sampling and modeling differences, the excess risk values in Table 9 are based on Japanese baselines while the coefficients in Table 10 reflect UNSCEAR’s effort to transport the risks from the Japanese population to that of the United States. However, it is clear that the total radiation-related tumor incidence showed a general slow decline with age at exposure.

The studies in rodents of chemicals with mutagenic modes of action similarly support a

general decline in induced cancer risk with age at exposure and similarly show some differences for individual tumor sites. In general, the earliest two or three postnatal weeks in mice and rats appeared to be the most susceptible, though some degree of increased susceptibility through puberty in rats (beginning around 5–7 weeks) and mice (beginning around 4–6 weeks) for some types of tumors exists.

All the acute dosing studies that demonstrated carcinogenicity with animals of different ages used chemicals with a mutagenic mode of action (Tables 4 and 6). These studies provide the clearest demonstrations of periods of differential susceptibility because the exposure rate is constant at the different ages. The repeated dose studies also include several of the most informative studies for assessing perinatal carcinogenesis, notably those on vinyl chloride and DEN (Tables 2 and 4). The vinyl chloride studies by Maltoni and colleagues are part of a large series of studies on this compound that included exposures to different concentrations for varying durations, including some at early lifestages (Maltoni et al., 1984). The DEN study by Peto et al. (1984) used a unique chronic study design in which groups of rats were exposed to multiple drinking water concentrations starting at 3, 6, or 20 weeks of life. This design provides information on the susceptibility of early exposure periods within a nearly lifetime exposure.

Beyond the analysis described here, there are conceptual biological rationales that would suggest DNA-damaging agents would have greater impacts on early lifestages. Growth involves substantial levels of cell replication, even in organs that in adults are only very slowly replicating, thus increasing the likelihood that a cell will undergo division before the DNA damage caused by the mutagen has been repaired. Increased replication also can lead to a greater division of initiated cells, leading to a larger number of initiated cells per specified dose. These periods of cell replication can vary for different tissues. For example, DMBA appears to be more effective at initiating mammary tumors in 6-8 week old rats, which are undergoing development of that tissue, than during earlier or later periods (Meranze et al., 1969). While tumor promotion processes can be very dependent upon the duration of promotion, initiation processes can occur in relatively brief periods (e.g., the single-dose studies in animals or radiation exposure in humans). Most tumors take extended periods to develop, making damage that occurs earlier in life more likely to result in tumors prior to death than would exposures that occur later in life. While some of these observations may also pertain to other modes, all of them (with some differences among tumor sites) appear to be potentially relevant to a greater susceptibility to mutagenic modes of action during early-life stages (vs. later-life stages).

The information on lifestage susceptibility for chemicals inducing cancers through modes of action other than direct DNA interaction is more varied, showing an increase in tumor incidence during perinatal exposure versus exposures of mature animals (e.g., polybrominated

biphenyls induced liver tumors), no tumors from perinatal exposure (e.g., ethylene thiourea induced thyroid tumors), no effect of combined perinatal and adult exposure (e.g., DPH liver tumors in rats and female mice), and different tumors from perinatal exposure versus adult exposure (e.g., DES, ascorbate). These variations are likely a result of the modes of action of these chemicals and the pharmacokinetic differences in doses during different periods of life. No studies were evaluated that were directly comparable to the single-dose studies with mutagens, which clearly show significant differences in tumor responses after explicitly controlled doses at different lifestages.

Some evidence for an effect of early-lifestage exposures on tumor incidence was observed in studies with polybrominated biphenyls, amitrole, DDT, dieldrin, and diphenylhydantoin. These studies show increased incidence of tumors in mice from perinatal exposure, though only those for polybrominated biphenyls were statistically significant. (A nonstatistically significant increase also was observed in male rats with polybrominated biphenyls.) Combined perinatal and adult exposures generally gave statistically significant increases, though not necessarily for each sex and species (rat and mice) in the diphenylhydantoin and polybrominated biphenyl studies.

There are important demonstrations of chemicals acting through modes of action other than mutagenic to cause different tumor types with early-lifestage exposures compared with exposures for adults, e.g., tamoxifen and DES (Carthew et al., 2000; Carthew et al., 1996, Gass et al., 1964; Newbold et al., 1990, 1997, 1998). In addition, studies with *in utero* exposure to atrazine (Fenton and Davis, 2002), DES, and arsenic (Waalkes et al., 2003) indicate that early-life exposures to compounds can alter susceptibility of endocrine and reproductive organs. Three of these compounds (i.e., DES, genistein, and tamoxifen) bind to the estrogen receptor. Ongoing studies on ethinyl estradiol, nonylphenol, and genistein by the National Toxicology Program will add to this database for estrogens (Laurenzana et al., 2002; Newbold et al., 2001). These studies will evaluate cancer incidence in offspring exposed *in utero*, during lactation, and through adulthood via diet. A study with genistein found uterine tumor development to be dependent upon early-lifestage exposures (Newbold et al., 2001). Another recent study of estrogen found a shorter latency for mammary tumors in mice exposed at 8 and 12 weeks as compared to mice exposed at 4 or 18 weeks, indicating a susceptible period between 8 to 12 weeks of exposure (Yang, 2003). Thus, there is an actively growing database from which to consider issues of childhood exposure and cancer for compounds acting through the estrogen receptor or other mechanisms of endocrine disruption.

The ability to estimate with any accuracy the juvenile to adult cancer potency ratio depends very much on the experimental design used. The lifetime design has less ability to

distinguish increased susceptibility from early-life exposure than the other types of designs. Consider two different experimental designs. In the first, the "lifetime" design, a group of animals are exposed starting as juveniles, and exposure continues through adulthood. A second group are exposed only in adulthood, and the juvenile:adult ratio results from a comparison of tumor incidences in the two groups. In the second, the "repeated" design, one group of animals is exposed only during the juvenile period, and is then followed through adulthood to assess tumor incidence, and a second group of animals is exposed only through adulthood. The lifetime design turns out to be a particularly insensitive design for estimating the juvenile:adult ratio.

The following example demonstrates the magnitude of the problem: Suppose the risk per day of exposure of a chemical is ten fold greater in the juvenile period as in the adult period, and animals exposed through adulthood at a particular dose level have an extra risk of 60% for having at least one tumor, while 1% of control animals have tumors. The adult exposure period is 94 weeks, while the juvenile exposure period is 4 weeks. Thus, in the lifetime design, the group of animals exposed as juveniles will receive a total of 98 weeks of exposure, (4 in juvenile and 94 in adult), while those receiving the adult-only exposure receive 94 weeks of exposure. In the repeated design, animals exposed as juveniles receive only 4 weeks of exposure, while the adults receive 94 weeks, just as in the lifetime design. Each group starts with 50 animals. Under these assumptions, using equations (1) and (2) from Section 2.3, the expected number of animals with tumors in the three treatment groups (control, juvenile-exposed, adult-exposed groups) in the two designs is:

	Number of animals with tumors		
	Control	**Early-life exposure**	**Adult exposure**
Lifetime	1	36	30
Repeated	1	16	30

Notice that in the "lifetime" design, only six more juvenile-exposed animals have tumors than in the adult-exposed group, whereas in the "repeated" design, 16 juvenile-exposed animals have tumors. The data in the lifetime design are consistent with the hypothesis of no tumors being induced during the juvenile period: the ratios 36/50 and 30/50 are not statistically significantly different. In other words, the data from the lifetime design are statistically consistent with the hypothesis of *no risk at all* during the juvenile period, even though the real response is a 10 times greater risk from early-life exposure. The difference between the results from the two different study designs is due to the one-hit model: each additional week of a long exposure contributes less than the previous week to the total number of animals with tumors.

Note that, even if the one-hit model is not correct, chronic exposure probably results in a non-statistically significant increase for the lifetime exposure including juveniles as compared with only adult exposure.

The proper measure of relative potency of an exposure in the juvenile period relative to an exposure in the adult period is the ratio of doses in the two periods that give the same incidence of tumors. However, most of the data sets used in this report contained only one non-control dose, precluding the extensive dose-response modeling that would be required to estimate this ratio of doses. However, this document largely considered chemicals for which a mutagenic mode of action has been established and for which a linear, no-threshold dose-response function is assumed for the low-dose range being considered for risk assessment. In the case of the linear dose-response function, the analysis of the relative response from the same dose will produce the same value as ratio of doses that produces the same incidence of tumors.

For a one-hit dose-response equation, the probability of developing a tumor after the same dose and duration in the juvenile or adult period is

$$P_a = 1 - (1 - P_0)e^{-m_a x}$$
$$P_j = 1 - (1 - P_0)e^{-m_j x}$$

for dose x. Suppose we want to calculate the dose D_a or D_j that results in a given incidence of tumors after an adult or juvenile exposure. From equation 1, D_a and D_j equal:

$$D_a = \frac{-\ln\left(\frac{1-P_c}{1-P_0}\right)}{m_a}$$
$$D_j = \frac{-\ln\left(\frac{1-P_c}{1-P_0}\right)}{m_j}$$

Thus, the ratio $D_a/D_j = m_j/m_a$, the ratio calculated in this document.

In summary, this analysis supports the conclusion that there can be greater susceptibility for the development of tumors as a result of exposures to chemicals acting through a mutagenic mode of action, when the exposures occur in early lifestages as compared with later lifestages. Thus, this Supplemental Guidance recommends for chemicals with a mutagenic mode of action for carcinogenesis when chemical-specific data on early-life exposure are absent, a default

approach using estimates from chronic studies (i.e., cancer slope factors) with appropriate modifications to address the potential for differential risk of early-lifestage exposure. For chemicals acting through a non-mutagenic mode of action, e.g., hormonally mediated carcinogens, the available data suggest that other approaches may need to be developed for addressing cancer risk estimates from childhood exposures. This is a particular concern because the tumors arising from hormonally active chemicals appear to involve different sites when exposure is during early-life versus adulthood, an effect that has been observed relatively infrequently. Development of such approaches would require additional research to provide an expanded scientific basis for their support, including additional research and the possible development of new toxicity testing protocols that consider early lifestage dosing.

The current data do also not allow analysis of some issues of potential interest for risk assessment, e.g., potential increased risk of childhood cancer, from *in utero* or childhood exposures. Assessing the role of environmental exposures on childhood cancers is difficult, but additional research could include epidemiological studies or experimental studies with animals genetically designed to express cancers analogous to human childhood cancers. Rigorous quantification of exposure doses at different lifestages and in rodent pups in experimental studies would be useful for evaluating whether there is greater childhood susceptibility. Pharmacokinetic modeling could better define the internal doses to improve determination of the magnitude of increased susceptibility.

5. GUIDANCE FOR ASSESSING CANCER RISKS FROM EARLY-LIFE EXPOSURE

Consistent with the approach and recommendations of the U.S. EPA cancer risk assessment guidelines (U.S. EPA, 2004), any assessment of cancer susceptibility will begin with a critical analysis of the available information. Figure 3 shows the proposed steps in the process. The potential for increased susceptibility to cancer from early-life exposure, relative to comparable exposure later in life, generally warrants explicit consideration for each assessment.

When developing quantitative estimates of cancer risk, the Agency recommends integration of age-specific values for both exposure and toxicity/potency where such data are available and appropriate. Children, in general, are expected to have some exposures that differ from those of adults (either higher or lower), due to differences in size, physiology, and behavior. For example, children are generally assumed to eat more food and drink more water relative to their body weight than adults. Children's normal activities, such as putting their hands into their mouths or playing on the ground, can result in exposures to contaminants that adults do not encounter. Moreover, children and adults exposed to the same concentration of an agent in food, water, or air may receive different (higher or lower) internal doses due to differences, for example, in intake, metabolism, or absorption rates. Children are less likely than adults to be exposed to products typically used in industrial settings and often have more limited diets than adults. When assessing risks, if the data are available and relevant, it is important to include exposure that is measured or modeled for all lifestages, including exposures during childhood and during adulthood. EPA continues to develop better tools for assessing childhood exposure differences, such as the *Child-Specific Exposure Factors Handbook* (U.S. EPA, 2002a), and models, such as Stochastic Human Exposure and Dose Simulation (SHEDS) and Consolidated Human Activity Database (CHAD) (McCurdy et al., 2000; Zartarian et al., 2000)

Mode-of-action studies can be a source of data on quantitative differences between children and adults (Figure 3, Box 1). If the available information is sufficient to establish the agent's mode of action for early-life and adult exposures, then the implications for early-life exposure of that mode of action are used to develop separate risk estimates for childhood exposure. Pertinent information can be obtained both from agent-specific studies and from other

studies that investigate the general properties of the particular mode of action. All data indicating quantitative differences between children and adults are considered in developing those portion(s) of the risk estimates for exposure estimates that include childhood exposure. Some examples include the potential for children to have a different internal dose of the active agent or a change in a key precursor event (see Section 2.4.3.4 of the *Guidelines for Cancer Risk Assessment*).

When the mode of action cannot be established (Figure 3, Box 2), the policy choice would be to use linear extrapolation to lower doses such that risk estimates are based on a lifetime average daily exposure without further adjustment. No general adjustment is recommended at this time. This policy choice is consistent with past U.S. EPA practice that has been favorably evaluated over the years. The result would be expected to produce plausible upper bound risk estimates, based on the use of linear extrapolation as a default in the absence of information on the likely shape of the dose-response curve.

When a mode of action other than mutagenicity is established, if it is nonlinear (Figure 3, Box 3) or linear (Figure 3, Box 4), no general adjustment is recommended at this time. Although the available studies (discussed previously) indicates that higher or lower cancer risks may result from early-life exposure, there is insufficient information or analyses currently available to determine a general adjustment at this time. As other modes of action become better understood, this information may include data on quantitative differences between children and adults. If such data are available, an analysis of the differences could be used to adjust risk estimates for childhood exposure. EPA expects to expand this Supplemental Guidance to specifically address modes of action other than mutagenicity when sufficient data are available and analyzed.

When the data indicate a mutagenic mode of action,[5] the available studies (discussed

5 Determination of chemicals that are operating by a mutagenic mode of action entails evaluation of test results for genetic endpoints, metabolic profiles, physicochemical properties, and structure-activity analyses in a weight-of-evidence approach (Waters et al., 1999). Established protocols are used to generate the data (Cimino, 2001; OECD, 1998; U.S. EPA, 2002b); however, it is recognized that newer methods and technologies such as those arising from genomics can provide useful data and insights to a mutagenic mode of action. Carcinogens acting through a mutagenic mode of action generally interact with DNA and can produce such effects as DNA adducts and/or breakage. Carcinogens with a mutagenic mode of action often produce positive effects in multiple test systems for different genetic endpoints, particularly gene mutations and structural chromosome aberrations, and in tests performed *in vivo*, which generally are supported by those performed *in vitro*. This mode of action is addressed in more detail in Section 2.3.5 of EPA's cancer guidelines (U.S. EPA, 2005).

above) indicate higher cancer risks resulting from a given exposure occurring early in life when compared with the same amount of exposure during adulthood. However, chemical-specific data relating to mode of action (e.g., toxicokinetic or toxicodynamic information) may suggest that even though a compound has a mutagenic mode of action, higher cancer risks may not result. Such data should be considered before applying the age-dependent adjustment factors.

If the available, chemical-specific information includes an epidemiologic study of the effects of childhood exposure or an animal bioassay involving early-life exposure (Figure 3, Box 5), then these studies are analyzed to develop risk estimates (i.e., cancer slope factors) that specifically address any potential for differential potency in early lifestages. An example is the IRIS assessment of vinyl chloride (U.S. EPA, 2000b; c).

In the absence of early-life studies on a specific chemical under consideration (Figure 3, Box 6), the extrapolation from the point of departure to lower doses employs linear extrapolation (see Section 3.3.1 of the U.S. EPA [2005] cancer guidelines). This choice is based on mode-of-action data indicating that mutagens can give rise to cancers with an apparently low-dose linear response. Adjustments to the resultant risk estimates are specified with regard to childhood exposures. This approach is adopted because risk estimates based on an average daily exposure prorated over a lifetime do not consider the potential for higher cancer risks from early-life exposure.

The adjustments described below reflect the potential for early-life exposure to make a greater contribution to cancers appearing later in life. The 10-fold adjustment represents an approximation of the weighted geometric mean tumor incidence ratio from juvenile or adult exposures in the repeated dosing studies (see Table 8). This adjustment is applied for the first 2 years of life, when toxicokinetic and toxicodynamic differences between children and adults are greatest (Ginsberg et al., 2002; Renwick, 1998). Toxicokinetic differences from adults, which are greatest at birth, resolve by approximately 6 months to 1 year, while higher growth rates extend for longer periods. The 3-fold adjustment represents an intermediate level of adjustment that is applied after 2 years of age through <16 years of age. This upper age limit represents middle adolescence following the period of rapid developmental changes in puberty and the conclusion of growth in body height in NHANES data (Hattis et al., 2005). Efforts to map the approximate start of mouse and rat bioassays (i.e., 60 days) to equivalent ages in humans ranged from 10.6 to 15.1 years (Hattis et al., 2005). Data are not available to calculate a specific dose-response adjustment factor for the 2 to <16-year age range, so EPA selected the 3-fold

adjustment because it reflects a midpoint, i.e., approximately half the difference between 1 and 10 on a logarithmic scale ($10^{1/2}$), between the 10-fold adjustment for the first two years of life and no adjustment (i.e., 1-fold) for adult exposure. EPA also recognizes that exposures occurring near the end of life may have little effect on lifetime cancer risk, but lacks adequate data at present to provide an adjustment for this "wasted dose" effect. Similarly, since most of the studies involved only one latency period, the potential effect of early-life exposure on latency for the observed tumors could not be evaluated. The lack of data on effect on latency also limited the types of analyses that could be performed, e.g., more complex dose-response functions, such as multi-stage or clonal expansion models, could not be evaluated. Thus, the potential effects of early-life exposures on latency were not evaluated. Finally, as the adjustment factors are derived from a weighted geometric mean of the data evaluated, these adjustment will both over-estimate and under-estimate the potential potency for early-life exposure for chemicals with a mutagenic mode of action for carcinogenesis. An examination of the data in the tables demonstrates that some of the ratios were less than one, while others exceeded 10. For this reason, the Supplemental Guidance emphasizes that chemical-specific data should be used in preference to these default adjustment factors whenever such data are available.

The following adjustments represent a practical approach that reflects the results of the preceding analysis, which concluded that cancer risks generally are higher from early-life exposure than from similar exposure durations later in life:

- For exposures before 2 years of age (i.e., spanning a 2-year time interval from the first day of birth up until a child’s second birthday), a 10-fold adjustment.

- For exposures between 2 and <16 years of age (i.e., spanning a 14-year time interval from a child’s second birthday up until their sixteenth birthday), a 3-fold adjustment.

- For exposures after turning 16 years of age, no adjustment.

Clearly other age groups, such as an age group experiencing pubertal changes in physiology, or approximately ages 9 - 15, may experience changes in biological processes that could lead to modifications in the susceptibility to the effects of some carcinogens, depending on the mode of action. This Supplemental Guidance focuses on carcinogens with a mutagenic mode

of action. For any mode of action, the Agency is interested in identifying lifestages that may be particularly sensitive or refractory for carcinogenesis, and believes that the mode of action framework as described by EPA's cancer guidelines (U.S. EPA, 2005), is an appropriate mechanism for elucidating these lifestages. In general, the Agency's analyses of lifestages that may be susceptible will depend on three factors: (1) establishing the mode of action for carcinogenesis; (2) using knowledge about the biological and toxicological key events in that mode of action that are likely to be affected by lifestages; and (3) the availability, or development, of data that allow analysis of the effects of chemicals acting by that mode of action during the relevant ages. For each mode of action evaluated, therefore, the various age groupings determined to be at a differential risk, which may differ significantly from those proposed for the mutagenic mode of action, are expected to be evaluated independently of other modes of action. When data, including well established mode of action data, are available that allow specific evaluation of lifestage differences in toxicokinetics or toxicodynamics that would lead to lesser or greater susceptibility from early-life exposures to carcinogens, then those data should be used, as generally discussed in EPA's cancer guidelines (U.S. EPA, 2005), in preference to the default procedures described in this Supplemental Guidance.

The 10-fold and 3-fold adjustments in slope factor are to be combined with age-specific exposure estimates when estimating cancer risks from early life exposure to carcinogens that act through a mutagenic mode of action. It is important to emphasize that these adjustments are combined with corresponding age-specific estimates of exposure to assess cancer risk. For example, for a 70-year lifetime, where there are data showing negligible exposure to children, the estimated cancer risk from childhood exposure would be also negligible and the lifetime cancer risk would be reduced to that resulting from the relevant number of years of adult exposure (in the absence of specific information, 55 years). Where there are data (measured or modeled) for childhood exposures, the age-group specific exposure values are used along with the corresponding adjustments to the slope factor. Where there are no relevant data or models for childhood exposures and only lifetime average exposure data are available, the lifetime exposure data are used with the adjustments to the slope factor for each age segment.

It is recognized that, when the exposure is fairly uniform over a lifetime, the effect of these adjustments on estimated lifetime cancer risk are small relative to the overall uncertainty of

such estimates. These adjustments can be applied when estimating the cancer risk resulting from childhood exposure. These adjustments are applied when developing risk estimates from conventional animal bioassays or epidemiologic studies of effects of adult exposure. Some examples follow in the next section.

The Agency has also carefully considered both the advantages and disadvantages to extending the default potency adjustment factors to carcinogenic chemicals for which the mode of action remains unknown. It is the Agency's long-standing science policy position that use of the linear low-dose extrapolation approach (without further adjustment) provides adequate public health conservatism in the absence of chemical-specific data indicating differential early-life susceptibility. At the present time, therefore, EPA is recommending these age-dependent adjustment factors only for carcinogens acting through a mutagenic mode of action based on a combination of analysis of available data and the above-mentioned science policy position. In general, the Agency prefers to rely on analyses of data, rather than general defaults. When data are available for a susceptible lifestage, they should be used directly to evaluate risks for that chemical and that lifestage on a case-by-case basis. In this analysis, the data for non-mutagenic carcinogens, when the mode of action is unknown, were judged to be too limited and the modes of action too diverse to use this as a category for which a general default adjustment factor approach can be applied.

6 COMBINING LIFESTAGE DIFFERENCES IN EXPOSURE AND DOSE-RESPONSE WHEN ASSESSING CARCINOGEN RISK - SOME EXAMPLES FOR CARCINOGENS THAT ACT THROUGH A MUTAGENIC MODE OF ACTION

It is important for the risk assessor to consider lifestage differences in both exposure and dose-response when assessing cancer risk resulting from early-life exposures. As discussed in Section 5, age dependent adjustments factors (ADAFs) in dose response (i.e., slope factors) are combined with age specific exposure estimates when assessing cancer risks. This is a departure from the way cancer risks have historically been based upon the premise that risk is proportional to the daily average of lifetime dose. This Supplemental Guidance recommends an integrative approach that can be used to assess total lifetime risk resulting from lifetime or less-than-lifetime exposure during a specific portion of a lifetime.

The following examples can help demonstrate how to apply this guidance by integrating potential lifestage differences in exposure and/or dose-response (potency), and also demonstrate what the resulting impacts are on calculated risks. These hypothetical examples consider risks from both lifetime, as well as less-than-lifetime oral exposures. Risks associated with inhalation exposure to carcinogens that act via a mutagenic mode of action are calculated in similar fashion by applying the appropriate ADAF(s) along with the corresponding inhalation unit risk estimate, using pertinent estimates of exposure concentration.

Note again, ADAFs are only to be used for agents with a mutagenic mode of action for carcinogenesis when chemical-specific data are absent. For all modes of action, when chemical-specific data are available for early-life exposure, those data should be used.

6.1 CALCULATING LIFETIME RISKS ASSOCIATED WITH LIFETIME EXPOSURES

Example 1: Consider a scenario of exposure to a carcinogen with a **nonmutagenic** mode of action. Suppose the oral cancer slope factor derived from a typical animal study (i.e., where dosing begins after puberty) is estimated to be 2 per mg/kg-d, and the exposure rate remains constant throughout life at 0.0001 mg/kg-d (this is equivalent to saying the daily average of lifetime dose rate is equal to 0.0001 mg/kg-d). The risk from lifetime exposure is calculated by multiplying the slope factor and the exposure rate:

$$\text{Risk} = (2 \text{ per mg/kg-d}) \times (0.0001 \text{ mg/kg-d})$$

$= 2 \times 10^{-4}$

Example 2: Now consider the same exposure scenario for a carcinogen with a **mutagenic** mode of action for which the oral cancer slope factor, derived from a typical animal study where dosing begins after puberty, is also estimated to be 2 per mg/kg-d. In this case, ADAFs are used, as follows.

a. To calculate lifetime risk for a population with average life expectancy of 70 years, sum the risk associated with each of the three relevant time periods:

- Risk during the first 2 years of life (where the ADAF = 10);
- Risk for ages 2 through < 16 (ADAF = 3); and
- Risk for ages 16 until 70 years (ADAF = 1).

Thus, risk equals the sum of:

- Risk for birth through < 2 yr = (2 per mg/kg-d) x 10 (ADAF) x (0.0001 mg/kg-d) x 2yr/70yr
  $= 0.6 \times 10^{-4}$
- Risk for ages 2 through < 16 = (2 per mg/kg-d) x 3 (ADAF) x (0.0001 mg/kg-d) x (13yr/70yr)
  $= 1.1 \times 10^{-4}$
- Risk for ages 16 until 70 = (2 per mg/kg-d) x 1 (ADAF) x (0.0001 mg/kg-d) x (55yr/70yr)
  $= 1.6 \times 10^{-4}$

Risk $= 0.6 \times 10^{-4} + 1.1 \times 10^{-4} + 1.6 \times 10^{-4}$
$= 3.3 \times 10^{-4}$

b. If exposure varies with age, then such differences are also included. Now suppose the same example as immediately above, except that exposure for ages 1 through <12 was twice as high as exposure for all other ages. In this case, sum the risk associated with each of the five relevant time periods in which exposure rates and/or potencies (slope

factors) vary:

Risk equals the sum of:

- Risk for birth through < 1 yr (1yr) = (2 per mg/kg-d) x 10 (ADAF) x 0.0001 mg/kg-d x 1yr/70yr
  $= 0.3 \times 10^{-4}$
- Risk for ages 1 through < 2 (1yr) = (2 per mg/kg-d) x 10 (ADAF) x 0.0002 mg/kg-d x 1yr/70 yr
  $= 0.6 \times 10^{-4}$
- Risk for ages 2 through < 12 (10yr) = (2 per mg/kg-d) x 3 (ADAF) x 0.0002 mg/kg-d x 10yr/70yr
  $= 1.7 \times 10^{-4}$
- Risk for ages 12 through < 16 (4yr) = (2 per mg/kg-d) x 3 (ADAF) x 0.0001 mg/kg-d x 4yr/70yr
  $= 0.3 \times 10^{-4}$
- Risk for ages 16 until 70 years (55yr) = (2 per mg/kg-d) x 1 (ADAF) x 0.0001 mg/kg-d x 55yr/70yr
  $= 1.6 \times 10^{-4}$

Risk $= 0.3 \times 10^{-4} + 0.6 \times 10^{-4} + 1.7 \times 10^{-4} + 0.3 \times 10^{-4} + 1.6 \times 10^{-4}$
$= 4.5 \times 10^{-4}$

6.2 CALCULATING LIFETIME RISKS ASSOCIATED WITH LESS THAN LIFETIME EXPOSURES

If exposure only occurs for a limited number of years (for example, consider a family that lives near a source of exposure for a five-year period of time before moving away), it is critical to combine lifestage differences in exposure and dose-response for the relevant time interval. The examples presented below demonstrate how adjusting potency and/or exposure can affect the assessment of cancer risk.

Example 3: If exposure to a carcinogen with a mutagenic mode of action with an oral slope factor equal to 2 per mg/kg-d occurs during adulthood for only 5 years, the daily average of lifetime dose is time weighted to apportion risk for the number of years of exposure by a factor of 5/70:

$$\text{Risk} = (2 \text{ per mg/kg-d}) \times (0.0001 \text{ mg/kg-d}) \times (5\text{yr}/70\text{yr})$$
$$= 1.4 \times 10^{-5}$$

Example 4: If this 5-year exposure occurs during childhood, the risk calculations are adjusted to consider the potential for higher potency from early-life exposure. Assessors should remember that the age dependent adjustment factors for carcinogens with a mutagenic mode of action are applied only to exposure periods occurring up to age 16.

a. For a child exposed between ages 5 and 10, only a 3-fold ADAF is applied because the exposure occurs entirely between ages 2 and <16 years:

$$\text{Risk} = 3 \text{ (ADAF)} \times (2 \text{ per mg/kg-d}) \times (0.0001 \text{ mg/kg-d}) \times (5 \text{ yr}/70 \text{ yr})$$
$$= 4.3 \times 10^{-5}$$

b. For an exposure between ages 13 and <18, a 3-fold ADAF is applied only to the 3-year portion occurring before age 16:

Risk equals the sum of:

- Risk for ages 13 through < 16 (3yr) $= 3 \text{ (ADAF)} \times (2 \text{ per mg/kg-d}) \times (0.0001 \text{ mg/kg-d}) \times (3 \text{ yr}/70 \text{ yr})$
  $= 2.6 \times 10^{-5}$
- Risk for ages 16 through < 18 (2yr) $= 1 \text{ (ADAF)} \times (2 \text{ per mg/kg-d}) \times (0.0001 \text{ mg/kg-d}) \times (2 \text{ yr}/70 \text{ yr})$
  $= 0.6 \times 10^{-5}$

$$\text{Risk} = 2.6 \times 10^{-5} + 0.6 \times 10^{-5}$$

$= 3.2 \times 10^{-5}$

c. For a child exposed from birth through age 5, different ADAFs are applied to the periods before and after age 2:

Risk equals the sum of:

- Risk for birth through < 2 (2yr) $= 10 \text{ (ADAF)} \times (2 \text{ per mg/kg-d}) \times (0.0001 \text{ mg/kg-d}) \times (2 \text{ yr}/70 \text{ yr})$
  $= 5.7 \times 10^{-5}$
- Risk for ages 2 through < 5 (3yr) $= 3 \text{ (ADAF)} \times (2 \text{ per mg/kg-d}) \times (0.0001 \text{ mg/kg-d}) \times (3 \text{ yr}/70 \text{ yr})$
  $= 2.6 \times 10^{-5}$

Risk $= 5.7 \times 10^{-5} + 2.6 \times 10^{-5}$
$= 8.3 \times 10^{-5}$

Example 5: Lifetime risk calculations based on less-than-lifetime exposure to a carcinogen with a mutagenic mode of action include any lifestage changes in potency as well as exposure. In this example, again consider a scenario of 5 years of exposure to a carcinogen with a mutagenic mode of action, but suppose that the exposure rate is found to vary from 0.0002 mg/kg-d during the first 2 years of life, to 0.0001 mg/kg-d during the last 3 years.

a. For a child exposed between birth and age 5, sum the risk associated with the two relevant time periods:

Risk equals the sum of:

- Risk for birth through < 2 (2yr) = 10 (ADAF) x (2 per mg/kg-d) x (0.0002 mg/kg-d) x (2 yr/70 yr)
  $= 11.4 \times 10^{-5}$
- Risk for ages 2 through < 5 (3yr) = 3 (ADAF) x (2 per mg/kg-d) x (0.0001 mg/kg-d) x (3 yr/70 yr)
  $= 2.6 \times 10^{-5}$

Risk $= 11.4 \times 10^{-5} + 2.6 \times 10^{-5}$
$= 1.4 \times 10^{-4}$

b. For comparison, a similar risk calculation for 5 years of exposure later in life (after age 16) in which the first 2 years of exposure are double that of the next 3 years are carried out without any adjustment for potency:

Risk equals the sum of:

- Risk for first 2 years of adult exposure = 1 (ADAF) x (2 per mg/kg-d) x (0.0002 mg/kg-d) x (2yr/70yr)
  $= 1.1 \times 10^{-5}$
- Risk for final 3 years of adult exposure = 1 (ADAF) x (2 per mg/kg-d) x (0.0001 mg/kg-d) x (3yr/70yr)
  $= 0.9 \times 10^{-5}$

Risk $= 1.1 \times 10^{-5} + 0.9 \times 10^{-5}$
$= 2 \times 10^{-5}$

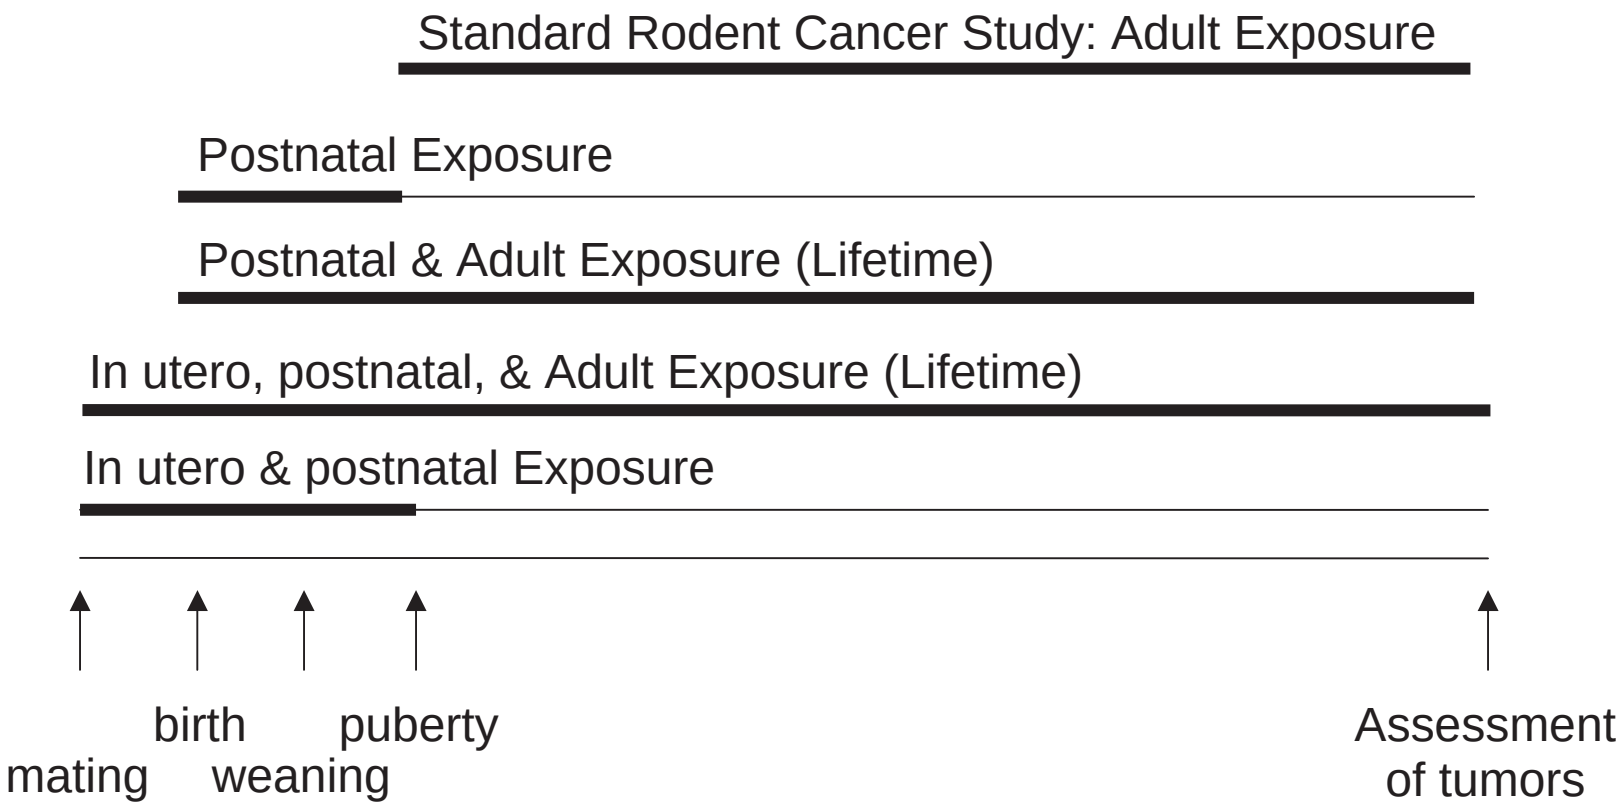

Figure 1. Study designs.

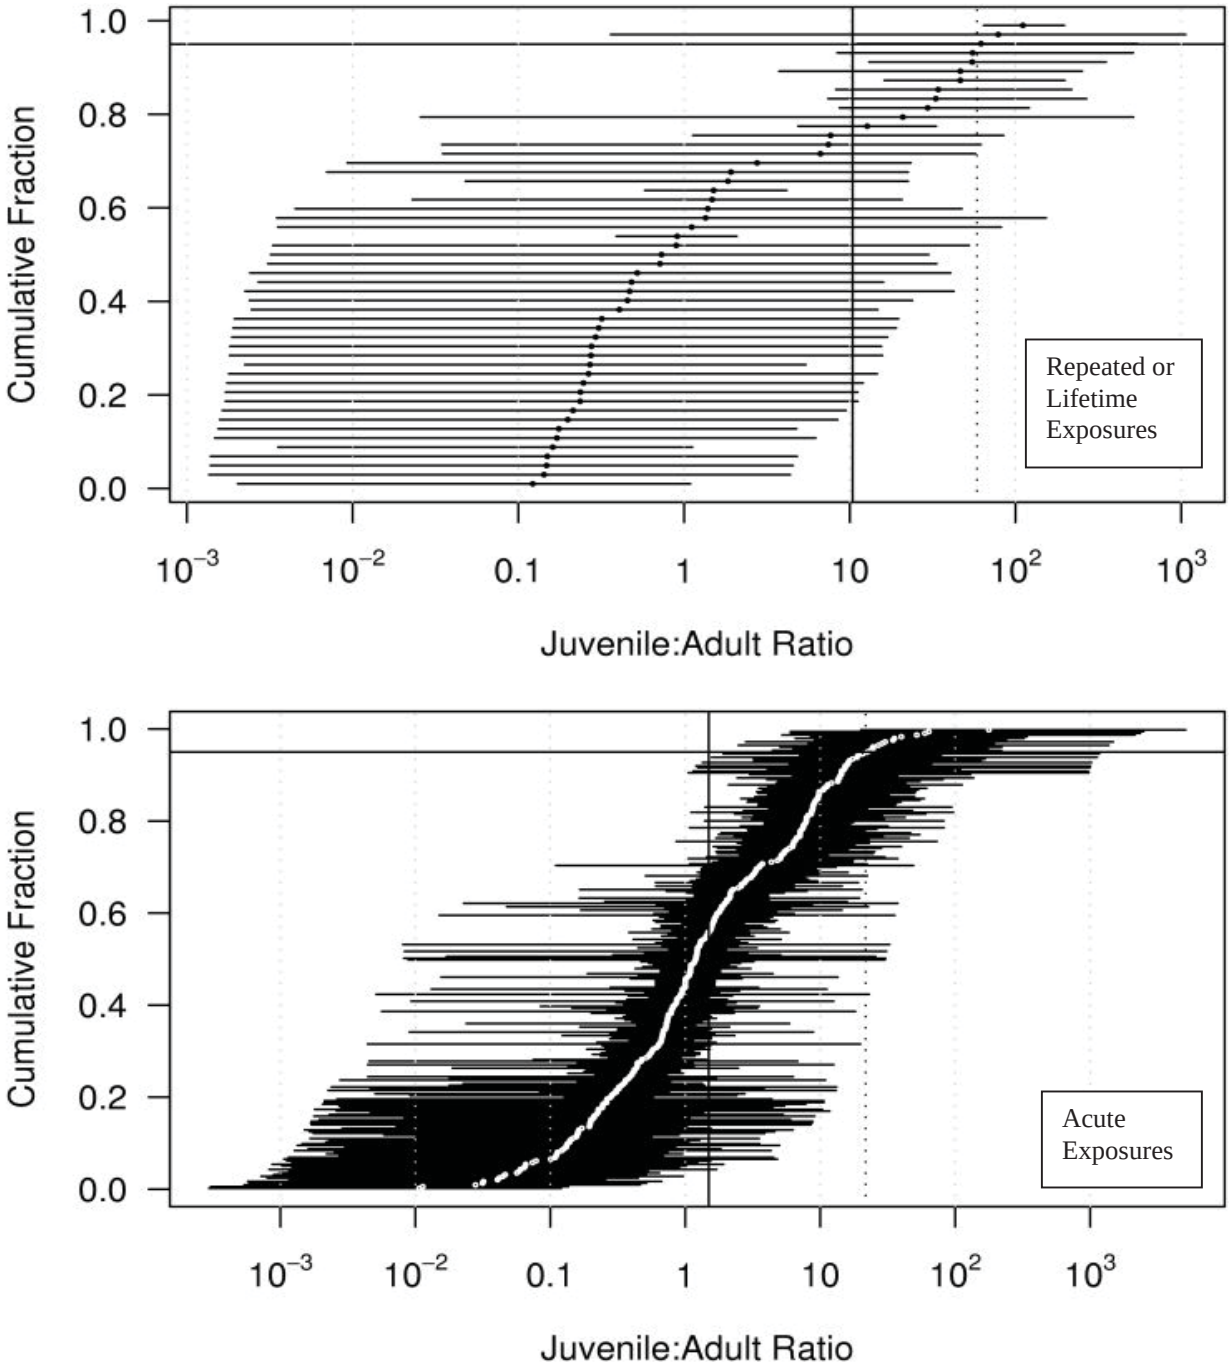

Figure 2: Posterior, unweighted geometric means and 95% confidence intervals for the ratios of juvenile to adult cancer potency for carcinogens acting primarily through a mutagenic mode of action. The top panel is for repeated and lifetime exposure studies (geometric mean in black), the bottom panel is for acute exposure studies mutagens (geometric mean in white). The horizontal lines to the left and right of each geometric mean correspond to 95% confidence limits. The vertical dark line represents the inverse-variance weighted geometric mean of the posterior geometric means. The horizontal dark line represents the 95th percentile of the unweighted distribution, with the vertical, dotted line establishing it value.

Table 1b. List of chemicals considered in this analysis. (These are chemicals for which both early-life and adult exposure are reported in the same animal experiment.)

Chemical	References	Study type	Mutagenic mode of action
Amitrole	Vesselinovitch (1983)	Repeat dosing	
Benzidine	Vesselinovitch et al. (1975b)	Repeat dosing	X
Benzo[*a*]pyrene (BaP)	Vesselinovitch et al. (1975a)	Acute exposure	X
Dibenzanthracene (DBA)	Law (1940)	Acute exposure	X
Dichlorodiphenyltrichloroethane (DDT)	Vesselinovitch et al. (1979)	Repeat dosing Lifetime exposure	
Dieldrin	Vesselinovitch et al. (1979)	Repeat dosing Lifetime exposure	
Diethylnitrosamine (DEN)	Peto et al. (1984)	Lifetime exposure	X
	Vesselinovitch et al. (1984)	Acute exposure	
Dimethylbenz[*a*]anthracene (DMBA)	Meranze et al. (1969)	Acute exposure	X
	Pietra et al. (1961)	Acute exposure	
	Walters (1966)	Acute exposure	
Dimethylnitrosamine (DMN)	Hard (1979)	Acute exposure	X
Diphenylhydantoin, 5,5- (DPH)	Chhabra et al. (1993b)	Repeat dosing Lifetime exposure	
Ethylnitrosourea (ENU)	Naito et al. (1981)	Acute exposure	X
	Vesselinovitch et al. (1974)	Acute exposure	
	Vesselinovitch (1983)	Acute exposure	
Ethylene thiourea (ETU)	Chhabra et al. (1992)	Repeat dosing Lifetime exposure	
3-Methylcholanthrene (3-MU)[a]	Klein (1959)	Repeat dosing	X
Methylnitrosourea (NMU)	Terracini and Testa (1970) Terracini et al. (1976)	Acute exposure Acute exposure	X
Polybrominated biphenyls (PBBs)	Chhabra et al. (1993a)	Repeat dosing Lifetime exposure	
Safrole	Vesselinovitch et al. (1979)	Repeat dosing Lifetime exposure	X
Urethane	Chieco-Bianchi et al. (1963) Choudari Kommineni et al. (1970) De Benedictis et al. (1962) Fiore-Donati et al. (1962)	Acute exposure Acute exposure Acute exposure Acute exposure	X
	Klein (1966)	Acute exposure Lifetime exposure	
	Liebelt et al. (1964)	Acute exposure	
	Rogers (1951)	Acute exposure	
Vinyl chloride (VC)	Maltoni et al. (1984)	Repeat dosing	X

[a] Formerly known as 20-methylcholanthrene.

Table 2. Methodological information and tumor incidence for animal studies with early postnatal and juvenile and adult repeated exposures

Chemical	Species (strain)	Target site	Age when first dosed	Dose route, # doses	Dose	Duration of exposure	Age at death	Tumors[a]		Comments	Reference
								M	F		
Amitrole	Mice ($B6C3F_1$)	liver	Control	None	Control: 0 ppm	N/A	90 weeks	1/98 (1%)	0/96 (0%)	Incidences are mice with adenomas or carcinomas.	Vesselinovitch (1983)
			Gestation day 12	Diet, to mothers	500 ppm	Gestation day 12 to delivery		6/74 (8%)[b]	0/83 (0%)[b]		
			Newborn	Diet, to mothers	500 ppm	Birth until weaning		10/45 (22%)[b]	0/55 (0%)[b]		
			At weaning	Diet, to offspring	500 ppm	From weaning to 90 weeks		20/55 (36%)[b]	9/49 (18%)[b]		
Benzidine	Mice ($B6C3F_1$)	liver	Control	None	Control: 0 ppm	N/A	90 weeks	1/98 (1%)	0/100 (0%)	Higher sensitivity in males during perinatal period, in females during adulthood. Incidences are mice with adenomas or carcinomas.	Vesselinovitch et al. (1975b) Vesselinovitch et al. (1979a)
			Gestation day 12	Diet, to mothers	150 ppm	Gestation day 12 to delivery		17/55 (31%)[c]	2/62 (3%)[d]		
			Newborn	Diet, to mothers	150 ppm	Birth until weaning		62/65 (95%)[c]	2/43 (5%)[d]		
			At weaning	Diet, to offspring	150 ppm	From weaning to 90 weeks		22/50 (44%)[c]	47/50 (94%)[c]		
			Gestation day 12	Diet, to mothers	150 ppm	Gestation day 12 until weaning		49/49 (100%)[c]	12/48 (25%)[c]		
			Gestation day 12	Diet, to mothers	150 ppm	Gestation day 12 until 90 weeks		50/50 (100%)[c]	47/50 (94%)[c]		
DDT Dichlorodiphenyl-trichloroethane	Mice ($B6C3F_1$)	liver	Control	None	Control: 0 ppm	N/A	90 weeks	1/50 (2%)	—		Vesselinovitch et al. (1979b)
			Week 1	Gavage, daily	230 µg	Weeks 1–4		5/49 (10%)[d]	—		
			Week 5	Diet, daily	150 ppm	Weeks 5–90		8/49 (16%)[d]	—		
			Week 1	Gavage, daily until 4 weeks, then in diet	230 µg 150 ppm (diet)	Weeks 1–90		10/50 (20%)[c]	—

[a] Where not delineated by gender, data combined by study authors or gender not specified. Where percentages only are given, number of subjects not specified.
[b] Not evaluated by authors.
[c] Evaluated but not significant compared with controls.
[d] Study also included mammary fibroadenomas and fibromas as well as other types of cancers.
[e] 8–9 weeks old.
[f] Includes survivors up to 40 weeks only.
[g] Significant compared with controls.

i.p. = intraperitoneal injection; s.c. = subcutaneous injection

Atrazine and Its Metabolites in Drinking-water

Background document for development of
WHO *Guidelines for Drinking-water Quality*

Atrazine and Its Metabolites in Drinking-water
Background document for development of WHO *Guidelines for Drinking-water Quality*

Printed by the WHO Document Production Services, Geneva, Switzerland

Preface

One of the primary goals of the World Health Organization (WHO) and its Member States is that "all people, whatever their stage of development and their social and economic conditions, have the right to have access to an adequate supply of safe drinking water." A major WHO function to achieve such goals is the responsibility "to propose ... regulations, and to make recommendations with respect to international health matters ...."

The first WHO document dealing specifically with public drinking-water quality was published in 1958 as *International Standards for Drinking-water*. It was subsequently revised in 1963 and in 1971 under the same title. In 1984–1985, the first edition of the WHO *Guidelines for Drinking-water Quality* (GDWQ) was published in three volumes: Volume 1, Recommendations; Volume 2, Health criteria and other supporting information; and Volume 3, Surveillance and control of community supplies. Second editions of these volumes were published in 1993, 1996 and 1997, respectively. Addenda to Volumes 1 and 2 of the second edition were published in 1998, addressing selected chemicals. An addendum on microbiological aspects reviewing selected microorganisms was published in 2002. The third edition of the GDWQ was published in 2004, the first addendum to the third edition was published in 2006 and the second addendum to the third edition was published in 2008. The fourth edition will be published in 2011.

The GDWQ are subject to a rolling revision process. Through this process, microbial, chemical and radiological aspects of drinking-water are subject to periodic review, and documentation related to aspects of protection and control of public drinking-water quality is accordingly prepared and updated.

Since the first edition of the GDWQ, WHO has published information on health criteria and other supporting information to the GDWQ, describing the approaches used in deriving guideline values and presenting critical reviews and evaluations of the effects on human health of the substances or contaminants of potential health concern in drinking-water. In the first and second editions, these constituted Volume 2 of the GDWQ. Since publication of the third edition, they comprise a series of free-standing monographs, including this one.

For each chemical contaminant or substance considered, a lead institution prepared a background document evaluating the risks for human health from exposure to the particular chemical in drinking-water. Institutions from Canada, Japan, the United Kingdom and the United States of America (USA) prepared the documents for the fourth edition.

Under the oversight of a group of coordinators, each of whom was responsible for a group of chemicals considered in the GDWQ, the draft health criteria documents were submitted to a number of scientific institutions and selected experts for peer review. Comments were taken into consideration by the coordinators and authors. The draft documents were also released to the public domain for comment and submitted for final evaluation by expert meetings.

During the preparation of background documents and at expert meetings, careful consideration was given to information available in previous risk assessments carried out by the International Programme on Chemical Safety, in its Environmental Health Criteria monographs and Concise International Chemical Assessment Documents, the International Agency for Research on Cancer, the Joint FAO/WHO Meetings on Pesticide Residues and the Joint FAO/WHO Expert Committee on Food Additives (which evaluates contaminants such as lead, cadmium, nitrate and nitrite, in addition to food additives).

Further up-to-date information on the GDWQ and the process of their development is available on the WHO Internet site and in the current edition of the GDWQ.

Acknowledgements

The first draft of Atrazine and Its Metabolites in Drinking-water, Background document for development of WHO *Guidelines for Drinking-water Quality* (GDWQ), was prepared by Mr J.K. Fawell, United Kingdom, to whom special thanks are due. This background document is an update of the background document published in the second edition of the GDWQ.

The work of the following working group coordinators was crucial in the development of this document and others contributing to the fourth edition:

Dr J. Cotruvo, J. Cotruvo Associates, USA (*Materials and chemicals*)
Mr J.K. Fawell, United Kingdom (*Naturally occurring and industrial contaminants* and *Pesticides*)
Ms M. Giddings, Health Canada (*Disinfectants and disinfection by-products*)
Mr P. Jackson, WRc-NSF, United Kingdom (*Chemicals – practical aspects*)
Professor Y. Magara, Hokkaido University, Japan (*Analytical achievability*)
Dr Aiwerasia Vera Festo Ngowi, Muhimbili University of Health and Allied Sciences, United Republic of Tanzania (*Pesticides*)
Dr E. Ohanian, Environmental Protection Agency, USA (*Disinfectants and disinfection by-products*)

The draft text was discussed at the Expert Consultation for the fourth edition of the GDWQ, held on 9–13 November 2009. The final version of the document takes into consideration comments from both peer reviewers and the public. The input of those who provided comments and of participants at the meeting is gratefully acknowledged.

The WHO coordinators were Mr R. Bos and Mr B. Gordon, WHO Headquarters. Ms C. Vickers provided a liaison with the International Programme on Chemical Safety, WHO Headquarters. Mr M. Zaim, Public Health and the Environment Programme, WHO Headquarters, provided input on pesticides added to drinking-water for public health purposes.

Ms P. Ward provided invaluable administrative support at the Expert Consultation and throughout the review and publication process. Ms M. Sheffer of Ottawa, Canada, was responsible for the scientific editing of the document.

Many individuals from various countries contributed to the development of the GDWQ. The efforts of all who contributed to the preparation of this document and in particular those who provided peer or public domain review comments are greatly appreciated.

Acronyms and abbreviations used in the text

ADI	acceptable daily intake
DACT	diaminochlorotriazine
DEA	deethyl-atrazine
DIA	deisopropyl-atrazine
DWLOC	Drinking Water Levels of Comparison (USA)
FAO	Food and Agriculture Organization of the United Nations
GAC	granular activated carbon
JMPR	Joint FAO/WHO Meeting on Pesticide Residues
LC_{50}	median lethal concentration
LD_{50}	median lethal dose
LH	luteinizing hormone
LOAEL	lowest-observed-adverse-effect level
NOAEL	no-observed-adverse-effect level
PAC	powdered activated carbon
USA	United States of America
USEPA	United States Environmental Protection Agency
UV	ultraviolet
WHO	World Health Organization

Table of contents

The atrazine drinking-water guideline prepared for the Third Edition of the WHO Guidelines for Drinking-water Quality has been revised following the recent Joint FAO/WHO Meeting on Pesticide Residues (JMPR) evaluation of atrazine and its environmental metabolites (FAO/WHO, 2007).

This background document is based on and largely extracted from this recent JMPR evaluation. Except for the critical studies on which the guidelines are based, primary references are given only for text that has not been extracted from this report. The interested reader should refer to the toxicological monograph published by FAO/WHO (2009) for more detailed information and primary references.

1. GENERAL DESCRIPTION

1.1 Identity

Chemical Abstracts Service Registry No.: 1912-24-9
Molecular formula: $C_8H_{14}ClN_5$

The International Union of Pure and Applied Chemistry name for atrazine is 6-chloro-N^2-ethyl-N^4-isopropyl-1,3,5-triazine-2,4-diamine.

1.2 Physicochemical properties

Some physical and chemical properties of atrazine that are relevant to its environmental fate are summarized in Table 1.

Table 1: Physicochemical properties of atrazine[a]

Property	Value
Melting point	175–177 °C
Density	1.187 g/cm^3 at 20 °C
Water solubility	30 mg/l at 20 °C
Log octanol–water partition coefficient	2.3
Vapour pressure	40×10^{-6} Pa at 20 °C

[a] From Meister (1989); Royal Society of Chemistry (1991); Worthing (1991).

1.3 Major uses and sources in drinking-water

Atrazine is a selective systemic herbicide of the chlorotriazine class, used for the control of annual broadleaf and grassy weeds (Worthing, 1991). Key crops in which atrazine-containing herbicides are used include maize, sorghum and sugarcane, with some other minor uses of local importance. Atrazine and its metabolites have been found in surface water and groundwater as a result of the use of atrazine as a pre-emergent or early post-emergent herbicide. The source of the residue should be considered when interpreting water monitoring data. Assessments should be based on whether diffuse sources (e.g. runoff from an agricultural field) or point sources (e.g. an accidental spill or inappropriate disposal) have contributed to a detection in water. The presence of atrazine and its metabolites in surface water is most likely to be

intermittent, particularly in flowing water, but groundwater contamination will usually be relatively persistent.

1.4 Environmental fate

Atrazine can be degraded in surface water by photolysis and microorganisms via *N*-dealkylation and hydrolysis of the chloro substituent; the corresponding half-lives are greater than 100 days at 20 °C. Hydrolysis and microbial degradation also take place in soil, depending mainly on temperature, moisture and pH. Half-lives of 20–50 days at 20–25 °C have been found under laboratory conditions, increasing at lower temperatures (USEPA, 1988). These are similar to the half-lives found under natural conditions, but longer half-lives have been seen under special conditions (Schoen & Winterlin, 1987). Degradation rates normally decrease with increasing depth, and atrazine can be fairly stable in groundwater (Burnside, Fenster & Wicks, 1963).

Atrazine's degradation products in soil include several of the chloro-*s*-triazine metabolites commonly found in water (Keller, 1978) (see section 2). Unsubstituted amino metabolites and triazine are formed later and may be mineralized completely. Atrazine and its dealkylated metabolites are moderately to very mobile in sandy, silt and clay soils (Ciba-Geigy, 1986). Hydroxytriazines, however, are of low mobility (Helling, 1971) and persist for long periods in the soil (Kahn & Saidak, 1981).

2. ENVIRONMENTAL LEVELS AND HUMAN EXPOSURE

Atrazine and its chloro-*s*-triazine metabolites—deethyl-atrazine (DEA), deisopropyl-atrazine (DIA) and diaminochlorotriazine (DACT)—have been found in surface water and groundwater. The metabolite hydroxyatrazine is more commonly detected in groundwater than in surface water.

A number of studies have monitored the concentrations of atrazine in groundwater and surface water over the last two decades. Recent monitoring data show declining levels and incidences of detection of atrazine and its chloro-*s*-triazine metabolites (DIA, DEA and DACT) compared with data collected in the early 1990s; this reflects restrictions on the use of atrazine that were introduced in the late 1990s and early 2000s and the introduction of good agricultural practices in the European Union, the United States of America (USA) and other parts of the world. Therefore, older monitoring data generally represent an overestimate of environmental concentrations likely to arise from current use practices.

In surface water, the concentrations of the chlorotriazine metabolites of atrazine are generally less than those of atrazine itself, whereas the concentrations of these metabolites in rural wells are more similar to those of atrazine. The relative order of concentrations in rural wells in the USA was generally as follows: atrazine ~ DEA ~ DACT > DIA > hydroxyatrazine. However, concentrations of DEA that are several-fold higher than those of the parent compound have been reported.

Monitoring carried out in a number of countries indicates that concentrations of atrazine and its chloro-*s*-triazine metabolites in groundwater and surface water rarely exceed 2 µg/l and are commonly well below 0.1 µg/l, although concentrations may be higher in agricultural areas where large amounts of atrazine are used. In the past, its

use for weed control on non-crop land, such as railway lines and paved areas, gave rise to contamination of groundwater in particular, although this use has largely disappeared worldwide. The concentration of atrazine in public water supplies in the USA does not exceed the United States Environmental Protection Agency's (USEPA) Drinking Water Levels of Comparison (DWLOC)—the maximum concentrations in drinking-water that, when considered together with dietary exposure, do not exceed a level of concern—for any age group These DWLOCs, which account for atrazine plus its three chloro-*s*-triazine metabolites, range from 12.5 to 68 µg/l for intermediate (seasonal) or chronic (annual) exposure. Concentrations of atrazine in drinking-water in the United Kingdom are less than 0.1 µg/l, based on data measured when atrazine was registered and when good agricultural practices had been adopted. In Canada, concentrations of atrazine and its chloro-*s*-triazine metabolites did not exceed the interim guideline level (5 µg/l, includes metabolites) in any samples of drinking-water from 10 Canadian treatment plants in the cereal-growing regions of Ontario and Quebec (from groundwater and surface water). Levels of atrazine were below 0.83 µg/l, concentrations of DEA were below 0.35 µg/l, and DIA and DACT were found less often and at lower levels in treated surface water. Total chloro-*s*-triazine concentrations from raw water were below 0.5 µg/l in groundwater and well below 0.68 µg/l in surface water (Tauber, 2006).

It is expected that exposure of the public will be primarily through drinking-water.

3. KINETICS AND METABOLISM IN LABORATORY ANIMALS AND HUMANS

After oral administration to rats, ^{14}C-labelled atrazine was rapidly and almost completely absorbed, independent of dose and sex. Radioactivity was widely distributed throughout the body. Excretion was more than 93% of the administered dose within 7 days, primarily via the urine (approximately 73%) and to a lesser extent via the faeces (approximately 20%; approximately 7% via bile), with more than 50% being excreted within the first 24 h. The elimination half-life of radiolabel from the whole body was 31.3 h in rats; this prolonged half-life was caused by covalent binding of atrazine to cysteine sulfhydryl groups in the β-chain of rodent haemoglobin. Seven days after administration of a single low dose (1 mg/kg body weight), tissue residues represented 6.5–7.5% of the dose, with the highest concentrations in erythrocytes (≤0.63 mg/kg), liver (≤0.50 mg/kg) and kidneys (≤0.26 mg/kg).

Atrazine was extensively metabolized; more than 25 metabolites have been identified in rats. The major metabolic pathways were stepwise dealkylation via either DIA or DEA to DACT, the major metabolite. Dechlorination involving conjugation with glutathione was a minor pathway. The biotransformation of atrazine in rats and humans was qualitatively similar.

4. TOXICOLOGICAL SUMMARY

4.1 Atrazine

Atrazine was of low acute toxicity in rats exposed orally (median lethal dose [LD_{50}] 1870–3090 mg/kg body weight), dermally (LD_{50} >2000 mg/kg body weight) or by

inhalation (median lethal concentration [LC_{50}] >5.8 mg/l). Atrazine was not a skin irritant or an eye irritant in rabbits.

In short-term studies of toxicity in rats, dogs and rabbits, the consistent toxic effects noted across species included reduced body weight gain and food intake and a slight decrease in erythrocyte parameters. Also, liver weights and splenic haemosiderin deposition were increased in rats, whereas there was marked cardiac toxicity in dogs.

Atrazine was tested for genotoxicity in a large number of studies covering an adequate range of end-points. JMPR agreed that it is unlikely that atrazine is genotoxic.

Long-term studies of toxicity and carcinogenicity were conducted in mice and rats. As in short-term studies, reduced body weight gain and food intake and a decrease in erythrocyte parameters were noted consistently. Additionally, reduced survival of females and cardiovascular effects (atrial thrombi) in both sexes were observed in mice at high doses.

In three studies of carcinogenicity in mice, no treatment-related carcinogenic effects were observed at dietary concentrations up to about 386 and 483 mg/kg body weight per day in males and females, respectively. Overall, the no-observed-adverse-effect level (NOAEL) was 1.2 mg/kg body weight per day, on the basis of lower body weight/body weight gain at 38.4 mg/kg body weight per day and greater.

In one study of carcinogenicity in Fischer 344 rats fed diets containing atrazine at concentrations up to about 20 mg/kg body weight per day, there was no effect at any dose on the onset or incidence of tumours. The NOAEL was about 3.5 mg/kg body weight per day, on the basis of decreased body weight.

In seven studies of carcinogenicity in Sprague-Dawley rats fed diets containing atrazine at concentrations up to about 42 and 65 mg/kg body weight per day in males and females, respectively, an increased incidence of mammary tumours (adenomas, carcinomas, fibroadenomas) with or without an earlier onset (relative to controls) was observed in four studies, whereas there was an earlier onset of mammary tumours without any increase in their overall lifetime incidence in two studies. An earlier onset of pituitary tumours was also observed in one study, with no increase in incidence at term. Overall, the NOAEL for mammary carcinogenicity was 1.5 mg/kg body weight per day, on the basis of a statistically significant increased incidence in mammary tumours at 3.1 mg/kg body weight per day.

In a study of carcinogenicity in ovariectomized Sprague-Dawley rats, neither increases in mammary gland proliferative changes nor mammary tumours were seen at dietary concentrations up to about 21 mg/kg body weight per day, suggesting that the carcinogenic mode of action of atrazine in Sprague-Dawley rats is related to ovarian function.

In a study designed to evaluate the effects of atrazine on the pre-ovulatory luteinizing hormone (LH) surge and on the estrous cycle, groups of 90 female Sprague-Dawley (Crl:CD BR) rats received diets containing atrazine (purity, 97.1%) at a concentration of 0, 25, 50 or 400 mg/kg (equal to 0, 1.8, 3.65 and 29.44 mg/kg bw per day) for

26 weeks. Attenuation of the LH surge and subsequent disruption of the estrous cycle (characterized by an increase in days in estrus) were observed at and above 3.65 mg/kg body weight per day, with a NOAEL of 1.8 mg/kg body weight per day (Morseth, 1996). The NOAEL and lowest-observed-adverse-effect level (LOAEL) for these effects were comparable to those found in the studies of carcinogenicity. The effects on the LH surge and disruption of the estrous cycle were further supported by a number of short-term mechanistic studies. Additional experiments suggested that the effects of atrazine on LH and prolactin secretion are mediated via a hypothalamic site of action.

The postulated mode of action for atrazine-induced mammary tumours in female Sprague-Dawley rats involved disruption of the hypothalamic–pituitary–ovary axis. Atrazine modifies catecholamine function and the regulation of gonadotropin-releasing hormone pulsatility in the rat hypothalamus, with the consequence that the pulse of LH released from the pituitary gland is of insufficient amplitude or duration to trigger ovulation. The failure to ovulate results in persistent secretion of estrogen, which provides a feedback to the pituitary, leading to increased secretion of prolactin. As a result, atrazine accelerates the normal reproductive ageing process in female Sprague-Dawley rats, whereby reproductive senescence is characterized by persistent exposure to estrogen and prolactin. In contrast, women respond to reduced levels of LH by reductions in levels of estrogen. Thus, JMPR considered that the mode of carcinogenic action in certain susceptible rat strains is not relevant for human risk assessment.

Investigations of other modes of action did not provide any evidence that atrazine had intrinsic estrogenic activity or that it increased aromatase activity in vivo.

JMPR concluded that atrazine is not likely to pose a carcinogenic risk to humans.

Although carcinogenicity in humans was not a concern owing to the rat-specific mode of action, alterations in neurotransmitter and neuropeptide function regulating LH and secretion of prolactin may potentially induce adverse effects during critical periods of development (as found in special studies showing pregnancy loss, delayed puberty in males and females, and decreased suckling-induced prolactin release in lactating dams). Unlike the carcinogenic effects, the developmental effects do not appear to be specific to certain strains of rats, and JMPR therefore considered these effects to be relevant for risk assessment in humans.

In special studies of reproductive toxicity, exposure of rats during early pregnancy (i.e. the LH-dependent period) caused increased pre-implantation or post-implantation losses, including full-litter resorptions. Effects were seen at doses of ≥50 mg/kg body weight per day after treatment on days 6–10 of gestation, with a NOAEL of 25 mg/kg body weight per day. In contrast, exposure on days 11–15 of gestation (after the LH-dependent period of pregnancy) at a dose of 200 mg/kg body weight per day did not induce full-litter resorptions.

Suppression of the suckling-induced prolactin release in lactating rats was seen with atrazine at doses of ≥25 mg/kg body weight per day, with a NOAEL of 12.5 mg/kg body weight per day. Treatment of lactating rats on postnatal days 1–4 affected the development of tuberoinfundibular dopaminergic neurons in the pups (presumably

due to the lack of prolactin derived from the dam's milk), with the consequence of impaired regulation of prolactin secretion, hyperprolactinaemia prior to puberty and prostatitis in the adult male offspring.

A delay in sexual development was observed in female rats after exposure on postnatal days 21–46 at doses of ≥30 mg/kg body weight per day, with a NOAEL of 10 mg/kg body weight per day, and in male rats after exposure on postnatal days 23–53 at doses of ≥12.5 mg/kg body weight per day, with a NOAEL of 6.25 mg/kg body weight per day.

In a standard two-generation study of reproduction (conducted according to earlier guidelines, which did not include end-points such as estrous cyclicity and sexual development) in rats, there was no effect on fertility at 36.1 mg/kg body weight per day, the highest dose tested. The NOAEL for parental toxicity was 3.6 mg/kg body weight per day, on the basis of decreased body weight gains and food consumption. The NOAEL for reproductive toxicity was 3.6 mg/kg body weight per day, on the basis of decreased body weights of male pups at postnatal day 21.

In two studies of prenatal developmental toxicity in rats given atrazine on days 6–15 of gestation, the NOAELs for maternal toxicity were 10 or 25 mg/kg body weight per day on the basis of decreased body weight gain and food intake at 70 or 100 mg/kg body weight per day, respectively. The NOAELs for developmental toxicity were 10 or 25 mg/kg body weight per day on the basis of incomplete ossification at several sites at 70 or 100 mg/kg body weight per day, respectively. In a study of prenatal developmental toxicity in rabbits given atrazine on days 7–19 gestation, the NOAEL for maternal toxicity was 5 mg/kg body weight per day on the basis of clinical signs, abortion and decreased food intake and body weight gain at 75 mg/kg body weight per day. The NOAEL for developmental toxicity was 5 mg/kg body weight per day on the basis of increased resorptions, reduced litter size and incomplete ossification at 75 mg/kg body weight per day. In rats and rabbits, the developmental effects were observed only at maternally toxic doses.

JMPR concluded that atrazine was not teratogenic.

Studies using a variety of test systems in vitro and in vivo indicated that modulation of the immune system occurs after exposure to atrazine. However, effects suggestive of impaired function of the immune system were observed only at doses greater than those shown to affect neuroendocrine function, leading to disruption of the estrous cycle or developmental effects.

A range of epidemiological studies (including cohort studies, case–control studies, and ecological or correlational studies) assessed possible relationships between atrazine or other triazine herbicides and cancer in humans. For some cancer types, such as prostate or ovarian cancer and non-Hodgkin lymphoma, the increased risks reported in single studies either could be explained by the methodology used or had not been confirmed in more reliable studies. Thus, the weight of evidence from the epidemiological studies did not support a causal association between exposure to atrazine and the occurrence of cancer in humans.

4.2 Metabolites of atrazine

4.2.1 Chloro-s-triazine metabolites

The toxicity profiles and mode of action of the chloro-*s*-triazine metabolites were similar to those of atrazine; the potency of these metabolites with regard to their neuroendocrine-disrupting properties appeared to be similar to that of the parent compound.

Like atrazine, the chloro-*s*-triazine metabolites were of moderate or low acute oral toxicity in rats; LD_{50}s were 1110, 1240 and 2310–5460 mg/kg body weight for DEA, DIA and DACT, respectively.

Like atrazine, its chloro-*s*-triazine metabolites delayed sexual development of male rats exposed on postnatal days 23–53 at atrazine molar equivalent doses of ≥25 mg/kg body weight per day (DEA, DIA) and ≥12.5 mg/kg body weight per day (DACT), with NOAELs of 12.5 and 6.25 mg/kg body weight per day, respectively. Exposure of female rats to DACT on postnatal days 22–41 delayed sexual development at atrazine molar equivalent doses of ≥50 mg/kg body weight per day, and the NOAEL was 25 mg/kg body weight per day. Doses at which these effects occurred were similar to those observed for parent atrazine.

In short-term feeding studies in rats, the main effects of the chlorinated metabolites were similar to those of atrazine and included reduced body weight gain and decreased erythrocyte parameters and also, for DACT, disruption of the estrous cycle. The NOAELs were 3.2 mg/kg body weight per day for DEA and DIA and 7.6 mg/kg body weight per day for DACT.

In a 29/52-week study with DACT in Sprague-Dawley rats, effects comparable to those observed with atrazine (attenuation of the LH surge, increased incidences of mammary tumours) were seen at 270 mg/kg diet; the NOAEL was 48 mg/kg diet, equal to 3.4 mg/kg body weight per day. No long-term studies were performed with DEA or DIA.

In short-term feeding studies in dogs, the main effects of the chlorinated metabolites were similar to those of atrazine and included reduced body weight gain and decreased erythrocyte parameters, whereas DEA and DACT showed cardiac toxicity. The NOAELs were 3.7, 3.8 and 3.5 mg/kg body weight per day for DEA, DIA and DACT, respectively.

DEA, DIA and DACT did not show genotoxicity in an adequate range of tests in vitro and in vivo.

In studies of prenatal developmental toxicity in rats, the chlorinated metabolites induced increased incidences of fused sternebrae and/or incomplete ossification at doses of 25–100 mg/kg body weight per day; the NOAELs for developmental toxicity were 25, 5 and 2.5 mg/kg body weight per day for DEA, DIA and DACT, respectively. The effects were seen only at doses that also produced maternal toxicity.

4.2.2 Hydroxyatrazine

The metabolite hydroxyatrazine does not have the same mode of action or toxicity profile as atrazine and its chlorometabolites. The main effect of hydroxyatrazine was kidney toxicity (owing to its low solubility in water, resulting in crystal formation and a subsequent inflammatory response), and there was no evidence that hydroxyatrazine has neuroendocrine-disrupting properties. Also, the acute oral toxicity of hydroxyatrazine in rats (LD_{50} >5050 mg/kg body weight) was lower than that of atrazine or its chlorometabolites.

In short-term feeding studies, the main effects of hydroxyatrazine in rats included reduced body weight gain, increased water consumption, changes in clinical chemistry and urine analysis parameters, and kidney lesions. The overall NOAEL was 6.3 mg/kg body weight per day. In dogs, effects included reduced body weight gain and food consumption, changes in clinical chemistry and urine analysis parameters, and kidney lesions; the NOAEL was 5.8 mg/kg body weight per day.

In a 2-year study of toxicity and carcinogenicity in rats, the effects of hydroxyatrazine included clinical signs and increased mortality, reduced body weight gain and food consumption, increased water consumption, changes in haematological, clinical chemistry and urine analysis parameters, and kidney lesions. The NOAEL was 1.0 mg/kg body weight per day. There was no evidence of carcinogenicity (Chow & Hart, 1995).

Hydroxyatrazine did not show genotoxicity in an adequate range of tests in vitro and in vivo.

In a study of prenatal developmental toxicity in rats, the effects of hydroxyatrazine consisted of reduced food consumption and body weight gain in dams and increased incidences of incomplete and absent ossification in fetuses at 125 mg/kg body weight per day; the NOAEL was 25 mg/kg body weight per day for maternal and developmental toxicity. Exposure of female rats on postnatal days 22–41 at atrazine molar equivalent doses up to 200 mg/kg body weight per day did not delay sexual development.

5. PRACTICAL ASPECTS

5.1 Analytical methods and analytical achievability

Atrazine is determined by gas chromatography with nitrogen–phosphorus detection following extraction with pentane or ethyl acetate. The detection limit in tap water and river water is about 0.1 µg/l (Yokley & Cheung, 2000).

Atrazine is determined by gas chromatography/mass spectrometry with solid-phase extraction. The detection limit in raw water and drinking-water is 10 ng/l (Bruzzoniti et al., 2006). Extraction of the metabolites can be achieved using styrene-divinylbenzene sorbents. Detection limits for triazines determined by capillary gas chromatography with nitrogen thermionic specific detection and high-performance liquid chromatography with photodiode array absorption detection following extraction with styrene-divinylbenzene sorbents and elution with acetone were lower

than 5 ng/l (Drevenkar et al., 2002). Atrazine is also determined by isotope dilution gas chromatography/mass spectrometry with solid-phase extraction. The method detection limit in surface water is 1 ng/l (Planas et al., 2006). In the case of a large-volume injection approach using 50 µl of the 40-fold concentrated extract, the detection limit in river water is 2 ng/l (Schellin & Popp, 2007). Using a liquid chromatography/mass spectrometry method utilizing online solid-phase extraction (Koivunen et al., 2006) or ultra-performance liquid chromatography combined with tandem mass spectrometry (Gervais et al., 2008), the limit of quantification is 50 ng/l or 12 ng/l, respectively.

Other methods are included in the USEPA's (2009) document on *Analytical Methods Approved for Drinking Water Compliance Monitoring of Organic Contaminants.*

5.2 Treatment and control methods and performance

Coagulation and filtration are ineffective at removing atrazine. Only 7% removal was achieved with ferric chloride dosed with iron at at 14 mg/l, with an atrazine concentration of 0.84 µg/l (Normann, Haberer & Oehmichen, 1987). Aluminium sulfate (aluminium dose of 2 mg/l at pH 8) was also completely ineffective at reducing an atrazine concentration of 66 µg/l (Miltner et al., 1989). In laboratory tests, atrazine at 3 µg/l in river water was treated with aluminium sulfate (up to 10 mg/l as aluminium) or ferric sulfate (up 40 mg/l as iron), but no removal was observed (Jiang & Adams, 2006). Lime soda softening was also ineffective. Results from other studies also suggest that conventional coagulation-based water treatment processes are ineffective at reducing atrazine concentrations (Foster, Rachwal & White, 1991; Van Hoof, Ackermans & Celens, 1992).

A full-scale granular activated carbon (GAC) plant treating river water with an atrazine concentration of 0.3–2 µg/l, with an empty bed contact time of 15–20 min, treated 20 000 bed volumes before 0.1 µg/l was reached in the effluent (Normann, Haberer & Oehmichen, 1987). Results from other treatment works incorporating GAC have shown that the atrazine concentration can be reduced to 0.1 µg/l (contact times 19–20 min, bed lifetimes 20–24 months, initial atrazine concentrations 0.16–0.27 µg/l) (Croll, Chadwick & Knight, 1991). One study found that the adsorption capacity of GAC varied between 0.04 and 0.22 mg/g carbon, depending on the type of GAC used (Duguet, 1994). The same study also found that the concentration of natural organic matter present greatly affected the capacity of the carbon to adsorb atrazine (e.g. 20 mg of atrazine per gram carbon for distilled water, reduced to 0.6–0.15 mg/g for dissolved organic carbon in range 2–8 mg/l as carbon). GAC has been applied successfully to pesticide removal (including atrazine) using slow sand filtration, as a layer 75–200 mm thick, sandwiched between conventional sand media. Contact times are 30–60 min (Anon, 1994).

Powdered activated carbon (PAC) has been used to remove atrazine from surface waters, with only a seasonal requirement to reduce pesticide concentrations. A dose of 5 mg/l with 40 min contact in a PAC reactor (coupled with coagulation) reduced the influent concentration of atrazine (0.53 µg/l) to 0.08 µg/l; there was a further reduction to <0.05 µg/l in the final water due to the remaining capacity in the PAC once it was separated at the filtration stage (Haist-Gulde, Baldauf & Brauch, 1993). Tests with a batch reactor showed that PAC (3.3 mg/l) reduced the initial

concentration of atrazine (22.5 µg/l) by 60% after 75 min contact (Qi, 1994). Atrazine spiked into water at 5 µg/l was treated with two PACs at pH 7.5. At a PAC dose of 10 mg/l in deionized water, both achieved ~100% removal. In river water, the removals were reduced to ~95% and ~90%, respectively (Jiang & Adams, 2006). In the same study, desethylatrazine was also ~100% removed from deionized water. In river water, the removals were reduced to ~85% and ~70%, respectively.

At a waterworks, ozonation produced removals of 29% and 42% for concentrations of 0.17 µg/l and 0.19 µg/l, respectively (Brauch & Kuhn, 1988). Ozonation conditions, such as dissolved ozone concentration, contact time and applied ozone dose, affect removal efficiency, as well as factors influencing the decomposition of ozone to form hydroxyl radicals (e.g. pH, temperature, organic matter content and bicarbonate concentration) (Duguet, 1994). A combination of ozone and either ultraviolet (UV) radiation or hydrogen peroxide improves removal efficiency and results in bed life extension if associated with GAC adsorption (Duguet, 1994). At full scale, one treatment works achieved a reduction of approximately 40% (initial concentration 100–600 ng/l) with ozone alone (15 min contact, dose approximately 2.2 mg/l); for the same ozone dose, in combination with hydrogen peroxide (H_2O_2/O_3 = 0.4 by mass), there was an 80% reduction in atrazine concentration (Duguet, 1992). For the treatment of atrazine at 1 mg/l to below 0.1 µg/l, the life of the GAC bed was doubled by ozonation alone and increased nearly 6-fold by the combination of oxidants. Other studies have found removals of 60% using ozone at 2.2 mg/l with a contact time of 5 min on a solution containing atrazine at 3 µg/l (Meijers, Van der Veer & Kruithof, 1993). Pilot plant trials have achieved removals of atrazine between 30% and 60% with ozone doses of 2–4 mg/l and 5–15 min contact time (Foster, Rachwal & White, 1991). In a 9-month pilot study, raw water atrazine concentrations of 7–80 ng/l were hardly affected by aluminium sulfate coagulation treatment but were reduced by 66–96% when ozonation (1.5–2 mg/l, 20 min contact) was applied (Hua, Bennett & Letcher, 2006). A combination of bankside storage, ozonation and finally GAC filtration reduced the concentration of atrazine in river water from 0.32 µg/l to 0.11, 0.09 and <0.01 µg/l, respectively (Haist-Gulde, Baldauf & Brauch, 1993).

Membrane filtration using ultrafiltration techniques does not remove atrazine, but nanofiltration is more successful; one study indicated that removals of between 66% and 98% were achieved for atrazine at an initial concentration of 3–5 µg/l (Hofman, 1992). With nanofiltration, rejection rates varied between 75% and 100% for atrazine (influent atrazine 1 µg/l, combined with five other pesticides); the specific membrane type was an important factor in determining rejection rates. Pilot plant trials involving membrane filtration have achieved removals between 79% and 99% for atrazine (Hofman et al., 1993). Atrazine (10 µg/l) was 85–95% removed by a nanofiltration membrane (Chen et al., 2004). Atrazine (concentration not stated) was 80–85% removed by different nanofiltration membranes and 96% removed by a polyamide reverse osmosis membrane (Kosutic et al., 2005). A concentration of 0.5–1.5 mg/l was 98% and 68% removed by two polyvinyl alcohol/polyamide nanofiltration membranes, but only 15% and 11% removed by two polyethersulfone nanofiltration membranes (Kiso et al., 2000). Removals of 82%, 83% and 84% from a 150–300 µg/l solution were reported for three different nanofiltration membranes (Plakas et al., 2006); fouling of the membrane by calcium and humic acid worsened the performance. A full-scale (140 000 m^3/day) nanofiltration plant at Méry-sur-Oise, France, reduced a concentration of 850 ng/l to <50 ng/l (Cyna et al., 2002). In a pilot

plant study, DEA was spiked at 1 µg/l into distilled water, sand-filtered water and GAC-filtered water, then subjected to nanofiltration through composite polyamide membranes. Removals of 62–95% and 62–75% were obtained with two nanofiltration membranes (Boussahel, Baudu & Montiel, 2001). In another study (Boussahel et al., 2000), one of the membranes gave ~90% removal from a 1 µg/l solution, and the other gave ~70% removal. With both membranes, adsorption onto the membrane accounted for about 35% removal.

UV radiation was effective at reducing atrazine concentrations during laboratory studies. With an irrradiation time of 5 min, the atrazine concentration was reduced by almost 90%. With a longer duration of radiation, there was only a small further decrease in the atrazine concentration (Cermak & Cermakova, 1992). UV irradiation, at pilot plant scale, was found to be effective in decomposing atrazine in a chalk borehole water, up to 70% removal being achieved with UV doses of up to 700 Wh/m^3. Removal efficiency was constant over an influent concentration range of 0.1–0.5 µg/l (Bourgine et al., 1995). UV irradiation causes substantial photodecomposition but not complete mineralization (Le Brun et al., 1993).

A laboratory comparison of UV, hydrogen peroxide, ozone, ozone/UV, ozone/hydrogen peroxide, hydrogen peroxide/UV and ozone/hydrogen peroxide/UV demonstrated that all processes destroyed atrazine (hydrogen peroxide only at pH >10) and that UV/hydrogen peroxide gave the fastest degradation rate (Prado & Esplusgas, 1999). Treatment of 3 µg/l solutions of atrazine and DEA with 2 mg/l free chlorine and a 30 min contact time gave no removal (Jiang & Adams, 2006).

A number of point-of-use and point-of-entry water treatment systems based on activated carbon are available and are suitable for treating water that may be contaminated with atrazine. These systems should be used only on microbially safe drinking-water, they should be well flushed before each use and the filters should be changed frequently. Point-of-use and point-of-entry reverse osmosis systems could also be used for removal of atrazine.

Although specific published data on the removal of the atrazine metabolites are limited, what data there are suggest that these will behave in a manner similar to atrazine.

6. GUIDELINE VALUES

Drinking-water may contain metabolites of atrazine as well as atrazine itself. The chloro-*s*-triazine metabolites DEA, DIA and DACT share the same mode of action as atrazine and have a similar toxicological profile. Hence, JMPR decided to establish a group acceptable daily intake (ADI). Hydroxyatrazine, the plant and soil degradate, was not included because its mode of action and toxicological profile are different from those of atrazine and its chloro-*s*-triazine metabolites.

JMPR established a group ADI of 0–0.02 mg/kg body weight based on the NOAEL for atrazine of 1.8 mg/kg body weight per day identified on the basis of LH surge suppression and subsequent disruption of the estrous cycle seen at 3.6 mg/kg body weight per day in a 6-month study in rats, using a safety factor of 100 for interspecies and intraspecies variation. JMPR considered that this NOAEL is protective for the

consequences of neuroendocrine and other adverse effects caused by prolonged exposure to atrazine and its chloro-*s*-triazine metabolites.

Applying this group ADI to a 60 kg adult drinking 2 litres of water per day and allocating 20% of the total daily intake to drinking-water, as exposure to atrazine from other sources it expected to be low, a guideline value of 0.1 mg/l can be derived for atrazine and its chloro-*s*-triazine metabolites in drinking-water. This 20% allocation will be very conservative in most countries, as it is expected that exposure of the public will be primarily through drinking-water.

For hydroxyatrazine, JMPR established an ADI of 0–0.04 mg/kg body weight based on the NOAEL of 1.0 mg/kg body weight per day identified on the basis of kidney toxicity (caused by low solubility in water, resulting in crystal formation and a subsequent inflammatory response) at 7.8 mg/kg body weight per day in a 24-month study in rats, and using a safety factor of 25. A modified safety factor on the basis of kinetic considerations was deemed appropriate, as the critical effect of hydroxyatrazine is dependent on its physicochemical properties, and the interspecies variability for such effects is lower than for effects dependent on the area under the curve.

Applying this ADI to a 60 kg adult drinking 2 litres of water per day and allocating 20% of the total daily intake to drinking-water, a guideline value of 0.2 mg/l can be derived for hydroxyatrazine in drinking-water. Again, this 20% allocation will be very conservative in most countries, as it is expected that exposure of the public will be primarily through drinking-water.

Temperature in degrees Celsius (°C) may be converted to degrees Fahrenheit (°F) as follows:

$$°F=(1.8\times°C)+32$$

Horizontal coordinate information is referenced to the North American Datum of 1927 (NAD27).

Abbreviated water-quality units used in this report: Organic- and inorganic-constituent concentrations, water temperature, and other water-quality measures are given in metric units. Constituent concentrations are given in milligrams per liter (mg/L) or micrograms per liter (µg/L). Milligrams per liter are considered equivalent to parts per million at the reported concentrations. Micrograms per liter are considered equivalent to parts per billion at the reported concentrations.

Specific conductance (SC) of water is given in microsiemens per centimeter at 25 degrees Celsius (µS/cm at 25 °C). The unit is equivalent to micromhos per centimeter at 25 °C (µmho/cm), formerly used by the U.S. Geological Survey.

Turbidity is not quantified; determined from visual inspection of water clarity.

pH of water is given in standard units.

Additional abbreviations: milliliter (ml), millimeter (mm).

Herbicides and Their Transformation Products in Source-Water Aquifers Tapped by Public-Supply Wells in Illinois, 2001-02

By Patrick C. Mills (U.S. Geological Survey) and William D. McMillan (Illinois Environmental Protection Agency)

Abstract

During 2001-02, ground-water samples were collected from 117 public-supply wells distributed throughout Illinois to evaluate the occurrence of herbicides and their transformation products in the State's source-water aquifers. Wells were selected using a stratified-random method to ensure representation of the major types of source-water aquifers in the State. Samples were analyzed for 18 herbicides and 18 transformation products, including 3 triazine and 14 chloroacetanilide products. Herbicide compounds (field-applied parent herbicides and their transformation products) were detected in 34 percent of samples. A subset of samples was collected unfiltered to determine if analytical results for herbicides in unfiltered samples are similar to those in paired filtered samples and, thus, can be considered equally representative of herbicide concentrations in ground water supplied to the public. The study by the U.S. Geological Survey was done in cooperation with the Illinois Environmental Protection Agency.

Parent herbicides were detected in only 4 percent of all samples. The six most frequently detected herbicide compounds (from 5 to 28 percent of samples) were chloroacetanilide transformation products. The frequent occurrence of transformation products and their higher concentrations relative to those of most parent herbicides confirm the importance of obtaining information on transformation products to understand the mobility and fate of herbicides in ground-water systems. No sample concentrations determined during this study exceeded current (2003) Federal or State drinking-water standards; however, standards are established for only seven parent herbicides.

Factors related to the occurrence of herbicide compounds in the State's source-water aquifers include unconsolidated and unconfined conditions, various hydrogeologic characteristics and well-construction aspects at shallow depths, and proximity to streams. Generally, the closer an aquifer (or well location) is to a recharge area and (or) the stronger the hydraulic connection between an aquifer and a recharge area, the younger the ground water and the more vulnerable the aquifer will be to contamination by herbicide compounds. The weak relation between current (2001) statewide application rates of herbicides and current (2001-02) occurrence of herbicide compounds in source-water aquifers indicates that additional factors must be considered when relating herbicide-application rates to occurrence. These factors include historical application rates and the mobility and persistence of the various herbicide compounds in ground-water systems. Frequency of detection and concentrations of herbicides compounds in the State's source-water aquifers are indicated to be highest during the spring, when crops are planted and herbicides primarily are applied. Excess nitrate (concentrations of nitrate, as nitrogen, higher than 3 milligrams per liter) in ground water strongly indicates the co-occurrence of herbicide compounds. However, nitrate concentrations are not a reliable indicator of herbicide-compound concentrations. The inverse relation found between current use of land for corn and soybean production and current occurrence of herbicide compounds in underlying aquifers indicates that various factors, along with current agricultural land use, contribute to herbicide occurrence. These factors include, among others, land-use history, ground-water age, ground-water-flow patterns, geology, soil microbiology, and chemistry and persistence of the herbicide compounds. Detection of agriculture-

specific herbicide compounds in 71 percent of samples from urban areas with no current or recent agricultural land use near the sampled wells indicates that recharge to certain high-capacity supply wells may originate at considerable distances (up to about 10 miles) from the wells. Essentially no difference was found between the analytical results for herbicides in paired unfiltered and filtered samples, although additional study of this issue is warranted.

Introduction

Herbicides are used extensively in agricultural regions of the United States for control of competing grass and broadleaf weeds. Substantial advances in agricultural production during the past 35 years are associated directly with the increased use of herbicides. However, this increased use of herbicides has introduced concerns about their occurrence in water resources and their possible adverse effect on human health and the environment. Numerous studies have documented the occurrence of herbicides in ground water at the State (Detroy and others, 1988; Risch, 1994; Mehnert and others, 1995; Kolpin and others, 1997, 1998b, 2000b; Kalkhoff and others, 1998; Dana W. Kolpin, U.S. Geological Survey, written commun., 2004), regional (Kolpin and others, 1994, 1995, 1996, 1998a), and national (U.S. Environmental Protection Agency, 1990, 1992; Holden and others, 1992; Kolpin and others, 2000a, 2002) scales. Concerns about ground-water contamination by herbicides are high in many agricultural regions, particularly in Midwestern States, where ground water typically is the principal source of drinking water. The toxic effects of herbicides on humans and animals, and the disruption of reproductive cycles and food chains have been documented in various studies (Blaustein and Wake, 1990; Carbonell and other, 1995; Nemes-Kosa and Cserhati, 1995; Bain and LeBlanc, 1996; Longley and Sotherton, 1997; Ribas and others, 1997; Russell and others, 1997; Spawn and others, 1997; Andersen and others, 2002; Anderson and others, 2002; Crump and others, 2002; Sinclair and Boxall, 2003).

Despite the number of studies regarding the occurrence of herbicides in ground water, there remains an incomplete understanding of the factors that affect their distribution. Additionally, study of herbicide transformation products (also referred to as degradates, metabolites, or breakdown products) in ground water is comparatively limited. These transformation products result from microbial, physical, and chemical processes that alter the field-applied (parent) herbicides and commonly the products occur more frequently and at higher concentrations in ground water than their parent compounds (Kolpin and others, 1998b). Transformation products can, in some cases, have toxicity similar to their parent herbicide compounds (Belfroid and others, 1998; Tessier and Clark, 1995; Tixier and others, 2001), particularly if their chemical structure remains chlorinated.

Because herbicides are used heavily in Illinois corn and soybean production, various statewide studies have been conducted that evaluate the occurrence of herbicides and, in some cases, their transformation products in ground water (Mehnert and others, 1995; Kelly L. Warner and William S. Morrow, U.S. Geological Survey, written commun., 2003; Dana W. Kolpin, U.S. Geological Survey, written commun., 2004). However, none of these studies specifically address herbicide occurrence in the State's source-water aquifers – that is, aquifers that provide untreated water that is used to supply private wells and public drinking water (U.S. Environmental Protection Agency, 2003a) (figs. 1, 2). In an attempt to better understand the occurrence of herbicides in Illinois' source-water aquifers and the factors that affect their occurrence, 117 public-supply wells distributed throughout the State (figs. 1, 3) were sampled by the U.S. Geological Survey (USGS) from October 2001 through September 2002. The study, done in cooperation with the Illinois Environmental Protection Agency (IEPA), was part of an ongoing IEPA program to assess ambient ground-water quality in the State's source-water aquifers tapped for public supply (Illinois Environmental Protection Agency, 2003a). Since 1998, IEPA periodically has collected samples from a subset of the 360 public-supply wells in its ambient ground-water-quality network for analysis of selected triazine and chloroacetanilide herbicides. These analyses do not include every herbicide reportedly (U.S. Department of Agriculture, 2003) used in Illinois, including heavily used glyphosate (the active ingredient in Roundup), nor their transformation products. The present USGS-IEPA study provides analyses of all herbicides reportedly used in Illinois corn and soybean production during the past decade (1991-2001) (U.S. Department of Agriculture, 2003), some herbicides that may not have been used, and various transformation products of these herbicides.

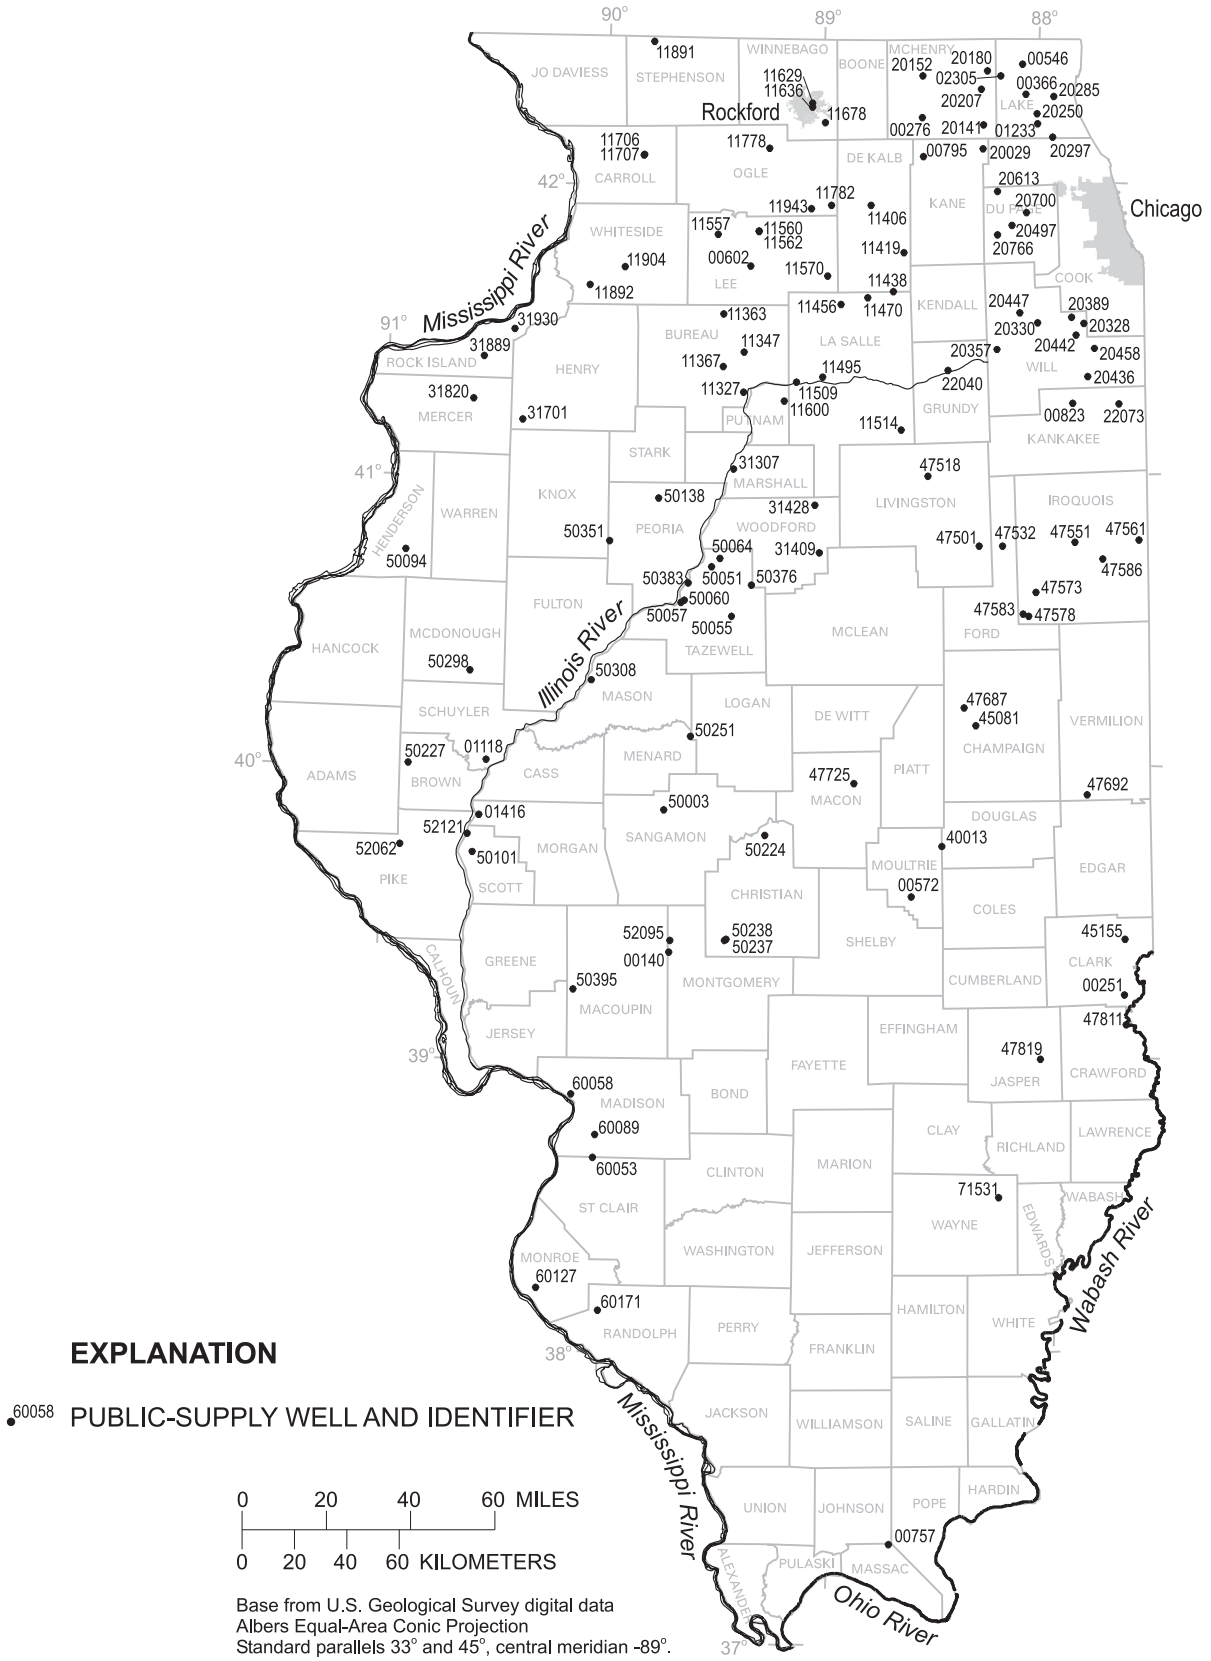

Figure 3. Locations of selected public-supply wells that tap source-water aquifers in Illinois.

Purpose and Scope

This report presents (1) analytical results for selected herbicides and their transformation products in samples collected from 117 public-supply wells in Illinois from October 2001 through September 2002, (2) analysis of selected factors that may relate to the occurrence of herbicides in the State's source-water aquifers or indicate their possible occurrence, and (3) results of herbicide analyses in paired unfiltered and filtered samples to determine if these two types of samples can be considered equally representative of herbicide concentrations in ground water supplied to the public. Analytical results are included for 18 herbicides and 18 transformation products, representing triazine, chloroacetanilide, and glyphosate compounds. Relational factors that were evaluated include herbicide use, hydrogeologic characteristics, well-construction aspects, land use, and occurrence of excess nitrate (concentrations of nitrate, as nitrogen, higher than 3 mg/L) in ground water.

Acknowledgments

Various persons and agencies are acknowledged for their contributions to the study. Wade Boring, Alan Fuhrmann, Laurie Moyer, Gregory White, Edward Wagner, Joseph Konczyk, and Matthew Campbell of the IEPA, Division of Public Water Supplies, scheduled sampling visits with well owners; provided location maps, routing instructions, well-construction details, and other study-related information; calibrated field water-quality meters; prepared wells for sampling; and collected ancillary water-quality data. Well operators and owners freely provided ancillary well information and access to the wells for sampling. Paul Terrio, Robert Kay, and Steven Stammer, USGS, Illinois District, assisted in collecting water samples.

Study Methods

The methods used for well selection, land-use determination, sample collection, laboratory analysis, quality assurance, and data analysis are described in the following sections of the report. Quality-assurance methods include on-site (sampling) and laboratory methods.

Well Selection and Land-Use Determination

Water samples collected in this study for analysis of herbicide compounds were obtained from wells selected by a stratified-random method (Illinois Environmental Protection Agency, 2003a). Criteria used for stratification included aquifer type, geologic-based vulnerability to contamination, and well depth. The selected wells tap major types of source-water aquifers in Illinois – that is, aquifers composed of sand and gravel or of Pennsylvanian- to Cambrian-age bedrock (generally classified as sand and gravel, Pennsylvanian, Mississippian, Silurian-Devonian, and Cambrian-Ordovician aquifers) (fig. 2). Most of the source-water aquifers tapped by the wells in this study (and other public-supply wells in this State) are principal aquifers, as classified by O'Hearn and Schock (1984) (fig. 1). These aquifers have a potential yield of 100,000 gal/d/mi^2, an area of at least 50 mi^2, and are categorized here as unconsolidated (sand and gravel), shallow bedrock (depth to top of aquifer is less than or equal to 500 ft), and deep bedrock (depth to top of aquifer is greater than 500 ft) aquifers (figs. 1, 2). The sand and gravel of the unconsolidated aquifers are deposits from glacial meltwater or streams. The bedrock aquifers generally consist of carbonate or sandstone. Fifty-four of the selected wells tap unconsolidated aquifers (well depths 28-404 ft), 54 tap shallow bedrock aquifers (well depths 71-1,870 ft), and 9 tap deep bedrock aquifers (well depths 820-2,591 ft).

As part of the study, extent of land use for corn and soybean (row-crop) production near the sampled wells was determined. On-site inspection, aerial photographs, and topographic maps were used to identify and estimate percentages of land used for row-crop production within radial distances of 1 and 2 mi of the wells. Trace percentages were estimated to be within the range from greater than 0 to 5 percent of land use. Other percentages were estimated within ranges of from greater than 5 to 25, greater than 25 to 50, greater than 50 to 75, and greater than 75 to 100 percent.

Sample Collection and Laboratory Analysis

Water samples for herbicide analysis were collected by USGS personnel using methods detailed in Kolpin and Burkart (1991) and Wilde and others (1997 to present). Prior to collection of these samples, the wells were purged and other water-quality samples, including

samples for nitrate analysis, were collected by IEPA personnel. Wells were purged through a raw-water tap (before chlorination or other chemical treatment) for 15 minutes or longer to remove water stored in the well casing and delivery piping (fig. 4). Using a calibrated field water-quality meter with an attached flow-through cell, values of water temperature, pH, specific conductance, and oxidation-reduction potential were monitored to ensure stabilization of these field water-quality characteristics and, thus, that the sample would be representative of aquifer water quality. Samples for herbicide analysis were passed through a 0.7 micron, baked, glass-fiber filter (fig. 5a) at a rate of 0.25 gal/min or less and collected in 125-ml, amber, baked-glass bottles (fig. 5b). To limit exposure of the sample to the atmosphere, the filtering equipment was connected directly to the sample tap at the well; more than 90 percent of the wells and sample taps were enclosed in a well house. The samples were shipped chilled (4° C or less) to the analytical laboratory within 2 days of collection.

The filtering equipment, including tubing, connectors, and filter plate, was constructed of Teflon or stainless steel to avoid leaching or adsorption of the organic herbicides. Before sampling, all equipment was cleaned thoroughly with a mixture of laboratory-grade (non-phosphate) soap and tap water and rinsed with deionized water. The water, obtained from the USGS, Illinois District office, has been tested periodically and found free of herbicide compounds.

Selected samples were collected to evaluate the relation between herbicide analytical results for unfiltered and filtered samples. The sampling method used in most herbicide studies by the USGS, particularly projects assisted by the USGS Organic Geochemistry Research Group (OGRG) (Kolpin and Burkart, 1991; Zimmerman and Thurman, 1999), requires filtering to provide samples that essentially are free of particulates. Traditionally, the IEPA collects unfiltered samples that represent total concentrations of constituents (dissolved and undissolved fractions). The IEPA sampling method is dictated by one aspect of their mission -- to evaluate and regulate the quality of drinking water (Illinois Environmental Protection Agency, 2003b). Ground water supplied to the public generally is not processed to remove particulates. Because ground water withdrawn by public-supply wells typically is essentially

Figure 4. Monitoring of field water-quality characteristics (temperature, pH, specific conductance, oxidation-reduction potential) for stabilization of values prior to collection of ground-water samples.

Figure 5. Ground-water sampling at well 47725, Oreana, Ill., for analysis of herbicide compounds: (A) routing of discharge from the well through Teflon tubing to a 0.7-micron, baked, glass-fiber filter enclosed in a stainless-steel filter plate, and (B) collection of samples in 125-milliliter, amber, baked-glass bottles (refer to figure 3, Macon Co., for well location; photographs by Steven E. Stammer, U.S. Geological Survey).

free of visible particulates, the following assumption was evaluated – herbicide-analytical results for unfiltered and filtered samples should be similar (cannot be differentiated statistically). If this assumption is valid, it would indicate that filtering is unnecessary for most samples collected from public-supply wells for herbicide analysis (assumed to be at least 95 percent of samples, as indicated by the samples collected during this study), because unfiltered-sample results can be considered as equally representative of herbicide concentrations as filtered-sample results in ground water supplied to the public. Elimination of filtering would (1) allow better comparison of herbicide-analytical results to those of other constituents from public-supply wells using IEPA methods and (2) substantially reduce the time and expense of sample collection.

Unfiltered samples were collected at 13 wells (11 percent of all samples) for comparison with the filtered samples that were collected routinely during the year-long study. Eleven of the wells were selected randomly. Two of the wells, including well 52095 and 50351 (fig. 3), were selected on the basis of field observations of clay-sized particulates on the filter media following routine sample collection (fig. 6).

Thirty-six herbicide compounds were analyzed by the USGS OGRG laboratory in Lawrence, Kans. Samples were analyzed for 16 herbicides and 3 triazine transformation products by gas chromatography/mass spectrometry (GC/MS) following solid-phase extraction (Zimmerman and Thurman, 1999; Kish and others, 2000); 14 chloroacetanilide transformation products (6 ethane sulfonic (ESA), 6 oxanilic (OA), and 2 sulfynil acetic (SAA) acids) by high-performance liquid chromatography/mass spectrometry (HPLC/MS) following solid-phase extraction (Zimmerman and others, 2000; Lee and others, 2001); and glyphosate, its transformation product amino methyl phosphonic acid (AMPA), and glufosinate by HPLC/MS following solid-phase extraction (Lee and others, 2002). The reporting limit for most herbicides and transformation products was 0.05 µg/L; the limit for glyphosate and related compounds was 0.1 µg/L.

Figure 6. Examples of clay-sized particulates on filter media for samples collected from two public-supply wells that tap source-water aquifers in Illinois, 2001-02 (filter diameter is 142 millimeters—about 5.5 inches; refer to figure 3, Montgomery Co. and Peoria Co., respectively, for well locations).

Quality Assurance

The quality-assurance program for the data collected during this study are divided into two categories: on-site (sampling) methods and laboratory methods. Discussion of those methods and results of quality-assurance evaluations follows.

Differences in paired quality-assurance samples were evaluated by the relative percent difference (RPD) method (U.S. Environmental Protection Agency, 1989). For this method,

$$RPD = \frac{(C1 - C2) \times 100 \text{ percent}}{(C1 + C2) / 2},$$

where

C1 is the concentration of the field sample,

and

C2 is the concentration of the quality-assurance sample.

The method is used to assess the relative magnitude to which the analytical results of the sample pairs differ, and possible bias in the analytical results; that is, whether concentrations are typically over- or under-estimated for a particular sample type.

Quality-assurance methods used during sample collection are described in the previous section "Sample Collection and Laboratory Analysis" and in Kolpin and Burkart (1991) and Wilde and others (1997 to present). Other on-site methods consisted of collecting equipment (or field) blanks and sample duplicates for analysis. Each equipment blank was collected after cleaning the filtering equipment following sample collection. The blanks were collected, as if routine field samples, by pumping laboratory-certified, volatile-organic-free water through the filtering equipment using a peristaltic pump. Analytical results of equipment-blank samples are used to evaluate the effectiveness of routine equipment-cleaning methods and the possibility of atmospheric contamination of the filtering equipment. Twelve equipment blanks were collected (10 percent of field samples). A pseudo-random process was used to select blank-sample sites. Sites were weighted to ensure that blanks were collected (1) during the primary period of herbicide application in Illinois (March-May) (30 percent of blanks) and (2) by each sampler (representing from 5 percent of the sites visited by a sampler to 22 percent of the sites visited by a sampler).

No herbicide compounds were detected in any of the equipment blanks. Five of the field samples collected immediately prior to collection of the blank samples had detectable concentrations of three to seven herbicide compounds, with a maximum concentration of 1.59 µg/L. Thus, equipment-cleaning methods used in the study were determined to be effective.

Each duplicate sample was collected after its associated routinely scheduled field sample was collected and the filtering equipment was cleaned. Thus, the duplicate-sample site was treated as if had not been sampled previously. Analytical results of duplicates are used to evaluate the random variation of sampling. Five duplicates were collected (4 percent of field samples). A pseudo-random process was used to select duplicate-sample sites. Sites were weighted to ensure that duplicates were collected by each sampler; duplicates were collected from 2 percent of the sites visited by a sampler to 15 percent of the sites visited by a sampler.

No herbicide compounds were detected in three of the paired field and duplicate samples. Two of the field samples had detectable concentrations of one to three herbicide compounds. RPD's for the detectable concentrations in the paired samples ranged from -15 to +8 percent. The RPD's are exaggerated by the low herbicide concentrations (0.06-0.41 µg/L). No difference in concentration between individual analyte pairs was greater than 0.02 µg/L. The measured differences in concentrations were at or near the expected variance of the analytical methods (Zimmerman and Thurman, 1999; Zimmerman and others, 2000). With minimal random variation associated with sample collection, the analytical results were determined to accurately represent ground-water quality at the sample sites.

Laboratory quality-assurance samples are used for evaluation of laboratory-analytical methods, which include guidelines for sample-holding times, quantitation-reporting limits, instrument calibration, sample preparation, and sample analysis. Laboratory quality-assurance methods consisted of collecting laboratory duplicates and spikes for analysis. Specific methods for selecting and preparing laboratory quality-assurance samples can be obtained from the OGRL laboratory, on request. Laboratory duplicates were prepared and evaluated for 15 samples analyzed primarily for parent triazine and chloroacetanilide herbicides by GC/MS, 12 samples analyzed for glyphosate and related compounds

by HPLC/MS, and 15 samples analyzed for chloroacetanilide transformation products by HPLC/MS.

No parent triazine, chloroacetanilide, or glyphosate-related herbicides were detected in any of the paired laboratory duplicates. Three of the paired field and laboratory-duplicate samples had detectable concentrations of one to three chloroacetanilide transformation products. RPD's for the detectable concentrations in the paired samples ranged from -13 to +15 percent. The RPD's are exaggerated by the low herbicide concentrations (0.06-0.18 µg/L). No difference in concentration between individual analyte pairs was greater than 0.01 µg/L. The measured differences in concentrations were within the expected variance of the analytical methods (Zimmerman and Thurman, 1999; Zimmerman and others, 2000). With minimal variability associated with sample preparation and analysis, the analytical results were determined to accurately represent ground-water quality at the sample sites.

Data Analysis

Selected factors that may relate to the occurrence of herbicide compounds in the source-water aquifers of the State or indicate their possible occurrence were analyzed graphically and statistically. Relational factors included herbicide use, hydrogeologic characteristics, well-construction aspects, land use, and occurrence of excess nitrate. Most of the factors have been identified in other studies of herbicides in ground water. Among these studies is a regional study of the Midwestern cornbelt States (fig. 1), including Illinois, conducted during 1991-94 (Kolpin and others, 1994, 1995, 1996, 1998a). The factors were reexamined in this study to determine whether the relations were consistent at a scale smaller than the Midwestern study and, in particular, whether they were consistent with hydrogeologic conditions specific to Illinois.

The correlation between frequency of detection (representing occurrence) of herbicide compounds in the State's source-water aquifers and the selected relational factors was examined using the Pearson's r method (Helsel and Hirsch, 1995). The method provides the degree of linear relation (from -1 to +1) between selected variables. A correlation of +1 indicates a perfect positive linear (but not causal) relation between two variables (for example, frequency of herbicide detection and confining-unit thickness). For the correlations, rank values were used to represent selected ranges of the measurable factors. For example, for the factor confining-unit thickness, ranks of 1 to 5 were used to represent the following intervals of increasing thickness: 0-10, 11-20, 21-50, 51-100, and greater than 100 ft. Examination of the histograms used to graphically evaluate the correlation between herbicide occurrence and the various relational factors verifies the linear relation between these variables and, thus, the use of the Pearson's r method. The Spearman's rank test was used to determine the covariance (degree of linear relation from -1 to +1) between nitrate and herbicide-compound concentrations; that is, whether, as nitrate concentrations increase, herbicide-compound concentrations tend to increase or decrease.

The difference in concentration of herbicide compounds determined from paired unfiltered and filtered samples was evaluated, in part, using the RPD method (U.S. Environmental Protection Agency, 1989). As described in the section "Quality Assurance", the method is used to assess the relative magnitude to which the analytical results of sample pairs differ. For the evaluation of unfiltered and filtered sample pairs, concentration C1 represents the unfiltered sample and C2 represents the filtered sample. It was assumed that if concentrations of the paired samples differ, concentrations of the unfiltered sample likely would be higher than those of the filtered sample.

Concentrations of herbicide compounds determined from paired unfiltered and filtered samples also were evaluated to determine if the resultant populations were statistically different. Various statistical tests were used, including the sign test, Wilcoxon signed-ranks test, and paired Student's *t*-test (Helsel and Hirsch, 1995). These tests were considered appropriate because the differences between values (concentrations) in the data pairs, although typically nonparametric (not distributed normally), can be considered symmetric. For paired data, the sign test determines whether values from one data set generally are larger, smaller, or different than values from its paired data set. This test may be used regardless of the distribution of the differences and, thus, is fully nonparametric. The Wilcoxon signed-ranks test determines whether the median difference between paired values is significantly different than zero. That is, do the paired data sets represent different populations? For this test, the distribution of the difference in paired values need not be normal but is assumed to be symmetric. The paired Student's *t*-test determines whether mean differ-

ence between paired values is significantly different than zero. For this test, the distribution of the difference in paired values is assumed to be normal.

A significance level of 0.05 was used for all statistical evaluations. This probability of error (ρ=0.05) means that there is 1 chance in 20 that the statistical test reported a significant difference between the paired data when there was not a significant difference. The smaller the ρ value, the greater is the certainty that a reported statistical difference is real.

Occurrence of Herbicides and Transformation Products

Analytical results for the study of herbicides and herbicide transformation products in source-water aquifers tapped for public supply in Illinois are presented in this section. Frequencies of detection and representative concentrations of the herbicide compounds are described and considered with respect to the results of other studies conducted in Illinois and elsewhere of herbicides in ground water. The analytical results, representing samples collected from October 2001 through September 2002, are summarized in table 1 and presented in full in appendixes 1 and 2. Location and construction information for the sampled wells and their field-measured characteristics of water quality also are presented in appendix 1.

Frequencies of Detection and Concentrations

Herbicide compounds were prevalent in Illinois' source-water aquifers, as indicated by the frequency (table 1) and spatial distribution of detected herbicides and (or) transformation products (fig. 7). Parent herbicides (atrazine and metolachlor) were detected in 4 percent of all samples, and parent herbicides and transformation products were detected in 34 percent of samples. Multiple herbicide compounds were detected in 70 percent of samples, with a median of three and a maximum of eight compounds in samples in which more than one compound was detected. Of the 11 detected compounds, 9 were transformation products (table 1; fig. 8). Six chloroacetanilide transformation products, including alachlor ESA (28 percent), metolachlor ESA (26 percent), metolachlor OA (14 percent), and acetochlor ESA (9 percent), were the most frequently detected compounds. Detection frequencies of ESA compounds consistently exceeded those of OA compounds for all chloroacetanilides (for example, alachlor ESA, 28 percent; alachlor OA, 6 percent).

Concentrations of detected herbicide compounds ranged from the reporting limit of 0.05 µg/L to 7.24 µg/L (metolachlor ESA), with concentrations of parent herbicides substantially lower than those of their transformation products (table1; fig. 9). The median concentration of detected parent herbicides was 0.07 µg/L, whereas the median concentration of all detected herbicide compounds, including transformation products, was 0.16 µg/L. The highest concentration of a parent herbicide (atrazine) was 0.22 µg/L, whereas concentrations of the chloroacetanilide transformation products in seven samples (including metolachlor ESA in four samples) exceeded 1 µg/L. Concentrations (maximum, mean, and usually median) of ESA compounds exceeded those of OSA compounds and both exceeded the concentrations of their parent compounds. As indicated by these findings, the frequency of detection and the concentration greatly increase for most herbicides when their transformation products also are considered (table 1; figs. 8, 9).

No concentrations exceeded Federal maximum contaminant levels (MCL's) or health advisory levels (U.S. Environmental Protection Agency, 2003b) (table 1) or Illinois standards (Illinois Pollution Control Board, 2003) established for the protection of public-water supplies. However, these levels have been established for only seven herbicides and have not been established for any transformation products. In addition, no regulatory levels consider the toxicity or aquatic effect of multiple compounds in water. The concentration of alachlor ESA in one sample exceeded the MCL (2 µg/L) of its parent compound. S-metolachlor was not analyzed for in this study. Recorded use of this herbicide began in 2000 with about 3 million pounds applied in that year and 4 million pounds applied in 2001 (U.S. Department of Agriculture, 2001). These herbicide-application rates rank fourth and third, respectively, in those years. S-metolachlor reportedly requires only 65 percent of the application rate of metolachlor, thus less active ingredient than that of metolachlor may be available for leaching to ground water (Ecologic-IPM, 2003).

Deethylatrazine, deisopropylatrazine, and cyanazine amide were the only transformation products of triazine herbicides analyzed for in this study. Other triazine transformation products that previously have been

Table 1. Summary statistics for herbicides and their transformation products in ground-water samples from selected public-supply wells that tap source-water aquifers in Illinois, October 2001–September 2002.

[µg/L, micrograms per liter; na, not applicable]

Analyzed for but not detected: acetochlor sulfynil acetic acid (SAA), alachlor SAA, ametryn, flufenacet, flufenacet ethanesulfonic acid (ESA), flufenacet oxanilic acid (OA), glufosinate, AMPA, pendimethalin, prometon, prometryn, propazine, and terbutryn; SAA, ESA, and OA are transformation products (TP) of the associated herbicides; AMPA is a transformation product of glyphosate. Reporting limit for most herbicide compounds was 0.05 µg/L; reporting limit for glyphosate, amino methyl phosphonic acid (AMPA), and glufosinate was 0.10 µg/L.

Maximum contaminant levels (MCL)[1] for atrazine, alachlor, simazine, and glyphosate are 3, 2, 4, and 700 µg/L, respectively; health advisory levels[1] for cyanazine, metolachlor, and metribuzin are 1, 100, and 200 µg/L, respectively.

detected in Illinois ground water but were not analyzed for in this study include hydroxyatrazine and deeythyldeisopropylatrazine (Kelly L. Warner and William S. Morrow, U.S. Geological Survey, written commun., 2003). Frequency of occurrence and concentrations of these compounds in ground water are expected to be low, as indicated by field experiments and (or) sampling history. Hydroxyatrazine has a greater tendency to sorb to soils than atrazine, its primary parent compound, or other atrazine transformation products (Barbash and Resek, 1996). Thus, frequent occurrence of hydroxyatrazine in ground water, particularly at concentrations above those of other atrazine compounds, would be unexpected.

Deeythyldeisopropylatrazine is a transformation product of the first-order products deethylatrazine, deisopropylatrazine, and hydroxyatrazine. In a study of herbicides in shallow ground water (depth less than about 50 ft) in central Illinois (Kelly L. Warner and William S. Morrow, U.S. Geological Survey, written commun., 2003), hydroxyatrazine was detected in only 4 percent of 69 samples collected for the study; the maximum concentration was 1.14 µg/L. Deeythyldeisopropylatrazine was detected in only 4 percent of 28 samples (1 sample); the maximum concentration was 1.0 µg/L.

The extensive use of alachlor, acetochlor, and metolachlor during the past decade (1991-2001) (fig. 10)

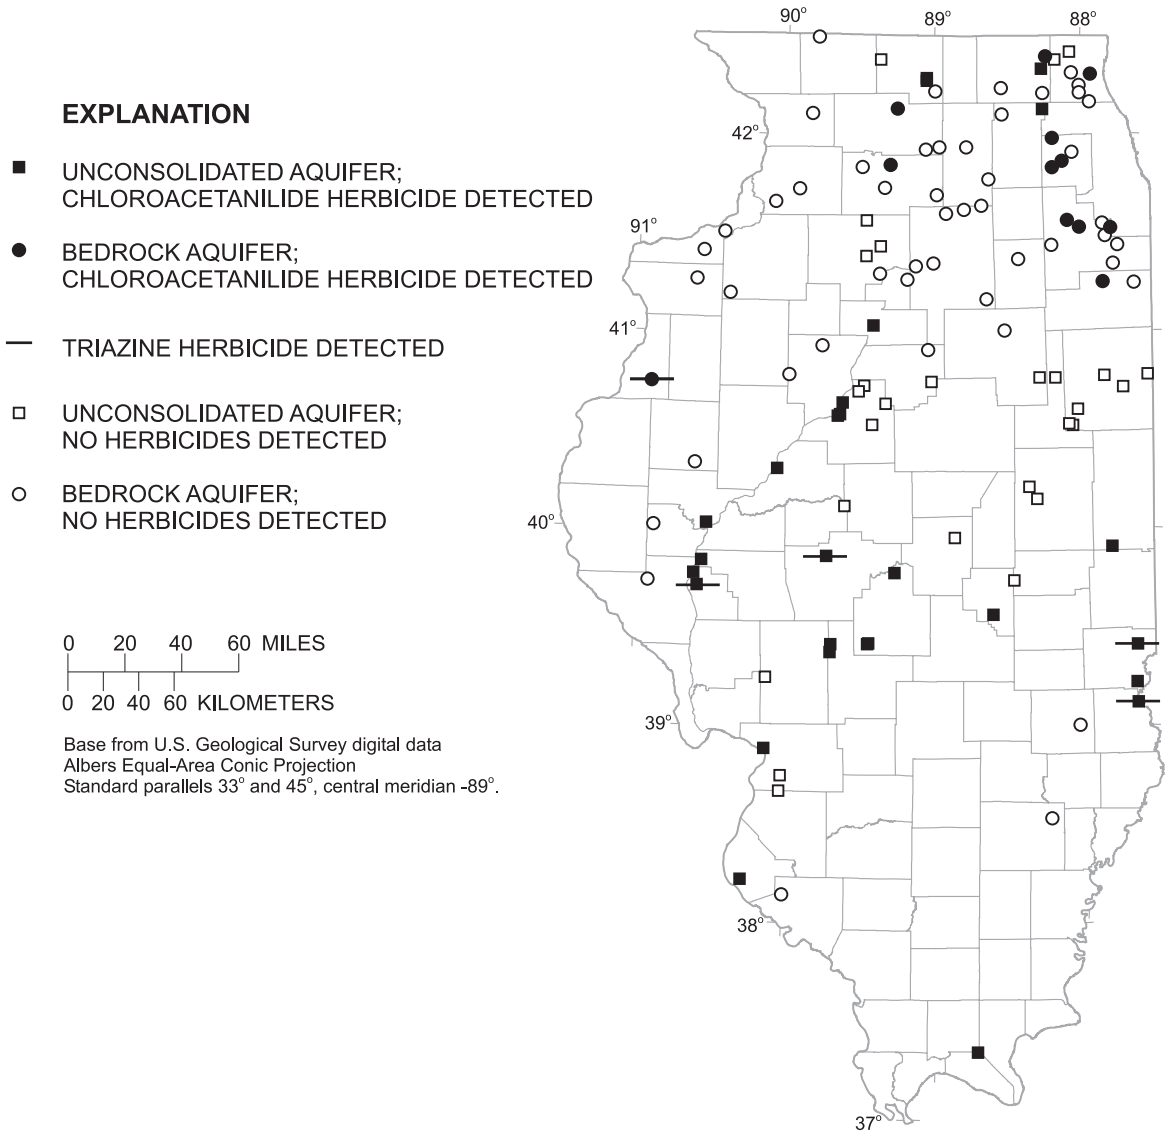

Figure 7. Locations of selected public-supply wells that tap source-water aquifers in Illinois, aquifer type (unconsolidated or bedrock) that the wells tap, and occurrence of herbicides or transformation products, 2001-02.

along with their comparatively low detection rates and concentrations in ground water as parent compounds and comparatively high detection rates and concentrations as transformation products (ESA and OA compounds) (table 1) confirms previous observations that each of these structurally related chloroacetanilide herbicides transforms similarly (Kolpin and others, 1996; Aga and others, 1995). Each of the parent herbicides degrade readily in the soil zone and persist in ground water as mobile transformed compounds. Furthermore, the frequencies of detection and concentrations in this and other studies (Kalkhoff and others, 1998, Kolpin and others, 2000b) for the parent compounds and their transformation products support conclusions that regardless of which chloroacetanilide, ESA compounds are more mobile and persistent than OA compounds (Kalkhoff and others, 1998). The finding that frequencies of detection of metolachlor compounds consistently are greater than those of the alachlor compounds and much greater than those of acetochlor compounds can be attributed, in part, to the extent to which these compounds have been used in Illinois (fig. 10) and other Midwestern States in recent years. However, the comparatively low occurrence of acetochlor relative to its comparatively heavy use since about 1995 indicates that differences in the physical properties and related rates of transformation of the various chloroacetanilide compounds are contributing factors (Kalkhoff and others, 1998) to the consistent ranking of the detection frequencies of these compounds.

The more even distribution between the detection frequencies of atrazine (detected in 3 percent of samples) and deethylatrazine (detected in 4 percent of samples) than that determined for the chloroacetanilide herbicides and their transformation products (table 1) is related to the comparatively slower transformation rate for atrazine, particularly under hypoxic conditions (Clay and others, 1995; Agertved and others, 1992; McMahon and others, 1992; Klint and others, 1993; Nair and Schnoor, 1992), and is indicative of the relative stability of atrazine and deethylatrazine (Thurman and others, 1992;

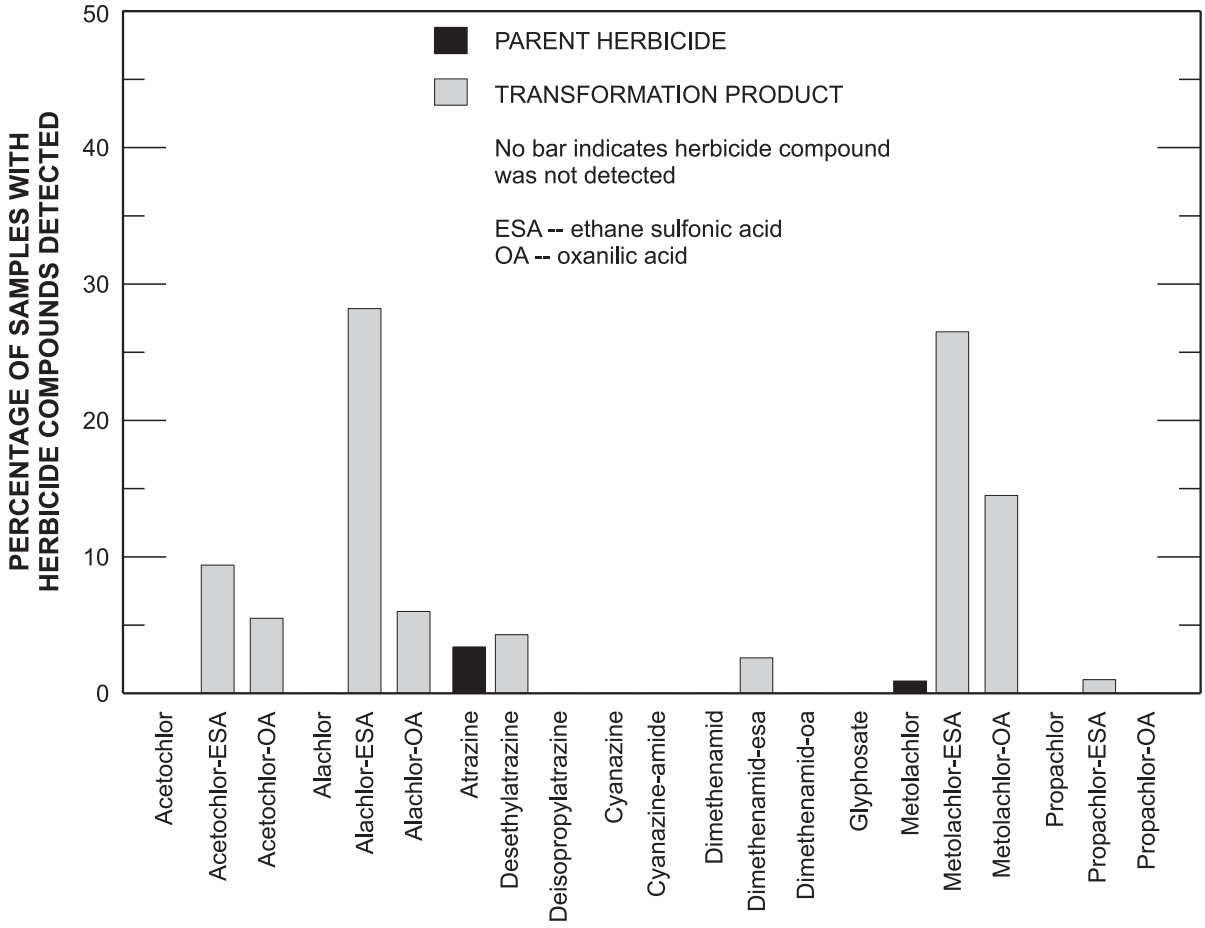

Figure 8. Frequency of detection of herbicides and their transformation products in source-water aquifers in Illinois, 2001-02.

Roy and Krapac, 1994; Jayachandran and others, 1994). The slow transformation of atrazine allows more of it to be transported to ground water than the parent chloroacetanilides.

The concentration ratios of deethylatrazine to atrazine (DAR's) recorded in this study (from 0.95 to 4.2) indicate that the atrazine detected in the ground-water samples likely was derived from slow infiltration through well-oxygenated soil, as typically associated with nonpoint sources (Adams and Thurman, 1991; Thurman and others, 1991). Such hydrogeologic conditions allow for increased transformation of atrazine to deethylatrazine by soil microorganisms. Rapid infiltration to poorly oxygenated hydrogeologic environments below the soil zone, as typically associated with point sources and (or) preferential flow, limits transformation of atrazine and, thus, results in lower DAR's than those recorded in this study (ratios may range down to 0.1 or less).

Deisopropylatrazine, a transformation product of atrazine, cyanazine, and simazine, was not detected in samples collected for this study. Its nondetection probably relates in part to (1) its instability relative to atrazine and deethylatrazine (Geller, 1980; Adams and Thurman, 1991) and (2) the limited recent and (or) historical use of cyanazine and simazine in Illinois row-crop production (fig. 10).

The extensive use of glyphosate since 1996 (fig. 10), following introduction of Roundup Ready soybeans, along with its nondetection in Illinois' source-water aquifers as either a parent compound or transformation product (AMPA) confirms previous observations (Giesy and others, 2000) that the mobility and persistence of glyphosate are low. Field and laboratory studies indicate that glyphosate sorbs strongly to soils and degrades readily by microbial processes (Extension Toxicology Network, 2003).

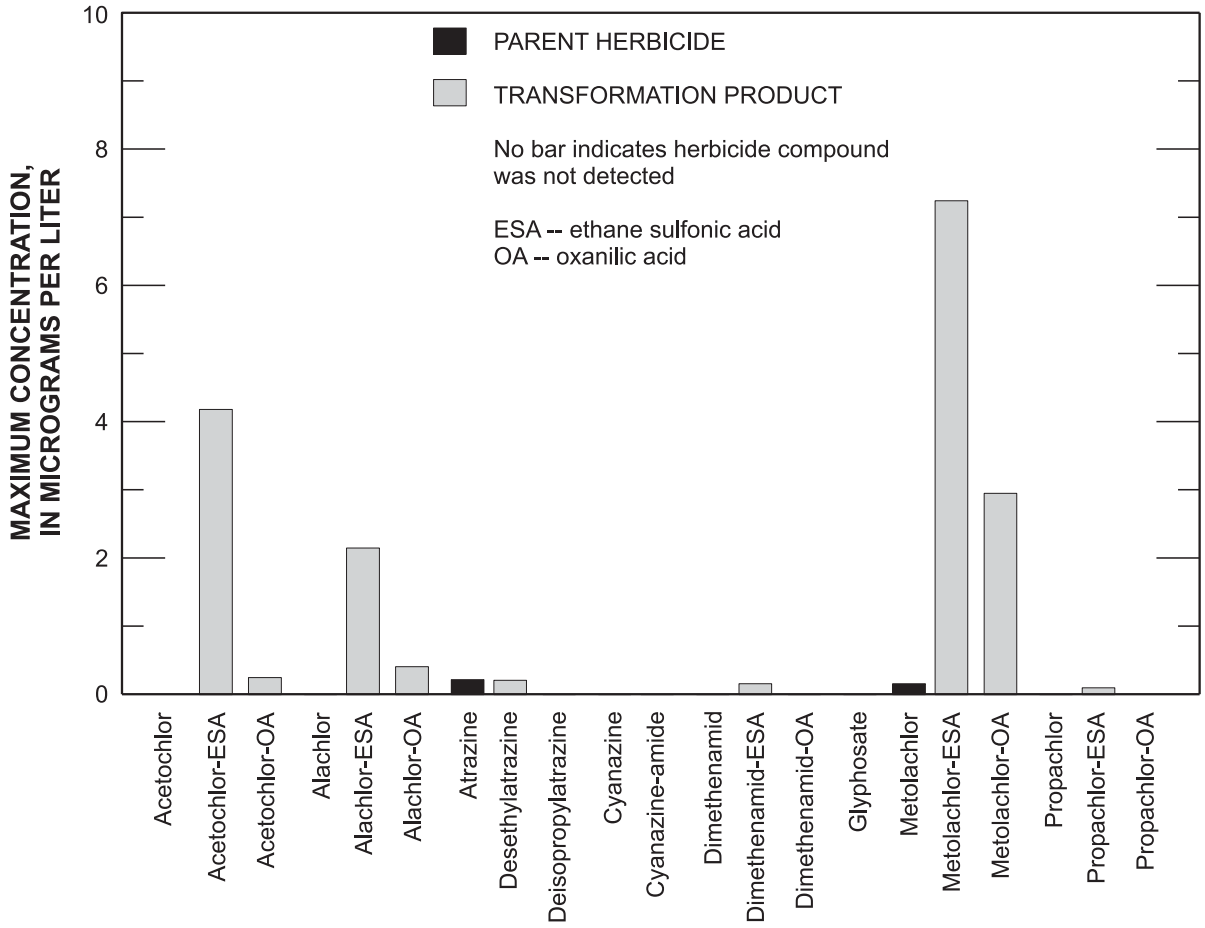

Figure 9. Maximum concentrations of herbicides and their transformation products in source-water aquifers in Illinois, 2001-02.

Comparison to Other Studies

The findings of the present study generally are similar to those of other statewide herbicide studies in Illinois (Dana W. Kolpin, U.S. Geological Survey, written commun., 2004) and Iowa (Kolpin and others, 1997, 1998b, 2000b; Kalkhoff and others, 1998), particularly for the various relations associated with frequencies of detection and concentrations between parent herbicides and their transformation products. In the previous statewide studies and the present study, transformation products were detected in groundwater samples more frequently and at higher concentrations than their parent compounds. Typically frequencies of detection and concentrations of almost all of the herbicide compounds analyzed for were lower in the present study than in the other statewide studies. For example, in the previous Illinois study (Dana W. Kolpin, U.S. Geological Survey, written commun., 2004), one or more parent herbicide or transformation products were detected in 56 percent of the ground-water samples collected from 55 wells during fall 2000; the maximum concentration detected was 40 µg/L (metalochlor ESA). In the Iowa study (Kalkhoff and others, 1998), one or more parent herbicide or transformation products were detected in 75 percent of the ground-water samples collected from 88 wells during summer 1996; the maximum concentration detected was 50 µg/L (alachlor ESA).

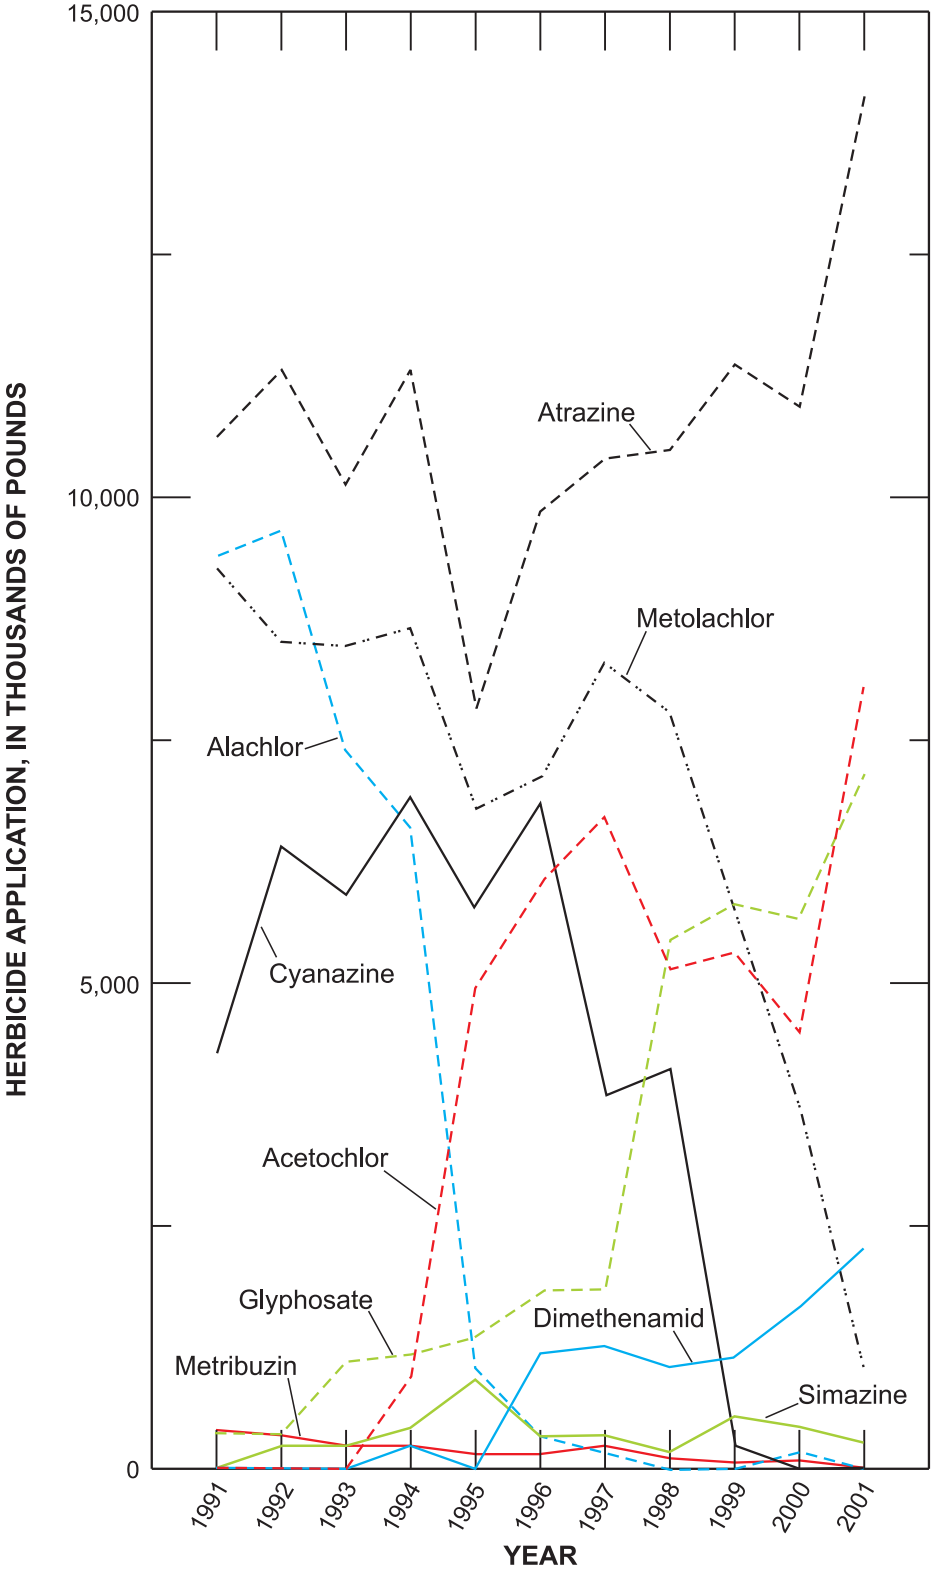

Figure 10. Annual herbicide-application rates in Illinois during 1991-2001 (herbicide-application-rate data are from U.S. Department of Agriculture, 2003; data are not reported for herbicides applied on less than 1 percent of corn and soybean acreage).

Each of the statewide studies described above used the same sample-collection methods, laboratories, analytical methods, and reporting concentrations, and analyzed for essentially the same herbicide compounds. Differences between the results of the present study and those of the previous Illinois study (Dana W. Kolpin, U.S. Geological Survey, written commun., 2004) can be attributed primarily to differences in the ground-water systems under investigation and the types of wells that were sampled. The previous study focused on aquifers expected to be vulnerable to herbicide contamination – that is, on shallow aquifers (unconsolidated and bedrock aquifers less than 50 ft below land surface) in areas where at least 25 percent of the land use was for row-crop production. Wells of various types were sampled, of which only 13 were public-supply wells. Differences between the results of the present study and those of the Iowa study cannot be attributed readily to differences in the ground-water systems under investigation and the types of wells that were sampled. The Iowa samples, like those in the present study, were collected from public-supply wells of various depths that tap Iowa's major types of source-water aquifers (alluvial, glacial drift, bedrock/karst, bedrock/nonkarst, as defined in that study). Temporal sampling bias (Detroy and others, 1988; Risch, 1994; Kolpin and others, 1994) likely accounts for much of the difference in results. In the present study, samples were collected year-round, whereas in the Iowa study, samples were collected during the summer growing season (thus, closer to the time of herbicide application).

The findings of the present study also are similar to those of the Midwestern study that included Illinois (Kolpin and others, 1994, 1995, 1996, 1998a). However, as with the statewide studies, frequencies of detection and concentrations of almost all of the herbicide compounds analyzed for were lower in the present study than in the Midwestern study. In the Midwestern study, one or more parent herbicide or atrazine-transformation products were detected in 28 percent of the ground-water samples collected from about 300 wells during summer 1991; the maximum concentration was 2.3 µg/L (deethylatrazine). Differences between the results of the present study and those of the Midwestern study can be attributed primarily to differences in the ground-water systems under investigation and the types of wells that were sampled. The focus of the Midwestern study was the same as that of the previous Illinois study (aquifers expected to be vulnerable to herbicide contamination) (Dana W. Kolpin, U.S. Geological Survey, written commun., 2004). As with the present study and the statewide studies, the same collection methods, laboratories, analytical methods, and reporting concentrations were used and essentially the same herbicide compounds were analyzed for (although analysis of transformation products in the Midwestern study was limited primarily to analysis of atrazine compounds).

Comparison of results of the present study with other large-scale studies is difficult because, typically, herbicide transformation products were not analyzed for in samples collected in other studies. In addition, higher analytical reporting limits and different well-selection and sample-collection methods usually were used in other studies. The largest comparable study of public-supply wells is the National Pesticide Survey (NPS) (U.S. Environmental Protection Agency, 1990, 1992). The frequency of detecting one or more herbicide compound was lower in the present study (4 percent, for parent herbicides) than in the NPS study (9 percent, for parent herbicides plus the atrazine transformation product deethylatrazine); concentrations were lower than MCL's or health advisory levels in both studies. Reasons for the greater frequency of detection in the NPS study than the present study are uncertain. Given the typically higher reporting limits and analysis of fewer transformation products in the NPS study, the comparatively higher detection frequencies of the NPS study could be attributed, in part, to differences in the population of wells/aquifers that were sampled and temporal sampling bias (use of herbicides may have been greater in and near the time of the NPS study than that of the present study).

Factors Related to Occurrence of Herbicide Compounds

Awareness of the types of herbicides identified in large-scale studies, such as the present study of Illinois' source-water aquifers, and the factors that may be related to their occurrence can aid in determining the vulnerability of various source-water aquifers to herbicide contamination by certain herbicides and developing more efficient strategies for sample collection. Sampling can be focused on herbicides that likely are to be detected in ground water and on locations and times where potential for contamination is greatest. Focused sampling should

reduce time and costs associated with the collection of samples and with regulatory management of these contaminants. As a result, there may be increased opportunities for addressing other water-quality issues, including further study of the toxicity of various herbicide transformation products and their fate and transport.

Various factors that may be related to the occurrence and detection of herbicides in Illinois' source-water aquifers are examined in the following section. These factors include herbicide use, various hydrogeologic characteristics, well-construction aspects, and land use. Excess nitrate in ground water also is examined as an indicator of herbicide occurrence. Specific herbicide-use factors examined include rates and timing of herbicide applications. Hydrogeologic characteristics examined include depth to the top of the aquifer, thickness of the confining unit, designation as a confined aquifer, and stream proximity. Well-construction aspects examined include well depth and depth to base of the well casing.

Herbicide Use

When only parent compounds are considered, a moderate positive relation (r = 0.72) was found between current (2001) herbicide-application rates and current (2001-02) frequency of detection of herbicides in Illinois' source-water aquifers (table 1). Atrazine, the most frequently detected parent herbicide in ground-water samples collected from these aquifers, is consistently the most heavily applied herbicide in Illinois (fig. 10). In 2001, about 14 million pounds of atrazine were applied to the State's corn crops -- almost double the amount of the next most heavily applied herbicides (acetochlor and glyphosate). Metolachlor, the only other parent herbicide that was detected during this study, was the second most heavily applied herbicide during most of 1991-98 (fig. 10).

When herbicide transformation products are considered, there is little to no relation between current herbicide-application rates and current frequency of detection of herbicide compounds in the State's source-water aquifers (r = -0.20) (fig. 11A). For example, in 2001,

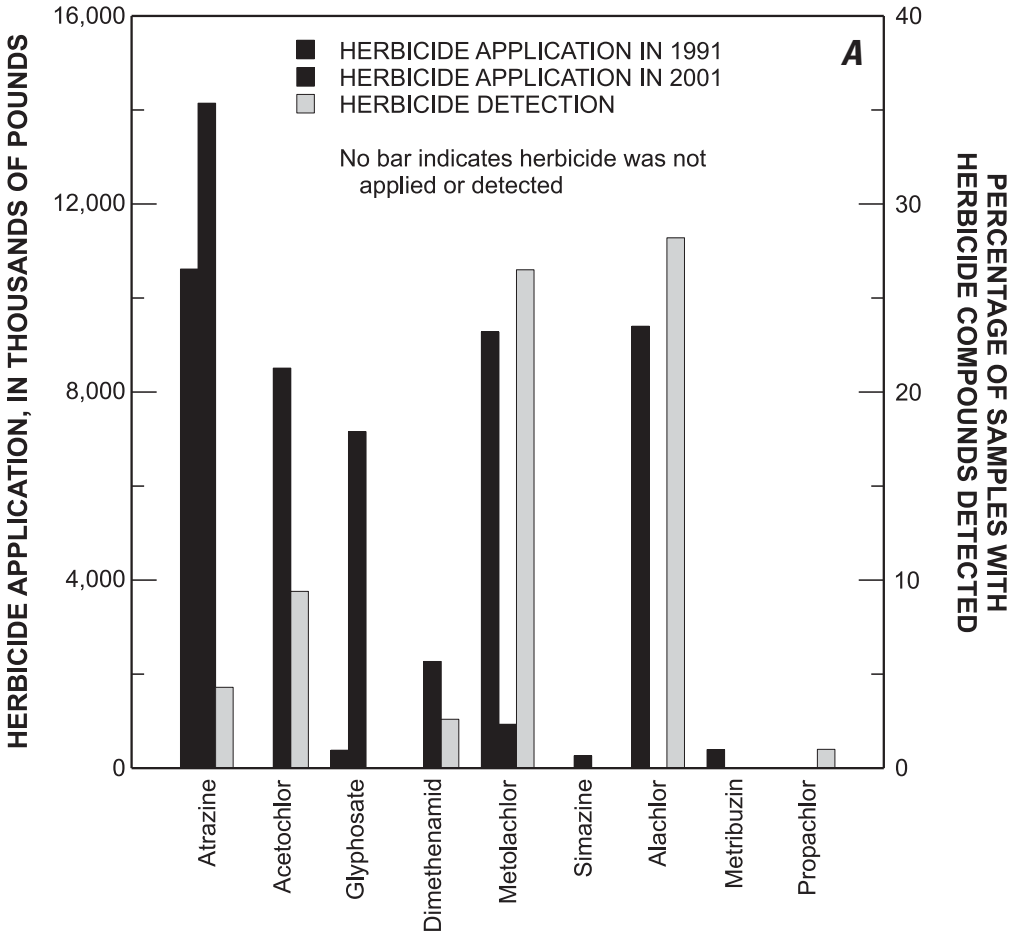

Figure 11. Relation of (A) frequency of detection of herbicides and their transformation products and (B) maximum total concentration of herbicides and their transformation products in source-water aquifers in Illinois (2001-02) to annual herbicide-application rates in Illinois (1991, 2001) (herbicide-application-rate data are from U.S. Department of Agriculture, 2003; data are not reported for herbicides applied on less than 1 percent of corn and soybean acreage).

there was no recorded use of alachlor in the State (U.S. Department of Agriculture, 2003). Yet, alachlor ESA was the most frequently detected herbicide compound (28 percent) in samples collected from these aquifers during approximately the same time period (2001-02). Similarly, there is little to no relation between current herbicide-application rates and current herbicide concentrations in the State's source-water aquifers (fig. 11B). The time lag between land application of herbicides and herbicide transport to ground water requires that the mobility and persistence of herbicide transformation products and historical herbicide-application rates be considered to better determine the relations between herbicide-application rates and the occurrence and concentrations of herbicides in source-water aquifers. Use of certain herbicides has varied substantially during the past decade (1991-2001) (figs. 10, 11). Other contributing factors related to hydrogeology, herbicide chemistry, and soil biochemistry that can affect the mobility and persistence of many herbicide transformation products also need to be considered when relating application rates of herbicides to their occurrence and concentrations in ground water. The weak relation between herbicide-application rates and detection frequency, as determined in this study, also may be attributed, in part, to the use of statewide-application-rate data. Annual statewide-application-rate data available from the U.S. Department of Agriculture (2003) were used for the examination, because location-specific data, even at the county scale, were not readily available.

When the timing of herbicide application during the cycle of crop planting to harvesting is considered, it is evident that herbicides and their transformation products are detected most frequently (50 percent of samples) in the State's source-water aquifers during the spring crop-planting and herbicide-application period (fig. 12). At least 90 percent of the annual application of the detected herbicides currently (2001) in use in Illinois (atrazine, acetochlor, dimethenamid, and metolaclor) is during March through June (most in Aril and May), primarily for pre-emergent control of competing weeds and grasses (Aaron Hager, University of Illinois Extension, oral commun., 2003; Dennis P. McKenna, Illinois Department of Agriculture, written commun., 2003).

Concentrations of herbicide compounds detected in the State's source-water aquifers also are indicated to be highest during the spring crop-planting and herbicide-application period. The highest total concentration of all wells sampled during an application period was from samples collected in the spring period (26.7 µg/L). Additionally, three of the five highest total concentrations (12.9, 2.7, and 2.1 µg/

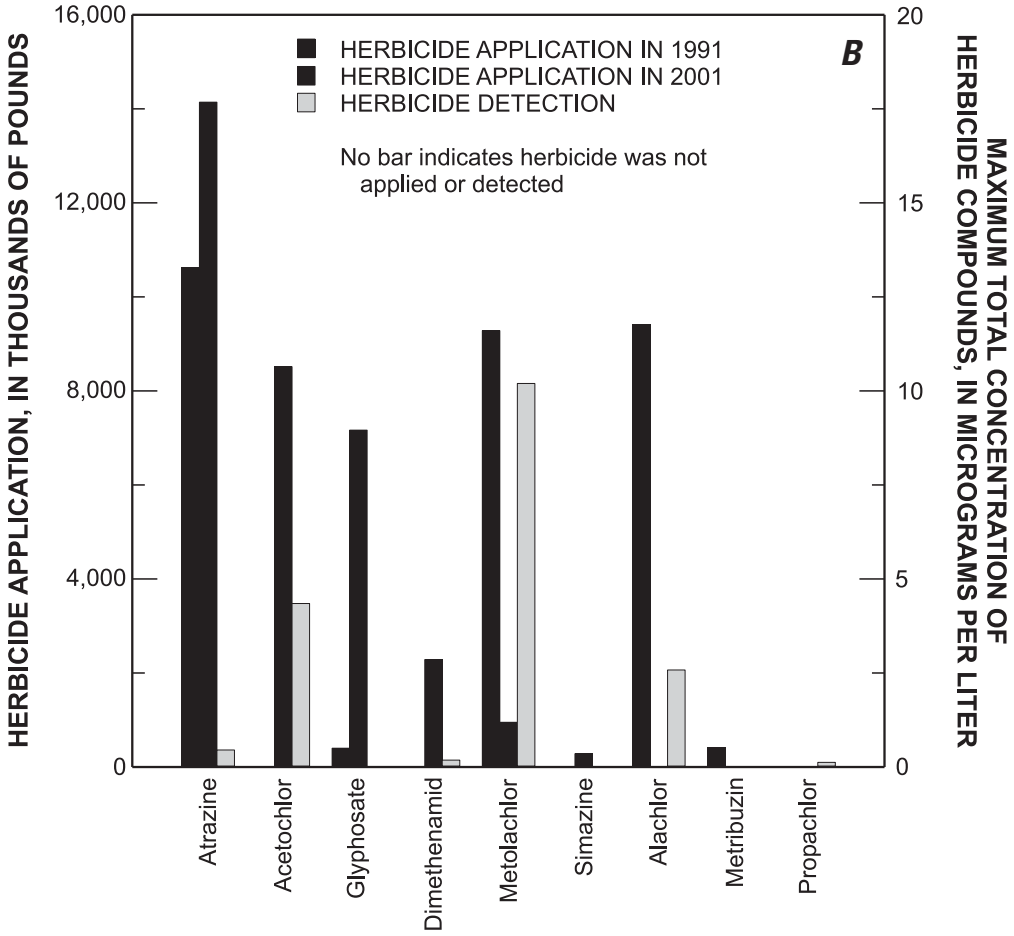

Figure 11. – Continued.

L; 1st, 4th, and 5th highest, respectively) in samples from individual wells and three of the five detections of parent compounds were from samples collected during this period. The comparatively high frequency of detection of herbicide compounds during the fall through winter crop- harvesting (and post-harvesting) period seems to represent the detection of increasing numbers of herbicide compounds with low concentrations as the parent herbicides transform and (or) the transportation of herbicide compounds in ground water to increasing distances from their application source areas. The higher percentage of sample wells open to unconsolidated aquifers in the crop-harvesting period (33 percent) than in the summer crop-growing period (17 percent) also may account for the comparatively high frequency of detection of herbicide compounds in the crop-harvesting period (fig. 12). Eighty-four percent of herbicide-compound detections were in samples from wells open to unconsolidated aquifers in which the ground water typically is recharged more recently than in bedrock aquifers.

Hydrogeology

Ground water typically is younger in unconsolidated aquifers than in bedrock aquifers. The younger age of ground water in unconsolidated aquifers can be attributed, in part, to the comparatively shallower depths and more rapid recharge rates of most unconsolidated aquifers (Kolpin and others, 2000b). Considering the factors of age and aquifer depth, unconsolidated aquifers are expected to be more vulnerable to contamination by herbicide compounds than bedrock aquifers; shallow bedrock aquifers are expected to be more vulnerable to contamination than deep bedrock aquifers.

Herbicide compounds were detected in more than twice as many samples from unconsolidated source-water aquifers in Illinois (representing 46 percent of sample locations) than from shallow bedrock aquifers (representing 46 percent of sample locations) (figs. 7, 13). No herbicide compounds were detected in samples from deep bedrock aquifers (representing 8 percent of sample locations). As indicated previously, source-water bedrock aquifers in Illinois are considered to be shallow where the depth to the top of the aquifer is less than or equal to 500 ft and are considered to be deep where the depth to the top of the aquifer is greater than 500 ft. Depth to the top of shallow bedrock aquifers with detections of herbicide compounds ranged from 71 to 246 ft, with 85 percent of the detections from aquifers with depths of 150 ft or less.

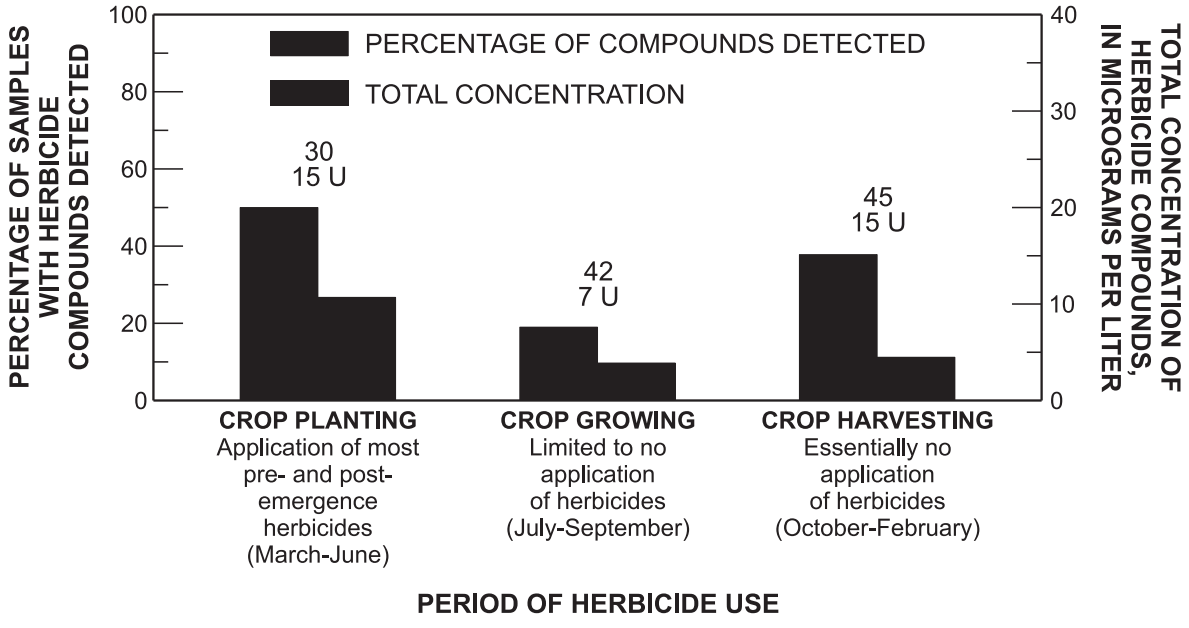

Figure 12. Relation of frequency of detection and total concentration of herbicides and their transformation products in source-water aquifers in Illinois to timing of herbicide application, 2001-02 (total number of wells and number of wells open to unconsolidated aquifers (U) in herbicide-application period are shown above bar).

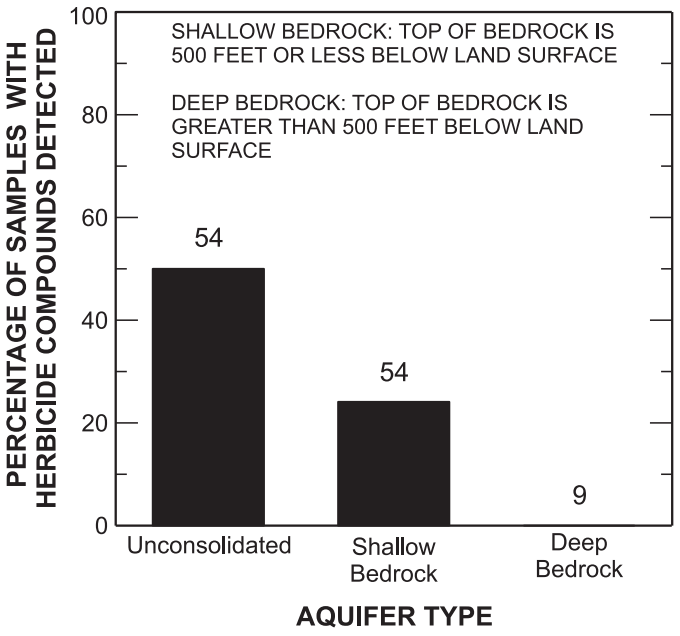

Figure 13. Relation of frequency of detection of herbicides and their transformation products in source-water aquifers in Illinois to aquifer type, 2001-02 (total number of samples in aquifer type is shown above bar).

With travel times for recharge to most confined aquifers (whether bedrock or unconsolidated) used in Illinois for public-water supply expected to be greater than 50 years (assuming only advective water movement through continuous porous media), occurrence of herbicide compounds in these aquifers generally should not be expected. Most synthetic organic herbicides, including the herbicides examined in this study, have been used routinely for less than about 40 years. By standard definition, aquifers are considered confined when the potentiometric surface (water level) in the aquifer is above the top of the aquifer; confined aquifers are bounded above and below by lithologic units of distinctly lower permeability than that of the aquifer (U.S. Geological Survey, 1989). For the present study, water-level data generally were unavailable for direct designation of aquifers as confined or unconfined and, thus, the relation between aquifer confinement and herbicide occurrence in the State's source-water aquifers could not be evaluated directly. Alternatively, thickness of the confining unit, frequently used as an indirect indicator of aquifer confinement, was evaluated to determine its relation to occurrence of herbicide compounds. For the evaluation, designations of confining-unit thickness were made by IEPA on the basis of geologic information available from well-construction logs or from other sources (Illinois Environmental Protection Agency, 1995).

There was a strong inverse relation (r = -0.93) between confining-unit thickness and frequency of detection of herbicide compounds in Illinois' source-water aquifers (fig. 14). Herbicide compounds were detected in 88 percent of samples from wells that tap aquifers confined below low-permeability units 10 ft thick or less and in 47 percent or less of samples from wells that tap aquifers confined below low-permeability units greater than 10 ft thick. Aquifer depth (depth to the top of the aquifer) seemed to be a factor where herbicide compounds were detected in samples from aquifers confined by units greater than 10 ft thick. For example, for aquifers confined below units greater than 10 to 20 ft thick, herbicides were not detected where aquifer depths exceeded 163 ft. Unexpectedly, herbicide compounds were detected in 20 percent of samples (4 samples) from wells that tap aquifers presumably confined below units greater than 50 ft thick (to a maximum thickness of 153 ft). One of the wells (00572) (fig. 3) where herbicide compounds were detected tapped an unconsolidated aquifer; three of the wells (20180, 20766, 20328) tapped a shallow bedrock aquifer of fractured carbonate (Silurian). For this study, construction logs of the sampled

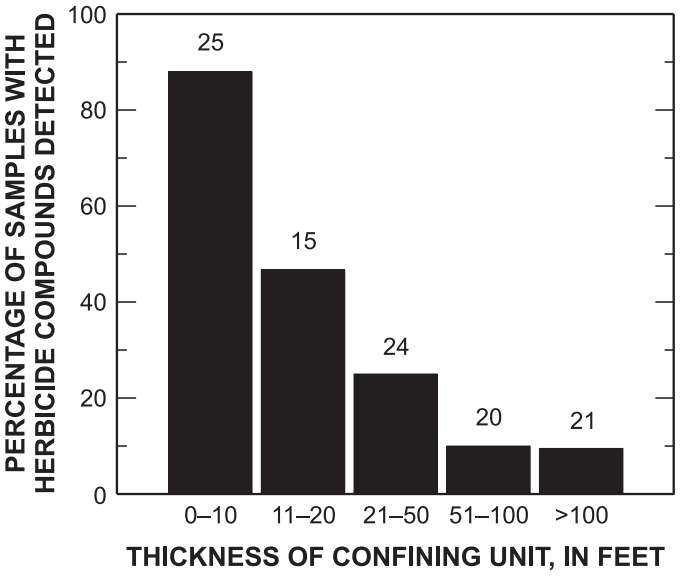

Figure 14. Relation of frequency of detection of herbicides and their transformation products in source-water aquifers in Illinois to thickness of the confining unit, 2001-02 (>, greater than; total number of samples in classification is shown above bar, confining-unit thicknesses were not available for 12 sampled wells).

wells were unavailable for evaluation of the lithology and lateral extent of the confining units. However, the occurrence of herbicide compounds in these samples indicates that the confining units in the vicinity of the sampled wells may not be vertically and (or) horizontally continuous. The occurrence of herbicide compounds in samples from three wells that tapped a fractured-carbonate aquifer indicates the fractures may, in some undetermined way, contribute to preferential movement of water and herbicides through the confining unit that overlies the aquifer.

Wells included in IEPA's ambient ground-water-quality well network have been designated officially as tapping either confined or unconfined aquifers to evaluate the vulnerability of Illinois' source-water aquifers to contamination (Illinois Environmental Protection Agency, 1995). The primary approach used for the official designations was a weighted-ranking method that includes five hydrogeologic criteria determined from well-construction logs and other data sources. For example, one criteria is – Does at least one contiguous unit of impermeable geologic materials greater than 10 ft thick overlie the aquifer (excluding the top 10 ft of soil materials)? When sufficient data are unavailable for the weighted-ranking method, the designations are based on alternative hydrogeologic-related vulnerability criteria (Berg and others, 1984), tritium data (Illinois Environmental Protection Agency, 2003c; Mills and others, 2002, p. 9), evidence of human sources of contaminants (such as synthetic organic compounds), and (or) information from detailed hydrogeologic investigations of the aquifer (Wade Boring, Illinois Environmental Protection Agency, oral commun., 2003). Each of these approaches for designating aquifers as confined or unconfined for the evaluation of aquifer vulnerability to contamination is based on the assumption that ground water from confined aquifers generally represents old recharge (about 50 years or older) and ground water in unconfined aquifers generally represents comparatively young recharge (about 50 years or younger). Thus, ground water in confined aquifers generally is considered to be less vulnerable to anthropogenic contamination (contaminants from human sources) than ground water in unconfined aquifers.

Aquifer confinement, as designated by the IEPA, was related strongly to frequency of detection of herbicide compounds in Illinois' source-water aquifers (fig. 15). Herbicide compounds were detected in samples from 11 percent of wells that tap aquifers designated as confined (representing 68 percent of wells/aquifers) and 84 percent of wells that tap aquifers designated as unconfined (representing 32 percent of wells/aquifers). Most of the samples (71 percent) obtained from aquifers designated as confined were obtained from bedrock aquifers. All detections of herbicide compounds in samples from confined aquifers were from bedrock aquifers.

Ground-water age and aquifer vulnerability to contamination by herbicide compounds can be related to proximity and hydraulic connection to recharge areas (Kolpin and others, 1998b). Generally, the closer and (or) better the hydraulic connection to a recharge area, the younger the ground water and more vulnerable an aquifer is to herbicide contamination. The length of the recharge flow path, in part, determines the time available for transport, transformation, or sorption of herbicides. This is important particularly if a thick unsaturated zone overlies an aquifer and, thus, extensive aerobic and biotic transformation of herbicides can result. One indication of proximity to a recharge area is the depth from land surface of various hydrogeologic characteristics (top of aquifer, for example) and well-construction aspects (base of well casing, for example). In this study, depth to the top of an aquifer (or aquifer depth) is defined as depth to

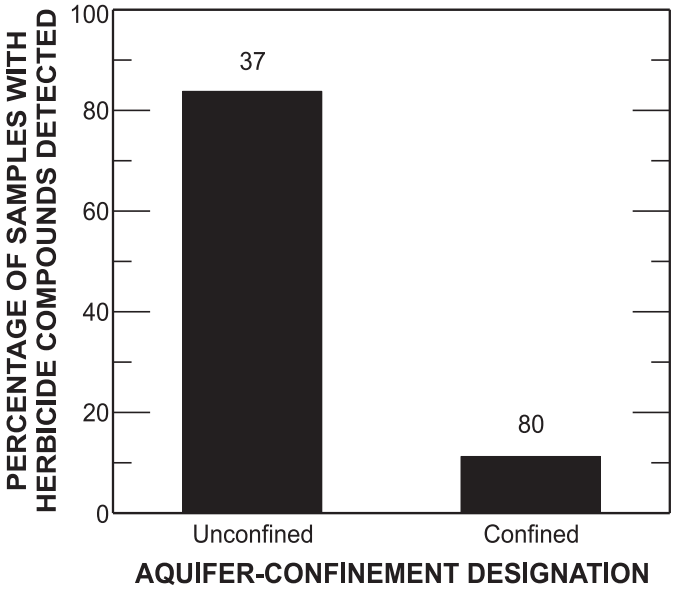

Figure 15. Relation of frequency of detection of herbicides and their transformation products in source-water aquifers in Illinois to designation as a confined aquifer (policy designation of the Illinois Environmental Protection Agency), 2001-02 (total number of samples in designation is shown above bar).

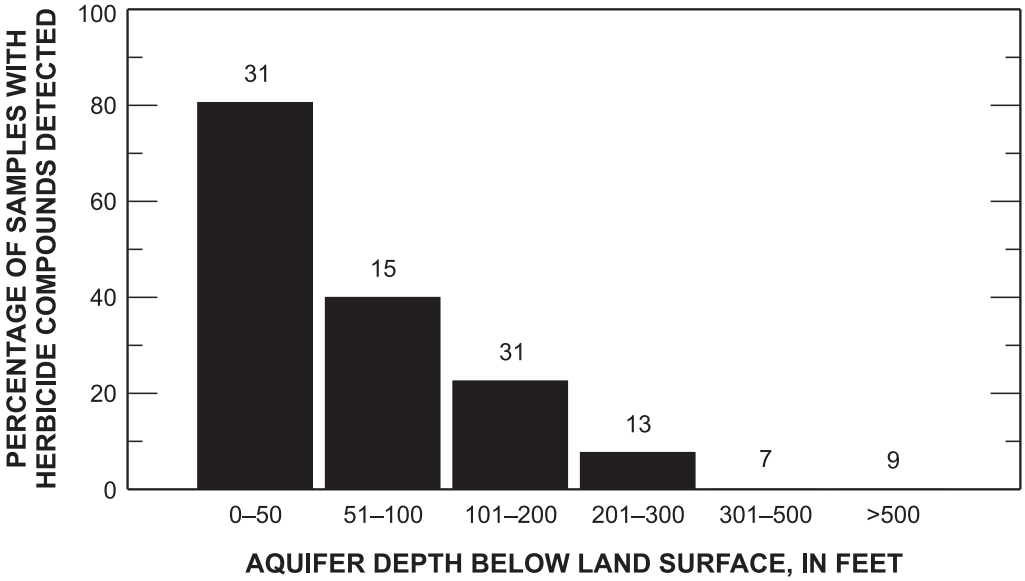

Figure 16. Relation of frequency of detection of herbicides and their transformation products in source-water aquifers in Illinois to aquifer depth, 2001-02 (aquifer depth is the depth from land surface to the top of aquifer material; >, greater than; total number of samples in depth interval is shown above bar; aquifer depths were not available for 11 sampled wells).

the top of the aquifer material, regardless of whether the aquifer material is fully saturated.

There was a strong inverse relation (r = -0.92) between aquifer depth and frequency of detection of herbicide compounds in Illinois' source-water aquifers, with a monotonic decline in detections with increasing aquifer depth (fig. 16). The number of samples with detected herbicides from aquifers within 50 ft of land surface was almost twice the number from all other aquifer-depth intervals (25 and 14 samples, respectively). No herbicide compounds were detected in samples from aquifers with depths greater than 300 ft. Of the various depth-related factors examined in the study of Midwestern cornbelt States that included Illinois, aquifer depth was associated most strongly with detection of herbicide compounds (Kolpin and others,1994).

Proximity of public-supply wells to a stream was related positively to the frequency of detection of herbicide compounds in Illinois' source-water aquifers (fig. 17). Herbicide compounds were detected in 70 percent of samples from the 10 wells within 100 ft of a stream, but in only 31 percent of samples from wells that were further than 100 ft from a stream (fig. 16). Similarly, herbicides were detected in 47 percent of samples from the 34 wells within about 0.25 mi of a stream, but in only 29 percent of samples from wells that were located more remotely (greater than 0.25 mi from a stream). Additionally, herbicides were detected in 78 percent of samples from the nine wells that tap unconsolidated (alluvial) aquifers adjacent to the Illinois and Mississippi Rivers (fig. 3). Two wells (50237, 50238; fig. 3) with the highest total (12.93, 5.13 µg/L, respectively) and individual (7.24, 4.18, 2.95, and 2.15 µg/L) concentrations of four herbicide compounds (metolachlor ESA, acetochlor ESA, metolachlor OA, and alachlor ESA, respectively) were immediately adjacent to a stream.

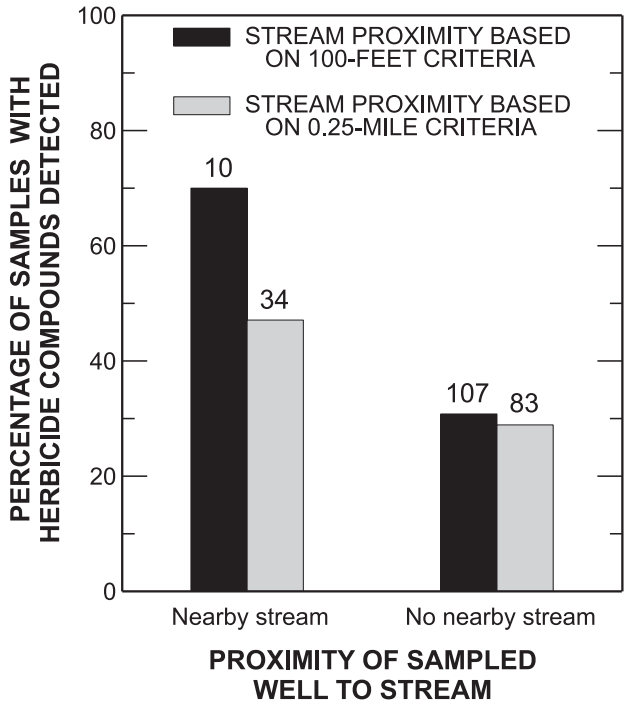

Figure 17. Relation of frequency of detection of herbicides and their transformation products in source-water aquifers in Illinois to proximity of well to a stream, 2001-02 (total number of samples in stream-proximity interval is shown above bar)

Kolpin and others (1994) report similar findings in their study of Midwestern States.

There are various hydrogeologic factors that could contribute to the greater frequency of detection of herbicide compounds and, possibly, higher concentrations in samples from wells near streams. Wells near streams may draw some water from the streams, as hydraulic gradients between the aquifer and stream are reversed during periods of high stream stage and (or) groundwater withdrawal by pumping. Herbicides frequently occur in streams in the Midwestern States and typically their frequencies of occurrence and concentrations substantially exceed those in ground water (Fuhrer and others, 1999). In addition, flow paths, possibly from many areas in an aquifer, tend to converge near discharge locations, such as streams. This comparatively wide source area providing recharge to near-stream wells can increase the likelihood of herbicide contamination of the water provided by the wells. Water in near-stream alluvial aquifers also tends to be younger than water in other aquifers (Kolpin and others, 2000b). The younger the ground water, the closer the source of recharge and potentially contaminating herbicides are likely to be.

Well Construction

As with aquifer depth, there was a strong inverse relation (r = -0.95) between well depth (depth from land surface to base of the well) and frequency of detection of herbicide compounds in Illinois' source-water aquifers (fig. 18). However, the decline in detection frequency associated with increasing well depth was less monotonic (more irregular) than the decline in detection frequency associated with increasing aquifer depth or another construction-related factor (well-casing depth) that was examined. Other studies indicate a weaker relation than this study does between frequency of herbicide detection and well depth (Holden and others, 1992; Kolpin and others, 1994; Dana W. Kolpin, U.S. Geological Survey, written commun., 2004). Herbicide compounds were detected in 100 percent of samples (6 samples) from wells 50 ft deep or less and 79 percent of samples from wells greater than 50 ft deep and less than about 100 ft deep. Detection frequencies in samples from wells between 100 and 500 ft deep were less than half the detection frequency in samples from shallower wells. In addition, herbicide compounds were detected in 7 percent of samples (2 samples) from wells greater than 500 ft deep (to a maximum of 769 ft deep).

The comparatively weaker association between well depth and herbicide detection than that between aquifer depth or well-casing depth and herbicide detection likely pertains to well-construction aspects. Many of the wells included in the study (54 percent) tap bedrock aquifers and, thus, are open to the aquifer from the base of the well casing to the base of the well (lengths of open intervals were up to 1,300 ft). Water may enter these wells from various depths in the aquifer. Generally, screened intervals of wells that tap unconsolidated aquifers more closely approximate total well depths than do open intervals of wells that tap bedrock aquifers.

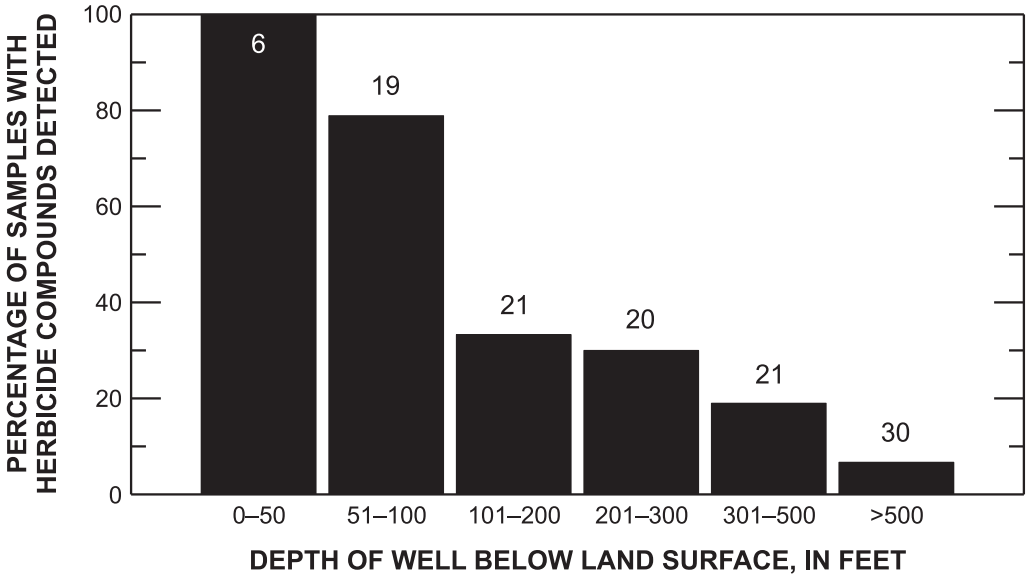

Figure 18. Relation of frequency of detection of herbicides and their transformation products in source-water aquifers in Illinois to well depth, 2001-02 (>, greater than; total number of samples in depth interval is shown in or above bar).

Well-casing depth should provide a more realistic indicator of distance from recharge areas (and, thus, vulnerability to herbicide contamination) than does total well depth. Well-casing depth represents the top of the open interval of a well and, thus, the shallowest depth below land surface at which ground water may enter a well. As with well depth, there was a strong inverse relation (r = -0.93) between casing depth and frequency of detection of herbicide compounds in Illinois' source-water aquifers (fig. 19), yet a stronger monotonic relation was indicated than that for well depth. Herbicides were detected in 93 percent of samples from wells with casing depths 50 ft or less and the detections declined steadily with increasing depth. No herbicides were detected in samples from wells with casings depths greater than 300 ft.

There are various explanations other than those given previously for the unexpected detection of herbicide compounds in samples of older ground water from confined aquifers, deep wells, or below thick confining units. Three of the explanations are (1) any given sample water mass is a composite of waters of multiple ages; thus, mixing of only a small quantity of recent recharge containing herbicide compounds with older recharge is necessary to result in detection of trace concentrations, (2) water quality can be affected at recharge locations that are remote from locations of older ground water and the effects can persist over long horizontal flow paths if ground-water velocities are sufficiently rapid and herbicide compounds are sufficiently persistent, and (3) recent recharge may circumvent confining units and (or) move rapidly to depth in an aquifer by preferential flow through fractures or improperly constructed (grouted), damaged, or unused wells.

Land Use

Land use was evaluated to determine a possible relation to the frequency of detection of herbicide compounds in Illinois' source-water aquifers. Frequencies were compared with percentage of land used for corn or soybean (row-crop) production within radial distances of 1 and 2 mi from sampled wells. Because of the routine use of herbicides in row-crop production, a positive relation between frequency of herbicide detection and percentage of land used for row-crop production is expected. However, there was a strong inverse relation (r = -0.81) between frequency of detection of herbicide compounds in ground-water samples collected from the source-water aquifers and percentage of land used in row-crop production (fig. 20). There was little difference in the results for the 1- and 2-mi radial distances.

Interestingly, herbicide transformation products were detected in 71 percent of the samples (5 of 7 samples) from wells with no identified corn or soybean production within a 2-mi radius. One of the samples with detected transformation products was from a well (50383; fig. 3) located adjacent to the Illinois River, indicating that recharge to this well, in part, originates greater than 2 mi from the well and (or) all or part of the recharge is from the river. Four of the five samples with detected transformation products were collected from-

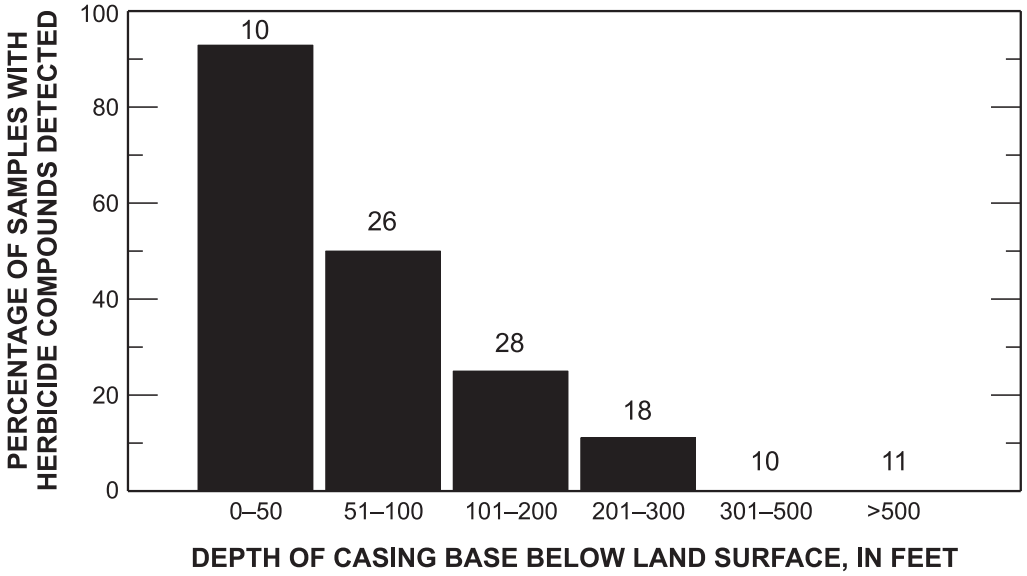

Figure 19. Relation of frequency of detection of herbicides and their transformation products in source-water aquifers in Illinois to depth to base of the well casing, 2001-02 (>, greater than; total number of samples in depth interval is shown above bar).

wells in urbanized areas of Rockford (11629, 11636) and suburban Chicago (20285, 20497). Detections in urban areas have been reported by others (Barbash and others, 1999). Metolachlor, detected as an ESA compound in one sample, sometimes is used in non-agricultural settings (about 1 percent of total national use); however, alachlor, detected as an ESA compound in all four samples, reportedly is not (Barbash and others, 1999). The detections of herbicide compounds in these urban areas may be attributable to previous agricultural activity in the area of the wells, particularly near one well location in suburban Chicago. The detections also indicate the possibility that recharge to the high-capacity public-supply wells that were sampled may originate up to about 10 mi from the wells. Finally, although least likely, atmospheric deposition may account for the occurrence of these herbicide compounds in the urban ground waters (U.S. Geological Survey, 1995; Dana W. Kolpin, U.S. Geological Survey, oral commun., 2003).

Other studies that consider the relation between land use and occurrence of herbicide compounds in ground water report similar findings (Kolpin and others, 1994; Kolpin and others, 1997). Even when land-use patterns are considered in detail (for example, more land-use categories are applied, locations are mapped, and estimated areas contributing recharge to wells are removed from the statistical analysis), the relation between land use and occurrence of herbicide compounds in ground water seems only to be strengthened marginally (Kolpin and others, 1997). These findings pertaining to land use indicate the complexity of identifying factors and relations associated with the occurrence and concentrations of herbicide compounds in source-water aquifers and other ground waters. Many factors can contribute collectively to the occurrence of herbicides in ground water, including historical trends in land and herbicide use, ground-water age, local flow patterns, geology, soil microbiology, and herbicide chemistry. Furthermore, the detections of herbicide compounds in urban areas point to the necessity of evaluating ground-water-flow systems and mapping areas contributing recharge to wells in detail in development of aquifer-protection strategies by water-resources managers.

Excess Nitrate

Nitrogen fertilizers are used commonly in conjunction with herbicides to increase crop production and frequently nitrate is detected in aerobic ground water where these fertilizers are used (Nolan and others, 1997). Because the occurrence of nitrate in aerobic ground water can indicate the proximity of a source of ground-water recharge, nitrate occurrence, particularly as excess nitrate, also may indicate the co-occurrence of herbicide compounds (Kolpin and others, 1994; Kolpin and others, 2002; Dana W. Kolpin, U.S. Geological Survey, written commun., 2004). In ground water, concentrations of nitrate, as nitrogen, higher than 3.0 mg/L generally are considered to represent excess nitrate; this is considered the division between natural and human sources of nitrate (Madison and Brunett, 1985). Some research indicates concentrations as low as 2.0 mg/L (Mueller

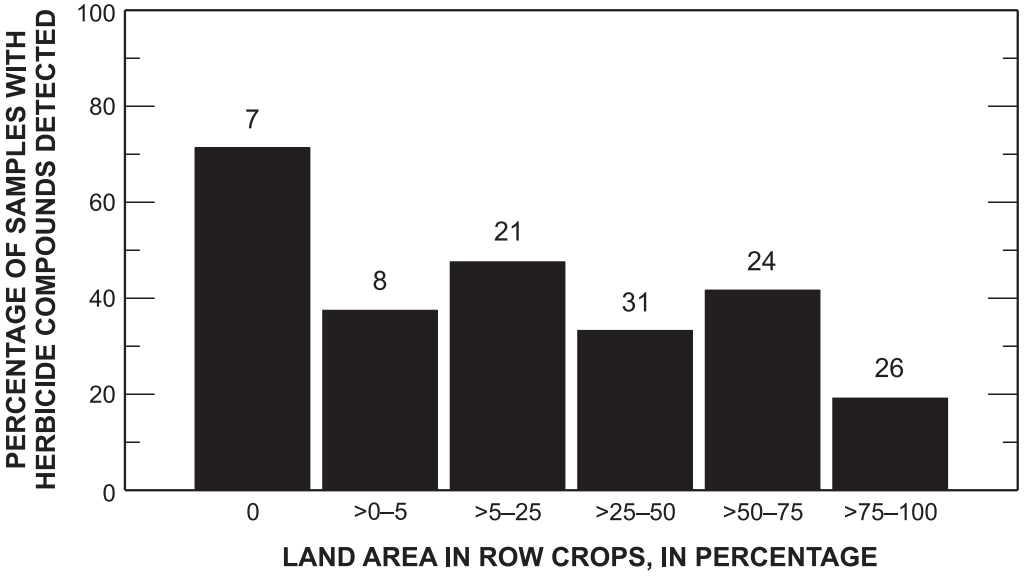

Figure 20. Relation of frequency of detection of herbicides and their transformation products in source-water aquifers in Illinois to percentage of land area used for corn and soybean (row crop) production within a 2-mile radius of the sampled wells, 2001-02 (>, greater than; total number of samples in land-area interval is shown above bar).

and Helsel, 1996) or even 1 mg/L (Nolan and Hitt, 2003) represent excess nitrate.

The occurrence of excess nitrate in Illinois' source-water aquifers generally was indicative of the co-occurrence of herbicide compounds (fig. 21), particularly if nitrate concentrations greater than 1 mg/L are considered representative of excess nitrate. Herbicide compounds were detected in 100 percent of samples (8 of 8) with nitrate concentrations greater than 3.0 mg/L and less than 10 mg/L and in 89 percent of samples (8 of 9) with concentrations greater than 1 mg/L and less than 3.0 mg/L. However, herbicide compounds also were detected in numerous samples with nitrate concentrations less than 1 mg/L, which is below the lowest level considered to represent excess nitrate. Herbicide compounds were detected in 83 percent of samples (5 of 6) with nitrate concentrations greater than 0.2 mg/L and less than 1 mg/L and in 21 percent of samples (19 of 90) with nitrate concentrations less than or equal to 0.2 mg/L. No nitrate concentrations exceeded the MCL of 10 mg/L. The detection of herbicide compounds in samples with nitrate concentrations less than 1 mg/L may be explained, in part, by differences in the amounts of nitrogen fertilizer and herbicide applied near the ground-water-sample sites, and the timing of the application and subsequent transport of these compounds to ground water.

Nitrate (as nitrogen) concentrations in ground-water samples do not seem a reliable indicator of concentrations of herbicide compounds in Illinois' source-water aquifers. A weak to moderate positive relation (r = 0.52) was indicated between nitrate concentrations and total concentrations of herbicide compounds in samples from the State's public-supply wells (fig. 22). The limited strength of this correlation may be attributed, in part, to the relative stability of nitrate concentrations in ground water; concentrations of herbicide compounds generally decrease with time. Water samples collected for this study represent various ages of ground water. Additionally, nitrogen-based fertilizer applications are not restricted to the spring-planting period to the extent of herbicide applications; nitrogen-based fertilizers often are applied during the fall, after crops have been harvested.

Representativeness of Unfiltered Samples

The herbicide analytical results of paired unfiltered and filtered samples were evaluated to determine if the results for unfiltered samples significantly differ from those for filtered samples. Similarity in the results should indicate that the analytical results from unfiltered samples are as representative as those from filtered samples of herbicide concentrations in ground water supplied to the public.

For the purpose of this evaluation, equivalent concentrations were assumed when no herbicide compound(s) (concentrations were less than the reporting limit) was detected in either of the paired samples. Actual differences in concentrations that are less than

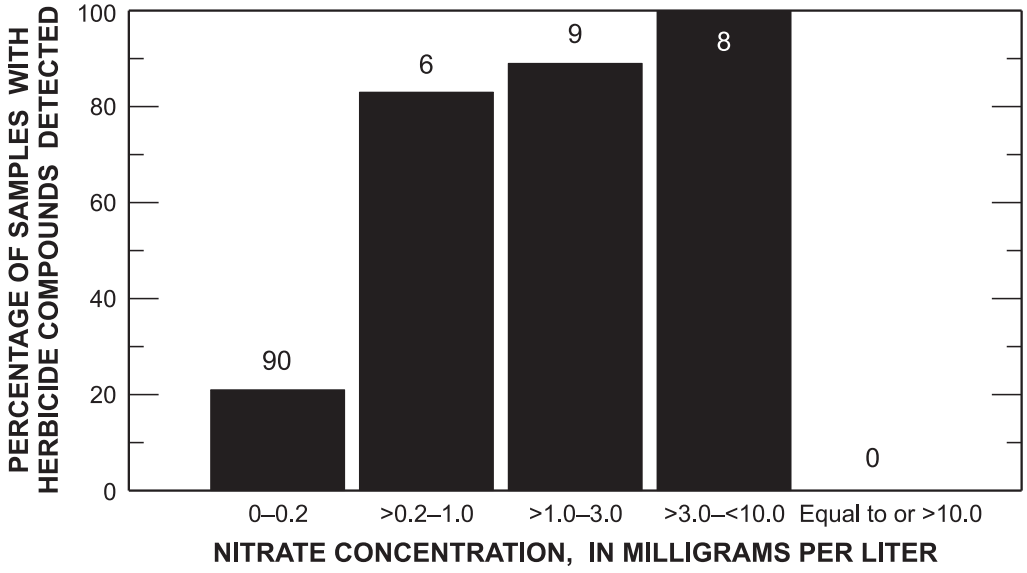

Figure 21. Relation of frequency of detection of herbicides and their transformation products in source-water aquifers in Illinois to concentrations of nitrate (as nitrogen), 2001-02 (>, greater than; <, less than; ≥, greater than or equal to; total number of samples in concentration interval is shown in and above bar).

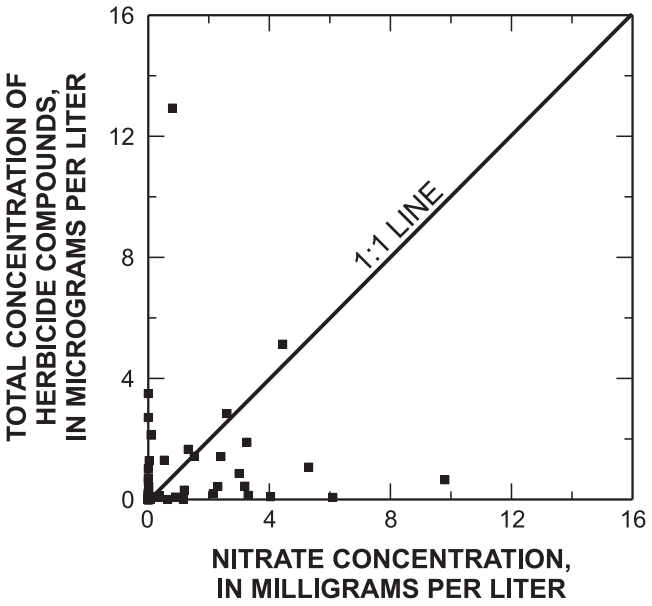

Figure 22. Relation of total concentration of herbicides and their transformation products in source-water aquifers in Illinois to concentration of nitrate (as nitrogen), 2001-02 (herbicide concentrations below the reporting limit of 0.05 microgram per liter are normalized to 0 microgram per liter; nitrate concentrations below the reporting limit of 0.10 milligram per liter are normalized to 0 milligram per liter).

the reporting limits used in this study (0.05 or 0.10 µg/L) can be ignored here because the concentrations would be substantially lower (more than an order of magnitude) than those of applicable Federal (U.S. Environmental Protection Agency, 2003b) or State (Illinois Pollution Control Board, 2003) drinking-water standards. These regulatory standards represent the benchmark for this evaluation. Concentrations that fall below the reporting limits used in this study are well below those of regulatory concern.

No particulates of any size were observed in the 117 water samples collected. However, clay-sized particulates were observed on the filter media of six samples, representing 5 percent of the samples (fig. 6; appendix 1). No difference in analytical results was recorded in 396 of 400 analyte pairs that resulted from analysis of up to 36 herbicide compounds in 13 samples (table 2; fig. 23). Glyphosate, AMPA, and glufosinate were not detected in the nine sample pairs that were analyzed; parent chloroacetanilides were not detected in the eight sample pairs. Triazine compounds were detected in only one of eight sample pairs. For the two detected compounds, the RPD was 0 in one analyte pair (atrazine) and -10 percent in the other (deethylatrazine, with a -0.02 µg/L difference in concentration between the unfiltered (0.19 µg/L) and filtered (0.21 µg/L) sample. Chloroacetanilide transfomation products were detected in only 2 of 11 sample pairs. For the two detected compounds (alachlor ESA and metolachlor ESA) in each sample pair, RPD's ranged from 0 to 18 percent, with no difference in concentration greater than 0.01 µg/L. The measured differences in concentrations were within the expected variability of the analytical methods (Zimmerman and Thurman, 1999; Zimmerman and others, 2000) and, therefore, unlikely to represent consequences of differing sample-collection methods. The statistical evaluation of the paired unfiltered and filtered samples supports this conclusion. There was no significant difference in the analytical results of the paired samples, as indicated by the results of the signed, Student's t, and Wilcoxon signed-ranks tests ($\rho = 0.62$, 0.71, and 0.88, respectively).

Although this initial evaluation of herbicide analytical results of unfiltered and filtered samples indicates that there is essentially no difference between resulting concentrations, some unresolved concerns remain regarding the comparative results. Concentrations of herbicide compounds in more than 99 percent of the

analyte pairs were below reporting limits, and of the few compounds that were detected, most of the measured concentrations were low (less than 0.25 µg/L, thus, an order of magnitude or more lower than typical MCL's for herbicides (table 1; appendix 1)). Additionally, comparative analyses were done on only two water samples from wells with observable particulates on the filter media. The evaluation of about 10 more unfiltered/filtered sample pairs (thus, representing about 20 percent of total field samples) could provide more conclusive results regarding the representativeness of unfiltered herbicide samples. Further evaluation of unfiltered/filtered sample pairs would benefit from pairs that represent (1) high herbicide-compound concentrations, as measured during the initial evaluation and (2) samples with visible particulates, including those from wells at which particulates previously were identified, but unfiltered samples were not collected (and, if possible, wells where particulates are identified for the first time during the additional sampling). Before the results of this evaluation are applied to uses other than regulation of herbicides in public-water supplies, the evaluation probably should be repeated using more sensitive laboratory analytical methods with lower reporting limits than those used in this evaluation.

Summary

During 2001-02, the U.S. Geological Survey, in cooperation with the Illinois Environmental Protection Agency, studied the occurrence and factors related to the distribution of herbicides and their transformation products (also referred to as degradates, metabolites, or breakdown products) in source-water aquifers tapped by the State's public-supply wells. Herbicides, used heavily in Illinois to control grass and weeds during production of corn and soybeans (row crops), have been detected in ground water in other studies in Illinois and the Midwestern States.

Ground-water samples were collected from 117 public-supply wells selected using a stratified-random method to ensure distributed representation of the major types of source-water aquifers (sand and gravel; Pennsylvanian to Cambrian bedrock) in the State. Samples were analyzed for 18 herbicides and 18 transformation products, including 3 triazine and 14 chloroacetanilide products. Eleven percent of the herbicide samples were collected unfiltered to determine if analytical results of unfiltered samples collected from public-supply wells are similar to the results of paired filtered samples and, thus, can be considered equally representative of herbicide concentrations in ground water supplied to the public.

Herbicide compounds (field-applied parent herbicides and their transformation products) were detected in 34 percent of all samples collected; only 4 percent of the samples contained residues of parent herbicides. The six most frequently detected herbicide compounds (from 6 to 28 percent of samples) were transformation products of the chloroacetanilides metolachlor, alachlor, and acetochlor. The frequent occurrence of transformation products and their higher concentration relative to those of most other parent herbicides confirm the importance of obtaining information on transformation products to understand the mobility and fate of herbicides in ground-water systems. No concentrations exceeded current (2003) Federal or State drinking-water standards; however, standards are established for only seven parent herbicides. In addition, the toxicity and aquatic effects of multiple herbicide compounds in water are not considered in the setting of standards.

Factors related to the occurrence of herbicide compounds in the State's source-water aquifers include unconsolidated and unconfined conditions, various hydrogeologic characteristics (top of aquifer, for example) and well-construction aspects (base of well casing, for example) at shallow depths, and proximity to streams. Generally, the closer an aquifer (or well location) is to a recharge area and (or) the stronger the hydraulic connection between an aquifer and a recharge area, the younger the ground water and the more vulnerable the aquifer will be to contamination by herbicide compounds. The weak relation ($r = -0.20$) between current (2001) statewide application rates of herbicides (in pounds) and current (2001-02) occurrence of herbicide compounds in source-water aquifers indicates that additional factors must be considered when relating herbicide-application rates to occurrence. These factors include historical application rates and the mobility and persistence of the various herbicide compounds in ground-water systems. Frequency of detection and concentrations of herbicides compounds in the State's source-water aquifers are indicated to be highest during the spring, when crops are planted and herbicides are primarily applied. Excess nitrate (concentrations

of nitrate, as nitrogen, higher than 3 mg/L) in ground water strongly indicates the co-occurrence of herbicide compounds. However, nitrate concentrations are not a reliable indicator of herbicide-compound concentrations. Concentrations of nitrate and total concentrations of herbicide compounds in samples were weakly to moderately related (r = 0.52). The strong inverse relation (r = -0.81) between current use of land for corn and soybean production and current occurrence of herbicide compounds in underlying aquifers indicates that various factors, along with current agricultural land use, contribute to herbicide occurrence. These factors include, among others, land-use history, ground-water age, ground-water-flow patterns, geology, soil microbiology, and chemistry and persistence of the herbicide compounds. Detection of agriculture-specific herbicide compounds in 71 percent of samples from urban areas with no current or recent agricultural land use near the sampled wells indicates that recharge to the high-capacity supply wells may originate at considerable distances (up to about 10 mi) from the wells. Essentially no difference was found between the analytical results for herbicides in paired unfiltered and filtered samples, although additional study of this issue is warranted. Further evaluation of unfiltered/filtered sample pairs would benefit from pairs that represent (1) high herbicide-compound concentrations, as measured during the initial evaluation and (2) samples with visible particulates, including those from wells at which particulates previously were identified, but unfiltered samples were not collected.

Awareness of the types of herbicides identified in large-scale studies, such as this study, and the factors that may be related to their occurrence can aid in determining the vulnerability of various source-water aquifers to herbicide contamination and result in more efficient strategies for sample collection. Sampling could be focused on herbicide compounds that likely are to be detected in ground water and on locations where potential for contamination is greatest.

* = Carcinogen

** = Mutagen

ATSDR = Agency for Toxic Substances and Disease Registry, U.S. Department of Health and Human Services.

CalEPA = Office of Environmental Health Hazard Assessment, California Environmental Protection Agency.

HNTAC = Human Nonthreshold Toxicant Advisory Concentration.

HNTAC - Mutagen = Human Nonthreshold Toxicant Advisory Concentration for Mutagens.

HTTAC = Human Threshold Toxicant Advisory Concentration.

IRIS = Integrated Risk Information System (National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency).

Irrigation = The standard is based on beneficial use for irrigation of crops, per “Water Quality Criteria”, by National Academy of Sciences.

LCMRL = Lowest Concentration Minimum Reporting Level, formerly termed "PQL".

LLOQ = Lower Limit of Quantitation, formerly termed "PQL".

Lead/Copper Rule = The standard is 50% of the U.S. EPA “action level” of 0.015 mg/L for lead. The U.S. EPA action level applies at the service connection. The standard is reduced by 50% as a safety margin, based on the assumption that 50% of water would be treated.

Livestock = The standard is based on beneficial use for watering livestock, per “Water Quality Criteria”, by National Academy of Sciences.

MAC = Maximum Allowable Concentration. The standard is promulgated at 35 Ill. Adm. Code 611.300.

MCL = The standard is based the Maximum Contaminant Level (“MCL”), promulgated by U.S. EPA, Office of Water, and Illinois EPA Primary Drinking Water Standards at 35 Ill. Adm. Code 611.

PPRTV = Provisional Peer-Reviewed Toxicity Value (Superfund Health Risk Technical Support Center, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency).

PQL = Practical Quantitation Limit.

U.S. EPA OW = United States Environmental Protection Agency Office of Water.

95% Confidence Value = The standard is the 95% confidence concentration stated in Illinois EPA's "Integrated Water Quality Report and Section 303(d) List".

Toxicological Review of Benzo[a]pyrene

Executive Summary

[CASRN 50-32-8]

January 2017

Integrated Risk Information System
National Center for Environmental Assessment
Office of Research and Development
U.S. Environmental Protection Agency
Washington, DC

EXECUTIVE SUMMARY

Summary of Occurrence and Health Effects

Benzo[a]pyrene is a five-ring polycyclic aromatic hydrocarbon (PAH). Benzo[a]pyrene (along with other PAHs) is released into the atmosphere as a component of smoke from forest fires, industrial processes, vehicle exhaust, cigarettes, and through the burning of fuel (such as wood, coal, and petroleum products). Oral exposure to benzo[a]pyrene can occur by eating certain food products, such as charred meats, where benzo[a]pyrene is formed during the cooking process, or by eating foods grown in areas contaminated with benzo[a]pyrene (from the air and soil). Dermal exposure may occur from contact with soils or materials that contain soot, tar, or crude petroleum products or by using certain pharmaceutical products containing coal tars, such as those used to treat the skin conditions, eczema and psoriasis. The magnitude of human exposure to benzo[a]pyrene and other PAHs depends on factors such as lifestyle (e.g., diet, tobacco smoking), occupation, and living conditions (e.g., urban versus rural setting, domestic heating, and cooking methods).

Animal studies demonstrate that exposure to benzo[a]pyrene is associated with developmental (including developmental neurotoxicity), reproductive, and immunological effects. In addition, epidemiology studies involving exposure to PAH mixtures have reported associations between internal biomarkers of exposure to benzo[a]pyrene (benzo[a]pyrene diol epoxide-DNA adducts) and adverse birth outcomes (including reduced birth weight, postnatal body weight, and head circumference), neurobehavioral effects, and decreased fertility.

Studies in multiple animal species demonstrate that benzo[a]pyrene is carcinogenic at multiple tumor sites (alimentary tract, liver, kidney, respiratory tract, pharynx, and skin) by all routes of exposure. In addition, there is strong evidence of carcinogenicity in occupations involving exposure to PAH mixtures containing benzo[a]pyrene, such as aluminum production, chimney sweeping, coal gasification, coal-tar distillation, coke production, iron and steel founding, and paving and roofing with coal tar pitch. An increasing number of occupational studies demonstrate a positive exposure-response relationship with cumulative benzo[a]pyrene exposure and lung cancer.

Effects Other Than Cancer Observed Following Oral Exposure

In animals, oral exposure to benzo[a]pyrene has been shown to result in developmental toxicity (including developmental neurotoxicity), reproductive toxicity, and immunotoxicity. Developmental effects in rats and mice include neurobehavioral changes and cardiovascular effects following gestational exposures. Reproductive and immune effects include decreased sperm counts, ovary weight, and follicle numbers, and decreased immunoglobulin and B cell numbers and thymus weight following oral exposures in adult animals. In humans, benzo[a]pyrene exposure occurs in conjunction with other PAHs and, as such, attributing the observed effects to

benzo[a]pyrene is complicated. However, some human studies report associations between particular health endpoints and internal measures of exposure, such as benzo[a]pyrene-deoxyribonucleic acid (DNA) adducts, or external measures of benzo[a]pyrene exposure. Overall, the human studies report developmental, neurobehavioral, reproductive, and immune effects that are generally analogous to those observed in animals, and provide qualitative, supportive evidence for hazards associated with benzo[a]pyrene exposure.

Oral Reference Dose (RfD) for Effects Other Than Cancer

Organ- or system-specific RfDs were derived for hazards associated with benzo[a]pyrene exposure where data were amenable (see Table ES-1). These organ- or system-specific reference values may be useful for subsequent cumulative risk assessments that consider the combined effect of multiple agents acting at a common site.

Developmental toxicity, represented by neurobehavioral changes persisting into adulthood, was chosen as the basis for the overall oral RfD as the available data indicate that developmental neurotoxicity represents the most sensitive hazard of benzo[a]pyrene exposure. The neurodevelopmental study by Chen et al. (2012) was used to derive the RfD. Altered responses in three behavioral tests (i.e., Morris water maze, elevated plus maze, and open field tests) were selected to represent the critical effect of abnormal behavior, due to the consistency (i.e., each of these responses were affected in two separate cohorts of rats, including testing as juveniles and as adults; similar effects in these behavioral tests were observed across studies) and sensitivity of these responses, and the observed dose-response relationship of effects across dose groups. Benchmark dose (BMD) modeling for each of the three endpoints resulted in $BMDL_{1SD}$ values that clustered in the range $0.092–0.16$ mg/kg-day. The lower end of this range of BMDLs, 0.092 mg/kg-day, was selected to represent the point of departure (POD) from these three endpoints for RfD derivation.

The overall RfD was calculated by dividing the POD for altered behavior in three tests of nervous system function by a composite uncertainty factor (UF) of 300 to account for the extrapolation from animals to humans (10), for interindividual differences in human susceptibility (10), and for deficiencies in the toxicity database (3).

Table ES-1. Organ/system-specific RfDs and overall RfD for benzo[a]pyrene

Effect	Basis	RfD (mg/kg-d)	Confidence
Developmental	Neurobehavioral changes Gavage neurodevelopmental study in rats (postnatal days [PNDs] 5–11) Chen et al. (2012)	3×10^{-4}	Medium
Reproductive	Decreased ovarian follicles and ovary weight Gavage subchronic (60 d) reproductive toxicity study in rats Xu et al. (2010)	4×10^{-4}	Medium
Immunological	Decreased thymus weight and serum IgM Gavage subchronic (35 d) study in rats De Jong et al. (1999) and Kroese et al. (2001)	2×10^{-3}	Low
Overall RfD	**Developmental toxicity (including developmental neurotoxicity)**	3×10^{-4}	**Medium**

Confidence in the Overall Oral RfD

The overall confidence in the RfD is medium. Confidence in the principal study (Chen et al., 2012) is medium. The design, conduct, and reporting of this neurodevelopmental study was good and a wide variety of neurotoxicity endpoints were measured across 40 litters of rats. However, some uncertainty exists regarding the authors' use of dam rotation across litters (an attempt to reduce potential nurturing bias) and a within-litter dosing design, by potentially introducing maternal stress or other unanticipated consequences in the pups, and some informative experimental details were omitted, including the sensitivity of some assays at the indicated developmental ages and lack of reporting of individual animal- or gender-specific data for all outcomes. Several subchronic and developmental studies covering a wide variety of endpoints are also available; however, a multigeneration toxicity study with exposure throughout development and across generations is not available, and the available neurotoxicity studies did not comprehensively evaluate all potentially vulnerable lifestages of nervous system development. Therefore, confidence in the database is medium.

Effects Other Than Cancer Observed Following Inhalation Exposure

In animals, inhalation exposure to benzo[a]pyrene has been shown to result in developmental and reproductive toxicity. Studies in rats following inhalation exposure show decreased embryo/fetal survival and nervous system effects in offspring, and decreased testes weight and sperm counts in adult animals. Overall, the available human PAH mixtures studies report developmental and reproductive effects that are generally analogous to those observed in animals, and provide qualitative, supportive evidence for the hazards associated with benzo[a]pyrene exposure.

Inhalation Reference Concentration (RfC) for Effects Other Than Cancer

An attempt was made to derive organ- or system-specific RfCs for hazards associated with benzo[a]pyrene exposure where data were amenable (see Table ES-2). These organ- or system-specific reference values may be useful for subsequent cumulative risk assessments that consider the combined effect of multiple agents acting at a common site.

Developmental toxicity, represented by decreased embryo/fetal survival, was chosen as the basis for the proposed inhalation RfC as the available data indicate that developmental effects represent a sensitive hazard of benzo[a]pyrene exposure. The developmental inhalation study in rats by Archibong et al. (2002) and the observed decreased embryo/fetal survival (i.e., increased resorptions) following exposure to benzo[a]pyrene on gestation days (GDs) 11–20 were used to derive the overall RfC. The lowest-observed-adverse-effect level (LOAEL) of 25 μg/m³ based on decreased embryo/fetal survival was selected as the POD. The LOAEL was adjusted to account for the discontinuous daily exposure to derive the POD_{ADJ} and the human equivalent concentration (HEC) was calculated from the POD_{ADJ} by multiplying by the regional deposited dose ratio ($RDDR_{ER}$) for extrarespiratory (i.e., systemic) effects, as described in *Methods for Derivation of Inhalation Reference Concentrations and Application of Inhalation Dosimetry* (U.S. EPA, 1994b). These adjustments resulted in a POD_{HEC} of 4.6 μg/m³, which was used as the POD for RfC derivation.

The RfC was calculated by dividing the POD by a composite UF of 3,000 to account for toxicodynamic differences between animals and humans (3), interindividual differences in human susceptibility (10), LOAEL-to-no-observed-adverse-effect level (NOAEL) extrapolation (10), and deficiencies in the toxicity database (10).

Table ES-2. Organ/system-specific RfCs and overall RfC for benzo[a]pyrene

Effect	Basis	RfC (mg/m³)	Confidence
Developmental	Decreased embryo/fetal survival Developmental toxicity study in rats (GDs 11–20) Archibong et al. (2002)	2×10^{-6}	Low-medium
Reproductive	Reduced ovulation rate and ovary weight Premating study in rats (14 d) Archibong et al. (2012)	3×10^{-6}	Low-medium
Overall RfC	**Developmental toxicity**	2×10^{-6}	Low-medium

Confidence in the Overall Inhalation RfC

The overall confidence in the RfC is low-to-medium. Confidence in the principal study (Archibong et al., 2002) is medium. The conduct and reporting of this developmental inhalation study were adequate; however, a NOAEL was not identified. Confidence in the database is low due to the lack of a multigeneration toxicity study and the lack of information on varied toxicity

endpoints following subchronic and chronic inhalation exposure. However, confidence in the RfC is bolstered by consistent systemic effects observed by the oral route (including reproductive and developmental effects) and similar effects observed in human populations exposed to PAH mixtures.

Evidence for Human Carcinogenicity

Under EPA's *Guidelines for Carcinogen Risk Assessment* (U.S. EPA, 2005a), benzo[a]pyrene is "carcinogenic to humans" based on strong and consistent evidence in animals and humans. The evidence includes an extensive number of studies demonstrating carcinogenicity in multiple animal species exposed via all routes of administration and increased cancer risks, particularly in the lung and skin, in humans exposed to different PAH mixtures containing benzo[a]pyrene. Mechanistic studies provide strong supporting evidence that links the metabolism of benzo[a]pyrene to DNA-reactive agents with key mutational events in genes that can lead to tumor development. These events include formation of specific DNA adducts and characteristic mutations in oncogenes and tumor suppressor genes that have been observed in humans exposed to PAH mixtures. This combination of human, animal, and mechanistic evidence provides the basis for characterizing benzo[a]pyrene as "carcinogenic to humans."

Quantitative Estimate of Carcinogenic Risk From Oral Exposure

Lifetime oral exposure to benzo[a]pyrene has been associated with forestomach, liver, oral cavity, jejunum or duodenum, and auditory canal tumors in male and female Wistar rats, forestomach tumors in male and female Sprague-Dawley rats, and forestomach, esophagus, tongue, and larynx tumors in female B6C3F_1 mice (male mice were not tested). Less-than-lifetime oral exposure to benzo[a]pyrene has also been associated with forestomach tumors in more than 10 additional bioassays with several strains of mice. The Kroese et al. (2001) and Beland and Culp (1998) studies were selected as the best available studies for dose-response analysis and extrapolation to lifetime cancer risk following oral exposure to benzo[a]pyrene. These studies included histological examinations for tumors in many different tissues, contained three exposure levels and controls, contained adequate numbers of animals per dose group (~50/sex/group), treated animals for up to 2 years, and included detailed reporting methods and results (including individual animal data).

Time-weighted average (TWA) daily doses were converted to human equivalent doses (HEDs) on the basis of (body weight [BW])$^{3/4}$ scaling (U.S. EPA, 1992). EPA then used the multistage-Weibull model for the derivation of the oral slope factor. This model was used because it incorporates the time at which death-with-tumor occurred and can account for differences in mortality observed between the exposure groups. Using linear extrapolation from the $BMDL_{10}$, human equivalent oral slope factors were derived for each gender/tumor site combination (slope factor = $0.1/BMDL_{10}$) reported by Kroese et al. (2001) and Beland and Culp (1998). The oral slope factor of **1 per mg/kg-day** based on the tumor response in the alimentary tract (forestomach,

esophagus, tongue, and larynx) of female B6C3F$_1$ mice (Beland and Culp, 1998) was selected as the factor with the highest value (most sensitive) among a range of slope factors derived.

Quantitative Estimate of Carcinogenic Risk From Inhalation Exposure

Inhalation exposure to benzo[a]pyrene has been associated with squamous cell neoplasia in the larynx, pharynx, trachea, nasal cavity, esophagus, and forestomach of male Syrian golden hamsters exposed for up to 130 weeks to benzo[a]pyrene condensed onto sodium chloride particles (Thyssen et al., 1981). Supportive evidence for the carcinogenicity of inhaled benzo[a]pyrene comes from additional studies with hamsters exposed to benzo[a]pyrene via intratracheal instillation. The Thyssen et al. (1981) bioassay represents the only study of lifetime exposure to inhaled benzo[a]pyrene.

A time-to-tumor dose-response model was fit to the TWA continuous exposure concentrations and the individual animal incidence data for the overall incidence of tumors in the upper respiratory tract or pharynx. The inhalation unit risk of $\mathbf{6 \times 10^{-4}\ per\ \mu g/m^3}$ was calculated by linear extrapolation (slope factor = $0.1/\text{BMCL}_{10}$) from a BMCL_{10} of $0.16\ \text{mg/m}^3$ for the occurrence of upper respiratory and upper digestive tract (forestomach) tumors in male hamsters chronically exposed by inhalation to benzo[a]pyrene (Thyssen et al., 1981).

Quantitative Estimate of Carcinogenic Risk From Dermal Exposure

Skin cancer in humans has been documented to result from occupational exposure to complex mixtures of PAHs including benzo[a]pyrene, such as coal tar, coal tar pitches, unrefined mineral oils, shale oils, and soot. In animal models, numerous dermal bioassays have demonstrated an increased incidence of skin tumors with increasing dermal exposure of benzo[a]pyrene in all species tested, although most benzo[a]pyrene bioassays have been conducted in mice.

Carcinogenicity studies in animals by the dermal route of exposure are available for benzo[a]pyrene and are supportive of the overall cancer hazard. A quantitative estimate of skin cancer risk from dermal exposure is not included in this assessment, as methodology for interspecies extrapolation of dermal toxicokinetics and carcinogenicity are still under development.

Susceptible Populations and Lifestages

Benzo[a]pyrene has been determined to be carcinogenic by a mutagenic mode of action in this assessment. According to the *Supplemental Guidance for Assessing Susceptibility from Early Life Exposure to Carcinogens* (U.S. EPA, 2005b), individuals exposed during early life to carcinogens with a mutagenic mode of action are assumed to have an increased risk for cancer. The oral slope factor of $1\ \text{per mg/kg-day}$ and inhalation unit risk of $0.0006\ \text{per } \mu\text{g/m}^3$, calculated from data applicable to adult exposures, do not reflect presumed early life susceptibility to this chemical. Although some chemical-specific data exist for benzo[a]pyrene that demonstrate increased early life susceptibility to cancer, these data were not considered sufficient to develop separate risk estimates for childhood exposure. In the absence of adequate chemical-specific data to evaluate differences in

age-specific susceptibility, the *Supplemental Guidance* (U.S. EPA, 2005b) recommends that age-dependent adjustment factors (ADAFs) be applied in estimating cancer risk. The ADAFs are 10- and 3-fold adjustments that are combined with age specific exposure estimates when estimating cancer risks from early life (<16 years of age) exposures to benzo[a]pyrene.

Regarding effects other than cancer, there are epidemiological studies that report associations between developmental effects (decreased postnatal growth, decreased head circumference, and neurodevelopmental delays), reproductive effects, and internal biomarkers of exposure to benzo[a]pyrene. Studies in animals also indicate alterations in neurological development and heightened susceptibility to reproductive effects following gestational or early postnatal exposure to benzo[a]pyrene. More preliminary data suggest that effects on cardiovascular, kidney, pulmonary, and immune system development may result from early life exposures, although few in vivo developmental studies exist to confirm these findings.

Key Issues Addressed in Assessment

The overall RfD and RfC were developed based on effects observed following exposure to benzo[a]pyrene during a critical window of development. The derivation of a general population toxicity value based on exposure during development has implications regarding the evaluation of populations exposed outside of the developmental period and the averaging of exposure to durations outside of the critical window of susceptibility. Discussion of these considerations is provided in Sections 2.1.5 and 2.2.5.

DISCLAIMER

This document has been reviewed in accordance with U.S. Environmental Protection Agency policy and approved for publication. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

PREFACE

The Office of Health and Environmental Assessment (OHEA) has prepared this Interim Guidance Document at the request of the Office of Emergency and Remedial Response. The purpose of this publication is to provide interim guidance for the quantitative risk assessment of polycyclic aromatic hydrocarbons (PAH).

For a more complete discussion of potential hazards from PAH exposure, the reader is referred to the 1992 Drinking Water Criteria Document for Polycyclic Aromatic Hydrocarbons (PAH). A literature search was not done in support of this short guidance document. A comprehensive, multimedia document for polycyclic aromatic hydrocarbons is in preparation by OHEA.

This document was prepared by Drs. Rita Schoeny and Ken Poirier, Environmental Criteria and Assessment Office, Cincinnati, OH and reviewed by Jeanette Wiltse, Office of Health and Environmental Assessment, and Drs. V. James Cogliano and Robert McGaughy, Human Health Assessment Group, OHEA, Washington, DC.

TABLE OF CONTENTS

LIST OF TABLES

INTRODUCTION

The Office of Health and Environmental Assessment (OHEA) recently completed an extensive document entitled "Drinking Water Criteria Document (DWCD) for Polycyclic Aromatic Hydrocarbons (PAHs)." In this document, weight-of-evidence judgments of Group B2, probable human carcinogen, are presented for seven PAHs; namely, benz[a]anthracene (BAA), benzo[b]fluoranthene (BBF), benzo[k]-fluoranthene (BKF), benzo[a]pyrene (BAP), chrysene (CHY), dibenz[a,h]anthracene (DBA), and indeno[1,2,3-cd]pyrene (IDP). All of these categorizations were found appropriate by the Carcinogen Risk Assessment Verification Endeavor (CRAVE), and files are available on the Agency's Integrated Risk Information System (IRIS) data base (U.S. EPA, 1993).

The 1986 Guidelines for Carcinogen Risk Assessment (U.S. EPA, 1986) support the calculation of quantitative risk estimates for those materials for which there is a reasonable concern for potential human health risk; for example, PAHs categorized as B2, probable human carcinogen. In the 1992 DWCD for PAHs, a quantitative risk estimate for oral exposure to BAP was given as a range of values from 4.5-9.0 per (mg/kg)/day with a geometric mean of 5.8 per (mg/kg)/day; the drinking water unit risk calculated from the mean was 1.7E-4 per (µg/L) (U.S. EPA, 1992).

NOTE: At the June 1992 meeting of the CRAVE a revised risk estimate was verified. It was noted that an error had been made in the 1991 document "Dose-Response Analysis of Ingested Benzo[a]pyrene" which is cited in the DWCD for PAHs. In the calculation of the doses in the Brune et al. (1981) study it was erroneously concluded that doses were given in units of mg/year, whereas it was in fact mg/kg/year. When the doses are corrected the slope factor is correctly calculated as 11.7 per (mg/kg)/day as opposed to 4.7 per (mg/kg)/day as reported in the DWCD. The correct range of slope factors is 4.5-11.7 per (mg/kg)/day with a geometric mean of 7.3 per (mg/kg)/day. A drinking water unit risk based on the revised slope factor is 2.1E-4 per (µg/L). These values are being changed on IRIS and an Erratum to the DWCD is being prepared.

Data were insufficient for the calculation of slope factors for any other PAHs discussed in the DWCD. While PAHs in general, and BAP in particular, are well-studied as carcinogens, data are by and large unsuitable for the calculation of quantitative risk estimates by conventional methods for one or more of the following reasons.

- Data were from exposures not typically used in deriving quantitative estimates for oral or inhalation exposure (e.g., skinpainting or subcutaneous exposure).
- Study populations were too small.
- Studies were done at only one exposure level.
- Dose-response data were not reported.

EPA quantitative risk estimates for mixtures of PAHs have often assumed that all carcinogenic PAHs are equipotent to BAP, and that the carcinogenic effect of the mixture can be estimated by the sum of the effects of each individual PAH (U.S. EPA, 1980). It has been recognized that some PAHs are less carcinogenic in animal studies than is BAP, so that application of this policy could result in an overestimation of the effect of those PAHs. On the other hand, PAH mixtures are likely to contain carcinogenic PAHs that are not considered indicator compounds and thus would not be measured. Some PAHs, moreover, have been shown to be more potent animal carcinogens than BAP.

This practice has been inconsistent; some risk assessments applied the BAP slope factor to all measured PAHs, rather than only those categorized as probable or possible human carcinogens. This would be expected to result in an overestimation of the mixture risk. Other risk assessments have used comparative potencies for PAHs published in the open literature, those cited in a contractor report to EPA (Clement Associates, 1988), or those based on ranking of PAHs presented in an Erratum to the Ambient Water Quality Criteria for PAHs (U.S. EPA, 1983).

This paper presents some comparative risk estimates for assessment of potentially carcinogenic PAHs. These are not proposed as toxicity equivalency factors

(TEF). A series of guiding criteria have been discussed for the application of a TEF to mixtures (U.S. EPA, 1991). They include the following:

1. A demonstrated need for the TEF. The PAHs meet this criterion. PAHs are found in all media; as a group they are among the most common contaminants at waste sites. PAHs are the subject of constant inquiry at the Superfund Technical Support Center. The lack of numerical estimates of risk for any PAH except BAP has had the potential for negative impacts on many risk-based regulatory decisions.
2. A well-defined group of chemicals. This criterion is also met. Any compound consisting of three or more fused aromatic rings qualifies as a PAH. At this time OHEA is limiting the definition to exclude all compounds with substituents on the ring or compounds with anything other than carbon and hydrogen in their composition. For purposes of this paper (and the Multimedia Document in preparation), only those PAHs classified as B2, probable human carcinogen, are being considered.
3. A broad base of toxicologic data. The data for PAHs are limited. Studies have, for the most part, been confined to carcinogenicity, genotoxicity and metabolism studies (generally concerned with the identification of metabolites that are genotoxic or carcinogenic). For this reason and others below, a weighting of potential potency is recommended only for carcinogenicity.
4. Consistency in the relative toxicity of congeners across toxicological endpoints, both *in vivo* and *in vitro*. As noted above there is not a broad toxicological data base. Consistency is observed among cancer bioassays in various animal models and by different routes. The point of congruency is in the generation of biologically active metabolites; if the PAH is administered to a system capable of "activating" metabolism, then tumors will be observed. If the site of administration is capable of metabolism (e.g., skin), contact point tumors will be observed. If the PAH can be absorbed and metabolized, then distant site tumors will also be observed. There are data which show that genotoxicity for individual PAHs and mixtures of PAHs are generally proportional to tumorigenicity. There are also

some limited data to indicate that immunotoxicity is roughly correlated with carcinogenic potency. Data for other noncancer effects are generally lacking but indicate that carcinogenicity is the most sensitive endpoint for PAH toxicity. The ranking of potential potency in this document is recommended only for PAH carcinogenicity.

5. Demonstrated additivity between the toxicity of individual congeners. Few studies have been reported which are an adequate test of an additivity assumption. In this regard the data bases for PAH, PCB congeners and dibenzo-p-dioxins and dibenzofurans are about of equal quality. Both additive and nonadditive effects have been observed for the carcinogenicity or genotoxicity of PAHs by various routes. Both inhibition and cocarcinogenicity have been observed for mixtures of PAHs; effects are dependent on route and proportion of materials and solvents (see U.S. EPA, 1992 for a review). It is logical to assume that in skin PAHs act as their own promoters; most B2, probable human carcinogens, in this group have been shown to be complete carcinogens in mouse skin. There have been few demonstrations that one PAH can serve as a promoter for a different PAH. According to the Guidelines for the Health Risk of Chemical Mixtures (U.S. EPA, 1986), ". . . none of the models for toxicant interactions can predict the magnitude of toxicant interactions in the absence of extensive data." The Guidelines make no recommendation as to the use of any risk model for promotion.
The guidelines further state the following:

> Based on current information, additivity assumptions are expected to yield generally neutral risk estimates (i.e., neither conservative nor lenient) and are plausible for component compounds that induce similar types of effects at the same sites of action (U.S. EPA, 1986).

A National Research Council Report (NRC, 1988) notes that a consideration of the mathematical considerations of low-dose extrapolation shows that interactions which are demonstrable at high doses will not be detectable at low doses. All of the above indicates that the use of an additivity assumption for PAHs is not

contraindicated and is consistent with the practice of the Risk Assessment Guidelines.

6. Some mechanistic rationale as to why TEFs would be applicable to a particular group of chemicals. This criterion is met for PAHs assuming that one accepts the hypothesis that mutation or some DNA change is a necessary step in carcinogenesis. All the PAHs for which ranking of potential potency is proposed can be shown both to induce tumors in animals and genetic changes (generally mutations) in some systems.
7. Some method of gaining consensus as to what TEFs ought to be. This process has not yet been undertaken for PAHs. The proposed ranking of potential potency was developed by a small group of OHEA scientists and has received only OHEA review.

In summary, not all of the guiding criteria are met for TEF. For this reason OHEA has chosen not to label the risk assessment numbers in this document a "toxicity equivalency factor" but rather an "estimated order of potential potency." It should be recognized in the application of these risk estimates that there are many limitations. First, these risk estimates are applicable only to cancer evaluation. Second, additivity of PAH response has not been proved (or refuted). Last, the estimated order of potential potency described herein is an OHEA interim recommendation and does not constitute an Agency consensus.

ESTIMATED ORDERING OF POTENTIAL POTENCIES OF PAHS

In studies of rodents, wherein BAP was assayed for carcinogenicity in conjunction with other PAHs, a range of carcinogenic potencies were observed. For example, as seen in Table 1, several PAHs were less effective in tumor induction in a mouse lung adenoma assay than was BAP at smaller or equivalent doses (LaVoie et al., 1987). Likewise, ranges of potency have been observed in many species and by different routes; for example, intrapulmonary injection in rat lungs (Table 2) and skin painting in mice (Table 3).

Inspection of these data suggest that one should be able to estimate orders of potential carcinogenic potencies for various PAHs by comparison with the activity of a standard compound. If BAP is used as the standard, then estimates of individual slope factors could be done as a percentage of the calculated slope factor for BAP. This approach could be applied to estimating the amounts of group B2 (probable human carcinogen) PAHs in a particular exposure situation and calculating their weighted contribution (by comparison to BAP) to total carcinogenic activity of the mixture.

The choice of the data set or sets to be used for estimating the potency is important, as is the modeling procedure used to provide estimates of carcinogenic activity. A discussion of various approaches is given in the DWCD (U.S. EPA, 1992).

Previous work attempted to derive relative potencies for PAHs. One derivation was done by T. Thorslund of ICF-Clement Associates on contract to U.S. EPA. An interim report (Clement Associates, 1988) is described in some detail in U.S. EPA (1992). In this report data were used from studies wherein BAP and several other PAHs were administered in the same time frame by routes including skin painting, intraperitoneal or subcutaneous injection, and lung implantation. For each study considered, a comparison was made between BAP carcinogenic activity and the activity of a particular PAH in that same report.

Two forms of dose-response models were used: either $P(d) = 1-\exp[-a(1+bd)]$; or $P(d) = 1-\exp[-a(1+bd)^2]$, where a and b are background and exposure-related parameters, respectively (Clement Associates, 1988). The first equation is simply a one-hit model, which is a special case (one-stage) of the multistage model. The second equation is a special case of the multistage model with two stages and an additional assumption that the first and second transition rates are identical relative to their respective background rates. In the application of these models it was assumed that carcinomas can develop from papillomas. For studies which reported only combined tumors or did not classify tumors, the simple form, or one-stage model was used. The two-stage model was used for data in which malignant tumors were reported separately.

In deriving the potency for each PAH relative to BAP, it was assumed that the PAHs and BAP have similar dose-response curves, but that it takes a proportionally

larger concentration of non-BAP material to induce an equivalent tumor response. The relative potency of each PAH was calculated as the ratio of the estimated transition rates with the potency of BAP indexed as 1. Point estimates (maximum likelihood estimates) were compared rather than upper bounds. An example of relative potencies from one data set is given in Table 4. In this and all subsequent tables, transition rates and relative potencies for PAHs are given as reported in Clement Associates (1988). This is to allow the reader to follow derivation of the numbers; it is acknowledged that the number of significant figures is a reflection only of the precision of numerical calculations and does not accurately transmit the degree of experimental uncertainty.

The result of all calculations based on 11 separate studies is a range of comparative potencies; the ranges reported in Clement Associates (1988) for PAHs classified as B2, probable human carcinogen, are given in Table 5.

Clement Associates (1988) selected what they considered to be the most appropriate relative potency for each PAH based on a consideration of qualitative differences in studies. Their selections are presented in Table 6. It should be noted that the application of study selection criteria other than those described in the Clement Associates (1988) report could result in the selection of different "most appropriate" relative potencies. In this context, a peer review panel convened in 1988 to review the DWCD on PAHs and felt that potencies based on the Deutsch-Wenzel et al. (1983) study would be less reliable than those based on other bioassays because of the unusual route of exposure (surgical implantation of wax pellets in the lung). Arguments for the validity of this exposure method have also been presented, however.

Other approaches for obtaining a single estimate of relative potency are feasible; for example, taking a mean, a weighted mean, or some other measure of central tendency of the individual estimates comprising the range. Calculated means are given in Table 7 as well as order of magnitude potencies based on the following rounding scheme: 0.51-5.0 = 1.0; 0.051-0.50 = 0.1; 0.0051-0.050 = 0.01.

The approach chosen here was to select a test system that provides a complete set of comparisons. Of the data sets modeled in Clement 1988, mouse skin painting

bioassays wherein PAHs were tested as complete carcinogens rather than as initiators only, meets this criterion. This data set is compiled from four reports with standard study protocols, using adequate numbers of test animals (20-36). These studies are not without deficiencies. For example, neither the Bingham and Falk (1969) paper nor Wynder and Hoffmann (1959) reported solvent control tumor incidences. Estimated orders of potential potencies based on skin painting tests as reported by Clement (1988) are given in Table 8. These are rounded to orders of magnitude using the rule presented above.

The values in Table 8 are recommended for interim use. They are based on well conducted studies using a standard, easily comparable endpoint well-known to be associated with exposure to PAHs; namely, complete carcinogenesis after repeated exposure to mouse skin. The potencies of PAH for comparison were calculated by Clement Associates (1988) using both forms of the model (one and two stages as indicated in Table 8). For this exercise no claim as to biological relevance is made for the modeling procedure; rather, it represents a convenient curve-fitting procedure, based on plausible assumptions. It is recommended that only the order of magnitude ranking be used. The quality of the data and the analysis thereof do not support any greater precision.

CONCLUSIONS

The values in Table 8 are provided for interim use. Research on relative potencies for PAHs and on the development of a TEF methodology is being undertaken by OHEA and other parts of the Agency. Areas of research include: the assumption of additivity of carcinogenic activity of PAHs; the basis for choice of studies and data sets; and the choice of modeling procedures.

In summary, a series of relative potency values (orders of magnitude) is provided as temporary guidance for the risk evaluation of PAHs. It is recognized that the list of PAHs in Table 8 is not sufficiently extensive to meet the needs of Programs and Regions; part of the continuing work on PAHs will be the consideration of the expert panel approach of ranking PAH hazards undertaken by OERR. Also in progress is

work to expand the series to include PAH for which there are animal carcinogenicity studies that did not include BAP as a positive control.

The guidance in this paper should be applied only to assessment of carcinogenic hazard from oral exposure to PAHs. There is currently no inhalation unit risk for BAP that has been found acceptable by the CRAVE. At this time, there is no basis for judgment that BAP or other PAHs will be equipotent by oral and inhalation routes. The documented effects of particulate matter and other cocarcinogens on BAP carcinogenic effects in animal lungs are confounding issues for the derivation of an inhalation unit risk for BAP and the establishment of potencies for inhalation vs. oral exposure to other PAHs.

In order to apply this guidance of relative potencies to mixtures, empirical data are needed on the additivity (or lack thereof) of carcinogenic effects of PAHs. Results of testing simple mixtures of PAHs and mixture components must be compared to assessments made from bioassays of complex environmental mixtures. Research of this nature is being undertaken by the U.S. EPA Health Effects Research Laboratory and by several research groups under contract to the Electrical Power Research Institute.

TABLE 1

Incidence of Lung Adenomas Observed in Newborn Mice for Various PAHs[a]

Treatment	Total Dose (umol)	Lung Adenomas	
		Incidence	% Response
Control[b]	0	0/35	0
Benzo[a]pyrene	1.1	23/31	74.2
Benzo[b]fluoranthene	0.5	5/32	15.6
Benzo[j]fluoranthene	1.1	15/39	38.5
Benzo[k]fluoranthene	2.1	4/34	11.8
Indeno[1,2,3-cd]pyrene	2.1	1/20	5.0

TECHNICAL SUPPORT DOCUMENT FOR CANCER POTENCY FACTORS

APPENDIX B.

Chemical-specific summaries of the information used to derive unit risk and cancer potency values.

ACETALDEHYDE

CAS No: 75-07-0

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1998)

Molecular weight	44.05
Boiling point	20.5° C
Vapor pressure	740 mm
Conversion factor	1 ppm = 1.8 mg/m^3

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor	2.7 E-6 $(\mu g/m^3)^{-1}$
Slope Factor	1.0 E-2 $(mg/kg\text{-}day)^{-1}$

[Calculated from rat nasal tumor incidence data (Wouterson *et al.*, 1986) by OEHHA (1993) using a linearized, time-dependent multistage procedure.]

III. CARCINOGENIC EFFECTS

Human Studies

Bittersohl (1974) conducted a morbidity survey to study the incidence of total cancer in an aldol and aliphatic aldehyde factory in the German Democratic Republic (GDR). The work force in this factory was potentially exposed to a product primarily consisting of acetaldol (70)% combined with smaller, but variable, amounts of acetaldehyde; butylaldehyde; crotonaldehyde; "large" condensed aldehydes such as hexatrial, hexatetral, and ethylhexal; traces of acrolein; and 20 to 22% water. The observation period extended from 1967 to 1972. The study cohort consisted of 220 people, approximately 150 were employed for more than 20 years. Acetaldehyde concentrations were found to range from 0.56 to 1 ppm.

Nine cases of cancer (five squamous cell carcinomas of the bronchi, two squamous cell carcinomas of the mouth cavity, one adenocarcinoma of the stomach, and one adenocarcinoma of the cecum) were identified in male workers during the 6-year study period. An incidence rate of 6,000 per 100,000 population (9 cases/150 individuals employed for more than 20 years) for total cancer was calculated for this study cohort, compared to 1,200 per 100,000 in the general population. All cases had a history of smoking.

This study had the following major methodological limitations: the incidence rate was not age adjusted; concurrent exposure to other chemicals and cigarette smoke occurred; duration of exposure was short; a small number of subjects was studied; and information on subject selection, age, and sex distribution was lacking. Because of the limitations, the International Agency for Research on Cancer (IARC, 1985) considered this study to be inadequate to evaluate the carcinogenicity of acetaldehyde.

Animal Studies

Rats

Woutersen *et al.* (1984, 1986) exposed groups of 105 male and female SPF-Wistar rats to atmospheres containing acetaldehyde concentrations of 0, 750, 1500, or 3000/1000 ppm (0, 1350, 2700 or 5400/1800 mg/m^3, respectively), 6 hours/day, 5 days/week for up to 28 months. The highest concentration was gradually decreased from 3000 ppm (days 0 to 141) to 1000 ppm (from day 313 forward) because of severe growth retardation, loss of body weight, and early mortality.

Treatment-related nonneoplastic histopathological lesions were observed in the nose, larynx, and lungs, with the most severe lesions seen in the nose and in the vocal cord region of the larynx. Nasal tumors observed were mainly squamous cell carcinomas and adenocarcinomas originating from the respiratory and olfactory epithelium, respectively. Tumor incidences are listed in Table 1. The incidences of adenocarcinomas were significantly ($p < 0.01$) higher in both sexes of rats at all exposure concentrations when compared to controls. Squamous cell carcinomas were significantly ($p < 0.01$) increased in males in the mid- and high-dose groups and in females in the high-dose group. No laryngeal or lung tumors were seen in male rats and tumors observed in the other organs of treated rats were comparable to those in the controls. The presence of nasal tumors at all exposure levels suggested that the latency period for nasal tumor induction was independent of the acetaldehyde concentration. The authors concluded that under the conditions of this study, acetaldehyde was carcinogenic to the nasal mucosa of rats.

Table 1: Nasal tumor incidence in male and female Wistar rats exposed to acetaldehyde by inhalation (Woutersen *et al.*, 1986)

Sex	Exposure Concentration (ppm)	Nasal Tumor Incidence
males	0	1/49
	750	17/52
	1500	41/53
females	0	0/50
	750	6/48
	1500	36/53

In an extension of the above study, Woutersen and Feron (1987) examined the process of regeneration of damaged nasal mucosa in rats exposed to acetaldehyde at concentrations as described above for 52 weeks. Animals were sacrificed after a recovery period of 26 weeks. The number of nasal tumors observed was almost the same as in the lifetime study, which indicated that proliferative epithelial lesions of the nose may develop into tumors even without continued acetaldehyde exposure.

Hamsters

Feron *et al.* (1982) exposed groups of male and female Syrian golden hamsters to room air (0 ppm) or to decreasing concentrations of acetaldehyde. The initial concentration was 2500 ppm (4500 mg/m^3), which was gradually decreased (between weeks 9 and 44) to 1650 ppm (2970 mg/m^3) 6 hours/day, 5 days/week for 52 weeks. Acetaldehyde-induced nonneoplastic lesions were seen in the nose, larynx, and trachea. Tumors were seen in both the nose (adenoma, adenocarcinoma, and anaplastic carcinoma) and the larynx (carcinoma *in situ*, squamous cell carcinoma, and adenosquamous carcinoma). The tumor incidences were 2/27 (7%) and 6/23 (26%) in males and 1/26 (4%) and 4/26 (20%) in females for the nose and larynx, respectively; no nasal or laryngeal tumors were observed in the controls. Only the increases in laryngeal tumors were statistically significant ($p < 0.05$) compared to controls. Under the conditions of this study, acetaldehyde was considered to be carcinogenic in male and female hamsters.

In a second part of the above study (Feron, 1979), groups of male Syrian golden hamsters were exposed by inhalation to 0 or 1500 ppm (2700 mg/m^3) acetaldehyde vapor 7 hours/day, 5 days/week for 52 weeks. The animals also received a concurrent, weekly intratracheal instillation of 0, 0.625, 0.125, 0.225, 0.5, or 1 mg benzo[a]pyrene (BaP) in saline for the same duration. Simultaneous exposure to acetaldehyde and BaP induced marked nonneoplastic lesions in the nasal cavity and trachea which disappeared after the 26-week recovery period. No respiratory tract tumors were seen in hamsters exposed to acetaldehyde alone. Various types of benign and malignant respiratory tract tumors were found in male hamsters treated with BaP or BaP plus acetaldehyde. The results of this study indicated no evidence for carcinogenicity of acetaldehyde and limited evidence of co-carcinogenicity. This study had a number of methodological limitations such as the exposure level exceeding the maximum tolerated dose (MTD).

Feron *et al.* (1982) repeated the above study using male and female Syrian golden hamsters. Some of the animals were also treated with subcutaneous injections of 0.0625% diethylnitrosamine (DENA) once every 3 weeks. The enhancing effect of BaP-initiated respiratory tract tumor formation observed in this study was similar to that observed in the previous study (Feron, 1979). There was no evidence that acetaldehyde exposure increased the incidence or affected the type of DENA-induced tumors in any part of the respiratory tract. Based upon these findings, the authors concluded: "acetaldehyde is an irritant as well as a carcinogen to the nose and larynx with a weak initiating and a strong 'promoting' (co-carcinogenic) activity."

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The IARC concluded that there is inadequate evidence in humans and sufficient evidence in experimental animals for the carcinogenicity of acetaldehyde (IARC, 1985). Therefore IARC classified acetaldehyde as class 2B, a possible human carcinogen. The U.S. EPA, using the guidelines for Carcinogen Risk Assessment, has classified acetaldehyde as a Group B2 probable human carcinogen, based on sufficient evidence of carcinogenicity in animals and inadequate evidence in humans (IRIS, 1997). OEHHA staff concurred that acetaldehyde is a potential human carcinogen.

OEHHA staff have used the rat nasal tumor data from the Woutersen *et al.* (1986) inhalation study and hamster laryngeal tumor data from the Feron *et al.* (1982) inhalation study to assess the cancer potency with the multistage model. Acetaldehyde tumors occurred in the nasal area for rats and in the larynx for hamsters. While it is assumed that the respiratory tract is the only organ affected by acetaldehyde, tumors in the nose in rats and in the upper larynx of hamsters do not directly mean that only tumors in the nose or larynx would occur in humans. Unlike the rodents, humans are not obligate nose breathers. Thus, the entire human respiratory tract, including the lung, may be at risk for cancer induction by acetaldehyde.

Methodology

Data from the Woutersen *et al.* (1986) inhalation study were used to calculate cancer risk from the male and female rat nasal carcinoma incidence. Three types of nasal tumors were observed: squamous cell carcinomas, adenocarcinomas, and carcinomas *in situ*. OEHHA staff used only 49-53 (out of 55) animals of each group that were examined for nasal changes in the quantitative risk assessment. Doses were converted to an equivalent continuous dose (US EPA, 1987; IRIS, 1997), because the animals were exposed for only 6 hours/day, 5 days/week. Because of the excessive morbidity with the animals exposed at the highest concentration (3000 ppm) and the eventual lowering of the concentration to 1000 ppm, data from this group were not used in deriving the cancer potency.

Using the computer program GLOBAL86 (Howe *et al.*, 1986), a linearized, time-independent multistage procedure was fit to the nasal carcinoma dose-response data. The male rat nasal tumor data yielded a maximum likelihood estimate (MLE) for q_1 of 1.6×10^{-8} ppb^{-1}, and an Upper 95% Confidence Limit (UCL) on q_1 (q_1*) of 3.2×10^{-6} ppb^{-1}. The female rat data yielded a somewhat lower risk with a q_1* equal to 9.3×10^{-7} ppb^{-1}. For acetaldehyde, 1 ppb = 1.8 $\mu g/m^3$. Using the latter units, the MLE for q_1 equals 8.8×10^{-9} $(\mu g/m^3)^{-1}$ and the 95% UCL for q_1 (q_1*) equals 1.8×10^{-6} $(\mu g/m^3)^{-1}$ for the male rat data.

The following scaling factors are used for scaling from animals to humans: 1.5 for the 400 g male rat and 1.6 for the 250 g female rat, assuming 70 kg body weight for both human sexes. Using these scaling factors, risk values of 1.6×10^{-6} ppb^{-1} from female rat data and 4.8×10^{-6} ppb^{-1} from male rat data were obtained.

For rat nasal carcinomas, contact scaling factors were obtained: 5.6 for a 400 g male rat and 6.5 for a 250 g female rat, again assuming both human sexes have 70 kg body mass. The resultant risks of 6.3×10^{-6} ppb^{-1} for female rats and 2.7×10^{-5} ppb^{-1} for male rats would be used only to predict nasal or respiratory system cancers.

In the case of acetaldehyde, a best value of 2.7×10^{-6} $(\mu g/m^3)^{-1}$ (4.8×10^{-6} ppb^{-1}) was chosen from the range. The value was obtained from the male rat (more sensitive to tumor induction than the female rat) data using an interspecies surface area correction factor of body weight to the 2/3 power.

ACETAMIDE

CAS No: 60-35-5

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1994)

Molecular weight	59.07
Boiling point	222 °C
Melting point	81 °C
Vapor pressure	not available
Air concentration conversion	1 ppm = 2.416 mg/m^3

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 2.0 E-5 $(\mu g/m^3)^{-1}$
Slope Factor: 7.0 E-2 $(mg/kg\text{-}day)^{-1}$
[Male Fischer 344 rat liver tumor data (Fleischman *et* al., 1980), contained in Gold *et al.* database (1990), expedited Proposition 65 methodology (Cal/EPA, 1992), cross-route extrapolation.]

III. CARCINOGENIC EFFECTS

Human Studies

No studies on the potential carcinogenic effects of acetamide on humans are known to exist.

Animal Studies

Dessau and Jackson (1955) exposed 5 Rockland albino rats to acetamide by gavage (4 g/kg body weight/day in distilled water) for 205 days. One animal developed an hepatocellular adenoma.

Male Wistar rats (25/group) were fed diet containing 0, 1.25, 2.5 or 5% acetamide for 1 year (Jackson and Dessau, 1961). One rat/group was sacrificed at monthly intervals; the remaining animals were sacrificed at 1 year. Liver tumors (described as trabecular carcinomas or adenocarcinomas) were seen in 0/25, 4/24, 6/22 and 1/18 animals from the control, low, medium and high dose groups. In the same study, a group of 50 male Wistar rats were fed a diet containing 5% acetamide for 1 year. One animal was killed weekly for 26 weeks, after which 1 animal was killed every other week. Liver tumors (trabecular carcinomas or adenocarcinomas) were observed in 4/48 animals treated for 38-42 weeks, compared to 0/43 in controls.

Male Wistar rats were fed control diet (15 animals), or diets containing 2.5% acetamide (40 animals), 2.5% acetamide + 5.6% L-arginine L-glutamate (40 animals), or 5.6% L-arginine L-glutamate (15 animals) for 1 year. Hepatomas were observed in 2/8 animals fed acetamide alone and killed after 1 year; 7/16 animals fed acetamide alone for 1 year followed by control diet for 3 months also developed liver tumors. In contrast, 1/11 animals fed diet containing acetamide + L-arginine L-glutamate for 1 year developed hepatomas, and 1/19 animals fed diet containing

acetamide + L-arginine L-glutamate for 1 year followed by control diet for 3 months developed hyperplastic liver nodules, but not tumors. No liver tumors were noted in either the control or 5.6% L-arginine L-glutamate treatment groups (Weisburger *et al.*, 1969).

Fleischman *et al.*(1980) fed male and female C57BL/6 mice (50/sex/group) and Fischer 344 rats (50/sex/group) a diet containing 1.18% (mice) or 2.36% (mice, rats) acetamide for 365 consecutive days; animals were then fed a control diet for an additional 4 months. Male mice demonstrated a treatment-related increase in hematopoietic tumors, primarily malignant lymphomas; tumor incidence was 7/50 and 7/46 for the low and high dose groups, respectively, compared to 0/95 for the pooled (male and female) control group. Neoplastic nodules and hepatocellular carcinomas were observed in both male and female rats. However, the incidence, speed of onset and frequency of metastases were greater in males (Fleischman *et al.*, 1980). No liver tumors were noted in control animals. Incidence data for hepatocellular carcinomas in F344 rats, the most sensitive species tested, are given in Table 1.

Table 1: Incidence of hepatocellular carcinomas in F344 rats treated with acetamide by dietary administration (Fleischman *et al.*, 1980).

Dietary Concentration (%)	Average Dose[1] (mg/kg-day)	Tumor Incidence[2]	
		Male	Female
0	0	0/50	0/49
2.36	710	41/47	33/48

1. Doses as reported by Gold *et al*. (1984).

2. Decreased survival of treatment group according to Gold *et al.* (1990) (56% survival at study termination compared to 86% for controls); potency may be an underestimate (Cal/EPA, 1992).

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The carcinogenicity bioassay by Fleischman *et al*. (1980) indicated that acetamide causes hematopoietic tumors in male C57BL/6 mice, and hepatocellular carcinomas in male and female Fischer 344 rats. Rats were more sensitive than mice, and male rats were more sensitive than female rats in this study; therefore, the male Fischer 344 rat liver tumor data was used as the basis of a cancer potency factor.

Methodology

Expedited Proposition 65 methodology (with cross-route extrapolation) was used to derive a cancer potency factor. A unit risk factor was then calculated by OEHHA/ATES from the cancer potency factor using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

Melting point	84.5
Vapor pressure	0.007 mm Hg at 25°C
Air concentration conversion	1 ppm = 2.91 mg/m^3

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 1.3 E-3 $(\mu g/m^3)^{-1}$
Slope Factor: 4.5 E+0 $(mg/kg\text{-}day)^{-1}$
[Calculated by US EPA/IRIS (1988, 1993) from female Fischer 344 rat tumor data (central nervous system, mammary and thyroid glands, uterus, oral cavity) (Johnson *et al*., 1986) using a linearized multistage procedure, extra risk; adopted by CDHS/RCHAS (1990).]

III. CARCINOGENIC EFFECTS

Human Studies

US EPA (1993) reviewed a study of cancer mortality in workers exposed to acrylamide by Collins (1984). Data from a long duration exposure group (10 individuals) and a short duration/intermittent exposure group (52 individuals) was analyzed using a standardized proportional mortality ratio (SPMR) procedure. No excess mortality for all types of cancer combined was noted in either group. Mortality from lung and central nervous system cancer appeared to be slightly elevated. However, the SPMRs were not significantly different from expected values, due to small group size. US EPA (1993) also noted additional study limitations including underrepresentation of the potential at-risk worker population, incomplete cause of death ascertainment, and incomplete exposure data.

Sobel *et al*. (1986) studied the mortality experience of 371 workers (365 white males, 6 white females) employed in acrylamide monomer production and polymerization operations at the Michigan Division of the Dow Chemical Company from 1955 through 1979. Vital status followup was performed from the date of the first potential exposure to December 31, 1982. Mortality comparisons were made between the cohort and United States white male mortality rates; comparisons were made with a subcohort of workers previously exposed to organic dyes both included and excluded. Slight excesses of mortality from all cancers (11 observed/7.9 expected), digestive tract cancer (4 observed/1.9 expected) and respiratory tract cancer (4 observed/2.9 expected) were observed in the total cohort; these excesses were not observed when the organic dye exposure subcohort was excluded. The authors concluded that the study did not support a relationship between acrylamide exposure and general or specific cancer mortality. However, US EPA (1988) considers this study insufficient to assess the carcinogenicity of acrylamide in humans

because of small cohort size, multiple chemical exposures, limited followup, and short exposure duration (167 cohort members had < 1 year of employment; 109 had 1-4 years of employment).

Animal Studies

Bull *et al*. (1984a) exposed female Sencar mice and male and female A/J mice to acrylamide. Female Sencar mice (40/treatment group) were exposed to 0, 12.5, 25.0 or 50.0 mg/kg body weight acrylamide by gavage, intraperitoneal injection or dermal application. Doses were administered 6 times over a 2 week period; total doses were 0, 75, 150 and 300 mg/kg. Acrylamide was dissolved in distilled water for gavage and intraperitoneal injection administration, and in ethanol for dermal application. Two weeks after the cessation of acrylamide exposure, 1.0 µg 12-*O*-tetradecanoyl-phenol-13-acetate (TPA) dissolved in 0.2 ml acetone was applied to the shaved back of each animal 3 times/week for 20 weeks. A promotion control group was included which received 300 mg/kg acrylamide followed by dermal applications of 0.2 ml acetone on the same treatment schedule and duration as the animals receiving TPA. All animals were sacrificed at 52 weeks, and were evaluated for the presence of skin tumors. Male and female A/J mouse (40/sex/treatment group) acrylamide exposures were conducted at laboratories of the US EPA (Cincinnati, OH) and the Medical College of Ohio (Toledo, OH) (MCO) . Animals exposed at US EPA received acrylamide dissolved in distilled water by gavage 3 times/week for 8 weeks at doses of 0, 6.25, 12.5 or 25 mg/kg. Animals exposed at MCO initially received acrylamide by intraperitoneal injection 3 times/week for 8 weeks at doses of 0, 1, 3, 10, 30 or 60 mg/kg; however, peripheral neuropathy and decreased survival forced treatment termination on the 60 mg/kg group after the 11th injection. An untreated control group was also included. Animals were sacrificed after either 7 months (US EPA) or 6 months (MCO) and examined for lung adenomas. Acrylamide induced skin tumors (squamous cell papillomas and carcinomas) in TPA-promoted female Sencar mice in a dose-dependent manner when administered by gavage, intraperitoneal injection or dermal application. Acrylamide did not induce skin tumors by any route of administration in animals not receiving TPA. Tumor incidence data from female Sencar mice exposed to acrylamide are listed in Table 1.

The incidence of lung adenomas in both male and female A/J mice exposed to acrylamide by either gavage or intraperitoneal injection was significantly increased in a dose-related manner (Bull *et al*., 1984a). Tumor incidence data for animals treated by intraperitoneal injection is listed in Table 2; numerical tumor incidence data for animals exposed to acrylamide by gavage was not listed.

Acrylamide dissolved in water was administered by gavage (0, 75, 150 or 200 mg/kg body weight, divided into 6 equal portions) to female ICR-Swiss mice (40 animals/treatment group) over a 2 week period (Bull *et al*., 1984b). Two weeks after the last acrylamide exposure, the animals were exposed 3 times/week to dermal applications of 2.5 µg TPA for 20 weeks. Another group of 20 animals were exposed to a total dose of 300 mg/kg acrylamide, but received dermal applications of acetone alone. All animals were sacrificed after 52 weeks. Acrylamide caused a significant dose-related increase in the incidence of skin tumors (papillomas and carcinomas combined). The incidence in animals also receiving TPA was 0/35, 4/34, 4/32 and 13/32 (number of animals with tumors/number of animals examined) for the control, low, mid and high dose groups, respectively; the skin tumor incidence in animals receiving 300 mg/kg acrylamide but not TPA was 10/36. Acrylamide-treated animals also demonstrated a significant dose-related increase in the incidence

of lung tumors (alveolar and bronchiolar adenomas and carcinomas). The incidence in animals also receiving TPA was 4/36, 8/34, 6/36 and 11/34 for the control, low, mid and high dose groups, respectively; the lung tumor incidence in animals receiving 300 mg/kg acrylamide but not TPA was 14/36.

Table 1. Skin tumor (squamous cell papillomas and carcinomas) incidence in female Sencar mice exposed to acrylamide (Bull *et al*., 1984a)

Total administered dose[1] (mg/kg body weight)	Route of administration	TPA[2]	Tumor incidence
0	gavage	+	2/40
75		+	12/40
100		+	23/40
300		+	30/40
300		-	0/20
0	intraperitoneal injection	+	0/40
75		+	10/40
100		+	13/40
300		+	21/40
300		-	0/20
0	dermal	+	7/40
75		+	4/40
100		+	11/40
300		+	18/40
300		-	0/20

1. The exposure duration was less than lifetime (2 weeks); the total administered dose listed was not adjusted to reflect a less-than-lifetime exposure.
2. TPA = 12-*O*-tetradecanoyl-phenol-13-acetate

Table 2. Lung adenoma incidence in male and female A/J mice exposed to acrylamide by intraperitoneal injection (Bull *et al*., 1984a)

Dose level[1] (mg/kg body weight)	Percent of animals with tumors	
	males	females
0	13	8
1	50	35
3	38	53
10	59	79
30	93	93

1. The exposure duration was less than lifetime (8 weeks); the dose level listed was not adjusted to reflect a less-than-lifetime exposure.

Robinson *et al*. (1986) exposed female SENCAR, BALB/c, A/J and ICR-Swiss mice (60 mice/strain/treatment group) to a single 50 mg/kg body weight dose of acrylamide by intraperitoneal injection; 2 days later 40 of the 60 mice in each treatment group received 1.0 µg (SENCAR), 2.5 µg (A/J and ICR-Swiss) or 5.0 µg (BALB/c) TPA in 0.2 ml acetone applied dermally 3 times/week for 20 weeks. The remaining 20 mice/strain/treatment group received acetone alone for the same treatment schedule and duration. All animals were sacrificed at 40 weeks, and were only examined for the number of skin papillomas and lung adenomas/animal. Acrylamide induced a significant increase in the number of skin papillomas and lung adenomas per animal in SENCAR mice receiving TPA treatment. The total number of animals bearing tumors was not listed. No significant increase in either tumor type was noted in the other mouse strains tested; tumor data for the animals receiving acrylamide but not TPA was not reported.

Male and female Fischer 344 rats (90/sex/treatment group) were exposed to acrylamide in drinking water for 2 years (Johnson *et al*., 1986). Acrylamide water concentrations were adjusted to provide dosages of 0, 0.01, 0.1, 0.5 or 2 mg/kg body weight/day. Interim sacrifices (10 animals/sex/treatment group) were performed at 6, 12 and 18 months. A maximum tolerated dose (MTD) was achieved based on decreased weight gain, increased mortality during the last 4 months of the study and the appearance of several toxic effects (including peripheral nerve degeneration) in the 2 mg/kg/day group. Increases in the incidences of a number of tumor types were observed in the 2.0 mg/kg/day exposure group animals. An increased incidence of thyroid gland-follicular epithelium tumors was observed in both males and females. In females, increased tumor incidences were noted in the mammary glands, central nervous system, oral tissues, uterus and clitoral gland. An increased incidence of scrotal mesothelioma was noted in males, in both the 2.0 and 0.5 mg/kg/day exposure group; additionally, although not statistically significant, the incidence of scrotal mesothelioma in the 0.1 mg/kg/day group was greater than either the control group or historical control incidences. Male rats in the 2.0 mg/kg/day exposure group also had a significant increase in adrenal pheochromocytomas, and an increased incidence of central nervous system tumors when compared to historical controls but not when compared to concurrent controls. Tumor incidence data is listed in Table 3.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The studies by Bull *et al*. (1984a, 1984b), Robinson *et al*. (1986) and Johnson *et al*. (1986) indicate that acrylamide is capable of acting as both an initiator and a complete carcinogen in animals. However, only the Johnson *et al*. (1986) study contained a data set suitable for generating a cancer potency factor. Female Sencar mice developing tumors after exposure to acrylamide in the study by Bull *et al*. (1984a) were also additionally exposed to TPA; animals not exposed to TPA did not develop skin tumors. Female A/J mice exposed in that study to acrylamide by either gavage or intraperitoneal injection developed an increased incidence of lung adenomas without requiring TPA exposure. However, the animals were not evaluated for tumor types other than lung adenomas, and numerical tumor incidence data for animals exposed to acrylamide by gavage was not listed. Also, the exposure and observation durations for animals exposed by gavage (8 weeks and 7 months, respectively) and by intraperitoneal injection (8 weeks and 6 months, respectively) were short. Female ICR-Swiss mice exposed to acrylamide by gavage in the study by Bull *et al*. (1984b) were generally also exposed to TPA; only one exposure group was included which received acrylamide (300 mg/kg) but not TPA. Additionally, the exposure duration was only 2 weeks and the exposure duration was less than lifetime (52 weeks). In the study by Robinson *et al*. (1986), all animals for which tumor incidence data was reported were exposed to TPA as well as acrylamide. Animals in the Johnson *et al*. (1986) study were exposed to acrylamide alone for the lifetime of the animals, and were comprehensively examined for tumors. For these reasons, tumor incidence data from the Johnson *et al*. (1986) study was used to derive a cancer potency factor for acrylamide.

Methodology

As recommended in the US EPA Guidelines for Carcinogen Risk Assessment (1986), US EPA (1988) pooled tumor incidence data from different tumor sites, under the consideration that risk numbers derived from site-specific tumor incidence data potentially may not be predictive of, and may in fact underestimate, "whole-body" risks that are determined using the pooled individual animal data. The dose-response curves for each sex based on the pooled tumor incidence (benign and malignant) constituted the data sets of choice for risk assessment. Tumors at a particular site were added into the pool only when the tumor site had statistically significantly increased incidence at least at the high dose level (treated vs. control). The female rat was considered to be

the more sensitive sex, as there were significantly increased tumor incidences at a greater number of sites than in the males; the female rat tumor data was therefore used as the basis of a risk estimate. A linearized multistage procedure (GLOBAL 83) was used to calculate a cancer potency factor (q_1^*) from the female rat tumor incidence data. Surface area scaling was employed to transform animal cancer potency factors to human cancer potency factors, using the relationship ($q_{human} = q_{animal} * (bw_h / bw_a)^{1/3}$), where q_{human} is the human potency, q_{animal} is the animal potency, and bw_h and bw_a are the human and animal body weights, respectively. Body weight values used for humans and rats were 70 kg and 0.2 kg, respectively. No exposure route adjustment was made to the risk estimates because data exists which indicates that the pharmacokinetics and tissue distribution of acrylamide were not significantly affected by the dose administered or the route of administration (Dearfield *et al*., 1988). US EPA calculated a cancer potency value (q_{human}) of 4.5 E+0 $(mg/kg\text{-}day)^{-1}$. A unit risk factor was then calculated from the cancer potency factor by OEHHA/ATES using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day. The unit risk should not be used if the air concentration exceeds 8 $\mu g/m^3$, as above this concentration the unit risk may not be appropriate.

ACRYLONITRILE

CAS No: 107-13-1

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1994)

Molecular weight	53.06
Boiling point	77.3°C
Melting point	-82°C
Vapor pressure	100 mm Hg at 23°C
Air concentration conversion	1 ppm = 2.2 mg/m^3

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 2.9 E-4 $(\mu g/m^3)^{-1}$
Slope Factor: 1.0 E+0 $(mg/kg\text{-}day)^{-1}$
[Human respiratory tract cancer incidence data (O'Berg, 1980), relative risk model (US EPA, 1983), reevaluated by CDHS/RCHAS (1988).]

III. CARCINOGENIC EFFECTS

Human Studies

Cancer incidence and mortality in a cohort of 1345 male workers exposed to acrylonitrile at a E.I. du Pont de Nemours and Co., Inc. textile plant in Camden SC was studied by O'Berg (1980). The study cohort was identified as having had potential exposure to acrylonitrile in the period between plant startup in 1950 and 1966. The 1966 cutoff date allowed for a 10-year follow-up through the end of 1976. Worker exposure levels were assessed qualitatively by the author and a committee of six DuPont employees with long-term experience in the acrylonitrile exposure area; plant environmental monitoring data was not available for the 1950-1966 period. High, moderate and low exposure categories were established. The U.S. Environmental Protection Agency (US EPA) (1983) noted that DuPont representatives agreed that 5, 10 and 20 ppm might be used to represent the low medium and high exposure classification levels. Expected numbers of cancer cases and deaths were calculated from both DuPont corporate data and from the 1969-1971 National Cancer Institute survey data set. However, the author only listed the results of cancer incidence and mortality calculations using the DuPont "control" data set as the source of the expected numbers of cancer cases and mortality; US EPA (1983) stated that the presentation of results based on this control cohort only would ignore the possible effects of other chemicals on the company control cohort. Exposed workers demonstrated 25 cases of all types of cancer, with 20.5 expected. Of these cases, 8 were lung cancer versus 4.4 expected. For workers employed during plant startup (1950-1952) and exposed for at least 6 months, 8 cases of lung cancer were noted vs. 2.6 expected ($p < 0.01$). Most of this excess occurred during the latest followup period (1970-1976) (6 cases of lung cancer vs. 1.5 expected, $p < 0.01$). Total cancer cases in this period were also significantly increased (17 observed, 5.6 expected, $p < 0.01$). Also, a trend was observed correlating increased cancer risk with increased severity of exposure. Workers in the moderate exposure group with a

probable latent period of at least 15 years exhibited 13 cases of cancer of all types vs. 5.5 expected, and 5 cases of lung cancer vs. 1.4 expected ($p < 0.05$).

One potential confounding factor in this study is the lack of controls for tobacco smoking. US EPA (1983) investigated the possible impact of smoking on lung cancer incidence in the O'Berg (1980) study. DuPont provided additional data on 32 of 36 cancer cases reported on in the plant under study (some cases were not in the study cohort) and on smoking data for a matched group of non-cancer cases. Of the 32 cancer cases for which smoking data was available, 22 were cancer types other than lung, and 16 of the non-lung cancer cases (73%) were smokers. Of the matched noncancer controls, 25 (69%) were smokers. US EPA estimated that 70% of the plant population were smokers and 30% nonsmokers, and of the smoker population, 50% were "moderate" smokers and 20% were "heavy" smokers. Based on the assumption that the relative risk of lung cancer for nonsmokers, moderate, and heavy smokers is 1, 10 and 20, respectively, US EPA adjusted the number of expected lung cancer cases in the study cohort to reflect the smoking prevalence data. The number of expected lung cancer cases after adjustment for smoking is 1.61 cases. This is about 15% higher than the 1.4 cases expected without considering smoking differences; however, this adjustment did not substantially alter the significance of the increased prevalence of lung cancer in the workers exposed to acrylonitrile. US EPA (1983) concluded that the observations by O'Berg (1980) of a statistically significant excess of lung cancer in acrylonitrile-exposed workers constitutes significant evidence that acrylonitrile is likely to be a human carcinogen.

A followup to the O'Berg (1980) study was conducted by O'Berg *et al*. (1985). Observations of cancer incidence and mortality for the study cohort of 1345 DuPont workers exposed to acrylonitrile was extended through 1981 for mortality and through 1983 for cancer incidence. Exposed workers demonstrated 43 cases of all types of cancer, with 37.1 expected. Of these cases, 10 were lung cancer versus 4.4 expected. These rates were in excess but were not statistically significant. Additionally, prostate cancer rates were significantly elevated, with 6 cases observed compared to 1.8 cases expected ($p < 0.05$).

Theiss *et al.* (1980) (reviewed by US EPA, 1983) conducted a cohort mortality study of 1469 workers from 12 factories owned by the BASF company in the Federal Republic of Germany (FRG). BASF purchased acrylonitrile during the study period in order to produce styrene-acrylonitrile and acrylonitrile-butadiene-styrene polymers in addition to organic intermediate products. Processing methods differed between factories, and worker exposure data was not available. The study population was defined as all workers employed for over 6 months in acrylonitrile processing from the time of first use of acrylonitrile (approximately 1956) to the study cut-off date of May 15, 1978. The cohort included 1081 German workers and 338 workers of other nationalities. Followup was 98% complete on the German workers, but only 56% complete on the foreign workers. Expected deaths were calculated from mortality rates for the city of Ludwigshafen, the state of Rheinhessen-Pfalz, and the FRG as a whole. An elevated risk of cancer (all types) mortality was noted in the study cohort (27 observed, 20.5 expected based on FRG mortality rates). The study cohort also demonstrated a significantly elevated risk of lung cancer (11 observed, 5.65 expected based on FRG rates, $p < 0.05$; 5.92 expected based on Rheinhessen-Pfalz rates, $p < 0.05$). An excess significant risk of lung cancer remained after 78 cohort members from one factory who reported "contact with other substances since proven to be carcinogenic" were removed from the calculations (9 observed, 4.37 expected based on FRG mortality rates, $p <$

0.05); additionally, a significant excess risk of lymphatic cancer was seen (4 observed, 1.38 expected based on FRG mortality rates, $p < 0.05$).

US EPA (1983) noted that the members of the study cohort were exposed to a number of other carcinogens, including vinyl chloride, and distillation residues including polycyclic aromatic hydrocarbons, cadmium, ß-napthylamine, dimethyl sulfate and epichlorohydrin. Additionally, tobacco smoking was a potential confounding factor; all lung cancer cases were smokers. However, US EPA also noted that the lung cancer risk associated with exposure to acrylonitrile estimated from this study could actually be an underestimate of the actual risk because 1) combining workers from 12 factories between which acrylonitrile exposure levels varied could have lend to an underestimate of risk due to the inclusion of unexposed or minimally exposed workers; 2) the "healthy worker" effect could have resulted in an underestimate of risk; 3) followup on the relatively youthful cohort was insufficient, and did not allow sufficient latency in the cohort segments most at risk - only 447.1 person-years were accumulated in members over 64 years of age and 4) underascertainment of vital status (12% of the study cohort were lost to followup) may have resulted in an undercount of observed deaths. US EPA concluded that it was possible that exposure to acrylonitrile might be related to the excess risk of lung cancer demonstrated by the study cohort of Theiss *et al*. (1980).

Werner and Carter (1981) studied the mortality of 1111 men who worked in acrylonitrile polymerization and acrylic fiber production (6 plants, located in England, Northern Ireland, Scotland and Wales) from 1950 to 1968; surveillance was continued to the end of 1978. An excess of total cancer deaths was noted (21 observed, 18.6 expected) but was not statistically significant. Expected deaths were calculated from mortality rates from England and Wales combined. Only 68 deaths from all causes had occurred as of the end of 1978; 72.4 were expected. An excess of deaths from all types of cancer combined was noted (21 observed, 18.6 expected), but this excess was not statistically significant. Significant increases in deaths due to stomach cancer were noted in all age groups combined (5 observed, 1.9 expected, $p < 0.05$), with deaths in the 55-64 age group comprising the largest portion of those deaths (3 observed, 0.7 expected, $p < 0.05$). A statistically significant elevated risk of lung cancer was also noted in the 15-44 age group (3 observed, 0.7 expected, $p < 0.05$), but not in other age groups or in all age groups combined. The authors note the lack of acrylonitrile exposure data, including potential differences in exposure levels between the 6 plants surveyed. US EPA (1983) also notes the relatively short followup in the cohort subgroup which would be expected to have incurred the greatest risk, the 158 men having the earliest exposure (during the 1950-1958 period). US EPA (1983) concluded that because of the relative youth of the cohort resulting in a small number of expected deaths, the lack of followup, and the lack of control for smoking, the findings of this study are only suggestive.

A cohort mortality study of 327 white male workers employed for 2 or more years between January 1, 1940 and July 1, 1971 at a rubber manufacturing plant in Akron OH who were potentially exposed to acrylonitrile was conducted by Delzell and Monson (1982). Acrylonitrile exposure levels were not reported. Cause-specific expected deaths were calculated based on both U.S. age and calendar specific white male mortality and mortality rates for other rubber workers from the same city; however, most results reported in this study used expected deaths calculated using U.S. white male mortality rates. An excess risk of lung cancer mortality was observed when either U.S. mortality rates (9 observed, 5.9 expected) or Akron rubber industry mortality rates (9 observed,

4.7 expected) were used to calculate expected lung cancer deaths. Workers employed for 5-15 years and followed for at least 15 years demonstrated a significantly increased risk of lung cancer (4 observed, 0.8 expected, $p < 0.01$). Cohort members could potentially have been exposed to other chemicals used in the same area (butadiene, styrene, vinyl pyridine). Also, smoking controls were not included. However, US EPA (1983) commented that the possibility that the excess risk of lung cancer demonstrated in this study was due to acrylonitrile exposure could not be dismissed.

Chen *et al*. (1987) examined cancer incidence and mortality in a cohort of 1083 male employees at a E.I. du Pont de Nemours and Co., Inc. textile plant in Waynesboro, VA who were potentially exposed to acrylonitrile in the period 1944-1970. Worker exposure levels were assessed by an Exposure Classification Committee consisting of seven DuPont employees with long-term experience in the acrylonitrile exposure area; plant environmental monitoring data was not available for the 1944-1970 period. High, moderate and low exposure categories were established. Expected numbers of deaths were calculated from both U.S. and DuPont mortality rates; however, the authors only listed the results of cancer incidence and mortality calculations using the DuPont "control" data set as the source of the expected numbers of cancer cases and mortality. No significant increase in incidence was noted for either all types of cancer (37 observed, 36.5 expected) or lung cancer (5 observed, 6.9 expected). However, a significant increase in the incidence of prostate cancer (5 observed, 1.9 expected) was noted; of these, 4 occurred in the 1975-1983 period (0.9 expected).

US EPA (1983) also reviewed several unpublished studies of cancer mortality and/or morbidity potentially caused by acrylonitrile (Kiesselbach *et al*., 1980; Zack, 1980; Gaffey and Strauss, 1981; Herman, 1981; Stallard, 1982). These studies indicated no cancer increase in workers potentially exposed to acrylonitrile. However, US EPA concluded that due to design and methodological deficiencies including short followup, small cohort size and young cohort age, "none of these studies can be cited as adequate evidence that acrylonitrile is not carcinogenic".

Animal Studies

Maltoni *et al*. (1977) (reviewed by US EPA, 1983) exposed male and female Sprague-Dawley rats (30/sex/exposure group) to 0, 5, 10, 20 or 40 ppm acrylonitrile by inhalation for 4 hours/day, 5 days/week for 12 months. The animals were then maintained for the remainder of their lifetime. Slight increases in the incidence of the following tumor types were noted: mammary gland tumors in males and females, nonglandular forestomach tumors in males and skin tumors in females. Tumor incidence data are listed in Table 1.

The authors claimed that these results indicated a "border-line carcinogenic effect". US EPA (1983) noted that low sensitivity of this study due to the low concentrations of acrylonitrile used and the short duration of acrylonitrile exposure (12 months). Additionally, male and female Sprague-Dawley rats (40/sex/group) were exposed to 0 or 5 mg/kg body weight acrylonitrile by gavage 3 times/week for 52 weeks.

Table 1. Tumor incidence in male and female Sprague-Dawley rats exposed to acrylonitrile by inhalation (Maltoni *et al*., 1977)

Tumor type	Tumor incidence Acrylonitrile concentration (ppm)				
	0	5	10	20	40
mammary tumors (females)	5/30	10/30	7/30	10/30	7/30
mammary tumors (males)	1/30	0/30	1/30	4/30	4/30
nonglandular forestomach papillomas (males)	0/30	1/30	2/30	0/30	3/30
skin carcinomas (females)	0/30	4/30	1/30	1/30	1/30

On spontaneous death, a moderate increase in the incidence of female rat mammary gland tumors and nonglandular forestomach tumors was noted. US EPA (1983) commented that although the observation period was relatively short (52 weeks) and only a single dose level was used, this study provides additional evidence for the carcinogenicity of acrylonitrile.

A three-generation reproductive study on the effect of acrylonitrile exposure in male and female Charles River rats [CRL:COBS CD (SD) BR] was conducted by Litton-Bionetics, Inc. for the Chemical Manufacturers Association (Beliles *et al*., 1980; reviewed by US EPA, 1983). The rats and their offspring were exposed to drinking water containing 0, 100 or 500 ppm acrylonitrile starting 15 days post-weaning and were mated after 100 days. After delivery of two litters, the animals were exposed to acrylonitrile for approximately 45 weeks. After exposure, all animals in generations F_0, F_1b and F_2b were sacrificed and examined histologically. Second-generation rats in the 500 ppm exposure group demonstrated a significant increase in the incidence of astrocytomas and Zymbal gland tumors. Tumor incidence data are listed in Table 2.

Table 2. Tumor incidence data in Charles River rats during a three-generation reproductive study (Beliles *et al*., 1980)

Tumor type	Generation	Tumor incidence Acrylonitrile dose (ppm)		
		0	100	500
astrocytomas	F_0	0/19	1/20	2/25
	F_1b	0/20	1/19	4/17
	F_2b	0/20	1/20	1/20
Zymbal gland	F_0	0/19	0/20	1/25
	F_1b	0/20	2/19	4/17
	F_2b	0/20	0/20	3/20

Bio/Dynamics Inc. conducted a study on the toxicity and carcinogenicity of acrylonitrile in Sprague-Dawley rats (Bio/Dynamics, 1980a) for the Monsanto Company (St. Louis, MO); the results of this study were subsequently submitted to the US EPA by the Monsanto Company on June 30, 1980. Male and female Sprague-Dawley rats (100/sex/treatment group) were exposed to acrylonitrile in drinking water at concentrations of 0,1, and 100 ppm. Interim sacrifices (10/sex/treatment group) were conducted at 6, 12 and 18 months. The study was terminated at less than 2 years because of low survival rates; males were sacrificed at 22 months and females were

sacrificed at 19 months. Statistically significant increases were noted in the incidence of astrocytomas of the brain and spinal cord, adenomas and carcinomas of the Zymbal gland, and nonglandular forestomach squamous cell papillomas and carcinomas in males and females of the 100 ppm group. Tumor incidence data are listed in Table 3.

Table 3. Tumor incidences in male and female Sprague-Dawley rats exposed to acrylonitrile in drinking water (Bio/Dynamics, 1980a)

Tumor type	Dose level (ppm)	Tumor incidence	
		males	females
brain astrocytomas	0	2/98	0/99
	1	3/95	1/100
	100	23/97	32/97

NA - not analyzed

A similar study was conducted by Bio/Dynamics Inc. on the toxicity and carcinogenicity of acrylonitrile in Fischer 344 rats (Bio/Dynamics, 1980b) for the Monsanto Company (St. Louis, MO); the results of this study were subsequently submitted to the US EPA by the Monsanto Company on December 12, 1980. Male and female Fischer 344 rats (100/sex/acrylonitrile treatment group; 200/sex/control group) were exposed to acrylonitrile in the drinking water at concentrations of 0,1, 3, 10, 30 and 100 ppm. Interim sacrifices (10/sex/acrylonitrile treatment group; 20/sex/control group) were conducted at 6, 12 and 18 months. The study was designed to be 24 months in duration; however, because of poor survival, all females were sacrificed at 23 months. Males were continued on study until 26 months, when survival rates comparable to females were achieved. Statistically significant increases were noted in the incidence of astrocytomas of the brain and spinal cord in males (30 and 100 ppm groups) and females (10, 30 and 100 ppm group), adenomas and carcinomas of the Zymbal gland in males (30 and 100 ppm groups) and females (10, 30 and 100 ppm groups), and nonglandular forestomach squamous cell papillomas and carcinomas in males (3, 10 and 30 ppm groups) and females (30 ppm group). Tumor incidence data are listed in Table 4.

Table 4. Tumor incidences in male and female Fischer 344 rats exposed to acrylonitrile in drinking water (Bio/Dynamics, 1980b)

* Statistically significant at $p < 0.05$

Male and female Sprague-Dawley rats (Spartan strain) (100/sex/group) were exposed to acrylonitrile by gavage at dose levels of 0, 0.1 and 10 mg/kg-day, 5 days/week in a study conducted by Bio/Dynamics Inc. for the Monsanto Company (St. Louis, MO) (Bio/Dynamics, 1980c). Study termination was originally planned for 24 months; however, because only 10 and 13 high dose males and females, respectively, were still alive at 20 months, all surviving animals in all groups were killed during the 20th month to ensure that at least 10 animals/sex/group were available for histopathological examination. Interim sacrifices were performed at 6, 12 and 18 months (10 animals/sex/group). Statistically significant increases in tumor incidence were noted in the following tumor types: brain astrocytomas and Zymbal gland squamous cell carcinomas (high dose males and females), stomach papillomas and carcinomas and intestinal tumors (high dose males), and mammary gland tumors (high dose females). Tumor incidence data are listed in Table 5.

Table 5. Tumor incidence in male and female Sprague-Dawley rats (Spartan strain) exposed to acrylonitrile by gavage (Bio/Dynamics, 1980c)

Tumor type	Sex	Tumor incidence Dose level (mg/kg-day)		
		0	0.10	10.0

Intestine	male female	0/100 NA	1/100 NA	6/100 NA
mammary gland	male female	NA 7/101	NA 6/100	NA 22/101

Dow Chemical Company (Midland, MI) performed a study in which male and female Sprague-Dawley rats (48 animals/sex/acrylonitrile exposure group; 80 animals/sex/control group) were exposed to acrylonitrile in drinking water for 2 years (Quast *et al*., 1980a). For the first 21 days of the study, the concentrations used were 0, 35, 85 and 210 ppm; the two higher concentrations were subsequently raised to 100 and 300 ppm. Animals at the highest 2 concentrations demonstrated treatment-related toxicity after 9 months. The mean administered doses of acrylonitrile were calculated to be 0, 3.42, 8.53 and 21.18 mg/kg-day for males and 4.36, 10.76 and 24.97 mg/kg-day for females for the 35, 100 and 300 ppm exposure groups, respectively. All surviving animals were sacrificed at 24 months. Statistically significant increases in tumor incidence were noted for the following tumor types: central nervous system tumors (astrocytomas, gliomas) in males and females (all treatment groups), Zymbal gland adenomas and carcinomas in females (all treatment groups) and males (300 ppm group), nonglandular forestomach squamous cell papillomas and carcinomas in males (all treatment groups) and females (100, 300 ppm groups), tongue squamous cell papillomas and carcinomas in males (all treatment groups) and females (100, 300 ppm groups), mammary gland tumors (benign and malignant) in females (35, 100 ppm groups), and small intestine cystadenocarcinomas in females (100, 300 ppm). Tumor incidence data are listed in Tables 6 and 7.

Table 6. Tumor incidence in male Sprague-Dawley rats exposed to acrylonitrile in drinking water (Quast *et al.*, 1980a)

Tumor type	Tumor incidence Acrylonitrile dose level (ppm)			
	0	35	100	300
brain and/or spinal cord[1]	1/80	12/47	22/48	30/48

4. Adenomas and carcinomas

Male and female Sprague-Dawley rats (Spartan substrain; 100 animals/sex/exposure group) were exposed to acrylonitrile by inhalation in a study conducted by Dow Chemical Company for the Chemical Manufacturers Association (Quast *et al.*, 1980b). Study animals were exposed to 0, 20 or 80 ppm of acrylonitrile for 6 hours/day, 5 days/week for 2 years. Statistically significant increases in tumor incidence were noted for the following tumor types: brain and spinal cord glial cell tumors (males and females), mammary gland adenocarcinomas (females), small intestine tumors (benign and malignant) (males), tongue squamous cell papillomas and carcinomas (males) and Zymbal gland tumors (males and females). All tumor incidence increases were noted at the highest concentration tested, 80 ppm, except for brain and spinal cord glial cell tumors in females, which were also noted in the 20 ppm group. Tumor incidence data are listed in Table 8.

Table 8. Tumor incidence in male and female Sprague-Dawley rats exposed to acrylonitrile by inhalation (Quast *et al.*, 1980b)

Tumor type	Sex	Tumor incidence Acrylonitrile concentration (ppm)		
		0	20	80
Brain and/or spinal cord glial cell tumors[1]	male	0/100	4/99	22/99
	female	0/100	8/100	21/100

small intestine[1]	male	2/99	2/20	15/98
Zymbal gland tumors[1]	male	2/100	4/100	11/100
	female	0/100	1/100	11/100

1. Benign and/or malignant

Bigner *et al.* (1987) exposed male and female Fischer 344 rats to acrylonitrile in drinking water. Exposure groups were as follows: 147 males and 153 females exposed to 500 ppm acrylonitrile; 50 males and 50 females exposed to 500 ppm acrylonitrile; 50 males and 50 females exposed to 100 ppm acrylonitrile and 51 males and 49 female control animals. The study was not complete at the time of the report (18 months of exposure); however, they reported 49 primary brain tumors in 215 animals examined from the high dose treatment groups.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Acrylonitrile has been demonstrated to cause cancer in humans (O'Berg, 1980; Werner and Carter, 1981; Delzell and Monson, 1982) and rats; routes of administration for rats include gavage (Bio/Dynamics, 1980c), oral exposure (Beliles *et al*., 1980; Bio/Dynamics, 1980a; Bio/Dynamics, 1980b; Quast *et al*., 1980a; Bigner *et al.* 1987) and inhalation (Maltoni *et al*., 1977; Quast *et al*., 1980b). US EPA (1991) chose to use the O'Berg acrylonitrile occupational exposure study as the basis of derivation of a cancer potency factor for acrylonitrile. This study demonstrated the carcinogenicity of acrylonitrile in a cohort which was sufficiently large and which was followed for an adequate time period. Exposure levels were estimated by representatives of the company employing the study cohort, and a dose-response relationship was observed for the increased cancer risk. This increased risk remained after adjusting for smoking. US EPA (1983) noted that the cancer potency values for acrylonitrile derived from human exposure (O'Berg, 1980) was within one order of magnitude of the cancer potencies derived from rat oral exposure (Bio/Dynamics, 1980a; Bio/Dynamics, 1980b; Quast *et al*., 1980a) and inhalation exposure (Quast *et al*., 1980b) studies.

Methodology

A unit risk (UR) for acrylonitrile was calculated by US EPA (1991) from a relative risk model adjusted for smoking and based on a continuous lifetime equivalent of occupational exposure using the relationship

$$UR = PO\ (R-1) / X = 1.5E\text{-}4/ppb * 0.45\ ppb/\mu g/m^3 = 6.8E\text{-}5\ (\mu g/m^3)^{-1}$$

where: PO = 0.036 = background lifetime probability of death from respiratory cancer
R = 5.0/1.6 = 3.1 = relative risk of respiratory cancer adjusted for smoking (O'Berg, 1980)
X = 500 ppb = continuous equivalent lifetime exposure when 9 years = estimated average exposure duration, and 60 years = estimated maximum possible age at the end of the observation period.

CDHS (1988) reestimated the unit risk factor for acrylonitrile, using the standard lifespan typically assumed by CDHS in risk assessments (70 years) and taking into account the uncertainty in the relative risk estimate. The unit risk was corrected using the following relationship:

$$B^* = B(95) * (70/60)^3$$

where B^* is the unit risk and B(95) is the upper 95% bound on B. This bound was estimated directly by substituting R(95), the upper 95% confidence bound on R, which was found to be 6.6; the second factor $[(70/60)^3]$ was used to extrapolate from a 60 year observation period to a 70 year observation period. The resulting unit risk factor derived was 2.9E-4 $(\mu g/m^3)^{-1}$.

ALLYL CHLORIDE

CAS No: 107-05-1

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1994)

Molecular weight	76.5
Boiling point	44.96°C
Freezing point	-134.5°C
Vapor pressure	295.5 mm Hg at 20°C
Air concentration conversion	1 ppm = 3.13 mg/m^3

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 6.0 E-6 $(\mu g/m^3)^{-1}$

Slope Factor: 2.1 E-2 $(mg/kg\text{-}day)^{-1}$

[Linearized multistage procedure (GLOBAL82) (US EPA, 1986) fitted to NCI (1977) female mouse forestomach tumor data, body weight scaling, adopted by RCHAS/OEHHA (1994), cross-route extrapolation.]

III. CARCINOGENIC EFFECTS

Human Studies

A retrospective cohort mortality study of 1,064 male workers potentially exposed to epichlorohydrin and allyl chloride was conducted by Olsen *et al*. (1994). Study subjects had a minimum of 1 month work experience between 1957-1986 in the production or use of epichlorohydrin and allyl chloride and 1 year total employment duration at Dow Chemical's Texas Operations (Freeport, TX). Job exposure categorization was used to quantify individual exposure based on an evaluation of work practices, production processes and available environmental monitoring data. Vital status follow-up occured through 1989; 66 total deaths were recorded. Standardized mortality ratios (SMR) for all malignant neoplasms or lung cancer were not significantly increased when compared to external (U.S.) or internal (Texas Operations) populations. The authors noted that the study results are limited by the cohort's size, duration of follow-up, relatively few number of observed and expected deaths, and the level of potential epichlorohydrin and allyl chloride exposure.

Animal Studies

Several studies exist on the potential carcinogenicity of allyl chloride in animals; these studies have been reviewed by IARC (1985) and U.S. EPA (1986, 1991).

Male and female $B6C3F_1$ mice and Osborne-Mendel rats (50/group) were exposed to allyl chloride (technical grade; 98% pure) by gavage daily 5 days/week for 78 weeks (NCI, 1977). Exposure groups for mice were initially 172 or 199 mg/kg body weight for males and 129 or 258 mg/kg for

females. Exposure groups for rats were initially 70 or 140 mg/kg body weight for males and 55 or 110 mg/kg for females. Due to toxicity, the initial doses were reduced as the study progressed. Final time-weighted average doses for the 78 week dosing period were 172 and 199 mg/kg/day for male mice; 129 and 258 mg/kg/day for female mice; 57 and 77 mg/kg/day for male rats and 55 and 73 mg/kg/day for female rats. Mice and rats were observed for an additional 13 and 30-33 weeks after the end of the dosing period, respectively. Excessive mortality (50% after 14-38 weeks) was noted in the high-dose rats (both sexes) and male mice. The number of surviving animals in all low-dose groups and high-dose female mice were adequate to evaluate late-developing tumor risk.

No significant increases in tumor incidence were noted in rats. Proliferative nonneoplastic lesions of the stomach were noted in mice of both sexes. In male mice, squamous cell carcinomas of the stomach were found in 0/29 controls (17 vehicle and 12 untreated), 2/36 low-dose animals, and 0/10 high-dose animals (only 10 survived past 52 weeks). In female mice, squamous cell papillomas and carcinomas of the forestomach were found in 0/39 controls (19 vehicle and 20 untreated), 3/47 low-dose animals (2 carcinomas) and 3/45 high-dose animals (no carcinomas). Tumor incidence was not significantly increased compared to controls for either dose group of either sex. However, the combined tumor incidence in females and the carcinoma incidence in low-dose males was significantly increased at both doses compared to historical vehicle controls (1/180 female mice with squamous cell papilloma or carcinoma of the forestomach; 1/180 male mice with squamous cell carcinoma of the forestomach). The authors considered the findings to be strongly suggestive of carcinogenicity in mice because of the rarity of the tumor type involved and because the proliferative lesions demonstrated could be preneoplastic.

Female Ha:ICR Swiss mice (30/group) were exposed to allyl chloride by topical application (31 or 94 mg allyl chloride in 0.2 ml acetone) 3 times/week for 63-85 weeks (Van Duuren *et al*., 1979). Skin tumors were not induced. Lung and stomach papillomas were induced in both the low dose group (3 stomach, 14 lung papillomas) and the high dose group (3 stomach, 12 lung papillomas, 1 glandular stomach adenocarcinoma). Tumor incidences were not significantly increased compared to vehicle or untreated controls (control incidence not reported).

Female Ha:ICR Swiss mice (30/group) received a single dermal application of 94 mg technical grade allyl chloride in 0.2 ml acetone followed 2 weeks later by dermal applications of 5 µg 12-*O*-tetradecanoylphorbol 13-acetate (TPA) 3 times/week for life (median survival 61-82 weeks) (Van Duuren *et al*., 1979). Skin papilloma incidence was significantly increased (7/30 treated animals compared to 6/90 TPA control animals, $p < 0.025$) and time to tumor was decreased (first tumor in treated animals at day 197 compared to day 449 in TPA controls) in allyl chloride -treated animals.

Male and female A/St mice (10/group) received intraperitoneal injections of allyl chloride in tricaprylin 3 times/week for 8 weeks; total doses were 1.2, 2.9 and 5.9 g/kg body weight (Theiss *et al*., 1979). Animals were killed 24 weeks after exposure initiation. The only pathological endpoint examined was the induction of lung tumors as determined by gross examination. The average number of adenomas/mouse (20 animals/group, both sexes combined) was 0.19 ± 0.1, 0.60 ± 0.2, 0.50 ± 0.27 and 0.60 ± 0.15 in the control, low, medium and high-dose groups,

respectively. The incidence of lung adenomas in the high-dose group was significantly increased ($p < 0.05$ by Student's T-test or chi-square test).

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The NCI (1978) carcinogenicity bioassay demonstrated a statistically significant increased incidence of squamous cell papillomas and carcinomas of the forestomach in low-dose male mice (2/46, $p < 0.029$) and low-dose (3/47; $p < 0.003$) and high-dose (3/45; $p < 0.003$) female mice when compared to tumor incidences in male (1/180) and female (1/180) historical controls. The female mouse tumor incidence data from this study was chosen as the basis of a cancer potency factor because it demonstrated induction of a rare tumor type by allyl chloride in the most sensitive sex of a sensitive species.

Methodology

Transformed doses were calculated as follows:

transformed dose = experimental dose × (5 days/7 days) × (78 weeks/92 weeks)

Animals were dosed 5 days/week, and the duration of exposure and of the experiment were 78 and 92 weeks, respectively. Experimental doses were 129 and 258 mg/kg/day; transformed doses were 78 and 156 mg/kg/day. A linearized multistage procedure (GLOBAL82) was then applied to the tumor incidence data; the resulting unadjusted cancer potency factor (q_1^*) was 1.01 E-3 $(mg/kg/day)^{-1}$. A q_1^* for humans was calculated from the unadjusted q_1^* as follows:

human q_1^* = unadjusted $q_1^* \times (70\ kg/0.025\ kg)^{1/3} \times (104\ weeks/92\ weeks)^3$
= 2.1 E-2 $(mg/kg/day)^{-1}$

The reference human body weight and the average female mouse weight were 70 kg and 0.025 kg, respectively, and the experiment length and the mouse lifespan were 92 weeks and 104 weeks, respectively. A unit risk factor of 6.0 E-6 $(\mu g/m^3)^{-1}$ was derived from the human q_1^* by OEHHA/ATES using an inspiration rate of 20 m^3/day.

[Male rat liver tumor data (NCI, 1978), contained in Gold *et al*. database (1984), expedited Proposition 65 methodology (Cal/EPA, 1992), cross-route extrapolation.]

III. CARCINOGENIC EFFECTS

Human Studies

No studies on the potential carcinogenic effects of 2-aminoanthraquinone (2-AA) on humans are known to exist.

Animal Studies

Results from the National Cancer Institute (NCI) (1978) feeding study in male and female B6C3F$_1$ mice and Fischer 344 rats are tabulated in Gold *et al*. (1984). 2-Aminoanthraquinone (technical grade, unspecified impurities) was administered in feed to groups of 50 male and 50 female animals of each species. Matched control groups were included for each mouse dose group (50 animals/sex/species). Control groups of 50 male and 25 female rats were also included; these animals were observed for 107-109 weeks. Diet fed to mice contained 5000 or 10000 mg/kg 2-AA; diet fed to female rats contained 2000 mg/kg 2-AA. Diet fed to male rats contained 10000 or 20000 mg/kg 2-AA for the first 10 weeks; this was reduced to 2500 or 5000 mg/kg for the remaining 68 weeks. For rats, NCI reported the time-weighted average dietary concentrations to be 0.69% and 0.35% for high and low dose males, and 0.2% for treated females over a 78-week period. An additional observation period of 28-32 weeks was included after treatment ended. High and low dose mice of both sexes were administered time-weighted average dietary concentrations of 1.0% (over 80 weeks) and 0.5% (over 78 weeks) respectively, and were observed for an additional 15-16 weeks after treatment ended.

At study termination, 82, 78, 94 and 86% of male mice and 78, 76, 88 and 76% of female mice were still alive in the low-dose control, high-dose control, low-dose and high-dose groups, respectively. In male rats, 54% of the controls, 64% of low-dose and 70% of high-dose animals

were alive at the end of the study. Insufficient numbers of female rats survived to the latter portion of the experimental period to permit analysis of late-developing tumors.

High-dose male and female mice demonstrated a significantly increased incidence of hepatocellular carcinomas. Tumor incidence in male mice was 12/46 in low-dose controls, 6/48 in high-dose controls, 20/47 in low-dose animals, and 36/49 ($p < 0.001$) in high-dose animals; in female mice, the frequencies were 4/46, 1/50, 5/47 and 12/47 ($p < 0.001$) (NCI, 1978; Murthy *et* al., 1979). A dose-dependent increase in hepatic neoplastic nodules and hepatocellular carcinomas ($p < 0.001$) was noted in 18/41 low-dose and 18/45 high dose males; tumors were observed in 0/36 control male rats.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The NCI carcinogenicity bioassay of 2-AA indicated that 2-AA induced tumor formation in both rats and mice. The cancer potency value derived is based on the dose-response data for hepatic tumors in the more sensitive sex and species, the male rat (Cal/EPA, 1992).

Methodology

Expedited Proposition 65 methodology (with cross-route extrapolation) was used to derive a cancer potency factor. The average dose administered to the male rat high-dose group as calculated by Gold *et al*. (1984) was 102 mg/kg/day. Analysis of the data set using the computer program TOX_RISK (Crump *et al*., 1991) indicated that inclusion of the high dose group resulted in a p-value of = 0.05 based on the chi-square goodness-of-fit test, indicating non-linearity. Following procedures described by US EPA (Anderson *et al*., 1983), the high dose group was excluded from the analysis to correct for the poor fit (Cal/EPA, 1992). A unit risk factor was then calculated by OEHHA/ATES from the cancer potency factor using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

ANILINE

CAS No: 62-53-3

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1994)

Molecular weight	93.12
Boiling point	184-186°C
Melting point	-6.3°C
Vapor pressure	0.67 mm Hg at 25°C
Air concentration conversion	1 ppm = 3.82 mg/m^3

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 1.6 E-6 ($\mu g/m^3$)$^{-1}$
Slope Factor: 5.7 E-3 (mg/kg-day)$^{-1}$
[Derived from a cancer potency factor calculated by US EPA/IRIS (1990, 1994) from male rat primary splenic sarcoma incidence data (CIIT, 1982) using a linearized multistage procedure, extra risk; adopted by CDHS/RCHAS (1990)]

III. CARCINOGENIC EFFECTS

Human Studies

US EPA (1994) reviewed a study that examined the occurrence of bladder tumors in British workers in the chemical dye industry (Case *et al.*, 1954). A group of 4622 men employed for more than 6 months in the United Kingdom chemical industry during the period 1910-1952 were studied. In a subgroup of 1233 men exposed solely to aniline, one death from bladder cancer was observed compared to 0.83 expected from English/Welsh male mortality data. Among the entire group (who had generally been exposed to a number of aromatic amines including napthylamine, benzidine, auramine and aniline; no detailed exposure information was available), 127 deaths from bladder cancer were observed compared to 4.1 expected. The authors concluded that the data provided insufficient evidence to suggest that aniline itself causes bladder tumors.

Animal Studies

Forty-three male and female Osborne-Mendel rats were fed diets containing 330 mg/kg aniline hydrochloride for up to 1032 days (White *et al.*, 1948). Hepatomas and splenic sarcomas were noted in 4 and 3 animals, respectively. No control group was included in the study; however, the authors claimed that liver and spleen tumors were rare in the rat strain used in the study.

IARC (1982) reviewed a study by Druckrey (1950) in which rats (random bred, sex unspecified) were exposed to aniline hydrochloride in drinking water (22 mg/rat/day) over their lifetime. Mortality was quite high; 50% mortality occurred at day 450 and 100% mortality at day 750. No tumors were observed in the treated animals; however, only the bladder, liver, spleen and kidney were evaluated for tumors.

Male and female Fischer 344 (F344) rats and B6C3F$_1$ mice were fed diets containing aniline hydrochloride for 103 weeks (NCI, 1978). Rats were fed diets containing 0, 3000 or 6000 mg/kg diet aniline hydrochloride; mice were fed diets containing 0, 6000 or 12000 mg/kg diet aniline hydrochloride. Group sizes were 50/sex/group, except for high dose female mice (n = 49), and control rats (25/sex). Surviving rats and mice were sacrificed at 107-108 and 107 weeks, respectively. No significantly increased treatment-related tumor incidences were noted in treated mice. Male rats demonstrated significantly elevated incidences of hemangiosarcomas in the spleen, as well as fibrosarcomas and sarcomas (not otherwise specified) in multiple organs of the body cavity and spleen. There were also significant dose-related trends in the incidence of hemangiosarcomas, sarcomas or fibrosarcomas and malignant pheochromocytomas. For female rats, a dose-related trend was observed in the incidence of fibrosarcomas and sarcomas in the spleen and in multiple organs of the body cavity. No fibrosarcomas, or sarcomas of the spleen or multiple organs of the body cavity were observed in pooled (249 female and 250 male) control animals. Tumor incidence data is listed in Table 1.

Table 1. Aniline hydrochloride-induced tumor incidence data in male and female Fischer 344 rats (NCI, 1978)

Tumor type	Sex	Tumor incidence aniline hydrochloride dietary concentration (mg/kg diet)		
		0	3000	6000
spleen hemangiosarcoma	male	0/25	19/50	20/46
spleen fibrosarcoma/sarcoma NOS	male	0/25	7/50	9/46
multiple organ fibrosarcoma/sarcoma NOS	male	0/25	2/50	9/48
	female	0/24	1/50	7/50
adrenal pheochromocytomas	male	2/24	6/50	12/44

NOS = not otherwise specified

Hagiwara *et al.* (1980) administered aniline in the diet at a concentration of 300 mg/kg diet to 28 male Wistar rats over a period of 80 weeks. An untreated control group of 28 rats was also included. No significant increase in tumor incidences were observed as a result of aniline exposure. However, the treatment group sizes used were relatively small, and the exposure was relatively low and less than lifetime.

Male and female CD-F rats (130/sex/exposure group) were exposed to aniline hydrochloride in the diet for 2 years at exposure levels of 0, 10, 30 and 100 mg/kg body weight/day (CIIT, 1982). An increased incidence of primary splenic sarcomas was noted in the male 100 mg/kg exposure group (high dose group); stromal hyperplasia and fibrosis of the splenic red pulp, a potential sarcoma precursor lesion, was also observed in high dose males, and to a lesser degree, in high dose females. No fibrosarcomas, stromal sarcomas, capsular sarcomas or hemangiosarcomas were noted in female rats. Tumor incidence data is listed in Table 2.

Table 2: Incidence of splenic tumors in male CD-F rats fed diets containing aniline hydrochloride (CIIT, 1982)

Dietary aniline hydrochloride concentration (approximate) (ppm)	Aniline hydrochloride exposure level (mg/kg body weight/day)	Human equivalent dose[1] $(mg/kg/day)^{-1}$	Tumor incidence[2]
0	0	0	0/64
200	10	1.23	0/90
600	30	3.69	1/90
2000	100	12.29	31/90

1. Calculation of the doses included a correction for the difference in molecular weight of aniline and aniline hydrochloride (compound administered) (US EPA, 1992).
2. Tumor incidence includes fibrosarcomas, stromal sarcomas, capsular sarcomas, and hemangiosarcomas as reported by US EPA (1992).

Syrian golden hamsters (15 male and 15 female) received subcutaneous injections of aniline (521 mg/kg body weight; total dose 9219 mg/kg) for 52 weeks (Hecht *et al*., 1983). Although mean survival was reduced in the aniline-treated groups, no increase in tumor incidence was observed. However, the experimental exposure was less than lifetime, and the number of exposed animals was small.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Cancer potency values are based on the most sensitive site, species and study demonstrating carcinogenicity of a particular chemical, unless other evidence indicates that the value derived from that data set is not appropriate (CDHS, 1985). Male rat spleen tumor data (CIIT, 1982) was used to generate a cancer potency factor for aniline. Male rats in the high-dose group showed a marked increase in the incidence of splenic tumors (see Table 2). US EPA (1994) also noted the presence of stromal hyperplasia and fibrosis of the splenic red pulp in high-dose males and, to a lesser degree, in females; this may represent a precursor lesion of sarcoma.

Methodology

A linearized multistage procedure (US EPA,1980) was used to calculate a slope factor of 5.7 E-3 $(mg/kg\text{-}day)^{-1}$ from the CIIT (1982) male splenic tumor incidence data. Calculation of the transformed doses for aniline included a correction for the difference in molecular weights of aniline and aniline hydrochloride, the form in which the compound was administered in the NCI and CIIT bioassays. Calculation of the unit risk by OEHHA/ATES from the US EPA slope factor assumed a body weight of 70 kg and an inspiration rate of 20 m^3/day.

ARSENIC (INORGANIC)

CAS No: 7440-38-2

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1998)

Molecular weight	74.92
Boiling point	613 °C (sublimes)
Melting point	817 °C @ 28 atm
Vapor pressure	1 mm Hg at 372 °C
Air concentration conversion	1 ppm = 2.21 mg/m^3

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 3.3 E-3 $(\mu g/m^3)^{-1}$
Slope Factor: 1.2 E+1 $(mg/kg\text{-}day)^{-1}$
[Human occupational exposure lung tumor incidence (Enterline *et al*., 1987a);. relative risk model, adjusted for interaction with tobacco smoking (CDHS, 1990).]

Oral slope factor: 1.5 E+0 $(mg/kg\text{-}day)^{-1}$
[Human skin cancer incidence (Tseng *et al*., 1968, 1977), time- and dose-related formulation of the multistage procedure (U.S. EPA, 1988).]

III. CARCINOGENIC EFFECTS

Human Studies

Inhalation

Cancer mortality has been studied among workers employed in three major smelters in the U.S., in (1) Tacoma, Washington, (2) Anaconda, Montana, and (3) Garfield, Utah. Smelter workers in Sweden (Ronnskarverken) and in Japan (Sagnoseki-Machi) and cohorts of both miners and smelter workers in China have also been studied.

Enterline and Marsh (1982) and Enterline *et al*. (1987a) examined the longest follow-up period for the Tacoma, Washington cohort. The 1982 report used cumulative doses based on urinary arsenic measurements. Standardized mortality ratios (SMRs) for respiratory cancer ranged from 170 for those receiving the lowest intensity and shortest duration of exposure, to 578 for those with the highest intensity and with 20-29 years duration of exposure. A strong dose-response relationship was evident only when the analysis was limited to the 582 retired workers in the cohort. In the 1987 reanalysis, Enterline and colleagues incorporated newly available historical air sampling data (Enterline *et al*., 1987a); in this study, the dose-response relationship appears more clearly.
The Anaconda, Montana cohort was also the subject of numerous publications. Lee-Feldstein (1983, 1986) divided the 8,045 men of the full study group into nine subcohorts based on arsenic exposure and year of first employment. When considering only those men who had been in their maximum exposure category for at least 12 months, each of the nine subcohorts, except for one

subgroup which had a very small sample size, showed significantly elevated respiratory cancer rates relative to the combined male population of Idaho, Montana and Wyoming (Lee-Feldstein, 1983). Lee-Feldstein (1983) also investigated the association of sulfur dioxide (SO_2) with respiratory cancer in this cohort. Findings from this study could not conclude that arsenic trioxide was the primary environmental agent causing the excessive respiratory cancer seen in the study group.

In another study, Lee-Feldstein (1986) incorporated quantitative exposure estimates based on industrial hygiene data collected between 1943 and 1958. In all but the latest-employed cohort, a statistically significant linear dose-response relationship was observed between arsenic exposure and the directly standardized death rate (DSDR) for respiratory cancer. Lee-Feldstein (1986) reiterated that the latest-employed cohort may not have been followed long enough to display a dose-related mortality pattern, and the men in this cohort may have experienced prior exposures which confound the relationship between arsenic exposure and respiratory cancer mortality. Also, men who were younger at the start of employment were at greater risk for lung cancer than those who began employment later in life. Further analysis of the same cohort by Welch *et al.* (1982) and Higgins *et al*. (1985) confirmed the linear dose-response relationship between exposure and respiratory cancer.

The Garfield, Utah smelter was studied by Rencher *et al*. (1977), who found a three- to five-fold increase in the proportion of deaths due to lung cancer among smelter workers when compared to workers in the mine or concentrator. Similar results were reported by Tokudome and Kuratsune (1976) who studied 839 copper smelter workers in Japan. A dose-response effect on respiratory cancer was observed using either duration of employment or intensity of exposure. For the same duration of employment, risks were greater among those employed in earlier periods.

Workers at the Ronnskarverken smelter in Sweden experienced lung cancer mortality at about five times the rate of residents of the county (Wall, 1980). Pershagen *et al*. (1981) conducted a nested case-control study within this cohort, focusing on the interrelationship of smoking, arsenic and lung cancer. For smokers and nonsmokers, the age-standardized rate ratios (SRRs) were 3.0 and 2.9. Among roaster workers, the most heavily exposed in this plant, the SRRs were 4.4 and 4.5. Exposures were not quantified in this analysis.

Other studies of cancer incidence and mortality among workers at the Ronnskar smelter in Sweden confirmed the excess lung cancer risk (Sandstrom *et al*., 1988; Jarup *et al*., 1989a,b). An analysis of age-adjusted rates by calendar year showed a decline in lung cancer starting in the mid-1970s, possibly due to lower exposures, earlier notification of health problems, and/or changing smoking habits (Sandstrom *et al*., 1988). However, among the most recently hired cohort, lung cancer incidence was greater than expected.

Taylor *et al*. (1989) conducted a case-control study among tin miners in China to examine the relationship between arsenic exposure and lung cancer. After adjusting for tobacco use and radon exposure, the risk of lung cancer for subjects in the highest quartile of arsenic exposure was 22.6-fold higher than for those in the lowest quartile. Duration but not intensity of exposure appeared to be a predictor of lung cancer risk.

Another report from China covers a cohort consisting of workers employed at two copper smelters, one arsenic smelter and a mine (Wu, 1988). Wu reported that nearly 19,000 person-years were followed, resulting in 40 lung cancer deaths.

Enterline *et al*. (1987b) analyzed data from eight smelters with fairly low levels (relative to the Anaconda, Tacoma, and Ronnskar smelters) of arsenic. When data from the six smelters were combined and examined, the results suggested an increasing trend in risk with increasing exposure ($p = 0.06$). A significant effect was observed for cumulative exposure to arsenic and for smoking.

Reports on cancer and insecticide manufacturing exposures to arsenic were by Ott *et al*. (1974), Baetjer *et al*. (1975b; as cited in Mabuchi *et al*., 1979), Mabuchi *et al*. (1979), and Sobel *et al*. (1988). A study of orchardists who potentially sprayed arsenic-containing pesticides is reviewed by Wicklund *et al*. (1988). The report by Mabuchi *et al*. (a more extensive follow-up of the same cohort Baetjer analyzed) found a sharp increase in the lung cancer SMR with increasing duration of employment among those predominantly exposed to arsenic, although no increase was observed for those with exposure to arsenic only. However, more than 99 percent of this latter group were employed for five years or less.

Ott *et al*. (1974) observed a marked increase in respiratory cancer mortality with increasing cumulative dose in workers previously employed in an insecticide manufacturing plant. Sobel *et al*. (1988) updated the study by Ott *et al.* by 9 additional years of follow-up and by tracing more than 99% of those who had been lost to follow-up in the study by Ott *et al*. The 9 follow-up years yielded a non-statistically significant respiratory cancer SMR of 116.

A case-control study of deaths among orchardists (Wicklund *et al*., 1988) found no association between exposures to arsenic-containing pesticides and respiratory cancer, after controlling for smoking.

In summary, for smelter workers, the association between respiratory cancer mortality and arsenic exposure is a consistent, replicable finding of substantial magnitude with a clear dose-response relationship, and high statistical significance. The mortality data on workers employed in the manufacturing of insecticides provide further evidence that arsenic acts as a respiratory tract carcinogen.

Oral

Chronic exposure to high levels of arsenic in drinking water has been identified as increasing skin cancer incidence in humans (US EPA, 1988, 1995).

In a region on the southwest coast of Taiwan, artesian well water with high arsenic concentrations ranging from 0.01-1.82 ppm had been in use for more than 45 years (Tseng *et al*., 1968, 1977). 40,421 inhabitants of 37 villages of the regions were examined for skin lesions, peripheral vascular disorders and cancers. The study identified 7,418 cases of hyperpigmentation, 2,868 of keratosis (Type A/benign), 428 of skin cancer (squamous cell carcinoma, basal cell carcinoma, *in situ* squamous cell carcinoma, and Type B keratoses/intraepidermal carcinomas) and 360 cases of

Blackfoot disease. The incidence rates for keratosis and skin cancer were 183.5 and 10.6/1000, respectively. A control population of 7,500 people did not exhibit any of the above disorders.

The above exposed population was divided into "low", "mid" and "high" exposure groups based upon the well-water arsenic concentration in each village (<0.3, 0.3-0.6, and >0.6 ppm, respectively). A dose-response relationship was identified for the prevalence of skin cancer and Blackfoot disease (no dose-response data was presented for hyperpigmentation and keratosis). The prevalence of both disease was also found to increase with age. Males were found to have higher prevalence rates than females (male to female ratios for skin cancer and Blackfoot disease were 2.9 and 1.3, respectively).

Additional studies of chronic human arsenic exposure resulting in increased skin cancer or internal organ cancer incidence have been identified and reviewed (Fierz, 1965; Borgono and Greiber, 1972; Cebrian *et al*., 1983; Yue-Zhen *et al*., 1985; Chen *et al*., 1985, 1986; reviewed by US EPA, 1988).

Animal Studies

There were two animal inhalation studies on the carcinogenicity of arsenic available at the time the document *Report to the Air Resources Board on Inorganic Arsenic. Part B. Health Effects of Inorganic Arsenic Compounds* was written (CDHS, 1990). Berteau *et al.* (1977, 1978) exposed mice to a respirable aerosol of arsenic(III) (containing approximately 27 mg arsenic(III)/m^3) for 40 minutes/day for 26 days and 20 minutes/day thereafter. Inhaled doses were approximately 1.3 mg arsenic/kg/day and 0.69 mg arsenic/kg/day. No evidence of neoplasia was observed grossly in exposed animals.

In an inhalation study of arsenic trioxide, Glaser *et al*. (1986) exposed 20 rats for 18 months, at approximately 60 µg arsenic/kg/day and 40 rats at approximately 20 µg arsenic/kg/day. No tumors were observed in exposed animals. The report lacked important methodological details, including sampling to verify exposure levels. Also, the study tested fewer animals than required by standard cancer bioassay protocols.

In an arsenic (III) trioxide-treated group of 47 male hamsters, Pershagen *et al*. (1984) found three carcinomas: two of bronchi or lungs (an adenocarcinoma, and an anaplastic carcinoma) and one of larynx or trachea (a squamous cell carcinoma). These carcinomas were not statistically significant when considered in relation to the concurrently treated controls but were statistically significant when considering additional controls from the same colony ($p = 0.01$, one-tailed test). In female hamsters, benign lung tumors (adenomas) were induced by intratracheal instillation of a suspension of solid arsenic trioxide in a phosphate buffer (Ishinishi *et al*., 1983; Ishinishi and Yamamoto, 1983), but Ohyama *et al*. (1988) did not induce lung tumors in male hamsters similarly treated with arsenic trioxide or gallium arsenide.

Arsenic (V) has also induced tumors in animals. Calcium arsenate injected intratracheally induced lung adenomas in male hamsters (Pershagen and Bjorklund, 1985) and leukemia and lymphoma were produced by sodium arsenate by subcutaneous injection in mice (Osswald and Goerttler, 1971).

Among oral studies, only one study reported positive findings. Tumors, including adenocarcinomas of the skin, lung, and lymph nodes, were noted in mice given Fowler's solution (potassium arsenite), but the report lacks experimental details necessary for critical assessment (Knoth, 1966; as reviewed in U.S. EPA, 1984).

Other oral studies reported that arsenite (3 μg arsenic/l in drinking water) reduced the total tumor incidence in male and female white Charles River CD mice (Kanisawa and Schroeder, 1967), and enhanced the growth rate of "spontaneous" (common) mammary tumors in female inbred C3H mice (Schrauzer and Ishmael, 1974; Schrauzer *et al*., 1978).

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Inhalation

The International Agency for Research on Cancer (IARC) evaluated arsenic in 1980 and classified "arsenic and arsenic compounds" in Group 1, which includes the "chemicals and groups of chemicals (which) are causally associated with cancer in humans." Ingestion of arsenic is associated with cancer at sites different from those associated with arsenic inhalation: ingestion is associated with skin cancer, while inhalation results in lung neoplasms.

In contrast, arsenic has not conclusively produced carcinogenesis in animals. Arsenic produces tumors in animals, but these tumors are rarely malignant. The few reports of carcinogenic effects of arsenic compounds in animals are seriously flawed. The hypothesis that arsenic may act as a tumor promoter has been tested but not proven in animals.

CDHS (1990) used human data for its cancer risk assessment of arsenic because (1) these data showed a strong, consistent association with increased respiratory cancer in epidemiologic studies, (2) quantitative exposure measurements were made in several of these studies, and (3) clear dose-response relationships were observed. No risk assessment has been conducted using animal data because the cancer bioassays using relevant routes of exposure have been negative and because no adequate inhalation bioassay has been published.

The quantitative cancer risk assessment for arsenic considered data from the occupational mortality studies of smelter workers in Anaconda, Montana by Welch *et al*. (1982), Higgins *et al*. (1985) and Lee-Feldstein (1986), and in Tacoma, Washington by Enterline *et al*. (1987a).

Oral

US EPA (1995) conducted a review of the available literature and identified the studies by Tseng *et al*. (1968, 1977) as the key references for quantifying ingested arsenic cancer potency. US EPA stated that these studies demonstrate a causal association between arsenic ingestion and an elevated risk of skin cancer. These data were considered reliable for the following reasons: 1) the study and control populations (40,421 and 7,500, respectively) were large enough to provide reliable estimates of the skin cancer incidence rates; 2) a statistically significant elevation in skin cancer incidence in the exposed population compared to the control population was observed many years after first exposure; 3) a pronounced skin cancer dose-response by exposure level was demonstrated; 4) the exposed and control populations were similar in occupational and socioeconomic status, with ingestion of arsenic-contaminated drinking water the only apparent difference between the two groups, and 5) over 70% of the observed skin cancer cases were pathologically confirmed.

Methodology

Inhalation

Data from the Anaconda and Tacoma smelters show nonlinear relationships between cumulative dose and the relative risk (or SMR) for death from lung cancer. These dose-response curves are concave downward (their slopes remain positive but decrease as exposure increases). Notwithstanding this observation, the staff of DHS used linear models for this risk assessment. In these models, the dose of arsenic was measured as cumulative $\mu g/m^3$-years; the response was measured as the relative increase in risk over the background (risk ratio). In addition, the models assume that the mechanism of carcinogenesis is a nonthreshold process.

The data from Enterline *et al*. (1987a), Higgins *et al*. (1985), and Lee-Feldstein (1986) were fitted to the model. The regression model used to achieve a linear extrapolation is described by the equation:

$$E[obs_i] = [\alpha + \beta(d_i)] \times Exp_i$$

where $E[\cdot]$ represents the expectation of a random variable, d_i represents the average cumulative dose of arsenic (in $\mu g/m^3$-years) for exposure group i, obs_i represents the observed number of deaths in exposure group i, Exp_i represents the expected number of deaths in group i based on the standard population, α represents the risk ratio predicted for a cumulative dose (d) of zero, and β is the slope parameter (in $[\mu g/m^3\text{-years}]^{-1}$).

To calculate unit risk, the staff of DHS selected the MLE (maximum likelihood estimate) slope and upper 95% confidence limit (UCL) based on use of the four lowest exposure groups from the Enterline *et al*. (1987a) analysis.
A risk assessment was also conducted using an adjustment for the strong interaction between arsenic and smoking observed in several occupational cohorts. The prevalence of smoking was independent of the level of arsenic exposure in the Anaconda cohort (Welch *et al*., 1982), but may have been higher than in the general population. Also, there appeared to be no reason for smokers

to be distributed differently among the exposure levels in the Tacoma cohort, hence smoking was assumed to be independent of arsenic exposure in this cohort as well.

Each dose-specific crude SMR was adjusted taking the low-dose SMR in each study as the baseline. Next, a nonsmokers' SMR and a smokers' SMR were derived. From the nonsmokers' SMR, observed and expected deaths among nonsmokers were inferred. Finally, a regression model was fitted to the inferred nonsmokers' data to find the slope of the line relating cumulative arsenic dose to excess relative risk. This procedure was applied to the data of Enterline *et al.* (1987a) under the assumption that the interaction between smoking and arsenic varies as a function of dose, and that the joint effects at low doses are multiplicative.

The MLE for β was 2.30×10^{-4} using the data on nonsmokers from the study by Enterline *et al.* (1987a). An 95% UCL was estimated and used in evaluating unit risks.

Risks were evaluated separately by sex and for four smoking categories: never, former, light (< 1 pack/day) and heavy smokers. Unit risks for these categories range from 400 to 8,400 per million persons, with upper bounds ranging from 630 to 13,000 per million.

The staff of DHS recommended that the range of risk for ambient exposures to arsenic be based on the 95% UCL predicted from fitting a linear model to the human data adjusted for interaction with smoking. The staff of DHS further recommended that the overall unit risk, 3.3×10^{-3} per $\mu g/m^3$, be considered the best estimate of the upper bound of risk.

Oral

A generalized multistage procedure with both linear and quadratic dose assumptions was used to predict the prevalence of skin cancer as a function of arsenic concentration in drinking water (d) and age (t), assuming exposure to a constant dose rate since birth. F(t,d) represents the probability of developing skin cancer by age t after lifetime exposure to arsenic concentration d. The procedure used is expressed as follows: $F(t,d) = 1 - \exp[-g(d)\, H(t)]$, where g(d) is a polynomial in dose with non-negative coefficients, and H(t) is $(t-w)^k$, where k is any positive real number, and $t > w$ for induction time w. The cancer potency calculation was based on skin cancer incidence data for Taiwanese males (Tseng *et al.*, 1968) because their skin cancer prevalence rates were higher than the females studied. The calculation was also based on several assumptions listed below.

1. The mortality rate was equal for both diseased (skin cancer) and nondiseased persons.

2. The population composition (with respect to skin cancer risk factors) remained constant over time, implying that there was no cohort effect.
3. Skin cancers were not surgically removed from diseased persons.

The population at risk was classified into 4 age groups (0-19, 20-39, 40-59 and ≥ 60 years of age) and three dose groups (0 - 0.3, 0.3 - 0.6 and > 0.6 ppm drinking water arsenic concentration) for males and females separately from the reported prevalence rates (Tseng *et al.*, 1968, 1977) as percentages. The assumption was made that the Taiwanese persons had a constant arsenic exposure from birth, and that males and females consumed 3.5 L and 2 L drinking water/day,

respectively. The multistage procedure was used to predict dose-specific and age-specific skin cancer prevalence rates associated with ingestion of inorganic arsenic. Both linear and quadratic model fitting of the data were conducted. The maximum likelihood estimate (MLE) of skin cancer risk for a 70 kg person drinking 2 L of water/day, adjusted for U.S. population survivorship by life-table analysis, ranged from 1 E-3 to 2 E-3 for an arsenic intake of 1 µg/kg/day. Expressed as a single value, the cancer unit risk for drinking water is 5 E-5 $(\mu g/L)^{-1}$; the corresponding cancer potency value is 1.5 E-0 $(mg/kg/day)^{-1}$.

ASBESTOS

CAS No: 1332-21-4

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB (1998) except as noted)

Molecular weight	not applicable
Boiling point	decomposes
Melting point	decomposes at 600ºC (NIOSH, 1994)
Vapor pressure	not applicable
Air concentration conversion	not applicable

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 6.3 E-2 $(\mu g/m^3)^{-1}$ [1.9 E-4 (100 PCM fibers/m^3)$^{-1}$; see Appendix D]
Slope Factor: 2.2 E+2 $(mg/kg\text{-}day)^{-1}$
[Human occupational asbestos lung tumor and mesothelioma incidence data, excess relative risk model (CDHS, 1986).]

III. CARCINOGENIC EFFECTS

Human Studies

Asbestos has been consistently demonstrated to be carcinogenic in humans and is recognized as a human carcinogen by the International Agency for Research on Cancer (IARC, 1977; NRC, 1984; Ontario Royal Commission, 1984). In occupational cohort mortality studies, exposure to the three principal commercial forms of asbestos – chrysotile, amosite, and crocidolite – has been repeatedly linked with increased risks for lung cancer, mesothelioma and, to a lesser extent, other neoplasm, particularly gastrointestinal and laryngeal cancer (IARC, 1977; NRC, 1984). Occupational exposure to anthophyllite has been associated with an increased risk for lung cancer. Cigarette smoking acts synergistically with occupational exposure to asbestos in increasing the risk of lung cancer, but not mesothelioma (Hammond *et al.*, 1979; NRC, 1974).

Tremolite and actinolite are often contaminants of other ores and have not been extensively studied with respect to their biological effects in humans.

The epidemiologic studies on asbestos are extensive. These have been reviewed by the Consumer Product Safety Commission (1983), the National Academy of Sciences (NRC, 1984), Nicholson (1985), and the Ontario Royal Commission (1984). The relevant studies used in deriving the cancer risk for asbestos are summarized in the tables below.

Table 1: Summary of epidemiologic studies used in quantitative risk assessment for lung cancer.

Study	Cohort Occupation	Fiber type	Sex	Cohort Number	F/U	Lung Cancer Mortality

Animal Studies

Many studies using laboratory animals have been conducted to investigate the carcinogenic potential of various forms of asbestos administered by inhalation, by ingestion (in food or drinking water), and via intraperitoneal and intrapleural injection or deposition. The animal studies have been reviewed by Condie (1983), NRC (1984), and Nicholson (1985).

Gross *et al*. (1967) exposed male rats to airborne chrysotile to a mean concentration of 86 mg/m^3, 30 hours/week for their lifetime and found that a large number of treated animals developed malignant lung tumors (24/72; adenocarcinomas, squamous cell carcinomas and fibrosarcomas, compared to 0/39 for controls) and one developed mesothelioma. Reeves *et al*. (1971) exposed rats, rabbits, mice and hamsters to amosite, crocidolite or chrysotile at a concentration of approximately 48 mg/m^3, 16 hours/week for up to two years. No lung tumors were reported in control or treated hamsters, mice or rabbits. Lung tumors were found in 2/31 rats exposed to crocidolite; no lung tumors were reported for the controls or other fiber exposure groups. In a similar study, Reeves *et al*. (1974) found that gerbils, guinea pigs, hamsters and rabbits exposed to amosite, crocidolite or chrysotile at a concentration of approximately 49 mg/m^3, 16 hours/week for up to two years did not develop lung tumors. Lung tumor incidences in rats exposed to chrysotile, amosite or crocidolite were 3/43, 4/46 and 3/36, respectively; no lung tumors were noted in the 12 controls. Lung tumors were noted in the chrysotile-exposed mice (2/18), but this incidence was not significantly increased compared to controls (1/6).

Wagner *et al*. (1974) compared the carcinogenic effect of five different Union Internationale contre le Cancer (UICC) asbestos samples, amosite, anthophyllite, crocidolite, chrysotile (Canadian), and chrysotile (Rhodesian). Exposure varied from 9.7 to 14.7 mg/m^3 from one day to 24 months, although all animals were followed for their lifetimes. Malignant lung tumors (adenocarcinoma and squamous cell carcinoma) were found in rats from all five asbestos exposure groups (11/146, 16/145, 16/141, 17/137, and 30/144, for the respective fiber types). All but the group exposed to Rhodesian chrysotile had at least one animal demonstrating a mesothelioma. Davis *et al*. (1978) exposed rats to chrysotile (2 or 10 mg/m^3), crocidolite (5 or 10 mg/m^3), or amosite (10 mg/m^3).

Twenty percent (8/40) of the animals exposed to 10 mg/m^3 chrysotile developed malignant lung tumors. One out of 40 animals exposed to the low concentration of chrysotile (2 mg/m^3) developed a peritoneal mesothelioma. Neither amosite nor crocidolite induced malignant lung tumors in the rats.

Several long-term ingestion studies have been conducted on asbestos. Cunningham *et al*. (1977) and Gross *et al*. (1974) fed diets containing chrysotile to rats. Neither study indicated that ingested chrysotile induced an increased incidence of intestinal tumors. Smith *et al*. (1980) reported that amosite given to male and female hamsters via their drinking water did not significantly increase the incidence of cancer. In a lifetime rat feeding study using a diet containing 10% chrysotile, there was some evidence of penetration of asbestos into the colonic mucosa and possible cytotoxicity to the colonic tissues (Donham *et al*., 1980). McConnell *et al*. (1983a, b) reported on a number of studies conducted by the National Toxicology Program (NTP) in which hamsters and rats were fed diets containing different types of asbestos. These studies were generally negative; however, NTP (1985) stated that there was some evidence of carcinogenicity in male rats exposed to intermediate-range (size) chrysotile asbestos as indicated by an increased incidence of adenomatous polyps in the large intestine.

A number of studies have shown that intrapleural administration of asbestos results in the development of mesothelioma (Donna, 1970; Reeves *et al*., 1971; Pylev and Shabad, 1973; Shabad *et al*., 1974; Smith and Hubert, 1974). Chrysotile, amosite, anthophyllite, and crocidolite have all induced mesothelioma when administered intrapleurally to rats, rabbits, and/or hamsters.
Wagner *et al*. (1973) demonstrated a dose-response relationship between the amount of asbestos (superfine chrysotile or crocidolite) administered intraperitoneally and incidence of mesothelioma in treated rats. Stanton and Wrench (1972) showed that commercial asbestos fibers as well as glass and other mineral fibers implanted onto the pleural surface of rats were able to induce formation of mesotheliomas.

Maltoni and Annoseia (1974) found that intraperitoneal injection of crocidolite into Sprague-Dawley rats resulted in over 60% developing mesothelial tumors. Pott and Friedrichs (1972) and Pott *et al*. (1976) reported that several commercial varieties of asbestos, as well as other fibrous materials, induced peritoneal mesotheliomas in mice and rats injected intraperitoneally.

In summary, the animal studies clearly indicated that asbestos is carcinogenic in a variety of species when administered by inhalation or directly into the peritoneum or pleural space. Results of bioassays where asbestos was ingested are inconclusive.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The IARC and US EPA carcinogen classifications for asbestos are 1 and A, respectively – that is, a known human carcinogen. Ample data exists indicating that asbestos induces lung tumors and mesotheliomas in both humans and animals. In cases where both human and animal cancer data exist for a substance and both are suitable for quantitative risk assessment, use of the human data

is preferred by OEHHA. The cancer quantitative risk assessment of asbestos was therefore based on human occupational lung cancer and mesothelioma incidence data, since both posed potential population risks at ambient concentrations of asbestos.

Methodology

The CDHS (1986) risk assessment relies extensively on work done by the Consumer Product Safety Commission (1983), the National Academy of Sciences (NRC, 1984), Nicholson (1985), and the Ontario Royal Commission (1984). As with these risk assessments, the DHS risk assessment on asbestos was based exclusively on the results of occupational epidemiologic studies.

Animal bioassay data were excluded from this analysis as there are numerous epidemiologic studies of populations occupationally exposed to asbestos, which contain or have been supplemented with exposure data adequate for purposes of quantitative risk assessment.

DHS adapted linear models developed and/or used in the work cited above to estimate risks of mesothelioma and lung cancer to the general population. The models extrapolate risks observed in numerous occupationally exposed cohorts to lower levels of asbestos found in the general environment. In this case the range of extrapolation was four to five orders of magnitude. Results are presented below.

Table 3: Estimated lifetime risks of lung cancer and mesothelioma due to continuous exposure to 0.0001 fibers/cm^3 of asbestos (expressed as cases per million population)

Exposure Group	Lung Cancer	Mesothelioma
Male Smokers	11 (110)	24 (120)
Female Smokers	5 (50)	32 (160)
Male Nonsmokers	2 (15)	32 (160)
Female Nonsmokers	1 (6)	38 (190)

Numbers in parentheses represent approximate upper 95% confidence limits.

The use of excess lung cancer lifetime risk values between 11 and 110 per million for 0.0001 fibers/cm^3***** of asbestos exposure were recommended. (*****Fiber/cm^3 = asbestos fibers ≥ 5μm in length, ≥ 0.3 μm in width, with a length/width ratios of ≥ 3:1. Such fiber counts can be converted to total fibers measurable by transmission electron microscopy (TEM) by multiplying by 100 to 1,000. Therefore, 0.0001 (PCM) fibers/cm^3 = 0.01 to 0.1 TEM fibers/cm^3 = 10,000 to 100,000 TEM fibers/m^3.) For mesothelioma, recommended lifetime risk values are between 18 and 190 per million for each 0.0001 fibers/cm^3***** of asbestos exposure. These recommendations are based on best estimates and approximate upper confidence limits for the groups theoretically at highest risk for lung cancer and mesothelioma: male smokers and female nonsmokers, respectively. The above values represent theoretical lifetime risk of cancer assuming continuous average daily exposure to 0.0001 fibers/cm^3***** throughout life.

These fibers can be measured by phase contrast microscopy (PCM) and for historical reasons represent the basis for all recent asbestos risk assessments. The unit risk factor selected for asbestos is 1.9 E-4 (100 PCM fibers/m^3)$^{-1}$ and in units of μg/m^3, 6.3 E-2(μg/m^3)$^{-1}$. This was based on mesothelioma in female nonsmokers. The original TAC unit risk value has been converted

using a factor of 0.003 µg asbestos = 100 asbestos fibers which has been derived from information published by U.S. EPA (1985) (see Appendix D). The number of asbestos fibers associated with a given mass of asbestos can vary appreciably. Also, U.S. EPA (1985) has stated that this conversion factor is the geometric mean of measured relationships between optical fiber counts and mass airborne chrysotile in several published studies. The range of the conversion factor between the different studies is large (0.0005 - 0.015 µg asbestos/100 asbestos fibers) and carries with it an appreciable uncertainty. Use of the unit risk factor listed in the asbestos TAC document [1.9 E-4(100PCM fibers/m^3)$^{-1}$], wherever possible, will result in a more precise risk estimation.

BENZENE

CAS No: 71-43-2

I. PHYSICAL AND CHEMICAL PROPERTIES (from HSDB, 1998)

Molecular weight	78.1
Boiling point	80.1° C
Melting point	5.5° C
Vapor pressure	100 mm Hg @ 26.1° C
Air concentration conversion	1 ppm = 3.2 mg/m^3 @ 25° C

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor	2.9 E-5 $(\mu g/m^3)^{-1}$
Slope Factor	1.0 E-1 $(mg/kg\text{-}day)^{-1}$

[Human occupational exposure leukemia incidence (Rinsky *et al.*, 1981); excess risk calculated using a Weighted Cumulative Exposure/relative risk procedure (CDHS, 1984).]

III. CARCINOGENIC EFFECTS

Human Studies

Case studies of workers exposed to benzene were responsible for generating the hypothesis that benzene causes leukemia in humans. Epidemiological studies performed to test the hypothesis supported the causal nature of the benzene-leukemia association. A summary of some of the more salient features from 23 major epidemiologic studies are shown in Table 1.

Table 1: Epidemiologic studies of carcinogenicity in humans.

Study	Population Studied	Duration	Results[1]
Tabershaw Cooper Assoc. (1974)	petroleum industry workers		Increase in rate of lymphomas (NS)
Thorpe (1974)	petroleum industry workers	1962-1972	Leukemia SMR=121 (NS) (SMR in worker controls = 60)
Aksoy *et al*. (1974, 1976)	Shoemakers exposed to 210-650 ppm benzene	1967-1975	Annualized crude rate of acute leukemia 2-fold greater than expected
McMichael *et al*. (1976)	rubber industry workers		Excess in mortality from: chronic lymphatic leukemia, myelogenous leukemia, lymphosarcoma
Vigliani (1976)	patients with benzene hemopathy; exposures estimated at 200-500 ppm	1942-1975 1959-1974	Leukemia incidence: 11/66 13/135 Estimated relative risk (RR)=20

Table 1 (continued): Epidemiologic studies of carcinogenicity in humans.

Study	Population Studied	Duration	Results[1]
Infante *et al*. (1977)	748 rubber industry workers followed to 7/75		1940-1949: 7 cases of myeloid/monocytic leukemia SMR=506 (U.S. white males) SMR=474 (worker controls)
Ott *et al*. (1978)	benzene workers (Dow); 594 workers followed to 1973	1938-1970	2 deaths from anemia (one pernicious, one aplastic); 3 deaths from leukemia. Mortality results NS but leukemia rates exceed expectation ($p < 0.05$)
Fishbeck *et al*. (1978)	10 chemical workers exposed to benzene	1953-1963	Changes in blood but '… no persisting significant adverse health effects.'
Brandt *et al*. (1978)	case-control study of 50 acute non-lymphocytic leukemia	1969-1977	History of exposure to petroleum products among cases.
Vianna and Polan (1979)	workers in NY State exposed to benzene		RR=2.1 lymphosarcoma RR=1.6 reticulum cell sarcoma RR=1.6 Hodgkin's Disease For workers > 45 years old, the observed number of cases was SS greater than the expected number.
Greene *et al*. (1979)	U.S. Gov't Printing Office workers		Higher proportion of deaths from multiple myeloma, leukemia, and Hodgkin's disease related to exposure to benzene (SS).
Linos *et al*. (1980)	case-control study of 138 leukemics		4 cases found, 3 were chronic lymphocytic leukemia. RR = 3.3 (NS)
Schottenfeld *et al*. (1981)	worker cancer registry compiled by API		Incidence of lymphocytic leukemia & multiple myeloma increased (SS).
Rushton and Alderson (1981)	petroleum refinery workers		Risk of leukemia increased 2-fold in high and medium benzene exposed vs. low exposed ($p = 0.05$).
Rinsky *et al*. (1981)	continuation of follow-up of Infante study		SMR=560 leukemia SMR=2100 leukemia in workers with 5 or more years exposure.
Thomas *et al*. (1982)	refinery workers		SMRs for multiple myeloma and other lymphomas elevated (SS)
Hanis *et al*. (1982)	refinery and chemical workers		SMR for cancer of the lymphopoietic tissues elevated but NS.
Decoufle *et al*. (1983)	chemical plant workers; 259 men followed through 1977	1960-1974	SMR=377 (SS) L & H SMR=682 (SS) leukemia
Tsai *et al*. (1983)	454 refinery workers		No deaths observed from L & H cancer; 0.42 expected (NS).
Arp *et al*. (1983)	rubber industry workers		For lymphocytic leukemia: RR=4.5 (NS) benzene exposure RR=4.5 (NS) other solvent exposure
Environmental Health Associates (Wong *et al*., 1983)	chemical workers	1946-1975	SMRs elevated (NS) for L & H cancer, leukemia, non-Hodgkin's lymphoma; RR=3.2 (SS) L & H cancer (vs. worker control). Dose-response trend found, SMRs for lung cancer and several other cancers elevated (NS)

[1] NS = not statistically significant; SS = statistically significant ($p < 0.05$)
SMR = standardized mortality ratio; L & H = lymphocytic and hematopoietic cancer

Animal Studies

Available experimental data prior to 1976 has been summarized by Maltoni *et al.* (1983). These earlier studies did not provide evidence for carcinogenicity in animals. Since then two significant series of bioassay studies have been reported, those of Maltoni *et al.* (1983) and the National Toxicology Program (NTP, 1983).

In a series of oral studies, reported by Maltoni *et al.* (1983), rats were administered benzene via gavage tube. Male and female Sprague-Dawley rats were administered benzene at 0, 50 or 250 mg/kg benzene in olive oil, 4 to 5 times per week, for 52 weeks. Dose-related increases were observed for Zymbal gland carcinoma in the female rats only. In Sprague-Dawley rats administered 0 and 500 mg/kg benzene in olive oil, 4 to 5 times per week for 104 weeks significant increases relative to controls were reported for Zymbal gland carcinoma (males and females), and oral cavity carcinoma (males and females).

Maltoni *et al.* (1983) also chronically exposed pregnant Sprague-Dawley rats (breeders) and their offspring to high concentrations of benzene using a complex dosing regimen. Exposure concentrations ranged from 200 to 300 ppm. Among the breeders, a slight increase (not significant) in the incidences of Zymbal gland carcinoma and mammary tumors were reported. Among offspring, significant increased incidences in Zymbal gland tumors and non-significant increases in cancers of oral and nasal cavity, mammary gland and liver were reported. Selected study data are listed in Table 2.

Table 2: Maltoni *et al.* (1983) benzene rat bioassay summary

Organ (Site)	Tumor Type	Route of Exposure	Sex	Dose (mg/kg-day)	Cochran-Armitage Linear Trend Test	Fisher Exact Test	Difference in Cancer Attack Rate per 100 (Dose-Control)
Zymbal gland	carcinomas	gavage[1]	F		$p < 0.001$		
				13.9	----	$p = 0.25$	6.7
				66.7	----	$p = 0.003$	25.0
Hemolympho -reticular	'leukemias'	gavage[1]	M		$p = 0.005$		
				13.9	----	$p = 1.0$	0.0
				66.7	----	$p = 0.078$	12.1
Mammary	carcinomas	gavage[1]	F		$p = 0.091$		
				13.9	----	$p = 0.5$	3.3
				66.7	----	$p = 0.178$	11.9
Zymbal gland	carcinomas	gavage[2]	F	321.4	N/A (single dose level)	$p = 0.007$	15.0
	carcinomas	gavage[2]	M, F	321.4		$p < 0.001$	14.0
Oral Cavity	carcinomas	gavage[2]	M	321.4	N/A (single dose level)	$p = 0.003$	17.5
	carcinomas	gavage[2]	M, F	321.4		$p < 0.001$	13.7
Zymbal gland	carcinomas	inhalation[3]	F	17	N/A (single dose level)	$p = 0.27$	3.9

Table 2 (continued): Maltoni *et al.* (1983) benzene rat bioassay summary.

Organ (Site)	Tumor Type	Route of Exposure	Sex	Dose (mg/kg-day)	Cochran-Armitage Linear Trend Test	Fisher Exact Test	Difference in Cancer Attack Rate per 100 (Dose-Control)
Zymbal gland	carcinomas	inhalation[4]	M, F	16.4	N/A (single dose level)	$p = 0.002$	5.1
Liver	hepatomas	inhalation[5]	F	1.42	N/A (single dose level)	$p = 0.022$	5.1

[2]Experiment 2: (#BT902), 92-week interim results, dosing to be carried out for 104 weeks, 118-week interim results.
[3]Experiment 3: (#BT4004), inhalation exposure of 13-week old breeder rats for 104 weeks, 118-week interim results.
[4]Experiment 4: (#BT4004), inhalation exposure of 12-day old embryos for 104 weeks. Dose *in utero* not considered, 118-week interim results.
[5]Experiment 5: (#BT4006), inhalation exposure of 12-day old embryos for 15-weeks. Dose *in utero* not considered, 118 week interim results.

The National Toxicology Program (NTP, 1983) conducted a 2-year bioassay on the carcinogenic effects of oral (gavage) exposure to benzene in F344 rats and $B6C3F_1$ mice. Female rats and mice were administered benzene in corn oil at doses of 0, 25, 50, and 100 mg/kg, 5 days/week, for 103 weeks. Male rats and mice were administered benzene at doses of 0, 50, 100, and 200 mg/kg, 5 days/week for 103 weeks. In F344 rats, statistically significant dose-related increases in the incidences of neoplasms were reported for the oral cavity (males and females), Zymbal gland (males and females), uterus (females) and skin (males). In $B6C3F_1$ mice, statistically significant dose-related increases in the incidences of tumors were reported for the Zymbal gland (males and females), ovary (females), mammary gland (females), Harderian gland (males and females), lung (males and females), preputial gland (males) and for lymphoma/leukemia combined (males and females). Selected study data are listed in Table 3.

Table 3: Summary of NTP bioassay results for significant neoplasms[1,2].

Organ (site)	Tumor Type	Species	Sex	Cochran-Armitage Trend Test	Fisher Exact Test	Difference in Cancer Attack Rate per 100 (High Dose - Control)
Zymbal gland	squamous cell carcinoma	rat	M	$p < 0.001$	$p < 0.001$	30
		rat	F	$p < 0.001$	$p < 0.001$	28

[2]Comparison of highest dose group with control. Mice of both sexes and female rats were administered 71.4 mg/kg-day by gavage, male rats were administered 143 mg/kg-day.

In summary, benzene has been shown to be carcinogenic in animal studies either by inhalation or oral routes of administration. Cancer was observed at multiple sites in these studies.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

CDHS (1984) used both animal and human data for this quantitative risk assessment. The cancer potency estimates based on animal data were obtained from data on Zymbal gland carcinomas in rats exposed via inhalation or gavage by Maltoni *et al.* (1983); and Zymbal gland carcinomas, preputial gland carcinomas, and lymphoma or leukemia in male mice or mammary carcinomas in female mice exposed by gavage by the National Toxicology Program (NTP, 1983). The epidemiological studies analyzed were those of leukemia in workers exposed to benzene via inhalation reported by Infante *et al.* (1984), Rinsky *et al.* (1981), Aksoy *et al.* (1974; 1976), Aksoy (1977), and Ott *et al.* (1978).

Methodology

A summary of the calculated low-dose risk assessments from a number of animal and human studies is shown in Table 4. The epidemiological data were analyzed using a linear nonthreshold model to estimate risk. The animal data were analyzed by fitting a linearized multistage procedure to dose-response data from the animal cancer bioassays. The results of the U.S. EPA's Carcinogen Assessment Group (CAG) epidemiologic-based assessments are also included in the table for comparative purposes (U.S. EPA, 1979).

CDHS (1984) recommended that cancer potency values in the range of 24 to 170 × 10^{-6} per ppb (i.e., 0.024 to 0.17/ppm) be used in estimating risks from low level exposure to benzene. Slightly higher upper bound values were obtained when shortened survival times in the studies analyzed were taken into account. Assuming that humans breathe 20 m^3 per day and weigh 70 kg and that an air concentration of 1 ppm benzene is equivalent to 3.25 mg/m^3, the CDHS range of potency values is equivalent to 0.03 to 0.2 $(mg/kg\text{-}day)^{-1}$.

In 1988, CDHS (under Proposition 65) recommended that the potency value of 0.1 $(mg/kg\text{-}day)^{-1}$ [unit risk = 2.9 × 10^{-5} $(\mu g/m^3)^{-1}$] be used to estimate risk specific intake levels from exposure to benzene. This value falls within the range of estimates derived by CDHS (1984) and the U.S. EPA (1979, 1985), and is the upper 95% confidence bound estimate from the analysis of human data considered most credible by the U.S. EPA.

Subsequent to the development of the benzene TAC cancer unit risk value, OEHHA described new benzene occupational exposure cancer epidemiology data in the 2001 Public Health Goal (PHG) for Benzene in Drinking Water document (OEHHA, 2001)

Yin *et al.* (1987) reported on a large retrospective cohort study of benzene-exposed workers in China. The study examined 28,460 exposed workers from 233 factories and 28,257 control workers from different industries. Thirty leukemia cases were identified (23 acute, 7 chronic) in the exposed workers compared with four cases in the unexposed controls (SMR 574, $p < 0.01$). Exposure estimates from grab-samples taken at the time of the survey ranged from 3 to 313 ppm with the majority of exposures in the range of 16 to 157 ppm.

A number of detailed reports describing further study and analysis of the Chinese Worker Cohort have been published. Yin *et al.* (1994) reported that the cohort had been expanded to include 74,828 benzene-exposed workers (since 1949) and 35,805 controls from 712 factories located in 12 Chinese cities. Dosemeci *et al.* (1994) described the exposure assessment methods. Quantitative estimates of benzene exposure took into account job title and assignment to individual work units, and reflected exposures of individual workers. Li *et al.* (1994) investigated gender differences in hematopoietic and lymphoproliferative disorders and other cancers among the benzene-exposed cohort. No statistically significant differences in cancer mortality were observed for males versus females, although the number of cases for most endpoints was small.

Travis *et al.* (1994) reported on the hematopoietic malignancies and other blood disorders in the benzene-exposure workers in China. Eighty-two hematopoietic neoplasms and related disorders were observed, including 32 cases of acute leukemia, seven cases of myelodysplastic syndromes,

nine cases of chronic granulocytic leukemia, 20 cases of malignant lymphoma, and nine cases of aplastic anemia. In the control workers, 13 hematological malignancies were observed, including six leukemias. Yin *et al*. (1996) reported the overall cancer findings among the expanded benzene-exposed and control worker cohorts. An increased incidence in the benzene-exposed group compared to controls was observed for leukemia (RR 2.6, 95 percent CI = 1.3 to 5.0), malignant lymphoma (RR 3.5, 95 percent CI = 1.2 to 14.9), and lung cancer deaths (RR 1.4, 95 percent CI = 1.0 to 2.0). Among leukemia cases, incidence of acute myelogenous leukemia was increased in the benzene-exposed group (RR 3.1, 95 percent CI = 1.2 to 10.7). Significant increases were also reported for aplastic anemia and myelodysplastic syndromes.

The best upper-bound estimates of leukemia risk resulting from continuous lifetime air exposures of the general population to benzene in the benzene PHG document (OEHHA, 2001) were similar for the U.S. rubber workers (0.044 ppm^{-1}), the Chinese workers (0.056 ppm^{-1}), and for the mean of the two studies combined (0.050 ppm^{-1}). The three lifetime risk estimates all convert to a population-based cancer potency of 0.1 $(mg/kg\text{-}d)^{-1}$ for oral exposures after rounding, which can be scaled to 0.05 $(mg/kg\text{-}d)^{-1}$ for inhalation exposures. These values are similar to the TAC benzene cancer potency value of 0.1 $(mg/kg\text{-}d)^{-1}$.

Subsequent to the development of the benzene TAC cancer unit risk value, OEHHA described new benzene occupational exposure cancer epidemiology data in the 2001 Public Health Goal (PHG) for Benzene in Drinking Water document (OEHHA, 2001)

BENZIDINE

CAS No: 92-87-5

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1994)

Molecular weight	184.2
Boiling point	402°C
Melting point	115-120°C
Vapor pressure	0.0005 mm Hg
Air concentration conversion	1 ppm = 7.53 mg/m^3 @ 25°C

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 1.4 E-1 $(\mu g/m^3)^{-1}$
Slope Factor: 5.0 E+2 $(mg/kg\text{-}day)^{-1}$
[Calculated from a cancer potency factor derived by RCHAS/OEHHA (CDHS, 1988)]

III. CARCINOGENIC EFFECTS

Human Studies

Case *et al.* (1954) examined mortality among British chemical workers exposed to benzidine. Among the population examined (total number not specified), ten deaths were certified as due to bladder cancer. The death rate from bladder cancer in the male Welsh and English population predicts 0.72 deaths from this cause, giving a standard mortality ratio of 13.9 (10/0.72, $p < 0.001$). Non-fatal bladder cancers were also noted among the exposed population.

Mancuso and El-Atar (1967) examined the incidence of urinary tract cancer among 639 male employees of an Ohio plant where benzidine and β-naphthylamine were made, with potential exposure occurring between 1938 and 1939. Six cases of bladder cancer occurred among white workers, giving a population incidence of 204 per 10^5. The expected incidence of bladder cancer among Ohio white males is 4.4 per 10^5. The authors do not present the significance of the change in incidence because of exposure of workers to other compounds.

Zavon *et al.* (1973) conducted a prospective study of workers exposed to benzidine during its manufacture. The authors report on the health surveillance of all 25 employees of a chemical plant who were exposed to benzidine from 3 to 28 years (1930-1958). During the 13 year follow-up period (1957-1970), 11 cases of transitional cell bladder cancer and 2 cases of benign bladder tumors developed. Among the workers with bladder cancers,

two also developed kidney carcinomas and one a benign tumor of the kidney. No background tumor incidences were reported. The average exposure duration for workers with tumors was 13.6 years, whereas the average exposure duration for those without tumors was 8.9 years. Levels of urinary benzidine were measured at the beginning of the follow-up period of the study, with samples taken at the beginning and end of the work day and at the before the work week began. Mean levels were reported to be ~0.01 mg/l before shift, ~0.04 mg/l after shift, and ~0.004 mg/l Monday morning. Quantitative estimates of exposure have been based on these levels. Exposure conditions at the time of the sampling were reported to be representative of conditions in the previous years of plant operation. Air sampling at different locations in the chemical plant showed benzidine concentrations ranged from <0.007 to 17.6 mg/m^3. Potential confounding variables in the study include smoking and exposure to other carcinogens in the work environment such as β-naphthylamine, o-toluidine, and dichlorobenzidine.

Tsuchiya *et al.*(1975) report on the incidence of bladder cancer among 1303 Japanese workers employed in benzidine production or use. Among workers involved in the manufacture of benzidine 61/542 developed bladder cancer. Among workers involved in benzidine use, 11/761 developed bladder cancer. Exposure levels to benzidine and population background incidence of bladder cancer in the Japanese population were not provided in the study. A statistically significant difference in bladder cancer incidence was observed between workers involved in benzidine production versus those involved in benzidine use ($p < 10^{-10}$, Fisher's exact test).

Meigs *et al.* (1986) conducted a 30-year follow-up study of 597 male workers at a benzidine manufacturing plant in Connecticut. Workers were categorized based upon time of employment, but benzidine levels were not quantitated. Among workers in the high exposure category (> 2 years of employment) 6/105 developed bladder cancer. Among workers in the medium (6 mo.-2 yrs.) and low (1 day-6 mo.) exposure categories, 1/147 and 0/345 developed bladder cancer, respectively. Connecticut cancer statistics predict 1.77 cases of bladder cancer in an unexposed population of 597 people. A significant difference in incidence between high exposure workers and unexposed populations was found ($p < 0.003$).

Animal Studies

Saffioti *et al.*(1967) exposed Syrian Golden hamsters (30/sex/group) for life to 0 or 1000 ppm benzidine or benzidine dihydrochloride in feed, and examined them for evidence of liver tumors. Among animals treated with benzidine, 19/22 males and 6/26 females developed cholangiomatous liver tumors (none in controls). Among animals treated with benzidine dihydrochloride, 10/20 males and 12/27 females developed cholangiomatous liver tumors (none in controls). Liver tumor incidence was found to be significantly elevated in exposed animals in each group ($p < 0.001$, Fisher's exact test).

Griswold *et al* .(1968) treated female Sprague-Dawley rats with benzidine by oral gavage. Animals received 1.2 or 2.5 mg/dose (10 animals/group) or 3.5 or 5 mg/dose (20 animals/group) every 3 days, with a total of 10 administrations. After 9 months, surviving

animals were examined for tumors. Increased incidence of mammary carcinoma was found in benzidine treated groups, with 5/10, 7/9, and 4/5 showing tumors in the 1.2, 2.5, and 5 mg dose groups, respectively, versus 3/127 in control animals. There were no survivors among the animals receiving 3.5 mg benzidine. Miakawa and Yoshida (1975) fed female dd strain mice (50/group) diet containing either 0 or 0.2% benzidine for 280 days. Hepatocellular carcinomas were identified in 11 of 32 mice surviving 140 days or more, whereas no hepatocellular carcinomas were reported among control mice. The significance level of the difference in incidence was $p < 0.001$ by Fisher's exact test.

Littlefield *et al.*(1984) exposed male and female F_1 generation mice (BALB/c males × C57BL females) to benzidine in drinking water for life (~33 months). Mice from a cross of F_1 generation males and females were also exposed as above . Exposure levels and incidence of hepatocellular carcinomas are presented in Table 1. Significant differences in the incidence of hepatocellular carcinoma were observed in all exposed groups ($p < 0.05$, Fisher's exact test). Frith *et al.* (1980) also exposed F_1 and F_2 generation mice (BALB/c males × C57BL/6 females) to 30-400 ppm benzidine dihydrochloride in drinking water for 40, 60, or 80 weeks at which time animals were sacrificed. As in the Littlefield *et al.* (1984) study, animals showed a dose-dependent increase in hepatocellular carcinoma incidence. This effect was also shown to be dependent upon duration of exposure.

Table 1. Incidence of hepatocellular carcinoma in F_1 and F_2 generation mice (BALB/c × C57BL) exposed to benzidine in drinking water (Littlefield *et al.*, 1984).

hepatocellular carinoma incidence					
males			Females		
exposure level (ppm)	F_1	F_2	exposure level (ppm)	F_1	F_2
0	14/125	17/123	0	3/124	10/125
30	24/119	20/118	20	51/120	54/119
40	30/96	20/95	30	52/95	43/95
60	32/71	23/72	40	45/72	31/71
80	35/71	24/71	60	55/71	37/72
120	61/71	37/71	80	60/69	51/69
160	49/71	32/71	120	64/72	56/72

Vesselinovitch *et al.* (1975) treated male $B6C3F_1$ mice with feed containing 150 ppm benzidine dihydrochloride from weeks 6 to 45 of life. Groups of 50 mice thus treated were sacrificed at 45, 60, 75, or 90 weeks and examined for liver tumors. Hepatoma incidence was reported to be 8/50, 20/50, 31/50, and 35/50, respectively, at successive sacrifice times, while only one hepatoma was found among 98 control animals sacrificed at 90 weeks ($p < 0.001$; Fisher's exact test). Among the animals with hepatomas, the incidence of hepatocellular carcinoma was 2/50, 5/50, 14/50, and 24/50, respectively, at the successive sacrifice times.

Two other feeding studies have been conducted. Boyland *et al.* (1954) found cases of hepatocellular carcinoma in rats fed diet containing 0.017% benzidine or benzidine plus

tryptophan for life. Inadequate study size, data on controls and poor survival, however, limit the usefulness of this study. Marhold *et al.* (1968) found no tumors in lifetime benzidine feeding study, but poor survival also limits the study's value.

Zabezhinski (1970) exposed 48 albino rats (male and female numbers not specified) to 10-20 mg/m^3 benzidine aerosol for 4 hours/day, 5 days/week for 20 months. Among animals surviving at 13 months, 5/28 developed leukemia (0/21 untreated; p =0.052)
Tumors have also been observed in animals injected subcutaneously with benzidine. They include hepatocellular carcinomas, Zymbal gland tumors and injection-site tumors (Spitz *et al*., 1950; Bonser *et al*, 1956; Pliss, 1964; Prokofjeva, 1971). Intraperitoneal injection of benzidine resulted in the induction of mammary tumors in a single study (Morton *et al*, 1981).

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The data presented by Zavon *et al*. (1973) are the only human cancer data appropriate for the development of a cancer potency value for benzidine. The US EPA (1986, 1987, 1988), Allen *et al.* (1987), and CDHS (1988) have each provided estimates of cancer potency based on human data. However, different assumptions made in the calculation of exposure levels has resulted in different estimates of the cancer potency. Potencies derived in these studies assume that cancer risk is proportional to cumulative exposure. Previously, IARC (1982) had suggested that benzidine cancer risk be based on the assumption that the empirical distribution of cumulative incidence rate is a function of the duration of continual exposure. Derivations of cancer potencies from the human data using these different methodologies and exposure assessments are described in the *Methodology* section below.

Cancer potency values have also been derived from animal studies, in particular those of Griswold *et al*. (1968), Miakawa and Yoshida (1975), Saffioti *et al* (1967), and Littlefield *et al*. (1984). Resulting potency estimates were well below those derived from the human data, suggesting humans may be more sensitive to the carcinogenic effects of benzidine, and therefore animal data are not appropriate for use in the establishing a cancer potency value. CDHS has based its benzidine cancer potency value on the human data of Zavon *et al*. (1973) using exposure level assessment modifications of Allen *et al.* (1987) and the methodology of US EPA (1986, 1987, 1988).

Methodology

US EPA (1986, 1987, 1988) made exposure estimates from the Zavon *et al.* study (1973) based upon reported mean urinary concentrations of 0.04 mg/l. Assuming that average body weight is 70 kg, average urinary output is 1.2 l/day, and 1.45% of absorbed benzidine is excreted in the urine, US EPA calculated the average daily dose to be 0.047 mg/kg-day. Adjusting this value for work time exposure, with 11.46 years the average time exposed,

56.5 years the average age of the cohort, and 240 work days per year, final lifetime exposure levels were calculated to be 0.0063 mg/kg-day.

US EPA (1986,1987, 1988) based estimates of cancer potency on the following relationship where p(t) is the probability of developing a tumor in a study of cohort of average age t at the end of the follow-up period (56.5 years) and an average lifespan t_L (71.3 years), exposed to dose level d (0.0063 mg/kg-day), and assuming that background tumor incidence is negligible:

$$\text{cancer potency} = \frac{-\ln(1 - p(t))}{(d)(\frac{t}{t_L})^3}$$

With this model, US EPA used total tumor incidence (13/25, both benign and malignant) in its calculation, giving a final potency value of 234 $(mg/kg\text{-}day)^{-1}$ (See Table 2). Using the upper 95% confidence bound on the tumor incidence (0.68 vs. 0.52) resulted in a cancer potency value of 363 $(mg/kg\text{-}day)^{-1}$.

Using mean urine benzidine concentrations reported at the beginning (0.01 mg/l) and end (0.04 mg/l) of the work day, Allen *et al.* (1987) adjusted benzidine exposure estimates on the assumption of linear increases in urine concentration during the workday and first-order decay during non-work hours. The resulting average urine concentration during workdays was 0.023 mg/l. Based on assumptions that 1.5% of the inhaled benzidine is present in the urine (100% absorption), urinary output is 1.5 l/day, breathing rate is 10 m^3/8-hour work day, and average exposure time of the cohort is 11.24 years, Allen *et al.* (1987) estimated average cumulative dose to be 2.59 mg-yrs/m^3.

Allen *et al.* (1987) calculated potency using this dose value and the malignant tumor incidence only [p(t) = 11/25 = 0.44] with a background tumor incidence factor (α = 0.002; NIH, 1981) and without using a time adjustment factor. That is:

$$\text{cancer potency} = \frac{-\ln [1 - p(t)] + \alpha}{d}$$

The resulting estimate of cancer potency from work place exposure was 0.22 $(mg{\cdot}yrs/m^3)^{-1}$. with upper and lower 90% confidence bounds of 0.81 and 0.045 $(mg{\cdot}yrs/m^3)^{-1}$. Cancer potency from continuous lifetime exposure was calculated by assuming 240 workdays of a 365 day year and 10 of 20 m^3/day total air breathed during the workday. Potencies thus expressed are 0.67 $(mg\text{-}yr/m^3)^{-1}$ with upper and lower confidence bounds of 2.5 and 0.14 $(mg\text{-}yr/m^3)^{-1}$. Assumptions of 70 kg body weight, 70 yr lifespan, and 20 m^3/day breathing rate (CDHS, 1988) result in a cancer potency of 160 $(mg/kg\text{-}day)^{-1}$ with upper and lower 90% confidence bounds of 600 and 30 $(mg/kg\text{-}day)^{-1}$.

An estimate of cancer potency was also made based on a description of cumulative risk described by IARC (1982) (CDHS, 1988). IARC (1982) describe risk based on the assumption that the risk varies linearly with the duration of exposure. IARC (1982) report

the data from Zavon *et al.* (1973) show a cumulative bladder tumor incidence of 25% among workers exposed to benzidine for 15 years. Under such an assumption, cancer potency (B) from lifetime (t_L = 70 yrs) exposure can be based on the following relationship, where $C(t_1)$ is the experimentally derived cumulative tumor incidence (25%) and $d(t_1)$ is the average daily dose at time t_1 (15 years):

$$B = [C(t_1)/d(t_1)] \times [(t_L/t_1)^k]$$

The factor k describes the relationship of time of exposure to potency, in this case k=1 because of the assumption of linear proportionality. From this relationship, CDHS (1988) derived a cancer potency value. Using the average daily dosing derived by Allen *et al.* (0.023 mg/kg-day) and the cumulative incidence data described by IARC (1982), the calculated cancer potency was 50 $(mg/kg\text{-}day)^{-1}$ with upper and lower 95% confidence bounds of 130 and 16 $(mg/kg\text{-}day)^{-1}$ derived from the confidence bounds of the dose.

CDHS (1988) considers the Allen *et al* .(1987) estimation of daily urine concentration of 0.023 mg/l to be the most useful for establishing exposure levels. Assuming 1.5 ℓ/day urinary output, 70 kg body weight, 240 work days per year, and average duration of exposure 11.46 yrs in a cohort of 56.5 yrs average age, lifetime average exposure is 0.0044 mg/kg-day. Using the US EPA (1986, 1987, 1988) methodology and the upper 95% confidence bound on incidence [p(t) = 0.68], the cancer potency is 5.0 E+2 $(mg/kg\text{-}day)^{-1}$.

A unit risk factor of 0.14 $(\mu g/m^3)^{-1}$ was derived by OEHHA/ATES assuming a breathing rate of 20 m^3/day, 70 kg body weight, and 100% fractional absorption of inhaled benzidine.

Table 2. Benzidine cancer potencies derived from Zavon *et al.* (1973).

Source of methodology	Potency $[(mg/kg\text{-}day)^{-1}]$	Upper 95% confidence bound $[(mg/kg\text{-}day)^{-1}]$
US EPA (1986, 1987, 1988)	234	363
Allen *et al.*(1987)	160	600
IARC (1982)*	50	130
CDHS (1988)		500

*Estimate based on IARC methodology using the dosage estimation of Allen *et al.* (1987).

Oral: male and female gastric tumor (papillomas and squamous cell carcinomas) incidence (Neal and Rigdon, 1967), cancer potency factor calculated using a linearized multistage procedure (OEHHA, 1993).]

III. CARCINOGENIC EFFECTS

Human Studies

The predominant sources of airborne benzo[*a*]pyrene (BaP) are combustion processes. Thus, this compound rarely enters the environment alone but rather is associated with additional PAHs and other components frequently present in both vapor phase and particulate form. Available epidemiological information, therefore, is from persons exposed to mixtures such as tobacco smoke, diesel exhaust, air pollutants, synthetic fuels, or other similar materials. Several IARC publications have been dedicated to the analysis of cancer in processes which involve exposure to polynuclear aromatic compounds (PAHs) (IARC, 1983; 1984a; 1984b; 1985; 1987). The types of cancer reported are often consistent with the exposure pathway: scrotal cancer and lung cancer in chimney sweeps exposed to soot; skin cancer (including scrotal cancer) where shale oils are used; and lung cancer where airborne exposure of PAHs occurs, such as in iron and steel foundries.

Shamsuddin and Gan (1988) examined several human tissues collected at surgery or autopsy using rabbit high-specificity antibody to benzo[*a*]pyrene diol epoxide (BPDE)-DNA adducts and light immunocytochemistry. Antigenicity was detected in the lung, ovary, placenta, uterine cervix, and white blood cells. Their results indicated that the tissue concentration of adducts varies substantially in the human population and that BPDE-DNA adducts can be detected in human tissues by immunochemical techniques.

Five of twelve human lung samples obtained at surgery, from smokers or former smokers, showed positive antigenicity for BPDE-DNA adducts (Garner *et al.*, 1988). Higher DNA-adduct levels were detected in the white blood cells of Finnish iron workers with jobs in high PAH exposure areas than in the white blood cells of workers with jobs in low PAH exposure areas (Perera *et al.*, 1988; Hemminki *et al.*, 1990). Workers were classified as high, medium, or low BaP exposure and there was a highly significant correlation between BaP exposure and DNA-adduct levels (Reddy *et al.*, 1991). A similar observation was noted by Ovrebo *et al.* (1992) in a study of workers exposed around coke ovens. Perera *et al.* (1993) extended the technique and found that PAH adducts were higher in an industrialized area in winter than both in a more rural area in winter and in the same urban area in summer (when less burning of fuel would occur).

In studies looking at PAH-derived adducts bound to serum protein, higher levels of PAH-albumin adducts were found in foundry workers and in roofers than in their respective reference groups (Lee *et al.*, 1991). Smokers had higher levels of BaP-derived adducts bound to serum protein than non-smokers, and workers in high BaP exposure areas (foundry) had two to three times the levels of workers in low exposure areas (Sherson *et al.*, 1990).

Studies with human placental tissues have shown that aryl hydrocarbon hydroxylase (AHH) activity is several times higher in smokers than non-smokers and that this activity increases in a sigmoidal manner with increased numbers of cigarettes smoked (Gurtoo *et al.*, 1983). Genetic factors probably contribute to this variability and, ultimately, to susceptibility of individuals to tumor development (Manchester and Jacoby, 1984).

Animal Studies

BaP is carcinogenic by intratracheal, inhalation, and dermal exposure, by intraperitoneal injection, and when given in the diet.

(a) Inhalation and Intratracheal Exposures

Early experiments by Saffiotti *et al.* (1968) indicated that PAHs are at least weakly carcinogenic to the respiratory tract. A mixture of BaP (3 mg) and Fe_2O_3 (hematite, 0.25 μm) (3 mg) in a saline suspension was administered to Syrian golden hamsters by intratracheal instillation, once per week for 15 weeks. Most surviving animals receiving BaP plus Fe_2O_3 developed tumors of the respiratory tract (mostly bronchogenic carcinoma) whereas control animals receiving Fe_2O_3 only or those receiving no treatment did not develop tumors.

Subsequently, Saffiotti *et al.* (1972) determined the carcinogenic dose-response relationship after intratracheal instillation of a suspension of BaP and Fe_2O_3 in male and female Syrian golden hamsters. Test materials were administered once weekly for 30 weeks at 2.0, 1.0, 0.5, and 0.25 mg BaP/animal and an equivalent weight of Fe_2O_3 (hematite) as particulate carrier. Tumors were not present in animals receiving ferric oxide or in untreated controls. Respiratory tract tumors (including squamous cell carcinomas of

the larynx, of the trachea, and of the bronchi, adenocarcinomas of the bronchi, and adenomas of the bronchi and of the bronchioles and alveoli) developed in all groups of BaP/Fe_2O_3 treated animals. The response was dose related.

In another experiment, Feron *et al.* (1973) gave male Syrian golden hamsters intratracheal doses of 0, 0.0625, 0.125, 0.5, or 1 mg BaP weekly for 52 weeks. A variety of tumors were produced throughout the respiratory tract, including bronchoalveolar adenomas and carcinomas.

Thyssen *et al.* (1980) conducted an inhalation study in which male Syrian golden hamsters were exposed to BaP condensation aerosol (in 0.1% saline; particle size ranging from 0.2 to 1.5 μm) for 10 to 16 weeks at a concentration of 9.8 to 44.8 mg BaP/m^3. Neoplastic changes in the respiratory tract were not seen.

In a subsequent experiment, Thyssen *et al.* (1981) exposed male Syrian golden hamsters to BaP condensed onto sodium chloride particles at BaP concentrations of 2.2, 9.5, and 46.5 mg BaP/m^3. Tumors were not observed in the respiratory tract of the unexposed control group or the group that received 2.2 mg/m^3. The incidence of tumors in this organ system increased in a dose dependent manner for the 9.5 and 46.5 mg/m^3 exposure groups. Papillomas, papillary polyps, and squamous cell carcinomas were seen in the nasal cavity, larynx, trachea, pharynx, esophagus, and forestomach. Lung tumors were absent.

(b) Feeding Studies

Feeding of pelletized chow containing BaP (50 to 250 ppm BaP for 4 to 6 months) to male and female CFW mice caused gastric tumors (papillomas and squamous cell carcinomas), pulmonary adenomas, and leukemia (Rigdon and Neal, 1966; 1969; Neal and Rigdon, 1967). The pulmonary adenomas, gastric tumors, and leukemia occurred independently of each other (Rigdon and Neal, 1969). The overall data strongly suggest a positive carcinogenic effect since there were no gastric tumors in 289 control mice while 178 out of 454 mice fed various levels of BaP had gastric tumors (Neal and Rigdon, 1967).

(c) Dermal Application

BaP has been shown to be carcinogenic by dermal application (ATSDR, 1990). Wynder and associates demonstrated a positive dose-response relationship for BaP-induction of skin tumors in Swiss and in C57BL mice and showed a tumor response at doses as low as 0.001% BaP applied topically in acetone every 2 weeks for up to 2 years (Wynder and Hoffmann, 1959; Wynder *et al.*, 1957; 1960). In addition, incidences of 95% for papillomas and carcinomas of the skin were obtained by chronic administration (3 times weekly for 1 year) of 0.001% BaP to the skin of Swiss mice (Wynder and Hoffman, 1959). Extensive experiments conducted by Conney and associates demonstrated the tumor initiating activity of BaP and several of its epoxide and hydroxy derivatives (summarized by US EPA, 1979 and by Conney, 1982).

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

A very large number of experiments have demonstrated that BaP causes tumors at several sites, by several routes of administration, in both sexes, and in several animal species. Many studies, however, are very limited in scope or in data reported and are not suitable for risk assessment (Zeise and Crouch, 1984).

OEHHA guidelines prescribe that risk assessment use the most sensitive sex, site, and species where a significant increase in cancer incidence is observed (CDHS, 1985). Since there is no adequate information regarding the carcinogenicity of BaP to humans from epidemiological studies, data from animal bioassays were extrapolated to estimate human cancer risk. Potency estimates were derived by OEHHA (1993) from gastric tumors (papillomas and squamous cell carcinomas) observed in male and female mice due to feeding of BaP (Neal and Rigdon, 1967), respiratory tract tumors in hamsters from the inhalation bioassay of Thyssen *et al.* (1981), and from data obtained after intratracheal administration of BaP (Saffiotti *et al.*, 1972; Feron *et al.*, 1973). The dose-response data from these studies are presented in Tables 1-4 below.

Table 1: Gastric tumors in mice from feeding benzo[*a*]pyrene[a].

Exposure (ppm)	Calculated daily dose (mg/kg-day) (animal)	Incidence of gastric tumors
0	0	0/289
1	0.078	0/25
10	0.781	0/24
20	1.563	1/23
30	2.344	0/37
40	3.126	1/40
45	3.516	4/40
50	3.908	24/34
100	7.815	19/23
250	19.538	66/73

Methodology

Cancer risk associated with exposure to ambient levels of BaP was estimated by extrapolating from the experimental data to ambient levels by means of the best fitting linearized multistage procedure GLOBAL86 (Howe *et al.*, 1986). In addition, other models were fit to the data for comparison. In its risk assessment, the US EPA used the data for stomach tumors from oral exposure to BaP in mice and the data for respiratory tract tumors from inhalation exposure in hamsters to estimate cancer potency and unit risks associated with exposure to BaP (US EPA, 1984).

For BaP there is compelling evidence that it is genotoxic and an initiator of tumorigenesis. Therefore, OEHHA staff treated BaP-induced carcinogenesis as a nonthreshold phenomenon and, as such, applied a nonthreshold, linear extrapolation model for cancer potency estimation.

The linearized multistage model was fit to the respiratory tract tumor data resulting from inhalation exposure of hamsters to BaP (OEHHA, 1993; Thyssen *et al.*, 1981). The data from the highest dose group were not used since these animals had an appreciably shortened lifespan (59 weeks versus 96 weeks in other groups) (Thyssen *et al.*, 1981; US EPA, 1984). By considering the conditions of exposure given in the report and using an inhalation rate of 0.063 m^3/day and a "standard" body weight of 0.12 kg for hamsters (US EPA, 1988), a dose of BaP in mg/kg-day was estimated. A q_1^* (animal) equal to 0.43 $(mg/kg\text{-}day)^{-1}$ is obtained. Multiplying by the interspecies surface area correction factor of $(70/0.1)^{1/3}$ yields a human equivalent $q_1^* = 1.1 \times 10^{-3}$ $(\mu g/m^3)^{-1}$ for inhalation.

Because of the limited amount of data currently available for risk assessment of BaP, the inhalation unit risk of 1.1×10^{-3} $(\mu g/m^3)^{-1}$ based on respiratory tract tumors in hamsters is used as a best value for inhalation exposures. For exposures to BaP by other routes, the potency of 11.5 $(mg/kg\text{-}day)^{-1}$ based on gastric tract tumors in mice can be used (Neal and Rigdon, 1967).

Cancer Potency for Other PAHs

IARC (1987; 1989) has classified a number of PAHs, their mixtures and derivatives, as carcinogens (Group 1, Groups 2A and Group 2B) and a large number of PAHs into Group 3, a class of chemicals for which there are no human data but limited or inadequate data in animals (Tables 5 and 6). The US EPA has classified several PAHs in Group B2, possibly carcinogenic to humans and Group D, unclassifiable as to carcinogenicity (Table 7).

In their risk assessment, OEHHA staff concluded that while the studies available for carcinogenic risk assessment of BaP are not ideal for risk assessment, those for practically all other individual PAHs are less complete for risk assessment (OEHHA, 1993). However, there are extensive data establishing the genotoxicity, and in some cases the carcinogenicity, of many PAHs or their genotoxic metabolites. In other cases, some PAHs are not considered carcinogens. Several authors have used mutagenicity and various tests of carcinogenicity to rank several PAHs for their relative carcinogenicity (e.g., Deutsch-

Wenzel *et al.*, 1983; Bingham and Falk, 1969; Habs *et al.*, 1980; Wynder and Hoffman, 1959; Wislocki *et al.*, 1986) and their relative genotoxicity (Brown, 1989). Many of these comparisons were summarized by Clement Associates (1988) and Krewski *et al.* (1989). In these analyses dibenz(*a,h*)anthracene was shown to be more potent than BaP, while other PAHs tested were less or much less potent. These comparisons indicated that considering all PAHs to be equivalent in potency to BaP would overestimate the cancer potency of a PAH mixture, but such an assumption would be health protective and is likely to be helpful in a screening estimate of PAH risks (OEHHA, 1993).

If one assumes that PAHs are as carcinogenic as they are genotoxic, then their hazard relative to BaP would be dependent on their concentration in the environment. In light of the limited information available on other PAHs, BaP remains an important representative or surrogate for this important group of chemically diverse air pollutants.

Selection of Risk Values for Other PAHs

BaP was chosen as the primary representative of the class because of the large amount of toxicological data available on BaP (versus the relatively incomplete database for other PAHs), the availability of monitoring techniques for BaP, and the significant exposure expected (and found). Nisbet and LaGoy (1992) presented a Toxic Equivalency Factor (TEF) scheme for 17 PAHs. The paper was an extension of earlier work by other investigators (Clement Associates, 1987; 1988; Krewski *et al.*, 1989). Along similar lines, OEHHA has developed a Potency Equivalency Factor (PEF) procedure to assess the relative potencies of PAHs and PAH derivatives as a group. This would address the impact of carcinogenic PAHs in ambient air since they are usually present together.

Due to the variety of data available on the carcinogenicity and mutagenicity of PAHs, an order of preference for the use of available data in assessing relative potency was developed. If a health effects evaluation and quantitative risk assessment leading to a cancer potency value had been conducted on a specific PAH, then those values were given the highest preference.

Table 5: IARC groupings of PAHs, mixtures with PAHs, and derivatives.

If potency values have not been developed for specific compounds, a carcinogenic activity relative to BaP, rather than a true potency, can be developed. These relative activity values are referred to by OEHHA as PEFs. For air contaminants, relative potency to BaP based on data from inhalation studies would be optimal. Otherwise, intrapulmonary or intratracheal administration, such as those published by Deutsch-Wenzel *et al.* (1983), would be most relevant, since such studies are in the target organ of interest. Next in order of preference is information on activity by the oral route and skin painting. Intraperitoneal and subcutaneous administration rank at the bottom of the *in vivo* tests considered useful for PEF development because of their lack of relevance to environmental exposures. Next in decreasing order of preference are genotoxicity data which exist for a large number of compounds. In many cases genotoxicity information is restricted to mutagenicity data. Finally, there are data on structure-activity relationships among PAH compounds. Structure-activity considerations may help identify a PAH as carcinogenic, but at this time have not been established as predictors of carcinogenic potency.

Using this order of preference, PEFs were derived for 21 PAHs and are presented in Table 8. The cancer potencies of four other PAH compounds are given in Table 9. Explanation of the derivation of each PEF, type of data used in the derivation, and the relevant references are given below.

Table 8: OEHHA PEF weighting scheme for PAHs[1]

PAH or derivative	PEF
benzo[*a*]pyrene	1.0 (index compound)
benz[*a*]anthracene	0.1
benzo[b]fluoranthene	0.1
benzo[*j*]fluoranthene	0.1
benzo[k]fluoranthene	0.1

Source: [1]OEHHA (1993), [2]OEHHA (2004): It is assumed that unit risks for inhalation have the same relative activities as cancer potencies for oral intake.

Potency and Potency Equivalency Factors (PEFs) for Selected PAHs

1. Benzo[*a*]pyrene. Benzo[*a*]pyrene (BaP) was the index compound for relative potency and for Potency Equivalency Factors (PEF) for PAHs and derivatives. It has a cancer potency of 11.5 $(mg/kg\text{-}day)^{-1}$ and inhalation unit risk of 1.1×10^3 $(\mu g/m^3)^{-1}$. For the potency equivalency scheme, it was assigned a PEF of 1.

2. Dibenz[*a*,*h*,]anthracene. An expedited potency of 4.1 $(mg/kg\text{-}day)^{-1}$ was derived using the linearized multistage model with the only dose-response data set available - a drinking water study (Snell and Stewart, 1962) which reported alveolar carcinomas of the lung in male DBA/2 mice due to dibenz[*a*,*h*]anthracene (incidence = 14/21 at 28.3 mg/kg-day versus 0/25 in controls). An inhalation unit risk can be obtained from a potency under the assumption that the chemicals are equally absorbed and are equally potent by oral and inhalation routes and that a 70 kg person inhales 20 cubic meters of air per day. When the potency in units of $(mg/kg\text{-}day)^{-1}$ is divided by 3500 (70 kg * 1000 µg/mg/20 m^3), an inhalation unit risk is obtained in units of $(\mu g/m^3)^{-1}$.

3. 7,12-Dimethylbenzanthracene. An expedited potency of 250 $(mg/kg\text{-}day)^{-1}$ was derived. The only study listed in the Gold *et al.* cancer potency (TD50) database (Gold *et al.*, 1984; 1986; 1987; 1989; 1990) is the feeding study by Chourolinkov *et al.* (1967) in female albino mice. Significant increases in malignant angioendotheliomas of the mesenteric intestine and papillomas of the forestomach were observed in animals treated with 0.39 mg/kg-day of 7,12-dimethylbenzanthracene. Cancer potency is based on mesenteric intestine angioendothelioma incidence (incidence = 49/75 versus 0/40 in controls).

4. 3-Methylcholanthrene. An expedited potency of 22 $(mg/kg\text{-}day)^{-1}$ was derived. Results of 3 studies in male Long Evans rats, one study in an unspecified strain of female rats, and 10 studies in female Wistar rats were included in the Gold *et al.* database. All studies in female rats found highly significant increases in tumors of the mammary gland. The cancer potency for 3-methylcholanthrene was taken as the geometric mean of cancer potencies estimated from 9 of the 10 studies in female rats (Shay *et al.*, 1962; Gruenstein *et al.*, 1964; Shay *et al.*, 1961). The upper bound on potency could not be estimated from one of the studies by Shay *et al.* (1961), because 100% of the treated animals developed mammary gland tumors.

5. 5-Nitroacenaphthene. An expedited potency of 0.13 $(mg/kg\text{-}day)^{-1}$ was derived based on the combined incidence of benign and malignant tumors of the ear canal in female rats. Usable studies were feeding studies by Takemura *et al.* (1974) in female Syrian golden hamsters and by the National Cancer Institute (1978) in male and female $B6C3F_1$ mice and F344 rats. The compound 5-nitroacenaphthene induced increases in tumor incidences at multiple sites in rats and female mice. Rats were the most sensitive species; the sensitivity of males were similar to that of females.

6. Benzo[*b*]fluoranthene. Benzo[*b*]fluoranthene was assigned a PEF of 0.1. Clement Associates (1988) applied both a two stage model and the multistage model to various data sets for several PAHs. The two models generally gave similar results for relative potency. In order to verify the results, OEHHA staff (OEHHA, 1993) used GLOBAL86 to fit the multistage model to the tumor data used by Clement Associates and obtained relative cancer potencies similar to those obtained by Clement Associates. Clement Associates (1988) used the mouse skin carcinogenesis data obtained by Habs *et al.* (1980) and the intrapulmonary administration to rats by Deutsch-Wenzel *et al.* (1983) to estimate a cancer potency for benzo[*b*]fluoranthene relative to BaP. As an example of the type of data used,

Deutsch-Wenzel *et al.* obtained pulmonary tumor incidences of 0, 2.9, and 25.7% after intrapulmonary administration of 0.1, 0.3, and 1 mg benzo[*b*]fluoranthene, respectively, whereas they obtained 11.8, 60.0, and 94.3% tumor incidence after the same doses of benzo[*a*]pyrene. Clement Associates estimated a relative cancer potency for benzo[*b*]fluoranthene of 0.140 after fitting the two stage model to the data and 0.105 after fitting the multistage model. Using the data of Habs *et al.* a relative cancer potency of 0.167 was obtained with the two stage model and 0.201 with the multistage model. The results from the multistage model were averaged, then rounded (down) to 0.1 to obtain the PEF. OEHHA obtained a relative potency of 0.208 for benzo[*b*]fluoranthene fitting the multistage model to the data from Habs *et al.* OEHHA staff were also able to reproduce the calculations for the two stage model in the accepted model for cancer risk assessment in California; results from the multistage model have been used to obtain PEFs although the two models usually gave the same PEF.

7. Benzo[*j*]fluoranthene. Benzo[*j*]fluoranthene was assigned a PEF of 0.1. Clement Associates (1988) used the mouse skin carcinogenesis data obtained by Habs *et al.* (1980) to estimate a cancer potency relative to BaP of 0.0648. OEHHA staff estimated 0.065 using the same data. This was rounded to 0.1 to obtain the PEF. Clement Associates did not use the data of Deutsch-Wenzel *et al.* (1983) on benzo[*j*]fluoranthene to calculate a relative potency but Deutsch-Wenzel *et al.* found that it was very similar in tumorigenic activity to benzo[*k*]fluoranthene.

8. Benzo[*k*]fluoranthene. Benzo[*k*]fluoranthene was assigned a PEF of 0.1. Clement Associates (1988) used mouse skin carcinogenesis data obtained by Habs *et al.* (1980) to obtain a cancer potency relative to BaP of 0.0235 and the intrapulmonary administration to rats by Deutsch-Wenzel *et al.* (1983) to estimate a PEF of 0.085. Because the latter was obtained by the pulmonary route it was chosen to be the basis of the PEF. The value was rounded to 0.1 to obtain the PEF.

9. Benz[*a*]anthracene. Benz[*a*]anthracene was assigned a PEF of 0.1. In the case of benz[*a*]anthracene, mouse skin carcinogenesis data obtained by Bingham and Falk (1969) were used by Clement Associates (1988) to calculate potencies for benz[*a*]anthracene. For this chemical the multistage model gave a relative potency of 0.0137. Using the two stage model a higher cancer potency of 0.145 relative to BaP was obtained. In the Wislocki *et al.* (1986) report, in which lung adenomas were induced in newborn mice, benz[*a*]anthracene (2.8 micromoles) was less carcinogenic (12/71 or 17% versus 7/138 or 5% in controls) relative to 0.56 micromoles BaP (24/64 or 38% versus 7/138 in controls). The relative potency was 0.08, which rounds to 0.1. Since the US EPA was using a PEF of 0.1 for this PAH (US EPA, 1993b) and the data from the Wislocki study were consistent with a PEF of 0.1, a value of 0.1 was selected by OEHHA.

10. Dibenz[*a,j*]acridine. Dibenz[*a,j*]acridine was assigned a PEF of 0.1. Warshawsky *et al.* (1992) compared the tumor-initiating ability of dibenz[*a,j*]acridine to BaP in mouse skin. Two hundred nanomoles of each compound were applied to groups of 30 mice, then the skin lesion was promoted with a phorbol ester for 24 weeks. Twenty-seven out of 30 BaP mice (90%) had skin papillomas, while 17 of 30 (57%) of the dibenz[*a,j*]acridine mice

had skin papillomas. The multistage model was fit to both sets of data and the ratio of upper 95% confidence limits on the linear coefficient was 0.36. This was rounded to a PEF of 0.1.

11. Dibenz[*a*,*h*]acridine. Dibenz[*a*,*h*]acridine was also assigned a PEF of 0.1. Its carcinogenic classification by IARC was based on studies published in 1940 and earlier and the studies did not appear appropriate for estimation of a PEF. Since its structure is similar to dibenz[*a*,*j*]acridine, it was assigned the same PEF as dibenz[*a*,*j*]acridine until usable compound-specific bioassay data becomes available.

12. 7H-Dibenzo[*c*,*g*]carbazole. 7H-dibenzo[*c*,*g*]carbazole was assigned a PEF of 1.0. Warshawsky *et al.* (1992) compared the tumor-initiating ability of 7H-dibenzo[*c*,*g*]carbazole to BaP in mouse skin. Two hundred nanomoles of each compound were applied to 30 mice, then promoted with a phorbol ester for 24 weeks. Twenty-seven out of 30 BaP-treated mice (90%) had skin papillomas, while 26 of 30 (87%) of the dibenzo[*a*,*j*]acridine-treated mice had skin papillomas for a relative tumorigenic activity of 0.97. This was rounded to a PEF of 1.

13. Dibenzo[*a*,*l*]pyrene. Dibenzo[*a*,*l*]pyrene was assigned a PEF of 10. Cavalieri *et al.* (1989; 1991) studied the tumor-initiating and dose-response tumorigenicity of dibenzo[*a*,*l*]pyrene in mouse skin and rat mammary gland. BaP was used as a reference compound in some experiments. Dibenzo[*a*,*l*]pyrene was the most potent member of the group. Several levels of PAHs were tested. When results from 33.3 nanomoles of dibenzo[*a*,*l*]pyrene as a skin tumor initiator (with promotion by a phorbol ester) were compared to results using the same amount of BaP, dibenzo[*a*,*l*]pyrene induced skin tumors in 23/24 (96%) of the animals while BaP induced tumors in 10/23 (43%) which resulted in a relative potency of 5.8. Dibenzo[*a*,*l*]pyrene induced approximately 5 times as many tumors per tumor-bearing animal. In a second experiment 4 nanomoles of each chemical were compared. Ninety-two percent (22/24) of the dibenzo[*a*,*l*]pyrene-treated mice had tumors but only 4% (1/24) of the BaP animals, which yielded a relative potency of 25.1. In a third experiment 100 nM were compared without promotion. Twenty-nine percent (7/24) of the dibenzo[*a*,*l*]pyrene-treated mice had tumors but only 4% (1/24) of the BaP animals, for a relative potency of 4. Finally, with direct application to the mammary gland, 0.25 and 1.0 nanomoles dibenzo[*a*,*l*]pyrene led to tumors in all the rats treated (19 and 20 per group, respectively) whereas only one animal in the 0.25 micromoles BaP group showed a tumor for a relative potency greater than 100. Based on its much greater tumorigenic activity than BaP in the above tests, dibenzo[*a*,*l*]pyrene was assigned a PEF of 10.

14. Dibenzo[*a*,*h*]pyrene. Dibenzo[*a*,*h*]pyrene was assigned a PEF of 10 since, in the experiments by Cavalieri *et al.* (1989) in which all four dibenzo[a]pyrenes were studied, its tumor causing activity was similar to dibenzo[*a*,*l*]pyrene. For example, when used to initiate tumors in mouse skin, 18 of 24 (75%) of mice treated with dibenzo[*a*,*h*]pyrene had tumors compared to 22 of 24 (92%) with dibenzo [*a*,*l*]pyrene. Controls showed skin tumors in 2 of 23 mice (9%).

15. Dibenzo[*a*,*i*]pyrene. Dibenzo[*a*,*i*] pyrene was assigned a PEF of 10 since, in the experiments by Cavalieri *et al.* (1989) in which all four dibenzo[*a*]pyrenes were studied, its tumor-causing activity was similar to dibenzo[a,l]pyrene. For example, when used to initiate tumors in mouse skin, 15 of 24 (63%) of mice treated with dibenzo[a,i]pyrene had tumors compared to 22 of 24 (92%) with dibenzo-[*a*,*l*]pyrene. Controls showed skin tumors in 2 of 23 mice (9%).

16. Dibenzo[*a*,*e*]pyrene. Dibenzo[*a*,*e*]pyrene was assigned a PEF of 1.0. Dibenzo[*a*,*e*]pyrene was the least potent of the four dibenzo[*a*]pyrenes studied by Cavalieri *et al.* (1989; 1991). In the experiments in which all four dibenzo[*a*]pyrenes were compared (Cavalieri *et al.*, 1989), its tumor-causing activity was approximately one-tenth to one-twentieth that of dibenzo[*a*,*l*]pyrene.

17. Indeno[1,2,3-*cd*]pyrene. Indeno[1,2,3-*cd*]pyrene was assigned a PEF of 0.1. Clement Associates (1988) used the mouse skin carcinogenesis data obtained by Habs *et al.* (1980) and by Hoffman and Wynder (1966) and the lung tumor data obtained by Deutsch-Wenzel *et al.* (1983) after intrapulmonary administration to estimate cancer potencies relative to BaP of 0.0302, 0.0292, and 0.246, respectively. These were averaged and rounded to obtain a PEF of 0.1.

18. 5-Methylchrysene. 5-Methylchrysene was assigned a PEF of 1.0. The activity of 5-methylchrysene relative to BaP has been studied by Hecht *et al.* (1976) using skin tumor initiation with phorbol ester (tetradecanoy1 phorbol acetate) promotion as well as skin tumor induction in mice. In the skin tumor induction test the tumorigenic activities of 5-methylchrysene and BaP were comparable enough so that a PEF of 1.0 was selected for 5 methylchrysene. Weekly application of 0.01% 5-methylchrysene led to skin carcinomas in 10 of 15 mice treated for up to 62 weeks, while 0.01% BaP led to skin carcinomas in 14 of 18 mice. The results for 0.005% of the 2 chemicals were 6 of 9 and 7 of 10, respectively.

19. 1-Nitropyrene. 1 Nitropyrene has been assigned a PEF of 0.1. In the Wislocki *et al.* (1986) report, in which lung tumors were induced in newborn mice, 1-nitropyrene (0.7 micromoles) was weakly carcinogenic in males (6/34 or 18% versus 4/45 or 9% in controls) and not carcinogenic in females (3/50 or 6% versus 2/34 or 6% in controls) relative to 0.56 micromoles BaP (13/37 or 35% in males versus 1/28 or 4% in control males and 13/27 or 48% in females versus 0/31 in control females). The relative potency was 0.348 in males and 0.076 in females. A PEF of 0.1 was assigned based on the experiment.

20. 4-Nitropyrene. 4-Nitropyrene was assigned a PEF of 0.1. Wislocki *et al.* (1986) compared the lung tumorigenicity of nitrated derivatives of pyrene to BaP in a newborn mouse assay. The background incidences were 4% in males and 0% in females. The administration of 2.8 micromoles of 4-nitropyrene gave a net incidence of 34% tumors in males and 31% in females, while 0.56 micromoles BaP gave 31% tumors in males and 48% in females. The potency of 4-nitropyrene relative to BaP was 0.23 in males and 0.12 in females. These were averaged and rounded to a PEF of 0.1.

21. 1,6-Dinitropyrene. 1,6-Dinitropyrene was assigned a PEF of 10. In the Wislocki *et al.* (1986) report, 1,6-dinitropyrene (0.2 micromoles) was weakly carcinogenic in inducing lung tumors in females (2/29 versus 0/31 in controls) and essentially not carcinogenic in males (1/25 versus 1/28 in controls) relative to 0.56 micromoles BaP (see 1-nitropyrene above for BaP data). The weak response combined with the low dose of 1,6-dinitropyrene (0.2 micromoles) relative to BaP (0.56 micromoles) resulted in a relative potency of 0.52 in females and 0.54 in males. In an intratracheal injection experiment (Takayama *et al.*, 1985) hamsters were given 26 weekly instillations of 0.5 mg BaP. All 10 males and 9 of 10 females developed respiratory tract tumors. A unit risk of 2.9×10^{-2} $(\mu g/m^3)^{-1}$ obtained from the female data which is 6.4 times the unit risks obtained from intratracheal studies using BaP and 26 times that using inhalation data. In a study by Iwagawa *et al.* (1989) using several doses of 1,6-dinitropyrene or BaP implanted directly into the lungs, a relative potency of 5.1 was obtained from the resulting lung cancer data. In light of the two experiments showing high relative potency and of 1,6-dinitropyrene's strong mutagenicity, a PEF of 10 appeared to be more appropriate than 1.0.

22. 1,8-Dinitropyrene. 1,8-Dinitropyrene was assigned a PEF of 1.0. In the Wislocki *et al.* (1986) report, 1,8-dinitropyrene (0.2 micromoles) was weakly carcinogenic in females (2/29 versus 0/31 in controls) and not carcinogenic in males (1/31 versus 1/28 in controls) relative to 0.56 micromoles BaP. However, due again to the low dose of 1,8-dinitropyrene chosen, the relative potency was 0.46 in females and 0.41 in males. In view of the high PEF of 1,6-dinitropyrene derived above and the very high mutagenicity of 1,8-dinitropyrene, the default PEF of 1.0 was assigned to 1,8-dinitropyrene until better *in vivo* data becomes available to derive a PEF.

23. 6-Nitrochrysene. 6-Nitrochrysene was assigned a PEF of 10. In the Wislocki *et al.* (1986) report, 0.7 micromoles of 6-nitrochrysene gave a net incidence of 76% lung tumors in males (28/33 versus 4/45 in controls) and 84% in females (36/40 versus 2/34 in controls). The potency of 6-nitrochrysene relative to BaP was 3.27 in males and 2.50 in females. In the newborn mouse assay of Busby *et al.* (1988), "(t)he ED50 for total lung tumors was 0.02 μmol for 6-NC and 0.2 μmol for BaP, thus showing a 10-fold higher potency for 6-NC compared with the 25-fold difference noted with tumor multiplicity." In a subsequent report (Busby *et al.*, 1989), 0.03 micromoles of 6-nitrochrysene caused lung adenomas and adenocarcinomas in 19/26 males and 13/22 females (versus controls of 13/91 in males and 7/101 in females) while 0.24 micromoles BaP caused lung adenomas and adenocarcinomas in 13/28 males and 19/27 females (against the same controls). The relative potencies were 17.51 for males and 6.17 for females. Based on the several experiments a PEF of 10 was selected.

24. 2-Nitrofluorene. 2-Nitrofluorene was assigned a PEF of 0.01. Miller *et al.* (1955) fed 2-nitrofluorene at a level of 1.62 mmol(215 mg)/kg diet to rats. This is estimated to give an animal dose of 33.1 mg/kg-day and a human equivalent dose of 4.7 mg/kg-day. In one experiment 17 of 20 male rats (85%) developed forestomach tumors by 12 months. In another experiment 4 of 9 female rats (44%) developed mammary tumors by 10 months. These experiments yielded cancer potencies of 0.25 and 0.62 $(mg/kg\text{-}day)^{-1}$, approximately

0.02 and 0.05 that of BaP obtained in this risk assessment. The values of 0.02 and 0.05 were averaged and rounded down to obtain a PEF of 0.01.

25. Chrysene. Chrysene was assigned a PEF of 0.01. Clement Associates (1988) used the mouse skin carcinogenesis data obtained by Wynder and Hoffman (1959) to estimate a cancer potency relative to BaP of 0.0132. This was rounded to obtain a PEF of 0.01.

BENZYL CHLORIDE

CAS No: 100-44-7

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1994)

Molecular weight	126.58
Boiling point	179°C
Melting point	-43 to -48°C
Vapor pressure	1 mm Hg at 22°C
Air concentration conversion	1 ppm = 5.26 mg/m^3

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 4.9 E-5 $(\mu g/m^3)^{-1}$
Slope Factor: 1.7 E-1 $(mg/kg\text{-}day)^{-1}$
[Cancer potency factor derived by US EPA/IRIS (1989) from female rat C-cell thyroid tumor incidence data (Lijinsky, 1986) using a linearized multistage procedure, extra risk; adopted by RCHAS/CDHS (1991).]

III. CARCINOGENIC EFFECTS

Human Studies

Several studies report on cancer mortality in workers occupationally exposed to benzyl chloride.

Sakabe *et al*. (1976) studied cancer incidences among 41 workers exposed to chemicals including benzyl chloride over 18 years (ending in 1972) in a plant producing benzoyl chloride in Japan. Four cases of cancer were reported among the workers: two fatal cases of lung cancer, one fatal maxillary malignant lymphoma, and one squamous cell carcinoma of the lung (still surviving in 1973). The range of employment duration among the workers with cancer was 6 to 14 years. Both cases of lung cancer were in smokers. The expected number of lung cancer deaths among 41 Japanese males was 0.06. In addition to smoking, another potential confounding factor is the reporting of exposure to other compounds in the work environment including benzotrichloride, benzoyl chloride, toluene, chlorine gas, hydrogen chloride, benzal chloride, and other chlorinated toluenes and polymers. Exposure levels were not quantitated.

Sakabe and Fukuda (1977) also reported on cancer deaths among workers exposed to chemicals including benzyl chloride in another plant involved with the production of benzoyl peroxide and benzoyl chloride between 1952 and 1963. Two lung cancer deaths (one a smoker) were reported. Expected number of deaths and exposure levels were not reported, and workers were also exposed to other chemicals as listed in the description of the study by Sakabe *et al*. (1976).

Sorahan *et al*. (1983) studied cancer mortality among British workers occupationally exposed to a number of compounds including toluene, benzotrichloride, benzoyl chloride, benzyl chloride, and benzal chloride during the course of producing chlorinated toluenes. Five digestive system cancers and 5 respiratory system cancers were reported among 163 male workers employed more than 6 months between 1961 and 1970. Expected mortality rates from these tumors in England and Wales were 1.24 and 1.78, respectively, and the mortality ratio was significantly elevated. Smoking rates were not reported among the workers. Cumulative exposure and death from any cancer among workers employed before 1951 was shown to be significantly correlated by survival analysis using the Cox Proportional Hazard Model, although this was not the case when entry cohorts were combined.

Wong and Morgan (1984) studied cancer mortality among a cohort of 697 workers employed from 1 to more than 35 years in a chlorination plant in Tennessee. Workers were exposed to benzyl chloride, benzoyl chloride, and benzotrichloride. Deaths from respiratory cancers were reported for 7 workers, 5 of whom were exposed for more than 15 years. Expected mortality for U.S. males in a group of this size was 2.84 deaths (1.32 deaths for the subgroup exposed > 15 years). No data on smoking was reported.

Animal Studies

Lijinsky (1986) treated F344 rats (52/sex/dose) and B6C3F$_1$ mice (52/sex/dose) with benzyl chloride in corn oil by gavage. The rats were dosed with 0, 15, and 30 mg/kg/day benzyl chloride and mice with 0, 50 and 100 mg/kg/day benzyl chloride, with treatments 3 days/week for 2 years. Animals were histopathologically examined 3-4 weeks after the end of the treatment using the NCI bioassay protocol. Survival in both species was not significantly affected by treatment. The incidence of C-cell adenoma/carcinoma of the thyroid was significantly increased in female rats in the high-dose group compared to control animals (14/52 treated vs. 4/52 control; $p < 0.01$ by Fisher's exact test). In male mice in the high-dose group, significantly increased incidences were found for hemangioma/hemangiocarcinoma (5/52 treated vs. 0/52 control), forestomach carcinoma (8/52 treated vs. 0/51 control) and forestomach carcinoma/papilloma (32/52 treated vs. 0/51 control). In male mice in the low-dose group only, an increased incidence of hepatic carcinoma/adenoma (28/52 treated vs. 17/52 control) was reported. In female mice in the low- and high-dose groups, an increased incidence of forestomach carcinoma/papilloma (5/50 low-dose, 19/51 high-dose vs. 0/52 control) was reported.

Injection-site sarcomas developed in 3 of 14 BD-strain rats administered benzyl chloride in peanut oil subcutaneously weekly for 51 weeks at 40 mg/kg-week and 6 of 8 rats administered 80 mg/kg-week (Druckrey *et al*., 1970). Mean induction time was 500 days.

Poirier *et al*. (1975) treated A/H mice (20/dose) 3 times weekly over 24 weeks intraperitoneally with a total dose of 0.6, 1.5 or 2 g benzyl chloride/kg body weight in tricaprylin. Surviving animals were sacrificed at 24 weeks. Among the survivors, lung tumors were found in 4/15, 7/16, and 2/8 animals, respectively. Animals treated with tricaprylin alone had an average of 0.22 lung tumors/mouse and animals receiving no

treatment had 0.21 lung tumors/mouse. The incidence of lung tumors in treated animals was not found to be statistically significant from control animals.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Human studies do not provide adequate data for the development of a cancer potency value because of the presence of confounding factors in the studies (multiple compound exposures, no data on smoking status) and no reporting of exposure levels. The animal study by Lijinsky (1986) showing development of thyroid tumors in female rats, and forestomach papillomas and carcinomas in male and female mice provides data from which cancer potency values can be derived.

Methodology

Cancer potency values were derived by US EPA (1989) from the tumor incidence data presented in the study by Lijinsky (1986). The experimentally administered doses (15 and 30 mg/kg) were converted to time-weighted dosage based on the dosing schedule (3 times/week) and the experimental duration (107.5 weeks). The human equivalent dose (HED) was calculated based on an assumed experimental animal body weight (bw_a) of 0.35 kg and human body weight (bw_h) of 70 kg using the following relationship:

$$HED = \text{time-weighted dose} \times (bw_a/bw_h)^{1/3}$$

The calculated human equivalent doses in the Lijinsky (1986) study were 1.06 and 2.12 mg/kg-day. A linearized multistage procedure (CDHS, 1985) was applied to the tumor incidence data for thyroid tumors in female rats (4/52 controls, 8/51 low-dose, 14/52 high-dose), forestomach tumors in male mice (0/51 controls, 5/50 low-dose, 32/52 high-dose) and forestomach tumors in female mice (0/52 controls, 5/50 low-dose, 19/51 high-dose). This resulted in estimations of the upper 95% confidence bound of cancer potency (q_1^*) of 0.17, 0.056, and 0.12 $(mg/kg\text{-}day)^{-1}$, respectively. Selection of the cancer potency value is made in the most sensitive species and site; therefore, the cancer potency value [0.17 $(mg/kg\text{-}day)^{-1}$] derived from the female rat C-cell thyroid tumor data was chosen.

A unit risk value of 4.9 E-5 $(\mu g/m^3)^{-1}$ was derived by ATES/OEHHA assuming a human breathing rate of 20 m^3/day, a human body weight of 70 kg, and 100% fractional absorption after inhalation exposure.

BERYLLIUM

CAS No: 7440-41-7

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1994)

Molecular weight	9.012
Boiling point	2970°C
Melting point	1287°C
Vapor pressure	10 mm Hg @ 1860°C

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 2.4 E-3 $(\mu g/m^3)^{-1}$
[Calculated by US EPA (1992) from the human inhalation exposure data of Wagoner *et al.* (1980).]

III. CARCINOGENIC EFFECTS

Human Studies

US EPA (1992) reviewed several studies that found increased incidences of lung cancer in beryllium processing workers. A cohort mortality study of 3055 white males employed at a single beryllium processing plant in Pennsylvania with a median duration of employment of 7.2 months demonstrated a statistically significant increased incidence of mortality due to lung cancer in the entire cohort, as well as in the 2068 cohort members followed for 25 years or more since initial employment (Wagoner *et al.,* 1980). Recalculation of the number of expected deaths using 1968-1975 lung cancer mortality data indicated that the increased incidence was significant only among workers followed for 25 years or more (Bayliss, 1980; MacMahon, 1977, 1978), and was not significant when the number of expected deaths was adjusted for smoking (US EPA, 1986).

Earlier studies of workers from the same beryllium processing plant alone or combined with workers from other beryllium plants reported a statistically significant increase in lung cancer mortality (Bayliss and Wagoner, 1977; Mancuso, 1970, 1979, 1980). These studies made no adjustment for smoking and had methodological constraints and deficiencies that precluded their use to establish a causal relationship between beryllium exposure and lung cancer.

Animal Studies

Slight, non-statistically significant increases in cancer incidence (all tumor types) were observed in male Long-Evans rats (52/sex/group) following lifetime exposure to 5 ppm beryllium sulfate administered in the drinking water (Schroeder and Mitchener, 1975a).

Tumors were observed in 9/33 treated and 4/26 control rats. High mortality during the study resulting from a pneumonia epidemic at 20 months greatly reduced the power of this study to detect any potential carcinogenic effect of beryllium exposure. A non-statistically significant increase in combined lymphoma and leukemia incidence was observed in female Swiss mice administered 5 ppm beryllium sulfate in drinking water for life (9/52 exposed, 3/47 controls) (Schroeder and Mitchener 1975b).

Male and female Wistar-derived rats were exposed to diet containing beryllium sulfate at concentrations of 0, 5, 50, or 500 ppm for life (Morgareidge *et al*., 1977). Reticulum cell carcinomas of the lung were observed in 10/49 male control animals, 17/35 low dose animals, 16/40 intermediate dose animals, and 12/39 high dose animals, respectively. Since the results were published only as an abstract, and since no response was seen at the highest dose, these results are considered to be only suggestive for the induction of cancer via this route.

Beryllium and beryllium compounds have been shown to cause statistically significant tumor increases in male and female rhesus monkeys and several strains of rats via inhalation and intratracheal installation, and the induction of osteosarcomas in rabbits by intravenous or intramedullary injection. Studies describing the induction of lung tumors (adenomas, adenocarcinomas) by beryllium via inhalation during exposure periods of up to 72 weeks are listed in Table 1. Intratracheal instillation of beryllium also resulted in the induction of lung tumors and extrapulmonary lymphosarcomas and fibrosarcomas in rats (Groth *et al*., 1980; Ishinishi *et al*., 1980).

Table 1. Induction of lung tumors in animals exposed to beryllium via inhalation

Study	Species/strain	Compound
Reeves *et al*., 1967	male, female Sprague-Dawley rats	beryllium sulfate
Schepers, 1961	male, female Sherman and Wistar rats	beryllium phosphate, beryllium fluoride, zinc beryllium silicate
Wagner *et al*., 1969	male Charles River CR-CD rats	beryl ore
Vorwald, 1968	male, female rhesus monkeys	beryllium sulfate

Beryllium compounds were shown to induce osteogenic sarcomas in rabbits by intravenous injection in 12 studies and by intramedullary injection in 4 studies (US EPA, 1991)

V. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Wagoner *et al*. (1980) studied a cohort of 3055 white males employed at a single beryllium processing plant in Pennsylvania (exposed to beryllium metal, oxide or hydroxide) sometime between January 1, 1942 and December 31, 1967 with a median duration of employment of 7.2 months. A significantly increased incidence of mortality due to lung

cancer was observed in the entire cohort (47 observed versus 34.29 expected, $p < 0.05$), as well as in the 2068 cohort members followed for 25 years or more since initial employment (20 observed versus 10.79 expected, $p < 0.01$). When the number of expected deaths was recalculated using 1968-1975 lung cancer mortality data, significance was lost for the cohort overall (38.2 expected), but not for the subgroup followed for 25 years or more (13.36 expected, $p \approx 0.05$) (Bayliss, 1980; MacMahon, 1977, 1978). However, significance was lost for the subgroup when the number of expected deaths was adjusted for smoking (14.67 expected) (US EPA, 1986).

The data of Wagoner *et al*. (1980) was used for the quantitation of cancer potency due to inhalation exposure despite study limitations. Human inhalation exposure is usually to beryllium oxide rather than other beryllium salts. Animal studies utilizing beryllium oxide have used intratracheal instillation instead of inhalation exposure. The use of the available human data therefore avoids uncertainties due to cross-species extrapolation, and uses the most relevant route of administration and beryllium species.

Methodology

A risk assessment was performed based on the occupational exposure study of Wagoner *et al*. (1980). The narrowest range for median exposure that could be obtained on the basis of available information was 100 to 1000 $\mu g/m^3$. Effective dose was calculated by adjusting for the duration of daily (8 of 24 hours) and annual (240 of 365 days) exposure, and the fraction of the lifetime at risk (time from start of employment to study termination). Smoking-adjusted expected lung cancer deaths were found to range from 13.91 to 14.67 (based on exposure range) compared to 20 observed. Relative risk estimates of 1.36 and 1.44 were calculated and the 95% confidence limits of these estimates used to calculate the lifetime cancer risk (Table 2). These estimates were based on one data set and a range of estimated exposure levels and times. To account for estimation uncertainties, unit risks were derived using two estimates each of concentration, fraction of lifetime exposed and relative risk. The listed unit risk factor [2.4 E-3 $(\mu g/m^3)^{-1}$] is the arithmetic mean of the 8 derived unit risks. US EPA has stated that this unit risk may not be appropriate if the air concentration exceeds 4 $\mu g/m^3$ and should not be used under those circumstances.

Table II. Effective dose, upper-bound estimate of relative risk and unit risk of carcinogenicity due to human beryllium exposure via inhalation (US EPA, 1992).

Beryllium concentration in workplace ($\mu g/m^3$)	Fraction of lifetime	Effective dose ($\mu g/m^3$)	95% upper-bound estimate of relative risk	Unit risk/ ($\mu g/m^3$)
100	1.00	21.92	1.98	1.61E-3
			2.09	1.79E-3
	0.25	5.48	1.98	6.44E-3
			2.09	7.16E-3

BIS(2-CHLOROETHYL)ETHER

CAS No: 111-44-4

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1994)

Molecular weight	143.02
Boiling point	176-178.5°C
Melting point	-24.5°C
Vapor pressure	0.7 mm Hg @ 20°C
Air concentration conversion	1 ppm = 5.8 mg/m^3

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 7.1 E-4 $(\mu g/m^3)^{-1}$
Slope Factor: 2.5 E+0 $(mg/kg\text{-}day)^{-1}$
[Calculated from a cancer potency factor derived by RCHAS/OEHHA (CDHS, 1988)]

III. CARCINOGENIC EFFECTS

Human Studies

There are no human carcinogenicity studies available for bis(2-chloroethyl)ether (BCEE).

Animal Studies

Two studies address the carcinogenicity of bis(2-chloroethyl)ether by the oral route of exposure. Innes *et al.* (1969) administered 100 mg/kg body weight bis(2-chloroethyl)ether by oral gavage to two F_1 generation strains of mice termed X (C57BL/6 × C3H/Anf) and Y (C57BL/6 × AKH) (18/sex/strain) from day 7 to 28 of life, without adjusting the initial dose to account for weight gain. After 28 days, BCEE was added to feed at a concentration of 300 ppm for 76 weeks. Surviving animals were sacrificed at 80 weeks. Ninety animals of each strain were included as controls. Tumor incidence in surviving animals is summarized in Table 1. A statistically significant increase in hepatomas ($p < 0.05$) was noted in both males and females of strain X and in males of strain Y. No other tumor type showed significant increases in incidence.

Charles River CD rats (26/sex/group) were treated with 0, 25 or 50 mg/kg-day bis(2-chloroethyl)ether by gavage for 18 months by Weisburger *et al.* (1981). Animals were observed for 2 years. No carcinogenic effects were observed, although the authors report increased mortality among the high-dose females and reduction in mean weight among high-dose males and females.

Van Duuren *et al.* (1972) report on two experimental approaches to evaluate the carcinogenicity of bis(2-chloroethyl)ether; a subcutaneous injection study and an initiation study by dermal application. ICR/Ha Swiss mice (30 females) were injected weekly with 1 mg BCEE for 68 days. No tumors remote from the injection site were observed. Two sarcomas were noted at the injection site (2/30) but were not found to be statistically different from controls (0/30) ($p > 0.05$ by Fisher's Exact Test).

Van Duuren *et al.* (1972) also treated ICR/Ha Swiss mice (20 females/group) with a single dose of 1 mg BCEE applied to the skin followed by three applications/week of the tumor promoter phorbol myristate acetate (PMA) in acetone for life. Control groups included animals not treated with BCEE and animals treated with BCEE but without the promoter. Skin papillomas were noted among animals treated with both BCEE and PMA, but the incidence was not significantly higher than among control animals (3/20 treated, 2/20 controls; $p>0.05$ by Fisher's Exact Test). No tumors were observed among animals treated only with BCEE.

Theiss *et al.* (1977) injected A/St mice (20 males) intraperitoneally with 8, 20, or 40 mg/kg BCEE 3 times/week for 8 weeks. After 24 weeks all surviving mice were sacrificed and examined only for lung tumors. The incidence of tumors among treated animals was not found to be significantly higher than among controls.

Table 1. Incidence of tumors in rats treated with bis(2-chloroethyl)ether* (Innes *et al.*,1969).

		Tumor Incidence			
		Strain X		Strain Y	
Tumor Type/Treatment		female	male	female	male
hepatomas	treated	4/18**	14/16**	0/18	9/17**
	control	0/87	8/79	1/82	5/90
pulmonary tumors	treated	0/18	0/16	0/18	2/16
	control	3/83	5/79	3/92	10/90
lymphomas	treated	0/18	2/16	0/18	0/17
	control	4/87	5/79	4/82	1/90

* F_1 generation mice were administered 100 mg/kg body weight bis(2-chloroethyl)ether by oral gavage from day 7 to 28 of life and subsequently in feed at a concentration of 300 ppm for 76 weeks (calculated dose is 39 mg/kg-day). Surviving mice were sacrificed at 80 weeks.

** statistically significant increase in incidence ($p < 0.001$ by Fisher's exact test)

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

In the absence of studies in humans useful in evaluating the carcinogenicity of bis(2-chloroethyl)ether, a single animal study (Innes *et al.*, 1969) has been identified as appropriate for the development of a cancer potency value. The most sensitive endpoint from this study is the development of hepatomas in treated male strain X rats. Other studies either do not show development of tumors (Weisburger, 1981) or experimental duration/dosing limited the interpretation of negative data (Van Duuren, 1972; Theiss, 1977).

Methodology

Lifetime average dose estimates from the Innes *et al.* study (1969) have been calculated to be 39 mg/kg-day bis(2-chloroethyl)ether (US EPA, 1980). A linearized multistage procedure polynomial was applied to the tumor incidence data (CDHS, 1985; Anderson, 1983). The upper 95% confidence bound on the cancer potency estimate is termed q_1^*. Using the data presented in Table 1, the following cancer potencies were derived from groups showing significant increases in hepatoma incidence:

animal group	q_1^* (mg/kg-day)$^{-1}$
Strain X - males	0.086
Strain X - females	0.013
Strain Y - males	0.031

The selection of the cancer potency value has been based on the q_1^* value from the most sensitive sex and strain in this case, 0.086 (mg/kg-day)$^{-1}$ in Strain X males derived from Innes *et al.*(1969). Calculation of the cancer potency in animals (q_{animal}) can be made from the following relationship, where T is the natural lifespan of the animal (104 weeks) and T_e is the experimental duration (80 weeks):

$$q_{animal} = q_1^* \times (T/T_e)^3$$

The resulting q_{animal} is 0.19 (mg/kg-day)$^{-1}$. Conversion to human cancer potency (q_{human}) is based on the following relationship, where bw_{animal} is the assumed body weight for the test species (0.03 kg - mice; US EPA, 1980) and bw_{human} is the assumed human body weight (70 kg):

$$q_{human} = q_{animal} \times (bw_h/bw_a)^{1/3}$$

The estimate of q_{human} based on this relationship is 2.5 (mg/kg-day)$^{-1}$. A unit risk value based upon air concentrations was derived by OEHHA/ATES assuming a human breathing rate of 20 m^3/day, 100% fractional absorption, and average human body weight of 70 kg. The calculated unit risk value is 7.1 E-4 ($\mu g/m^3$)$^{-1}$.

BIS(CHLOROMETHYL)ETHER

CAS No: 542-88-1

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1994)

Molecular weight	114.96
Boiling point	106°C
Melting point	-41.5°C
Vapor pressure	30 mm Hg at 22°C
Air concentration conversion	1 ppm = 4.75 mg/m^3

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 1.3 E-2 $(\mu g/m^3)^{-1}$
Slope Factor: 4.6 E+1 $(mg/kg\text{-}day)^{-1}$
[Calculated from potency value derived by RCHAS, cross-route extrapolation (CDHS, 1988)]

III. CARCINOGENIC EFFECTS

Human Studies

Increases in the incidence of lung cancer have been reported in a number of studies of workers exposed to both bis(chloromethyl)ether (BCME) and chloromethyl methyl ether (CMME). Some of these studies involve workers primarily exposed to CMME contaminated with 1-8 % BCME. Exposure to CMME, a known human carcinogen, is a confounding variable in these studies. However, there are several studies in which individuals were known to have been exposed to BCME, but exposure to CMME was not known to have occurred and appears unlikely.

Theiss *et al*. (1973) (reviewed by IARC, 1973) reported a retrospective study of a small group of BCME workers exposed between 1956 and 1962. Six cases of lung cancer were found in 18 men employed in a testing facility; 5 of the 6 men were smokers. Two additional lung cancer cases were found in a group of 50 production workers. Five of the 8 total cases were oat-cell carcinomas. Exposure periods were 6-9 years, and tumor latency was 8-16 years.

Sakabe (1973) reported on lung cancer cases occurring in 32 workers exposed to BCME in a Japanese dyestuff factory in the period 1955-1970. Five cases of lung cancer were reported compared to 0.024 expected cases ($p < 0.001$). One case was reported to be oat-cell carcinoma; the others were of mixed histological types. Duration of exposure to BCME ranged from 4 to 7 years; cancer mortality latency ranged from 8 to 14 years after initial exposure. It was noted that all the workers that developed lung cancer were also smokers, and that 4 of the 5 cases were also exposed to other industrial chemicals.

Lemen *et al*. (1976) conducted a retrospective cohort study of cancer incidence in a group of 115 white male anion-exchange resin manufacturing workers in San Mateo County, California. Worker tobacco smoking status was evaluated and used to adjust expected tumor incidence rates. Five cases of lung cancer were observed compared to 0.54 cases expected ($p < 0.01$), representing a nine-fold increased lung cancer risk. The histological type of lung cancer primarily observed was small cell-undifferentiated; exposure ranged from 7.6 to 14 years (mean of 10 years). The mean induction-latency period was 15 years. No quantitative worker exposure evaluation was performed.

The studies described above demonstrated a significant increase in lung cancer incidence, predominantly small-cell-undifferentiated carcinoma. This histologic type is not the one generally associated with smoking (squamous cell carcinoma).

Animal Studies

Male Sprague-Dawley rats and golden Syrian hamsters (50/exposure group) received 1, 3, 10 or 30 exposures (6 hours/exposure) to 1 ppm BCME by inhalation (Drew *et al*., 1975). After exposure, the animals were exposed for the remainder of their lifetime. Median survival time for hamsters receiving 0, 1, 3, 10 or 30 exposures was 675, 620, 471, 137 and 42 days, respectively. Median survival time for exposed rats was 467, 457, 168, 21 and 23 days, respectively. One rat in the 3 exposure group developed a squamous-cell carcinoma of the skin; additionally, one hamster in the 1 exposure group developed an undifferentiated nasal tumor. These tumor incidences were not statistically significant. However, the study treatment durations were short, and survival of the treated animals was poor.

Kuschner *et al*. (1975) exposed male Sprague-Dawley rats and golden Syrian hamsters to BCME by inhalation. Groups of 100 hamsters and 70 rats were exposed to 0.1 ppm BCME 6 hours/day, 5 days/week. Control group sizes were not stated. Exposure was generally for the life of the animals. After 80 exposures, 57/70 rats were still alive; 20 rats were then removed from the exposure schedule and observed for the remaining life of the animals. Mortality at 60 weeks was approximately 90% for rats (both animals exposed for their entire lifetime and animals receiving 80 exposures) and hamsters; corresponding control mortality at 60 weeks was approximately 40% and 15% for rats and hamsters, respectively. Two rats in the group receiving 80 exposures developed tumors; the tumor types were a nasal esthesioneuroepitheloma and a keratinizing squamous cell carcinoma of the lung. Additionally, one hamster developed an undifferentiated carcinoma of the lung. No corresponding tumors were reported in control rats or hamsters. Additional groups of rats were given 0, 10, 20, 40, 60, 80 or 100 6-hour exposures to 0.1 ppm BCME (group sizes 240, 50, 50, 20, 20, 30, and 30, respectively), then observed for the life of the animals. Mortality of the exposed animals in all exposure groups was equivalent to that of controls. Nasal and lung tumors were noted in the exposed animals. Nasal tumor types included esthesioneuroepithelomas, unclassified malignant olfactory tumors, squamous cell carcinomas involving the turbinates and gingiva, poorly differentiated epithelial tumors and adeno-carcinomas of the nasal cavity. Lung tumors included squamous cell carcinomas and adeno-carcinomas. Tumor incidence data for combined respiratory tract tumors is listed in Table 1.

Table 1. Bis(chloromethyl)ether-induced respiratory tract tumors in male Sprague-Dawley rats (Kuschner *et al*., 1975)

Number of exposures (6 hours, 0.1 ppm)	Human equivalent[1] $(mg/kg/day)^{-1}$	Tumor incidence[2]
0	0	0/240
10	0.00027	11/41
20	0.000541	3/46
40	0.00105	4/18
60	0.00184	4/18
80	0.00347	15/34
100	0.00373	12/20

1. Calculated by US EPA (1991)
2. Incidence of respiratory tract cancers in animals surviving beyond 210 days.

Male Sprague-Dawley rats (Spartan substrain) (120/group) and Ha/ICR mice (144-157/group) were exposed to 0, 1, 10 or 100 ppb BCME by inhalation for 6 hours/day, 5 days/week for 6 months (Leong *et al*., 1981). The animals were then observed for the duration of their lifespan. No significant increases in mortality were associated with BCME exposure, except for the 100 ppb exposure group; all animals in this group were dead by 19 months. Significant treatment-related increases in the incidence of respiratory tract tumors were noted. Tumor types included nasal esthesioneuroepithelomas and carcinomas, and pulmonary adenomas. Tumor incidence data is listed in Table 2.

Table 2. Bis(chloromethyl)ether-induced nasal tumors in male Sprague-Dawley rats (Leong *et al*., 1981)

Concentration[1] (ppb)	Tumor Incidence[2]
0	0/112
1	0/113
10	0/111
100	97/112

1. Animals were exposed to 0, 1, 10, 100 ppb BCME for 6 hours/day, 5 days/week for 6 months.
2. Incidence of nasal tumors as reported by CDHS (1988).

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Cancer potency factors for BCME were derived from male Sprague-Dawley rat respiratory tract tumor data (Kuschner *et al*., 1975; Leong *et al*., 1981). Cancer potency values are based on the most sensitive site, species and study demonstrating carcinogenicity of a particular chemical, unless other evidence indicates that the value derived from that data set is not appropriate (CDHS, 1985). The Kuschner *et al.* (1975) study used relatively high exposure levels of BCME. The exposure levels used in the Leong *et al*. (1981) study were lower, and the dose-response exhibited is highly non-linear. Therefore, a cancer potency estimated from the Leong *et al*. (1981) data set may be more representative of low-dose rate potency. For low dose exposures to BCME (below 1 ppb), the potency value was calculated from dose-response data published by Leong *et al*. (1981); for periodic high dose exposures (at or above 1 ppb BCME), the potency was derived from the study by Kuschner *et al*. (1975) (CDHS, 1988).

Methodology

Cancer potency factors (q_1^*) were derived using a linearized multistage procedure (CDHS, 1985) with the dose-response data for male Sprague-Dawley rat respiratory tract tumors (Kuschner *et al.*, 1975) and nasal tumors (Leong *et al*., 1981). Absorbed doses were calculated assuming complete absorption of inhaled BCME, using an inspiration rate of 0.29 m^3/day for Sprague-Dawley rats. The dose from a continuous exposure to 1 ppb BCME (4.7 µg/m^3) would therefore be 1.36 µg/day, or 2.6 µg/kg-day. The cancer potency factors (q_1^*) derived from the Leong *et al*. (1981) and Kuschner (1975) data sets were 8.9 $(mg/kg/day)^{-1}$ and 47 $(mg/kg/day)^{-1}$, respectively. Surface area scaling was employed to transform animal cancer potency factors to human cancer potency factors, using the relationship ($q_{human} = q_{animal} * (bw_h / bw_a)^{1/3}$), where q_{human} is the human potency, q_{animal} is the animal potency, and bw_h and bw_a are the human and animal body weights, respectively. Body weight values used for humans and Sprague-Dawley rats were 70 kg and 0.52 kg, respectively. The human cancer potency factors (q_1^*) derived from the Leong *et al*. (1981) and Kuschner (1975) data sets were 45.6 $(mg/kg/day)^{-1}$ and 240 $(mg/kg/day)^{-1}$, respectively. The unit risk factor was derived by OEHHA/ATES from the low dose exposure cancer potency value using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

III. CARCINOGENIC EFFECTS

Human Studies

Several studies have examined cancer mortality rates among industrial workers who were likely to have been exposed to butadiene. However, these studies generally considered workers likely to have had contemporaneous exposure to other potential carcinogens (most notable styrene). Nevertheless, studies of two work environments are sufficiently specific to butadiene exposure to provide limited supporting evidence for the carcinogenic effects observed in animal bioassays. These studies are a case-control study of rubber workers by Matanoski *et al.* (1989) and cohort studies of a butadiene manufacturing plant by Downs *et al.* (1987) and Divine (1990). In addition, Checkoway and Williams (1982) observed statistical associations of blood abnormalities with butadiene exposure at a facility where excess leukemia and lymphoma had been reported.

The first epidemiological study evaluating the possibility of an increased risk of carcinogenicity following occupational exposure to butadiene and other compounds was conducted by the National Institute of Occupational Safety and Health (NIOSH). A study conducted at the University of North Carolina (Spirtas, 1976) prompted NIOSH to examine the issue of styrene-butadiene exposures and a possible link to leukemia (NIOSH, 1976). Leukemia rates in the area surrounding the Port Neches plants, Texas, were found to be above national rates.

McMichael *et al.* (1976) examined deaths occurring from 1964 through 1973 in a male population which had been employed at a large tire manufacturing plant in Akron, Ohio. Standardized Mortality Ratios (SMRs) for the study population indicated that deaths due to several types of cancer exceed rates for the 1968 U.S. male population. Statistically

significantly elevated SMRs were found for stomach cancer (171) and lymphatic and hematopoietic cancers (136). Other solvents and monomers to which these workers were exposed included styrene, benzene, and toluene. Work for five years or more in the synthetic plant was associated with significantly elevated risk ratios for lymphatic and hematopoietic neoplasms (6.2), lymphatic leukemia (3.9), and stomach cancer (2.2).

Andjelkovich *et al.* (1976, 1977) reported the mortality experience of 8,418 white male workers in a large rubber manufacturing plant, also in Akron, Ohio. The cohort was initially divided into two age groups, those under 65 and those 65 or older. SMRs were elevated (but not necessarily significantly) in both age groups in both cohorts for cancers of the stomach, large intestine, and prostate as well as for lymphosarcoma. The SMR for monocytic leukemia (311) was significantly elevated for this entire cohort.

Another cohort of 13,570 white males who had worked for ≥ 5 years in a Goodrich plant in Akron, Ohio was examined for mortality outcome from 1940-1976 (Monson and Fine, 1978). External comparisons (SMR) of mortality, based on U.S. white males, and internal comparisons of incidence were performed in this study. Leukemia and lymphatic cancers were elevated in a number of job categories as was the incidence of gastrointestinal cancer. Solvents were suggested by the authors to have been responsible for the increased incidences; the elevation cannot be specifically attributed to butadiene.

In an investigation of the health effects of styrene exposure, Ott *et al.* (1980) studied 2,904 employees of Dow Chemical plants who had worked for at least one year over the years from 1937 to 1970. SMRs for leukemia (176) and for lymphatic and hematopoietic neoplasms (132) were elevated but not significantly. Therefore, as with the previous studies (McMichael *et al.*, 1976; Andjelkovich *et al.*, 1976, 1977; Monson and Fine, 1978), this report is suggestive of an increase in incidence of lymphatic and hematopoietic cancers in a cohort associated with multiple types of chemical exposures. The increase cannot be definitely attributed to butadiene exposure.

White male workers who had been employed for at least six months in two SBR plants in eastern Texas were studied for an excess of leukemia (Meinhardt *et al.*, 1982) and an attempt was made to correlate the results to occupational chemical exposures. There were 1,662 study subjects in plant A and 1,094 in plant B. Workers were followed from 1943-1976 at plant A from 1950-1976 at plant B. There were no significantly elevated SMRs observed from workers in plant B. In plant A, SMRs were elevated but not significantly for lymphatic and hematopoietic neoplasms (155) and for several subcategories within that classification including leukemia (203).

Divine (1990) found a significantly elevated SMR for lymphosarcoma among 2,582 workers in a butadiene manufacturing facility. The SMR for lymphosarcoma was even higher in those with routine exposure to butadiene. Matanoski *et al.* (1990) observed an excess of leukemia and lymphatic and hematopoietic cancers in black production workers and an elevated SMR for residual cancers of the lymphohematopoietic system for all production workers in several styrene-butadiene rubber (SBR) plants in the U.S. and Canada. Presumably, in SBR plants, production workers had the highest likelihood of

exposure to butadiene, although they may have been exposed to other substances that are, or may be, linked to some of these cancers. While it is difficult to establish a causal relation with butadiene exposure, the fact that cancers of the lymphohematopoietic system were reported in mice suggests that the association deserves close attention in future studies.

Animal Studies

Inhalation of butadiene has been shown to induce tumors in mice and rats at multiple sites. These sites include the heart, lung, mammary gland, ovaries, forestomach, liver, pancreas, Zymbal gland, thyroid, testes, and hematopoietic system. Butadiene is only one of two chemicals known to induce cancer of the heart in laboratory animals.

Mice

The most detailed evaluations of the carcinogenicity of butadiene are the mouse inhalation studies sponsored by the National Toxicology Program (NTP), mouse I (NTP, 1984), and mouse II (Melnick *et al.*, 1990). The nominal doses of study I were 0, 652 or 1,250 ppm administered 6 hours/day, 5 days/week for either 60 weeks (males) or 61 weeks (females). Fifty animals per sex/dose were used. Although the study was designed for 103 weeks, early deaths resulted largely from malignant neoplasms involving multiple organs (heart, hematopoietic lymphomas, lung, mammary gland, ovaries, forestomach, and liver). The incidences of total significant tumor bearing animals (i.e., the number of animals bearing one or more significant tumors) at control, middle, and high doses were 2/50, 43/49, and 40/45 in the males and 4/48, 31/48, and 45/49 in the females. Tumor incidence data are provided in Table 1.

In study II, lower exposure concentrations of butadiene (i.e., 0, 6.25, 20, 62.5, 200, and 625 ppm) were used than had been employed in the first study. Interim sacrifices at 40 and 65 weeks of exposure were also added to the original study design in order to follow progression of lesions. As in the previous study, hemangiosarcomas of the heart, hematopoietic lymphomas, squamous cell neoplasms of the forestomach, alveolar-bronchiolar neoplasms, and/or adenocarcinomas of the mammary gland were frequently observed in mice which died between weeks 40 and 65 of the study. Tumor incidence data used in the quantitative risk assessment are given in Table 2.

Rats

A two-year rat inhalation toxicity/carcinogenicity study (Hazleton Europe, 1981) was also evaluated. Groups of 100 per sex/dose were exposed to 0, 1,000, or 8,000 ppm butadiene for 6 hours/day, 5 days/week for 105-111 weeks. Unlike the mouse I study, survival of treated animals was not adversely affected in the first year of the study, but during the second year there was a statistically significant relationship between mortality and air concentration of butadiene. The published incidences (Owen, 1987) are slightly different form those given by U.S. EPA (1985). The total significant tumor incidences (number of animals bearing one or more significant tumors) in males based on U.S. EPA criteria and 1987 published incidences are 4/100, 5/100 and 20/100 for the control, low, and high dose groups (Leydig cell tumors, pancreatic exocrine tumors, and Zymbal gland tumors). Total female significant tumor incidences in the control, low and high dose groups were: 18/100, 19/100, and 41/100 (mammary carcinoma, thyroid follicular cell tumors, and Zymbal gland tumors). Tumor incidence data are shown in Table 3.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

OSHA (1990) has classified butadiene as a "potential occupational carcinogen". U.S. EPA (1985) and IARC (1987) have concluded that the evidence for carcinogenicity of butadiene in animals is sufficient. These organizations have classified the chemical as Group B2 and 2B respectively in their schemes of ranking potential human carcinogens.

With respect to quantitative risk assessment, the epidemiological data base is still considered inadequate for predicting risks of community exposure to butadiene. Thus, the quantitative risk assessment presented in this document relies on data from animal bioassays rather than epidemiologic studies. Cancer potencies were calculated using tumor incidence data from NTP (1984), Melnick *et al.* (1990), and Hazelton Europe (1981).

Methodology

Cancer potency estimates were made for mice and rats using total significant tumor incidences and individual site incidences, three measures of dose, and the linearized multistage procedure of low dose extrapolation. The most sensitive tumor site was the lung alveolar and bronchiolar neoplasms in female mice (mouse II bioassay data of Melnick *et al.*, 1990). The continuous internal dose was considered to be the best measure of dose available. When interspecies equivalent units of mg/m^2 surface area were used, the resulting upper range of human cancer potency based on all rodent assays was 4.4×10^{-6} to 3.6×10^{-4} $(\mu g/m^3)^{-1}$. The range of upper bound risk is based on the two orders of magnitude difference between potency figures for the mouse and the rat. This difference has been the subject of much additional metabolic and kinetic investigation. In addition to a higher metabolic rate for butadiene in the mouse, limited detoxification and accumulation of the primary reactive genotoxic metabolite (BMO) may be a significant factor in the increased susceptibility of mice to butadiene-induced carcinogenesis. The most detailed evaluation of the carcinogenicity of butadiene has been conducted in the mouse.

The staff of the Office of Environmental Health Hazard Assessment concluded that, for use in risk assessment, the quality of the mouse II bioassay data is superior to that of the rat data. The primary reasons for this conclusion are: 1) the use of lower, more relevant dose levels in the mouse II study; 2) the use of five dose levels in the mouse II study, compared to two in the rat study; 3) the presence of two mouse studies; 4) the fact that the rat study has not been replicated; 5) the consistency in sites of carcinogenicity between the two mouse studies; 6) the greater detail in the available mouse data which allows in-depth analysis; and 7) suggestions from limited epidemiological observations that butadiene exposure may be associated in humans with lymphatic and hematopoietic cancers, effects that were seen in mice. The analysis above using lung alveolar and bronchiolar neoplasm incidences in female mice (mouse II bioassay data of Melnick *et al.*, 1990) resulted in a cancer potency of 6.0 $(mg/kg\text{-}day)^{-1}$, and a cancer unit risk of 1.7×10^{-4} $(\mu g/m^3)^{-1}$.

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB (1998) except as noted)

Molecular weight	112.41
Boiling point	765 ºC
Melting point	321 ºC
Vapor pressure	1 mm Hg at 394 ºC
Air concentration conversion	1 ppm = 1.8 mg/m^3 (from NIOSH, 1994)

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 4.2 E-3 $(\mu g/m^3)^{-1}$
Slope Factor: 1.5 E+1 $(mg/kg\text{-}day)^{-1}$
[Human occupational exposure lung cancer data (Thun *et al*., 1985), Poisson regression model fitted by CDHS (1986), resulting model parameters applied to California life table to calculate cancer risk, reevaluated by CDHS (1990).]

III. CARCINOGENIC EFFECTS

Human Studies

US EPA has reviewed the epidemiologic evidence on health effects due to cadmium exposure (US EPA, 1985). Most of the studies were occupational mortality studies in which cause-specific death rates were compared to expected rates based on a standard population, with the ratio of observed to expected deaths yielding a standardized mortality ratio (SMR). Outcomes examined in these investigations included cancer of the respiratory tract, prostate, bladder, kidney, and gastrointestinal tract. The results were not entirely consistent, but the evidence for an effect of cadmium exposure was strongest for lung cancer, prostate cancer and renal cancer.

Lemen *et al*. (1976) found an excess of prostate cancer deaths among 292 workers employed for greater than two years in a job with potential cadmium exposure. The excess was significant if the analysis assumed a 20-year latency period. However, a follow-up study of this cohort by Thun *et al*. (1985) uncovered no new deaths due to prostatic cancer. The authors suggested that given the generally nonfatal nature of the disease, mortality studies frequently may not be sensitive enough to detect a potentially real association with incidence of prostate cancer. Sorahan and Waterhouse (1983, 1985) followed up a 1967 report by Kipling and Waterhouse which had found a highly significant excess incidence of prostatic cancer. Both the incidence report (Sorahan and Waterhouse, 1985) and the mortality study (Sorahan and Waterhouse, 1983) found no significantly elevated risk if the original four index cases were excluded. However, inclusion of these cases in the analysis yielded a highly significant association. For mortality, using cumulative years of high

exposure to cadmium, the *p*-value was less than 0.05 when controlling for sex, year of study, employment, age at starting employment, and duration of employment. For morbidity, using more than one year of high exposure, the value of *p* was less than 0.001 (1.99 expected, 8 observed, *p*-value not given by authors but calculated by DHS staff based on a Poisson distribution). Tumor incidence was determined using the Birmingham Regional Cancer Registry. The authors do not provide information on completeness of ascertainment by this registry.

The SMR study by Andersson *et al*. (1984) and the matched case-control study by Ross *et al*. (1983) both failed to reject the null hypothesis of no effect on risk of prostate cancer. However, the SMR was considered "possibly" increased and the lack of statistical significance could have been due to deficiencies in the measure of exposure. Similarly in the study by Ross *et al*., the odds ratio (OR) for cadmium exposure among prostatic cancer cases as compared to controls was 2. The smallest OR which would have an 80% chance of being detected as statistically significant in a study this size is 4; therefore, the lack of significance should be interpreted cautiously. In general, the power of these studies was not sufficient to detect the small relative risks for prostate cancer deaths expected from cadmium exposure.

The evidence available at that time appeared to be inconclusive regarding the effect of cadmium exposure on prostatic cancer. Given the highly significant early reports, it may be that cadmium acts as a promoting agent, inducing earlier tumors in those already susceptible. This effect may have been reduced markedly in recent years due to the lowering of exposure levels, sometimes by an order of magnitude or more (Thun *et al*. 1985, Andersson *et al*. 1984, Sorahan and Waterhouse 1985). Therefore, those with earlier exposure may have been at highest risk, and the cohorts most recently studied, being heterogeneous with respect to their exposures, show only nonsignificant increases in prostate cancer incidence, e.g., a doubling or less, and no increase in mortality. Because the human studies repeatedly found some elevation in risk, albeit a nonsignificant one, the staff of DHS decided that the evidence does not permit a conclusive rejection of a possible effect of cadmium on prostate cancer.

Table 1 summarizes the epidemiologic evidence relating respiratory cancer SMR's to cadmium exposure. A significantly increased risk of respiratory cancer deaths was seen by Lemen *et al*. (1976), Thun *et al*. (1985), Sorahan and Waterhouse (1983), Varner (1983), and Armstrong and Kazantzis (1983), but not by Inskip *et al*. (1982) nor by Andersson *et al*. (1984). However, the assessment of exposure in the two towns investigated by Inskip *et al*. relied only on 1979 soil samples for exposure from 1939 to 1979. Even with a questionable exposure assessment, males in the exposed town had a lung cancer SMR which, while not statistically significant, was nearly double that of males in the unexposed town (101 vs. 55). The other negative study (Andersson *et al*., 1984) had low statistical power to detect a SMR of less than 200. In other studies, the range of SMR's for respiratory cancer was 120-230 (see Table 1). The staff of DHS concluded that the two negative studies for respiratory cancer are not convincing evidence of no effect, due to low statistical power in one study and poor exposure data in the other.

The study by Thun *et al*. (1985) showed a positive dose-response relationship where dose was expressed as cumulative mg-days/m^3. Varner (1983) reported the lung cancer PMR (proportional mortality ratio) to be elevated. Sorahan and Waterhouse (1983), in two separate analyses, found an elevated risk of respiratory cancer. The first analysis was based on the SMR and included all potentially exposed workers. The second analysis used the regression method of life tables (RMLT) and assessed exposure by cumulative years employed in a (1) high exposure job or (2) high or moderate exposure job or (3) high or moderate exposure job excluding welding. Measures (2) and (3) resu1ted in a significant effect of exposure on respiratory cancer, particularly for those with more than 30 years of follow-up.

Table 1: Association Between Cadmium Exposure and Respiratory Cancer Mortality

Authors	SMR	Significant at $p < 0.05$
Sorahan and Waterhouse 1983	127	Y
Lemen *et al*., 1976	235	Y
Thun *et al*., 1985	229	Y
Armstrong and Kazantzis 1983	126[a]	Y
Inskip *et al*., 1982	101[b]	N
Andersson *et al*., 1984	120	N

[a] For workers with >10 years exposure in the "always low" category (the number of workers with "ever medium" and "ever high" exposures was small).
[b] vs. SMR-55 for the unexposed town.

Heavier smoking among cadmium workers as compared to the general population could account for the small but statistically significant SMR for lung cancer (126) observed by Armstrong and Kazantzis (1983) for those exposed >10 years at the "always low" category. No smoking histories were available. Sorahan and Waterhouse (1983) also lacked data on smoking, but they argue that smoking was unlikely to have been a confounder for two reasons. First, their analysis showed an increasing association with duration of employment, while smoking habits are unlikely to be well-correlated with duration of employment. Secondly, deaths from other diseases of the respiratory system were not elevated, as they would have been if the cohort had included a disproportionate number of smokers. However, the effect of nickel hydroxide could not be disentangled from that of cadmium oxide in this cohort.

The strongest evidence for cadmium-induced carcinogenicity in humans is the study conducted by Thun *et al*. (1985). The characteristics of this study which make it particularly convincing are the quality of the exposure data and the analysis of potential confounding. Since the quantitative results of this study constituted the basis for the DHS risk assessment of cadmium, a full description of this study is presented below.

Thun *et al*. (1985) conducted a follow-up of the report by Lemen *et al*. (1976), who had found an increase in mortality from respiratory and prostate cancer and from nonmalignant lung disease in a cohort of cadmium smelter workers. Thun *et al*. (1985) expanded the cohort and extended the follow-up period. The final cohort included those hired after 1925

and employed 6 months or longer in production areas of the plant during the period 1940-1969. The cause-specific death rates were adjusted by the indirect method to yield standardized mortality ratios (SMRs) and by the direct method to yield standardized rate ratios (SRRs). The SMR for lung cancer in the overall cohort was 147, while for those with 2 or more years of employment it was 229, with a 95% confidence interval of (131,371).

Exposure data that had been collected since the 1940's allowed evaluation of the lung cancer SMR by dose. Industrial hygiene measurements for departments and job sites with potential cadmium exposure were available (Smith *et al*. 1980). These were combined with individual work histories for each member of the cohort in order to assign an exposure level to each work day. Interruptions of employment were taken into account and exposure levels were adjusted to reflect respirator usage in departments where these were worn. A cumulative exposure in mg-years/m^3 was then assigned to each person-year of follow-up for each worker. The range of cumulative exposures was divided into three categories and both SMRs and SRRs were calculated for each category. The results are shown in Table 2 using US white males as the comparison population, and in Table 3 using Colorado white males as the comparison population. (Thun presented the analysis using Colorado white males as the control group at the Fifth International Cadmium Conference, February 1986, in San Francisco. This analysis assumes that pre-1950 lung cancer rates equaled those in 1950, since cause-specific rates were not tabulated in that state before 1950.)

Table 2: Lung Cancer (ICD 162-163) Mortality By Cumulative Exposure White Male Cadmium Workers Hired on or After 1/1/26 Compared to U.S. Death Rates (Adapted from Thun *et al*. (1986), Table 7)

Exposure (cumulative mg/m^3)					
Range	Median	Person years at risk	Deaths	SMR	SRR
≤384	184.1	7005	2	53	0.48
385-1920	795.6	5825	7 (6)*	152 (130)*	1.55 (l.33)*
≥1921	2761.6	2214	7	280	3.45
U.S. WHITE MALES				100	1.00

* Numbers in parentheses exclude one lung cancer death which was originally miscoded as being due to another cause.

The data indicate a clear dose-response relationship between cumulative cadmium exposure and the risk of death due to lung cancer. Using the US population as the comparison group, both the SMR and the SRR rise from about 1/2 the expected at "low" cumulative exposure to about 3 times the expected at high cumulative exposure. Both of

these measures of risk are larger when the Colorado population is used as a standard, with the SRR rising from 0.7 to over 5.0.

Table 3: Lung Cancer (ICD 162-163) Mortality by Cumulative Exposure; White Male Cadmium Workers Hired on or After 1/1/26 Compared to Colorado Death Rates, 1950-79 (Adapted from Thun *et al.* 1985, Table 8).

Cumulative exposure (mg-days/m^3)	Person-years at risk	Deaths	SMR	SRR
≤384 385-1920 ≥1921	7005 5825 2214	2 7(6)* 7	76 212(182)* 387	.70 2.29(l.96)* 5.09
Colorado white males			100	1.00

* Numbers in parentheses exclude one lung cancer death which was originally miscoded as being due to another cause.

Thun *et al*. (1985) calculated the standardized rate ratio (SRR) for each of 3 exposure groups. (The person-years at risk, rather than individual workers, were classified by cumulative exposure to that point in time.) The SRR is suitable for subgroup comparisons, but not for external comparisons. A regression of the SRRs yielded a slope of 7.33×10^{-7} which differed from zero with a probability of 0.0001.

Selection criteria described by Thun *et al*. (1985) appear to have been unbiased: all retired, deceased, and active employees who had worked a minimum of 6 months in production areas of the plant were included in the cohort. In calculating cumulative exposure, dates of interruption of employment were accounted for. Since more than 80% of the workers were followed for 20 or more years it is likely that the follow-up was sufficient for many latent cadmium-induced cancers to become manifest and lead to death. Trained nosologists evaluated the death certificates. As indicated by Thun *et al*., one lung cancer death was originally miscoded as being due to another cause. Removal of this death from the lung cancer deaths (i.e. restoring it to the original, but incorrect coding) is necessary in order that the comparison with general population rates be unbiased (since miscodings also occur in the general population). However, the findings are not altered in any substantial way by this reclassification.

Exposure categories were chosen prior to the analysis. The cumulative exposure for all person-years was miscalculated by Thun *et al*. (1985) because they included non-workdays. This does not cause bias for purposes of. inference since the misclassification was equivalent for all exposure categories. It would, however, alter the dose-response relationship, and therefore DHS staff adjusted for this error in conducting their risk assessment, since an overestimate of exposure would result in an underestimation of potency. The corrected exposures are shown in Tables 2 and 3.

If the cadmium-exposed workers included a disproportionate number of individuals with exposures to other agents responsible for lung cancer, then the observed association might be spurious. The potential confounders with regard to lung cancer mortality in this cohort were smoking and arsenic exposure.

(a) Smoking:

Indirect evidence that smoking was not a confounder in this cohort is provided by the cardiovascular death rate in this cohort, which was 35% lower than expected based on U.S. white male death rates. If this cohort included a higher proportion of total smokers or heavy smokers as compared to the general population of white males in the same age categories, then one would expect an increase (or at least not a deficit) in the cardiovascular death rate as well.

Data on the smoking habits of these workers were provided to Thun *et al*. (1985) by the company. The data came from company medical records and from a questionnaire survey mailed to surviving workers or the next-of-kin in 1982. The results of this survey have elicited differing interpretations depending on the choice of measure of smoking and on the choice of the comparison group. The 1985 paper by Thun *et al*. reported data on 70% of the workers. For these workers, the data indicated that as of 1982, 77.5% were current or former smokers compared to 72.9% current or former smokers among U.S. white males 20 years or older reported in the 1965 Health Interview Survey (HIS) conducted by the National Center for Health Statistics. It is clear that these 2 figures are not comparable since data from 1982 for the exposed group were compared with data from 1965 for the control group.

In the updated report by Thun *et al*. (1986), presented at the Fifth International Cadmium Conference in San Francisco, February 6, 1986, the authors provided a more meaningful comparison by limiting the smoking analysis to the 49% of the cohort for whom lifetime smoking histories were available. These data indicated that as of 1965 a larger percentage of the cadmium-exposed cohort were nonsmokers and a smaller percentage were heavy smokers compared to general population rates available from the HIS. The year 1965 was chosen since this was the midpoint of the study.

The percent who "ever smoked" was 77.5% in the cadmium-exposed cohort, and 76% in the total HIS sample. The data on the cadmium workers represented information from only 36% of the cohort. Given that the cohort under study was considerably older than the HIS sample, that the HIS survey was done about 10 years earlier than the survey of the cadmium cohort, and that different information was reported from these two surveys, the differences between the smoking habits of the total HIS sample and those of the cadmium-exposed workers do not appear to be very large.

The magnitude of confounding from differential smoking habits can be assessed. A method to estimate the contribution of smoking to lung cancer mortality in the cohort is described by Axelson (1978). The method is applied to the lifetime smoking histories summarized by Thun *et al*. (1985). The calculations (summarized in Table 4) are based on information

regarding smoking habits in the exposed group, smoking habits in the comparison group, and the relative risk for lung cancer at each level of smoking. In view of the data indicating a deficit of smokers in this cohort compared to the general population, the baseline SMR for lung cancer would have been reduced 30%.

It is unknown, however, whether the smoking histories of the 49% sample were representative of the cohort as a whole, and whether the histories themselves were biased, since they were collected retrospectively. While smoking may have confounded the relationship between cadmium and lung cancer, it is unlikely that smoking was responsible for all of the excess. Furthermore, if the smoking habits in this cohort were correctly reported, i.e., if the observed deficit of smokers was real, then the excess of lung cancer deaths is larger than originally calculated. In other words, confounding due to smoking did not create the appearance of a nonexistent carcinogenic effect from cadmium; rather, the confounding reduced the apparent magnitude of cadmium's carcinogenicity.

Table 4: Technique Used to Adjust for Cigarette Smoking (Thun *et al*., 1986)

Population	Percent of Population, 1965 Nonsmokers[3] (1X)	Moderate[1] Smokers (10X)	Heavy [2] Smokers (20X)	Rate Ratio of Overall Population Relative to Nonsmokers	Rate Ratio Relative to U.S.
Exposed	48.4%	40.8%	10.8%	6.724	0.70
U.S.	27.1%	53%	20%	9.571	1.0

1. 1-24 cigarettes/day
2. 25+ cigarettes/day
3. The numbers in parentheses refer to the relative risk for lung cancer associated with each level of smoking.
4. Usable information available on 250 persons hired after 1926.

(b) Arsenic

The plant employing the workers in this cohort refined cadmium metals and compounds from 1926 onwards. Between 1918 and 1925 it had functioned as an arsenic smelter. Therefore, the analysis by Thun *et al*. excluded workers employed prior to January 1, 1926. (For those employed prior to 1926 the lung cancer SMR was 714). Nevertheless, it is possible that residues of arsenic contributed to the lung cancer excess for those first employed in 1926 or later.

To estimate the possible contribution of arsenic to lung cancer in this cohort, Thun *et al.*:

(1) identified the departments and job categories which were likely to have involved continued exposure to arsenic;

(2) calculated the proportion of person-years spent in areas with probable arsenic exposure based on personnel records (20%);

(3) evaluated industrial hygiene measurements to estimate air concentrations (range - 300 to 700 $\mu g/m^3$; Thun used midpoint - 500 $\mu g/m^3$);

(4) estimated the total years of employment for workers in the cohort (1728 years);

(5) based on (2), (3), and (4), estimated that total arsenic exposure amounted to 345.6 person-years of exposure to air levels of 500 $\mu g/m^3$;

(6) assumed a 75% respirator protection factor (i.e. inhaled exposures were 25% of air concentrations or 125 $\mu g/m^3$. This yielded a total exposure of 43,200 μg-years/m^3.

Using a risk assessment model developed by OSHA for arsenic carcinogenicity, Thun calculated that 43,200 $\mu g/m^3$ years of exposure to arsenic would contribute no more than 0.768 lung cancer deaths. This may represent an overestimate of the contribution of the arsenic exposure to the lung cancer excess. The reasons submitted by Thun are as follows:

1) Only a fraction of jobs in the "arsenic areas" had exposures as high as the furnace area (500 $\mu g/m^3$);

2) The high exposure jobs were frequently staffed with brief employment-entry (sic) level workers who are not in the study cohort;

3) Urinary arsenic levels on workers in the "high arsenic" areas from 1960-80 averaged only 46 $\mu g/l$ (equaling an inhaled arsenic of 14 $\mu g/m^3$);

4) Thus, assuming an average inhaled arsenic concentration of 125 $\mu g/m^3$ for these years overestimates the dose by 9-fold;

5) ASARCO has previously argued that the OSHA risk assessment overestimates "by a factor of three or more" the expected increase in mortality from respiratory cancer. (Thun, personal communication; cited in CDHS, 1986)

The last issue with respect to confounding concerns the combined effects of arsenic and smoking on lung cancer, which are more than additive, though probably less than multiplicative. Therefore, if any of the workers who were exposed to arsenic were smokers, there could also be confounding from the interactive effect of these two exposures. However, when relative risks are small (e.g., less than 1.3), there is very little difference between additive and multiplicative effects. Since it is unlikely that in this cohort the relative risk associated with either arsenic or smoking is larger than 1.3, the effect of any interaction is likely to be negligible. (If both relative risks are 1.3, multiplying yields 1.69, adding yields 1.6, difference = .09.)

In conclusion, given the low level of arsenic exposure and the evidence indicating a deficit of smokers in this cohort, DHS staff decided that the apparent association between cadmium exposure and lung cancer were not likely to be explained by confounding from smoking and/or arsenic exposure.

To summarize the DHS staff's findings with regard to the study by Thun *et al*. (1985) - the SMR of 2.3 in those with more than 2 years of cadmium exposure and the dose-response relationship are unlikely to be explained by chance, by bias, or by confounding from smoking and/or arsenic exposure. The staff of DHS concluded that the excess of lung cancer deaths in the study by Thun *et al*. (1985) is best explained by exposure to high levels of cadmium. The DHS staff further concluded that this study constitutes strong evidence of human carcinogenicity.

Animal Studies

Cadmium has been the subject of numerous studies in experimental animals to determine its carcinogenic potential. These studies have been extensively reviewed elsewhere (IARC 1973, 1976; EPA 1981, 1985); only the inhalation and intratracheal administration studies will be discussed here.

Sanders and Mahaffey (1984) examined the carcinogenic potential of cadmium oxide in male rats by intratracheal instillation. The rats were treated one, two or three times with 25 μg of cadmium oxide. The first administration was given at 70 days of age and then at 100 and 130 days of age depending on the total dose to be given (25, 50, or 75 μg). The animals were then followed for their lifetime. No differences were found in survival times or organ weights between treated and control groups. Using life-table and contingency table statistical analyses a significant increase in benign mammary fibroadenomas was observed in the high dose group. Additionally, there was a significant increase in the number of rats in the high dose group that had three or more tumor types.

Hadley *et al*. (1979) exposed a group of 61 male Wistar strain rats one time to an airborne cadmium oxide aerosol concentration of 60 mg/m^3 for 30 minutes. The mass median diameter of the particles was 1.4 μm with a geometric standard deviation of 1.9 μm. Seventeen animals were used as controls. Twenty-seven exposed animals died within three days from acute pulmonary edema. The remaining animals were then observed for one year. No morphological changes were noted in the lungs of exposed animals, although one animal did have a well-differentiated pulmonary adenocarcinoma. The authors observed that this tumor's relatively short latency period and the low spontaneous incidence (0.1%) of such tumors suggested that it resulted from cadmium exposure.

Both the Sander and Mahaffey (1984) study and the Hadley *et al*.(1979) study were not adequate to assess carcinogenic potency, since the animals were only exposed for short periods and, in the Hadley *et al*. (1979) study, were not followed for sufficient time. Without continuous exposure, effects in the lungs may not occur or the study may not be sensitive enough to detect adverse effects.

In the only long-term inhalation study available to the cadmium TAC document, Takenaka *et al*. (1983) exposed rats to several concentration of a cadmium chloride aerosol. Groups of 40 male Wistar rats were exposed to a continuous (23.5 hours/day) airborne concentration of 13.4, 25.7, or 50.8 µg of cadmium/m^3 of air for 18 months. A control group of 41 rats was exposed to filtered room air. The aerodynamic mass median diameter of the aerosol particles was 0.55 µm with a arithmetic standard deviation of 0.48 µm and a geometric standard deviation of 1.8 µm. The rats were followed for an additional 13 months before surviving rats were sacrificed.

There were no statistically significant differences seen in body weight or survival between exposed and control groups. The incidence of lung carcinomas was significantly increased ($p > 0.014$, Fisher's exact test) in all exposure groups. Three lung tumor types were identified, adenocarcinoma, epidermoid carcinoma, and mucoepidermoid carcinoma. The numbers of animals in each group that had these tumor types are given in Table 5. The first lung tumor was observed at 20 months. In the high-dose group, the first tumors were observed at 23 months and 23 out of 25 animals in this group dying or sacrificed after 27 months had lung tumors. Therefore, these appear to be late-developing tumors.

Table 5: Lung tumors in rats exposed to cadmium chloride aerosols (Takenaka *et al*., 1983)

Exposure Group	# rats with tumors				
	# rats examined histologically	Adenocarcinoma	Epidermoid Carcinoma	Mucoepidermoid Carcinoma	Total Carcinomas
Control	38	0	0	0	0
13.4 µg/m^3	39	4	2	0	6
25.7 µg/m^3	38	16	5	0	20[b]
50.8 µg/m^3	35	15	8	3	25[b]

a Airborne exposure concentrations are based on the cadmium, not cadmium chloride, concentration.

b One rat had both an adenocarcinoma and an epidermoid carcinoma.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

A quantitative cancer risk assessment for cadmium using the data from the occupational mortality study by Thun et al. (1985) and extrapolating to ambient levels in California was done by DHS staff. The exposure data in this study were based on industrial hygiene measurements and individual work histories. These measurements consisted of historical area monitoring samples and, when appropriate, were adjusted to reflect respirator protection in departments where respirators had been worn. For workers employed 6 months or longer in production areas of the plant the person-years of follow-up were

divided into 3 categories according to cumulative exposure in mg-days/m^3 (see Table 6). The risk of death from lung cancer for each exposure group was measured by the standardized mortality ratio (SMR). The data indicated a clear dose-response, with SMRs of 53, 152 and 280 for the low, moderate and high exposure groups. Because the study related quantified exposure levels to quantified measures of lung cancer risk, the data were suitable for a risk assessment.

Table 6: Cadmium Exposure Levels of Workers in Thun *et al*. (1985) Occupational Exposure Study

	Cumulative exposure in mg-days/m^3			Equivalent lifetime dose rate* in μg/m^3
	Range reported by Thun *et al*.	Median	Median adjusted for 240 workdays/year	Median
Low	≤584	280	184.1	2
Middle	585-2920	1210	795.6	11.8
High	≥2921	4200	2761.6	41.0

* Assumes 24 hour/day exposure and an estimated average lifetime of 61.5 years.

Methodology

A Poisson regression model was fitted to the data. In this model the observed deaths are a function of two variables: the dose and the expected deaths. The function has two parameters: one for the carcinogenic potency of cadmium, the other to account for the healthy worker effect.

Obs_i = observed deaths in exposure group i

Exp_I = expected deaths in exposure group i based on the indirect method of age adjustment

d_i = median dose received by group I

The model is then expressed as:

$E[\ Obs_i\ ] = (1 + \beta d_i) \times \alpha \times Exp_i$ where E[ ] represents the expectation of a random variable, α = healthy worker effect, and β = potency of cadmium per unit dose.

This model predicts that in the absence of cadmium exposure ($d_i = 0$), the observed deaths will equal the expected deaths times some factor which distinguishes the workers from the general population, a factor which can be termed the "healthy worker effect". The appropriateness of this model is indicated by the mortality experience of the low exposure group, which had an SMR for lung cancer of 53. (The cohort also had a low SMR for cardiovascular deaths.) This model therefore separates the carcinogenic effect of cadmium

from the opposing, healthy worker effect. Using a nonlinear regression procedure (NLIN), the parameters were estimated at:

$\hat{\alpha}$ = 0.500 (unitless parameter) and
$\hat{\beta}$ = 0.0017 (cumulative mg-days/m^3)$^{-1}$

the 95% (two-tailed) upper confidence limit for β was 0.0079, and the χ^2 goodness-of-fit statistic was 0.15 (1 df, p = 0.70). Lung cancer deaths predicted by the model were compared with the observed lung cancer deaths for the three exposure groups (Table 7).

Table 7: Lung Cancer Deaths Among Cadmium-Exposed Workers: Observed And Predicted (Data of Thun *et al*., 1985)

	Cumulative Exposure Groups		
	Low	Middle	High
Observed	2	6	7
Predicted*	2.94	5.99	7.44

* Linear relative risk model with healthy worker effect, U.S. controls.

With these estimates of the parameters, the model was then applied to the California population to predict the excess number of lung cancer deaths induced by cadmium exposure. First, a current life table was produced for California males and females separately, using five-year age intervals. The background hazard of lung cancer death for each five-year age interval was calculated using 1980 census data for California (Bureau of the Census, 1982) and age-specific death rates for California from 1979-80 vital statistics data (California Department of Health Services, 1982) by standard statistical techniques (Chiang, 1984). These were then summed over a lifetime.

Next, using the estimated value for β and setting α = 1 for the general population (i.e. no healthy worker effect), the hazard of lung cancer death given a continuous lifetime exposure to 1 μg/m^3 cadmium was calculated from the model. Using these hazard rates, a new life table was constructed. Subtracting the background probability of a lung cancer death from that obtained for an exposed population resulted in a range of risk for excess lifetime cancer from 2×10^{-3} to 1.2×10^{-2} (μg/m^3)$^{-1}$. CDHS also suggested that a "best" cancer unit risk value for regulatory purposes was 1.6×10^{-3} (μg/m^3)$^{-1}$ for cadmium in air.

CDHS (1990) reviewed the previous CDHS (1986) estimate of parameters generated from the fit of the Poisson regression model to the Thun *et al.* (1985) lung tumor data. The 97.5% upper confidence limit for β was calculated for a number of values of α that were in the range $0.5 < \alpha < 1.0$. All of the calculated 97.5% upper confidence limit for β were less than the corresponding values calculated from the statistical analysis program used previously by CDHS (1986).

CDHS (1990) decided that it is reasonable to restrict α to values between 0.5 and 1.0. If α were less than 0.5, the study cohort background incidence of respiratory cancer would be less than 50% of the incidence among males in the Colorado population. On the other hand, CDHS (1990) concluded that it was not appropriate to assume that the background incidence of respiratory cancer is higher ($\alpha > 1$) in the study cohort than it is in the control population. Because the lung cancer incidence for Colorado males is 72% of the rate for U.S. males, CDHS selected the value $\alpha = 0.7$ as a reasonable midrange estimate. With this choice, the values of the MLE and 95% UCL for 0 are 0.0017 and 0.0028 $(\text{mg-days/m}^3)^{-1}$, respectively. When the upper confidence limit estimate for β is used to estimate lifetime cancer risk from the data and life-table methodology used by CDHS (1986), the resulting cancer unit risk is 4.1×10^{-3} $(\mu\text{g/m}^3)^{-1}$. This value is within the range of unit risks (2×10^{-3} to 1.2×10^{-2} $(\mu\text{g/m}^3)^{-1}$) contained in the cadmium TAC document and approved by the Scientific Review Panel.

Unit Risk Factor: 4.2 E-5 $(\mu g/m^3)^{-1}$
Slope Factor: 1.5 E-1 $(mg/kg\text{-}day)^{-1}$
[Calculated from mouse liver tumor incidence data (Edwards *et al*., 1942) using a linearized multistage procedure, extra risk (US EPA, 1984); revised by CDHS (1987).]

III. CARCINOGENIC EFFECTS

Human Studies

Capurro (1979) reported a study on the residents in a rural valley polluted by vapors from a solvent recovery plant for at least 10 years. Chloroform, benzene, methyl isobutyl ketone, trichloroethylene and 26 other organic agents were detected in the air in addition to carbon tetrachloride (Capurro, 1973). The author reported four excess cases of lymphoma. Attributing these cancer cases to carbon tetrachloride alone would be inappropriate due to exposure to the other contaminants.

In a preliminary study of 330 laundry and dry cleaning workers, Blair *et al*. (1979) examined occupational exposure to carbon tetrachloride and other dry cleaning agents. Information from death certificates indicated an excess of deaths from lung, cervical and liver cancer, and leukemia. Katz and Jowett (1981) studied female laundry and dry cleaning workers in Wisconsin. Their results failed to show an overall increase in malignant neoplasms, but they did report an elevated risk for cancers of the kidney and genitals (unspecified), along with smaller excesses of bladder and skin cancer and lymphosarcoma. However, the use of carbon tetrachloride has been of only minor importance in dry cleaning since the 1950's and quantitative data on exposure to carbon tetrachloride were not presented in these studies.

Hernberg *et al*. (1984) reported a case-control study on primary liver cancer and exposure to solvents. Of 126 cases, two had a history of exposure to carbon tetrachloride, among

other solvents. They concluded that there was an association between primary liver cancer and exposure to "solvent" among women, but not for men.

Two reports were published on cancer mortality in a population of rubber workers (Checkoway *et al*., 1984; Wilcosky *et al*., 1984). Information on cause of death was reported earlier by McMichael *et al*. (1974). They reported a significantly elevated odds ratio relating carbon tetrachloride with lymphatic leukemia (OR = 15.3, $p < 0.0001$) and lymphosarcoma and reticulum cell sarcoma (OR = 4.2, $p < 0.05$). Attributing these outcomes to carbon tetrachloride alone is inappropriate since different solvents were used simultaneously in a given process area. A high degree of correlation also existed between exposure to several other solvents and the incidence of lymphatic leukemia (carbon disulfide, ethyl acetate, acetone, and hexane) and lymphosarcoma (xylenes, carbon disulfide and hexane). Although some of these solvents are not recognized carcinogens, these potentially confounding exposures, the lack of association of carbon tetrachloride exposures with these cancers in other studies, and the small number of cases (19/6678), preclude any causal inference from this study.

In summary, the epidemiological studies and human case reports are inadequate for use in a quantitative risk assessment.

Animal Studies

Mice

Edwards (1941) and Edwards and Dalton (1942) administered carbon tetrachloride by gavage to different strains of male and female mice (Strains A, C, CH3 and Y) two to three times a week for 8 to 23 weeks. To assess the tumor-producing ability of carbon tetrachloride, animals were necropsied 12 to 21 weeks after the last treatment. For those animals exposed to approximately 2100 mg/kg of carbon tetrachloride the incidence of hepatoma was 88.2 percent (strain CH3). Whether the carbon tetrachloride-induced hepatomas were malignant was not established histologically in the study. The animals were dosed on a non-daily schedule for a maximum of 16 weeks and sacrificed starting at 4 months of age. Since tumor expression is a function of both dosage and the latency period, any risk assessment based on these studies, with their short observational periods, will underestimate the true carcinogenic risk. In another experiment Edwards and Dalton (1942) administered 1, 2, or 3 doses of carbon tetrachloride (≈260 to 2100 mg/kg) followed by long-term observation in Strain A mice. The doses were hepatotoxic, but when the animals were examined 12 months later no tumors were observed.

Edwards *et al.* (1942) treated 56 male and 19 female L mice with 0.1 ml of 40% carbon tetrachloride 2 or 3 times/week over 4 months, for a total of 46 treatments. Animals were killed 3 to 3.5 months after the last treatment. The combined hepatoma incidence of treated male and female mice was 47% (34/73 vs. 2/152 in the untreated controls) (Table 1).

Eschenbrenner and Miller (1943; 1946) extensively examined carbon tetrachloride-induced tumor production in Strain A mice. In the first study they administered 30 doses

of carbon tetrachloride at intervals of one to five days (0, ≈160, 315, 625, 1250 and 2500 mg/kg). All animals were examined for tumors at 150 days following the first dose. Centrilobular liver necrosis was observed at all exposure levels. They reported that the incidence of hepatomas was increased as the time interval between doses increased.

In a second study Eschenbrenner and Miller (1946) administered the same total quantity of carbon tetrachloride, either in 30 doses at four-day intervals or in 120 doses on consecutive days. This study was conducted to determine the effect of liver necrosis on tumor development. They found that mice receiving the smaller dose over 120 days (a "non-necrotizing" dose) developed tumors at roughly the same or greater rate as those animals that received necrotizing doses (30 large doses at four-day intervals). The tumor incidence was not statistically significant. It appears that liver necrosis was not a required precondition for the production of tumors with carbon tetrachloride. This study showed that the total length of the exposure period (i.e., 120 versus 30 days), not the time between doses, may have been the major determining factor in the production of tumors.

Three NCI mouse bioassays used carbon tetrachloride as a positive control (NCI, 1976a,b; 1977; Weisburger, 1977) and excess mortality was a severe problem in the studies. Mice ($B6C3F_1$, males and females) were dosed by gavage (0, 1250 and 2500 mg/kg body weight) for 5 days/week for up to 78 weeks and they were to be sacrificed at 92 weeks. However, only 14% of the animals survived to 78 weeks and less than 1% survived to 92 weeks. This compares with 66% of the controls surviving the 92-week experiment. Hepatocellular carcinoma was found in almost every treated animal (Table 1). Carcinomas were observed as early as 16 weeks for the low-dose female group. The high mortality and virtual 100% tumor response are the more serious limitations of this study for use in quantitative risk assessment.

Table 1: Carbon tetrachloride-induced liver tumor incidence in mice.

Study	Strain	Dose (mg/kg-day)	Tumor incidence
Edwards et al., 1941	strain Y (male, female)	0	2/152 (2%)
		≈2100	34/73 (47%)
NCI 1976a,b; 1977	$B6C3F_1$ (male, female)	0	6/157 (4%)
		1250	89/89 (100%)
		2500	90/93 (97%)

Rats

Reuber and Glover (1970) compared the carcinogenicity of carbon tetrachloride in 12-week-old male rats (Japanese, Osborne-Mendel, Wistar, Black and Sprague-Dawley strains). The animals were subcutaneously injected (0, 2080 mg/kg body weight) twice a week for up to 105 weeks. Corn oil was administered to controls. All the Black and Sprague-Dawley strains died within 18 weeks. No carcinomas were observed. Hyperplastic nodules and hepatic carcinoma were reported in the other three strains (80%, 20%; 63%, 31%; 14%, 14% for Japanese, Osborne-Mendel and Wistar rats, respectively).

Other lesions reported were hemangiomas (13% and 8% for Japanese and Osborne-Mendel rats, respectively), carcinomas of the thyroid gland (20% and 23% for Japanese and Osborne-Mendel rats, respectively), and subcutaneous leiomyosarcoma (7% in Japanese rats). Cirrhosis was reported in all animals. Due to the small group size, poor survival of several strains and the incomplete reporting of the total dosage, and most importantly, the inappropriate route of exposure (subcutaneous injections), this study was not used in a quantitative risk assessment. As in the mouse studies, NCI used carbon tetrachloride as a positive control in rat bioassays for chloroform, 1,1,1-trichloroethane and trichloroethylene (NCI, 1976a,b; 1977; Weisburger, 1977). The Osborne-Mendel rats were administered a time-weighted average dose of carbon tetrachloride by gavage for 78 weeks (47, 97 and 80, 159 mg/kg body weight, respectively for males and females). Hepatic carcinomas were found at both doses in both sexes (4%, 4% and 8%, 2% in low and high dosage, males and females, respectively). A lower incidence was reported in the high-dose females, but this may have been a result of that dose group's high mortality rate prior to tumor expression. Tumors in other tissues were not discussed.

Male and female Syrian golden hamsters were administered carbon tetrachloride in corn oil weekly by gavage (190 and 380 mg/kg of body weight, respectively) for a total of 30 weeks (Della Porta *et al*., 1961). Following treatment, the animals were kept 25 weeks, sacrificed and examined. Only eight of the original 20 animals survived the full 55 weeks. Carcinomas were not observed in the animals that died prior to the 43rd week, but one or more liver-cell carcinomas were reported in all the surviving animals, indicating that tumors may be produced at lower levels in this species. Liver tumor incidence in carbon tetrachloride-treated animals (males and females combined) was 10/19 (53%) compared to 0/80 (0%) for controls.

In summary, carbon tetrachloride has been shown to produce liver tumors in mice, rats and hamsters by the oral and subcutaneous routes. No inhalation cancer bioassays have been conducted.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Carbon tetrachloride has been observed to induce liver tumors in male and female hamsters, mice and rats, as described above. CDHS (1987) decided that the tumor incidence data from studies by Della Porta *et al.* (1961) (hamster), Edwards *et al.* (1942) (mouse) and NCI (1977a, b) (mouse) were suitable for use in developing a quantitative risk assessment.

Methodology

A health assessment document for carbon tetrachloride was prepared by US EPA (1984). This document contained a quantitative cancer risk assessment for carbon tetrachloride. A linearized multistage procedure was applied to liver tumor incidence data (Della Porta *et*

al., 1961; Edwards *et al.*, 1942; NCI 1976a, b; 1977 [rat, mouse]) to estimate a cancer unit risk.

The quantitative risk assessment of carbon tetrachloride conducted by US EPA (1984) using the linearized multistage procedure was modified by DHS (1987) by: 1) applying an absorption fraction of 50% instead of 40%; 2) omitting one rat bioassay US EPA used (NCI, 1976a, b; 1977); 3) assuming an average inhalation intake of 18 µg/day instead of 20 µg/day; and 4) presenting the range of resulting unit risks instead of the geometric mean. DHS chose not to include the NCI rat bioassay data in the unit risk estimation because when the data are adjusted for excess mortality there is no statistically significant association between dose and tumor response. Cross-route extrapolation was used to calculate inhalation unit risk values from oral exposure data. Using an absorption fraction of 50%, an estimated human weight of 60 kg and an estimated respiration rate of 18 m^3/day, the unit inhalation intake is 4.5 times the unit oral intake. Therefore, the US EPA 95% upper confidence limit oral cancer risk values calculated were multiplied by a factor of 4.5 to obtain the values of 1.5×10^{-4} $(\mu g/m^3)^{-1}$ (Della Porta *et al.*, 1961), 4.2×10^{-5} $(\mu g/m^3)^{-1}$ (Edwards *et al.*, 1942) and 9.9×10^{-6} $(\mu g/m^3)^{-1}$ (NCI, 1976a, b; 1977 [mouse]). The cancer unit risk of 4.2×10^{-5} $(\mu g/m^3)^{-1}$ was recommended by CDHS for continuous air exposures.

III. CARCINOGENIC EFFECTS

Human Studies

Comprehensive reviews of the human studies of dioxin exposure and cancer risk available at the time the document entitled *Health Effects of Chlorinated Dioxins and Dibenzofurans* was written for the Toxic Air Contaminant (TAC) program (CDHS, 1986) are found in US EPA (1984) and Veterans Administration (VA) (1981, 1984). A more recent review of human dioxin exposure and cancer risk studies can be found in ATSDR (1999).

Dioxins have never been intentional products. In human exposure studies, PCDDs (polychlorinated dibenzo-*p*-dioxins) and PCDFs (polychlorinated dibenzofurans) have only been present as contaminants of other toxic chemicals, such as herbicides. Hence all studies of human PCDD/PCDF exposures have been studies of exposure to chemical mixtures that may have contained PCDD and PCDF.

VA (1981, 1984) summarized what is known about the presence of PCDD and PCDF in commercially-used chemicals. In general, PCDDs and PCDFs may be present as contaminants in the herbicide 2,4,5-trichlorophenoxyacetic acid (2,4,5T). Levels of 2,3,7,8-TCDD in 2,4,5-T have been found as high as six parts per million (Rappe *et al.* 1982). Another widely used herbicide, 2,4-dichlorophenoxyacetic acid (2,4-D) is generally regarded as uncontaminated with 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD). Cochrane

et al. (1982) did detect traces of di-, tri-, and TetraCDD as high as one part per billion in technical grade 2,4-D from Canada. However, the TetraCDD isomer found in these samples was the 1,3,6,8-TCDD isomer, not the more toxic 2,3,7,8-TCDD.

Agent Orange, which was a mixture of 2,4,5-T and 2,4-D, has been shown to contain 2,3,7,8-TCDD concentrations as high as 15-47 parts per million with an average of about 2 ppm (VA 1981). PCDDs and/or PCDFs have also been found in the parts per million range in commercially used polychlorinated biphenyls (PCB), trichlorophenol (TCP), tetrachlorophenol, and pentachlorophenol (PCP) (Rappe *et al*. 1982, Hardell 1983).

Several case/control studies have been conducted in Sweden and in New Zealand. In these countries, phenoxyacetic acids and chlorophenols were used extensively for agriculture and forestry. After clinical observations of several patients with soft-tissue sarcomas (STS) and a history of heavy exposure to phenoxyacetic acids, Hardell and Sandstrom (1979) conducted a case/control study of STS and herbicide exposure. Cases were drawn from a university hospital in Northern Sweden, and consisted of 52 adult males with STS diagnosed between 1970 and 1977. Controls were drawn from general population registries, at a 4:1.matching ratio, and matched to cases on sex, age, place of residence, and vital status (whether alive or deceased). The investigators considered only non-malignant deaths for deceased controls. Study subjects (or their next of kin) provided exposure histories by a mailed questionnaire with a telephone follow-up. The odds ratio (OR) for exposure to phenoxyacetic acids only (excluding subjects exposed to chlorophenols) was 5.3 (95% confidence interval (95% CI) 2.4-11.5). For exposure to chlorophenols only (excluding those exposed to phenoxyacetic acids) the OR was 6.6 (95% CI 2.1-20.9).

To confirm these findings, Ericksson *et al*. (1981) replicated this study in Southern Sweden, using cases from a cancer registry. Similar study methods were used, including matching controls from a population registry (at a 2:1 ratio), and determining exposure by mail and telephone questionnaires. The investigators calculated separate odds ratios for exposure to phenoxy acids known to be contaminated with PCDD and PCDF (OR-17.0; 95% CI 2.1-140.0) and for exposure to phenoxy acids thought to be free of PCDD and PCDF (OR-4.2; 95% CI 1.2-14.9). When exposure was dichotomized into categories of 30 days or less, or more than 30 days, the ORs were 5.7 and 8.5, respectively, possibly indicating a dose-response trend.

One of the drawbacks of this study is that, exposure histories were provided by the study subjects; therefore, the results may be influenced by recall bias. Cases (or their next of kin) may be more likely to recall an exposure than a healthy person. In order to investigate this possible bias, Hardell (1981) duplicated the study methods using cases of colon cancer. Here there was no significant association with exposure to herbicides. Therefore, Hardell concluded that the association with STS was not due to reporting differences between diseased cases and healthy controls.

Smith *et al*. (1984) reported a similar case/control study in New Zealand. Here, male cases of STS were gathered from a national cancer registry, with controls also being selected from the same registry. This method of control selection was designed to avoid differential recall. Unlike the Swedish studies, however, the New Zealand study showed no significant

associations with reported phenoxy herbicide spraying. The authors suggested that if dioxin were the necessary agent, that Swedish herbicides may have been more contaminated than New Zealand herbicides. However, Smith *et al*. (1984) note that the Swedish investigators also found a significant association between STS and non-dioxin-contaminated herbicides, indicating that if the association were true, dioxin would not be the sole agent.

Another case/control study reported in brief by Olsen and Jensen (1984) of cases from the Danish Cancer Registry failed to show an association between nasal cancer and chlorophenol exposure, although nasal cancer was associated with occupational exposure to wood dust.

In a letter to Lancet, Milham (1982) reported proportionate mortality data from Washington state indicating that farmers suffered a significantly larger proportion of deaths due to STS. No other group occupationally exposed (foresters, orchardists, tree farmers) showed an excess of STS; however, the exposure assessment was based on occupations taken from death certificates. Furthermore, Milham indicated that 2,4-D was the predominant herbicide used, and 2,4-D is not generally contaminated with 2,3,7,8-TCDD.

A cohort study of phenoxy acid herbicide applicators in Finland was reported by Riihimaki *et al*. (1983). A historical cohort of 1926 herbicide applicators was assembled from the records of four large employers, including the Finnish Highway Authority and State Railways. These male workers had used chlorinated phenoxyacids for at least two weeks between 1955 and 1971. Their mortality between 1972 and 1980 was studied by comparing their names against population registers. National mortality figures provided expected age-standardized numbers of deaths. Deaths from all causes, and for all cancers, were less than expected. The power of this study to detect an increase in STS was poor, however, as only 0.1 case of STS was expected based on general population rates. Furthermore, as deaths in the cohort were studied only after 1972, 45 deaths that occurred in this group before 1972 were not tallied. (Even for post-1971 deaths, however, the follow-up period may also have been too short for a sufficient tumor latency period to have elapsed.)

There have been four potentially exposed occupational cohorts studied in the United States. Zack and Suskind (1980) reported the follow-up of Monsanto employees in Nitro, West Virginia, who were involved in a 1949 accident during the processing of trichlorophenol. A sudden violent reaction released fumes and residues into a building interior. Apparently, the released chemical mixture was not analyzed, but the authors assumed that it contained TCDD, as exposed workers developed chloracne. A historical cohort of 121 white male employees was assembled from company records on the basis of their having exhibited skin disorders "attributed to the 1949 TCP process accident." Their vital status was traced through 1978, providing a maximum of 29 years of follow-up per person. The standardized mortality ratio (SMR) for all causes of death in this cohort (relative to US white males) was significantly decreased (32 observed deaths vs. 46.4 expected). One cancer site showed an excess: lung cancer (5 observed vs. 2.85 expected), although this SMR of 1.75 was not statistically significant. Interestingly, there occurred one STS, a fibrous histiocytoma. However, the authors calculated SMRs (and expected numbers of deaths) only for causes with five or more observed deaths.

Zack and Gaffey (1983) described another cohort from this plant, composed of 884 male workers employed for at least one year between 1955 and 1977. It is not clear whether workers exposed in the 1949 accident were included. The same methods were used to calculate SMRs. Only 25 malignancies occurred, compared to 30.9 expected. However, two specific sites were notably elevated: lung cancer, with 14 observed vs. 9.9 expected (SMR 1.4; 95% CI 0.8-2.4), and bladder cancer, with 9 observed vs. 0.9 expected (SMR 9.9; 95% CI 4.5-18.8). One STS occurred in a worker judged to have been exposed to TCDD. One drawback to this study is that exposure histories were only constructed for the 163 decedents - and only 36% of these were judged to have had potential exposure to 2,4,5-T (and therefore TCDD). Therefore, the true exposed cohort may only have been one-third the size of the entire study group.

Cook *et al*. (1980) presented a similar historical cohort study of Dow chemical employees. In 1964, chloracne occurred in workers in a trichlorophenol manufacturing area. Industrial hygiene investigations concluded that TCDD was responsible and changes were made in the operations to decrease exposure. Levels of TCDD during this period were unknown because concentrations fell below the limit of detection at that time, 0.02 µg/ml of air (Cook 1981a); however, wipe samples were positive for TCDD. Cook *et al.* (1980) assembled a cohort of 39 workers thought to have high exposure potential, and 22 workers thought to have lower exposure. Among the high-exposure group, 87% had a history of chloracne, compared to 68% of the low-exposure group. Their vital status was determined through 1978. There were only four deaths (vs 7.8 expected based on US white males), although three of these deaths were due to neoplasms (vs 1.6 expected). One neoplasm was a fibrosarcoma.

Another Dow cohort was investigated by Ott *et al*. (1980). This cohort contained 204 white males involved in 2,4,5-T production between 1951 and 1971. The authors determined each worker's vital status through 1976, resulting in a median length of time since first exposure of about 20 years. Only one malignancy (a respiratory cancer) was recorded vs. 3.6 expected from US population rates. This cancer death occurred among the employees with 20 or more years of latency; in this group 0.9 deaths were expected.

Besides the small sample size, there are other problems with using this study for risk assessment. The exposure to TCDD may have been minimal. Environmental sampling of the breathing zone in 1969 revealed 2,4,5-T concentrations between 0.2 and 0.8 mg/m^3. Product specifications at that time called for a maximum TCDD concentration of 1 ppm. Assuming the maximum level of both 2,4,5-T in the breathing zone, and TCDD in the 2,4,5-T, the concentration of TCDD in the breathing zone would have been 10^{-6} of the concentration of 2,4,5-T, or 0.8 ng/m^3. Ott *et al*. also noted that 157 of the 204 workers (77%) were exposed for less than one year. Furthermore, a review of medical records of the cohort uncovered no cases of chloracne.

A further analysis of Dow employees was presented by Bond *et al*. (1983), who reported a morbidity survey on the combined cohorts previously described by Cook *et al.* (1980) and Ott *et al*. (1980). Bond *et al.* found few differences between the morbidity of these workers and a matched control group of workers from other locations in the plant. There were,

however, more ulcers and diseases of the digestive system (excluding liver) in the 2,4,5-T cohort, at roughly twice the prevalence in the controls. However, because the investigators only studied cohort members who participated in company medical programs between 1976 and 1978, only 69% of the original cohort was included. The study did not include workers who had died, retired, or left the company, raising the possibility that the most affected workers might have been missed.

Following the publication of the four US mortality studies, reports began to appear in Lancet of four additional cases of STS among these cohorts, bringing the apparent total to seven (Honchar and Halperin 1981, Cook 1981b, Moses and Selikoff 1981, Johnson *et al*. 1981). The proportion of deaths in these merged cohorts due to STS appeared to be far greater than would be expected (Fingerhut and Halperin 1983), although there is great difficulty in estimating expected rates of STS using general population statistics (Cook and Cartmill 1984). Fingerhut (cited in VA 1984) had the diagnoses of the seven cases reviewed by two pathologists. The pathologists could only agree on a diagnosis of STS for three of the seven, another three being reclassified, and the last diagnosis being disputed. Of the three definite cases, only two had frank chloracne to corroborate exposure. The VA review (1984) concluded that the occurrence of even two cases of STS among these relatively small cohorts warranted continued surveillance.

Other cohort studies of occupational exposures have come from Great Britain, West Germany, and the Netherlands. May (1973 and 1982) only briefly described the aftermath of a 1968 accidental release of TCP with a "higher than normal" concentration of TCDD. A total of 79 cases of chloracne were recorded, but May did not specify how many workers were exposed, so that an attack rate cannot be calculated. A survey of 46 of these workers, who were still with the company 10 years later, revealed that roughly half still had some chloracne (May, 1982). There were no other clinical problems reported, and no cases of cancer (although clearly few if any would be expected in a group this small).

Thiess *et al*. (1982) published a carefully-reported study of 74 workers exposed to dioxins during a 1953 reactor accident in a German 2,4,5-T plant. After a 23-year follow-up, this cohort exhibited seven deaths due to malignancies (vs. 4.09 expected from West German population rates), including three deaths due to stomach cancer (vs. 0.7 expected). The latter was statistically significant at a one-sided 95% level. No cases of STS occurred, although less than 0.1 would have been expected.

A mortality study of workers present at an explosion in an herbicide factory in Amsterdam was summarized by Dalderup and Zellenrath (1983). Between 200 and 500 g of TCDD were thought to have been liberated. The investigation traced 141 of 145 workers potentially exposed, and 69 (49%) had developed chloracne. After 20 years of follow-up, 8 of the workers had died with cancer (vs. 6.9 expected), yielding an SMR of 1.2 (95% CI 0.5-2.3). No STS deaths were seen. Unfortunately, the authors did not calculate SMRs separately for the group with frank chloracne (an indicator of stronger exposure), as the crude mortality for this chloracne group was 20%, and for the non-chloracne group 15%.

At the time the dioxin TAC document was prepared (CDHS, 1986), reports were starting to appear in the literature on the effects of Agent Orange herbicide exposure in Vietnam. However, most of those reports were at the time primarily anecdotal, or interim results. Agent Orange was composed of equal parts 2,4-D and 2,4,5-T, and about 90,000 tons of herbicides were sprayed in Vietnam between 1962 and 1971. Hay (1983) mentioned evidence from Vietnamese studies that "suggests a link" between herbicide exposure and liver cancer, but provided no details. Sarma and Jacobs (1982) reported three patients with STS who claimed Agent Orange exposure while serving in Vietnam.

The US Air Force's Ranch Hands study (summarized by VA, 1984) had released some initial results at the time the dioxin TAC document was prepared. This was a cohort study of some 1200 military personnel who worked on Operation Ranch Hand, the herbicide spraying operation. These subjects were matched (in a 5:1 ratio) with personnel who flew only cargo missions in Vietnam. As of 1983, the total mortality rates were nearly identical between the two groups. Only four cases of cancer had occurred among the exposed, and none were STS. The investigators stressed the preliminary nature of the data, the relatively low power of a study of this size to detect rare tumors such as STS, and the relatively short latency period up to that time (12-21 years).

A report by Greenwald *et al*. (1984) gave the results of a case/control study of STS in New York State. Cases of STS (n = 281) diagnosed between 1962 and 1980, who were between the ages of 18 to 29 during the war in Vietnam, were selected from the state cancer registry. Cases were individually age matched to living controls drawn from drivers' license files. The investigators gathered exposure information from subjects or next of kin by a telephone questionnaire. The questions focused on Vietnam service (and Agent Orange exposure in particular), but included other exposures such as chemical manufacturing and herbicide spraying in general. Only 3% of the cases and 4% of the controls had a history of Agent Orange, dioxin, or 2,4,5-T exposure. None of the various exposures proved statistically significant.

The power of this study can be criticized, with exposures as rare as they were. Also, the inclusion of cancer cases from the early 1960s can be questioned. These cases would not have had sufficient latency to have been caused by an exposure in Vietnam.

In 1983, an Australian Royal Commission began investigating the effects of Agent Orange exposure to Australian Vietnam veterans. However, their report, released in 1985, does not supply much information on the effects of PCDDs. The executive summary concluded that "only a very limited number of Australian servicemen were ever directly exposed," and further, that the dose received by the majority of Australian veterans was "so minute that it may, without doubt, be ignored," (e.g., it noted that no Australians developed chloracne). Not surprisingly, the Commission found no evidence of any cancer excess among the "exposed" servicemen (Royal Commission, 1985).

There are only a few cases where dioxin exposure of the general population has been documented; the Seveso incident in Italy, is one of them. In 1976, a chemical plant producing 2,4,5-trichlorophenol, exploded and released into the air several chemicals including TCDD in the vicinity of Seveso. The Seveso incident represents a unique event

in the sense that exposure to the toxic chemical was not limited to occupational exposure by workers but the whole population was affected by the TCDD release in the area surrounding a pentachlorophenol manufacturing facility that experienced an explosion and fire releasing dioxins into the atmosphere. Children, woman and men of various age were exposed to different degrees depending on the distance and direction from the origin of the plume.

Abate *et al*. (1982) summarized the series of studies following the 1976 accidental release of TCDD from a TCP-producing plant in Seveso, Italy. The investigators looked at mortality rates for 11 municipalities for four years after the accident and reported no increase in cancer mortality. These studies served mainly to provide baseline rates for future studies, because clearly not enough time had elapsed to provide the minimum 10 to 20 years required for an increased cancer risk to become manifest (Bruzzi, 1983).
Fifteen years after the industrial accident, Bertazzi et al. (1997) examined the cancer mortality among residents (20 to 74 years old) of Seveso by comparing populations living in dioxin contaminated areas (divided into three zones: highest, lower and lowest zone of exposure to dioxin, zone A, B, and R, respectively) with population from neighboring noncontaminated areas (zone nonABR). No increase for all-cancer mortality, or major specific sites like respiratory cancer among males and breast cancer among females, was found. However, other specific cancer mortality was observed and could be associated with dioxin exposure. Table 1 represents cancer mortality for men and women living in zone B.

Increased mortality from stomach cancer (RR = 2.4; 95% CI = 0.8-5.7) was reported 10 years after the accident in women living in zone B. In men, increased mortality from rectal cancer (RR = 6.2; 95% CI = 1.7-15.9) was observed. Leukemia in men represented one of the highest risks seen in zone B for hematologic neoplasms and was statistically significant (RR = 3.1; 95% CI = 1.3-6.4). Multiple myeloma in women (RR = 6.6; 95% CI = 1.8-16.8), and Hodgkin's disease in both genders (RR = 3.3; 95% CI = 0.4-11.9 in men; and RR = 6.5; 95% CI = 0.7-23.5 in women) were also noted in that zone. In the young population (20,000 subjects aged 0 to 19 years old), some cases of cancer were also found (Pesatori et al., 1993). Cancer cases noted included two ovarian cancers and Hodgkin’s lymphoma; myeloid leukemia represented the most evident increase although not statistically significant (RR = 2.7; 95% CI = 0.7-11.4). Two cases of thyroid cancer were also reported (RR = 4.6; 95% CI = 0.6-32.7). This observation represents an important result because of its magnitude and its correlation with experimental observations. None of the elevated cancer incidences in zone A, the area with the highest exposure, were statistically significant; however, this area also had the smallest population. Additionally, it should be noted that the Seveso population was exposed to 2–3 orders of magnitude times the level of dioxin normally experienced by the general population of industrialized countries. In 1997, individuals living in the contaminated area at the time of the accident still experienced high level of plasma TCDD 20 years after the industrial accident in Seveso. Geometric means for plasma TCDD concentration for individuals who lived in zone A, B and nonABR (control zone) in 1976 were 53.2, 11.0 and 4.9 ppt, respectively. Women in these three groups represented the gender with the highest plasma TCDD contamination (Landi et al., 1997). The authors concluded that the results indicate a

positive association between dioxin exposure and certain cancers, but further study is needed to clarify this association.

Table 1. Female and male deaths in zone B for selected causes, 1976-1991, ten years or more since first exposure (latency) and duration of exposure (length of stay in contaminated area) (Adapted from Bertazzi et al., 1997).

Animal Studies

Van Miller *et al.* (1977a,b) reported the results of a study in which rats were fed diets containing from 1 ppt to 1 ppm of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) for 78 weeks. Surviving rats were killed after 95 weeks. Laparotomies were performed on all surviving rats at 65 weeks and all tumors were biopsied. Rats in the three highest dose groups, receiving 50 ppb or more, died early. A variety of tumors were found in rats receiving 5 ppt to 5 ppb while no-neoplasms were found in the control or low-dose groups. The absence of tumors in these two groups is unusual in this strain of rats. In addition, because of the small number of animals in each group (10) the study was inadequate to determine the carcinogenic potential of TCDD.

Toth *et al*. (1979) administered TCDD to male Swiss/H/Riop strain mice by gavage once a week for a year, then followed them for their lifetime. The weekly doses were 0.007,

0.7, and 7.0 µg/kg. Analysis of the results from this study focused on the incidence of liver tumors. A significant increase in the incidence of liver tumors was observed in the intermediate-dose group compared to the four separate control groups. The high-dose group, however, had an incidence of liver tumors that was similar to the control group. This finding may be explained by the early mortality in the high-dose group. The average life span was 424 days for this group, compared to average life spans of between 577 and 651 days for the control groups. If the treated animals had lived it is possible that more tumors may have formed.

Kociba *et al*. (1978) conducted a two-year feeding study in male and female Sprague-Dawley rats given diets containing 2200, 210, or 22 parts per trillion (w/w) TCDD for two years. Consumption of these diets resulted in daily doses of 0.1, 0.01, and 0.001 µg/kg body weight, respectively. There were 50 male and 50 female rats in each treatment group and 86 animals of each sex in the control group. There was a statistically significant ($p < 0.05$) increase in cumulative mortality for the high-dose female group in the latter half of the study. Body weights of the male and female high-dose groups were significantly ($p < 0.05$) reduced for the last three quarters of the study; however, food intake was not altered. The combined incidence of hepatocellular carcinomas and hepatocellular neoplastic nodules in the intermediate and high-dose groups of female rats was increased above the control group. Statistically significant increased incidences of stratified squamous cell carcinomas of the hard palate and/or nasal
turbinates were observed in both male and female high-dose groups. The male group also had an increased incidence of squamous cell carcinoma of the tongue, while the female group had an increased incidence of keratinizing squamous cell carcinoma of the lung.

US EPA (1981) reviewed this study and had an independent pathologist, Robert Squire, review the tissue pathology. The incidences of significant tumors reported by Kociba *et al*. (1978) and by Squire (US EPA, 1981) are given in Table 2 for male and female rats. The results of Squire's review did not differ greatly from those reported by Kociba *et al*. (1978).

CDHS staff members concurred with earlier reviewers (IARC 1982, EPA 1984) that the study reported by Kociba *et al*. (1978) was an adequately conducted chronic carcinogenicity bioassay of TCDD, with significant effects observed at the two higher dose levels.

Table 2: Tumor incidences in Osborne-Mendel rats receiving 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) in the diet for two years (US EPA, 1984)

Tumor type, sex	Dose level (µg/kg-day)			
	0	0.001	0.01	0.1
	Tumor incidence[a]			
Tongue, stratified squamous cell carcinoma				
male	0/76 (0/77)	1/49 (1/44)	1/49 (1/49)	4/42 ($p = 0.015$) (3/44) ($p = 0.046$)
Nasal turbinates/hard palate, squamous cell carcinoma				
male	0/51 (0/55)	1/34 (1/34)	0/27 (0/26)	4/30 ($p = 0.017$) (6/30) ($p = 0.002$)
female	1/54 (0/54)	0/30 (0/30)	1/27 (1/27)	5/24 ($p = 0.009$) (5/22) ($p = 0.001$)
lung, keratinizing squamous cell carcinoma				
female	0/86 (0/86)	0/50 (0/50)	0/49 (0/49)	7/49 ($p < 0.001$) (8/47) ($p < 0.001$)
Liver, hepatocellular hyperplastic nodules, carcinomas				
female	9/86 (16/86)	3/50 (8/50)	18/50 ($p < 0.001$) (27/50) ($p < 0.001$)	34/48 ($p < 0.001$) (33/47) ($p < 0.001$)

P values determined using Fisher's exact test.

[a] Number of animals with tumor over number of animals examined (incidence reported by Kociba *et al.*, 1978). Numbers in parentheses give the incidence reported by Squire (US EPA, 1984).

The National Toxicology Program (NTP 1982a) conducted an oncogenicity bioassay of TCDD in male and female Osborne-Mendel rats. They were administered TCDD in a 9:1 corn oil:acetone vehicle by gavage at dose levels of 0.005, 0.025, or 0.25 µg/kg twice a week for 104 weeks. The treatment groups consisted of 50 rats of each sex and a vehicle control group that was made up of three subgroups of 25 rats of each sex. An untreated control group, also made up of three subgroups of 25 rats of each sex, was included in the study, but not in the statistical analysis of the results by NTP. At the dose levels used, TCDD did not have a significant effect on survival of any treatment group. The high-dose group of male rats did have a statistically-significant increased incidence of subcutaneous tissue fibromas, but it was not considered biologically significant because of the variability found. All male treatment groups had significantly ($p < 0.05$) increased incidences of thyroid follicular cell adenomas or adenomas and carcinomas, although the low- and intermediate-dose level group incidences were not significant when compared to the untreated control group by CDHS staff. The female high-dose group had significantly ($p < 0.05$) increased incidences of several tumor types, including subcutaneous tissue fibrosarcomas, liver neoplastic nodules or hepatocellular carcinomas, and adrenal cortical adenomas. Of these 3 tumors, NTP considered only the liver tumors to be related to TCDD

administration. The incidences of these tumors are given in Table 3. Toxic hepatitis was found in 14 male and 32 female high-dose level rats.

Table 3: Tumor incidences in male and female Osborne-Mendel rats given 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) by gavage for two years (NTP, 1982a)

Sex, tumor type	Dose level (µg/kg-week)			
	0	0.01	0.05	0.5
	Tumor incidence[a]			
Males				
Thyroid				
Follicular cell adenoma	1/69	5/48 ($p = 0.042$)	6/50 ($p = 0.021$)	10/50 ($p = 0.001$)
Follicular cell adenoma/carcinoma	1/69	5/48 ($p = 0.042$)	8/50 ($p = 0.004$)	11/50 ($p < 0.001$)
Females				
Subcutaneous tissue, fibrosarcoma	0/75	2/50	3/50	4/49 ($p = 0.023$) [3][b]

[a] Number of animals with tumor over number of animals examined.
[b] Number of animals with hepatocellular carcinoma.
NOS = Not otherwise specified. *P* values determined using Fisher's exact test.

NTP (1982a) also conducted a carcinogenicity bioassay with TCDD in male and female $B6C3F_1$ hybrid strain mice. The protocol was similar to that used in the rat study with male mice receiving the same doses of TCDD. Female rats, however, received larger doses of 0.02, 0.1 or 1.0 µg/kg twice a week. These dose levels did not have a statistically significant effect on survival of any treatment group. Male mice in the highest dose group had a significantly increased incidence of hepatocellular carcinomas. The high-dose female group had significantly increased incidences of subcutaneous tissue fibrosarcomas, hepatocellular adenomas or carcinomas, and thyroid follicular-cell adenomas. NTP considered only liver tumors and thyroid tumors to be related to TCDD administration. NTP also considered histiocytic lymphomas to have been increased in the high-dose female group; however, the staff of DHS did not consider that these lymphomas were increased when the incidences in all control subgroups were considered. The observed tumor incidences in both male and female mice are given in Table 4. Toxic hepatitis was observed in 44 male and 34 female high-dose group animals. It was also observed in several animals of the other treatment groups.

Table 4: Tumor incidences in male and female B6C3F$_1$ mice given 2,3,7,8-Tetrachloro-dibenzo-*p*-dioxin (TCDD) by gavage for two years (NTP, 1982a).

Sex, tumor type	Dose level (µg/kg-week)[a]			
	0	0.01 (0.04)	0.05 (0.2)	0.5 (2.0)
	Tumor incidence[b]

hepatocellular adenoma or carcinoma	3/73	6/50	6/48	11/47 (p = 0.002)
thyroid, follicular cell adenoma	0/69	3/50	1/47	5/46 (p - 0.009)

P values determined using Fisher's exact test.
[a] Dose administered to male mice; dose administered to female mice in parentheses.
[b] Number of animals with tumor over number of animals examined.

Both rat and mouse carcinogenicity bioassays conducted by NTP appear to have been done in an adequate manner. The number of treatment groups and the large dose range used in the studies are not typical of NTP bioassays, although it was similar to that used by Kociba *et al*. (1978). However, it may not have been large enough to include a dose level which produced no effect. Most significantly increased tumor incidences only occurred in the high-dose level groups, but a statistically significant dose-related trend was found in all groups.

NTP (1982b) also conducted a dermal oncogenicity bioassay on TCDD in male and female Swiss-Webster mice. TCDD in an acetone suspension was applied to the skin three days per week for 104 weeks. The male rats received 0.001 µg per application and the females received 0.005 µg per application. Separate groups of male and female mice were treated with one application of 50 µg 7,12-dimethylbenz(*a*)anthracene (DMBA) one week prior to the start of TCDD treatments. The only significantly (p = 0.01) increased incidences of tumors observed were among female mice. Both the TCDD- and DMBA/TCDD-treated groups had a similar incidences of fibrosarcoma in the integumentary system (8/27 and 8/29, respectively), compared to the vehicle control of 2/41. In NTP's judgment, the results of this experiment indicated that TCDD was carcinogenic.

HexaCDDs have been tested for carcinogenicity by NTP (1980a) in both Osborne-Mendel rats and B6C3F$_1$ mice. The bioassay tested a mixture of HexaCDDs containing 31 percent 1,2,3,6,7,8-HexaCDD and 67 percent l,2,3,7,8,9-HexaCDD. Lower chlorinated PCDDs made up the remaining 2% of the mixture, including 0.04 percent TetraCDDs. Male and female rats and male mice received weekly doses of 1.25, 2.5 or 5 µg/kg, administered by

gavage twice a week. The female mice were administered doses of 2.5, 5.0, or 10 μg/kg/week.

A dose-related "toxic hepatitis", which was noninflammatory and consisted of degenerative changes in the liver, was observed in treated rats. The treated groups of female rats had significantly increased incidences of liver neoplastic nodules. Four high-dose animals were diagnosed as having hepatocellular carcinoma. The mice also had a dose-related incidence of "toxic hepatitis" and the high-dose male and female mouse groups had statistically significant increased incidences of hepatocellular adenomas and combined incidences of hepatocellular adenomas and carcinomas. The incidences of these tumors are given in Table 5.

Several pathologists have independently evaluated the slides made from the female rat livers in this bioassay. The re-evaluations found fewer neoplastic nodules and carcinomas than did the original evaluation. Although the incidences of neoplastic nodules and carcinomas are probably lower than originally reported, the incidence is still significant in the high-dose group. The results of four separate evaluations of the liver pathology of the female rats are given in Table 6.

A dermal application carcinogenicity bioassay of the same mixture of HexaCDD in male and female Swiss-Webster mice was also conducted by NTP (1980b). This study was similar to the TCDD dermal oncogenicity bioassay in its protocol. Thirty mice of each sex were treated with 0.005 μg of the dioxin mixture three times per week for the first 16 weeks, which was increased to 0.01 μg thereafter. A similar group was initially treated once with 50 μg DMBA before being treated with the HexaCDD mixture. Thirty untreated and 45 vehicle-treated mice of each sex were used as controls. Although there was a slight increase in fibrosarcomas of the integumentary system, this was not considered by NTP to be a significant carcinogenic response. DMBA pretreatment had no additional effect.

DHS staff members agreed with IARC (1982) that there is adequate evidence to support a conclusion that TCDD is carcinogenic to rats and mice and that TCDD should be considered a potential carcinogen to humans. The NTP bioassays (NTP 1980a) of HexaCDDs also indicated that the mixture used was tumorigenic.

Table 5: Tumor incidences in female Osborne-Mendel rats and male and female B6C3F$_1$ mice given HexaCDD by gavage for two years (NTP, 1980a)

Sex, species, tumor type	Dose level (µg/kg-week)

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Several human epidemiological studies of PCDD exposure reviewed in the dioxin TAC document (CDHS, 1986) reported results which suggested an increase in cancer incidence or mortality associated with PCDD exposure (Hardell and Sandstrom, 1979; Ericksson *et al*., 1981; Zack and Gaffey, 1983). However, these and the other studies described in the dioxin TAC document suffer from a number of limitations. The characterization of exposure to PCDD/PCDF were at best, uncertain. Usually the exposure occurred at a time when there were no sensitive measures of exposure levels. Exposure was often based on job title, self-reported use of substances which may have had PCDD contamination, or exposure to an event thought to have liberated PCDDs. Additionally, none of the human exposures described have been solely to PCDDs or PCDFs, but rather to a mixture of chemicals. PCDDs were only trace contaminants of other toxic chemicals. Many of the occupationally exposed subjects were exposed only briefly (e.g., during an accidental release), or worked in a possibly contaminated environment for a short time. For example, more than 75% of the workers studied by Ott *et al*. (1980) had been exposed for less than one year. Finally, many of the discussed studies, including the four US cohorts, have been hampered by small samples. Studies of only a few hundred subjects lack sufficient power to detect small increases in the risk of rare tumors. For these reasons, DHS staff members concluded that the epidemiologic data available at the time the dioxin TAC document was written provided insufficient information to conclude whether or not PCDDs or PCDFs are human carcinogens.

CDHS (1986) found that the most sensitive species, sex, and site for the induction of cancer by TCDD is the male mouse with hepatocellular adenomas or carcinomas (NTP, 1982a). This response is an order of magnitude greater than the least sensitive species, sex, and site examined, the female mouse subcutaneous fibromas. It is interesting to note that there is less than a four-fold difference in the unit risk between animal species for liver tumors. CDHS therefore developed an inhalation cancer unit risk value for TCDD based on the NTP (1982a) male mouse hepatocellular adenoma/carcinoma tumor data. CDHS also developed an inhalation cancer unit risk value for HexaCDD based on the most sensitive species, sex, and site for the induction of cancer. The data set chosen was the NTP (1980b) female rat liver neoplastic nodule or hepatocellular carcinoma incidence data as evaluated by Hildebrandt (1983).

Methodology

GLOBAL79 was used to fit a linearized multistage procedure to the NTP (1982a) male mouse hepatocellular adenoma/carcinoma tumor data for TCDD, and the NTP (1980b) female rat neoplastic nodule/hepatocellular carcinoma data for HexaCDD as evaluated by Hildebrandt (1983). This procedure provided point estimates of the extra risk for both the maximum likelihood estimate (MLE) and the linearized 95% upper confidence value (UCL). The UCL is calculated by maximizing the linear term of the procedure, or forcing a best fitting linear term if one is not present. This method of calculating the UCL is

consistent both with the expected low-dose linearity and the linear nonthreshold theory of carcinogenesis. The slope of the 95% UCL, q_1*, is taken as a plausible upper bound of cancer potency of TCDD at low doses.

The animal exposure data (NTP 1980a, 1982a) was converted into equivalent human exposures by applying appropriate scaling factors. The following assumptions were made: Oral and inhalation routes are equivalent, the concentration of TCDD in the air was assumed to be the daily oral dose, the route of exposure does not affect absorption, and there is no difference in metabolism and pharmacokinetics between animals and humans. The total weekly dose levels were averaged over the entire week to get the daily dose level. This procedure assumes that daily dosing of the animals in the NTP studies would have given the same results as did the actual twice weekly dosing schedule. Since the half-life of TCDD is relatively long, both dosing schedules should produce similar concentrations of TCDD in the animal tissues, and therefore would be expected to give similar results. The calculated daily doses are given in Table 7. Human equivalent exposures are listed in Table 8.

Because the animal dose levels for TCDD were converted to human equivalent exposure from inhalation, the 95% UCL, q_1*, is a measure of the greatest potential excess cancer risk for humans. If the lifetime daily exposure is expressed in $\mu g/m^3$, then q_1* is the excess risk associated with this exposure. Since q_1* for humans is a unit measure of excess lifetime cancer risk associated with exposure to TCDD, it is termed the unit risk. With the unit risk, the 95% UCL of excess risk may be calculated for any low-level exposure to TCDD by the equation R = unit risk × dose, where R is the 95% UCL of excess lifetime cancer risk. The cancer unit risks calculated by CDHS using the above procedure for TCDD and HexaCDD were 38 $(\mu g/m^3)^{-1}$ and 1 $(\mu g/m^3)^{-1}$, respectively.

Table 7: Calculated daily dose levels for NTP (1980a, 1982a) TCDD and HexaCDD chronic studies in rats and mice (CDHS, 1986)

Chemical	Animal	Reported Dose Level (µg/kg-week)	Calculated Dose Level (µg/kg-day)
TCDD	male and female rats, male mice	0.01 0.05 0.5	0.0014 0.0071 0.071
	female mice	0.04 0.2 2.0	0.0057 0.029 0.29
HexaCDD	female rats	1.25 2.5 5.0	0.18 0.36 0.71
	female mice	2.5 5.0 10	0.36 0.71 1.40

Table 8: Calculated equivalent human exposure to TCDD and HexaCDD based on daily animal dose levels from NTP (1980a, 1984a) carcinogenicity studies (CDHS, 1986)

Chemical	Animal	Daily Dose Level (µg/kg-day)	Airborne Concentration for Equivalent Human Exposure (ng/m^3)
TCDD	female rat (0.45)[a]	0.0014	0.93
		0.0071	4.6
		0.071	46
	male mice (0.048)	0.0014	0.44
		0.0071	2.2
		0.071	22
	female mice (0.04)	0.0057	1.7
		0.029	8.4
		0.29	84
HexaCDD	female rats (0.45) a	0.18	120
		0.36	230
		0.71	460
	female mice (0.04)	0.36	100
		0.71	210
		1.43	420

[a] Number in parentheses is animal body weight in kilograms.

CDHS recognized that total PCDD/PCDF in the air is composed of dozens of PCDD and PCDF homologues and isomers. The chemicals in such a mixture are difficult to quantitate analytically. As a result, usually only total PCDD and total PCDF are measured. In the Air Toxics Hot Spots program, certain dioxin sources are required to perform stack testing and speciate the 2,3,7,8-congeners. Thus, more data are becoming available to adequately characterize the risk from dioxin sources in California.

To estimate cancer risks from such mixtures requires information about: (1) the proportion of each PCDD and PCDF in the mixture, and (2) the carcinogenic potency of each. However, these data are not generally available. The proportion of isomers differs depending on the emission source, and only three isomers had been tested for carcinogenic potency (2,3,7,8-TCDD and a mixture of 1,2,3,6,7,8- and l,2,3,7,8,9-HexaCDD). It was also recognized that not all 2,3,7,8-isomer PCDDs and PCDFs are equally carcinogenic. The results of the bioassays on TCDD and HexaCDD suggested that carcinogenic potency may decline in homologues more chlorinated than TCDD. It was therefore assumed that PCDDs and PCDFs that are not chlorinated on the 2,3,7,8 positions or do not have at least one ring position open are noncarcinogenic. Additionally, it was also considered that the 2,3,7,8-isomer PentaCDD has a carcinogenic potency equivalent to TCDD, and that 2,3,7,8-isomer HeptaCDD is equivalent in carcinogenic potency to 2,3,7,8-isomer HexaCDD. The potencies for the homologous PCDDs were also used for the PCDFs. Using this approach, the potency of a given concentration of PCDDs would be 2% of the potency of TCDD. The potency of a mixture of PCDFs would be 3% of the potency of TCDD.

Another toxicity equivalency factor (TEF) scheme was developed after 1986 during an international symposium (NATO/CCMS, 1988a,b), and it was adopted by US EPA (US EPA, 1989) and the Department of Toxic Substances Control (DTSC) (DTSC, 1992). The international scheme, referred to as ITEFs, is based on experimental cancer and noncancer data for many 2,3,7,8-PCDDs and 2,3,7,8-PCDFs and on the assumption that the mechanism of all PCDD/PCDF-related biologic effects are based on initial binding to a specific protein, the *Ah* receptor. Because the ITEF scheme incorporated more experimental data from cancer and noncancer studies for more PCDDs/PCDFs than does the CTEF scheme, the replacement of the CTEFs by the ITEFs was considered appropriate for use in risk assessment. This approach also increases uniformity among Cal/EPA guidelines. The TEFs contained in the dioxin TAC (CDHS, 1986) document and the ITEFs are listed in Table 8. The cancer unit risks and potency factors for chlorinated dibenzo-*p*-dioxins and dibenzofurans listed in the 1999 chemical summary and Hot Spots Unit Risk and Cancer Potency Values table (OEHHA, 1999) were generated by applying the appropriate ITEFs to the cancer unit risk and potency factor for 2,3,7,8-TCDD calculated in the dioxin TAC document.

As TEFs for PCDDs and PCDFs were developed, considerable efforts went into the study of quantitative structure activity relationships (QSAR) for polychlorinated biphenyls (PCBs). PCB congeners substituted in the para and at least 2 of the meta positions but not at any of the ortho positions can adopt structural conformations most resembling that of 2,3,7,8-TCDD, therefore have the greatest potency and exert their toxicity through the *Ah* receptor pathway. These coplanar PCB congeners are structurally similar to 2,3,7,8-tetrachorodibenzo-*p*-dioxin and therefore are termed dioxin-like PCBs. Introduction of one chlorine in the ortho position results in a decrease in toxic potency and PCBs with more than one chlorine in the ortho positions lack some effects exerted by non- and mono-ortho PCBs. These PCB congeners show a different spectrum of toxic effects (Safe, 1994).

In 1991, U.S. EPA considered using the TEF methodology for PCBs. They noted that only a small subset of the 209 PCB congeners elicits dioxin-like activity and meet the criteria for inclusion in the TEF methodology. In an attempt to harmonize TEF schemes for dioxin-like compounds, the World Health Organization - European Center for Environmental Health (WHO-ECEH) and the International Program on Chemical Safety (IPCS) generated a database consisting of almost 1,200 peer-reviewed publications, representing all the available toxicological data for PCBs up to the end of 1993. From a selected number of these publications and based on four inclusion criteria, the WHO-ECEH and the IPCS proposed TEF values for 13 dioxin-like PCBs (Ahlborg *et al.*, 1994). The inclusion criteria are:

1. The compound should show structural similarity to PCDDs and PCDFs.
2. It should bind to the *Ah* receptor.
3. It should induce dioxin-specific biochemical and toxic responses.
4. It should be persistent and accumulate in the food chain.

In addition, the first WHO PCB TEF consultation (Ahlborg *et al.*, 1994) recommended expanding the current database to include all relevant information on PCDDs, PCDFs and other dioxin-like compounds that satisfied the four inclusion criteria.

Some terminologies and definitions applicable to TEFs were reviewed prior to the second WHO-ECEH consultation (van Leeuwen, 1997). The term TEF, used in the past to describe any experimental end point to be compared with TCDD was reconsidered since not all end points are "toxic" end points. For example, end points such as binding to the *Ah* receptor and induction of ethoxyresorufin-O-deethylase (EROD) are mostly considered biological/biochemical responses. Therefore, experimental end points, for which numerical values are compared to the response to TCDD, should be termed "Relative Potency" values (REPs). These REPs could be the result of a single laboratory experiment looking at a single end point. REPs are derived from the available data either used as reported in each publication, or calculated by comparing dose-response curves or ratios of medium effective doses (ED_{50}), median lethal dose (LD_{50}), median effective concentration (EC_{50}) etc. A chemical's TEF is then derived from all available REPs examined for that compound. Thus, the term TEF is be restricted to describe an overall estimate of the order-of-magnitude of the toxicity of a compound relative to the toxicity of TCDD. This estimate is derived by consensus, using careful scientific judgment of all available data (van Leeuwen, 1997; van den Berg *et al.*, 1998). The derivation of TEF consensus using *Ah* receptor-specific end points gives more weight to toxic responses than to biochemical (e.g., enzyme induction) responses and it puts more weight on *in vivo* data than on *in vitro* results. In fact, the weighting order of contributing *in vivo* data was: chronic > subchronic > subacute > acute.

In its most recent consultation in 1997, the WHO-ECEH proposed amendments to the previous NATO/WHO I-TEF scheme (NATO/CCMS, 1989). For revision of the existing mammalian TEFs, the WHO-ECEH committee agreed that if the available information was considered insufficient to warrant a change, the existing value would remain. The suggested WHO_{97} TEFs for humans and mammals along with the CTEFs and ITEFs are presented in Table 9. Taking advantage of new data and understanding of the underlying mechanisms of toxicity of dioxin-like compounds, the WHO-ECEH's re-evaluation and extension of the TEF concept lead to the following amendments:

1) For 1,2,3,7,8-PeCDD, an increase in TEF value from 0.5 to 1.0 was recommended, based on new *in vivo* tumor promotion data and CYP 1A1/A2 induction potencies from subchronic studies.

2) For OCDD, the TEF value was reduced from 0.001 to 0.0001 based on a recalculation of the old data in which exposure versus tissue concentrations were compared (administered dose); originally the TEF was based on body burdens of the chemical following subchronic exposures.

3) For OCDF, the TEF value was changed from 0.001 to 0.0001 based on new *in vivo* EROD induction potency values (81) and an expected structural similarity with OCDD; thus, for the *in vivo* situation, a change in analogy with OCDD is recommended.

The Scientific Review Panel on Toxic Air Contaminants (SRP) reviewed and endorsed the use of the WHO_{97} TEFs in Hot Spots risk assessments at its June 20, 2003 meeting. The cancer unit risks and potency factors for chlorinated dibenzo-*p*-dioxins and dibenzofurans and polychlorinated biphenyls listed in this chemical summary and the Hot Spots Unit Risk and Cancer Potency Values table were generated by applying the appropriate WHO_{97} TEFs to the cancer unit risk and potency factor for 2,3,7,8-TCDD calculated in the dioxin TAC document.

Table 9: Toxicity equivalency factors for chlorinated dibenzo-*p*-dioxins and dibenzofurans (relative to 2,3,7,8-TCDD)

CHLORINATED PARAFFINS (average chain length C12, 60% chlorine by weight)

CAS No: 108171-26-2

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB (1994) except where noted)

Molecular weight	411 (average) [NTP, 1986]
Boiling point	not available
Melting point	not available
Vapor pressure	not available
Air concentration conversion	1 ppm = 17 mg/m^3 (approximate)

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 2.5 E-5 $(\mu g/m^3)^{-1}$
Slope Factor: 8.9 E-2 $(mg/kg\text{-}day)^{-1}$
[NTP (1986) female mouse liver tumor data, contained in Gold *et* al. database (1990), expedited Proposition 65 methodology (OEHHA, 1992), cross-route extrapolation.]

III. CARCINOGENIC EFFECTS

Human Studies

No studies on the potential carcinogenic effects of chlorinated paraffins are known to exist.

Animal Studies

Male and female $B6C3F_1$ mice and Fischer 344N rats (50/sex/group) were treated by gavage with a commercial-grade chlorinated paraffin product dissolved in corn oil 5 days/week; treatment duration was 103 and 104 weeks for mice and rats, respectively (NTP, 1986). Exposure levels were 0, 125 and 250 mg/kg body weight for mice, and 0, 312 and 625 mg/kg for rats. Significant increases in the incidence of liver tumors were noted in male and female mice; the incidence of alveolar and bronchiolar carcinoma was significantly increased in male mice, as was the combined incidence of thyroid follicular-cell adenomas and carcinomas in female mice. Tumor incidences in mice are listed in Table 1.

Significant increases in liver tumor incidence were noted in male and female rats. Significant increases were also noted in the incidence of leukemia in male rats, and in the incidence of thyroid follicular-cell tumors in female rats. Tumor incidences in rats are listed in Table 2.

Table 1. Tumors induced in $B6C3F_1$ mice by gavage administration of chlorinated paraffins (NTP, 1986)

Dose (mg/kg bw)	Hepatocellular adenomas	Hepatocellular adenomas and carcinomas	Alveolar/bronchiolar carcinomas	Thyroid follicular-cell tumors
Males				
0	11/50	20/50	0/50	
125	20/50	34/50	3/50	
250	29/50	38/50	6/50	
Females				
0	0/50	3/50		8/50
125	18/50	22/50		12/49
250	22/50	28/50		13/49

Table 2. Tumors induced in Fischer 344 rats by gavage administration of chlorinated paraffins (NTP, 1986)

Dose (mg/kg bw)	Hepatocellular carcinomas	Hepatocellular adenomas and carcinomas	Mononuclear cell leukemia	Thyroid follicular-cell tumors
Males				
0	0/50	0/50	7/50	
312	10/50	13/50	12/50	
625	16/48	16/50	14/50	
Females				
0	0/50	0/50		0/50
312	4/50	5/50		6/50
625	7/50	7/50		6/50

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Results of the NTP (1986) gavage study of chlorinated paraffins in male and female $B6C3F_1$ mice and F344 rats are listed in Gold *et al*. (1990). Benign and malignant liver tumors were observed in both sexes and species; significant elevations in tumor incidences at other sites were also observed. Estimates of cancer potency are similar for male and female mice and male rats. Cancer potency is based on dose-response data for benign and malignant liver tumors in female mice (see Table 1) (OEHHA, 1992).

Methodology

Expedited Proposition 65 methodology (with cross-route extrapolation) was used to derive a cancer potency factor. A unit risk factor was then calculated by OEHHA/ATES from the cancer potency factor using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

CHLOROFORM

CAS No.: 67-66-3

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1998)

Molecular weight	119.49
Boiling point	61° C
Melting point	-63.5° C
Vapor pressure	200 mm Hg 25º C
Air concentration conversion	1 ppm = 4.9 mg/m^3 at 25º C

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 5.3 E-6 $(\mu g/m^3)^{-1}$
Slope Factor: 1.9 E-2 $(mg/kg\text{-}day)^{-1}$
[Calculated by CDHS (1990) using a nonthreshold linear procedure. This unit risk is the arithmetic average of unit risks generated by CDHS and Bogen *et al.* (1989) for renal tumors observed in rats and mice reported by Jorgenson *et al.* (1985) and NCI (1976), and the geometric mean for supporting data sets (Roe *et al.*, 1979; Tumasonis *et al.*, 1985).]

III. CARCINOGENIC EFFECTS

Human Studies

There is no information currently available in the open literature which examines the potential relationship between exposure to chloroform in an occupational setting and human cancer. However, several studies are available which examine the relationship between trihalomethanes (THM) in drinking water and human cancer.

Many studies have concentrated on chlorination of water and concomitant production of halogenated carcinogens as a causative factor in human cancers. Cantor *et al.* (1978) compared age-adjusted cancer mortality rates by site and sex for whites in the years 1968-71 to measures of THM and the drinking water. A weighed linear regression model was used to predict cancer rates in 923 U.S. counties which were over 50% urban in 1970. Reasonably strong associations between bladder cancer and THM levels in drinking water were found after controlling for confounding by urbanization, ethnicity, social class, and county industrialization. The association was not changed by controlling for occupation in certain high-risk (for bladder cancer) industries nor by lung cancer rates used as a surrogate measure for cigarette smoking. The measure of THM most associated with bladder cancer in both white males and females was that of bromine-containing trihalomethanes (BTHM). Chloroform and total trihalomethanes (TTHM) were not as well associated. There were inconsistent associations between other cancer sites and THM levels. However, there was some evidence of and association of chloroform in drinking water with kidney cancer in males, which Cantor *et al.* believed warrants further study.

Hogan *et al.* (1979) examined the potential association between chloroform levels in finished drinking water supplies and various site-specific cancer mortality rates. The most consistent associations were between chloroform "exposure" and cancers of the bladder, rectum and large intestine. Hogan *et al.* stated that the results of this ecological study must be interpreted with caution and the association between chloroform levels in drinking water and certain types of cancer (e.g., bladder, large intestine and rectum) warrant further study.

Carlo and Mettlin (1980) analyzed 4,255 cases of cancer reported in Erie County, NY, between 1973 and 1976 for any relationship between cancer and type of water source, THM levels, and a variety of socioeconomic variables. No significant association between THM and cancers were noted in the regression analyses for the total population. When regression analyses were conducted for population stratified by race-sex, a significant association was found between THM levels in drinking water and pancreatic cancer in white males ($p <$ 0.05). The investigators caution that the lack of association between THM and pancreatic cancer in other sex-race groups and absence of association between THM and other cancer raises doubts as to the validity of this finding.

Brenniman *et al.* (1980) conducted a case-control study in Illinois to determine whether an association exists between chlorination of drinking water and gastrointestinal and urinary tract cancers. Cases (3,208) and controls (43,666) were classified according to residence in chlorinated and unchlorinated groundwater communities. Elevated risk was found for cancers of the gallbladder, large intestine, total gastrointestinal, and urinary tract for women. However, the investigators considered the results tenuous because, when the data were subclassified according to several control variables, the associations were not strengthened. Many confounding factors were not controlled including smoking, diet, ethnicity, and occupation.

Alavanja *et al.* (1980) conducted a case-control study on all gastrointestinal and urinary tract cancer deaths occurring from January 1, 1968 through December 31, 1970 in seven counties in New York. There was a statistically significant excess risk of stomach cancer in females, and of stomach, esophagus, large intestine, rectum, liver and kidney, pancreas, and urinary bladder in males residing in chlorinated water areas in the seven counties studied. The investigators concluded that the excess risk was associated with living in chlorinated areas of certain counties and was not due to a disparity in the age, race, or ethnic distribution, or to urban/rural classification, hazardous occupation, or a surface vs. ground water difference. Several confounding factors were not controlled including cigarette smoking and diet.

The association between site-specific cancer mortality and THM exposure, as estimated by chlorine dose, was investigated by Young *et al.* (1981). Cases were obtained from death certificates provided by the Wisconsin Bureau of Health Statistics and consisted of all white female deaths that occurred 1972-77 within 28 counties due to malignant neoplasms of esophagus, stomach, colon, rectum, liver, bile ducts, pancreas, urinary bladder, kidney, lung, breast, and brain. Only death from colon cancer was associated with chlorine dose (- < 0.05). The risk of colon cancer, calculated as odds ratios, was over twice as great when

the water source was affected by rural runoff. This variable was tested because of the assumption that rural runoff increased the organic precursors to THMs. While the association of colon cancer with chlorination and rural runoff factors is provocative, the findings of this study must be considered inconclusive due to the possible underestimation of risk associated with misclassification error and spurious contribution from unknown colon cancer risk factors (Young *et al.*, 1981).

Wilkins and Comstock (1981) conducted a nonconcurrent prospective study to investigate possible relationships between products of water chlorination and human cancer. Site and sex-specific incidence rates for malignant neoplasm of liver, biliary passages, kidney, and bladder were constructed from hospital records, a cancer registry, and death certificates. Incidence rates for cancer of the bladder among men and cancer of the liver among women were not significant relative to the other exposure groups among persons using water from the chlorinated surface supply. While the results were only weakly suggestive, Wilkins and Comstock noted that bladder cancer has been suggestively linked with chloroform and other indices of THM in drinking water in other studies.

Gottlieb and Carr (1982) studied the potential relationship between chlorination of drinking water and cancer in 20 south Louisiana parishes. Chlorinated surface water was associated with a significant risk for rectal cancer ($p = 0.012$). The odds ratio for rectal cancer in groups receiving high chlorination level (> 1.09 ppm chlorine) to groups with no chlorinations is 1.53 (95% CI=1.15-2.04) in surface water supplied areas. Gottlieb and Carr concluded that there appears to be some cancer risk associated with water chlorination, but definitive studies are needed with respect to the role of industrial confounders and the importance of co-contaminants.

Lawrence *et al.* (1984) used a case-control approach to study the association of chloroform exposure via drinking water to colorectal cancer in white female teachers in upstate New York. Analysis was based on 395 cases of colon and rectal cancer and 395 control noncancer deaths matched with respect to age and year of death. No effect of cumulative chloroform exposure on incidence of colorectal cancer deaths was observed.

Cantor *et al.* (1987) examined the association between use of chlorinated drinking water and bladder cancer by a case-control study design. The investigators interviewed 2,982 cases and 5,782 controls in 10 geographic areas of the U.S. Risk of bladder cancer was primarily associated with use of tap water rather than nontap beverages. Among white males, the coefficients for tap and nontap beverages were 0.176 ($p < 0.001$) and 0.037 ($p = 0.42$), and among white females, the coefficients were 0.123 ($p = 0.09$) and 0.089 ($p = 0.39$), respectively. It was suggested that nonvolatile components of tap water may be associated with risk of bladder cancer since both heated and nonheated tap water beverages were significantly associated with bladder cancer risk among males. The relative risk increased with increasing tap water intake. While this investigation was quite thorough in many respects, there is a need for confirmation of these findings. The contribution of chloroform in the etiology of human bladder cancer in men may be overshadowed by other nonvolatile chemicals present in the drinking water.

Overall, the present epidemiological evidence suggests an association between chlorinated drinking water consumption and human cancer, particularly bladder and gastrointestinal cancers. However, these relationships cannot be directly correlated to chloroform exposure because many other carcinogens are found in drinking water including other chlorinated halomethanes, brominated halomethanes, industrial pollutants, and nonvolatile halogenated compounds.

Animal Studies

The National Cancer Institute conducted carcinogenesis bioassays of chloroform in both sexes of Osborne-Mendel rats and $B6C3F_1$ mice (NCI, 1976). Mice and rats were given either corn oil or chloroform in corn oil by gavage, 5 days/week for 78 weeks. Time-weighted average doses for female rats were 100 and 200 mg/kg, and for male and female mice were 138 and 277 mg/kg, and 238 and 477 mg/kg, respectively. Tumor incidences are listed in Table 1.

A statistically significant increase ($p < 0.05$) in epithelial tumors of renal tubular origin was noted in the treated males. Ten carcinomas, two of which had metastasized, and three adenomas of renal tubular origin were found in 12 high dose male rats. In the low dose males, two carcinomas and two adenomas of tubular origin were observed in four out of 50 animals. Among the 48 high dose female rats, one tubular epithelial carcinoma and one renal squamous cell carcinoma were observed. No renal epithelial tumors were noted in matched or colony controls. The NCI reported that these type of tumors rarely occur spontaneously in Osborne-Mendel rats.

The incidence of thyroid tumors in female rats was statistically higher than controls in both treated groups ($p = 0.05$, Fisher exact test) but not in treated male rats. The incidence of hepatocellular carcinoma or neoplastic nodules was not increased in the chloroform-treated rats. Although inflammatory pulmonary lesions occurred in all test groups, the lesions were more severe and occurred more frequently in the chloroform-treated rats.

The incidence of hepatocellular carcinomas in mice was significantly elevated in all treatment groups ($p < 0.001$, Fisher exact test). The NCI reported that in their experience the spontaneous incidence of hepatocellular carcinomas in $B6C3F_1$ mice is about 5-10% in males and 1% in females. The NCI concluded that chloroform treatment was associated with increased incidences of hepatocellular carcinomas in male and female mice and renal epithelial tumors in male rats.

In addition, Reuber (1979), based on his examination of the histological sections from the NCI study, concluded that chloroform treatment was also associated with cancer of the liver in rats and an increased incidence of malignant lymphomas in mice. However, the NCI did not agree with his findings.

The carcinogenicity of chloroform given in drinking water was evaluated in male Osborne-Mendel rats and female $B6C3F_1$ mice (Jorgenson *et al.*, 1985). The chloroform used (technical grade), was found to contain 100 ppb diethylcarbonate, and trace amounts of

1,1-dichloroethane, dichloroethylene, carbon tetrachloride, and an unidentified C_5H_{10} hydrocarbon. Time-weighted average doses of chloroform calculated based on water consumption rates and body weight, ranged up to 160 and 263 mg/kg-day for rats and mice, respectively. Two control groups were used, an untreated control, and a control group of animals with restricted access to water.

Jorgenson *et al.* observed a dose-related significant increase in renal tubular cell adenomas and adenocarcinomas in male rats, but found no treatment-related increases in tumor incidence in the female mice (Table 1). The lack of liver tumors in female $B6C3F_1$ mice is in sharp contrast to the results of the NCI study. A major difference between the NCI study and the Jorgenson study is the mode of administration. Administration of chloroform to rats in a corn oil vehicle slowed the gastrointestinal absorption of chloroform relative to the absorption rate observed after administration as a bolus in water (Withey *et al*., 1983). In the Jorgenson *et al*. study, the rats received small doses of chloroform each time they drank water. The corn oil vehicle effect (Withey *et al.*, 1983) may have diminished the differences in absorption kinetics expected with the two different methods of administration. Therefore, any differences in peak blood concentrations between the NCI study and the Jorgenson study may not have been sufficient to account for the difference in liver tumor incidence. Physiologic or metabolic changes produced by corn oil consumption might interact with chemical carcinogens altering the production of liver tumors (Bull *et al.*, 1986; Newberne *et al.*, 1979).

A series of experiments was conducted by the Huntingdon Research Center to determine the effects of chronic ingestion of chloroform in a toothpaste base in mice, rats, and beagle dogs. In the first set of experiments (Roe *et al.*, 1979), doses of 17 and 60 mg chloroform/kg were administered by gavage in toothpaste to male and female ICI mice, 6 days/week for 80 weeks followed by a 16 week observation period (Experiment I). Controls (N=104) were treated with 1 ml chloroform-free toothpaste/kg-day. Aside from increased nonneoplastic liver lesions (moderate fatty degeneration), the only significant difference in pathology reported was an increase in the incidence of kidney tumors in high dose male mice, three were hypernephromas (tubular adenocarcinoma) and the remainder were adenomas (tumor incidences listed in Table 1). The incidence of renal tumors in high-dose male ICI mice was significantly greater than control mice ($p = 0.00012$, Fisher exact test). None of the female ICI mice examined developed renal tumors (Roe *et al.*, 1979). Roe *et al.* (1979) also investigated other components of the toothpaste base for carcinogenicity using male ICI mice. No lesion in this part of the study could be correlated with treatment.

In a third mouse experiment (Experiment III), Roe *et al.* (1979) compared the effects of toothpaste containing 3.5% chloroform on male mice of four different strains (C57BL, CBA, CF/1, and ICI). Treatment with chloroform was not associated with any increase in liver or lung neoplasms relative to vehicle-treated controls in any of the four strains tested but was associated with significantly higher incidences of moderate to severe kidney pathology in CBA and CF/1 mice relative to the controls ($p < 0.0001$, chi-square test).

Palmer *et al.* (1979) gave groups of 50 Sprague-Dawley rats (both sexes) 0 or 60 mg chloroform/kg-day, 6 days/week by gavage in a toothpaste base for 80 weeks, followed by a 15 week observation period. There were no differences in the incidences of tumors of any site examined, including brain, lung, liver, kidney, and mammary gland, between treated and control animals. Heywood *et al.* (1979) investigated the carcinogenicity of chloroform in a toothpaste base in beagle dogs. Groups of male and female dogs received toothpaste base with 0, 15 or 30 mg chloroform/kg-day, 6 days/week for 7.5 years (8-16 dogs/sex), followed by a 20-24 week recovery period. Treatment with chloroform at the high dose was associated with significant elevations in SGPT levels but no treatment-related tumors were observed.

Chloroform treatment of rats via drinking water was associated with hepatic neoplastic nodules and hepatic adenofibrosis (Tumasonis *et al.*, 1985). Chloroform was administered to male and female Wistar rats in the drinking water at about 220 mg/kg/day and 160 mg/kg/day for the female and male rats, respectively. The incidence of hepatic neoplastic nodules was significantly elevated in treated females compared to controls ($p < 0.03$, Fisher exact test). In males, the incidence of hepatic neoplastic nodules did not differ in control and chloroform-treated groups. Increased incidences of hepatic adenofibrosis were observed in chloroform-treated males and females relative to controls. In contrast to the NCI and the Jorgenson *et al.* studies, renal tumors were not associated with chloroform treatment. However, Tumasonis *et al.* indicated that kidneys were only examined when grossly observable lesions were evident. Hence, kidney tumors may have been missed by this protocol. Tumasonis *et al.* concluded that chloroform is a hepatocarcinogen in Wistar rats.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Chloroform is carcinogenic to rats and mice (NCI, 1976; Roe *et al.*, 1979; Jorgenson *et al.*, 1985). The International Agency for Research on Cancer (IARC) has classified chloroform as a possible human carcinogen (Group 2B). Similarly, the U.S. EPA has placed chloroform in Group B2 in their classification scheme, based on sufficient evidence of carcinogenicity in animals, but inadequate epidemiologic evidence. Current evidence and understanding of the carcinogenic process is insufficient to classify chloroform as either a genotoxic or epigenetic carcinogen, and it is possible that both types of effects are involved.

Table 1: Chloroform carcinogenicity bioassay tumor incidence data used to estimate cancer potency (CDHS, 1990)

Study	Strain/Species	Sex	Tumor Site	Lifetime Daily Dose (mg/kg-day)	Tumor Incidence
NCI (1976)	$B6C3F_1$ mouse	M	hepatocellular carcinoma	control 83 167	1/18 18/50 44/45

[a] toothpaste base was used as the vehicle; [b] arachis oil was used as the vehicle

The estimation of cancer risk to humans from exposure to chloroform by CDHS (1990) is based on animal studies. Data were chosen based primarily on statistical significance, as discussed below.

Methodology

The following data sets were evaluated to estimate chloroform cancer potency: 1) Liver tumor data in male and female $B6C3F_1$ mice, and renal tubular cell tumors in male Osborne-Mendel rats from the NCI (1976) study were chosen because statistically significant increases in these tumor types were observed in chloroform treated animals relative to controls; 2) Renal tubular cell tumor data in male Osborne-Mendel rats from the Jorgenson *et al.* (1985) study and in male ICI mice in the Roe *et al.* (1979) study were used for risk estimation based on a statistically significant increase in kidney tumors in

chloroform treated animals relative to controls; 3) Liver cholangiocarcinoma ("adenofibrosis") data in female rats from Tumasonis *et al.* (1985), and from Reuber's reanalysis of the NCI (1976) slides (Reuber, 1979) were also analyzed with the linearized multistage model (GLOBAL86). Administered doses were transformed to lifetime doses by adjusting for the number of days exposed per week and the ratio of the length of exposure to the length of the experiment (exposure plus observation period).

Calculated q_1* values from the above studies ranged from 8.1×10^{-4} to 1.9×10^{-2} $(mg/kg\text{-}day)^{-1}$. These represent cancer potency estimates for rats and mice and must be converted to theoretical equivalent potency values for humans. This conversion is based on equivalency of dose per unit surface area according to Anderson *et al.* (1983). These "human" cancer potencies range from 4.2×10^{-3} to $2.6 \times l0^{-1}$ $(mg/kg\text{-}day)^{-1}$. Scaling factors ranged from 5.19 to 13.57.

The NCI (1976) and Jorgenson *et al.* (1985) studies were the most thorough studies in terms of the number of doses tested, sample size, histological examination of the animals, and other procedural and statistical methods presented. As such, CDHS placed more confidence in the potency slopes from these studies than in the other studies. The potency slopes derived from Roe *et al.* (1979) and Tumasonis *et al.* (1985) fall within the range of those from the NCI and Jorgenson studies.

Bogen *et al.* (1989) used a physiologically based pharmacokinetic (PBPK) model to estimate metabolized dose for chloroform to use in the analysis of cancer potency with the linearized multistage model to carcinogenicity bioassay data from NCI (1976), Jorgenson *et al.* (1985), Roe *et al.* (1979), and Tumasonis *et al.* (1985). In the application of the model, the liver was considered to metabolize chloroform through a saturable enzyme system following Michaelis-Menten kinetics. This approach is consistent with the evidence that chloroform metabolites are responsible for toxicity and probably for the carcinogenicity of chloroform. The potency estimates made from these studies ranged from 4.8×10^{-3} to 5.0×10^{-1} $(mg/kg\text{-}day)^{-1}$. These corresponded to unit risks of 4.5×10^{-6} to 4.7×10^{-4} $(ppb)^{-1}$. These potency estimates are incorporated into DHS staff's best estimate of cancer potency for chloroform.

There are no studies on the carcinogenicity of chloroform by the inhalation route. Therefore, estimation of the cancer risk from exposure to chloroform in the ambient air required extrapolation from the oral route. In so doing, it is assumed that chloroform is also carcinogenic by the inhalation route, and that the risk posed by an absorbed inhaled dose of chloroform is equivalent to that posed by the same dose absorbed after oral administration. In the final risk range, the DHS staff included tumor sites that did not appear to be vehicle-dependent. Therefore, the liver tumors were not included in the range of risks or the best estimate of risk, due to the possible potentiation of liver tumors by the corn oil vehicle.

The best estimate of unit risk was considered by CDHS (1990) to be the arithmetic average of unit risks generated by CDHS (1990) and Bogen *et al.* (1989) for rat renal tumors in Jorgenson *et al.* (1985) and NCI (1976) and of the geometric mean for supporting data sets

(Roe *et al.*, 1979; Tumasonis *et al.*, 1985). This unit risk, 5.3 E-6 $(\mu g/m^3)^{-1}$, represents the best estimate using a nonthreshold linear procedure and using most of the data on the carcinogenicity of chloroform. It included analysis by PBPK modeling of metabolized dose, as well as analysis of potency based on applied dose.

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 4.6 E-6 $(\mu g/m^3)^{-1}$
Slope Factor: 1.6 E-2 $(mg/kg\text{-}day)^{-1}$
[Male rat urinary bladder tumor data (NCI, 1978), contained in Gold *et al.* (1990), expedited Proposition 65 methodology (Cal/EPA, 1992), cross-route extrapolation.]

III. CARCINOGENIC EFFECTS

Human Studies

No studies on the potential carcinogenic effects of 4-chloro*o*-o-phenylenediamine in humans are known to exist.

Animal Studies

Male and female Fischer 344 (F344) rats and B6C3F$_1$ mice were fed diets containing 4-chloro-*o*-phenylenediamine (NCI, 1978). Dietary 4-chloro-*o*-phenylenediamine concentrations and treatment durations for rats and mice are listed in Table 1. Treatment group sizes were 50 animals/sex/species/group, except for low-dose male rats, where a group size of 49 was used.

At study termination, 84, 84 and 70% of male mice, and 72, 88 and 78% of female mice in the control, low-dose and high-dose groups, respectively, were still alive. Survival in treated rats was somewhat lower; 64, 80 and 56% of male rats and 72, 84 and 54% of female rats in the control, low-dose and high-dose groups, respectively, were still alive at study termination. Significantly increased treatment-related liver tumor (hepatocellular adenomas, carcinomas) incidences were noted in both male and female mice. These data are listed in Table 2. A significant dose-related trend was also noted in the increased incidence of urinary bladder carcinomas in male (transitional cell papillomas, carcinomas) and female (papillary or transitional cell carcinomas) rats (Table 2). Increases in the incidence of forestomach tumors also occurred in both male and female rats. The

forestomach tumor increases were not statistically significant; however, these tumors are rare in F344 rats.

Table 1. Study design summary for NCI (1978) carcinogenicity bioassay of 4-chloro-*o*-phenylenediamine in Fischer 344 rats and B6C3F$_1$ mice.

Sex/species	Treatment group	4-chloro-*o*-phenylenediamine concentration (mg/kg diet)	Observation period		Time-weighted average concentration (mg/kg diet)
			Treated (weeks)	Untreated (weeks)	
Male rats	control	0		105	
	low-dose	5000	78	27	
	high-dose	10000	78	28

	low-dose	752		11/50
	high-dose	1500		10/50

1. Doses as reported by Gold *et al.* (1984).
2. Tumor incidences as reported by Gold *et al.* (1984).

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Gold *et al.* (1984) list results of the NCI (1978) feeding study in male and female B6C3F$_1$ mice and F344 rats. Benign and malignant neoplasms of the liver were elevated in treated male and female mice. Forestomach tumors were also observed in treated rats; these tumors are relatively uncommon in this strain. In addition, substantial increases in the incidences of urinary bladder cancers were seen in rats of both sexes. Dose-response data are given in Table 2. Rats appear to be more sensitive than mice. Quantitative analysis of dose-response data for urinary bladder tumors indicate that male and female rats have nearly the same sensitivity. The upper confidence bound on potency for data on male rats is slightly higher, and this is the value used as a cancer potency for 4-chloro-*o*-phenylenediamine (Cal/EPA, 1992).

Methodology

Expedited Proposition 65 methodology (with cross-route extrapolation) was used to derive a cancer potency factor. A unit risk factor was then calculated by OEHHA/ATES from the cancer potency factor using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

Melting point	not available
Vapor pressure	not available
Air concentration conversion	1 ppm = 7.3 mg/m^3

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 7.7 E-5 $(\mu g/m^3)^{-1}$
Slope Factor: 2.7 E-1 $(mg/kg\text{-}day)^{-1}$
[Male and female mouse hemangioma and hemangiosarcoma tumor data (Weisburger *et* al., 1978; NCI, 1979), contained in Gold *et* al. database (1984), expedited Proposition 65 methodology (Cal/EPA, 1992), cross-route extrapolation.]

III. CARCINOGENIC EFFECTS

Human Studies

IARC (1990) reviewed studies by Currie (1933) and Uebelin and Pletscher (1954) which investigated bladder tumor incidence in small groups of male workers exposed to *p*-chloro-*o*-toluidine; one case of bladder carcinoma was discovered (Currie, 1933).

A cohort study by Ott and Langner (1983) investigated 342 male workers involved in the manufacture of organic dyes in the US between 1914 and 1958. One plant area involved 117 workers with potential exposure to *p*-chloro-*o*-toluidine and other raw materials and intermediates, including *ortho*-toluidine. Followup of this subcohort from 1940 to 1975

indicated that a nonsignificant excess of total cancer deaths occurred (12 observed, 8 expected) and no bladder cancer was observed.
Two studies were conducted on a cohort of 355 male workers in *p*-chloro-*o*-toluidine manufacturing plants in the Federal Republic of Germany (FRG) who had been followed up for mortality from 1929 to 1982. No deaths due to bladder cancer were found in the first study (Stasik *et al*., 1985). The second study examined a subcohort of 116 workers exposed prior to 1970 (the implementation date of improved exposure controls) with presumed high *p*-chloro-*o*-toluidine exposure levels. Excluding 2 cases of urinary bladder carcinomas in the current work force, 6 cases of bladder carcinoma were found between January 1983 and June 1986 in hospital and other institution records. No cancer registry data was available for the area of the FRG where the plant was located; cancer registration rates for a different area of the FRG was therefore used as a basis of comparison. The expected number of tumors was 0.11 based on sex- and age-specific cancer rates. Two patients had hemorrhagic cystitis thought to be due to massive exposure to *p*-chloro-*o*-toluidine. Cigarette smoking was discounted as a confounding variable after reviewing patient smoking histories (3 patients were nonsmokers). Quantitative exposure data was unavailable, but the predominant chemical exposure was to *p*-chloro-*o*-toluidine; however, exposure to other amines could have occurred.

Animal Studies

Male and female random-bred CD-1 albino mice (derived from HaM/ICR mice) and male Charles River CD Sprague-Dawley-derived rats (25/sex/group) were fed diets containing *p*-chloro-*o*-toluidine hydrochloride (97-99% pure) as part of a larger carcinogenicity study of several compounds (Weisburger *et al*., 1978). Mouse exposure levels were 0, 750 or 1500 mg/kg diet and 0, 2000 or 4000 mg/kg diet for males and females, respectively; the mice were fed treated diet for 18 months, followed by an additional 3 month observation period. Rats were fed diet containing 2000 or 4000 mg/kg diet *p*-chloro-*o*-toluidine for 3 months; the doses were then reduced to 500 and 1000 mg/kg diet for 15 months. An untreated control group (25 males) was included. All rats were killed after 24 months. Tumor incidence differences between control and exposed rat groups were not statistically significant. Hemangiomas and hemangiosarcomas were observed in male and female mice; tumor incidence data is listed in Table 1. These tumor types were found in 5/99 male and 9/102 female pooled controls from the larger carcinogenicity study, but were not present in the simultaneous controls.

Diets containing *p*-chloro-*o*-toluidine hydrochloride (99% pure) were fed to groups of male and female B6C3F$_1$ mice and Fischer 344 (F344) rats (50 animals/sex/species/treatment group) (NCI, 1979). Exposure levels for mice were 3750 or 15000 and 1250 or 5000 mg/kg diet for males and females, respectively. Exposure levels for rats were 1250 or 5000 mg/kg diet. Untreated control groups (20 animals/sex/species) were included. Exposed animals were fed treated diet for the duration of the study. All surviving mice were killed at 99 weeks; however, all high-dose females had died by 92 weeks. All surviving rats were killed at 107 weeks.

Exposure to *p*-chloro-*o*-toluidine did not affect mortality of either male or female rats; a dose-related increase in mortality was noted for both male and female mice (NCI, 1979). However, sufficient numbers of mice of each sex were at risk for tumor development for determination of tumor incidence significance. The percentage of mice surviving to study week 52 was at least 95% for all sexes and treatment groups. No significant tumor incidence increase was observed in male or female F344 rats as a result of *p*-chloro-*o*-toluidine exposure. Significant treatment-related increases ($p < 0.001$) were observed in the incidence of both hemangiosarcomas and hemangiomas and hemangiosarcomas combined in both male and female mice. Tumor incidence data is listed in Table 1.

Table 1: Incidence of vascular tumors (hemangiomas and hemangiosarcomas) in male and female mice treated with *p*-chloro*-o*-toluidine hydrochloride by dietary administration

Study	Sex/Strain	Dietary concentration (mg/kg diet)	Average Dose[1] (mg/kg-day)	Tumor Incidence
Weisburger *et al*. (1978)[2]	male CD-1	0 750 1500	0 90 180	0/14 12/20 13/20
Weisburger *et al*. (1978)[3]	female CD-1	0 2000	0 260	0/15 18/19
NCI (1979)[2]	male $B6C3F_1$	0 3750 15000	0 450 1800	0/20 6/50 41/50
NCI (1979)[3]	female $B6C3F_1$	0 1250	0 162	1/20 43/50

1. Doses as reported by Gold *et al*. (1984).
2. Decreased survival according to Gold *et al*.; a time-to-tumor analysis was performed using TOX_RISK (Crump *et al*., 1991; Cal/EPA, 1992).
3. Analysis of the data set using the computer program TOX_RISK (Crump *et al*., 1991) indicated that inclusion of the high dose group resulted in a *p*-value of = 0.05 based on the chi-square goodness-of-fit test, indicating non-linearity. Following procedures described by US EPA (Anderson *et al*., 1983; US EPA, 1986), the high dose group was excluded from the analysis to correct for the poor fit (Cal/EPA, 1992).

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

On the basis of positive bioassay results, the hydrochloride salt of *p*-chloro*-o*-toluidine was classified as a compound with sufficient evidence of carcinogenicity in animals by IARC

(1987). The results of feeding studies on by NCI (1979) using male and female $B6C3F_1$ mice and Fischer 344 rats and by Weisburger *et al.* (1978) using male and female CD-1 HaM/ICR mice and male Charles River CD rats are reported in Gold *et al.* (1984). In contrast to rats, mice are sensitive to *p*-chlor*o*-*o*-toluidine hydrochloride-induced carcinogenicity. Vascular tumors (hemangiomas and hemangiosarcomas) were induced in treated mice of both strains and sexes tested.

Methodology

Expedited Proposition 65 methodology (with cross-route extrapolation) was used to derive a cancer potency factor. The cancer potency for *p*-chlor*o*-*o*-toluidine is based on the bioassay results for the hydrochloride, adjusted for differences in molecular weight. An overall cancer potency was estimated by taking the geometric mean of the 4 values derived from dose-response data for vascular tumors from each of the mouse sex and strains tested (male and female CD-1 and $B6C3F_1$ mice) (Weisburger *et* al., 1978; NCI, 1979; see Table 1). Male $B6C3F_1$ mouse survival in the NCI (1979) study was poor; a cancer potency for that sex and strain was therefore derived using a time-to-tumor analysis (Crump *et al.*, 1991; Cal/EPA, 1992). A unit risk factor was then calculated by OEHHA/ATES from the cancer potency factor using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

CHROMIUM (HEXAVALENT)

CAS No: 18540-29-9

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 1998)

Molecular weight	51.966
Boiling point	2642 °C
Melting point	1900 °C
Vapor pressure	1 mm Hg at 1616 °C
Air concentration conversion	not available

II. HEALTH ASSESSMENT VALUES

Unit Risk Factor: 1.5 E-1 $(\mu g/m^3)^{-1}$
Slope Factor: 5.1 E+2 $(mg/kg\text{-}day)^{-1}$
[Human lung cancer mortality data (Mancuso, 1975), linearized multistage procedure, extra risk (US EPA, 1984), reevaluated by CDHS (1985).]

Oral Slope Factor: 4.2 E-1$(mg/kg\text{-}day)^{-1}$
[Calculated by CDHS (1991) from female mouse benign and malignant stomach tumor data (Borneff *et al.*, 1968), using a linearized multistage procedure.]

III. CARCINOGENIC EFFECTS

Human Studies

Several reviewers have summarized the epidemiologic studies examining the effects of chromium exposure on cancer morbidity and/or mortality (IARC, 1980; Hayes, 1982; US EPA, 1984). The chromium Toxic Air Contaminant (TAC) document (CDHS, 1985) included a summary table listing 14 occupational studies reporting an increase in cancer morbidity and/or mortality (primarily but not exclusively lung cancer). At the time the chromium TAC document was released, the relevant studies with exposure data were those by Pokrovskaya and Shabynina (1973, as cited in US EPA, 1984), Mancuso (1975) and Langard *et al*. (1980).

Pokrovskaya and Shabynina (1973) compared the cancer mortality of a group of ferroalloy workers in the Soviet Union to the local population for the time period 1955-1969. No specific cohort was defined nor were the number of cancer cases, individuals in the comparison groups, or person-years at risk given. Workers in the plant were reported to be exposed to low-solubility chromium compounds with concentrations of hexavalent chromium exceeding the allowable level of $0.01 mg/m^3$ by 2 to 7 times. In addition, some workers were exposed to smelting process fumes for the chromium ore, which included benzo[*a*]pyrene.

Age-specific cancer mortality ratios (SMR) were reported. The ratios for cancers in males aged 50-59 were significantly increased ($p < 0.001$) for all sites (SMR = 3.3), lung (SMR = 6.67), and esophagus (SMR = 2.0). Esophageal cancer mortality was also elevated among 60-69 year old males (SMR = 11.3, $p < 0.001$). However, the lack of methodological detail reporting as well as the absence of a defined worker cohort leave the results of this study open to question.

Mancuso and Hueper (1951) studied the lung cancer-chromium association in employees of the Painesville, Ohio chromate plant. A cohort of workers was defined as consisting of employees who had worked for at least one year during the period 1931-1949. The male population of the county in which the plant was located served as the comparison group. Denominator data were not reported; rather, the results were presented as proportionate mortality ratios (PMR). The PMR for cancer of the respiratory system was 18.2% (6/33) among chromate workers and 1.2% among the general male population. This difference is significant at $p < 0.01$. The authors also stated that about 96% of the workers were exposed predominantly to insoluble chromium (chromite ore; Cr(III)), suggesting that insoluble chromium, because of its relatively long pulmonary retention time may have played a causal role in carcinogenesis. However, since all work environments were contaminated with both trivalent and hexavalent chromium, (i.e., both insoluble and soluble chromium) the data are too limited to ascribe the carcinogenic form.

Mancuso (1975) followed up a segment of this population (new employees for the years 1931-37). A major concern of the author was to determine whether an association existed between lung cancer deaths and exposure to chromium of different oxidation states and solubilities. Data from a 1949 industrial hygiene study of the plant were used to derive weighted average exposures to insoluble, soluble and total chromium which were then applied to the worker cohort. Water-soluble chromium was considered to be hexavalent while insoluble chromium was assumed to be trivalent. The author noted that since the plant's inception in 1931, production had dramatically increased, possibly increasing chromium dust concentrations. This was likely to have continued until 1949, when the company instituted control measures, which markedly reduced the exposure. Thus, the 1949 exposure data probably represent an average exposure for the cohort; that is, the data underestimate exposure from 1931 to 1949 and overestimate it subsequently.

Of the 332 cohort employees, 173 (52%) had died by 1974, including 41 from lung cancer. No comparison to a reference group was made. The age-adjusted data showed an increase in lung cancer rates with increasing exposure to chromium, regardless of solubility (and hence oxidation state). No statistical evaluation of those trends was reported, but the staff of DHS tested the data and found a statistically significant positive trend ($p < 0.001$).

Langard *et al*. (1980) studied the incidence of cancer in male workers at a Norwegian ferroalloy plant (chromium and silicon alloys were produced). The cohort studied included all men who had worked at least one year in the period 1928-77, but the analysis focused on 976 workers who started before January 1, 1960. Both overall cancer mortality and incidence were lower than would have been expected based on national data. Lung cancer incidence was elevated; however, 7 cases were found among ferrochromium workers while

3.1 were expected ($p > 0.05$). The authors note that the expected rate may be inflated because the age-corrected lung cancer rate in the population of the county in which the plant is located is only 58% of the incidence in the whole country. Applying 58% to the expected rate results in a significant increase in the incidence ratio ($p < 0.01$). Furthermore, using non-ferrochromium workers as an internal referent population resulted in an 8.5-fold increase in lung cancer incidence ($p = 0.026$). Exposure data were based on a 1975 industrial hygiene survey of the plant. The total chromium content of dust was "with few exceptions" below 1 mg/m^3. This level probably underestimates past exposures. Water-soluble chromium (assumed to be hexavalent) ranged from 11-33% of the total. The presence of high levels of Cr(VI) in previous years was also confirmed by the finding of' 2 workers with nasal septum perforations. Exposure to asbestos and low levels of polycyclic aromatic hydrocarbons also occurred, but concentrations were not reported. However, since the 243 ferrosilicon workers studied were similarly exposed yet experienced no lung cancers, the
effect of these exposures may be minimal.

Table 1 Age, chromium exposure concentrations, lung cancer mortality and person-years of exposure for male chromate workers (Mancuso, 1975; as cited in US EPA, 1998).

Age (years)	Midrange (μg/m^3)	Deaths from Lung Cancer	Person Years
50	5.66	3	1345
	25.27	6	931
	46.83	6	299
60	4.68	4	1063
	20.79	5	712
	39.08	5	211
70	4.41	2	401
	21.29	4	345

Animal Studies

There have been at least eighty reported attempts to induce cancer in rodents by administration of chromium compounds by various routes. These have been reviewed by IARC (1980, 1982) and US EPA (1984). US EPA (1998) has stated that hexavalent chromium compounds were carcinogenic in animal assays producing the following tumor types: intramuscular injection site tumors in Fischer 344 and Bethesda Black rats and in C57BL mice; intraplural implant site tumors for various chromium VI compounds in Sprague-Dawley and Bethesda Black rats; intrabronchial implantation site tumors for various Cr VI compounds in Wistar rats; and subcutaneous injection site sarcomas in Sprague-Dawley rats.

It was noted in the chromium TAC document that at the time of document preparation, no chromium compound had been unequivocally shown to cause a significantly increased number of neoplasms in experimental animals after exposure by inhalation. At least 7 experiments involving dusts containing Cr(VI) and/or Cr(III) compounds had been conducted. Although Nettesheim et al. (1971) reported a significantly increased incidence of alveologenic (not bronchogenic) adenomas and adenocarcinomas in mice exposed to calcium chromate dust (13 mg/m3) over their lifetimes for 5 hr/day, 5 days/wk, this conclusion could not be confirmed on the basis of the data reported. The authors' statistical methodology was not reported. Fourteen treated animals (6 males and 8 females) developed tumors, whereas only 5 control animals (3 males and 2 females) did. However, the numbers of exposed and control animals were not reported, nor was the distribution of tumor types, so that the claim of a significant increase of treatment-related tumor incidence could not be validated. CDHS (1990) found that a later study (Glaser *et al*., 1986) reported increases in tumors of the lung, pharynx, pituitary, pancreas, and liver of male rats exposed for 18 months to aerosols of $Na_2Cr_2O_7$ at chromium concentrations of 100 mg/m^3. Statistical criteria used for the evaluation of tumor increases were not discussed by the authors. When analyzed by staff of CDHS, the incidence of respiratory tumors in the high-dose group, 4/19, was found to be significantly increased above the incidence, 0/37, in controls.

CDHS (1990) also described a oral chromium carcinogenicity bioassay done by Borneff *et al.* (1968). Male and female NMRI mice were exposed to 1 mg K_2CrO_4 per day (added to the regular diet); a control group of 79 females and 47 males was maintained on regular diet for three generations. During 880 days of observation, each generation was dosed for two years. Approximately two-thirds of the animals in both the treatment and the control group died during months 8-11. Necropsies were performed on 66 dosed females and 35 dosed males and on 79 female and 47 male controls. Two carcinomas of the stomach were found in dosed females, but no stomach carcinomas were found in dosed males or controls. In addition, benign stomach tumors (papillomas and hyperkeratomas) were seen in 9 females and 2 males given chromium and in 2 females and 3 males in the control group. The increased incidence of malignant stomach tumors was not significant when compared with controls, but the incidence of malignant or benign stomach tumors in dosed females, 11/66, was significantly increased above 2/79, the incidence in controls ($p = 0.003$).

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Inhalation

A number of human occupational studies (relevant reviews listed above) have demonstrated that inhalation exposure to chromium results in an increased risk of lung cancer mortality in humans. An occupational exposure study by Mancuso (1975) was used by US EPA (1984) as the basis for an inhalation cancer unit risk for chromium. This study demonstrated the carcinogenicity of chromium in a cohort which was sufficiently large and

which was followed for an adequate time period. Data from an industrial hygiene study were used to derive weighted average exposures to insoluble, soluble and total chromium which were then applied to the worker cohort. Table 1 lists the age, exposure and lung cancer mortality study data.

Oral

Borneff *et al.* (1968) exposed male and female NMRI mice to 1 mg K_2CrO_4 per day for two years. A significantly increased incidence of stomach carcinomas were noted in female mice; a significantly increased incidence of benign stomach tumors (papillomas and hyperkeratomas) were noted in both male and female mice.

Methodology

Inhalation

US EPA (1984) used both multistage linearized "competing risks" and "crude" procedures to estimate human cancer risks associated with chromium inhalation exposure from the data set of Mancuso (1975). The resulting cancer unit risk (1.2 E-2 $(\mu g/m^3)^{-1}$) (US EPA, 1998) was a maximum likelihood estimate (MLE) derived from the "competing risks" procedure, calculated on the basis of total chromium exposure. It was also assumed that the smoking habits of chromate workers were similar to those of the U.S. white male population. CDHS (1985) adopted the US EPA linear nonthreshold procedure to estimate low-dose chromium inhalation cancer risk. A multistage linearized "crude" procedure was used to derive a cancer unit risk of 1.5 E-1 $(\mu g/m^3)^{-1}$, which was the 95% upper confidence limit for the estimate of the relative risk in the Mancuso (1975) study. The cancer mortality in Mancuso (1975) was assumed to be due to Cr(VI), which was further assumed to be no less than one-seventh of total chromium. This contrasts with the unit risk developed by US EPA (1984), which was calculated on the basis of total chromium exposure.

Oral

An oral cancer potency factor for chromium(VI) was derived from the benign and malignant mouse stomach tumor incidence data reported by Borneff *et al.* (1968). From the average weight of the treated mice, 31 grams, the dose of 1 mg/day of K_2CrO_4 (0.26 mg/day Cr) was calculated to be 8.39 mg/kg-day, and from the incidence of benign and malignant stomach tumors combined, the oral cancer potency of Cr(VI) was calculated using a linearized multistage procedure to be 3.17×10^{-2} $(mg/kg\text{-}day)^{-1}$ (CDHS, 1991). Surface-area scaling was used to extrapolate the animal cancer potency to human cancer potency. The scaling factor was calculated by taking the ratio, human body weight divided by animal body weight, raised to the one-third power. This extrapolation factor, $(70\ kg/0.031\ kg)^{1/3}$, was calculated to be 13.1. Multiplying the above potency estimate, 3.17×10^{-2} $(mg/kg\text{-}day)^{-1}$, made from the mouse study, by the extrapolation factor gives the estimate, 0.42 $(mg/kg\text{-}day)^{-1}$, for the carcinogenic potency of Cr(VI) ingested by humans.

Unit Risk Factor: Can be calculated using PEF factors contained in the benzo[*a*]pyrene Toxic Air Contaminant (TAC) document (OEHHA, 1993).

Slope Factor: Can be calculated using PEF factors contained in the benzo[*a*]pyrene TAC document (OEHHA, 1993).

III. CARCINOGENIC EFFECTS

Human Studies

Henry (1947) reviewed 3753 cases of cutaneous epitheliomata (epitheliomatous ulceration or cancer of the skin) reported to the British Medical Inspector of Factories from 1920 to 1945. Thirty five cases (12 of the scrotum) had creosote exposure. Henry (1946) also reported that the crude mortality rate for scrotal cancer during 1911-1938 for British brickmakers exposed to creosote oil was 29 per million men based on 9 verified cases as compared to a national average of 4.2 per million and rates of 1 per million or less for groups not exposed to suspected skin carcinogens.

A cohort study reported on 123 Swedish workers who treated wood with creosote and were exposed to both creosote and arsenic between 1950 and 1980 (Axelson and Kling, 1983; reviewed in IARC, 1985). Eight workers died of cancer compared to 6 expected. Three cancer deaths (leukemia, pancreas and stomach) were observed compared to 0.8 expected in a subgroup of 21 workers exposed only to creosote for five or more years.

A case-referent study of Swedish workers examined potential relationships between past occupational and radiation exposure and multiple myeloma (Flodin *et al*., 1987). Exposure assessment employed a mailed questionnaire that asked questions about occupational (including coal tar creosote) and radiation exposure. Data analysis using the Miettinen confounder score technique indicated that an increased prevalence of multiple myeloma was associated with occupational exposure to coal tar creosote (crude rate ratio = 6.0, p = 0.001). The rate ratio point estimate for creosote exposure increased to 9.0 after age

stratification. The power of this study was limited by differences between the case group and the referent group in the number of smokers and gender composition.

Creosote contains many of the same compounds present in other polycyclic aromatic hydrocarbon (PAH) mixtures (roofing tar pitch, coke oven emissions) known to be human carcinogens (US EPA, 1986; ATSDR, 1990).

Animal Studies

Female C57BL mice (10 animals/group) were exposed to blended creosote oil (a mixture of creosote, anthracene oils and naphthalene recovery residue oil) in toluene. One drop (8.7 - 9 µl) of a 20% or 80% solution was applied to the skin three times/week for the animals' lifetimes or until tumors developed (21 - 44 weeks and 18 - 35 weeks for the 20% and 80% solution exposure groups, respectively). All treated mice developed skin papillomas and 7 mice in each group developed epidermoid carcinomas, some of which metastasized to pulmonary or regional lymph nodes. None of the vehicle control animals developed skin tumors (Poel and Kammer, 1957).

Female Swiss mice (30/group) were treated twice weekly with one drop of a 2% solution of creosote in acetone applied dermally for 70 weeks. Skin tumors (including 16 carcinomas) were reported in 23 of 26 surviving mice. The average tumor latency period was 50 weeks. No vehicle control group was included; however, no animals in a control group of 50 mice receiving a single application of 1% 7,12-dimethylbenz[*a*]anthracene in mineral oil developed tumors after 80 weeks (Lijinsky *et al*., 1957).

Undiluted creosote applied topically twice weekly (25 µl) to 30 random-bred female mice for 28 weeks induced an average of 5.4 papillomas per animal; 82% of the mice had carcinomas. The average time to tumor for papillomas and carcinomas was 20 and 26 weeks, respectively. No vehicle control group was included in the study (Boutwell and Bosch, 1958). In a similar study, a group of 24 albino mice treated dermally with 25 µl creosote twice weekly for 5 months and housed in stainless steel cages exhibited 139 lung adenomas (5.8 tumors/mouse) after 8 months. A group of 29 mice born and housed in creosote-treated wood cages treated dermally with 25 µl creosote for 5 months demonstrated 315 lung adenomas (10.8 tumors/mouse) after 8 months. A control group (19 mice) housed in stainless steel cages demonstrated 9 lung adenomas (0.5 tumors/mouse) after 8 months (Roe *et al.*, 1958).

V. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Creosote has been demonstrated to cause skin and lung tumors in mice after dermal exposure, and is predominantly composed of PAH; similar PAH-containing coal tar products (roofing tar pitch, coke oven emissions) have been shown to be human carcinogens (US EPA, 1986; ATSDR, 1990). Creosote has been given B1 and 2A classifications (probable human carcinogen) by US EPA (1987) and IARC (1985),

respectively. No creosote carcinogenicity bioassay study suitable for quantitative risk assessment exists. However, a cancer unit risk factor for the PAH benzo[*a*]pyrene (BaP) derived from an inhalation exposure study (Thyssen *et al*., 1981) has been developed, along with Potency Equivalency Factors (PEFs) for several related PAHs. (OEHHA, 1993).

Thyssen *et al*. (1981) exposed male Syrian golden hamsters (24/group) by inhalation to 0. 2.2, 9.5 or 46.5 mg BaP/m^3 in a sodium chloride aerosol (greater than 99% of the particle diameters were between 0.2 and 0.5 μm). The hamsters were exposed to BaP daily for 4.5 hours/day for the first 10 weeks of exposure; subsequent exposure was daily for 3 hours/day. Total treatment duration was 95 weeks. Animals dying in the first year of the study were replaced. The effective number of animals in the control, 2.2, 9.5 and 46.5 mg/m^3 exposure groups were 27, 27, 26 and 25, respectively. Survival time for the 46.5 mg/m^3 exposure group was significantly reduced (60 weeks) when compared to controls (96 weeks). Survival times for the other exposure groups were similar to controls. Respiratory tract (including nasal cavity, larynx and trachea) tumor incidence was significantly increased in a dose-dependent manner in the 9.5 and 46.5 mg/m^3 exposure groups (34.6% and 52%, respectively, compared to controls); those exposure groups also demonstrated an increase in upper digestive tract (including pharynx, esophagus and forestomach) tumor incidence (27% and 56%, respectively). This study was selected as the basis of a cancer potency factor for exposure to BaP by inhalation because it used the most sensitive species and sex demonstrating a dose response and using the most relevant exposure route.

Methodology

A linearized multistage procedure (GLOBAL86) (Howe and van Landingham, 1986) was used with the Syrian golden hamster respiratory tract tumor incidence data of Thyssen *et al*. (1981) to calculate a cancer potency factor. Data from the highest exposure group (46.5 mg/m^3) was not used due to the shortened lifespan of the hamsters in this group. Administered dose for the 2.2 and 9.5 mg/m^3 exposure groups based on an inspiration rate of 0.063 m^3/day and a body weight of 0.1 kg was 0.152 and 0.655 mg/kg/day, respectively. Surface area scaling was then used to extrapolate a human cancer potency factor and an inhalation unit risk factor (using assumptions of 70 kg body weight and 20 m^3/day inspiration rate). Creosote is approximately 91% PAH, nitro-PAH or hydroxy-PAH (Wright *et al*., 1985); a unit risk for creosote can be calculated using the unit risk value for BaP and the PEFs for related PAHs (OEHHA, 1993).

Slope Factor: 1.5 E-1 $(mg/kg\text{-}day)^{-1}$
[Female mouse urinary bladder tumor data (NCI, 1979), contained in Gold *et* al. (1984), expedited Proposition 65 methodology, with cross-route extrapolation.]

III. CARCINOGENIC EFFECTS

Human Studies

No studies on the potential carcinogenic effects of *p*-cresidine in humans are known to exist.

Animal Studies

Male and female Fischer 344 (F344) rats and B6C3F$_1$ mice (50 animals/sex/species/group) were fed diets containing *p*-cresidine (NCI, 1979). The study design is outlined in Table 1. Dose levels for male and female mice were reduced after 21 weeks; the study report did not describe the rationale for the dose reduction.

Mortality in mice was dose-related and associated with the development of bladder tumors; mortality in rats was also dose-related and was related to development of urinary bladder and nasal cavity tumors. Survival percentages after 75 weeks of treatment are listed in Table 2. Significant incidence increases were seen for urinary bladder tumors in male and female rats (squamous-cell or transitional-cell carcinomas) and mice (transitional-cell carcinomas), for liver tumors in female mice (hepatocellular adenomas or carcinomas) and male rats (neoplastic liver nodules, hepatocellular carcinomas or cholangiocarcinomas), and for nasal cavity tumors (primarily nasal cavity tumors) in male and female rats. These data are listed in Table 2. Nonsignificant increases in nasal cavity tumors were also observed in male and female mice.

Table 1. Study design summary for NCI (1979) carcinogenicity bioassay of *p*-cresidine in Fischer 344 rats and B6C3F$_1$ mice.

Sex/species	Treatment group	*p*-cresidine dietary concentration (mg/kg diet)	Observation period	
			Treated (weeks)	Untreated (weeks)
Male rats	control	0		106
	low-dose	5000	104	1

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Results of the NCI (1979) feeding study in male and female B6C3F$_1$ mice and Fischer 344 rats are listed in Gold *et al*. (1984). Urinary bladder tumors as well as tumors at other sites were observed in both sexes of mice and rats. The most sensitive site appears to be the urinary bladder. Both sexes of both species show similar sensitivities at this site. The potency derived from dose-response data on female mice (benign and malignant urinary bladder tumors) is slightly greater than those for the other groups and is taken as the best estimate here (see Table 2).

Methodology

Expedited Proposition 65 methodology (with cross-route extrapolation) was used to derive a cancer potency factor. Because female mouse survival was poor, the potency was derived using a time-to-tumor analysis (Crump *et al*., 1991; Cal/EPA, 1992). A unit risk factor was then calculated by OEHHA/ATES from the cancer potency factor using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

III. CARCINOGENIC EFFECTS

Human Studies

No studies on the potential carcinogenic effects of cupferron in humans are known to exist.

Animal Studies

Male and female Fischer 344 (F344) rats and $B6C3F_1$ mice were exposed to diets containing cupferron (NCI, 1978). A summary of the experimental design is outlined in Table 1. Treatment periods were followed by an observation period during which animals were fed control diet. Male and female mouse dose levels were reduced after 35 weeks. Group sizes were 50 animals/sex/species/group except for the high-dose male mouse group, which consisted of 49 animals.

Cupferron induced significantly increased incidences of forestomach squamous-cell carcinomas, hepatocellular neoplastic nodules and carcinomas in male and female rats, hemangiosarcomas in male and female rats and mice, auditory sebaceous gland tumors in female mice and rats, hepatocellular carcinomas in female mice and Harderian gland adenomas in male and female mice. Hemangiosarcoma incidence data is listed in Table 2.

Table 1. Experimental design for carcinogenicity bioassay of cupferron using male and female Fischer 344 (F344) rats and B6C3F$_1$ mice (NCI, 1978)

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Results of the NCI (1978) feeding study in male and female B6C3F_1 mice and Fischer 344 rats are listed in Gold *et al*. (1984). Benign and malignant vascular tumors as well as tumors at other sites were observed in mice and rats of both sexes treated with cupferron. Cancer potency is based on the data for vascular tumors in the male rat (see Table 2) because the rat is the more sensitive of the species tested, and the male appears to be slightly more sensitive than the female (Cal/EPA, 1992).

Methodology

Expedited Proposition 65 methodology (with cross-route extrapolation) was used to derive a cancer potency factor. Analysis of the data set using the computer program TOX_RISK (Crump *et al*., 1991) indicated that inclusion of the high dose group resulted in a p-value of = 0.05 based on the chi-square goodness-of-fit test, indicating non-linearity. Following procedures described by US EPA (Anderson *et al*., 1983), the high dose group was excluded from the analysis to correct for the poor fit (Cal/EPA, 1992). A unit risk factor was then calculated by OEHHA/ATES from the cancer potency factor using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

III. CARCINOGENIC EFFECTS

Human Studies

No studies on the potential carcinogenic effects of 2,4-diaminoanisole in humans are known to exist.

Animal Studies

Male and female Fischer 344 (F344) rats and B6C3F_1 mice were fed diets containing 2,4-diaminoanisole (DAA) sulfate (NCI, 1978). Mice were fed diets containing 1200 or 2400 mg/kg DAA sulfate for 78 weeks and were observed for an additional 18-19 weeks. Rats were fed diets containing 5000 mg/kg DAA sulfate for 78 weeks, or diet containing 1250 mg/kg DAA sulfate for 10 weeks, then 1200 mg/kg diet for 68 weeks, followed by a 29 week observation period. Matched control groups were provided for each dose group. Group sizes were 50 animals/sex/species/group with the exception of the male rat high-dose control group (49 animals). Mortality of control and treated rats and mice were similar by the end of the study. Significantly increased incidences of thyroid tumors were seen in both mice (males - follicular cell adenomas; females - follicular cell adenomas, carcinomas) and rats (follicular cell adenocarcinomas, carcinomas, papillary adenocarcinomas and cystadenocarcinomas). Increased skin tumor incidences (squamous-cell carcinomas, basal-cell carcinomas, sebaceous adenocarcinomas) were observed in male rats. Male and female rats both had increased incidences of preputial or clitoral gland adenomas, papillomas or carcinomas and Zymbal gland tumors (males - squamous cell carcinomas, sebaceous adenocarcinomas; females - sebaceous adenocarcinomas). Tumor incidence data is listed in Table 1.

Table 1: Tumor induction in Fischer 344 rats and B6C3F$_1$ mice by dietary administration of 2,4-diaminoanisole (NCI, 1978)

Sex/species	Dose group	Average Dose[1] (mg/kg-day)	Tumor type	Tumor Incidence[2]
Male mouse	control	0	thyroid	1/100
	low dose	116		0/50
	high dose	234		11/50

	low dose	44		0/50
	high dose	182		4/50

1. Doses reported by Gold *et al*., 1984.
2. Tumor incidences reported by Gold *et al*., 1984.

Diets containing 2,4-diaminoanisole at concentrations of 0, 1200, 2400 or 5000 mg/kg diet were fed to female F344 rats (40 - 60/group) for up to 82-86 weeks (Evarts and Brown, 1980). An additional 15 rats were fed diet containing 5000 mg/kg diet for 10 weeks, then fed control diet and observed for up to 87 weeks. Thyroid tumor incidences (follicular-cell adenomas or carcinomas or C cell carcinomas) were 1/37 in controls, 2/47 in the low-dose group, 3/33 in the mid-dose group and 31/40 in the high-dose group; in addition, 3/12 animals exposed to the 5000 mg/kg diet for 10 weeks had thyroid tumors. Clitoral gland tumors (squamous-cell, sebaceous-cell or squamous-sebaceous-cell carcinomas) were

noted in 0/37 controls, 8/47 of the low-dose group, 15/33 of the mid-dose group and 9/40 of the high dose-group, as well as in 1/12 of the animals in the 10 week high-dose group.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Cancer potency for 2, 4-diaminoanisole was derived from that for the sulfate using a molecular weight conversion (Cal/EPA, 1992):

$$q_h\,(\text{base}) = q_h\,(\text{sulfate}) \times \frac{\text{MW(sulfate)}}{\text{MW(base)}}$$

where q_h is the human potency and MW is the molecular weight. This conversion assumes that the intake of equivalent moles of the two forms of the chemical results in equivalent concentrations of the active species *in vivo*. Gold *et al.* (1984) list the results of the NCI (1978) feeding studies in male and female F344 rats and $B6C3F_1$ mice, and the feeding study by Evarts and Brown (1980) in female F344 rats. Cancer potency is based on dose-response data for benign and malignant thyroid tumors in male rats, the most sensitive sex and species (see Table 1) (Cal/EPA, 1992).

Methodology

Expedited Proposition 65 methodology (with cross-route extrapolation) was used to derive a cancer potency factor. A unit risk factor was then calculated by OEHHA/ATES from the cancer potency factor using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

III. CARCINOGENIC EFFECTS

Human Studies

No studies on the carcinogenic potential of 2,4-diaminotoluene in humans are known to exist.

Animal Studies

IARC (1978) reviewed a study by Umeda (1955) in which 20 rats of mixed strain and sex were injected subcutaneously with 0.5 ml of a 0.4% solution of 2,4-diaminotoluene at weekly intervals. No tumor induction was noted in 11 rats that died in the first 8 months of the study. All 9 surviving rats, which received 29-44 weekly injections, developed subcutaneous sarcomas. No concurrent control group was included in this study; however, another group of 12 rats exposed to 11 subcutaneous injections of xanthene in propylene glycol over 10 months did not develop local sarcomas.

Male Wistar rats were fed diets containing 0, 0.06% or 0.1% 2,4-diaminotoluene for 30-36 weeks (12 animals/treatment group, 6 animals/control group) (Ito *et al.*, 1969). Exposure to 2,4-diaminotoluene caused an increased incidence of hepatocellular carcinomas in the treated animals (0/6, 7/11, and 9/9 in the control, low-dose and high-dose groups, respectively).

Male and female Fischer 344 (F344) and $B6C3F_1$ mice were fed diets containing 2,4-diaminotoluene (NCI, 1979). Treatment group sizes were 50 animals/sex/species/group; matched control group sizes were 20 animals/sex/species/group. The study design is

outlined in Table 1. Male and female rat low- and high-dose levels were reduced after 40 weeks.

Table 1. Experimental design of 2,4-diaminotoluene carcinogenicity bioassay using male and female F344 rats and B6C3F$_1$ mice (NCI, 1979)

Sex/species	Study group	dietary 2,4-diaminotoluene (ppm)	Study time (weeks)	Time-weighted average dose[c] (ppm)
Male rat	matched control	0	103	0
	low dose	125	40	
		50	63	79
	high dose	250	40	
		100	39[a]	176
Female rat	matched control	0	103	0
	low dose	125	40	
		50	63	79
	high dose	250	40	
		100	44[b]	171
Male,female mouse	matched control	0	101	
	low dose	100	101	
	high dose	200	101	

a. Test diet administration was terminated at the time indicated and all high-dose males were killed because of morbidity.

b. Test diet administration was terminated at the time indicated and all high-dose females except four were killed because of morbidity.

c. Time-weighted average dose $= \dfrac{\sum (\text{dose in ppm} \times \text{weeks at that dose})}{\sum (\text{weeks receiving each dose})}$

Significantly increased tumor incidences were observed in treated rats; hepatocellular adenomas, carcinomas and neoplastic nodules in male and female rats, mammary gland adenomas and carcinomas in female rats, and subcutaneous fibromas in male rats. Significant increases in tumor incidence were also noted in female mice; hepatocellular carcinomas in the low- and high-dose groups, and lymphomas in the low-dose group. No significant tumor induction was noted in male mice. Tumor incidence data is listed in Table 2.

Table 2. 2,4-Diaminotoluene-induced tumor incidence in F344 rats and B6C3F$_1$ mice (NCI, 1978)

Sex/species	Study group	Average dose[a] (mg/kg-day)	Tumor type	Tumor incidence[b]
Male rats	matched controls	0	liver tumors[c]	0/20
			subcutaneous fibromas	0/20
	low dose	3.2	liver tumors[c]	5/50
			subcutaneous fibromas	15/50
	high dose	7.0	liver tumors[c]	10/50
			subcutaneous fibromas	19/50
Female rats	matched controls	0	liver tumors[c]	0/20
			mammary gland tumors	0/20
	low dose	3.95	liver tumors[c]	0/50
			mammary gland tumors	11/50
	high dose	8.55	liver tumors[c]	6/50
			mammary gland tumors	14/50
Female mice	matched controls	0	liver tumors	0/20
			lymphomas	2/20
	low dose	13.0	liver tumors	13/50
			lymphomas	29/50
	high dose	26.0	liver tumors	18/50
			lymphomas	11/50

a. Doses as reported by Gold *et al*. (1984).
b. Tumor incidences as reported by Gold *et al*. (1984)
c. Includes hepatocellular neoplastic nodules, adenomas and carcinomas

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Results of the NCI (1978) feeding studies of 2, 4-diaminotoluene in male and female B6C3F$_1$ mice and F344 rats are listed by Gold *et al*. (1984). Significant increases in tumors were seen in rats of both sexes and in female mice. The study results indicated that rats are more sensitive than mice. The female rat appears to be slightly more sensitive than the male, although the study is not sensitive enough to definitively distinguish between the two. Cancer potency is based on mammary gland tumors in the female rat (see Table 2).

Methodology

Expedited Proposition 65 methodology (with cross-route extrapolation) was used to derive a cancer potency factor. Because female rat survival was poor in this study, the potency was derived using a time-to-tumor analysis (Crump *et al*., 1991; Cal/EPA, 1992). The individual animal data for the time-to-tumor analysis were obtained from TOX_RISK (Crump *et al*., 1991). A unit risk factor was then calculated by OEHHA/ATES from the cancer potency factor using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

III. CARCINOGENIC EFFECTS

Human Studies

Two occupational epidemiological studies, Hearn *et al.* (1984) and Wong *et al.* (1984), were conducted using data from workers exposed during the formulation or manufacture of 1,2-dibromo-3-chloropropane (DBCP). The study by Hearn *et al.* (1984) examined a cohort of 550 chemical workers exposed to a variety of compounds, including DBCP. Twelve of the subjects in this cohort died from cancer (7.7 expected). In the study by Wong *et al.* (1984) 9 cases of respiratory cancer were reported in a cohort of 1034 workers exposed to DBCP (5.0 expected). Neither of these studies produced statistically significant ($p < 0.05$) associations between DBCP exposure and expected cancer incidence. In addition, it was not possible to account for all confounding chemical exposures in these studies. Therefore these studies were considered by IARC (1987) to be inadequate and were not used for the derivation of the cancer potency of DBCP.

An epidemiological study conducted by Jackson *et al.* (1982) found an association between DBCP in drinking water and increased incidence of stomach cancer and leukemia. In this study, patterns of DBCP contamination of well water in Fresno County, California were compared with deaths from selected cancers in the same area from 1970 to 1979. The cancers studied included stomach, esophageal, liver, kidney, and breast cancers in addition to lymphoid leukemia. Significant relationships between DBCP exposure level and cancer deaths were tested by Bartholomew's trend test. Exposed individuals were grouped into those with less than 0.05 ppb, those with 0.05 up to 1.0 ppb, and those with greater than 1.0 ppb DBCP in the drinking water. Mortality was age-adjusted using 20-year age groups. Significant trends for incidence of stomach cancer and lymphoid leukemia were found.

Results may have been confounded by smoking habits, ethnicity, and exposure to other carcinogens.

Additional analysis of these data by Environmental Health Associates (EHA, 1986) and sponsored by the Shell Oil Company did not show the above association. These data included corrections for ethnicity. This study used a different method for estimating DBCP concentrations. Although the associations between cancer incidence and DBCP exposure failed to reach significance at the $p < 0.05$ level in the EHA study, the magnitude of the associations in the high and low exposure groups were approximately the same as described in the Jackson *et al*. (1982) study. The trend for cancer risk and DBCP exposure is most closely related to the time of residence of the test subjects (Table 1).

Table 1. Relative risk of human gastric cancer in areas with high[1] concentrations of DBCP in the drinking water compared with areas of low[2] DBCP (Jackson *et al*., 1982).

Time of Residence	Relative Risk for Gastric Cancer
1 year at death	1.29
1 year prior to death	1.55
10 years prior to death	3.05

[1] DBCP concentrations greater than 1.0 ppb.
[2] DBCP concentrations less than 0.05 ppb.

Animal Studies

DBCP is a carcinogen in at least two laboratory rodent species by inhalation, ingestion, or dermal exposure. Tumors following DBCP exposure can arise not only at the site of application, but also at distal sites. Because of its carcinogenicity to multiple species, DBCP is assumed to represent a carcinogenic threat to humans (CDHS, 1985).

Three sets of long-term bioassays using mice and rats were conducted respectively by the National Cancer Institute (NCI, 1978), the National Toxicology Program (NTP, 1982) and Hazelton Laboratories (1977, 1978). In the NCI (1978) study, DBCP was administered by oral gavage to both sexes of rats and mice. Two major problems with this study, early mortality and nearly 100% forestomach carcinoma rate, precluded its usefulness in determining a cancer potency value. The inhalation study by NTP (1982) had much better survival rates than those observed in the gavage study, and carcinogenicity was observed for tissues at or near the site of the initial chemical contact.

In the NTP study, groups of 50 B6C3F1 mice or 50 F344 rats of either sex were exposed by inhalation to 0, 0.6 or 3.0 ppm DBCP for 6 hours/day, 5 days/week, for 76-103 weeks. Surviving high-dose rats were killed at week 84. High-dose female mice and low- and high-dose male mice were killed at week 76. Low-dose rats and female mice were killed at week 104. A significant increase in the combined incidence of nasal tumors was found in male and female rats at both concentrations (Table 2a, 2b). In mice, the combined

incidence of nasal tumors was significantly increased in females at both concentrations, and in males exposed to the high concentration. Proliferative lesions were observed at sites distal to the lung in the mice, including the kidney, forestomach, and spleen.

Table 2a. Incidence of combined nasal cancers from DBCP Inhalation exposure in rats and mice (NTP, 1982)

	Tumor Incidence DBCP Concentration (ppm)		
Species	0	0.6	3.0
F-344 Rats (males)	0/50	32/50	39/49
F-344 Rats (females)	1/50	21/50	32/50
B6C3F1 Mice (males)	0/45	1/42	21/48
B6C3F1 Mice (females)	0/50	11/50	38/50

Table 2b. Incidence of combined lung cancers from DBCP inhalation exposure in mice (NTP, 1982)

	Tumor Incidence DBCP Concentration (ppm)		
Species	0	0.6	3.0
B6C3F1 Mice (males)	0/41	3/40	11/45
B6C3F1 Mice (females)	4/50	12/50	18/50

In the studies conducted by the Hazelton Laboratories (1977, 1978), mice (50 males or females per group) or rats (60 males or females per group) were exposed to DBCP in the diet for 78 weeks. The intended daily doses were 0, 0.3, 1.0 and 3.0 mg/kg per day. Both species exhibited dose-dependent increases in forestomach squamous cell papillomas and carcinomas. The mouse study contained experimental errors in the diet preparation and food consumption measurements. Spillage of the food and evaporation in the mouse study may have resulted in an overestimate of the actual average daily exposure. For the rats, diets were prepared every two weeks, therefore loss of DBCP in the food due to evaporation was less significant than in the mouse study. The average amount of DBCP in the diet was estimated assuming first-order evaporation loss (Shell Oil Company, 1986). Using this model, the average daily doses of DBCP in the mouse study were 0, 0.3, 1.6 and 4.8 mg/kg per day. The study conducted by Hazelton Laboratories used lower doses than those in the NCI study, providing better information on the lower end of the dose-response curve. However, the times of death or times of tumor appearance were not reported. In addition, the study conducted by Hazelton Laboratories was terminated at 78 weeks in the case of the mice but lasted for 104 weeks in the case of the rats.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The Hazelton Laboratories (1977) study in female CD-1 mice was chosen as the critical study for the derivation of the cancer potency factor. In this study, female mice had a tumor incidence of 19/50 in the high dose group. No tumors were observed in the controls, and no histopathological examination was determined in the low and mid dose groups. The problem of food spillage and evaporation of the DBCP from the food bias the data toward an underestimation of the true cancer potency. Despite this fact, the data from this study gives a higher potency than that calculated from the rat data. The cancer potency for DBCP is based on the incidence of forestomach squamous cell carcinomas in the Hazelton Laboratory study, and is consistent with the incidence of stomach carcinomas in female mice in the NCI gavage study. In addition, the inhalation study conducted by NTP produced tumors at sites distal to the lung, including the forestomach. The cancer potency based on the NTP inhalation study is close to, but slightly lower than the potency derived from the Hazelton Laboratories study. The Hazelton Laboratory study was therefore taken to be the most appropriate animal data for the derivation of the cancer potency value.

Based on the calculated cancer potency derived from the animal studies, significant increases in cancer incidence would not be expected in the human occupational studies. The duration of exposure was too brief, the exposure too recent, and the number of subjects too small. In the ecological and case-control environmental studies by Jackson *et al*. (1982) and EHA (1986), a significant increase in the number of cancers would indicate that the true human cancer potency is an order of magnitude higher than that calculated from the animal studies.

Methodology

A linearized multistage procedure was used to estimate the cancer potency of DBCP from the Hazelton Laboratories (1977) data in female CD-1 mice (Crump *et al*., 1982). The actual daily doses received by the mice were estimated to be 0, 0.3, 1.6 and 4.8 mg/kg/day (Shell Oil Company, 1986). The 95% upper confidence bound on the dose-response slope was used to derive the human cancer potency value for DBCP.

The animal cancer potency, q_{animal}, was calculated from the linear slope using the lifetime scaling factor $q_{animal} = q_1^* \times (T/T_e)^3$, where T/T_e is the ratio of the experimental duration to the lifetime of the animal. An estimated value for the human cancer potency was determined using the relationship $q_{human} = q_{animal} \times (bw_h/bw_a)^{1/3}$, where bw is the default body weight of human or animal (mouse).

Using these relationships, a human cancer potency (q_{human}) of 6.6 $(mg/kg \times day)^{-1}$ was derived (CDHS, 1988). An airborne unit risk factor was calculated by OEHHA/ATES from the q_{human} value using the default parameters of 70 kg human body weight and 20 m^3/day breathing rate.

Unit Risk Factor: 1.1 E-5 $(\mu g/m^3)^{-1}$
Slope Factor: 4.0 E-2 $(mg/kg\text{-}day)^{-1}$
[Calculated from a cancer potency factor derived by CDHS (1988)]

III. CARCINOGENIC EFFECTS

Human Studies

There are several case reports of human leukemia associated with occupational exposure to chlorinated benzenes, including 1,4 - dichlorobenzene (1,4-DCB) (Girard *et al.*, 1969). One case of chronic lymphocytic leukemia involved exposure to a solvent mixture of 80% ortho-, 2% meta-, and 15% para-dichlorobenzene. The association between leukemia and 1,4 - dichlorobenzene exposure was confounded by multiple chemical exposure.

Animal Studies

Loeser and Litchfield (1983) conducted a chronic inhalation carcinogenicity bioassay in male and female Alderly Park rats. In this study, groups of 76-79 rats were exposed to 0, 75, or 500 ppm p-DCB 5 hours/day, 5 days/week for 76 weeks. Control rats exhibited a high mortality rate and did not differ significantly from treated rats in overall tumor incidence (Table 1) or in the incidence of animals with multiple tumors and malignant tumors.

Table 1. Tumor incidence in rats exposed to 1,4-dichlorobenzene (DCB) in air for 76 weeks (Loeser and Litchfield, 1983)

Concentration of 1,4-DCB	Combined Tumors (males)	Combined Tumors (females)
0 ppm	39/60	55/61
75 ppm	31/60	54/61
500 ppm	35/60	53/58

A parallel experiment was conducted using groups of 75 Swiss mice of either sex (Loeser and Litchfield, 1983). In this experiment, female mice were exposed to 0, 75, or 500 ppm 1,4 – DCB for 5 hours/day, 5 days/week, for 57 weeks. A similar experiment in male mice was terminated due to high mortality due to fighting and respiratory infections. As with the rats, no significant increase in any tumor type was detected.

The National Toxicology Program (NTP, 1987) studied the carcinogenicity of 1,4 - DCB in male and female F344 rats and B6C3F1 mice via chronic (103 week) oral intubation. Male rats were given 0, 150, or 300 mg/kg 1,4 - DCB for 5 days/week for 103 weeks. Male and female mice, and female rats were given 0, 300, or 600 mg/kg for the same duration. Sentinel animals were killed periodically to test for infectious pathogenic agents. The survival of male rats given 300 mg/kg was significantly lower than controls after 97 weeks, but the survival of treated female rats was unchanged from controls. The time-weighted average doses in the study were 0, 214, and 428 mg/kg/day for the mice, and 0, 107, and 214 mg/kg/day for the rats. Male rats treated with 1,4-DCB displayed nephropathy and mineralization and hyperplasia of renal tubules. The incidence of renal tubular adenocarcinomas was also dose-dependently increased in the male rats (1/50, 3/50, or 7/50 for the 0, 107, or 214 mg/kg groups, respectively). A significant dose-dependent increase in the incidence of mononuclear cell leukemia (5/50, 7/50, or 11/50 for the 0, 107, or 214 mg/kg groups, respectively) was observed in the male rats. Additionally, an increasing trend in the incidence of mesothelioma was observed in the male rats (1/50, 0/50, 4/50, for the 0, 107, or 214 mg/kg groups, respectively).

Mice of both sexes exposed to 1,4 - DCB had significantly increased incidence of hepatocellular adenomas and carcinomas (NTP, 1987). In addition, four male mice exposed to 428 mg/kg were found to have hepatoblastomas, a rare hepatocellular carcinoma. The incidence of follicular thyroid cell adenomas was increased in female mice exposed to 428 mg/kg ($p < 0.038$). As with the male rats, male mice showed evidence of kidney tubule damage when treated with 1,4 - DCB. Females were not similarly affected.

NTP concluded from these data that 1,4 - DCB was carcinogenic to male rats, but not female rats. In addition, NTP concluded that the increased incidence of hepatocellular adenomas and carcinomas was evidence of carcinogenicity in male and female mice.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The study by NTP (1987) was chosen by CDHS (1988) as the key study for the development of a cancer potency value for 1,4-DCB. In the NTP (1987) study, mice and rats exhibited significant increases in several types of tumors. The mice were exposed for 5 days/week, resulting in average daily doses of 0, 214, and 428 mg/kg/day 1,4-DCB. Mice of either sex exhibited a significant increase in hepatocellular carcinomas or adenomas. The incidence of hepatocarcinomas or adenomas was 17/50, 22/49, and 40/50 in the control, 214, and 428 mg/kg/day groups, respectively. In addition, male rats showed a significant increase in kidney adenomas and mononuclear cell leukemia. The cancer

potency for 1,4-DCB was calculated from the male mouse hepatocarcinoma and adenoma data.

Methodology

A linearized multistage procedure was used to estimate the cancer potency of 1,4-DCB from the NTP (1987) data in male B6C3F1 mice (Crump *et al*., 1982). The concentrations of 1,4-DCB given in the feed were 0, 214, or 428 mg/kg/day. The premature mortality of animals without tumors was subtracted from the sample groups. The 95% upper confidence bound on the dose-response slope was used to derive the human cancer potency value.

The animal cancer potency, q_{animal}, was calculated from the linear slope using the lifetime scaling factor $q_{animal} = q_1^* \times (T/T_e)^3$, where T/T_e is the ratio of the experimental duration to the lifetime of the animal. In this case, the scaling factor was equal to 1. An estimated value for the human cancer potency was determined using the relationship $q_{human} = q_{animal} \times (bw_h/bw_a)^{1/3}$, where bw is the default body weight of human or animal (mouse).

Using these relationships, a human cancer potency (q_{human}) of 0.04 $[mg/kg\text{-}day]^{-1}$ was calculated (CDHS, 1988). An airborne unit risk factor of 1.1E-5 $(\mu g/m^3)^{-1}$ was calculated by OEHHA/ATES from the q_{human} value using the default parameters of 70 kg human body weight and 20 m^3/day breathing rate.

[Calculated from a cancer potency factor derived by RCHAS/OEHHA (CDHS, 1988)]

III. CARCINOGENIC EFFECTS

Human Studies

The body of literature addressing the carcinogenicity of 3,3'-dichlorobenzidine in humans is scant. Three retrospective epidemiological studies of occupational exposure have been conducted, focusing on the possibility that 3,3'-dichlorobenzidine is a bladder carcinogen like its parent compound, benzidine. None of the studies approximates exposure levels.

Gerarde and Gerarde (1974) conducted a study of 175 workers involved in the manufacture and use of dichlorobenzidine in a chemical manufacturing plant in the United States between 1938 and 1957. Workers were segregated from benzidine exposure. No bladder tumors were found among the exposed workers. General population incidence of bladder tumors predicts 0-2 cases in a cohort of this size.

Gadian (1975) conducted a study of 35 British workers exposed to dichlorobenzidine who had been segregated from exposure to benzidine in a chemical plant from 1953 to 1973. Cumulative hours of exposure were tabulated for all workers. No tumors were reported among the exposed workers at the end of the study (through 1973).

MacIntyre (1975) reports on bladder tumor incidence among 225 Scottish production and service workers, 119 of which had more than 5 years of exposure to dichlorobenzidine and 36 of which were exposed more than 16 years before the time of the study. No bladder tumors were reported among the study subjects.

Animal Studies

Stula *et al.* (1975) conducted a study on ChR-CD rats (50/sex/group), exposing animals to 1000 ppm 3,3'-dichlorobenzidine in feed for life (mean survival 51 weeks), with an interim exposed group of 6 rats/group sacrificed after 12 months. Control animals receiving no added compound were observed for up to two years (mean survival 81 weeks (males) and 90 weeks (females)). Male animals showed statistically significant increases in incidences of granulocytic leukemias (9/44 treated vs. 2/44 control; $p < 0.05$ by Fisher's exact test), mammary adenocarcinomas (7/44 treated vs. 0/44 control; $p < 0.01$), and Zymbal gland carcinomas (8/44 treated vs. 0/44 control; $p < 0.01$). Female animals only showed increased incidence of mammary adenocarcinomas (26/44 treated vs. 3/44 control; $p < 0.01$).

Stula *et al.* (1978) later conducted a study on six female beagle dogs, administering 100 mg 3,3'-dichlorobenzidine in gelatin capsules 3 times/week for 6 weeks followed by 100 mg, 5 times/week for up to 7.1 years, plus 6 untreated control animals sacrificed at 8-9 years of age. One animal which died during the course of the study (3.5 years) showed no sign of tumors, whereas another animal which died at 6.6 years showed both undifferentiated liver carcinoma and papillary transitional cell carcinoma of the bladder. Among the animals surviving to the end of the study there was an increased incidence of hepatocellular carcinoma (3/4 treated vs. 0/6 control; $p < 0.05$) and papillary transitional cell carcinoma of the bladder (4/4 treated vs. 0/6 control; $p < 0.01$). Control animals showed a high incidence of adenocarcinoma and carcinoma of the mammary gland (4/6).

Pliss (1959) reports on carcinogenesis in Rappolovskii white rats exposed to 3,3'-dichlorobenzidine in feed for 12 months. The addition of 10-20 mg added to feed in the form of a paste (50% with water) 6 days/week resulted in an estimated total dose of 4.5 g/animal. A group of 130 animals receiving injections of octadecylamine and methylstearylamine were termed a "historical control". Twenty-two of 29 animals were examined for tumors at the time of the first tumor's appearance. Findings included tumors of Zymbal gland (7/29), mammary gland (7/29), skin (3/29), bladder (3/29), hematopoietic system (3/29), adenocarcinoma of the ileum (2/29), connective tissue (2/29), salivary gland (2/29), liver (1/29), and thyroid (1/29). No tumors were reported among "control" animals. Pliss (1959, 1963) also conducted studies exposing rats to 3,3'-dichlorobenzidine by the subcutaneous route. In the first study (Pliss, 1959), animals (25 female, 36 male) received 120 mg 3,3'-dichlorobenzidine weekly for 10-11 months. The dose was reduced to 20 mg/rat after the sixth month due to toxicity. The same "control"animals were used as with the feeding study. The author notes the appearance of tumors of the Zymbal gland (10/35), mammary gland (6/35), skin (5/35), hematopoietic system (2/35), connective tissue (2/35), salivary gland (1/35), and local subcutaneous sarcomas (7/35) among animals surviving to the time of the appearance of the first tumors.

Griswold *et al.* (1968) dosed 20 female Sprague-Dawley rats with 300 mg 3,3'-dichlorobenzidine in sesame oil by gavage (10 doses at three day intervals) and observed the animals after 9 months for incidence of mammary tumors. Control groups included a

negative control (sesame oil only) and a positive control (7,12-dimethylbenz[a]anthracene). No tumors were observed in treated animals, but a 3% incidence was observed in the negative controls and 100% incidence in positive control animals. Osanai *et al.* (1976) treated 26 male ICR/JCL mice (plus 39 untreated control mice) with feed containing 0.1% 3,3'-dichlorobenzidine for 12 months with an interim sacrifice group at 6 months. Hepatomas were observed in all treated animals at 6 and 12 months ($p < 0.01$) and among control animals at an incidence of 0%, 9.5% (2/21) and 38.55% (5/13) at 6,12, and 18 months, respectively.

Tatematse *et al.* (1977) fed 22 male Wistar rats a diet containing 0.3% 3,3'-dichlorobenzidine alone or in sequence with o-N-butyl-N-(4-hydroxybutyl)nitrosamine (0.1% in drinking water), N-[4-(5-nitro-2-furyl)-2-thiazolyl]formamide (0.15% in the diet) and N-fluorenylacetamide (0.025% in the drinking water) over a four week period. Twelve untreated animals served as controls. Animals were observed for a 40 week period. Only animals receiving combined exposures showed effects which included some bladder tumors and histological changes of the liver.

Saffiotti *et al.* (1967) and Sellakumar *et al.* (1969) report on a feeding study in which Syrian golden hamsters (30/sex/group) were exposed to 0.1% or 0.3% 3,3'-dichlorobenzidine in feed; an untreated control group (30/sex) was included. No significant carcinogenic effects were observed in the 0.1% 3,3'-dichlorobenzidine group. The 0.3% 3,3'-dichlorobenzidine group, however, showed increased incidence of transitional cell carcinomas of the bladder (4/30 treated, 0/30 control; $p = 0.056$ by Fisher's exact test). Other observations included some liver-cell and cholangiomatous tumors.

A single study suggests that 3,3'-dichlorobenzidine may act as a transplacental carcinogen (Golub *et al.*, 1974). Pregnant female BALB/c mice given 2 mg 3,3'-dichlorobenzidine (in 0.1 ml sesame oil) five times during the last week of pregnancy, showed increased incidence of lymphoid leukemia among the offspring of exposed animals (7/24 treated, 0/30 control; $p < 0.01$). This effect, however, could also have occurred by exposure via lactation.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

An IARC (1982) review of the human epidemiological studies deemed them inadequate for evaluating carcinogenicity due to the relatively small size of the cohorts, inadequate time since first exposure, and/or incomplete follow-up of exposed workers.

The only carcinogenesis studies amenable to the development of cancer potency values are those conducted by Stula *et al.* (1975, 1978) showing the induction of granulocytic leukemia, mammary adenocarcinoma, and Zymbal gland carcinoma in rats and papillary transitional cell carcinomas of the bladder and hepatocellular carcinomas in beagle dogs exposed to 3,3'-dichlorobenzidine. Limitations of the other available studies including

poor study design, inadequate scope of endpoints, and unclear interpretation of dose extrapolation, preclude the development of cancer potency values from these studies.

Methodology

The most sensitive experimentally determined endpoint for tumor development is mammary adenocarcinoma induction in female rats exposed to 3,3'-dichlorobenzidine (26/44 treated, 3/44 control) (Stula *et al*., 1975). A linearized multistage procedure (CDHS, 1985) applied to these data resulted in an estimation of the upper 95% confidence bound of cancer potency (q_1^*) of 0.023 $(mg/kg\text{-}day)^{-1}$. With a study duration of 49.9 weeks for females (T_e) and a natural lifespan assumption of 104 weeks (T), the cancer potency for animals (q_{animal}) was derived to be 0.21 $(mg/kg\text{-}day)^{-1}$ from the following relationship:

$$q_{animal} = q_1^* \times (T/T_e)^3$$

Human cancer potency (q_{human}) of 1.2 $(mg/kg\text{-}day)^{-1}$ based upon body weight assumptions of 0.35 kg for female rats (bw_a) and 70 kg for humans (bw_h) and the following relationship:

$$q_{human} = q_{animal} \times (bw_h/bw_a)^{1/3}$$

A unit risk value of 3.4 E-4 $(\mu g/m^3)^{-1}$ based upon air concentrations was derived by OEHHA/ATES assuming a human breathing rate of 20 m^3/day, a human body weight of 70 kg, and 100% fractional absorption after inhalation exposure.

III. CARCINOGENIC EFFECTS

Human Studies

No studies on the potential carcinogenic effects of 1,1-dichloroethane in humans are known to exist.

Animal Studies

Male and female Osborne-Mendel rats and $B6C3F_1$ mice were exposed to 1,1-dichloroethane dissolved in corn oil by gavage (NCI, 1977). The study design is summarized in Tables 1a and 1b. Dosing was performed once/day, 5 days/week. Dosing of the low- and high-dose mouse treatment groups was performed cyclically in the latter part of the experimental period; one exposure-free week was followed by 4 weeks of exposure.

Dose-related increases were noted in mammary adenocarcinomas and hemangiosarcomas in female rats. Statistically significant increases were observed in endometrial stromal polyps in high-dose female mice (4/46 compared to 0/79 for controls, $p = 0.017$) and in hepatocellular carcinomas in high-dose male mice (8/32 compared to 6/72 in pooled vehicle controls, $p = 0.027$). Female rat tumor incidence data is listed in Table 2.

Klaunig *et al*. (1986) exposed male $B6C3F_1$ mice to 1,1-dichloroethane in drinking water for 52 weeks. Exposure levels were 0, 835 and 2500 mg/l. Group sizes were 35 mice/group; 10 mice/group were killed after 24 weeks. Histology was only performed on kidney, liver and lung samples. No treatment-related increase in tumor incidence was

noted. However, histological examination was only performed on a limited number of tissues, and only male mice were used.

Table 1a. Study design for carcinogenicity bioassay of 1,1-dichloroethane (1,1-DCE): Osborne-Mendel rats (NCI, 1977)

Sex	Group	Group Size	1,1-DCE dose (mg/kg bw)	Observation period (weeks)		Time-weighted average dosage[1] (78 weeks)

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Gold *et al.* (1984) list the results of the NCI (1977) gavage studies in male and female $B6C3F_1$ mice and Osborne Mendel rats. Cancer potency for 1, 1-dichloroethane is based on mammary gland adenocarcinomas observed in female rats, the most sensitive of the species/sex combinations tested (see Table 2). Because female rat survival was poor in this study, the potency was derived using a time-to-tumor analysis (Crump *et al.*, 1991; Cal/EPA, 1992).

Methodology

Expedited Proposition 65 methodology (with cross-route extrapolation) was used to derive a cancer potency factor. A unit risk factor was then calculated by OEHHA/ATES from the cancer potency factor using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

[Calculated from a cancer potency value derived for a Proposed Maximum Contaminant Level (CDHS, 1988)]

III. CARCINOGENIC EFFECTS

Human Studies

Thiess *et al.* (1978; reviewed by US EPA, 1994) report on a study of mortality among 221 workers involved in di-(2-ethylhexyl)phthalate (DEHP) production. Potential exposure periods range from 3 months to 24 years and the mean follow-up period was 11.5 years. Among workers exposed for more than 15 years, incidences of pancreatic carcinoma (1 case) and uremia (1 case with urethral and bladder papillomas) were elevated over incidence in the corresponding age group of the general population. No quantitation of exposure levels was reported.

Animal Studies

The National Toxicology Program (NTP, 1982; Kluwe *et al.,*1982) assayed the carcinogenic effects of di-(2-ethylhexyl)phthalate on rats and mice. Fischer F344 rats (50/sex/group) were treated with diet containing 0, 6000, or 12000 ppm DEHP for 103 weeks. $B6C3F_1$ mice (50/sex/group) were treated with diet containing 0, 3000, or 6000 ppm DEHP for 103 weeks. Survivors were sacrificed and examined histologically at 105 weeks. Survival of rats was not found to be significantly influenced by DEHP treatment. Increased incidence of hepatocellular carcinoma or hepatic neoplastic nodules was reported in male and female high-dose treated rats (see Table 1). The increase in incidence was found to be dose-related ($p < 0.01$). Among treated high-dose male and female mice, and

low-dose female mice, hepatocellular carcinoma incidence was increased. The increase in incidence was found to be dose-related ($p < 0.05$).

Table 1. Incidence of hepatocellular carcinoma in male and female $B6C3F_1$ mice and F344 rats fed diet containing DEHP (NTP, 1982).

	3,000	14/48	7/50[3]
	6,000	19/50[2]	17/50[4]

[1] Fischer F344 rats were treated with 0, 6000, or 12000 ppm DEHP in their diet for 103 weeks. $B6C3F_1$ mice were treated with 0, 3000, or 6000 ppm DEHP in their diet for 103 weeks. Survivors were sacrificed after 105 weeks.
[2] $p < 0.05$. [3] $p < 0.01$. [4] $p < 0.001$.

Carpenter *et al.* (1953) maintained 2 month old Sherman rats (32/sex/group) on a diet containing 0, 400, 1300, or 4000 ppm DEHP up to two years. Animals were sacrificed at one year with the exception of a subgroup of a maximum of 8 rats/sex/dose which were exposed for an additional year. A group of 80 F_1 generation rats, the progeny of females in the highest dose group exposed for more than 120 days, were exposed for one year to diet containing 4000 ppm DEHP. Survivors were sacrificed after one year. No malignant tumors were observed among treated animals. Three rats in the 4000 ppm DEHP dose group, four in the 1300 dose group, two in the 400 ppm dose group, and five in the control group were reported to have benign tumors. Two benign tumors in the treated F_1 rats (vs. one in the control group) had benign tumors. Mortality at two years was reported to be 70.3% among control animals and between 60 and 70% among the treated groups. Poor survival of animals precluded evaluation of carcinogenicity from this study.

Carpenter *et al.* (1953) also treated hybrid guinea pigs (~23/sex/dose) with diet containing 0, 1300, or 4000 ppm DEHP for 1 year, at which time animals were sacrificed. Survival among exposed animals was decreased. No carcinogenic effects were observed.

Carpenter *et al.* (1953) also treated 4 dogs with gelatin capsules containing a volume of 0.03 ml/kg body weight DEHP five days per week for 19 doses, then with 0.06 ml/kg body weight DEHP for 240 doses. Four control animals were also included in the study. No tumors were observed in treated or control animals.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The only data appropriate for the development of a cancer potency value come from the NTP (1982) study which showed a dose-related effect of DEHP on the incidence of hepatocellular carcinoma in Fischer 344 rats and $B6C3F_1$ mice. This study was conducted by standard protocols with an adequate number of animals and thorough reporting of results.

Methodology

For the purpose of developing a cancer potency in humans, US EPA (1986, 1987) converted the exposure levels of rats and mice in the NTP (1982) study to human equivalent doses (HEDs). Dosage levels were first converted from parts per million in the diet to mg/kg-day based upon reported food disappearance rates. The resulting daily low and high dose estimates were 322 and 674 mg/kg-day for male rats, 394 and 774 mg/kg-day for female rats, 672 and 1325 mg/kg-day for male mice, and 799 and 1821 mg/kg-day for female mice. HEDs were based on the following relationship, with D the applied dose level, bw_a the experimental animal body weight, bw_h the assumed human body weight, l_e the length of exposure, L_e the length of the study, and L the lifespan of the animal:

$$HED = D \times \frac{l_e}{L_e} \times \left(\frac{bw_a}{bw_h}\right)^{\frac{1}{3}} \times \left(\frac{L_e}{L}\right)^3$$

Using the derived HED values, US EPA (1987) applied the multistage procedure of Howe and Crump (Global 82; 1982) to the combined incidence data of hepatocellular carcinomas and neoplastic nodules reported by NTP (1982). The resulting upper 95% confidence bounds on the cancer potency (q_{human}) are presented in Table 2. The highest, and thus most sensitive, cancer potency value is derived from the incidence of hepatocellular carcinomas in male $B6C3F_1$ mice, with a q_{human} value of 8.4 E-3 $(mg/kg\text{-}day)^{-1}$. Selection of the cancer potency value for DEHP comes from the most sensitive site and species of tumor induction in experimental animals in the absence of human data appropriate for developing a potency value.

Table 2. Human cancer potency values derived by US EPA (1986, 1987) from the NTP (1982) study.

species	sex	q_{human} $[(mg/kg\text{-}day)^{-1}]$
F344 rats	male	2.95 E-3
	female	3.52 E-3
$B6C3F_1$ mice	male	8.36 E-3
	female	4.73 E-3

A unit risk value of 2.4 E-6 $(\mu g/m^3)^{-1}$ was derived by OEHHA/ATES assuming a 70 kg average human body weight, 20 m^3/day human breathing rate, and 100% fractional absorption.

Slope Factor: 4.6 E+0 $(mg/kg\text{-}day)^{-1}$
[Female rat liver tumor data (Kirby and Peacock, 1947), contained in Gold *et al.* database (1984), expedited Proposition 65 methodology (Cal/EPA, 1992), cross-route extrapolation.]

III. CARCINOGENIC EFFECTS

Human Studies

No studies on the potential carcinogenic effects of *p*-dimethylaminoazobenzene (DAB) in humans are known to exist.

Animal Studies

IARC (1974) reviewed a number of studies on the carcinogenic potential of DAB in animals. DAB was initially reported by Kinosita (1937) to induce liver tumors in rats after dietary exposure; tumors were produced after 50 or more days of treatment (smallest total dose, 176 mg DAB). Sherman, Wistar and Evans rats were found to be equally susceptible to the induction of liver tumors after exposure to diets containing 600 mg/kg DAB (Sugiura and Rhoads, 1941).

Kirby and Peacock (1947) exposed male and female Wistar-derived rats to a low-protein diet (12% casein) containing 0 or 600 mg/kg diet DAB. Group sizes were 8 animals/sex/group except for treated females, where the group consisted of 7 animals. Four male rats received treated diet for 28 weeks, followed by control diet; the other animals received treated diet for 33 weeks. At the end of the treatment period, all animals received control diet until sacrifice at 52 weeks. Both male and female rats developed hepatomas; Gold *et al.* (1984) list a tumor incidence of 0/8 and 5/7 for control and treated (average dose, 20.9 mg/kg-day) females, respectively.

Druckrey and Küpfmüller (1948; reviewed by IARC, 1975) exposed rats to 1, 3, 10, 20 or 30 mg DAB/day by gavage for the life of the animals. All doses induced the formation of liver tumors; the induction time was inversely proportional to the dose, ranging from 34 days (30 mg/day) to 700 days (1 mg/day). For exposure groups in the 3-30 mg/day range, the total carcinogenic dose was about 1000 mg. Daily exposures of 0.1 or 0.3 mg/rat did not induce tumors.

Druckrey (1967) exposed rats to 5 mg DAB/rat by gavage for 40, 60, 100, 140 or 200 days, then observed the animals for the remainder of their lifespan. Percent incidences of liver carcinomas were 20, 26, 49, 80 and 81, respectively.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The feeding study by Kirby and Peacock (1947) conducted in Wistar-derived albino rats is listed in Gold *et al*. (1984). Cancer potency is based on liver tumors in the female rats.

Methodology

Expedited Proposition 65 methodology (with cross-route extrapolation) was used to derive a cancer potency factor. A unit risk factor was then calculated by OEHHA/ATES from the cancer potency factor using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

Unit Risk Factor: 8.9 E-5 $(\mu g/m^3)^{-1}$
Slope Factor: 3.1 E-1 $(mg/kg\text{-}day)^{-1}$
[calculated from a potency factor derived by US EPA (1987) and adopted by CDHS (see Final Statement of Reasons)]

III. CARCINOGENIC EFFECTS

Human Studies

No data are available addressing the carcinogenicity of 2,4-dinitrotoluene (2,4-DNT) in humans.

Animal Studies

Lee *et al.* (1978) exposed male and female CD rats to practical grade 2,4-DNT in feed at concentrations of 0, 15, 100, and 700 ppm for 720 days. Animals were sacrificed at 750 days. Decreased weight gain and lifespan were observed among animals in the highest treatment group. Noncancer toxic effects observed included toxic anemia and aspermatogenesis. Tumors observed included fibromas of the connective tissue of male rats and fibroadenoma of the mammary gland of female rats. The incidence data for liver and mammary tumors in female rats are presented in Table 1. Significantly increased incidence was found in the highest dose group for liver tumors ($p = 4 \times 10^{-4}$; Fisher's exact test), mammary gland tumors ($p = 1.75 \times 10^{-4}$), and combined mammary gland and liver tumors ($p = 7 \times 10^{-5}$). Mammary tumor incidence among male rats was 1/37, 0/37, 0/29, and 17/23 in the 0, 15, 100, and 700 ppm 2,4-DNT dose groups, respectively. Only the highest dose group showed significantly increased tumor incidence ($p = 4 \times 10^{-9}$).

Table 1. Incidence of liver and mammary gland tumors among female CD rats exposed to practical grade 2,4-dinitrotoluene (2,4-DNT) in feed for 24 months (Lee *et al.*, 1978).

treatment level (ppm)	tumor incidence liver[1]	mammary gland[2]	combined
0	0/31	11/31	11/31
15	3/43	12/43	13/43
100	3/35	18/35	18/35
700	30/42	34/43	35/43

[1] Tumor incidence includes neoplastic nodules and hepatocellular carcinoma of the liver.
[2] Tumor incidence includes adenoma, fibroadenoma, fibroma, or adenocarcinoma of the mammary gland.

The National Cancer Institute (NCI, 1978) conducted a study exposing Fischer rats and $B6C3F_1$ mice to practical-grade 2,4-DNT (>95% pure). Male and female Fischer rats (50/sex/group) were exposed to feed containing 0.02% or 0.008% 2,4-DNT (time-weighted concentrations). Control groups consisted of 25 rats/sex for the high-dose group and 50 rats/sex for the low-dose group. The treatment period was 78 weeks long and the observation period continued for 26 weeks. Among treated male rats in both high- and low-dose groups, the incidence of benign fibroma of the skin and subcutaneous tissue was increased over controls (high-dose: 13/49 treated vs. 0/25 control, $p = 0.003$; low-dose: 7/49 treated vs. 0/46 control, $p = 0.008$ by Fisher's exact test). Among treated female rats in the high-dose group, the incidence of fibroadenoma of the mammary gland was increased over control animals (23/50 treated vs. 4/23 control, $p = 0.016$).

In the same study (NCI, 1978), male and female $B6C3F_1$ mice (50/sex/group) were treated with diet containing 0.04% or 0.008% 2,4-DNT (time-weighted concentrations). Groups of 50 mice/sex served as controls for the high- and low-dose groups. The treatment period lasted 78 weeks and the animals were observed for an additional 13 weeks. No significant increase in tumor incidence was observed among treated animals.

Ellis *et al.* (1979) (also reported by Lee *et al.,*1985) exposed male and female CD (Sprague-Dawley) rats (38/sex/group) to 0, 15, 100, or 700 ppm 2,4-DNT in feed. At 12 months, 8 rats/group were sacrificed for necropsy; the remainder were sacrificed at 24 months. Cumulative deaths during the course of the study ranged from 55 to 100% in male rats and 60 to 97% in female rats, including control animals. Histopathological outcomes of animals that died during the course of the experiment (but after 52 weeks) were included in the final incidence data along with the incidence data among survivors. Tumors showing statistically significant increases ($p < 0.05$ by Fisher's exact test) were hepatocellular carcinomas and mammary gland tumors among female rats in the highest dose group. Hepatocellular carcinomas were reported in 18/34 treated high-dose female rats vs. 0/23 control rats ($p = 4.3 \times 10^{-6}$). Mammary gland tumors, including both benign and malignant tumors of epithelial or mesenchymal origin, were reported in 33/35 treated high-dose female rats vs. 11/23 control rats ($p < 0.0001$).

Ellis *et al.*(1979) (also reported by Hong *et al.,* 1985) exposed male and female CD-1 mice (38/sex/group) to 0, 100, 700, or 5000 ppm 2,4-DNT in feed as described in the rat study above. Since over 70% of the mice in the highest dose group died before 12 months, these animals were not included in the analysis. Mortality among the remaining dose groups and controls ranged from 70 to 85%. Tumor incidence data were drawn from animals surviving at least 12 months. A significantly increased incidence of renal tumors was found among male mice in the 700 ppm 2,4-DNT dose group (19/28 treated vs. 0/33 control; $p = 1.32 \times 10^{-9}$, Fisher's exact test). Renal tumor types included cystic papillary adenomas, solid renal cell carcinomas, and cystic papillary carcinomas. No significantly increased tumor incidence was reported among female mice.

Ellis *et al.* (1979, 1985) treated beagle dogs (6/sex/group) with 2,4-DNT in gelatin capsules daily for 2 years at dose rates of 0, 0.2, 1.5, or 10 mg/kg body weight. The highest dose was lethal to five of the 12 treated animals. Throrough examination of all animals upon sacrifice showed no evidence of carcinogenicity of 2,4-DNT.

The Chemical Industry Institute of Toxicology (CIIT, 1982) exposed male and female F344 rats (130/sex/dose) to technical grade DNT (76% 2,4-DNT and 19% 2,6-DNT) feed such that daily dosing was 0, 3.5, 10.0, and 35.0 mg/kg-day. The entire high-dose group was sacrificed at 55 weeks due to significantly reduced survival. Twenty rats (/sex) were examined histopathologically at this time. The animals in the remaining dose groups were sacrificed at the scheduled time of 104 weeks. The incidences of hepatocellular carcinoma and neoplastic nodules of the liver are reported in Table 1. Cholangiocarcinomas were also reported in 3/20 high-dose male rats (at 55 weeks) and 2/23 mid-dose male rats (at 104 weeks).

Table 1. Tumor incidence in male and female F344 rats exposed to technical grade dinitrotoluene (DNT) in feed (CIIT, 1982).

tumor type	males (mg/kg-day)				females (mg/kg-day)			
	0	3.5	10.0	35.0*	0	3.5	10.0	35.0*
hepatocellular carcinoma	1/61	9/70	22/23	20/20	0/57	0/61	40/68	11/20
neoplastic nodules	9/61	11/70	16/23	5/20	5/57	12/61	53/68	12/20

*All the high-dose group animals were sacrificed at 55 weeks due to significantly reduced survival. Histopathological examinations were performed on 20 rats/sex.

Leonard *et al.* (1987) exposed 20 male CDF(F344)/CrlBR rats to 2,4-DNT in the diet for 12 months such that daily dose rate was 27 mg/kg-day. No evidence of carcinogenicity was found, however, the study was short in duration and the number of animals was small.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

The US EPA (1980) derived a cancer potency value based on the tumor incidence data in the study by Lee *et al.* (1978) showing the induction of liver and mammary tumors in female CD rats. This study was selected over the NCI (1978) study because of published reservations by NCI concerning the adequacy of the study for estimating cancer potency in humans.

Methodology

The US EPA (1980) calculated a "transformed" dose rate of 0, 0.71, 3.9, and 34.0 mg/kg-day for the animals in the study by Lee *et al.* (1978) exposed to 0, 15 100 and 700 ppm 2,4-DNT in their diet, respectively. A linearized multistage procedure was applied to the combined mammary gland and liver tumor incidence data presented in Table 1 in order to calculate an animal cancer potency value (q_{animal}). The calculated q_{animal} was 0.058 $(mg/kg\text{-}day)^{-1}$. The q_{animal} was converted to a human cancer potency (q_{humna}) based on the following relationship, where bw_{animal} is the assumed body weight for the test species (Lee *et al.*, 1978; bw_{animal} = 0.464 kg) and bw_{human} is the assumed human body weight (70 kg):

$$q_{human} = q_{animal} \times (bw_h/bw_a)^{1/3}$$

The resulting q_{human} is 0.31 $(mg/kg\text{-}day)^{-1}$.

A unit risk value based upon air concentrations was derived by OEHHA/ATES using an assumed human breathing rate of 20 m^3/day, 70 kg human body weight, and 100% fractional absorption after inhalation exposure. The calculated unit risk value is 8.9 E-5 $(\mu g/m^3)^{-1}$.

III. CARCINOGENIC EFFECTS

Human Studies

The two human epidemiological studies of the potential carcinogenicity of 1,4-dioxane (Thiess *et al*. (1976); Buffler *et al*. (1978)) did not show significant changes in the incidence of carcinogenicity. However, neither study had sufficient statistical power to detect moderate changes in cancer incidence due to the small size of the sample groups or the short duration of the studies.

In the study by Thiess *et al*. (1976), 74 German workers were exposed to various concentrations of 1,4-dioxane for an average of 24.9 years. Of the 74 workers, 24 were working at the end of the follow-up period (1964 - 1974), 23 were no longer working, 15 had retired, and 12 had died. Of the 12 deaths, two were attributed to neoplastic diseases (1 lamellar epithelial carcinoma and 1 myelofibrotic leukemia). The expected number of deaths during this period in the cohort was 14.5, based on Federal Republic of Germany mortality statistics. The overall death rate and the cancer death rate were not significantly increased over controls.

Buffler *et al*. (1978) studied the mortality of 165 workers exposed to 1,4-dioxane in a dioxane-manufacturing and processing facility in Texas. The employees were exposed to dioxane for at least 1-month up to 21 years (April, 1954 to June, 1975), and were divided into two cohorts. The cohort of manufacturing workers was composed of 100 individuals, and the processing workers numbered 65. The concentrations of dioxane in the workplaces were less than 25 ppm. Seven deaths occurred in the manufacturing cohort (4.9 expected), two from neoplasms (0.9 expected). Five deaths occurred in the processing cohort (4.9 expected), one from cancer (0.8 expected). These mortality and cancer rates were not

higher than the expected from Texas age- and sex-specific death rates for 1960-1969. Due to the small sample size and short exposure period of the study, the authors concluded that the negative results were not conclusive.

Animal Studies

Male Wistar rats (n = 26) were given drinking water containing 1% dioxane for 63 weeks (Argus *et al.*, 1965). A group of 9 rats given untreated water were used as controls. Six hepatomas, one kidney tumor, and one case of leukemia were found in the treated animals. One lymphosarcoma was found in the control group. The increased incidence of cancer in the treated animals was not statistically significant ($p < 0.05$). However, due to the small size of the control group, this study was of very limited sensitivity, and therefore inconclusive.

Another drinking water study in male rats was conducted by Hoch-Ligeti *et al*. (1969) and further reported on by Argus *et al*. (1973). In this study, male Charles River rats (30 per group) were given 0, 0.75, 1.0, 1.4, or 1.8% dioxane in their drinking water from 2-3 months of age for 13 months. Animals were killed 16 months following treatment or earlier if tumors in the nasal cavity were observed. Survival data was not reported. Nasal histological examinations were only performed on animals with grossly visible tumors. The incidence of tumors found in this study are presented in Table 1.

Table 1. Tumor incidence in male Charles River rats exposed to 1,4-dioxane in drinking water (Hoch-Ligeti *et al*., 1969; Argus *et al*., 1973).

	Tumor Incidence				
1,4-Dioxane Concentration (%)	0	0.75	1.0	1.4	1.8
Hepatocarcinomas	0/30	0/30	0/30	2/30	2/30
Nasal tumors	0/30	1/30	1/30	2/30	2/30
Hepatic tumors (total)	NR	4/30	8/30	16/30	25/30

NR = Not reported

Kociba *et al*. (1974) studied the effects of dioxane in the drinking water of male and female Sherman rats. Rats (60/sex/group) were exposed to 0, 0.01, 0.1, or 1.0% dioxane for 2 years. Actual dosages of dioxane were estimated using drinking water consumption and body weight data. The dosages were 0, 9, 94, or 1015 mg/kg/day for the males, and 0, 14, 148, or 1599 mg/kg/day in females. Because the tumor incidence data are averaged for the combined male and female responses, the doses were also averaged. Mortality in the combined high dose group was 45% after 1 year of exposure, compared with 12% in the control group. The tumor incidence data is summarized in Table 2.

King *et al*. (1975) exposed male and female B6C3F1 mice (50/sex/group) to dioxane in the drinking water for 40-43 weeks. Concentrations of dioxane used were 0, 0.5, or 1.0 %. No tumors were observed in any group at the end of the treatment period. According to IARC

(1976), the duration of this study was insufficient to detect hepatocarcinoma, the tumor most commonly found in the National Cancer Institute (NCI, 1978) study.

Table 2. Tumor incidence in male and female Sherman rats exposed to dioxane in drinking water (Kociba *et al*., 1974).

	Tumor Incidence			
1,4-Dioxane Concentration (%)	0	0.01	0.1	1.0
Hepatocarcinomas	1/120	0/120	1/120	10/120
Nasal tumors	0/120	NR	NR	3/120

NR = Not reported

The NCI conducted a bioassay on male and female $B6C3F_1$ mice (50/sex/group) given 0, 0.5, or 1.0% dioxane in the drinking water from 5 weeks to 90 weeks (NCI, 1978). Mortality of the male rats was only 10% in the male mice after 91 weeks. Mortality in the female mice increased with increasing dose, up to 44% in the high dose group. Tumor incidence data from this study is presented in Table 3. The incidence of hepatocarcinomas was significantly increased in both the male and female mice exposed to the low and high concentrations of dioxane, compared with controls.

Table 3. Tumor incidence in male and female $B6C3F_1$ mice exposed to 1,4-dioxane in the drinking water (NCI, 1978).

	Tumor Incidence		
1,4-dioxane Concentration	0	0.5	1.0
Hepatocarcinomas (males)	2/49	18/50	24/47
Hepatocarcinomas (females)	0/50	12/48	29/37

In addition to the mouse study. the National Cancer Institute (1978) also exposed male and female Osborne-Mendel rats to 0, 0.1, or 1.0 % dioxane in their drinking water for 110 or 90 weeks, respectively. The incidences of nasal tumors in these groups were 0/33, 12/33, and 16/33 in the males, and 0/34, 10/35, and 8/35 in the females.

Male guinea pigs (20/group) were exposed to 0 or 0.5-2.0% dioxane in the drinking water for 23 months. After 28 months, the animals were killed and tumor incidence was recorded. Tumor incidences in the treated animals included 3 animals with hepatomas, 2 with gall bladder carcinomas, and one with adenoma of the kidney. Tumors were not found in the controls (n = 10). Although the cancer incidences were not significantly different from the controls, IARC (1976) concluded that dioxane caused liver and gall bladder tumors.

In an inhalation study, Torkelson *et al*. (1974) exposed groups of 288 male or female Wistar rats to 111 ppm 1,4-dioxane for 7 hours/day, 5 days/week, for 2 years. Control rats (192

male or female rats) were exposed to filtered room air. Weight gain among males and females was not affected by dioxane treatment compared with controls. Survival rates were not significantly different between control and treated rats. Similarly, the tumor incidence was not significantly different with dioxane treatment. The estimated equivalent dose rate from the inhalation study was 100 mg/kg/day, based on default values for rat body weight and breathing rate. This estimated dose is much lower than that used in the drinking water studies described above.

Male and female Swiss-Webster mice (30/sex/group) were exposed dermally to an unspecified concentration of dioxane in acetone 3 times/week (King *et al*., 1975). Dioxane was tested either as a complete carcinogen for 60 weeks, or as a promoter, following a single exposure to DMBA followed by 59-week exposure to dioxane. Control mice were treated with the acetone vehicle alone or with DMBA. Dioxane was a significant promoter of skin carcinomas compared to controls treated with DMBA only. However, no significant increase in skin papillomas or carcinomas was observed in the test for complete carcinogenicity.

The tumor-intitiating properties of dioxane were investigated using the tumor promoter 12-O-tetradecanoylphorbol-13-acetate (TPA) in Sencar mice (40 females/group) (Bull *et al*., 1986). Mice were exposed to a single oral, topical, or subcutaneous dose of 1,000 mg/kg dioxane, followed by TPA in acetone 3 times per week for up to 52 weeks. No significant increase in skin tumor incidence was reported in the mice, however, tumor incidence was not reported and length of observation was not specified.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Five studies (Argus *et al*., 1965; Hoch-Ligeti *et al*., 1969; Argus *et al*., 1973; Kociba *et al*., 1974; and NCI, 1978) allow the estimation of cancer potency values for dioxane. Of these studies, only the Kociba *et al*. (1974) and NCI (1978) studies were considered for the determination of the cancer potency factor for dioxane.

In the Argus *et al*. (1965) study, 26 adult male Wistar rats were given drinking water containing 1% dioxane for 63 weeks. The estimated dose of dioxane by the authors was 300 mg/day. The incidence of liver hepatomas (6/26) in the treated animals was significantly higher than in untreated control animals (0/9) but not significantly different from historical control animals. The cancer incidence in the treated animals is considered biologically significant, but is not quantitatively suitable for use as the basis of a cancer potency factor for dioxane.

The Hoch-Ligeti *et al*. (1969) and Argus *et al*. (1973) study failed to demonstrate significant differences in tumor incidences between treated and control rats. The trend for increasing tumors was marginally signficant ($p < 0.07$). When analyzed, these data yield a human cancer potency factor of 2.0×10^3 to 5.8×10^3 $(mg/kg\text{-}day)^{-1}$.

In the Kociba *et al.* (1974) study, 60 male and female Sherman rats were exposed to concentrations of dioxane of 0, 0.01, 0.1, and 1.0 % for 716 days. The tumor incidence for the combined male and female data set was 1/120, 0/120, 1/120, and 10/120. Using the multistage procedure and an interspecies scaling factor, an estimate for human cancer potency of dioxane was 5.7×10^{-4} $(mg/kg/day)^{-1}$. This dataset was not used since tumor incidences for males and females were averaged.

The National Cancer Institute (1978) exposed male and female Osborne-Mendel rats to 0, 0.1, or 1.0 % dioxane in their drinking water for 110 or 90 weeks, respectively. The incidence of nasal tumors were 0/33, 12/33, and 16/33 in the males, and 0/34, 10/35, and 8/35 in the females. From measured water consumption and body weight data, the human cancer potency from a multistage polynomial fit of these data was 9.5×10^{-3} $(mg/kg/day)^{-1}$ from male rat data, and 4.9×10^{-3} $(mg/kg/day)^{-1}$ from female rat data. An adjustment for early mortality following the procedure of EPA (1988) yielded cancer potencies of 1.1×10^{-2} $(mg/kg/day)^{-1}$ and 6.0×10^{-3} $(mg/kg/day)^{-1}$ from male and female rat data, respectively. The NCI (1978) study using B6C3F1 mice was used as the basis for the cancer potency for dioxane. This study contained the best data on the most sensitive species and sex, and the most sensitive target tissue. In this study, 50 male or female mice were exposed to 0, 0.5, or 1.0% dioxane for 90 weeks. Average doses were determined from weekly measurements of water consumption. The estimated doses were 0, 720, and 830 mg/kg/day for the males and 0, 380, and 860 mg/kg/day for the females. The incidence of hepatocarcinomas were 2/49, 18/50, and 24/47 for males, and 0/50, 12/48, and 29/37 for the females. The incidence of hepatocarcinomas or adenomas were 8/49, 19/50, and 28/47 in males, and 0/50, 21/48, and 35/37 in females.

Methodology

A linearized multistage procedure (CDHS, 1985) was applied to the female mouse combined hepatocellular carcinoma and adenoma incidence from the NCI (1978) study. The animal cancer potencies were 8.3×10^{-4} and 1.4×10^{-3} $(mg/kg/day)^{-1}$, for the males and females, respectively. The animal cancer potency, q_{animal}, was calculated from the linear slope using the lifetime scaling factor $q_{animal} = q_1^* \times (T/T_e)^3$, where T/T_e is the ratio of the experimental duration to the lifetime of the animal. The animal cancer potencies were therefore adjusted for the short duration of the experiment, using the factor $(104/90)^3$. A value for the human cancer potency was determined using the relationship $q_{human} = q_{animal} \times (bw_h/bw_a)^{1/3}$, where bw is the default body weight of human or animal (mouse). Body weights for interspecies scaling were assumed to be 0.04 and 0.035 kg for males and females, respectively. The combined incidence of hepatocarcinomas and adenomas in males and females gave human cancer potencies of 1.5×10^{-2}, and 2.7×10^{-2} $(mg/kg/day)^{-1}$, respectively. The combined incidence of hepatocarcinomas and adenomas in females was used to derive the human cancer potency for dioxane of 2.7×10^{-2} $(mg/kg/day)^{-1}$. The airborne unit risk factor for dioxane of 7.7 E-6 $(\mu g/m^3)^{-1}$ was calculated by OEHHA/ATES assuming a human body weight of 70 kg and an inhalation rate of 20 m^3/day.

III. CARCINOGENIC EFFECTS

Human Studies

A retrospective cohort mortality study of 533 white male Dow Chemical Company employees with potential epichlorohydrin (ECH) exposure for at least 1 month between October 1957 and November 1976 was performed by Shellenberger *et al*. (1979; reviewed by US EPA, 1984). Two cancer deaths were observed; this was less than the number expected (3.5) for the entire group. However, in a review of this study, US EPA (1984) pointed out that this study is inadequate for ECH carcinogenicity evaluation because of low exposures, short exposure duration, a short study period and the very young age of the cohort.

Enterline (1978, 1981; reviewed by US EPA, 1984) conducted a retrospective cohort mortality study of epichlorohydrin workers for Shell Oil Company. The cohort consisted of 864 workers at Shell plants in Louisiana and Texas; deaths were compared by cause with expected deaths in Louisiana and Texas, respectively. Study data were analyzed by vital status as of December 31, 1977 and as of December 31, 1979 (reported by Enterline in 1978 and 1981, respectively) for the cohort exposed to ECH for at least 3 months before January 1, 1966. Overall mortality in the ECH-exposed group was not increased compared to controls; a non-statistically significant increase in respiratory cancer and leukemias was reported (standardized mortality ratios (SMRs) of 146.2 and 224.7, respectively). Additionally, the data reported in 1978 indicated an apparent increase with increasing latent period since 11 of 12 of the respiratory cancer or leukemia deaths occurred in workers 15 or more years after first exposure. The possibility existed that increasing observation time would reveal more respiratory cancer/leukemia deaths. However, the 1981 report (Enterline, 1981) including the most recent data indicated that the SMRs for both

respiratory cancer and leukemia in the ECH-exposed group decreased, especially for those with greater than 15 years since first exposure. US EPA (1984) also noted that smoking was a potential confounder, exposure analysis failed to show a dose-response trend, and exposure to multiple chemicals was also a potential confounder. The SMR for respiratory cancer was much higher in workers exposed in the isopropyl alcohol manufacturing unit to other chemicals in addition to ECH than in the group exposed to ECH alone (SMRs = 214.8 and 63.3, respectively). US EPA (1984) concluded that the studies by Enterline (1978, 1981) provide only limited evidence for the human carcinogenicity of ECH.

Tassignon *et al*. (1983) studied the mortality of workers exposed to ECH in four European manufacturing plants which produced ECH, epoxy resins, glycerin and other ECH-derived specialty chemicals. Data was collected on 606 male workers with at least one year of exposure to ECH starting at least 10 years before December 31, 1978. No excess cancer mortality due to ECH exposure was observed; however, the authors noted that the small cohort size, short duration of the observation period and the limited number of deaths due to low average age (42 years) limited the power of the study.

Animal Studies

Female ICR/Ha Swiss mice were treated with ECH by dermal application, subcutaneous injection or intraperitoneal injection (Van Duuren *et al*., 1974). Dermal applications were performed 3 times/week; 2 mg ECH in 0.1 ml acetone was applied to 50 animals for 83 weeks. Untreated and vehicle control groups of 100 and 50 animals, respectively, were included. No increased incidence in skin tumors were noted in the treated animals. Intraperitoneal injections were performed weekly for 64 weeks; 1 mg ECH in 0.05 ml tricaprylin was injected into 30 animals. Untreated and vehicle control groups of 100 and 30 animals, respectively, were included. No treatment-related tumor induction was noted in the exposed animals. Subcutaneous injections were performed weekly for 83 weeks; 1 mg ECH dissolved in 0.05 ml tricaprylin was injected into 50 animals. Untreated and vehicle control groups of 100 and 50 animals, respectively, were included. An increased incidence of injection site tumors was noted (6/50 sarcomas, 1/50 adenocarcinomas) in the treated animals as compared to controls (no tumors in untreated controls, 1/50 sarcomas in vehicle controls).

Laskin *et al.* (1980) exposed male non-inbred Sprague-Dawley rats to 10, 30 or 100 ppm ECH by inhalation for the lifetime of the animals. Exposure durations were 6 hours/day, 5 days/week. Control groups consisted of 50 untreated animals and 100 air-treated animals. All groups demonstrated a high degree of early mortality, primarily due to respiratory disease (50% mortality by 64 weeks). Of a group of animals exposed to 100 ppm ECH for 6 weeks, 18/140 developed nasal cavity tumors, which were primarily squamous cell carcinomas. A group of 100 animals exposed for life (approximately 144 weeks) to 30 ppm developed 2 respiratory tract tumors; 1 larynx squamous papilloma and 1 nasal squamous cell carcinoma. The laryngeal tumor was misidentified in the original manuscript as a nasal tumor (US EPA, 1984). These tumor incidences were not significant when compared to those of the control group; however, they were significant when compared to the 1920 historical control animals from that laboratory, none of which had

developed nasal squamous carcinoma. No nasal or respiratory tract tumors were noted in a group of 100 animals exposed for life to 10 ppm. No equivalent nasal or respiratory tumors were noted in the control groups. CDHS (1988) noted that only 18%, 26% and approximately 50% of the animals in the 30 ppm, 10 ppm and 100 ppm dose groups, respectively, survived to mean time-to-tumor observed in the 100 ppm group (86 weeks).

Konishi *et al*. (1980) exposed male Wistar rats (18/group) to epichlorohydrin in drinking water at concentrations of 0, 375, 750 or 1500 ppm for up to 81 weeks; treatment was intermittently suspended between 60 and 81 weeks for all three epichlorohydrin treatment groups due to toxicity. Total dose for the 375, 750 and 1500 ppm treatment groups was 5.0, 8.9 and 15.1 g/animal, respectively. A dose-related increase in forestomach tumor (papillomas and squamous cell carcinomas) incidence was observed. Tumor incidence data is listed in Table 1.

Table 1: Incidence of forestomach tumors in male Wistar rats exposed to epichlorohydrin in drinking water (Konishi *et al*., 1980)

Concentration (ppm)	Calculated dose[1] (mg/kg-day)	Tumor incidence	
		papillomas	squamous cell carcinomas
0	0	0/10	0/10
375	15.1	0/9	0/9
750	31.9	1/10	1/10
1500	76.1	7/12	2/10

1. As listed in CDHS (1988).

Male and female ICR/HA Swiss mice (50/sex/group) were exposed to pure (99.9%) trichlorethylene (TCE), industrial grade (99.4%) TCE, or TCE containing 0.8% ECH, 0.8% 1,2-epoxybutane, or 0.8% ECH and 0.8% 1,2-epoxybutane by gavage for 104 weeks (Henschler *et al*., 1984). Corn oil vehicle control groups were included. Initial dosing provided TCE exposures of 2400 mg/kg/day^{-1} and 1800 mg/kg/day^{-1} for male and female mice, respectively. Because of toxicity, dosing was halted for all groups during weeks 35-40, 65 and 69-78. All doses were reduced by a factor of 2 at week 40. Mortality was significantly increased compared to controls in all male treatment groups, and in female treatment groups receiving pure TCE and TCE/ECH. Significant increases in the incidence of squamous cell carcinomas of the forestomach were observed in both male and female animals exposed to TCE/ECH. The tumor incidence in animals exposed to pure TCE was comparable to control values. Tumor incidence data is listed in Table 2.

Male and female Wistar rats (50/sex/group) were exposed to 0, 2 or 10 mg/kg body weight epichlorohydrin by gavage 5 times/week for 2 years (Wester *et al*., 1985). Intestinal obstruction by trichobezoars (hairballs) resulted in intercurrent mortality after 4 months. Cumulative incidences for control, low-dose and high-dose animals, respectively, were 8, 16 and 19 for females, and 1, 0 and 5 for males. The study diet formulation was changed at 4 months; this resulted in decreased mortality from this cause for the remainder of the

study. The percentage of surviving animals after 1 and 2 years of treatment is listed in Table 3.

Table 2. Epichlorohydrin-induced forestomach tumor incidence in male and female Swiss mice (Henschler *et al*., 1984)

Treatment group	Tumor incidence[1]	
	males	females
vehicle controls	1/50	1/50
pure trichloroethylene	1/50	0/50
pure trichloroethylene + 0.8% epichlorohydrin	8/50	12/50

1. Papilloma and squamous cell carcinoma incidences combined.

Table 3. Survival of male and female Wistar rats exposed to epichlorohydrin by gavage (Wester *et al*., 1985)

Dose level (mg/kg body weight)	% survival after 1 year of treatment		% survival after 2 years of treatment	
	males	females	males	females
0	98	80	76	62
2	94	62	62	40
10	90	62	58	44

Treatment-related increases in the incidence of forestomach tumors (papillomas and squamous cell carcinomas) were observed in both male and female animals. Tumor incidence data is listed in Table 4.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Cancer potency values are based on the most sensitive site, species and study demonstrating carcinogenicity of a particular chemical, unless other evidence indicates that a value derived from that data set would not be appropriate (CDHS, 1985). Several studies describe ECH-induced tumor incidence data which can be used to generate a cancer potency factor (male Wistar rat forestomach papilloma and squamous cell carcinoma data, Konishi *et al*. (1980); male Sprague-Dawley rat nasal tumor data, Laskin *et al.* (1980); male and female ICR/HA Swiss mouse forestomach squamous cell carcinoma data, Henschler *et al.* (1984); male and female Wistar rat papilloma and squamous cell carcinoma data, Wester *et al.* (1985). The data from the study by Konishi *et al*. (1980) was chosen by CDHS (1988) as the basis for a cancer potency factor for ECH. Data from the Laskin *et al*. (1980) study was considered to be less suitable for generating a cancer potency factor than data from the Konishi *et al.* (1980) study because of the poor survival of the study animals. The studies by Henschler *et al.* (1984) and Wester *et al.*, (1985) contained potential confounding factors. The ECH-exposed animals in the Henschler *et al.* (1984)

study were also exposed to trichloroethylene. The animals used in the Wester *et al.* (1985) study exhibited trichobezoar-induced intestinal obstructions early in the study due to the diet composition; CDHS (1988) noted that those obstructions could have been a contributing factor to the observed forestomach carcinogenesis.

Table 4. Epichlorohydrin-induced forestomach tumor incidence in male and female Wistar rats (Wester *et al.*, 1985)

Sex	Dose level (mg/kg body weight)	Tumor type	Tumor incidence
male	0 2 10	papilloma	1/50 6/49 4/49
	0 2 10	squamous cell carcinoma	0/50 6/49 35/49
female	0 2 10	papilloma	2/47 3/44 0/39
	0 2 10	squamous cell carcinoma	0/47 2/44 24/39

Methodology

A linearized multistage procedure (CDHS, 1985) was applied to male Wistar rat forestomach papilloma and carcinoma incidence data (Konishi *et al.*, 1980). US EPA (1984) lists the half-life of ECH in water as 0.69 days. Assuming first order decay due to hydrolysis, this corresponds to an average concentration throughout the day of 63% of the concentration of the freshly prepared solution. The control, low, mid and high dose groups were reported to have received cumulative doses of 0, 5.0, 8.9 and 15.1 grams (Konishi *et al.*, 1980); however, these data do not compensate for hydrolysis loss of ECH. CDHS (1988) estimated the actual daily exposures after hydrolysis compensation for the low, mid and high dose groups to be 15.1, 31.9 and 76.1 mg/kg-day, respectively. This assumes a body weight of 400 grams for a control Wistar rat, and utilizes the body weight data supplied by Konishi *et al*. (1980) which indicated that the low, mid and high dose animals weighed 7.7, 22.4 and 44.9% less than the controls, respectively. Upper 95% confidence bounds on carcinogenic potency (q_1^*) were estimated using the incidences of forestomach tumors in animals surviving to the end of the study (81 weeks) and the above dose estimates. Estimates of lifetime potency values (q_{animal}) were calculated from the q_1^* derived from the 81 week study using the relationship $q_{animal} = q_1^* * (104/81)^3$. Estimates for q_{animal} of 0.015 and 0.011 $(mg/kg\text{-}day)^{-1}$ were obtained for the benign squamous cell papillomas and malignant squamous cell carcinomas, respectively. The fitted dose response functions associated with these potency estimates exhibited significant upward curvature (p = 0.03). Surface area scaling was employed to transform animal cancer potency factors to human cancer potency factors, using the relationship ($q_{human} = q_{animal}$ *

$(bw_h / bw_a)^{1/3}$), where q_{human} is the human potency, q_{animal} is the animal potency, and bw_h and bw_a are the human and animal body weights, respectively. Human carcinogenic potency values (q_{human}) of 0.08 and 0.06 mg/kg-day^{-1} were derived from the q_{animal} values for benign squamous cell papillomas and malignant squamous cell carcinomas, respectively. A unit risk factor was calculated by OEHHA/ATES from the benign squamous cell papilloma data-derived q_{human} value using a reference human body weight of 70 kg and an inspiration rate of 20 m^3/day.

ETHYLBENZENE

CAS No: 100-41-4

I. PHYSICAL AND CHEMICAL PROPERTIES (From HSDB, 2003)

Molecular weight	106.2
Boiling point	136.2°C
Melting point	-94.9°C
Vapor pressure	9.6 mm Hg @ 25°C
Air concentration conversion	1 ppm = 4.35 mg/m^3 @ 25°C

II. HEALTH ASSESSMENT VALUES

Unit Risk: 2.5×10^{-6} $(\mu g/m^3)^{-1}$
Inhalation Cancer Potency: 0.0087 $(mg/kg\text{-}day)^{-1}$
Oral Cancer Potency: 0.011 $(mg/kg\text{-}day)^{-1}$
[Calculated from male rat renal tumor data (NTP, 1999), using the linearized multistage (LMS) methodology with lifetime weighted average (LTWA) doses (OEHHA, 2007).

III. METABOLISM and CARCINOGENIC EFFECTS

Metabolism

Ethylbenzene is rapidly and efficiently absorbed in humans via the inhalation route (ATSDR, 1999). Human volunteers exposed for 8 hours to 23-85 ppm retained 64% of inspired ethylbenzene vapor (Bardodej and Bardodejova, 1970). Gromiec and Piotrowski (1984) observed a lower mean uptake value of 49% with similar ethylbenzene exposures. There are no quantitative oral absorption data for ethylbenzene or benzene in humans but studies with [^{14}C]-benzene in rats and mice indicate gastrointestinal absorption in these species was greater than 97% over a wide range of doses (Sabourin *et al*., 1987).
Most of the metabolism of ethylbenzene is governed by the oxidation of the side chain (Fishbein, 1985). Engstrom (1984) studied the fate of ethylbenzene in rats exposed to 300 or 600 ppm (1305 or 2610 mg/m^3) ethylbenzene for six hours. Engstrom assumed 60 percent absorption of inhaled ethylbenzene and calculated that 83% of the 300 ppm dose was excreted in the urine within four hours of exposure. At the higher exposure of 600 ppm only 59 percent of the dose was recovered in the urine within 48 hr of exposure. Fourteen putative ethylbenzene metabolites were identified in the urine of exposed rats. The principal metabolites were 1-phenylethanol, mandelic acid, and benzoic acid. Metabolism proceeded mainly through oxidation of the ethyl moiety with ring oxidation appearing to play a minor role. Other metabolites included acetophenone, ω-hydroxyacetophenone, phenylglyoxal, and 1-phenyl-1, 2-ethandiol. Ring oxidation products include p-hydroxy- and m-hydroxyacetophenone, 2-ethyl- and 4-ethylphenol. With the exception of 4-hydroxyacetophenone all these other metabolites were seen only in trace amounts.

The metabolism of ethylbenzene was studied in humans (number unstated) exposed at 23 to 85 ppm (100 to 370 mg/m^3) in inhalation chambers for eight hours (Bardodej and Bardodejova, 1970). About 64 percent of the vapor was retained in the respiratory tract and only traces of ethylbenzene were found in expired air after termination of exposure. In 18 experiments with ethylbenzene, the principal metabolites observed in the urine were: mandelic acid, 64%; phenylglyoxylic acid, 25%; and 1-phenylethanol, 5%.

Engstrom *et al.* (1984) exposed four human male volunteers to 150 ppm ethylbenzene (653 mg/m^3) for four hours. Urine samples were obtained at two-hr intervals during exposure and periodically during the next day. For the 24-hr urine the metabolites were: mandelic acid, 71.5 ± 1.5%; phenylglyoxylic acid, 19.1 ± 2.0%; 1-phenylethanol, 4.0 ± 0.5%; 1-phenyl-1, 2-ethanediol, 0.53 ± 0.09%; acetophenone, 0.14 ± 0.04%; ω-hydroxyacetophenone, 0.15 ± 0.05%; m-hydroxyacetophenone, 1.6 ± 0.3%; and 4-ethylphenol, 0.28 ± 0.06%. A number of the hydroxy and keto metabolites were subject to conjugation. Differences were observed between the concentrations obtained with enzymatic and acid hydrolysis. For example, 50% of maximal yield of 4-ethylphenol was obtained with glucuronidase or acid hydrolysis and 100% with sulfatase indicating the presence of glucuronide and sulfate conjugates of this metabolite. Alternatively, acetophenone gave only 30-36% yield with enzymatic treatment but 100% with acid hydrolysis indicating the presence of other conjugates not susceptible to glucuronidase or sulfatase. The metabolic scheme proposed by Engstrom *et al.* (1984) is shown with modifications in Figure 1. The metabolism of ethylbenzene is similar in several respects to benzene in that benzene produces phenol, catechols and hydroquinone metabolites. As noted below these metabolites and their ethyl analogs participate in redox cycles generating the reactive oxygen species hydrogen peroxide, superoxide, and hydroxyl radical.

Gromiec and Piotrowski (1984) measured ethylbenzene uptake and excretion in six human volunteers exposed at concentrations of 18 to 200 mg/m^3 for eight hours. Average retention of ethylbenzene in the lungs was 49 ± 5% and total excreted mandelic acid accounted for 55 ± 2% of retained ethylbenzene.

Tardif *et al.* (1997) studied physiologically-based pharmacokinetic (PBPK) modeling of ternary mixtures of alkyl benzenes including ethylbenzene in rats and humans. As part of this investigation they determined Vmax and Km kinetic parameters for the rat by best fit of model simulations to the time-course data on the venous blood concentrations of ethylbenzene following single exposures. The maximal velocity (Vmax) was 7.3 mg/hr-kg body weight and the Michaelis-Menten affinity constant (Km) was 1.39 mg/L. For the human PBPK model the Vmax value from the rat was scaled on the basis of $(\text{body weight})^{0.75}$. All other chemical and metabolic parameters were unchanged.

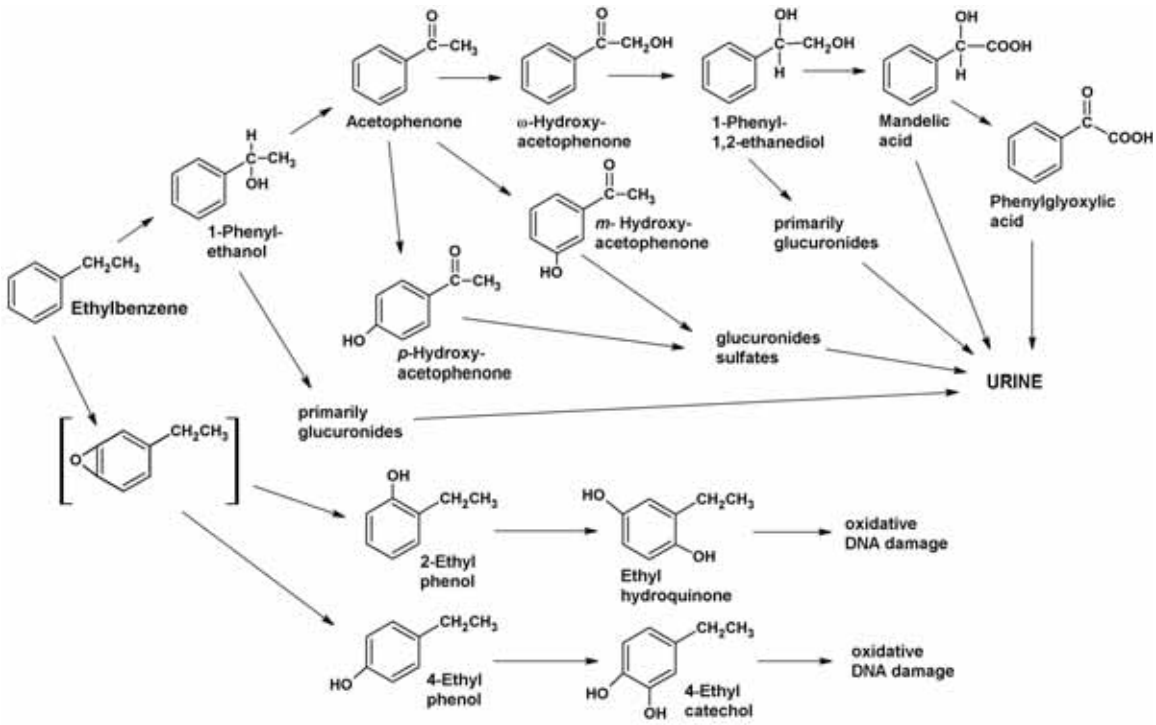

Figure 1. Ethylbenzene Metabolism (modified from Engstrom *et al.*, 1984).

The scaling of rodent metabolism of alkylbenzenes to humans was evaluated using kinetic data in an exposure study with human volunteers. Four adult male subjects (age, 22-47; body weight, 79-90 kg) were exposed to 33 ppm ethylbenzene for 7 hr/d in an exposure chamber. Urine samples were collected during (0-3 hr) and at the end (3-7 hr) of exposure and following exposure (7-24 hr). For the 0-24 hr collections mandelic acid amounted to 927 ± 281 μmol and phenylglyoxylic acid 472 ± 169 μmol. Venous blood (5.5 to 8 hr) and expired air (0.5 to 8 hr) were also measured in the subjects and exhibited good correspondence with PBPK model predictions. It is interesting that the metabolism of ethylbenzene in these human subjects was not significantly affected by simultaneous exposure to the other alkyl benzenes (toluene and xylene) studied. The metabolic parameters for ethylbenzene used by Haddad *et al.* (2001) and in the internal dosimetry modeling presented below were based on this study.

The oxidation of ethylbenzene to 1-phenylethanol by human liver microsomes and recombinant human cytochrome P450s was investigated by Sams *et al.* (2004). Human liver microsomes from seven subjects (four male, three female, age 37-74) and microsomes expressing recombinant human CYP1A2, 2A6, 2B6, 2C9*1(Arg144), 2C19, 2D6, 2E1, and 3A4 co-expressed with cytochrome P450 reductase/cytochrome b5 were both obtained from commercial sources. Kinetic experiments were conducted with microsomes and ethylbenzene over a 10-5000 μ*M* substrate concentration range. For chemical inhibition experiments, selective inhibitors of specific CYP isoforms were used to obtain maximum inhibition of the target CYP with minimum effect on other CYPs. Eadie-Hofstee plots (V vs. V/S) indicated that the reaction of ethylbenzene to 1-phenylethanol with human liver microsomes was biphasic with low and high affinity components. The Michaelis-Menten

equation was fit to the data and kinetic constants obtained by regression analysis. One microsome preparation was found to give a noticeably less curved Eadie-Hofstee plot and metabolized ethylbenzene at a much higher rate than the other preparations (Vmax = 2922 pmol/min/mg). It was excluded from the statistical analysis. For the high affinity reaction the mean Vmax was 689 ± 278 pmol/min/mg microsomal protein and the Km = 8.0 ± 2.9 μ*M* (n = 6). For the low affinity reaction the Vmax was 3039 ± 825 pmol/min/mg and Km = 391 ± 117 μ*M* (n = 6). The intrinsic clearance values of Vmax/Km were 85.4 ± 15.1 and 8.3 ± 3.0 for the high and low affinity reactions, respectively. The high affinity component of pooled human liver microsomes was inhibited 79%-95% by diethyldithiocarbamate, and recombinant CYP2E1 metabolized ethylbenzene with a low Km of 35 μ*M* and low Vmax of 7 pmol/min/pmol P450 indicating that the CYP2E1 isoform catalyzed this component. Recombinant CYP1A2 and CYP2B6 exhibited high Vmaxs (88 and 71 pmol/min/pmol P450, respectively) and Km's (502 and 219 μ*M*, respectively), indicating their role in the low affinity component. The mean Vmax and Km values above were used by OEHHA in addition to those from Haddad *et al.* (2001) in our human PBPK modeling of ethylbenzene.

Charest-Tardif *et al*. (2006) characterized the inhalation pharmacokinetics of ethylbenzene in male and female B6C3F1 mice. Initially groups of animals were exposed for four hr to 75, 200, 500 or 1000 ppm ethylbenzene. Subsequently groups of animals were exposed for six hr to 75 and 750 ppm for one or seven consecutive days. The maximum blood concentration (Cmax, mean (± SD), n = 4) observed after four hr exposure to 75, 200, 500 and 1000 ppm was 0.53 (0.18), 2.26 (0.38), 19.17 (2.74), and 82.36 (16.66) mg/L, respectively. The blood AUCs were 88.5, 414.0, 3612.2, and 19,104.1 (mg/L)-min, respectively, in female mice, and 116.7, 425.7, 3148.3, 16039.3 (mg/L)-min, respectively in male mice. The comparison of Cmax and kinetics of ethylbenzene in mice exposed to 75 ppm indicated similarity between 1 and 7-day exposures. However, at 750 ppm elimination of ethylbenzene appeared to be greater after repeated exposures. Overall, the single and repeated exposure PK data indicate that ethylbenzene kinetics is saturable at exposure concentrations above 500 ppm but is linear at lower concentrations.

Backes *et al*. (1993) demonstrated that alkylbenzenes with larger substituents (e.g., ethylbenzene, m-, p-xylene, n-propylbenzene) were effective inducers of microsomal enzymes compared to those with no or smaller substituents (benzene, toluene). Cytochrome P450 2B1 and 2B2 levels were induced with the magnitude of induction increasing with hydrocarbon size. P450 1A1 was also induced but less than 2B. A single intraperitoneal (i.p.) dose of 10 mmol/kg in rats was selected for optimum induction response with no overt toxic effects.

Bergeron *et al*. (1999) using the same daily dose of ethylbenzene for up to ten days observed changes in expression of CYP 2B1, 2B2, 2E1, and 2C11. While CYP 2C11 and 2E1 were attenuated by repeated dosing of ethylbenzene, CYP 2Bs were elevated after initial dosing despite the absence of detectable 2B1 or 2B2 mRNA. The authors interpreted this observation as the initial ethylbenzene dose leading to an increase in ethylbenzene clearance and an overall decrease in tissue ethylbenzene levels with repeated dosing and decreased induction effectiveness.

Serron *et al*. (2000) observed that treatment of rats with ethylbenzene (i.p., 10 mmol/kg) led to increased free radical production by liver microsomes compared to corn oil controls. Oxygen free radical generation was measured *in vitro* by conversion of 2', 7'-dichlorofluorescein diacetate (DCFH-DA) to its fluorescent product 2', 7'-dichlorofluorescein (DCF). A significant elevation (40%) of DCF was seen despite lack of effect on overall P450 levels. The DCF product formation was inhibited by catalase but not by superoxide dismutase suggesting a H_2O_2 intermediate. Anti-CYP2B antibodies inhibited DCF production indicating involvement of CYP2B. As noted above ethylbenzene treatment induces increased production of CYP2B.

While the doses in these studies were quite high at over 1000 mg/kg-d by the intraperitoneal route, earlier studies by Elovaara *et al*. (1985) showed P450 induction in livers of rats exposed to 50, 300 and 600 ppm (218, 1305 and 2610 mg/m^3) for 6 hours/day, 5 days/week for up to 16 weeks. So it is possible that the types of effects discussed above, notably the production of reactive oxygen species via induced CYP 2B, may have occurred during the cancer bioassays.

Genotoxicity

In vitro and *in vivo* animal studies

Ethylbenzene has been tested for genotoxicity in a variety of *in vitro* and *in vivo* genotoxicity assays. Those studies have been reviewed by ATSDR (1999). Ethylbenzene has not demonstrated genotoxicity in *Salmonella* reverse mutation assays. Those studies are listed in Table 1. All studies were performed in the presence and absence of metabolic activation (rat liver S9), and were negative. It has not been tested in strains sensitive to oxidative DNA damage.

Table 1. Ethylbenzene *Salmonella* reverse mutation studies

Test strains	**Reference**

TA97, TA98, TA100, TA1535	NTP, 1986
TA97, TA98, TA100, TA1535	NTP, 1999
TA98, TA100	Kubo *et al*., 2002

Ethylbenzene also did not induce mutations in the WP2 and WP2uvrA strains of *Escherichia coli* in the presence and absence of metabolic activation (Dean *et al*., 1985), or in *Saccharomyces cerevisiae* strains JDl (Dean *et al*., 1985), XVl85-14C, and D7 as measured by gene conversion assays (Nestmann and Lee, 1983).

Ethylbenzene has been observed to induce mutations in L5178Y mouse lymphoma cells at the highest nonlethal dose tested (80 µg/mL) (McGregor *et al*., 1988; NTP, 1999).

However, NTP noted significant cytotoxicity at this dose level (relative total growth was reduced to 34% and 13% of the control level in each of two trials).

Data on the ability of ethylbenzene to induce chromosomal damage in non-human mammalian cells are negative. Ethylbenzene did not cause chromosomal damage in rat liver epithelial-like (RL4) cells (Dean *et al*., 1985). Additionally, ethylbenzene did not induce an increase in either sister chromatid exchanges (SCE) or chromosomal aberrations in Chinese hamster ovary (CHO) cells in the presence or absence of metabolic activation (NTP 1986, 1999).

The frequency of micronucleated erythrocytes in bone marrow from male NMRI mice exposed to ethylbenzene by intraperitoneal injection was not significantly increased compared to controls (Mohtashamipur *et al*., 1985). Additionally, ethylbenzene did not increase the frequency of micronucleated erythrocytes in peripheral blood from male and female $B6C3F_1$ mice treated for 13 weeks with ethylbenzene (NTP, 1999).

Midorikawa *et al* (2004) reported oxidative DNA damage induced by the metabolites of ethylbenzene, namely ethylhydroquinone and 4-ethylcatechol. Ethylbenzene was metabolized to 1-phenylethanol, acetophenone, 2-ethylphenol, and 4-ethylphenol by rat liver microsomes *in vitro*. 2-Ethylphenol and 4-ethylphenol were ring-dihydroxylated to ethylhydroquinone (EHQ) and 4-ethylcatechol (EC). These dihydroxylated metabolites induced DNA damage in ^{32}P-labeled DNA fragments from the human p53 tumor suppressor gene and induced the formation of 8-oxo-7, 8-dihydro-2'-deoxyguanosine in calf thymus DNA in the presence of Cu2+. Addition of exogenous NADH enhanced EC-induced oxidative DNA damage but had little effect on EHQ action. The authors suggest that Cu+ and H_2O_2 produced via oxidation of EHQ and EC were involved in oxidative DNA damage. NADH enhancement was attributed to reactive species generated from the redox cycle of EC → 4-ethyl-1, 2-benzoquinone → EC. The NADH-mediated conversion of 4-Ethyl-1, 2-benzoquinone appears to be the result of a two electron reduction which accelerates the redox reaction, resulting in enhanced DNA damage (Figure 2).

Similar effects of NADH were observed with benzene metabolites benzoquinone (BQ) and catechol (Hirakawa *et al*. 2002). In the presence of Cu^{2+} and endogenous NADH, catechol (1,2-BQH_2) induced more DNA damage than 1,4-BQH_2. In the absence of NADH the DNA damaging activities were reversed. In both cases, DNA damage resulted from base modification at guanine and thymine residues in addition to DNA strand breaks by Cu^+ and H_2O_2 generated during the oxidation of 1,2-BQH_2 and 1,4- BQH_2 to 1,2_BQ and 1,4-BQ, respectively (Hirakawa *et al*., 2002). The authors noted that NADH consumption in the presence of 1,2-BQH_2/1,2-BQ was faster than that in the 1,4-BQH_2/1,4-BQ system. The results suggest that the structure of 1,2-BQ may facilitate the two-electron reduction by NADH better than 1,4-BQ. Thus, the reduction of 1,2-BQ accelerates the turnover rate of the redox cycle in 1,2-BQH_2/1,2-BQ greater than in 1,4-BQH_2/1,4-BQ. The authors conclude that "…the NADH-dependent redox cycle may

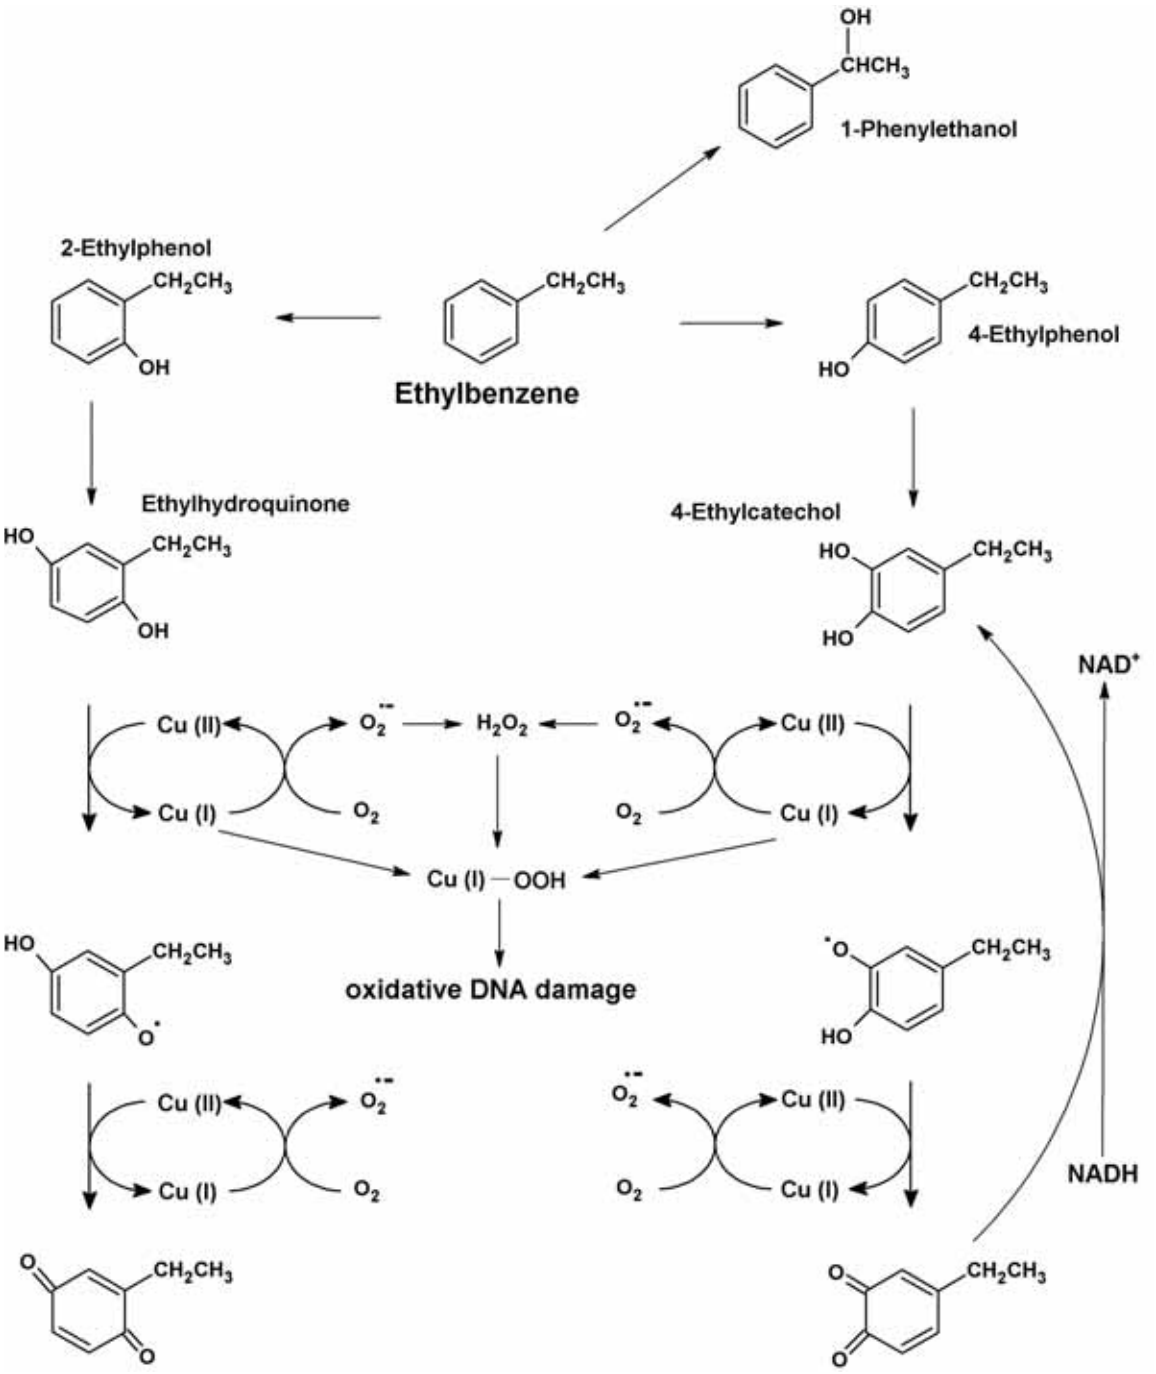

Figure 2. Possible mechanism of oxidative DNA damage induced by EHQ and EC. (Adapted from Midorikawa *et al*., 2004)

continuously generate reactive oxygen species, resulting in the enhancement of oxidative DNA damage. NADH, a reductant existing at high concentrations (100- 200 μM) in certain tissues, could facilitate the NADH-mediated DNA damage observed in this study under physiological conditions."(Hirakawa *et al*., 2002).

Similar reactions were also observed with methylcatechols, toluene metabolites that participated in Cu^{2+}-mediated DNA damage, which was enhanced by NADH compared with methylhydroquinone (Nakai *et al*., 2003; Murata *et al*., 1999).

In vitro and *in vivo* human studies

Norppa and Vainio (1983) exposed human peripheral blood lymphocytes to ethylbenzene in the absence of metabolic activation. The authors reported that ethylbenzene induced a marginal increase in SCEs at the highest dose tested, and that the increase demonstrated a dose-response.

Holz *et al*. (1995) studied genotoxic effects in workers exposed to volatile aromatic hydrocarbons (styrene, benzene, ethylbenzene, toluene and xylenes) in a styrene production plant. Peripheral blood monocytes were assayed for DNA adducts using a nuclease P1-enhanced ^{32}P-postlabeling assay, and DNA single strand breaks, SCEs and micronuclei frequencies in peripheral blood lymphocytes were determined in workers and controls. No significant increases in DNA adducts, DNA single strand breaks, SCEs or total micronuclei were noted in exposed workers. Significantly increased kinetochore-positive micronuclei (suggestive of aneuploidy-induction) were noted in total exposed workers, exposed smokers, and exposed non-smokers. However, the mixed exposures made it impossible to ascribe the kinetochore-positive micronuclei increase in exposed workers solely to ethylbenzene exposure.

The effects of benzene and ethylbenzene exposure on chromosomal damage in exposed workers were examined by Sram *et al*. (2004). Peripheral blood lymphocytes from exposed workers and controls were analyzed for chromosomal aberrations. Exposure to ethylbenzene resulted in a significant increase in chromosomal aberrations. A reduction in ethylbenzene concentration due to improved workplace emissions controls resulted in a reduction in chromosomal damage in exposed workers. However, these workers were also exposed to benzene, making it impossible to determine if the chromosomal damage was due to ethylbenzene alone.

Ethylbenzene sunlight-irradiation products

Toda *et al*. (2003) found that sunlight irradiation of ethylbenzene resulted in the formation of ethylbenzene hydroperoxide (EBH). EBH induced oxidative DNA damage in the presence of Cu^{2+} as measured by the formation of 8-hydroxy-deoxyguanosine (8-OH-dG) adducts in calf thymus DNA. The Cu^{2+}-specific chelator bathocuproine strongly inhibited EBH-induced oxidative DNA damage. Superoxide dismutase (catalyzes superoxide decomposition) partly inhibited 8-OH-dG adduct formation, and catalase (catalyzes hydrogen peroxide decomposition) slightly inhibited 8-OH-dG adduct formation.

Summary of ethylbenzene genotoxicity

The above data indicate that ethylbenzene generally has not been demonstrated to induce gene mutations or chromosomal damage in bacteria, yeast or non-human mammalian cells, with the exception of positive results in the L5178Y mouse lymphoma cell mutation assay at concentrations producing significant cytotoxicity (McGregor *et al*., 1988; NTP, 1999). Data on the genotoxicity of ethylbenzene in humans is mixed (Norppa and Vainio, 1983; Holz *et al*., 1995; Sram *et al*., 2004), and interpretation of the epidemiological studies is made difficult because of confounding due to coexposures to other chemicals, including benzene. Ethylbenzene has been demonstrated to generate reactive oxygen species in liver microsomes from exposed rats (Serron *et al*., 2000), and ethylbenzene hydroperoxide (a sunlight-irradiation product) has been demonstrated to induce oxidative DNA damage in calf thymus DNA *in vitro* (Toda *et al*., 2003). The ethylbenzene metabolites EHQ and EC have demonstrated the ability to induce oxidative DNA damage in human DNA *in vitro* (Midorikawa *et al*., 2004).

Animal Cancer Bioassays

Maltoni *et al.* (originally reported in 1985; additional information published in 1997) studied the carcinogenicity of ethylbenzene in male and female Sprague-Dawley rats exposed via gavage. The authors reported an increase in the percentage of animals with malignant tumors associated with exposure to ethylbenzene. In animals exposed to 800 mg/kg bw ethylbenzene, Maltoni *et al.* (1997) reported an increase in nasal cavity tumors, type not specified (2% in exposed females versus 0% in controls), neuroesthesioepitheliomas (2% in exposed females versus 0% in controls; 6% in exposed males versus 0% in controls), and oral cavity tumors (6% in exposed females versus 2% in controls; 2% in exposed males versus 0% in controls). These studies were limited by inadequate reporting and were considered inconclusive by NTP (1999) and IARC (2000).

The National Toxicology Program (NTP, 1999; Chan *et al*., 1998) conducted inhalation cancer studies of ethylbenzene using male and female F344/N rats and $B6C3F_1$ mice. Groups of 50 animals were exposed via inhalation to 0, 75, 250 or 750 ppm ethylbenzene for 6.25 hours per day, 5 days per week for 104 (rats) or 103 (mice) weeks.

Survival probabilities were calculated by NTP (1999) using the Kaplan-Meier product-limit procedure. For male rats in the 75 ppm and 250 ppm exposure groups, survival probabilities at the end of the study were comparable to that of controls but significantly less for male rats in the 750 ppm exposure group (30% for controls and 28%, 26% and 4% for the 75 ppm, 250 ppm and 750 ppm exposure groups, respectively). NTP (1999) stated that the mean body weights of the two highest exposure groups (250 and 750 ppm) were "generally less than those of the chamber controls from week 20 until the end of the study." Expressed as percent of controls, the mean body weights for male rats ranged from 97 to 101% for the 75 ppm group, 90 to 98% for the 250 ppm group, and 81 to 98% for the 750 ppm group.

In female rats, survival probabilities were comparable in all groups (62% for controls and 62%, 68% and 72% for the 75 ppm, 250 ppm and 750 ppm exposure groups, respectively). NTP (1999) reported that the mean body weights of exposed female rats were "generally less than those of chamber controls during the second year of the study." Expressed as percent of controls, the mean body weights for female rats ranged from 92 to 99% for the 75 ppm group, 93 to 100% for the 250 ppm group, and 92 to 99% for the 750 ppm group.

The incidences of renal tumors (adenoma and carcinoma in males; adenoma only in females) were significantly increased among rats of both sexes in the high-dose group (males: 3/50, 5/50, 8/50, 21/50; females: 0/50, 0/50, 1/50, 8/49 in control, 75 ppm, 250 ppm and 750 ppm groups respectively [standard and extended evaluations of kidneys combined]). The incidence of testicular adenomas (interstitial and bilateral) was significantly elevated among high-dose male rats (36/50, 33/50, 40/50, 44/50 in control, 75 ppm, 250 ppm and 750 ppm groups respectively). NTP noted that this is a common neoplasm, which is likely to develop in all male F344/N rats that complete a natural life span; exposure to ethylbenzene "appeared to enhance its development." NTP concluded that there was clear evidence of carcinogenicity in male rats and some evidence in female rats, based on the renal tumorigenicity findings.

The survival probabilities at the end of the study for exposed male mice were comparable to that of controls (57% for controls and 72%, 64% and 61% for the 75 ppm, 250 ppm and 750 ppm exposure groups, respectively). The same was true for exposed female mice (survival probabilities at end of study: 71% for controls and 76%, 82% and 74% for the 75 ppm, 250 ppm and 750 ppm exposure groups, respectively). Mean body weights in exposed male mice were comparable to those of controls. NTP (1999) reported that the mean body weights in exposed female mice were greater in the 75 ppm group compared to controls after week 72, and generally lower in the 750 ppm group compared to controls from week 24 through week 68. Expressed as percent of controls, the ranges of mean body weights in exposed female mice were 96 to 110% in the 75 ppm group, 93 to 108% in the 250 ppm group, and 92 to 101% in the 750 ppm group.

Increased incidences of alveolar/bronchiolar adenoma and adenoma or carcinoma (combined) were observed in male mice in the high-dose group (7/50, 10/50, 15/50, 19/50 in control, 75 ppm, 250 ppm and 750 ppm groups respectively). Among female mice in the high-dose group, the incidences of combined hepatocellular adenoma or carcinoma and hepatocellular adenoma alone were significantly increased over control animals (for adenomas and carcinomas the tumor incidences were 13/50, 12/50, 15/50, 25/50 in control, 75 ppm, 250 ppm and 750 ppm groups, respectively). NTP (1999) concluded that these findings provided some evidence of carcinogenicity in male and female mice.

Human Studies of Carcinogenic Effects

Studies on the effects of workplace exposures to ethylbenzene have been complicated by concurrent exposures to other chemicals, such as xylenes and benzene. IARC (2000) concluded that there was inadequate evidence in humans for the carcinogenicity of ethylbenzene.

Mode of Action for Ethylbenzene carcinogenesis

A mode of action (MOA) is a clear explanation of the critical events in an agent's influence on the development of tumors. An MOA analysis includes physical, chemical, and biological information and the entire range of information developed in the assessment contributes to a reasoned judgement concerning the plausibility of potential MOAs (U.S.EPA, 1996). An agent may work by more than one MOA at different sites and at the same tumor site. Inputs into an MOA analysis include tumor data in humans, animals, and in structural analogs, genetic toxicity and other key data e.g. on metabolites, DNA or protein adducts, oncogene activation and shape of the dose response. In any event conflicting data and data gaps often require careful evaluation before reaching any conclusions with respect to a prospective MOA (U.S.EPA, 1996).

OEHHA has not determined a convincing mode of action (MOA) for any of the tumor sites evaluated in this report. Various MOAs have been suggested for the tumors induced by ethylbenzene in rodent species. For instance it has been hypothesized that rat kidney tumor incidence increases are the result of ethylbenzene or its metabolites increasing the incidence and/or severity of chronic progressive nephropathy (CPN), a common process in aged control rats (Hard, 2002). However, OEHHA and others (Seely *et al.*, 2002) have found no basis to support a conclusion that the sole or primary cause of the kidney tumors is exacerbation of CPN. Similarly, it has been suggested that an increase in eosinophilic foci in the liver, possibly associated with induction of cytochrome P450 enzymes, is involved in the mechanism of production of the liver tumors. In fact, the data from which a correlation between liver eosinophilic foci and liver tumors was inferred are not consistent or convincing in this respect. Moreover, such MOAs have not been adequately elucidated with respect to their quantitative dose-response relations, or how significant they are with respect to other MOAs, possibly involving genotoxicity, which may also be operating.

A proposed MOA for ethylbenzene-induced tumors, especially those in the mouse lung, involves the generation of quinone metabolites. This is analogous to the actions of styrene and naphthalene, which are also carcinogenic. OEHHA recognizes the plausibility of quinone metabolites participating in a potential MOA for ethylbenzene-induced lung cancer in mice (see *Genotoxicity* above). However, a suggestion that the role of these metabolites is confined to cytotoxicity (resulting in promotion of spontaneous tumors) is not convincing. The observation of oxidative DNA damage *in vitro* (Midorikawa *et al.*, 2004) supports a role for quinone metabolites in carcinogenic initiation, following the analogy with benzene (a well-known genotoxic carcinogen targeting multiple sites in various species including humans). The observation of chromosomal damage in peripheral blood lymphocytes of workers exposed to ethylbenzene and benzene (Sram *et al.*, 2004) may be indicative of quinone metabolite induced DNA damage. Thus, the involvement of quinone metabolites is plausible and supported by at least some data. Although this does not of itself establish the quantitative nature of the dose-response relationship, a mechanism involving oxidative DNA damage might display low-dose linearity. Since ring oxidation may produce a genotoxic epoxide metabolite it is possible that more than one metabolic

process which generates genotoxic intermediates may be operating. In our view the genotoxicity of ethylbenzene, particularly with respect to oxidative DNA effects, merits further investigation.

OEHHA therefore concludes that the limited data do not conclusively establish any particular MOA for ethylbenzene carcinogenesis. However, one or more genotoxic processes appear at least plausible and may well contribute to the overall process of tumor induction. Because of this, the default linear approach has been used for extrapolating the dose-response curve to low doses.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Unit risk values for ethylbenzene were calculated based on data in male and female rats and mice from the studies of NTP (1999) utilizing both linearized multistage and benchmark dose methods. The incidence data used to calculate unit risk values are listed below in Tables 2 thru 6. The methodologies for calculating average concentration, lifetime weighted average (LTWA) dose and PBPK adjusted internal dose are discussed below. An internal dose metric representing the amount of ethylbenzene metabolized per kg body weight per day (metabolized dose) was used in the dose response analysis with published PBPK modeling parameters. In addition, for the mouse, recent pharmacokinetic data simulating mouse bioassay conditions were used to improve PBPK model predictions (Tables 5 and 6).

The metabolized dose metric is considered the most appropriate metric for assessment of carcinogenic risks when the parent compound undergoes systemic metabolism to a variety of oxidative metabolites which may participate in one or more mechanisms of carcinogenic action, and the parent compound is considered unlikely to be active. In this case the dose response relation is likely to be more closely related to the internal dose of metabolites than of the parent compound. Other metrics commonly investigated using PBPK methods are the area under the concentration-time curve (AUC), and the maximum concentration (Cmax) for parent or metabolites in blood and target tissues. The PBPK metabolized dose metric was used in the ethylbenzene dose-response analysis.

Table 2. Incidence of renal tubule adenoma or carcinoma in male rats exposed to ethylbenzene via inhalation and relevant dose metrics (from NTP, 1999).

Chamber concentration (ppm)	Average concentration[a] (mg/m^3)	LTWA dose[b] (mg/kg-day)	PBPK metabolized dose[c] (mg/kg-d)	Tumor incidence[d]		Statistical significance[e]	
				Quantal Response	%	Fisher Exact Test	TrendTest
0	0	0	0	3/42	7.1		
75	60.7	35.6	19.09	5/42	11.9	$p = 0.356$	$p < 0.001$
250	202	119	58.78	8/42	19.0	$p = 0.0972$	
750	607	356	124.26	21/36	58.3	$p < 0.001$	

a. Average concentration during exposure period calculated by multiplying chamber concentration by 6.25 hours/24 hours, 5 days/7 days, and 4.35 $mg/m^3/ppm$.
b. Lifetime weighted average doses determined by multiplying the lifetime average concentrations during the dosing period by the male rat breathing rate (0.264 m^3/day) divided by the male rat body weight (0.450 kg). The duration of exposure was 104 weeks, so no correction for less than lifetime exposure was required.
c. Rodent PBPK models were used to estimate internal doses under bioassay conditions; methods are described in detail below.
d. Effective rate. Animals that died before the first occurrence of tumor (day 572) were removed from the denominator. Total number of tumors/number of survivors.
e. The *p*-value listed next to each dose group is the result of pair wise comparison with controls using the Fisher exact test. The *p*-value listed for the trend test is the result obtained by the National Toxicology Program (NTP, 1999) using the life table, logistic regression and Cochran-Armitage methods, with all methods producing the same result.

Table 3. Incidence of testicular adenoma in male rats exposed to ethylbenzene via inhalation and relevant dose metrics (from NTP, 1999).

Chamber concentration (ppm)	Average concentration[a] (mg/m^3)	LTWA dose[b] (mg/kg-day)	PBPK metabolized dose[c] (mg/kg-d)	Tumor incidence[d]		Statistical significance	
				Quantal Response	%	Fisher Exact Test[e]	Trend Test
0	0	0	0	36/48	75.0		
75	60.7	35.6	19.09	33/46	71.7	$p = 0.450$N	$p < 0.001$[f]

Methodology

Linearized Multistage Approach

The default approach, as originally delineated by CDHS (1985), is based on a linearized form of the multistage model of carcinogenesis (Armitage and Doll, 1954). Cancer potency is estimated from the upper 95% confidence limit, q_1^*, on the linear coefficient q_1 in a model relating lifetime probability of cancer (*p*) to dose (d):

$$p = 1 - \exp[-(q_0 + q_1 d + q_2 d^2 + \cdots + q_j d^j)] \qquad (1)$$

with constraints, $q_i \geq 0$ for all i. The default number of parameters used in the model is n, where n is the number of dose groups in the experiment, with a corresponding polynomial degree of n-1.

The parameter q_1^* is estimated by fitting the above model to dose response data using MSTAGE (Crouch, 1992). For a given chemical, the model is fit to one or more data sets. The default approach is to select the data for the most sensitive species and sex.

To estimate animal potency, q_{animal}, when the experimental exposure is less than lifetime the parameter q_1* is adjusted by assuming that the lifetime incidence of cancer increases with the third power of age. The durations of the NTP experiments were at least as long as the standard assumed lifetime for rodents of 104 weeks, so no correction for short duration was required.

Benchmark Dose Methodology

U.S. EPA (2005) and others (*e.g.* Gaylor *et al.*, 1994) have more recently advocated a benchmark dose method for estimating cancer risk. This involves fitting a mathematical model to the dose-response data. A linear or multistage procedure is often used, although others may be chosen in particular cases, especially where mechanistic information is available which indicates that some other type of dose-response relationship is expected, or where another mathematical model form provides a better fit to the data. A point of departure on the fitted curve is defined: for animal carcinogenesis bioassays this is usually chosen as the lower 95% confidence limit on the dose predicted to cause a 10% increase in tumor incidence (LED_{10}). Linear extrapolation from the point of departure to zero dose is used to estimate risk at low doses either when mutagenicity or other data imply that this is appropriate, or in the default case where no data on mechanism are available. The slope factor thus determined from the experimental data is corrected for experimental duration in the same way as the q_1^* adjustments described for the linearized multistage procedure. In the exceptional cases where data suggesting that some other form of low-dose extrapolation is appropriate, a reference dose method with uncertainty factors as required may be used instead.

The quantal tumor incidence data sets were analyzed using the BMDS software (version 1.3.2) of U.S.EPA (2000). In general the program models were fit to the data with the X^2 fit criterion ≥ 0.1. In those cases when more than one model gave adequate fit the model that gave the best fit in the low dose region (visually and by X^2 residual) was chosen for the LED_{10} estimation.

Implementation of LMS and BMD Methodology

The linearized multistage approach and the benchmark dose methodology were both applied to the tumor incidence data for ethylbenzene in the NTP (1999) studies. No nonlinear mode of carcinogenic action has been established for ethylbenzene. Hard (2002) suggested that "chemically induced exacerbation of CPN [chronic progressive nephropathy] was the mode of action underlying the development of renal neoplasia" in the NTP ethylbenzene studies. In a retrospective evaluation of NTP chronic studies, Seely *et al.* (2002) found that renal tubule cell neoplasms (RTCNs) "tend to occur in animals with a slightly higher severity of CPN than animals without RTCNs. However, the differential is minimal and clearly there are many male F344 rats with severe CPN without RTCNs." Seely *et al.* (2002) go on to say that "the data from these retrospective reviews suggest that an increased severity of CPN may contribute to the overall tumor response. However, any contribution appears to be marginal, and additional factors are likely involved."

Stott *et al.* (2003) reported accumulation of the male rat specific protein α2u-globulin in 1-week and 4-week inhalation studies of ethylbenzene in groups of six (1-week study) or eight (4-week study) male rats; the accumulation measured as an increase in hyaline droplets in proximal convoluted tubules was statistically significant only in the 1-week study. In the 13-week and 2-year inhalation studies of ethylbenzene, NTP (1992; 1999) found no evidence of an increase in hyaline droplets in treated rats. NTP (1999) therefore dismissed any involvement of α2u-globulin accumulation in renal tumor development in rats. The fact that the lesion appears in both male and female rats further argues against the involvement of α2u-globulin in the development of kidney toxicity. This mechanism was discounted by Hard (2002) as well. Stott *et al.* (2003) also postulated mechanisms of tumorigenic action involving cell proliferation and/or altered cell population dynamics in female mouse liver and male mouse lung. Stott et al. (2003) propose various hypothetical mechanisms which might involve nonlinear dose responses but the metabolism data clearly show the formation of epoxides and related oxidative metabolites, which could potentially be involved in a genotoxic mechanism of carcinogenic action possibly similar to benzene. Midorikawa *et al*. (2004) reported that the oxidative metabolism of ethylbenzene metabolites ethylhydroquinone and 4-ethylcatechol resulted in oxidative DNA damage *in vitro*. In view of the variety of metabolites and possible modes of action a low-dose linearity assumption is considered appropriate when extrapolating from the point of departure to obtain an estimate of the cancer risk at low doses with the BMD methodology as is use of the LMS approach.

Calculation of Lifetime Weighted Average Dose

Male and female rats (NTP, 1999) were exposed to ethylbenzene for 6.25 hours/day, five days/week for 104 weeks. Male and female mice (NTP, 1999) were exposed to ethylbenzene for 6.25 hours/day, five days/week for 103 weeks. Average concentrations, expressed in mg/m^3, during the exposure period were calculated by multiplying the reported chamber concentrations by 6.25 hours/24 hours, five days/seven days and 4.35 mg/m^3/ppm.

The average body weights of male and female rats were calculated to be 0.450 kg and 0.282 kg, respectively, based on data for controls reported by NTP (1999). The average body weights of male and female mice were estimated to be approximately 0.0429 kg and 0.0389 kg, respectively,

based on data for controls reported by NTP (1999). Inhalation rates (I) in m^3/day for rats and mice were calculated based on Anderson *et al.* (1983):

$$I_{rats} = 0.105 \times (bw_{rats}/0.113)^{2/3} \quad (3)$$

$$I_{mice} = 0.0345 \times (bw_{mice}/0.025)^{2/3} \quad (4)$$

Breathing rates were calculated to be 0.264 m^3/day for male rats, 0.193 m^3/day for female rats, 0.0494 m^3/day for male mice, and 0.0463 m^3/day for female mice. Lifetime weighted average (LTWA) doses were determined by multiplying the average concentrations during the dosing period by the appropriate animal breathing rate divided by the corresponding animal body weight. For mice, the exposure period (103 weeks) was less than the standard rodent lifespan (104 weeks), so an additional factor of 103 weeks/104 weeks was applied to determine lifetime average doses.

Physiologically Based Pharmacokinetic (PBPK) Modeling

The carcinogenic potency of ethylbenzene was calculated using rodent PBPK models to estimate internal doses under bioassay conditions. Extrapolations to human potencies were done using interspecies scaling. For comparison, a human PBPK model was used to estimate risk-specific doses for occupational and ambient environmental exposure scenarios. The PBPK models were comprised of compartments for liver, fat, vessel poor tissues (e.g., muscle), vessel rich tissues, and lung. Typical model parameters are given in Table 7 for flow-limited PBPK models and a model diagram is shown in Figure 2. Chemical and metabolic parameters for mouse and human models were taken from Haddad *et al.* (2001) and additionally from Sams *et al.* (2004) for human metabolism. The rat PBPK model was based on Dennison *et al.* (2003). Simulations were conducted using Berkeley Madonna (v.8.3.9) software (e.g., 6.25 hr exposure/day x 5 days/wk for one week simulations of bioassay exposure levels, see sample model equations in Appendix A). The chemical partition coefficients used in the Haddad et al. model were: blood:air, 28.0; fat:blood, 55.57; liver:blood, 2.99; muscle:blood, 0.93; and vessel rich:blood, 2.15 (Haddad *et al.*, 2001). For the Dennison et al. rat model the chemical partition coefficients were: blood:air, 42.7; fat:blood, 36.4; liver:blood, 1.96; muscle:blood, 0.609; and vessel rich:blood, 1.96. The metabolic parameters from Haddad *et al.* (2001) were: VmaxC = 6.39 mg/hr/kg body weight scaled to the ¾ power of body weight; Km = 1.04 mg/L. For the rat model the metabolic parameters were: VmaxC = 7.60 mg/kg-d scaled to the 0.74 power of body weight and Km = 0.1 mg/L. A second set of human metabolic parameters from Sams *et al.* (2004) was also used. In this case constants for low and high affinity saturable pathways were incorporated into the models: high affinity Vmax = 689 pmol/min/mg microsomal protein, Km = 8.0 μM; low affinity Vmax = 3039 pmol/min/mg protein, Km = 391 μM. A value of 28 mg/mL liver for microsomal protein concentration was assumed. Published values we reviewed ranged from 11 to 35 mg/g tissue. The value we used was similar to that of Kohn and Melnick (2000) (30 mg/g liver) and Medinsky *et al.* (1994) (35 mg/g liver). All model units were converted to moles, liters, or hours for simulation. A molecular weight of 106.16 g/mol for ethylbenzene was used throughout. In addition to PBPK modeling based on published parameters the recent pharmacokinetic data of Charest-Tardif *et al.* (2006) was used in the mouse PBPK modeling for comparison purposes. During the final revisions of this document we obtained the recently published paper of Nong *et al.* (2007), which describes a mouse PBPK model for ethylbenzene inhalation based on the pharmacokinetic data of Charest-Tardif *et al.*

(2006) and other parameter measurements. This model differs from that of Haddad *et al*. (2001) in having gender- and dose-specific chemical and metabolic parameters. The model also includes metabolism by lung and vessel-rich tissues in addition to liver. We employed the Nong *et al*. model in simulations of bioassay conditions identical to the Haddad *et al.* (2001) and Charest-Tardif *et al*. (2006) based models run previously, except that only the BMD dose response analysis was performed with the resulting total metabolized dose.

Although no systematic evaluation of PBPK model parameter uncertainty was conducted, the fact that we essentially used two rat models (Haddad *et al*., 2001 in the first draft and Dennison *et al*., 2004 in the revised draft) and two mouse models (Haddad *et al*. 2001, and Nong *et al*. 2007) and three key metabolic parameters (Charest-Tardif *et al*., 2006) for the mouse addresses this concern to some extent. The potency estimates in all cases were similar indicating a relative insensitivity to the PBPK parameters varied.

Johansen and Filser (1992) studied a series of volatile organic chemicals including ethylbenzene and developed theoretical values for clearance of uptake (CLupt) defined as the product of the rate constant for transfer of chemical from air to body and the volume of air in a closed chamber. The CLupt values were based on alveolar ventilation (Qalv), cardiac output (Qtot), and blood:air partition coefficients (Pbi). For most chemicals the experimentally determined values for inhalation uptake in rats and mice were about 60% of the theoretical values. The values determined for ethylbenzene in the rat of 70 mL/min for CLupt and 73 mL/min for alveolar ventilation are about 50% the value given in Table 7 (i.e., 4.38 L/hr vs. 8.58 L/hr). In the work described below selected simulations were run with lower alveolar ventilation rates for comparison with the main analysis.

The primary model prediction was the amount of ethylbenzene metabolized over the course of the simulation. The AUCs, the areas under the concentration x time curves for mixed venous concentration and liver concentration of ethylbenzene, were also recorded. The values for one week simulations of the amount metabolized (mmoles) were divided by 7d/week and body weight in kg to give daily values and multiplied by the molecular weight to give the PBPK metabolized dose in mg/kg-d. These values were then used in the dose response assessment of individual tumor site incidences using the benchmark dose software of U.S. EPA (BMDS v. 1.3.2) to obtain ED_{10}s, LED_{10}s and curve fit statistics.

Table 7. Parameters for Ethylbenzene PBPK Models.

Parameter	**Mouse**	**Rat**	**Human**
Alveolar ventilation rate Qalv, L/hr	$15*BW^{0.7}$	$12*BW^{0.74}$	$36*BW^{0.7}$ occ $15*BW^{0.7}$ env
Cardiac output Qtot, L/hr	$15*BW^{0.7}$	$15*BW^{0.74}$	$18*BW^{0.7}$ occ $15*BW^{0.7}$ env
Blood flows (fraction of cardiac output)			
Fat, Qf	0.09	0.07	0.05

Internal to External Dose Conversion

In order to estimate external equivalent air concentrations associated with internal doses, the PBPK models were used. Simulation of 10 ppb ethylbenzene for 8 hours in the human PBPK model with the Haddad *et al*. (2001) parameters resulted in the predicted uptake of 3.04 µmoles in tissues and blood compared to 3.96 µmoles inhaled, or an uptake of 77%. Practically all of the 3.04 µmoles represents metabolized ethylbenzene. Based on these results, OEHHA assumed that all absorbed ethylbenzene is metabolized at low dose. Thus, for the inhalation route, the internal metabolized dose is converted to an external dose by applying an uptake factor of 77%. As noted above, uptake values of 49 to 65% have been observed in studies with human subjects exposed via inhalation to ethylbenzene. OEHHA has occasionally used a default value of 50% for inhalation uptake of similar volatile organic compounds.

For the oral route at low dose, OEHHA assumed that ethylbenzene is 100% metabolized and that uptake of ethylbenzene is also 100%. Thus, at low dose, the internal metabolized dose of ethylbenzene would be equivalent to an external applied dose by the oral route. No conversion factor for internal to external dose is necessary in this case.

Interspecies Extrapolation

Interspecies extrapolation from experimental animals to humans is normally based on the following relationship, where bw_h and bw_a are human and animal body weights, respectively, and potency (*e.g.*, q_{animal}) is expressed on a per dose per body weight basis (e.g., $(mg/kg\text{-}d)^{-1}$ see Watanabe *et al*. (1992):

$$q_{human} = q_{animal} \times \left(\frac{bw_h}{bw_a} \right)^{1/4} \qquad (2)$$

This is equivalent to an adjustment based on $(\text{human body weight})^{3/4}$ relative to the animal body weight or $BWh^{3/4}/BWa^{4/4} = (BWh/BWa)^{4/4-3/4} = (BWh/BWa)^{1/4}$. This is the default relationship currently recommended by OEHHA and by U.S. EPA (2005)

Alternatively, when performing calculations based on applied dose in terms of air concentrations, the assumption has sometimes been made that air concentration values are equivalent between species (CDHS, 1985). However, using the interspecies scaling factor shown above is preferred because it is assumed to account not only for pharmacokinetic differences (*e.g.*, breathing rate, metabolism), but also for pharmacodynamic considerations i.e. tissue responses to chemical exposure.

When extrapolating from an animal potency in terms of PBPK adjusted internal dose, only a pharmacodynamic scaling factor is required. Since an equal contribution of pharmacokinetic and pharmacodynamic considerations is assumed, animal potency values already adjusted for pharmacokinetic considerations require a scaling factor of only $(bw_h/bw_a)^{1/8}$:

$$q_{human} = q_{animal} \times \left(\frac{bw_h}{bw_a} \right)^{1/8} \qquad (3)$$

Derivation of the Human Inhalation Unit Risk Value

To derive the human inhalation unit risk value, the human internal potency value based on PBPK metabolized dose is multiplied by the human breathing rate (assumed to be 20 m^3/day), divided by the human body weight (assumed to be 70 kg) and multiplied by the estimated inhalation uptake factor in humans (0.77 for ethylbenzene). This yields a human inhalation unit risk value in terms of external air concentration.

For the case of LTWA doses, the human inhalation unit risk value is derived by multiplying the human inhalation cancer potency value by the human breathing rate (assumed to be 20 m^3/day), divided by the human body weight (assumed to be 70 kg). Because the LTWA doses represent external applied dose from an inhalation study, no uptake factor is necessary in deriving the unit risk value.

Inhalation and Oral Cancer Potency Values

The cancer potency derived based on internal doses (i.e., PBPK metabolized dose) is equivalent to the oral cancer potency, because of the assumption of 100% oral uptake and 100% metabolism of ethylbenzene at low doses. To derive the inhalation cancer potency, the human inhalation unit risk value is multiplied by the human body weight (assumed to be 70 kg) and divided by the human breathing rate (assumed to be 20 m^3/day).

For the case of LTWA doses, the human cancer potency derived based on these external applied doses from the inhalation study is equivalent to the inhalation cancer potency. To determine the oral cancer potency, the inhalation cancer potency is multiplied by the ratio of the oral to inhalation uptake factors (i.e., 1/0.77).

Example Calculations – BMD Approach

In this section, example calculations of the human cancer potency values (oral and inhalation) and the human unit risk value based on the LED_{10} for the male rat kidney tumor data and either the PBPK metabolized doses or the LTWA doses are provided. The same logic would apply to the derivation using the LMS methodology, with the only difference being that the animal potency is taken directly from the MSTAGE program under the LMS approach instead of being calculated from the LED_{10} in the BMD approach. To distinguish the results obtained under the two approaches, the terms P_{animal}, P_{human}, and U_{human} were used for the values derived using the BMD methodology.

Calculations based on BMD methodology and PBPK metabolized doses

Under the BMD methodology, the ED_{10}s and LED_{10}s are obtained from the BMDS program, with the animal potency value being simply $0.1/LED_{10}$ (i.e., 10% risk (0.1) divided by the 95% lower confidence limit on the dose that induced 10% risk or LED_{10}; this is the definition of a slope). To obtain the animal potency based on internal dose ($P_{animal\_internal}$), 0.1 is divided by the LED_{10} derived for the male rat kidney tumor data and the PBPK metabolized doses:

$$P_{animal\_internal} = 0.1/LED_{10} = 0.1/25.38 = 0.00394\ (mg/kg\text{-}d)^{-1}$$

The human potency value based on internal dose ($P_{human\_internal}$) is calculated from the animal potency as follows:

$$P_{human\_internal} = 0.00394\ (mg/kg\text{-}day)^{-1} \times (70\ kg/0.450\ kg)^{1/8}$$
$$= 0.0074\ (mg/kg\text{-}day)^{-1}$$

$P_{human\_internal}$ is equivalent to the oral human potency, because of the assumptions of 100% oral uptake and 100% metabolism of ethylbenzene at low dose.

The human unit risk value (U_{human}) is derived from the internal human cancer potency as follows:

$$U_{human} = 0.0074\ (mg/kg\text{-}day)^{-1} \times (20\ m^3/day/70\ kg) \times 0.77$$
$$= 1.64 \times 10^{-3}\ (mg/m^3)^{-1}$$
$$= 1.64 \times 10^{-6}\ (\mu g/m^3)^{-1}$$

As noted above the value of 0.77 was based on the prediction of the human ethylbenzene PBPK model, assuming exposure to low levels of ethylbenzene, and is similar to values obtained in studies with human subjects. By applying this uptake factor and assuming that the metabolism of ethylbenzene is 100% at low dose, the resulting unit risk value is expressed in terms of external concentration.

The inhalation cancer potency is derived from the unit risk value as follows:

$$P_{human\_inhalation} = 1.64 \times 10^{-3}\ (mg/m^3)^{-1} \times (70\ kg/20\ m^3/day)$$
$$= 0.0057\ (mg/kg\text{-}day)^{-1}$$

<u>Calculations based on BMD methodology and LTWA doses</u>

The LED_{10} based on the male rat kidney data and the LTWA doses is determined using the BMDS software. The animal potency, which in this case is the inhalation animal potency (P_{animal_inh}), is determined by dividing the LED_{10} into 0.1:

$$P_{animal\_inh} = 0.1/LED_{10} = 0.1/42.62 = 0.002346\ (mg/kg\text{-}d)^{-1}$$

The human inhalation cancer potency (P_{human_inh}) is derived from the animal potency using the interspecies scaling factor:

$$P_{human\_inh} = 0.002346\ (mg/kg\text{-}day)^{-1} \times (70\ kg/0.450\ kg)^{1/4}$$
$$= 0.0083\ (mg/kg\text{-}day)^{-1}$$

The unit risk factor is derived from the human inhalation cancer potency as follows:

$$U_{human} = 0.0083\ (mg/kg\text{-}day)^{-1} \times (20\ m^3/day/70\ kg)$$

$= 2.4 \times 10^{-3} (mg/m^3)^{-1}$
$= 2.4 \times 10^{-6} (\mu g/m^3)^{-1}$

For the calculation based on LTWA doses, the oral cancer potency is derived from the inhalation cancer potency by multiplying by the ratio of uptake factors (1/0.77):

$$P_{human\_oral} = 0.0083 (mg/kg\text{-}day)^{-1} \times (1/0.77)$$
$$= 0.011 (mg/kg\text{-}day)^{-1}$$

Results and Discussion

Linearized multistage approach

Tables 8a and 8c list the q_{animal}, q_{human} and unit risk values based on the linearized multistage approach. The cancer potencies and unit risk values were derived using the applied LTWA doses and PBPK adjusted internal doses, as described above. The most sensitive tumor sites are the male rat testicular interstitial cell adenoma and the male rat kidney adenoma and carcinoma, when the LTWA doses are used. If PBPK doses are used, the most sensitive sites are the male rat testicular interstitial cell adenoma and the male mouse lung. Regardless of whether LTWA or PBPK doses are used, the results based on the male mouse lung tumor data, the female mouse liver tumor data, and the male rat renal tumor data are comparable, producing unit risk values of approximately 0.002 $(mg/m^3)^{-1}$. Further, the results using either the LTWA doses or the PBPK metabolized doses are quite similar indicating that the PBPK modeling does not markedly improve the estimates. Some of the inherent uncertainty associated with PBPK modeling is demonstrated by the fact that the results based on the PBPK modeling using the Charest-Tardif parameters differ by roughly a factor of two for the mice compared to the results derived based on the other equally valid PBPK modeling approach.

The testicular interstitial cell adenoma site gives the highest values. However, the very high background incidences of this tumor make it less reliable and suitable for dose-response analysis than the male rat kidney site.

Thus, the unit risk value of 0.0025 $(mg/m^3)^{-1}$ derived based on the LMS approach from the male rat kidney tumor data using the LTWA doses is selected as the representative value for ethylbenzene. It is very similar to the estimate derived using the PBPK approach (0.0026 $(mg/m^3)^{-1}$), and does not require the many assumptions made in applying the more complex PBPK approach.

Table 8a. Cancer potency and unit risk values for ethylbenzene derived using the linearized multistage procedure (LMS) with applied LTWA doses based on data from NTP (1999).

Sex, species	**Site, tumor type**	**q_{animal_inh}** **$(mg/kg\text{-}day)^{-1}$**	**q_{human_inh}[a]** **$(mg/kg\text{-}day)^{-1}$**	**Human unit risk value[b]** **$(mg/m^3)^{-1}$**	**Goodness-of-fit test[c]**
Male rats	Renal tubule carcinoma or adenoma	0.002472	0.0087	**0.0025**	$p = 0.81$

b. Unit risk was determined by multiplying the human internal cancer potency in $(mg/kg\text{-}day)^{-1}$ by the human breathing rate (20 m^3/day) divided by human body weight (70 kg) and by an uptake factor of 0.77, as described above.

c. A p-value of 0.1 or greater for the chi-square goodness-of-fit test indicates an adequate fit with the BMD procedure.

d. These values obtained with PBPK model adjusted to approximate the mouse pharmacokinetic data of Charest-Tardif *et al.* (2006).

e. These values obtained with the PBPK model of Nong *et al.* (2007). Cardiac output = 24BW^0.75; Alveolar ventilation = 0.68*Cardiac output.

Benchmark Dose Approach

Tables 8b and 8d list the P_{animal}, P_{human}, and human unit risk values based on the BMD approach. The cancer potencies and unit risk values were derived using the applied LTWA doses and PBPK adjusted internal doses, as described above. As expected the results from the BMD approach are quite similar to those just described using the LMS approach. Unit risk values ranged from 0.00054 to 0.0063 $(mg/m^3)^{-1}$. When LTWA doses are used, the most sensitive sites are the male rat testicular interstitial cell adenoma and the male rat kidney adenoma and carcinoma. When PBPK doses are used, the most sensitive sites are the male rat testicular interstitial cell adenomas and the male mice lung tumors. Regardless of whether LTWA or PBPK doses are used, the unit risk values based on male rat kidney, male mouse lung, and female mouse liver are comparable at approximately 0.002 $(mg/m^3)^{-1}$. The results based on the Charest-Tardif PBPK parameters are about a factor of two to four less than those based on the PBPK parameters from Haddad. The results obtained with the Nong *et al.* (2007) PBPK model were similar to the Charest-Tardif *et al.* (2006) adjusted mouse model. This is not surprising since they are largely based on the same kinetic data (Table 8d). The various estimates indicate some of the uncertainty in the PBPK approach.

As discussed above, the male rat testicular tumors are not considered appropriate for unit risk and potency estimation because of the high background rate. The preferred unit risk value of 0.0025 $(mg/m^3)^{-1}$, is derived from the male rat kidney data based on LTWA doses with the LMS method. The value derived using the BMD approach based on LTWA doses is not significantly different (0.0026 $(mg/m^3)^{-1}$).

Human PBPK Models

Initial predictions of risk-specific exposure concentrations from a human PBPK model used metabolic parameters from Haddad *et al.* (2001), two exposure scenarios, and two methods of risk estimation. The exposure scenarios utilized were an occupational-like time of exposure (8.0 hr exposure/day x 5 d/week; 7 days simulation) and a continuous environmental time of exposure (24 hr/d x 7d/week; 10 days simulation). Two methods of risk estimation were used. In method I a human potency value, P_{human}, was used to estimate an internal dose equivalent to 1 x 10^{-6} lifetime theoretical risk (e.g., 10^{-6} risk/0.0087 $(mg/kg`-d)^{-1}$ = 1.15 x 10^{-4} mg/kg-d.) The human PBPK model with differing exposure scenarios was then used to estimate the external ethylbenzene concentrations resulting in that internal dose. In method II the animal LED_{10} was divided by 10^5 to obtain the 10^{-6} risk specific dose and the equivalent external concentration was adjusted for possible pharmacodynamic (PD) differences between rats and humans (i.e., $(70/0.45)^{1/8}$). For the tumor site of male rat kidney the 1 x 10^{-6} values from the human models vary by 2-fold (0.48 to 0.79 ppb; Table 9). The same analysis was repeated with the human metabolic parameters from Sams *et al.* (2004) and the range was similar (0.33 to 0.74 ppb). PBPK models with higher body weight of 90 kg and 40% body fat gave only slightly higher ppb predictions. According to the discussion above, the preferred value for the unit risk of ethylbenzene is 2.5 x 10^{-6} $(\mu g/m^3)^{-1}$, based on the data for male rat kidney tumors. With the human model unit risk estimates ranged from 1.27 x 10^{-6} to 3.06 x 10^{-6} ppb^{-1} (2.9 x 10^{-7} to 7.0 x 10^{-7} $[\mu g/m^3]^{-1}$ at 4.35 $\mu g/m^3$/ppb) or somewhat lower than the animal PBPK based values. These unit risk estimates from the human PBPK models were not used as final values due to issues of tumor site concordance and human variability and

parameter uncertainty. The information is provided here for comparative purposes and methodology development.

Table 9. Estimates of Virtually Safe Exposure Levels (ppb) based on Human PBPK Modeling[a]

Method/Model	Occupational Scenario	Environmental Scenario
I . Human Potency based		
70 kg human 20% fat Haddad	0.70	0.50
20% fat Sams	0.66	0.33
90 kg human 40% fat Haddad	0.79	0.56
40% fat Sams	0.74	0.34
II. Animal LED_{10} based		
70 kg human 20% fat Haddad	0.68	0.48
20% fat Sams	0.64	0.32
90 kg human 40% fat Haddad	0.74	0.53
40% fat Sams	0.69	0.34

[a] Note: Values are calculated for 1 x 10^{-6} theoretical lifetime cancer risk. Occupational scenario was 8.0 hr/d x 5 days/week, for one-week simulations; environmental scenario was continuous exposure for one week. Method I used the human potency (Ph) in $(mg/kg\text{-}d)^{-1}$ to calculate a 10^{-6} risk internal dose in metrics of ethylbenzene metabolized by the liver (AMET, μmol/d). Method II uses the animal LED_{10} to calculate a 10^{-6} risk dose. The human models were the 70 kg default with 20% fat and a 90 kg variant with 40% fat (and comparatively less muscle). The Ph was based on the male rat kidney tumors of 0.0087 $(mg/kg\text{-}d)^{-1}$. Inhalation was 20 m^3/d. The models were run with metabolic parameters from Haddad *et al*. (2001) and Sams *et al*. (2004).

Conclusion

The male rat was the most sensitive sex and species tested by NTP (1999) in the inhalation carcinogenesis studies of ethylbenzene. While the highest potency and unit risk values were obtained for rat testicular adenomas, the high background rate of this common tumor made interpretation difficult. NTP considered the increased incidences of renal tubule carcinoma or adenoma to provide clear evidence of the carcinogenic activity of ethylbenzene, and this site was considered to be the more reliable basis for estimating human cancer potency.

OEHHA has examined various proposals for the mode of action of ethylbenzene in causing the observed increases in tumor incidence in rodent lung, kidney and liver. Some of these involve cytotoxicity or exacerbation of existing degenerative processes, which might be considered capable of increasing tumor incidence by a non-genotoxic mechanism, although the precise implications of these proposals for dose-response relationships have not been fully explored.

Moreover, it appears likely that metabolism of ethylbenzene involves generation of reactive metabolites. These metabolites include quinone/hydroquinone species capable of causing oxidative DNA damage and carcinogenesis, analogous to the processes established for benzene and some similar carcinogens. OEHHA concludes that overall, the limited data do not conclusively establish any particular mode of action for ethylbenzene carcinogenesis, and indeed several of the proposed processes may be influential. However, one or more genotoxic processes appear at least plausible and may well contribute to the overall process of tumor induction. Because of this, the default linear approach has been used for extrapolating the dose-response curve to low doses.
