NOTICE OF FILING

TO: See Service List

PLEASE TAKE NOTICE that I have today filed with the Illinois Pollution Control Board, Illinois EPA's MOTION FOR ACCEPTANCE; APPEARANCES; CERTFICIATE OF ORGINATION; STATEMENT OF REASONS; and PROPOSED AMENDMENTS TO 35 ILL. ADM. CODE 620, GROUNDWATER QUALITY STANDARDS, a copy of which is served upon you.

Respectfully submitted,

ILLINOIS ENVIRONMENTAL
PROTECTION AGENCY

MOTION FOR ACCEPTANCE

NOW COMES the Illinois Environmental Protection Agency (Illinois EPA), by and through its attorneys, and pursuant to 35 Ill. Adm. Code 102.106, 102.200, and 102.202, moves the Illinois Pollution Control Board to accept the Illinois EPA'S proposal for the adoption of a proposed amendments to 35 Ill. Adm. Code 620, Groundwater Quality.

This regulatory proposal includes:

1) Notice of Filing;
2) Appearances of Attorneys for the Illinois EPA;
3) Certification of Origination;
4) Statement of Reasons (including attachments);
5) Proposed Amendments; and
6) Certificate of Service

Respectfully submitted,

CERTIFICATE OF ORIGINATION

NOW COMES the ILLINOIS ENVIRONMENTAL PROTECTION AGENCY (Illinois EPA) by its attorneys, and pursuant to 35 Ill. Adm. Code 102.202(i), the Illinois EPA certifies that the regulatory proposal in the above captioned matter amends the most recent version of Part 620 of the Illinois Pollution Control Board's regulation, as published on the Board's website.

IN THE MATTER OF:	)	
	)	RXXX-XXX
PROPOSED AMENDMENTS TO	)	
GROUNDWATER QUALITY	)	(Rulemaking – Public Water
(35 Ill. Adm. Code 620)	)	Supplies)

STATEMENT OF REASONS

NOW COMES the Illinois Environmental Protection Agency (Illinois EPA or Agency) by and through its counsel and submits its Statement of Reasons to the Illinois Pollution Control Board (Board) pursuant to 415 ILCS 5/27 and 5/28, and 35 Ill. Adm. Code 102.200 and 102.202. Upholding the policy of the Illinois Groundwater Protection Act (IGPA), this proposal seeks to amend 35 Ill. Adm. Code 620, keeping groundwater quality standards current as scientific data and methods supporting the development of groundwater quality standards have evolved.

I. STATUTORY AUTHORITY

Part 620 of the Board's rules pertain to "various aspects of groundwater quality." *See* 35 Ill. Adm. Code 620.105. As such, Part 620 is subject to the IGPA.

Adopted in 1987, the IGPA set forth that:

> …it is the policy of the State of Illinois to restore, protect, and enhance the groundwaters of the State, as a natural and public resource. The State recognizes the essential and pervasive role of groundwater in the social and economic well-being of the people of Illinois, and its vital importance to the general health, safety, and welfare. It is further recognized as consistent with this policy that the groundwater resources of the State be utilized for beneficial and legitimate purposes; that waste and degradation of the resources be prevented; and that the underground water resource be

> managed to allow for maximum benefit of the people of the State of Illinois.

See 415 ILCS 55/2(b).

Implementing the policy above, Section 55/8(a) of the IGPA required the Illinois EPA to establish and propose comprehensive water quality standards specifically for the protection of the groundwater by July 1, 1989. *See* 415 ILCS 55/8(a). In preparing such regulations, the IGPA required the Agency to:

> …address, to the extent feasible, those contaminants which have been found in the groundwaters of the State and which are known to cause, or are suspected of causing, cancer, birth defects, or any other adverse effect on human health according to nationally accepted guidelines.

See 415 ILCS 55/8(a).

In addition, Section 55/8(b) of the IGPA required the Board to promulgate the water quality standards for groundwater within two years after the date upon which the Agency filed proposed regulations. *See* 415 ILCS 55/8(b).

II. BACKGROUND

In 1989, Illinois EPA established and proposed comprehensive water quality standards specifically for the protection of groundwater. In 1991, the Board promulgated water quality standards for groundwater. *See* Groundwater Quality Standards (35 Ill. Adm. Code 620, R89-14(B) (November 7,1991) (R89-14(B)). Although satisfying the mandate of the IGPA with the proposal and adoption of Part 620; Groundwater Quality, the Board acknowledged the need to continually revise the numeric groundwater quality standards as new information develops. *See* Id. at 19. Therefore, to ensure that the numerical groundwater quality standards continued to evolve with the supporting

scientific data and methods, the Board stated an expectation "of regular updates" to the groundwater quality standards from the Agency. *See* Id.

This point was reiterated in the most recent rulemaking, R08-18. There, the Board recognized the Agency's position, that to prevent the degradation of the groundwater resources it is periodically necessary to: 1) amend the groundwater quality standards to account for new scientific data, 2) update the groundwater standards that have been amended at the federal level, 3) update technical references that are in the Incorporations by Reference, and 4) address any additional groundwater parameters that have been discovered. *See* R08-18, at 4.

To meet the Board's stated expectations and to keep the groundwater quality standards current with the latest scientific data and methods, the Agency has proposed, and the Board has adopted amendments to the groundwater quality standards multiple times over the years. In 1994, the principal amendments included: 1) the addition of Class I and Class II groundwater quality standards for sixteen chemicals for which standards had not previously been promulgated, 2) the modification of certain preventive notification and response provisions, including listing of ten of the new sixteen chemicals, and 3) making various amendments of a conforming nature. *See* Groundwater Protection: Amendments to Groundwater Quality Standards 35 Ill. Adm Code. 620, R93-27 (Aug. 11, 1994) (R93-27).

In 1997, the Board adopted amendments to conform the groundwater quality standards to the Site Remediation Program. *See* Site Remediation Program (Brownfields) and Groundwater Quality Standards (35 Ill. Adm. Code 740 and 35 Ill. Adm. Code 620),

R97-11 (June 5, 1997) (R97-11).[1] In 2002, The Board adopted amendments which included a preventive response level in addition to Class I and Class II groundwater quality standards for methyl tertiary-butyl ether (MTBE). *See* Proposed MTBE and Compliance Determination Amendments to Groundwater Quality Standards: 35 Ill. Adm. Code 620, R01-14 (Jan. 24, 2002) (R01-14).

Finally, based upon new scientific data, federal amendments, and technical references, 35 Ill. Adm. Code 620 Groundwater Quality standards were last updated in 2012. *See* Proposed Amendments Groundwater Quality Standards (35 Ill. Adm. Code 620), R08-18 (October 4, 2012). The amendments added groundwater quality standards for chemical constituents detected in Illinois groundwater that had established toxicity values or that had groundwater remediation objectives under the Tiered Approach to Corrective Action Objectives (TACO) (35 Ill. Adm. Code 742). *See* Id. In all, 39 chemical constituents were added. In addition, revisions were made to the Class I groundwater quality standard for arsenic. *See* Id.

III. REGULATORY PROPOSAL

A. Regulatory Proposal: Purpose and Effect

The Illinois EPA now submits this proposal to amend 35 Ill. Adm. Code 620; Groundwater Quality. The purpose of this proposal is to uphold the stated policy of the IGPA. This is accomplished by keeping the groundwater quality standards current with the evolution of scientific data and methods supporting the development of the groundwater quality standards. Specifically, the proposal achieves this purpose with the inclusion of ten new chemicals, three new atrazine

[1] In 1997, the Agency proposed, and the Board adopted additional amendments to Part 620. However, these amendments were of a non-substantive, "housekeeping" nature. *See* Amendments to 35 Ill. Adm. Code Subtitle F (Parts 601-620), R96-18 (May 1, 1997).

metabolites, and updated procedures in Subpart F and Appendix A for selecting toxicity values consistent with current scientific data and methods. This includes methods for calculating groundwater quality standards when Maximum Contaminant Levels (MCLs) or Maximum Contaminant Level Goals (MCLG) are not available. In addition, definitions and references are updated. Site specific groundwater standards for designated Class III Special Resource Groundwater are also proposed. Finally, this proposal includes groundwater quality standards for six Per- and Polyfluoroalkyl Substances (PFAS) including perfluorooctanoic acid (PFOA), perfluorooctanesulfonic acid (PFOS), perfluorononanoic acid (PFNA), perfluorohexanesulfonic acid (PFHxS), perfluorobutanesulfonic acid (PFBS), and hexafluoropropylene oxide dimer acid (HFPO-DA).

B. Regulatory Proposal: Language

The following is a Section-by-Section summary of the Illinois EPA's proposed language. Illinois EPA is providing both Ms. Hawbaker's and Mr. Dunaway's pre-filed testimony for a more in-depth and technical review of the proposed language. *See* Carol Hawbaker Testimony (Attachment 1) and Lynn Dunaway Testimony (Attachment 2).

SUBPART A: GENERAL

Section 620.110 Definitions

The Agency proposes adding the following definitions to Section 620.110: "Chemical Abstract Service Registry Numbers or CASRN," "Lower Limit of Quantitation or LLOQ," "Lowest Concentration Minimum Reporting Level or LCMRL," and "Mutagen." In addition, the Agency proposes to update the

definition of "Carcinogen" to maintain consistency with the current U.S. EPA Integrated Risk Information System and the definition of "Detection" to language currently utilized in test methods. Finally, the Agency proposes to remove the definition of "Practical Quantitation Level or PQL" as it is replaced by the terms "Lower Limit of Quantitation or LLOQ" and "Lowest concentration minimum reporting level (LCMRL), as analytical methods have updated the terminology to describe levels of quantitation in analyses.

Section 620.125 Incorporations by Reference

The Agency proposes to add Illinois EPA's "Integrated Water Quality Report and Section 303(d) List" and the National Academy of Science "Water Quality Criteria" (1973) to this Section, while also adding and updating several test methods. The Agency proposes to add and update references from the U.S. EPA Office of Research and Development, National Center for Environmental Assessment, the U.S. EPA Risk Assessment Forum, and the U.S. EPA Office of Resource Conservation and Recovery. Finally, the Agency proposes updating the U.S. EPA groundwater guidance and the Code of Federal Regulation references to the most recent edition.

SUBPART B: GROUNDWATER CLASSIFICATION

Section 620.210 Class I: Potable Groundwater

The Agency proposes removing permeameter as an acceptable means to determine hydraulic conductivity. This removal is because the collection of samples for its use has a high potential to alter the sample's hydraulic conductivity and are therefore not sufficient representatives of in-situ hydraulic

conductivity. Further, the permeameter analysis accounts for vertical hydraulic conductivity, whereas in-situ methods measure hydraulic conductivity on a horizontal plane.

The Agency proposes adding the wellhead protection area of a community water supply well or well field as a specific area to which Class I groundwater quality standards are applicable. The wellhead protection area is added because site specific hydrogeologic parameters are used to estimate the area from which the groundwater will enter a community well or well field from within the aquifer material.

Section 620.250 Groundwater Management Zone

The Agency proposes adding a list of standard documentation that must be included with all groundwater management zone (GMZ) applications. Submission of a standardized list of documents makes review and approval of a GMZ more efficient. In addition, some of the information will provide documentation of the complete set of corrective actions required, the time required to complete them, and evidence supporting the efficacy of the corrective action(s).

SUBPART C: NONDEGRADATION PROVISIONS FOR APPROPRIATE GROUNDWATERS

Section 620.302 Applicability of Preventive Notification and Preventive Response Activities

Section 602.302(b)

Section 620.302(a) provides the applicability of preventive notification and preventive response activities.[2] For the purposes of subsection (a), Section

[2] 35 Ill. Adm. Code 620.302(a):
Preventive notification and preventive response as specified in Sections 620.305through 620.310

620.302(b) provides a list of persons that conduct groundwater monitoring. To make the list in this subsection more comprehensive, the Agency proposes adding examples of persons that conduct groundwater monitoring.

Section 620.310 Preventive Response Activities

The Agency proposes updating the table in Section 620.310(a)(3)(A)(i) to include the Chemical Abstracts Service Registry Numbers (CASRN) for each constituent.[3] The Agency also proposes adding a table at Section 620.310(a)(3)(A)(ii) depicting the constituents in the subsection. This table will provide a clear representation of the constituents subject to the preventive response activities. Along with this addition of the proposed constituents are carcinogens with health-based standards that are not set at the LLOQ or LCMRL, and carcinogens with MCLs that are no longer based on the LLOQ or LCMRL because these constituents can be reliably detected at lower concentrations. The Agency proposes not including chemicals in the table that now utilize LLOQs/LCMRLs as the Class I standard because they cannot be reliably detected at lower concentrations. Finally, the Agency proposes to remove the Board note, as many carcinogens with groundwater quality standards based on the MCL and set at PQLs, now have LLOQs or LCMRLs that are below the MCL, making these carcinogens subject to the non-degradation provisions at Section 620.310.

---

applies to:

1) Class I groundwater under Section 620.210(a)(1), (a)(2), or (a)(3) that is monitored by the persons listed in subsection (b); or
2) Class III groundwater that is monitored by the persons listed in subsection (b).

[3] CASRNs are unique numerical identifiers that are directly tied to a specific chemical. Chemicals can be associated with several names or synonyms for identification. The CASRN allows the user to know the specific chemical in reference.

SUBPART D: GROUNDWATER QUALITY STANDARDS

Section 620.410 Groundwater Quality Standards for Class I: Potable Resource Groundwater

The Agency proposes to add Class I groundwater quality standards for ten new chemicals as they have been identified in the groundwater in Illinois and may cause a hazard to human health. In addition, tables are updated to add a CASRN for each constituent. The Agency proposes to add footnotes detailing the basis of the groundwater quality standards. This allows users to easily identify the sources of the standards. In addition, the notations identify carcinogens (where previously an asterisk was used as an identifier) and include the identification of carcinogens that operate via mutagenic mode of action. The Agency also proposes to update the applicable Class I groundwater quality standards based on updated methodologies in 620 Subpart F and Appendix A. In addition, updates for the beneficial use of potable resource groundwater (the use of more stringent livestock and irrigation values, in lieu of action levels and MCLs for copper and selenium) are proposed. The Agency is proposing the use of livestock and irrigation criteria for these constituents because the livestock and irrigation criteria are more stringent than current standards. Potable resource groundwater is also used for the watering of livestock and the irrigation of the crops/produce. Finally, maintaining consistency with U.S. EPA, the Agency proposes to update the groundwater quality standards based on the MCLs for radium 226 and radium 228 to a groundwater quality standard based on an updated MCL for radium (combined 226+228).

The Agency proposes removing the explosive constituents table at Section 620.410(c) and more appropriately integrating those constituents into a table at Section 620.410(b). In addition, the Agency proposes moving atrazine from Section 620.410(b) to the complex chemical mixtures tables at Section 620.410(c) with the addition of atrazine metabolites. With the addition of the metabolites, it becomes a complex organic chemical mixture, and thus more appropriate for subsection (c).

Section 620.420 Groundwater Quality Standards for Class II: General Resource Groundwater

In Section 620.420, the Agency proposes adding Class II groundwater quality standards for ten new chemicals and two chemicals listed in Section 620.410 without prior Class II groundwater quality standards. In addition, the Agency proposes updating the constituent tables adding a CASRN for each constituent and updating applicable Class II groundwater quality standards. Footnotes detailing the sources of the standards and carcinogenicity are also proposed. The Agency proposes removing the explosive constituents table at Section 620.420(c) and more appropriately integrating the constituents into the table at Section 620.420(b). Finally, the Agency proposes moving atrazine from Section 620.420(b) to the complex chemical mixtures tables at Section 620.420(c) with the addition of atrazine metabolites. With the addition of the metabolites, it becomes a complex organic chemical mixture, and thus more appropriate for subsection (c).

Section 620.430 Groundwater Quality Standards for Class III: Special Resource Groundwater.

The proposed language in Section 620.430 establishes location specific Class III groundwater quality standards for six dedicated nature preserves (DNPs), as designated pursuant Section 620.230(b). Chloride and pH location specific Class III groundwater quality standards are established at four "cave" DNPs which will provide added protection to assist in the preservation and ideally the enhancement of the critical environment for the Federally and State endangered Illinois Cave Amphipod. In addition, a chloride location specific Class III groundwater quality standards is established for two "wetland" DNPs which will provide added protection for the preservation and ideally the enhancement of wetland ecosystems which provide habitat for numerous State threatened and endangered plant species. Please see Attachment 2 for the required justification in support of the location specific proposed groundwater quality standards. *See* R89-14(B) at 20.

Section 620.440 Groundwater Quality Standards for Class IV: Other Groundwater

The Agency proposes to update the names of explosive constituents.

Section 620.450 Alternative Groundwater Quality Standards

The Agency proposes to update the names of explosive constituents.

SUBPART E: GROUNDWATER MONITORING AND ANALYTICAL PROCEDURES

Section 620.510 Monitoring and Analytical Requirements

The proposed language in this Section requires the use of the 2009 Unified Guidance to determine background groundwater quality unless other methods are

specified by regulation. In addition, because "PQL" is an outdated term, the proposed language replaces the use of the "PQL" with either the "LLOQ" or "LCMRL" to the analytical method of the chemical.

SUBPART F: HEALTH ADVISORIES

Section 620.601 Purpose of a Health Advisory

Section 620.601(b)

The Agency proposes updating the Illinois Administrative Code references to more thoroughly and accurately reflect the factors that must be considered when establishing a new source of public water supply.

Section 620.605 Issuance of a Health Advisory

Section 620.605(b)(1)

Amendments in Section 620.605(b)(1) designate the more stringent toxicity value of the (Human Threshold Toxicant Advisory Concentration (HTTAC) or Human Nonthreshold Toxicant Advisory Concentration (HNTAC) as the guidance value in the absence of a Maximum Contaminant Level (MCL) or Maximum Contaminant Level Goal (MCLG).

Section 620.605(b)(2)

The Agency proposes removing the Human Nonthreshold Toxicant Advisory Concentration (HNTAC) language and equation and relocating it to Appendix A.

Section 620.APPENDIX A Procedures for Determining Human Toxicant Advisory Concentrations for Class I: Potable Resource Groundwater

Section 620.Appendix A(a)

The proposed language in Section Appendix A(a) includes updates clarifying language for the calculation of noncancer effects, and updates the per capita daily water ingestion rate from an average adult rate of 2 liters per day ("L/d") to an average child water ingestion rate 0.78 L/d. The Agency proposes updating the exposure population from an average adult to a child aged 0 – 6 years. The Agency proposes the use of a child population for evaluating noncarcinogenic effects as a more sensitive receptor than an adult when considering exposure via the oral, or ingestion, route. The use of a child exposure population is consistent with 35 Ill. Adm. Code 742 for calculating ingestion remediation objectives for noncancer effects. U.S. EPA methods found at U.S. EPA's Regional Screening Levels ("RSLs") calculate screening levels for both an adult and a child for exposure to residential tapwater and both the adult and child must be addressed.

Section 620.Appendix A(b)(1)

The proposed language to Section 620.Appendix A(b)(1) updates the body weight for calculating the Acceptable Daily Exposure from an average adult to 15 kg, representative of a child 0-6 years of age.

Section 620.Appendix A(b)(2)

The Agency proposes building upon the toxicity hierarchy used to derive oral reference doses in the 2012 amendments, based on updates in 2013 and 2021 to the original toxicity hierarchy referenced in PCB R08-18. See Ms. Hawbaker's

testimony for more detailed information regarding U.S. EPA's updates to its toxicity hierarchy. The updates to the toxicity hierarchy are incorporated into RSLs decision tree for selecting toxicity values for development of its screening levels. The Agency generally uses the toxicity values found in the RSL table when calculating TACO Tier 2 remediation objectives and intends to utilize the RSLs when updating its TACO amendments. The toxicity values for calculating groundwater quality standards in Part 620 and remediation objectives in Part 742 need to be consistent.

Section 620.Appendix A(b)(3)

The Agency proposes revising the methodology used to calculate oral references doses when an oral reference dose is not available from the toxicity hierarchy. This update will make the language consistent with the U.S. EPA Reference Dose Guidance and Species Extrapolation Guidance. The method currently described in (b)(3), (b)(4), (b)(5), and (b)(6) of Appendix A is outdated. Updated methods and models to derive oral reference doses have replaced the method described in these subsections.

Section 620.Appendix A(b)(4)

The Agency proposes removing the language as described in Section (b)(3) of Appendix A and clarifying the usage of uncertainty factor consistent with updated methods for calculating oral reference doses.

Section 620.Appendix A(b)(5)

The Agency proposes removing the outdated language as described in Section (b)(3) of Appendix A.

Section 620.Appendix A(b)(6)

The Agency proposes removing the outdated language as described in Section (b)(3) of Appendix A.

Section 620.Appendix A(d)

Proposed Section (d) in Appendix A adds methods describing the calculation of HNTAC guidance levels (removed from Section 620.605(b)(2)) and updates the methods in accordance with U.S. EPA guidance. The updated methods are based on processes prescribed in the Guidelines for Carcinogen Risk Assessment and Supplemental Guidance for Assessing Susceptibility for Early-Life Exposure to Carcinogens, both added to the Incorporations by Reference. It also updates the exposure factors based on 2011 updates to the Exposure Factor Handbook. The methods are used by U.S. EPA to calculate RSLs for carcinogen risks of drinking contaminated residential tapwater.

Section 620.Appendix A(d)(1)

Proposed Section (d)(1) in Appendix A adds an equation for calculating HNTAC guidance level for chemicals designated as carcinogens that operate through a mutagenic mode of action. Mutagens are expected to cause irreversible changes to DNA, which would exhibit a greater risk in early-life versus later-life exposures. The equation for calculating a standard for mutagens uses potency adjustments to account for greater exposure risk during early life periods. The methods are based on Guidelines for Carcinogen Risk Assessment and Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens; both incorporated by reference in Section 620.125.

Section 620.Appendix A(d)(2)

Based on updated methods in the Guidelines for Carcinogen Risk Assessment and Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens, proposed Section (d)(2) of Appendix A updates the equation for calculating HNTAC guidance levels for chemicals designated as carcinogens that are not designated as mutagens.

Section 620.APPENDIX B Procedures for Determining Hazard Indices for Class I: Potable Resource Groundwater for Mixtures of Similar Acting Substances

Section 620.Appendix B(c)

The Agency proposes removing the language specific to mixtures of ortho-dichlorobenzene and para-dichlorobenzene, and 1,1-dichloroethane and 1,1,1- trichloroethane, and adding a reference to Appendix E. Many chemicals have similar-acting health effects. Adding Appendix E assists the user in determining if chemicals detected together in groundwater have similar-acting effects, making them subject to the mixture rule.

Section 620.Appendix B(f)(2)

The Agency proposes replacing the use of the "PQL" with the "LLOQ" or "LCMRL," as appropriate, to the analytical method of the chemical.

Section 620.APPENDIX C Guidelines for Determining When Dose Addition of Similar-Acting Substances in Class I: Potable Resource Groundwaters is Appropriate

The Agency proposes replacing the use of the "PQL" with the "LLOQ" or "LCMRL," as appropriate, to the analytical method of the chemical.

Section 620.APPENDIX E Similar Acting Substances

The Agency proposes adding tables of similar acting non-carcinogenic and carcinogenic constituents for convenient reference.

IV. OUTREACH

A. Community Outreach

On September 14, 2018, the Agency presented to stakeholders proposed amendments to the groundwater quality standard. This proposal included groundwater quality standards for PFOA and PFOS based on the Health Advisory Level of 70 nanograms per liter finalized by the U.S. EPA in May 2016. The Agency held a 21-day comment period.

On December 24, 2019, the Agency again presented to stakeholders updated proposed amendments to the groundwater quality standards. This came after an update in scientific data which resulted in a significant change to the Agency's proposed groundwater quality standards. Specifically, the ATSDR published the Peer Reviewed Toxicological Profile establishing toxicity criteria for PFOA and PFOS using updated studies resulting in lowered dose minimum risk levels and providing toxicity values for PFHxS and PFNA in units of milligrams per kilogram per day. The Agency held a 38- day comment period.

On January 28, 2020, due to stakeholder response, the Agency redistributed to stakeholders the proposed amendments to the groundwater quality standards and extended the comment period for an additional 30 days.[4] On

[4] Comments were received from 3M; the City of Springfield, Office of Public Utilities (CWLP); the Illinois Attorney General's Office, Environmental Bureau; Susan Smith; the Illinois Department of Transportation, Bureau of Design & Environment; PDC Laboratories, Inc.; Eurofins; PDC Technical Service, Inc., Andrews Engineering (on behalf of Republic Services), Millennium Waste Incorporated, and Waste

February 13, 2020, the Agency held a question-and-answer session regarding the proposed amendments. During this session, the Agency outlined the methodology used in developing the PFAS groundwater quality standards. *See* Illinois EPA's Development of Proposed PFAS Groundwater Quality Standards for 35 Ill. Adm. Code Part 620; Hawbaker, Carol Proposed Updates to 35 Ill. Adm. Code 410 and 420, Power Point (February 13, 2020); and 620 Update Tables for Outreach (Attachment 3). In addition, the Agency summarized the proposed amendments and key provisions, and answered questions during the session.

On May 12, 2021, the Agency presented to stakeholders updated proposed amendments to the groundwater quality standard amendments. After a review of potential exposure receptors for calculating noncarcinogen standards, the Illinois EPA utilized child exposure factors for children 0-6 years of age to protect more sensitive populations from the harmful effects of drinking contaminated groundwater. Illinois EPA updated all groundwater quality standards calculated using the HTTAC, including groundwater standards for the newly proposed constituents, for a child population, which resulted in more protective groundwater quality standards. In addition, the Agency utilized the California EPA cancer toxicity value for PFOA. Calculating PFOA as a carcinogen with this value and the proposed updated methodology to account for childhood exposure to carcinogens resulted in more protective groundwater quality standards.

Management - each as members of the Illinois Chapter of the National Waste & Recycling Association; the PFAS Regulatory Coalition; the Illinois Environmental Council; Dynegy Midwest Generation, LLC, Kincaid Generation, LLC, Illinois Power Resources Generating Company, and Electric Energy Inc.; Illinois American Water; the American Chemistry Council; the Illinois Environmental Regulatory Group; the Department of the Army, United States Army Corps of Engineers; and the Illinois Association of Wastewater Agencies.

The Agency accepted and considered all public comments regarding the proposed groundwater quality standards for six weeks, until June 25, 2021.[5] During this time, the Agency held a public meeting on May 26, 2021 to outline the updated methodology used in developing the PFAS groundwater quality standards. *See* Hawbaker, Carol Illinois Environmental Protection Agency Proposed Updates to 35 Ill. Adm. Code 620 Power Point, (May 26, 2021) (Attachment 4). In addition, the Agency summarized the proposed amendments and key provisions, and answered questions. *See* 35 Ill. Adm. Code 620; Groundwater Quality Pre-Filing Public Comment Period Factsheet and Overview of Proposed Changes; and Table – Part 620 Proposed Groundwater Quality Standards Excel Spreadsheet (Attachment 4). Industry, environmental groups, State agencies, and other potentially interested parties were invited.

During both the 2020 and the 2021 public comment periods, a significant number of commenters asked about the process that Illinois EPA used to develop the groundwater quality standards. In response, the Agency presented on and outlined the methodology used in developing the groundwater quality standards at both the question-and-answer session on February 13, 2020, and the public meeting on May 26, 2021. *See* Attachments 3 and 4.

In addition, several commenters asked if Illinois EPA considered the impact of the groundwater standards on cleanup and permit programs (e.g., solid waste landfills). The Agency acknowledges that certain regulations administered by the Bureau of Land

[5] The Agency received comments from the Illinois Environmental Regulatory Group; the PFAS Regulatory Coalition; PDC Technical Services; the Natural Resources Defense Council in collaboration with the Illinois Environmental Council Sierra Club, Illinois Chapter; GSI Environmental, Inc. on behalf of Midwest Generation LLC.; PDC Laboratories, Inc.; Eurofins; The International Molybdenum Association; the National Waste and Recycling Association; the American Chemistry Council; St. John-Mittelhauser & Associates, Inc.; Illinois American Water; and the Illinois Groundwater Advisory Council.

are tied to the Board's groundwater quality standards, and as such the adoption or amendment of any groundwater quality standard could impact land cleanup and permit programs. Separate and apart from this proceeding, the Agency has reached out to commenters and the regulated community involved in the land cleanup and permit programs to begin discussions regarding potential changes to those programs following the completion of this rulemaking. Specifically, on June 25, 2021, the Agency met with members of the Site Remediation Advisory Committee of the Illinois Chamber of Commerce's Illinois Environmental Regulatory Group. This group represents parties that are interested in impacts to the Agency's remedial programs. On August 19, 2021 and November 15, 2021, the Agency met with representatives of the landfill industry.

B. Groundwater Advisory Council and Interagency Coordinating Committee on Groundwater

In addition to engaging with the public and stakeholders during the drafting process of Part 620, the Agency coordinated with both the Groundwater Advisory Council (GAC) and the Interagency Coordinating Committee on Groundwater (ICCG). On September 19, 2021, following three meetings and a request from the ICCG Chairman to provide comments, the GAC provided a Recommendation to the ICCG Chairman and Agency representatives regarding the proposed groundwater quality standards amendments.[6] The Recommendation contained a list of items the GAC believes the Agency has not provided along with a statement indicating that

> …if the Agency continues to move forward with the proposal, it is the GAC's position that the Illinois EPA sufficiently address these questions in the Proposed rulemaking and/or Statement of Reasons to provide the most robust and transparent proposal to the Illinois Pollution Control Board for a more effective and workable standard.

[6] 415 ILCS 55/5 requires the GAC to, among other things, review, evaluate, and make recommendations on State groundwater protection laws, regulations, and procedures.

See GAC Recommendation (Attachment 5).

On October 14, 2021, following a review of the GAC Recommendation, the ICCG provided to both the Agency and GAC a written Response stating the following:

> The ICCG as a whole entity does not have the expertise to answer or comment on the GAC questions/comments on the proposed changes to the 35 Ill. Adm. Code 620 Groundwater Quality standards. These changes to the Groundwater Quality standards are being proposed by the Illinois EPA, who has the expertise and knowledge to address this (GAC) Recommendation. Therefore, it is the Committee's stated opinion that the GAC Recommendation should be addressed by the Illinois EPA in the Statement of Reason or before the Illinois Pollution Control Board. Further, this Response by ICCG does not specifically endorse or disapprove of the proposed rule changes and individual ICCG member reserves the right to provide additional comment, questions, or concerns during the rule making process.

See ICCG Response (Attachment 6). The ICCG concluded that "by providing this written memorandum and the Response within, the ICCG has met its Statutory obligations under the Illinois Groundwater Protection Act." [7] *See* Id.

On November 18, 2021, the Illinois EPA responded in writing to the GAC Recommendation, indicating that while the Agency believes each applicable point of concern raised by the Council has been sufficiently addressed in the Statement of Reasons and Testimony, each point may be further addressed during the proposed rulemaking proceeding before the Board. *See* Agency Reply (Attachment 7).

V. AFFECTED SOURCES AND FACILITES

While Part 620 establishes groundwater quality standards, it is the various permitting and cleanup programs that implement the standards. Therefore, it is those

[7] 415 ILCS 55/4 requires the ICCG to, among other things, review and evaluate State groundwater protection laws, regulations, and procedures, to consider findings and recommendations that are provided by the GAC, and to respond to the GAC findings and recommendation in writing.

sources and facilities subject to the permitting requirements and cleanup programs that will be impacted by the proposed groundwater quality standard amendments.

VI. TECHNICAL FEASIBILITY AND ECONOMIC REASONABLENESS

When promulgating regulations under the Act, Section 27 requires the Board to consider "the technical feasibility and economic reasonableness of measuring or reducing the particular type of pollution." *See* 415 ILCS 5/27(a). In addition, the Board must also determine "whether the proposed rule has any adverse economic impact on the people of the State of Illinois." *See* 415 ILCS 5/27(b). Consistent with prior Board determinations, the groundwater quality standards proposed today are technically feasible and economically reasonable and will not adversely impact the people of the State of Illinois.

A. Prior Evaluations and Determinations

The Board has evaluated the technical feasibility and economic reasonableness of groundwater standards on multiple occasions. Each evaluation concluding the amendments to be technical feasible and economically reasonable.

First, in 1991, with the initial adoption of the groundwater quality standards. Those regulations included numerical standards for 60 constituents. The mandated[8] (*See* 415 ILCS 55/8(d)) economic impact study (EcIS) of those 60 constituents "determined that the most significant costs of the regulations can be expected to be groundwater remediation costs, i.e., those costs associated with returning contaminated groundwater to compliance with standards." *See* R89-14(B) at 22. Following the EcIS determination, the Board noted the importance in the distinction

[8] The Board determined in R08-18, that from a plain reading of the statutory language in 415 ILCS 55/8(d), the mandate for IDNR to conduct an economic impact study on the Agency's proposal only applied to the initial promulgation of Part 620 and not to subsequent amendments. *See* R08-18 at 25.

between groundwater quality standards and cleanup standards or requirements. *See* Id. at 24. As such, the Board pointed out that "site specific considerations would most likely determine the nature of the required remediation and what actual cost is to be borne by any particular entity, industry, or government." *See* Id. at 24-25.

The Board continued in its discussion stating:

> Another factor in consideration of the EcIS' cost estimates is that the instant regulations do not create or require any new corrective action program; all such programs are part of other regulations already in place or proposed (e.g., RCRA, CERCLA, LUST, waterwell setback regulations, etc.). The EcIS investigators recognized that the remedial costs properly associated with the instant rules should be "incremental costs over and above the costs associated with the currently applicable regulations for water quality standards and cleanup criteria."

See Id. at 25, emphasis in original.

The Board stated further:

> The fact that the EcIS investigators attributed to today's groundwater quality standards all the costs of any potential future remedial action is a serious flaw in the EcIS analysis. Cleanup of contaminants to the levels stated in these rules as required by an appropriate agency during remediation does not mean that all the costs of cleanup should be attributed to adoption of today's rules.

See Id.

What is more, the Board indicated the following economic benefits would result from the adoption of groundwater standards: reduction of carcinogenic health risks; reduced expenses for treatment of water at wellheads; and reduced expenses for obtaining water supplies. *See* Id at 23-26.

Next[9], the Board adopted new groundwater standards for Methyl Tertiary-Butyl Ether (MTBE) on January 24, 2002. *See* R01-14. There, the Board recognized the

[9] The Board amended the ground water quality standards in 1994 with the addition of 16 Class I and II standards, however the Agency could not find any discussion regarding technical feasibility and economic reasonableness in the Board Orders. *See* R93-27.

Agency's position that the addition of MTBE as a groundwater quality parameter would not change the Board's economic reasonableness and technical feasibility conclusions from the regulatory proceeding in which the Board's original groundwater regulations became effective – docket R89-14(B). *See* R01-14 at 7. Similarly, just as was concluded in R89-14(B), the Board found any significant economic impacts to be a result of remediation efforts. *See* Id. However, the Board balanced this consideration with the safety of drinking water supplies and the costs of changing water supplies if a water supply became contaminated. The Board stated that it "places a very high value on the safety of drinking water supplies and finds that safety must be paramount in this matter." *See* Id at 10.

Finally, the Board last updated the groundwater standards in its Order dated October 4, 2012. *See* R08-18. There, the Board again recognized the Agency's position that the addition of the proposed numeric standards would not change the Board's economic reasonableness and technical feasibility conclusions from the regulatory proceeding in which the Board's original groundwater regulations became effective – docket R89-14(B). *See* Id. at 26. In addition, the Board reiterated the Agency's statement that the proposed revisions would not create new corrective or monitoring programs, and TACO remediation objectives had already been established for most chemicals at issue. *See* Id. at 27. Further, the Board agreed with the Agency's statement that the revised standards would be phased into existing programs over time and the economic impact of applying the revised standards in other programs would be incremental. *See* Id.

The Board concluded its discussion on technical feasibility and economic

reasonableness adding "that in the IGPA, the General Assembly found 'contamination of Illinois groundwater will . . . adversely impact the economic viability of the State' and 'protection of groundwater is a necessity for future economic development in this State.' 415 ILCS 5/2(a) (2010)." *See* Id. After noting economic benefits that would result from adopting groundwater standards, the Board found the proposed amendments "to be designed for furthering the General Assembly's intent of protecting groundwater not only for the health of Illinois citizens, but also for their economic well-being. *See* Id. Ultimately, the Board reiterated its first notice determination that the proposed amendments would not have an adverse economic impact on the people of Illinois. *See* Id.

B. Current Proposal

Consistent with the Board's numerous prior evaluations and determinations, the proposed groundwater quality standard amendments are technically feasible and economically reasonable. As the Board stated in R89-14(B), there is an important distinction between the Part 620 groundwater quality standards and cleanup standards or requirements, and it is through the cleanup programs implementing the groundwater quality standards where the economic impacts can be expected. *See* R89-14(B) at 22. Maintaining this difference, the proposed amendments simply establish the groundwater quality standards. They do not establish clean-up standards or requirements. In addition, the proposed groundwater quality standards do not require new corrective action or monitoring programs. It is through these existing programs cleanup standards and programs in which the proposed groundwater quality standards will be implemented.

Consistent with the Board's determination after reviewing the IGPA required EcIS and with the numerous prior Board Orders updating the groundwater quality standards, any significant economic impacts will be a result of remediation efforts (*See* R89-14 (B) at 22, R01-14 at 7) and would be incremental (*See* 89-14(B) at 25 and R08-18 at 27). The proposed groundwater quality standards will be phased into existing programs, as appropriate, over time. For example, the adoption of new groundwater quality standards will trigger changes to the cleanup standards used in Bureau of Land cleanup programs. These changes will be implemented through amendments to the cleanup standards set forth in the Board's TACO rules. The economic impact resulting from those amendments will be addressed in the appropriate rulemakings as they occur over time.

As the Board stated in R08-18, there is no information suggesting that the proposed amendments would impose an economic or technical burden significantly different from that resulting from prior Part 620 rulemakings. *See* R08-18 at 27. Therefore, as previously determined by the Board, the groundwater quality standards proposed today are technically feasible and economically reasonable and will not adversely impact on the people of the State of Illinois.

VII. AGENCY WITNESSES AND TESTIMONY

The Illinois EPA will present two witnesses during the Board's hearing on this proposal, Ms. Carol Hawbaker and Mr. Lynn Dunaway. Pre-filed written testimony for each witness is attached hereafter. *See* Attachments 1 and 2.

VIII. SUPPORTING DOCUMENTS

A. Relied Upon Documents

The Illinois Administrative Procedure Act provides that all proposed rulemakings must include:

> a descriptive title or other description of any published study or research report used in developing the rule, the identity of the person who performed such study, and a description of where the public may obtain a copy of any such study or research report. If the study was performed by an agency or by a person or entity that contracted with the agency for the performance of the study, the agency shall also make copies of the underlying data available to members of the public upon request if the data are not protected from disclosure under the Freedom of Information Act.

See 5 ILCS I00/5-40(b)(3.5). The Board's procedural rules require the same information to be included with any rulemaking proposal filed with the Board. *See* 35 Ill. Adm. Code 102.202(e). The following list constitutes the studies and reports that the Illinois EPA used in developing the proposed amendments:

Title 35: Environmental Protection, Subtitle G: Waste Disposal, Chapter I: Pollution Control Board, Subchapter f: Risk Based Cleanup Objectives, Part 742 Tiered Approach to Corrective Action Objectives, effective July 15, 2013.

IX. CONCLUSION

WHEREFORE, for the reasons stated above, the Illinois EPA asks the Board to accept this Statement of Reasons and proceed to hearings on the above-captioned rulemaking proposal.

Respectfully submitted,

ILLINOIS ENVIRONMENTAL PROTECTION AGENCY

By: /s/ Sara Terranova
Sara Terranova
Assistant Counsel
Division of Legal Counsel

ATTACHMENT 1

TESTIMONY OF CAROL L. HAWBAKER ON PROPOSED

UPDATED GROUNDWATER QUALITY STANDARDS

My name is Carol L. Hawbaker. I am the Lead Worker in the Office of Toxicity Assessment ("OTA") of the Illinois Environmental Protection Agency's ("Illinois EPA") Associate Director's Office ("ADO"). I have been employed at Illinois EPA since September of 2000, first as a Project Manager in Bureau of Land's Leaking Underground Storage Program; then, as an Environmental Risk Assessor in OTA. As an Environmental Protection Specialist IV, or Lead Worker, for OTA, my primary responsibilities include the development and use of procedures for toxicity and environmental risk assessments, review of toxicity and risk data in support of Illinois EPA programs, review of human health and ecological risk assessment for projects enrolled in state and federal programs, and review of exposure, risk assessment, and fate and transport models.

I am a member of U.S. Environmental Protection Agency's ("U.S. EPA") Environmental Council of the States and Association of State and Territorial Health Officials PFAS Science Group and a participant in State Risk Assessors Teleconference Group. I also participate in workgroups within the Illinois EPA focusing on updates to cleanup objectives and procedures utilized in developing cleanup objectives, including taking a lead role in drafting updates to 35 Ill. Adm. Code 742.

I received a Bachelor of Science in History from Illinois State University in 1995 and subsequently received 48 hours of educational credit towards a Master in Science degree in

Environmental Studies with a focus on environmental risk assessment and toxicology; after which I received certification in Environmental Risk Assessment.

Testimonial Statement

Background and Basis

My testimony will focus on the following topics:

- The addition of new chemical constituents proposed to be added to Part 620;
- Updates to Part 620.310(a)(3)(A);
- Updates to Part 620.410 Class I: Groundwater Quality Standards for Potable Resource Groundwater ("standards");
- Updates to Part 620.420 Class II: Groundwater Quality Standards for General Resource Groundwater ("standards");
- Updates to methodologies used to calculate when a Maximum Contaminant Level ("MCL") or Maximum Contaminant Level Goal ("MCLG") is not available for a constituent, located at Part 620, Subpart F and Appendix A; and
- Updates to Appendix B for similar-acting substances, including a new Appendix E, providing tables listing similar-acting constituents and affected target organs or health effects.

For clarity, I will begin with updates to Subpart F and Appendix A. These updates form the basis for updates to the Class I standards at Part 620.410 for several constituents.

I. Updates to Subpart F: Health Advisories and Appendix A

Part 620, Subpart F and Appendix A, provide the basis for developing Illinois Pollution Control Board ("Board") rulemaking proposals for new or revised numerical standards (35 Ill.

Adm. Code 620.601(c)). The Board adopted Subpart F: Health Advisories and Appendix A procedures for determining a Human Threshold Toxicant Advisory Concentration ("HTTAC") for developing noncancer health-based standards for Class I: Potable Resource Groundwater on November 7, 1991. The Board adopted Subpart F: Health Advisories procedures for determining a Human Nonthreshold Toxicant Advisory Concentration ("HNTAC") for developing cancer risk-based standards for Class I: Potable Resource Groundwater on October 4, 2012. Since those times, Illinois EPA developed Class I standards using this procedure for contaminants found in groundwater that do not have MCLs or MCLGs. Of the 115 constituents currently listed in Part 620.410 Groundwater Quality Standards for Class I: Potable Resource Groundwater, 39 constituents currently have Class I standards based on the procedures specified in Subpart F and Appendix A.

Subpart F: Health Advisories

Part 620.601(b): Updates the applicable regulation for siting and source water requirements.

Part 620.605(b)(1): Updates the language to allow for a Class I standard to be set at the lower value calculated from either the HTTAC noncancer equation or the HNTAC cancer equation. By choosing the lower of the two concentrations, a person ingesting groundwater is protected from both cancer effects and other noncancer adverse health effects. The method of choosing the lower of the concentrations is consistent with the methods prescribed in 35 Ill. Adm. Code 742: Tiered Approach to Corrective Action Objectives ("TACO"). Thomas C. Hornshaw, in prefiled testimony dated May 29, 2008 for the Board's rulemaking docket PCB R08-18 (Attachment 1A), discussed Illinois EPA's desire to make Part 620 consistent with TACO, as the standards are used in TACO as groundwater remediation objectives for the groundwater ingestion exposure route.

TACO selects the more stringent remediation objective calculated by carcinogen and noncarcinogen methods. In addition, the term practical quantitation limit ("PQL") is replaced by the terms lower limit of quantitation ("LLOQ"), as specified in EPA Publication SW-846, and lowest concentration minimum reporting level ("LCMRL"), specified in drinking water methods incorporated by reference at Section 620.125. Analytical methods have updated, and the terminology to describe levels of quantitation in analyses have also updated. Definitions for LLOQ and LCMRL are added to the definitions at Section 620.110. Procedures for quantifying these limits are available in the analytical method procedures.

As the standards calculated using the methods at Part 620, Subpart F and Appendix A are based on the protection of human health from ingesting groundwater, and MCLs are promulgated for drinking water, drinking water methods are appropriate for analyzing Class I potable resource groundwater. When discussing Class I potable resource groundwater, the Board stated the following in its Final Opinion and Order for R89-14(B): In the Matter of Groundwater Quality Standards (35 Ill. Adm. Code 620), dated November 7, 1991:

> "The Board believes that among the most necessary facets of the State's groundwater protection program is the need to protect all drinkable water at a drinkable level. Similarly, the Board does not believe that current actual use should be the sole control of whether potable groundwater is afforded the protection necessary to maintain potability; we simply cannot allow the sullying of a resource that future generations may need. For the same reason the term "Potable Resource Groundwater", rather than "Potable Use Groundwater", is employed in the title of this class."

Part 620.605(b)(2): Deletes the language methodology and equation for calculating HNTACs for carcinogens. This information is updated and moved to Appendix A.

Part 620.Appendix A: Procedures for Determining Human Toxicant Advisory Concentrations for

Class I: Potable Resource Groundwater

The proposal updates the title of Appendix A by removing the term "Threshold" and making "Concentration" plural due to the addition of the HNTAC procedures to Appendix A.

Appendix A(a):

- Specifies the HTTAC calculation is for noncancer effects. The HTTAC equation calculates a drinking water level at which no adverse effects are expected to occur.
- Adjusts the per capita daily water consumption from an average adult rate of 2 liters per day to an average child rate of 0.78 liters per day for a child aged 0 – 6 years. To be protective of more sensitive receptors, such as young children, from adverse health effects from ingesting groundwater, Illinois EPA proposes to utilize child exposure factors when calculating threshold toxicant advisory concentrations for noncancer effects. The proposed use of child exposure factors is consistent with TACO's use of child exposure factors for evaluating the ingestion exposure route for noncarcinogens. In addition to updating the per capita daily water consumption rate, body weight found at Appendix A(b)(2) is updated from an average adult body weight of 70 kilograms to a body weight of 15 kilograms, equivalent of a child aged 0 – 6 years. The source for the child exposure factor values is U.S. EPA Office of Solid Waste and Emergency Response ("OSWER") Directive 9200.1-120, "Subject: Human Health Evaluation Manual, Supplemental Guidance: Update of Standard Default Exposure Factors," dated February 6, 2014 and included as Attachment 1B. The child exposure factors are also listed at U.S. EPA's Regional Screening Levels for Chemical Contaminants at Superfund Sites ("RSL") User's Guide, available at:

https://www.epa.gov/risk/regional-screening-levels-rsls-users-guide. The RSL databases and equations utilize the most up-to-date methodologies, exposure assumptions, chemical-physical properties, and toxicity values within OSWER's toxicity hierarchy. Illinois EPA is in the process of drafting updates to TACO to align it with RSL methodology and procedures. Adjusting the exposure factors from an adult to a young child protects both children and adults from harmful effects of exposure via ingestion of chemicals in drinking water.

Appendix A(b)(1):

- Adjusts the language to refer to the Acceptable Daily Exposure ("ADE") as representing the maximum amount of the threshold toxicant, if ingested daily by a child aged 0 – 6 years, will result in no adverse effects.

Appendix A(b)(2):

- Adjusts the language to allow for the selection of toxicity values based on various OSWER Directives issued over the years discussing hierarchies and procedures for selecting human health toxicity values in Superfund risk assessments. Thomas C. Hornshaw's prefiled testimony in Attachment 1A, discusses the first revision of the hierarchy of human health toxicity values recommended for use in risk assessments, issued on December 5, 2003 (OWSER Directive 9285.7-53), included in Attachment 1C. OSWER Directive 9285.7-53 recommends the following revised toxicity value hierarchy as follows:

  Tier 1: U.S. EPA Integrated Risk Information System ("IRIS");

  Tier 2: U.S. EPA Provisional Peer-Reviewed Toxicity Values ("PPRTV");

Tier 3: Other Toxicity Values.

The Directive goes on to state:

> "The third tier includes other sources of information. Priority should be given to sources that provide toxicity information based on similar methods and procedures as those used for Tier I and Tier II, contain values which are peer reviewed, are available to the public, and are transparent about the methods and processes used to develop the values."

The Directive further states:

> "Additional sources may be identified for Tier 3. Toxicity values that fall within the third tier in the hierarchy include, but need not be limited to, the following sources:
>
> - The California Environmental Protection Agency ("Cal EPA") toxicity values are peer reviewed and address both cancer and non-cancer effects.
>
> - The Agency for Toxic Substances and Disease Registry ("ATSDR") Minimal Risk Levels ("MRLs") are estimates of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse non-cancer health effects over a specified duration of exposure. The ATSDR MRLs are peer reviewed and are available at http://www.atsdr.cdc.gov/mrls.html on the ATSDR website.
>
> - Health Effects Assessment Summary Tables ("HEAST") toxicity values are Tier 3 values. It should be noted that EPA's HEAST has not been updated since 1997."

On May 16, 2013, U.S. EPA's OSWER Human Health Regional Risk Assessors Forum issued, "Tier 3 Toxicity Value White Paper" ("Paper"). The Paper discusses a tentative ranking of Tier 3 toxicity sources implemented by the U.S. EPA Regional Screening Level ("RSL") workgroup, included in Attachment 1C. The Paper lists the Tier 3 ranking for sources as follows:

1. United States Health and Human Services Agency for Toxic Substances and Disease Registry ("ATSDR") dose minimal risk levels ("dose MRL");
2. California EPA, Office of Environmental Health Hazard Assessment ("OEHHA") toxicity values;
3. PPRTV "Appendix" values;
4. Health Effects Assessment Summary Table ("HEAST").

On May 26, 2021, U.S. EPA Office of Land and Emergency Management ("OLEM") issued a Memorandum with the Subject, "Recommendations of the Use of Chronic or Subchronic Noncancer Values for Superfund Human Health Risk Assessments." The Memorandum, included in Attachment 1C, discusses the use of subchronic or intermediate toxicity values in place of chronic values when the subchronic values are based on updated methodologies and/or more recent studies. When subchronic toxicity values are calculated using a human equivalency dose based on a time-weighted average serum concentration, an uncertainty factor of one may be used to extrapolate a chronic dose.

The toxicity value hierarchy discussed above is used by U.S. EPA for human health risk assessments and represents the method of selection by RSL for RSL's toxicity values. In the matter of the proposed amendments to groundwater quality standards (R08-18), the Board's Final Opinion and Order of the Board, dated October 4, 2012, states the following regarding the use of U.S. EPA's toxicity hierarchy to determine a verified oral reference dose:

> "The Board found that the Agency appropriately relied upon the revised toxicity hierarchy of the United States Environmental Protection Agency (USEPA) to account for new scientific data in proposing updates to the Board's groundwater quality standards. *See* R08-18 GQS, slip op. at 9-11. Next, the Board found that the addition to Part 620 of 39 chemical constituents detected in Illinois groundwater that have established toxicity values or groundwater remediation objectives in TACO is consistent with the IGPA (415 ILCS 55 (2010)) and the Act. *Id.* at 11-12."

OTA sets its toxicity values for TACO, and Part 620, to be consistent with the toxicity values listed at RSL, with a few exceptions:

- Cancer toxicity values are not utilized for chemicals that do not meet the definition of a "carcinogen" as stated in Section 620.110 and Section 742.200.
- RSL does not list an oral reference dose for Methyl-tertiary-butyl-ether ("MTBE"). Illinois EPA developed an oral reference dose for MTBE using the processes in Part 620 Appendix A for constituents that do not have a verified oral reference dose. On January 24, 2002, the Board approved Illinois EPA's oral reference dose and adopted a Class I standard for MTBE at the Board's Final Opinion and Order in the Matter of Proposed MTBE and Compliance Determination to Groundwater Quality Standards: 35 Ill. Adm. Code 620 (Illinois Pollution Control Board: R01-14, Rulemaking – Public Water Supply).
- For vanadium (Chemical Abstract Services Registry Number ("CASRN") 7440-62-2), RSL utilizes a toxicity value derived from vanadium pentoxide

(CASRN 1314-62-1), developed by IRIS and issued June 30, 1988. RSL user's guide provides the following statement regarding the basis of the vanadium's oral reference dose ("RfD"):

> "The oral RfD toxicity value for Vanadium, used in this website, is derived from the IRIS oral RfD for Vanadium Pentoxide by factoring out the molecular weight (MW) of the oxide ion. Vanadium Pentoxide (V_2O_5) has a molecular weight of 181.88. The two atoms of Vanadium contribute 56% of the MW. Vanadium Pentoxide's oral RfD of 9E-03 mg/kg-day multiplied by 56% gives a Vanadium oral RfD of 5.04E-03 mg/kg-day."

Illinois EPA utilizes a PPRTV oral RfD toxicity value of 7E-05 mg/kg-day for vanadium (CASRN 7440-62-2), issued on September 30, 2009, included in Attachment 1D.

- Although not listed on the RSL tables, RSL uses toxicity values for perfluorooctanoic acid ("PFOA") and perfluorooctanesulfonic acid ("PFOS"), developed by U.S. EPA Office of Water for U.S. EPA's May 2016 PFOA and PFOS Drinking Water Health Advisories, in its screening level calculator. The 2016 Office of Water Health Effect Support Documents for PFOA and PFOS are included in Attachment 1D.

PFOA and PFOS are constituents proposed to be added to Part 620. The Illinois EPA is proposing Class I standards for PFOS developed using the intermediate dose-MRL of 2E-06 milligrams per kilogram per day (mg/kg-day), calculated by ATSDR and discussed in, "Toxicological Profile for Perfluoroalkyls," released May 2021 and included in Attachment 1D. Illinois EPA

selected the ATSDR value due to the addition of a modifying factor (10) to account for the adverse effect of decreased immune response, and ATSDR's position within the toxicity hierarchy.

PFOA meets Section 620.110's definition of a carcinogen. In 2017, International Agency for Research on Cancer ("IARC") classified PFOA as Group 2B: possibly carcinogenic to humans, meeting the definition of a carcinogen in Section 620.110. Therefore, the Illinois EPA calculated both noncancer and cancer standards to determine the most stringent standard. For noncancer effects, Illinois EPA selected the ATSDR intermediate dose MRL of 3E-06 mg/kg-day for calculating an HTTAC, due to ATSDR's use of updated studies when compared to studies used by U.S. EPA Office of Water to develop an oral RfD for its 2016 PFOA Drinking Water Health Advisory. To calculate a standard based on cancer risks, Illinois EPA utilized California EPA's peer-reviewed oral slope factor ("SF_o") of 143 $(mg/kg\text{-}day)^{-1}$, as its cancer toxicity value to calculate an HNTAC based on a one in one million cancer risk. California EPA's toxicity profile is also included in Attachment 1D. The Illinois EPA selected the California EPA value because of its use of more recent studies than relied upon for determining cancer risks for the U.S. EPA 2016 Drinking Water Health Advisory, and the source of the value is within the toxicity hierarchy recommended by the U.S EPA.

Hexafluoropropylene oxide dimer acid ("HFPO-DA"), perfluorohexanesulfonic acid ("PFHxS"), and perfluorononanoic acid ("PFNA") are not included in the RSL database. Illinois EPA selected the toxicity value for

HFPO-DA from U.S. EPA's Office of Water toxicological profile, titled, "Human Health Toxicity Values for Hexafluoropropylene Oxide (HFPO) Dimer Acid and Its Ammonium Salt (CASRN 13252-13-6 and CASRN 62037-80-3)", finalized on October 25, 2021 and included in Attachment 1D. Illinois EPA selected toxicity values for PFHxS and PFNA from ATSDR's PFAS toxicological profile referenced above.

Appendix A(b)(3)-(6):

Appendix A(b)(3)-(6) are updated to reflect updated procedures used to develop noncancer toxicity values, primarily Benchmark Dose ("BMD") modeling and the development of a Human Equivalent Dose ("HED") using pharmacokinetic ("PBPK") modeling. The proposed updates are based on recommended procedures discussed in U.S. EPA's, "A Review of the Reference Dose and Reference Concentration Processes," dated 2002, and "Guidance for Applying Quantitative Data to Develop Data-Derived Extrapolation Factors for Interspecies and intraspecies Extrapolation," dated 2014, and are included as Attachment 1E.

Appendix A(d):

Section "d" is added to Appendix A to add the procedures for calculating an HNTAC for carcinogens. These procedures are removed from Part 620.605(b) and placed in Appendix A. In addition, the Illinois EPA proposes updating the procedures for calculating an HNTAC to be consistent with updates to U.S. EPA methods for calculating health-based carcinogen screening levels for Superfund sites. Illinois EPA bases the current methodology for calculating an HNTAC on the groundwater ingestion remediation objective equation for carcinogens found in TACO. The equation currently listed in both TACO and Part 620 has been updated by U.S. EPA to account for

exposure during both childhood and adulthood. The current method in Part 620 accounts only for exposure as an adult and uses outdated exposure factors such as the drinking water ingestion rate, body weight, and exposure duration; all updated by U.S. EPA in 2014. In addition, U.S. EPA developed procedures for calculating risk-based values for carcinogens acting through a mutagenic mode of action. The updated carcinogen procedures are based on "Guidelines for Carcinogenic Risk Assessment," and "Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens," both dated March 2005, by U.S. EPA Risk Assessment Forum, included in Attachment 1F. The proposed updated HNTAC equations and the supporting equations to calculate the age-adjusted resident tap water ingestion rate for carcinogens are provided in Attachment 1G and available on-line at: https://www.epa.gov/risk/regional-screening-levels-rsls-equations. Illinois EPA is drafting updates to its TACO regulations so that they are consistent with the methods and equations described in U.S. EPA's RSL User's Guide.

Appendix A(d)(1):

Introduces an equation used by U.S. EPA for calculating ingestion screening levels for residential tap water, for exposure to a carcinogen acting through a mutagenic mode of action. A mutagenic mode of action is expected to cause irreversible changes to DNA; and, would exhibit a greater carcinogenic effect for exposures occurring in early-life stages than with later life exposures. To account for increased risks from early-life exposure to mutagens, potency adjustments are applied to drinking water exposure factors for children less than 16 years of age. To further explain: a potency factor of 10 is applied to drinking water exposure factors for exposure to a mutagen during ages 0 – 2 years, a potency factor of 3 is applied to drinking water exposure factors for exposure to a mutagen during ages 2 – 6 years and ages 6 – 16 years, and a potency

factor of 1 is applied to drinking water exposure factors for exposure to a mutagen for an adult. U.S. EPA lists the following constituents in Part 620 as mutagens in the RSL User's Guide at: https://www.epa.gov/risk/regional-screening-levels-rsls-users-guide#mutagens

CASRN	Constituent
56-55-3	Benzo(a)anthracene
205-99-2	Benzo(b)fluoranthene
207-08-9	Benzo(k)fluoranthene
50-32-8	Benzo(a)pyrene
218-01-9	Chrysene
53-70-3	Dibenzo(a,h)anthracene
75-09-2	Dichloromethane (methylene chloride)
193-39-5	Indeno(1,2,3-c,d)pyrene
79-01-6	Trichloroethylene
75-01-4	Vinyl Chloride

As benzo(a)pyrene, dichloromethane, trichloroethylene, and vinyl chloride have established MCLs, standards for these constituents are not calculated using the methods at Appendix A(d)(1). The Class I standards for these 4 mutagens are based on MCLs.

Appendix A(d)(2):

Updates the HNTAC equation to be consistent with updates by U.S. EPA. This includes updates to exposure factors such as body weight, exposure duration, and daily water ingestion rates, specified by OSWER Directive 9200.1-120 (Attachment 1B). The update also includes the above-referenced methodology for calculating an age-adjusted drinking water ingestion rate to account for exposures during both childhood and as an adult.

The proposed updates to Subpart F and Appendix A, result in updated standards for the 39 constituents presently listed in Part 620 that rely on the methods in these sections for developing Class I standards. For those constituents that have calculated standards less than each's applicable LLOQ or LCMRL, the LLOQ or LCMRL is the Class I standard, a table comparing health-based

standards with the applicable LLOQ or LCMRL is included as part of Attachment 1I as supporting documentation for the proposed Class I potable resource standards.

II. Introduction of New Constituents

Illinois EPA proposes the addition and establishment of standards for 10 constituents to Part 620. All have been detected in groundwater in Illinois. 6 of the proposed constituents are per- and polyfluoroalkyls ("PFAS"). Illinois EPA documented detections of proposed per- and polyfluoroalkyls perfluorobutanesulfonic acid ("PFBS"), PFHxS, PFOS, and PFOA in finished water of public water supplies across Illinois as a result of Illinois EPA's statewide investigation into the prevalence and occurrence of PFAS in finished drinking water. With the investigation over 99 percent complete, PFAS have been detected in the finished water of public water supplies that provide drinking water for over 2 million consumers (16.1 percent of the population in Illinois, based on the 2020 census), with over 910,000 of those consumers receiving drinking water from community water supply wells (7.2 percent of the population in Illinois). In addition, approximately 500,000 people are served by non-community public water systems per Illinois Department of Public Health website at: http://dph.illinois.gov/topics-services/environmental-health-protection/non-community-public-water-systems. Non-community public water systems included facilities such as schools, daycares, factories, restaurants, resorts, churches, were not included as part of Illinois EPA's statewide investigation. Further, thousands more utilize groundwater from private potable wells, usually without access to treatment technologies. The above-referenced PFAS were also found in community water supply wells, prompting the issuance of Statewide Health Advisories for the constituents. PFAS does not have any taste, color, or odor

in drinking water. The only way to confirm the presence of PFAS is through proper sampling and analysis.

The Illinois EPA also proposes the addition of another PFAS: HFPO-DA. HFPO-DA is also referred to as "GenX", a trade name for a processing technology that produces fluoropolymers without PFOA; and is a replacement product for PFOA. HFPO-DA is detected in groundwater during sampling for purposes other than the statewide PFAS sampling initiative. In October 2021, U.S. EPA Office of Water issued its final human health toxicity assessment for HFPO-DA. Information regarding U.S. EPA Office of Water's finalization of its human health toxicity assessment is available at: https://www.epa.gov/chemical-research/human-health-toxicity-assessments-genx-chemicals. U.S. EPA Office of Water qualifies as an additional Tier 3 toxicity value source, although it is not specifically mentioned in Tier 3 hierarchy referenced in the 2013 Paper.

PFAS are human-made chemicals often referred to as "forever chemicals", due to the strength of carbon – fluorine bonds. The strength of this bond does not allow for PFAS to break down easily under natural conditions. PFAS are mobile in soil and groundwater and have been shown to bioaccumulate, or build up, in blood and organs over time. Although PFOA and PFOS are no longer manufactured in the United States, they have been replaced with other PFAS alternatives such as PFBS. PFOA and PFOS are still used in manufacturing in other countries, so consumer goods imported to the United States may contain PFOA or PFOS.

PFAS are used in many industrial and consumer processes to make everyday items non-stick, or water-, oil-, or stain-resistant. Examples of items containing PFAS are:

- Food packaging - fast food containers, lunch meat paper, disposable plates, and bowls, and oil-, water- and grease-resistant coatings on food packaging
- Commercial household products - non-stick coated cookware (Teflon), cleaning products, waxes, polishes, and adhesives
- Clothing and fabric textiles - stain- and water-resistant carpeting and upholstery, water repellant clothing, tents, umbrellas, shoes, and leather goods
- Cosmetics and personal care products - shampoos, conditioners, sunscreens, cosmetics, and dental floss
- Building and exterior use products - paints and sealants
- Industrial use - metal plating and finishing, wire coatings, automotive fluids, and the manufacture of artificial turf
- Firefighting foam - aqueous film-forming foam ("AFFF")

PFAS has been measured in indoor air, outdoor air, dust, food, water, and various consumer products. Occupational exposure to PFAS for some individuals, such as those working in PFAS manufacturing facilities, installing or treating carpets, or firefighters using PFAS containing firefighting foams, may be higher than exposure to the general public. Potential routes of PFAS exposure include ingestion, dermal, and inhalation.

The general population is primarily exposed to PFAS through the ingestion of contaminated food, water, dust, and hand-to-mouth contact with PFAS treated products, such as carpets and textiles or cosmetics and lotions containing PFAS. Infants and toddlers have higher exposure to PFAS due to having a single source of nutrition (breast-feeding or formula-feeding), by hand-to-mouth transfer due to being in contact with treated carpets and furniture; and have

greater indoor dust ingestion. Once swallowed, PFAS can enter the bloodstream due to its ability to bind to blood proteins such as albumin, and typically distributes to the liver, kidneys, and blood. Most humans have detections of PFAS in the blood, primarily PFOA and PFOS; but the levels of these PFAS found in human blood are decreasing as PFOA and PFOS is phased out of production. PFAS is also found in umbilical cord blood and breastmilk from highly exposed humans.

Food grown in water or soil contaminated with PFAS, and food packaging treated with PFAS can cause PFAS to transfer to food, directly exposing people to PFAS upon consumption. PFAS biomagnifies through trophic levels, meaning that its concentration increases as it moves upward through the food chain. This becomes a concern for humans because of the variety of foods that we eat including vegetables, fish, livestock, and wildlife.

In addition to the proposed PFAS, Illinois EPA proposes to add three inorganic constituents (aluminum, lithium, and molybdenum), and 1 polycyclic aromatic hydrocarbon (1-methylnapthalene).

Illinois EPA also proposes to include atrazine metabolites desethyl-atrazine ("DEA"), desisopropyl-atrazine ("DIA"), and diaminochlorotriazine ("DACT") as part of the total atrazine standard. The proposed addition of the metabolites is based on recommendations in World Health Organization's ("WHO") document titled, "Atrazine and Its Metabolites in Drinking-Water", published in 2010, and included in Attachment 1H. Toxicity profiles indicating the metabolites had similar properties and modes of action as atrazine formed WHO's basis for the addition of the metabolites. Further, United States Geological Survey ("USGS") in cooperation with Illinois EPA, published, "Herbicides and Their Transformation Products in Source-Water Aquifers Tapped by

Public-Supply Wells in Illinois, 2001-02", to demonstrate the presence of atrazine metabolites in Illinois groundwater. The USGS document is also included in Attachment 1H.

III. Updates to Part 620.310 Preventive Response Activities

The tables located at Section 620.310 are updated to include CASRNs. CASRNs are numerical identifiers unique to each constituent. As constituents can have several identifying names, the use of a CASRN assists in verifying a specific constituent of concern.

Illinois EPA proposes the removal of para-dichlorobenzene and ethylbenzene from the table at Section 620.310(a)(3)(A)(i), as the constituents are now classified as carcinogens. Therefore, the numerical criteria for these constituents at Section 620.310(a)(3)(A)(i) are no longer applicable.

Illinois EPA proposes the addition of the following constituents to the table at Section 620.310(a)(3)(A)(ii), based on proposed additions to Part 620:

CASRN	Constituent
7429-90-5	Aluminum
7439-98-7	Molybdenum
13252-13-6	HFPO-DA (hexafluoropropylene oxide dimer acid, GenX)
90-12-0	1-Methylnaphthalene
375-73-5	PFBS (perfluorobutanesulfonic acid)
355-46-4	PFHxS (perfluorohexanesulfonic acid)
375-95-1	PFNA (perfluorononanoic acid)
1763-23-1	PFOS (perfluorooctanesulfonic acid)

Lithium and PFOA are not included in the table because the standards are based on the LLOQ or LCMRL. The terms represent the lowest level an analyte may be quantified by analysis. Standards set at these levels are not included, based on testimony by Richard P. Cobb, P. G., in prefiled testimony dated May 29, 2008 for the Board's rulemaking docket PCB R08-18

(Attachment 1A), where Mr. Cobb discussed the basis for the preventive response activities. Mr. Cobb's testimony stated, in part:

> The Board's final opinion and order on groundwater quality standards indicates that the numerical standard is not meant to be a level to pollute up to and included specific preventive standards prohibiting contamination above detectable levels that threaten a preclusion of use.

Therefore, constituents whose standards are based on the LLOQ or LCMRL are not included in the table.

Illinois EPA proposes to add the following existing Part 620 constituents to the table at Section 620.310(a)(3)(A)(ii), as the Class I standards are noncancer health-based standards, and not based on an LLOQ or LCMRL; therefore, the preventive response activities apply:

CASRN	Constituent
2691-41-0	HMX (octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine)
98-95-3	Nitrobenzene
121-82-4	RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine)
118-96-7	TNT (2,4,6-trinitrotoluene)

Illinois EPA also proposes to add the following existing Part 620 carcinogen constituents to the table at Section 620.310(a)(3)(A)(ii), as the Class I standards are health-based standards, and not based on an LLOQ, or LCMRL. Therefore, the preventive response activities apply:

CASRN	Constituent
319-84-6	*alpha*-BHC (*alpha*-benzene hexachloride)
56-55-3	Benzo(a)anthracene
205-99-2	Benzo(b)fluoranthene
207-08-9	Benzo(k)fluoranthene
218-01-9	Chrysene
53-70-3	Dibenzo(a,h)anthracene
123-91-1	1,4-Dioxane (*p*-dioxane)
193-39-5	Indeno(1,2,3-c,d)pyrene

Finally, Class I standards for many carcinogens are based on the MCL or MCLG promulgated by U.S. EPA, Office of Water, and Illinois Primary Drinking Water Standards at 35 Ill. Adm. Code 611. The Board Note included at Section 620.310(a)(3)(A), states:

> Constituents that are carcinogens have not been listed in subsection (a)(3)(A) because the standard is set at the PQL and any exceedence thereof is a violation subject to corrective action.

Due to updates in analytical methods that can quantify contaminants at lower levels, many carcinogens whose Class I standards are based on the MCL are no longer set at the practical quantitation limit ("PQL"), now proposed to be referred to as the LLOQ or LCMRL. As a result, preventive response activities also apply to the following carcinogen constituents that do not rely on a limit of quantitation as the Class I standard:

CASRN	**Constituent**	**Class I Standard (mg/L)**	**LLOQ or LCMRL (mg/L)**	**Analytical Method**
71-43-2	Benzene	0.005	0.00003	EPA 524.3
50-32-8	Benzo(a)pyrene	0.0002	0.0001	EPA 525.2
56-23-5	Carbon tetrachloride	0.005	0.000098	EPA 524.3
12798-03-6	Chlordane	0.002	0.0002	EPA 525.2
67-66-3	Chloroform	0.07	0.002	EPA 8260B
96-12-8	1,2-Dibromo-3-chloropropane (dibromochloropropane)	0.0002	0.00002	EPA 504.1
106-46-7	*p*-Dichlorobenzene (1,4-dichlorobenzene)	0.075	0.000065	EPA 524.3
107-06-2	1,2-Dichloroethane	0.005	0.000051	EPA 524.3
75-09-2	Dichloromethane (methylene chloride)	0.005	0.00025	EPA 524.3
78-87-5	1,2-Dichloropropane	0.005	0.000065	EPA 524.3
117-81-7	Di(2-ethylhexyl)phthalate	0.006	0.0006	EPA 525.2
100-41-4	Ethylbenzene	0.7	0.000085	EPA 524.3
106-93-4	Ethylene dibromide (1,2-dibromoethane)	0.00005	0.00001	EPA 504.1
58-89-9	*gamma*-HCH (*gamma*-hexachlorocyclohexane, lindane)	0.0002	0.00002	EPA 525.2

CASRN	Constituent	Class I Standard (mg/L)	LLOQ or LCMRL (mg/L)	Analytical Method
76-44-8	Heptachlor	0.0004	0.00004	EPA 525.2
1024-57-3	Heptachlor epoxide	0.0002	0.00002	EPA 525.2
1336-36-3	PCBs (polychlorinated biphenyls as decachloro-biphenyl)	0.0005	0.0001	EPA 8082A
87-86-5	Pentachlorophenol	0.001	0.0004	EPA 515.4
127-18-4	Tetrachloroethylene	0.005	0.000081	EPA 524.3
8001-35-2	Toxaphene	0.003	0.001	EPA 525.2
79-01-6	Trichloroethylene	0.005	0.000091	EPA 524.3
75-01-4	Vinyl Chloride	0.002	0.000092	EPA 524.3

The Illinois EPA proposes to add the above carcinogens to the table at Section 620.310(a)(3)(A)(ii), and requests the Board remove the Board Note, as the Board Note is no longer applicable.

One chemical is removed from Section 620.310(a)(3)(A)(ii): MCPP (mecoprop). The updated proposed standard for MCPP is the LLOQ for the constituent. Therefore, preventive response activities are not applicable.

IV. Updates to Class I Standards at Section 620.410

The tables located at Section 620.410 are updated to include CASRNs and notations beneath the tables providing the basis of the standards and as identifiers of carcinogens, including carcinogens operating with a mutagenic mode of action. The addition of notations at the bottom of each table assists the user in determining the basis of the proposed standards. A table listing Class I groundwater quality standards proposed for updates in comparison with the current values is included in Attachment 1I. The table also includes the basis for the current standards and the proposed standards; and provides toxicity values (noncancer oral reference doses ("RfD"), relative source contributions ("RSC"), and cancer oral slope factors ("SF_o")) used for the calculations of

health based standards at Appendix A, including the sources of the RfD and SF_o toxicity values. RSCs generally have default values of 0.2, although the values may be altered by other resources and professional judgement.

For the thirty-nine constituents with current Class I standards based on procedures in Part 620 Subpart F and Appendix A, all have been recalculated using the proposed methods specified in Subpart F and Appendix A. Those constituents are:

CASRN	Constituent
83-32-9	Acenaphthene
67-64-1	Acetone
120-12-7	Anthracene
319-84-6	*alpha*-BHC (*alpha*-benzene hexachloride)
56-55-3	Benzo(a)anthracene
205-99-2	Benzo(b)fluoranthene
207-08-9	Benzo(k)fluoranthene
65-85-0	Benzoic acid
78-93-3	2-Butanone (methyl ethyl ketone)
75-15-0	Carbon disulfide
218-01-9	Chrysene
53-70-3	Dibenzo(a,h)anthracene
1918-00-9	Dicamba
75-71-8	Dichlorodifluoromethane
75-34-3	1,1-Dichloroethane
84-66-2	Diethyl phthalate
84-74-2	Di-*n*-butyl phthalate
99-65-0	1,3-Dinitrobenzene
121-14-2	2,4-Dinitrotoluene
606-20-2	2,6-Dinitrotoluene
123-91-1	1,4-Dioxane (*p*-dioxane)
206-44-0	Fluoranthene
86-73-7	Fluorene
2691-41-0	HMX (octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine)
193-39-5	Indeno(1,2,3-c,d)pyrene
98-82-8	Isopropylbenzene (cumene)
93-65-2	MCPP (Mecoprop)
1634-04-4	MTBE (methyl tertiary-butyl ether)
91-57-6	2-Methylnaphthalene

CASRN	Constituent
95-48-7	2-Methylphenol (*o*-cresol)
91-20-3	Naphthalene
98-95-3	Nitrobenzene
14797-73-0	Perchlorate
129-00-0	Pyrene
121-82-4	RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine)
118-96-7	TNT (2,4,6-trinitrotoluene)
75-69-4	Trichlorofluoromethane
99-35-4	1,3,5-Trinitrobenzene
7440-62-2	Vanadium

In addition to recalculating health-based standards with the proposed procedures specified in Part 620.Subpart F and Appendix A, the following constituents are recalculated with updated toxicity values:

CASRN	Constituent
56-55-3	Benzo(a)anthracene
205-99-2	Benzo(b)fluoranthene
207-08-9	Benzo(k)fluoranthene
218-01-9	Chrysene
53-70-3	Dibenzo(a,h)anthracene
121-14-2	2,4-Dinitrotoluene
606-20-2	2,6-Dinitrotoluene
123-91-1	1,4-Dioxane (*p*-dioxane)
193-39-5	Indeno(1,2,3-c,d)pyrene
121-82-4	RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine)
7440-62-2	Vanadium

Updated toxicological profiles for the constituents are included in Attachment 1I. Illinois EPA notes the toxicological profile for vanadium is not included in Exhibit 9, as it is included in Attachment 1D.

After the recalculation of the health-based standards for the constituents, Illinois EPA compared the updated standards with LLOQs/LCMRLs for groundwater and drinking water

analytical methods. A table is included in Attachment 1I depicting health-based standards compared with LLOQ/LCMRLs.

The ten constituents proposed to be added to Section 620.410 are added to the tables as follows:

Part 620.410(a) Inorganic Chemical Constituents	
CASRN	**Constituent**
7429-90-5	Aluminum
7439-93-2	Lithium
7439-98-7	Molybdenum

Part 620.410(b) Organic Chemical Constituents	
CASRN	**Constituent**
13252-13-6	HFPO-DA (hexafluoropropylene oxide dimer acid, GenX)
90-12-0	1-Methylnaphthalene
375-73-5	PFBS (perfluorobutanesulfonic acid)
355-46-4	PFHxS (perfluorohexanesulfonic acid)
375-95-1	PFNA (perfluorononanoic acid)
335-67-1	PFOA (perfluorooctanoic acid)
1763-23-1	PFOS (perfluorooctanesulfonic acid)

The proposed standards for the newly added chemicals are based on proposed procedures at Part 620 Subpart F and Appendix A. Toxicological profiles for the constituents are included in Attachment 1I. Illinois EPA notes the toxicological profiles for the PFAS constituents are not included in Attachment 1I, as they are included in Attachment 1D.

Further updates to Section 620.410 include:

- Updates to the basis of the Class I standards for cobalt, nickel, and zinc from beneficial use for livestock to HTTACs, as human health standards are more stringent. Toxicological profiles for cobalt, nickel, and zinc are included in Attachment 1I.

- Update to the basis of the Class I standard for copper from 50 percent of the U.S. EPA "action level" for copper to beneficial use for livestock. The proposed value is from, "Water Quality Criteria", by National Academy of Sciences, 1972. The livestock value is more stringent, and the Illinois EPA assumes livestock may also utilize potable resource groundwater for its drinking water. Information regarding the basis of the livestock value is included in Attachment 1I.
- Update to the basis of fluoride (sodium fluoride) from the U.S. EPA MCL to beneficial use for livestock. The proposed value is from, "Water Quality Criteria", by National Academy of Sciences, 1972. The livestock value is more stringent. Information regarding the basis of the livestock value is included in Attachment 1I.
- Combination of radium-226 and radium-228 individual standards to a radium (combined 226+228) standard of 5 pCi/L. The value is based on the updated U.S. EPA MCL for radium (combined 226+228). Information verifying the updated MCL is included in Attachment 1I.
- Update to the basis of selenium from the U.S. EPA MCL to beneficial use for irrigation of crops and produce. The proposed value is from, "Water Quality Criteria", by National Academy of Sciences, 1972. The irrigation value is more stringent, and the Illinois EPA assumes that crops may be irrigated with Class I potable resource groundwater. Information regarding the basis of the irrigation value is included in Attachment 1I.

- Update the basis of silver from a maximum allowable concentration ("MAC") listed at 35 Ill. Adm. Code 611.300 to a health-based standard. Silver is no longer listed at 35 Ill. Adm. Code 611.300. The toxicological profile for silver is included in Attachment 1I.
- Add carcinogen designations to four existing constituents and 1 proposed constituent:

CASRN	Constituent	Classification	Source	Year
106-46-7	*p*-Dichlorobenzene (1,4-dichlorobenzene)	2B	IARC	1999
100-41-4	Ethylbenzene	2B	IARC	2000
58-89-9	*gamma*-HCH (*gamma*-hexachlorocyclohexane, lindane)	1	IARC	2018
98-82-8	Isopropylbenzene (cumene)	2B	IARC	2018
335-67-1	PFOA (perfluorooctanoic acid)	2B	IARC	2017

IARC: International Agency for Research on Cancer.

The carcinogen designations are available at: https://monographs.iarc.who.int/agents-classified-by-the-iarc/ .

- Deletion of explosive constituents table at Section 620.410(c), with the movement of the constituents to the table at Section 620.410(b).
- Move complex organic chemical mixtures to Section 620.410(c).
- Move atrazine from the table at Section 620.410(b), to a table at Section 620.410(c)(2), complex organic chemical mixtures, with the proposed addition of total atrazine with metabolites.
- Relabel subsection (e) to (d) and (f) to (e) due to the deletion of the explosive constituents at subsection (c).

V. Updates to Class II Standards at Section 620.420

The tables located at Section 620.420 are updated to include CASRNs, notations beneath the tables providing the basis of the standards, and identifiers of carcinogens, plus carcinogens operating with a mutagenic mode of action. The addition of notations at the bottom of each table assists the user in determining the source of the proposed standards. A table listing Class II groundwater quality standards proposed for updates in comparison with the current values is included as Attachment 1J. The table also includes the basis for the current and proposed standards; and provides the chemical-specific data for organics used to determine treatment efficiency and the application of a treatment factor. The source of the chemical-specific data is U.S. EPA RSL chemical-specific parameters table. The Illinois EPA is working to update the Part 742 TACO regulations to be consistent with the chemical-specific data used by the U.S. EPA in its risk assessments.

Richard P. Cobb's prefiled testimony filed May 28, 2008 for the Board's rulemaking docket PCB R08-18 (Attachment 1A), discussed the basis for establishing Class II groundwater quality standards. Mr. Cobb's testimony states in part:

> The final opinion and order of the Board (Docket R89-14(B)), for establishing Class II groundwater quality standards (35 Ill. Adm. Code 620), published November 7, 1991, pages 19 and 20 states that:
>
> 'Part 620.420 establishes standards for Class II: General Resource Groundwaters. Because groundwaters are placed in Class II because they are quality-limited, quantity-limited, or both (see Subpart B discussion above), it is necessary that the standards that apply to these waters reflect this range of possible attributes. Among the factors considered in determining the Class II numbers are the capabilities of treatment technologies to bring Class II waters to qualities suitable for potable use (R3 at 75) ["R3" means the transcript from the Board's May 1991 hearing on this matter, and "at 75" is page 75]. Thus, many Class II

> standards are based on MCL's as modified to reflect treatment capabilities. For some parameters the Class II standards are based on support of a use other than potability (e.g., livestock water, irrigation, industrial use) where a different use requires a more stringent standard (R3 at 1148))'.

Proposed updates to Section 620.420(a)(1) include:

- The addition of lithium and molybdenum, with the proposed Class II standards based the beneficial use for irrigation of crops and produce for both constituents. Information regarding the basis of the irrigation values for lithium and molybdenum are included in Attachment 1J.
- Updates to the Class II standards, based on updates to the Class I standards for fluoride (sodium fluoride) and perchlorate.

Proposed updates to Section 620.420(a)(2) include:

- The addition of aluminum, with a proposed Class II standard based on beneficial use for livestock. Information regarding the basis of the livestock value is included in Attachment 1J.
- The addition of radium (combined 226+228) and silver, both based on proposed Class I standards.
- Updates to the Class II standards, based on updates to the Class I standards, for copper and selenium.

Proposed updates to Section 620.420(b)(1) include the application of treatment factors for all the organic constituents as discussed in Richard P. Cobb's prefiled testimony filed May 28, 2008 for the Board's rulemaking docket PCB R08-18 (Attachment 1A). Mr. Cobb discusses

the decision-making process for the use of a treatment factor (TF) of five when determining Class II standards for organics, by stating:

> Treatment Factor - A five fold treatment factor ("5X") was used to derive a proposed Class II standard for organic compounds with a K_{oc} value greater than (>) ethylbenzene's K_{oc} of 363 liters per kilogram (L/kg) at 20 ^{0} C or a Henry's Law constant greater than methylene chloride's (8.98 X 10^{-2} unit less at 20 ^{0} C). A five fold treatment factor equates to a removal efficiency of 80%. This is a very economical approach, since most of the BATs achieve a 99% removal rate. The Class I standard was proposed where either or both were below the factors detailed above.

The Illinois EPA wishes to clarify the appropriate organic carbon coefficient (K_{oc}) for ethylbenzene is 446 L/kg, per U.S. EPA RSL guidance. In addition, the Henry's Law constant (H') is temperature dependent. The appropriate H' value for methylene chloride at 20 ^{0} C is 0.11, and is calculated by setting the groundwater system temperature to 20 ^{0} C in the RSL calculator

For organic constituents with health-based Class I standards, the Illinois EPA evaluated the chemical-specific data for each constituent and applied a treatment factor of five to the updated Class I standard, when applicable, in Section 620.420(b) and (c).

Further updates to Section 620.420 include:

- Deletion of explosive constituents table at Section 620.420(c), with the movement of the constituents to the table at Section 620.420(b).
- Moving complex organic chemical mixtures to Section 620.420(c).
- Move atrazine from the table at Section 620.420(b), to a table at Section 620.420(c)(2), complex organic chemical mixtures, with the proposed addition of total atrazine with metabolites.

- Relabeling subsection (e) to (d) due to the deletion of the explosive constituents at subsection (c).

VI. Similar-Acting Substances

Part 620 Appendix B(d), states:

> When two or more substances occur together in a mixture, the additivity of the toxicities of some or all of the substances will be considered when determining health-based standards for Class I: Potable Resource Groundwater.

Part 620 Appendix B describes a mixture for the purposes of Appendix B, stating,

> a 'mixture' means two or more substances which are present in Class I: Potable Resource Groundwater which may or may not be related either chemically or commercially, but which are not complex mixtures of related isomers and congeners which are produced as commercial products (for example, PCBs or technical grade chlordane).

To assist users in determining if a mixture of similar-acting substances is present in Class I groundwater, Illinois EPA proposes to add Appendix E. Appendix E provides tables of substances having similar-acting noncancer and cancer effects. The addition of similar-acting substances tables in Appendix E, no longer requires the description of a few of the similar-acting substances currently provided in Part 620 Appendix B(c). Therefore, Illinois EPA proposes to remove the specific similar-acting substances listed at Appendix B(c) and refer users to Appendix E for a complete list of similar-acting substances.

VII. The Addition of Appendix E: Similar-acting Substances

Appendix E consists of two tables:

- Table A: Similar-acting Noncarcinogens
- Table B: Similar-acting Carcinogens

The tables list target organs or health effects, with substances included Section 620.410 listed beneath the applicable target organ or effect. If only one constituent affects a target organ, the effect is not included, as two or more constituents are required to be considered a mixture. The source of a toxicity metadata used to determine constituents with similar-acting effects is the toxicity metadata provided in the RSL calculator; with the exception of: MTBE, HFPO-DA, PFHxS, PFNA, PFOS, PFOA, and vanadium. As noted above under Section I of my testimony, these constituent's toxicity values are not based on values provided in the U.S. EPA RSL database. The target organs or health effects for MTBE, HFPO-DA, PFHxS, PFNA, PFOS, PFOA, and vanadium are based on the toxicological profiles included in Attachment 1D. Tables listing toxicity metadata are included as Attachment 1K.

VIII. Conclusion

This concludes my portion of Illinois EPA's testimony for the proposed amendments to Part 620.

Reg. 4063, effective February 23, 2007; amended in R11-09 at 37 Ill. Reg. 7506, effective July 15, 2013.

NOTE: Italics indicates statutory language.

SUBPART A: INTRODUCTION

Section 742.100 Intent and Purpose

a) This Part sets forth procedures for evaluating the risk to human health posed by environmental conditions and developing remediation objectives that achieve acceptable risk levels.

b) The purpose of these procedures is to provide for the adequate protection of human health and the environment based on the risks to human health posed by environmental conditions while incorporating site related information.

Section 742.105 Applicability

a) Any person, including a person required to perform an investigation pursuant to the Illinois Environmental Protection Act [415 ILCS 5] (Act), may elect to proceed under this Part to the extent allowed by State or federal law and regulations and the provisions of this Part and subject to the exceptions listed in subsection (h) below. A person proceeding under this Part may do so to the extent such actions are consistent with the requirements of the program under which site remediation is being addressed.

b) This Part is to be used in conjunction with the procedures and requirements applicable to the following programs:

1) Leaking Underground Storage Tanks (35 Ill. Adm. Code 731 and 734);

2) Site Remediation Program (35 Ill. Adm. Code 740); and

3) RCRA Part B Permits and Closure Plans (35 Ill. Adm. Code 724 and 725).

c) The procedures in this Part may not be used if their use would delay response action to address imminent and substantial threats to human health and the environment. This Part may only be used after actions to address such threats have been completed.

d) This Part may be used to develop remediation objectives to protect surface waters, sediments or ecological concerns, when consistent with the regulations of other programs, and as approved by the Agency.

e) A no further remediation determination issued by the Agency prior to July 1, 1997 pursuant to Section 4(y) of the Act or one of the programs listed in subsection (b) of this Section that approves completion of remedial action relative to a release shall remain in effect in accordance with the terms of that determination.

f) Site specific groundwater remediation objectives determined under this Part for contaminants of concern may exceed the groundwater quality standards established pursuant to the rules promulgated under the Illinois Groundwater Protection Act [415 ILCS 55] as long as done in accordance with Sections 742.805 and 742.900(c)(9). (See 415 ILCS 5/58.5(d)(4))

g) Where contaminants of concern include polychlorinated byphenyls (PCBs), a person may need to evaluate the applicability of regulations adopted under the Toxic Substances Control Act (15 USC 2601).

h) This Part may not be used in lieu of the procedures and requirements applicable to landfills under 35 Ill. Adm. Code 807 or 811 through 814.

i) An evaluation of the indoor inhalation exposure route under this Part addresses the potential of contaminants present in soil gas or groundwater to reach human

receptors within buildings. This Part does not address the remediation or mitigation of any contamination within a building from a source other than soil gas or groundwater, such as the building structure itself and products within the building.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.110 Overview of Tiered Approach

a) This Part presents an approach for developing remediation objectives (see Appendix A, Illustrations A and B) that include an option for exclusion of pathways from further consideration, use of area background concentrations as remediation objectives and three tiers for selecting applicable remediation objectives. An understanding of human exposure routes is necessary to properly conduct an evaluation under this approach. In some cases, applicable human exposure routes can be excluded from further consideration prior to any tier evaluation. Selecting which tier or combination of tiers to be used to develop remediation objectives is dependent on the site-specific conditions and remediation goals. Tier 1 evaluations and Tier 2 evaluations are not prerequisites to conducting Tier 3 evaluations.

b) A Tier 1 evaluation compares the concentration of contaminants detected at a site to the corresponding remediation objectives for residential and industrial/commercial properties contained in Appendix B, Tables A, B, C, D, E, G, H and I. To complete a Tier 1 evaluation, the extent and concentrations of the contaminants of concern, the groundwater class, the land use classification, human exposure routes at the site, and, if appropriate, soil pH, must be known. If remediation objectives are developed based on industrial/commercial property use, then institutional controls under Subpart J are required. For the indoor inhalation exposure route, institutional controls under Subpart J are required to use remediation objectives in Appendix B, Table H or Table I.

c) A Tier 2 evaluation uses the risk based equations from the Soil Screening Level (SSL) model, Risk Based Corrective Action (RBCA) model and modified Johnson and Ettinger (J&E) model documents listed in Appendix C, Tables A, C and L, respectively. In addition to the information that is required for a Tier 1 evaluation, site-specific information is used to calculate Tier 2 remediation objectives. As in Tier 1, Tier 2 evaluates residential and industrial/commercial properties only. If remediation objectives are developed based on industrial/commercial property use, then institutional controls under Subpart J are required. For the indoor inhalation exposure route, institutional controls under Subpart J are required to develop remediation objectives pursuant to Appendix C, Table L.

d) A Tier 3 evaluation allows alternative parameters and factors, not available under a Tier 1 or Tier 2 evaluation, to be considered when developing remediation objectives. Remediation objectives developed for conservation and agricultural properties can only be developed under Tier 3.

e) Remediation objectives may be developed using area background concentrations or any of the three tiers if the evaluation is conducted in accordance with applicable requirements in Subparts D through I. When contaminant concentrations do not exceed remediation objectives developed under one of the tiers or area background procedures under Subpart D, further evaluation under any of the other tiers is not required.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.115 Key Elements

To develop remediation objectives under this Part, the following key elements shall be addressed.

a) Exposure Routes

1) This Part identifies the following as potential exposure routes to be addressed:

A) Outdoor inhalation;

B) Indoor inhalation;

C) Soil ingestion;

D) Groundwater ingestion; and

E) Dermal contact with soil.

2) The evaluation of exposure routes under subsections (a)(1)(A), (a)(1)(B), (a)(1)(C) and (a)(1)(D) is required for all sites when developing remediation objectives or excluding exposure pathways. Evaluation of the dermal contact exposure route is required for use of RBCA equations in Appendix C, Table C or use of formal risk assessment under Section 742.915.

3) The groundwater ingestion exposure route is comprised of two components:

A) Migration from soil to groundwater (soil component); and

B) Direct ingestion of groundwater (groundwater component).

4) The outdoor inhalation route is comprised of two components:

A) Migration from soil through soil gas to outdoor air (soil component); and

B) Migration from soil gas to outdoor air (soil gas component).

5) The indoor inhalation exposure route is comprised of two components:

A) Migration from soil gas to indoor air (soil gas component); and

B) Migration from groundwater through soil gas to indoor air (groundwater component).

b) Contaminants of Concern

The contaminants of concern to be remediated depend on the following:

1) The materials and wastes managed at the site;

2) The extent of the no further remediation determination being requested from the Agency pursuant to a specific program; and

3) The requirements applicable to the specific program, as listed at Section 742.105(b) under which the remediation is being performed.

c) Land Use

The present and post-remediation uses of the site where exposures may occur shall be evaluated. The land use of a site, or portion thereof, shall be classified as one of the following:

1) Residential property;

2) Conservation property;

3) Agricultural property; or

4) Industrial/commercial property.

d) Environmental Media of Concern

This Part provides procedures for developing remediation objectives for the following environmental media:

1) Soil;

2) Soil gas;

3) Groundwater.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.120 Site Characterization

Characterization of the extent and concentrations of contamination at a site shall be performed before beginning development of remediation objectives. The actual steps and methods taken to characterize a site are determined by the requirements applicable to the specific program under which site remediation is being addressed.

SUBPART B: GENERAL

Section 742.200 Definitions

Except as stated in this Section, or unless a different meaning of a word or term is clear from the context, the definition of words or terms in this Part shall be the same as that applied to the same words or terms in the Act.

"Act" means the Illinois Environmental Protection Act [415 ILCS 5].

"ADL" means Acceptable Detection Limit, which is the detectable concentration of a substance that is equal to the lowest appropriate Practical Quantitation Limit (PQL) as defined in this Section.

"Agency" means the Illinois Environmental Protection Agency.

"Agricultural Property" means any real property for which its present or post-remediation use is for growing agricultural crops for food or feed either as harvested crops, cover crops or as pasture. This definition includes, but is not limited to, properties used for confinement or grazing of livestock or poultry and for silviculture operations. Excluded from this definition are farm residences, farm outbuildings and agrichemical facilities.

"Aquifer" means *saturated (with groundwater) soils and geologic materials which are sufficiently permeable to readily yield economically useful quantities of water to wells, springs, or streams under ordinary hydraulic gradients.* (Illinois Groundwater Protection Act [415 ILCS 55/3(a)])

"Area Background" means *concentrations of regulated substances that are consistently present in the environment in the vicinity of a site that are the result of natural conditions or human activities, and not the result solely of releases at the site.* [415 ILCS 5/58.2]

"ASTM" means the American Society for Testing and Materials.

"Board" means the Illinois Pollution Control Board.

"Building" means a man-made structure with an enclosing roof and enclosing walls (except for windows and doors) that is fit for any human occupancy for at least six consecutive months.

"Building Control Technology" means any technology or barrier that affects air flow or air pressure within a building for purposes of reducing or preventing contaminant migration to the indoor air.

"Cancer Risk" means a unitless probability of an individual developing cancer from a defined exposure rate and frequency.

"Cap" means a barrier designed to prevent the infiltration of precipitation or other surface water, or impede the ingestion or inhalation of contaminants.

"Capillary Fringe" means the zone above the water table in which water is held by surface tension. Water in the capillary fringe is under a pressure less than atmospheric.

"Carcinogen" means *a contaminant that is classified as a category A1 or A2 carcinogen by the American Conference of Governmental Industrial Hygienists; a category 1 or 2A/2B carcinogen by the World Health Organization's International Agency for Research on Cancer; a "human carcinogen" or "anticipated human carcinogen" by the United States Department of Health and Human Service National Toxicological Program; or a category A or B1/B2 carcinogen* or as "carcinogenic to humans" or "likely to be carcinogenic to humans" *by the United States Environmental Protection Agency in the integrated risk information system or a final rule issued in a Federal Register notice by the USEPA.* [415 ILCS 5/58.2]

"Class I Groundwater" means groundwater that meets the Class I: Potable Resource Groundwater criteria set forth in 35 Ill. Adm. Code 620.

"Class II Groundwater" means groundwater that meets the Class II: General Resource Groundwater criteria set forth in 35 Ill. Adm. Code 620.

"Conservation Property" means any real property for which present or post-remediation use is primarily for wildlife habitat.

"Construction Worker" means a person engaged on a temporary basis to perform work involving invasive construction activities including, but not limited to, personnel performing demolition, earth-moving, building, and routine and emergency utility installation or repair activities.

"Contaminant of Concern" or "Regulated Substance of Concern" means *any contaminant that is expected to be present at the site based upon past and current land uses and associated releases that are known to the* person conducting a remediation *based upon reasonable inquiry.* [415 ILCS 5/58.2]

"County Highway" means county highway as defined in the Illinois Highway Code [605 ILCS 5].

"District Road" means district road as defined in the Illinois Highway Code [605 ILCS 5].

"Engineered Barrier" means a barrier designed or verified using engineering practices that limits exposure to or controls migration of the contaminants of concern.

"Environmental Land Use Control" means an instrument that meets the requirements of this Part and is placed in the chain of title to real property that limits or places requirements upon the use of the property for the purpose of protecting human health or the environment, is binding upon the property owner, heirs, successors, assigns, and lessees, and runs in perpetuity or until the Agency approves, in writing, removal of the limitation or requirement from the chain of title.

"Exposure Route" means the transport mechanism by which a contaminant of concern reaches a receptor.

"Federally Owned Property" means real property owned in fee by the United States of America on which institutional controls are sought to be placed in accordance with this Subpart.

"Federal Landholding Entity" means that federal department, agency, or instrumentality with the authority to occupy and control the day-to-day use, operation and management of Federally Owned Property.

"Free Product" means a contaminant that is present as a non-aqueous phase liquid for chemicals whose melting point is less than 30°C (e.g., liquid not dissolved in water).

"GIS" means Geographic Information System.

"GPS" means Global Positioning System.

"Groundwater" means underground water which occurs within the saturated zone and geologic materials where the fluid pressure in the pore space is equal to or greater than atmospheric pressure. [415 ILCS 5/3.64]

"Groundwater Quality Standards" means the standards for groundwater as set forth in 35 Ill. Adm. Code 620.

"Hazard Quotient" means the ratio of a single substance exposure level during a specified time period to a reference dose for that substance derived from a similar exposure period.

"Highway" *means any public way for vehicular travel which has been laid out in pursuance of any law of this State, or of the Territory of Illinois, or which has been established by dedication, or used by the public as a highway for 15 years, or which has been or may be laid out and connect a subdivision or platted land with a public highway and which has been dedicated for the use of the owners of the land included in the subdivision or platted land where there has been an acceptance and use under such dedication by such owners, and which has not been vacated in pursuance of law. The term "highway" includes rights of way, bridges, drainage structures, signs, guard rails, protective structures and all other structures and appurtenances necessary or convenient for vehicular traffic. A highway in a rural area may be called a "road", while a highway in a municipal area may be called a "street".* (Illinois Highway Code [605 ILCS 5/2-202])

"Highway Authority" means *the Department* of Transportation *with respect to a State highway;* the Illinois State Toll Highway with respect to a toll highway; *the County Board with respect to a county highway or a county unit district road if a discretionary function is involved and the County Superintendent of Highways if a ministerial function is involved; the Highway Commissioner with respect to a township or district road not in a county unit road district; or the corporate authorities of a municipality with respect to a municipal street.* (Illinois Highway Code [605 ILCS 5/2-213])

"Human Exposure Pathway" means a physical condition which may allow for a risk to human health based on the presence of all of the following: contaminants of concern; an exposure route; and a receptor activity at the point of exposure that could result in contaminant of concern intake.

"Industrial/Commercial Property" means any real property that does not meet the definition of residential property, conservation property or agricultural property.

"Infiltration" means the amount of water entering into the ground as a result of precipitation.

"Institutional Control" means a legal mechanism for imposing a restriction on land use, as described in Subpart J.

"Intrusive activities" means activities that would affect potential flow of contaminants into a building (e.g., breaching the integrity of a foundation due to repairs or installation of utilities).

"Land Use Control Memoranda of Agreement" mean agreements entered into between one or more agencies of the United States and the Illinois Environmental Protection Agency that limit or place requirements upon the use of Federally Owned Property for the purpose of protecting human health or the environment.

"Man-Made Pathways" means *constructed* physical conditions *that may allow for the transport of regulated substances including, but not limited to, sewers, utility lines, utility* or elevator *vaults, building foundations, basements, crawl spaces, drainage ditches, previously excavated and filled areas* or sumps. [415 ILCS 5/58.2]

"Natural Pathways" means *natural* physical conditions that may allow *for the transport of regulated substances including, but not limited to, soil, groundwater, sand seams and lenses, and gravel seams and lenses.* [415 ILCS 5/58.2]

"Person" means an *individual, trust, firm, joint stock company, joint venture, consortium, commercial entity, corporation (including a government corporation), partnership, association, state, municipality, commission, political subdivision of a state, or any interstate body including the United States government and each department, agency, and instrumentality of the United States.* [415 ILCS 5/58.2]

"Point of Human Exposure" means the points at which human exposure to a contaminant of concern may reasonably be expected to occur. The point of human exposure is at the source, unless an institutional control limiting human exposure for the applicable exposure route has been or will be in place, in which case the point of human exposure will be the boundary of the institutional control. Point of human exposure may be at a different location than the point of compliance.

"Populated Area" means:

an area within the boundaries of a municipality that has a population of 10,000 or greater based on the year 2000 or most recent census; or

an area less than three miles from the boundary of a municipality that has a population of 10,000 or greater based on the year 2000 or most recent census.

"Potable" means *generally fit for human consumption in accordance with accepted water supply principles and practices.* (Illinois Groundwater Protection Act [415 ILCS 55/3(h)])

"PQL" means practical quantitation limit or estimated quantitation limit, which is the lowest concentration that can be reliably measured within specified limits of precision and accuracy for a specific laboratory analytical method during routine laboratory operating conditions in accordance with "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods", EPA Publication No. SW-846, incorporated by reference in Section 742.210. When applied to filtered water samples, PQL includes the method detection limit or estimated detection limit in accordance with the applicable method revision in: "Methods for the Determination of Organic Compounds in Drinking Water", Supplement II", EPA Publication No. EPA/600/4-88/039; "Methods for the Determination of Organic Compounds in Drinking Water, Supplement III", EPA Publication No. EPA/600/R-95/131, all of which are incorporated by reference in Section 742.210.

"Q_{soil}" means the volumetric flow rate of soil gas from the subsurface into the enclosed building space.

"RBCA" means Risk Based Corrective Action as defined in ASTM E-1739-95, as incorporated by reference in Section 742.210.

"RCRA" means the Resource Conservation and Recovery Act of 1976 (42 USC 6921).

"Reference Concentration" or "RfC" means an estimate of a daily exposure, in units of milligrams of chemical per cubic meter of air (mg/m^3), to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a portion of a lifetime (up to approximately seven years, subchronic) or for a lifetime (chronic).

"Reference Dose" or "RfD" means an estimate of a daily exposure, in units of milligrams of chemical per kilogram of body weight per day (mg/kg/d), to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a portion of a lifetime (up to approximately seven years, subchronic) or for a lifetime (chronic).

"Regulated Substance" means *any hazardous substance as defined under Section 101(14) of the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (P.L. 96-510) and petroleum products including crude oil or any fraction thereof, natural gas, natural gas liquids, liquefied natural gas, or synthetic gas usable for fuel (or mixtures of natural gas and such synthetic gas).* [415 ILCS 5/58.2]

"Rendered inoperable" means having become unable to operate effectively, including, but not limited to, being shut down as part of routine maintenance or due to a malfunction, power failure, or vandalism.

"Residential Property" *means any real property that is used for habitation by individuals, or* where children have the opportunity for exposure to contaminants through ingestion or inhalation (indoor or outdoor) at educational facilities, health care facilities, child care facilities or recreational areas. [415 ILCS 5/58.2]

"Right of Way" means *the land, or interest therein, acquired for or devoted to a highway.* (Illinois Highway Code [605 ILCS 5/2-217])

"Saturated Zone" means a subsurface zone in which all the interstices or voids are filled with water under pressure greater than that of the atmosphere.

"Similar-Acting Chemicals" are chemical substances that have toxic or harmful effect on the same specific organ or organ system (see Appendix A.Tables E and F for a list of similar-acting chemicals with noncarcinogenic and carcinogenic effects).

"Site" means *any single location, place, tract of land or parcel of property, or portion thereof, including contiguous property separated by a public right-of-way.* [415 ILCS 5/58.2]

"Slurry Wall" means a man-made barrier made of geologic material which is constructed to prevent or impede the movement of contamination into a certain area.

"Soil Gas" means the air existing in void spaces in the soil between the groundwater table and the ground surface.

"Soil Saturation Limit" or "C_{sat}" means the contaminant concentration at which the absorptive limits of the soil particles, the solubility limits of the available soil moisture, and saturation of soil pore air have been reached. Above the soil saturation concentration, the assumptions regarding vapor transport to air and/or dissolved phase transport to groundwater (for chemicals that are liquid at ambient soil temperatures) do not apply, and alternative modeling approaches are required.

"Soil Vapor Saturation Limit" or "C_v^{sat}" means the maximum vapor concentration that can exist in the soil pore air at a given temperature and pressure.

"Solubility" means a chemical specific maximum amount of solute that can dissolve in a specific amount of solvent (groundwater) at a specific temperature.

"SPLP" means Synthetic Precipitation Leaching Procedure (Method 1312) as published in "Test Methods for Evaluating Solid Waste, Physical/Chemical

Methods", USEPA Publication No. SW-846, as incorporated by reference in Section 742.210.

"SSL" means Soil Screening Levels as defined in USEPA's Soil Screening Guidance: User's Guide and Technical Background Document, as incorporated by reference in Section 742.210.

"State Highway" means State highway as defined in the Illinois Highway Code [605 ILCS 5].

"Stratigraphic Unit" means a site-specific geologic unit of native deposited material and/or bedrock of varying thickness (e.g., sand, gravel, silt, clay, bedrock, etc.). A change in stratigraphic unit is recognized by a clearly distinct contrast in geologic material or a change in physical features within a zone of gradation. For the purposes of this Part, a change in stratigraphic unit is identified by one or a combination of differences in physical features such as texture, cementation, fabric, composition, density, and/or permeability of the native material and/or bedrock.

"Street" means street as defined in the Illinois Highway Code [605 ILCS 5].

"TCLP" means Toxicity Characteristic Leaching Procedure (Method 1311) as published in "Test Methods for Evaluating Solid Waste, Physical/Chemical Methods", USEPA Publication No. SW-846, as incorporated by reference in Section 742.210.

"Toll Highway" means toll highway as defined in the Illinois Highway Code [605 ILCS 5].

"Total Petroleum Hydrocarbon" or "TPH" means the additive total of all petroleum hydrocarbons found in an analytical sample.

"Township Road" means township road as defined in the Illinois Highway Code [605 ILCS 5].

"Unconfined Aquifer" means an aquifer whose upper surface is a water table free to fluctuate under atmospheric pressure.

"Volatile Chemicals" means chemicals with a Dimensionless Henry's Law Constant of greater than 1.9×10^{-2} or a vapor pressure greater than 0.1 Torr (mmHg) at 25°C. For purposes of the indoor inhalation exposure route, elemental mercury is included in this definition.

"Water Table" means the top water surface of an unconfined aquifer at atmospheric pressure.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.205 Severability

If any provision of this Part or its application to any person or under any circumstances is adjudged invalid, such adjudication shall not affect the validity of this Part as a whole or any portion not adjudged invalid.

Section 742.210 Incorporations by Reference

a) The Board incorporates the following material by reference:

Agency for Toxic Substances and Disease Registry (ATSDR) Minimal Risk Levels (MRLs), U.S. Environmental Protection Agency, 1600 Clifton Road, Mailstop F32, Atlanta, Georgia 30333, (770) 488-3357 (November 2007).

ASTM International. 100 Barr Harbor Drive, West Conshohocken PA 19428-2959, (610) 832-9585.

ASTM D 2974-00, Standard Test Methods for Moisture, Ash and Organic Matter of Peat and Other Organic Soils, approved August 10, 2000.

ASTM D 2488-00, Standard Practice for Description and Identification of Soils (Visual-Manual Procedure), approved February 10, 2000.

ASTM D 1556-00, Standard Test Method for Density and Unit Weight of Soil in Place by the Sand-Cone Method, approved March 10, 2000.

ASTM D 2167-94, Standard Test Method for Density and Unit Weight of Soil in Place by the Rubber Balloon Method, approved March 15, 1994.

ASTM D 2922-01, Standard Test Methods for Density of Soil and Soil-Aggregate in Place by Nuclear Methods (Shallow Depth), approved June 10, 2001.

ASTM D 2937-00e1, Standard Test Method for Density of Soil in Place by the Drive-Cylinder Method, approved June 10, 2000.

ASTM D 854-02, Standard Test Methods for Specific Gravity of Soil Solids by Water Pycnometer, approved July 10, 2002.

ASTM D 2216-98, Standard Test Method for Laboratory Determination of Water (Moisture) Content of Soil and Rock by Mass, approved February 10, 1998.

ASTM D 4959-00, Standard Test Method for Determination of Water (Moisture) Content of Soil by Direct Heating, approved March 10, 2000.

ASTM D 4643-00, Standard Test Method for Determination of Water (Moisture) Content of Soil by the Microwave Oven Method, approved February 10, 2000.

ASTM D 5084-03, Standard Test Methods for Measurement of Hydraulic Conductivity of Saturated Porous Materials Using a Flexible Wall Permeameter, approved November 1, 2003.

ASTM D 422-63 (2002), Standard Test Method for Particle-Size Analysis of Soils, approved November 10, 2002.

ASTM D 1140-00, Standard Test Methods for Amount of Material in Soils Finer than the No. 200 (75 μm) Sieve, approved June 10, 2000.

ASTM D 3017-01, Standard Test Method for Water Content of Soil and Rock in Place by Nuclear Methods (Shallow Depth), approved June 10, 2001.

ASTM D 4525-90 (2001), Standard Test Method for Permeability of Rocks by Flowing Air, approved May 25, 1990.

ASTM D 2487-00, Standard Classification of Soils for Engineering Purposes (Unified Soil Classification System), approved March 10, 2000.

ASTM D 1945-03, Standard Test Method for Analysis of Natural Gas by Gas Chromatography, approved May 10, 2003.

ASTM D 1946-90, Standard Practice for Analysis of Reformed Gas by Gas Chromatography, approved June 1, 2006.

ASTM E 1527-00, Standard Practice for Environmental Site Assessments: Phase I Environmental Site Assessment Process, approved May 10, 2000. Vol. 11.04.

ASTM E 1739-95 (2002), Standard Guide for Risk-Based Corrective Action Applied at Petroleum Release Sites, approved September 10, 1995.

ASTM E 2121-09, Standard Practice for Installing Radon Mitigation Systems in Existing Low-Rise Residential Buildings, approved November 1, 2009.

ASTM E 2600-10, Standard Practice for Assessment for Vapor Intrusion into Structures on Property Involved in Real Estate Transactions, approved June 2010.

c) This Section incorporates no later editions or amendments.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.215 Determination of Soil Attenuation Capacity

a) The concentrations of organic contaminants of concern remaining in the soil shall not exceed the attenuation capacity of the soil, as determined under subsection (b) of this Section.

b) The soil attenuation capacity is not exceeded if:

1) The sum of the organic contaminant residual concentrations analyzed for the purposes of the remediation program for which the analysis is performed, at each discrete sampling point, is less than the natural organic carbon fraction of the soil. If the information relative to the concentration of other organic contaminants is available, such information shall be included in the sum. The natural organic carbon fraction (f_{oc}) shall be either:

A) A default value of 6000 mg/kg for soils within the top meter and 2000 mg/kg for soils below one meter of the surface; or

B) A site-specific value as measured by the analytical method referenced in Appendix C, Table F, multiplied by 0.58 to estimate the fraction of organic carbon, as stated in, Nelson and Sommers (1982), as incorporated by reference in Section 742.210;

2) The total petroleum hydrocarbon concentration is less than the natural organic carbon fraction of the soil as demonstrated using a method approved by the Agency. The method selected shall be appropriate for the contaminants of concern to be addressed; or

3) Another method, approved by the Agency, shows that the soil attenuation capacity is not exceeded.

(Source: Amended at 31 Ill. Reg. 4063, effective February 23, 2007)

Section 742.220 Determination of Soil Saturation Limit

a) For any organic contaminant that has a melting point below 30°C, the remediation objective for the outdoor inhalation exposure route developed under Tier 2 shall not exceed the soil saturation limit, as determined under subsection (c).

b) For any organic contaminant that has a melting point below 30°C, the remediation objective under Tier 2 for the soil component of the groundwater ingestion exposure route shall not exceed the soil saturation limit, as determined under subsection (c).

c) The soil saturation limit shall be:

1) The value listed in Appendix A, Table A for that specific contaminant;

2) A value derived from Equation S29 in Appendix C, Table A; or

3) A value derived from another method approved by the Agency.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.222 Determination of Soil Vapor Saturation Limit

a) For any volatile chemical, the soil gas remediation objective for the indoor and outdoor inhalation exposure routes developed under Tier 2 shall not exceed the soil vapor saturation limit, as determined under subsection (b).

b) The soil vapor saturation limit shall be:

1) The value listed in Appendix A, Table K for that specific contaminant;

2) A value derived from Equation J&E5 in Appendix C, Table L; or

3) A value derived from another method approved by the Agency.

(Source: Added at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.225 Demonstration of Compliance with Soil and Groundwater Remediation Objectives

Compliance with soil and groundwater remediation objectives is achieved if each sample result does not exceed that respective remediation objective unless a person elects to proceed under subsections (c), (d) and (e).

a) Compliance with groundwater remediation objectives developed under Subparts D through F and H through I shall be demonstrated by comparing the contaminant concentrations of discrete samples at each sample point to the applicable groundwater remediation objective. Sample points shall be determined by the program under which remediation is performed.

b) Unless the person elects to composite samples or average sampling results as provided in subsections (c) and (d), compliance with soil remediation objectives developed under Subparts D through G and I shall be demonstrated by comparing the contaminant concentrations of discrete samples to the applicable soil remediation objective.

1) Except as provided in subsections (c) and (d), compositing of samples is not allowed.

2) Except as provided in subsections (c) and (d), averaging of sample results is not allowed.

3) Notwithstanding subsections (c) and (d), compositing of samples and averaging of sample results is not allowed for the construction worker population.

4) The number of sampling points required to demonstrate compliance is determined by the requirements applicable to the program under which remediation is performed.

c) If a person chooses to composite soil samples or average soil sample results to demonstrate compliance relative to the soil component of the groundwater ingestion exposure route, the following requirements apply:

1) A minimum of two sampling locations for every 0.5 acre of contaminated area is required, with discrete samples at each sample location obtained at every two feet of depth, beginning at six inches below the ground surface for surface contamination and at the upper limit of contamination for subsurface contamination and continuing through the zone of contamination. Alternatively, a sampling method may be approved by the Agency based on an appropriately designed site-specific evaluation. Samples obtained at or below the water table shall not be used in compositing or averaging.

2) For contaminants of concern other than volatile chemicals:

A) Discrete samples from the same boring may be composited; or

B) Discrete sample results from the same boring may be averaged.

3) For volatile chemicals:

A) Compositing of samples is not allowed.

B) Discrete sample results from the same boring may be averaged.

4) Composite samples may not be averaged. An arithmetic average may be calculated for discrete samples collected at every two feet of depth through the zone of contamination as specified in subsection (c)(1).

d) If a person chooses to composite soil samples or average soil sample results to demonstrate compliance relative to the outdoor inhalation exposure route or ingestion exposure route, the following requirements apply:

1) A person shall submit a sampling plan for Agency approval, based upon a site-specific evaluation;

2) For volatile chemicals, compositing of samples is not allowed;

3) All samples shall be collected within the contaminated area;

4) Composite samples may not be averaged. Procedures specified in "Calculating Upper Confidence Limits for Exposure Point Concentrations at Hazardous Waste Sites", USEPA Office of Emergency and Remedial Response, OSWER 9285.6-10 (December 2002), as incorporated by reference in Section 742.210, or an alternative procedure approved by the Agency, shall be used to determine sample averages.

e) When averaging under this Section, if no more than 15% of sample results are reported as "non-detect", "no contamination", "below detection limits", or similar terms, such results shall be included in the averaging calculations as one-half the reported analytical detection limit for the contaminant. However, when performing a test for normal or lognormal distribution for the purpose of calculating a 95% Upper Confidence Limit of the mean for a contaminant, a person may substitute for each non-detect value a randomly generated value between, but not including, zero and the reported analytical detection limit. If more than 15% of sample results are "non-detect", procedures specified in "Guidance for Data Quality Assessment, Practical Methods for Data Analysis, EPA QA/G-9, QA00 Update", EPA/600/R-96/084 (July 2000), as incorporated by reference in Section 742.210, or an alternative procedure approved by the Agency shall be used to address the non-detect values, or another statistically valid procedure approved by the Agency may be used to determine an average.

f) All soil samples collected after August 15, 2001 shall be reported on a dry weight basis for the purpose of demonstrating compliance, with the exception of the TCLP and SPLP and the property pH.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.227 Demonstration of Compliance with Soil Gas Remediation Objectives for the Outdoor and Indoor Inhalation Exposure Routes

a) For purposes of the outdoor inhalation exposure route and the indoor inhalation exposure route, compliance with soil gas remediation objectives developed under any tier shall be demonstrated in accordance with this Section by comparing the contaminant concentrations of discrete samples at each sample point to the applicable soil gas remediation objective.

b) This Section applies to exterior soil gas samples for the outdoor inhalation exposure route, near-slab soil gas samples collected outside of an existing building for the indoor inhalation exposure route, and exterior soil gas samples collected at the footprint of a potential building for the indoor inhalation exposure route. Proposals to use sub-slab soil gas data for the indoor inhalation exposure route shall follow Section 742.935(c).

c) Sample points shall be determined by the program under which remediation is performed.

d) When collecting soil gas samples:

1) Use rigid-wall tubing made of nylon or Teflon® or other material approved by the Agency;

2) Use gas-tight, inert containers to hold the sample. For light sensitive or halogenated volatile chemicals, these containers shall be opaque or dark-colored;

3) Purge three volumes before obtaining each discrete soil gas sample;

4) Use a helium tracer or other leak apparatus detection system approved by the Agency; and

5) Limit the flow rate to 200 ml/min.

e) Soil gas samples shall be analyzed using a National Environmental Laboratory Accreditation Program (NELAP) certified laboratory.

f) Soil gas remediation objectives shall be compared to concentrations of soil gas collected at a depth at least 3 feet below ground surface and above the saturated zone.

(Source: Added at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.230 Agency Review and Approval

a) Documents and requests filed with the Agency under this Part shall be submitted in accordance with the procedures applicable to the specific program under which remediation is performed.

b) Agency review and approval of documents and requests under this Part shall be performed in accordance with the procedures applicable to the specific program under which the remediation is performed.

SUBPART C: EXPOSURE ROUTE EVALUATIONS

Section 742.300 Exclusion of Exposure Route

a) This Subpart sets forth requirements to demonstrate that an actual or potential impact to a receptor or potential receptor from a contaminant of concern can be excluded from consideration from one or more exposure routes. If an evaluation under this Subpart demonstrates the applicable requirements for excluding an exposure route are met, then the exposure route is excluded from consideration and no remediation objective(s) need be developed for that exposure route.

b) No exposure route may be excluded from consideration until characterization of the extent and concentrations of contaminants of concern at a site has been performed. The actual steps and methods taken to characterize a site shall be determined by the specific program requirements under which the site remediation is being addressed.

c) As an alternative to the use of the requirements in this Subpart, a person may use the procedures for evaluation of exposure routes under Tier 3 as set forth in Section 742.925.

(Source: Amended at 25 Ill. Reg. 10374, effective August 15, 2001)

Section 742.305 Contaminant Source and Free Product Determination

No exposure route shall be excluded from consideration relative to a contaminant of concern unless the following requirements are met:

a) The sum of the concentrations of all organic contaminants of concern shall not exceed the attenuation capacity of the soil as determined under Section 742.215;

b) The concentrations of any organic contaminants of concern remaining in the soil shall not exceed the soil saturation limit as determined under Section 742.220;

c) Any soil which contains contaminants of concern shall not exhibit any of the characteristics of reactivity for hazardous waste as determined under 35 Ill. Adm. Code 721.123;

d) Any soil which contains contaminants of concern shall not exhibit a pH less than or equal to 2.0 or greater than or equal to 12.5, as determined by SW-846 Method 9040B: pH Electrometric for soils with 20% or greater aqueous (moisture) content or by SW-846 Method 9045C: Soil pH for soils with less than 20% aqueous (moisture) content as incorporated by reference in Section 742.210;

e) Any soil which contains contaminants of concern in the following list of inorganic chemicals or their salts shall not exhibit any of the characteristics of toxicity for hazardous waste as determined by 35 Ill. Adm. Code 721.124: arsenic, barium, cadmium, chromium, lead, mercury, selenium or silver;

f) If contaminants of concern include polychlorinated biphenyls (PCBs), the concentration of any PCBs in the soil shall not exceed 50 parts per million as determined by SW-846 Methods; and

g) The concentration of any contaminant of concern in soil gas shall not exceed 10% of its Lower Explosive Limit (LEL) as measured by a hand held combustible gas indicator that has been calibrated to manufacturer specifications.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.310 Outdoor Inhalation Exposure Route

The outdoor inhalation exposure route may be excluded from consideration if:

a) The requirements in subsection (a)(1) or (a)(2) are met:

1) An approved engineered barrier is in place that meets the requirements of Subpart K; or

2) The only contaminants of concern are benzene, toluene, ethylbenzene, and total xylenes, and a demonstration of active biodegradation has been made for benzene, toluene, ethylbenzene, and total xylenes such that no outdoor inhalation exposure will occur. This demonstration shall be submitted to the Agency for review and approval;

b) The requirements of Sections 742.300 and 742.305 are met;

c) Safety precautions for the construction worker are taken if the Tier 1 construction worker remediation objectives are exceeded; and

d) An institutional control, in accordance with Subpart J, will be placed on the property.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.312 Indoor Inhalation Exposure Route

The indoor inhalation exposure route may be excluded from consideration if:

a) None of the contaminants of concern are listed on Appendix A, Table J and none of the contaminants of concern are volatile chemicals, as defined in Section 742.200; or

b) The requirements in subsections (b)(1)(A), (B) or (C) and (b)(2) and (b)(3) are met:

1) Exclusion options when the contaminants of concern are volatile chemicals:

A) No building or man-made pathway exists or will be placed above contaminated soil gas or groundwater exceeding Tier 1 remediation objectives for residential property (Appendix B, Table H), provided, however, that there is also no soil or groundwater contamination exceeding Tier 1 remediation objectives for residential property (Appendix B, Table A) or Class I groundwater (Appendix B, Table E) located 5 feet or less, horizontally, from any existing or potential building or man-made pathway; or

B) An approved building control technology is in place or will be placed that meets the requirements of Subpart L; or

C) If the contaminants of concern are benzene, toluene, ethylbenzene, and total xylenes only, a demonstration of active biodegradation has been made for benzene, toluene, ethylbenzene, and total xylenes such that no indoor inhalation exposure will occur. This demonstration shall be submitted to the Agency for review and approval;

2) The requirements of Sections 742.300 and 742.305 are met; and

3) An institutional control, in accordance with Subpart J, will be placed on the property.

(Source: Added at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.315 Soil Ingestion Exposure Route

The soil ingestion exposure route may be excluded from consideration if:

a) The requirements of Sections 742.300 and 742.305 are met;

b) An approved engineered barrier is in place that meets the requirements of Subpart K;

c) Safety precautions for the construction worker are taken if the Tier 1 construction worker remediation objectives are exceeded; and

d) An institutional control, in accordance with Subpart J, will be placed on the property.

(Source: Amended at 25 Ill. Reg. 10374, effective August 15, 2001)

Section 742.320 Groundwater Ingestion Exposure Route

The groundwater ingestion exposure route may be excluded from consideration if:

a) The requirements of Sections 742.300 and 742.305 are met;

b) The corrective action measures have been completed to remove any free product to the maximum extent practicable;

c) The source of the release is not located within the minimum or designated maximum setback zone or within a regulated recharge area of a potable water supply well;

d) As demonstrated in accordance with Section 742.1015, for any area within the measured and modeled extent of groundwater contamination above what would otherwise be the applicable Tier 1 groundwater remediation objectives, an ordinance adopted by a unit of local government is in place that effectively prohibits the installation of potable water supply wells (and the use of such wells);

e) As demonstrated using Equation R26, in Appendix C, Table C, in accordance with Section 742.810, the concentration of any contaminant of concern in groundwater within the minimum or designated maximum setback zone of an existing potable water supply well will meet the applicable Tier 1 groundwater remediation objective; and

f) As demonstrated using Equation R26, in Appendix C, Table C, in accordance with Section 742.810, the concentration of any contaminant of concern in groundwater discharging into a surface water will meet the applicable surface water quality standard under 35 Ill. Adm. Code 302.

(Source: Amended at 31 Ill. Reg. 4063, effective February 23, 2007)

SUBPART D: DETERMINING AREA BACKGROUNDS

Section 742.400 Area Background

This Subpart provides procedures for determining area background concentrations for contaminants of concern. Except as described in Section 742.415(c) and (d) of this Subpart, area background concentrations may be used as remediation objectives for contaminants of concern at a site.

Section 742.405 Determination of Area Background for Soil

a) Soil sampling results shall be obtained for purposes of determining area background levels in accordance with the following procedures:

1) For volatile chemicals, sample results shall be based on discrete samples;

2) Unless an alternative method is approved by the Agency, for contaminants other than volatile chemicals, sample results shall be based on discrete

samples or composite samples. If a person elects to use composite samples, each 0.5 acre of the area to be sampled shall be divided into quadrants and 5 aliquots of equal volume per quadrant shall be composited into 1 sample;

3) Samples shall be collected from similar depths and soil types, which shall be consistent with the depths and soil types in which maximum levels of contaminants are found in the areas of known or suspected releases; and

4) Samples shall be collected from areas of the site or adjacent to the site that are unaffected by known or suspected releases at or from the site. If the sample results show an impact from releases at or from the site, then the sample results shall not be included in determining area background levels under this Part.

b) Area background shall be determined according to one of the following approaches:

1) Statewide Area Background Approach:

A) The concentrations of inorganic chemicals in background soils listed in Appendix A, Table G may be used as the upper limit of the area background concentration for the site. The first column to the right of the chemical name presents inorganic chemicals in background soils for counties within Metropolitan Statistical Areas. Counties within Metropolitan Statistical Areas are identified in Appendix A, Table G, Footnote a. Sites located in counties outside Metropolitan Statistical Areas shall use the concentrations of inorganic chemicals in background soils shown in the second column to the right of the chemical name.

B) Soil area background concentrations determined according to this statewide area background approach shall be used as provided in Section 742.415(b) of this Part. For each parameter whose sampling results demonstrate concentrations above those in Appendix A, Table G, the person shall develop appropriate soil remediation objectives in accordance with this Part, or may determine area background in accordance with subsection (b)(2).

2) A statistically valid approach for determining area background concentrations appropriate for the characteristics of the data set, and approved by the Agency.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.410 Determination of Area Background for Groundwater

a) Groundwater sampling results shall be obtained for purposes of determining area background in accordance with the following procedures:

1) Samples shall be collected from areas of the site or adjacent to the site that are unaffected by releases at the site;

2) The background monitoring wells shall be sufficient in number to account for the spatial and temporal variability, size, and number of known or suspected off-site releases of contaminants of concern, and the hydrogeological setting of the site;

3) The samples shall be collected in consecutive quarters for a minimum of one year for each well unless another sample schedule is approved by the Agency;

4) The samples shall be collected from the same stratigraphic unit(s) as the groundwater contamination at the site; and

5) The background monitoring wells shall be located hydraulically upgradient from the release(s) of contaminants of concern, unless a person demonstrates to the Agency that the upgradient location is undefinable or infeasible.

b) Area background shall be determined according to one of the following approaches:

1) Prescriptive Approach:

A) If more than 15% of the groundwater sampling results for a chemical obtained in accordance with subsection (a) of this Section are less than the appropriate detection limit for that chemical, the Prescriptive Approach may not be used for that chemical. If 15% or less of the sampling results are less than the appropriate detection limit, a concentration equal to one-half the detection limit shall be used for that chemical in the calculations contained in this Prescriptive Approach.

B) The groundwater sampling results obtained in accordance with subsection (a) of this Section shall be used to determine if the sample set is normally distributed. The Shapiro-Wilk Test of Normality shall be used to determine whether the sample set is normally distributed, if the sample set for the background well(s) contains 50 or fewer samples. Values necessary for the Shapiro-Wilk Test of Normality shall be determined using Appendix A,

Tables C and D. If the computed value of W is greater than the 5% Critical Value in Appendix A, Table D, the sample set shall be assumed to be normally distributed, and the Prescriptive Approach is allowed. If the computed value of W is less than 5% Critical Value in Appendix A, Table D, the sample set shall be assumed to not be normally distributed, and the Prescriptive Approach shall not be used.

C) If the sample set contains at least ten sample results, the Upper Tolerance Limit (UTL) of a normally distributed sample set may be calculated using the mean (x) and standard deviation(s), from:

$$UTL = x + (K \bullet s),$$

where K = the one-sided normal tolerance factor for estimating the 95% upper confidence limit of the 95th percentile of a normal distribution. Values for K shall be determined using Appendix A, Table B.

D) If the sample set contains at least ten sample results, the UTL shall be the upper limit of the area background concentration for the site. If the sample set contains fewer than ten sample results, the maximum value of the sample set shall be the upper limit of the area background concentration for the site.

E) This Prescriptive Approach shall not be used for determining area background for the parameter pH.

2) Another statistically valid approach for determining area background concentrations appropriate for the characteristics of the data set, and approved by the Agency.

Section 742.415 Use of Area Background Concentrations

a) A person may request that area background concentration determined pursuant to Sections 742.405 and 742.410 be used according to the provisions of subsection (b) of this Section. Such request shall address the following:

1) The natural or man-made pathways of any suspected off-site contamination reaching the site;

2) Physical and chemical properties of suspected off-site contaminants of concern reaching the site; and

3) The location and justification of all background sampling points.

b) Except as specified in subsections (c) and (d) of this Section, an area background concentration may be used as follows:

1) To support a request to exclude a chemical as a contaminant of concern from further consideration for remediation at a site due to its presence as a result of background conditions; or

2) As a remediation objective for a contaminant of concern at a site in lieu of an objective developed pursuant to the other procedures of this Part.

c) An area background concentration shall not be used *in the event that the Agency has determined in writing that the background level for a regulated substance poses an acute threat to human health or the environment at the site when considering the post-remedial action land use.* (Section 58.5(b)(3) of the Act)

d) *In the event that the concentration of a regulated substance of concern on the site exceeds a remediation objective adopted by the Board for residential land use, the property may not be converted to residential use unless such remediation objective or an alternative risk-based remediation objective for that regulated substance of concern is first achieved.* If the land use is restricted, there shall be an institutional control in place in accordance with Subpart J. (Section 58.5(b)(2) of the Act)

(Source: Amended at 31 Ill. Reg. 4063, effective February 23, 2007)

SUBPART E: TIER 1 EVALUAION

Section 742.500 Tier 1 Evaluation Overview

Section 742.500 Tier 1 Evaluation Overview

a) A Tier 1 evaluation compares the concentration of each contaminant of concern detected at a site to the baseline remediation objectives provided in Appendix B, Tables A, B, C, D, E, G, H and I. Use of Tier 1 remediation objectives requires only limited site-specific information: concentrations of contaminants of concern, groundwater classification, land use classification, and, if appropriate, soil pH. (See Appendix B, Illustration A.)

b) Although Tier 1 allows for differentiation between residential and industrial/commercial property use of a site, an institutional control under Subpart J is required where remediation objectives are based on an industrial/commercial property use.

c) For the indoor inhalation exposure route:

1) Appendix B, Tables H and I apply only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls; and

2) Institutional controls under Subpart J are required to use remediation objectives in Appendix B, Table H or Table I.

d) Any given exposure route is not a concern if the concentration of each contaminant of concern detected at the site is below the Tier 1 value of that given route. In such a case, no further evaluation of that route is necessary.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.505 Tier 1 Soil, Soil Gas and Groundwater Remediation Objectives

a) Soil

1) Outdoor Inhalation Exposure Route

A) The Tier 1 soil remediation objectives for this exposure route based upon residential property use are listed in Appendix B, Table A.

B) The Tier 1 soil remediation objectives for this exposure route based upon industrial/commercial property use are listed in Appendix B, Table B. Soil remediation objective determinations relying on this table require use of institutional controls in accordance with Subpart J.

C) For this exposure route, it is acceptable to determine compliance by meeting either the soil or soil gas remediation objectives.

2) Ingestion Exposure Route

A) The Tier 1 soil remediation objectives for this exposure route based upon residential property use are listed in Appendix B, Table A.

B) The Tier 1 soil remediation objectives for this exposure route based upon industrial/commercial property use are listed in Appendix B, Table B. Soil remediation objective determinations relying on this table require use of institutional controls in accordance with Subpart J.

3) Soil Component of the Groundwater Ingestion Route

A) The Tier 1 soil remediation objectives for this exposure route based upon residential property use are listed in Appendix B, Table A.

B) The Tier 1 soil remediation objectives for this exposure route based upon industrial/commercial property use are listed in Appendix B, Table B.

C) The pH-dependent Tier 1 soil remediation objectives for identified ionizable organics or inorganics for the soil component of the groundwater ingestion exposure route (based on the total amount of contaminants present in the soil sample results and groundwater classification) are provided in Appendix B, Tables C and D.

D) Values used to calculate the Tier 1 soil remediation objectives for this exposure route are listed in Appendix B, Table F.

4) Evaluation of the dermal contact with soil exposure route is not required under Tier 1.

b) Soil Gas

1) Outdoor Inhalation Exposure Route

A) The Tier 1 soil gas remediation objectives for this exposure route based upon residential property use are listed in Appendix B, Table G.

B) The Tier 1 soil gas remediation objectives for this exposure route based upon industrial/commercial property use, including the construction worker population, are listed in Appendix B, Table G. Soil gas remediation objective determinations relying on an industrial/commercial scenario require use of institutional controls in accordance with Subpart J.

C) For this exposure route, it is acceptable to determine compliance by meeting either the soil or soil gas remediation objectives.

2) Indoor Inhalation Exposure Route

A) The Tier 1 soil gas remediation objectives for this exposure route are listed in Appendix B, Tables H and I.

B) The Tier 1 soil gas remediation objectives for this exposure route are based on a default water-filled soil porosity value of 0.15 cm^3/cm^3 and the assumed presence of a building with a 10-cm thick, full concrete slab-on-grade.

C) Appendix B, Table H shall be used when any soil or groundwater contamination is located 5 feet or less, vertically or horizontally, from the existing or potential building or man-made pathway. In this scenario, the mode of contaminant transport is both diffusion and advection, which sets the Q_{soil} value at 83.33 cm^3/sec. Appendix B, Table H applies only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls. Pursuant to Section 742.1000(a)(9), soil gas remediation objective determinations relying on Appendix B, Table H require the use of institutional controls in accordance with Subpart J.

D) Appendix B, Table I may be used only when all soil and groundwater contamination is located more than 5 feet, vertically and horizontally, from the existing or potential building or man-made pathway. In this scenario, the mode of contaminant transport is diffusion only, which sets the Q_{soil} value at 0.0 cm^3/sec. Appendix B, Table I applies only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls. Pursuant to Section 742.1000(a)(7) and (a)(9), soil gas remediation objective determinations relying on Appendix B, Table I require the use of institutional controls in accordance with Subpart J. As an alternative to using Appendix B, Table I, it is permissible to use Appendix B, Table H.

E) To determine whether the Q_{soil} value can be set at 0.0 cm^3/sec, the site evaluator shall demonstrate that all soil and groundwater located 5 feet or less, vertically or horizontally, from the existing or potential building or man-made pathway meets the Tier 1 remediation objectives for residential property listed in Appendix B, Table A, and the Tier 1 remediation objectives for Class I groundwater listed in Appendix B, Table E, respectively.

c) Groundwater

1) The Tier 1 groundwater remediation objectives for the groundwater component of the groundwater ingestion route are listed in Appendix B, Table E.

2) The Tier 1 groundwater remediation objectives for this exposure route are given for Class I and Class II groundwaters, respectively.

3) The evaluation of 35 Ill. Adm. Code 620.615 regarding mixtures of similar-acting chemicals shall be considered satisfied for Class I groundwater at the point of human exposure if:

A) No more than one similar-acting noncarcinogenic chemical as listed in Appendix A, Table E is detected in the groundwater at the site; and

B) No carcinogenic contaminant of concern as listed in Appendix A, Table I is detected in any groundwater sample associated with the site, using analytical procedures capable of achieving either the 1 in 1,000,000 cancer risk concentration or the ADL, whichever is greater.

4) If the conditions of subsection (c)(3) of this Section are not met, the Class I groundwater remediation objectives set forth in Appendix B, Table E shall be corrected for the cumulative effect of mixtures of similar-acting chemicals using the following methodologies:

A) For noncarcinogenic chemicals, the methodologies set forth at Section 742.805(c) or Section 742.915(h) shall be used; and

B) For carcinogenic chemicals, the methodologies set forth at Section 742.805(d) or Section 742.915(h) shall be used.

5) For the groundwater component of the indoor inhalation exposure route, the Tier 1 groundwater remediation objectives are listed in Appendix B, Tables H and I.

A) The Tier 1 groundwater remediation objectives for this exposure route are based on a default water-filled soil porosity value of 0.15 cm^3/cm^3 and the assumed presence of a building with a 10-cm thick, full concrete slab-on-grade.

B) Appendix B, Table H shall be used when any soil or groundwater contamination is located 5 feet or less, vertically or horizontally, from the existing or potential building or man-made pathway. In this scenario, the mode of contaminant transport is both diffusion and advection, which sets the Q_{soil} value at 83.33 cm^3/sec. Appendix B, Table H applies only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls. Pursuant to Section 742.1000(a)(9), groundwater remediation objective determinations relying on Appendix B, Table H require the use of institutional controls in accordance with Subpart J.

C) Appendix B, Table I may be used only when all soil and groundwater contamination is located more than 5 feet, vertically and horizontally, from the existing or potential building or man-made pathway. In this scenario, the mode of contaminant transport

is diffusion only, which sets the Q_{soil} value at 0.0 cm^3/sec. Appendix B, Table I applies only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls. Pursuant to Section 742.1000(a)(7) and (a)(9), groundwater remediation objective determinations relying on Appendix B, Table I require the use of institutional controls in accordance with Subpart J. As an alternative to using Appendix B, Table I, it is permissible to use Appendix B, Table H.

D) To determine whether the Q_{soil} value can be set at 0.0 cm^3/sec, the site evaluator shall demonstrate that all soil and groundwater located 5 feet or less, vertically or horizontally, from the existing or potential building or man-made pathway meets the Tier 1 remediation objectives for residential property listed in Appendix B, Table A, and the Tier 1 remediation objectives for Class I groundwater listed in Appendix B, Table E, respectively.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.510 Tier 1 Remediation Objectives Tables for the Ingestion, Outdoor Inhalation and Soil Component of the Groundwater Ingestion Exposure Routes

a) Soil remediation objectives are listed in Appendix B, Tables A, B, C and D.

1) Appendix B, Table A is based upon residential property use.

A) The first column to the right of the chemical name lists soil remediation objectives for the soil ingestion exposure route.

B) The second column lists the soil remediation objectives for the outdoor inhalation exposure route.

C) The third and fourth columns list soil remediation objectives for the soil component of the groundwater ingestion exposure route for the respective classes of groundwater:

i) Class I groundwater; and

ii) Class II groundwater.

D) The final column lists the Acceptable Detection Limit (ADL), only when applicable.

2) Appendix B, Table B is based upon industrial/commercial property use.

A) The first and third columns to the right of the chemical name list the soil remediation objectives for the soil ingestion exposure route based on two receptor populations:

i) Industrial/commercial; and

ii) Construction worker.

B) The second and fourth columns to the right of the chemical name list the soil remediation objectives for the outdoor inhalation exposure route based on two receptor populations:

i) Industrial/commercial; and

ii) Construction worker.

C) The fifth and sixth columns to the right of the chemical name list the soil remediation objectives for the soil component of the groundwater ingestion exposure route for two classes of groundwater:

i) Class I groundwater; and

ii) Class II groundwater.

D) The final column lists the acceptable detection limit (ADL), only when applicable.

3) Appendix B, Tables C and D set forth pH specific soil remediation objectives for inorganic and ionizing organic chemicals for the soil component of the groundwater ingestion route.

A) Table C sets forth remediation objectives based on Class I groundwater and Table D sets forth remediation objectives based on Class II groundwater.

B) The first column in Tables C and D lists the chemical names.

C) The second through ninth columns to the right of the chemical names list the pH based soil remediation objectives.

4) For the inorganic chemicals listed in Appendix B, Tables A and B, the soil component of the groundwater ingestion exposure route shall be evaluated using TCLP (SW-846 Method 1311) or SPLP (SW-846 Method 1312), incorporated by reference at Section 742.210 unless a person chooses to evaluate the soil component on the basis of the total amount of

contaminant in a soil sample result in accordance with subsection (a)(5) of this Section.

5) For those inorganic and ionizing organic chemicals listed in Appendix B, Tables C and D, if a person elects to evaluate the soil component of the groundwater ingestion exposure route based on the total amount of contaminant in a soil sample result (rather than TCLP or SPLP analysis), the person shall determine the soil pH at the site and then select the appropriate soil remediation objectives based on Class I and Class II groundwaters from Tables C and D, respectively. If the soil pH is less than 4.5 or greater than 9.0, then Tables C and D cannot be used.

6) Unless one or more exposure routes are excluded from consideration under Subpart C, the most stringent soil remediation objective of the exposure routes (i.e., soil ingestion exposure route, outdoor inhalation exposure route, and soil component of the groundwater ingestion exposure route) shall be compared to the concentrations of soil contaminants of concern measured at the site. When using Appendix B, Table B to select soil remediation objectives for the ingestion exposure route and outdoor inhalation exposure routes, the remediation objective shall be the more stringent soil remediation objective of the industrial/commercial populations and construction worker populations.

7) Confirmation sample results may be averaged or soil samples may be composited in accordance with Section 742.225.

8) If a soil remediation objective for a chemical is less than the ADL, the ADL shall serve as the soil remediation objective.

b) Groundwater remediation objectives for the groundwater component of the groundwater ingestion exposure route are listed in Appendix B, Table E. However, Appendix B, Table E must be corrected for cumulative effect of mixtures of similar-acting noncarcinogenic chemicals as set forth in Section 742.505(c)(3) and (c)(4).

1) The first column to the right of the chemical name lists groundwater remediation objectives for Class I groundwater, and the second column lists the groundwater remediation objectives for Class II groundwater.

2) To use Appendix B, Table E of this Part, the 35 Ill. Adm. Code 620 classification for groundwater at the site shall be determined. The concentrations of groundwater contaminants of concern at the site are compared to the applicable Tier 1 groundwater remediation objectives for the groundwater component of the groundwater ingestion exposure route in Appendix B, Table E.

c) Soil gas remediation objectives for the outdoor inhalation exposure route are listed in Appendix B, Table G.

1) The first column to the right of the chemical name lists the soil gas remediation objectives for residential populations.

2) The second and third columns to the right of the chemical names list the soil gas remediation objectives for the outdoor inhalation exposure route based on two receptor populations:

A) Industrial/commercial; and

B) Construction worker.

d) For contaminants of concern not listed in Appendix B, Tables A, B, E, and G, a person may request site-specific remediation objectives from the Agency or propose site-specific remediation objectives in accordance with 35 Ill. Adm. Code 620, Subpart I of this Part, or both.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.515 Tier 1 Remediation Objectives Tables for the Indoor Inhalation Exposure Route

a) For the indoor inhalation exposure route:

1) Appendix B, Tables H and I apply only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls; and

2) Institutional controls under Subpart J are required to use remediation objectives in Appendix B, Table H or Table I.

b) When the mode of contaminant transport is both diffusion and advection as described in Section 742.505 (i.e., any soil or groundwater contamination is located 5 feet or less, vertically or horizontally, from the existing or potential building or man-made pathway), the remediation objectives for soil gas or groundwater listed in Appendix B, Table H shall be used.

1) The first column to the right of the chemical name lists the soil gas remediation objectives for residential receptors.

2) The second column lists the soil gas remediation objectives for industrial/commercial receptors.

3) The third column lists the groundwater remediation objectives for residential receptors.

4) The fourth column lists the groundwater remediation objectives for industrial/commercial receptors.

c) Only when the mode of contaminant transport is diffusion only as described in Section 742.505 (i.e., all soil and groundwater contamination is located more than 5 feet, vertically and horizontally, from the existing or potential building or man-made pathway), the remediation objectives for soil gas and groundwater listed in Appendix B, Table I may be used.

1) The first column to the right of the chemical name lists the soil gas remediation objectives for residential receptors.

2) The second column lists the soil gas remediation objectives for industrial/commercial receptors.

3) The third column lists the groundwater remediation objectives for residential receptors.

4) The fourth column lists the groundwater remediation objectives for industrial/commercial receptors.

d) If using Appendix B, Table H, compliance is determined by meeting either the soil gas remediation objectives or the groundwater remediation objectives.

e) If using Appendix B, Table I, compliance is determined by meeting both the soil gas remediation objectives and the groundwater remediation objectives.

f) For volatile chemicals not listed in Appendix B, Table H or I, a person may request site-specific remediation objectives from the Agency or propose site-specific remediation objectives in accordance with Subpart I, or both.

g) As an alternative to using Appendix B, Table I pursuant to subsection (c), it is permissible to use Appendix B, Table H pursuant to subsection (b).

(Source: Added at 37 Ill. Reg. 7506, effective July 15, 2013)

SUBPART F: TIER 2 GENERAL EVALUATION

Section 742.600 Tier 2 Evaluation Overview

a) Tier 2 remediation objectives are developed through the use of equations which allow site-specific data to be used. (See Appendix C, Illustrations A and B.) The

equations, identified in Appendix C, Tables A, C, and L may be used to develop Tier 2 remediation objectives.

b) Tier 2 evaluation is only required for contaminants of concern and corresponding exposure routes (except where excluded from further consideration under Subpart C) exceeding the Tier 1 remediation objectives. When conducting Tier 2 evaluations, the values used in the calculations must have the appropriate units of measure as identified in Appendix C, Tables B, D, and M.

c) Any development of remediation objectives using site-specific information or equations outside the Tier 2 framework shall be evaluated under Tier 3.

d) Any development of a remediation objective under Tier 2 shall not use a target hazard quotient greater than one at the point of human exposure or a target cancer risk greater than 1 in 1,000,000 at the point of human exposure.

e) In conducting a Tier 2 evaluation, the following conditions shall be met:

1) For each discrete sample, the total soil contaminant concentration of either a single contaminant or multiple contaminants of concern shall not exceed the attenuation capacity of the soil as provided in Section 742.215.

2) Remediation objectives for noncarcinogenic compounds which affect the same target organ, organ system or similar mode of action shall meet the requirements of Section 742.720.

3) The soil remediation objectives based on the outdoor inhalation exposure route and the soil component of the groundwater ingestion exposure routes shall not exceed the soil saturation limit as provided in Section 742.220.

4) The soil gas remediation objectives based on the indoor and outdoor inhalation exposure routes shall not exceed the soil vapor saturation limit provided pursuant to Section 742.222.

f) Tier 2 remediation objectives for the indoor inhalation exposure route shall be calculated for either soil gas or groundwater if a Q_{soil} value of 83.33 cm^3/sec is used.

g) Tier 2 remediation objectives for the indoor inhalation exposure route shall be calculated for both soil gas and groundwater if a Q_{soil} value of 0.0 cm^3/sec is used.

h) If the calculated Tier 2 soil remediation objective for an applicable exposure route is more stringent than the corresponding Tier 1 remediation objective, then the Tier 1 remediation objective applies.

i) If the calculated Tier 2 soil remediation objective for an exposure route is more stringent than the Tier 1 soil remediation objectives for the other exposure routes, then the Tier 2 calculated soil remediation objective applies and Tier 2 soil remediation objectives for the other exposure routes are not required.

j) If the calculated Tier 2 soil remediation objective is less stringent than one or more of the soil remediation objectives for the remaining exposure routes, then the Tier 2 values are calculated for the remaining exposure routes and the most stringent Tier 2 calculated value applies.

k) If a contaminant has both carcinogenic and noncarcinogenic effects for any applicable exposure route or receptor, remediation objectives shall be calculated for each effect and the more stringent remediation objective shall apply. The toxicological-specific information is described in Section 742.705(d).

l) For the indoor inhalation exposure route:

1) Appendix C, Table L applies only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls; and

2) Institutional controls under Subpart J are required to develop remediation objectives pursuant to Appendix C, Table L.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.605 Land Use

a) Present and post-remediation land use is evaluated in a Tier 2 evaluation. Acceptable exposure factors for the Tier 2 evaluation for residential, industrial/commercial, and construction worker populations are provided in the far right column of Appendix C, Tables B, D, and M. Use of exposure factors different from those in Appendix C, Tables B, D, and M must be approved by the Agency as part of a Tier 3 evaluation.

b) If a Tier 2 evaluation is based on an industrial/commercial property use, then:

1) Construction worker populations shall also be evaluated, except for the indoor inhalation exposure route; and

2) Institutional controls are required in accordance with Subpart J.

c) For the indoor inhalation exposure route, institutional controls under Subpart J are required to develop remediation objectives pursuant to Appendix C, Table L.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.610 Chemical and Site Properties

a) Physical and Chemical Properties of Contaminants

Tier 2 evaluations require information on the physical and chemical properties of the contaminants of concern. The physical and chemical properties used in a Tier 2 evaluation are contained in Appendix C, Table E. If the site has contaminants not included in this table, a person may request the Agency to provide the applicable physical and chemical input values or may propose input values under Subpart I. If a person proposes to apply values other than those in Appendix C, Table E, or those provided by the Agency, the evaluation shall be considered under Tier 3.

b) Soil and Groundwater Parameters

1) A Tier 2 evaluation requires examination of soil and groundwater parameters. The parameters that may be varied, and the conditions under which these parameters are determined as part of Tier 2, are summarized in Appendix C, Tables B, D, and M. If a person proposes to vary site-specific parameters outside of the framework of these tables, the evaluation shall be considered under Tier 3.

2) To determine site-specific physical soil parameters, a minimum of one boring per 0.5 acre of contamination shall be collected. This boring must be deep enough to allow the collection of the required field measurements. The site-specific physical soil parameters must be determined from the portion of the boring representing the stratigraphic units being evaluated. For example, if evaluating the soil component of the groundwater ingestion exposure route, two samples from the boring will be required:

A) A sample of the predominant soil type for the vadose zone; and

B) A sample of the predominant soil type for the saturated zone.

3) A site-specific SSL dilution factor (used in developing soil remediation objectives based upon the protection of groundwater) may be determined by substituting site information in Equation S22 in Appendix C, Table A. To make this demonstration, a minimum of three monitoring wells shall be used to determine the hydraulic gradient. As an alternative, the default dilution factor value listed in Appendix C, Table B may be used. If monitoring wells are used to determine the hydraulic gradient, the soil taken from the borings shall be visually inspected to ensure there are no significant differences in the stratigraphy. If there are similar soil types in

the field, one boring shall be used to determine the site-specific physical soil parameters. If there are significant differences, all of the borings shall be evaluated before determining the site-specific physical soil parameters for the site.

4) Not all of the parameters identified in Appendix C, Tables B, D, and M need to be determined on a site-specific basis. A person may choose to collect partial site-specific information and use default values as listed in Appendix C, Tables B, D, and M for the rest of the parameters.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

SUBPART G: TIER 2 SOIL EVALUATION

Section 742.700 Tier 2 Soil and Soil Gas Evaluation Overview

a) Tier 2 remediation objectives are developed through the use of models which allow site-specific data to be considered. Appendix C, Tables A, C, and L list equations that shall be used under a Tier 2 evaluation to calculate soil remediation objectives prescribed by the SSL, RBCA, and modified J&E models, respectively. (See also Appendix C, Illustration A.)

b) Appendix C, Table A lists equations that are used under the SSL model. (See also Appendix C, Illustration A.) The SSL model has equations to evaluate the following human exposure routes:

1) Soil ingestion exposure route;

2) Outdoor Inhalation exposure route; and

3) Soil component of the groundwater ingestion exposure route.

c) Evaluation of the dermal exposure route is not required under the SSL model.

d) Appendix C, Table C lists equations that are used under the RBCA model. (See also Appendix C, Illustration A.) The RBCA model has equations to evaluate human exposure based on the following:

1) The combined exposure routes of outdoor inhalation of vapors and particulates, soil ingestion and dermal contact with soil;

2) The outdoor inhalation exposure route from subsurface soils;

3) Soil component of the groundwater ingestion exposure route; and

4) Groundwater ingestion exposure route.

e) Appendix C, Table L lists equations that are used under the modified J&E model. The modified J&E model has equations to evaluate human exposure by the indoor inhalation exposure route. The modified model allows for the development of soil gas remediation objectives. For the indoor inhalation exposure route:

1) Appendix C, Table L applies only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls; and

2) Institutional controls under Subpart J are required to develop soil gas remediation objectives pursuant to Appendix C, Table L.

f) The equations in either Appendix C, Table A, C, or L may be used to calculate remediation objectives for each contaminant of concern under Tier 2, if the following requirements are met:

1) The Tier 2 soil or soil gas remediation objectives for the ingestion and outdoor inhalation exposure routes shall use the applicable equations from the same approach (i.e., SSL equations in Appendix C, Table C). For the indoor inhalation exposure route, only the J&E equations can be used.

2) The equations used to calculate soil remediation objectives for the soil component of the groundwater ingestion exposure route are not dependent on the approach utilized to calculate soil remediation objectives for the other exposure routes. For example, it is acceptable to use the SSL equations for calculating Tier 2 soil remediation objectives for the ingestion and outdoor inhalation exposure routes, and the RBCA equations for calculating Tier 2 soil remediation objectives for the soil component of the groundwater ingestion exposure route.

3) Combining equations from Appendix C, Tables A, C, and L to form a new model is not allowed. In addition, Appendix C, Tables A, C, and L must use their own applicable parameters identified in Appendix C, Tables B, D, and M, respectively.

g) In calculating soil or soil gas remediation objectives for industrial/commercial property use, applicable calculations shall be performed twice: once using industrial/commercial population default values and once using construction worker population default values. The more stringent soil or soil gas remediation objectives derived from these calculations must be used for further Tier 2 evaluations. The indoor inhalation exposure route does not apply to the construction worker population.

h) Tier 2 data sheets provided by the Agency shall be used to present calculated Tier 2 remediation objectives, if required by the particular program for which remediation is being performed.

i) The RBCA equations which rely on the parameter Soil Water Sorption Coefficient (k_s) can only be used for ionizing organics and inorganics by substituting values for k_s from Appendix C, Tables I and J, respectively. This will also require the determination of a site-specific value for soil pH.

j) For the outdoor inhalation exposure route, it is acceptable to use either Section 742.710 to develop a soil remediation objective or Section 742.712 to develop a soil gas remediation objective to determine compliance with the pathway.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.705 Parameters for Soil Remediation Objective Equations

a) Appendix C, Tables B, D, and M list the input parameters for the SSL, RBCA, and J&E equations, respectively. The first column lists each symbol as it is presented in the equation. The next column defines the parameters. The third column shows the units for the parameters. The fourth column identifies where information on the parameters can be obtained (i.e., field measurement, applicable equations, reference source, or default value). The last column identifies how the parameters can be generated.

b) Default Values

Default values are numerical values specified for use in the Tier 2 equations. The fourth column of Appendix C, Tables B, D, and M denotes if the default values are from the SSL model, RBCA model, modified J&E model or some other source. The last column of Appendix C, Tables B, D, and M lists the numerical values for the default values used in the SSL, RBCA, and J&E equations, respectively.

c) Site-specific Information

Site-specific information is a parameter measured, obtained, or determined from the site to calculate Tier 2 remediation objectives. The fourth column of Appendix C, Tables B, D, and M identifies those site-specific parameters that may require direct field measurement. For some parameters, numerical default inputs have been provided in the last column of Appendix C, Tables B, D, and M to substitute for site-specific information. In some cases, information on the receptor or soil type is required to select the applicable numerical default inputs. Site-specific information includes:

1) Physical soil parameters identified in Appendix C, Table F. The second column identifies the location where the sample is to be collected. Acceptable methods for measuring or calculating these soil parameters are identified in the last column of Appendix C, Table F;

2) Institutional controls or engineered barriers, pursuant to Subparts J and K, describe applicable institutional controls and engineered barriers under a Tier 2 evaluation; and

3) Land use classification

d) Toxicological-specific Information

1) Toxicological-specific information is used to calculate Tier 2 remediation objectives for the following parameters, if applicable:

A) Oral Chronic Reference Dose (RfD_o, expressed in mg/kg-d);

B) Oral Subchronic Reference Dose (RfD_s, expressed in mg/kg-d, shall be used for construction worker remediation objective calculations);

C) Oral Slope Factor (SF_o, expressed in $(mg/kg\text{-}d)^{-1}$);

D) Inhalation Unit Risk Factor (URF expressed in $(\mu g/m^3)^{-1}$);

E) Inhalation Chronic Reference Concentration (RfC, expressed in mg/m^3);

F) Inhalation Subchronic Reference Concentration (RfC_s, expressed in mg/m^3, shall be used for construction worker remediation objective calculations);

G) Inhalation Chronic Reference Dose (RfD_i, expressed in mg/kg-d);

H) Inhalation Subchronic Reference Dose (RfD_{is}, expressed in mg/kg-d, shall be used for construction worker remediation objective calculations); and

I) Inhalation Slope Factor (SF_i, expressed in $(mg/kg\text{-}d)^{-1}$);

2) Toxicological information can be obtained by following the guidelines in OSWER Directive 9285.7-53, as incorporated by reference in Section 742.210, or the program under which the remediation is being performed.

e) Chemical-specific Information

Chemical-specific information used to calculate Tier 2 remediation objectives is listed in Appendix C, Table E.

f) Calculations
Calculating numerical values for some parameters requires the use of equations listed in Appendix C, Tables A, C, and L. The parameters that are calculated are listed in Appendix C, Tables B, D, and M.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.710 SSL Soil Equations

a) This Section sets forth the equations and parameters used to develop Tier 2 soil remediation objectives for the three exposure routes using the SSL approach.

b) Soil Ingestion Exposure Route

1) Equations S1 through S3 form the basis for calculating Tier 2 remediation objectives for the soil ingestion exposure route using the SSL approach. Equation S1 is used to calculate soil remediation objectives for noncarcinogenic contaminants. Equations S2 and S3 are used to calculate soil remediation objectives for carcinogenic contaminants for residential populations and industrial/commercial and construction worker populations, respectively.

2) For Equations S1 through S3, the SSL default values cannot be modified with site-specific information.

c) Outdoor Inhalation Exposure Route

1) Equations S4 through S16, S26 and S27 are used to calculate Tier 2 soil remediation objectives for the outdoor inhalation exposure route using the SSL approach. To address this exposure route, organic contaminants and mercury must be evaluated separately from fugitive dust using their own equations set forth in subsections (c)(2) and (c)(3), respectively.

2) Organic Contaminants

A) Equations S4 through S10 are used to calculate Tier 2 soil remediation objectives for organic contaminants and mercury based on the outdoor inhalation exposure route. Equation S4 is used to calculate soil remediation objectives for noncarcinogenic organic contaminants in soil for residential and industrial/commercial populations. Equation S5 is used to calculate soil remediation objectives for noncarcinogenic organic

contaminants and mercury in soil for construction worker populations. Equation S6 is used to calculate soil remediation objectives for carcinogenic organic contaminants in soil for residential and industrial/commercial populations. Equation S7 is used to calculate soil remediation objectives for carcinogenic organic contaminants in soil for construction worker populations. Equations S8 through S10, S27 and S28 are used for calculating numerical values for some of the parameters in Equations S4 through S7.

B) For Equation S4, a numerical value for the Volatilization Factor (VF) can be calculated in accordance with subsection (c)(2)(F). The remaining parameters in Equation S4 have either SSL default values listed in Appendix C, Table B or toxicological-specific information (i.e., RfC), which can be obtained by following the guidelines in OSWER Directive 9285.7-53, as incorporated by reference in Section 742.210 or requested from the program under which the remediation is being performed.

C) For Equation S5, a numerical value for the Volatilization Factor adjusted for Agitation (VF') can be calculated in accordance with subsection (c)(2)(G). The remaining parameters in Equation S5 have either SSL default values listed in Appendix C, Table B or toxicological-specific information (i.e., RfC), which can be obtained by following the guidelines in OSWER Directive 9285.7-53, as incorporated by reference in Section 742.210 or requested from the program under which the remediation is being performed.

D) For Equation S6, a numerical value for VF can be calculated in accordance with subsection (c)(2)(F). The remaining parameters in Equation S6 have either default values listed in Appendix C, Table B or toxicological-specific information (i.e., URF), which can be obtained by following the guidelines in OSWER Directive 9285.7-53, as incorporated by reference in Section 742.210 or requested from the program under which the remediation is being performed.

E) For Equation S7, a numerical value for VF' can be calculated in accordance with subsection (c)(2)(G). The remaining parameters in Equation S7 have either default values listed in Appendix C, Table B or toxicological-specific information (i.e., URF), which can be obtained by following the guidelines in OSWER Directive 9285.7-53, as incorporated by reference in Section 742.210 or requested from the program under which the remediation is being performed.

F) The VF can be calculated for residential and industrial/commercial populations using one of the following equations based on the information known about the contaminant source and receptor population:

i) Equation S8, in conjunction with Equation S10, is used to calculate VF assuming an infinite source of contamination; or

ii) If the area and depth of the contaminant source are known or can be estimated reliably, mass limit considerations may be used to calculate VF using Equation S26.

G) The VF' can be calculated for the construction worker populations using one of the following equations based on the information known about the contaminant source:

i) Equation S9 is used to calculate VF' assuming an infinite source of contamination; or

ii) If the area and depth of the contaminant source are known or can be estimated reliably, mass limit considerations may be used to calculate VF' using Equation S27.

3) Fugitive Dust

A) Equations S11 through S16 are used to calculate Tier 2 soil remediation objectives using the SSL fugitive dust model for the outdoor inhalation exposure route. Equation S11 is used to calculate soil remediation objectives for noncarcinogenic contaminants in fugitive dust for residential and industrial/commercial populations. Equation S12 is used to calculate soil remediation objectives for noncarcinogenic contaminants in fugitive dust for construction worker populations. Equation S13 is used to calculate soil remediation objectives for carcinogenic contaminants in fugitive dust for residential and industrial/commercial populations. Equation S14 is used to calculate soil remediation objectives for carcinogenic contaminants in fugitive dust for construction worker populations. Equations S15 and S16 are used for calculating numerical quantities for some of the parameters in Equations S11 through S14.

B) For Equation S11, a numerical value can be calculated for the Particulate Emission Factor (PEF) using Equation S15. This equation relies on various input parameters from a variety of

sources. The remaining parameters in Equation S11 have either SSL default values listed in Appendix C, Table B or toxicological-specific information (i.e., RfC), which can be obtained by following the guidelines in OSWER Directive 9285.7-53, as incorporated by reference in Section 742.210 or requested from the program under which the remediation is being performed.

C) For Equation S12, a numerical value for the Particulate Emission Factor for Construction Worker (PEF') can be calculated using Equation S16. The remaining parameters in Equation S12 have either SSL default values listed in Appendix C, Table B or toxicological-specific information (i.e., RfC), which can be obtained by following the guidelines in OSWER Directive 9285.7-53, as incorporated by reference in Section 742.210 or requested from the program under which the remediation is being performed.

D) For Equation S13, a numerical value for PEF can be calculated using Equation S15. The remaining parameters in Equation S13 have either default values listed in Appendix C, Table B or toxicological-specific information (i.e., URF), which can be obtained by following the guidelines in OSWER Directive 9285.7-53, as incorporated by reference in Section 742.210 or requested from the program under which the remediation is being performed.

E) For Equation S14, a numerical value for PEF' can be calculated using Equation S16. The remaining parameters in Equation S14 have either default values listed in Appendix C, Table B or toxicological-specific information (i.e., URF), which can be obtained by following the guidelines in OSWER Directive 9285.7-53, as incorporated by reference in Section 742.210 or requested from the program under which the remediation is being performed.

d) Soil Component of the Groundwater Ingestion Exposure Route

The Tier 2 remediation objective for the soil component of the groundwater ingestion exposure route can be calculated using one of the following equations based on the information known about the contaminant source and receptor population:

1) Equation S17 is used to calculate the remediation objective assuming an infinite source of contamination.

A) The numerical quantities for four parameters in Equation S17, the Target Soil Leachate Concentration (C_w), Soil-Water Partition Coefficient (K_d) for non-ionizing organics, Water-Filled Soil Porosity Theta w (θ_w) and Air-Filled Soil Porosity Theta a (θ_a), are calculated using Equations S18, S19, S20 and S21,

respectively. Equations S22, S23, S24 and S25 are also needed to calculate numerical values for Equations S18 and S21. The pH-dependent K_d values for ionizing organics can be calculated using Equation S19 and the pH-dependent Koc values in Appendix C, Table I.

B) The remaining parameters in Equation S17 are Henry's Law Constant (H'), a chemical specific value listed in Appendix C, Table E and Dry Soil Bulk Density (ρ_b), a site-specific based value listed in Appendix C, Table B.

C) The default value for GW_{obj} is the Tier 1 groundwater objective. For chemicals for which there is no Tier 1 groundwater remediation objective, the value for GW_{obj} shall be the concentration determined according to the procedures specified in 35 Ill. Adm. Code 620, Subpart F. As an alternative to using Tier 1 groundwater remediation objectives or concentrations determined according to the procedures specified in 35 Ill. Adm. Code 620, Subpart F, GW_{obj} may be developed using Equations R25 and R26, if approved institutional controls are in place as required in Subpart J.

2) If the area and depth of the contaminant source are known or can be estimated reliably, mass limit considerations may be used to calculate the remediation objective for this exposure route using Equation S28. The parameters in Equation S28 have default values listed in Appendix C, Table B.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.712 SSL Soil Gas Equation for the Outdoor Inhalation Exposure Route

a) This Section sets forth the equation and parameters used to develop Tier 2 soil gas remediation objectives for the outdoor inhalation exposure route using the SSL approach.

b) Equation S30 is used to calculate Tier 2 soil gas remediation objectives for the outdoor inhalation exposure route for residential, industrial/commercial, and construction worker populations.

c) Equations S4 through S16, S26 and S27, which calculate Tier 2 soil remediation objectives as described in Section 742.710(c), form the basis for developing the Tier 2 soil gas remediation objectives for the outdoor inhalation exposure route using the SSL model.

d) The remaining parameters used to calculate Equation S30 are listed in Appendix C, Table B, except for Dimensionless Henry's Law Constant (25°C), a chemical specific value listed in Appendix C, Table E.

(Source: Added at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.715 RBCA Soil Equations

a) This Section presents the RBCA model and describes the equations and parameters used to develop Tier 2 soil remediation objectives.

b) Ingestion, Outdoor Inhalation, and Dermal Contact

1) The two sets of equations in subsections (b)(2) and (b)(3) shall be used to generate Tier 2 soil remediation objectives for the combined ingestion, outdoor inhalation, and dermal contact with soil exposure routes.

2) Combined Exposure Routes of Soil Ingestion, Outdoor Inhalation of Vapors and Particulates, and Dermal Contact with Soil

A) Equations R1 and R2 form the basis for deriving Tier 2 remediation objectives for the set of equations that evaluates the combined exposure routes of soil ingestion, outdoor inhalation of vapors and particulates, and dermal contact with soil using the RBCA approach. Equation R1 is used to calculate soil remediation objectives for carcinogenic contaminants. Equation R2 is used to calculate soil remediation objectives for noncarcinogenic contaminants. Soil remediation objectives for the outdoor inhalation exposure route from subsurface soils must also be calculated in accordance with the procedures outlined in subsection (b)(3) of this Section and compared to the values generated from Equations R1 or R2. The smaller value (i.e., R1 and R2 compared to R7 and R8, respectively) from these calculations is the Tier 2 soil remediation objective for the combined exposure routes of soil ingestion, outdoor inhalation, and dermal contact with soil.

B) In Equation R1, numerical values are calculated for two parameters:

i) The volatilization factor for surficial soils (VF_{ss}) using Equations R3 and R4; and

ii) The volatilization factor for surficial soils regarding particulates (VF_p) using Equation R5.

C) VF_{ss} uses Equations R3 and R4 to derive a numerical value. Equation R3 requires the use of Equation R6. Both equations must be used to calculate the VF_{ss}. The lowest calculated value from these equations must be substituted into Equation R1.

D) The remaining parameters in Equation R1 have either default values listed in Appendix C, Table D or toxicological-specific information (i.e., SF_o, SF_i), which can be obtained by following the guidelines in OSWER Directive 9285.7-53, as incorporated by reference in Section 742.210 or requested from the program under which the remediation is being performed.

E) For Equation R2, the parameters VF_{ss} and VF_p are calculated. The remaining parameters in Equation R2 have either default values listed in Appendix C, Table D or toxicological-specific information (i.e., RfD_o, RfD_i), which can be obtained by following the guidelines in OSWER Directive 9285.7-53, as incorporated by reference in Section 742.210 or requested from the program under which the remediation is being performed.

F) For chemicals other than inorganics which do not have default values for the dermal absorption factor (RAF_d) in Appendix C, Table D a dermal absorption factor of 0.5 shall be used for Equations R1 and R2. For inorganics, dermal absorption may be disregarded (i.e., $RAF_d = 0$).

3) Outdoor Inhalation Exposure Route from Subsurface Soils (soil below one meter)

A) Equations R7 and R8 form the basis for deriving Tier 2 remediation objectives for the outdoor inhalation exposure route from subsurface soils using the RBCA approach. Equation R7 is used to calculate soil remediation objectives for carcinogenic contaminants. Equation R8 is used to calculate soil remediation objectives for noncarcinogenic contaminants.

B) For Equation R7, the carcinogenic risk-based screening level for air ($RBSL_{air}$) and the volatilization factor for soils below one meter to ambient air (VF_{samb}) have numerical values that are calculated using Equations R9 and R11, respectively. Both equations rely on input parameters from a variety of sources.

C) The noncarcinogenic risk-based screening level for air ($RBSL_{air}$) and the volatilization factor for soils below one meter to ambient air (VF_{samb}) in Equation R8 have numerical values that can be calculated using Equations R10 and R11, respectively.

c) Soil Component of the Groundwater Ingestion Exposure Route

1) Equation R12 forms the basis for deriving Tier 2 remediation objectives for the soil component of the groundwater ingestion exposure route using the RBCA approach. The parameters, groundwater at the source (GW_{source}) and Leaching Factor (LF_{sw}), have numerical values that are calculated using Equations R13 and R14, respectively.

2) Equation R13 requires numerical values that are calculated using Equation R15.

3) Equation R14 requires numerical values that are calculated using Equations R21, R22, and R24. For non-ionizing organics, the Soil Water Sorption Coefficient (k_s) shall be calculated using Equation R20. For ionizing organics and inorganics, the values for k_s are listed in Appendix C, Tables I and J, respectively. The pH-dependent k_s values for ionizing organics can be calculated using Equation R20 and the pH-dependent K_{oc} values in Appendix C, Table I. The remaining parameters in Equation R14 are field measurements or default values listed in Appendix C, Table D.

d) The default value for GW_{comp} is the Tier 1 groundwater remediation objective. For chemicals for which there is no Tier 1 groundwater remediation objective, the value for GW_{comp} shall be the concentration determined according to the procedures specified in 35 Ill. Adm. Code 620, Subpart F. As an alternative to using the above concentrations, GW_{comp} may be developed using Equations R25 and R26, if approved institutional controls are in place as may be required in Subpart J.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.717 J&E Soil Gas Equations for the Indoor Inhalation Exposure Route

a) This Section sets forth the equations and parameters to be used to develop Tier 2 soil gas remediation objectives for the indoor inhalation exposure route using the modified J&E model.

b) Equations J&E1 and J&E2 calculate, for carcinogens and noncarcinogens, respectively, an acceptable concentration of the contaminant of concern in indoor air that adequately protects humans who inhale this air. Equation J&E3 converts indoor air concentrations from parts per million volume to milligrams per cubic meter.

c) Equation J&E4 calculates an acceptable concentration of the contaminant of concern in the soil gas at the source of contamination. This calculation is made using:

1) an attenuation factor developed in accordance with Equations J&E7 through 18; and

2) the acceptable concentration of the contaminant of concern in indoor air calculated in accordance with Equation J&E1 (for carcinogens) or J&E2 (for noncarcinogens).

d) The attenuation factor (Equation J&E7 or J&E8) accounts for the following processes:

1) Migration of contaminants from the source upwards through the vadose zone;

2) Migration of contaminants through the earthen filled cracks in the building's full concrete slab-on-grade or full concrete basement floor and walls; and

3) Mixing of the contaminants with air inside the building.

e) Equation J&E7 must be used when the mode of contaminant transport is both diffusion and advection. In this scenario, the Q_{soil} value equals 83.33 cm^3/sec as described in Section 742.505.

f) Equation J&E8 may be used only when the mode of contaminant transport is diffusion only. In this scenario, the Q_{soil} value equals 0.0 cm^3/sec as described in Section 742.505. As an alternative to using Equation J&E8 pursuant to this subsection, it is permissible to use Equation J&E7, in which case the Q_{soil} value equals 83.33 cm^3/sec as described in Section 742.505.

g) Equations J&E9a through J&E18 calculate input parameters for either Equation J&E7 or J&E8 (the equations used to calculate an attenuation factor). These equations assume there are "n" different soil layers between the source of the contamination and the floor of the building. Equations J&E11, 16, 17 and 18 shall be used to calculate the needed parameters for each of the n layers (the general soil layer is referred to as soil layer "i" and i = 1, 2, . . . n). Equations J&E16, 17, and 18 shall also be used to calculate needed parameters for the soil in the cracks of the building's full concrete slab-on-grade or full concrete basement floor and walls (it is through these cracks that contaminated soil gas is assumed to flow from the subsurface into the building). As reflected in Equation J&E14, the only crack assumed to be present is the floor-wall seam gap. To calculate the surface area of the enclosed space at or below grade, Equation J&E12a shall be

used for a building with a full concrete slab-on-grade and Equation J&E12b shall be used for a building with a full concrete basement floor and walls.

h) The default representative subsurface temperature for Henry's Law Constant is 13°C. This value shall be used, as appropriate, in all calculations needed to represent the system by which contaminants migrate through the subsurface.

i) The calculated soil gas remediation objective shall be compared with the soil vapor saturation limit (C_v^{sat}, Equation J&E5) for each volatile chemical. The calculated C_v^{sat} shall use the default representative subsurface temperature specified in subsection (h). If the calculated soil gas remediation objective is greater than C_v^{sat}, then C_v^{sat} is used as the soil gas remediation objective.

j) The calculated soil gas remediation objective shall be compared to concentrations of soil gas collected at a depth at least 3 feet below ground surface and above the saturated zone. If a valid sample cannot be collected, a soil gas sampling plan shall be approved by the Agency under Tier 3.

(Source: Added at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.720 Chemicals with Cumulative Noncarcinogenic Effects

Appendix A, Table E lists the groups of chemicals from Appendix B, Tables A and B that have remediation objectives based on noncarcinogenic toxicity and that affect the same target organ. If more than one chemical detected at a site affects the same target organ (i.e., has the same critical effect as defined by the RfD), the initially calculated remediation value for each chemical in the group shall be corrected for cumulative effects by one of the following two methods:

a) Calculate the weighted average using the following equations:

$$W_{ave} = \frac{x_1}{CUO_{x_1}} + \frac{x_2}{CUO_{x_2}} + \frac{x_3}{CUO_{x_3}} + \ldots + \frac{x_a}{CUO_{x_a}}$$

where:

W_{ave}= Weighted Average

x_1 through x_a = Concentration of each individual contaminant at the location of concern. Note that, depending on the target organ/mode of action, the actual number of contaminants will range from 2 to 14.

$CUOx_a$ = A Tier 2 remediation objective must be developed

for each x_a.

If the value of the weighted average calculated in accordance with the equations above is less than or equal to 1.0, then the remediation objectives are met for those chemicals.

If the value of the weighted average calculated in accordance with the equations above is greater than 1.0, then additional remediation must be carried out until the level of contaminants remaining in the remediated area has a weighted average calculated in accordance with the equation above less than or equal to one.

b) Divide each individual chemical's remediation objective by the number of chemicals in that specific target organ group that were detected at the site. Each of the contaminant concentrations at the site is then compared to the remediation objectives that have been adjusted to account for this potential additivity. For the noncarcinogenic contaminants listed in Appendix A, Table E, a respective soil remediation objective need be no lower than the respective value listed in Appendix B, Table A or B.

SUBPART H: TIER 2 GROUNDWATER EVALUATION

Section 742.800 Tier 2 Groundwater Evaluation Overview

If the contaminant concentrations in the groundwater exceed the applicable Tier 1 remediation objectives, a person has the following options:

a) Demonstrate that the groundwater ingestion exposure route is excluded from consideration pursuant to Subpart C;

b) Demonstrate that the groundwater contamination is at or below area background concentrations in accordance with Subpart D and, if necessary, an institutional control restricting usage of the groundwater is in place in accordance with Subpart J;

c) Remediate to Tier 1 remediation objectives;

d) Propose and obtain approval of Tier 2 groundwater remediation objectives in accordance with Section 742.805 and remediate to that level, if necessary;

e) Conduct a Tier 3 evaluation in accordance with Subpart I; or

f) Obtain approval from the Board to:

1) Reclassify the groundwater pursuant to 35 Ill. Adm. Code 620.260; or

2) Use an adjusted standard pursuant to Section 28.1 of the Act. [415 ILCS 5/28.1].

Section 742.805 Tier 2 Groundwater Remediation Objectives

a) To develop a groundwater remediation objective under this Section that exceeds the applicable Tier 1 groundwater remediation objective, or for which there is no Tier I groundwater remediation objective, a person may request approval from the Agency if the person has performed the following:

1) Identified the horizontal and vertical extent of groundwater for which the Tier 2 groundwater remediation objective is sought;

2) Taken corrective action, to the maximum extent practicable to remove any free product;

3) Using Equation R26 in accordance with Section 742.810, demonstrated that the concentration of any contaminant of concern in groundwater will meet:

A) The applicable Tier 1 groundwater remediation objective at the point of human exposure; or

B) For any contaminant of concern for which there is no Tier 1 groundwater remediation objective, the concentration determined according to the procedures specified in 35 Ill. Adm. Code 620 at the point of human exposure. A person may request the Agency to provide these concentrations or may propose these concentrations under Subpart I;

4) Using Equation R26 in accordance with Section 742.810, demonstrated that the concentration of any contaminant of concern in groundwater within the minimum or designated maximum setback zone of an existing potable water supply well will meet the applicable Tier 1 groundwater remediation objective or, if there is no Tier 1 groundwater remediation objective, the concentration determined according to the procedures specified in 35 Ill. Adm. Code 620. A person may request the Agency to provide these concentrations or may propose these concentrations under Subpart I;

5) Using Equation R26 in accordance with Section 742.810, demonstrated that the concentration of any contaminant of concern in groundwater discharging into a surface water will meet the applicable water quality standard under 35 Ill. Adm. Code 302;

6) Demonstrated that the source of the release is not located within the minimum or designated maximum setback zone or within a regulated recharge area of an existing potable water supply well; and

7) If the selected corrective action includes an engineered barrier as set forth in Subpart K to minimize migration of contaminants of concern from the soil to the groundwater, demonstrated that the engineered barrier will remain in place for post-remediation land use through an institutional control as set forth in Subpart J.

b) A groundwater remediation objective that exceeds the water solubility of that chemical (refer to Appendix C, Table E for solubility values) is not allowed.

c) The contaminants of concern for which a Tier 1 remediation objective has been developed shall be included in any mixture of similar-acting chemicals under consideration in Tier 2. The evaluation of 35 Ill. Adm. Code 620.615 regarding mixtures of similar-acting chemicals shall be considered satisfied for Class I groundwater at the point of human exposure if either of the following requirements are achieved:

1) Calculate the weighted average using the following equations:

$$W_{ave} = \frac{x_1}{CUOx_1} + \frac{x_2}{CUOx_2} + \frac{x_3}{CUOx_3} + \ldots + \frac{x_a}{CUOx_a}$$

where:

W_{ave} = Weighted Average

x_1 through x_a = Concentration of each individual contaminant at the location of concern. Note that, depending on the target organ, the actual number of contaminants will range from 2 to 33.

$CUOx_a$ = A Tier 1 or Tier 2 remediation objective must be developed for each x_a.

A) If the value of the weighted average calculated in accordance with the equations above is less than or equal to 1.0, then the remediation objectives are met for those chemicals.

B) If the value of the weighted average calculated in accordance with the equations above is greater than 1.0, then additional remediation must be carried out until the level of contaminants remaining in the remediated area has a weighted average calculated in accordance with the equation above less than or equal to one; or

2) Divide each individual chemical's remediation objective by the number of chemicals in that specific target organ group that were detected at the site. Each of the contaminant concentrations at the site is then compared to the remediation objectives that have been adjusted to account for this potential additivity.

d) The evaluation of 35 Ill. Adm. Code 620.615 regarding mixtures of similar-acting chemicals is considered satisfied if the cumulative risk from any contaminants of concern listed in Appendix A, Table I, plus any other contaminants of concern detected in groundwater and listed in Appendix A, Table F as affecting the same target organ/organ system as the contaminants of concern detected from Appendix A, Table I, does not exceed 1 in 10,000.

e) Groundwater remediation objectives for the indoor inhalation exposure route shall be developed in accordance with Section 742.812. For the indoor inhalation exposure route:

1) Appendix C, Table L applies only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls; and

2) Institutional controls under Subpart J are required to develop groundwater remediation objectives pursuant to Appendix C, Table L.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.810 RBCA Calculations to Predict Impacts from Remaining Groundwater Contamination

a) Equation R26 predicts the contaminant concentration along the centerline of a groundwater plume emanating from a vertical planar source in the aquifer (dimensions S_w wide and S_d deep). This model accounts for both three-dimensional dispersion (x is the direction of groundwater flow, y is the other horizontal direction, and z is the vertical direction) and biodegradation.

1) The parameters in this equation are:

$X =$ distance from the planar source to the location of concern, along the centerline of the groundwater plume (i.e., y=0, z=0)

$C_x =$ the concentration of the contaminant at a distance X from the source, along the centerline of the plume

C_{source} = the greatest potential concentration of the contaminant of concern in the groundwater at the source of the contamination, based on the concentrations of contaminants in groundwater due to the release and the projected concentration of the contaminant migrating from the soil to the groundwater. As indicated above, the model assumes a planar source discharging groundwater at a concentration equal to C_{source}.

α_x = dispersivity in the x direction (i.e., Equation R16)

α_y = dispersivity in the y direction (i.e., Equation R17)

α_z = dispersivity in the z direction (i.e., Equation R18)

U = specific discharge (i.e., actual groundwater flow velocity through a porous medium; takes into account the fact that the groundwater actually flows only through the pores of the subsurface materials) where the aquifer hydraulic conductivity (K), the hydraulic gradient (I) and the total soil porosity θ_T must be known (i.e., Equation R19)

λ= first order degradation constant obtained from Appendix C, Table E or from measured groundwater data

S_w = width of planar groundwater source in the y direction

S_d = depth of planar groundwater source in the z direction

2) The following parameters are determined through field measurements: U, K, I, θ_T, S_w, S_d.

A) The determination of values for U, K, I and θ_T can be obtained through the appropriate laboratory and field techniques;

B) From the immediate down-gradient edge of the source of the groundwater contamination values for S_w and S_d shall be determined. S_w is defined as the width of groundwater at the source which exceeds the Tier 1 groundwater remediation objective. S_d is defined as the depth of groundwater at the source which exceeds the Tier 1 groundwater remediation objective; and

C) Total soil porosity can also be calculated using Equation R23.

b) Once values are obtained for all the input parameters identified in subsection (a) of this Section, the contaminant concentration C_x along the centerline of the plume at a distance X from the source shall be calculated so that X is the distance from the down-gradient edge of the source of the contamination at the site to the point where the contaminant concentration is equal to the Tier 1 groundwater remediation objective or concentration determined according to the procedures specified in 35 Ill. Adm. Code 620, Subpart F.

1) If there are any potable water supply wells located within the calculated distance X, then the Tier 1 groundwater remediation objective or concentration shall be met at the edge of the minimum or designated maximum setback zone of the nearest potable water supply down-gradient of the source. To demonstrate that a minimum or maximum setback zone of a potable water supply well will not be impacted above the applicable Tier 1 groundwater remediation objective or concentration determined according to the procedures specified in 35 Ill. Adm. Code 620, Subpart F, X shall be the distance from the C_{source} location to the edge of the setback zone.

2) To demonstrate that no surface water is adversely impacted, X shall be the distance from the down-gradient edge of the source of the contamination site to the nearest surface water body. This calculation must show that the contaminant in the groundwater at this location (C_x) does not exceed the applicable water quality standard.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.812 J&E Groundwater Equations for the Indoor Inhalation Exposure Route

Groundwater remediation objectives for the indoor inhalation exposure route are calculated using the modified J&E model as described in Section 742.717, except as follows:

a) In Equation J&E9a, the total number of layers of soil that contaminants migrate through from the source to the building shall include a capillary fringe layer.

b) The thickness of the capillary fringe layer is 37.5 cm.

c) The volumetric water content of the capillary fringe shall be 90 % of the total porosity of the soil that comprises the capillary fringe.

d) Equations J&E7 and J&E8 calculate an acceptable groundwater remediation objective.

1) This calculation is made using:

A) the soil gas remediation objective calculated in accordance with Equation J&E4; and

B) the assumption that this gas is in equilibrium with any contamination in the groundwater.

2) Equation J&E7 must be used when the mode of contaminant transport is both diffusion and advection. In this scenario, the Q_{soil} value equals 83.33 cm^3/sec as described in Section 742.505.

3) Equation J&E8 may be used only when the mode of contaminant transport is diffusion only. In this scenario, the Q_{soil} value equals 0.0 cm^3/sec as described in Section 742.505. As an alternative to using Equation J&E8 pursuant to this subsection, it is permissible to use Equation J&E7, in which case the Q_{soil} value equals 83.33 cm^3/sec as described in Section 742.505.

e) A groundwater remediation objective that exceeds the water solubility of that chemical (refer to Appendix C, Table E for solubility values) is not allowed. If the calculated groundwater remediation objective is greater than the water solubility of that chemical, then the solubility is used as the groundwater remediation objective.

(Source: Added at 37 Ill. Reg. 7506, effective July 15, 2013)

SUBPART I: TIER 3 EVALUATION

Section 742.900 Tier 3 Evaluation Overview

a) Tier 3 sets forth a flexible framework to develop remediation objectives outside of the requirements of Tiers 1 and 2. Although Tier 1 and Tier 2 evaluations are not prerequisites to conduct Tier 3 evaluations, data from Tier 1 and Tier 2 can assist in developing remediation objectives under a Tier 3 evaluation.

b) The level of detail required to adequately characterize a site depends on the particular use of Tier 3. Tier 3 can require additional investigative efforts beyond those described in Tier 2 to characterize the physical setting of the site. However, in situations where remedial efforts have simply reached a physical obstruction additional investigation may not be necessary for a Tier 3 submittal.

c) Situations that can be considered for a Tier 3 evaluation include, but are not limited to:

1) Modification of parameters not allowed under Tier 2;

2) Use of models different from those used in Tier 2;

3) Use of additional site data, such as results of indoor air sampling, to improve or confirm predictions of exposed receptors to contaminants of concern;

4) Analysis of site-specific risks using formal risk assessment, probabilistic data analysis, and sophisticated fate and transport models (e.g., requesting a target hazard quotient greater than 1 or a target cancer risk greater than 1 in 1,000,000);

5) Requests for site-specific remediation objectives because an assessment indicates further remediation is not practical;

6) Incomplete human exposure pathways not excluded under Subpart C;

7) Use of toxicological-specific information not available from the sources listed in Tier 2;

8) Land uses which are substantially different from the assumed residential or industrial/commercial property uses of a site (e.g., a site will be used for recreation in the future and cannot be evaluated in Tier 1 or 2);

9) Requests for site-specific remediation objectives that exceed Tier 1 groundwater remediation objectives so long as the following is demonstrated:

A) *To the extent practical, the exceedance of the groundwater quality standard has been minimized and beneficial use appropriate to the groundwater that was impacted has been returned; and*

B) *Any threat to human health or the environment has been minimized* [415 ILCS 5/58.5(d)(4)(A)]; and

10) Use of building control technologies, other than those described in Subpart L, to prevent completion of the indoor inhalation exposure route.

d) For requests of a target cancer risk ranging between 1 in 1,000,000 and 1 in 10,000 at the point of human exposure or a target hazard quotient greater than 1 at the point of human exposure, the requirements of Section 742.915 shall be followed. Requests for a target cancer risk exceeding 1 in 10,000 at the point of human exposure are not allowed.

e) Requests for approval of a Tier 3 evaluation must be submitted to the Agency for review under the specific program under which remediation is performed. When reviewing a submittal under Tier 3, the Agency shall consider *whether the interpretations and conclusions reached are supported by the information gathered* [415 ILCS 58.7(e)(1)]. The Agency shall approve a Tier 3 evaluation if

the person submits the information required under this Part and establishes through such information that public health is protected and that specified risks to human health and the environment have been minimized.

f) If contaminants of concern include polychlorinated biphenyls (PCBs), requests for approval of a Tier 3 evaluation must additionally address the applicability of 40 CFR 761.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.905 Modifications of Parameters

Any proposed changes to Tier 2 parameters which are not provided for in Tier 2 shall be submitted to the Agency for review and approval. A submittal under this Section shall include the following information:

a) The justification for the modification; and

b) The technical and mathematical basis for the modification.

Section 742.910 Alternative Models

Any proposals for the use of models other than those specified in Tier 2 shall be submitted to the Agency for review and approval. A submittal under this Section shall include the following information:

a) Physical and chemical properties of contaminants of concern;

b) Contaminant movement properties;

c) Contaminant availability to receptors;

d) Receptor exposure to the contaminants of concern;

e) Mathematical and technical justification for the model proposed;

f) A licensed copy of the model, if the Agency does not have a licensed copy of the model currently available for use; and

g) Demonstration that the models were correctly applied.

Section 742.915 Formal Risk Assessments

A comprehensive site-specific risk assessment shall demonstrate that contaminants of concern at a site do not pose a significant risk to any human receptor. All site-specific risk assessments shall be submitted to the Agency for review and approval. A submittal under this Section shall address the following factors:

a) Whether the risk assessment procedure used is nationally recognized and accepted including, but not limited to, those procedures incorporated by reference in Section 742.210;

b) Whether the site-specific data reflect actual site conditions;

c) The adequacy of the investigation of present and post-remediation exposure routes and risks to receptors identified at the site;

d) The appropriateness of the sampling and analysis;

e) The adequacy and appropriateness of toxicity information;

f) The extent of contamination;

g) Whether the calculations were accurately performed;

h) Similar-acting chemicals shall be specifically addressed. At a minimum, the chemicals subject to this requirement are identified in Appendix A, Tables E and F; and

i) Proposals seeking to modify the target risk consistent with Section 742.900(d) shall address the following factors:

1) the presence of sensitive populations;

2) the number of receptors potentially impacted;

3) the duration of risk at the differing target levels; and

4) the characteristic of the chemicals of concern.

SOURCE: Amended at 21 Ill. Reg. 16391, effective December 8, 1997.

Section 742.920 Impractical Remediation

Any request for site-specific remediation objectives due to impracticality of remediation shall be submitted to the Agency for review and approval. Any request for site-specific remediation objectives due to impracticality of remediation that involves the indoor inhalation exposure route

shall follow Section 742.935 in lieu of this Section. A submittal under this Section shall include the following information:

a) The reasons why the remediation is impractical;

b) The current extent and modeled migration of contamination;

c) Geology, including soil types and parameters;

d) The potential impact to groundwater;

e) Results and locations of sampling events;

f) Map of the area, including all utilities and structures; and

g) Present and post-remediation uses of the area of contamination, including human receptors at risk.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.925 Exposure Routes

Technical information may demonstrate that there is no actual or potential impact of contaminants of concern to receptors from a particular exposure route. In these instances, a demonstration excluding an exposure route shall be submitted to the Agency for review and approval. A demonstration that involves the indoor inhalation exposure route shall follow Section 742.935 in lieu of this Section. A submittal under this Section shall include the following information:

a) A description of the route evaluated;

b) A description of the site and physical site characteristics;

c) A discussion of the result and possibility of the route becoming active in the future; and

d) Technical support that may include, but is not limited to, the following:

1) a discussion of the natural or man-made barriers to that exposure route;

2) calculations and modeling;

3) physical and chemical properties of contaminants of concern; and

4) contaminant migration properties.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.930 Derivation of Toxicological Data

If toxicological-specific information is not available for one or more contaminants of concern from the sources incorporated by reference in Section 742.210, the derivations of toxicological-specific information shall be submitted for Agency review and approval.

Section 742.935 Indoor Inhalation Exposure Route

a) Exclusion of Exposure Route

Site information may demonstrate that there is no actual or potential impact of contaminants of concern to receptors from the indoor inhalation exposure route. In these instances, a demonstration excluding the exposure route shall be submitted to the Agency for review and approval. A submittal under this Section shall include the following information:

1) A description of the site, physical site characteristics, existing and planned buildings, and existing and planned man-made pathways; and

2) A discussion of the possibility of the route becoming active in the future.

b) Exclusion of Exposure Route Using Building Control Technologies

Any proposals to use building control technologies as a means to prevent or mitigate human exposures under the indoor inhalation exposure route that differ from the requirements of Subpart L shall be submitted to the Agency for review and approval. A submittal under this Section shall include the following information:

1) A description of the site and physical site characteristics;

2) The current extent and modeled migration of contamination;

3) Geology, including soil types and parameters;

4) Results and locations of sampling events;

5) Scaled map of the area, including all buildings and man-made pathways;

6) A description of building characteristics and methods of construction, including a description of man-made pathways;

7) Present and post-remediation uses of the land that are at issue due to the area of contamination, including human receptors at risk;

8) A description of any building control technologies currently in place or proposed for installation that can reduce or eliminate the potential for completion of the exposure route, including design and construction specifications;

9) Information regarding the effectiveness of any building control technologies currently in place or proposed for installation and a schedule for performance testing to show the effectiveness of the control technology. For buildings not yet constructed, an approved building control technology shall be in place and operational prior to human occupancy;

10) Identification of documents reviewed and the criteria used in the documents for determining whether building control technologies are effective and how those criteria compare to existing or potential buildings or man-made pathways at the site; and

11) A description as to how the effectiveness of the building control technologies will be operated and maintained for the life of the buildings and man-made pathways, or until soil gas and groundwater contaminant concentrations have reached remediation objectives that are approved by the Agency. This includes provisions for potential extended system inoperability due to power failure or other disruption.

c) Calculations and Modeling Used to Establish Soil Gas Remediation Objectives

The calculations and modeling shall account for contaminant transport through the mechanisms of diffusion and advection. Proposals to use soil gas data, including sub-slab samples, to establish remediation objectives for the indoor inhalation exposure route that differ from the requirements of Section 742.227 shall be submitted to the Agency for review and approval. A submittal under this Section shall include the following information:

1) Scaled map of the area, showing all buildings and man-made pathways (current and planned);

2) The current extent and modeled migration of contamination;

3) Geology, including soil types and parameters;

4) Depth to groundwater (including seasonal variation) and flow direction;

5) Location of soil gas sampling points;

6) A discussion of soil gas sampling procedures that, at a minimum, addresses the following:

A) sampling equipment;

B) soil gas collection protocol, including field tests and weather conditions; and

C) laboratory analytical methods.

d) Calculations and Modeling Used to Establish Soil Remediation Objectives

The calculations and modeling shall account for contaminant transport through the mechanisms of diffusion and advection. Any proposals to use soil data in lieu of soil gas data to establish remediation objectives for the indoor inhalation exposure route shall be submitted to the Agency for review and approval. A submittal under this Section shall include the following information:

1) Scaled map of the area, showing all buildings and man-made pathways (current and planned);

2) The current extent and modeled migration of contamination;

3) Geology, including soil types and parameters;

4) Location of soil sampling points;

5) A discussion of soil sampling procedures that, at a minimum, addresses the following:

A) sampling equipment;

B) soil collection protocol, including field tests and weather conditions; and

C) laboratory analytical methods;

6) Mathematical and technical justification for the model proposed; and

7) Demonstration that the model was correctly applied.

e) Calculations and Modeling Used to Establish Groundwater Remediation Objectives

The calculations and modeling shall account for contaminant transport through the mechanisms of diffusion and advection. Proposals to use groundwater data to establish remediation objectives for the indoor inhalation exposure route that differ from the requirements of Sections 742.805 and 742.812 shall be submitted to the Agency for review and approval. A submittal under this Section shall include the following information:

1) Scaled map of the area, showing all buildings and man-made pathways (current and planned);

2) The current extent and modeled migration of contamination;

3) Geology, including soil types and parameters and the thickness of the capillary fringe;

4) Depth to groundwater (including seasonal variation) and flow direction;

5) Results and locations of groundwater sampling events;

6) Mathematical and technical justification for the model proposed; and

7) Demonstration that the model was correctly applied.

(Source: Added at 37 Ill. Reg. 7506, effective July 15, 2013)

SUBPART J: INSTITUTIONAL CONTROLS

Section 742.1000 Institutional Controls

a) Institutional controls in accordance with this Subpart must be placed on the property when remediation objectives are based on any of the following assumptions:

1) Industrial/Commercial property use;

2) Target cancer risk greater than 1 in 1,000,000;

3) Target hazard quotient greater than 1;

4) Engineered barriers;

5) The point of human exposure is located at a place other than at the source;

6) Exclusion of exposure routes;

7) A diffusion only mode of contaminant transport for the indoor inhalation exposure route;

8) Use of an indoor inhalation building control technology;

9) For the indoor inhalation exposure route, the presence of a building with a full concrete slab-on-grade or a full concrete basement floor and walls; or

10) Any combination of the above.

b) The Agency shall not approve any remediation objective under this Part that is based on the use of institutional controls unless the person has proposed institutional controls meeting the requirements of this Subpart and the requirements of the specific program under which the institutional control is proposed. A proposal for approval of institutional controls shall provide identification of the selected institutional controls from among the types recognized in this Subpart.

c) The following instruments may be institutional controls subject to the requirements of this Subpart J and the requirements of the specific program under which the institutional control is proposed:

1) No Further Remediation Letters;

2) Environmental Land Use Controls;

3) Land Use Control Memoranda of Agreement;

4) Ordinances adopted and administered by a unit of local government;

5) Agreements between a property owner (or, in the case of a petroleum leaking underground storage tank, the owner or operator of the tank) and a highway authority with respect to any contamination remaining under highways; and

6) Agreements between a highway authority that is also the property owner (or, in the case of a petroleum leaking underground storage tank, the owner or operator of the tank) and the Agency with respect to any contamination remaining under the highways.

d) No Further Remediation Letters and Environmental Land Use Controls that meet the requirements of this Subpart and the recording requirements of the program under which remediation is being performed are transferred with the property.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.1005 No Further Remediation Letters

a) A No Further Remediation Letter issued by the Agency under 35 Ill. Adm. Code 732 or 740 may be used as an institutional control under this Part if the requirements of subsection (b) of this Section are met.

b) A request for approval of a No Further Remediation Letter as an institutional control shall meet the requirements applicable to the specific program under which the remediation is performed.

(Source: Amended at 25 Ill. Reg. 10374, effective August 15, 2001)

Section 742.1010 Environmental Land Use Controls

a) An Environmental Land Use Control (ELUC) is an institutional control that may be used under this Part to impose land use limitations or requirements related to environmental contamination. ELUCs are only effective when approved by the Agency in accordance with this Part. Activities or uses that may be limited or required include, but are not limited to, prohibition of use of groundwater for potable purposes, restriction to industrial/commercial uses, operation or maintenance of engineered barriers, indoor inhalation building control technologies, or worker safety plans. ELUCs may be used in the following circumstances:

1) When No Further Remediation Letters are not available, including but not limited to when contamination has migrated off-site or outside the remediation site; or

2) When No Further Remediation Letters are not issued under the program for which a person is undergoing remediation.

b) Recording requirements:

1) An ELUC approved by the Agency pursuant to this Section must be recorded in the Office of the Recorder or Registrar of Titles for the county in which the property that is the subject of the ELUC is located. A copy of the ELUC demonstrating that it has been recorded must be submitted to the Agency before the Agency will issue a no further remediation determination.

2) An ELUC approved under this Section will not become effective until officially recorded in the chain of title for the property that is the subject of the ELUC in accordance with subsection (b)(1) of this Section.

3) Reference to the recorded ELUC must be made in the instrument memorializing the Agency's no further remediation determination. Recording of the no further remediation determination and confirmation of

recording must be in accordance with the requirements of the program under which the determination was issued.

4) The requirements of this Section do not apply to Federally Owned Property for which the Federal Landholding Entity does not have the authority under federal law to record land use limitations on the chain of title.

5) The requirements of this Section apply only to those sites for which a request for a no further remediation determination has not yet been made to the Agency by January 6, 2001.

c) Duration:

1) Except as provided in this subsection (c), an ELUC shall remain in effect in perpetuity.

2) *At no time shall any site for which an ELUC has been imposed as a result of remediation activities under this Part be used in a manner inconsistent with the land use limitation unless attainment of objectives appropriate for the new land use is achieved and a new* no further remediation determination has been *obtained and recorded in accordance with* the program under which the ELUC was first imposed or the Site Remediation Program (35 Ill. Adm. Code 740) [415 ILCS 58.8(c)]. In addition, the appropriate release or modification of the ELUC must be prepared by the Agency and filed on the chain of title for the property that is the subject of the ELUC.

A) For a Leaking Underground Storage Tank (LUST) site under 35 Ill. Adm. Code 731 or 734 or a Site Remediation Program site under 35 Ill. Adm. Code 740, an ELUC may be released or modified only if the NFR Letter is also modified under the Site Remediation Program to reflect the change;

B) For a RCRA site under 35 Ill. Adm. Code 721-730, an ELUC may be released or modified only if there is also an amended certification of closure or a permit modification.

3) In addition to any other remedies that may be available, a failure to comply with the limitations or requirements of an ELUC may result in voidance of an Agency no further remediation determination in accordance with the program under which the determination was made. The failure to comply with the limitations or requirements of an ELUC may also be grounds for an enforcement action pursuant to Title VIII of the Act.

d) An ELUC submitted to the Agency must match the form and contain the same substance, except for variable elements (e.g., name of property owner), as the model in Appendix F and must contain the following elements:

1) Name of property owners and declaration of property ownership;

2) Identification of the property to which the ELUC applies by common address, legal description, and Real Estate Tax Index/Parcel Index Number;

3) A reference to the Bureau of Land LPC numbers or 10-digit identification numbers under which the remediation was conducted;

4) A statement of the reason for the land use limitation or requirement relative to protecting human health and the surrounding environment from soil, groundwater, and/or other environmental contamination;

5) The language instituting such land use limitations or requirements;

6) A statement that the limitations or requirements apply to the current owners, occupants, and all heirs, successors, assigns, and lessees;

7) A statement that the limitations or requirements apply in perpetuity or until:

A) The Agency determines that there is no longer a need for the ELUC;

B) The Agency, upon written request, issues to the site that received the no further remediation determination that relies on the ELUC a new no further remediation determination approving modification or removal of the limitations or requirements;

C) The new no further remediation determination is filed on the chain of title of the site subject to the no further remediation determination; and

D) A release or modification of the land use limitation is filed on the chain of title for the property that is the subject of the ELUC;

8) Scaled site maps showing:

A) The legal boundary of the property to which the ELUC applies;

B) The horizontal and vertical extent of contaminants of concern above applicable remediation objectives for soil, groundwater, and soil gas to which the ELUC applies;

C) Any physical features to which an ELUC applies (e.g., engineered barriers, monitoring wells, caps, indoor inhalation building control technologies); and

D) The nature, location of the source, and direction of movement of the contaminants of concern;

9) A statement that any information regarding the remediation performed on the property for which the ELUC is necessary may be obtained from the Agency through a request under the Freedom of Information Act [5 ILCS 140] and rules promulgated thereunder; and

10) The dated, notarized signatures of the property owners or authorized agent.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.1012 Federally Owned Property: Land Use Control Memoranda of Agreement

a) A Land Use Control Memorandum of Agreement (LUC MOA) between one or more agencies of the federal government and the Illinois Environmental Protection Agency is the institutional control that shall be used under this Part to impose land use limitations or restrictions related to environmental contamination on Federally Owned Property. A LUC MOA may be used only for Federally Owned Property. Each LUC MOA, at a minimum, must require that the Federal Landholding Entities responsible for the Federally Owned Property do the following:

1) Provide adequate identification of the location on the Federally Owned Property of each site with land use limitations or requirements. Such identification shall be by means of common address, notations in any available facility master land use plan, site specific GIS or GPS coordinates, plat maps, or any other means which identifies the site in question with particularity;

2) Implement periodic site inspection procedures to ensure adequate oversight by the Federal Landholding Entities of such land use limitation or requirement;

3) Implement procedures for the Federal Landholding Entities to periodically advise the Agency of continued compliance with the maintenance of the land use control and site inspection requirements included in the LUC MOA;

4) Implement procedures for the Federal Landholding Entities to notify the Agency of any planned or emergency changes in land use that may adversely impact any site with land use limitations or requirements; and

5) Notify the Agency at least 60 days in advance of a conveyance by deed or fee simple title, by the Federal Landholding Entities, of a site with land use limitations or requirements, to any entity that will not remain or become a Federal Landholding Entity, and provide the Agency with information about how the Federal Landholding Entities will ensure that the requirements of Section 742.1010 are to be satisfied upon conveyance of that site.

a) Any LUC MOA entered into pursuant to this Section remains effective only so long as title to the affected property is retained by the United States.

(Source: Amended at 31 Ill. Reg. 4063, effective February 23, 2007)

Section 742.1015 Ordinances

a) An ordinance adopted by a unit of local government that effectively prohibits the installation of potable water supply wells (and the use of such wells) may be used as an institutional control to meet the requirements of Section 742.320(d) or 742.805(a)(3) if the requirements of this Section are met. A model ordinance is found in Appendix G. Ordinances prohibiting the installation of potable water supply wells (and the use of such wells) that do not expressly prohibit the installation of potable water supply wells (and the use of such wells) by units of local government may be acceptable as institutional controls if the requirements of this Section are met and a Memorandum of Understanding (MOU) is entered into under subsection (i) of this Section. For purposes of this Section, a unit of local government is considered to be expressly prohibited from installing and using potable water supply wells only if the unit of local government is included in the prohibition provision by name. The prohibition required by this Section shall satisfy the following requirements at a minimum:

1) The prohibition shall not allow exceptions for potable water well installation and use other than for the adopting unit of local government;

2) The prohibition shall apply at all depths and shall not be limited to particular aquifers or other geologic formations;

3) If the prohibition does not apply everywhere within the boundaries of the unit of local government, the limited area to which the prohibition applies shall be easily identifiable and clearly defined by the ordinance (e.g., narrative descriptions accompanied by maps with legends or labels showing prohibition boundaries, or narrative descriptions using fixed, common reference points such as street names). Boundaries of prohibitions limited by area shall be fixed by the terms of the ordinance and shall not be subject to change without amending the ordinance in which the prohibition has been adopted (e.g., no boundaries defined with reference to zoning districts or the availability of the public water supply); and

4) The prohibition shall not in any way restrict or limit the Agency's approval of the use of the ordinance as an institutional control pursuant to this Part (e.g., no restrictions based on remediation program participation, no restrictions on persons performing remediation within the prohibition area who may use the ordinance).

b) A request for approval of a local ordinance as an institutional control shall provide the following:

1) A copy of the ordinance restricting groundwater use certified by an official of the unit of local government in which the site is located that it is a true and accurate copy of the ordinance, unless the Agency and the unit of local government have entered an agreement under subsection (i) of this Section, in which case the request may alternatively reference the MOU. The ordinance must demonstrate that potable use of groundwater from potable water supply wells is prohibited;

2) A scaled map or maps delineating the area and extent of groundwater contamination modeled above the applicable remediation objectives including any measured data showing concentrations of contaminants of concern in which the applicable remediation objectives are exceeded;

3) A scaled map delineating the boundaries of all properties under which groundwater is located that exceeds the applicable groundwater remediation objectives;

4) Information identifying the current owners of each property identified in subsection (b)(3); and

5) A copy of the proposed written notification to the unit of local government that adopted the ordinance and to the current owners identified in subsection (b)(4) that includes the following information:

A) The name and address of the unit of local government that adopted the ordinance;

B) The ordinance's citation;

C) A description of the property being sent notice by adequate legal description, reference to a plat showing the boundaries of the property, or accurate street address;

D) Identification of the party requesting to use the groundwater ordinance as an institutional control, and a statement that the party

has requested approval from the Agency to use the ordinance as an institutional control;

E) A statement that use of the ordinance as an institutional control allows contamination above groundwater ingestion remediation objectives to remain in groundwater beneath the affected properties, and that the ordinance strictly prohibits human and domestic consumption of the groundwater;

F) A statement as to the nature of the release and response action with the site name, site address, and Agency site number or Illinois inventory identification number; and

G) A statement that more information about the remediation site may be obtained by contacting the party requesting the use of the groundwater ordinance as an institutional control or by submitting a FOIA request to the Agency.

c) Written notification proposed pursuant to subsection (b)(5) must be sent to the unit of local government that adopted the ordinance, as well as to all current property owners identified in subsection (b)(4). Written proof that the notification was sent to the unit of local government and the property owners shall be submitted to the Agency within 45 days from the date the Agency's no further remediation determination is recorded. Such proof may consist of the return card from certified mail, return receipt requested, a notarized certificate of service, or a notarized affidavit.

d) Unless the Agency and the unit of local government have entered into a MOU under subsection (i), the current owner or successors in interest of a site who have received approval of use of an ordinance as an institutional control under this Section shall:

1) Monitor activities of the unit of local government relative to variance requests or changes in the ordinance relative to the use of potable groundwater at properties identified in subsection (b)(3); and

2) Notify the Agency of any approved variance requests or ordinance changes within 30 days after the date such action has been approved.

e) The information required in subsections (b)(1) through (b)(5) and the Agency letter approving the groundwater remediation objective shall be submitted to the unit of local government. Proof that the information has been filed with the unit of local government shall be provided to the Agency.

f) Any ordinance or MOU used as an institutional control pursuant to this Section shall be recorded in the Office of the Recorder or Registrar of Titles of the county

in which the site is located together with the instrument memorializing the Agency's no further remediation determination pursuant to the specific program within 45 days after receipt of the Agency's no further remediation determination.

g) An institutional control approved under this Section shall not become effective until officially recorded in accordance with subsection (f). The person receiving the approval shall obtain and submit to the Agency within 30 days after recording a copy of the institutional control demonstrating that it has been recorded.

h) The following shall be grounds for voidance of the ordinance as an institutional control and the instrument memorializing the Agency's no further remediation determination:

1) Modification of the ordinance by the unit of local government to allow potable use of groundwater;

2) Approval of a site-specific request, such as a variance, to allow potable use of groundwater at a site identified in subsection (b)(3);

3) Violation of the terms of an institutional control recorded under Section 742.1005 or Section 742.1010; or

4) Failure to provide notification and proof of such notification pursuant to subsection (c).

i) The Agency and a unit of local government may enter into a MOU under this Section if the unit of local government has adopted an ordinance satisfying subsection (a) and if the requirements of this subsection are met. The MOU submitted to the Agency must match the form and contain the same substance as the model in Appendix H and shall include the following:

1) Identification of the authority of the unit of local government to enter the MOU;

2) Identification of the legal boundaries, or equivalent, under which the ordinance is applicable;

3) A certified copy of the ordinance;

4) A commitment by the unit of local government to notify the Agency of any variance requests or proposed ordinance changes at least 30 days prior to the date the local government is scheduled to take action on the request or proposed change;

5) A commitment by the unit of local government to maintain a registry of all sites within the unit of local government that have received no further remediation determinations pursuant to specific programs; and

6) If the ordinance does not expressly prohibit the installation of potable water supply wells (and the use of such wells) by units of local government, a commitment by the unit of local government:

A) To review the registry of sites established under subsection (i)(5) prior to siting potable water supply wells within the area covered by the ordinance;

B) To determine whether the potential source of potable water may be or has been affected by contamination left in place at those sites; and

C) To take whatever steps are necessary to ensure that the potential source of potable water is protected from the contamination or treated before it is used as a potable water supply.

j) A groundwater ordinance may not be used to exclude the indoor inhalation exposure route.

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.1020 Highway Authority Agreements and Highway Authority Agreement Memoranda of Agreement

a) An agreement with a highway authority may be used as an institutional control where the requirements of this Section are met and the Agency has determined that no further remediation is required as to the property(ies) to which the agreement is to apply. Highway Authority Agreements submitted to the Agency, except for those agreements with the Illinois Department of Transportation, must match the form and contain the same substance, except for variable elements, as the model in Appendix D.

b) As part of the agreement the highway authority shall agree to:

1) Prohibit the use of groundwater under the highway right of way that is contaminated above residential Tier 1 remediation objectives from the release as a potable supply of water; and

2) Limit access to soil contamination under the highway right of way that is contaminated above residential Tier 1 or construction worker remediation objectives, whichever is less, from the release. Access to soil contamination may be allowed if, during and after any access, public health and the environment are protected.

c) The agreement shall provide the following:

1) Fully executed signature blocks by the highway authority and the owner of the property (or, in the case of a petroleum leaking underground storage tank, the owner or operator of the tank) from which the release occurred;

2) A scaled map delineating the area and extent of soil and groundwater contamination above the applicable Tier 1 remediation objectives or a statement that either soil or groundwater is not contaminated above the applicable Tier 1 residential remediation objectives;

3) Information showing the concentration of contaminants of concern within the zone in which the applicable Tier 1 remediation objectives are exceeded;

4) A stipulation of the information required by subsections (c)(2) and (3) of this Section in the agreement if it is not practical to obtain the information by sampling the highway right-of-way; and

5) Information identifying the highway authority having jurisdiction.

d) Highway Authority Agreements must be referenced in the instrument that is to be recorded on the chain of title for the remediation property.

e) Violation of the terms of an Agreement approved by the Agency as an institutional control under this Section shall be grounds for voidance of the Agreement as an institutional control and the instrument memorializing the Agency's no further remediation determination.

f) Failure to provide all of the information required in subsections (b) and (c) of this Section will be grounds for denial of the Highway Authority Agreement as an institutional control.

g) In instances in which the highway authority is also the property owner of the site, a Highway Authority Agreement may not be used. In such cases, the highway authority shall instead enter into a Highway Authority Agreement Memorandum of Agreement (HAA MOA) between the highway authority and the Agency. An HAA MOA may be used as an institutional control where the requirements of this Section are met and the Agency has determined that no further remediation is required as to the property(ies) to which the agreement is to apply. HAA MOAs submitted to the Agency must match the form and contain the same substance, except for variable elements, as the model in Appendix E.

h) As part of the HAA MOA the highway authority shall agree to:

1) Prohibit the use of groundwater under the highway right of way that is contaminated above residential Tier 1 or construction worker remediation objectives, whichever are less, from the release as a potable supply of water; and

2) Limit access to soil contamination under the highway right of way that is contaminated above residential Tier 1 or construction worker remediation objectives, whichever are less, from the release. Access to soil

contamination may be allowed if, during and after any access, public health and the environment are protected.

i) The HAA MOA shall provide the following:

1) Information identifying the site by common address or legal description or both;

2) The Illinois Emergency Management Agency's (IEMA) incident number for the site, if one has been assigned;

3) A scaled map delineating the current and estimated future area and extent of soil and groundwater contamination above the applicable Tier 1 or construction worker remediation objectives, whichever are less, or a statement that either soil or groundwater is not contaminated above the applicable Tier 1 residential remediation objectives;

4) Information prepared by the highway authority that lists each contaminant of concern that exceeds its Tier 1 residential or construction worker remediation objective, its Tier 1 residential remediation objective, and its concentrations within the zone where Tier 1 residential or construction worker remediation objectives, whichever is less, are exceeded;

5) A scaled map prepared by the highway authority showing the area of the highway authority's right of way that is governed by the HAA MOA;

6) If samples have not been collected within the right of way because of impracticability, a stipulation by the parties that, based on modeling, soil and groundwater contamination exceeding Tier 1 residential or construction worker remediation objectives, whichever is less, does not and will not extend beyond the boundaries of the right-of-way;

7) A stipulation by the highway authority that it has jurisdiction over the right of way that gives it sole control over the use of the groundwater and access to the soil located within or beneath the right of way;

8) A stipulation by the highway authority that it agrees to limit access by itself and others to soil within the right of way exceeding Tier 1 residential or construction worker remediation objectives, whichever is less. Access may only be allowed if human health (including worker safety) and the environment are protected during and after any access. The highway authority may construct, reconstruct, improve, repair, maintain, and operate a highway upon the right of way, or allow others to do the same by permit. The highway authority and others using or working in the right of way under permit have the right to remove soil or groundwater from the right of way and dispose of the same in accordance with applicable environmental laws and regulations. The highway authority agrees to issue all permits for work in the right of way, and make all existing permits for work in the right of way, subject to the following or substantially similar conditions:

A) As a condition of this permit the permittee shall request the office issuing this permit to identify sites in the right of way where a HAA MOA governs access to soil that exceeds the Tier 1 residential remediation objectives of 35 Ill. Adm. Code 742; and

B) The permittee shall take all measures necessary to protect human health (including worker safety) and the environment during and after any access to such soil;

9) A stipulation that the HAA MOA shall be referenced in the Agency's no further remediation determination issued for the release(s);

10) A stipulation that the highway authority shall notify the Agency of any transfer of jurisdiction over the right of way at least 30 days prior to the date the transfer takes effect. The HAA MOA shall be null and void upon the transfer unless the transferee agrees to be bound by the agreement as if the transferee were an original party to the agreement. The transferee's agreement to be bound by the terms of the agreement shall be memorialized at the time of transfer as a rider to this agreement that references the HAA MOA and is signed by the highway authority, or subsequent transferor, and the transferee;

11) A stipulation that the HAA MOA will become effective on the date the Agency issues a no further remediation determination for the release(s). It shall remain effective until the right of way is demonstrated to be suitable for unrestricted use and the Agency issues a new no further remediation determination to reflect there is no longer a need for the HAA MOA, or until the agreement is otherwise terminated or voided;

12) A stipulation that in addition to any other remedies that may be available, the Agency may bring suit to enforce the terms of the HAA MOA or may, at its sole discretion, declare the HAA MOA null and void if the highway authority or a transferee violates any term of the HAA MOA. The highway authority or transferee shall be notified in writing of any such declaration; and

13) A fully executed signature block by the highway authority and a block for the Agency's Director.

(Source: Amended at 31 Ill. Reg. 4063, effective February 23, 2007)

SUBPART K: ENGINEERED BARRIERS

Section 742.1100 Engineered Barriers

a) Any person who develops remediation objectives under this Part based on engineered barriers shall meet the requirements of this Subpart and the requirements of Subpart J relative to institutional controls.

b) The Agency shall not approve any remediation objective under this Part that is based on the use of engineered barriers unless the person has proposed engineered barriers meeting the requirements of this Subpart.

c) The use of engineered barriers can be recognized in calculating remediation objectives only if the engineered barriers are intended for use as part of the final corrective action.

d) Any no further remediation determination based upon the use of engineered barriers shall require effective maintenance of the engineered barrier. The maintenance requirements shall be included in an institutional control under Subpart J. This institutional control shall address provisions for temporary breaches of the barrier by requiring the following if intrusive construction work is to be performed in which the engineered barrier is to be temporarily breached:

1) The construction workers shall be notified by the site owner/operator in advance of intrusive activities. Such notification shall enumerate the contaminant of concern known to be present; and

2) The site owner/operator shall require construction workers to implement protective measures consistent with good industrial hygiene practice.

e) Failure to maintain an engineered barrier in accordance with that no further remediation determination shall be grounds for voidance of the determination and the instrument memorializing the Agency's no further remediation determination.

Section 742.1105 Engineered Barrier Requirements

a) Natural attenuation, access controls, and point of use treatment shall not be considered engineered barriers. Engineered barriers may not be used to prevent direct human exposure to groundwater without the use of institutional controls.

b) For purposes of determining remediation objectives under Tier 1, engineered barriers are not recognized.

c) The following engineered barriers are recognized for purposes of calculating remediation objectives that exceed residential remediation objectives:

1) For the soil component of the groundwater ingestion exposure route, the following engineered barriers are recognized if they prevent completion of the exposure pathway:

A) Caps or walls constructed of compacted clay, asphalt, concrete or other material approved by the Agency; and

B) Permanent structures such as buildings and highways.

2) For the soil ingestion exposure route, the following engineered barriers are recognized if they prevent completion of the exposure pathway:

A) Caps or walls constructed of compacted clay, asphalt, concrete, or other material approved by the Agency;

B) Permanent structures such as buildings and highways; and

C) Soil, sand, gravel, or other geologic materials that:

i) Cover the contaminated media;

ii) Meet the soil remediation objectives under Subpart E for residential property for contaminants of concern; and

iii) Are a minimum of three feet in depth.

3) For the outdoor inhalation exposure route, the following engineered barriers are recognized if they prevent completion of the exposure pathway:

A) Caps or walls constructed of compacted clay, asphalt, concrete, or other material approved by the Agency;

B) Permanent structures such as buildings and highways; and

C) Soil, sand, gravel, or other geologic materials that:

i) Cover the contaminated media;

ii) Meet the soil remediation objectives under Subpart E for residential property for contaminants of concern; and

iii) Are a minimum of ten feet in depth and not within ten feet of any manmade pathway.

4) For the ingestion of groundwater exposure route, the following engineered barriers are recognized if they prevent completion of the exposure pathway:

A) Slurry walls; and

B) Hydraulic control of groundwater.

d) Unless otherwise prohibited under Section 742.1100, any other type of engineered barrier may be proposed if it will be as effective as the options listed in subsection (c).

(Source: Amended at 37 Ill. Reg. 7506, effective July 15, 2013)

SUBPART L: BUILDING CONTROL TECHNOLOGIES

Section 742.1200 Building Control Technologies

a) Any person who develops remediation objectives under this Part based on building control technologies shall meet the requirements of this Subpart and the requirements of Subpart J relative to institutional controls.

b) The Agency shall not approve any remediation objective under this Part that is based on the use of building control technologies unless the person has proposed building control technologies meeting the requirements of the following:

1) This Subpart L or Subpart I; and

2) Subpart J relative to institutional controls.

c) The use of building control technologies can be recognized in determining remediation objectives only if the building control technologies are intended for use as part of the final corrective action.

d) An approved building control technology shall be in place and operational prior to human occupancy.

e) Any no further remediation determination based upon the use of building control technologies shall require effective maintenance of the building control technology. The maintenance requirements shall be included in an institutional control under Subpart J. This institutional control shall address provisions for inoperability by requiring the following if the building control technology is rendered inoperable:

1) The site owner/operator shall notify building occupants and workers in advance of intrusive activities. The notification shall enumerate the contaminant of concern known to be present;

2) The site owner/operator shall require building occupants and workers to implement protective measures consistent with good industrial hygiene practice; and

3) For a school, the school administrator shall notify the Agency, the school board, and every parent or legal guardian for all enrolled students when a building control technology is rendered inoperable for a period of five consecutive calendar days during the school year when school is in session. For purposes of the preceding sentence, any occurrence of inoperability, regardless of its duration, results in the date of the occurrence constituting a day of inoperability. For purposes of this subsection (e)(3), the term "school" means any public educational facility in Illinois, including grounds and/or campus, consisting of students, comprising one or more grade groups or other identifiable groups, organized as one unit with one or more teachers to give instruction of a defined type. Public educational facility includes, but is not limited to, primary and secondary (kindergarten-12th grade), charter, vocational, alternative, and special education schools. Public educational facility does not include junior colleges, colleges, or universities. For purposes of this subsection (e)(3), the term "school administrator" means the school's principal, or similar administrator responsible for the school's operations, or his or her designee.

f) Failure to install or maintain a building control technology in accordance with a no further remediation determination shall be grounds for voidance of the determination and the instrument memorializing the Agency's no further remediation determination.

(Source: Added at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.1205 Building Control Technology Proposals

A proposal to use a building control technology under this Subpart shall include the following information:

a) A description of the site and physical site characteristics;

b) The current extent and modeled migration of contamination;

c) Geology, including soil types and parameters;

d) Results and locations of sampling events;

e) Scaled map of the area, including all buildings and man-made pathways;

f) A description of building characteristics and methods of construction, including a description of man-made pathways; and

g) Present and post-remediation uses of the land that are at issue due to the area of contamination, including human receptors at risk.

(Source: Added at 37 Ill. Reg. 7506, effective July 15, 2013)

Section 742.1210 Building Control Technology Requirements

a) Natural attenuation, access controls, and point of use treatment shall not be considered building control technologies.

b) For purposes of determining compliance with remediation objectives under Tier 1, building control technologies are not recognized.

c) The following building control technologies are recognized for purposes of pathway exclusion under Section 742.312.

1) Sub-slab depressurization (SSD) systems meeting the following requirements:

A) A suction pit is installed that is at least two cubic feet and extends at least 6 inches below the slab (larger suction pits may be excavated as needed to achieve the performance criteria in subsection (c)(1)(B));

B) A PVC pipe of at least 3 inches in diameter extends from the suction pit to the intake side of an in-line fan capable of achieving a static vacuum of at least 0.25 inches water column (wc) at the suction point and measureable vacuum at the farthest edges of the area served by the suction pit under worst case conditions (all exhaust fans and heating systems running, during cold weather) as determined by a differential pressure reading of at least -0.003 inches wc below the slab or visible downward flow of air at test holes using chemical or smoke sticks;

C) All visible cracks and joints in the slab (including the place where the pipe exits the slab) and foundation walls are sealed;

D) The pipe exhausts outside the building at least 10 feet above ground and at least 10 feet from any door or window; and

E) Additional suction pits meeting the requirements of subsection (c)(1)(A) shall be installed as necessary to achieve measureable vacuum below the slab in all areas, including in any area where subsurface or foundation conditions (e.g., a sub-slab grade beam) prevent adequate suction field extension.

2) Sub-membrane depressurization (SMD) systems meeting the following requirements:

A) A non-woven geotextile is installed on the exposed earthen material;

B) A cross-laminated polyethylene membrane liner at least 0.10 mm (or 4 mil) thick is placed over the geotextile and sealed to foundation walls using a low volatile adhesive that is recommended by the liner manufacturer (e.g., acrylic latex adhesive);

C) A 3 inch diameter PVC pipe extends from a hole cut in the liner to the intake side of an in-line fan capable of achieving a static vacuum of at least 0.25 inches water column (wc) at the riser pipe and measureable vacuum at the farthest edges of the liner under worst case conditions (all exhaust fans running during cold weather) as determined by a differential pressure reading of at least -0.003 inches wc below the liner or visible downward flow of air in test holes using chemical or smoke sticks;

D) The pipe is sealed to the liner;

E) The pipe exhausts outside the building at least 10 feet above ground and at least 10 feet from any door or window; and

F) No leaks based on smoke stick tests along the entire perimeter of the liner (i.e., at all sealed edges) with the fan running. Where leaks are identified, appropriate repairs are undertaken and smoke stick testing repeated until no leaks are detected.

3) Membrane barrier systems when placed below concrete slabs meeting the following requirements:

A) The membrane is impermeable to volatile chemicals and is not less than 1.5 mm (or 60 mil) thick;

B) The membrane is sealed to foundation walls and any penetrating pipes according to membrane manufacturer/installer recommendations;

C) The membrane is installed in accordance with the manufacturer's requirements and by an applicator trained and approved by the manufacturer;

D) A smoke test of the membrane system (where smoke is injected below the installed liner prior to slab installation), in accordance with the manufacturer's requirements, is performed to ensure no leaks exist. Where leaks are identified, appropriate repairs are undertaken and smoke testing repeated until no leaks are detected;

E) The membrane is puncture resistant to slab installation construction activities and protected by sand layers or geotextiles as recommended by the manufacturer; and

F) Construction activities following membrane installation do not damage, puncture or tear the membrane or otherwise compromise its ability to prevent the migration of volatile chemicals.

4) Vented raised floors meeting the following requirements:

A) An interconnected void system below the slab sufficient to allow free movement of air and communication of negative pressures to all points below the slab;

B) Sealing of all construction joints, open cracks, and penetrations through the slab (e.g., for utilities and riser pipes) with a low volatile caulk; and

C) At least one 3 inch diameter riser pipe venting to the atmosphere above the roof line (at least 10 feet from any doors or windows) for each 5000 square feet of membrane area, with the capability of converting passively vented floor systems to actively vented or SSD systems meeting the performance requirements of subsection (c)(1).

Section 742.APPENDIX A General

Section 742.TABLE E Similar-Acting Noncarcinogenic Chemicals

Adrenal Gland
Isopropylbenzene

Cholinesterase Inhibition
Aldicarb
Carbofuran

Circulatory System
Alachlor
Antimony (ingestion only)
Benzene
Cobalt (ingestion only)
2,4-D
cis-1,2-Dichloroethylene (ingestion only)
2,4-Dimethylphenol
2,4-Dinitrotoluene
2,6-Dinitrotoluene
Ensosulfan
Fluoranthene
Fluorene
Methylene Chloride (inhalation only)
Nickel (Res. & I/C only) (inhalation only)
Nitrate as N
Nitrobenzene (ingestion only)
Selenium
Simazine
Styrene (ingestion only)
1,3,5-Trinitrobenzene
Zinc

Decreased Body Weight Gain
Atrazine
Bis(2-chloroethyl)ether
Cyanide
1,2-Dichlorobenzene (inhalation only)
Diethyl phthalate (ingestion only)
Ensosulfan
2-Methylphenol (o-cresol)
Naphthalene (ingestion only)
Nickel (ingestion only)
n-Nitrosodiphenylamine
Phenol (ingestion only)
Simazine
Tetrachloroethylene (ingestion only)

1,1,1-Trichloroethane (ingestion only)
Vinyl acetate (ingestion only)
Xylenes (Res. & I/C only) (ingestion only)

Endocrine System
Cyanide
1,2-Dibromoethane (ingestion only)
Di-n-octyl phthalate (ingestion only)
Nitrobenzene
1,2,4-Trichlorobenzene (ingestion only)

Eye
2,4-Dinitrophenol
n-Nitrosodiphenylamine
Polychlorinated biphenyls (PCBs)
Trichloroethylene

Gastrointestinal System
Beryllium (ingestion only)
Copper
1,3-Dichloropropene (*cis* + *trans*) (ingestion only)
Endothall
Fluoride
Hexachlorocyclopentadiene (ingestion only)
Iron
Methyl bromide (ingestion only)
Methyl tertiary-butyl ether (ingestion only)

Immune System
4-Chloroaniline
2,4-Dichlorophenol
Mercury (ingestion only)
Polychlorinated biphenyls (PCBs)

Kidney
Acetone (ingestion only)
Aldrin (CW only)
Barium
Bromodichloromethane (ingestion only)
Cadmium
2,4-D
Dalapon
1,1-Dichloroethane
1,2-Dichloroethane (CW only) (ingestion only)
Ensosulfan
Ethylbenzene (ingestion only)
Fluoranthene

gamma-HCH (gamma-BHC)
Hexachloroethane (ingestion only)
Isopropylbenzene
Mecoprop (MCPP)
Methyl tertiary-butyl ether (inhalation only)
Pentachlorophenol
Pyrene
Toluene (ingestion only)
2,4,5-Trichlorophenol
Vinyl acetate (ingestion only)

Liver
Acenapthene
Aldrin (Res. & I/C only)
Bis(2-ethylhexyl)phthalate (Res. & I/C only) (ingestion only)
Bromoform
Butyl Benzyl Phtalate (ingestion only)
Carbon Tetrachloride
Chlordane
Chlorobenzene (ingestion only)
Chlorodibromomethane (ingestion only)
Chloroform
2,4-D
DDT
1,2-Dibromoethane (ingestion only)
1,2-Dichlorobenezene (CW only) (ingestion only)
1,4-Dichlorobenzene
Dichlorodifluoromethane
1,2-Dichloroethane (inhalation only)
1,1-Dichloroethylene
trans-1,2-Dichloroethylene
1,2-Dichloropropane (ingestion only)
Dieldrin (Res. & I/C only)
2,4-Dinitrotoluene
2,6-Dinitrotoluene
Di-n-octyl phthalate (ingestion only)
p-Dioxane
Endrin
Ethylbenzene (ingestion only)
Fluoranthene
Heptachlor
Heptachlor epoxide
Hexachlorobenzene
alpha-HCH (alpha-BHC
gamma-HCH (gamma-BHC)
High Melting Explosive, Octogen (HMX)
Isophorone (inhalation only)

Methyl tertiary-butyl ether
Methylene Chloride (ingestion only)
Pentachlorophenol
Phenol (inhalation only)
Picloram
Styrene (ingestion only)
Tetrachloroethylene (ingestion only)
Toxaphene (CW only)
2,4,5-TP (Silvex)
1,2,4-Trichlorobenzene (inhalation only)
1,1,1-Trichloroethane (inhalation only)
1,1,2-Trichloroethane (ingestion only)
2,4,5-Trichlorophenol
2,4,6-Trinitrotoluene (TNT)
Vinyl Chloride

Mortality
Di-n-butyl phthalate (ingestion only)
Xylenes (Res. & I/C only) (ingestion only)

Nervous System
Butanol (ingestion only)
Carbon disulfide (inhalation only)
Cyanide
Dieldrin (CW only)
2,4-Dimethylphenol
2,4-Dinitrotoluene
2,6-Dinitrotoluene
Endrin
Hexachloroethane (inhalation only) (CW only)
Manganese
Mercury (inhalation only)
2-Methylphenol (o-cresol)
Phenol (inhalation only)
Selenium
Styrene (inhalation only)
Tetrachloroethylene (inhalation only)
Toluene (inhalation only)
Trichloroethylene
Xylenes (CW only) (ingestion only)
Xylenes (inhalation only)

Reproductive System
Arsenic (inhalation only)
Bis(2-ethylhexyl)phthalate (CW only) (ingestion only)
Boron
2-Butanone

Carbofuran
Carbon disulfide (ingestion only)
2-Chlorophenol
1,2-Dibromo-3-chloropropane
1,2-Dibromoethane (ingestion only)
Dicamba
Dinoseb
Ethylbenzene (inhalation only)
Isophorone (inhalation only)
Methoxychlor
Royal Demolition Explosive , Cyclonite (RDX)
2,4,6-Trichlorophenol

Respiratory System
Antimony (inhalation only)
Benzoic Acid (inhalation only)
Berryllium (inhalation only)
Cadmium (inhalation only)
Chromium (hex) (inhalation only)
Cobalt (inhalation only)
1,2-Dibromoethane (inhalation only)
trans-1,2-Dichloroethylene (inhalation only)
1,2-Dichloropropane (inhalation only)
1,3-Dichloropropene (*cis* + *trans*) (inhalation only)
Hexachlorocyclopentadiene (inhalation only)
Methyl bromide (inhalation only)
Naphtalene (inhalation only)
Nickel (inhalation only)
Nitrobenezene (inhalation only)
Vinyl acetate (inhalation only)

Skin
Arsenic (ingestion only)
Polychlorinated biphenyls (PCBs)
Selenium
Silver

Spleen
1,3-Dinotrobenzene
1,3,5-Trinitrobenzene

[a] Chicago means within the corporate limits of the City of Chicago.

[b] Metropolitan area means a populated area, as defined in Section 742.200, (other than the City of Chicago) that is located within any county in a Metropolitan Statistical Area listed in Appendix A, Table G, footnote a.

[c] Non-Metropolitan area means a populated area, as defined in Section 742.200, that is not located within any county in a Metropolitan Statistical Area listed in Appendix A, Table G, footnote a.

"*" indicates that the ADL is less than or equal to the specified remediation objective.
NA means not available; no PQL or EQL available in USEPA analytical methods.

Chemical Name and Soil Remediation Objective Notations

[a] Soil remediation objectives based on human health criteria only.
[b] Calculated values correspond to a target hazard quotient of 1.
[c] No toxicity criteria available for the route of exposure.
[d] Soil saturation concentration ($C_{[sat]}$) = the concentration at which the absorptive limits of the soil particles, the solubility limits of the available soil moisture, and saturation of soil pore air have been reached. Above the soil saturation concentration, the assumptions regarding vapor transport to air and/or dissolved phase transport to groundwater (for chemicals which are liquid at ambient soil temperatures) have been violated, and alternative modeling approaches are required.
[e] Calculated values correspond to a cancer risk level of 1 in 1,000,000.
[g] Chemical-specific properties are such that this route is not of concern at any soil contaminant concentration.
[h] 40 CFR 761 contains applicability requirements and methodologies for the development of PCB remediation objectives. Requests for approval of a Tier 3 evaluation must address the applicability of 40 CFR 761.
[l] Soil remediation objective for pH of 6.8. If soil pH is other than 6.8, refer to Appendix B, Tables C and D of this Part.
[j] Ingestion soil remediation objective adjusted by a factor of 0.5 to account for dermal route.
[k] A preliminary remediation goal of 400 mg/kg has been set for lead based on *Revised Interim Soil Lead Guidance for CERCLA Sites and RCRA Corrective Action Facilities*, OSWER Directive #9355.4-12.
[l] Potential for soil-plant-human exposure.
[m] The person conducting the remediation has the option to use: 1) TCLP or SPLP test results to compare with the remediation objectives listed in this Table; 2) where applicable, the total amount of contaminant in the soil sample results to compare with pH specific remediation objectives listed in Appendix B, Table C or D of this Part (see Section 742.510); or 3) the appropriate background value listed in Appendix A, Table G. If the person conducting the remediation wishes to calculate soil remediation objectives based on background concentrations, this should be done in accordance with Subpart D of this Part.
[n] The Agency reserves the right to evaluate the potential for remaining contaminant concentrations to pose significant threats to crops, livestock, or wildlife.
[o] For agrichemical facilities, remediation objectives for surficial soils which are based on field application rates may be more appropriate for currently registered pesticides. Consult the Agency for further information.
[p] For agrichemical facilities, soil remediation objectives based on site-specific background concentrations of Nitrate as N may be more appropriate. Such determinations shall be conducted in accordance with the procedures set forth in Subparts D and I of this Part.
[q] The TCLP extraction must be done using water at a pH of 7.0.
[r] Value based on dietary Reference Dose.

[s] Value for Ingestion based on Reference Dose for Mercuric chloride (CAS No. 7487-94-7); value for Inhalation based on Reference Concentration for elemental Mercury (CAS No. 7439-97-6). Inhalation remediation objective only applies at sites where elemental mercury is a contaminant of concern.

[t] For the ingestion route for arsenic, see 742.Appendix A, Table G.

[u] Value based on Reference Dose for Thallium sulfate (CAS No. 7446-18-6).

[v] Value based on Reference Dose adjusted for dietary intake.

[w] For sites located in any populated area as defined in Section 742.200, Appendix A, Table H may be used.

[x] The remediation objectives for these chemicals must also include the construction worker inhalation objective in Appendix B, Table B.

"*" indicates that the ADL is less than or equal to the specified remediation objective.

NA means Not Available; no PQL or EQL available in USEPA analytical methods.

Chemical Name and Soil Remediation Objective Notations (2nd, 5th thru 8th Columns)

[a] oil remediation objectives based on human health criteria only.
[b] Calculated values correspond to a target hazard quotient of 1.
[c] No toxicity criteria available for this route of exposure.

[d] Soil saturation concentration ($C_{[sat]}$) = the concentration at which the absorptive limits of the soil particles, the solubility limits of the available soil moisture, and saturation of soil pore air have been reached. Above the soil saturation concentration, the assumptions regarding vapor transport to air and/or dissolved phase transport to groundwater (for chemicals which are liquid at ambient soil temperatures) have been violated, and alternative modeling approaches are required.

[e] Calculated values correspond to a cancer risk level of 1 in 1,000,000.

[g] Chemical-specific properties are such that this route is not of concern at any soil contaminant concentration.

[h] 40 CFR 761 contains applicability requirements and methodologies for the development of PCB remediation objectives. Requests for approval of a Tier 3 evaluation must address the applicability of 40 CFR 761.

[i] Soil remediation objective for pH of 6.8. If soil pH is other than 6.8, refer to Appendix B, Tables C and D in this Part.

[j] Ingestion soil remediation objective adjusted by a factor of 0.5 to account for dermal route.

[l] Potential for soil-plant-human exposure.

[m] The person conducting the remediation has the option to use: (1) TCLP or SPLP test results to compare with the remediation objectives listed in this Table; (2) the total amount of contaminant in the soil sample results to compare with pH specific remediation objectives listed in Appendix B, Table C or D of this Part (see Section 742.510); or (3) the appropriate background value listed in Appendix A, Table G. If the person conducting the remediation wishes to calculate soil remediation objectives based on background concentrations, this should be done in accordance with Subpart D of this Part.

[n] The Agency reserves the right to evaluate the potential for remaining contaminant concentrations to pose significant threats to crops, livestock, or wildlife.

[o] For agrichemical facilities, remediation objectives for surficial soils which are based on field application rates may be more appropriate for currently registered pesticides. Consult the Agency for further information.

[p] For agrichemical facilities, soil remediation objectives based on site-specific background concentrations of Nitrate as N may be more appropriate. Such determinations shall be conducted in accordance with the procedures set forth in Subparts D and I of this Part.

[q] The TCLP extraction must be done using water at a pH of 7.0.

[r] Value based on dietary Reference Dose.

[s] Value for Ingestion based on Reference Dose for Mercuric chloride (CAS No. 7487-94-7); value for Inhalation based on Reference Concentration for elemental Mercury (CAS No. 7439-97-6). Inhalation remediation objective only applies at sites where elemental mercury is a contaminant of concern.

[t] For the ingestion route for arsenic for industrial/commercial, see 742.Appendix A, Table G.

[u] Value based on Reference Dose for Thallium sulfate (CAS No. 7446-18-6).

[w] Value based on Reference Dose adjusted for dietary intake.

[x] For any populated areas as defined in Section 742.200, Appendix A, Table H may be used.

[y] Value based on maintaining fetal blood lead below 10 ug/d1, using the USEPA adults Blood Lead Model.

Chemical Name and Groundwater Remediation Objective Notations

[a] The groundwater remediation objective is equal to the ADL for carcinogens according to the procedures specified in 35 Ill. Adm. Code 620.

[b] Oral Reference Dose and/or Reference Concentration under review by USEPA. Listed values subject to change.

[c] Value listed is also the Groundwater Quality Standard for this chemical pursuant to 35 Ill. Adm. Code 620.410 for Class I Groundwater or 35 Ill. Adm. Code 620.420 for Class II Groundwater.

[d] This chemical is included in the Total Dissolved Solids (TDS) Groundwater Quality Standard of 1,200 mg/l pursuant to 35 Ill. Adm. Code 620.410 for Class I Groundwater or 35 Ill. Adm. Code 620.420 for Class II Groundwater.

(Source: Amended at 31 Ill. Reg. 4063, effective February 23, 2007)

Chemical Name and Groundwater Remediation Objective Notations

[a] The Equation S17 is used to calculate the Soil Remediation Objective for the Soil Component of the Groundwater Ingestion Route; this equation requires calculation of the Target Soil Leachate Concentration (C_w) from Equation S18: $C_w = DF \times GW_{obj}$.

[b] Value listed is the Water Health Based Limit (HBL) for this chemical from Soil Screening Guidance: User's Guide, incorporated by reference at Section 742.210. The HBL is equal to the non-zero MCLG (if available); the MCL (if available); or, for carcinogens, a cancer risk of 1.0E-6, and for noncarcinogens is equal to a Hazard Quotient of 1.0. NOTE: These GW_{obj} concentrations are not equal to the Tier 1 Groundwater Remediation Objectives for the Direct Ingestion of Groundwater Component of the Groundwater Ingestion Route, listed in Section 742.Appendix B, Table E.

[c] Value listed is also the Groundwater Quality Standard for this chemical pursuant to 35 Ill. Adm. Code 620.410 for Class I Groundwater or 35 Ill. Adm. Code 620.420 for Class II Groundwater.

Chemical Name and Remediation Objective Notations

[a] For the outdoor inhalation exposure route, it is acceptable to determine compliance by meeting either the soil or soil gas remediation objectives. The soil remediation objectives for the outdoor inhalation route are located in Appendix B, Tables A and B.

[b] Calculated values correspond to a target hazard quotient of 1.

[c] Calculated values correspond to a cancer risk level of 1 in 1,000,000.

[d] PCBs are a mixture of different congeners. The appropriate values to use for the physical/chemical and toxicity parameters depend on the congeners present at the site. Persons remediating sites should consult with IEPA Bureau of Land (BOL) if calculation of Tier 2 or 3 remediation objectives is desired.

[e] The value shown is the C_v^{sat} value of the chemical in soil gas. The C_v^{sat} of the chemical becomes the remediation objective if the calculated value exceeds the C_v^{sat} value or if there are no toxicity criteria available for the inhalation route of exposure.

[f] Value for the inhalation exposure route is based on Reference Concentration for elemental Mercury (CAS No. 7439-97-6). Inhalation remediation objectives only apply at sites where elemental Mercury is a contaminant of concern.

Chemical Name and Remediation Objective Notations

[a] Compliance is determined by meeting either the soil gas remediation objectives or the groundwater remediation objectives. See Sections 742.505 and 742.515.

[b] Calculated values correspond to a target hazard quotient of 1.

[c] Calculated values correspond to a cancer risk level of 1 in 1,000,000.

[d] PCBs are a mixture of different congeners. The appropriate values to use for the physical/chemical and toxicity parameters depend on the congeners present at the site. Persons remediating sites should consult with BOL if calculation of Tier 2 or 3 remediation objectives is desired.

[e] Groundwater remediation objective calculated at 25°C. For Dalapon and 1,2-Dibromo-3-chloropropane, the critical temperature (T_c) and enthalpy of vaporization at the normal boiling point ($H_{v,b}$) are not available. For Xylenes (total), the enthalpy of vaporization at the normal boiling point ($H_{v,b}$) is not available.

[f] The value shown is the C_v^{sat} value of the chemical in soil gas. The C_v^{sat} of the chemical becomes the remediation objective if the calculated value exceeds the C_v^{sat} value or if there are no toxicity criteria available for the inhalation route of exposure.

[g] The value shown is the solubility of the chemical in water. The solubility of the chemical becomes the remediation objective if the calculated value exceeds the solubility or if there are no toxicity criteria available for the ingestion route of exposure.

[h] Value for the inhalation exposure route is based on Reference Concentration for elemental Mercury (CAS No. 7439-97-6). Inhalation remediation objectives only apply at sites where elemental Mercury is a contaminant of concern.

[i] The value shown is the Groundwater Remediation Objective listed in Appendix B, Table E.

[j] Calculated values for the remediation objectives in this table are based on the assumption that the existing or potential building has a full concrete slab-on-grade, though the remediation objectives in this table are also considered protective of occupants of buildings with full concrete basement floors and walls. This table applies only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls. Institutional controls under Subpart J are required to use remediation objectives in this table. This table does not apply when the existing or potential building has neither a full concrete slab-on-grade nor a full concrete basement floor and walls, such as a building with an earthen crawl space, an earthen floor, a stone foundation, a partial concrete floor, or a sump. In such cases, site evaluators have the option of excluding the indoor inhalation exposure route under Section 742.312, meeting the building control technology requirements under Subpart L, or proposing an alternative approach under Tier 3.

Chemical Name and Remediation Objective Notations

[a] Compliance is determined by meeting both the soil gas remediation objectives and the groundwater remediation objectives. See Sections 742.505 and 742.515.

[b] Remediation objectives relying on this table require use of institutional controls in accordance with Subpart J.

[c] Calculated values correspond to a target hazard quotient of 1.

[d] Calculated values correspond to a cancer risk level of 1 in 1,000,000.

[e] PCBs are a mixture of different congeners. The appropriate values to use for the physical/chemical and toxicity parameters depend on the congeners present at the site. Persons remediating sites should consult with BOL if calculation of Tier 2 or 3 remediation objectives is desired

[f] Groundwater remediation objective calculated at 25°C. For Dalapon and 1,2-Dibromo-3-chloropropane, the critical temperature (T_c) and enthalpy of vaporization at the normal boiling point ($H_{v,b}$) are not available. For Xylenes (total), the enthalpy of vaporization at the normal boiling point ($H_{v,b}$) is not available.

[g] The value shown is the C_v^{sat} value of the chemical in soil gas. The C_v^{sat} of the chemical becomes the remediation objective if the calculated value exceeds the C_v^{sat} value or if there are no toxicity criteria available for the inhalation route of exposure.

[h] The value shown is the solubility of the chemical in water. The solubility of the chemical becomes the remediation objective if the calculated value exceeds the solubility or if there are no toxicity criteria available for the inhalation route of exposure.

[i] Value for the inhalation exposure route is based on Reference Concentration for elemental Mercury (CAS No. 7439-97-6). Inhalation remediation objectives only apply at sites where elemental Mercury is a contaminant of concern.

[j] Calculated values for the remediation objectives in this table are based on the assumption that the existing or potential building has a full concrete slab-on-grade, though the remediation objectives in this table are also considered protective of occupants of buildings with full concrete basement floors and walls. This table applies only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls. Institutional controls under Subpart J are required to use remediation objectives in this table. This table does not apply when the existing or potential building has neither a full concrete slab-on-grade nor a full concrete basement floor and walls, such as a building with an earthen crawl space, an earthen floor, a stone foundation, a partial concrete floor, or a sump. In such cases, site evaluators have the option of excluding the indoor inhalation exposure route under Section 742.312, meeting the building control technology requirements under Subpart L, or proposing an alternative approach under Tier 3.

Section 742.APPENDIX C Tier 2 Illustrations and Tables

Section 742.Table C RBCA Equations

Equations for the combined exposures routes of soil ingestion inhalation of vapors and particulates, and dermal contact with soil	Remediation Objectives for Carcinogenic Contaminants (mg/kg)	$$\frac{TR \bullet BW \bullet AT_C \bullet 365\frac{d}{yr}}{EF \bullet ED \bullet \left\{\left[SF_o \bullet 10^{-6}\frac{kg}{mg} \bullet \left(\left(IR_{soil} \bullet RAF_o\right)+\left(SA \bullet M \bullet RAF_d\right)\right)\right]+\left[SF_i \bullet IR_{air} \bullet \left(VF_{ss}+VF_p\right)\right]\right\}}$$	**R1**
	Remediation Objectives for Non-carcinogenic Contaminants (mg/kg)	$$\frac{THQ \bullet BW \bullet AT_n \bullet 365\frac{d}{yr}}{EF \bullet ED \bullet \left[\frac{10^{-6}\frac{kg}{mg}\left[\left(IR_{soil} \bullet RAF_o\right)+\left(SA \bullet M \bullet RAF_d\right)\right]}{RfD_o}+\frac{IR_{air} \bullet \left(VF_{ss}+VF_p\right)}{RfD_i}\right]}$$	**R2**
	Volatilization Factor for Surficial Soils, VF_{ss} (kg/m^3) Whichever is less between R3 and R4	$$VF_{ss}=\frac{2 \bullet W \bullet \rho_s \bullet 10^3\frac{cm^3 \cdot kg}{m^3 \cdot g}}{U_{air} \bullet \delta_{air}} \bullet \sqrt{\frac{D_s^{eff} \bullet H'}{\pi \bullet \left[\theta_{ws}+\left(k_s \bullet \rho_s\right)+\left(H' \bullet \theta_{as}\right)\right] \bullet \tau}}$$	**R3**
		$$VF_{ss}=\frac{W \bullet \rho_s \bullet d \bullet 10^3\frac{cm^3 \cdot kg}{m^3 \cdot g}}{U_{air} \bullet \delta_{air} \bullet \tau}$$	**R4**

	Volatilization Factor for Surficial Soils Regarding Particulates, VF_p (kg/m^3)	$$VF_p = \frac{P_e \bullet W \bullet 10^3 \frac{cm^3 \cdot kg}{m^3 \cdot g}}{U_{air} \bullet \delta_{air}}$$	**R5**
	Effective Diffusion Coefficient in Soil Based on Vapor-Phase Concentration D_s^{eff} (cm^2/s)	$$D_s^{eff} = \frac{D^{air} \bullet \theta_{as}^{3.33}}{\theta_T^2} + \frac{D^{water} \bullet \theta_{ws}^{3.33}}{H' \bullet \theta_T^2}$$	**R6**
Equations for the ambient vapor inhalation (outdoor) route fromsubsurface soils	Remediation Objectives for Carcinogenic Contaminants (mg/kg)	$$\frac{RBSL_{air} \bullet 10^{-3}}{VF_{samb}}$$	**R7**
	Remediation Objectives for Non-carcinogenic Contaminants (mg/kg)	$$\frac{RBSL_{air} \bullet 10^{-3}}{VF_{samb}}$$	**R8**

	Carcinogenic Risk-Based Screening Level for Air, $RBSL_{air}$ (ug/m^3)	$$RBSL_{air} = \frac{TR \bullet BW \bullet AT_c \bullet 365 \frac{d}{yr} \bullet 10^3 \frac{ug}{mg}}{SF_i \bullet IR_{air} \bullet EF \bullet ED}$$	**R9**
	Noncarcinogenic Risk-Based Screening Level for Air, $RBSL_{air}$ (ug/m^3)	$$RBSL_{air} = \frac{THQ \bullet RfD_i \bullet BW \bullet AT_n \bullet 365 \frac{d}{yr} \bullet 10^3 \frac{ug}{mg}}{IR_{air} \bullet EF \bullet ED}$$	**R10**
	Volatilization Factor - Subsurface Soil to Ambient Air, VF_{samb} $(mg/m^3)/(mg/kg_{soil})$	$$VF_{samb} = \frac{H' \bullet \rho_s \bullet 10^3 \frac{cm^3 \cdot kg}{m^3 \cdot g}}{\left[\theta_{ws} + \left(k_s \bullet \rho_s\right) + \left(H' \bullet \theta_{as}\right)\right] \bullet \left[1 + \frac{\left(U_{air} \bullet \delta_{air} \bullet L_s\right)}{\left(D_s^{eff} \bullet W\right)}\right]}$$	**R11**

Equations for the Soil Component of the Groundwater Ingestion Exposure Route	Remediation Objective (mg/kg)	$\frac{GW_{source}}{LF_{sw}}$ NOTE: This equation can only be used to model contaminant migration not in the water bearing unit.	**R12**
	Groundwater at the source, GW_{source} (mg/L)	$GW_{source} = \frac{GW_{comp}}{C_{(x)}/C_{source}}$	**R13**
	Leaching Factor, LF_{sw} $(mg/L_{water})/(mg/kg_{soil})$	$LF_{sw} = \frac{\rho_s \bullet \frac{cm^3 \cdot kg}{L \cdot g}}{\left[\theta_{ws} + (k_s \bullet \rho_s) + (H' \bullet \theta_{as})\right] \bullet \left[1 + \frac{(U_{gw} \bullet \delta_{gw})}{(I \bullet W)}\right]}$	**R14**
	Steady-State Attenuation Along the Centerline of a Dissolved Plume, $C_{(x)}/C_{source}$	$C_{(x)}/C_{source} = \exp\left[\left(\frac{X}{2\alpha_x}\right) \bullet \left(1 - \sqrt{1 + \frac{4\lambda \bullet \alpha_x}{U}}\right)\right] \bullet erf\left[\frac{S_w}{4 \bullet \sqrt{\alpha_y \bullet X}}\right] \bullet erf\left[\frac{S_d}{2 \bullet \sqrt{\alpha_z \bullet X}}\right]$ NOTE: 1. This equation does not predict the contaminant flow within bedrock and may not accurately predict downgradient concentrations in the presence of a confining layer. 2. If the value of the First Order Degradation Constant (λ) is not readily available, then set $\lambda = 0$.	**R15**
	Longitudinal Dispersivity, α_x (cm)	$\alpha_x = 0.10 \bullet X$	**R16**

Transverse Dispersivity, α_y (cm)	$\alpha_y = \frac{\alpha_x}{3}$	**R17**
Vertical Dispersivity, α_z (cm)	$\alpha_z = \frac{\alpha_x}{20}$	**R18**
Specific Discharge, U (cm/d)	$U = \frac{K \bullet i}{\theta_T}$	**R19**
Soil-Water Sorption Coefficient, k_s	$k_s = K_{oc} \bullet f_{oc}$	**R20**
Volumetric Air Content in Vadose Zone Soils, θ_{as} (cm^3_{air}/cm^3_{soil})	$\theta_{as} = \theta_T - \frac{(w \bullet \rho_s)}{\rho_w}$	**R21**
Volumetric Water Content in Vadose Zone Soils, θ_{ws} (cm^3_{water}/cm^3_{soil})	$\theta_{ws} = \frac{w \bullet \rho_s}{\rho_w}$	**R22**
Total Soil Porosity, θ_T (cm^3/cm^3_{soil})	$\theta_T = \theta_{as} + \theta_{ws}$	**R23**

	Groundwater Darcy Velocity, U_{gw} (cm/yr)	$U_{gw} = K \bullet i$	**R24**
Equations for the Groundwater Ingestion Exposure Route	Remediation Objective for Carcinogenic Contaminants (mg/L)	$\frac{TR \bullet BW \bullet AT_r \bullet 365 \frac{d}{yr}}{SF_o \bullet IR_w \bullet EF \bullet ED}$	**R25**
	Dissolved Hydrocarbon Concentration along Centerline, $C_{(x)}$ (mg/L_{water})	$C_{(x)} = C_{source} \bullet \exp\left[\left(\frac{X}{2\alpha_x}\right) \bullet \left(1 - \sqrt{1 + \frac{4\lambda \bullet \alpha_x}{U}}\right)\right] \bullet erf\left[\frac{S_w}{4 \bullet \sqrt{\alpha_y \bullet X}}\right] \bullet erf\left[\frac{S_d}{2 \bullet \sqrt{\alpha_z \bullet X}}\right]$ NOTE: 1. This equation does not predict the contaminant flow within bedrock and may not accurately predict downgradient concentrations in the presence of a confining layer. 2. If the value of the First Order Degradation Constant (λ) is not readily available, then set $\lambda = 0$.	**R26**

Section 742.APPENDIX C Tier 2 Illustrations and Tables

Section 742.Table D RBCA Parameters

Symbol	Parameter	Units	Source	Parameter Value(s)
AT_c	Averaging Time for Carcinogens	yr	RBCA	70
AT_n	Averaging Time for Noncarcinogens	yr	RBCA	Residential = 30 Industrial/Commercial = 25 Construction Worker = 0.115
BW	Adult Body Weight	kg	RBCA	70
C_{source}	The greatest potential concentration of the contaminant of concern in the groundwater at the source of the contamination, based on the concentrations of contaminants in groundwater due to the release and the projected concentration of the contaminant migrating from the soil to the groundwater.	mg/L	Field Measurement	Site-Specific
$C_{(x)}$	Concentration of Contaminant in Groundwater at Distance X from the source	mg/L	Equation R26 in Appendix C, Table C	Calculated Value

Symbol	Parameter	Units	Source	Parameter Value(s)
$C_{(x)}/C_{source}$	Steady-State Attenuation Along the Centerline of a Dissolved Plume	unitless	Equation R15 in Appendix C, Table C	Calculated Value
d	Lower Depth of Surficial Soil Zone	cm	Field Measurement	100 or Site-Specific (not to exceed 100)
D^{air}	Diffusion Coefficient in Air	cm^2/s	Appendix C, Table E	Chemical-Specific
D^{water}	Diffusion Coefficient in Water	cm^2/s	Appendix C, Table E	Chemical-Specific
D_s^{eff}	Effective Diffusion Coefficient in Soil Based on Vapor-Phase Concentration	cm^2/s	Equation R6 in Appendix C, Table C	Calculated Value
ED	Exposure Duration	yr	RBCA	Residential = 30 Industrial/Commercial = 25 Construction Worker = 1
EF	Exposure Frequency	d/yr	RBCA	Residential = 350 Industrial/Commercial = 250 Construction Worker = 30
erf	Error Function	unitless	Appendix C, Table G	Mathematical Function

Symbol	Parameter	Units	Source	Parameter Value(s)
f_{oc}	Organic Carbon Content of Soil	g/g	RBCA or Field Measurement (See Appendix C, Table F)	Surface Soil = 0.006 Subsurface Soil = 0.002 or Site-Specific
GW_{comp}	Groundwater Objective at the Compliance Point	mg/L	Appendix B, Table E, 35 IAC 620.Subpart F, or Equation R25 in Appendix C, Table C	Site-Specific
GW_{source}	Groundwater Concentration at the Source	mg/L	Equation R13 in Appendix C, Table C	Calculated Value
H'	Henry's Law Constant	cm^3_{water}/cm^3_{air}	Appendix C, Table E	Chemical-Specific
i	Hydraulic Gradient	cm/cm (unitless)	Field Measurement (See Appendix C, Table F)	Site-Specific
I	Infiltration Rate	cm/yr	RBCA	30
IR_{air}	Daily Outdoor Inhalation Rate	m^3/d	RBCA	20
IR_{soil}	Soil Ingestion Rate	mg/d	RBCA	Residential = 100 Industrial/Commercial = 50 Construction Worker = 480
IR_w	Daily Water Ingestion Rate	L/d	RBCA	Residential = 2 Industrial/Commercial = 1

Symbol	Parameter	Units	Source	Parameter Value(s)
K	Aquifer Hydraulic Conductivity	cm/d for Equations R15, R19 and R26 cm/yr for Equation R24	Field Measurement (See Appendix C, Table F)	Site-Specific
K_{oc}	Organic Carbon Partition Coefficient	cm^3/g or L/kg	Appendix C, Table E or Appendix C, Table I	Chemical-Specific
k_s (non-ionizing organics)	Soil Water Sorption Coefficient	cm^3_{water}/g_{soil}	Equation R20 in Appendix C,Table C	Calculated Value
k_s (ionizing organics)	Soil Water Sorption Coefficient	cm^3_{water}/g_{soil}	Equation R20 in Appendix C, Table C	Chemical and pH-Specific (See Appendix C, Table I)
k_s (inorganics)	Soil Water Sorption Coefficient	cm^3_{water}/g_{soil}	Appendix C, Table J	Chemical and pH-Specific
L_s	Depth to Subsurface Soil Sources	cm	RBCA	100
LF_{sw}	Leaching Factor	$(mg/L_{water})/(mg/kg_{soil})$	Equation R14 in Appendix C, Table C	Calculated Value
M	Soil to Skin Adherence Factor	mg/cm^2	RBCA	0.5

Symbol	Parameter	Units	Source	Parameter Value(s)
Pe	Particulate Emission Rate	g/cm^2-s	RBCA	$6.9 \bullet 10^{-14}$
RAF_d	Dermal Relative Absorption Factor	unitless	RBCA	0.5
RAF_d (PNAs)	Dermal Relative Absorption Factor	unitless	RBCA	0.05
RAF_d (inorganics)	Dermal Relative Absorption Factor	unitless	RBCA	0
RAF_o	Oral Relative Absorption Factor	unitless	RBCA	1.0
$RBSL_{air}$	Carcinogenic Risk-Based Screening Level for Air	ug/m^3	Equation R9 in Appendix C, Table C	Chemical-, Media-, and Exposure Route-Specific
$RBSL_{air}$	Noncarcinogenic Risk-Based Screening Level for Air	ug/m^3	Equations R10 in Appendix C, Table C	Chemical-, Media-, and Exposure Route-Specific
RfD_i	Inhalation Reference Dose	mg/kg-d	IEPA (IRIS/HEAST[a])	Toxicological-Specific
RfD_o	Oral Reference Dose	mg/(kg-d)	IEPA (IRIS/HEAST[a])	Toxicological-Specific (Note: for Construction Worker use subchronic reference doses)
SA	Skin Surface Area	cm^2/d	RBCA	3,160

Symbol	Parameter	Units	Source	Parameter Value(s)
S_d	Source Width Perpendicular to Groundwater Flow Direction in Vertical Plane	cm	Field Measurement	For Migration to Groundwater Route: Use 200 or Site-Specific For Groundwater remediation objective: Use Site-Specific
S_w	Source Width Perpendicular to Groundwater Flow Direction in Horizontal Plane	cm	Field Measurement	Site-Specific
SF_i	Inhalation Cancer Slope Factor	$(mg/kg\text{-}d)^{-1}$	IEPA (IRIS/HEAST[a])	Toxicological-Specific
SF_o	Oral Slope Factor	$(mg/kg\text{-}d)^{-1}$	IEPA (IRIS/HEAST[a])	Toxicological-Specific
THQ	Target Hazard Quotient	unitless	RBCA	1
TR	Target Cancer Risk	unitless	RBCA	Residential = 10^{-6} at the point of human exposure Industrial/Commercial = 10^{-6} at the point of human exposure Construction Worker = 10^{-6} at the point of human exposure
U	Specific Discharge	cm/d	Equation R19 in Appendix C, Table C	Calculated Value

Symbol	Parameter	Units	Source	Parameter Value(s)
U_{air}	Average Wind Speed Above Ground Surface in Ambient Mixing Zone	cm/s	RBCA	225
U_{gw}	Groundwater Darcy Velocity	cm/yr	Equation R24 in Appendix C, Table C	Calculated Value
VF_p	Volatilization Factor for Surficial Soils Regarding Particulates	kg/m^3	Equation R5 in Appendix C, Table C	Calculated Value
VF_{samb}	Volatilization Factor (Subsurface Soils to Ambient Air)	$(mg/m^3_{air})/(mg/kg_{soil})$ or kg/m^3	Equation R11 in Appendix C, Table C	Calculated Value
VF_{ss}	Volatilization Factor for Surficial Soils	kg/m^3	Use Equations R3 and R4 in Appendix C, Table C	Calculated Value from Equation R3 or R4 (whichever is less)
W	Width of Source Area Parallel to Direction to Wind or Groundwater Movement	cm	Field Measurement	Site-Specific

Symbol	Parameter	Units	Source	Parameter Value(s)
w	Average Soil Moisture Content	g_{water}/g_{soil}	RBCA or Field Measurement (See Appendix C, Table F)	0.1, or Surface Soil (top 1 meter) = 0.1 Subsurface Soil (below 1 meter) = 0.2, or Site-Specific
X	Distance along the Centerline of the Groundwater Plume Emanating from a Source. The x direction is the direction of groundwater flow	cm	Field Measurement	Site-Specific
α_x	Longitudinal Dispersitivity	cm	Equation R16 in Appendix C, Table C	Calculated Value
α_y	Transverse Dispersitivity	cm	Equation R17 in Appendix C, Table C	Calculated Value
α_z	Vertical Dispersitivity	cm	Equation R18 in Appendix C, Table C	Calculated Value
δ_{air}	Ambient Air Mixing Zone Height	cm	RBCA	200

Symbol	Parameter	Units	Source	Parameter Value(s)
δ_{gw}	Groundwater Mixing Zone Thickness	cm	RBCA	200
θ_{as}	Volumetric Air Content in Vadose Zone Soils	cm^3_{air}/cm^3_{soil}	RBCA or Equation R21 in Appendix C, Table C	Surface Soil (top 1 meter) = 0.28 Subsurface Soil (below 1 meter)= 0.13, Or Gravel = 0.05 Sand = 0.14 Silt = 0.16 Clay = 0.17, or Calculated Value
θ_{ws}	Volumetric Water Content in Vadose Zone Soils	cm^3_{water}/cm^3_{soil}	RBCA or Equation R22 in Appendix C, Table C	Surface Soil (top 1 meter) = 0.15 Subsurface Soil (below 1 meter) = 0.30, or Gravel = 0.20 Sand = 0.18 Silt = 0.16 Clay = 0.17, or Calculated Value

Symbol	Parameter	Units	Source	Parameter Value(s)
θ_T	Total Soil Porosity	cm^3/cm^3_{soil}	RBCA or Equation R23 in Appendix C, Table C	0.43, or Gravel = 0.25 Sand = 0.32 Silt = 0.40 Clay = 0.36, or Calculated Value
λ	First Order Degradation Constant	d^{-1}	Appendix C, Table E	Chemical-Specific
π	pi			3.1416
ρ_b	Soil Bulk Density	g/cm^3	RBCA or Field Measurement (See Appendix C, Table F)	1.5, or Gravel = 2.0 Sand = 1.8 Silt = 1.6 Clay = 1.7, or Site-Specific
ρ_w	Water Density	g/cm^3	RBCA	1
τ	Averaging Time for Vapor Flux	s	RBCA	$9.46 \bullet 10^8$

Chemical Abstracts Service (CAS) registry number. This number in the format xxx-xx-x, is unique for each chemical and allows efficient searching on computerized data bases.

[a] Soil remediation objectives are determined pursuant to 40 CFR 761, as incorporated by reference at Section 742.210(b) (the USEPA "PCB Spill Cleanup Policy"), for most sites; persons remediating sites should consult with BOL if calculation of Tier 2 or 3 remediation objectives is desired. PCBs are a mixture of different congeners. The appropriate values to use for the physical/chemical parameters depend on congeners present at the site.

[b] Dimensionless Henry's Law Constant at 13°C is not calculated because the chemical is not volatile and does not require evaluation under the indoor inhalation exposure route.

[c] Dimensionless Henry's Law Constant = 20°C

[d] These chemicals are ionizing and its K_{oc} value will change with pH. The K_{oc} values listed in this table is the effective K_{oc} at pH of 6.8. If the site-specific pH is values other than 6.8, the K_{oc} value listed in Section 742, Appendix C, Table I should be used.

[e] The values in this table were taken from the following sources (in order of preference): SCDMS online database (http://www.epa.gov/superfund/sites/npl/hrsres/tools/scdm.htm); CHEMFATE online database (http://www.srcinc.com/what-we-do/databaseforms.aspx?id=381); PhysProp online database (http://www.srcinc.com/what-we-do/databaseforms.aspx?id-386); Water9

(http://www.epa.gov/ttn/chief/software/water/) for diffusivity values; and Handbook of Environmental Degradation Rates by P.H. Howard (1991) for first order degradation constant values.

Section 742.APPENDIX C: Tier 2 Illustrations and Tables

Section 742.Table F: Methods for Determining Physical Soil Parameters

Methods for Determining Physical Soil Parameters		
Parameter	Sampling Location[a]	Method
ρ_b (soil bulk density)	Surface	ASTM - D 1556-90 Sand Cone Method[b]
		ASTM - D 2167-94 Rubber Balloon Method[b]
		ASTM - D 2922-91 Nuclear Method[b]
	Subsurface	ASTM - D 2937-94 Drive Cylinder Method[b]
ρ_s (soil particle density)	Surface or Subsurface	ASTM - D 854-92 Specific Gravity of Soil[b]
w (moisture content)	Surface or Subsurface	ASTM - D 4959-89 (Reapproved 1994) Standard[b]
		ASTM - D 4643-93 Microwave Oven[b]
		ASTM - D2216-92 Laboratory Determination[b]
		ASTM - D3017-88 (Reapproved 1993) Nuclear Method[b]
		Equivalent USEPA Method (e.g., sample preparation procedures described in methods 3541 or 3550)
f_{oc} (fraction organic carbon content)	Surface or Subsurface	ASTM - D 2974-00 Moisture, Ash, and Organic Matter appropriately adjusted to estimate the fraction of organic carbon as stated in Nelson and Sommers (1982)[b]

Methods for Determining Physical Soil Parameters		
Parameter	Sampling Location[a]	Method
η or θ_T (total soil porosity)	Surface or Subsurface (calculated)	Equation S24 in Appendix C, Table A for SSL Model, or Equation R23 in Appendix C, Table C for RBCA Model, or Equation J&E 16 in Appendix C, Table L for J&E Model
θ_a or θ_{as} (air-filled soil porosity)	Surface or Subsurface (calculated)	Equation S21 in Appendix C, Table A for SSL Model, or Equation R21 in Appendix C, Table C for RBCA Model, or Equation J&E 18 in Appendix C, Table L for J&E Model
θ_w or θ_{ws} (water-filled soil porosity)	Surface or Subsurface (calculated)	Equation S20 in Appendix C, Table A for SSL Model, or Equation R22 in Appendix C, Table C for RBCA Model, or Equation J&E 17 in Appendix C, Table L for J&E Model
K (hydraulic conductivity)	Surface or Subsurface	ASTM - D 5084-90 Flexible Wall Permeameter[b]
		Pump Test
		Slug Test
i (hydraulic gradient)	Surface or Subsurface	Field Measurement

[a] This is the location where the sample is collected

[b] As incorporated by reference in Section 742.120.

Section 742.APPENDIX C: Tier 2 Tables

Section 742.Table L: J&E Equations[a]

Indoor air remediation objectives (mg/m^3)	For carcinogenic contaminants	$RO_{indoor\ air} = \frac{TR \times AT_c \times 365 \frac{days}{yr}}{ED \times EF \times URF \times 1000 \frac{\mu g}{mg}}$	**J&E1**
	For noncarcinogenic contaminants	$RO_{indoor\ air} = \frac{THQ \times AT_{nc} \times 365 \frac{days}{yr} \times RfC}{ED \times EF}$	**J&E2**
To convert mg/m^3 from parts per million volume		$mg/m^3 = \frac{ppmv \times MW}{24.45}$ Note: 24.45 equals the molar volume of air in liters at normal temperature (25°C) and pressure (760 mm Hg).	**J&E3**

Soil gas remediation objective (mg/m^3)		$RO_{soil\ gas} = \frac{RO_{indoor\ air}}{\alpha}$	**J&E4**
Soil Vapor Saturation Limit (mg/m^3-air)		$C_v^{sat} = \frac{P \times MW}{R \times T} \times 10^6$	**J&E5**
Groundwater remediation objectives		$RO_{gw} = \frac{RO_{soil\ gas}}{H'_{TS} \times 1000 \frac{L}{m^3}}$	**J&E6**
Attenuation factor	Attenuation factor when the mode of contaminant transport is both diffusion and advection Q_{soil} = 83.33 cm^3/sec	$\alpha = \frac{\left[\left(\frac{D_T^{eff} \times A_B}{Q_{bldg} \times L_T}\right) \times \exp\left(\frac{Q_{soil} \times L_{crack}}{D_{crack}^{eff} \times A_{crack}}\right)\right]}{\left[\exp\left(\frac{Q_{soil} \times L_{crack}}{D_{crack}^{eff} \times A_{crack}}\right) + \left(\frac{D_T^{eff} \times A_B}{Q_{bldg} \times L_T}\right) + \left(\frac{D_T^{eff} \times A_B}{Q_{soil} \times L_T}\right)\left[\exp\left(\frac{Q_{soil} \times L_{crack}}{D_{crack}^{eff} \times A_{crack}}\right) - 1\right]\right]}$	**J&E7**

	Attenuation factor when the mode of contaminant transport is diffusion only Q_{soil}= 0 cm^3/sec	$$\alpha = \frac{\left(\frac{D_T^{eff} \times A_B}{Q_{bldg} \times L_T}\right)}{\left[1+\left(\frac{D_T^{eff} \times A_B}{Q_{bldg} \times L_T}\right)+\left(\frac{D_T^{eff} \times A_B \times L_{crack}}{L_T \times D_{crack}^{eff} \times A_{crack}}\right)\right]}$$	**J&E8**
Total overall effective diffusion coefficient for vapor transport in porous media for multiple soil layers (cm^2/s)		$$D_T^{eff} = \frac{L_T}{\sum_{i=1}^{n} L_i / D_i^{eff}}$$	**J&E9a**
	In Equation J&E9a, the following condition must be satisfied:	$$\sum_{i=1}^{n} L_i = L_T$$	**J&E9b**
Source to building separation (cm)		$$L_T = D_{source} - L_F$$	**J&E10**
Effective diffusion coefficient for each soil layer (cm^2/s)		$$D_i^{eff} = D_i\left(\frac{\theta_{a,i}^{3.33}}{\theta_{T,i}^2}\right)+\left(\frac{D_w}{H'_{TS}}\right)\left(\frac{\theta_{w,i}^{3.33}}{\theta_{T,i}^2}\right)$$	**J&E11**

Surface area of enclosed space at or below grade (cm^2)	For a building with a full concrete slab-on-grade	$A_B = (L_B \times W_B)$	**J&E12a**
Surface area of enclosed space at or below grade (cm^2)	For a building with a full concrete basement floor and walls	$A_B = (L_B \times W_B) + (2 \times L_F \times L_B) + (2 \times L_F \times W_B)$	**J&E12b**
Building ventilation rate (cm^3/s)		$Q_{bldg} = \left(\frac{L_B \times W_B \times H_B \times ER}{3600 \frac{sec}{hr}} \right)$	**J&E13**
Area of total cracks (cm^2)		$A_{crack} = 2 \times (L_B + W_B) \times w$	**J&E14**
Effective diffusion coefficient through the cracks (cm^2/s)		$D_{crack}^{eff} = D_i \left(\frac{\theta_{a,crack}^{3.33}}{\theta_{T,crack}^2} \right) + \left(\frac{D_w}{H_{TS}'} \right) \left(\frac{\theta_{w,crack}^{3.33}}{\theta_{T,crack}^2} \right)$	**J&E15**

Total porosity		$\theta_{T_i} = 1 - \frac{\rho_{bi}}{\rho_s}$	**J&E16**
Water-filled soil porosity		$\theta_w = (W)\left(\frac{\rho_b}{\rho_w}\right)$	**J&E17**
Air-filled soil porosity		$\theta_a = \theta_T - \theta_w$	**J&E18**

[a] This table contains equations based on the assumption that the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls. This table applies only when the existing or potential building has a full concrete slab-on-grade or a full concrete basement floor and walls. Institutional controls under Subpart J are required to develop remediation objectives pursuant to this table. This table does not apply when the existing or potential building has neither a full concrete slab-on-grade nor a full concrete basement floor and walls, such as a building with an earthen crawl space, an earthen floor, a stone foundation, a partial concrete floor, or a sump. In such cases, site evaluators have the option of excluding the indoor inhalation exposure route under Section 742.312, meeting the building control technology requirements under Subpart L, or proposing an alternative approach under Tier 3.

Section 742.APPENDIX C: Tier 2 Tables

Section 742.Table M: J&E Parameters

Symbol	Parameter	Units	Source	Tier 1 or Calculated Value
A_B	Surface area of enclosed space at or below grade	cm^2	Equation J&E 12a or 12b, Appendix C, Table L	Residential = 1×10^6 Industrial/Commercial = 4.0×10^6
A_{crack}	Area of total cracks	cm^2	Equation J&E 14, Appendix C, Table L	Calculated Value
AT_c	Averaging time for carcinogens	year	SSL, May 1996	70
AT_{nc}	Averaging time for noncarcinogens	year	AT_{nc}= ED	Residential = 30 Industrial/Commercial = 25
C_v^{sat}	Soil vapor saturation limit	mg/m^3-air	Equation J&E 5, Appendix C, Table L	Chemical-Specific or Calculated Value
D_{crack}^{eff}	Effective diffusion coefficient through the cracks	cm^2 /s	Equation J&E 15, Appendix C, Table L	Calculated Value
D_i	Diffusivity in air	cm^2 /s	Appendix C, Table E	Chemical-Specific

Symbol	Parameter	Units	Source	Tier 1 or Calculated Value
D_i^{eff}	Effective diffusion coefficient for each soil layer	cm^2 /s	Equation J&E 11, Appendix C, Table L	Calculated Value
D_{source}	Distance from ground surface to top of contamination	cm	Field Measurement	Soil Gas Contamination = 152.4 Groundwater Contamination = 304.8 Site-Specific
D_T^{eff}	Total overall effective diffusion coefficient	cm^2 /s	Equation J&E 9a, Appendix C, Table L	Calculated Value
D_w	Diffusivity in water	cm^2 /s	Appendix C, Table E	Chemical-Specific
ED	Exposure duration	year	Residential: SSL, May 1996 Industrial/Commercial: SSL 2002	Residential = 30 Industrial/Commercial = 25
EF	Exposure frequency	day/year	Residential: SSL, May 1996 Industrial/Commercial: SSL 2002	Residential = 350 Industrial/Commercial = 250

Symbol	Parameter	Units	Source	Tier 1 or Calculated Value
ER	Air exchange rate	exchanges per hour	Illinois EPA	Residential = 0.53 Industrial/Commercial = 0.93
f_{oc}	Fraction organic carbon content	g/g	SSL, May 1996, or Field Measurement Appendix C, Table F	0.002 or Site-Specific
H_B	Height of building	cm	Illinois EPA	Slab on Grade Residential = 244 Industrial/Commercial = 305 or Site-Specific in Tier 3 Basement Residential = 427 Industrial/Commercial = 488 or Site-Specific in Tier 3
H'_{TS}	Dimensionless Henry's law constant at the system (soil) temperature 13°C	unitless	Appendix C, Table E	Chemical-Specific

Symbol	Parameter	Units	Source	Tier 1 or Calculated Value
L_B	Length of building	cm	Illinois EPA	Residential = 1000 Industrial/Commercial = 2000 or Site-Specific in Tier 3
L_{crack}	Slab thickness	cm	US EPA, Users Guide 2004	10
L_F	Distance from ground surface to bottom of slab	cm	US EPA, Users Guide 2004	10 (slab on grade) 200 (basement)
L_i	Thickness of soil layer i	cm	Field Measurement For capillary fringe, USEPA, 2004	Site-Specific For capillary fringe, 37.5 cm
L_T	Distance from bottom of slab to top of contamination	cm	Field Measurement or Equation J&E 10, Appendix C, Table L	142.4 or Site-Specific
MW	Molecular weight	g/mole	Illinois EPA	Chemical-Specific

Symbol	Parameter	Units	Source	Tier 1 or Calculated Value
n	Total number of layers of different types of soil vapors migrate through from source to building (if source is groundwater, include a capillary fringe layer of 37.5 cm as one of the layers)	unitless	Field measurement	Site-Specific
P	Vapor Pressure	atm	Appendix C, Table E	Chemical-Specific
Q_{bldg}	Building ventilation rate	cm^3/s	Equation J&E 13, Appendix C, Table L	Slab on Grade Residential = 3.59×10^4 Industrial/Commercial = 3.15×10^5 or Site-Specific in Tier 3 Basement Residential = 6.28×10^4 Industrial/Commercial = 5.04×10^5 or Site-Specific in Tier 3

Symbol	Parameter	Units	Source	Tier 1 or Calculated Value
Q_{soil}	Volumetric flow rate of soil gas into the enclosed space	cm^3/s	US EPA, Users Guide for Evaluating Subsurface Vapor Intrusion into Buildings 2004	If L_T is less than 5 feet (152 cm), Q_{soil} equals 83.33 If L_T is 5 feet (152 cm) or greater, Q_{soil} equals zero An input value of zero requires an institutional control. See Section 742.505(b) and (c).
R	Ideal gas constant	atm-L/mol-K	US EPA, Users Guide 2004	0.08206
RfC	Reference concentration	ug/m^3	Illinois EPA: http://www.epa.state.il.us/land/taco/toxicity-values.xls	Toxicological-Specific
RO_{gw}	Groundwater remediation objective	mg/L	Appendix B, Table E, or Equation J&E 6, Appendix C, Table L	Chemical-Specific or Calculated Value
$RO_{indoor\ air}$	Indoor air remediation objective	mg/m^3	Equations J&E 1 and 2, Appendix C, Table L	Calculated Value

Symbol	Parameter	Units	Source	Tier 1 or Calculated Value
$RO_{soil\ gas}$	Soil gas remediation objective	mg/m^3	Equation J&E 4, Appendix C, Table L	Calculated Value
S	Solubility in water	mg/L	Appendix C, Table E	Chemical-Specific
T	Temperature	K	US EPA, Users Guide 2004	286 (converted from 13°C)
THQ	Target hazard quotient for a chemical	unitless	SSL, May 1996	1
TR	Target risk or the increased chance of developing cancer over a lifetime due to exposure to a chemical	unitless	SSL, May 1996	Residential = 10^{-6} at the point of human exposure Industrial/Commercial = 10^{-6} at the point of human exposure
URF	Unit risk factor	$(ug/m^3)^{-1}$	Illinois EPA: http://www.epa.state.il.us/land/taco/toxicity-values.xls	Toxicological- Specific

Symbol	Parameter	Units	Source	Tier 1 or Calculated Value
w	Floor-wall seam gap	cm	US EPA, Users Guide 2004	0.1
W	Moisture content	g of water/g of soil	Field Measurement, Appendix C, Table F	Site-Specific
W_B	Width of building	cm	Illinois EPA	Residential = 1000 Industrial/Commercial = 2000 or Site-Specific in Tier 3
α	Attenuation factor	unitless	Equations J&E 7 or 8, Appendix C, Table L	Site-Specific
θ_a	Air-filled soil porosity	cm^3/cm^3	SSL, May 1996 or Equation J&E 18, Appendix C, Table L	0.28 or Calculated Value
$\theta_{a,crack}$	Air-filled porosity for soil in cracks	cm^3/cm^3	SSL, May 1996 or Equation J&E 18, Appendix C, Table L	0.13
$\theta_{a,i}$	Air-filled porosity of soil layer i	cm^3/cm^3	SSL, May 1996 or Equation J&E 18, Appendix C, Table L	0.13 or Calculated Value For capillary fringe, $\theta_{a,i} = 0.1\ \theta_{T,i}$

Symbol	Parameter	Units	Source	Tier 1 or Calculated Value
$\theta_{T,crack}$	Total porosity for soil in cracks	cm^3/cm^3	SSL, May 1996 or Equation J&E 16, Appendix C, Table L	0.43
$\theta_{T,i}$	Total porosity of soil layer i	cm^3/cm^3	SSL, May 1996 or Equation J&E 16, Appendix C, Table L	0.43 or Calculated Value
θ_w	Water-filled soil porosity	cm^3/cm^3	SSL, May 1996 or Equation J&E 17, Appendix C, Table L	0.15 or Calculated Value
$\theta_{w,crack}$	Water-filled porosity for soil in cracks	cm^3/cm^3	SSL, May 1996 or Equation J&E 17, Appendix C, Table L	0.15
$\theta_{w,i}$	Water-filled porosity of soil layer i	cm^3/cm^3	SSL, May 1996 or Equation J&E 17, Appendix C, Table L For capillary fringe, US EPA, Users Guide 2004	0.15 or Calculated Value For capillary fringe = 0.375 or 0.9 $\theta_{T,i}$

Symbol	Parameter	Units	Source	Tier 1 or Calculated Value

Section 742.APPENDIX D Highway Authority Agreement

HIGHWAY AUTHORITY AGREEMENT

This Agreement is entered into this ____ day of _____, 200_ pursuant to 35 Ill. Adm. Code 742.1020 by and between the (1)_____ ("Property Owner") *[or, in the case of a petroleum leaking underground storage tank, the owner/operator of the tank ("Owner/Operator")]* and (2) *Name of Entity in Control of the Right-of-Way* ("Highway Authority"), collectively known as the "Parties."

[Use this paragraph for sites with petroleum leaking underground storage tank(s)] **WHEREAS,** _____ is the owner or operator of one or more leaking underground storage tanks presently or formerly located at *common address or description of Site location* ("the Site");

[Use this paragraph for sites that do not have petroleum leaking underground storage tanks] **WHEREAS,** _____ is the owner of the property located at *common address or description of Site location* ("the Site");

WHEREAS, as a result of one or more releases of contaminants [*insert either "from the above referenced underground storage tanks" or "at the above referenced Site"*] ("the Release(s)"), soil and/or groundwater contamination at the Site exceeds the Tier 1 residential remediation objectives of 35 Ill. Adm. Code 742;

WHEREAS, the soil and/or groundwater contamination exceeding Tier 1 residential remediation objectives extends or may extend into the Highway Authority's right-of-way;

WHEREAS, the Owner/Operator or Property Owner is conducting corrective action in response to the Release(s);

WHEREAS, the Parties desire to prevent groundwater beneath the Highway Authority's right-of-way that exceeds Tier 1 remediation objectives from use as a supply of potable or domestic water and to limit access to soil within the right-of-way that exceeds Tier 1 residential remediation objectives so that human health and the environment are protected during and after any access;

NOW, THEREFORE, the Parties agree as follows:

1. The recitals set forth above are incorporated by reference as if fully set forth herein.

2. *[Use this paragraph if IEMA has issued an incident number]* The Illinois Emergency Management Agency has assigned incident number(s) to the Release(s).

3. Attached as Exhibit A is a scaled map(s) prepared by the *[Owner/Operator or Property Owner]* that shows the Site and surrounding area and delineates the

current and estimated future extent of soil and groundwater contamination above the applicable Tier 1 residential remediation objectives as a result of the Release(s). *[Use the following sentence if either soil or groundwater is not contaminated above applicable Tier 1 residential remediation objectives:* [Soil] [Groundwater] is not contaminated above the applicable Tier 1 residential remediation objectives.*]*

4. Attached as Exhibit B is a table(s) prepared by the *[Owner/Operator or Property Owner]* that lists each contaminant of concern that exceeds its Tier 1 residential remediation objective, its Tier 1 residential remediation objective and its concentrations within the zone where Tier 1 residential remediation objectives are exceeded. The locations of the concentrations listed in Exhibit B are identified on the map(s) in Exhibit A.

5. Attached as Exhibit C is a scaled map prepared by the *[Owner/Operator or Property Owner]* showing the area of the Highway Authority's right-of-way that is governed by this agreement ("Right-of-Way"). Because Exhibit C is not a surveyed plat, the Right-of-Way boundary may be an approximation of the actual Right-of-Way lines.

6. *[Use this paragraph if samples have not been collected within the Right-of-Way, sampling within the Right-of-Way is not practical, and contamination does not extend beyond the Right-of-Way].* Because the collection of samples within the Right-of-Way is not practical, the Parties stipulate that, based on modeling, soil and groundwater contamination exceeding Tier 1 residential remediation objectives does not and will not extend beyond the boundaries of the Right-of-Way.

7. The Highway Authority stipulates it has jurisdiction over the Right-of-Way that gives it sole control over the use of the groundwater and access to the soil located within or beneath the Right-of-Way.

8. The Highway Authority agrees to prohibit within the Right-of-Way all potable and domestic uses of groundwater exceeding Tier 1 residential remediation objectives.

9. The Highway Authority further agrees to limit access by itself and others to soil within the Right-of-Way exceeding Tier 1 residential remediation objectives. Access shall be allowed only if human health (including worker safety) and the environment are protected during and after any access. The Highway Authority may construct, reconstruct, improve, repair, maintain and operate a highway upon the Right-of-Way, or allow others to do the same by permit. In addition, the Highway Authority and others using or working in the Right-of-Way under permit have the right to remove soil or groundwater from the Right-of-Way and dispose of the same in accordance with applicable environmental laws and regulations. The Highway Authority agrees to issue all permits for work in the

Right-of-Way, and make all existing permits for work in the Right-of-Way, subject to the following or a substantially similar condition:

As a condition of this permit the permittee shall request the office issuing this permit to identify sites in the Right-of-Way where a Highway Authority Agreement governs access to soil that exceeds the Tier 1 residential remediation objectives of 35 Ill. Adm. Code 742. The permittee shall take all measures necessary to protect human health (including worker safety) and the environment during and after any access to such soil.

10. This agreement shall be referenced in the Agency's no further remediation determination issued for the Release(s).

11. The Agency shall be notified of any transfer of jurisdiction over the Right-of-Way at least 30 days prior to the date the transfer takes effect. This agreement shall be null and void upon the transfer unless the transferee agrees to be bound by this agreement as if the transferee were an original party to this agreement. The transferee's agreement to be bound by the terms of this agreement shall be memorialized at the time of transfer in a writing ("Rider") that references this Highway Authority Agreement and is signed by the Highway Authority, or subsequent transferor, and the transferee.

12. This agreement shall become effective on the date the Agency issues a no further remediation determination for the Release(s). It shall remain effective until the Right-of-Way is demonstrated to be suitable for unrestricted use and the Agency issues a new no further remediation determination to reflect there is no longer a need for this agreement, or until the agreement is otherwise terminated or voided.

13. In addition to any other remedies that may be available, the Agency may bring suit to enforce the terms of this agreement or may, in its sole discretion, declare this agreement null and void if any of the Parties or any transferee violates any term of this agreement. The Parties or transferee shall be notified in writing of any such declaration.

14. This agreement shall be null and void if a court of competent jurisdiction strikes down any part or provision of the agreement.

15. This agreement supersedes any prior written or oral agreements or understandings between the Parties on the subject matter addressed herein. It may be altered, modified or amended only upon the written consent and agreement of the Parties.

16. Any notices or other correspondence regarding this agreement shall be sent to the Parties at following addresses:

Manager, Division of Remediation Management
Bureau of Land
Illinois Environmental Protection Agency

Property Owner or Owner/Operator
[*Address*]

P.O. Box 19276
Springfield, IL 62974-9276

Section 742.APPENDIX E Highway Authority Agreement Memorandum of Agreement

HIGHWAY AUTHORITY AGREEMENT MEMORANDUM OF AGREEMENT

This Memorandum of Agreement is entered by and between the Illinois Environmental Protection Agency ("Agency") and *Name of Local Government* ("Highway Authority"), collectively known as the "Parties."

[Use this paragraph for sites with petroleum leaking underground storage tank(s)]
WHEREAS, the Highway Authority is the owner or operator of one or more leaking underground storage tanks presently or formerly located at *common address or description of Site location* ("the Site");

[Use this paragraph for sites where the highway authority is also the property owner]
WHEREAS, the Highway Authority is the owner of the property located at *common address or description of Site location* ("the Site");

WHEREAS, as a result of one or more releases of contaminants [*insert either "from the above referenced underground storage tanks" or "at the above referenced Site"*] ("the Release(s)"), soil and/or groundwater contamination at the Site exceeds the Tier 1 residential remediation objectives of 35 Ill. Adm. Code 742;

WHEREAS, the soil and/or groundwater contamination exceeding Tier 1 residential remediation objectives extends or may extend into the Highway Authority's right-of-way adjacent to the Site;

WHEREAS, the Highway Authority is conducting corrective action in response to the Release(s);

WHEREAS, the Parties desire to prevent groundwater beneath the Highway Authority's right-of-way that exceeds Tier 1 residential remediation objectives from use as a supply of potable or domestic water and to limit access to soil within the right-of-way that exceeds Tier 1 residential remediation objectives so that human health and the environment are protected during and after any access;

NOW, THEREFORE, the Parties agree as follows:

1. The recitals set forth above are incorporated by reference as if fully set forth herein.

2. [Use this paragraph if IEMA has issued an incident number] The Illinois Emergency Management Agency has assigned incident number(s) to the Release(s).

3. Attached as Exhibit A is a scaled map(s) prepared by the Highway Authority that shows the Site and surrounding area and delineates the current and estimated future extent of soil and groundwater contamination above the applicable Tier 1 residential remediation objectives as a result of the Release(s). [Use the following sentence if either soil or groundwater is not contaminated above applicable Tier 1 residential remediation objectives: [Soil] [Groundwater] is not contaminated above the applicable Tier 1 residential remediation objectives.]

4. Attached as Exhibit B is a table(s) prepared by the Highway Authority that lists each contaminant of concern that exceeds its Tier 1 residential remediation objective, its Tier 1 residential remediation objective and its concentrations within the zone where Tier 1 residential remediation objectives are exceeded. The locations of the concentrations listed in Exhibit B are identified on the map(s) in Exhibit A.

5. Attached as Exhibit C is a scaled map prepared by the Highway Authority showing the area of the Highway Authority's right-of-way that is governed by this agreement ("Right-of-Way"). Because Exhibit C is not a surveyed plat, the Right-of-Way boundary may be an approximation of the actual Right-of-Way lines.

6. *[Use this paragraph if samples have not been collected within the Right-of-Way, sampling within the Right-of-Way is not practical, and contamination does not extend beyond the Right-of-Way].* Because the collection of samples within the Right-of-Way is not practical, the Parties stipulate that, based on modeling, soil and groundwater contamination exceeding Tier 1 residential remediation objectives does not and will not extend beyond the boundaries of the Right-of-Way.

7. The Highway Authority stipulates it has jurisdiction over the Right-of-Way that gives it sole control over the use of the groundwater and access to the soil located within or beneath the Right-of-Way.

8. The Highway Authority agrees to prohibit within the Right-of-Way all potable and domestic uses of groundwater exceeding Tier 1 residential remediation objectives.

9. The Highway Authority further agrees to limit access by itself and others to soil within the Right-of-Way exceeding Tier 1 residential remediation objectives. Access shall be allowed only if human health (including worker safety) and the environment are protected during and after any access. The Highway Authority may construct, reconstruct, improve, repair, maintain and operate a highway upon the Right-of-Way, or allow others to do the same by permit. In addition, the Highway Authority and others using or working in the Right-of-Way under permit have the right to remove soil or groundwater from the Right-of-Way and dispose of the same in accordance with applicable environmental laws and regulations. The Highway Authority agrees to issue all permits for work in the

Right-of-Way, and make all existing permits for work in the Right-of-Way, subject to the following or a substantially similar condition:

As a condition of this permit the permittee shall request the office issuing this permit to identify sites in the Right-of-Way where a Highway Authority Memorandum of Agreement governs access to soil that exceeds the Tier 1 residential remediation objectives of 35 Ill. Adm. Code 742. The permittee shall take all measures necessary to protect human health (including worker safety) and the environment during and after any access to such soil.

10. This agreement shall be referenced in the Agency's no further remediation determination issued for the Release(s).

11. The Agency shall be notified of any transfer of jurisdiction over the Right-of-Way at least 30 days prior to the date the transfer takes effect. This agreement shall be null and void upon the transfer unless the transferee agrees to be bound by this agreement as if the transferee were an original party to this agreement. The transferee's agreement to be bound by the terms of this agreement shall be memorialized at the time of transfer in a writing ("Rider") that references this Highway Authority Memorandum of Agreement and is signed by the Highway Authority, or subsequent transferor, and the transferee.

12. This agreement shall become effective on the date the Agency issues a no further remediation determination for the Release(s). It shall remain effective until the Right-of-Way is demonstrated to be suitable for unrestricted use and the Agency issues a new no further remediation determination to reflect there is no longer a need for this agreement, or until the agreement is otherwise terminated or voided.

13. In addition to any other remedies that may be available, the Agency may bring suit to enforce the terms of this agreement or may, in its sole discretion, declare this agreement null and void if the Highway Authority or a transferee violates any term of this agreement. The Highway Authority or transferee shall be notified in writing of any such declaration.

14. This agreement shall be null and void if a court of competent jurisdiction strikes down any part or provision of the agreement.

15. This agreement supersedes any prior written or oral agreements or understandings between the Parties on the subject matter addressed herein. It may be altered, modified or amended only upon the written consent and agreement of the Parties.

16. Any notices or other correspondence regarding this agreement shall be sent to the Parties at following addresses:

THE ABOVE SPACE FOR RECORDER'S OFFICE

Model Environmental Land Use Control

THIS ENVIRONMENTAL LAND USE CONTROL ("ELUC"), is made this _____ day of _____, 20__, by _____, ("Property Owner") of the real property located at the common address_____("Property").

WHEREAS, 415 ILCS 5/58.17 and 35 Ill. Adm. Code 742 provide for the use of an ELUC as an institutional control in order to impose land use limitations or requirements related to environmental contamination so that persons conducting remediation can obtain a No Further Remediation determination from the Illinois Environmental Protection Agency ("IEPA"). The reason for an ELUC is to ensure protection of human health and the environment. The limitations and requirements contained herein are necessary in order to protect against exposure to contaminated soil, groundwater, or soil gas that may be present on the property as a result of [**VARIABLE**] activities. Under 35 Ill. Adm. Code 742, the use of risk-based, site-specific remediation objectives may require the use of an ELUC on real property, and the ELUC may apply to certain physical features (e.g., engineered barriers, indoor inhalation building control technologies, monitoring wells, caps, etc.).

WHEREAS, _____ [**the party performing remediation**] intends to request risk-based, site specific soil, groundwater, or soil gas remediation objectives from IEPA under 35 Ill. Adm. Code 742 to obtain risk-based closure of the site, identified by Bureau of Land [**10-digit LPC or Identification number**] _____ , utilizing an ELUC.

NOW, THEREFORE, the recitals set forth above are incorporated by reference as if fully

set forth herein, and the Property Owner agrees as follows:
Date: _____ By: _____

Director

Section One. Property Owner does hereby establish an ELUC on the real estate, situated in the County of _____, State of Illinois and further described in Exhibit A attached hereto and incorporated herein by reference (the "Property").

Attached as Exhibit B are site maps that show the legal boundary of the Property, any physical features to which the ELUC applies, the horizontal and vertical extent of the contaminants of concern above the applicable remediation objectives for soil, groundwater, or soil gas, and the nature, location of the source, and direction of movement of the contaminants of concern, as required under 35 Ill. Adm. Code 742.

Section Two. Property Owner represents and warrants **he/she** is the current owner of the Property and has the authority to record this ELUC on the chain of title for the Property with the Office of the Recorder or Registrar of Titles in _____ County, Illinois.

Section Three. The Property Owner hereby agrees, for **himself/herself**, and **his/her** heirs, grantees, successors, assigns, transferees and any other owner, occupant, lessee, possessor or user of the Property or the holder of any portion thereof or interest therein, that [**INSERT RESTRICTION (e.g. the groundwater under the Property shall not be used as a potable supply of water, and any contaminated groundwater or soil that is removed, excavated, or disturbed from the Property described in Exhibit A herein must be handled in accordance with all applicable laws and regulations**)].

Section Four. This ELUC is binding on the Property Owner, **his/her** heirs, grantees, successors, assigns, transferees and any other owner, occupant, lessee, possessor or user of the Property or the holder of any portion thereof or interest therein. This ELUC shall apply in perpetuity against the Property and shall not be released until the IEPA determines there is no longer a need for this ELUC as an institutional control; until the IEPA, upon written request, issues to the site that received the no further remediation determination a new no further remediation determination approving modification or removal of the limitation(s) or requirement(s); the new no further remediation determination is filed on the chain of title of the site subject to the no further remediation determination; and until a release or modification of the land use limitation or requirement is filed on the chain of title for the Property.

Section Five. Information regarding the remediation performed on the Property may be obtained from the IEPA through a request under the Freedom of Information Act (5 ILCS 140) and rules promulgated thereunder by providing the IEPA with the [10-digit LPC or identification number] listed above.

Section Six. The effective date of this ELUC shall be the date that it is officially recorded in the chain of title for the Property to which the ELUC applies.

WITNESS the following signatures:

Section 742.APPENDIX G Model Ordinance

ORDINANCE NUMBER _____

AN ORDINANCE PROHIBITING THE USE OF GROUNDWATER AS A POTABLE WATER SUPPLY BY THE INSTALLATION OR USE OF POTABLE WATER SUPPLY WELLS OR BY ANY OTHER METHOD

WHEREAS, certain properties in the City [Village] of _____, Illinois have been used over a period of time for commercial/industrial purposes; and

WHEREAS, because of said use, concentrations of certain chemical constituents in the groundwater beneath the City [Village] may exceed Class I groundwater quality standards for potable resource groundwater as set forth in 35 Illinois Administrative Code 620 or Tier 1 remediation objectives as set forth in 35 Illinois Administrative Code 742; and

WHEREAS, the City [Village] of _____ desires to limit potential threats to human health from groundwater contamination while facilitating the redevelopment and productive use of properties that are the source of said chemical constituents;

NOW, THEREFORE, BE IT ORDAINED BY THE CITY COUNCIL OF THE CITY [VILLAGE] OF _____, ILLINOIS:

Section One. Use of groundwater as a potable water supply prohibited.

[Except for such uses or methods in existence before the effective date of this ordinance,] The use or attempt to use as a potable water supply groundwater from within the corporate limits of the City [Village] of _____, as a potable water supply, by the installation or drilling of wells or by any other method is hereby prohibited. This prohibition [expressly includes] [does not include] the City [Village] of _____.

Section Two. Penalties.

Any person violating the provisions of this ordinance shall be subject to a fine of up to _____ for each violation.

Section Three. Definitions.

"Person" is any individual, partnership, co-partnership, firm, company, limited liability company, corporation, association, joint stock company, trust, estate, political subdivision, or any other legal entity, or their legal representatives, agents or assigns.

"Potable water" is any water used for human or domestic consumption, including, but not limited to, water used for drinking, bathing, swimming, washing dishes, or preparing foods.

Section Four. Memorandum of Understanding.

'[This Section is only necessary if ordinance does not expressly prohibit installation of potable water supply wells by the city or village--could be separate resolution]

The Mayor of the City [Village] of _____ is hereby authorized and directed to enter into a Memorandum of Understanding with the Illinois Environmental Protection Agency ("Illinois EPA") in which the City [Village] of _____ assumes responsibility for tracking all sites that have received no further remediation determinations from the Illinois EPA, notifying the Illinois EPA of changes to this ordinance, and taking certain precautions when siting public potable water supply wells.

Section Five. Repealer.

All ordinances or parts of ordinances in conflict with this ordinance are hereby repealed insofar as they are in conflict with this ordinance.

Section Six. Severability.

If any provision of this ordinance or its application to any person or under any circumstances is adjudged invalid, such adjudication shall not affect the validity of the ordinance as a whole or of any portion not adjudged invalid.

Section Seven. Effective date.

This ordinance shall be in full force and effect from and after its passage, approval and publication as required by law.

ADOPTED: _____ APPROVED: _____

(Date) (Date)

_____ _____

(City Clerk) (Mayor)

Section 742.APPENDIX H Memorandum of Understanding

MEMORANDUM OF UNDERSTANDING BETWEEN _____ AND THE ILLINOIS ENVIRONMENTAL PROTECTION AGENCY REGARDING THE USE OF A LOCAL GROUNDWATER OR WATER WELL ORDINANCE AS AN ENVIRONMENTAL INSTITUTIONAL CONTROL

I. PURPOSE AND INTENT

A. This Memorandum of Understanding ("MOU") between _____ and the Illinois Environmental Protection Agency ("Illinois EPA") is entered into for the purpose of satisfying the requirements of 35 Ill. Adm. Code 742.1015 for the use of groundwater or water well ordinances as environmental institutional controls. The Illinois EPA has reviewed the groundwater or water well ordinance of _____ (Attachment A) and determined that the ordinance prohibits the use of groundwater for potable purposes and/or the installation and use of new potable water supply wells by private entities but does not expressly prohibit those activities by the unit of local government itself. In such cases, 35 Ill. Adm. Code 742.1015(a) provides that the unit of local government may enter into an MOU with the Illinois EPA to allow the use of the ordinance as an institutional control.

B. The intent of this Memorandum of Understanding is to specify the responsibilities that must be assumed by the unit of local government to satisfy the requirements for MOUs as set forth at 35 Ill. Adm. Code 742.1015(i).

II. DECLARATIONS AND ASSUMPTION OF RESPONSIBILITY

In order to ensure the long-term integrity of the groundwater or water well ordinance as an environmental institutional control and that risk to human health and the environment from contamination left in place in reliance on the groundwater or water well ordinance is effectively managed, _____ hereby assumes the following responsibilities pursuant to 35 Ill. Adm. Code 742.1015(d)(2) and (i):

A. _____ will notify the Illinois EPA Bureau of Land of any proposed ordinance changes or requests for variance at least 30 days prior to the date the local government is scheduled to take action on the proposed change or request (35 Ill. Adm. Code 742.1015(i)(4));

B. _____ will maintain a registry of all sites within its corporate limits that have received "No Further Remediation" determinations in reliance on the ordinance from the Illinois EPA (35 Ill. Adm. Code 742.1015(i)(5));

C. _____ will review the registry of sites established under paragraph II. B. prior to siting public potable water supply wells within the area covered by the ordinance (35 Ill. Adm. Code 742.1015(i)(6)(A));

D. _____ will determine whether the potential source of potable water has been or may be affected by contamination left in place at the sites tracked and reviewed under paragraphs II. B. and C. (35 Ill. Adm. Code 742.1015(i)(6)(B)); and

E. _____ will take action as necessary to ensure that the potential source of potable water is protected from contamination or treated before it is used as a potable water supply (35 Ill. Adm. Code 742.1015(i)(6)(C)).

NOTE: Notification under paragraph II. A. above or other communications concerning this MOU should be directed to:

Manager, Division of Remediation Management
Bureau of Land
Illinois Environmental Protection Agency
P.O. Box 19276
Springfield, IL 62794-9276

III. SUPPORTING DOCUMENTATION

The following documentation is required by 35 Ill. Adm. Code 742.1015(i) and is attached to this MOU:

A. Attachment A: A copy of the groundwater or water well ordinance certified by the city clerk or other official as the current, controlling law (35 Ill. Adm. Code 742.1015(i)(3));

B. Attachment B: Identification of the legal boundaries within which the ordinance is applicable (certification by city clerk or other official that the ordinance is applicable everywhere within the corporate limits; if ordinance is not applicable throughout the entire city or village, legal description and map of area showing sufficient detail to determine where ordinance is applicable) (35 Ill. Adm. Code 742.1015(i)(2));

C. Attachment C: A statement of the authority of the unit of local government to enter into the MOU (council resolution, code of ordinances, inherent powers of mayor or other official signing MOU -- attach copies) (35 Ill. Adm. Code 742.1015(i)(1)).

IN WITNESS WHEREOF, the lawful representatives of the parties have caused this MOU to be signed as follows:

FOR: _____
(Name of city or village)

BY: _____ DATE: _____
(Name and title of signatory)

FOR: Illinois Environmental Protection Agency

BY: _____ DATE: _____
Manager, Division of Remediation Management

ERRATA SHEET NUMBER 2

NOW COMES the Illinois Environmental Protection Agency through one of its attorneys, Kimberly Geving, and submits this ERRATA SHEET NUMBER 2 to the Illinois Pollution Control Board and the participants on the Service List. Please note that the errata changes reflect amendments to our proposal as submitted to the Board on February 15, 2008 and not to the existing rule.

Tom Hornshaw or Rick Cobb will provide testimony in support of these changes at the first hearing.

BEFORE THE ILLINOIS POLLUTION CONTROL BOARD

IN THE MATTER OF:	)	
	)	
GROUNDWATER	)	R08-18
QUALITY STANDARDS	)	
AMENDMENTS:	)	(Rulemaking-Public Water Supplies)
35 ILL. ADM. CODE 620	)	

TESTIMONY OF RICHARD P. COBB, P.G., ON NEW PROPOSED GROUNDWATER QUALITY STANDARDS

My name is Richard P. Cobb. I am a licensed professional geologist and the Deputy Manager of the Division of Public Water Supplies of the Illinois Environmental Protection Agency's ("EPA") Bureau of Water ("BOW"). My primary responsibilities include managing the Groundwater and Source Water Protection, Field Operations, and the Administrative Sections of the Division. Further, I assist with administering the public water supervision program under the federal Safe Drinking Water Act ("SDWA"). Additionally, my responsibility includes the integration of source water protection with traditional water supply engineering and treatment practices, and to further assist with linking Clean Water Act and SDWA programs. I also directly manage the BOW's Groundwater Section. The groundwater section applies Geographic Information System ("GIS") programs, global positioning system technology, hydrogeologic models (including, 3D geologic visualization, vadose zone, groundwater flow, particle tracking, solute transport, and geochemical models), and geostatistical programs for groundwater protection and remediation. I represent the BOW on Illinois EPA's Contaminant Evaluation Group, Strategic Management Planning Team, Environmental Justice Committee, Information Management Steering Committee, and GIS Steering Committee. Since 1985 I have worked on the development of legislation, rules, and regulations. I have also served as a primary Agency witness at Illinois

Pollution Control Board ("Board") proceedings in the matter of groundwater quality standards, technology control regulations, regulated recharge areas, maximum setback zones, clean-up regulations, and water well setback zone exceptions. Furthermore, I have served as a primary Agency witness in enforcement cases under these laws and regulations.

For further detail on my qualifications I have enclosed a copy of my Curriculum Vitae in Attachment I. This testimony, the statement of reasons, and attachments included with this testimony describe the basis for the proposed regulations.

I. PURPOSE OF THE PROPOSAL

The purpose of my testimony today is to provide the background required to propose new groundwater quality standards ("Standards") under Section 8 of the Illinois Groundwater Protection Act ("IGPA") (415 ILCS 55/8(b)(1) (1998)). The term Standards includes the nondegradation requirements for Class I and Class III groundwater as specified by the Board's adopted regulations at:

> SUBPART D: GROUNDWATER QUALITY STANDARDS
>
> Section 620.401 Applicability
>
> Groundwaters must meet the standards appropriate to the groundwater's class as specified in this Subpart and the nondegradation provisions of Subpart C.

Further, the Board's Groundwater Standards Final Opinion and Order (R89-14 (B)), November 1991, on Page 16 had this to say about nondegradation:

> It has sometimes been said that casting the nondegradation provision as it is today is equivalent to allowing pollution up to the standard. The Board believes that this characterization is too simplistic. Among other matters, the whole preventive notification and response program (see following) is directed toward an early alert to, and staving off of, **any increase in contamination in the sensitive groundwater/potential source situations.** (Emphasis added)

Dr. Thomas Hornshaw, Manager of the Illinois EPA's Toxicity Assessment Unit, will provide the supporting toxicological basis for the proposed groundwater standards where appropriate.

II. BACKGROUND

Since the inception of the Illinois Environmental Protection Act ("Act") in 1970, it has been the policy of the State of Illinois to restore, protect, and enhance the groundwater of the State as a natural and public resource. Groundwater has an essential and pervasive role in the social and economic well-being of Illinois, and it is vitally important to general health, safety, and welfare. Groundwater resources should be utilized for beneficial and legitimate purposes; waste and degradation of the resource should be prevented; and the underground water resource should be managed to allow for maximum benefit of the State. Groundwater used as drinking water is one of the highest beneficial uses of the groundwater resource. The IGPA defines "Resource groundwater" as groundwater that is presently being or in the future capable of being put to beneficial use by reason of being of suitable quality (415 ILCS 55/3(j)).

The Act included Sections 11 and 12(a). Section 11 describes part of the purpose of Title III, as follows:

> "...assure that no contaminants are discharged into waters without being given the degree of treatment or control necessary to prevent pollution."

Section 11(b) of the 2005 Act includes the same purpose statement. Water pollution was defined in Section 3(a) of the 1970 version of the Act the same as it is to this day. Moreover, Section 12(a) of the 1970 version of the Act includes the following:

> **" No person shall: (a) cause, threaten or allow the discharge of contaminants into the environment in any State so as to cause or tend to cause water pollution** in Illinois, either alone or in combination with matter from other sources,

> or so as to violate regulations or standards adopted by the Pollution Control Board under this Act." (Emphasis added)

The term "threat" in Section 12(a) of the Act established Illinois' original narrative nondegradation standard. The Board's final order and opinion, for 35 Ill. Adm. Code: Subtitle C, indicated that:

> "...Standards are **applicable to groundwaters that are a present or are a potential source of water for potable use or for food** processing, except where deviation is due to natural causes. It is significant to note that these standards **apply in situ; that is they are ambient water quality standards. They also apply irrespective of whether they are used by a public water supplier, a private water supplier, or have the potential for being so used.** (Emphasis added).

Additionally, the Board's opinion, in regard to *Water Quality Standards Revisions* (#R71-14), and *Water Quality Standards for Intrastate Waters* (SWB-14) (#R71-20) indicated the following:

> "203 General Standards. Today's revision is based upon the principle that **all waters should be protected against nuisances and against health hazards to those near them;** that all waters naturally capable of supporting aquatic life, with the exception of a few highly industrialized streams consisting primarily of effluents in the Chicago area, should be protected to support such life; **and that waters that are used for public water supply should be clean enough that ordinary treatment processes will assure their potability..."**
>
> "...**Since general criteria apply to all waters designated for public water supply**, the present regulation omits separate requirements for those parameters whose general standards are tight enough to protect public water supplies: boron, chromium, copper, fluoride, mercury, silver and zinc. The remaining standards are based largely upon Public Health Service standards, as amplified by the Green Book and by McKee and Wolf. While the PHS explicitly states that its standards are intended to prescribe the quality of finished rather than of raw water, **it is clear from the evidence that many of the metals and other contaminants here listed are not substantially affected by ordinary water supply treatment, and therefore, as the Green Book recommends, the raw water must itself meet the standard to assure satisfactory finished water." (Emphasis added)**

The phrase "ordinary treatment processes", emphasized in the Board's opinion above, is one of the keys to understanding Illinois' nondegradation requirements for groundwater. First, it is

important to note that there is a significant difference between what is considered ordinary treatment processes for surface water versus groundwater sources of drinking water. All community water systems ("CWS") using surface water apply coagulation, sedimentation, filtration, disinfection, and treatment for taste and odor. Private drinking water systems do not use surface water as a source of drinking water, due to the inherent vulnerability of surface water resources to contamination and the associated cost for treating such water. A private drinking water system is defined as a system that serves an owner occupied single family dwelling (415 ILCS 55/9(a)). Secondly, there is a significant difference between what is considered ordinary treatment processes for a small CWS using groundwater versus a private drinking water system well. The small CWS using groundwater has more treatment infrastructure resources available than the owner of a private well. Lastly, a private well owner typically only has to chlorinate his or her well to use the groundwater for potable uses. Thus, this defines the lowest common denominator of what ordinary treatment processes means to the protection of Class I: Potable Resource Groundwater. In other words, the Act and Board regulations prohibit a person from causing, threatening or allowing contamination of potable resource groundwater above what is not removed by ordinary treatment processes in a private drinking water system well. For example, a plume of tritium at a concentration above background or naturally occurring levels, moving toward a private drinking water system well, is considered a threat to diminishing the existing Class I groundwater resource, since tritium cannot be removed by advanced treatment processes let alone ordinary treatment processes. This diminishment of resource groundwater (415 ILCS 55/3(j)) may lead to preclusion of the use of the well if the private well owner chooses not to use it (e.g., suitability) due to the contamination.

The Illinois Supreme Court also determined the following in *Central Illinois Public Service Company v. Pollution Control Board*, 116 Ill.2d 397:

> The Board, at the outset, disagrees with CIPS' interpretation of the definition of water pollution in the Act. **The Board argues that the Act treats water as a resource, and that pollution occurs whenever contamination is likely to render water unusable. Under the Board's interpretation there is not need to show that harm *will* occur, only that harm *would* occur if the contaminated water were to be used.** Since the Board is charged with administering the Environmental Protection Act, its interpretation of the statute is entitled to deference. (*Massa v. Department of Registration & Education* (1987), 116 Ill.2d 376, 107 Ill.Dec, 661, 507 N.E.2d 814; *Illinois Consolidated Telephone Co. v. Illinois Commerce Com.* (1983), 95 Ill.2d 142, 152, 69 Ill.Dec. 78, 447 N.E.2d 295.) **Under the Board's view any contamination which prevents the State's water resources from being usable would constitute pollution, thus allowing the Board to protect those resources from necessary diminishment.** CIPS' interpretation, on the other hand would mean that water rendered unusable would not be polluted so long as use of the water ceased subsequent to contamination. **We find the Board's interpretation preferable to CIPS' interpretation, especially considering the deference we must accord to the Board.** (Emphasis added)

The Illinois EPA framed and the Board adopted the following after the legal cornerstones detailed above:

> Section 620.301 General Prohibition Against Use Impairment of Resource Groundwater
>
> a) **No person shall cause, threaten or allow the release of any contaminant to a resource groundwater such that:**
>
> 1) Treatment or additional treatment is necessary to continue an existing use or to assure a potential use of such groundwater; or
>
> **2) An existing or potential use of such groundwater is precluded.** (Emphasis added)

In summary, the conclusions and facts, provided above, clearly provide the supporting foundation for Standards, as follows:

- The original Act and regulations establish that no person shall discharge contaminants that threaten, cause or allow contamination;
- The intent of this multi-tiered standard is to prevent degradation of the resource up to the numerical standard;
- The Board clearly established that current and potential sources of potable resource groundwater were to be protected;
- Section 12(a) of the Act is integrated with Board regulations to prohibit polluting up to the numerical standards in such regulations;
- The Board's opinions in the matters, quoted above, indicate that resource groundwater should be protected such that a private water supply would be able to obtain clean drinking water through ordinary treatment processes;
- The Board's opinion on Illinois' Groundwater Protection Plan is "...that unreasonable waste and degradation of the resources be prohibited;"
- Public Act 85-863 indicates that waste and degradation of the resources be prevented and includes this as a factor that the Board must consider in adopting comprehensive groundwater quality standard regulations;
- The Illinois Supreme Court has upheld the Board's view that any contamination that prevents the State's water resources from being usable would constitute pollution, thus allowing the Board to protect those resources from unnecessary diminishment; and
- The Board's final opinion and order on groundwater quality standards indicates that the numerical standard is not meant to be a level to pollute up to and included

specific preventive standards prohibiting contamination above detectable levels that threaten a preclusion of use.

III. CONTAMINANTS COMMONLY DETECTED IN ILLINOIS GROUNDWATER

The Illinois EPA evaluated the electronically reported groundwater data for all Illinois Resource Conservation and Recovery Act ("RCRA") and Solid Waste facilities under our purview. The Illinois EPA Bureau of Land ("BOL") Permit Section provides regulatory oversight for these facilities. A data query was conducted for a list of approximately 300 groundwater parameters not included in 35 Ill. Adm. Code 620, Subpart C. The data set evaluated spanned from April 1984 to April 2004. Illinois EPA has also evaluated confirmed groundwater contaminants at various cleanup sites.

The Illinois EPA is proposing a groundwater standard for perchlorate based on the new reference dose published by United States Environmental Protection Agency ("U.S. EPA") and recommended by the National Academy of Science ("NAS"). The Illinois EPA proposes to use the default Relative Source Contribution ("RSC") term of 20 percent. Additionally, Illinois EPA is proposing an amendment to the existing groundwater standard of 0.050 milligrams per liter ("mg/l") for arsenic based on the amendment of the federal drinking water standard or maximum contaminant level ("MCL") for arsenic to 0.010 mg/l. The Board MCL for drinking water has already been amended to 0.010 mg/l at 35 Ill. Adm. Code 611.301.

Arsenic is a naturally occurring element in the earth's crust. Arsenic is found in the deep bedrock materials throughout Illinois, as well as in the shallow glacial materials that cover the northern two-thirds of the State. Arsenic is dissolved naturally from these materials and enters groundwater. For further detail, see *Arsenic in Illinois Groundwater*, developed by Rick Cobb,

Ken Runkle of IDPH and Steve Wilson of the Illinois State Water Survey ("ISWS"), published on November 20 2001, in Attachment II and at http://www.epa.state.il.us/water/groundwater/publications/arsenic/index.html.

There are also a number of incorporations by reference that need to be updated in the Board's groundwater quality standards regulation.

IV. THE AGENCY'S PROPOSAL

A. Section 620.110 Definitions

Illinois EPA proposes that the federal register reference (56 Fed. Reg. 3526-3597) in the Method Detection Limit ("MDL") portion of the "Detection" definition should be replaced by 40 CFR Part 136, Appendix B (2006) citation.

Illinois EPA also proposes to add the "Wellhead protection area" or "WHPA" definition from 35 Ill. Adm. Code 611.101 to 35 Ill. Adm. Code 620.110. This definition is used in conjunction with 2 new proposed incorporations by reference. These new provisions support an amendment to Subsection 620.505(a)(5) for enhancing the hydrogeologic processes in that Section. A WHPA represents a CWS well's recharge area delineated beyond an applicable setback zone, as described in Subsection 17.1(a)(2) of the Act (415 ILCS 5/17.1(a)(2)). Hydrogeologists refer to this as a "contributing recharge area." Groundwater modelers also call this a "capture zone." These terms are used interchangeably by hydrogeologists. In addition, the definition of "Wellhead Protection Program" ("WHPP"), also codified by the Board under 35 Ill. Adm. Code 611.101, is also proposed to be added here since it elaborates on the definition of WHPA, and the two new incorporations by reference that are being proposed. This existing Board definition also provides the nexus between a WHPP and a groundwater protection needs assessment.

There were also amendments made to existing Board definitions due to the revisions of the cross referenced citations in the Act.

B. Section 620.125 Incorporations by Reference

There are new references that need to be added to the Incorporations by Reference in the Board's Standards. The American Society for Testing and Materials ("ASTM") standard has been revised. Further, changes have been proposed because the Federal Register citations have been codified into the Code of Federal Regulations ("CFR"). In addition, many new supplements have been adopted and included in 40 CFR. Additionally, original references have been updated. Further, the sources from which this information is obtained has changed and has been revised. Illinois also proposes a new incorporation by reference to include Illinois' Approved Wellhead Protection Program Document and Guidance Document for Groundwater Protection Needs Assessment because they are used to improve hydrogeologic assessment aspects of Section 620.505 Compliance Determination provisions.

C. The word "or" needs to be deleted from Section 620.201(a)(4).

D. Section 620.310(a)(3)(A)(ii) Preventive Response Activities

Illinois EPA proposes that the Board amend this subsection to include preventive response levels for the following contaminants, which are not classified as carcinogens, with proposed Class I standards based on a statistical increase above background:

> Acenaphthene; acetone; anthracene; benzoic acid; carbon disulfide; 2-butanone (MEK); dicamba, dichlorodifluoromethane; 1,1-dichloroethane; diethylphthalate; di-n-butyl phthalate; di-n-octylphthalate; fluoranthene; fluorine; isopropylbenzene (Cumene); MCPP (Mecoprop); 2-methylnaphthalene; 2-methylphenol; molybdenum; naphthalene; pyrene; trichlorofluoromethane; and vanadium.

E. Section 620.410(a)

The standards proposed below are based on either a U.S.EPA or Board MCL, a reference dose ("RfD") in U.S. EPA's Integrated Risk Information System ("IRIS"), U.S. EPA Health Effects Assessment Summary Table ("HEAST") RfD, Provisional Peer Reviewed Toxicity Values ("PPRTV") RfD, IRIS Slope Factor ("SFo"), or MDL used to derive the 35 Ill. Adm. Code 620, Subpart F, Appendix A: Human Threshold Toxicant Advisory Concentration for Tiered Approach for Correction Objectives ("TACO") (35 Ill. Adm. Code 742) groundwater ("GW") objectives. In addition, we are proposing to amend the existing Subpart F procedures to establish a new procedure that utilizes a 10^{-6} risk level versus the default PQL that was used in the 1980's. Many of the PQLs have dropped significantly and may be well below the respective10-6 risk level. Since 1991, the 10^{-6} risk level has become widely accepted and is used in the Board's TACO regulations. In addition to the 10^{-6} risk level, water solubility is being proposed as a factor. If an organic chemical is present at concentrations in groundwater exceeding its solubility a two-phase system may exist, and the behavior and migration of the chemical in such a system may be difficult to predict. Thus, the water solubility is the proposed basis for several contaminants where the 10^{-6} risk level exceeds water solubility. Dr. Hornshaw's testimony will go into more detail on these proposed amendments.

Carcinogens are denoted in the proposed Class I standards by an asterisk ("*"). Illinois EPA proposes that the Board amend Subsection 620.410(a) to include a Class I: Potable Resource Groundwater Standard for the following inorganic contaminants listed below:

Inorganic Chemicals *Denotes a carcinogen	Proposed Class I Standard (mg/l)	Basis
Arsenic*	0.010	Board and U.S. EPA MCL
Molybdenum	0.035	IRIS RfD
Perchlorate	0.0049	IRIS RfD
Vanadium	0.049	TACO GW Objective

F. Section 620.410(b)

The Illinois EPA proposes to the Board that this subsection be amended to include a Class I: Potable Resource Groundwater Standard for the following organic contaminants:

Volatile Organic Compounds ("VOCs") * Denotes a carcinogen	Proposed Class I Standard (mg/l)	Basis
Acetone	6.3	TACO GW Objective
2-Butanone (MEK)	4.2	IRIS RfD
Carbon disulfide	0.7	TACO GW Objective
Chloroform*	0.0002	TACO GW Objective
Dichlorodifluoromethane	1.4	IRIS RfD
1,1-Dichloroethane	1.4	PPRTV RfD
Isopropylbenzene (Cumene)	0.7	IRIS RfD
Trichlorofluoromethane	2.1	IRIS RfD

Semivolatile Organic Compounds * Denotes a carcinogen	Proposed Class I Standard (mg/l)	Basis
Acenaphthene	0.42	TACO GW Objective
Anthracene	0.043	Water Solubility
Benzo(a)anthracene*	0.00013	TACO GW Objective
Benzo(b)fluoranthene*	0.00018	TACO GW Objective
Benzo(k)fluoranthene*	0.00017	TACO GW Objective
Benzoic acid	28.0	TACO GW Objective
Chrysene*	0.0063	Water Solubility
Dibenzo (a,h,) anthracene*	0.0003	TACO GW Objective
Diethyl phthalate	5.6	TACO GW Objective
Di-n-butyl phthalate	0.7	TACO GW Objective
Di-n-octyl phthalate	0.02	Water Solubility
Fluoranthene	0.21	Water Solubility
Fluorene	0.28	TACO GW Objective
Indeno(1,2,3-cd)pyrene*	0.000022	Water solubility

2-Methylnaphthalene	0.028	IRIS RfD
2-Methylphenol	0.35	TACO GW Objective
Naphthalene	0.14	TACO GW Objective
p-Dioxane*	0.0077	10^{-6} cancer risk
Pyrene	0.21	TACO GW Objective
Pesticides/PCBs * Denotes a carcinogen		
alpha-BHC*	0.00011	TACO GW Objective
Dicamba	0.21	IRIS RfD
MCPP (Mecoprop)	0.007	IRIS RfD

G. Section 620.410(c)

The Illinois EPA proposes that the Board amend the Class I: Potable Resource Groundwater Standards to include a new subsection to for the following explosive contaminants:

Explosives * Denotes a carcinogen	**Proposed Class I Standard (mg/l)**	**Basis**
1,3-Dinitrobenzene	0.0007	IRIS RfD
2,4-Dinitrotoluene*	0.0001	10^{-6} Cancer risk level
2,6-Dinitrotoluene*	0.00031	TACO GW Objective
HMX	1.4	IRIS RfD
Nitrobenzene	0.0035	TACO GW Objective
RDX	0.084	IRIS RfD
1,3,5-Trinitrobenzene	0.84	IRIS RfD
2,4,6-Trinitrotoluene	0.014	IRIS RfD

H. Section 620.420(a)

The final opinion and order of the Board (Docket R89-14(B)), for establishing Class II groundwater quality standards (35 Ill. Adm. Code 620), published November 7, 1991, pages 19 and 20 states that:

> Section 620.420 establishes standards for Class II: General Resource Groundwaters. Because groundwaters are placed in Class II because they are quality-limited, quantity-limited, or both (see Subpart B discussion above), it is necessary that the standards that apply to these waters reflect this range of possible attributes. Among the factors considered in determining the Class II numbers are the capabilities of

treatment technologies to bring Class II waters to qualities suitable for potable use (R3 at 75) ["R3" means the transcript from the Board's May 1991 hearing on this matter, and "at 75" is page 75]. Thus, many Class II standards are based on MCL's as modified to reflect treatment capabilities. For some parameters the Class II standards are based on support of a use other then potability (e.g., livestock water, irrigation, industrial use) where a different use requires a more stringent standard (R3 at 1148)).

The same principle is applied to these proposed Class II standards here today. The standards proposed below are based on irrigation and livestock watering from the National Academy of Sciences, 1972, *Water Quality Criteria*.

Illinois EPA proposes that Subsection 620.410(a) be amended to include a Class II: General Resource Groundwater Standard for the following inorganic chemicals:

Inorganic Chemicals	Reference Proposed Class I Standard (mg/l)	Proposed Class II Standard (mg/l)	Basis for Class II
Arsenic	0.010	0.2	Irrigation
Molybdenum	0.035	0.035	Class I standard (Irrigation criterion is 10)
Perchlorate	0.0049	0.0049	0X
Vanadium	0.049	0.1	Irrigation

I. Section 620.420(b)

Most of the original groundwater standards for organic compounds were based on U.S. EPA MCLs. Best Available Treatment ("BAT") technology removal efficiencies are published in the CFR and 35 Ill. Adm. Code 611, Subpart F. However, none of the contaminants in this proposal, with the exception of arsenic standard, has a codified MCL. Thus, the Illinois EPA used some of the same factors used by U.S. EPA to develop BAT surrogates.

Air Stripping - Due to the high volatility of many of the organic compounds, air stripping is an efficient and cost effective treatment technology (35 Ill. Adm. Code 611, Subpart F). Air

stripping is a proven, effective means to remove VOCs from groundwater as detailed in 35 Ill. Adm. Code 611, Subpart F. Less volatile compounds (e.g., low Henry's Law Constants) are not as easily removed via air stripping (Canter, L.W., and R.C. Knox, 1985, (*Ground water pollution control*, Lewis Publishers). In contrast, compounds with lower Henry's Law Constants are more difficult to remove by air stripping than compounds with high constants. Methylene chloride has one of the lowest Henry's Law Constants at 8.98 X 10^{-2} unit less at 20° Celsius ("C") (35 Ill. Adm. Code 742) in comparison to other VOCs. Where multiple VOCs are present, the compound with the lowest Henry's Law Constant will generally be the limiting compound in the design of the air stripper.

Carbon Adsorption - Carbon adsorption is also is an efficient and cost effective treatment technology (35 Ill. Adm. Code 611, Subpart F) for removing various organic contaminants. Activated carbon is widely used to remove organic compounds (American Water Works Association, 1995, *Water Treatment*). The process of adsorption onto activated carbon requires the contaminated groundwater to come into contact with carbon, which selectively adsorbs organic constituents by a surface attraction phenomenon (due to chemical and physical properties). The organic molecules are attracted to the internal pores of the carbon granules (U.S. EPA, 1989). A coefficient referred to as partition or sorption coefficient (Log K_{oc}) represents the ratio of adsorbed chemical per unit weight of organic carbon to the aqueous concentration (Montgomery, J.H., and L.M. Welkom, 1995, *Groundwater chemicals desk reference*, Volume I, Lewis Publishers.). This value provides an indication of the tendency of a chemical to partition between organic carbon particles and water (Montgomery, 1995). Compounds that bind strongly to organic carbon have characteristically low solubilities, whereas compounds, such as methyl

tertiary butyl ether ("MTBE"), with low tendencies to adsorb to organic particles have high solubilities. Correlations between K_{oc} and the solubility of organic compounds in water have shown a log-log linear relationship (Montgomery, 1995).

Treatment Factor - A five fold treatment factor ("5X") was used to derive a proposed Class II standard for organic compounds with a K_{oc} value greater than (>) ethylbenzene's K_{oc} of 363 liters per kilogram at 20° C or a Henry's Law constant greater than methylene chloride's (8.98 X 10^{-2} unit less at 20° C). A five fold treatment factor equates to a removal efficiency of 80%. This is a very economical approach, since most of the BATs achieve a 99% removal rate. The Class I standard was proposed where either or both were below the factors detailed above.

Illinois EPA proposes that the Board amend Subsection 620.420(b) to include a Class II: General Resource Groundwater Standard for the following organic compounds:

Volatile Organic Compounds	Reference Proposed Class I Standard (mg/l)	Proposed Class II Standard (mg/l)	Basis For Class II
Acetone	6.3	6.3	TACO GW Objective
2-Butanone (MEK)	4.2	4.2	0X
Carbon disulfide	0.7	3.5	TACO GW Objective
Chloroform	0.0002	0.001	TACO GW Objective
Dichlorodifluoromethane	1.4	7.0	5X
1,1-Dichloroethane	1.4	7.0	5X
Isopropylbenzene (Cumene)	0.7	3.5	5X
Trichlorofluoromethane	2.1	10.5	5X
Semivolatile Organic Compounds			
Acenaphthene	0.42	2.1	TACO GW Objective
Anthracene	0.043	0.043	Water Solubility
Benzo(a)anthracene	0.00013	0.00065	TACO GW Objective
Benzo(b)fluoranthene	0.00018	0.0009	TACO GW Objective
Benzo(a)pyrene	0.0002	0.0016	Water Solublity
Benzo(k)fluoranthene	0.00017	0.0008	Water Solubility
Benzoic acid	28.0	28.0	TACO GW Objective
Chrysene	0.0063	0.0063	Water Solubility

Diethyl phthalate	5.6	5.6	TACO GW Objective
Dibenzo (a,h,) anthracene	0.0003	0.0015	TACO GW Objective
Di-n-butyl phthalate	0.7	3.5	TACO GW Objective
Di-n-octyl phthalate	0.02	0.02	Water Solubility
Fluoranthene	0.21	0.21	Water Solubility
Fluorene	0.28	1.4	TACO GW Objective
Indeno(1,2,3-cd)pyrene	0.000022	0.000022	Water Solubility
2-Methylnaphthalene	0.028	0.14	5X
2-Methylphenol	0.35	0.35	TACO GW Objective
Naphthalene	0.14	0.22	TACO GW Objective
p-Dioxane	0.0077	0.0077	10^{-6} Cancer risk
Pyrene	0.21	1.05	TACO GW Objective
Pesticides/PCBs			
alpha-BHC	0.00011	0.00055	TACO GW Objective
Dicamba	0.21	0.21	0X
MCPP (Mecoprop)	0.007	0.035	5X
Methoxychlor	0.04	0.045	Water Solubility

In addition, the existing Class II standard for Benzo(a)pyrene should be amended to 0.0002 mg/l based on its water solubility. Additionally, the Class II standard for Methoxychlor should be amended to 0.045 mg/l based on its water solubility.

J. Section 620.420(c)

This new subsection has been amended to propose a Class II: General Resource Groundwater Standard for the following explosive compounds:

Explosives	Reference Proposed Class I Standard (mg/l)	Proposed Class II Standard (mg/l)	Basis
1,3-Dinitrobenzene	0.0007	0.0007	0X
2,4-Dinitrotoluene	0.0001	0.0001	0X
2,6-Dinitrotoluene	0.00031	0.00031	TACO GW Objective
HMX	1.4	1.4	0X
Nitrobenzene	0.0035	0.0035	0X
RDX	0.084	0.084	0X
1,3,5-Trinitrobenzene	0.84	0. 84	0X
2,4,6-Trinitrotoluene	0.014	0.014	0X

K. Section 620.440 Groundwater Quality Standards for Class IV: Other Groundwater

Explosives are used during various phases of mining. It is not expected that residuals of explosive contaminants will even be detectable after reclamation has been completed for a previously mined area (e.g., excavation left after the coal seam(s) have been removed). However, the Illinois EPA and the Office of Mines and Minerals believe it is important to establish a Class IV standard for explosives within previously mined areas. Designation of a previously mined area is being proposed because it moves the compliance point from the pit of the mine to the boundary of the permitted area. This is necessary because we want to establish a monitoring point that will assess the potential for off-site contamination of resource groundwater beyond the permitted boundary. The alternative would establish a compliance point in the pit of the mine. We already know, expect, and accept that this area would be impacted by TDS, sulfate and other contaminants listed in Class IV previously mined areas. It is simply an environmental cost of doing coal mining. In addition, setting a compliance point at the permitted boundary is certainly consistent with monitoring programs under other Board regulations such as the solid waste landfill monitoring requirements.

L. Section 620.450 Alternative Groundwater Quality Standards

Section 620.450(b) establishes the applicable coal reclamation groundwater standards. A new Subsection 620.450(b)(3)(D) is proposed to include explosive contaminants. Thus, the existing concentration of these contaminants, if present post reclamation, is proposed to be the applicable standard within the permitted area. This establishes an appropriate compliance point for resource groundwater beyond the permitted area.

M. Section 620.505(a)(5)

Section 620.505 contains the provisions for determining compliance with the Board's groundwater quality standards. Appropriate monitoring points are selected based on the ability to represent groundwater quality accurately. When this Section was originally drafted and ultimately adopted by the Board in 1991, the Groundwater Protection Needs Assessment ("GPNA") provisions of the Act (415 ILCS 5/17.1) had not been fully developed or implemented. In addition, Illinois' WHPP had not yet been approved by U.S. EPA. Further, not much progress had been made with delineations during subsequent groundwater standards update proceedings. However, as a result of the source water assessment requirements and grant funding available under the 1996 SDWA amendments, over 300 WHPA's have been delineated beyond the applicable setback zones for CWS wells. These delineations have been conducted based on Illinois' *Guidance Document for Conducting Groundwater Protection Needs Assessments* and Illinois' approved WHPP. Therefore, this proposed amendment is intended to utilize this new hydrogeologic data where it is available.

Before proceeding it is important to provide some historical background. The 1986 amendments to the SDWA required States to develop and implement WHPPs after approval by U.S. EPA. In 1987, U.S. EPA published its *Guidelines for Delineation of Wellhead Protection Areas.* The development of U.S. EPA's WHPA delineation guidance included a *Model Assessment for Delineating Wellhead Protection Areas.* Paul van der Heijde of the International Ground-Water Modeling Center ("IGWMC") conducted this assessment for U.S. EPA. After the SDWA requirements in 1986 to delineate WHPAs and the subsequent requirements to provide recharge area delineation technical assistance under Illinois law in 1987, the ISWS developed new models, such as GWPATH (Shafer, J.M., 1987, *Reverse pathline calculation of time-related capture zones in nonuniformflow*, Ground Water, v. 25, no. 3, pp. 283-289) and conducted

research pursuant to Section 7 of the IGPA (415 ILCS 55/7(b)(4)) that further advanced WHPA modeling techniques (Wehrmann, H.A., and M.D. Varljen, 1990, *A comparison between regulated setback zones and estimated recharge areas around several municipal wells in Rockford*, IL, Proceedings of the NWWA 1990 Conference, February 20-21, 1990, Kansas City, MO. pp. 497-511).

The ISWS, Illinois State Geological Survey ("ISGS"), and the Illinois EPA collaborated to develop a nexus between WHPAs, and the delineation requirements under the Act, so that one approach would meet both requirements. The hydrologic term that describes the recharge area of a pumping well is referred to as a "contributing recharge area" because it is a subset of an overall aquifer recharge area supplying groundwater to a well. Another term used to describe a contributing recharge area is referred to as a capture zone. Capture zone models predict the pathlines of groundwater flow that contribute recharge to a pumping well. The outline of a capture zone, containing pathlines, is a WHPA or contributing recharge area. A time of travel ("TOT") can also be related to a capture zone. Illinois uses the 5-year TOT travel as the minimum threshold for WHPA delineations. This approach was presented to the Interagency Coordinating Committee on Groundwater ("ICCG") (415 ILCS 55/4) and the Groundwater Advisory Council ("GAC") (415 ILCS 55/5). After ICCG and GAC approval, this was presented to U.S. EPA for their approval. U.S. EPA fully approved Illinois' WHPP in1991.

The Illinois EPA and the surveys then collaborated on four pilot GPNA projects, starting in 1991, to further develop the technical basis for WHPA delineation. Pilot GPNA's were conducted for the following CWSs: Pleasant Valley Public Water District ("PWD"); Village of Cary; Village of Woodstock; and City of Pekin. These sites were purposely chosen because of their location within two priority groundwater protection planning regions, established by the ICCG and GAC,

and based on the hydrogeologic data provided by *Illinois Potential for Aquifer Recharge Map,* developed by the ISWS and ISGS pursuant to Subsections 17.2(a) and 17.2(b) of the Act.

Another reason for choosing the City of Pekin for a pilot GPNA was that the ISWS was conducting research specifically on the uncertainty associated with modeling WHPAs at the Pekin wells (Varljean, M.D., and J.M. Shafer, October 1991, *Assessment of Uncertainty in Time-Related Capture Zones Using Conditional Simulation of Hydraulic Conductivity,* Ground Water, v. 29, no. 5, pp. 737-748). This allowed for further collaboration between the ISWS and Illinois EPA on developing and applying appropriate WHPA modeling techniques.

The industry standard United States Geological Survey ("USGS"), numerical groundwater flow model ("MODFLOW"), and groundwater pathline model ("MODPATH") was used on these pilot projects. The IGWMC's WHPA modeling assessment (van der Heijde, P.K.M, 1988, *Model Assessment for Delineating Wellhead Protection Areas)* document, evaluated the usability and the reliability of these USGS models. Evaluation of reliability included if: 1) the model's theory and coding had been "peer reviewed"; 2) if the models had been "verified"; and 3) if these models had been "field validated". MODFLOW and MODPATH met all of these criteria.

MODFLOW and MODPATH were used to delineate the WHPAs for Pekin, Cary, and Pleasant Valley PWD GPNAs. The Illinois EPA and the ISWS worked on the development of the Pekin flow model, Clark Engineers developed the Pleasant Valley PWD model, and Baxter and Woodman developed the model for the Village of Cary. The Woodstock pilot, conducted by the ISGS, focused on geologic mapping techniques that can be used in the GPNA (Berg, R.C. 1994. *Geologic Aspects of a Groundwater Protection Needs Assessment for Woodstock, Illinois*: Illinois State Geological Survey Environmental Geology 146).

Illinois EPA worked with the Central Groundwater Protection Planning Committee, designated by our Director pursuant to Section 17.2 of the Act, and comprised of local stakeholders, to develop a local overlay zoning ordinance based on the Pekin WHPA. The Central Committee facilitated working with the City of Pekin, the Illinois American Water Company, local business, and other interest groups to develop and adopt Pekin's WHPA ordinance. The ordinance was adopted by the Pekin City Council in 1995.

Following the implementation of the pilot GPNA's the Illinois EPA, ISGS and ISWS began work on the development of *A Guidance Document for Conducting Groundwater Protection Needs Assessments* that was published 1995. The WHPA delineation process described in this guidance document was based on: 1) the ISWS's vast experience (For example; ASTM's *Standard Guide for Subsurface Flow and Transport Modeling,* ASTM 5880-95, was based in part on ISWS's ground breaking modeling work done in the late 60's and early 70's); 2) U.S. EPA's *Guidelines for Delineation of Wellhead Protection Areas;* 3) IGWMC's *Model Assessment for Delineating Wellhead Protection Areas;* and 4) the four pilot GPNAs.

The Illinois EPA used the WHPA modeling conducted for the Pleasant Valley PWD to develop a regulated recharge area proposal for submission to the Board. The Illinois EPA prepared this proposal in response to a request from the Central Committee pursuant their authority under Section 17.3 of the Act. Illinois EPA must prepare a proposal in response to a regional committee request. The Board held a series of hearings at which the WHPA modeling techniques were discussed in detail. Illinois' *Guidance Document for Conducting Groundwater Protection Needs Assessments* was included as an attachment to my testimony in that proceeding. The Board adopted a regulated recharge area for Pleasant Valley based on Illinois' WHPA modeling, which became effective September 1, 2001.

The Village of Marquette Height's maximum setback zone proposed by the Illinois EPA and adopted by the Board on May 4, 2007 was based Illinois' WHPA modeling. This proposal was also based on a recommendation from the Central Committee.

In summary, Illinois' *Guidance Document for Conducting Groundwater Protection Needs Assessments* is used to provide technical assistance on how to conduct WHPA modeling pursuant to Subsection 17.1(i) of the Act. Moreover, over 300 WHPA's have been delineated on a state wide basis for CWS wells using these processes.

The amendment to this subsection is intended to utilize the hydrologeologic information where WHPAs have been delineated for CWS wells according to the hydrogeologic procedures in a *Guidance Document for Conducting Groundwater Protection Needs Assessments.*

N. Section 620.510

The proposed amendments to the monitoring and analytical requirements are a result of the updates and revisions to the incorporations by reference in Section 620.125.

O. Section.620.605

The federal register citations have been updated to the relevant Code of Federal Regulation references.

P. Section 620.Appendix A

Section 620.Appendix A(b)(2) has also been amended to replace federal register with 40 CFR citations.

Q. Section 620.Appendix A

Section 620.Appendix A(b)(2) has also been amended to replace federal register with 40 CFR citations.

Dr. Hornshaw will provide testimony on further changes to Subpart F.

V. CONCLUSION

This concludes my testimony. I will be happy to address any questions.

ATTACHMENT I - CURRICULUM VITAE of RICHARD P. COBB, P.G.

Work Experience

Deputy Manager, Division of Public Water Supplies (DPWS), Bureau of Water (BOW), Illinois Environmental Protection Agency (EPA). (5/02- Present) My primary responsibilities include managing the: Groundwater Section, Field Operation Section, and the Administrative Support Unit of the Division. Further, I assist with administering the public water supervision program under the federal Safe Drinking Water Act ("SDWA") and the Wellhead Protection Program ("WHPP") approved by the United States Environmental Protection Agency ('U.S. EPA"). Additionally, my responsibility includes the integration of source water protection with traditional water supply engineering and treatment practices, and to further assist with linking Clean Water Act and SDWA programs. I also directly manage the BOW's Groundwater Section. The Groundwater Section applies Geographic Information System ("GIS") programs, global positioning system ("GPS") technology, hydrogeologic models (3D geologic visualization, vadose zone, groundwater flow, groundwater particle tracking, solute transport, and geochemical models), and geostatistical programs for groundwater protection and remediation projects. The Groundwater Section also continues to operate a statewide ambient groundwater monitoring program for the assessment of groundwater protection and restoration programs. I also do extensive coordination with federal, state and local stakeholders including the Governor appointed Groundwater Advisory Council ("GAC"), the Interagency Coordinating Committee on Groundwater ("ICCG"), four Priority Groundwater Protection Planning Committees, Illinois Source Water Protection Technical and Citizens Advisory Committee, and with the Ground Water Protection Council ("GWPC"), Association of State Drinking Water Administrators ("ASDWA"), and the Association of State and Interstate Water Pollution Control Administrators ("ASWIPCA") to develop and implement groundwater protection policy, plans, and programs. I represent the BOW on Illinois EPA's: Contaminant Evaluation Group ("CEG"); Strategic Management Planning Team; Environmental Justice Committee; Information Management Steering Committee; and the GIS Steering Committee. Since starting with Illinois EPA in 1985, I have worked on the development of legislation, rules and regulations. I have also served as a primary Illinois EPA witness before Senate and House legislative committees, and at Illinois Pollution Control Board ("Board") proceedings in the matter of groundwater quality standards, technology control regulations, cleanup regulations, regulated recharge areas, maximum setback zone, and water well setback zone exceptions. Furthermore, I have served as primary Illinois EPA witness in enforcement matters.

Manager, Groundwater Section, DPWS, BOW, Illinois EPA. (9/92-5/02) My primary responsibilities included development and implementation of Illinois statewide groundwater quality protection, USEPA approved WHPP, and source water protection program. The Groundwater Section worked with the United States Geological Survey ("USGS") to refine Illinois EPA's ambient groundwater monitoring network using a random stratified probability based design. The Groundwater Section continued to operate a statewide ambient groundwater monitoring program for the assessment of groundwater protection and restoration programs based on the new statistically-based design. I co-authored a *Guidance Document for Conducting*

Groundwater Protection Needs Assessments with the Illinois State Water and Illinois State Geological Surveys. I also continued to conduct extensive coordination with federal, state and local stakeholders including the Governor appointed GAC, the ICCG, four Priority Groundwater Protection Planning Committees, Illinois Source Water Protection Technical and Citizens Advisory Committee, and at the national level as Co-chair of the GWPC Ground Water Division to develop and implement groundwater protection policy, plans, and programs. I also served periodically as Acting Manager for the Division of Public Water Supplies. Additionally, the Groundwater Section provided hydrogeologic technical assistance to the BOW Permit Section and Mine Pollution Control Program to implement source water protection, groundwater monitoring and aquifer evaluation and remediation programs. I continued to work on the development of legislation, rules and regulations. I also served as a primary Illinois EPA witness at Board proceedings in the matter of groundwater quality standards, technology control regulations, regulated recharge areas and water well setback zone exceptions. Furthermore, I served as an Agency witness in enforcement matters.

Acting Manager, Groundwater Section, DPWS, BOW, Illinois EPA. (7/91-9/92) My responsibilities included continued development and implementation of Illinois statewide groundwater quality protection, U.S. EPA approved WHPP, and ambient groundwater monitoring program. The Groundwater Section developed the Illinois EPA's WHPP pursuant to Section 1428 of the SDWA and was fully approved by U.S. EPA. Illinois EPA was the first state in U. S. EPA Region V to obtain this approval. I performed extensive coordination with state and local stakeholders including the Governor appointed GAC, the ICCG to develop and implement groundwater protection, plans, policy, and programs. Developed and implemented the establishment of Illinois' Priority Groundwater Protection Planning Committees. Developed and implemented Pilot Groundwater Protection Needs Assessments. The Groundwater Section also provided hydrogeologic technical assistance to the BOW Permit Section and Mine Pollution Control Program staff to develop groundwater monitoring and aquifer evaluation, remediation and/or groundwater management zone programs. I also served as a primary Agency witness at Board proceedings in the matter of groundwater quality standards and technology control regulations. Additionally, I served as an Agency total quality management ("TQM") facilitator, and TQM trainer.

Manager of the Hydrogeology Unit, Groundwater Section, DPWS, Illinois EPA (7/88-7/91) Managed a staff of geologists and geological engineers that applied hydrogeologic and groundwater modeling principals to statewide groundwater protection programs. Developed, and integrated the application of GIS, GPS, geostatistical, optimization, vadose zone, solute transport, groundwater flow and particle tracking computer hardware/software into groundwater protection and remediation projects. Conducted extensive coordination with state and local stakeholders including the Governor appointed GAC and ICCG to develop and implement groundwater protection policy, plans, and programs. Developed and implemented a well site survey program to inventory potential sources of contamination adjacent to community water supply wells. Additionally, I worked on the development of rules to expand setback zones based on the lateral area of influence of community water supply wells. Furthermore, I provided administrative support to the Section manager in coordination, planning, and supervision of the groundwater program. I also assisted with the development of grant applications and subsequent management

of approved projects. In addition, I assisted the section manager with regulatory and legislative development in relation to the statewide groundwater quality protection program. I also served on the Illinois EPA's Cleanup Objectives Team ("COT").

Environmental Protection Specialist I, II, and III, Groundwater Section, DPWS, Illinois EPA. (7/85-7/88) I was the lead worker and senior geologist in the development and implementation of Illinois statewide groundwater quality protection program. I worked on the development of Illinois EPA's ambient groundwater monitoring network, and field sampling methods and procedures with the USGS. I published the first state-wide scientific paper on volatile organic compound occurrence in community water supply wells in Illinois. In addition, I assisted with the development of *A Plan for Protecting Illinois Groundwater*, and the legislation that included the *Illinois Groundwater Protection Act*.

Consulting Well Site Geologist, Geological Exploration (GX) Consultants, Denver Colorado. (3/81-12/83) I worked as a consulting well site geologist in petroleum exploration and development for major and independent oil companies. I was responsible for the geologic oversight of test drilling for the determination and presence of petroleum hydrocarbons. Prepared geologic correlations and performed analysis of geophysical logs, drilling logs and drill cuttings. Supervised and analyzed geophysical logging. Made recommendations for conducting and assisted with the analysis of drill stem tests and coring operations. In addition, I provided daily telephone reports and final written geologic reports to clients.

Undergraduate Teaching Assistant, Geology Department, Illinois State University. (3/79-3/81) I was responsible for teaching and assisting with lecture sessions, lab sessions, assignment preparation and grading for Petrology, Stratigraphy and Geologic Field Technique courses.

Undergraduate Education

B.S Geology, 1981, Illinois State University ("ISU"). Classes included field geology at South Dakota School of Mines and Technology, and Marine Ecology Paleoecology at San Salvador Field Station, Bahamas

Post Graduate Education

Applied Hydrogeology, 1984, ISU Graduate Hydrogeology Program

Engineering Geology, 1984, ISU Graduate Hydrogeology Program

Geochemistry for Groundwater Systems, 1986, USGS National Training Center

Hydrogeology of Waste Disposal Sites, 1987, ISU Hydrogeology Program

Hydrogeology of Glacial Deposits in Illinois, 1995, ISU Graduate Hydrogeology Program

MODFLOW, MODPATH and MT3D groundwater modeling, 1992, USGS National Training Center

24 Hour Occupational Health & Safety Training, 1994

Computer Modeling of Groundwater Systems, 1995, ISU Graduate Hydrogeology Program

Introduction to Quality Systems Requirements and Basic Statistics, 2001, U.S. EPA

Source Water Contamination Prevention Measures, 2001, U.S.EPA, Drinking Water Academy

Fate and Transport Processes and Models, 2006, Risk Assessment and Management Group, Inc.,

National Response Plan (NRP), an Introduction IS-00800.A, 2007, EMI

National Incident Management System (NIMS) an Introduction *IS-00700*, 2006, Emergency Management Institute (EMI),

Intermediate ICS for Expanding Incidents *IS-00300*, 2008, EMI

ICS for Single Resources and Initial Action Incidents *IS-00200*, 2006, EMI,

Introduction to the Incident Command System (ICS) *IS-00100*, 2006, EMI

License

Licensed Professional Geologist 196-000553, State of Illinois, expires 3/31/2009

Certification

Certified Professional Geologist 7455, Certified by the American Institute of Professional Geologists 4/88

Certified Total Quality Management Facilitator, 5/92, Organizational Dynamics Inc.,

Summary of Computer Skills

I am proficient with using the following computer programs ARC VIEW, Aqtesolv, SURFER, WHPA, DREAM, AQUIFEM, MODFLOW, MODPATH, and MT3D.

Professional Representation

Illinois EPA liaison to the ***GAC*** and representative on the ***ICCG*** (1988 – present)

Senate Working Committee on Geologic Mapping.

Illinois EPA representative and subcommittee chairman, ***State Certified Crop Advisory Board***, and ***Ethics and Regulatory Subcommittee*** established in association with the American Society of Agronomy/American Registry of Certified Professionals in Agronomy, Crops and Soils (1995 – 2001)

Illinois groundwater quality standards regulations technical work group (1988 – 1991).

ICCG State Pesticide Management Plan Subcommittee for the protection of groundwater.

Illinois EPA representative, ***State task group involved with developing the siting criteria for a low level radioactive waste site in Illinois.***

Fresh Water Foundation's Groundwater Information System (GWIS) project in the great lakes basin.

Illinois EPA technical advisor, ***four priority regional groundwater protection planning committees*** designated by the Director to advocate groundwater protection programs at the local level (1991 – present)

Groundwater Subcommittee of the National Section 305(b) Report, of the Clean Water Act Consistency Workgroup.

Ground Water Protection Council's Wellhead Protection Subcommittee.

Co-Chair, ***Groundwater Division of the GWPC*** on (September 1997 to 2003)

Chairman, ***Illinois' Source Water Protection Technical and Citizens Advisory Committee.***

United States Environmental Protection Agency National Ground Water Report Work Group. One of 10 state representatives serving on a work group sponsored by U.S. EPA headquarters charged with development of a national report to be submitted to the U.S. Congress on the status and needs for groundwater protection programs across the country. (January 1999 to July 2000)

Illinois EPA representative, ***Northeastern Illinois Planning Commission Water Supply Task Force.*** The purpose of this task force is to assist the Commission in the development of a Strategic Plan for Water Resource Management. (March 1999 to 2001)

GWPC/U.S. EPA Futures Forum Work Group providing input on source water protection for the next 25 years. (January 1999 to 2001)

GWPC/ASDWA work group providing input into the U.S. EPA Office of Ground and Drinking Water Strategic Plan for Source Water Protection. June 2000 to March 2005.

Co-Chair, ***U.S. EPA Headquarters/GWPC/ASDWA/ASWIPCA workgroup to develop the second Ground Water Report to Congress***. March 2002 –present.

Chair, ***ICCG Groundwater Contamination Response Subcommittee*** responsible for developing a new strategy for responding to groundwater contamination and the subsequent notification of private well owners. March 2002 – April 2002.

Illinois EPA representative, ***ICCG Water Quantity Planning Subcommittee*** working on development of a surface and groundwater quantity- planning program for Illinois. June 2002 – January 2003

Chair, ***ICCG Right-to-Know (RTK) Subcommittee,*** *2006*

GWPC, Groundwater Science and Research Advisory Board, 2007

Professional Affiliation

American Institute of Professional Geologists
Illinois Groundwater Association
Ground Water Protection Council
National Groundwater Association -Association of Groundwater Scientists and Engineers
Sigma Xi – The Scientific Research Society

Honors

Sigma Xi - Elected to *Sigma Xi* The Scientific Research Society for undergraduate research conducted and presented to the Illinois Academy of Science. 4/81

Director's Commendation Award - Participation in the development of the City of Pekin, Il. Groundwater Protection Program and commitment to the protection of Illinois groundwater. 7/95

Certificate of Appreciation - Outstanding contribution to the development of the Ground Water Guidelines for the National Water Quality Inventory 1996 Report to Congress from the United States Environmental Protection Agency Office of Ground Water and Drinking Water. 8/96

Groundwater Science Achievement Award - Illinois Groundwater Association for outstanding leadership and service in the application of groundwater science to groundwater protection in Illinois and in the development of the wellhead protection program and pertinent land-use regulations. 11/97

Certificate of Appreciation - GWPC for distinguished service, remarkable dedication, valuable wisdom and outstanding contribution as a GWPC member, division co-chair and special committee member. 9/99

Drinking Water Hero Recognition - United States Environmental Protection Agency Administrator Carol Browner at the 25th Anniversary of the Federal Safe Drinking Water Act Futures Forum in Washington D.C. 12/99.

Certificate of Recognition - United States Environmental Protection Agency Region V Administrator Fred Lyons for outstanding achievements in protecting Illinois' groundwater resources. 12/99

Exemplary Systems in Government (ESIG) Award - Nomination by the Governor's Office of Technology from the Urban and Regional Information Systems Association (URISA) for the Illinois EPA's Source Water Assessment and Protection Internet Geographic Information System. 6/01

Expert Witness Experience

IN THE MATTER OF: GROUNDWATER QUALITY STANDARDS (35 ILL. ADM. CODE 620), R89-14(B) (Rulemaking). Subject: I served as the principal witness recommending adoption of this Illinois EPA Agency proposal. R89-14(B) was adopted by the Board. The standards became effective January 1991.

STATE OIL COMPANY vs. DR. KRONE, McHENRY COUNTY and ILLINOIS EPA, PCB 90-102 (Water Well Exception). Subject: This case involved obtaining an exception from the owner of a non-community water supply well for placing new underground gasoline storage tanks within the 200-foot setback zone of well. I served as the principal witness for Illinois EPA on this case. The Board granted the exception with conditions.

People vs. AMOCO OIL COMPANY and MOBIL CORPORATION, Case no. 90-CH-79, Tenth Judicial Court, Tazewell County, Illinois. Subject: Groundwater contamination resulting from releases at above ground bulk petroleum storage terminals resulting in violation of Illinois' Groundwater Quality Standards Regulations (35 Illinois Administrative Code 620). I served as the principal Illinois EPA witness on this case. The case was settled with a penalty of $125,000 and the requirement of a comprehensive corrective action program.

IN THE MATTER OF: GROUNDWATER PROTECTION: REGULATIONS FOR EXISTING AND NEW ACTIVITIES WITHIN SETBACK ZONES AND REGULATED RECHARGE AREAS (35 ILL. ADM. CODE 601, 615, 616 and 617), R89-5 (Rulemaking). Subject: I served as the principal Illinois EPA witness supporting adoption of this Agency proposal. R89-5 was adopted by the Board and became effective January 1992.

HOUSE BILL 171 METHYL TERTIARY BUTYL ETHER (MTBE) ELIMINATION ACT, House Environmental and Energy Committee. Subject: This law required the phase out MTBE within 3 years of enactment. I served as a principal Illinois EPA witness in support of the proposed legislation. The legislation was adopted as Public Act 92-0132 on July 24 2001. PA 92-132 required the ban of MTBE within three years.

IN THE MATTER OF: GROUNDWATER QUALITY STANDARDS (35 ILL. ADM. CODE 620), R93-27 (Rulemaking). Subject: I served as the principal Illinois EPA witness recommending amendments of new constituent standards in this Agency proposal.

SHELL OIL COMPANY vs. COUNTY of DuPAGE and THE ILLINOIS ENVIRONMENTAL PROTECTION AGENCY, PCB 94-25 (Water Well Setback Exception). Subject: A new underground gasoline storage tank was seeking an exception from the Illinois Pollution Control Board in relation to a private drinking water supply well setback zone. The DuPage County and the Illinois EPA held that the tank would be a significant hazard and opposed the exception. I served as the principal Illinois EPA witness. Shell withdrew the petition from the Board after hearings were held.

People ex rel. Ryan v. STONEHEDGE, INC., 288 Ill.App.3d 318, 223 Ill.Dec. 764, 680 N.E.2d 497 (Ill.App. 2 Dist. May 22, 1997). Subject: The State brought Environmental Protection Act action against company engaged in business of spreading deicing salt, alleging that salt stored on company's industrial property leaked into area's groundwater supply, thereby contaminating it. The Circuit Court, McHenry County, James C. Franz, J., granted company's motion for summary judgment. State appealed. The Appellate Court, Colwell, J., held that: (1) wells existing before Illinois Water Well Construction Code was enacted are not "grandfathered" in as being in compliance with Code, so as to be automatically subject to testing for groundwater contamination, and (2) fact issues precluded summary judgment on claim arising from alleged deposit of at least 50,000 pounds of salt in pile within 200 feet of two existing water supply wells. Affirmed in part and reversed in part; cause remanded.

People vs. STONEHEDGE INC. Case no. 94-CH-46, Circuit Court of the 19th Judicial Circuit, McHenry County. Subject: This case involved a violation of the potable well setback zone provisions of Section 14.2 of the Illinois Environmental Protection Act. Stonehedge Inc. placed a salt pile of greater than 50,000 pounds within the 200 foot setback of multiple private drinking water supply wells. I served as an Agency principal witness. Stonehedge Inc. was found to be guilty of violating the setback prohibition in this case and was assessed a penalty of $1,500 and attorneys fees of $4,500.

SALINE VALLEY CONSERVANCY DISTRICT vs. PEABODY COAL COMPANY, Case No. 99-4074-JLF, United States District Court for the Central District of Illinois. Subject: Groundwater contamination from the disposal of 12.8 million tons of coarse coal refuse, slurry and gob. Witness for the Illinois EPA. This is an on-going case.

IN THE MATTER OF: PROPOSED REGULATED RECHARGE AREAS FOR PLEASANT VALLEY PUBLIC WATER DISTRICT, PROPOSED AMENDMENTS TO (35 ILL. ADM. CODE 617), R00-17 (Rulemaking). Subject: I served as the principal Illinois EPA witness supporting adoption of this Agency proposal. The proposal was adopted on July 26, 2001 and became effective September 1, 2001.

IN THE MATTER OF: PROPOSED AMENDMENTS TO TIERED APPROACH TO CORRECTIVE ACTION OBJECTIVES (35 Ill. Adm. Code 742), (R00-19(A) and R00-19(B)) (Rulemaking). Subject: I served as a supporting Illinois EPA witness recommending inclusion of MTBE in this Agency proposal.

IN THE MATTER OF: NATURAL GAS-FIRED, PEAK-LOAD ELECTRICAL GENERATION FACILITIES (PEAKER PLANTS), R01-10 (Informational Hearing) Subject: I served as a supporting Illinois EPA witness to discuss the impact of peaker plants on groundwater.

IN THE MATTER OF: GROUNDWATER QUALITY STANDARDS AND COMPLIANCE POINT AMENDMENTS (35 ILL. ADM. CODE 620), R01- 14 (Rulemaking). Subject: I served as the principal Illinois EPA witness recommending amendments of a groundwater standard for MTBE and compliance point determinations in this Agency proposal. The Board adopted the proposal unanimously on January 24, 2002.

TERESA LeCLERCQ; AL LeCLERCQ; JAN LeCLERCQ; WALT LeCLERCQ, individually; and on behalf of all persons similarly situated vs. THE LOCKFORMER COMPANY, a division of MET-COIL SYSTEMS CORPORATION, Case no. 00 C 7164, United States District Court, Northern District of Illinois. Subject: I was called as a witness by Lockformer Company to testify about a Well Site Survey prepared and published in 1989 by the Illinois EPA for Downers Grove community water supply.

TERESA LeCLERCQ; AL LeCLERCQ; JAN LeCLERCQ; WALT LeCLERCQ, individually; and on behalf of all persons similarly situated vs. THE LOCKFORMER COMPANY, a division of MET-COIL SYSTEMS CORPORATION, Case no. 00 C 7164, United States District Court, Northern District of Illinois. Subject: I was called as a witness by Lockformer Company to testify about groundwater contamination in the Lisle and Downers Grove area.

HOUSE BILL 4177 PRIVATE WELL TESTING PROPERTY TRANSFER and DISCLOSURE ACT, House Environmental and Energy Committee. Subject: Legislation to require volatile organic chemical contamination testing of private wells at the time of property transfer and reporting to the Illinois Department of Public Health and the Illinois EPA. I served as a principal Illinois EPA witness in support of the proposed legislation. The legislation was not supported due to the opposition from the realtors association.

MATTER OF PEOPLE vs. PEABODY COAL, PCB 99-134 (Enforcement). Subject: the State of Illinois developed an amended complaint against Peabody Coal Company (PCC) for violation of the groundwater quality standard for total dissolved solids, chloride, iron, manganese, and sulfate. I developed testimony to address PCC's affirmative defense of challenging the basis for the groundwater quality standards for these contaminants.

IN THE MATTER OF: PROPOSED AMENDMENTS TO TIERED APPROACH TO CORRECTIVE ACTION OBJECTIVES (35 Ill. Adm. Code 742) (TACO), (Rulemaking). Subject: I served as the Illinois EPA witness supporting amendments TACO to include wellhead protection areas. September 2004.

MAXMIUM SETBACK ZONES FOR MARQUETTE HEIGHTS PUBLIC WATER SUPPLY (35 ILL. ADM. CODE 618), R05-09 (Rulemaking). Subject: Pursuant to request by the Village of Marquette Heights the Illinois EPA developed a maximum setback zone for the Marquette Heights community water supply wells. I served as Illinois EPA's principal witness. The proposal was adopted on May 4, 2006.

IN THE MATTER OF: STANDARDS AND REQUIREMENTS FOR POTABLE WATER WELL SURVEYS AND FOR COMMUNITY RELATIONS ACTIVITIES PERFORMED IN CONJUNCTION WITH AGENCY NOTICES OF THREATS FROM CONTAMINATION UNDER P.A. 94-134 (35 Ill. Adm. Code 1505), R06-023 (Rulemaking), JANUARY 2006. I served as an Agency panel witness to support the adoption of the RTK regulation.

IN THE MATTER OF: PROCEDURES REQUIRED BY P. A. 94-849 FOR REPORTING RELEASES OF RADIONUCLIDES AT NUCLEAR POWER PLANTS: NEW 35 Ill. Adm. Code 1010, R07-20. I served as the Agency primary witness in this proceeding.

Public Act 92-0132 (***MTBE Elimination Act***), July 24 2001.

Executive Order #5 - requires the ICCG to designate a subcommittee to develop an integrated groundwater and surface water resources agenda and assessment report. The report shall analyze the burden's on Illinois finite water resources, quantify Illinois' water resources, and prioritize an agenda to plan for the protection of these water resources. The Director of the Department of

Natural Resources chaired this subcommittee. The ICCG and GAC shall use the subcommittee's agenda and report to establish a water-quantity planning procedure for the State. The Governor signed executive order #5 on Earth Day April 22, 2001.

Amendments to Sections 2, 3 and 4 of the Illinois Groundwater Protection Act 415 ILCS 55/2 to establish a Groundwater and Surface Water Quantity Protection Planning Program, January 2002, 3 pp. These amendments were never adopted due to opposition from the Illinois Farm Bureau.

Public Act 92 –652 (Senate Bill 2072)- Amends the Illinois Groundwater Protection Act to require the Environmental Protection Agency to notify the Department of Public Health, unless notification is already provided, of the discovery of any volatile organic compound in excess of the Board's Groundwater Quality Standards or the Safe Drinking Water Act maximum contaminant level. The Governor signed this into law as Public Act 29-652 (effective July 25, 2002).

House Bill 4177 - Amends the Illinois Groundwater Protection Act. Provides that before property that has a well used for drinking water on it can be sold, the owner must have the well water tested for volatile organic chemical groundwater contaminants. Provides that if the well water does not meet the Illinois Pollution Control Board's Groundwater Quality Standards (35 Il Adm Code Part 620), the owner shall notify the Illinois Department of Public Health (IDPH) and the prospective buyer of the property. The realtors association July 2002 opposed House Bill 4177.

House Resolution 1010 - The resolution drafted by in cooperation with Senator Patrick Dunn' staff urge the Illinois Environmental Protection Agency to further strengthen its public outreach efforts by developing, after negotiations with individuals representing areas affected by contamination and other relevant State agencies, a procedure to notify property owners whenever the Agency has confirmed an exceedence of applicable health and safety standards, using scientifically credible data and procedures under Illinois regulations. HR 1010 was adopted by voice vote on June 1, 2004.

Public Act 94-314 (Senate Bill 0214) – This is referred to as Right-to-Know (RTK) law. The law includes providing the Illinois EPA with administrative order authority (AO), information order authority, and established the requirements for providing notices to residents or business exposed or potentially exposed to contamination. The Illinois EPA had been seeking this type of AO authority for the past 35 years. Senate Bill 0214 was unanimously passed by both the Senate and the House May 2005. The legislation was signed into law by the Governor July 27, 2005.

Public Act 94-849 (House Bill 1620) - Amends the Environmental Protection Act. Requires the owner or operator of a nuclear power plant to report to the Environmental Protection Agency any unpermitted release of a contaminant within 24 hours. The bill was sign by the Governor on June 12, 2006.

Arsenic in Illinois Groundwater

Illinois Department of Natural Resources
Illinois Department of Public Health
Illinois Environmental Protection Agency

November 20, 2001

What are the Sources of Arsenic in Illinois Groundwater?

Arsenic is a naturally occurring element in the earth's crust. Arsenic is found in the deep bedrock materials throughout Illinois, as well as in the shallow glacial materials that cover the northern two-thirds of the state. Arsenic is dissolved naturally from these materials and enters groundwater. Many other states have a similar problem.

Why is Arsenic a Concern?

Dissolved arsenic found in Illinois' groundwater is generally in inorganic form and is considered toxic. The Department of Health and Human Services lists arsenic as a known carcinogen. Ingesting inorganic arsenic over many years (chronic exposure) increases the risk of skin cancer and tumors of the bladder, kidney, liver, and lung. It has also been found to cause blood vessel damage, heart problems, darkening of the skin, and nervous system damage. Recently, the National Academy of Sciences (NAS) has reviewed the updated toxicological data base for arsenic and has determined that cancer risks from arsenic exposures are greater than previously estimated. This prompted a call to lower the drinking water standard for arsenic in order to protect human health.

About 35 percent of Illinois residents use groundwater for their water source. In addition, approximately 90 percent of rural citizens utilize groundwater from private wells for their source of water. In total, over four million Illinois residents use groundwater.

Regulation of Arsenic in Drinking Water

The national drinking water standard for arsenic has been 50 micrograms per liter (µg/L), which is 50 parts per billion. This standard was set in 1942. The World Health Organization has set a guideline of 10 µg/L. The United States Environmental Protection Agency (USEPA) recently evaluated the drinking water standard for arsenic and on October 30, 2001, USEPA recommended that the standard be lowered to 10 µg/L.

The new rule will be phased in such that compliance to the national drinking water standard for arsenic will be required by 2006 for all public water supplies. The Illinois Pollution Control Board has final say on Illinois' adoption of the national standard and typically the national regulation is quickly adopted and made law in Illinois. It is anticipated that the adoption of the national standard in Illinois will be finalized before the end of the year. At that point, the federal standard will become the law in Illinois as well. In Illinois, the IEPA and Illinois Department of Public Health (IDPH) are responsible for enforcing the standard for all

community and non-community public water supplies.

An ongoing debate centers around the high costs of removing arsenic, especially for regulated small communities and unregulated individual homes, versus the health benefits of lowering the arsenic standard.

Public Groundwater Supplies

The new national standard for arsenic, 10 µg/L, applies to all community and non-community public water supplies. Figure 1 shows the locations of community public groundwater supplies where, utilizing existing treatment, finished water will likely exceed the new standard unless additional treatment is applied. These data, based on sampling conducted by the Illinois Environmental Protection Agency (IEPA), indicate that arsenic is prevalent in groundwater in many parts of the state.

For the community water supply data included in the Illinois State Water Survey (ISWS) Water Quality Database, which are of well water samples taken prior to treatment, 2.1 percent of the samples had arsenic levels of 50 µg/L or greater, and about 11 percent were above 10 µg/L.

Communities with arsenic levels above the standard in the raw water supplies treat their water so that the finished water provided to their residents is below the standard.

How Much Arsenic Is Found In Illinois' Private Wells?

Private water supplies and wells are not regulated for the amount of arsenic present in their drinking water. Because most private water supplies are not tested for arsenic and few have available treatment to remove arsenic, the health risks to domestic well owners may be higher than for public water supplies.

In Illinois, only a few private well data are available statewide for determining the concentration of arsenic in groundwater. One exception is in Tazewell County, where the Tazewell County Health Department sampled 590 private wells for arsenic in 1985.

Groundwater is the sole source of drinking water in most of Tazewell County. There is wide variability in arsenic concentration over relatively small areas (Figure 2). Little information regarding well depth was available for evaluating these data, but additional research in Tazewell, McLean, and Logan counties by the ISWS indicated that the shallower aquifers had a greater percentage of samples with high arsenic concentrations, compared to the deeper sand and gravel aquifer. These results suggest that shallow glacial materials may contribute more to the arsenic found in groundwater than previously believed.

In Tazewell County, of the 590 samples tested, 202 (34 percent) had arsenic concentrations at or above 50 µg/L. 350 samples (59 percent) had arsenic concentrations at or above 10 µg/L. This is much greater than the percentage of arsenic concentrations in public wells, which are usually much deeper. Only 7 (4 percent) of the more than 180 community groundwater wells in Tazewell County had arsenic concentrations above 50 µg/L and about 70 (39 percent) had arsenic concentrations above 10 µg/L in their ambient water samples

That arsenic concentrations vary dramatically over a relatively short distance indicates

that local conditions dictate arsenic concentration in groundwater, and it is difficult to make regional generalizations.

Effect of a New Arsenic Rule in Illinois

For Illinois residents served by public water supplies, compliance with a new arsenic rule will reduce their exposure to arsenic in groundwater. It will also likely have economic impacts due to higher treatment costs. Illinois residents served by untreated private wells will continue to experience the same exposures and health risks as before, but because the arsenic standard will be lower, the perceived health risks may be greater. Private well water can be treated at a cost.

In Illinois, many communities remove iron and manganese from their raw water to reduce the hardness of the water. Data from the IEPA on the water quality of both raw water and finished water indicate that some communities also are lowering their arsenic levels by using these treatment methods. For example, at Monticello, the change in arsenic concentration from raw water to finished water was 53 µg/L to 10.7 µg/L. At Clinton, arsenic concentrations dropped from 36 µg/L to 18.9 µg/L.

The USEPA recently published a report outlining the available technologies and associated increased costs for removing arsenic. For large communities, the average cost per person will likely be reasonable, but for small communities, the average cost per person will likely be significant. The USEPA estimates that the average cost per person in a community with 200 people will be 10 times the average cost per person in a community with 20,000 people. IEPA has estimated a total cost of $40 million to remove arsenic below 10 µg/L for 50 community water supplies in Illinois. Figure 3 illustrates the distribution of the 50 community water supplies relative to the projected cost of reducing arsenic to less than 10 µg/L.

The rule also, for the first time, requires non-community, non-transient public water supplies (e.g., schools, small businesses, etc.) to comply with the new standard. At this time it is unknown how many of the existing 440 supplies in this category will have to install treatment. The rule requirements for monitoring, reporting, and possible additional treatment could present financial burdens on these facilities.

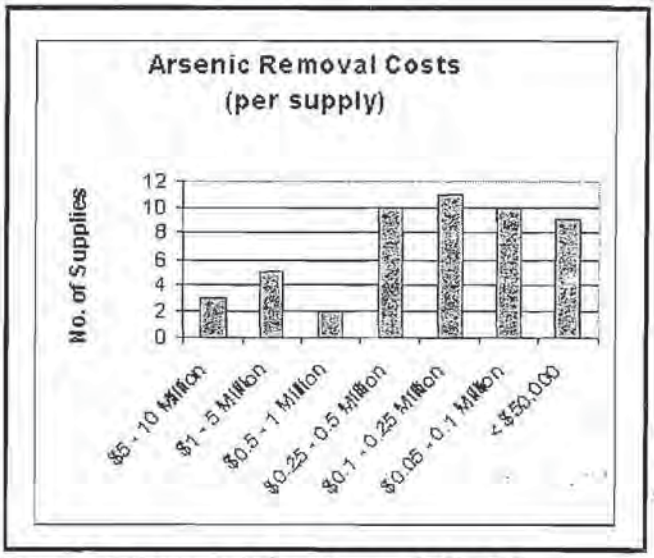

Figure 3. Projected Number and Cost of Removing Arsenic from Community Water Supply Wells in Illinois

There are a number of options for individual well owners who are concerned about the arsenic levels in their drinking water. Reverse osmosis, ultra-filtration, and ion exchange are available technologies for removing arsenic from private well water. These treatments, especially reverse osmosis, are effective in removing arsenic, but there are installation and maintenance costs. According to USEPA, the cost of treating a private system would range

between $400 and $5000 a year, depending on the amount of treated water and the method of treatment. Purchasing bottled water is another option.

What Activities Are Being Undertaken to Address The Arsenic Problem?

The Public Service Laboratory Program at the ISWS provides Illinois residents with water sample analyses for their private drinking water supplies (http://www.sws.uiuc.edu/chem/psl/), but arsenic is not routinely determined. The ISWS is looking into adding arsenic to the constituents evaluated in water samples. The Midwest Technology Assistance Center for Small Public Water Systems (MTAC), housed at the ISWS, is currently supporting research on arsenic treatment technologies that will lead to reduced treatment costs for the removal of arsenic in small public water systems. The ISWS is discussing with other agencies the feasibility of initiating a program to sample public, non-community wells and private wells throughout Illinois. Their goal is to characterize arsenic occurrence throughout Illinois and to identify the characteristics of the aquifers and groundwater chemistry that promote high arsenic concentrations.

The IDPH has a regulatory role for non-community public water supplies and an advisory role for private water supplies. The new rule will require, for the first time, non-community public water supplies test for arsenic. Residents with private well results can contact the IDPH Toxicology Section for a health-based assessment of the data. IDPH has a pamphlet entitled "Arsenic in Groundwater" available on the IDPH home page (http://www.idph.state.il.us) and by mail.

The IEPA is involved with various activities associated with implementing the federal Safe Drinking Water Act, the Illinois Groundwater Protection Act, and the Clean Water Act. IEPA has analyzed applicable treatment technologies and costs associated with the treatment of arsenic in community water supplies that would potentially exceed a maximum contaminant level (MCL) of 10 µg/L. Presentations have been made at seminars and meetings explaining the content of the published federal drinking water standards and possible impacts on water supplies that exceed the new standard. Water supplies that exceed the standard are required to provide Public Notice to customers of adverse health effects associated with arsenic and publish this notice in a newspaper having local circulation. All water supplies that exceed half the arsenic standard are also required to notify customers in the annual Consumer Confidence Report. IEPA has a monitoring program in place to evaluate arsenic in ambient groundwater used by community water supplies, and surface water in rivers and streams. These data from community water supply wells have been further assessed in relation to the supplies that potentially exceed an MCL of 10 µg/L, and to their existing treatment and treatment processes. The IEPA has made the arsenic data collected from community water supply wells available to the public from the Source Water Assessment and Protection Internet Geographic Information System at http://www.epa.state.il.us/water/groundwater/source-water-quality-program.html

BEFORE THE ILLINOIS POLLUTION CONTROL BOARD

IN THE MATTER OF:	)	
	)	R08-18
PROPOSED AMENDMENTS TO	)	(Rulemaking-Public Water Supplies)
GROUNDWATER QUALITY	)	
STANDARDS	)	
(35 Ill. Adm. Code 620)	)	
	)	

TESTIMONY OF THOMAS C. HORNSHAW

Qualifications

My name is Thomas C. Hornshaw. I am a Senior Public Service Administrator and the Manager of the Toxicity Assessment Unit of the Illinois Environmental Protection Agency (Agency). I have been employed at the Agency since August of 1985, providing expertise to the Agency in the area of environmental toxicology. Major duties of my position include development and use of procedures for toxicity and risk assessments, review of toxicology and hazard information in support of Agency programs and actions, and critical review of risk assessments submitted to the Agency for various cleanup and permitting activities.

I was a member of the Agency's Cleanup Objectives Team until February of 1993, when that Team's responsibilities were assumed mainly by the Toxicity Assessment Unit. I was also a member of the Groundwater Standards Technical Team during the development of the Groundwater Quality Standards. These two teams have looked in depth at the problems involved with determining acceptable residual concentrations of chemicals in soil and/or groundwater.

I received Bachelor of Science (with honors) and Master of Science degrees in Fisheries Biology from Michigan State University, East Lansing, Michigan. I also received a dual Doctor of Philosophy degree from Michigan State University, in Animal Science and Environmental Toxicology. I am a member of the Society of Environmental Toxicology and Chemistry and

Sigma Xi, the Scientific Research Society. I have authored or co-authored six papers published in peer-reviewed scientific journals, one report issued through the U.S. Environmental Protection Agency, and have written or co-written six articles which have appeared in trade journals. I have also presented nineteen posters and/or talks describing facets of my graduate work and my work at the Agency at various regional and national meetings. A more descriptive account of my work and educational background and a list of publications, posters, and talks are included in a Curriculum Vitae presented as Exhibit A to this testimony.

Testimonial Statement

In my testimony today I will describe how chemicals that have been detected and confirmed in groundwater were selected for addition to Part 620. I will also discuss updates needed in Part 620 to make this rule consistent with groundwater remediation objectives listed in Part 742 (TACO) for several chemicals detected in groundwater but not currently included in Part 620. Then I will briefly discuss the development of the new standards that are proposed for this update. But first I will describe changes in the hierarchy for selecting the most appropriate toxicity information for evaluating a chemical, changes that have impacted the development of groundwater standards for certain chemicals.

I. TOXICITY INFORMATION HIERARCHY

On December 5, 2003, USEPA issued a memorandum (OSWER Directive 9285.7-53) from Michael B. Cook, Director of the Office of Superfund Remediation and Technology Information, to the Superfund National Policy Managers, Regions 1-10, on Human Health Toxicity Values in Superfund Risk Assessments. This memo revised the hierarchy for selecting human health toxicity values that had been used since the issuance of the original hierarchy in the 1989 Risk Assessment Guidance for Superfund (RAGS). The RAGS hierarchy, which has

also been used by the Toxicity Assessment Unit in developing human health toxicity values, was to first use values from EPA's Integrated Risk Information System (IRIS) database, if available, or else values from the most recent Health Effects Assessment Summary Tables (HEAST). If no toxicity value was available from these sources, then values could be derived from literature sources or a request could be made to EPA's National Center for Environmental Assessment (NCEA) for provisional toxicity values.

The revised hierarchy still specifies the IRIS database as the first option for toxicity values, but now includes second and third tiers of data sources. The second tier is a recently introduced database, EPA's Provisional Peer Reviewed Toxicity Values (PPRTVs) available from NCEA. The third tier, Other Toxicity Values, includes three named sources but could also include other sources as appropriate. The three named sources are the Agency for Toxic Substances and Disease Registry's (ATSDR) Minimal Risk Levels (MRLs), developed for ATSDR risk assessments, California EPA's toxicity values, developed to support various rules and programs, and EPA's HEAST, which was last updated in 1997.

The Toxicity Assessment Unit has adopted this hierarchy, with some minor revisions, as the basis for determining the toxicity values for its activities. As we began using the new hierarchy, we became aware of some minor issues that ultimately lead to certain revisions of the hierarchy. To keep this portion of my testimony brief, I will illustrate three issues that resulted in a minor revision:

- PPRTVs are retired by EPA after a certain period of time, leading us to question what should be the role of retired values; we ultimately decided to continue using them instead of going to tier three.

- EPA does not provide guidance on which value to use if more than one value is available from the three named sources in tier three; we ultimately decided to use the lowest of the tier three values available in such cases.
- IRIS does not contain values for subchronic exposures, only values for chronic exposures, so there is essentially no first tier for shorter-duration exposures; however, some chronic IRIS values use an Uncertainty Factor to extrapolate to chronic exposures from a study of subchronic duration, and we have used the IRIS value with this Uncertainty Factor removed as the first tier when available.

The Toxicity Assessment Unit has used this new hierarchy to re-evaluate the soil and groundwater objectives for all the chemicals currently included in Part 742 (TACO), other than those groundwater objectives that are based on a Maximum Contaminant Level from the Safe Drinking Water Act (which would require a change at the federal level). Changes needed in TACO because of this new hierarchy will be included when the Agency's next revision to TACO is proposed to the Board, and these changed values for groundwater are also included in the list of chemicals we are proposing to be added to Part 620 to make it consistent with TACO, as discussed below. We have also used this hierarchy to derive the proposed standards for the newly detected chemicals that must be added to Part 620, also discussed below. Finally, as Mr. Cobb has testified, the Agency has determined that no groundwater standard or objective should exceed the water solubility for a chemical, and the one-in-a-million risk concentration for a carcinogen should be considered along with the chemical's analytical detection limit to derive the most appropriate groundwater objective. These factors have been included in the development of the Agency's proposal for updating Part 620.

II. ADDING NEWLY DETECTED CHEMICALS

In preparation for updating Part 620, the Agency's Bureau of Land reviewed analytical results from many remediation activities to determine what chemicals had been detected in groundwater and confirmed by resampling. The master list from this review, consisting of chemicals detected primarily at Resource Conservation and Recovery Act (RCRA), solid waste disposal, and Department of Defense and Superfund sites, was then reviewed by the Toxicity Assessment Unit to determine which of the chemicals had sufficient toxicity values to support the development of a new groundwater standard. After this review, the Toxicity Assessment Unit decided that, in addition to those chemicals already included in TACO, any chemical on the master list for which a toxicity value was available in the IRIS database would be an appropriate candidate for inclusion in the Part 620 update. Thus, in addition to the TACO chemicals discussed below, the following chemicals were added to the proposed update: 2-Butanone (Methyl ethyl ketone, MEK), Dicamba, Dichlorodifluoromethane, p-Dioxane, 1,3-Dinitrobenzene, the explosive HMX, Isopropylbenzene (Cumene), Mecoprop (MCPP), 2-Methylnaphthalene, Molybdenum, Perchlorate, the explosive RDX, Trichlorofluoromethane, 1,3,5-Trinitrobenzene, and 2,4,6-Trinitrotoluene (TNT).

III. ADDING GROUNDWATER OBJECTIVES FROM TACO

In this proposed update to Part 620 the Agency determined that it is now necessary that chemicals that have Groundwater Remediation Objectives in TACO Part 742.Appendix B, Table E, are not included in Sections 620.410 and 620.420, and have been detected and confirmed in groundwater should be added to Sections 620.410 and 620.420, so that these two rules are consistent. Thus, after all the TACO Groundwater Remediation Objectives were updated

according to the new toxicity value hierarchy as described above and compared to solubility limits and one-in-a-million cancer risk concentrations (for carcinogens), the following chemicals not included in Part 620 were added to this proposed update: Acenaphthene, Acetone, Anthracene, Benzo(a)anthracene, Benzo(b)fluoranthene, Benzo(k)fluoranthene, Benzoic acid, alpha-BHC, Carbon disulfide, Chloroform, Chrysene, Dibenzo(a,h)anthracene, Di-n-butyl phthalate, Diethyl phthalate, 2,4- and 2,6-Dinitrotoluene, Di-n-octyl phthalate, Fluoranthene, Fluorene, Indeno(1,2,3-c,d)pyrene, 2-Methylphenol, Naphthalene, Nitrobenzene, Pyrene, and Vanadium.

IV. DERIVING THE NEW STANDARDS

In order to accommodate the changes regarding the one-in-a-million cancer risk concentration for carcinogens and solubility limits for all chemicals, it was necessary to change the wording of Part 620. Subpart F. Specifically, changes were needed in Section 620.605, as follows:

- In Section 620.605(b)(1), insert at the beginning "Except as specified in Section 620.605(c), if..." (no changes to the rest of this section).
- Amend Section 620.605(b)(2) to read "Except as specified in Section 620.605(c), if the chemical substance is a carcinogen, the guidance level for any such chemical substance is the one-in-one-million cancer risk concentration, unless the concentration for such substance is less than the lowest appropriate PQL specified in "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods," EPA Publication No. SW-846, incorporated by reference at Section 620.125 for such substance. If the concentration for such substance is less than the lowest appropriate PQL for the substance specified in SW-

846, the guidance level is the lowest appropriate PQL. The one-in-one-million cancer risk concentration, the Human Nonthreshold Toxicant Advisory Concentration (HNTAC), shall be determined according to the following equation:" The equation then follows the text in the proposed amendment.

- Add a new Section 620.605(c), "If the guidance level determined for a chemical pursuant to Section 620.605(a) or (b) exceeds the water solubility of that chemical, the guidance level shall be the water solubility."

The new hierarchy for toxicity values was used to identify the most appropriate values for the chemicals to be added, and the procedures of Part 620. Subpart F (including the new sections described above), were used to derive the standards that are being proposed. Please note that all proposed values now contain two significant figures, to be consistent with a Toxicity Assessment Unit policy decision that specifies two significant figures be used for all new and updated standards and objectives.

V. TESTIMONY REGARDING ERRATA SHEET 2

In Errata Sheet Number 2 the Agency proposes to make changes to its initial filing regarding certain chemicals listed in Sections 620.410(b) and 620.420(b). Additional corrections are necessary for several reasons. First, selection criteria for groundwater standards have been revised and now require a comparison of each carcinogenic constituent's health-based concentration (the 10^{-6} risk level) with its corresponding analytical method detection limit. The greater of these values is then compared to the constituent's reported water solubility. The lower of these two values then becomes the standard. Second, source information used by the Agency concerning chemical/physical properties was recently updated and has subsequently been incorporated into the Agency's database. Finally, crucial sources for toxicological values that

form the bases for health-based standards have been updated and expanded necessitating subsequent updates to the Agency database.

A brief explanation of the reason for each of the changes follows:

Section 620.410(b):

- Anthracene- The solubility-based standard is corrected to two significant figures.
- Benzo(k)fluoranthene- For this carcinogen, the standard is corrected to the detection limit of 0.00017 mg/L since it does not exceed the water solubility value of 0.0008 mg/L.
- Chrysene- The 10^{-6} risk level of 0.012 mg/L would be the standard because it is greater than the detection limit of 0.0016 mg/L; however, the standard is corrected to the chemical water solubility of 0.0063 mg/L, which should not be exceeded.
- 1,1-Dichloroethane- The standard is corrected to reflect a revised toxicological reference dose value.
- Fluoranthene- The solubility-based standard is corrected to two significant figures.
- Indeno(1,2,3-cd)pyrene- The standard is corrected to the chemical's water solubility, which should not be exceeded.
- 2-Methylnaphthalene- The standard is revised to correct a typographical error.
- P-Dioxane- The standard is corrected to the 10^{-6} cancer risk concentration of 0.0077 mg/L because it is greater than the detection limit of 0.005 mg/L.
- Pyrene- The standard is corrected to the health-based value of 0.21 mg/L following an increase in pyrene's reported water solubility concentration.
- 2,4-Dinitrotoluene- The standard is corrected to the 10^{-6} cancer risk level of 0.0001 mg/L because it is greater than the originally proposed detection limit of 0.00002 mg/L.

Section 620.420(b):

- Anthracene- The solubility-based standard is corrected to two significant figures.
- Benzo(a)pyrene- The solubility-based standard is corrected to two significant figures.
- Chrysene- The 10^{-6} risk level of 0.012 mg/L would be the standard because it is greater than the detection limit of 0.0016 mg/L; however, the standard is corrected to the chemical water solubility of 0.0063 mg/L, which should not be exceeded.

- 1,1-Dichloroethane- The standard is corrected to reflect a revised toxicological reference dose value.
- Fluoranthene- The solubility-based standard is corrected to two significant figures.
- Indeno(1,2,3-cd)pyrene- The standard is corrected to the chemical's water solubility, which should not be exceeded.
- p-Dioxane- The standard is corrected to the 10^{-6} cancer risk concentration of 0.0077 mg/L because it is greater than the detection limit of 0.005 mg/L.
- Pyrene- The standard is corrected to the health-based value of 1.05 mg/L following an increase in pyrene's reported water solubility concentration.
- 2,4-Dinitrotoluene- The standard is corrected to the 10^{-6} cancer risk level of 0.0001 mg/L because it is greater than the originally proposed detection limit of 0.00002 mg/L.

Concluding Statement

This concludes my portion of the Agency's testimony for the proposed amendments to Part 620.

ILLINOIS POLLUTION CONTROL BOARD
November 7, 1991

IN THE MATTER OF:	)	
	)	
GROUNDWATER QUALITY STANDARDS	)	R89-14(B)
(35 ILL. ADM. CODE 620)	)	(Rulemaking)

ADOPTED RULE. FINAL ORDER.

OPINION AND ORDER OF THE BOARD (by R.C. Flemal):

This matter comes before the Board pursuant to Section 8 of the Illinois Groundwater Protection Act ("IGPA"), Ill. Rev. Stat. 1989, ch. 111½, pars. 7451 et seq. Section 8 mandates inter alia that the Board promulgate "regulations establishing comprehensive water quality standards which are specifically for the protection of groundwater" (IGPA at Section 8(a)). The purpose of today's action is make final adoption of these groundwater quality standards and the associated basic framework.

PROCEDURAL HISTORY

The Agency filed its original proposal on September 21, 1989.

On January 31, 1990 the Department of Energy and Natural Resources ("DENR") filed the Economic Impact Statement ("EcIS"), which pursuant to the IGPA was prepared concurrently with development of the Agency's proposal.

On March 26, 1990 an alternative proposal was filed by the McHenry County Defenders, Citizens for a Better Environment, and the Illinois Chapter of the Sierra Club (collectively as "Defenders").

On June 1, 1990 the Agency filed its second proposal within Public Comment ("PC") #16.

Hearings on the various proposals and the EcIS were held on December 12 and 13, 1989, and February 14, March 29, and May 7, 1990[1].

---

[1] Transcripts of the December 1989 to May 1990 hearings, which are numbered consecutively, are herein cited in the form "R1 at ____".

The Board wishes to acknowledge the special contribution made by Michelle C. Dresdow, who has served as Hearing Officer throughout these proceedings.

Based on the cumulative record then available, the Board on September 27, 1990 advanced its own proposed rule, which was published for First Notice on November 2, 1990[2]. Hearings were held on this proposal on December 4 and 5, 1990[3].

On February 19, 1991 the Agency filed its third amended proposal, which the Board on February 28, 1991 proposed for First Notice as Docket B[4]. Hearing was held on the Docket B proposal on May 30, 1991[5]. At hearing the Agency offered further amendments to its proposal based on renewed discussions, conferences, and negotiation sessions with interested persons. The text of these amendments, which was entered as Exhibit T[6], had been distributed to interested persons prior to the May 30, 1991 hearing.

On July 25, 1991 the Board proposed the Docket B regulations, with modifications, for Second Notice[7]. Given the magnitude of the changes, the Board withheld filing of the Second Notice proposal with the Joint Committee on Administrative Rules ("JCAR") to allow for an additional comment period of 15 days. No comments filed during this period persuaded the Board to recede from its July 25 action, and the proposal was accordingly filed with JCAR.

On October 22, 1991 JCAR issued a certificate of no objection to the proposed rules. Prior to the issuance of the certificate, JCAR staff alerted the Board to several non-substantive grammatical and typographical errors. In addition,

---

The Board wishes to acknowledge the special contribution made by Michelle C. Dredow, who has served as Hearing Officer throughout these proceedings.

[2] 14 Ill. Reg. 17822, November 2, 1990.

[3] Transcripts of the December 1990 hearings are herein cited in the form "R2 at _____".

[4] Publication occurred at 15 Ill. Reg. 4234, March 22, 1991.

[5] The transcript of the May 1991 hearing is herein cited in the form "R3 at _____".

[6] The text of the proposed amendments entered as Exhibit T are often referred to in the transcript of the May 30, 1991 hearing as the "May 15 proposal", based upon the date contained on that document.

[7] By the same Order the Board Closed Docket A and withdrew its provisions from further consideration, save for the amendment to 35 Ill. Adm. Code.Part 303 which was transferred to Docket B.

JCAR staff recommended seven other changes involving sections 620.110, 620.250(a)(2), 620.302(b)(1), 620.450(b)(3)(A)(ii), 620.510(b)(1), 620.601(b) and 620.Appendix A(c)(1)(iii). These changes are discussed below in appropriate parts of this opinion and are incorporated into today's order.

The Board is pleased with the high quality perspective that has been brought to bear on this matter, both in hearing testimony and public comments. The Board expresses its appreciation to the many persons who have contributed in one form or another.

STATUTORY FRAMEWORK

The IGPA was enacted by the Illinois General Assembly as an outgrowth of long-standing concern by the General Assembly and the citizens of the State that the State's rich and valued groundwater resources be protected. The IGPA is a multi-faceted policy and program statement designed to provide that protection and to assure the continued viability of the State's groundwater resources. The policy statement of the IGPA is found at Section 2(b) (Ill. Rev. Stat. 1989, ch. 111½, ¶7452(b)), and reads:

> ... it is the policy of the State of Illinois to restore, protect, and enhance the groundwaters of the State, as a natural and public resource. The State recognizes the essential and pervasive role of groundwater in the social and economic well-being of the people of Illinois, and its vital importance to the general health, safety, and welfare. It is further recognized as consistent with this policy that the groundwater resources of the State be utilized for beneficial and legitimate purposes; that waste and degradation of the resources be prevented; and that the underground water resources be managed to allow for maximum benefit of the people of the State of Illinois.

The particular mandate of the IGPA pertinent to today's action occurs at Section 8 (Ill. Rev. Stat. 1989, ch. 111½, ¶7458). Section 8 reads:

> a. The Agency, after consultation with the Committee and the Council, shall propose regulations establishing comprehensive water quality standards which are specifically for the protection of groundwater. In preparing such regulations, the Agency shall address, to the extent feasible, those contaminants which have been found in the groundwaters of the State and which are known to cause, or suspected of causing, cancer, birth defects, or any other adverse effect on human health according to nationally accepted

guidelines. Such regulations shall be submitted to the Board by July 1, 1989.

b. Within 2 years after the date upon which the Agency files the proposed regulations, the Board shall promulgate the water quality standards for groundwater. In promulgating these regulations, the Board shall, in addition to the factors set forth in Title VII of the Environmental Protection Act, consider the following:

1. recognition that groundwaters differ in many important respects from surface waters, including water quality, rate of movement, direction of flow, accessibility, susceptibility to pollution, and use;

2. classification of groundwaters on an appropriate basis, such as their utility as a resource or susceptibility to contamination;

3. preference for numerical water quality standards, where possible, over narrative standards, especially where specific contaminants have been commonly detected in groundwaters or where federal drinking water levels or advisories are available;

4. application of nondegradation provisions for appropriate groundwaters, including notification limitations to trigger preventive response activities;

5. relevant experiences from other states where groundwater protection programs have been implemented; and

6. existing methods of detecting and quantifying contaminants with reasonable analytical certainty.

c. To provide a process to expedite promulgation of groundwater quality standards, the provisions of this Section shall be exempt from the requirements of subsection (b) of Section 27 of the "Environmental Protection Act", approved June 29, 1970, as amended; and shall be exempt from the provisions of Sections 4 and 5 of "An Act in relation to natural resources, research, data collection and environmental studies", approved July 1, 1978, as amended.

d. The Department of Energy and Natural Resources, with the cooperation of the Committee and the Agency, shall conduct a study of the economic impact of the regulations developed pursuant to this Section. The study shall include, but need not be limited to, consideration of the criteria established in subsection (a) of Section 4 of "An Act in relation to natural resources, research, data collection and environmental studies", approved July 1, 1978, as amended. This study shall be conducted concurrently with the development of the regulations developed pursuant to this Section. Work on this study shall commence as soon as is administratively practicable after the Agency begins development of the regulations. The study shall be submitted to the Board no later than 60 days after the proposed regulations are filed with the Board.

The Department shall consult with the Economic Technical Advisory Committee during the development of the regulations and the economic impact study required in this Section and shall consider the comments of the Committee in the study.

e. The Board may combine public hearings on the economic impact study conducted by the Department with any hearings required under Board rules.

In the following sections of this Opinion the Board discusses the various provisions that comprise today's adopted rules.

PART 303
CONFORMING AMENDMENT

Although the principal regulations adopted today consist of new Part 620, the promulgation of Part 620 requires a conforming amendment to 35 Ill. Adm. Code: Subtitle C, Part 303. Since the proposed amendments to Part 303 were published in the Illinois Register on November 2, 1990, more than one year ago, the Board is required to return to first notice on the Part 303 amendments only. Therefore, under separate Opinion and Order, the Board opens a docket C in this proceeding and again sends the Part 303 amendments to first notice.

PART 620
SUBPART A: GENERAL PROVISIONS

New 35 Ill. Adm. Code. Part 620 is designed to contain the principal provisions of today's action. It consists of six

Subparts plus two appendices. Subpart A sets out the general provisions applicable to the entire Part 620.

Except for generally non-substantive changes within the definitions and incorporations sections made in response to post-First Notice public comments[8], Subpart A remains essentially as proposed by the Agency in its third amended proposal.

Purpose -- Section 620.105

Section 620.105 sets forth the purpose of the Part. The Defenders had suggested insertion within this Section of the phrase "to assure that the groundwater resources of the State be utilized for beneficial and legitimate purposes, that waste and degradation of the resources be prevented, and that the underground water resource be managed to allow for maximum benefit of the people of the State of Illinois" (Def. Exh. 7 at proposed Section 620.101). This language comes from the policy statement found at Section 2(b) of the IGPA. While the Board fully stands behind this policy statement, the Board believes that today's Section 620.105 language is a better descriptor of the contents of the Part 620 rules, and therefore opts to use this version. The Board believes that this narrow purpose statement more clearly alerts the public to what is being regulated.

Definitions -- Section 620.110

Section 620.110 contains definitions applicable to Part 620. The intent is to present those definitions necessary for a reading of Part 620, including both definitions that are particular to the Part and those that are statutory; statutory definitions are capitalized, pursuant to standard form.

At second notice, JCAR recommended deletion of the phrase "unless otherwise provided" from the introductory statement at the beginning of this definitions section. The Board agrees to make this change.

General Prohibitions -- Section 620.115

Section 620.115 contains a general prohibition against threatening, causing or allowing a violation of the Illinois Environmental Protection Act, IGPA, or Board regulations, including this Part.

Incorporations by Reference -- Section 620.125

---

[8] See discussion at p. 5-8 of Second Notice Opinion, July 25, 1991.

Section 620.125 sets forth incorporations by reference as used within Part 620.

Exemptions from Subtitle C Standards -- Section 620.130

Section 620.130 exempts groundwaters from the General Use Standards or Public and Food Processing Standards of Subparts B and C of 35 Ill. Adm. Code 302. This change, in combination with amendment to Section 303.203 (see above), clarifies the relationship between 35 Ill. Adm. Code.Subtitle C and today's rules.

Exclusion for Underground Water in Certain Man-Made Conduits -- Section 620.135

Section 620.135 explicitly excludes any underground waters that occur in certain man-made conduits from the application of today's regulations. The man-made conduits included are subsurface drains, tunnels, reservoirs, storm sewers, tiles, and sewers[9]. Waters in such conduits do not have the conventional characteristics and properties of groundwater, and it is therefore inappropriate to apply to them water quality standards that are based upon groundwater characteristics and properties.

It is perhaps arguable that Section 620.135 is not necessary since the definition of groundwater itself would seemingly exclude water in most, if not all, of the man-made conduits listed. Thus, if these waters are not groundwaters, groundwater standards would not apply to them. However, the record attests that there is sufficient confusion on this matter (see Agency Statement of Reasons, p. 11; PC #9; PC #10; PC #13) to warrant a definitive exclusion for water in man-made conduits.

It should be recognized that water in man-made conduits is not excused from all water quality standards. To the extent that such waters are "Waters of the State", they would be subject to the water quality standards of Subtitle C. As well, if such waters are discharged to the surface, they would be subject to water quality standards applicable to surface waters. The Illinois Department of Agriculture notes this conclusion with respect to drainage from agricultural field tiles:

> It is inappropriate to apply any numbers or standards to water in a drainage tile except surface water standards at the point of discharge to a surface water,

[9] Specifically not included are waters within wells or other structures designed to tap groundwater.

at which point one also must consider the effects of mixing. PC #9 at p. 1.

PART 620
SUBPART B: GROUNDWATER CLASSIFICATION

Subpart B sets out today's general groundwater classification system, criteria for classifying specific groundwaters, the concept of management zones, and procedures for amending the classification of any specific groundwater.

Groundwater classification is a well-recognized tool for the optimizing of groundwater protection efforts. Among its many utilities are the opportunity of recognizing the different values, uses, and vulnerabilities of groundwaters (Defenders Exh. 6). Today's rules specifically accord with the mandate of the IGPA at Section 8(b)(2) that the Board consider "classification of groundwaters on an appropriate basis, such as their utility as a resource or susceptibility to contamination".

List of Groundwater Classes -- Section 620.201

Section 620.201 establishes that there are four classes of groundwater. In addition, it establishes that some groundwaters may fall into groundwater management zones, pursuant to Section 620.201. Every groundwater in the State belongs to one of the four classes or to the waters in a groundwater management zone.

The four classes of groundwater derive from concepts presented over the full history of this proceeding, beginning with the Agency's original proposal and the Defenders' counter proposal, and culminating in the Agency's third amended proposal (Docket B). Perhaps no other facet of this proceeding has focused as much effort as has determining how best to classify the State's groundwaters.

Basic to the groundwater classification effort is the concept that groundwater constitutes a valued resource. This principle is articulated in the opening sentence of the State's Groundwater Protection Policy:

> . . . it is the policy of the State of Illinois to restore, protect, and enhance the groundwaters of the State, as a natural and public resource. IGPA, Section 2(b).

It is recognized, however, that not all groundwaters constitute the same level of resource; some groundwaters have greater resource value by virtue of their higher quality, quantity, accessibility, etc. Moreover, it is generally agreed that the degree of protection required is in some measure a function of the nature of the particular groundwater resource. This concept constitutes one of the bases for groundwater classification, and the application of different water quality standards, monitoring and remedial requirements, etc., to the different classes.

It is to be further recognized that potability[10] generally constitutes the "highest" use to which groundwaters are put. Potability, as a further generality, requires the highest degree of protection, including the most stringent standards, to maintain the use. Potable-use also is by far the largest use to which groundwaters in Illinois are put, and will be put in any foreseeable future. Given these circumstances, it is apparent that any successful program of groundwater management must give special focus to potable groundwaters. Emphasis on potable groundwaters is recognized in the declaration that the first class of Illinois groundwaters consists of the potable resource groundwaters.

Potable Groundwaters Class -- Section 620.210

Section 620.210 establishes the definition of a Class I: Potable Resource Groundwater. Included are all groundwaters that are located 10 feet or more below the land surface and that, by any one of several tests, produce groundwater in quantities sufficient to sustain a potable use. In addition, Section 620.210 specifically identifies that the Board may add groundwaters to Class I via the adjusted standards procedures spelled out at 620.260.

The tests used to determine potable quantities include demonstrated use, thicknesses associated with aquifers found in various rock types, or suitable hydrogeologic parameters. The latter include water in strata capable of a sustained yield of at least 150 gallons per day in a borehole of reasonable size and over a typical collection thickness[11].

Class I groundwaters clearly include a very broad range of groundwaters. This is fully intended. Moreover, it should be noted that Class I groundwaters include groundwaters of potential potable use as well as groundwaters currently experiencing potable use. A recurrent question regarding the resource-protection concept of groundwater protection has been whether potentially usable groundwaters should be afforded like

---

[10] "Potable" is defined at in the IGPA as meaning "generally fit for human consumption in accordance with accepted water supply principles and practices" (Ill. Rev. Stat. 1989, ch. 111 1/2, par. 7453(h)).

[11] The 150 gallons per day limit is that limit which the USEPA defines as a yield sufficient for a groundwater to serve as water source for a household unit (Defender's Exh. 6, p. 39, 45; PC #16 at p. 12-16). The qualifications regarding sustainability of yield and size of borehole plus the hydraulic conductivity condition were first proposed and discussed by the Agency at the May 30, 1991 hearing (R3 at 18-23; Exh. T).

protection to groundwaters actually being used (e.g., R1 at 26, 968-9; PC #6 and #8). The Board previously addressed this issue in R86-8[12]. It there noted:

> Resource groundwaters are, at the minimum, those groundwaters which are presently being put to conventional use by reason of being of suitable quality, having local demand, and having been actually developed. Much of the record also shows that resource groundwaters ought also to include those groundwaters which have the potential for being put to conventional use. This perspective is straightforward, in that it suggests that potential resources should be protected against the eventuality that at least some of them will find use in the future. The Board believes that this is a wholly correct perspective, and accordingly concludes that resource groundwaters should include groundwaters of potential use. (Id. at II-3)

The Board believes that this perspective remains correct today, and accordingly it is incorporated into today's rules. Moreover, the Board believes that the General Assembly also endorsed this perspective by defining in the IGPA that a "'resource groundwater' means a groundwater that is presently being or in the future capable of being put to beneficial use" (IGPA at Section 3(j), Ill. Rev. Stat. 1989, ch. 111 1/2, par. 7453(j); emphasis added). That is, the Board believes that among the most necessary facets of the State's groundwater protection program is the need to protect all drinkable water at a drinkable level. Similarly, the Board does not believe that current actual use should be the sole control of whether potable groundwater is afforded the protection necessary to maintain potability; we simply cannot allow the sullying of a resource that future generations may need. For the same reason the term "Potable Resource Groundwater", rather than "Potable Use Groundwater", is employed in the title of this class.

The Board also notes that today's rules do not attempt to limit the definition of potability by qualifiers relating to time of travel to existing wells or stratigraphic position, as have some earlier proposals. This is in keeping with the position that all naturally potable groundwaters should be recognized as such, irrespective of whether they are currently experiencing use as a potable water supply.

Among the concepts not adopted today is the proposition espoused by the Defenders that to Class I groundwaters should be added all groundwaters hydrologically connected to and upgradient of potable resource groundwaters (R2 at 523; R3 at 269-70); under

---

[12] In the Matter of: A Plan for Protecting Illinois Groundwater, R86-8, Report of the Board, August 28, 1986.

the instant rules most such groundwaters would be Class II groundwaters. The Defender's concept is not adopted because it offers little additional groundwater protection at a substantial increase in the regulatory burden.

Lastly, the Board notes that the 10-foot rule arises from the need to recognize that many surface activities can impact very shallow underground water without also impacting the great bulk of potable groundwaters. For example, the agricultural community has expressed substantial concern that establishing standards for groundwater would critically impact agriculture by disallowing the chemical alteration of all subsurface waters, including disallowing use of agricultural chemicals that operate through roots. To assure that this erroneous interpretation is not fostered, and to assure that legitimate use of agricultural chemicals or other legitimate activities are not proscribed, it was proposed at the December 4, 1990 hearing that the potable resource (Class I) groundwater standards specifically apply only to groundwaters below a depth of 10 feet, irrespective of whether these waters would otherwise qualify as potable waters; groundwaters shallower than 10 feet would always be Class II, III, or IV, depending upon the local circumstances.

The Board today endorses the "10-foot" rule as a reasonable compromise between the need to protect potable groundwaters and the need to carry on legitimate surface activities, of which agriculture is but one.

As a further observation on the "10-foot" rule, the Board notes that question has been raised whether potable groundwaters found below 10 feet, but located in a geologic unit that meets one of the thickness criteria only because a part of the unit is at a depth less than 10 feet, would still be considered a Class I water (R3 at 300). The Board intends that the answer to this question be "yes". Simply, if the water is below 10 feet and is naturally potable, it should be supported as a potable water resource. Prior to Second Notice a Board Note to this effect was added to Section 620.210 upon the recommendation of the Agency (PC #58 ¶4).

The General Resource (Default) Class -- Section 620.220

Class II: General Resource Groundwater is, by definition at Section 620.220, the default groundwater class. That is, Class II consists of those groundwaters that are not Class I, III, or IV. For example, a groundwater occurring in a thin shale unit that is not actually producing potable groundwater and that has a hydraulic conductivity less than 1×10^{-4} cm/sec would fall into Class II unless one of the special conditions of Class III or IV should apply. In general, a groundwater would fall into Class II if it is not potable by virtue of quantity or quality limitations, if it has not been otherwise specially classified

according to Class III procedures, or if it is not otherwise limited pursuant to Class IV qualifications.

The Board anticipates that groundwaters in "tight" hydrogeologic units will constitute one of the most common occurrences of Class II groundwaters. These are groundwaters that are unavailable in quantities sufficient for most uses. Another common occurrence is likely to be groundwaters that are not so saline as to warrant classification as Class IV: Other Groundwater, but that nevertheless are too saline to be potable without treatment.

Given the several ways that a groundwater may be classified as a Class II groundwater, in the long term it may be advisable to either subdivide Class II or split out additional classes from Class II. However, the Board believes that this endeavor, should it be undertaken, best awaits some experience with the more general classification adopted here.

Special Resource Groundwater -- Section 620.230

Section 620.230, Class III: Special Resource Groundwater, is derived in concept from the Defenders' proposal, which in turn is based on the United States Environmental Protection Agency's ("USEPA") groundwater classification strategies[13]. The Defenders contend that in certain circumstances a groundwater may take on an ecologically vital role, as for example when its discharge supports a vital wetland (R1 at 969-971). Other examples might include caves, lakes, ponds, streams, and perhaps even the more moist varieties of prairies and forests. In general, the Board believes that the concept of special treatment of unique or ecologically vital groundwaters via more stringent standards is a meritorious concept.

In its First-Notice form Section 620.230 provided for the placement of a groundwater in Class III only though the formal action of the Board pursuant to Section 620.250. At the May 30, 1991 hearing, with the support of the Illinois Nature Preserves Commission (PC #50) and the Illinois Department of Conservation (PC #52), the Agency proposed that groundwaters that contribute to a dedicated nature preserve, as listed by the Agency, also be designated as Class III groundwaters via an alternate, more expeditious route found at subsection (b) (R3 at 24-7). As the Agency notes:

> This will provide a more expedited process to list sites that have already been designated by the Nature Preserve Commission, and also will allow for a review

---

[13] See Guidelines for Ground-Water Classification under the EPA Ground-Water Protection Strategy, USEPA Office of Ground-Water Protection, November 1986: Defender's Exh. 6.

> of these sites on a case-by-case basis. Sixty sites have been identified by the Commission as nature preserves that may have an important relationship to groundwaters. The review of this information on a case-by-case basis is important to help determine what relation groundwater has to these sites. (R3 at 26)

The Board notes that any person who feels aggrieved by an Agency decision under subsection (b) would still have recourse to bring the action before the Board pursuant to subsection (a). Moreover, as the Defenders correctly observe, the listing process would "only resolve the question of which nature preserves would be designated as containing Class III groundwater; there may still need to be a Board proceeding to determine the appropriate groundwater standards to apply" (PC #57 at p. 6).

Other Groundwater -- Section 620.240

Section 620.240 sets out criteria for classifying Class IV: Other Groundwater. The purpose of the class is to accommodate certain waters that, due to particular practices or natural conditions, are limited in their resource potential. Included are groundwaters that are naturally saline, groundwaters that occur in the zone of attenuation surrounding a landfill, groundwaters in mining-disturbed areas, and affected groundwaters associated with potential primary or secondary sources, as defined in the IGPA. The class also would contain any groundwater designated by the Board as an exempt aquifer.

Several modifications of Section 620.240 were made in response to First Notice comments. The interested person is direction to the Second Notice Opinion of July 25, 1991 at p. 13-15 for a description and discussion of these modifications.

Groundwater Management Zones -- Section 620.250

Section 620.250 provides for establishment of a management zone within each class of groundwater. A management zone is identified by the Agency for groundwaters that have become impaired due to contamination. In any management zone the goal is remediation, if practicable, of the groundwater to the level of the standards applicable to that class of groundwater (R3 at 32).

Unlike most of the other provisions of today's rules, the concept of a management zone was first introduced into this proceeding in the Agency's Docket B proposal. Previously the various proposals had entertained a "Remedial Groundwater" class into which various "substandard" but potentially remediable groundwaters were to reside temporarily or permanently (e.g., see Section 620.230 of the Board's Docket A proposal, September 27, 1990). As the Agency observes, a persistent problem with a remedial class of groundwater concerns the class to which

remedial groundwaters return after remediation (R3 at 32). As an alternative to a separate remedial class, the Agency turned to the groundwater management zone (Id.). Moreover, the management zone concept also provides a better coupling with RCRA and CERCLA regulations (Id. at 33).

At second notice, JCAR recommended that the form required for the confirmation of an adequate corrective action pursuant to 35 Ill. Adm. Code 620.250(a)(2) be made an appendix to the rule. The Board has agreed to do so, and the form is placed at Appendix D in today's order.

Adjusted Standards -- Section 620.260

Section 620.260 specifies that reclassification of any groundwater can occur as a result of an adjusted standard proceeding before the Board, in accord with the adjusted standard provisions of the Illinois Environmental Protection Act. The Section also specifies the level of justification required of a petitioner and other information to allow the Board to determine the adjusted standard, pursuant to Section 28.1 of the Act.

The Board notes that, in addition to an adjusted standard, recourse to reclassification of a particular groundwater also would be available via the site-specific rulemaking process. Since, there are differences in proofs, conduct of hearings, etc., between adjusted standards proceedings and rulemaking proceedings, any interested person would be advised to consider both before choosing a course of action.

PART 620
SUBPART C: NONDEGRADATION AND PREVENTIVE NOTIFICATION/RESPONSE

Subpart C contains nondegradation provisions and general preventive notification and response actions. These, in part, set the framework for the remainder of Part 620.

Nondegradation -- Section 620.301

Section 620.301 states the basic nondegradation provision of today's rules. Its essence is a prohibition against impairment of any existing or potential use of groundwaters.

A principal area of contention in this proceeding has been whether nondegradation ought to encompass some more stringent prohibition. Alternate proposals have included a prohibition against causing or allowing a statistically significant alteration in groundwater chemistry, or of causing or allowing any change in groundwater chemistry.

The Board today declines to generally extend nondegradation beyond the prohibition against loss of use[14]. The Board does this with some reluctance. Perhaps at some time in the future this step can be taken. However, today we simply do not have the information base, or resources necessary to obtain the information base, upon which to found universal judgments of no (statistical) change in groundwater chemistry.

It has sometimes been said that casting the nondegradation provision as it is today is equivalent to allowing pollution up to the standard. The Board believes that this characterization is too simplistic. Among other matters, the whole preventive notification and response program (see following) is directed toward an early alert to, and staving off, of any increase in contamination in the most sensitive groundwater/potential source situations. Moreover, in other regulations, such as the Board's landfill regulations at 35 Ill. Adm. Code 810-815 and the groundwater regulations at 35 Ill. Adm. Code 615 and 616[15], additional proscriptions against allowing of groundwater quality modifications also occur.

The Board believes that the proper way to characterize today's nondegradation provision is that it consists of the baseline, rule-of-general-applicability. In specific circumstances dictated both by today's rule and by other regulations license to alter the State's groundwaters is significantly more proscribed. Moreover, the Board also would anticipate, as we gain better understanding of the many dynamics of groundwater and sources of groundwater pollution, that these proscriptions also will expand. In fact, at subsection (d) the Board emphasizes its intention of providing for such different nondegradation provisions, including more stringent provisions, applicable under specific circumstances.

Applicability of Preventive Notification/Response -- Section 620.302

Section 620.302 sets forth the circumstance under which preventive notification and preventive response is applicable; the section is a prelude to the preventive notification and response provisions found in Section 620.305 and 620.310. In

---

[14] There is one area in which the Board has previously determined that no statistical increase in groundwater contaminants is allowable. That is at the bounds of the zone of attenuation associated with landfills. The Board intends that nothing in today's action overturn this prior determination.

[15] In the Matter of: Groundwater Protection: Regulations for Existing and New Activities Within Setback Zones and Regulated Recharge Areas, (35 Ill. Adm. Code 601, 615, 616, and 617), R89-5, currently in Second Notice.

general, preventive notification and response is applicable only to persons who conduct groundwater monitoring pursuant to some other State or Federal program (R3 at 39). In addition, preventive notification and response is associated only with the high-quality, high-use groundwaters, Class I and Class III groundwaters.

At the recommendation of JCAR, the Board has agreed to insert the appropriate citations after the phrase "state or Federal law or regulation" at 620.302(b)(1).

Preventive Notification Procedures -- Section 620.305

Preventive notification consists of (a) confirmation of results and (b) notification of interested persons. If it is the owner or operator who is required to monitor, the appropriate regulatory agency must be notified of the results. If it is a government agency that is required to monitor, it is the owner or operator who must be notified.

The preventive notification procedures for Class I groundwaters are triggered when numerical limits associated with either of two classes of contaminants is exceeded. These are the contaminants found at Section 620.310(a)(3)(A), which consist of the toxic heavy metals and the more common organic and petrochemical contaminants, and the contaminants identified as carcinogens at Section 620.410(b). For Class III groundwaters the preventive notification trigger is the detection of a contaminant for which there is a standard pursuant to Section 620.430.

It is important to note that these preventive notification triggers are generally much lower than the water quality standard for the same constituents. This is in keeping with the philosophy of becoming alert and reacting to potential problems in high-value groundwaters before these problems can grow to an unmanageable scale. It is further in keeping with the principle that in general it is much more expensive, including public expense, to remediate contaminated groundwater than it is to prevent the occurrence of groundwater contamination.

Preventive Response Activities and Levels -- Section 620.310

Section 620.310 describes preventive response activities that are required upon receipt of a preventive notification. The Section also specifies the preventive response levels[16] used to determine if a detected concentration requires a preventive response. In either case, the purpose of this Section to is to

[16] Prior to the submission of the Docket B proposal, these limits were called "corrective action levels" (e.g., R1 at 114-129).

provide a nexus between the body of today's rules and existing and future regulatory programs that need triggers for corrective action. No new corrective action program is today adopted.

The preventive response levels are set with several conditions in mind (R3 at 43). Among these are that all levels are at or above the practical quantitation limit (PQL); carcinogens, which have potable resources standards set at PQLs (see Section 620.410), are not listed because there is no basis for establishing a preventive response level below a PQL (PC #47 at p. 15). Exceedence[17] of background is employed for metals and the non-carcinogenic organic constituents.

PART 620
SUBPART D: GROUNDWATER QUALITY STANDARDS

Subpart D constitutes the focus of the instant regulations. Within it are contained the actual groundwater standards as mandated by the IGPA. Since the groundwater standards are closely tied to the groundwater classification system of Subpart B, the form of Subpart D parallels that of Subpart B.

Introduction -- Sections 620.401 and 620.405

Section 620.401 establishes the connection between the groundwater classification system presented in Subpart B and the groundwater standards of Subpart D, which is that all groundwater must meet the standards specified for the class to which the groundwater belongs. Section 620.405 provides a narrative standard that prohibits violation of the numeric standards of this Subpart.

Standards for Potable Resource Groundwater -- Section 620.410

Section 620.410 contains the groundwater standards applicable to the Potable Resource Groundwater found in Class I (see discussion of Section 620.210, above). In general, the standards found in this Section are equal to the USEPA's Maximum Concentration Levels ("MCLs)" applicable "at-the-tap" pursuant to the Safe Drinking Water Act ("SDWA"). The MCL levels are specified as water quality standards under the principle that groundwaters that are naturally potable should be available for drinking water supply without treatment.

---

[17] The Board notes that within Section 620.310 and several subsequent sections of the First Notice proposal, the word *exceedence* was incorrectly spelled as exceedance. *Exceedence* is derived from the verb *exceed*, which in turn is derived from the Latin *excedere* via the Middle French *exceder* and the Middle English *exceden*; Latin infinitives ending in "ere" generate English nouns ending in "ence".

An historical difficulty with incorporation of numeric standards within regulations is the need to constantly revise the numbers as new information is developed. This difficulty has a particular presence in the instant matter because the USEPA is in the process of a major MCL promulgation effort. Even over the short course of this proceeding the Agency has had to several times revise its standards recommendations in keeping with USEPA's action on MCLs (e.g., PC #47 at p. 17-9; R3 at 49-50; Exh. T; PC #52 at p. 25, 27); it is to be expected that the current MCL list will continue to experience changes within the coming years.

At the First Notice of Docket A the Board proposed to address the matter of changing standards/MCLs of Section 620.410 in what it considered a novel and advantageous method. The Board noted:

> Ordinarily [the USEPA promulgation of new standards/MCLs] would imply that Part 620 regulations would have to be regularly reopened and updated to accommodate new MCLs. However, the Board today proposes a stratagem that both forestalls the need to constantly update the MCL list at Section [620.410] and also assures that the MCLs of Section [620.410] remain current. The stratagem consists of identifying the groundwater standards that apply to Potable Resource Groundwaters as being identical with the MCLs found at 35 Ill. Adm. Code 611.Subpart F. 35 Ill. Adm. Code 611.Subpart F contains the "identical in substance" MCLs promulgated pursuant to the SDWA and the Act. As such, 611.Subpart F is subject to updates every six months, pursuant to the Board's SDWA "identical in substance" update program. (Docket A, Opinion p. 17)

At Second Notice of the instant rules the Board receded from this stratagem in the interest of moving this proceeding forward. However, the Board there noted and here continues to note that it expects from the Agency regular[18] updates of the groundwater standards, parallel to those undertaken for the Public Water Supply Standards at 611.Subpart F.

General Resource Groundwater Standards -- Section 620.420

Section 620.420 establishes standards for Class II: General Resource Groundwaters. Because groundwaters are placed in Class II because they are quality-limited, quantity-limited, or both (see Subpart B discussion above), it is necessary that the

[18] The Board notes that the Defenders urge a regular (perhaps every three years) review of both the Class I and Class II standards (e.g., R3 at 257).

standards that apply to these waters reflect this range of possible attributes. Among the factors considered in determining the Class II numbers are the capabilities of treatment technologies to bring Class II waters to qualities suitable for potable use (R3 at 75). Thus, many Class II standards are based on MCLs as modified to reflect treatment capabilities. For some parameters the Class II standards are based on support of a use other than potability (e.g., livestock watering, irrigation, industrial use) where the different use requires a more stringent standard (R3 at 114-8).

Standards Applicable to Special Resource Groundwaters -- Section 620.430

Section 620.430 specifies that the standards applicable to Class III: Special Resource Groundwater are the same standards applicable to Class I groundwater, except as may be provided by the Board in a proceeding pursuant to Section 620.260. Accordingly, the default values of the standards are the Class I standards, with more stringent standards possible if a justification is made for them.

Standards Applicable to Other Groundwater -- Section 620.440

The existing concentration is the basic standard to be applicable to Class IV Groundwater. It is also provided that specific exceptions apply to groundwaters within a zone of attenuation of a landfill, as defined pursuant to 35 Ill. Adm. Code 811 and 814, and within a previously mined area as defined at Section 620.110. Within a zone of attenuation existing concentrations are not to be exceeded except as caused by leachate. Within a previously mined area existing concentrations are not to be exceeded except for pH, total dissolved solids, and those major ions (chloride, iron, manganese, and sulfate), which are typically disturbed as a result of coal mining.

Alternate Groundwater Standards -- Section 620.450

Section 620.450 recognizes that special groundwater standards are necessarily associated with certain activities, as contrasted to native types of groundwater. These activities today are identified to include sites undergoing corrective action or equivalent corrective processes and sites for surface and underground coal mining activities.

At the recommendation of JCAR, the Board agreed to cite the appropriate citation to 62 Ill. Adm. Code 1780.21(f) and (g) at 620.450(b)(3)(A)(ii).

PART 620
SUBPART E: GROUNDWATER MONITORING AND ANALYTICAL PROCEDURES

Subpart E sets out some minimal conditions associated with groundwater monitoring and analytical procedures. These constitute rules-of-general-applicability; in other regulations further conditions and proscriptions may be added to these. It is to be particularly noted that today's rules contain no new required monitoring program.

An important part of Subpart E is found in the Compliance Procedures of Section 620.505. This Section specifies where compliance determinations may be made. As the Agency notes, this Section "recognizes the practical limitations associated with groundwater monitoring and cleanup under a building, landfill, or tank" (PC #47 at p. 23). Also specified in Section 620.505 are the conditions necessary for a water or monitoring well to serve as a compliance point.

For Section 620.510(b)(1), at the recommendation of JCAR, the Board inserted the word "regulatory" after the word "appropriate", to make it clear that what is referred to is the appropriate regulatory agency.

PART 620
SUBPART F: HEALTH ADVISORIES

Subpart F establishes procedures for developing and issuing a Health Advisory. A Health Advisory is a means for the Agency to establish a guidance level for a chemical substance or a mixture of chemical substances for which a standard has not yet been set under Subpart D. This advisory process is intended to mirror the procedure used by USEPA to account for substances detected in groundwater that do not have a promulgated standard. Also, the Agency notes that this Subpart would codify existing practice by the Agency (Statement of Reasons, p. 28-36).

Because the Health Advisory provision and its attendant Appendices have been presented to the Board without apparent controversy, and because the Board has not itself proposed substantive amendment to the Agency's version, the Board will not here discuss these matters further. The interested person is directed to the Agency's Statement of Reasons, p. 28-36, for more discussion and explanation.

Two changes to the Health Advisory material were recommended by JCAR and accepted by the Board. These are to update certain phraseology and citations connected with the change in public water supply regulations cited in Section 620.601(b); and to delete the term "approximately" and add the terms "at least 5%" in Section 620.Appendix A(c)(1)(iii).

ECONOMIC IMPACT

EcIS Document

On January 31, 1990, DENR filed the EcIS in this matter, titled: "Economic Impact Study for Proposed Groundwater Quality Standards, 35 IL. Admin. Code 620" (DENR Exh. 5). The EcIS was prepared by Camp Dresser & McKee, Inc. The study evaluated groundwater remediation costs using historical data on groundwater contamination in the State and also examined benefits consisting of reduced health risks through decreased exposure to contaminants in groundwater. Pursuant to Section 8 of the IGPA and in an effort to expedite the promulgation of the regulations, the EcIS was conducted concurrently with the development of the regulations. Therefore, the EcIS document focused on various options under consideration during the development of the original Agency proposal, over two years prior to today's action.

Cost Analysis

The EcIS investigators determined that the most significant costs of the regulations can be expected to be groundwater remediation costs; i.e., those costs associated with returning contaminated groundwater to compliance with the standards.

To estimate remediation costs, the EcIS investigators used historical data on groundwater contamination in the State. The analysis focused on costs for prototypical remediation of six parameters representing organic, inorganic, and pesticide contaminants. Cleanup cost estimates ranged from $8.83-$8.85 million for the organic contaminants, $12.84-$13.64 million for the pesticides, and $9.10 million for the inorganic contaminants, per incident over a 20 year period. To derive statewide cleanup costs, the estimated per facility costs were multiplied by an estimated number of sites of contamination (24 volatile organic compound incidents and four pesticide incidents). The estimated costs for these remedial actions would range from $263-$267 million.

By using data on existing incidence of groundwater contamination, the EcIS investigators further assumed that costs could be higher for three reasons. These are that although the Agency did not report an incidence for inorganic contamination of public water supply facilities, it is highly probable that the incidence would be greater than zero. Also, since the regulations could include a greater number of VOC's than the Safe Drinking Water Act MCLs, a greater incidence of contamination can be expected. Lastly, the EcIS investigators believe that the actual number of cleanups required would more likely be closer to the number of facilities that exceed the detection limit than the number that exceed an MCL. The statement is based on their belief that once a contaminant is detected, groundwater

contamination is already likely to exceed enforcement or potable use standards somewhere at the site[19].

Given these considerations, and based upon estimates derived from existing contamination incidences, the EcIS investigators reported estimated costs of $1,141 million for VOC remediation, $238 million for pesticide remediation, and $610 million for inorganic remediation, leading to a total estimated state-wide cleanup cost of $1.99 billion. This was calculated only for sites within 3000 feet of community water supply wells, since the proposed Class I standards at the time of EcIS development were proposed to be applied only within the 3000-foot distance.

In its most recent comments, DENR estimates that the costs under today's version of the rules could be higher since Class I has been expanded to include a larger volume of the State's groundwaters. The EcIS investigators estimated costs 50% higher should Class I (as defined sometime before the completion of the EcIS in January 1990) include all groundwaters rather than the 3000-foot zone. Therefore DENR states that costs for the entire State would be $3.1 billion. DENR recognizes that the addition of provisions for groundwater management zones and adjusted standards options could offset the increase (PC #55).

Benefits Analysis

The EcIS investigators report that the primary benefit of groundwater standards is "reduced health risks through decreased exposure to contaminants in groundwater". They explain the benefits thusly:

> These benefits can be expressed as decreased health care expenses, lower health insurance premiums, reduction in pain and suffering, and a better quality of life for Illinois citizens. Reductions in excess cancer risks . . . [and a]lthough not examined quantitatively, a corresponding decrease in non-carcinogenic health risks also can be anticipated as a result of the proposed regulations.
>
> A second major benefit of the proposed regulations is preservation of groundwater as a resource for future generations. By preventing contamination where possible through preventive management practices and by

---

[19] For the same reasons, the EcIS investigators believe that the economic impact of trigger limits which would be somewhere between detection levels and potable use standards would not result in cost savings due to early detection of contamination. That is, they believe that once there is detection, there would most likely already be contamination above potable use standards somewhere on the site, which would require remediation.

> addressing existing contamination through groundwater remediation, the value of the resource is preserved and the availability of groundwater for future use is greatly enhanced.
>
> Other non-quantifiable benefits include avoided decreases in property values proximal to sites of groundwater contamination, avoided restrictions in siting for private and community potable wells, and avoided negative impact on wildlife and ecology of areas served by groundwater base flow. Additionally, the aesthetic value of the state's groundwater reserves will be enhanced by the proposed regulations. Finally, . . . a major portion of the costs of cleanups can actually be considered benefits for engineering firms, construction firms, water utilities, and other parties involved in groundwater remediation.
>
> (EcIS at 6-8 to 6-10)

In Appendix D to the EcIS the EcIS investigators listed information on the toxicological effects of substances to be regulated. Section 5.2.4 of the EcIS discusses calculations of carcinogenic risk factors based on USEPA risk levels defined in terms of excess cancer risks.

Discussion and Comments

One of the major points brought out in comments surrounding and at the March 29, 1990 EcIS hearing is that the EcIS authors did not base analysis upon what was then the Agency's proposal (R. 697-702; PC #16, R89-14 Board First Notice Opinion and Order, September 27, 1990). This was mainly because the EcIS was statutorially required to be conducted concurrently with the development of the proposal. This was done in an effort to inject economic analysis into the process at an early stage. However, it did not anticipate that the proposal would undergo a series of major revisions after completion of the EcIS. Thus, even had the EcIS been conducted on the Agency's proposal as it stood in March 1990, the EcIS could not have addressed the changes in subsequent proposals, including the rules today adopted. Therefore, any examination of economic impact that includes the EcIS must consider the context in which the study was developed and the lack of availability to the EcIS investigators of subsequent revisions.

With that preface, the Board recognizes that if remediation to the level of today's standards is subsequently required through other programs, costs of remediation of groundwater could be substantial. It is important to remember, however, that these are groundwater quality standards, not cleanup standards or requirements. As the EcIS authors realized, site specific considerations can and most likely will determine the nature of

required remediation and what actual cost is to be borne by any particular entity, industry, or government[20]. As stated concerning the concurrent R89-5 proceeding, there is difficulty in applying economic analysis to a rule of general applicability. This is especially true where there are as many varied conditions and unknown circumstances as are likely to be encountered here. It also must be borne in mind that exception procedures associated with adjusted standards and features such as the groundwater management zones must temper any attempt to broadly cast cost estimates.

Another factor in consideration of the EcIS' cost estimates is that the instant regulations do not create or require any new corrective action program; all such programs are part of other regulations already in place or proposed (e.g., RCRA, CERCLA, LUST, waterwell setback regulations, etc.). It is accordingly not appropriate to attribute to today's regulations the cost of corrective actions that are not prompted by today's regulations. The EcIS investigators recognized that the remedial costs properly associated with the instant rules should be "incremental costs over and above the costs associated with the currently applicable regulations for water quality standards and cleanup criteria", but further stated that they did not consider the costs of these other programs because of "the limited number of remediations brought under the current regulatory scheme" (EcIS at ii).

The fact that the EcIS investigators attributed to today's groundwater quality standards all the costs of any potential future remedial action is a serious flaw in the EcIS analysis. Cleanup of contaminants to the levels stated in these rules as required by an appropriate agency during remediation does not mean that all the costs of cleanup should be attributed to adoption of today's rules. The remediation programs already require cleanup of most of the parameters listed in the instant regulations[21], in some cases to levels more stringent than in today's rules. That to date there have been few such cleanups in Illinois does not make the cost of all further cleanups attributable to today's rules.

---

[20] Much discussion at hearing and in subsequent comments concerned different treatment techniques and their costs (See generally, R1 at 889-97, 760-1; PC #5).

[21] Some of the parameters in the instant regulations, including iron, total dissolved solids, and boron, are not regulated under RCRA and CERCLA. However, the EcIS investigators observe that it would be unlikely that these parameters could be exceeded without a simultaneous exceedence of one or more parameters which are regulated under RCRA and CERCLA (R1 at 759).

A comprehensive list of benefits was included in the EcIS, though the EcIS investigators did not attempt to quantify them, save for the carcinogenic health risks. Additional benefits identified at hearing include reduced expenses to obtain alternate water supplies necessary to replace contaminated current supplies, and reduced expenses for treatment of water at well heads to render it potable or suitable for industrial use (R1 at 820, 830-2). It is important to note that although the benefits currently cannot be quantified, they are thereby no less real or substantial; it is only that they cannot be identified in terms of reliable, specific dollar figures.

ORDER

The Clerk of the Board is directed to submit the text of the following amendments to the Secretary of State for final notice pursuant to Section 6 of the Illinois Administrative Procedures Act.

TITLE 35: ENVIRONMENTAL PROTECTION
SUBTITLE F: PUBLIC WATER SUPPLIES
CHAPTER I: POLLUTION CONTROL BOARD

PART 620
GROUNDWATER QUALITY

SUBPART A: GENERAL

SUBPART B: GROUNDWATER CLASSIFICATION

SUBPART C: NONDEGRADATION PROVISIONS FOR APPROPRIATE GROUNDWATERS

SUBPART D: GROUNDWATER QUALITY STANDARDS

SUBPART E: GROUNDWATER MONITORING AND ANALYTICAL PROCEDURES

SUBPART F: HEALTH ADVISORIES

AUTHORITY: Implementing and authorized by Section 8 of the Illinois Groundwater Protection Act (Ill. Rev. Stat. 1989, ch. 111 1/2, par. 7458).

SOURCE: Adopted in R89-14(B) at ____ Ill. Reg., _____, effective _____.

NOTE: Capitalization denotes statutory language.

SUBPART A: GENERAL

Section 620.105 Purpose

This Part prescribes various aspects of groundwater quality, including method of classification of groundwaters, nondegradation provisions, standards for quality of groundwaters, and various procedures and protocols for the management and protection of groundwaters.

Section 620.110 Definitions

The definitions of the Environmental Protection Act (Ill. Rev. Stat. 1989, ch. 111 1/2, par. 1001 et seq.) and the Groundwater Protection Act (Ill. Rev. Stat. 1989, ch. 111 1/2, pars. 7451 et seq.) apply to this Part. The following definitions also apply to this Part.

"Act" means the Environmental Protection Act (Ill. Rev. Stat. 1989, ch. 111 1/2, pars. 1001 et seq.).

"Agency" means the Illinois Environmental Protection Agency.

"AQUIFER" MEANS SATURATED (WITH GROUNDWATER) SOILS AND GEOLOGIC MATERIALS WHICH ARE SUFFICIENTLY PERMEABLE TO READILY YIELD ECONOMICALLY USEFUL QUANTITIES OF WATER TO WELLS, SPRINGS, OR STREAMS UNDER ORDINARY HYDRAULIC GRADIENTS. (Section 3(b) of the IGPA)

"BETX" means the sum of the concentrations of benzene, ethylbenzene, toluene, and xylenes.

"Board" means the Illinois Pollution Control Board.

"Carcinogen" means a chemical, or complex mixture of closely related chemicals, which has been listed or classified in the Integrated Risk Information System or as specified in a final rule adopted by USEPA in accordance with USEPA Guidelines for Carcinogenic Risk Assessment, incorporated by reference at Section 620.125, to be a group A, B_1, or B_2 carcinogen.

"COMMUNITY WATER SUPPLY" MEANS A PUBLIC SUPPLY WHICH SERVES OR IS INTENDED TO SERVE AT LEAST 15 SERVICE CONNECTIONS USED BY RESIDENTS OR REGULARLY SERVES AT LEAST 25 RESIDENTS. (Section 3.05 of the Act)

"CONTAMINANT" MEANS ANY SOLID, LIQUID, OR GASEOUS MATTER, ANY ODOR, OR ANY FORM OF ENERGY, FROM WHATEVER SOURCE. (Section 3.06 of the Act)

"Corrective action process" means those procedures and practices that may be imposed by a regulatory agency when a determination has been made that contamination of groundwater has taken place, and are necessary to address a potential or existing violation of the standards set forth in Subpart D.

"Cumulative impact area" means the area, including the coal mine area permitted under the Surface Coal Mining Land Conservation Act (Ill. Rev. Stat. 1989, ch. 96 1/2, pars. 7901.01 et seq., as amended) and 62 Ill. Adm. Code 1700 through 1850, within which impacts resulting from the proposed operation may interact with the impacts of all anticipated mining on surface water and groundwater systems.

"Detection" means the identification of a contaminant in a sample at a value equal to or greater than the:

"Method Detection Limit" or "MDL" which means the minimum concentration of a substance that can be measured as reported with 99 percent confidence that the true value is greater than zero, pursuant to 56 Fed. Reg. 3526-3597, incorporated by reference at Section 620.125; or

"Method Quantitation Limit" or "MQL" which means the minimum concentration of a substance that can be measured and reported pursuant to "Test Methods for Evaluating Solid Wastes, Physical/ Chemical Methods", incorporated by reference at Section 620.125.

"Department" means the Illinois Department of Energy and Natural Resources.

"GROUNDWATER" MEANS UNDERGROUND WATER WHICH OCCURS WITHIN THE SATURATED ZONE AND GEOLOGIC MATERIALS WHERE THE FLUID PRESSURE IN THE PORE SPACE IS EQUAL TO OR GREATER THAN ATMOSPHERIC PRESSURE. (Section 3.64 of the Act)

"Hydrologic balance" means the relationship between the quality and quantity of water inflow to, water outflow from, and water storage in a hydrologic unit such as a drainage basin, aquifer, soil zone, lake, or reservoir. It encompasses the dynamic relationships among precipitation, runoff, evaporation, and changes in ground and surface water storage.

"IGPA" means the Illinois Groundwater Protection Act. (Ill. Rev. Stat. 1989, ch. 111 1/2, pars. 7451 et seq.)

"LOAEL" or "Lowest observable adverse effect level" means the lowest tested concentration of a chemical or substance which produces a statistically significant increase in frequency or severity of non-overt adverse effects between the exposed population and its appropriate control. LOAEL may be determined for a human population (LOAEL-H) or an animal population (LOAEL-A).

"NOAEL" or "No observable adverse effect level" means the highest tested concentration of a chemical or substance which does not produce a statistically significant increase in frequency or severity of non-overt adverse effects between the exposed population and its appropriate control. NOAEL may be determined for a human population (NOAEL-H) or an animal population (NOAEL-A)

"NON-COMMUNITY WATER SUPPLY" MEANS A PUBLIC WATER SUPPLY THAT IS NOT A COMMUNITY WATER SUPPLY. (Section 3.05)

"Off-site" means not on-site.

"On-site" means on the same or geographically contiguous property which may be divided by public or private right-of-way, provided the entrance and exit between properties is at a crossroads intersection and access is by crossing as opposed to going along the right-of-way. Noncontiguous properties owned by the same person but connected by a right-of-way which he controls and to which the public does not have access is also considered on-site property.

"Operator" means the person responsible for the operation of a site, facility or unit.

"Owner" means the person who owns a site, facility or unit or part of a site, facility or unit, or who owns the land on which the site, facility or unit is located.

"POTABLE" MEANS GENERALLY FIT FOR HUMAN CONSUMPTION IN ACCORDANCE WITH ACCEPTED WATER SUPPLY PRINCIPLES AND PRACTICES. (Section 3.65 of the Act)

"POTENTIAL PRIMARY SOURCE" MEANS ANY UNIT AT A FACILITY OR SITE NOT CURRENTLY SUBJECT TO A REMOVAL OR REMEDIAL ACTION WHICH:

IS UTILIZED FOR THE TREATMENT, STORAGE, OR DISPOSAL OF ANY HAZARDOUS OR SPECIAL WASTE NOT GENERATED AT THE SITE; OR

IS UTILIZED FOR THE DISPOSAL OF MUNICIPAL WASTE NOT GENERATED AT THE SITE, OTHER THAN LANDSCAPE WASTE AND CONSTRUCTION AND DEMOLITION DEBRIS; OR

IS UTILIZED FOR THE LANDFILLING, LAND TREATING, SURFACE IMPOUNDING OR PILING OF ANY HAZARDOUS OR SPECIAL WASTE THAT IS GENERATED ON THE SITE OR AT OTHER SITES OWNED, CONTROLLED OR OPERATED BY THE SAME PERSON; OR

STORES OR ACCUMULATES AT ANY TIME MORE THAN 75,000 POUNDS ABOVE GROUND, OR MORE THAN 7,500 POUNDS BELOW GROUND, OF ANY HAZARDOUS SUBSTANCES. (Section 3.59 of the Act)

"POTENTIAL ROUTE" MEANS ABANDONED AND IMPROPERLY PLUGGED WELLS OF ALL KINDS, DRAINAGE WELLS, ALL INJECTION WELLS, INCLUDING CLOSED LOOP HEAT PUMP WELLS, AND ANY EXCAVATION FOR THE DISCOVERY, DEVELOPMENT OR PRODUCTION OF STONE, SAND OR GRAVEL. (Section 3.58 of the Act)

"POTENTIAL SECONDARY SOURCE" MEANS ANY UNIT AT A FACILITY OR A SITE NOT CURRENTLY SUBJECT TO A REMOVAL OR REMEDIAL ACTION, OTHER THAN A POTENTIAL PRIMARY SOURCE, WHICH:

IS UTILIZED FOR THE LANDFILLING, LAND TREATING, OR SURFACE IMPOUNDING OF WASTE THAT IS GENERATED ON THE SITE OR AT OTHER SITES OWNED, CONTROLLED OR OPERATED BY THE SAME PERSON, OTHER THAN LIVESTOCK AND LANDSCAPE WASTE, AND CONSTRUCTION AND DEMOLITION DEBRIS; OR

STORES OR ACCUMULATES AT ANY TIME MORE THAN 25,000 BUT NOT MORE THAN 75,000 POUNDS ABOVE GROUND, OR MORE THAN 2,500 BUT NOT MORE THAN 7,500 POUNDS BELOW GROUND, OF ANY HAZARDOUS SUBSTANCES; OR

STORES OR ACCUMULATES AT ANY TIME MORE THAN 25,000 GALLONS ABOVE GROUND, OR MORE THAN 500 GALLONS BELOW GROUND, OF PETROLEUM, INCLUDING CRUDE OIL OR ANY FRACTION THEREOF WHICH IS NOT OTHERWISE SPECIFICALLY LISTED OR DESIGNATED AS A HAZARDOUS SUBSTANCE; OR

STORES OR ACCUMULATES PESTICIDES, FERTILIZERS, OR ROAD OILS FOR PURPOSES OF COMMERCIAL APPLICATION OR FOR DISTRIBUTION TO RETAIL SALES OUTLETS; OR

STORES OR ACCUMULATES AT ANY TIME MORE THAN 50,000 POUNDS OF ANY DE-ICING AGENT; OR

IS UTILIZED FOR HANDLING LIVESTOCK WASTE OR FOR TREATING DOMESTIC WASTEWATERS OTHER THAN PRIVATE SEWAGE DISPOSAL SYSTEMS AS DEFINED IN THE PRIVATE SEWAGE DISPOSAL LICENSING ACT, Ill. Rev. Stat. 1989, ch. 111 1/2, par. 116.301 et seq. (Section 3.60 of the Act)

"Practical Quantitation Limit" or "PQL" means the lowest concentration or level that can be reliably measured within specified limits of precision and accuracy during routine laboratory operating conditions in accordance with "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods", EPA Publication No. SW-846, incorporated by reference at Section 620.125.

"Previously mined area" means land disturbed or affected by coal mining operations prior to February 1, 1983.

(Board Note: February 1, 1983, is the effective date of the Illinois permanent program regulations implementing the Surface Coal Mining Land Conservation and Reclamation Act (Ill. Rev. Stat. 1989, ch. 96 1/2, pars. 7901.1 et seq., as amended) as codified in 62 Ill. Adm. Code 1700 through 1850.)

"Property class" means the class assigned by a tax assessor to real property for purposes of real estate taxes.

(Board Note: The property class [rural property, residential vacant land, residential with dwelling, commercial residence, commercial business, commercial office, or industrial] is identified on the property record card maintained by the tax assessor in accordance with the Illinois Real Property Appraisal Manual [February 1987], published by the Illinois Department of Revenue, Property Tax Administration Bureau.)

"PUBLIC WATER SUPPLY" MEANS ALL MAINS, PIPES AND STRUCTURES THROUGH WHICH WATER IS OBTAINED AND DISTRIBUTED TO THE PUBLIC, INCLUDING WELLS AND WELL STRUCTURES, INTAKES AND CRIBS, PUMPING STATIONS, TREATMENT PLANTS, RESERVOIRS, STORAGE TANKS AND APPURTENANCES, COLLECTIVELY OR SEVERALLY, ACTUALLY USED OR INTENDED FOR USE FOR THE PURPOSE OF FURNISHING WATER FOR DRINKING OR GENERAL DOMESTIC USE AND WHICH SERVE AT LEAST 15 SERVICE CONNECTIONS OR WHICH REGULARLY SERVE AT LEAST 25 PERSONS AT LEAST 60 DAYS PER YEAR. A PUBLIC WATER SUPPLY IS EITHER A "COMMUNITY WATER SUPPLY" OR A "NON-COMMUNITY WATER SUPPLY". (Section 3.28 of the Act)

"Regulated entity" means a facility or unit regulated for groundwater protection by any state or federal agency.

"Regulatory agency" means the Illinois Environmental Protection Agency, Department of Public Health, Department of Agriculture, Department of Mines and Minerals, and the Office of State Fire Marshal.

"REGULATED RECHARGE AREA" MEANS A COMPACT GEOGRAPHIC AREA, AS DETERMINED BY THE BOARD pursuant to Section 17.4 of the Act, THE GEOLOGY OF WHICH RENDERS A POTABLE RESOURCE GROUNDWATER PARTICULARLY SUSCEPTIBLE TO CONTAMINATION. (Section 3.67 of the Act)

"RESOURCE GROUNDWATER" MEANS GROUNDWATER THAT IS PRESENTLY BEING, OR IN THE FUTURE IS CAPABLE OF BEING, PUT TO BENEFICIAL USE BY REASON OF BEING OF SUITABLE QUALITY. (Section 3.66 of the Act)

"SETBACK ZONE" MEANS A GEOGRAPHIC AREA, DESIGNATED PURSUANT TO THIS ACT, CONTAINING A POTABLE WATER SUPPLY WELL OR A POTENTIAL SOURCE OR POTENTIAL ROUTE HAVING A CONTINUOUS BOUNDARY, AND WITHIN WHICH CERTAIN PROHIBITIONS OR REGULATIONS ARE APPLICABLE IN ORDER TO PROTECT GROUNDWATERS. (Section 3.61 of the Act)

"Site" MEANS ANY LOCATION, PLACE, TRACT OF LAND, AND FACILITIES, INCLUDING BUT NOT LIMITED TO, BUILDINGS AND IMPROVEMENTS USED FOR PURPOSES SUBJECT TO REGULATION OR CONTROL BY the ACT OR REGULATIONS THEREUNDER. (Section 3.43 of the Act)

"Spring" means a natural surface discharge of an aquifer from rock or soil.

"Threshold dose" means the lowest dose of a chemical at which a specified measurable effect is observed and below which it is not observed.

"Treatment" means the technology, treatment techniques, or other procedures for compliance with 35 Ill. Adm. Code: Subtitle F.

"UNIT" MEANS ANY DEVICE, MECHANISM, EQUIPMENT, OR AREA (EXCLUSIVE OF LAND UTILIZED ONLY FOR AGRICULTURAL PRODUCTION). (Section 3.62) of the Act)

"USEPA" or "U.S. EPA" means the United States Environmental Protection Agency.

Section 620.115 Prohibition

No person shall cause, threaten or allow a violation of the Act, the IGPA or regulations adopted by the Board thereunder, including but not limited to this Part.

Section 620.125 Incorporations by Reference

a) The Board incorporates the following material by reference:

b) This Section incorporates no later editions or amendments.

Section 620.130 Exemption from General Use Standards and Public and Food Processing Water Supply Standards

Groundwater is not required to meet the general use standards and public and food processing water supply standards of 35 Ill. Adm. Code 302.Subparts B and C.

Section 620.135 Exclusion for Underground Waters in Certain Man-Made Conduits

This Part does not apply to underground waters contained in man-made subsurface drains, tunnels, reservoirs, storm sewers, tiles or sewers.

SUBPART B: GROUNDWATER CLASSIFICATION

Section 620.201 Groundwater Designations

All groundwaters of the State are designated as:

a) One of the following four classes of groundwater in accordance with Sections 620.210 through 620.240:

1) Class I: Potable Resource Groundwater

2) Class II: General Resource Groundwater;

3) Class III: Special Resource Groundwater;

4) Class IV: Other Groundwater; or

b) A groundwater management zone in accordance with Section 620.250.

Section 620.210 Class I: Potable Resource Groundwater

Except as provided in Sections 620.230, 620.240, or 620.250, Potable Resource Groundwater is:

a) Groundwater located 10 feet or more below the land surface and within:

1) The minimum setback zone of a well which serves as a potable water supply and to the bottom of such well;

2) Unconsolidated sand, gravel or sand and gravel which is 5 feet or more in thickness and that contains 12 percent or less of fines (i.e. fines which pass through a No. 200 sieve tested according to ASTM Standard Practice D2488-84, incorporated by reference at Section 620.125);

3) Sandstone which is 10 feet or more in thickness, or fractured carbonate which is 15 feet of more in thickness; or

4) Any geologic material which is capable of a:

A) Sustained groundwater yield, from up to a 12 inch borehole, of 150 gallons per day or more from a thickness of 15 feet or less; or

B) Hydraulic conductivity of 1×10^{-4} cm/sec or greater using one of the following test methods or its equivalent:

i) Permeameter;

ii) Slug test; or

iii) Pump test.

b) Any groundwater which is determined by the Board pursuant to petition procedures set forth in Section 620.260, to be capable of potable use.

(Board Note: Any portion of the thickness associated with the geologic materials as described in subsections 620.210(a)(2), (a)(3) or (a)(4) should be designated as Class I: Potable Resource Groundwater if located 10 feet or more below the land surface.)

Section 620.220 Class II: General Resource Groundwater

Except as provided in Section 620.250, General Resource Groundwater is:

a) Groundwater which does not meet the provisions of Section 620.210 (Class I), Section 620.230 (Class III), or Section 620.240 (Class IV).

b) Groundwater which is found by the Board, pursuant to the petition procedures set forth in Section 620.260, to be capable of agricultural, industrial, recreational or other beneficial uses.

Section 620.230 Class III: Special Resource Groundwater

Except as provided in Section 620.250, Special Resource Groundwater is:

a) Groundwater that is determined by the Board, pursuant to the procedures set forth in Section 620.260, to be:

1) Demonstrably unique (e.g., irreplaceable sources of groundwater) and suitable for application of a water quality standard more stringent than the otherwise applicable water quality standard specified in Subpart D; or

2) Vital for a particularly sensitive ecological system.

b) Groundwater that contributes to a dedicated nature preserve that is listed by the Agency as set forth below:

1) A written request to list a dedicated nature preserve under this subsection must contain, at a minimum, the following information:

   A) A general description of the site and the surrounding land use;

   B) A topographic map or other map of suitable scale denoting the location of the dedicated nature preserve;

   C) A general description of the existing groundwater quality at and surrounding the dedicated nature preserve;

   D) A general geologic profile of the dedicated nature preserve based upon the most reasonably available information, including but not limited to geologic maps and subsurface groundwater flow directions; and

   E) A description of the interrelationship between groundwater and the nature of the site.

2) Upon confirmation by the Agency of the technical adequacy of a written request, the Agency shall publish the proposed listing of the dedicated nature preserve in the Environmental Register for a 45-day public comment period. Within 60 days after the close of the public comment period, the Agency shall either publish a final listing of the dedicated nature preserve in the Environmental Register or provide a written response to the requestor specifying the reasons for not listing the dedicated nature preserve.

3) At least once annually, the Agency shall publish in the Environmental Register a complete listing of all dedicated nature preserves listed under this subsection.

4) For purposes of this Section the term "dedicated nature preserve" means a nature preserve that is dedicated pursuant to the Illinois Natural Areas Preservation Act (Ill. Rev. Stat. 1989, ch. 105, pars. 701 et seq.).

Section 620.240 Class IV: Other Groundwater

Except as provided in Section 620.250, Other Groundwater is:

a) Groundwater within a zone of attenuation as provided in 35 Ill. Adm. Code 811 and 814;

b) Groundwater within a point of compliance as provided in 35 Ill. Adm. Code 724, but not to exceed a distance of 200 feet from a potential primary or secondary source.

c) Groundwater that naturally contains more than 10,000 mg/L of total dissolved solids;

d) Groundwater which has been designated by the Board as an exempt aquifer pursuant to 35 Ill. Adm. Code 730.104; or

e) Groundwater which underlies a potential primary or secondary source, in which contaminants may be present from a release, if the owner or operator of such source notifies the Agency in writing and the following conditions are met:

1) The outermost edge is the closest practicable distance from such source, but does not exceed:

A) A lateral distance of 25 feet from the edge of such potential source or the property boundary, whichever is less; and

B) A depth of 15 feet from the bottom of such potential source or the land surface, whichever is greater;

2) The source of any release of contaminants to groundwater has been controlled;

3) Migration of contaminants within the site resulting from a release to groundwater has been minimized;

4) Any on-site release of contaminants to groundwater has been managed to prevent migration off-site; and

5) No potable water well exists within the outermost edge as provided in subsection (e)(1).

f) Groundwater which underlies a coal mine refuse disposal area not contained within an area from which overburden has been removed, a coal combustion waste disposal area at a surface coal mine authorized under Section 21(s) of the Act, or an impoundment that contains sludge, slurry, or precipitated process material at a coal preparation plant, in which contaminants may be present, if such area or impoundment was placed into

operation after February 1, 1983, if the owner and operator notifies the Agency in writing, and if the following conditions are met:

1) The outermost edge is the closest practicable distance, but does not exceed:

A) A lateral distance of 25 feet from the edge of such area or impoundment, or the property boundary, whichever is less; and

B) A depth of 15 feet from the bottom of such area or impoundment, or the land surface, whichever is greater;

2) The source of any release of contaminants to groundwater has been controlled;

3) Migration of contaminants within the site resulting from a release to groundwater has been minimized;

4) Any on-site release of contaminants to groundwater has been managed to prevent migration off-site; and

5) No potable water well exists within the outermost edge as provided in subsection (e)(1).

g) Groundwater within a previously mined area, unless monitoring demonstrates that the groundwater is capable of consistently meeting the standards of Sections 620.410 or 620.420. If such capability is determined, groundwater within the previously mined area shall not be Class IV.

Section 620.250 Groundwater Management Zone

a) Within any class of groundwater, a groundwater management zone may be established as a three dimensional region containing groundwater being managed to mitigate impairment caused by the release of contaminants from a site:

1) That is subject to a corrective action process approved by the Agency; or

2) For which the owner or operator undertakes an adequate corrective action in a timely and appropriate manner and provides a written confirmation to the Agency. Such confirmation must be provided in a form as prescribed by the Agency.

b) A groundwater management zone is established upon concurrence by the Agency that the conditions as specified in subsection (a) are met and groundwater management continues for a period of time consistent with the action described in that subsection.

c) A groundwater management zone expires upon the Agency's receipt of appropriate documentation which confirms the completion of the action taken pursuant to subsection (a) and which confirms the attainment of applicable standards as set forth in Subpart D. The Agency shall review the on-going adequacy of controls and continued management at the site if concentrations of chemical constituents, as specified in Section 620.450(a)(4)(B), remain in groundwater at the site following completion of such action. The review must take place no less often than every 5 years and the results must be presented to the Agency in a written report.

Section 620.260 Reclassification of Groundwater by Adjusted Standard

Any person may petition the Board to reclassify a groundwater in accordance with the procedures for adjusted standards specified in Section 28.1 of the Act and 35 Ill. Adm. Code 106.Subpart G. In any proceeding to reclassify specific groundwater by adjusted standard, in addition to the requirements of 35 Ill. Adm. Code 106.Subpart G, and Section 28.1(c) of the Act, the petition shall, at a minimum, contain information to allow the Board to determine:

a) The specific groundwater for which reclassification is requested, including but not limited to geographical extent of any aquifers, depth of groundwater, and rate and direction of groundwater flow and that the specific groundwater exhibits the characteristics of the requested class as set forth in Sections 620.210(b), 620.220(b), 620.230, or 620.240(b);

b) Whether the proposed change or use restriction is necessary for economic or social development, by providing information including, but not limited to, the impacts of the standards on the regional economy, social benefits such as loss of jobs or closing of facilities, and economic analysis contrasting the health and environmental benefits with costs likely to be incurred in meeting the standards would be beneficial or necessary;

c) Existing and anticipated uses of the specific groundwater;

d) Existing and anticipated quality of the specific groundwater;

e) Existing and anticipated contamination, if any, of the specific groundwater;

f) Technical feasibility and economic reasonableness of eliminating or reducing contamination of the specific groundwater or of maintaining existing water quality;

g) The anticipated time period over which contaminants will continue to affect the specific groundwater;

h) Existing and anticipated impact on any potable water supplies due to contamination;

i) Availability and cost of alternate water sources or of treatment for those users adversely affected;

j) Negative or positive effect on property values; and

k) For special resource groundwater, negative or positive effect on:

1) The quality of surface waters; and

2) Wetlands, natural areas, and the life contained therein, including endangered or threatened species of plant, fish or wildlife listed pursuant to the Endangered Species Act, 16 U.S.C. 1531 et seq., or the Illinois Endangered Species Protection Act (Ill. Rev. Stat. 1989, ch. 8, par. 331 et seq.).

SUBPART C: NONDEGRADATION PROVISIONS FOR APPROPRIATE GROUNDWATERS

Section 620.301 General Prohibition Against Use Impairment of Resource Groundwater

a) No person shall cause, threaten or allow the release of any contaminant to a resource groundwater such that:

1) Treatment or additional treatment is necessary to continue an existing use or to assure a potential use of such groundwater; or

2) An existing or potential use of such groundwater is precluded.

b) Nothing in this Section shall prevent the establishment of a groundwater management zone pursuant to Section 620.250 or a cumulative impact area within a permitted site.

c) Nothing in this Section shall limit underground injection pursuant to a permit issued by the Agency under the Act or issued by the Department of Mines and Minerals under "An Act in relation to oil, gas, coal and other surface and underground resources and to repeal an Act herein named" (Ill. Rev Stat. 1989, ch. 96 1/2, pars. 5401 et seq., as amended).

d) Nothing in this Section shall limit the Board from promulgating nondegradation provisions applicable to particular types of facilities or activities which impact upon groundwater, including but not limited to landfills regulated pursuant to 35 Ill. Adm. Code.Subtitle G.

Section 620.302 Applicability of Preventive Notification and Preventive Response Activities

a) Preventive notification and preventive response as specified in Sections 620.305 through 620.310 applies to:

1) Class I groundwater under Section 620.210(a)(1), (a)(2), or (a)(3) which is monitored by the persons listed in subsection (b); or

2) Class III groundwater which is monitored by the persons listed in subsection (b).

b) For purposes of subsection (a), the persons that conduct groundwater monitoring are:

1) An owner or operator of a regulated entity for which groundwater quality monitoring must be performed pursuant to State or Federal law or regulation (e.g. Sections 106 and 107 of the Comprehensive Environmental Response, Compensation and Liability Act, (42 U.S.C. 9601, et seq.); Sections 3004 and 3008 of the Resource Conservation and Recovery Act, (42 U.S.C. 6901, et seq.); Sections 4(q), 4(v), 12(g), 21(d), 21(f), 22.2(f), 22.2(m) and 22.18 of the Act; 35 Ill. Adm. Code 724, 725, 730, 731, 750, 811 and 814.)"

2) An owner or operator of a public water supply well who conducts groundwater quality monitoring; or

3) A state agency which is authorized to conduct, or is the recipient of, groundwater quality monitoring data (e.g., Illinois Environmental Protection Agency, Department of Public Health, Department of Conservation, Department of Mines and Minerals, Department of Agriculture, Office of State Fire Marshall or Department of Energy and Natural Resources).

c) If a contaminant exceeds a standard set forth in Section 620.410 or Section 620.430, the appropriate remedy is corrective action and Sections 620.305 and 620.310 do not apply.

Section 620.305 Preventive Notification Procedures

a) Pursuant to groundwater quality monitoring as described in Section 620.302, a preventive notification must occur whenever a contaminant:

1) Listed under Section 620.310(a)(3)(A) is detected (except due to natural causes) in Class I groundwater; or

2) Denoted as a carcinogen under Section 620.410(b) is detected in Class I groundwater; or

3) Subject to a standard under Section 620.430 is detected (except due to natural causes) in Class III groundwater.

b) When a preventive notification is required for groundwater which is monitored by a regulated entity for the subject contaminant, the owner or operator of the site shall confirm the detection by resampling the monitoring well. This resampling shall be made within 30 days of the date on which the first sample analyses are received. The owner or operator shall provide a

preventive notification to the appropriate regulatory agency of the results of the resampling analysis within 30 days of the date on which the sample analyses are received, but no later than 90 days after the results of the first samples were received.

c) When a preventive notification is required for groundwater which is monitored by a regulatory agency, such agency shall notify the owner or operator of the site where the detection has occurred. The owner or operator shall confirm the detection by resampling within 30 days of the date of the notice by the regulatory agency. The owner or operator shall provide preventive notification to the regulatory agency of the results of the resampling analysis within 30 days of the date on which the sample analyses are received, but no later than 90 days after the results of the first samples were received.

d) When a preventive notification of a confirmed detection has been provided by an owner or operator pursuant to this Section, additional detections of the same contaminant do not require further notice, provided that the groundwater quality conditions are substantially unchanged or that preventive response is underway for such contaminant.

Section 620.310 Preventive Response Activities

a) The following preventive assessment must be undertaken:

1) If a preventive notification under Section 620.305(c) is provided by a community water supply:

A) The Agency shall notify the owner or operator of any identified potential primary source, potential secondary source, potential route, or community water supply well that is located within 2,500 feet of the wellhead.

B) The owner or operator notified under subsection (a)(1)(A) shall, within 30 days of the date of issuance of such notice, sample each water well or monitoring well for the contaminant identified in the notice if the contaminant or material containing such contaminant is or has been stored, disposed, or otherwise handled at the site. If a contaminant identified under Section 620.305(a) is detected, then the well must be resampled within 30 days of the date on which the first sample analyses are received. If a

contaminant identified under Section 620.305(a) is detected by the resampling, preventive notification must be given as set forth in Section 620.305.

C) If the Agency receives analytical results under subsection (a)(1)(B) that show a contaminant identified under Section 620.305(a) has been detected, the Agency shall:

i) Conduct a well site survey pursuant to Section 17.1(d) of the Act, if such a survey has not been previously conducted within the last 5 years; and

ii) Identify those sites or activities which represent a hazard to the continued availability of groundwaters for public use unless a groundwater protection needs assessment has been prepared pursuant to Section 17.1 of the Act.

2) If a preventive notification is provided under Section 620.305(c) by a non-community water supply or for multiple private water supply wells, the Department of Public Health shall conduct a sanitary survey within 1,000 feet of the wellhead of a non-community water supply or within 500 feet of the wellheads for multiple private water supply wells.

3) If a preventive notification under Section 620.305(b) is provided by the owner or operator of a regulated entity and the applicable standard in Subpart D has not been exceeded:

A) The appropriate regulatory agency shall determine if any of the following occurs for Class I: Potable Resource Groundwater:

i) The levels set forth below are exceeded or are changed for pH:

Constituent	Criterion (mg/L)
para-Dichlorobenzene	0.005
ortho-Dichlorobenzene	0.01
Ethylbenzene	0.03
Phenols	0.001
Styrene	0.01
Toluene	0.04

Xylenes	0.02

ii) A statistically significant increase occurs above background (as determined pursuant to other regulatory procedures (e.g., 35 Ill. Adm. Code 616, 724, 725 or 811)) for arsenic, cadmium, chromium, cyanide, lead or mercury (except due to natural causes); or for aldicarb, atrazine, carbofuran, endrin, lindane (gamma-hexachlor cyclohexane), 2,4-D, 1,1-dichloroethylene, cis-1,2-dichloroethylene, trans-1,2-dichloroethylene, methoxychlor, monochlorobenzene, 2,4,5-TP (Silvex) and 1,1,1-trichloroethane.

iii) For a chemical constituent of gasoline, diesel fuel, or heating fuel, the constituent exceeds the following:

Constituent	Criterion (mg/L)
BETX	0.095

iv) For pH, a statistically significant change occurs from background.

(Board Note: Constituents that are carcinogens have not been listed in subsection (a)(3)(A) because the standard is set at the PQL and any exceedence thereof is a violation subject to corrective action.)

B) The appropriate agency shall determine if, for Class III: Special Resource Groundwater, the levels as determined by the Board are exceeded.

C) The appropriate regulatory agency shall consider whether the owner or operator reasonably demonstrates that:

i) The contamination is a result of contaminants remaining in groundwater from a prior release for which appropriate action was taken in accordance with laws and regulations in existence at the time of the release;

ii) The source of contamination is not due to the on-site release of contaminants; or

iii) The detection resulted from error in sampling, analysis, or evaluation.

D) The appropriate regulatory agency shall consider actions necessary to minimize the degree and extent of contamination.

b) The appropriate regulatory agency shall determine whether a preventative response must be undertaken based on relevant factors including, but not limited to, the considerations in subsection (a)(3).

c) After completion of preventive response pursuant to authority of an appropriate regulatory agency, the concentration of a contaminant listed in subsection (a)(3)(A) in groundwater may exceed 50 percent of the applicable numerical standard in Subpart D only if the following conditions are met:

1) The exceedence has been minimized to the extent practicable;

2) Beneficial use, as appropriate for the class of groundwater, has been assured; and

3) Any threat to public health or the environment has been minimized.

d) Nothing in this Section shall in any way limit the authority of the State or of the United States to require or perform any corrective action process.

SUBPART D: GROUNDWATER QUALITY STANDARDS

Section 620.401 Applicability

Groundwaters must meet the standards appropriate to the groundwater's class as specified in this Subpart and the nondegradation provisions of Subpart C.

Section 620.405 General Prohibitions Against Violations of Groundwater Quality Standards

No person shall cause, threaten or allow the release of any contaminant to groundwater so as to cause a groundwater quality standard set forth in this Subpart to be exceeded.

Section 620.410 Groundwater Quality Standards for Class I: Potable Resource Groundwater

a) Inorganic Chemical Constituents

Except due to natural causes or as provided in Section 620.450, concentrations of the following chemical constituents must not be exceeded in Class I groundwater:

Constituent	Units	Standard
Arsenic	mg/L	0.05
Barium	mg/L	2
Boron	mg/L	2
Cadmium	mg/L	0.005
Chloride	mg/L	200
Chromium	mg/L	0.1
Cobalt	mg/L	1
Copper	mg/L	0.65
Cyanide	mg/L	0.2
Fluoride	mg/L	4.0
Iron	mg/L	5
Lead	mg/L	0.0075
Manganese	mg/L	0.15
Mercury	mg/L	0.002
Nickel	mg/L	0.1
Nitrate as N	mg/L	10
Radium-226	pCi/L	20
Radium-228	pCi/L	20
Selenium	mg/L	0.05
Silver	mg/L	0.05
Sulfate	mg/L	400
Total Dissolved Solids (TDS)	mg/L	1,200
Zinc	mg/L	5

b) Organic Chemical Constituents

Except due to natural causes or as provided in Section 620.450 or subsection (c), concentrations of the following organic chemical constituents must not be exceeded in Class I groundwater:

Constituent	Standard (mg/L)
Alachlor*	0.002
Aldicarb	0.003
Atrazine	0.003
Benzene*	0.005
Carbofuran	0.04
Carbon Tetrachloride*	0.005
Chlordane*	0.002
Endrin	0.002
Heptachlor*	0.0004
Heptachlor Epoxide*	0.0002
Lindane (Gamma-Hexachlor cyclohexane)	0.0002
2,4-D	0.07
ortho-Dichlorobenzene	0.6
para-Dichlorobenzene	0.075
1,2-Dichloroethane*	0.005
1,1-Dichloroethylene	0.007
cis-1,2-Dichloroethylene	0.07
trans-1,2-Dichloroethylene	0.1
1,2-Dichloropropane*	0.005
Ethylbenzene	0.7
Methoxychlor	0.04
Monochlorobenzene	0.1
Pentachlorophenol*	0.001
Phenols	0.1
Polychlorinated Biphenyls (PCB's) (as decachloro-bipehnyl)*	0.005
Styrene	0.1
2,4,5-TP (Silvex)	0.05
Tetrachloroethylene*	0.005
Toluene	1
Toxaphene*	0.003
1,1,1-Trichloroethane	0.2
Trichloroethylene*	0.005
Vinyl Chloride*	0.002
Xylenes	10

*Denotes a carcinogen.

c) Complex Organic Chemical Mixtures

Concentrations of the following chemical constituents of gasoline, diesel fuel, or heating fuel must not be exceeded in Class I groundwater:

Constituent	Standard (mg/L)
Benzene*	0.005
BETX	11.705

*Denotes a carcinogen.

d) pH

Except due to natural causes, a pH range of 6.5 - 9.0 units must not be exceeded in Class I groundwater.

e) Beta Particle and Photon Radioactivity

1) Except due to natural causes, the average annual concentration of beta particle and photon radioactivity from man-made radionuclides shall not exceed a dose equivalent to the total body organ greater than 4 mrem/year in Class I groundwater. If two or more radionuclides are present, the sum of their dose equivalent to the total body, or to any internal organ shall not exceed 4 mrem/year in Class I groundwater except due to natural causes.

2) Except for the radionuclides listed in subsection (e)(3), the concentration of man-made radionuclides causing 4 mrem total body or organ dose equivalent must be calculated on the basis of a 2 liter per day drinking water intake using the 168-hour data in accordance with the procedure set forth in NCRP Report Number 22, incorporated by reference at in Section 620.125(a).

3) Except due to natural causes, the average annual concentration assumed to produce a total body or organ dose of 4 mrem/year of the following chemical constituents shall not be exceeded in Class I groundwater:

Constituent	Critical Organ	Standard (pCi/1)
Tritium	Total body	20,000
Strontium-90	Bone marrow	8

Section 620.420 Groundwater Quality Standards for Class II: General Resource Groundwater

a) Inorganic Chemical Constituents

1) Except due to natural causes or as provided in Section 620.450 or subsection (a)(3) or (d), concentrations of the following chemical constituents must not be exceeded in Class II groundwater:

Constituent	Standard (mg/L)
Arsenic	0.2
Barium	2
Cadmium	0.05
Chromium	1
Cobalt	1
Cyanide	0.6
Fluoride	4.0
Lead	0.1
Mercury	0.01
Nitrate as N	100

2) Except as provided in Section 620.450 or subsection (a)(3) or (d), concentrations of the following chemical constituents must not be exceeded in Class II groundwater:

Constituent	Standard (mg/L)
Boron	2.0
Chloride	200
Copper	0.65
Iron	5
Manganese	10
Nickel	2
Selenium	0.05
Total Dissolved Solids (TDS)	1,200
Sulfate	400
Zinc	10

3) The standard for any inorganic chemical constituent listed in subsection (a)(2), for barium, or for pH does not apply to groundwater within fill material or within the upper 10 feet of parent material under such fill material on a site not within the rural property class for which:

A) Prior to the effective date of this Part, surficial characteristics have been altered by the placement of such fill material so as to impact the concentration of the parameters listed in subsection (a)(3), and any on-site groundwater monitoring of such parameters is available for review by the Agency.

B) On the effective date of this Part, surficial characteristics are in the process of being altered by the placement of such fill material, which proceeds in reasonably continuous manner to completion, so as to impact the concentration of the parameters listed in subsection (a)(3), and any on-site groundwater monitoring of such parameters is available for review by the Agency.

4) For purposes of subsection (a)(3), the term "fill material" means clean earthen materials, slag, ash, clean demolition debris, or other similar materials.

b) Organic Chemical Constituents

1) Except due to natural causes or as provided in Section 620.450 or subsection (b)(2) or (d), concentrations of the following organic chemical constituents must not be exceeded in Class II groundwater:

Constituent	Standard (mg/L)
Alachlor*	0.010
Aldicarb	0.015
Atrazine	0.015
Benzene*	0.025
Carbofuran	0.2
Carbon Tetrachloride*	0.025
Chlordane*	0.01
Endrin	0.01
Heptachlor*	0.002
Heptachlor Epoxide*	0.001
Lindane (Gamma-Hexachlor cyclohexane)	0.001
2,4-D	0.35
ortho-Dichlorobenzene	1.5
para-Dichlorobenzene	0.375
1,2-Dichloroethane*	0.025
1,1-Dichloroethylene	0.035
cis-1,2-Dichloroethylene	0.2
trans-1,2-Dichloroethylene	0.5

1,2-Dichloropropane*	0.025
Ethylbenzene	1.0
Methoxychlor	0.2
Monochlorobenzene	0.5
Pentachlorophenol*	0.005
Phenols	0.1
Polychlorinated Biphenyls (PCB's) (as decachloro-biphenyl)*	0.0025
Styrene	0.5
2,4,5-TP	0.25
Tetrachloroethylene*	0.025
Toluene	2.5
Toxaphene*	0.015
1,1,1-Trichloroethane	1.0
Trichloroethylene*	0.025
Vinyl Chloride*	0.01
Xylenes	10

*Denotes a carcinogen.

2) The standards for pesticide chemical constituents listed in subsection (b)(1) do not apply to groundwater within 10 feet of the land surface, provided that the concentrations of such constituents result from the application of pesticides in a manner consistent with the requirements of the Federal Insecticide, Fungicide and Rodenticide Act (7 U. S. C. 136 et seq.) and the Illinois Pesticide Act (Ill. Rev. Stat. 1989, ch. 5, pars. 801 et seq.).

c) Complex Organic Chemical Mixtures

Concentrations of the following organic chemical constituents of gasoline, diesel fuel, or heating fuel must not be exceeded in Class II groundwater:

Constituent	Standard (mg/L)
Benzene*	0.025
BETX	13.525

*Denotes a carcinogen.

d) pH

Except due to natural causes, a pH range of 6.5 - 9.0 units must not be exceeded in Class II groundwater that is within 5 feet of the land surface.

Section 620.430 Groundwater Quality Standards for Class III: Special Resource Groundwater

Concentrations of inorganic and organic chemical constituents must not exceed the standards set forth in Section 620.410, except for those chemical constituents for which the Board has adopted a standard pursuant to Section 620.260.

Section 620.440 Groundwater Quality Standards for Class IV: Other Groundwater

a) Except as provided in subsections (b) or (c), Class IV: Other Groundwater standards are equal to the existing concentrations of constituents in groundwater.

b) For groundwater within a zone of attenuation as provided in 35 Ill. Adm. Code 811 and 814, the standards specified in Section 620.420 must not be exceeded, except for concentrations of contaminants within leachate released from a permitted unit.

c) For groundwater within a previously mined area, the standards set forth in Section 620.420 must not be exceeded, except for concentrations of TDS, chloride, iron, manganese, sulfates, or pH. For concentrations of TDS, chloride, iron, manganese, sulfates, or pH, the standards are the existing concentrations.

Section 620.450 Alternative Groundwater Quality Standards

a) Groundwater Quality Restoration Standards

1) Any chemical constituent in groundwater within a groundwater management zone is subject to this Section.

2) Except as provided in subsections (a)(3) or (a)(4), the standards as specified in Sections 620.410, 620.420, 620.430, and 620.440 apply to any chemical constituent in groundwater within a groundwater management zone.

3) Prior to completion of a corrective action described in Section 620.250(a), the standards as specified in Sections 620.410, 620.420, 620.430, and 620.440 are not applicable to such released chemical constituent, provided that the initiated action proceeds in a timely and appropriate manner.

4) After completion of a corrective action as described in Section 620.250(a), the standard for such released chemical constituent is:

A) The standard as set forth in Section 620.410, 620.420, 620.430, or 620.440, if the concentration as determined by groundwater monitoring of such constituent is less than or equal to the standard for the appropriate class set forth in those sections; or

B) The concentration as determined by groundwater monitoring, if such concentration exceeds the standard for the appropriate class set forth in Section 620.410, 620.420, 620.430, or 620.440 for such constituent, and:

i) To the extent practicable, the exceedence has been minimized and beneficial use, as appropriate for the class of groundwater, has been returned; and

ii) Any threat to public health or the environment has been minimized.

5) The Agency shall develop and maintain a listing of concentrations derived pursuant to subsection (a)(4)(B). This list shall be made available to the public and be updated periodically, but no less frequently than semi-annually. This listing shall be published in the Environmental Register.

b) Coal Reclamation Groundwater Quality Standards

1) Any inorganic chemical constituent or pH in groundwater, within an underground coal mine, or within the cumulative impact area of groundwater for which the hydrologic balance has been disturbed from a permitted coal mine area pursuant to the Surface Coal Mining Land Conservation and Reclamation Act (Ill. Rev. Stat. 1989, ch. 96 1/2, pars. 7901.1 et seq., as amended) and 62 Ill. Adm. Code 1700 through 1850, is subject to this Section.

2) Prior to completion of reclamation at a coal mine, the standards as specified in Sections 620.410(a) and (d), 620.420(a) and (e), 620.430 and 620.440 are not applicable to inorganic constituents and pH.

3) After completion of reclamation at a coal mine, the standards as specified in Sections 620.410(a) and (d), 620.420(a), 620.430, and 620.440 are

applicable to inorganic constituents and pH, except:

A) The concentration of total dissolved solids (TDS) must not exceed:

i) The post-reclamation concentration or 3000 mg/L, whichever is less, for groundwater within the permitted area; or

ii) The post-reclamation concentration of TDS must not exceed the post-reclamation concentration or 5000 mg/L, whichever is less, for groundwater in underground coal mines and in permitted areas reclaimed after surface coal mining if the Illinois Department of Mines and Minerals and the Agency have determined that no significant resource groundwater existed prior to mining (62 Ill. Adm. Code 1780.21(f) and (g)); and

B) For chloride, iron, manganese and sulfate, the post-reclamation concentration within the permitted area must not be exceeded.

C) For pH, the post-reclamation concentration within the permitted area must not be exceeded within Class I: Potable Resource Groundwater as specified in Section 620.210(a)(4).

4) A refuse disposal area (not contained within the area from which overburden has been removed) is subject to the inorganic chemical constituent and pH requirements of:

A) 35 Ill. Adm. Code 303.203 for such area that was placed into operation after February 1, 1983, and before the effective date of this Part, provided that the groundwater is a present or a potential source of water for public or food processing;

B) Section 620.440(c) for such area that was placed into operation prior to February 1, 1983, and has remained in continuous operation since that date; or

C) Subpart D for such area that is placed into operation on or after the effective date of this Part.

5) For a refuse disposal area (not contained within the area from which overburden has been removed) that was placed into operation prior to February 1, 1983, and is modified after that date to include additional area, this Section applies to the area that meets the requirements of subsection (b)(4)(C) and the following applies to the additional area:

   A) 35 Ill. Adm. Code 303.203 for such additional refuse disposal area that was placed into operation after February 1, 1983, and before the effective date of this Part, provided that the groundwater is a present or a potential source of water for public or food processing; and

   B) Subpart D for such additional area that was placed into operation on or after the effective date of this Part.

6) A coal preparation plant (not located in an area from which overburden has been removed) which contains slurry material, sludge or other precipitated process material, is subject to the inorganic chemical constituent and pH requirements of:

   A) 35 Ill. Adm. Code 303.203 for such plant that was placed into operation after February 1, 1983, and before the effective date of this Part, provided that the groundwater is a present or a potential source of water for public or food processing;

   B) Section 620.440(c) for such plant that was placed into operation prior to February 1, 1983, and has remained in continuous operation since that date; or

   C) Subpart D for such plant that is placed into operation on or after the effective date of this Part.

7) For a coal preparation plant (not located in an area from which overburden has been removed) which contains slurry material, sludge or other precipitated process material, that was placed into operation prior to February 1, 1983, and is modified after that date to include additional area, this Section applies to the area that meets

the requirements of subsection (b)(6)(C) and the following applies to the additional area:

A) 35 Ill. Adm. Code 303.203 for such additional area that was placed into operation after February 1, 1983, and before the effective date of this Part, provided that the groundwater is a present or a potential source of water for public or food processing; and

B) Subpart D for such additional area that was placed into operation on or after the effective date of this Part.

SUBPART E: GROUNDWATER MONITORING AND ANALYTICAL PROCEDURES

Section 620.505 Compliance Determination

a) Compliance with standards at a site is to be determined as follows:

1) For a structure (e.g., buildings), at the closest practical distance beyond the outermost edge for the structure.

2) For groundwater that underlies a potential primary or secondary source, the outermost edge as specified in Section 620.240(e)(1).

3) For groundwater that underlies a coal mine refuse disposal area, a coal combustion waste disposal area, or an impoundment that contains sludge, slurry, or precipitated process material at a coal preparation plant, the outermost edge as specified in Section 620.240(f)(1) or location of monitoring wells in existence as of the effective date of this Part on a permitted site.

4) For a groundwater management zone, as specified in a corrective action process.

5) At any point at which groundwater monitoring is conducted using any water well or monitoring well that meets the following conditions:

A) For a potable well other than a community water supply well, a construction report has been filed with the Department of Public Health for such potable well, or such well has been located and constructed (or reconstructed) to meet the Illinois Water Well Construction Code (Ill. Rev. Stat. 1989, ch. 111 1/2, pars. 116.111 et seq., as amended) and 35 Ill. Adm. Code 920.

B) For a community water supply well, such well has been permitted by the Agency, or has been constructed in accordance with 35 Ill. Adm. Code 602.115.

C) For a water well other than a potable water well (e.g., a livestock watering well or an irrigation well), a construction report has been filed with the Department of Public Health or the Department of Mines and Minerals for such well, or such well has been located and constructed (or reconstructed) to

meet the Illinois Water Well Construction Code (Ill. Rev. Stat. 1989, ch. 111 1/2, pars. 116.111 et seq., as amended) and 35 Ill. Adm. Code 920.

D) For a monitoring well, such well meets the following requirements:

i) Construction must be done in a manner that will enable the collection of groundwater samples;

ii) Casings and screens must be made from durable material resistant to expected chemical or physical degradation that do not interfere with the quality of groundwater samples being collected; and

iii) The annular space opposite the screened section of the well (i.e., the space between the bore hole and well screen) must be filled with gravel or sand if necessary to collect groundwater samples. The annular space above and below the well screen must be sealed to prevent migration of water from adjacent formations and the surface to the sampled depth.

b) For a spring, compliance with this Subpart shall be determined at the point of emergence.

Section 620.510 Monitoring and Analytical Requirements

a) Representative Samples

A representative sample must be taken from locations as specified in Section 620.505.

b) Sampling and Analytical Procedures

1) Samples must be collected in accordance with the procedures set forth in the documents pertaining to groundwater monitoring and analysis, "Methods for Chemical Analysis of Water and Wastes, "Methods for the Determination of Organic Compounds in Drinking Water", "Practical Guide for Ground-Water Sampling", "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods" (SW-846), "Techniques of Water Resources Investigations of the United States Geological Survey, Guidelines for Collection and Field Analysis of Ground-Water Samples for Selected

Unstable Constituents", incorporated by reference at Section 620.125 or other procedures adopted by the appropriate regulatory agency.

2) Groundwater elevation in a groundwater monitoring well must be determined and recorded when necessary to determine the gradient.

3) The analytical methodology used for the analysis of constituents in Subparts C and D must be consistent with both of the following:

A) The methodology must have a PQL at or below the preventive response levels of Subpart C or the groundwater standard set forth in Subpart D, whichever is applicable; and

B) The methodology must be consistent with methodologies contained in "Methods for Chemical Analysis of Water and Wastes", "Methods for the Determination of Organic Compounds in Drinking Water", "Practical Guide for Ground-Water Sampling", "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods" (SW-846), "Techniques of Water Resources Investigations of the United States Geological Survey, Guidelines for Collection and Field Analysis of Ground-Water Samples for Selected Unstable Constituents", incorporated by reference at Section 620.125.

c) Reporting Requirements

At a minimum, groundwater monitoring analytical results must include information, procedures and techniques for:

1) Sample collection (including but not limited to name of sample collector, time and date of the sample, method of collection, and identification of the monitoring location);

2) Sample preservation and shipment (including but not limited to field quality control);

3) Analytical procedures (including but not limited to the method detection limits and the PQLs); and

4) Chain of custody control.

SUBPART F: HEALTH ADVISORIES

Section 620.601 Purpose of a Health Advisory

This Subpart establishes procedures for the issuance of a Health Advisory that sets forth guidance levels that, in the absence of standards under Section 620.410, must be considered by the Agency in:

a) Establishing groundwater cleanup or action levels whenever there is a release or substantial threat of a release of:

1) A hazardous substance or pesticide; or

2) Other contaminant that represents a significant hazard to public health or the environment.

b) Determining whether the community water supply is taking its raw water from a site or source consistent with the siting and source water requirements of 35 Ill. Adm. Code 611.114 and 611.115.

c) Developing Board rulemaking proposals for new or revised numerical standards.

d) Evaluating mixtures of chemical substances.

Section 620.605 Issuance of a Health Advisory

a) The Agency shall issue a Health Advisory for a chemical substance if all of the following conditions are met:

1) A community water supply well is sampled and a substance is detected and confirmed by resampling;

2) There is no standard under Section 620.410 for such chemical substance; and

3) The chemical substance is toxic or harmful to human health according to the procedures of Appendix A, B, or C.

b) The Health Advisory must contain a general description of the characteristics of the chemical substance, the potential adverse health effects, and a guidance level to be determined as follows:

1) If disease or functional impairment is caused due to a physiological mechanism for which there is a threshold dose below which no damage occurs, the guidance level for any such substance is the Maximum Contaminant Level Goal ("MCLG"), adopted

by USEPA for such substance, 56 Fed. Reg. 26460-26564, and 56 Fed. Reg. 3526-3597, incorporated by reference at Section 620.125. If there is no MCLG for the substance, the guidance level is the Human Threshold Toxicant Advisory Concentration for such substance as determined in accordance with Appendix A, unless the concentration for such substance is less than the lowest appropriate PQL specified in "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods", EPA Publication No. SW-846 (SW-846), incorporated by reference at Section 620.125 for the substance. If the concentration for such substance is less than the lowest appropriate PQL for the substance specified in SW-846, incorporated by reference at Section 620.125, the guidance level is the lowest appropriate PQL.

2) If the chemical substance is a carcinogen, the guidance level for any such chemical substance is the lowest appropriate PQL specified in SW-846, incorporated by reference at Section 620.125 for such substance.

Section 620.610 Publishing Health Advisories

a) The Agency shall publish the full text of each Health Advisory upon issuance and make the document available to the public.

b) The Agency shall publish and make available to the public, at intervals of not more than 6 months, a comprehensive and up-to-date summary list of all Health Advisories.

Section 620.615 Additional Health Advice for Mixtures of Similar-Acting Substances

a) The need for additional health advice appropriate to site-specific conditions shall be determined by the Agency when mixtures of chemical substances are detected, where two or more of the chemical substances are similar-acting in their toxic or harmful physiological effect on the same specific organ or organ system.

b) If mixtures of similar-acting chemical substances are present, the procedure for evaluating the mixture of such substances is specified in accordance with Appendices A, B, and C.

Section 620.Appendix A Procedures for Determining Human Threshold Toxicant Advisory Concentration for Class I: Potable Resource Groundwater

a) Calculating the Human Threshold Toxicant Advisory Concentration

For those substances for which USEPA has not adopted a Maximum Contaminant Level Goal ("MCLG"), the Human Threshold Toxicant Advisory Concentration is calculated as follows:

HTTAC = RSC x ADE/W

Where:

HTTAC = Human Threshold Toxicant Advisory Concentration in milligrams per liter (mg/L);

RSC = Relative contribution of the amount of the exposure to a chemical via drinking water when compared to the total exposure to that chemical from all sources. Valid chemical-specific data shall be used if available. If valid chemical-specific data are not available, a value of 20% (=0.20) must be used;

ADE = Acceptable Daily Exposure of substance in milligrams per day (mg/d) as determined pursuant to subsection (b); and

W = Per capita daily water consumption equal to 2 liters per day (L/d).

b) Procedures for Determining Acceptable Daily Exposures for Class I: Potable Resource Groundwater

1) The Acceptable Daily Exposure (ADE) represents the maximum amount of a threshold toxicant in milligrams per day (mg/d) which if ingested daily for a lifetime results in no adverse effects to humans. Subsections (b)(2) through (b)(6) list, in prescribed order, methods for determining the ADE in Class I: Potable Resource Groundwater.

2) For those substances for which the USEPA has derived a Verified Oral Reference Dose for humans, USEPA's Reference Dose given in milligrams per kilogram per day (mg/kg/d), as determined in accordance with methods provided in National Primary and Secondary Drinking Water Regulations;

Final Rule, 56 Fed. Reg. 3526-3597, (January 30, 1991), incorporated by reference at Section 620.125, must be used. The ADE equals the product of multiplying the Reference Dose by 70 kilograms (kg), which is the assumed average weight of an adult human.

3) For those substances for which a no observed adverse effect level for humans (NOAEL-H) exposed to the substance has been derived, the ADE equals the product of multiplying one-tenth of the NOAEL-H given in milligrams of toxicant per kilogram of body weight per day (mg/kg/d) by the average weight of an adult human of 70 kilograms (kg). If two or more studies are available, the lowest NOAEL-H must be used in the calculation of the ADE.

4) For those substances for which only a lowest observed adverse effect level for humans (LOAEL-H) exposed to the substance has been derived, one-tenth the LOAEL-H must be substituted for the NOAEL-H in subsection (b)(3).

5) For those substances for which a no observed adverse effect level has been derived from studies of mammalian test species (NOAEL-A) exposed to the substance, the ADE equals the product of multiplying 1/100 of the NOAEL-A given in milligrams toxicant per kilogram of test species weight per day (mg/kg/d) by the average weight of an adult human of 70 kilograms (kg). Preference will be given to animal studies having High Validity, as defined in subsection (c), in the order listed in that subsection. Studies having a Medium Validity must be considered if no studies having High Validity are available. If studies of Low Validity must be used, the ADE must be calculated using 1/1000 of the NOAEL-A having Low Validity instead of 1/100 of the NOAEL-A of High or Medium Validity, except as described in subsection (b)(6). If two or more studies among different animal species are equally valid, the lowest NOAEL-A among animal species must be used in the calculation of the ADE. Additional considerations in selecting the NOAEL-A include:

A) If the NOAEL-A is given in milligrams of toxicant per liter of water consumed (mg/L), prior to calculating the ADE the NOAEL-A must be multiplied by the average daily volume of water consumed by the mammalian test species in liters per day (l/d) and divided by the

average weight of the mammalian test species in kilograms (kg).

B) If the NOAEL-A is given in milligrams of toxicant per kilogram of food consumed (mg/kg), prior to calculating the ADE, the NOAEL-A must be multiplied by the average amount in kilograms of food consumed daily by the mammalian test species (kg/d) and divided by the average weight of the mammalian test species in kilograms (kg).

C) If the mammalian test species was not exposed to the toxicant each day of the test period, the NOAEL-A must be multiplied by the ratio of days of exposure to the total days of the test period.

D) If more than one equally valid NOAEL-A is available for the same mammalian test species, the best available data must be used.

6) For those substances for which a NOAEL-A is not available but the lowest observed adverse effect level (LOAEL-A) has been derived from studies of mammalian test species exposed to the substance, one-tenth of the LOAEL-A may be substituted for the NOAEL-A in subsection (b)(5). The LOAEL-A must be selected in the same manner as that specified in subsection (b)(5). One-tenth the LOAEL-A from a study determined to have Medium Validity may be substituted for a NOAEL-A in subsection (b)(3) if the NOAEL-A is from a study determined to have Low Validity, or if the toxicity endpoint measured in the study having the LOAEL-A of Medium Validity is determined to be more biologically relevant than the toxicity endpoint measured in the study having the NOAEL-A of Low Validity.

c) Procedures for Establishing Validity of Data from Animal Studies

1) High Validity Studies

A) High validity studies use a route of exposure by ingestion or gavage, and are based upon:

i) Data from animal carcinogenicity studies with a minimum of 2 dose levels and a control group, 2 species, both sexes, with 50 animals per dose per sex, and at least 50 percent survival at 15 months

in mice and 18 months in rats and at least 25 percent survival at 18 months in mice and 24 months in rats;

ii) Data from animal chronic studies with a minimum of 3 dose levels and a control group, 2 species, both sexes, with 40 animals per dose per sex, and at least 50 percent survival at 15 months in mice and 18 months in rats and at least 25 percent survival at 18 months in mice and 24 months in rats, and a well-defined NOAEL; or

iii) Data from animal subchronic studies with a minimum of 3 dose levels and control, 2 species, both sexes, 4 animals per dose per sex for non-rodent species or 10 animals per dose per sex for rodent species, a duration of at least 5% of the test species' lifespan, and a well-defined NOAEL.

B) Supporting studies which reinforce the conclusions of a study of Medium Validity may be considered to raise such a study to High Validity.

2) Medium Validity Studies

Medium validity studies are based upon:

A) Data from animal carcinogenicity, chronic, or subchronic studies in which minor deviations from the study design elements required for a High Validity Study are found, but which otherwise satisfy the standards for a High Validity Study;

B) Data from animal carcinogenicity and chronic studies in which at least 25 percent survival is reported at 15 months in mice and 18 months in rats (a lesser survival is permitted at the conclusion of a longer duration study, but the number of surviving animals should not fall below 20 percent per dose per sex at 18 months for mice and 24 months for rats), but which otherwise satisfy the standards for a High Validity Study;

C) Data from animal subchronic or chronic studies in which a Lowest Observable Adverse Effect Level (LOAEL) is determined, but which

otherwise satisfy the standards for a High Validity Study; or

D) Data from animal subchronic or chronic studies which have an inappropriate route of exposure (for example, intraperitoneal injection or inhalation) but which otherwise satisfy the standards for a High Validity Study, with correction factors for conversion to the oral route.

3) Low Validity Studies

Low validity studies are studies not meeting the standards set forth in subsection (c)(1) or (c)(2).

Section 620.Appendix B Procedures for Determining Hazard Indices for Class I: Potable Resource Groundwater for Mixtures of Similar-Acting Substances

a) This appendix describes procedures for evaluating mixtures of similar-acting substances which may be present in Class I: Potable Resource Groundwaters. Except as provided otherwise in subsection (c), subsections (d) through (h) describe the procedure for determining the Hazard Index for mixtures of similar-acting substances.

b) For the purposes of this appendix, a "mixture" means two or more substances which are present in Class I: Potable Resource Groundwater which may or may not be related either chemically or commercially, but which are not complex mixtures of related isomers and congeners which are produced as commercial products (for example, PCBs or technical grade chlordane).

c) The following substances listed in Section 620.410 are mixtures of similar acting substances:

1) Mixtures of ortho-Dichlorobenzene and para-Dichlorobenzene. The Hazard Index ("HI") for such mixtures is determined as follows:

HI = [ortho-Dichlorobenzene]\0.6 +
[para-Dichlorobenzene]\0.075

2) Mixtures of 1,1-Dichloroethylene and 1,1,1-trichloroethane. The Hazard Index ("HI") for such mixtures is determined as follows:

HI = [1,1-Dichloroethylene]\0.007 +
[1,1,1-trichloroethane]\0.2

d) When two or more substances occur together in a mixture, the additivity of the toxicities of some or all of the substances will be considered when determining health-based standards for Class I: Potable Resource Groundwater. This is done by the use of a dose addition model with the development of a Hazard Index for the mixture of substances with similar-acting toxicities. This method does not address synergism or antagonism. Guidelines for determining when the dose addition of similar-acting substances is appropriate are presented in Appendix C.

The Hazard Index is calculated as follows:

HI = [A]\ALA + [B]\ALB + . . . [I]\ALI

Where:

HI = Hazard Index, unitless.

[A], [B], [I] = Concentration of each similar-acting substance in groundwater in milligrams per liter (mg/L).

ALA, ALB, ALI = The acceptable level of each similar-acting substance in the mixture in milligrams per liter (mg/L).

e) For substances which are considered to have a threshold mechanism of toxicity, the acceptable level is:

1) The standards listed in Section 620.410; or

2) For those substances for which standards have not been established in Section 620.410, the Human Threshold Toxicant Advisory Concentration (HTTAC) as determined in Appendix A.

f) For substances which are carcinogens, the acceptable level is:

1) The standards listed in Section 620.410; or

2) For those substances for which standards have not been established under Section 620.410, the lowest appropriate PQL of USEPA-approved analytical methods specified in SW-846, incorporated by reference at Section 620.125, for each substance.

g) Since the assumption of dose addition is most properly applied to substances that induce the same effect by similar modes of action, a separate HI must be generated for each toxicity endpoint of concern.

h) In addition to meeting the individual substance objectives, a Hazard Index must be less than or equal to 1 for a mixture of similar-acting substances.

Section 620.Appendix C Guidelines for Determining When Dose Addition of Similar-Acting Substances in Class I: Potable Resource Groundwaters is Appropriate

a) Substances must be considered similar-acting if:

1) The substances have the same target in an organism (for example, the same organ, organ system, receptor, or enzyme).

2) The substances have the same mode of toxic action. These actions may include, for example, central nervous system depression, liver toxicity, or cholinesterase inhibition.

b) Substances that have fundamentally different mechanisms of toxicity (threshold toxicants vs. carcinogens) must not be considered similar-acting. However, carcinogens which also cause a threshold toxic effect should be considered in a mixture with other similar-acting substances having the same threshold toxic effect. In such a case, an Acceptable Level for the carcinogen must be derived for its threshold effect, using the procedures described in Appendix A.

c) Substances which are components of a complex mixture of related compounds which are produced as commercial products (for example, PCBs or technical grade chlordane) are not mixtures, as defined in Appendix B. Such complex mixtures are equivalent to a single substance. In such a case, the Human Threshold Toxicant Advisory Concentration may be derived for threshold effects of the complex mixture, using the procedures described in Appendix A, if valid toxicological or epidemiological data are available for the complex mixture. If the complex mixture is a carcinogen, the Health Advisory Concentration is the lowest appropriate PQL of USEPA-approved analytical methods specified in SW-846, incorporated by reference at Section 620.125.

Section 620.Appendix D Confirmation of an Adequate Corrective Action Pursuant to 35 Ill. Adm. Code 620.250 (a)(2).

Pursuant to 35 Ill. Adm. Code 620.250(a) if an owner or operator provides a written confirmation to the Agency that an adequate corrective action, equivalent to a corrective action process approved by the Agency, is being undertaken in a timely and appropriate manner, then a groundwater management zone may be established as a three-dimensional region containing groundwater being managed to mitigate impairment caused by the release of contaminants from a site. This document provides the form in which the written confirmation is to be submitted to the Agency.

Note 1. Parts I and II are to be submitted to IEPA at the time that the facility claims the alternative groundwater standards. Part III is to be submitted at the completion of the site investigation. At the completion of the corrective process, a final report is to be filed which includes the confirmation statement included in Part IV.

Note 2. The issuance of a permit by IEPA's Division of Air Pollution Control or Water Pollution Control for a treatment system does not imply that the Agency has approved the corrective action process.

Note 3. If the facility is conducting a cleanup of a unit which is subject to the requirements of the Resource Conservation and Recovery Act (RCRA) or the 35 Ill. Adm. Code 731 regulations for Underground Storage Tanks, this confirmation process is not applicable and cannot be used.

Note 4. If the answers to any of these questions require explanation or clarification, provide such in an attachment to this document.

Part I. Facility Information

Facility Name _____
Facility Address _____

County _____
Standard Industrial Code (SIC) _____

1. Provide a general description of the type of industry, products manufactured, raw materials used, location and size of the facility.

2. What specific units (operating or closed) are present at the facility which are or were used to manage waste, hazardous waste, hazardous substances or petroleum?

	YES	NO
Landfill	_____	_____
Surface Impoundment	_____	_____
Land Treatment	_____	_____
Spray Irrigation	_____	_____
Waste Pile	_____	_____
Incinerator	_____	_____
Storage Tank (above ground)	_____	_____
Storage Tank (underground)	_____	_____
Container Storage Area	_____	_____
Injection Well	_____	_____
Water Treatment Units	_____	_____
Septic Tanks	_____	_____
French Drains	_____	_____
Transfer Station	_____	_____

Other Units (Please describe)

_____

_____

3. Provide an extract from a USGS topographic or county map showing the location of the site and a more detailed scaled map of the facility with each waste management unit identified in Question 2 or known/suspected source clearly identified. Map scale must be specified and the location of the facility must be provided with respect to Township, Range and Section.

4. Has the facility ever conducted operations which involved the generation, manufacture, processing, transportation, treatment, storage or handling of "hazardous substances" as defined by the Illinois Environmental Protection Act? Yes _____ No _____ If the answer to this question is "yes" generally describe these operations.

5. Has the facility generated, stored or treated hazardous waste as defined by the Resource Conservation and Recovery Act? Yes _____ No _____ If the answer to this question is "yes" generally describe these operations.

6. Has the facility conducted operations which involved the processing, storage or handling of petroleum? Yes _____ No _____ If the answer to this questions is "yes" describe these operations.

7. Has the facility ever held any of the following permits?

   a. Permits for any waste storage, waste treatment or waste disposal operation. Yes _____ No _____ If

the answer to this question is "yes", identify the IEPA permit numbers.

b. Interim Status under the Resources Conservation and Recovery Act (filing of a RCRA Part A application). Yes _____ No _____ If the answer to this question is "yes", attach a copy of the last approved Part A application.

c. RCRA Part B Permits. Yes _____ No _____ If the answer to this question is "yes", identify the permit log number.

8. Has the facility ever conducted the closure of a RCRA hazardous waste management unit? Yes _____ No _____

9. Have any of the following State or federal government actions taken place for a release at the facility?

a. Written notification regarding known, suspected or alleged contamination on or emanating from the property (e.g., a Notice pursuant to Section 4(q) of the Environmental Protection Act)? Yes _____ No _____ If the answer to ths question is "yes", identify the caption and date of issuance.

b. Consent Decree or Order under RCRA, CERCLA, EPAct Section 22.2 (State Superfund), or EPAct Section 21(f) (State RCRA). Yes _____ No _____

c. If either of Items a or b were answered by checking "yes", is the notice, order or decree still in effect? Yes _____ No _____

10. What groundwater classification will the facility be subject to at the completion of the remediation? Class I _____ Class II _____ Class III _____ Class IV _____ If more than one Class applies, please explain.

11. Describe the circumstances which the release to groundwater was identified.

Based on my inquiry of those persons directly responsible for gathering the information, I certify that the information submitted is, to the best of my knowledge and belief, true and accurate.

_____	_____
Facility Name	Signature of Owner/Operator
_____	_____
Location of Facility	Name of Owner/Operator

EPA Identification Number _____ Date _____

PART II: Release Information

1. Identify the chemical constituents released to the groundwater. Attach additional documents as necessary.

Chemical Description	Chemical Abstract No.

2. Describe how the site will be investigated to determine the source or sources of the release.

3. Describe how groundwater will be monitored to determine the rate and extent of the release.

4. Has the release been contained on-site at the facility?

5. Describe the groundwater monitoring network and groundwater and soil sampling protocols in place at the facility.

6. Provide the schedule for investigation and monitoring.

7. Describe the laboratory quality assurance program utilized for the investigation.

8. Provide a summary of the results of available soil testing and groundwater monitoring associated with the release at the facility. The summary of results should provide the following information: dates of sampling; types of samples taken (soil or water); locations and depths of samples; sampling and analytical methods; analytical laboratories used; chemical constituents for which analyses were performed; analytical detection limits; and concentrations of chemical constituents in ppm (levels below detection should be identified as "ND").

Based on my inquiry of those persons directly responsible for gathering the information, I certify that the information submitted is, to the best of knowledge and belief, true and accurate and confirm that the actions identified herein will be undertaken in accordance with the schedule set forth herein.

Facility Name _____ Signature of Owner/Operator _____

_____ _____

Location of Facility | Name of Owner/Operator

EPA Identification Number | Date

Part III: Remedy Selection Information

1. Describe the selected remedy.

2. Describe other remedies which were considered and why they were rejected.

3. Will waste, contaminated soil or contaminated groundwater be removed from the site in the course of this remediation? Yes _____ No _____ If the answer to this question is "yes", where will the contaminated material be taken?

4. Describe how the selected remedy will accomplish the maximum practical restoration of beneficial use of groundwater.

5. Describe how the selected remedy will minimize any threat to public health or the environment.

6. Describe how the selected remedy will result in compliance with the applicable groundwater standards.

7. Provide a schedule for design, construction and operation of the remedy, including dates for the start and completion.

8. Describe how the remedy will be operated and maintained.

9. Have any of the following permits been issued for the remediation?

   a. Construction or Operating permit from the Division of Water Pollution Control. Yes _____ No _____

   b. Land treatment permit from the Division of Water Pollution Control. Yes _____ No _____ If the answer to this question is "yes", identify the permit number.

   c. Construction or Operating permit from the Division of Air Pollution Control. Yes _____ No _____ If the answer to this question is "yes", identify the permit number.

10. How will groundwater at the facility be monitored following completion of the remedy to ensure that the groundwater standards have been attained?

Based on my inquiry of those persons directly responsible for gathering the information, I certify that the information submitted is, to the best of my knowledge and belief, true and accurate and confirm that the actions identified herein will be undertaken in accordance with the schedule set forth herein.

Facility Name	Signature of Owner/Operator
Location of Facility	Name of Owner/Operator
EPA Identification Number	Date

PART IV: Completion Certification

This certification must accompany documentation which includes soil and groundwater monitoring data demonstrating successful completion of the corrective process described in Parts I-III.

Facility Name _____
Facility Address _____
_____
_____
County _____
Standard Industrial Code (SIC) _____
Date _____

Based on my inquiry of those persons directly responsible for gathering the information, I certify that an adequate corrective action, equivalent to a corrective action process approved by the Agency, has been undertaken and that the following restoration concentrations are being met:

Chemical Name	Chemical Abstract No.	Concentration (mg/l)

Facility Name	Signature of Owner/Operator
Location of Facility	Name of Owner/Operator

EPA Identification Number Date

IT IS SO ORDERED.

Board Member J.D. Dumelle concurred.

I, Dorothy M. Gunn, Clerk of the Illinois Pollution Control Board, hereby certify that the above Opinion and Order was adopted on the 14 day of November, 1991, by a vote of 7-0.

Dorothy M. Gunn

Dorothy M. Gunn, Clerk

UNITED STATES ENVIRONMENTAL PROTECTION AGENCY
WASHINGTON, D.C. 20460

FEB - 6 2014

OFFICE OF
SOLID WASTE AND
EMERGENCY RESPONSE

OSWER Directive 9200.1-120

MEMORANDUM

SUBJECT: Human Health Evaluation Manual, Supplemental Guidance: Update of Standard Default Exposure Factors

FROM: Dana Stalcup, Acting Director
Assessment and Remediation Division
Office of Superfund Remediation and Technology Innovation

TO: Superfund National Policy Managers, Regions 1 - 10

Purpose

The mission of the Superfund program is to protect human health and the environment consistent with the Comprehensive Environmental Response, Compensation and Liability Act, as amended, (CERCLA) and as implemented by the National Oil and Hazardous Substances Pollution Contingency Plan. The purpose of this directive is to update the Interim Final Standard Exposure Factors Guidance (1991), which is reflected in the attached table and is to be used:

- in the CERCLA remedial investigation and feasibility study process (e.g., assessing baseline health risks, developing preliminary remediation goals, evaluating risks of remedial alternatives),
- to evaluate health risks in the CERCLA removal program, and
- in the process of five-year reviews of selected remedies.

This guidance update supplements the *Risk Assessment Guidance for Superfund: Human Health Evaluation Manual, Part A* (RAGS, Part A) that was issued October 13, 1989. This guidance supersedes and replaces certain portions of OSWER Directive 9285.6-03, issued March 25, 1991 and updates the *Risk Assessment Guidance for Superfund, Part E,* issued July 2004 (RAGS, Part E). Other cleanup programs in the Office of Solid Waste and Emergency Response (OSWER) are welcome and encouraged to adopt the recommended exposure factors, much as they have historically adopted other aspects of the *Risk Assessment Guidance for Superfund* (RAGS).

Background

In September 2011, EPA's National Center for Environmental Assessment, Office of Research and Development (ORD/NCEA) issued a substantive update to its exposure assessment recommendations. *Exposure Factors Handbook – 2011 Edition*, referred to as EFH 2011 herein, provides information and recommendations on various physiological and behavioral factors commonly used in assessing exposure of adults and children to environmental chemicals. ORD/NCEA's recommended values for exposure factors are based on the results of studies deemed to be the most up-to-date and scientifically sound, based upon data available up to July 2011, and incorporates revisions made to the *Child-Specific Exposure Factors Handbook*, which was last updated and published in 2008. EFH 2011 is not a Superfund-specific document; rather, it provides a summary of the latest developments in exposure science and provides recommendations for a broad range of EPA programs.

Following the publication of EFH 2011, regional risk assessors received inquiries from other EPA program offices, states, the regulated community, and other interested parties regarding the applicability of the ORD/NCEA's recommendations for use in human health risk assessments. During the October 2011 to August 2012 period, the OSWER Human Health Regional Risk Assessors Forum (OHHRRAF) reviewed the recommendations in EFH 2011 in the context of the default exposure factors used in the Superfund program and to derive Regional screening levels. As a result of a consensus-driven process, the OHHRRAF identified several Superfund-specific default exposure factors that warranted updating, based upon recommendations from ORD/NCEA in EFH 2011. This guidance incorporates and adopts the updates recommended by the OHHRRAF.

Objective

This guidance has been developed to reduce variability and uncertainty in the exposure assumptions used by Regional Superfund staff to characterize exposures to human populations for human health risk assessments.

Implementation

This guidance supplements the *Risk Assessment Guidance for Superfund: Human Health Evaluation Manual* (RAGS), Part A through E. Where numerical values differ from those presented in Part A or E, the factors presented in this guidance should be considered updates to the older values. As new data become available, this Directive may be modified accordingly.

This report can be found at www.epa.gov/oswer/riskassessment/superfund_hh_exposure.htm
Please contact Richard Kapuscinski at (703) 305-7411 if you have questions or concerns.

Attachment 1. Recommended Default Exposure Factors (2014)

Symbol	Definition (units)	Previous Default Value	Currently Recommended Value	Source of current recommendation	Source of previous recommendation
Ingestion and Dermal Contact Rates					
IRW_c	Resident Drinking Water Ingestion Rate - Child (L/day)	1	0.78	U.S. EPA 2011a, Tables 3-15 and 3-33; weighted average of 90th percentile consumer-only ingestion of drinking water (birth to <6 years)	U.S. EPA 1989 (Exhibit 6-11)
IRW_a	Resident Drinking Water Ingestion Rate - Adult (L/day)	2	2.5	U.S. EPA 2011a, Table 3-33; 90th percentile of consumer-only ingestion of drinking water (≥ 21 years)	U.S. EPA 1989 (Exhibit 6-11)
IRS_c	Resident Soil Ingestion Rate - Child (mg/day)	200	200	U.S. EPA 2011a (Table 5-1); "upper-bound values" accounting for both soil and dust ingestion	U.S. EPA 1991a (pg. 15)
IRS_a	Resident Soil Ingestion Rate - Adult (mg/day)	100	100	U.S. EPA 1991a (pp. 6 and 15); EFH 2011 only provides a central tendency value	U.S. EPA 1991a (pg. 15)
IR_{iw}	Indoor Worker Soil Ingestion Rate (mg/day)	50	50	U.S. EPA 1991a (pp. 9-10, 15); EFH 2011 values not provided	U.S. EPA 1991a (pg. 15)
IR_{ow}	Outdoor Worker Soil Ingestion Rate (mg/day)	100	100	U.S. EPA 1991a (pg. 15), same as adult resident; EFH 2011 value not provided	U.S. EPA 1991a (pg. 15)
SA_{sc}	Resident skin surface area - child (cm^2)	2,800	2,373	U.S. EPA 2011a, Tables 7-2 and 7-8; weighted average of mean values for head, hands, forearms, lower legs, and feet (male and female, birth to < 6 years)(forearm and lower leg-specific data used when available, ratios for nearest available age group used elsewhere (per EPA 2011b))	U.S. EPA 2002 (Exhibit 1-2)
SA_{sa}	Resident skin surface area - adult (cm^2)	5,700	6,032	U.S. EPA 2011a, Tables 7-2 and 7-12; weighted average of mean values for head, hands, forearms, and lower legs (male and female, 21+ years)(forearm and lower leg-specific data used for males and female lower leg; ratio of male forearm to arm applied to female arm data).	U.S. EPA 2002 (Exhibit 1-2)
SA_{sow}	Worker skin surface area - adult (cm^2)	3,300	3,527	US EPA 2011a, Table 7-2; weighted average of mean values for head, hands, and forearms (male and female, 21+years) (similar assumptions for forearms as used in EPA 2011b)	U.S. EPA 2002 (Exhibit 1-2)
SA_{wc}	Resident Water Surface area - child (cm^2)	6,600	6,365	U.S. EPA 2011a, Table 7.9; weighted average of mean values for male and female children <6 years.	U.S. EPA 2004 (Exhibit 3-2)
SA_{wa}	Resident Water Surface area - adult (cm^2)	18,000	19,652	U.S. EPA 2011a, Table 7.9; weighted average of mean values for male and female adults, 21-78.	U.S. EPA 2004 (Exhibit 3-2)
AF_c	Resident soil adherence factor - child (mg/cm^2)	0.2	0.2	U.S. EPA 2004 (Exhibit 3-5), RAGS Part E	U.S. EPA 2002 (Exhibit 1-2)
AF_a	Resident soil adherence factor - adult (mg/cm^2)	0.07	0.07	U.S. EPA 2004 (Exhibit 3-5), RAGS Part E	U.S. EPA 2002 (Exhibit 1-2)
AF_{ow}	Worker soil adherence factor - adult (mg/cm^2)	0.2	0.12	U.S. EPA 2011a, Table 7-20 and Section 7.2.2; arithmetic mean of weighted average of body part-specific (hands, forearms, and face) mean adherence factors for adult commercial/industrial activities	U.S. EPA 2002 (Exhibit 1-2)
BW_c	Resident Body Weight - child (kg)	15	15	U.S. EPA 2011a, Table 8-1; weighted average of mean body weights (birth to <6 years)	U.S. EPA 1991a (pg. 15)
BW_a	Resident Body Weight - adult (kg)	70	80	U.S. EPA 2011a, Table 8-3; weighted mean values for adults 21 – 78	U.S. EPA 1991a (pg. 15)
BW_w	Worker Body Weight (kg)	70	80	U.S. EPA 2011a, Table 8-3; weighted mean values for adults 21 – 78	U.S. EPA 1991a (pg. 15)
Exposure Frequency, Exposure Duration, and Exposure Time Variables					

Attachment 1. Recommended Default Exposure Factors (2014)

Symbol	Definition (units)	Previous Default Value	Currently Recommended Value	Source of current recommendation	Source of previous recommendation
EF_r	Resident Exposure Frequency (days/yr)	350	350	U.S. EPA 1991a (pg. 15); value not provided in EFH 2011	U.S. EPA 1991a (pg. 15)
EF_w	Worker Exposure Frequency (days/yr)	250	250	U.S. EPA 1991a (pg. 15); value not provided in EFH 2011	U.S. EPA 1991a (pg. 15)
EF_{iw}	Indoor Worker Exposure Frequency (days/yr)	250	250	U.S. EPA 1991a (pg. 15); value not provided in EFH 2011	U.S. EPA 1991a (pg. 15)
EF_{ow}	Outdoor Worker Exposure Frequency (days/yr)	225	225	U.S. EPA 2002; value not provided in EFH 2011	U.S. EPA 1991a (pg. 15)
ED_r	Resident Exposure Duration (yr)	30	26	EPA 2011a, Table 16-108; 90th percentile for current residence time.	U.S. EPA 1991a (pg. 15)
ED_c	Resident Exposure Duration - child (yr)	6	6	U.S. EPA 1991a, Pages 6 and 15	U.S. EPA 1991a (pg. 15)

UNITED STATES ENVIRONMENTAL PROTECTION AGENCY
WASHINGTON, D.C. 20460

OFFICE OF
SOLID WASTE AND EMERGENCY
RESPONSE

December 5, 2003

OSWER Directive 9285.7-53

MEMORANDUM

SUBJECT: Human Health Toxicity Values in Superfund Risk Assessments

FROM: Michael B. Cook, Director /s/
Office of Superfund Remediation and Technology Innovation

TO: Superfund National Policy Managers, Regions 1 - 10

Purpose

This memorandum revises the hierarchy of human health toxicity values generally recommended for use in risk assessments, originally presented in Risk Assessment Guidance for Superfund Volume I, Part A, Human Health Evaluation Manual (RAGS) (OSWER 9285.7-02B, EPA/540/1-89/009, December 1989). (http://www.epa.gov/superfund/programs/risk/ragsa/index.htm)

It updates the hierarchy of human health toxicity values and provides guidance for the sources of toxicity information that should generally be used in performing human health risk assessments at Comprehensive Environmental Response Compensation and Liability Act (CERCLA or "Superfund") sites. It does not address the situation where new toxicity information is brought to the attention of the U.S. Environmental Protection Agency (EPA). It also does not provide guidance or address toxicity or reference values for ecological risk.

This memorandum presents current Office of Solid Waste and Emergency Response (OSWER) technical and policy recommendations regarding human health toxicity values in risk assessments. EPA and state personnel may use and accept other technically sound approaches, either on their own initiative, or at the suggestion of potentially responsible parties, or other interested parties. Therefore, interested parties are free to raise questions and objections about the substance of this memorandum and the appropriateness of the application of this document to a particular situation. EPA will, and States should, consider whether the recommendations or interpretations in this memorandum are appropriate in that situation. This memorandum does not impose any requirements or obligations on EPA, States, or other federal agencies, or the regulated community. The sources of authority and requirements in this matter are the relevant

statutes and regulations (e.g., CERCLA, Resource Conservation and Recovery Act). EPA welcomes public comments on this memorandum at any time and may consider such comments in future revisions of this memorandum.

Background

Superfund risk assessments are performed for a number of reasons, including to evaluate whether action is warranted under CERCLA, to establish protective cleanup levels, and to determine the residual risk posed by response actions. Generally, toxicity assessment is an integral part of risk assessment. Volume I, Part A of RAGS provides guidance on how to conduct the human health portion of the risk assessment. Chapter 7.4.1 presents a hierarchy of human health toxicity values for use in risk assessments at Superfund sites. The hierarchy presented in RAGS Part A is being updated to reflect that additional sources of peer reviewed values have become available since 1989. In addition, the EPA Health Effects Assessment Summary Tables (HEAST) document, which was identified as the second tier of data, has not been updated since 1997. As a result, HEAST may not provide the most current source of information on some contaminants.

This revised hierarchy recognizes that EPA should use the best science available on which to base risk assessments. In general, if health assessment information is available in the Integrated Risk Information System ["IRIS," http://www.epa.gov/iris/] for the contaminant under evaluation, risk assessors normally need not search further for additional sources of information. Since EPA's development and use of peer review in toxicity assessments, IRIS assessments have undergone external peer review in accordance with Agency peer review guidance at the time of the assessment. IRIS health assessments contain Agency consensus toxicity values. If such information is not available in IRIS, risk assessors should consider other sources of available data based on the hierarchy presented in this memorandum.

EPA recognizes that there may be other sources of toxicological information. As noted in the December 1993 memorandum entitled "Use of IRIS Values in Superfund Risk Assessment" (OSWER Directive 9285.7-16, December 21, 1993):

> "...IRIS is not the only source of toxicology information, and in some cases more recent, credible and relevant data may come to the Agency's attention. In particular, toxicological information other than that in IRIS may be brought to the Agency by outside parties. Such information should be considered along with the data in IRIS in selecting toxicological values; ultimately, the Agency should evaluate risk based upon its best scientific judgement and consider all credible and relevant information available to it."

This memorandum is intended to help regional risk assessors identify appropriate sources of toxicological information as a means of streamlining decisions. It does not specifically address the situation where additional scientific information is brought to the attention of EPA. In those cases, EPA risk assessors and decision makers should consider the information as appropriate on a case by case basis.

Revised Recommended Human Health Toxicity Value Hierarchy

This memorandum revises the recommended hierarchy of toxicological sources of information which Regional risk assessors and managers should initially consider for site-specific risk assessments. The revised recommended toxicity value hierarchy is as follows:

Tier 1- EPA's IRIS

Tier 2- EPA's Provisional Peer Reviewed Toxicity Values (PPRTVs) – The Office of Research and Development/National Center for Environmental Assessment/Superfund Health Risk Technical Support Center (STSC) develops PPRTVs on a chemical specific basis when requested by EPA's Superfund program.

Tier 3- Other Toxicity Values – Tier 3 includes additional EPA and non-EPA sources of toxicity information. Priority should be given to those sources of information that are the most current, the basis for which is transparent and publicly available, and which have been peer reviewed.

IRIS remains in the first tier of the recommended hierarchy as the generally preferred source of human health toxicity values. IRIS generally contains reference doses (RfDs), reference concentrations (RfCs), cancer slope factors, drinking water unit risk values, and inhalation unit risk values that have gone through a peer review and EPA consensus review process. IRIS normally represents the official Agency scientific position regarding the toxicity of the chemicals based on the data available at the time of the review.

The second tier is EPA's PPRTVs. Generally, PPRTVs are derived for one of two reasons. First, the STSC is conducting a batch wise review of the toxicity values in HEAST (now a Tier 3 source). As such reviews are completed, those toxicity values will be removed from HEAST, and any new toxicity value developed in such a review will be a PPRTV and placed in the PPRTV database. Second, Regional Superfund Offices may request a PPRTV for contaminants lacking a relevant IRIS value. The STSC uses the same methodologies to derive PPRTVs for both.

The third tier includes other sources of information. Priority should be given to sources that provide toxicity information based on similar methods and procedures as those used for Tier I and Tier II, contain values which are peer reviewed, are available to the public, and are transparent about the methods and processes used to develop the values. Consultation with the STSC or headquarters program office is recommended regarding the use of the Tier 3 values for Superfund response decisions when the contaminant appears to be a risk driver for the site. In general, draft toxicity assessments are not appropriate for use until they have been through peer review, the peer review comments have been addressed in a revised draft, and the revised draft is publicly available.

Additional sources may be identified for Tier 3. Toxicity values that fall within the third tier in the hierarchy include, but need not be limited to, the following sources.

- The California Environmental Protection Agency (Cal EPA) toxicity values are peer reviewed and address both cancer and non-cancer effects. Cal EPA toxicity values are available on the Cal EPA internet website at http://www.oehha.ca.gov/risk/chemicalDB//index.asp.
- The Agency for Toxic Substances and Disease Registry (ATSDR) Minimal Risk Levels (MRLs) are estimates of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse non-cancer health effects over a specified duration of exposure. The ATSDR MRLs are peer reviewed and are available at http://www.atsdr.cdc.gov/mrls.html on the ATSDR website.

- HEAST toxicity values are Tier 3 values. As noted above, the STSC is conducting a batch wise review of HEAST toxicity values. The toxicity values remaining in HEAST are considered Tier 3 values. The radionuclides HEAST toxicity values are available at http://www.epa.gov/radiation/heast/. The HEAST values on chemical contaminants are not currently available on an EPA internet site. They may be obtained by contacting a Superfund risk assessor.

Neither IRIS nor the PPRTV database contains radionuclide slope factors. Because EPA's Office of Radiation and Indoor Air (ORIA) obtains peer review on the radionuclide slope factors contained in Table 4 of HEAST (which are available on EPA/ORIA's internet website at http://www.epa.gov/radiation/heast/download.htm), routine consultation with STSC is generally not necessary on these values even when they may be a risk driver on a Superfund site. These radionuclide slope factors have been adopted by EPA in its Preliminary Remediation Goals for Radionuclide Calculator and are available on EPA's internet website at: http://epa-prgs.ornl.gov/radionuclides/ and the Soil Screening Guidance for Radionuclide documents, which are available at: http://www.epa.gov/superfund/resources/radiation/radssg.

Implementation

This memorandum provides a revised recommended hierarchy of human health toxicity values for Superfund sites and represents a revision of Chapter 7 of RAGS, Volume I, Part A. Superfund risk assessors should look to this hierarchy when evaluating risk for CERCLA response actions. Additional sources of toxicity values, which are not specifically referenced in this recommended hierarchy, can be considered.

Additional Information

Questions regarding this guidance or its use and implementation on a particular site should be directed to an EPA Regional Superfund risk assessor or toxicologist. Questions of a more general nature relating to this guidance should be directed to Mr. Dave Crawford of my staff at (703) 603- 8891, Crawford.Dave@epa.gov.

Tier 3 Toxicity Value White Paper[1]

1 Introduction

1.1 Purpose

The purpose of this white paper is to articulate the issues pertaining to Tier 3 toxicity values and provide recommendations on processes that will improve the transparency and consistency of identifying, evaluating, selecting, and documenting Tier 3 toxicity values for use in the Superfund and Resource Conservation and Recovery Act (RCRA) programs. This white paper will be used to assist regional risk assessors in selecting Tier 3 toxicity values as well as provide the foundation for future regional and national efforts to improve guidance and policy on Tier 3 toxicity values.

1.1.1 Specific Objectives

The specific objectives of this white paper are to:

- Inform the reader of the differences and similarities between Tier 3 toxicity values,
- Discuss existing criteria and guidance that are relevant to selecting the most scientifically defensible Tier 3 toxicity value,
- Compare the available options for identifying, evaluating, selecting, and documenting Tier 3 toxicity values,
- Provide specific examples of how Tier 3 toxicity values have been identified and selected by the regions, and
- Recommend a process for selecting Tier 3 toxicity values.

1.1.2 Scope

This white paper is limited to Tier 3 toxicity values as defined in Office of Solid Waste and Emergency Response (OSWER) Directive 9285.7-53 (2003 Toxicity Value Hierarchy) and provides recommendations on processes for identifying, evaluating, selecting, documenting, and communicating Tier 3 toxicity values for use in site-specific human health risk assessments.[2] This white paper has been reviewed by the regional risk assessors, and the recommendations are based on the consensus of the regional risk assessors. While not guidance or policy itself, the white paper is also written with the intent to assist

[1] *Disclaimer: This U.S. Environmental Protection Agency (EPA) document discusses the process of identifying and selecting Tier 3 toxicity values. This document is not a rule or regulation and it may not apply to a particular situation based upon the circumstances. This document does not change or substitute for any law, regulation, or any other legally binding requirement and is not legally enforceable. As indicated by the use of non-mandatory language such as "guidance," "recommend," "may," "should," and "can," it identifies policies and provides recommendations and does not impose any legally binding requirements.*

[2] The derivation of new toxicity values falls outside of the scope of this white paper.

others (regional risk assessors, regional risk assessment workgroups, Regional Toxics Integration Coordinators, and headquarters risk assessors) in developing formal or informal EPA regional and national guidance or policy.

1.2 Background

Toxicity values (including reference doses [RfD], reference concentrations [RfC], cancer slope factors, and inhalation unit risks) needed for use in human health risk assessment are generally derived by reviewing available dose-response data in animals or humans, selecting a point of departure in the data that is judged most suitable, and adjusting for associated uncertainties. Often, multiple data sets are available, and there may be a variety of options for deriving the toxicity values. In addition, there are a variety of options for fitting the data and selecting and applying uncertainty factors. For these reasons, there can sometimes be a number of alternative toxicity factors available from different sources for a specified chemical.

OSWER has developed a number of guidance documents which include recommendations for selecting toxicity values. The early guidance established the IRIS database as the preferred source for selecting toxicity values (EPA 1989, 1991, 1993). Subsequent guidance confirmed the preference for the use of IRIS values and made suggestions for appropriate sources of toxicological information that could be used for selecting or deriving toxicity factors in cases where no published IRIS value was available for a given chemical. These developments have led to the concept of applying a more formal or prescribed "hierarchy" for consulting data sources to select or derive toxicity values (EPA 2003, 2005, 2009). This section describes the existing policies used by the Superfund Program for selecting toxicity values, and when necessary, deriving appropriate values for site-specific risk assessment activities.

1.2.1 OSWER's Toxicity Value Hierarchy

1.2.1.1 Risk Assessment Guidance for Superfund (RAGS) Parts A and B

The first guidance on the hierarchy for selecting toxicity factors was provided in Risk Assessment Guidance for Superfund (RAGS) Part A (1989) and Part B (1991). These documents specify that the first preference is for toxicity values that are presented in EPA's Integrated Risk Information System (IRIS). The 1993 OSWER Directive titled "Use of IRIS Values in Superfund Risk Assessment" reconfirmed that IRIS values should be given the highest priority for application in Superfund risk assessments and that alternative toxicological information should only be considered on a case-by-case basis (http://www.epa.gov/oswer/riskassessment/pdf/irismemo.pdf). To this day, IRIS generally supersedes all other sources of toxicity information and is considered the "gold-standard" in terms of toxicological assessments. If no value was available in IRIS, the second preference was identified as the Health Effects Assessment Summary Tables (HEAST). HEAST provided up-to-date toxicity values in a tabular format, first quarterly and then annually for several years through 1997. Unlike IRIS, not all HEAST values went through a formal peer or EPA review process, and interim values were also included in the tables.

If toxicity values were not available on IRIS or in HEAST, then RAGS recommended, in no specified order, other sources such as EPA criteria documents (health advisory summaries), Agency for Toxic Substances and Disease Registry (ATSDR) toxicological profiles, or provisional toxicity assessments prepared by the National Center for Environmental Assessment (formerly the Environmental Criteria and Assessment Office).

1.2.1.2 2003 Directive Human Health Toxicity Values in Superfund Risk Assessments

In 2003, OSWER Directive 9285.7-53 revised Superfund's hierarchy of human health toxicity values, providing three tiers of toxicity values.[3] There were two important reasons for updating the RAGS toxicity hierarchy. First, additional sources of peer-reviewed values had become available, such as EPA's Provisional Peer Reviewed Toxicity Values (PPRTVs). Second, HEAST, which had been identified in RAGS as the second choice for toxicity information, had not been updated since 1997.

The revised hierarchy provided three tiers of toxicity values: IRIS as the first tier, PPRTVs as the second tier, and "other toxicity values" as the third tier. Example sources of Tier 3 toxicity values included California EPA (Cal/EPA) toxicity values, ATSDR Minimum Risk Levels (MRLs), and HEAST.

1.2.1.3 RAGS Part E and F

RAGS Part E (Dermal Guidance) and RAGS Part F (Inhalation Guidance) were the first supplemental guidance documents to be published after the 2003 OSWER directive. Although RAGS Part E, which was released in 2004, does not reference the 2003 OSWER directive or previous toxicity value hierarchies, this guidance discusses a process for estimating dermal toxicity values by extrapolating from approved oral toxicity values. In 2009, RAGS Part F cited the 2003 OSWER directive as the appropriate hierarchy for selecting toxicity values. RAGS Part F notes that extrapolation of toxicity values from the oral to the inhalation exposure route may not be appropriate in all cases.

1.2.2 Limitations of OSWER Guidance on Tier 3 Toxicity Value Selection

When no Tier 1 or Tier 2 toxicity value is available, but there are several Tier 3 values, it is necessary to decide which Tier 3 value is most appropriate. The merit of these values may vary depending on the scientific quality and rigor of the underlying toxicological studies and analysis and the extent of the peer review. Development of some available values (such as ATSDR MRLs[4] and Cal/EPA toxicity values), includes extensive literature review, rigorous data analysis using up-to-date guidance and methods to derive a toxicity value, and thorough peer review. Development of other toxicity values is not

[3] As an OSWER Directive, the hierarchy is also used by the Office of Brownfields & Land Revitalization (Brownfields), the Office of Emergency Management (OEM), the Office of Resource Conservation and Recovery (ORCR), and the Office of Underground Storage Tanks (OUST).

[4] ATSDR MRLs are limited to non-cancer effects only, but can include chronic, subchronic, and acute values.

necessarily based strictly on risk assessment practices, but may consider other factors. EPA Office of Water maximum contaminant levels (MCLs), for example, may be based on technological limitations in measurement or implementation.

The 2003 OSWER directive provides only limited guidance on selection of Tier 3 toxicity values, recommending that priority should be given to studies that are the most current, transparent in terms of their study or derivation methods, and that have been peer reviewed. Given the wide variety of sources for Tier 3 toxicity values, further guidance is warranted to assist risk assessors to select the most appropriate available Tier 3 value for use at Superfund and RCRA sites.

1.2.3 November 2009 Regional Risk Assessors Meeting

During a session of the November 2009 EPA Region Risk Assessors meeting, the regional risk assessors presented and discussed the approaches, challenges, and limitations for identifying and selecting Tier 3 toxicity values. Specific issues covered during the session included, but were not limited to, existing processes that regional risk assessors were using for identifying and selecting Tier 3 toxicity values, differences between Tier 3 toxicity value sources (for example, derivation methods, transparency, and use of uncertainty factors), and who is responsible for and what could be done to improve the Tier 3 toxicity value selection process. As a result of the presentations and ensuing discussions, the Regional Tier 3 Toxicity Value Workgroup was formed, consisting of a small group of regional risk assessors. The workgroup was given the broad task of developing processes for improving the selection of Tier 3 toxicity values. After the November meeting, the members of the workgroup met and charged themselves with building upon OSWER's toxicity value hierarchy by developing, evaluating, and recommending a processes for identifying and selecting Tier 3 toxicity values. Given that the charge and tasks were broad in scope, additional members and contacts were added to the workgroup, including representatives from headquarters and the regions responsible for the Regional Screening Level Table. Also, consistent with the workgroup's charge and tasks specified during the November 2009 meeting, the workgroup decided that these efforts would be documented in the form of a white paper.

2 Tier 3 Toxicity Values

Currently, there are a myriad of potential sources of ready-made Tier 3 toxicity values and additional sources that provide the data necessary to derive a Tier 3 toxicity value. The purpose of this section is to provide examples from each of these sources, since there are far too many to list. This section will also introduce the similarities and differences between the sources of potential ready-made Tier 3 toxicity values.

2.1 Sources

Tier 3 toxicity values and toxicity data can be derived from state, federal (U.S.), and international sources. The following sections provide examples of some of the most commonly used state, federal and international sources of Tier 3 toxicity values and toxicity data used by risk assessors.

2.1.1 Federal (Internal and External to EPA)

Both EPA and its individual program offices can be useful sources of Tier 3 toxicity values and data. Before a chemical file is posted on the IRIS database in its final form, it must undergo a series of drafts, internal and external peer reviews, and revisions. A major part of this process is development of the draft toxicological review document for the individual chemical. This document details all of the available human and animal toxicity data evaluated and the recommendation for a quantitative cancer or noncancer toxicity value. Although the use of draft IRIS toxicity values as Tier 3 values is generally not appropriate except as indicated in USEPA, 2003, the toxicity values and supporting data in the draft IRIS toxicological reviews can be useful when evaluating a potential Tier 3 toxicity value from another source. These draft documents are useful because the literature searches have been completed and documented, the toxicity values derived using EPA-recommended methodologies, and to a greater or lesser extent have undergone peer review. These draft toxicological reviews can be obtained from the Region's IRIS consensus reviewer and are posted on the web during the public review and comment period.

Individual program offices often develop sources of toxicity values, which are not researched and peer reviewed to the same extent as IRIS files, but are useful for specific chemicals and routes of exposure. One example is the HEAST (http://epa-heast.ornl.gov/) developed for EPA's Superfund and RCRA hazardous waste programs. The Office of Pollution Prevention and Toxics Substances maintains the Acute Exposure Guidelines Levels (AEGLs) database, which provides acceptable concentrations for once in a lifetime, short-term exposures to airborne concentrations of acutely toxic, high priority chemicals (http://www.epa.gov/oppt/aegl/index.htm). These acute values are based on the recommendations of a federal advisory committee consisting of scientists from the public and private sectors. The Office of Pesticide Programs and the National Center for Environmental Assessment in the Office of Research and Development (ORD) are other potential sources of toxicity values.

Outside of EPA, perhaps the best known source of federal toxicity values is ATSDR. This agency develops toxicological profiles for individual chemicals (available at http://www.atsdr.cdc.gov/toxprofiles/index.asp), which are similar to the IRIS Toxicological Reviews. In addition to a review of the available human and animal toxicity studies, the profiles recommend quantitative values for risk management decision-making.

2.1.2 State Toxicity Values

A number of state environmental regulatory programs develop and maintain databases of quantitative toxicity values. Perhaps the best known of these is the Cal/EPA toxicity values available on its Internet website at http://www.oehha.ca.gov/risk/chemicalDB/index.asp. Examples of other state databases of toxicity values include New Jersey Department of Environmental Protection (http://www.state.nj.us/dep/dsr), and the Texas Department of Environmental Quality (http://www.tceq.texas.gov/toxicology). States have also derived toxicity values for specific chemicals and routes of exposure. For example, the New York State Department of Health (NYSDOH) developed an air criteria document for trichloroethylene in 2006, which evaluated and derived noncancer and cancer toxicity values (NYSDOH 2006).

2.1.3 International Community

Quantitative toxicity information can be found on the websites for many international regulatory agencies. For example, Health Canada prepares screening assessments of priority chemicals under the Canadian Environmental Protection Act of 1999 (http://www.chemicalsubstanceschimiques.gc.ca/plan/index-eng.php). One database that provides information from a number of international sources is the International Toxicity Estimates for Risk (ITER) database, which can be found at http://iter.ctcnet.net/publicurl/pub_search_list.cfm. In addition to EPA's IRIS and the ATSDR databases, this site includes toxicity values from Health Canada, the International Agency for Research on Cancer (IARC), the International Programme on Chemical Safety (IPCS), the National Institute of Public Health and the Environment of the Netherlands (RIVM), as well as peer-reviewed values by independent parties, such as Toxicological Excellence for Risk Assessment.

2.1.4 Databases for Developing Toxicity Values

In addition to state, federal, and international databases with cancer and noncancer toxicity values, there are also a tremendous number of resources that can be researched to develop toxicity values for specific chemicals.[5] EPA has recently released ToxRefDB (http://actor.epa.gov/toxrefdb/faces/Home.jsp). This database captures detailed study design, dosing, and observed treatment-related effects on thousands of *in vivo* animal toxicity studies on hundreds of chemicals. This database was developed by the National Center for Computational Toxicology in

[5] The derivation of new toxicity values falls outside of the scope of this white paper. However, state, federal, and international databases can be useful resources for evaluating existing Tier 3 toxicity values.

partnership with the Office of Pesticide Programs. Examples of other databases include the National Library of Medicine Toxnet (http://toxnet.nlm.nih.gov/) and Micromedex (http://www.micromedex.com/products/hcs/), and the National Toxicology Program (NTP; http://ntp.niehs.nih.gov/). NTP provides toxicological information on over 500 chemicals through the publication of general Technical Reports on chemicals and chemical mixtures and the Scientific Review documents for chemicals and chemical agents which are listed in the Report on Carcinogens documents.

2.2 Similarities and Differences In How Toxicity Values Are Derived

As shown above, there are a large number of state, federal, and international resources for either obtaining or developing Tier 3 toxicity values. When obtaining toxicity values and data from these sources it is important to recognize that there are similarities and differences in how they develop toxicity values. This is important when comparing methodologies from external agencies and organizations to EPA's methodologies, as well as when comparing competing toxicity values. Similarities and differences may arise from the following elements:

- The quality and usability of the animal and human studies used to derive the toxicity values
- How adverse and critical effects are defined, and
- The methodologies used to derive the cancer or noncancer toxicity value

The first two elements are common to most of the databases and toxicity values discussed above. The methodologies used to calculate quantitative values are typically specific to the regulatory agency involved. These elements or guiding principles, which will be further discussed in Section 5.3.2, will serve as the basis for critical reviews of potential Tier 3 toxicity values.

In the case of competing toxicity values, differences between values may also be simply a result of the age of the toxicity values. Newer values will likely have more studies underlying their derivation. In addition, newer values may incorporate more current methods for evaluating dose/response relationships, such as physiologically-based pharmacokinetic (PBPK) modeling.

Although not discussed further in this white paper, a basic understanding of how to evaluate and assess the data usability of toxicity studies, identify the adverse and critical effect levels in a study, and evaluate the regulatory-specific methodologies used to derive cancer and noncancer toxicity values is useful for comparing, selecting, and developing chemical-specific toxicity values from multiple databases (Ibid).

3 Existing Publications Relevant to Tier 3 Toxicity Value Evaluation, Selection, and Use

This section summarizes existing publications that are relevant to the evaluation, selection and use of Tier 3 toxicity values. These publications include documents internal and external to EPA and include policy directives, guidance documents, handbooks, guidelines, and issue papers. In addition to summarizing these documents, the purpose of this section is to draw attention to elements of these documents that are critical in the evaluation of potential Tier 3 toxicity values.

3.1 Internal EPA Documents

3.1.1 2003 Hierarchy (OSWER Directive 9285.7-53)

As discussed in Section 1.1.1.2, EPA's Superfund program revised its hierarchy of human health toxicity values to incorporate EPA's PPRTVs and address the aging HEAST toxicity values. Although the 2003 guidance established an overall hierarchy for selecting toxicity values, it did not attempt to rank Tier 3 sources. Instead, it provides examples of Tier 3 sources and general recommendations regarding the prioritization of Tier 3 toxicity values. Specifically, in reference to Tier 3 toxicity values, the directive states:

> *Priority should be given to sources that provide toxicity information based on similar methods and procedures as those used for Tier I and Tier II, contain values which are peer reviewed, are available to the public, and are transparent about the methods and processes used to develop the values. Consultation with the Superfund Health Risk Technical Support Center (STSC) or headquarters program office is recommended regarding the use of the Tier 3 values for Superfund response decisions when the contaminant appears to be a risk driver for the site. In general, draft toxicity assessments are not appropriate for use until they have been through peer review, the peer review comments have been addressed in a revised draft, and the revised draft is publicly available.*

Although the directive does not go into great detail on selection of Tier 3 toxicity values, it is clear that it recommends that risk assessors select values that are derived using toxicological and risk assessment methods that are:

(1) Consistent with the Agency's methodologies;
(2) Transparent;
(3) Publicly available; and
(4) Have undergone peer review.

In addition, the directive recommends the involvement of ORD (Superfund Technical Support Center [STSC]) and headquarters and cautions against the use of draft toxicity values to ensure the scientific defensibility of Tier 3 toxicity values, especially risk-driving chemicals.

3.1.2 Peer Review Handbook

As indicated in the 2003 hierarchy memorandum and other publications specific to toxicity value selection and use (see for example, EPA 2009; ECOS 2007), peer review is one of several critical elements in selecting or giving preference to one toxicity value over another. Although not necessarily specific to toxicity value selection, EPA's Peer Review Handbook (EPA 2006) provides important information that is applicable to the evaluation and selection of Tier 3 toxicity values. The 3rd edition of the peer review handbook defines peer review as the following:

> *Peer review is a documented critical review of a specific Agency scientific and/or technical work product. Peer review is conducted by qualified individuals (or organizations) who are independent of those who performed the work, and who are collectively equivalent in technical expertise (i.e., peers) to those who performed the original work. Peer review is conducted to ensure that activities are technically supportable, competently performed, properly documented, and consistent with established quality criteria. Peer review is an in-depth assessment of the assumptions, calculations, extrapolations, alternate interpretations, methodology, acceptance criteria, and conclusions pertaining to the specific major scientific and/or technical work product and of the documentation that supports them. Peer review may provide an evaluation of a subject where quantitative methods of analysis or measures of success are unavailable or undefined such as research and development. Peer review is usually characterized by a one-time interaction or a limited number of interactions by independent peer reviewers. Peer review is encouraged during the early stages of the project or methods selection, and/or as part of the culmination of the work product, as appropriate. Regardless of the timing of peer review, the goal is ensuring that the final product is technically sound. (USEPA, 2006a)*

The importance of peer-review is re-affirmed in EPA's 2006 peer review policy, which states:

> *Peer review of all scientific and technical information that is intended to inform or support Agency decisions is encouraged and expected. Influential scientific information, including highly influential scientific assessments, should be peer reviewed in accordance with the Agency's Peer Review Handbook. All Agency managers are accountable for ensuring that Agency policy and guidance are appropriately applied in determining if their work products are influential or highly influential, and for deciding the nature, scope, and timing of their peer review. For highly influential scientific assessments, external peer review is the expected procedure. For influential scientific information intended to support important decisions, or for work products that have special*

importance in their own right, external peer review is the approach of choice (USEPA, 2006b).[6]

3.1.3 RAGS Part F

RAGS Part F also provides guidance on evaluation and selection of a Tier 3 toxicity value. In reference to EPA's toxicity value hierarchy, RAGS Part F states, "Priority in Tier 3 should be given to sources that are the most current and those that are peer reviewed. Consultation with the Superfund Headquarters office is recommended regarding the use of Tier 3 values for Superfund response decisions when the contaminant appears to be a risk driver for the site." In addition, this guidance provides a list of circumstances when route-to-route extrapolations from oral toxicity values might not be appropriate. This information could be useful in evaluating Tier 3 toxicity values that are based on route-to-route extrapolations.

3.1.4 Risk Assessment Guidelines

Multiple risk assessment guidelines have been published by EPA ranging from the Guidelines for Mutagenicity Assessment (1986) to the 2005 Guidelines for Carcinogen Risk Assessment. These guidelines , as well as other guidance documents pertaining to development of toxicity values (1994 *Methods for Derivation of Inhalation Reference Concentrations [RfCs] and Application of Inhalation Dosimetry*) provide specific guidance (including criteria to be met) on how the Agency derives toxicity values. These documents have and will continue to serve as the benchmark for evaluating toxicity values external to EPA.

3.1.5 Harmonized Test Guidelines

EPA's harmonized test guidelines (http://www.epa.gov/ocspp/pubs/frs/home/guidelin.htm) are documents that specify methods for use in testing pesticides and toxic substances and developing test data for submittal to the Agency. The guidelines typically specify the species to be tested, routes of administration, doses to be administered, and duration of study and endpoints to be assessed. These guidelines serve as the "gold standard" for performing toxicity testing and studies and, similar to the risk assessment guidelines discussed in Section 3.1.4, serve as a benchmark for evaluating the adequacy of a toxicity value's underlying study or studies.

3.2 Environmental Council of the States

[6] Influential scientific and highly influential scientific assessments involve precedential, novel, "cutting edge," or controversial issues, or the Agency has a legal or statutory obligation to conduct a peer review. Highly influential scientific assessments have a higher degree of influence, substance, interagency interest, and economic impact (EPA 2006a).

In April 2007, the Environmental Council of the States-U.S. Department of Defense Sustainability Work Group (ECOS-DoD Sustainability Work Group) released the issue paper (ECOS paper) titled "Identification and Selection of Toxicity Values/Criteria for Comprehensive Environmental Response, Compensation, and Recovery Act (CERCLA) and Hazardous Waste Site Risk Assessments in the Absence of IRIS Values." The ECOS paper, which was written in collaboration with EPA, Cal/EPA, and Department of Defense (DoD) scientists and risk assessors, is intended to provide guidance and a suggested framework for identifying and selecting toxicity values in the absence of IRIS values. The ECOS paper provides this guidance and framework in the form of seven preferences for identifying and ranking toxicity values. These preferences are provided below.

(1) *There should be a preference for transparent assessments (in which toxicity values are derived), that clearly identify the information used and how it was used.*

(2) *There should be a preference for assessments which have been externally and independently peer reviewed, where reviewers and affiliations are identified. Other things being equal, there should also be a preference for assessments with more extensive peer review. Panel peer reviews are considered preferable to letter peer reviews.*

(3) *There should be a preference for assessments that were completed with a previously established and publicly available methodology. Methodologies that themselves were externally peer reviewed are preferred over those that were not externally peer reviewed.*

(4) *While there should be a preference for assessments using established methodologies to derive toxicity values, these methodologies should also be informed by the current best scientific information and practices. New assessment methodologies should provide reproducible results and meet quality assurance and quality control requirements.*

(5) *There should be a preference for assessments that consider the quality of studies used, including the statistical power or lack thereof to detect effects; that corroborate data amongst pertinent studies; and that make best use of all available science.*

(6) *There should be a preference for assessments and values which are publicly available or accessible. There may be a further preference for toxicity assessments that invited and considered public comment (as well as, but not in lieu of, external peer review).*

(7) *Other things being equal, there should be a preference for toxicity values that are consistent with the duration of human exposure being assessed. For example, an externally peer reviewed subchronic reference dose (RfD) should be preferred to an externally peer reviewed chronic RfD when assessing an exposure of 2 years for non-cancer toxicity.* (ECOS 2007)

In conjunction with these seven preferences, the ECOS paper provides additional recommendations relevant to the selection of toxicity values. They include the overarching principle that risk assessors should continue to identify the most scientifically defensible toxicity value and that the selecting individuals have an understanding of the available sources of toxicity data and their strengths and weaknesses so that the most appropriate toxicity value is selected. Furthermore, although the seven preferences are generally intended for existing toxicity values, the ECOS paper specifically states that the preferences may be "used if an agency or party would like to propose an alternative to a toxicity value" (ECOS 2007).

4 Current and Past Regional Practices in Identifying and Selecting Tier 3 Toxicity Values

The purpose of this section is to summarize past and current practices used by regional and headquarters risks assessors to evaluate and select Tier 3 toxicity values. Specifically, this section discusses the evaluation and selection processes employed by the regional risk assessors to derive the regional screening levels. Also, this section provides detailed summaries of Tier 3 toxicity value consultations provided by regional and headquarters risk assessors.

4.1 Regional Screening Levels Table (Selection Process)

Risk-based screening levels for soil, air, and water have been in existence for nearly 20 years in EPA's Superfund Program. Similar to human health risk assessments, screening levels are derived using chemical-specific toxicity values combined with standard exposure factors that reflect Superfund's concept of a reasonable maximum exposure (RME). They have traditionally represented the point of departure of an excess lifetime cancer risk level of 1E-06 or a Hazard Quotient of 1 for noncancer effects.

In the past, risk-based screening levels were compiled in individual regional tables such as the Risk-Based Concentrations (RBC) table published by Region 3, the Human Health Medium-Specific Screening Levels (HHMSSL) table published by Region 6, and the Preliminary Remediation Goals (PRG) table published by Region 9. In general, if a substance had been assigned an EPA toxicity value, it was listed in the individual regional screening tables. In the case where a substance had more than one possible toxicity value, a toxicity hierarchy first described in RAGS Part A was applied. In some cases, each Region developed its own unique values (e.g., Region 3 RBCs for Fish Consumption).

One consequence of the 2003 toxicity values hierarchy memorandum (Human Health Toxicity Values in Superfund Risk Assessments, OSWER Directive 9285.7-53, December 5, 2003) was that the risk screening tables needed to be revised to reflect the new Agency preference for toxicity values. The guidance was clear with respect to the first two tiers in the hierarchy, and these tiers were used as "defaults" in the regional tables. However, it was less clear what was to be used as a Tier 3 source when there are competing sources. This lack of clarity could have led to inconsistencies in the regional screening tables if, for example, Region 3 used a different Tier 3 source than Region 9 or Region 6.

The regional offices that created screening tables have had a long history of communication and coordination to reduce (if not avoid) inconsistencies among the individual tables. Nonetheless, inconsistencies still existed. An important milestone was reached in 2008, when the various regional tables were harmonized into a single majority-consensus table known as the Regional Screening Levels (RSL) table. This table updated and superseded previous regional tables. Individual Regions are still able to develop independent (or non-consensus) screening values, however, they are not published as part of the RSL table. Individual Regions may also choose Tier 3 values different from the RSL table. It is not the responsibility of the RSL table workgroup to choose for, or dictate to the Regions. The RSL table workgroup merely makes recommendations. Representatives from all EPA regions and HQ are

encouraged to participate in the RSL table workgroup so that their valuable input is incorporated in the periodic updates and revisions to the screening table.

Establishing which toxicity values to use when there are no applicable Tier 1 or Tier 2 values is a challenge because the 2003 guidance did not provide a ranking or hierarchy for Tier 3 sources The RSL workgroup has proposed and implemented a tentative ranking of Tier 3 sources to include in the screening table. The RSL workgroup readily acknowledges that other toxicity values (e.g., State values) could be used to develop the screening values. It is NOT the mission or goal of the RSL workgroup to independently develop Tier 3 toxicity reference values in the absence of other sources, nor is it a practice of the workgroup to review values from all potential sources.

At present, the Tier 3 toxicity values from the following sources in the order in which they are presented below are used as the defaults in the RSL tables.

(1) The ATSDR Minimal Risk Levels (MRLs)
(2) Cal/EPA, Office of Environmental Health Hazard Assessment (OEHHA), toxicity values
(3) PPRTV Appendix "Screening Toxicity Values"
(4) HEAST

These sources are credible (rely on best available science, have undergone a high degree of scrutiny and peer review, are often considered by other Agencies).

An RSL calculator is also provided, which allows the user to use a different toxicity value or exposure assumptions other than the defaults. The RSL group anticipates that RSL's provisional hierarchy may change in the future to reflect recommendations in this white paper.

4.2 Tier 3 Toxicity Value Consultations

When there is no established Tier 3 value for high-priority chemicals that are likely to be risk drivers at a site, the regions have often performed their own evaluations of the science and/or sought headquarters guidance. With respect to headquarters consultations, key offices that have been involved include, but are not necessarily limited to, OSWER/OSRTI/SPB, OSWER/OEM, OSWER/OPM/PARMS, OSWER/ORCR/PMCAO, and ORD/NCEA. Below are several examples of how Tier 3 values have been evaluated and selected in the past at the regional and headquarters level.

4.2.1 Chromium (VI)

The 1998 IRIS file for chromium (VI) identified it as an inhalation carcinogen and provided an inhalation unit risk (IUR), but oral carcinogenicity could not be determined because no data were located in the available literature that suggested it was carcinogenic by the oral route of exposure (EPA 1998). However, several years later, a study by the National Toxicology Program (NTP) stated that oral exposure to chromium (VI) "provided *clear evidence of carcinogenic activity* in male and female rats and

mice based on the presence of benign and malignant tumors in rat oral mucosa and mouse small intestine" (NTP 2008) and suggested that the compound may be carcinogenic by mutagenic mode of action. In response to this study, some states (New Jersey and California) began the process of revising their water and soil standards based on the NTP study. EPA's Office of Pesticide Programs (OPP) also developed an oral slope factor and published a journal article on the chemical's mutagenic mode of action to support its risk assessment of chromated copper arsenate (McCarroll et al. 2010). In November 2008, the IRIS program began the reassessment of chromium VI for the oral route of exposure.

Region 2 appealed to headquarters in 2009 for guidance while working on a removal site because the state of the science had evolved faster than IRIS could be updated and several potential Tier 3 toxicity values were available. Specifically, Region 2 requested consultation on the use of New Jersey's oral slope factor (NJDEP 2009). In this request, Region 2 noted that although several potential Tier 3 sources are available, only New Jersey's oral slope factor met all the criteria in the 2003 hierarchy directive. The request was submitted to the Senior Science Advisor for OSWER on August 17, 2009, who consulted with representatives of OSRTI and OEM and concurred with this conclusion in an e-mail on September 28, 2009 (see Appendix B).

4.2.2 Perfluorooctanic Acid and Perfluorooctane Sulfonate

Perfluorooctanic acid (PFOA) and perfluorooctane sulfonate (PFOS) are emerging contaminants that have been found at sites in Region 4 and other regions. Because no toxicity values for these compounds are currently available in the IRIS or PPRTV databases, Region 4 requested that OSWER recommend what toxicity values would be appropriate to use. In response, OSRTI and OEM consulted scientists from EPA's Office of Water, Office of Pollution and Toxic Substances, and the Office of Research and Development regarding the use of the Office of Water's 2009 Provisional Health Advisories for PFOA and PFOS.

In an October 28, 2009, memorandum (see Appendix B), OSRTI and OEM recommended use of the provisional drinking water advisories for PFOA and PFOS and interim subchronic RfDs based on the advisory levels. Because the drinking water advisories address only water, OSWER's consultation included derivation of subchronic RfDs so that they could be used to derive removal action levels or screening levels for water and other media. The memorandum also outlines the ways the Provisional Health Advisories meet the criteria for a Tier 3 toxicity value as established in the hierarchy directive. Specifically, the consultation memorandum notes that the provisional advisories underwent internal and external review and draws attention to similarities between the Office of Water's methodology for deriving provisional advisory levels (and the subsequent subchronic RfDs) and IRIS assessments (deriving toxicity values using Benchmark Dose Level (BMDL), no observed adverse effects level [NOAEL], or lowest observed adverse effects level [LOAEL]).

4.2.3 Perchloroethylene

At about the time the 2003 toxicity value hierarchy was being finalized and released to the regional risk assessors, regions sent inquiries to OSWER regarding the use of Cal/EPA's cancer toxicity values for perchloroethyelene (PCE). Found at nearly half of all Superfund sites (ATSDR 1997), including numerous vapor intrusion sites, having toxicity values for this chemical was key to moving risk assessments and remedy decisions forward. Moving these activities forward was of special concern given that health organizations, such as IARC, had classified PCE as a probable human carcinogen (IARC 1995).[7]

In response, the Deputy Director of the Office of Emergency and Remedial Response (currently OSRTI), in consultation with the STSC, sent a letter to Region 10 on June 12, 2003, supporting the use of Cal/EPA's IUR and oral slope factor (see Appendix B), noting that there are similarities between how Cal/EPA and the IRIS program develop toxicity values and that Cal/EPA's presentation on how the toxicity values were developed is full, complete, and transparent. In regards to transparency and the use of the values in Superfund Program decision-making, the letter recommended that the appropriate documentation or link to the Cal/EPA website be provided. In addition, the letter included an excerpt from a Cal/EPA technical support document pertaining to PCE's inhalation unit risk value.

4.2.4 Trichloroethylene

Trichloroethylene (TCE), which is found at more than 1,500 sites, has a long and complicated history at EPA, especially within the IRIS and Superfund Programs. The IRIS cancer assessment and cancer toxicity values for TCE, which were released in 1987, were withdrawn in 1989.[8] Between 1989 and 2001, regions generally relied on the withdrawn values. In 2001, NCEA completed a preliminary draft assessment of the health risks posed by TCE. The new toxicity values, especially the cancer toxicity values, dramatically increased the calculated risks at the same exposure. Although these values were not loaded into the IRIS database, some regions continued to use them since they were briefly endorsed by STSC. After review by EPA's Science Advisory Board (SAB) in 2002, STSC no longer supported the use of the 2001 draft values. However, several regions continued to use the 2001 draft toxicity values. After the 2003 toxicity hierarchy memorandum was released, some regions began using the Cal/EPA toxicity values for TCE or a combination of Cal/EPA toxicity values and the 2001 draft toxicity values, while others continued to use only the 2001 draft toxicity values. The Region 9 PRG, Region 3 RBC, and Region 6 MSSLs used the 2001 draft noncancer and cancer toxicity values up until approximately the time the tables were consolidated into the RSLs in 2008. In 2008, the RSL tables began using the Cal/EPA cancer toxicity values.

[7] Prior to PCE's final Toxicological Review, which was posted on IRIS on February 10, 2012, IRIS only provided an RfD.

[8] TCE's final Toxicological Review was posted on IRIS on September 28, 2011.

In 2006, the NYSDOH released the *Trichloroethene Air Criteria Document*. That document, which underwent peer review, provided a noncancer inhalation toxicity value comparable to an EPA RfC. Because the NYSDOH toxicity value was final, had undergone peer-review, and its derivation was transparent, some regions began considering use of the value to assess noncancer health risks. Its use in risk assessments was significant, especially with respect to the vapor intrusion into indoor air pathway, because the NYSDOH value results in residential indoor air noncancer screening levels corresponding to a cancer risk of approximately 1E-05. In comparison, Cal/EPA provides a noncancer chronic REL that is 60 times greater than the NYSDOH value.

In 2008, Region 10 advised its states about Region 10's evaluation of TCE and provided two options for evaluating cancer risk: (1) use the geometric midpoint of the slope factor range from the 2001 NCEA assessment, or (2) use the Cal/EPA oral slope factor and inhalation unit risk, but adjust them upward by a factor of 10. When noncancer health hazards are evaluated, Region 10 recommended using the NYSDOH criterion.

In January 2009, OSWER released guidance on the recommended cancer and noncancer toxicity values (Cal/EPA cancer toxicity values and the NYSDOH noncancer inhalation toxicity value) (see Appendix B). The memorandum provided an extensive summary and evaluation of the available toxicity values from Cal/EPA, NYSDOH, and the Indiana Department of Environmental Management. It included a discussion on the toxicity values' underlying studies and methods used to derive the toxicity values and a detailed comparison of the competing noncancer inhalation toxicity values. However, the memo was withdrawn by OSWER in April 2009 to further evaluate the recommendations regarding the noncancer toxicity values for use in inhalation risk assessments (see Appendix B).

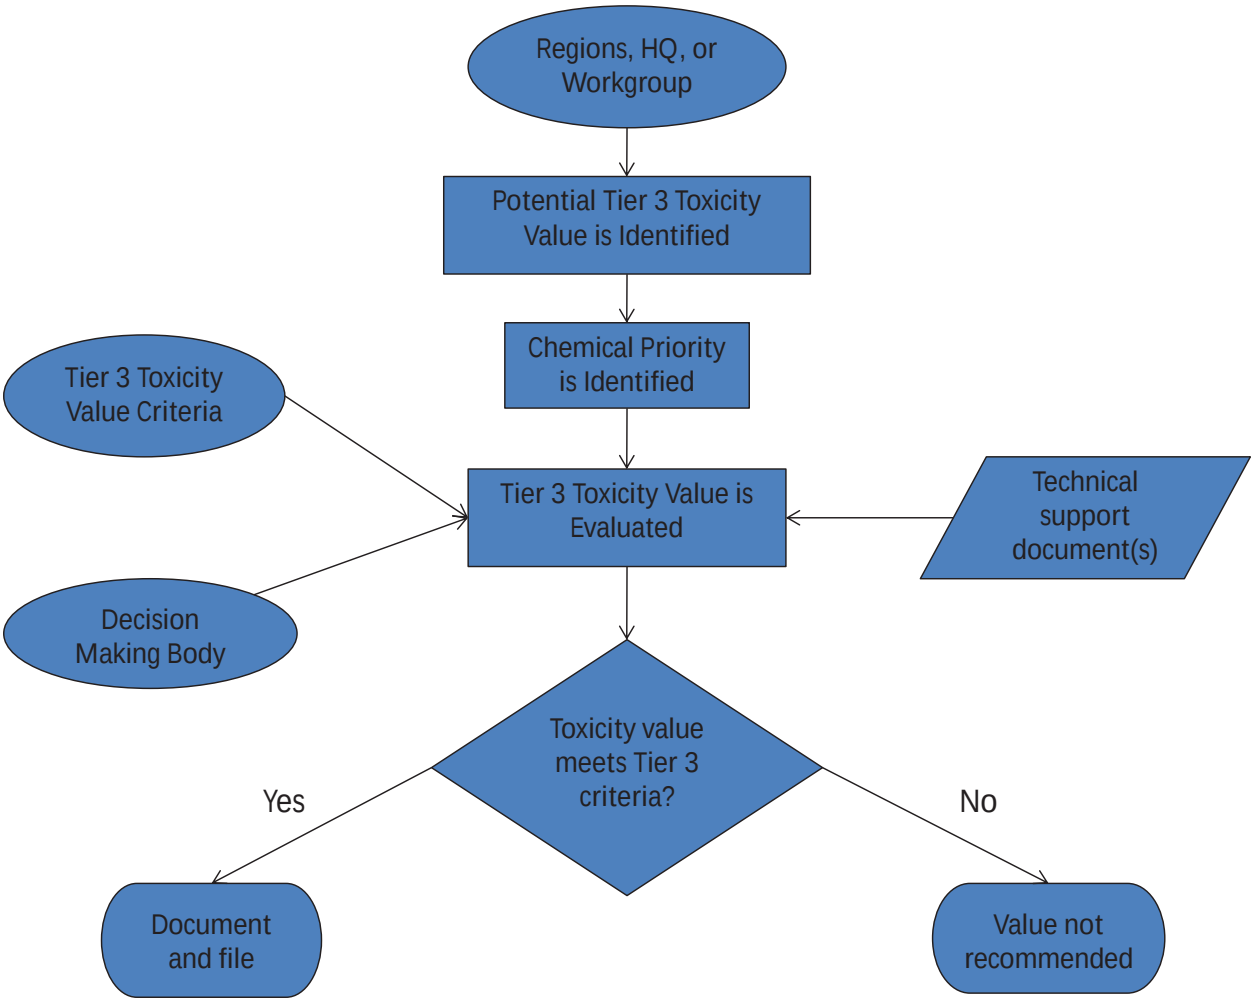
In April 2009, Region 7 provided guidance to the regional RCRA and Superfund programs on TCE toxicity values (see Appendix B). Specifically, the regional risk assessors recommended the use of the Cal/EPA cancer toxicity values and the NYSDOH non-cancer inhalation toxicity value, citing that they met the requirements of Tier 3 toxicity values (for example, had been peer-reviewed). With regards to the competing inhalation toxicity values, Region 7 provided rationale for selecting the NYSDOH value over the Cal/EPA REL.

During the spring 2011 RSL table update, the RSL workgroup provided a noncancer RfC for TCE based on the value derived by the NYSDOH (NYSDOH 2006).

5 Alternatives for Identifying, Evaluating, and Selecting, and Documenting Tier 3 Toxicity Values

As discussed in Section 1, the overall goal of the Regional Tier 3 Toxicity Value Workgroup is to establish a process that enhances the transparency and consistency of Tier 3 toxicity value identification, evaluation, selection, documentation, and communication. The steps in the overall process for selecting Tier 3 toxicity value are shown in Figure 1 below and described in the following sections. For this white paper, communication refers to the flow of information and overall coordination leading to selection and documentation of a Tier 3 toxicity value. Therefore, communication is part of the other steps and is not shown as a separate step. In addition, the priority of a chemical (regional or national interest) may play a significant role in determining the overall selection process and is therefore listed as a step in the selection process.

Figure 1. Tier 3 Toxicity Value Selection



5.1 Toxicity Value Identification

The regional risk assessors and RSL workgroup[9], through their routine work (site risk assessments and table updates), regularly encounter chemicals without Tier 1 and Tier 2 toxicity values. Thus, the identification of potential Tier 3 toxicity values has been largely their responsibility. This approach continues to be an option, however, this white paper also presents other potential avenues for identifying Tier 3 toxicity values. As an alternative to the regional risk assessors and RSL workgroup, a formal toxicity workgroup could be charged with identifying Tier 3 toxicity values, as well as other responsibilities (see Section 5.4.3.1). Although this responsibility is similar to the RSL workgroup, which looks at a broad range of chemicals, it is envisioned that the formal workgroup would look for potential Tier 3 toxicity values beyond the sources consulted by the RSL workgroup (for example, international sources). Furthermore, the workgroup's identification of potential Tier 3 toxicity could outpace the RSL workgroup because the former's sole focus would be to identify, evaluate, select, document, and communicate Tier 3 toxicity values.

If the responsibility for identifying potential Tier 3 toxicity values were assigned to a formal workgroup, several issues would need to be considered. First, the establishment of a new workgroup (assuming responsibilities are not subsumed within an existing workgroup) would require time and resources. In addition, it is uncertain whether the workload (new values being made available) would be sufficient to keep the group active. Furthermore, regional risk assessors and others will likely continue to search for Tier 3 toxicity values in their routine work (conducting risk assessments), leading to a duplication of effort. Thus, the value added of a formal workgroup is uncertain and would likely require the group to have multiple responsibilities to maintain member interest.

5.2 High vs. Low Priority

As a result of resource constraints, time, and other limitations and difficulties (such as potential controversy surrounding some chemicals), it is likely that no one alternative will be suitable as the sole means of evaluating and selecting all Tier 3 toxicity values. Thus, the priority of the chemical will likely dictate the entity that will evaluate and select a Tier 3 toxicity value. For instance, the examples provided in Section 4 clearly indicate that high-priority chemicals are elevated to headquarters.

The process for elevating Tier 3 toxicity values to headquarters and other entities (such as the RSL workgroup) has been rather informal in the past. If a more formalized and structured system of selecting Tier 3 toxicity values is implemented, a formal process for determining a chemical's priority may be needed, including criteria for distinguishing between those chemicals of low, medium, and high priority. This determination can be subjective and vary among the regions. Factors to consider in evaluating priority are described below. Of course, decision-making in regard to these criteria, especially a

[9] During the development of site-specific risk assessments, potentially responsible parties may identify Tier 3 toxicity values.

chemical's prevalence, may require coordination among the regions and headquarters, and the formal process may reinforce this requirement. Continued coordination and communication among potential decision-makers is also important so that elevation of a Tier 3 value to a headquarters or regional workgroup is efficient (chemicals are not elevated and then demoted).[10]

Below are a set of prioritization criteria that could be used to assist risk assessors, risk managers and others in assigning priority to a contaminant. Answering one of the questions below in the affirmative may not be sufficient to designate a contaminant as high priority. However, a preponderance of evidence should be adequate to support a high-priority designation. A contaminant with a high-priority designation would likely require a Tier 3 consultation by headquarters or a regional workgroup to ensure consistency across the Regions. Tier 3 contaminants that are not expected to drive health risks or remediation at a site, may be associated with mild health effects, are not encountered across multiple regions, or are not being considered for national rule making may be considered low priority. In this case, the decision to develop a Tier 3 toxicity value may be best left up to the individual region.[11]

Prioritization Criteria

- Does the contaminant have the potential to drive risks estimates and remediation at a site?

  Answering this question requires a minimum of toxicity information, such as a single subchronic or developmental study administered by the route of exposure expected to occur at the site. This information may be available from the database sources described in Section 2.1 or via an open literature search. If the answer to the question is yes, then the contaminant may be a candidate for a high-priority designation.

[10] Because regional risk assessors that submit potential Tier 3 toxicity values may have significant knowledge of the chemical, they may remain involved in the evaluation and selection process.

[11] In cases where the priority of a chemical falls somewhere in between high and low, best professional judgment should be used in deciding whether that chemical should be evaluated by headquarters or a regional workgroup (chemical evaluated as high priority) versus individual region (chemical evaluated as low priority). In cases of uncertainty, it is recommended a request be sent to the "Tier 3 Toxicity Value Steering Committee" (further discussed in Section 6.2), which would decide the priority designation and ultimately the proper action to be taken on a chemical-specific basis.

- Based on the available toxicity information and the concentration measured at the site, would the estimated human health effects be expected to be severe (irreversible damage affecting the function or viability of a receptor or target organ), moderate, or mild (transient, reversible effects)?

  Similar to the first question, answering this question requires a minimum of toxicity information. If the information suggests that the health effects to an individual would be severe or moderate, then the contaminant may be considered a high priority.

- Is the contaminant associated with a source or industry that is common across the region or multiple regions?

  The more prevalent a contaminant, especially across multiple regions, the more likely it is to receive a high-priority designation.

- Based on the chemical and physical properties of the contaminant, how likely is it that the remediation techniques used for the known risk drivers at the site would also remediate the contaminant in question?

  This question is not necessarily toxicological, but instead is a risk management question. If the remediation techniques being used at a site for the known risk drivers will also be successful in cleaning up the contaminant in question (based on what is known about the chemical and physical properties), it may not be efficient or necessary to delay a project while a Tier 3 toxicity value is being evaluated.

- Is the contaminant under consideration for rulemaking nationally?

  If EPA is considering the contaminant for rulemaking purposes, it should automatically be considered as a high-priority candidate. The best approach would be to ensure a consistent toxicity value across all regions and program offices because of the public visibility of the contaminant.

5.3 Toxicity Value Evaluation (Criteria for Selecting a Tier 3 Toxicity Value)

Per EPA risk assessment guidance and other relevant risk assessment publications, the ultimate goal of selecting a toxicity value for use in risk assessment is to select the most current and scientifically defensible value. With regard to the selection of Tier 3 toxicity values, this value is selected by applying a combination of the general guidance principles discussed in Section 2.2 and the recommendations and preferences discussed in EPA and non-EPA risk assessment guidance (see Section 3). The following sections outline a proposed process that could be used to evaluate and select Tier 3 toxicity values.

5.3.1 Basic Requirements for Consideration as a Tier 3 Values

After a potential Tier 3 toxicity value has been identified, the first step is to determine whether that value meets the basic requirements of a Tier 3 value. As discussed in OSWER's 2003 Toxicity Value Hierarchy, three key factors for a toxicity value to be considered in the selection of a scientifically defensible Tier 3 value are that the value is peer-reviewed, publically available, and that the source is transparent about the methods and procedures used to develop the value. These same factors are also discussed in several of the seven preferences provided in the ECOS paper and echoed in other EPA guidance (such as RAGS Part F). Despite the requirements implied in the aforementioned documents, the level of peer-review is not specified. Thus, per EPA's peer review policy, decision-makers (the entity evaluating a potential Tier 3 toxicity value) have to consider whether the level of peer review matches the significance of the chemical. Availability and transparency are more straightforward. However, decision-makers have to determine, for example, whether an Internet posting of a summary file of a toxicological assessment (instead of the entire toxicological file) meets the availability and transparency criteria unless an internet link to the entire file is provided.

It is also important to evaluate the quality and usability of the underlying data supporting the potential Tier 3 value. Although a precise level of data quality and usability has not been defined, some toxicity values may not be of suitable quality or usability even though they have been peer-reviewed and are publically available. For example, some toxicity values may be based on route-to-route extrapolations of peer-reviewed values. Therefore, this step may focus on major deficiencies that would preclude use of a potential Tier 3 toxicity value. When competing Tier 3 values are available, this step may also indicate the preferred value.

5.3.2 Tier 3 Toxicity Value Critical Review

Section 2.2 introduced the general guiding principles for evaluating the quality and usability of Tier 3 toxicity values. Specifically:

(1) The quality and usability of the animal and human studies used to derive the toxicity values,
(2) How adverse and critical effects are defined, and
(3) The methodologies used to derive the cancer or noncancer toxicity value.

This white paper proposes the use of the guiding principles to conduct a more critical evaluation of the potential Tier 3 toxicity value.

5.3.2.1 Quality and Usability of Toxicity Testing Studies

There are a number of factors to consider in evaluating whether an animal or human toxicity testing study should be used in developing a toxicity value. The first is whether the study was conducted per the appropriate testing guidelines for the regulatory agency. For EPA, these guidelines are the harmonized test guidelines discussed in Section 3.1.5. Other guidelines include the Good Laboratory Practice (GLP) and the Food and Drug Administration (FDA) and Organization for Economic Co-Operation and Development (OECD) guidelines. Per these guidelines and other relevant documents (see for example EPA 1994, 2002, 2005, and 2008), factors to consider in the critical evaluation of the quality and usability of toxicity testing studies include:

- What is the route of administration of test material?
- What is the animal species tested?
- What is the dose duration (acute, sub-chronic, or chronic)?
- Is the apparent difference treatment-related?
- Is the effect dose-dependent?
- Is the effect biologically significant (as opposed to statistically significant)?
- Are the effects seen in multiple species, strains, or both sexes?
- Are the results relevant to humans?
- Were the study results interpreted properly?
- Is supporting evidence such as physiologically based pharmacokinetic modeling, metabolism studies, or structure activity relationship studies available?

Note that both the individual studies and the database of human and animal toxicity testing studies can be ranked as having low, medium, or high confidence based on an evaluation of these factors (see Section 5.3.3).

5.3.2.2 Defining Adverse and Critical Effects

Another critical element in the evaluation of a toxicity value is how adverse and critical effects are defined. An adverse effect is defined by EPA as the biochemical change, functional impairment, or pathological lesion that impairs performance and reduces the ability of an organism to respond to additional challenge (http://www.epa.gov/iris/help_gloss.htm). The lowest dose level at which an adverse effect occurs is defined as the critical effect level and is typically expressed as the LOAEL or lowest observable effect level (LOEL). A dose level at which there are no statistically or biologically significant increases in the frequency or severity of any effect between the exposed population and its appropriate control is the NOAEL. The critical effect level can also be determined using a benchmark dose approach or categorical regression. Thus, it is useful to consider the following in checking a study:

- Were the study results interpreted properly?
- Was the effect identified as adverse truly a biologically significant adverse effect?
- Is the adverse effect consistent with what is known about the chemical and the other studies in the database?

It is also important that the critical effect level be adjusted to the dose metric of interest (for example, parts per million [ppm] in food to milligrams per kilogram per day [mg/kg-day] for the oral route), for duration of exposure (such as from periodic to daily or continuous exposure), and scaled from an animal to a human equivalent body weight or concentration. Without these adjustments, it is not possible to compare effect levels on an equivalent basis. A study that might appear to have the lowest point of departure on first glance may not when the correct dosimetric adjustments are made. The critical effect (NOAEL or LOAEL, point of departure if using a benchmark dose approach, and categorical regression) is used as the starting point for calculating toxicity reference values for threshold toxicants.

5.3.2.3 Derivation of Noncancer and Cancer Toxicity Values

As mentioned in Section 2.2.3, the methodologies used to calculate toxicity values are typically specific to the regulatory agency involved. Understanding their differences and similarities are also useful when potential Tier 3 toxicity values and competing values are evaluated. EPA, for example, uses an RfD approach to calculate toxicity values for threshold toxicants administered by the oral route of exposure. An RfC is estimated for the inhalation route. This approach determines the critical effect level in the principal study or studies and applies uncertainty factors to account for:

(1) Variation in susceptibility among the members of the human population (inter-individual or intraspecies variability);
(2) Uncertainty in extrapolating animal data to humans (interspecies uncertainty);
(3) Uncertainty in extrapolating from data obtained in a study with less-than-lifetime exposure (extrapolating from subchronic to chronic exposure);
(4) Uncertainty in extrapolating from a LOAEL rather than from a NOAEL; and
(5) Uncertainty associated with extrapolation when the database is incomplete.

The default for each of these uncertainty factors is a value of 10. The exact value (10, 3, or 1) of the uncertainty factor selected may depend on the quality of the studies available, the extent of the database, and scientific judgment. Some factors to consider when the default factor of 10 is replaced with a lesser value are chemical-specific toxicokinetic or toxicodynamic data, the severity of the effect, the slope of the dose-response curve, and the presence of developmental and reproductive studies. For a more in-depth discussion, please see EPA's report titled *A Review of the Reference Dose and Reference Concentration Process* (EPA 2002). When a toxicity value is evaluated from the ATSDR database (or any other state, federal, or international regulatory program), the application and interpretation of uncertainty factors will differ from EPA's approach. Understanding these differences is important because the application of uncertainty factors may alter the final toxicity value by 1 to 5 orders of magnitude.

Some regulatory agencies, such as Health Canada, may use a margin of exposure (MOE) approach. Instead of reducing the critical effect level by a number of uncertainty factors, the MOE approach compares site-specific exposures directly with the critical effect level. The resulting ratio is then evaluated to determine if there is an adequate margin of safety.

For carcinogenic substances, qualitative descriptors are often provided on the likelihood of a chemical agent to cause cancer in humans. EPA currently uses five recommended standard hazard descriptors: "Carcinogenic to Humans," "Likely to Be Carcinogenic to Humans," "Suggestive Evidence of Carcinogenic Potential," "Inadequate Information to Assess Carcinogenic Potential," and "Not Likely to Be Carcinogenic to Humans" (EPA 2005). Different regulatory agencies and health organizations will use different qualitative descriptors. For example, IARC classifies carcinogens as Group 1 (carcinogenic to humans), Group 2A (probably carcinogenic to humans), Group 2B (possibly carcinogenic to humans), Group 3 (not classifiable as to its carcinogenicity to humans) and Group 4 (probably not carcinogenic to humans).

Some regulatory agencies and health organizations will quantify the dose-response assessment of carcinogens, while some may simply regulate a toxicant if it is deemed to be a possible carcinogen. EPA provides a quantitative estimate of the dose-response relationship by fitting the cancer bioassay data within the range of observation and deriving a point of departure (the lowest data point adequately supported by the data). If the mode of action data supports nonlinearity, an RfD or RfC is calculated from the point of departure. If the mode of action data indicate the dose response curve is expected to have a linear component below the point of departure, a linear extrapolation below the point of departure is used. The slope of this line is the slope factor. Agencies may differ on their interpretation of whether the dose response curve is linear or non-linear below the point of departure, resulting in different calculations of a cancer toxicity values.

Other regulatory agencies and health organizations, particularly in Europe and Asia (World Health Organization [WHO], International Programme on Chemical Safety [IPCS], and International Life Science Institute Europe) support a MOE approach for assessing carcinogens, regardless of the mode of action. The MOE approach compares the margin between a dose or an exposure causing cancer in animals or humans (for example, the point of departure) with the estimated human exposure to that substance. The resulting ratio is then evaluated to determine if there is an adequate margin of safety.

5.3.3 Tier 3 Toxicity Value Confidence

This white paper proposes that the confidence in a particular Tier 3 toxicity value could be ranked as low, medium, or high as part of a critical review. Ranking the level of confidence could be useful for determining the relative appropriateness of using Tier 3 toxicity value in various steps of the human health risk assessment process, as well as assisting with the selection of a value when competing values are available. A value that receives a "low" confidence ranking may be helpful during the initial screening process (for example, when determining if an analyte is a chemical of concern and should be carried forward into the baseline risk assessment process); however, a toxicity value with a "low" confidence ranking may be not be suitable for use in the baseline risk assessment or development of preliminary remediation goals because of limitations in this value. For CERCLA and RCRA processes that undergo more critical examination, a toxicity value with a "medium" or "high" confidence ranking would be more appropriate.

Below are some examples using the guiding principles mentioned above and discussed in Section 2.2 in applying confidence rankings to toxicity values.

The first element is the quality and usability of the animal and human studies used to derive the toxicity values. If only one animal species is tested for a subchronic period of exposure using only one dose level by a route of administration not consistent with the exposure route being evaluated at a CERCLA or RCRA site, the confidence in the toxicity value would likely be considered to be "low." The value could be used during the screening process, but would likely be inappropriate for a baseline risk assessment. If the contamination levels at a CERCLA or RCRA site exceed screening levels based on a Tier 3 value with low confidence, then the risk assessor has several choices. One choice would be to move to a qualitative assessment of the contaminant during the baseline risk assessment. Another choice would be to submit the contaminant to the STSC for a more thorough evaluation and a second opinion on the usability of the database and toxicity value. A third option would be to retain the Tier 3 value in the baseline risk assessment and be prepared to defend the scientific credibility of the value as part of the uncertainty assessment.

The second element is how the adverse and critical effects are defined. If the adverse effect is consistent with the definition provided in EPA's IRIS database (http://www.epa.gov/iris/help_gloss.htm) and is both biologically and statistically significant, then a ranking of "medium" or "high" may be assigned.

The third element is an examination of the methodology used to derive the quantitative toxicity value from the defined adverse effect. If the methodology is consistent with the cancer or noncancer methodology described in EPA's IRIS database (http://www.epa.gov/iris/) or adequately accounts for uncertainty and variability within susceptible populations, then a confidence of "medium" or "high" can be assigned. The overall ranking from these elements will be useful in determining where in the CERCLA or RCRA process the toxicity value would be most appropriate to use.

5.4 Options for Tier 3 Toxicity Value Consultations

There are several possible options for the types of decision-making bodies that could provide Tier 3 toxicity value consultations. Some of the possible options, which are discussed in the following sections, include forming or consulting an Action Development Process Workgroup; forming or consulting a headquarters or regional workgroup, or having individual regions evaluate and select values. In addition, the range of potential options is further expanded when considering the scope of consultation. For example, the requestor could be responsible for performing the evaluation and the consultation workgroup provides only a brief review and approval. Alternatively, the consultation workgroup could be charged with conducting the full evaluation of the potential Tier 3 toxicity value. Section 4.1.1.2 provides some examples of how this has been done previously.

One factor that should be considered in making the decision is the potential impact of the Tier 3 toxicity value under consideration and whether it should be considered influential scientific information. Consistent with EPA's Information Quality Guidelines (http://www.epa.gov/QUALITY/informationguidelines/) and the Office Management and Budgets Peer Review Bulletin (http://www.whitehouse.gov/sites/default/files/omb/memoranda/fy2005/m05-03.pdf), influential scientific information is that which the agency reasonably can determine will have or does have a clear and substantial impact on important public policies or private sector decisions. Influential scientific information is expected to maximize quality, objectivity, utility, and integrity.

In addition to the visibility and priority of the chemical, there are several other key issues that will need to be considered in establishing processes for developing Tier 3 toxicity values. These issues include, but are not limited to, the overall coordination and process for requesting consultations, contract support, and documentation. Additional discussion on these issues is provided in the following "options" sections and in Section 5.5

5.4.1 Action Development Process Workgroup

The Action Development Process (ADP) is the Agency's accepted method for producing high-quality actions, such as regulations, policies, and risk assessments. It ensures that EPA uses the best available information to support its actions and that scientific, economic, and policy issues are adequately coordinated with the various stages of action development. More information is available on the Office of Policy, Economics & Innovation's (OPEI) Intranet site http://intranet.epa.gov/adplibrary. Tier 3 toxicity values that would be considered influential scientific information should generally be developed through the ADP. Typically, this process would be initiated by OSWER. Briefly, the process begins with a tiering by the Regulatory Steering Committee. There are three possible tiers related to the level of senior level management involvement and the extent of cross-agency influence: Tier 1 actions are signed by the Administrator and typically have broad cross-agency influence, Tier 2 actions are signed by Assistant Administrators and typically have some cross-agency influence, and Tier 3 actions are typically signed by Office Directors and generally have limited cross-agency influence. Development of Tier 3 toxicity values using the ADP would typically be considered a Tier 3 action. The ADP has a number of prescribed steps that are required for all Tier 1 and Tier 2 actions; Tier 3 actions can be less formal, but typically include Office of Management and Budget (OMB)-led interagency review.

5.4.2 Headquarters Consultation

Headquarters, including offices within OSWER and ORD, have advised regions in the past on the use of Tier 3 toxicity values. Typically, regions have submitted requests to OSWER, which has responded with its recommendations. These requests have included consultations on chromium (VI), PCE, PFOA, and PFOS. Generally, these consultations were led by OSWER, but also included input from ORD. In addition, consultations were often coordinated among various offices within OSWER, including the

science advisor, OSRTI, and OEM. The scope of these consultations also varied. Whereas much of the toxicity value evaluation for chromium (VI) was performed by Region 2, most of the toxicity value evaluation for PFOS and PFOAs was performed by OSWER and consulting programs.

This approach remains a viable method for evaluating and selecting Tier 3 toxicity values, especially for high-priority chemicals where consistency and headquarters support are paramount. The headquarters consultation could continue to be performed on an "informal" basis, or a more formalized consultation process could be adopted in the future. Under the informal process, regions would continue to send requests to any of the multiple risk assessment and toxicology program contacts in OSWER including, but not limited, to OSRTI, OEM, or PARMS. Those offices would be responsible for establishing the consultation workgroup. Under the formal consultation process, it is envisioned that all consultations would be led and authored by a designated office within OSWER (such as OSRTI) and include a small group of technical experts and representatives from various programs, regions, and laboratories (such as ORD).

Regardless of whether an informal or formal approach is taken, several key factors will need to be considered for headquarters consultations. First, headquarters may need to establish a point of contact for consultations to coordinate reviews. In other words, headquarters may need to designate an individual or group of individuals who could receive Tier 3 consultation requests. Likewise, to eliminate redundancy (same requests from multiple regions) and improve the communication of toxicological information, the regional risk assessors may need to establish a process for submitting requests. The OSWER Human Health Regional Risk Assessors Forum (OH2R2AF) and OH2R2AF toxicity workgroup could fulfill this role. Furthermore, depending on the scope of the consult and the resource and time constraints, contract support may be necessary to assist headquarters with the collection, evaluation, coordination, and documentation of information pertaining to the consult.

There are several benefits to using headquarters consultations. Because of its role in providing guidance and policy to the regions, and centralized location within the organization, headquarters-based consultations, which may be provided by a designated office in headquarters, are more likely to maintain a consistent approach in the application of review criteria compared with other alternatives that may rely on multiple entities to provide consults. Furthermore, as a result of its position of authority, headquarters consultations also add "greater weight and credibility" to a Tier 3 value. Headquarters consultations are also more likely to include involvement from other program offices at the national level (e.g.,OPP), which may add greater credibility to and support for a particular Tier 3 toxicity value.

Despite the benefits associated with headquarters consultations, there are some potential challenges. The biggest challenge pertains to the perception that headquarters is setting policy. There are specific requirements for headquarters for the development of guidance and policy (such as interagency and OMB review). Although consultations are not equivalent to agency guidance or policy, the perception that headquarters is setting policy, especially among high-priority chemicals, could stall efforts. Consultations could be delayed if the program office has to defend perceptions of setting policy to

management and others. Subject matter experts from other program offices may also be reluctant to provide input if it appears they are setting policy for their particular program.

Another potential challenge with this alternative is that it may not be well suited to handle low-priority chemicals. Headquarters will tend to have the greatest interest in chemicals that have significant affects on risk management decisions or that are found in numerous regions. Thus, headquarters could exhaust its resources and time in high-priority chemicals and have little time to complete consults on low-priority chemicals. Consults would also have to compete with other headquarters projects and priorities. Therefore, headquarters may have difficulties in getting adequate technical support from subject matter experts for the consult.

5.4.3 Regional Workgroup

Another method for evaluating and selecting a Tier 3 toxicity value is through the use of a regional workgroup. The regional workgroup could be established as a formal regional workgroup or as an *ad hoc* work group consisting of subject matter experts with expertise relevant to the chemicals being evaluated. These workgroups would be led by and generally consist of regional risk assessors and toxicologists.[12] Headquarters risk assessors and toxicologists could be involved, but serve more or less as advisors. It is anticipated that the regional workgroup would primarily focus on low- to medium-priority chemicals, but may provide guidance on the high-priority chemicals that would not be considered influential scientific information.

There are two existing regional workgroups that could evaluate and select Tier 3 toxicity values. They include the RSL workgroup and the newly formed OH2R2AF toxicity workgroup. Because these workgroups' primary roles are to maintain the RSL Table and to address overall toxicity value needs and issues within the regions, a separate workgroup focused on Tier 3 toxicity values may be a viable alternative. However, under this alternative, such a workgroup may require coordination and direction from an overarching workgroup, such as the RSL workgroup and OH2R2AF toxicity workgroup (see below).

The role of these workgroups could vary significantly. The regional workgroup's role could be limited to advising regions that have identified a potential Tier 3 toxicity value, which may include evaluating the toxicity value and providing recommendations regarding the candidate value. In addition to providing consultations, the regional workgroup's role could be expanded to identifying, reviewing, and providing recommendations on Tier 3 toxicity values independent of requests from regions. This latter role would likely require formation of a formal workgroup.

[12] Because regional risk assessors that submit potential Tier 3 toxicity values may have significant knowledge of the chemical, they may remain involved in the evaluation and selection process as a regional workgroup member or advisor.

Although the level of effort of these workgroups will depend on their scope and the amount of toxicological information available for a given compound, contract support may be necessary. Under the consultation role, contract support would likely be limited and vary according to the chemical. The requestor of the consult may perform the bulk of the evaluation. However, contract support may be necessary for a workgroup that is routinely involved in identifying, reviewing, and providing recommendations on Tier 3 toxicity values independent of requests.

5.4.3.1 Formal Regional Workgroup

A formal regional workgroup, presumably under the auspices of the OH2R2AF, could play a dual role as a consulting workgroup and workgroup that actively identifies, reviews, and makes recommendations on Tier 3 toxicity values. This workgroup would generally be composed of and led by regional staff. Its membership could be fixed or consist of a small group of permanent members whereby subject matter experts fill temporary membership positions on a chemical-specific basis. Likely roles for this workgroup, in addition to the those listed above, may include evaluating existing Tier 3 toxicity values provided in the RSL table and periodically reviewing Tier 3 sources for new or updated toxicity values. Additionally, this group could derive new toxicity values. However, the roles involving periodic review of existing Tier 3 toxicity values in the RSL table and the derivation of toxicity values fall outside the scope of this white paper.

There are several strengths and limitations of establishing a formal regional workgroup. It is envisioned that a formal regional workgroup would select a core membership, structure it's organization (perhaps by developing a charter), and schedule regular meetings. Such a group could be more easily tracked in terms of agenda and progress, and a formal structure would make the workgroup easier to manage and have clearer expectations. In addition, both the workgroup and its members would be more visible to headquarters and the regions and provide greater credibility to the selection of a toxicity value. In addition, it is likely that a formal workgroup would more likely maintain a consistent process (for example, in application of review criteria) for evaluating and recommending new Tier 3 toxicity values. However, if the workgroup is formalized and core membership is fixed, the workgroup may lack expertise and/or fail to reach out to others with expertise in a particular chemical or toxicity value development (Ibid). Lack of subject matter expertise would limit the scientific credibility and usability of the toxicity value, which is the end product. Furthermore, the workload may not require regularly scheduled meetings, potential resulting in loss of focus and interest among the workgroup members and less than satisfactory work products.

5.4.3.2 Ad Hoc Regional Workgroups

Regional workgroups, under the direction of a coordinating committee (such as the OH2R2AF toxicity workgroup), could also be formed on an as needed basis to provide consultation on the use of Tier 3 toxicity values. The coordinating committee would receive Tier 3 consultation requests and be charged with staffing an *ad hoc* regional workgroup with regional risk assessors and toxicologists with subject matter expertise relevant to the chemical in question. The group's charge would also include

establishing a workgroup chair (a regional risk assessor or toxicologist) who would be responsible for leading the consultation and documenting the consult (drafting the memorandum). ORD and headquarters could also participate on these workgroups, especially if the regions are lacking subject matter expertise. Given that this workgroup would be formed on an as-needed basis, it is not likely that it will be evaluating and providing recommendations on existing Tier 3 toxicity values or periodically reviewing Tier 3 sources for new or updated toxicity values. Those roles would likely be retained by existing workgroups, such as the RSL table workgroup and the regional risk assessors.

Regardless of whether the coordinating responsibilities fall within a new or existing workgroup, the coordinating committee will have to put itself into position to receive Tier 3 toxicity value consultation requests and assign workgroups in a timely and efficient manner. Thus, the coordinating committee will have to maintain visibility among the regional risk assessors so that it is known to whom requests should be sent. The coordinating committee will also have to maintain a list of subject matter experts to staff the workgroups. Maintaining this list would likely require the coordinating committee to reach out to the regional toxicologists and risk assessors and possibly others in headquarters to determine whether they can and would participate on the workgroup should their expertise be needed.

There are several strengths and benefits with the use of *ad hoc* regional workgroups. Unlike the formal regional workgroup, which is limited to the expertise of its members, an *ad hoc* regional workgroup could be staffed with members who already have expertise on a particular chemical or chemical group. This approach to staffing could decrease the amount of time it takes to provide a consult and provide greater credibility/weight to the consult. In addition, *ad hoc* regional workgroups may also better champion the needs and priority for a Tier 3 toxicity value on a chemical that has a region-specific or limited geographic distribution in the environment. Unlike a formal workgroup or headquarters consult, an *ad hoc* workgroup could be composed of members who all have an interest in the chemical in question and completing a consult. However, this composition also could bias the consult. An *ad hoc* regional workgroup would also be focused on one particular task and less likely to be distracted from competing priorities, thereby decreasing the amount of time for a consultation and potentially improving the quality of the review. Furthermore, assuming the *ad hoc* workgroups are well-coordinated, this option would likely maximize available resource by spreading the responsibilities among many versus a few.

Along with the strengths and benefits of an ad hoc workgroup, this option has its limitations and challenges. Several of these limitations and challenges could stem from the coordinating committee. As indicated above, coordination is a critical component of this option. Thus, this option would lack effectiveness if the coordinating committee is poorly organized and managed. In addition, the formation and staffing of an *ad hoc* work group for each new chemical under consideration may be cumbersome and time consuming for the coordinating committee. Because the *ad hoc* regional workgroup will likely be coordinated by a regional workgroup, it may also suffer from lack of membership or input from EPA in headquarters and ORD (such as OSWER risk assessor or NCEA scientist). From a planning perspective, an *ad hoc* workgroup may make it difficult to staff workgroups

with subject matter experts from ORD or headquarters on an as-needed basis, let alone regional subject matter experts.

Although this option allows for the tailoring of a workgroup around a particular expertise, multiple *ad hoc* workgroups can pose some additional challenges. The use of the *ad hoc* approach could reduce the likelihood that a consistent process would be maintained for evaluating and recommending new Tier 3 toxicity values. One workgroup may apply evaluation criteria differently than another group. Thus, additional guidance and direction on the use of criteria may be needed to improve consistency. Furthermore, an *ad hoc* workgroup needs a mandate or direction that will not ultimately put it at odds with another Tier 3 workgroup (clarity of relationship between *ad hoc* workgroups and the RSL Workgroup).

5.4.4 Joint Headquarters/Regional Workgroup

Risk assessors and toxicologists in the regions and headquarters (OSWER and ORD) have had a long history in working together in developing and implementing risk assessment guidance and toxicological assessments pertaining to Superfund and RCRA. In recent years, additional efforts (such as OH2R2AF) have been undertaken to enhance communication between headquarters and regional Superfund and RCRA risk assessors. A joint workgroup consisting of regional and headquarters risk assessors and toxicologists could be established to provide consults on Tier 3 toxicity values because many of these efforts involve workgroups consisting of a mixture of regional headquarters representatives. This option is nearly identical to the regional workgroup option discussed in Section 5.4.3, except that this workgroup could be led by either a headquarters or a regional risk assessor and would have to include members from both regions and headquarters. Note that the regional workgroups do not necessarily have to include headquarters representatives. Based on headquarters' greater role in such a workgroup, it is likely that this workgroup could work on medium- to high-priority chemicals.

The joint regional and headquarters workgroup also shares many of the same strengths and limitations that the regional workgroup option may offer. In addition, this option allows for more coordination between headquarters and the regions, which could provide greater transparency and credibility to Tier 3 toxicity value consultations over a regional workgroup. A greater role for headquarters may also increase the likelihood that subject matter experts from headquarters will be involved in providing the consult. However, the share of power between the regional risk assessors and headquarters could limit the joint workgroup's effectiveness. Competing interests (completing a site risk assessment versus setting policy) could slow the workgroup activity.

5.4.5 Individual Regions

Under this approach, individual regions would continue to use their current methods for identifying and selecting Tier 3 toxicity values. With the exception of the RSL table (and its predecessors), which have provided recommendations on Tier 3 values, regions have already been largely responsible for identifying Tier 3 toxicity values and providing guidance to responsible parties, states, and other entities.

However, regions have consulted headquarters and other regions for high-priority chemicals (such as chromium VI) or chemicals commonly found at sites. Therefore, this approach is anticipated for use with low- to medium-priority chemicals. The development of Tier 3 toxicity values for high-priority chemicals will likely need the input from a regional workgroup or headquarters, especially risk-driving chemicals. As stated in the 2003 OSWER toxicity value hierarchy, "Consultation with the STSC or headquarters program office is recommended regarding the use of the Tier 3 values for Superfund response decisions when the contaminant appears to be a risk driver for the site" (EPA 2003).

There are several strengths with the individual regions approach. To begin with, a relatively quick turnaround time is associated with the approach. Rather than waiting for a response from headquarters or a workgroup, decisions can be made within the region which assists in a quick turnaround time. Following the individual regions approach allows regions to retain control of the selection of Tier 3 values. Furthermore, it allows for development of a more complete and thorough risk assessment, which limits the possibility of underestimating risks.

As with the previous approaches, there are several limitations to individual regions evaluating and selecting Tier 3 values. For instance, there is potential for lack of transparency and consistency with regard to decision making. At times, information is not shared outside of the region, or even within the region (between the programs). The lack of transparency (or information sharing) creates a problem when different Tier 3 values are recommended by different regions. Because the criteria for selecting a Tier 3 value do not specify the level of peer review, it is possible that several values could be chosen for a chemical by different regions. The credibility of such a toxicity value is more likely to be questioned by a responsible party (RP), resulting in a greater chance of challenge, especially for risk-driving chemicals, which draw an additional level of scrutiny. Since the credibility of regionally selected Tier 3 values may vary greatly, it is important to consult experts who can identify limitations of published values. However, by definition, the regional approach discourages seeking expert advice across regions in decision making. This lack of a cross-regional approach contributes to the limitations since the toxicological expertise of the decision-maker within each region may vary extensively. Finally, this approach does not address high-priority chemicals, which may need to be sent to headquarters for a decision. It should also be noted that although it is possible for individual regions to identify available Tier 3 toxicity values for certain chemicals of use and interest, regions often lack appropriate resources and expertise to adequately evaluate and select a Tier 3 value. In such instances, assistance from headquarters and other groups are often necessary.

5.5 Documentation

As noted in previous sections, transparency is a necessary component of a Tier 3 toxicity value. Therefore, identification and selection of a Tier 3 toxicity value by EPA risk assessors must continue to be transparent. Transparency includes documenting the decisions and recommendations regarding the selection of a Tier 3 toxicity value and its supporting toxicological assessments and making these documents available to the public. The following sections discuss potential methods for documenting

and distributing decision documents and alternatives (repositories) for warehousing decision documents and supporting documentation (for example, toxicological assessments).

5.5.1 Decision Documents and Distribution

As shown in Section 4.2 and Appendix B, consults and recommendations on Tier 3 toxicity values have taken the form of e-mails, formal memoranda, or listings in a table (the RSL table) and the level of detail regarding the support of these values has differed. Although future consults and recommendations may take several forms, development of a process for selecting a Tier 3 toxicity value may need to consider the level of formality needed in consults and recommendations and the type of information to be included in the consult or recommendation. For example, formal signed memoranda may offer more of an authoritative voice than informal e-mails. With regards to the types of information to be provided in consults or recommendations, it may include, but may not be limited to, the following:

- Transparency, peer-review, and availability criteria met,
- Summary of the underlying studies,
- Methods for toxicity value derivation,
- Uncertainty Factors (RfCs and RfDs),
- Carcinogenic mechanism of action (MOA) (if available),
- Target organ and critical effect, and
- Confidence in toxicity value.

Also, before decision documents and toxicological assessments are warehoused (see Section 5.5.2), timely notification of such decisions may be of interest to regional risk assessors. Regional risk assessors have expressed interest in what other regions are doing to avoid re-inventing the wheel or being inconsistent. However, notification does not necessarily mean that all regional decisions have to be distributed outside of the region. There is the potential for inconsistency or that the value is not used in a risk assessment because it may take some time between a decision on a Tier 3 toxicity value and its use, for example, upload into a database. Thus, a process for selecting a Tier 3 toxicity value, should consider a method for notifying regional risk assessors of any decisions regarding a Tier 3 toxicity value. Typically, e-mails have been an effective tool for distributing this type of information and have been the case with most headquarters consults. However, these e-mails have often been distributed from the requesting region and may not have been distributed to all regional risk assessors. In addition, e-mails may not always be read by all recipients. Other potential methods that could expand the risk assessor audience may include broadcasts in the OH2R2AF newsletter or during the OH2R2AF calls. Finally, some consideration should be given to how this information will be shared with other audiences (such as state risk assessors before they are sent to a repository.

5.5.2 Repositories

Decision documents and supporting documentation (in this case, toxicological assessments) behind a Tier 3 toxicity value must be stored and available for retrieval by risk assessors, risk managers, and the public. The following sections discuss potential alternatives for warehousing this information. In addition, the potential repositories discussed below may not apply to all situations because individual regions may continue to develop their own Tier 3 values internally. However, it is expected that the regions that develop their own values would be responsible for storing their decision documents and supporting documentation, unless they plan to distribute the values beyond their region.

In addition, on-line repositories will require storage space, routine maintenance, and a point of contact (for adding or revising a Tier 3 toxicity value). Although it is not the intent of this document to discuss these issues in depth, costs and resources associated with storage and maintenance of decision documents and supporting documentation will have to be considered and evaluated. Given these potential constraints and other considerations (duplication of effort), links to non-EPA websites that contain the toxicological assessments may be a viable alternative to storing the toxicological assessments on EPA's website.

5.5.2.1 PPRTV Assessments Electronic Library

The PPRTV Assessments Electronic Library is a potential repository for Tier 3 toxicity values. The PPRTV electronic library, which has recently become publically available, is administered by OSRTI and maintained by Oak Ridge National Laboratory under an interagency agreement. Notwithstanding contractual arrangements, an additional menu could be added to the PPRTV electronic library to house Tier 3 toxicity values. Similar to the PPRTVs, the menu could contain a list of all chemicals with Tier 3 toxicity values. When a given chemical is selected, the user would be sent to a page that contains the Tier 3 toxicity values, decision documents, and the toxicological assessments.

5.5.2.2 Superfund Health Risk Technical Support Center (STSC)

The STSC provides technical support to EPA program and regional offices in the area of human health risk assessment, such as the development of PPRTV assessments and scientific consultations. In years past, the STSC has served as a repository for health risk assessment documents, such as hard copies of HEAST derivation support documents. For these reasons, the STSC could serve as a repository for Tier 3 consults, recommendations, and supporting documentation. However, , STSC may not be a viable alternative for storing recommendations on non-EPA toxicity values and their technical support documents because the STSC develops PPRTVs and provides support for interpreting EPA publications and guidance.

5.5.2.3 RSL Table Website

The RSL table website, which is posted by Regions 3, 6, and 9, is another potential repository for Tier 3 toxicity values. The RSL table website appears to be a logical choice as a potential repository for supporting documentation because the RSL table is typically the first EPA document to post Tier 3 toxicity values. The user's guide and supporting tables could be expanded to include a page that contains the decision documents. This page could also provide the toxicological assessments or links to the toxicological assessment on non-EPA websites. Because the RSL summary table already contains fields for toxicity values, a separate location listing Tier 3 toxicity values would not be necessary. Furthermore, although the RSL table is not an original source of toxicity values, it often serves as the initial destination for Superfund and RCRA risk assessors seeking the most current toxicity values used by EPA. Thus, use of the RSL table as a repository location for Tier 3 toxicity values could decrease the number of locations risk assessors would have to search for toxicity values. However, as noted above, the RSL table and its supporting documentation (such as the User's Guide) are posted on the Region 3, 6, and 9 websites. While only one Region (Region 3) stores the files (the other two provide links only), this option would require approval and coordination with the Regions' IT and risk assessment staff and management. Note that it is unknown whether the regions currently storing the RSL tables are capable of and willing to take on this additional duty as doing so requires additional storage and resources. Furthermore, the layout of a Tier 3 toxicity value repository would be subject to the individual region's formatting preferences.

5.5.2.4 Tier 3 Toxicity Value Database

Although no such database exists at present, an on-line database strictly for Tier 3 values could be developed. This database would be strictly for Tier 3 toxicity values and, like the IRIS and PPRTV databases, its location will be readily identifiable as a source for recommended Tier 3 toxicity values. It is envisioned that it would be formatted similar to the PPRTV library with drop-down menus. Although such a site would provide a centralized and distinct location for Tier 3 toxicity values, it may require a significant amount of additional money and resources to design and maintain compared with the use of an existing on-line repository.

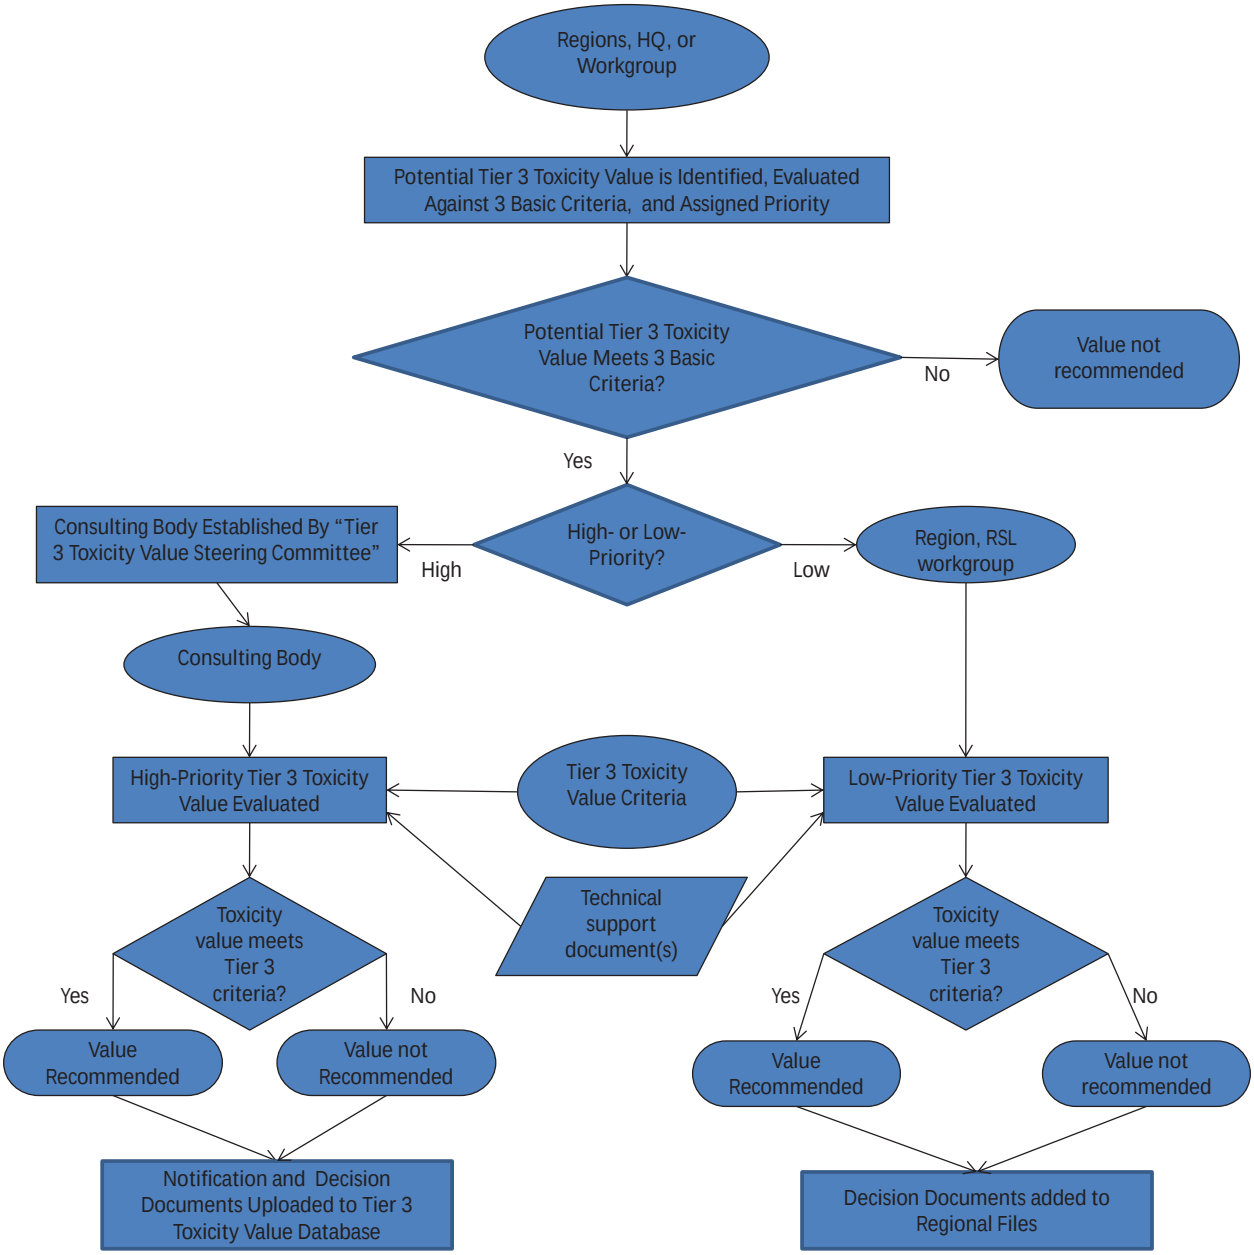
6 Recommended Option/Process and Path Forward

Overall, the Regional Tier 3 Toxicity Value Workgroup recommends a process that is flexible, consistent, efficient, and results in the evaluation and selection of Tier 3 toxicity values that are scientifically defensible. As discussed above, there is no "one size fits all," especially with respect to the decision-making body, for the evaluation and selection of Tier 3 toxicity values, and there are numerous combinations of potential processes for identifying, evaluating, selecting, and documenting Tier 3 toxicity values. Therefore, the following recommendations are provided as a path a candidate Tier 3 toxicity value may take from its initial identification to final selection and documentation. Figure 2 below illustrates this proposed path. Note that the recommendations apply to future Tier 3 toxicity values not already recommended by regional and headquarters risk assessors and the RSL table. However, those involved in the implementation of all or certain aspects of this white paper should consider existing Tier 3 toxicity values.

6.1 Toxicity Value Identification

The Tier 3 toxicity value workgroup recommends that the responsibility of identifying Tier 3 toxicity values remains with the regional and headquarters risk assessors and existing regional risk assessor workgroups (such as the RSL table team) to maintain flexibility and conserve time and resources. As discussed previously, these groups are most likely to encounter a potential Tier 3 toxicity value during development of a human health risk assessment and or a revision to the RSL table. Development of a formal workgroup, as discussed in Section 5.4.3.1, will require time and resources. Furthermore, as indicated in previous sections, the identification of potential Tier 3 values is not a frequent occurrence. Thus, the value of a formal workgroup is unclear, especially when regional risk assessors and others will likely continue to search for Tier 3 toxicity values in their routine work (risk assessments).

Figure 2. Proposed Tier 3 Toxicity Value Selection Process



6.2 Initial Evaluation and Chemical Prioritization

Beyond a more thorough and complete evaluation of a potential Tier 3 toxicity value, some steps must be taken to maintain a flexible and efficient process. We recommend that those who identify a potential Tier 3 toxicity value ensure that the toxicity value meets the three basic criteria outlined in Section 5.3.1, which include transparency, peer-reviewed, and public availability. Of course, these criteria are general in scope and a potential Tier 3 value meeting all three criteria at some level does not guarantee that it is scientifically defensible for use in human health risk assessments. At this time, other factors may also be considered and used to eliminate a potential Tier 3 value (for example, extrapolation of a toxicity value from an occupational standard, such as an Occupational Safety and Health Administration permissible exposure limit).

During the initial evaluation, this white paper recommends that the chemical be designated a low or high priority according to the prioritization criteria in Section 5.2. This designation is essential because it provides the basis for the recommendations in Section 6.3 on the type of consulting body to become involved. Note that additional prioritization of "high" priority chemicals will occur by the "Tier 3 Toxicity Value Steering Committee" (see Section 6.3.2.1). Because two of the prioritization criteria include the chemical's prevalence across the regions and level of interest at the national level (whether it would become the subject of a rule-making, for example), not to mention the potential subjective nature of those determinations, this white paper recommends that these efforts be coordinated with risk assessors and program representatives from other regions and headquarters via the "Tier 3 Toxicity Value Steering Committee."

6.3 Consulting Body

It is of the opinion of the Tier 3 toxicity value workgroup that no single process for evaluating and selecting a Tier 3 toxicity value will be the most efficient and timely for all potential scenarios where a potential Tier 3 toxicity value becomes available. Yet, the Tier 3 toxicity value workgroup also recognizes that a more formal process needs to be established to promote greater consistency and transparency among the regions. To meet these needs, this white paper recommends two separate approaches for evaluating and selecting a Tier 3 toxicity value. Because a chemical's significance and priority have previously defined the level of involvement by regional and headquarters risk assessors and toxicologists, it also serves as the critical determinant in selecting the appropriate approach. Specific details on the two approaches are provided in the following sections.

6.3.1 Low-Priority Chemicals

This white paper recommends that the Tier 3 toxicity values be evaluated and selected by the individual regions for chemicals that are designated as "low priority." However, this alternative does not necessarily preclude a region from consulting with others outside the region (such as STSC) regarding the use of a particular Tier 3 toxicity value. The "individual region" option appears to be the most practical for the "low-priority" chemicals, especially because it may allow for quicker decision making.

Chemicals with regional significance only, for example, may not draw enough interest from risk assessors from other regions or headquarters to staff workgroups, which could stall efforts to evaluate and select a value. A quick turnaround time is beneficial for non-risk driving chemicals so that it does not hold up decisions on risk-driving chemicals. Concerns with transparency and credibility are likely minimal for "low-priority" chemicals, especially non-risk driving chemicals. In addition, the RSL workgroup (under this approach) would continue to be responsible for evaluating and selecting Tier 3 toxicity values for "low-priority" chemicals because the RSL workgroup handles a wide array of chemicals ranging from "low priority" to "high priority."

6.3.2 High-Priority Chemicals

Even among high-priority chemicals, there may be varying expectations on the type of consult to be performed. Thus, it does not appear practical to recommend a specific consulting body. Instead, this white paper recommends a flexible and adaptive approach whereby potential Tier 3 toxicity value consultations be elevated to a "Tier 3 Toxicity Value Steering Committee." This committee (see Section 6.3.2.1) will be responsible for establishing the consulting body (such as an *ad hoc* workgroup, headquarters, or ADP) that best fits the situation and expectations of the risk assessors.

6.3.2.1 Tier 3 Toxicity Value Steering Committee

Although this white paper has not presented or evaluated potential workgroups that could fulfill the role as the "Tier 3 Toxicity Value Steering Committee," this white paper recommends that this role be subsumed by the OH2R2AF toxicity workgroup. This role falls within the scope of the OH2R2AF toxicity workgroup, which is to provide a forum to discuss and provide direction for OSWER human health risk assessors with regard to the use of toxicity values in removal and remedial actions. Furthermore, the OH2R2AF toxicity workgroup consists of members representing several regions and offices within headquarters. This broad range of representation enables the workgroup to more easily reach out to subject matter experts among the regions and headquarters, as well as to stay abreast of regional and national risk assessment issues that may affect the level of review that a potential Tier 3 toxicity value may receive.

Assuming the OH2R2AF toxicity workgroup takes on this responsibility, it may need to establish some guidelines or processes for elevating these chemicals and selecting the appropriate decision-making body. These guidelines and processes may include some of the following elements.

- Points of contact for elevating the chemical to the OH2R2AF toxicity workgroup.
- Criteria for determining which consulting entity will be used.
- Listing of subject matter experts (including regional and headquarters scientists and program representative) interested in participating in consultation workgroups.
- Who will be responsible for performing the review and evaluating the potential Tier 3 toxicity value's health risk assessment (will it be performed by the requestor, consultant, *ad hoc* workgroup members, or headquarters).

- Information requirements (health risk assessments and other documents pertaining to the derivation of a potential Tier 3 toxicity value).
- Who will be responsible for submitting consultation requests (for example, regional risk assessors, RTICs, managers, or division directors).

6.3.2.2 Other Considerations

This white paper generally recommends that the complete evaluation of potential high-priority Tier 3 toxicity values be the responsibility of the consulting body. This responsibility will ensure that subject matter experts are critically reviewing the underlying data behind a toxicity value. However, there is the potential that the consulting body may not perform the full review and evaluation. Previous examples include consultations on chromium VI and PCE. Consulting bodies may have time and resource constraints that prevent them (and individual members) from completing the full review and evaluation. In addition, duplication of effort may be of concern if the requestors perform this activity after a potential Tier 3 toxicity value has been initially identified as a matter of interest or routine. In these instances, consulting bodies may require that others (the requestor) perform the full review and evaluation of the toxicological support documentation and provide a summary of relevant information to the consulting body for additional evaluation and decision-making. The scope of the consulting body's review and evaluation of the underlying toxicological information may vary. As a result, decisions regarding the responsibility and extent of the review will likely require some degree of coordination with the original consultation requestor. These activities could be facilitated by a "Tier 3 Toxicity Value Steering Committee."

6.4 Toxicity Value Evaluation

Regardless of who is responsible for evaluating a potential Tier 3 toxicity value, the same set of criteria should be applied to all Tier 3 toxicity value evaluations. This white paper recommends that the ECOS criteria, guiding principles, and other relevant criteria and guidance outlined in the white paper be adopted as criteria for evaluating potential Tier 3 toxicity values. In addition to adopting the aforementioned criteria, this white paper also recommends that the confidence in the toxicity value be described in the evaluation. Evaluating and assigning confidence to toxicity values including the underlying study and overall database are standard practice and potentially critical elements in risk management decision-making. Confidence in a Tier 3 toxicity value would also be significant (a deciding factor) in instances where there are competing Tier 3 values.

Also, per Section 5.3.2, it is critical that those involved in the evaluation and selection process have, at a minimum, a basic understanding of how to evaluate and assess the data usability of toxicity studies, the adverse and critical effect levels in a study, and the methodologies used to derive toxicity values. Although these skills are likely to be present among the members of regional and headquarters workgroups, it is less certain at the "individual region" level. Thus, training and educational opportunities pertaining to the aforementioned skills should continue to be a priority among the risk assessors.

6.5 Documentation

The following recommendations on documentation are generally intended to address high-priority chemicals. In keeping with the theme of "low-priority" chemicals, decisions on how regions document and store "low-priority" Tier 3 toxicity values will be left to the regions and RSL workgroup. However, the Tier 3 toxicity value workgroup recommends that the regional risk assessors are notified of the selection of Tier 3 toxicity values in case these chemicals ever come up in other regions. To make this process efficient and less of a burden on the risk assessors who select a value, it is recommended that notification and storage of decision documents be coordinated through the "Tier 3 toxicity value steering committee."

6.5.1 Decision Documents

This white paper recommends that a formal system be put into place that documents selection of a Tier 3 toxicity value. This white paper further recommends that all decision documents for high-priority chemicals be provided in a formal memorandum from the selecting entity to the original requestor(s), "Tier 3 toxicity value steering committee" and other relevant workgroups, such as the RSL workgroup and the OH2R2AF toxicity workgroup (if different from the steering committee). The memorandum should provide the rationale for selecting a value (how it meets the evaluation criteria) and contain the following information (where applicable):

- Summary of underlying studies,
- Methods for toxicity value derivation,
- Uncertainty factors (RfDs and RfCs),
- Carcinogenic MOA and cancer classification (if available),
- Target organ/critical effect, and
- Confidence in toxicity value (critical for competing values).

The recommendation above also applies to situations where the consulting body does not recommend the use of a value or selects one value over another in the case of competing values. When a value is not selected, the response will focus on the particular criteria that are not met or other technical reasons for not recommending a value. If the rationale for rejecting a value is not documented, there is the potential that the same requests could be made in the future.

6.5.2 Repository

This white paper recommends that Tier 3 toxicity value decision documents and related documents (such as health risk assessments) be housed electronically at one of the existing EPA toxicity value websites or electronic libraries. To avoid duplication of effort, this white paper also recommends that

decision documents for toxicity values not selected by the consulting body be housed in the repository. Notwithstanding contractual and resource arrangements with EPA websites that contain toxicity value information, use of an existing EPA on-line location would not add to the number of EPA websites to search for a toxicity value and would make use of existing infrastructure and resources. In addition, it is recommended that the electronic library be publicly available and follow a format similar to the PPRTV electronic library (with drop-down menus)

Those involved in posting Tier 3 toxicity value consults, such as the "Tier 3 toxicity value steering committee," will have to consider whether the health risk assessment in support of a particular toxicity value needs to be posted on the website and if so, how this information will be housed. Health risk assessments can be lengthy documents, and posting them on EPA websites may not be feasible. However, health risk assessments in support of toxicity values are often provided electronically by the authors, which are typically federal and state health agencies (as is the case with ATSDR toxicological profiles). Therefore, links to websites containing those assessments may suffice.

7 Summary

While EPA has multiple policies, guidance, and guidelines to assist and/or direct risk assessors in the development and selection of toxicity values, specific guidance on selecting tier 3 toxicity values for use in Superfund and RCRA cleanup programs is limited. As a result, regional risk assessors have shared concerns over transparency and consistency of selecting Tier 3 toxicity values. In response, the Tier 3

Toxicity Workgroup developed this white paper to explore and recommend processes for enhancing the selection of Tier 3 toxicity values.

The process of selecting Tier 3 toxicity values consists of several steps including the identification, prioritization, evaluation, selection, documentation, and communication of Tier 3 toxicity values. Chapters 1 and 2 provide background on guidance and policies regional risk assessors follow to identify toxicity values and examples of some of the most commonly used federal, state and international sources of Tier 3 toxicity values and toxicity data. Chapter 2 also introduced the similarities and differences in how toxicity values are developed within each of those sources and recommended that a basic understanding on how to evaluate and assess the data usability of toxicity studies, identify the adverse and critical effect levels in a study and evaluate the regulatory-specific methodologies used to derive toxicity values is useful for comparing, selecting, and developing chemical-specific toxicity values. A number of publications, both internal and external to EPA, are summarized in Chapter 3, which provide guidance on how to evaluate the underlying basis of a toxicity value and provide a suggested framework for identifying and selecting toxicity values. Chapter 4 summarizes current and past practices of how regional risk assessors have identified, evaluated, and selected Tier 3 toxicity values.

Chapter 5 explores various options for identifying, evaluating, selecting, and documenting Tier 3 toxicity values. The chapter discusses alternatives for who would be responsible for identifying potential Tier 3 toxicity values and proposes a set of criteria for assigning priority to a chemical because a chemical's priority will likely dictate the entity that will provide a Tier 3 consultation. Chapter 5 also proposes a process for evaluating and selecting Tier 3 toxicity values, which includes two steps consisting of a basic evaluation and a critical review. The remainder and bulk of the chapter explores the options for Tier 3 toxicity value consultations and options for documenting and communicating the evaluation and selection of Tier 3 toxicity values. The options for documenting and communicating the selection of Tier 3 toxicity values include methods on how to document and distribute decision documents to regional risk assessors and alternatives for warehousing decision documents. The options for the Tier 3 toxicity value consultation process are summarized in the table below.

After consideration of the strengths and limitations of each of the alternatives and previous and current methods of selecting Tier 3 toxicity values, this white paper recommends a general process that retains flexibility, but also enhances consistency and transparency. Rather than recommend a “one size fits all” approach that could hinder efficiency and lengthen decision-making, this white paper recommends two approaches, one addressing low priority chemicals and the other addressing high priority chemicals. Proposed criteria for assigning priority are presented in Section 5.2.

For low priority chemicals, this white paper recommends that Tier 3 toxicity value decision-making be retained within the regions. While responsibility for selecting Tier 3 toxicity values remains within the regions, this white paper encourages regions to consult others outside of their own region, such as the OH2R2AF, RSL workgroup, and STSC. Regions may lack information, resources, and technical expertise to conduct chemical prioritizations and to evaluate and select Tier 3 toxicity values.

In regard to high priority chemicals, this white paper recommends the establishment of a "Tier 3 Toxicity Value Committee" that will be responsible for the overall coordination of the Tier 3 toxicity value selection process. The "Tier 3 Toxicity Value Committee," a role that can be subsumed by the OH2R2AF toxicity workgroup, would be mainly responsible for establishing the consulting body, i.e., the group responsible for evaluating and selecting a Tier 3 toxicity value, that best fits the needs and expectations of the risk assessors for the specific chemical. In addition, while decisions on how regions document and store "low priority" Tier 3 toxicity values will be left to the regions and RSL workgroup, a more formal and structured process for documenting, storing, and communicating "high priority" Tier 3 toxicity value selections is recommended. Specifically, this white paper recommends that all decision documents be provided in a formal memo from the reviewers to the requestor and would apply to situations where a toxicity value is recommended, not recommended, or one value is recommended over another, i.e., competing toxicity values. Furthermore, this whitepaper recommends that decisions be communicated to the regional risk assessors, via the "Tier 3 Toxicity Value Committee," and that the decision documents and other relevant information (e.g., health risk assessments) be stored within existing EPA toxicity value websites or electronic libraries.

Although this white paper recommends two approaches, it is important to point out that they both share some common recommendations including elements of the identification, prioritization, and evaluation steps. These common recommendations include, but are not limited to, prioritization criteria (discussed above) and the criteria and guiding principles used to evaluate candidate Tier 3 toxicity values. Regardless of the vehicle used to perform the evaluations, the same set of criteria and principles should be used to evaluate all potential Tier 3 toxicity values. Furthermore, to ensure consistent and proper application of review criteria, training will continue to be a critical for those individuals that may be involved in the evaluation and selection process.

Table 1. Options for Tier 3 Consultations

Option	Factors for Consultation	Strengths	Limitations
Action Development Process (ADP) Workgroup	ADP is the Agency's method for producing high quality actions such as regulations, policies, and risk assessments. Tier 3 toxicity values considered influential scientific information should be developed through ADP. Process typically initiated by Office of Solid Waste and Emergency Response (OSWER). Tiering process begun by Regulatory Steering Committee based on level of senior management involvement and extent of cross-agency influence: • Tier 1—actions signed by Administrator and have broad cross-agency influence • Tier 2 – actions signed by assistant Administrator and have some cross-agency influence • Tier 3 – actions signed by Office directors and have limited cross-agency influence	**	**
Headquarters Consultation	Regions submit requests to Headquarters. Typically, consultations are led by OSWER with input from the Office of Research and Development (ORD). Consultations are often coordinated among offices of OSWER including the Science Advisor, OSTRI, and OEM. Currently primarily performed on an "informal" basis. Could be formalized in future with consistent designated lead office within OSWER. Key factors include: • Headquarters establish contact to receive Tier 3 requests • Regional risk assessors establish a consistent process for submitting requests • Contract support may be necessary to assist within consultation	• Promote consistency among regions • More likely to maintain consistent process for providing consultations • Add "greater weight and credibility to Tier 3 values	• Perception that Headquarters is setting policy • Not well-suited to handle low-priority chemicals
Regional Workgroup	Formal or ad hoc group of subject matter experts with expertise relevant to chemicals being evaluated. Led and generally consisting of regional risk assessors and toxicologists. Primary focus would be on low- to medium-priority chemicals. Two existing regional workgroups: • Regional screening level (RSL) workgroup • Regional human health risk assessment forum (OH2R2AF) toxicity workgroup	Formal workgroup • Easier establishment and tracking of expectations and results • Visible to headquarters and regions resulting in greater credibility of Tier 3 values • Maintenance of consistent process Ad hoc workgroup • Formed with selected experts as necessary • May better champion needs and priority for regional-specific Tier 3 values • If well coordinated, will maximize results by spreading duties to many, rather than few	Formal workgroup • Fixed membership may fail to reach out to individuals/groups with particular expertise • Workload may not require regular meetings, resulting in loss of focus and interests among members Ad hoc workgroup • May lack effectiveness if not well-coordinated • Formation and staffing of multiple ad hoc workgroups may be cumbersome • May suffer from lack of headquarters input • Reduced likelihood of consistent process
Joint Headquarters/Regional Workgroup	Joint workgroup consisting of regional and headquarters risk assessors and toxicologists Similar to regional workgroup except the group could be led by either headquarters or regional individual and have members from both groups.	Similar to regional workgroup, as well as • Allows more coordination between headquarters and regions resulting in greater transparency and credibility of Tier 3 values • More likely to include subject matter experts from headquarters (as compared to regional workgroup)	Similar to regional workgroup, as well as • Sharing of power between headquarters and regions could limit effectiveness • Competing interests could slow workgroup activity
Individual regions	Individual regions would continue to use current methods for identifying and selecting Tier 3 values. Anticipated for use primarily with low- to medium-priority chemicals; high priority chemicals expected to include headquarters input.	• Relatively quick turn-around • Allows regions to maintain control of Tier 3 values • Allows development of more complete and thorough risk assessment	• Potential lack of transparency and reduced credibility of Tier 3 values • Lack of cross-regional approach limits access to and use of varied regional expertise • Approach does not address high priority chemicals which require headquarters input • Potential lack of regional resources and expertise in evaluating and selecting a Tier 3 value

**Unlike the other options, the ADP generally applies to specific circumstance as indicated in Section 5.4.1, i.e., Tier 3 toxicity values that are considered highly influential scientific information. Thus, the strengths and limitations of the ADP were not evaluated in this white paper.

APR – 9 2009

MEMORANDUM

SUBJECT: Withdrawal of the January 15, 2009, OSWER Guidance Entitled "Interim Recommended Trichloroethylene (TCE) Toxicity Values to Assess Human Health Risk and Recommendations for the Vapor Intrusion Pathway Analysis"

FROM: Barry N. Breen, Acting Assistant Administrator
Office of Solid Waste and Emergency Response

TO: Acting Regional Administrators, Regions 1 - 10

On January 15, 2009, the Office of Solid Waste and Emergency Response (OSWER) issued a guidance memorandum entitled "Interim Recommended Trichloroethylene (TCE) Toxicity Values to Assess Human Health Risk and Recommendations for the Vapor Intrusion Pathway Analysis." That guidance was subsequently distributed to EPA regional staff and managers. The Agency is withdrawing this guidance to further evaluate the recommendations regarding the non-cancer TCE toxicity value for use in risk assessments of inhalation exposures. Once this re-evaluation is complete, we will update you.

In the interim, toxicity values for TCE should be determined consistent with the National Contingency Plan (e.g., 40 CFR 300.430(e)) and the 2003 Toxicity Hierarchy (OSWER Directive 9285.7-53, December 5, 2003). The Directive provides guidance on a hierarchy of approaches regarding human health toxicity values in risk assessments, and provides guidance for regional risk assessors to help them identify appropriate sources of toxicological information that should generally be used in performing human health risk assessments at Comprehensive Environmental Response, Compensation and Liability Act (CERCLA or "Superfund") sites. This hierarchy of approaches is also appropriate for human health risk assessments at Resource Conservation and Recovery Act (RCRA) corrective action sites.

The guidance memorandum also addressed the vapor intrusion pathway and recommended a multiple lines of evidence approach in assessing sites for vapor intrusion. EPA expects to issue a separate document that will address the multiple lines of evidence approach as it relates to the vapor intrusion pathway.

If you have any questions, please contact Jayne Michaud in the Office of Superfund Remediation and Technology Innovation at 703-603-8847 or Mary Cooke in the Federal Facilities Restoration and Reuse Office at 703-603-8712.

APR 2 9 2009

MEMORANDUM

SUBJECT: Recommended Risk-Based Human Health Screening Levels and Interim Trichloroethylene Toxicity Values Update

FROM: Jeffery Robichaud
Chief
ENSV/EAMB

TO: AWMD – RCRA Branch Chiefs
SUPR – All Division Branch Chiefs

The purpose of this memo is to update the Region 7 RCRA and Superfund programs on the recommended risk-based human health screening levels and to provide recommendations on trichloroethylene (TCE) chronic toxicity values. As a reminder, the recommendations provided in this memo apply to risk assessment-related documents developed by or on behalf of EPA Region 7, as well as any relevant documents submitted to the Region for review and approval.

In a memo, dated December 14, 2007, the Region 7 risk assessors recommended the use of the Region 6 Human Health Medium-Specific Screening Levels (MSSLs) as the primary source of screening levels. At that time, the Region 6 MSSLs were recommended because they were regularly updated and were consistent with current toxicity values and EPA risk assessment guidance and policy. Also, as indicated in that memo, a regional effort was underway to consolidate the existing regional screening tables into a single set of screening values in order to improve consistency and incorporate updated guidance. In the fall of 2008, that effort was completed and the Regional Screening Table was posted on the Region 3 website, followed later by Regions 9 and 6.

Given that the Regional Screening Table is now available on the internet, the Regional risk assessors recommend the use of the Regional Screening Table and its supporting documents (e.g., User's Guide). The links to the table and supporting documentation are provided below.

- Region 3, http://www.epa.gov/reg3hwmd/risk/human/index.htm.
- Region 6, http://www.epa.gov/Region6/6pd/rcra_c/pd-n/screen.htm.
- Region 9, http://www.epa.gov/region09/superfund/prg/index.html.

Also, we have provided additional information to consider when using the tables. That information is provided below.

- Although Regions 3, 6, and 9 continue to use the Risk-Based Concentration (RBC), Preliminary Remediation Goal (PRG), and Medium-Specific Screening Level (MSSL) terminology on their respective websites, they all provide the same Regional Screening Table and supporting documents. Risk assessments and related documents should cite the Regional Screening Table.
- The inhalation exposure pathway screening level equations are consistent with EPA's inhalation dosimetry methodology (USEPA, 1994). Inhalation unit risk (IUR) and reference concentration (RfC) toxicity values are used in place of inhalation cancer slope factors and inhalation reference doses, respectively. Therefore, body weight and inhalation rate are no longer used when evaluating the inhalation pathway. This slightly impacts all screening levels and risk estimates that are based solely, or in part, on the inhalation exposure pathway.
- The Regional Screening Table provides a screening level for industrial air.
- The dermal contact pathway is not accounted for in the tap water screening levels.

With regards to TCE, it is currently undergoing reassessment by the Integrated Risk Information System (IRIS) program and interagency review and external peer review of the draft assessment are projected to begin in the fourth quarter of fiscal year (FY) 2009 and first quarter FY 2010, respectively. Until IRIS provides final toxicity values, specific guidance is provided by EPA headquarters, or new toxicity values become available that fall within EPA's toxicity value hierarchy (e.g., PPRTV database), we recommend the use of the following chronic toxicity values for TCE. When evaluating cancer risks, we recommend the use of California Environmental Protection Agency's (CalEPA) oral slope factor (SFo) of 0.013 $(mg/kg\text{-}day)^{-1}$ and IUR of 2.0E-06 $(\mu g/m^3)^{-1}$. When evaluating chronic non-cancer health hazards, we recommend the use of New York State Department of Health's (NYSDOH) air criterion of 10 $\mu g/m^3$. An oral reference dose (RfDo) is not available at this time and until one becomes available, we recommend that the uncertainties regarding the lack of the value be discussed in site-specific human health risk assessments. The use of these toxicity values is consistent with OSWER Directive 9285.7-53, which is OSWER's current policy on the selection of toxicity values in human health risk assessments. All three values have undergone peer review and are Tier 3 toxicity values.

Also, please note that CalEPA provides a chronic inhalation non-cancer toxicity value for TCE which is 60-fold greater than NYSDOH's air criterion. However, it is our professional judgment that CalEPA's Recommended Exposure Limit (REL) does not afford an adequate level of protection for long-term exposures to TCE and therefore, it should not be used in Superfund or RCRA Corrective Action risk assessments (and related documents) submitted to or conducted on behalf of EPA Region 7. Our reasons for supporting the use of the NYSDOH's non-cancer air criterion include, but are not limited to, the following:

- The NYSDOH value is based on more extensive presentation of health endpoints.
- The NYSDOH value is based on a more recent evaluation of the available health effects

literature, such as developmental and reproductive effects.

- The NYSDOH's critical study has clear strengths over CalEPA's REL critical study. First, the Rasmussen et al. (1993) study, which was used to derive NYSDOH's air criterion, had 99 subjects compared to CalEPA's critical study, the Vandervort and Polankoff (1973) study, which included 19 subjects. Second, the Rasmussen study evaluated clinical neurological endpoints whereas the Vandervort and Polankoff study looked at self-reported health endpoints via a questionnaire. Also, the Rasmussen study included concurrent biological monitoring that was used to estimate TCE air concentrations via pharmacokinetic modeling. The Vandervort and Polankoff study derived an exposure concentration from one day measurements.
- The lowest-observed-adverse-effect-level (LOAEL) used to derive the NYSDOH air criterion is $1/6^{th}$ the LOAEL used to derive the CalEPA REL.
- CalEPA's chronic REL is greater than the Agency for Toxic Substances and Disease Registry's (ATSDR) intermediate Minimal Risk Level (MRL), which covers exposures lasting from 14 days to 1 year. Although the ATSDR intermediate inhalation MRL is based on the subchronic rat study by Arito et al. (1994), the human pharmacokinetic adjusted LOAEL is similar to that of the human equivalent LOAELs observed in several human studies including the studies used by CalEPA and NYSDOH to derive chronic non-cancer inhalation values (NRC, 2006). Note that the ATSDR intermediate MRL is a peer-reviewed value that is recommended for use when evaluating subchronic exposures.

If you or your staff have any questions or need assistance regarding the Regional Screening Table or TCE's toxicity values, please contact Mike Beringer at x7351, Jeremy Johnson at x7510, Greg McCabe at x7709, or Kelly Schumacher at x7963. Specific questions on TCE's reassessment should be direct to Jeremy Johnson, the Region 7 IRIS Consensus Reviewer.

MEMORANDUM

TO: William Sette, Senior Science Advisor, Office of Solid Waste and Emergency Response

FROM: Chloe Metz, Risk Assessor, Emergency and Remedial Response Division, Region 2

DATE: August 17, 2009

RE: Classification of the Oral Slope Factor for Hexavalent Chromium (Cr VI) Developed by New Jersey as a Tier 3 Toxicity Value

---

As defined in OSWER directive 9285.7-53, a Tier 3 value, "Includes additional EPA and non-EPA sources of toxicity information. Priority should be given to those sources of information that are the most current, the basis for which is transparent and publicly available, and which have been peer reviewed." Region 2 believes that the oral slope factor for Cr VI of 0.5 $(mg/kg\text{-}day)^{-1}$ developed by Alan Stern of the New Jersey Department of Environmental Protection meets the above definition. The assessment is current (released in July, 2009) and was subject to an external peer review which is available online (http://www.state.nj.us/dep/dsr/chromium/peer-review-comments.pdf). Added support for the use of this OSF as a Tier 3 value is the fact that EPA-NCEA reviewed the draft risk assessment and concluded that it was, "Clearly written, understandable, and well organized, and it was, for the most part, consistent with EPA's risk assessment methodologies."

The hierarchy directive goes on to say that, "Consultation with the STSC or headquarters program office is recommended regarding the use of the Tier 3 values for Superfund response decisions when the contaminant appears to be a risk driver for the site." As such, Region 2 respectfully requests that OSWER provide written support for the use of the New Jersey OSF for Cr VI to determine action levels for the Garfield site where Cr VI is the only contaminant of concern.

RE: Classification of the Oral Slope Factor for Hexavalent Chromium (Cr VI) developed by New Jersey as a Tier 3 Toxicity Value

The purpose of this email is to provide written confirmation of OSWER's concurrence with Region 2 using the oral cancer slope factor for Cr VI recently finalized by the state of New Jersey. As noted in your memo, attached below, this toxicity value is based on the most recent science, has been peer reviewed, is publicly available, and, in the opinion of EPA's ORD, is "clearly written, understandable,and well organized", i.e. transparent. Thus, it fulfills all of OSWER's criteria for a Tier 3 Toxicity Value. Janine Dinan of the Office of Emergency Management, which is the lead OSWER office for this emergency cleanup activity, as well as Dave Crawford, in the Office of Superfund Remediation and Technology Innovation, and I, concur with this conclusion. If you have any further questions, please feel free to contact me.

Cr+6 Muta MOA for Carcinongenicity paper is published

William Sette to: Chloe Metz, Dave Crawford, Helen Dawson, Janine Dinan, Michael Sivak, Stiven Foster, Barbara Hostage 09/29/2009 10:02 AM

Cc: Michael Beringer, Nancy McCarroll

History: This message has been replied to and forwarded.

hi;

Attached please find this paper reflecting OPP's analysis that finds that this chemical has a mutagenic mode of action for carcinogenicity and that recommends that ADAFs be applied, consistent with EPA's Cancer Guidelines.

So it's recent, publically available, peer reviewed, and I leave the transparent open until we read it. That's all the criteria for Tier 3 use.

Bill

UNITED STATES ENVIRONMENTAL PROTECTION AGENCY
WASHINGTON, D.C. 20460

OFFICE OF
SOLID WASTE AND EMERGENCY
RESPONSE

June 12, 2003

OSWER No. 9285.7-75

Marcia L. Bailey, D. Env.
Environmental Toxicologist
U.S. Environmental Protection Agency, Region 10
Office of Environmental Assessment, Risk Evaluation Unit
1200 Sixth Avenue, OEA-095
Seattle, Washington 98101

Dear Dr. Bailey:

I am responding to recent inquiries concerning cancer toxicity values to evaluate inhalation and ingestion risks from exposure to tetrachloroethylene, also commonly known as perchloroethylene or "PCE," and specifically whether it would be appropriate to use a California Environmental Protection Agency (Cal EPA) inhalation unit risk value and oral slope factor. This letter supercedes an earlier version of this letter, which identified an incorrect source of the oral slope factor. This letter is consistent with the earlier letter regarding the inhalation unit risk value and its source.

In the absence of relevant values in the U.S. Environmental Protection Agency (EPA) Integrated Risk Information System (IRIS) or a value from EPA's National Center for Environmental Assessment/Superfund Technical Health Risk Support Center (STSC), which are the first two tiers of human health toxicity values in the EPA Superfund hierarchy, we would support consideration of the Cal EPA inhalation unit risk value from the Air Toxics Hot Spots Program and the oral slope factor from the Cal EPA Public Health Goal in Drinking Water.

In general, Cal EPA develops its toxicity values in a manner which is quite similar to the EPA IRIS program, in that many of the same databases and considerations are used. Cal EPA's assessments used information from some of the same sources or studies that EPA typically considers in the IRIS program, including the most recent relevant studies known to exist, and also considered this information in a manner similar to the EPA IRIS program.

In summary, having consulted on this matter with the STSC, the Office of Emergency and Remedial Response (OERR) supports use of the Cal EPA Air Toxics Hot Spots Program inhalation unit risk of 5.9 E-6 $(\mu g/m^3)^{-1}$ for Superfund sites as the best value available at this time until a U.S. EPA value becomes available. Having consulted with the STSC about the Cal EPA Public Health Goal in Drinking Water oral slope factor of 5.4E-1 $(mg/kg\text{-}day)^{-1}$ for PCE, we also support the use of this value until a U.S. EPA value becomes available.

The Cal EPA presents a full, complete and transparent presentation of the relevant information on their development of these values on their internet website. Documentation on the Air Toxics Hot Spots Program inhalation unit risk value can be found at this internet website: http://www.oehha.ca.gov/air/hot_spots/pdf/TSDNov2002.pdf . Since this website does not take you directly to the PCE discussion, and this can be difficult to find on the internet website, we have downloaded the eight pages pertaining to PCE and include them as an enclosure to this letter. Documentation on the Public Health Goal in Drinking Water oral slope factor can be found at this Cal EPA internet website: http://www.oehha.ca.gov/water/phg/pdf/PCEAug2001.pdf Because of the size of this document (75 pages) and because this website does take you directly to this document, we have not included this document as an enclosure to this letter. With respect to the transparency of any Superfund Program decisions which may use these values in selecting a response action, we recommend that the appropriate documentation from the Cal EPA website be provided, or the link to the relevant Cal EPA internet website be identified.

Thank you for your inquiry. If you have any questions, please contact Mr. Dave Crawford of my staff at (703) 603-8891.

Sincerely,

/s/

Unit Risk Factor: 5.9 E-6 $(\mu g/m^3)^{-1}$
Slope Factor: 2.1 E-2 $(mg/kg\text{-}day)^{-1}$
[Male mouse hepatocellular adenoma and carcinoma incidence data (NTP, 1986), cancer risk estimate calculated using a linearized multistage procedure and PBPK model dose adjustment (CDHS, 1991).

III. CARCINOGENIC EFFECTS

Human Studies

Epidemiological studies of perchloroethylene (PCE) exposure have been reviewed by Reichert (1983) and by the U.S. EPA (1985). Blair *et al.* (1979) analyzed the death certificates of 330 union laundry and dry-cleaning workers (out of a cohort of 10,000). Of 330 decedents, 279 had worked solely in dry-cleaning establishments. Increased mortality from cancers of the respiratory tract, cervix, and skin was documented, and when all malignancies were evaluated together, the number of observed deaths was significantly greater than expected ($p < 0.05$). Although an excess of liver cancer and leukemia was also observed, these increases were not statistically significant.

In an expanded study, Blair *et al.* (1990) reported on mortality among 5,365 dry cleaning union members. Statistically significant excesses of cancer of the esophagus and cervix and non-significant excesses for cancer of the larynx, lung, bladder, and thyroid were reported. Lack of PCE exposure data and lack of accounting for potential confounding factors, such as economic status, tobacco, or alcohol use, prevents any firm conclusion as to the association of PCE exposure and excess cancer.

Katz and Jowett (1981) analyzed the mortality patterns of 671 white female laundry and dry-cleaning workers. Occupational codes listed on the certificates did not distinguish between the two types of work. Data on the duration of employment were not available, nor were the investigators able to determine to which solvent(s) the individuals were exposed. Smoking history was not known. A significant increase in risk of death from cancer of the kidneys ($p < 0.05$) and genitals ($p < 0.01$) was

documented. An excess risk from skin and bladder cancer was also found; however, neither increase was statistically significant.

Other studies of laundry and dry-cleaning workers have also reported an increased risk of death from cervical cancer (Blair *et al.*, 1979; Kaplan, 1980); however, these investigators have not compared mortality data by low-wage occupation. Although not definitive, the findings of Katz and Jowett (1981) suggest that factor(s) other than (or in addition to) solvent exposure are important contributors to cervical cancer.

Kaplan (1980) completed a retrospective mortality study of 1,597 dry-cleaning workers exposed to PCE for at least one year (prior to 1960). The solvent history of approximately half of the dry-cleaning establishments was known. The inability of Kaplan to quantify solvent exposure adds an important confounding variable to the study (Kaplan, 1980). The mean exposure concentration of individuals to PCE was calculated to be 22 ppm for dry-cleaning machine operators and 3.3 ppm for all other jobs. Kaplan found an elevated SMR (182) for malignant neoplasms of the colon (11 observed deaths, 6.77 to 6.98 expected deaths). In addition to colon cancer, malignant neoplasms of the rectum, pancreas, respiratory system, urinary organs, and "other and unspecified sites (major)" were observed (Kaplan, 1980). Although the relatively small cohort in this study limits conclusions about the carcinogenic potential of PCE, the study (Kaplan, 1980) results suggest a relationship between colon cancer and solvent exposure.

A group of Danish laundry and dry-cleaning workers was identified from the Danish Occupational Cancer Register (Lynge *et al.*, 1990). From cancer incidence data for a 10-year period, a significant excess risk was found for primary liver cancer among 8,567 women (standardized incidence ratio 3.4, 95% confidence interval 1.4-7.0). No case of primary liver cancer was observed among 2,033 men, for whom the expected value was 1.1. Excess alcohol consumption did not appear to account for the excess primary liver cancer risk for women. However, no data was available on actual exposures of the study group to PCE or other chemicals.

Duh and Asal (1984) studied the cause(s) of mortality among 440 laundry and dry-cleaning workers from Oklahoma who died during 1975 to 1981. Smoking histories were not available and separation of the two groups by occupation was not possible. NIOSH reported that, although 75% of dry-cleaning establishments in the U.S. use PCE, Oklahoma may be unique in that petroleum solvents account for more that 50% of total solvents used during this period (NIOSH, 1980). Analysis of deaths due to cancer showed an increase for cancers of the respiratory system, lung, and kidney.

Brown and Kaplan (1987) conducted a retrospective, cohort-mortality study of workers employed in the dry-cleaning industry to evaluate the carcinogenic potential from occupational exposure to PCE. The study cohort consisted of 1,690 members of four labor unions (located in Oakland, Detroit, Chicago, and New York City). Individuals selected for the study had been employed for at least one year prior to 1960 in dry-cleaning shops using PCE as the primary solvent. Complete solvent-use histories were not known for about half of the shops included in the study. Because petroleum solvents were widely used by dry cleaners prior to 1960, most of the cohort had known or potential exposure to

solvents other than PCE (primary, various types of Stoddard solvents). The investigators also identified a subcohort of 615 workers who had been employed only in establishments where PCE was the primary solvent. The PCE exposure in shops included in the study was evaluated independently (Ludwig *et al.*, 1983). The geometric mean of time-weighted-average exposures was 22 ppm PCE for machine operators and approximately 3 ppm for other workers.

In summary, a statistically significant excess of deaths from urinary tract cancer was observed in those workers that were potentially exposed to both PCE and petroleum solvents. Individuals employed in shops where PCE was the primary solvent did not have an increased risk of mortality from kidney or bladder cancer. Although these findings do not rule out PCE as the causative agent of urinary tract cancer, the data suggest that other factors or agents may have contributed to the development of neoplastic disease. CDHS stated in the Toxic Air Contaminant document "Health Effects of Tetrachloroethylene" that until studies are completed that include a thorough analysis and quantification of PCE exposures, epidemiological studies will not be useful for the assessment of the human health risks of PCE (CDHS, 1991).

Animal Studies

Two lifetime bioassays have been completed on PCE (NCI, 1977; NTP, 1986). Additionally, three other studies have addressed the question of PCE carcinogenicity (Rampy *et al.*, 1978; Theiss *et al.*, 1977).

The National Cancer Institute (NCI) conducted a study in which B6C3F$_1$ mice and Osborne Mendel rats were administered PCE in corn oil by gavage, 5 days/week for 78 weeks (NCI, 1977). The time-weighted average daily doses of PCE were 536 and 1072 mg/kg for male mice, 386 and 722 mg/kg for female mice, 471 and 941 mg/kg for male rats, and 474 and 949 mg/kg for female rats. PCE caused a statistically significant increase in the incidence of hepatocellular carcinomas in mice of both sexes and both dosage groups ($p < 0.001$). The time to tumor development was considerably shorter in treated than in control mice. In untreated and vehicle control mice, hepatocellular carcinoma were first detected at about 90 weeks. In comparison, hepatocellular carcinomas in male mice were detected after 27 weeks (low dose) and 40 weeks (high dose) and in female mice after 41 weeks (low dose) and 50 weeks (high dose) (Table 1). The median survival times of mice were inversely related to dose. For control, low dose and high dose male mice, their median survival times were 90 weeks, 78 weeks and 43 weeks, respectively; for female mice, their median survival times were 90 weeks, 62 and 50 weeks, respectively. Early mortality occurred in all groups of rats dosed with PCE. NCI (1977) determined that the early mortality observed in rats in this bioassay were inappropriately high and because the optimum dosage was not used, the rat results preclude any conclusions regarding the carcinogenicity of PCE in rats. In addition, the PCE used in the NCI mouse and rat bioassays had a purity of 99%, with epichlorohydrin (ECH) used as a stabilizer. It has been suggested that the presence of this contaminant may have directly contributed to tumor induction.

The most definitive study of the carcinogenic potential of PCE was conducted by Battelle Pacific Northwest Laboratories for the National Toxicology Program (NTP, 1986). In this experiment,

$B6C3F_1$ mice and F344/N rats were exposed to 99.9% pure PCE by inhalation, 6 hours/day, 5 days/week for 103 weeks. Mice were exposed to concentrations of 0, 100, or 200 ppm; rats were exposed to concentrations of 0, 200, or 400 ppm. Both exposure concentrations produced significant increases in mononuclear cell leukemia in female rats (incidence in control, 18/50 animals; in rats receiving 200 ppm, 30/50; and in rats receiving 400 ppm, 29/50). Treated male rats also developed mononuclear cell leukemia in greater numbers than controls (controls, 28/50 animals; 200 ppm, 37/50; 400 ppm, 37/50) [Table 1]. Male rats (at the 200 ppm and 400 ppm PCE exposure levels) exhibited an increased incidence of both renal tubular-cell adenomas and adenocarcinomas. Although the increases were not statistically significant, they appeared to be dose-related.

Brain glioma (a rare tumor of neuroglial cells) was observed in one male control rat and in four male rats that were exposed to 400 ppm PCE (NTP, 1986). This increase was not statistically significant. However, because the historical incidence of these tumors is quite low (0.2% at Battelle Laboratories), the increased incidence in treated animals in this study is noteworthy. Both concentrations of PCE produced a statistically significant increase of hepatocellular carcinomas in treated mice of both sexes ($p < 0.001$). The incidence of these carcinomas in male mice was as follows: controls, 7/49 animals; low-dose, 25/49; and high-dose, 26/50. The incidence of hepatocellular carcinomas in treated female mice was: controls; 1/48 animals; low-dose, 13/50; high-dose, 36/50. Hepatocellular adenomas occurred in both sexes of mice and at both concentrations of PCE (Table 1). The incidence of adenomas was not statistically significant. However, the combined incidence of hepatocellular adenomas and hepatocellular carcinomas was significant. In males, the combined incidence was: controls, 16/49 animals; low-dose 31/49; ($p = 0.002$); adenomas and carcinomas was: controls, 4/48 animals; low-dose, 17/50 ($p = 0.001$); and high-dose, 38/50 ($p < 0.001$).

Table 1: PCE-induced tumor incidence in mice and rats

Study	Species	Sex	Concentration or dose	Tumor response	
				Type[a]	Incidence
NCI, 1977	Mice	Males	0 mg/kg-d	HC	2/17
			536 mg/kg-d	HC	32/49*
			1072 mg/kg-d	HC	27/48*
		Females	0 mg/kg-d	HC	2/20
			386 mg/kg-d	HC	19/48*
			772 mg/kg-d	HC	19/48*
NTP, 1986	Mice	Males	0 ppm	HC; HAC	7/49 ; 16/49
			100 ppm	HC; HAC	25/49*; 8/49(NS)
			200 ppm	HC: HAC	26/50*; 18/50(NS)
		Females	0 ppm	HC; HAC	1/48 ; 3/48
			100 ppm	HC; HAC	13/50*; 6/50(NS)
			200 ppm	HC; HAC	36/50*; 2/50(NS)

[a] HC = hepatocellular carcinomas; HAC = hepatocellular adenoma; ML = mononuclear cell leukemia.
*$p < 0.001$, Fisher Exact Test; **Probability level, Life Table Analysis. NS = not statistically significant

The NTP (1986) determined that, under the conditions of the study, there was "clear evidence of carcinogenicity" of PCE for male F344/N rats, "some evidence of carcinogenicity" of PCE for female

F344/N rats, and "clear evidence of carcinogenicity" of PCE for both sexes of $B6C3F_1$ mice. IARC reevaluated the evidence of carcinogenicity of PCE in 1987 using data from the NTP study and concluded that there was sufficient evidence that PCE is carcinogenic to animals (IARC, 1987). Other studies on PCE included those by Rampy *et al.* (1978) and Theiss *et al.* (1977). Rampy *et al.* (1978) exposed male and female Sprague-Dawley rats to PCE by inhalation (300 or 600 ppm) 6 hours/day, 5 days/week for 12 months. Animals were subsequently observed for 18 months. Pathological changes in the liver or kidney were not observed. Theiss and coworkers studied the ability of PCE to induce lung adenomas in A/St male mice (Theiss *et al.*, 1977). Animals 6 to 8 weeks old were given 80, 200, or 400 mg/kg of PCE in tricaprylin (intraperitoneally) three times a week. Each group received 14, 24, or 48 injections. Treated animals did not exhibit a significant increase in the average number of lung tumors when compared to controls.

IV. DERIVATION OF CANCER POTENCY

Basis for Cancer Potency

Perchloroethylene has been observed to induce mononuclear cell leukemia in male and female rats and liver tumors in male and female mice (NTP, 1986). CDHS (1992) decided that the tumor incidence data from this study were suitable for use in developing a quantitative risk assessment.

Methodology

Results from the 1986 NTP inhalation study were used as the basis for estimating the carcinogenic risk of PCE to humans. In this bioassay, PCE was 99.9% pure, and animals were exposed 6 hours/day, 5 days/week for 103 weeks. The mice in the 100 and 200 ppm dose groups were exposed to a time-weighted-average (TWA) of 16 and 32 ppm, respectively (e.g., 100 ppm × 6 hours/24 hours × 5 days/7 days). Similarly, rats in the 200 and 400 ppm dose groups were exposed to a TWA of 33 and 66 ppm, respectively.

The CDHS staff used the metabolized dose, adjusted to continuous lifetime exposure, to calculate the carcinogenic potency of PCE (CDHS, 1992). There are several uncertainties using this approach: 1) It was assumed that oxidative metabolism leads to the production of carcinogenic metabolites but the ultimate carcinogen(s) has not been well characterized. The metabolism of PCE is not well quantified in humans, and 20-40% of the absorbed PCE has not been accounted for. 2) The pharmacokinetic models used do not account for individual differences in metabolism and storage. The body burden depended on factors such as age, sex, exercise or workload, body mass, adipose tissue mass, pulmonary dysfunctional states, and individual differences in the intrinsic capacity to metabolize PCE.

Two pharmacokinetic models, the steady-state and the PB-PK approaches were used. They incorporated an 18.5% estimated applied dose as the fraction of the dose that is metabolized in humans. For the low-dose PCE risk assessment, the Crump multistage polynomial (Crump, 1984) was chosen.

This model, rather than a time dependent form of the multistage model, was chosen because most tumors were discovered only at the time of sacrifice, and survival in this study was relatively good. The cancer potency values derived using the two different pharmacokinetic approaches using the 1986 NTP rat and mouse studies ranged from 0.12 - 0.95 $(mg/kg\text{-}d)^{-1}$. When expressed as a function of human applied dose the values obtained ranged from 0.0025 to 0.093 $(mg/kg\text{-}d)^{-1}$. Using an estimated human weight of 70 kg, estimated breathing rate of 20 m^3/day and the PCE conversion factor of 1 ppb = 6.78 $\mu g/m^3$, the cancer unit risk values for PCE ranged from 0.2 - 7.2 $\times 10^{-5}$ $(ppb)^{-1}$. After considering the quality of the cancer bioassays and the uncertainty of human metabolism, CDHS (1992) decided that the best value for the PCE cancer unit risk was 4.0 $\times 10^{-5}$ $(ppb)^{-1}$ [5.9 $\times 10^{-6}$ $(\mu g/m^3)^{-1}$]. This value is derived from the tumor incidence data for the most sensitive species, sex, and tumor site, male mouse hepatocellular adenomas or carcinomas (NTP, 1986).

MEMORANDUM

SUBJECT: The Toxicity of Perfluorooctanic Acid (PFOA) and Perfluorooctane Sulfonate (PFOS)

FROM: Jamine Dinan, Environmental Health Scientist
Office of Emergency Management (OEM)
Office of Solid Waste and Emergency Response (OSWER)

Dave Crawford, Environmental Scientist
Office of Superfund Remediation and Technology Innovation (OSRTI)
Office of Solid Waste and Emergency Response (OSWER)

TO: Glenn Adams, Chief
Technical Services Section
Superfund Division
US EPA Region 4

Background

PFOA and PFOS have been found at sites in EPA Region 4 and in other regions. As a result, Region 4 has asked the Headquarter's Office of Superfund Remediation and Technology Innovation (OSRTI) and the Office of Emergency Management (OEM) to recommend toxicity values.

On December 5, 2003, OSRTI released guidance (OSWER Directive 9285.7-53) establishing a three-tiered hierarchy of human health toxicity values. Tier 1 is EPA's Integrated Risk Information System (IRIS). Tier 2 is the provisional peer reviewed toxicity values (PPRTVs) completed for the EPA Superfund Program by the EPA Superfund Health Risk Technical Health Risk Support Center. Tier 3 are toxicity values from other credible sources such as other federal or State agencies. Three sources of Tier 3 toxicity values were identified in

2003, but OSRTI also stated that additional Tier 3 sources may exist, and that additional Tier 3 sources may be identified in the future. As there are no toxicity values for PFOA or PFOS available in IRIS or as PPRTVs, this memorandum constitutes a Tier 3 consultation and recommends Tier 3 toxicity values for PFOA and PFOS.

Process

OSRTI and OEM consulted with several EPA program offices to discuss the use of the EPA Office of Water (OW) provisional health advisories as Tier 3 toxicity values. After weighing input from these offices, we make the following recommendations regarding the OW advisory and the interim oral non-cancer toxicity values for PFOA and PFOS.

Recommendations

On January 8, 2009 OW completed and released Provisional Health Advisories for PFOA and PFOS (See Attachment 1). Prior to the release of this assessment, OW invited, received and considered internal and external peer review comments on the then draft assessment. Although derived using methods that differ from the Superfund program's risk-based approaches, OSRTI and OEM find the OW provisional drinking water advisories of 0.4 µg/l for PFOA and 0.2 µg/l for PFOS credible as protective health-based concentrations for these contaminants in drinking water.

Because the OW provisional health advisories address only water consumption, oral reference dose values (RfDs), which can be used to address oral exposure to other media such as soil, were not developed. However, the methodology used by OW in deriving its provisional health advisories can also be used to derive subchronic RfD values for PFOA and PFOS, as shown below:

- **Perflurooctanoic Acid (PFOA)**

  For PFOA, the OW provisional health advisory relies on data from a sub-chronic study in mice (Lau, et al 2006) to derive a Benchmark Dose Level ($BMDL_{10}$) of 0.46 mg/kg-day[1]. When calculating toxicity values such as an RfD, a BMDL or a No Observed Adverse Effect Level (NOAEL) can be used to derive an RfD. In deriving an RfD for PFOA, certain numerical factors are applied to the BMDL to account for differences in the metabolism and sensitivity among test animals and humans to the effects of PFOA. Using the numerical factors presented in OW's provisional health advisory, a subchronic RfD can be developed, as follows:

[1] EPA toxicity assessments, including Integrated Risk Informaiton System (IRIS) assessments, using BML modeling in the derivation of an RfD typically use the 10% response level from the BML modeling ($BMDL_{10}$) to derive an RfD.

Subchronic RfD = $(BMDL_{10}) / UF_H * (UF_A = UF_{pharmacodynamic} * UF_{pharmacokinetic})$
= (0.46 mg/kg-day) / 10 * (3 * 81)
= **2E-4 mg/kg-day**

UF_H = a factor of 10 to account for variations in the dose-response (i.e., sensitivity) among humans to the effects of PFOS

UF_A = a factor to account for differences in the metabolism of PFOA in mice vs. humans
- $UF_{pharmacodynamic}$ = a factor of 3 to account for variations in the dose-response among mice to the effects of PFOA
- $UF_{pharmacokinetic}$ = a factor of 81[2] to account for differences in the rate of clearance of PFOA in mice vs. humans

- **Perfluorooctane Sulfonate (PFOS)**

For PFOS, the OW provisional health advisory relies on data from a sub-chronic study in monkeys (Seacat, et al. 2002) to derive a NOAEL of 0.03 mg/kg-day. As with PFOA, certain numerical factors are applied to the NOAEL to account for differences in the metabolism and sensitivity among test animals and humans to the effects of PFOS. Using the numerical factors presented in OW's provisional health advisory, a subchronic RfD can be developed, as follows:

Subchronic RfD = $(NOAEL) / UF_H * (UF_A = UF_{pharmacodynamic} * UF_{pharmacokinetic})$
= 0.03 mg/kg-day / 10 * (3 * 13)
= **8E-5 mg/kg-day**

UF_H = a factor of 10 to account for variations in the dose-response (i.e., sensitivity) among humans to the effects of PFOS
UF_A = a factor to account for differences in the metabolism of PFOS in monkeys vs. humans
- $UF_{pharmacodynamic}$ = a factor of 3 to account for variations in the dose-response among monkeys to the effects of PFOS
- $UF_{pharmacokinetic}$ = a factor of 13[3] to account for differences in the rate of clearance of PFOS in monkeys vs. humans

Currently, OEM has not established removal action levels for PFOA or PFOS as the basis for considering alternate water supplies, nor have these contaminants been addressed in the Regional Screening Levels for Chemical Contaminants at Superfund Sites. However, the Tier 3 sub-chronic RfDs presented in this memorandum may be used in the Superfund program's risk-based equations to derive Removal Action Levels and/or Screening Levels for water and other media, as appropriate.

[2] See Attachment 1, page 4 for additional details about this UF.
[3] See Attachment 1, pages 4 and 5 for additional details about this UF.

3

Please be aware that the recommendations made in this memorandum may be modified by OSRTI and OEM as the state of the science evolves with respect to deriving toxicity values and determining protective concentrations of PFOA and PFOS. Such changes may include the availability of an IRIS or a PPRTV assessment and/or the promulgation of a Safe Drinking Water Act Maximum Contaminant Level by OW.

Questions related to the use of this memorandum and its recommendations may be directed to Dave Crawford (703-603-8891) and to Janine Dinan (202-564-8737) in OEM.

OFFICE OF
LAND AND EMERGENCY
MANAGEMENT

MEMORANDUM

SUBJECT: Recommendations on the Use of Chronic or Subchronic Noncancer Values for Superfund Human Health Risk Assessments

FROM: Brigid Lowery, Director Brigid Lowery
Assessment and Remediation Division
Office of Superfund Remediation and Technology Innovation

TO: Superfund Emergency Management Divisions Directors, Regions 1 - 10

PURPOSE

The purpose of this memorandum is to provide recommendations from the Office of Land and Emergency Management (OLEM) regarding the use of the subchronic toxicity value rather than the chronic value for 19 specific chemicals as noted in the attachment.

This recommendation is based on OLEM's Human Health Regional Risk Assessment Forum's (OHHRRAF) Toxicity Workgroup evaluation of the toxicity of 32 chemicals. The OHHRRAF recommended using subchronic values in place of chronic values for 19 of the 32 chemicals OLEM concurs with the OHHRRAF recommendation. The Forum's recommendations may be applicable to EPA regional offices' activities to evaluate and address hazardous waste releases under the Comprehensive Environmental Response, Compensation and Liability Act, as amended (e.g., Hazard Ranking System scoring, remedial investigation and feasibility study process, and five-year reviews), and other OLEM risk evaluation efforts.

BACKGROUND

The Office of Solid Waste and Emergency Response[1] (OSWER) Directive 9285.7-53 **(***Human Health Toxicity Values in Superfund Risk Assessments*; December 5, 2003; commonly referred to as "the 2003 hierarchy guidance"), identifies an updated source hierarchy for human health toxicity values to consider when carrying out Superfund site risk assessments. It also states that "[t]his revised hierarchy recognizes that EPA should use the best science available on which to base risk assessments." Furthermore, the 2003 hierarchy guidance states that, "EPA and state personnel may use and accept other technically sound approaches," acknowledging "that there may be other sources of toxicological information," referring specifically to OSWER Directive

[1] The former name of what is now EPA's Office of Land and Emergency Management.

9285.7-16 (*Use of IRIS Values in Superfund Risk Assessment*; December 21, 1993), which offers similar guidance.[2]

The OHHRRAF Toxicity Workgroup identified 21 oral and 11 inhalation toxicity values where a subchronic toxicity value was lower than its corresponding chronic toxicity value. After review of relevant information, the Forum recommends use of the subchronic toxicity value rather than the chronic value for 19 of the 32. For the remaining 13 chemical toxicity values, the Forum recommends the chronic toxicity values be used.

The recommendations in the memorandum will be re-evaluated in the future as toxicity values are updated.

Please contact Michele Burgess (703-603-9003) or Laurence Libelo (703-603-8815) if you have any questions or require additional information.

[2] See OSWER Directive 9285.7-53, page 2, quoting OSWER Directive 9285.7-16: "...IRIS is not the only source of toxicology information, and in some cases more recent, credible and relevant data may come to the Agency's attention. In particular, toxicological information other than that in IRIS may be brought to the Agency by outside parties. Such information should be considered along with the data in IRIS in selecting toxicological values; ultimately, the Agency should evaluate risk based upon its best scientific judgement and consider all credible and relevant information available to it."

[a]Decisions regarding the most appropriate toxicity value when the subchronic value was more conservative than the chronic value in the Regional Screening Levels (RSLs).
[b]Intermediate-duration MRL = 0.02 ppm
[c]Intermediate-duration MRL = 0.07 ppm
[d]Intermediate-duration MRL = 0.01 ppm
[e]Intermediate-duration MRL = 0.03 ppm
[f]Values for food/water.
[g]Chronic-duration MRL; an intermediate-duration MRL of 0.0005 mg/kg-day was also available (ATSDR 2012).
*Indicates that selection of the subchronic value.

1. **Decisions that Require a Change in the RSLs (Inhalation).**

Acrylic Acid (CASRN 79-10-7). The IRIS chronic RfC (1994) and the PPRTV subchronic p-RfC (2010) are based on the same study (Miller et al. 1981). However, the PPRTV used BMD modeling and dosimetric conversion factors to account for pharmacokinetics differences between mice and people. The PPRTV value is selected based on the use of updated methodology.

Summary Table for Acrylic Acid (CASRN 79-10-7)		
Source (Year)	**IRIS (1994)**	**PPRTV (2010)**
Toxicity Value	Chronic RfC	Subchronic p-RfC
Critical Study	Miller et al. 1981	
Species/Strain/Sex	B6C3F1 mice (15/sex/group)	
Study Duration	6 hours/day, 5 days/week, for 13 weeks	
Critical Effect(s)	Focal degeneration of the nasal olfactory epithelium	
POD	$LOAEL_{[HEC]}$ = 0.33 mg/m^3	$BMDL10_{[HEC]}$ = 0.02 mg/m^3
Composite UF	300[a]	100[b]
Toxicity Value (mg/m^3)	0.001	0.0002
Selected Value (mg/m^3)	0.0002	
Rationale	Updated methodology	

[a]The composite UF of 300 is based on 10 for UF_H, 3 for UF_S, 3 for UF_A, and 3 for UF_L.
[b]The composite UF of 100 if based on 3 for UF_A, 10 for UF_H, and 3 for UF_D

2-Ethoxyethanol (2-EE) (CASRN 110-80-5). The subchronic p-RfC (PPRTV 2013) is based on a developmental toxicity study. The PPRTV determined that, based on duration-adjusted concentrations, minor and major skeletal defects in the offspring of Dutch rabbits (Doe 1984b) is a more sensitive endpoint than testicular (and hematological) effects in adult New Zealand White rabbits (Barbee et al. 1984a), which was the critical effect identified by IRIS (1991). In support, fetal effects (minor skeletal defects) were also observed in a developmental toxicity study using Wistar rats (Doe 1984b). BMD modeling (i.e., updated methodology) was used in the PPRTV assessment to determine the POD (compared to the IRIS $NOAEL_{HEC}$). A benchmark response (BMR) of 5% extra risk was used; it is standard EPA practice to use a BMR of 5% for developmental endpoints. Although the data from Doe (1984b) were provided on a per pup basis (rather than a per-litter basis), the sample size of each exposure group was calculated from the data provided. The PPRTV also noted that BMD modeling could not be applied to the less sensitive endpoints from the Barbee et al. (1984a) study because an abnormally large standard deviation was reported for one of the testis weights values, and no quantitative data for seminiferous tubule degeneration were provided. The PPRTV value is selected based on the evaluation of sensitive (developmental) endpoints and the use of updated methodology.

Summary Table for 2-Ethoxyethanol (CASRN 110-80-5)		
Source (Year)	**IRIS (1991)**	**PPRTV (2013)**
Toxicity Value	Chronic RfC	Subchronic p-RfC
Critical Study	Barbee et al. 1984a	Doe 1984b
Species/Strain/Sex	New Zealand White rabbits (10/sex/group)	Dutch rabbits (24 females/group)
Study Duration	6 hours/day, 5 days/week for 13 weeks	6 hours/day on GDs 6-18
Critical Effect(s)	Decreased hemoglobin, decreased testis weight, and seminiferous tubule degeneration	Fetal skeletal effects
POD	$NOAEL_{[HEC]}$ of 68 mg/m^3	$BMDL_{[5\%HEC]}$ of 4.23 mg/m^3
Composite UF	300[a]	100[b]
Toxicity Value (mg/m^3)	0.2	0.04
Selected Value (mg/m^3)	0.04	

Rationale	Different study; updated methodology

[a]The composite UF of 300 is based on 3 for UF_A, 10 for UF_H, and 10 for UF_S.

Vinyl Chloride (CASRN 75-01-4). The IRIS assessment is based on a dietary study that used PBPK modeling for route-to-route (R2R) extrapolation. The ATSDR assessment is based on a study (Thornton et al., 2002) that was not available when the IRIS assessment was completed (2000). Other differences between the ATSDR intermediate-duration MRL (2006) and the IRIS chronic RFC (2000) were due to rounding. IRIS divided the POD of 2.5 mg/m^3 by the composite uncertainty factor (UF_C) of 30 to arrive at 0.08 mg/m^3, which was rounded to 0.1 mg/m^3. ATSDR identified a POD of 1.25 ppm, which was rounded to 1 ppm prior to the application of uncertainty factors. The POD divided by the UF_C of 30 generated an intermediate-duration MRL of 0.03 ppm; using the conversion factor 1 ppm = 2.56 mg/m^3 resulted in a toxicity value of 0.08 mg/m^3. Differences in the toxicity values is an artifact of the derivation process used by each agency. The ATSDR value is selected based on new information.

Summary Table for Vinyl Chloride (CASRN 75-01-4)		
Source (Year)	**IRIS (2000)**	**ATSDR (2006)**
Toxicity Value	Chronic RfC	Intermediate-duration MRL
Critical Study	Til et al. 1983, 1991	Thornton et al. 2002
Species/Strain/Sex	Wistar rats (50 to 100/sex/group)	Sprague-Dawley rats (30/sex/group)
Study Duration	Lifetime dietary	4 hours/day for two generations
Critical Effect(s)	Liver cell polymorphism	Centrilobular hypertrophy (F1 females)
POD	$NOAEL_{[HEC]}$ = 2.5 mg/m^3 (based on PBPK model R2R extrapolation)	$LEC_{[10HEC]}$ = 1 ppm
Composite UF	30[a]	30[b]
Toxicity Value	0.1 mg/m^3	0.03 ppm (0.08 mg/m^3)
Selected Value (mg/m^3)	0.08	
Rationale	New study	

[a]The composite UF of 30 is based on 3 for UF_A, and 10 for UF_H.
[b]The composite UF of 30 is based on 3 for UF_A, and 10 for UF_H.

2. Decisions that Require a Change in the RSLs (Oral).

Acrylonitrile (CASRN 107-13-1). The study used to derive the intermediate-duration MRL (Tandon, 1988) identified a serious LOAEL for decreased sperm count and testicular tubule degeneration at 10 mg/kg-day and used a UF_C of 1000 to derive a chronic-duration MRL of 0.01 mg/kg-day (see footnote f of Table 2-2 in the ATSDR Toxicological Profile). According to the same table, the chronic-duration MRL was derived from Biodynamics (1980) based on a NOAEL of 4.2 mg/kg-day for decreased red blood cells (footnote h). Figure 2-2 erroneously shows that the chronic-duration MRL was derived from Biodynamics (1980) using a NOAEL based on decreased red blood cells of 0.14 mg/kg-day. The intermediate-duration ATSDR value is selected because it is more protective than the chronic-duration MRL.

Summary Table for Acrylonitrile (CASRN 107-13-1)		
Source (Year)	**ATSDR (1990)**	**ATSDR (1990)**
Toxicity Value	Chronic-duration MRL	Intermediate-duration MRL
Critical Study	Biodynamics 1980	Tandon 1988
Species/Strain/Sex	F344 rats	Mice
Study Duration	24 months	60 days
Critical Effect(s)	Decreased red cells	Decreased sperm count and testicular tubule degeneration
POD	NOAEL = 4.2 mg/kg-day	LOAEL = 10 mg/kg-day
Composite UF	100[a]	1000[b]
Toxicity Value (mg/kg-day)	0.04	0.01
Selected Value (mg/kg-day)	0.01	
Rationale	Different methodology	

[a]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.
[b]The composite UF of 1000 is based on 10 for UF_A, 10 for UF_H, and 10 for UF_L.

Atrazine (CASRN 1912-24-9). The intermediate-duration MRL from ATSDR (2003) is based on a study (Gojmerac et al. 1999) that was not available at the time of the IRIS assessment (1993). The critical effect identified by ATSDR is indicative of the potential for endocrine disruption, and results in a lower toxicity value than the chronic RfD. The ATSDR value is selected based on new information.

Summary Table for Atrazine (CASRN 1912-24-9)		
Source (Year)	**IRIS (1993)**	**ATSDR (2003)**
Toxicity Value	Chronic RfD	Intermediate-duration MRL
Critical Study	Ciba-Geigy Corp. 1986	Gojmerac et al. 1999
Species/Strain/Sex	Sprague-Dawley rats (20/sex/group)	Swedish Landance/Large Yorkshire pigs (9 young females/group)
Study Duration	2 years	19 days
Critical Effect(s)	Decreased body weight gain	Delayed estrus
POD	NOAEL = 3.5 mg/kg-day	LOAEL = 1 mg/kg-day
Composite UF	100[a]	300[b]
Toxicity Value (mg/kg-day)	0.035	0.003
Selected Value (mg/kg-day)	0.003	
Rationale	New study	

[a]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.
[b]The composite UF of 300 is based on 10 for UF_A, 3 for UF_H, and 10 for UF_L.

p-Chloroaniline (CASRN 106-47-8). The subchronic p-RfD (PPRTV 2008) is based on a study (NTP 1989) that was not available when the IRIS assessment was completed (1988). The PPRTV value is selected based on new information.

Summary Table for p-Chloroaniline (CASRN 106-47-8)		
Source (Year)	**IRIS (1988)**	**PPRTV (2008)**
Toxicity Value	Chronic RfD	Subchronic p-RfD
Critical Study	NCI 1979	NTP 1989
Species/Strain/Sex	F344 rats (20 to 50/sex/group)	F344 rats (15/sex/group)
Study Duration	78 weeks (24 weeks observation)	6 months (interim)
Critical Effect(s)	Non-neoplastic lesions of splenic capsule	Methemoglobin formation
POD	LOAEL = 12.5 mg/kg-day	$LOAEL_{[ADJ]}$ = 1.4 mg/kg-day
Composite UF	3000[a]	3000[b]
Toxicity Value (mg/kg-day)	0.004	0.0005
Selected Value (mg/kg-day)	0.0005	
Rationale	New study	

[a]The composite UF of 3000 is based on 10 for UF_A, 10 for UF_H, 10 for UF_L, and 3 for UF_D.
[b]The composite UF of 3000 is based on 10 for UF_A, 10 for UF_H, 3 for UF_L, and 10 for UF_D.

p-Cresol (CASRN 106-44-5). The chronic-duration MRL (ATSDR 2008) was based on a 2-year study that used a mixture of p- and m-cresols (CASRNs 95-48-7, 108-39-4, 1319-77-3, and 106-44-5); ATSDR considers the BRRC (1998) study, used in the PPRTV assessment to derive a subchronic p-RfD, an acute toxicity study (as per ATSDR policy). The PPRTV value is selected based on new information (i.e., data from a study not considered relevant to the ATSDR chronic-duration MRL).

Summary Table for p-Cresol (CASRN 106-44-5)		
Source (Year)	**ATSDR (2008)**	**PPRTV (2010)**
Toxicity Value	Chronic-duration MRL	Subchronic p-RfD
Critical Study	NTP 2008	BRRC 1988
Species/Strain/Sex	B6C3F1 mice (50/sex/group)	New Zealand White rabbits (14 females/group)
Study Duration	2 years	GDs 6-18
Critical Effect(s)	Bronchiolar hyperplasia of the lung and thyroid follicular degeneration	Mortality and clinical signs

POD	LOAEL = 100 mg/kg-day	NOAEL = 5 mg/kg-day
Composite UF	1000[a]	300[b]
Toxicity Value (mg/kg-day)	0.1	0.02
Selected Value (mg/kg-day)	0.02	
Rationale	Different study	

[a]The composite UF of 1000 is based on 10 for UF_A, 10 for UF_H, and 10 for UF_L
[b]The composite UF of 300 is based on 10 for UF_A, 10 for UF_H, and 3 for UF_D.

Ethyl Acetate (CASRN 141-78-6). The IRIS assessment and the PPRTV are based on the same study (American Biogenics 1986), but the PPRTV assessment (2013) used body weight$^{3/4}$ to calculate a human equivalent dose and reduced the interspecies UF to 3. The PPRTV value is selected based on updated methodology.

Summary Table for Ethyl Acetate (CASRN 141-78-6)		
Source (Year)	**IRIS (1987)**	**PPRTV (2013)**
Toxicity Value	Chronic RfC	Subchronic p-RfC
Critical Study	American Biogenics 1986	
Species/Strain/Sex	Sprague-Dawley rats (30/sex/group)	
Study Duration	90 days	
Critical Effect(s)	Mortality and body weight loss	Clinical signs
POD	NOAEL = 900 mg/kg-day	$NOAEL_{[HED]}$ = 216 mg/kg-day
Composite UF	1000[a]	300[b]
Toxicity Value (mg/m^3)	0.9	0.7
Selected Value (mg/m^3)	0.7	
Rationale	Updated methodology	

[a]The composite UF of 1000 is based on 10 for UF_A, 10 for UF_H, and 10 for UF_S.
[b]The composite UF of 300 is based on 3 for UF_A, 10 for UF_H, and 10 for UF_D.

Ethylbenzene (CASRN 100-41-4). The PPRTV assessment (2009) used BMD methodology and a toxicity study that was not available at the time of the IRIS assessment (1987). The PPRTV value is selected based on new information and the use of updated methodology.
*Note: The IRIS program is updating this assessment.

Summary Table Ethylbenzene (CASRN 100-41-4)

Source (Year)	IRIS (1987)	PPRTV (2009)
Toxicity Value	Chronic RfD	Subchronic p-RfD
Critical Study	Wolf et al. 1956	Mellert et al. 2007
Species/Strain/Sex	Albino rats (10 females/group and 20 female controls)	Wistar rats (10/sex/group)
Study Duration	5 days/week for 182 days	7 days/week for 13 weeks
Critical Effect(s)	Liver and kidney toxicity	Centrilobular hepatocyte hypertrophy (males)
POD	NOAEL = 97.1 mg/kg-day	$BMDL_{10}$ = 48 mg/kg-day
Composite UF	1000[a]	1000[b]
Toxicity Value (mg/kg-day)	0.1	0.05
Selected Value (mg/kg-day)	0.05	
Rationale	New study; updated methodology	

[a]The composite UF of 1000 is based on 10 for UF_A, 10 for UF_H, and 10 for UF_S.
[b]The composite UF of 1000 is based on 10 for UF_A, 10 for UF_H, and 10 for UF_D.

Ethylene Glycol (CASRN 107-21-1). ATSDR (2010) used a new study (Neeper-Bradley et al. 1995) that was not available when the IRIS assessment was completed (1987). In addition, the ATSDR assessment used BMD modeling to determine the POD (i.e., updated methodology). The ATSDR value is selected based on new information and the use of updated methodology.

Summary Table Ethylene Glycol (CASRN 107-21-1)		
Source (Year)	IRIS (1987)	ATSDR (2010)
Toxicity Value	Chronic RfD	Intermediate-duration MRL
Critical Study	DePass et al. 1986	Neeper-Bradley et al. 1995; Tyl 1989
Species/Strain/Sex	F344 rats (30/sex/group)	CD-1 mice (30 females/group)
Study Duration	2 years	GDs 6-15
Critical Effect(s)	Kidney toxicity	Bilateral extra lumbar ribs (offspring)
POD	NOEL = 200 mg/kg-day	$BMDL_{10}$ = 75.59 mg/kg-day
Composite UF	100[a]	100[b]
Toxicity Value (mg/kg-day)	2	0.8
Selected Value (mg/kg-day)	0.8	
Rationale	New study; updated methodology	

[a]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.
[b]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.

Heptachlor (CASRN 76-44-8). The ATSDR assessment derived a toxicity value based on developmental toxicity studies (Smialowicz et al. 2000; Moser et al. 2001) that evaluated sensitive endpoints and were not available when the IRIS assessment was completed (1987). The ATSDR value is selected based on the evaluation of sensitive (developmental) endpoints and new information.

Summary Table Heptachlor (CASRN 76-44-8)		
Source (Year)	**IRIS (1987)**	**ATSDR (2007)**
Toxicity Value	Chronic RfD	Intermediate-duration MRL
Critical Study	Velsicol Chemical 1955	Smialowicz et al. 2001†; Moser et al. 2001*
Species/Strain/Sex	CF white rats (20/sex/group)	Sprague-Dawley rats (15 to 20 females/group)
Study Duration	2 years	†GD 12-PND 71; pups exposed to day 42 *GD 12-PND 7 (dams); *PND 7-PND 21 or 42 (pups)
Critical Effect(s)	Increased liver weight (males)	†Immunological and *neurological effects
POD	NOEL = 0.15 mg/kg-day	LOAEL = 0.03 mg/kg-day
Composite UF	300[a]	300[b]
Toxicity Value (mg/kg-day)	0.0005	0.0001
Selected Value (mg/kg-day)	0.0001	
Rationale	New study	

[a]The composite UF of 300 is based on 10 for UF_A, 10 for UF_H, and 3 for UF_D.
[b]The composite UF of 300 is based on 10 for UF_A, 10 for UF_H, and 3 for UF_L.

Hexachlorobenzene (CASRN 118-74-1). The PPRTV (2010) derived a toxicity value from a study (Bourque et al. 1995) that was not available when the IRIS assessment was completed (1988). The PPRTV value is selected based on new information.

Summary Table Hexachlorobenzene (CASRN 118-74-1)		
Source (Year)	**IRIS (1988)**	**PPRTV (2010)**
Toxicity Value	Chronic RfD	Subchronic p-RfD
Critical Study	Arnold et al. 1985	Bourque et al. 1995
Species/Strain/Sex	Sprague-Dawley rats (50/sex/group)	Cynomolgus monkeys (4 females/group)
Study Duration	130 weeks	13 weeks
Critical Effect(s)	Liver effects	Degenerative changes in primary and growing ovarian follicles

POD	NOAEL = 0.08 mg/kg-day	LOAEL = 0.01 mg/kg-day
Composite UF	100[a]	1000[b]
Toxicity Value (mg/kg-day)	0.0008	0.00001
Selected Value (mg/kg-day)	0.00001	
Rationale	New study	

[a]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.
[b]The composite UF of 1000 is based on 10 for UF_A, 10 for UF_H, and 10 for UF_L.

Hexachlorocyclohexane, gamma (CASRN 58-89-9). The ATSDR assessment (2005) derived a toxicity value based on a study (Meera et al. 1992) that was not available when the IRIS assessment was completed (1987). The ATSDR value is based on the use of a newer and longer study (24-week study). Despite the use of fewer animals (6 females/group), the study is of higher quality than the principal study used for the IRIS assessment (Zoecon Corp. 1983) and identified a lower POD. The ATSDR value is selected based on new information.

Summary Table Hexachlorocyclohexane (CASRN 58-89-9)		
Source (Year)	**IRIS (1987)**	**ATSDR (2005)**
Toxicity Value	Chronic RfD	Intermediate-duration MRL
Critical Study	Zoecon Corp. 1983	Meera et al. 1992
Species/Strain/Sex	Wistar KFM-Han rats (20/sex/group)	Swiss mice (6 females/group)
Study Duration	12 weeks; 5/sex/group maintained on control diet for an additional 6 weeks	Up to 24 weeks
Critical Effect(s)	Liver and kidney toxicity (females)	Reduced activity of lymphoid follicles with prominent megakaryocytes and delayed hypersensitivity to immune challenge
POD	NOAEL = 0.33 mg/kg-day	LOAEL = 0.012 mg/kg-day
Composite UF	1000[a]	1000[b]
Toxicity Value (mg/kg-day)	0.0003	0.00001
Selected Value (mg/kg-day)	0.00001	
Rationale	New study	

[a]The composite UF of 1000 is based on 10 for UF_A, 10 for UF_H, and 10 for UF_S.
[b]The composite UF of 1000 is based on 10 for UF_A, 10 for UF_H, and 10 for UF_L.

1,2,4,5-Tetrachlorobenzene (CASRN 95-94-3). The PPRTV (2013) derived a toxicity value from a 28-day study that identified a LOAEL (0.041 mg/kg-day for thyroid effects) lower than the NOAEL (0.34 mg/kg-day for liver effects) in a chronic study used in the IRIS assessment (1987). The Chu et al. (1983) study, while mentioned in the IRIS assessment summary, was not considered for the derivation of a chronic RfD (duration < 90 days). In addition, the PPRTV assessment used body weight$^{3/4}$ to derive the POD. The PPRTV value is selected based on the use of updated methodology.

Summary Table 1,2,4,5-Tetrachlorobenzene (CASRN 95-94-3)		
Source (Year)	**IRIS (1987)**	**PPRTV (2013)**
Toxicity Value	Chronic RfD	Subchronic p-RfD
Critical Study	Chu et al. 1984	Chu et al. 1983
Species/Strain/Sex	Weanling Sprague-Dawley rats (15/sex/group)	Sprague-Dawley rats (10/sex/group)
Study Duration	13 weeks	28 days
Critical Effect(s)	Kidney lesions	Thyroid toxicity (males)
POD	NOAEL = 0.34 mg/kg-day	$LOAEL_{[HED]}$ = 0.0098 mg/kg-day
Composite UF	1000[a]	300[b]
Toxicity Value (mg/kg-day)	0.0003	0.00003
Selected Value (mg/kg-day)	0.00003	
Rationale	Different study; updated methodology	

[a]The composite UF of 1000 is based on 10 for UF_A, 10 for UF_H, and 10 for UF_S.
[b]The composite UF of 300 is based on 3 for UF_A, 10 for UF_H, and 10 for UF_L.

3. Decisions that Require No Change in the RSLs (Inhalation).

Ammonia (CASRN 7664-41-7). The IRIS chronic RfC (2016) and the PPRTV subchronic p-RfC (2005) are based on the same study (Holness et al. 1989). However, the IRIS assessment included more details with respect to the occupational cohort and used a different approach to select the POD. The IRIS assessment also indicated that, although there are no developmental toxicity studies and studies of reproductive and other systemic endpoints are limited, the likelihood of effects at the RfC is small because: 1) ammonia is endogenously produced in humans and animals, and changes in blood ammonia levels at the POD would be small relative to normal blood ammonia levels; and 2) EPA is not aware of any mechanisms by which ammonia can exert effects at the point of contact (the respiratory system) that could directly or indirectly affect tissues distal to the point of contact. The more recent and highly-peer reviewed IRIS value (2016) is chosen as a Tier 1 value using standard EPA methods (e.g., application of UFs). The IRIS value is retained based on updated methodology.

Summary Table for Ammonia (CASRN 7664-41-7)		
Source (Year)	**IRIS (2016)**	**PPRTV (2005)**
Toxicity Value	Chronic RfC	Subchronic p-RfC
Critical Study	Holness et al. 1989	
Species/Strain/Sex	52 humans; occupationally exposed	
Study Duration	Average = 12.2 years	
Critical Effect(s)	Decreased lung function and respiratory symptoms	
POD	$NOAEL_{[HEC]}$ = 4.9 mg/m^3	$NOAEL_{[HEC]}$ = 2.3 mg/m^3
Composite UF	10[a]	30[b]
Toxicity Value (mg/m^3)	0.5	0.1
Selected Value (mg/m^3)	0.5	
Rationale	Updated IRIS assessment (including methodology and application of UFs)	

[a]The composite UF of 10 is based on 10 for UF_H.
[b]The composite UF of 30 if based on 10 for UF_H, and 3 for UF_D.

Chlordane (CASRN 12789-03-6). Minor hepatic effects (hepatocellular vacuolization and hypertrophy) identified as adverse by ATSDR (1994) were not considered biologically significant in the IRIS assessment (1998). The IRIS assessment considered the NOAEL to be 1.0 mg/m^3 (rather than 0.1 mg/m^3), adjusted for continuous exposure, applied the regional deposited dose ratio (RDDR) to extrapolate from rats to humans, lowered the UF for interspecies extrapolation (UF_A) from 10 to 3, and accounted for the lack of a reproduction study (UF_D). The IRIS value is retained based on the use of updated methodology.

Summary Table for Chlordane (CASRN 12789-03-6)		
Source (Year)	**IRIS (1998)**	**ATSDR (1994)**
Toxicity Value	Chronic RfC	Intermediate-duration MRL
Critical Study	Khasawinah et al. 1989	
Species/Strain/Sex	Wistar rats (35 to 47/sex/group)	
Study Duration	8 hours/day, 5 days/week, for 13 weeks	
Critical Effect(s)	Increased liver weight and changes in blood chemistry	Mild liver lesions and changes in blood chemistry
POD	$NOAEL_{[HEC]}$ = 0.65 mg/m^3	NOAEL[ADJ] = 0.024 mg/m^3
Composite UF	1000[a]	100[b]

Toxicity Value (mg/m^3)	0.0007	0.0002
Selected Value (mg/m^3)	0.0007	
Rationale	Updated methodology	

[a]The composite UF of 1000 is based on 3 for UF_A, 3 for UF_D, 10 for UF_H, and 10 for UF_S.
[b]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.

1,1-Dichloroethylene (CASRN 75-35-4). Compared to the ATSDR intermediate-duration MRL (1994), the IRIS chronic RfC (2002) was based on a later study that evaluated a more comprehensive set of endpoints, used the 1994 Inhalation Dosimetry approach to calculate the HEC, and used BMD methodology. Chronic-duration studies (e.g., Quast et al. 1986) were not considered in the derivation of an intermediate-duration MRL. ATSDR did not derive a chronic-duration MRL based on the Quast et al. (1986) study because a serious LOAEL was identified for developmental effects following acute-duration exposure at a lower exposure concentration, precluding the derivation of a chronic-duration MRL. The IRIS value is retained based on new information (i.e., a study not considered for the derivation of the intermediate-duration MRL) and the use of updated methodology.

Summary Table for 1,1-Dichloroethylene (CASRN 75-35-4)		
Source (Year)	**IRIS (2002)**	**ATSDR (1994)**
Toxicity Value	Chronic RfC	Intermediate-duration MRL
Critical Study	Quast et al. 1986	Prendergast et al. 1967
Species/Strain/Sex	Sprague-Dawley rats (86 animals/group)	Hartley guinea pigs (15/group)
Study Duration	6 hours/day, 5 days/week, for up to 18 months	24 hours/day for 90 days
Critical Effect(s)	Liver toxicity (fatty change)	Liver effects (increased ALT and AP; decreased lipid content)
POD	$BMDL_{[10HEC]}$ = 6.9 mg/m^3	NOAEL = 5 ppm
Composite UF	30[a]	300[b]
Toxicity Value	0.2 mg/m^3	0.02 ppm (0.08 mg/m^3)
Selected Value (mg/m^3)	0.2	
Rationale	Different study and updated methodology	

[a]The composite UF of 30 is based on 3 for UF_A, and 10 for UF_H.
[b]The composite UF of 300 if based on 10 for UF_H, 10 for UF_A, and 3 as a modifying factor to account for the close proximity of serious effects observed at the range of 10-25 ppm.

Methyl *tert*-Butyl Ether (MTBE) (CASRN 1634-04-4). The IRIS chronic RfC (1993) is based on a chronic inhalation study (Chun et al. 1992); the ATSDR intermediate-duration MRL (1996) is based on a reproductive study (Neeper-Bradley 1991). Each study was evaluated in both assessments; dosimetric conversion factors were used in the IRIS assessment. The other difference between the two toxicity values is the conversion of the ATSDR MRL from ppm to mg/m^3. Rounded to one significant figure, the two reference values are identical. The RSL tables round to two digits and values; however, values are added as shown in the source document. The IRIS value is retained based on a different study (that results in a similar toxicity value as the intermediate-duration MRL) and the use of updated methodology.

Summary Table for MTBE (CASRN 1634-04-4)		
Source (Year)	**IRIS (1993)**	**ATSDR (1996)**
Toxicity Value	Chronic RfC	Intermediate-duration MRL
Critical Study	Chun et al. 1992	Neeper-Bradley 1991
Species/Strain/Sex	F344 rats (50/sex/group)	CD Sprague-Dawley rats (25/sex/group)
Study Duration	6 hours/day, 5 days/week, for 24 months	6 hours/day, 5 days/week, for up to 19 weeks
Critical Effect(s)	Increased liver and kidney weights; increased severity of renal lesions; clinical signs	Hypoactivity, lack of startle response, blepharospasm
POD	$NOAEL_{[HEC]}$ = 259 mg/m^3	$NOAEL_{[ADJ]}$ = 71 ppm
Composite UF	100[a]	100[b]
Toxicity Value	3 mg/m^3	2.5 mg/m^3 (0.7 ppm)
Selected Value (mg/m^3)	3	
Rationale	Different study; updated methodology	

[a]The composite UF of 100 is based on 3 for UF_A, 3 for UF_D, and 10 for UF_H.
[b]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.

Nitromethane (CASRN 75-52-5). The PPRTV subchronic and chronic p-RfC (2013) are based on the same study (NTP 1997). However, to derive the chronic p-RFC, the PPRTV used the phase of the study that was longer and used more animals (50/group rather than 10/group). The larger number of animals reduces the confidence limits when the BMD methodology is used. The chronic p-RfC value is retained based on new information (i.e., consideration of the longer/more robust phase of the same principal study).

Summary Table for Nitromethane (CASRN 75-52-5)		
Source (Year)	**PPRTV (2013)**	**PPRTV (2013)**
Toxicity Value	Chronic p-RfC	Subchronic p-RfC
Critical Study	NTP 1997	
Species/Strain/Sex	B6C3F1 mice (50/sex/group)	B6C3F1 mice (10/sex/group)
Study Duration	6.2 hours/day, 5 days/week, for 103 weeks	6.2 hours/day, 5 days/week, for 13 weeks
Critical Effect(s)	Hyaline degeneration of the respiratory epithelium	Hyaline droplets of the respiratory epithelium
POD	$BMDL_{[10HEC]}$ = 1.60 mg/m^3	$BMDL_{[10HEC]}$ = 1.31 mg/m^3
Composite UF	300[a]	300[b]

Toxicity Value (mg/m^3)	0.005	0.004
Selected Value (mg/m^3)	0.005	
Rationale	Same study	

[a]The composite UF of 300 is based on 3 for UF_A, 10 for UF_H, and 10 for UF_D.
[b]The composite UF of 300 is based on 3 for UF_A, 10 for UF_H, and 10 for UF_D.

Vinyl Acetate (CASRN 108-05-4). IRIS (1990) and ATSDR (1992) used 104-week and 90-day studies, respectively. The NOAEL/LOAEL and the toxicological endpoint are the same in both studies. IRIS applied the regional gas dose to respiratory region (RGDR) to extrapolate from rats to humans and lowered the UF for interspecies extrapolation (UF_A) from 10 to 3. ATSDR also applied the RGDR conversion but retained the UF_A at 10. The difference between the toxicity values is the selection of UFs. The decision about the most appropriate value to use does not consider the UFs used (which is subjective) but rather evaluates whether new information was available and/or updated methodology was used. The IRIS value is retained because the intermediate-duration MRL is not based on new information or updated methodology.

Summary Table for Vinyl Acetate (CASRN 108-05-4)		
Source (Year)	**IRIS (1990)**	**ATSDR (1992)**
Toxicity Value	Chronic RfC	Intermediate-duration MRL
Critical Study	Owen 1988; Beems 1988, Dreef-van der Meulen 1988	Hazleton 1980
Species/Strain/Sex	(Crl:CD-1[ICR]BR) mice (90/sex/group)	CD-1 mice (10/sex/group)
Study Duration	6 hours/day, 5 days/week, for 104 weeks	6 hours/day, 5 days/week, for 90 days
Critical Effect(s)	Nasal epithelial lesions	Respiratory effects (inflammation of nasal turbinate epithelium; mild multifocal bronchitis)
POD	$NOAEL_{[HEC]}$ = 5 mg/m^3	$NOAEL_{[HEC]}$ = 5 mg/m^3
Composite UF	30[a]	100[b]
Toxicity Value	0.2 mg/m^3	0.05 mg/m^3 (0.01 ppm)
Selected Value (mg/m^3)	0.2	
Rationale	Different methodology (selection of UFs)	

[a]The composite UF of 30 is based on 3 for UF_A, and 10 for UF_H.
[b]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.

4. Decisions that Require No Change in the RSLs (Oral).

Acrylamide (CASRN 79-06-1). The ATSDR (2012) assessment identified a study with a lower HED than the study used by IRIS (2010). The ATSDR assessment calculated the HED using a PBPK rat model (Sweeney et al. 2010). The rat PBPK model was used to estimate rat dose metrics to predict the rat blood time-weighted average (TWA) acrylamide dose associated with the rat NOAEL of 0.2 mg/kg/day, resulting in an HED of 0.038 mg acrylamide/kg/day The IRIS assessment used BMD modeling to characterize the dose-response relationship and determine the POD, resulting in a $BMDL_{05HED}$ of 0.27 mg/kg/day. A different method (using ADME data) was used to calculate the HED in the IRIS assessment. An internal dose in the rat (area under a time-concentration curve, AUC) was derived from the external exposure to acrylamide based on methods and data that characterize the relationship between hemoglobin adducts, serum levels, and administered dose as reported in several rat studies. The studies were used to estimate the internal dose in rats, to extrapolate to an internal dose in humans, and to estimate the daily human intake of acrylamide needed to produce that internal human dose. Advantages to the IRIS value include 1) effects observed at the LOAEL in Burek et al. (1980) were slight and reversible, 2) the identification of a NOAEL for the Burek et al. (1980) study was limited by the selection of dose levels, 3) the IRIS assessment considered Burek et al. (1980) and other chronic-duration studies and used updated methodology when the toxicity value was updated in 2010, and 4) the selection of the IRIS value adheres to the toxicity hierarchy (and there is no overwhelming evidence to switch to a similar toxicity value based on subchronic exposure). The IRIS value was retained based on a different study and updated methodology.

Summary Table for Acrylamide (CASRN 79-06-1)		
Source (Year)	**IRIS (2010)**	**ATSDR (2012)**
Toxicity Value	Chronic RfD	Intermediate-duration MRL
Critical Study	Johnson et al. 1986	Burek et al. 1980
Species/Strain/Sex	F344 rats (90/sex/group)	F344 rats (10/sex/group)
Study Duration	Up to 2 years	Up to 93 days
Critical Effect(s)	Degenerative nerve changes	Neurological effects (ultrastructural degeneration in sciatic nerve fibers)
POD	$BMDL_{[05HED]}$ = 0.053 mg/kg-day	$NOAEL_{[HED]}$ = 0.038 mg/kg-day
Composite UF	30[a]	30[b]
Toxicity Value (mg/kg-day)	0.002	0.001
Selected Value (mg/kg-day)	0.002	
Rationale	Updated methodology	

[a]The composite UF of 30 is based on 3 for UF_A, and 10 for UF_H.
[b]The composite UF of 30 is based on 3 for UF_A, and 10 for UF_H.

Acrylic Acid (CASRN 79-10-7). The PPRTV (2010) and IRIS (1994) assessments used the same study. However, the PPRTV included a UF_D of 3 to account for the lack of a developmental study by oral exposure. The PPRTV assessment noted that BMD modeling could not be performed because of the lack of measured variation for the critical endpoint. The assessment relied heavily on the published version of the study (Hellwig et al. 1997); additional data are available in the unpublished version (BASF 1993). The IRIS assessment indicated that an uncertainty factor for database inadequacy was not considered necessary owing to evidence from bioavailability studies (oral and intravenous routes) that there is no difference in the rate of elimination of acrylic acid in rats and mice. The IRIS value was retained because the PPRTV value is not based on new information or updated methods.

Summary Table for Acrylic Acid (CASRN 79-10-7)		
Source (Year)	**IRIS (1994)**	**PPRTV (2010)**
Toxicity Value	Chronic RfD	Subchronic p-RfD
Critical Study	BASF 1993, Hellwig 1997	
Species/Strain/Sex	Wistar rats (25/sex/group)	
Study Duration	Two generations	
Critical Effect(s)	Reduced pup weight	
POD	NOAEL = 53 mg/kg-day	
Composite UF	100[a]	300[b]
Toxicity Value (mg/kg-day)	0.5	0.2
Selected Value (mg/kg-day)	0.5	
Rationale	Retain IRIS based upon application of UFs	

[a]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.
[b]The composite UF of 300 is based on 10 for UF_A, 10 for UF_H, and 3 for UF_D.

1-1'-Biphenyl (CASRN 92-52-4). IRIS (2013) selected a different study to derive the RfD. In the IRIS assessment, the $BMDL_{10HEC}$ for kidney effects (Umeda et al. 2002) was lower than the $BMDL_{05}$ for developmental effects from Khera et al. (1979). The BMDL value selected by IRIS (2013) for Khera et al. (1979) was different than the BMDL value selected for the PPRTV due to differences in the critical endpoints selected. IRIS modeled the litter incidence of missing or unossified sternabrae (as the only anomaly that exhibited a dose-related increase when considered individually), whereas the PPRTV (2009) modeled the litter incidence of skeletal anomalies (combined). The PPRTV did not derive a chronic p-RfD; the PPRTV indicated that, "IRIS has derived a chronic value of 0.05 mg/kg-day based on a chronic-duration toxicity study of albino rats by Ambrose et al. (1960) with kidney damage as the critical effect. The IRIS database (U.S. EPA, 2010) should be checked to determine if any changes have been made" (the assessment has since been updated). The IRIS value was retained because the PPRTV value is not based on new information or updated methods.

Summary Table for 1,1'-Biphenyl (CASRN 92-52-4)		
Source (Year)	**IRIS (2013)**	**PPRTV (2011)**

Toxicity Value	Chronic RfD	Subchronic p-RfD
Critical Study	Umeda et al. 2002	Khera et al. 1979
Species/Strain/Sex	F344 rats (50/sex/group)	Wistar rats (18-20 females/group)
Study Duration	2 years	GDs 6-15
Critical Effect(s)	Renal papillary mineralization (males)	Increased incidence of litters with fetal skeletal anomalies
POD	$BMDL_{10HED}$ = 13.9 mg/kg-day	$BMDL_{05}$ = 9.59 mg/kg-day
Composite UF	30[a]	100[b]
Toxicity Value (mg/kg-day)	0.5	0.1
Selected Value (mg/kg-day)	0.5	
Rationale	Different study	

[a]The composite UF of 30 is based on 3 for UF_A, and 10 for UF_H.
[b]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.

Cyclohexanone (CASRN 108-94-1). The PPRTV included a UF_D of 3 whereas the IRIS assessment did not because it was not EPA practice at that time. BMD modeling could not be conducted because the body weight data were not provided in the principal study. The PPRTV value is based on a pilot study for the longer study (by the same authors) that forms the basis for the IRIS assessment. The PPRTV study was based on smaller group numbers (5/sex/group compared to 52/sex/group) and over a shorter duration (25 weeks compared to 2 years). The IRIS value was retained because the PPRTV value is not based on new information or updated methods.

Summary Table for Cyclohexanone (CASRN 108-94-1)		
Source (Year)	**IRIS (1987)**	**PPRTV (2010)**
Toxicity Value	Chronic RfD	Subchronic p-RfD
Critical Study	Lijinsky and Kovatch 1986	
Species/Strain/Sex	F344 rats (52/sex/group)	F344 rats (5/sex/group)
Study Duration	2 years	25 weeks
Critical Effect(s)	Depression in body-weight gain (both sexes)	Decreased weight gain (males)
POD	NOAEL = 462 mg/kg-day	NOAEL = 731 mg/kg-day
Composite UF	100[a]	300[b]
Toxicity Value (mg/kg-day)	5	2
Selected Value (mg/kg-day)	5	
Rationale	Different (phase of) study	

[a]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.
[b]The composite UF of 300 is based on 10 for UF_A, 10 for UF_H, and 3 for UF_D.

Endosulfan (CASRN 115-29-7). ATSDR (2015) used a lower NOAEL from a study (Banerjee and Hussain 1986) showing depressed immune response that was presumably not considered in the IRIS assessment (i.e., not mentioned in the IRIS summary documentation). Advantages to the IRIS value include 1) it is not known why the principal study used for derivation of the ATSDR MRL was not evaluated by the IRIS program, 2) data for depressed immune response in rats are not amenable to benchmark dose modeling (i.e., updated methodology was not used); and 3) selection of the IRIS value adheres to the toxicity hierarchy (and there is no overwhelming evidence to switch to a similar toxicity value based on subchronic exposure). The IRIS value was retained because the ATSDR value is not based on new information or updated methods.

Summary Table for Endosulfan (CASRN 115-29-7)		
Source (Year)	**IRIS (1994)**	**ATSDR (2015)**
Toxicity Value	Chronic RfD	Intermediate-duration MRL
Critical Study	Hoechst Celanese Corp 1989	Banerjee and Hussain 1986
Species/Strain/Sex	Sprague-Dawley rats (50/sex/group)	Wistar rats (10 to 12 males/group)
Study Duration	2 years	Up to 22 weeks
Critical Effect(s)	Decreased body weight gain; increased incidence of marked progressive glomerulonephrosis and blood vessel aneurysms (males)	Depressed immune response
POD	NOAEL = 0.6 mg/kg-day	NOAEL = 0.45 mg/kg-day
Composite UF	100[a]	100[b]
Toxicity Value (mg/kg-day)	0.006	0.005
Selected Value (mg/kg-day)	0.006	
Rationale	Retain IRIS value	

[a]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.
[b]The composite UF of 100 is based on 10 for UF_A, and 10 for UF_H.

Ethylene Glycol Monobutyl Ether (CASRN 111-76-2). IRIS (2010) derived a toxicity value from a chronic inhalation study (NTP 2000) using a PBPK model and BMD methodology to calculate the HED. The ATSDR assessment derived a toxicity value from a 13-week study (NTP 1993) with no NOAEL. The IRIS value was retained based on updated methodology.

Summary Table Ethylene Glycol Monobutyl Ether (CASRN 111-76-2)		
Source (Year)	**IRIS (2010)**	**ATSDR (2010)**
Toxicity Value	Chronic RfD	Intermediate-duration MRL
Critical Study	NTP 2000	NTP 1993
Species/Strain/Sex	F344/N rats and B6C3F1 mice (50/sex/group)	F344/N rats (10/sex/group)
Study Duration	6 hours/day, 5 days/week, for 2 years (inhalation)	13 weeks

Critical Effect(s)	Hemosiderin deposition in the liver	Hepatic effects
POD	BMDL[HED] = 1.4 mg/kg-day	LOAEL = 69 mg/kg-day
Composite UF	10[a]	1000[b]
Toxicity Value (mg/kg-day)	0.1	0.07
Selected Value (mg/kg-day)	0.1	
Rationale	Different study; updated methodology	

[a]The composite UF of 10 is based on 10 for UF_H.
[b]The composite UF of 1000 is based on 10 for UF_A, 10 for UF_H, and 10 for UF_L.

Pentachlorophenol (CASRN 87-86-5). ATSDR (2001) derived chronic and intermediate-duration toxicity values based on a two-generation and one-generation reproduction studies in mink that only used one dose. The studies in mink were not well-conducted and observations in the one-generation study could not be replicated in the two-generation study (as mentioned in the IRIS assessment). The IRIS value was retained because the ATSDR value is not based on new information or updated methodology; the principal study is not considered reliable.

Summary Table Pentachlorophenol (CASRN 87-86-5)		
Source (Year)	**IRIS (2010)**	**ATSDR (2001)**
Toxicity Value	Chronic RfD	Intermediate-duration MRL
Critical Study	Mecler 1996	Beard et al. 1997
Species/Strain/Sex	Beagle dogs (4/sex/dose)	Mink (10 females/group)
Study Duration	52 weeks	3 weeks prior to mating and throughout pregnancy and lactation
Critical Effect(s)	Hepatotoxicity	Reproductive effects
POD	LOAEL = 1.5 mg/kg-day	LOAEL = 1 mg/kg-day
Composite UF	300[a]	1000[b]
Toxicity Value (mg/kg-day)	0.005	0.001
Selected Value (mg/kg-day)	0.005	
Rationale	Different study and methodology	

[a]The composite UF of 300 is based on 10 for UF_A, 10 for UF_H, and 3 for UF_L.
[b]The composite UF of 1000 is based on 10 for UF_A, 10 for UF_H, and 10 for UF_L.

Vanadium pentoxide; CASRN 1314-62-1

Human health assessment information on a chemical substance is included in the IRIS database only after a comprehensive review of toxicity data, as outlined in the IRIS assessment development process. Sections I (Health Hazard Assessments for Noncarcinogenic Effects) and II (Carcinogenicity Assessment for Lifetime Exposure) present the conclusions that were reached during the assessment development process. Supporting information and explanations of the methods used to derive the values given in IRIS are provided in the guidance documents located on the IRIS website.

STATUS OF DATA FOR Vanadium pentoxide

File First On-Line 01/31/1987

Category (section)	Assessment Available?	Last Revised
Oral RfD (I.A.)	yes	06/30/1988
Inhalation RfC (I.B.)	not evaluated	
Carcinogenicity Assessment (II.)	not evaluated	

I. Chronic Health Hazard Assessments for Noncarcinogenic Effects

I.A. Reference Dose for Chronic Oral Exposure (RfD)

Substance Name — Vanadium pentoxide
CASRN — 1314-62-1
Last Revised — 06/30/1988

The oral Reference Dose (RfD) is based on the assumption that thresholds exist for certain toxic effects such as cellular necrosis. It is expressed in units of mg/kg-day. In general, the RfD is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. Please refer to the Background Document for an elaboration of these concepts. RfDs can also be derived for the noncarcinogenic health effects of substances that are also carcinogens. Therefore, it is essential to refer to other sources of

information concerning the carcinogenicity of this substance. If the U.S. EPA has evaluated this substance for potential human carcinogenicity, a summary of that evaluation will be contained in Section II of this file.

I.A.1. Oral RfD Summary

Critical Effect	Experimental Doses*	UF	MF	RfD
Decreased hair cystine **Rat Chronic Oral Study** **Stokinger et al., 1953**	NOAEL: 17.85 ppm converted to 0.89 mg/kg/day LOAEL: none	100	1	9E-3 mg/kg/day

*Conversion Factors: Adult rat food consumption assumed to be 5% bw/day.

I.A.2. Principal and Supporting Studies (Oral RfD)

Stokinger, H.E., W.D. Wagner, J.T. Mountain, F.R. Stacksill, O.J. Dobrogorski and R.G. Keenan. 1953. Unpublished results. Division of Occupational Health, Cincinnati, OH. (Cited in Patty's Industrial Hygiene and Toxicology, 3rd ed., 1981)

In this chronic study, an unspecified number of rats were exposed to dietary levels of 10 or 100 ppm vanadium (about 17.9 or 179 ppm vanadium pentoxide) for 2.5 years. The results of this unpublished study were summarized by Stokinger et al. (1981). The criteria used to evaluate vanadium toxicity were growth rate, survival, and hair cystine content. The only significant change reported was a decrease in the amount of cystine in the hair of animals ingesting vanadium.

Of the subchronic and chronic animal studies available, the lower dose level (17.9 ppm vanadium pentoxide) reported in the Stokinger et al. (1953) study is the highest oral NOAEL upon which an RfD can be derived. An oral RfD of 0.009 mg/kg/day (0.62 mg/day for a 70-kg person) can be calculated by assuming that rats eat food equivalent to 5% of their body weight and by applying an uncertainty factor of 100.

I.A.3. Uncertainty and Modifying Factors (Oral RfD)

UF — An uncertainty factor of 100 was applied, 10 for interspecies extrapolation and a factor of 10 to provide added protection for unusually sensitive individuals.

MF — None

I.A.4. Additional Studies/Comments (Oral RfD)

In a subchronic feeding study (Mountain et al., 1953), groups of five male Wistar rats were fed vanadium pentoxide at levels of 0, 25, or 50 ppm for 35 days, after which dietary levels of vanadium were increased to 100 and 150 ppm and continued for 68 days. There was a decrease in the amount of cystine in the hair of the high-dosed (50-150 ppm or 2.5-7.5 mg/kg/day, based on food consumption of 5% bw) rats. A significant decrease was also reported in erythrocyte and hemoglobin levels of the high-dosed rats. In an abstract of a subchronic inhalation study (Suguira, 1978), mice and rats exposed to 1 to 3 mg/cu.m vanadium pentoxide for 3 months, 6 hours/day developed histopathologic changes in their lungs and had a decrease in growth rate. Adverse effects were not detected in either species similarly exposed at 0.1 to 0.4 mg/cu.m.

Although several epidemiologic studies have been conducted on factory workers exposed to vanadium pentoxide for several years, the air concentration levels of vanadium pentoxide were measured only at scattered intervals, making it impossible to determine a minimum effective dose. Also, in cases of humans exposed to relatively high atmospheric concentrations of vanadium pentoxide for short periods of time, all individuals developed respiratory symptoms that usually subsided within 7-14 days.

I.A.5. Confidence in the Oral RfD

Study — Low
Database — Low
RfD — Low

Because of the lack of details in the reference study and the scarcity of data available on vanadium pentoxide, low confidence is assigned to both the study and the database. Low confidence in the RfD follows.

I.A.6. EPA Documentation and Review of the Oral RfD

Source Document — This assessment is not presented in any existing U.S. EPA document.

Other EPA Documentation — None

Agency Work Group Review — 02/26/1986

Verification Date — 02/26/1986

Screening-Level Literature Review Findings — A screening-level review conducted by an EPA contractor of the more recent toxicology literature pertinent to the RfD for Vanadium pentoxide conducted in September 2002 identified one or more significant new studies. IRIS users may request the references for those studies from the IRIS Hotline at hotline.iris@epa.gov or (202)566-1676.

I.A.7. EPA Contacts (Oral RfD)

Please contact the IRIS Hotline for all questions concerning this assessment or IRIS, in general, at (202)566-1676 (phone), (202)566-1749 (FAX) or hotline.iris@epa.gov (internet address).

I.B. Reference Concentration for Chronic Inhalation Exposure (RfC)

Substance Name — Vanadium pentoxide
CASRN — 1314-62-1

Not available at this time.

II. Carcinogenicity Assessment for Lifetime Exposure

Substance Name — Vanadium pentoxide
CASRN — 1314-62-1

The NTP (1985) has approved vanadium pentoxide for carcinogenicity testing; however, the route of administration has not been determined (i.e., oral, inhalation).

Commonly Used Abbreviations

BMD	Benchmark Dose
IRIS	Integrated Risk Information System
IUR	inhalation unit risk
LOAEL	lowest-observed-adverse-effect level
$LOAEL_{ADJ}$	LOAEL adjusted to continuous exposure duration
$LOAEL_{HEC}$	LOAEL adjusted for dosimetric differences across species to a human
NOAEL	no-observed-adverse-effect level
$NOAEL_{ADJ}$	NOAEL adjusted to continuous exposure duration
$NOAEL_{HEC}$	NOAEL adjusted for dosimetric differences across species to a human
NOEL	no-observed-effect level
OSF	oral slope factor
p-IUR	provisional inhalation unit risk
p-OSF	provisional oral slope factor
p-RfC	provisional inhalation reference concentration
p-RfD	provisional oral reference dose
RfC	inhalation reference concentration
RfD	oral reference dose
UF	uncertainty factor
UF_A	animal to human uncertainty factor
UF_C	composite uncertainty factor
UF_D	incomplete to complete database uncertainty factor
UF_H	interhuman uncertainty factor
UF_L	LOAEL to NOAEL uncertainty factor
UF_S	subchronic to chronic uncertainty factor

PROVISIONAL PEER-REVIEWED TOXICITY VALUES FOR VANADIUM AND ITS SOLUBLE INORGANIC COMPOUNDS OTHER THAN VANADIUM PENTOXIDE (CASRN 7440-62-2 and others)

Background

On December 5, 2003, the U.S. Environmental Protection Agency's (U.S. EPA) Office of Superfund Remediation and Technology Innovation (OSRTI) revised its hierarchy of human health toxicity values for Superfund risk assessments, establishing the following three tiers as the new hierarchy:

1) U.S. EPA's Integrated Risk Information System (IRIS).
2) Provisional Peer-Reviewed Toxicity Values (PPRTVs) used in U.S. EPA's Superfund Program.
3) Other (peer-reviewed) toxicity values, including
   - Minimal Risk Levels produced by the Agency for Toxic Substances and Disease Registry (ATSDR),
   - California Environmental Protection Agency (CalEPA) values, and
   - EPA Health Effects Assessment Summary Table (HEAST) values.

A PPRTV is defined as a toxicity value derived for use in the Superfund Program when such a value is not available in U.S. EPA's IRIS. PPRTVs are developed according to a Standard Operating Procedure (SOP) and are derived after a review of the relevant scientific literature using the same methods, sources of data, and Agency guidance for value derivation generally used by the U.S. EPA IRIS Program. All provisional toxicity values receive internal review by two U.S. EPA scientists and external peer review by three independently selected scientific experts. PPRTVs differ from IRIS values in that PPRTVs do not receive the multiprogram consensus review provided for IRIS values. This is because IRIS values are generally intended to be used in all U.S. EPA programs, while PPRTVs are developed specifically for the Superfund Program.

Because new information becomes available and scientific methods improve over time, PPRTVs are reviewed on a 5-year basis and updated into the active database. Once an IRIS value for a specific chemical becomes available for Agency review, the analogous PPRTV for that same chemical is retired. It should also be noted that some PPRTV documents conclude that a PPRTV cannot be derived based on inadequate data.

Disclaimers

Users of this document should first check to see if any IRIS values exist for the chemical of concern before proceeding to use a PPRTV. If no IRIS value is available, staff in the regional Superfund and Resource Conservation and Recovery Act (RCRA) program offices are advised to carefully review the information provided in this document to ensure that the PPRTVs used are appropriate for the types of exposures and circumstances at the Superfund site or RCRA facility in question. PPRTVs are periodically updated; therefore, users should ensure that the values contained in the PPRTV are current at the time of use.

It is important to remember that a provisional value alone tells very little about the adverse effects of a chemical or the quality of evidence on which the value is based. Therefore, users are strongly encouraged to read the entire PPRTV document and understand the strengths and limitations of the derived provisional values. PPRTVs are developed by the U.S. EPA Office of Research and Development's National Center for Environmental Assessment, Superfund Health Risk Technical Support Center for OSRTI. Other U.S. EPA programs or external parties who may choose of their own initiative to use these PPRTVs are advised that Superfund resources will not generally be used to respond to challenges of PPRTVs used in a context outside of the Superfund Program.

Questions Regarding PPRTVs

Questions regarding the contents of the PPRTVs and their appropriate use (e.g., on chemicals not covered, or whether chemicals have pending IRIS toxicity values) may be directed to the U.S. EPA Office of Research and Development's National Center for Environmental Assessment, Superfund Health Risk Technical Support Center (513-569-7300), or OSRTI.

INTRODUCTION

The U.S. Environmental Protection Agency's (U.S. EPA) Integrated Risk Information System (IRIS) (U.S. EPA, 2008) contains a file for vanadium pentoxide describing a chronic RfD and containing a message about assessing its carcinogenicity—but no chronic RfC. IRIS currently contains no files for elemental vanadium or other vanadium compounds. The Drinking Water Standards and Health Advisories list (U.S. EPA, 2006) does not include an RfD for any vanadium compound. The Health Effects Assessment Summary Table (HEAST; U.S. EPA, 1997) lists subchronic and chronic oral RfDs of 7×10^{-3} mg/kg-day for vanadium and 2×10^{2} mg/kg-day for vanadium sulfate. RfDs for both vanadium and vanadium sulfate were based on a chronic study in which rats were exposed to 5 mg/L vanadium as vanadyl sulfate for their lifetimes (Schroeder et al., 1970), as derived in U.S. EPA (1987). A total UF of 100 was used to derive the RfDs. The Agency for Toxic Substance and Disease Registry (ATSDR, 1992) derived an intermediate-duration oral minimal risk level (MRL) for vanadium of 3×10^{-3} mg/kg-day based on a NOAEL of 0.3 mg/kg-day in a 3-month drinking water study in rats by Domingo et al. (1985); renal and respiratory effects (renal hemorrhagic foci and pulmonary vascular infiltration) were seen at higher doses (0.6 mg/kg-day). A total UF of 100, reflecting UFs of 10 each for interspecies extrapolation and intraspecies variability, was applied to the NOAEL. ATSDR (1992) does not derive a chronic oral MRL.

Neither IRIS (U.S. EPA, 2008) nor the HEAST (U.S. EPA, 1997) reports an RfC for vanadium. ATSDR (1992) derived an acute-duration inhalation MRL of 0.0002 mg/m^3 for vanadium based on a study of human exposure to vanadium pentoxide, but it does not provide inhalation MRLs for other vanadium compounds. The American Conference of Governmental Industrial Hygienists (ACGIH, 2007) lists a time weighted average-threshold limit value (TWA-TLV) of 0.05 mg V_2O_5/m^3 for vanadium pentoxide dust or fume (respirable fraction), with a "notice of intended change" to 0.02 mg V/m^3 (inhalable fraction) based on upper and lower respiratory tract irritation. The National Institute for Occupational Safety and Health (NIOSH, 2008) lists a recommended exposure limit (REL) of 0.05 mg V/m^3 for vanadium

pentoxide dust or fume as a 15-minute ceiling value. NIOSH includes a note that this REL applies to all vanadium compounds except vanadium metal and vanadium carbide—for which a REL of 1 mg/m^3 TWA and 3 mg/m^3 short-term exposure limit (STEL) applies (by analogy to ferrovanadium dust). The Occupational Safety and Health Administration (OSHA, 2008) permissible exposure limit (PEL) applicable to vanadium pentoxide is a ceiling of 0.1 mg V_2O_5/m^3 for fume and 0.5 mg V_2O_5/m^3 for dust.

An assessment of the carcinogenicity of vanadium is not available on IRIS (U.S. EPA, 2008), in the HEAST (U.S. EPA, 1997), or in the Drinking Water Standards and Health Advisories list (U.S. EPA, 2006). The Chemical Assessments and Related Activities (CARA) list (U.S. EPA, 1991, 1994) includes a Health Effects Assessment (HEA) for vanadium and compounds (U.S. EPA, 1987) that assigned vanadium to cancer weight-of-evidence Group D (Not Classifiable as to Human Carcinogenicity) based on inconclusive animal data (under U.S. EPA 1986 Guidelines for Carcinogen Risk Assessment). Vanadium has not been evaluated under the U.S. EPA (2005) Guidelines for Cancer Risk Assessment. Vanadium is not included in the 11th Report on Carcinogens available from the National Toxicology Program (NTP, 2005). The International Agency for Research on Cancer (IARC, 2008) has not evaluated vanadium for potential carcinogenicity. For vanadium pentoxide, ACGIH (2007) has posted notice of intended change in cancer notation from A4 (Not Classifiable) to A3 (Confirmed Animal Carcinogen).

To identify toxicological information pertinent to the derivation of provisional toxicity values, literature searches were conducted from 1960s through December 2007 using the following databases: MEDLINE, TOXLINE, BIOSIS, TSCATS1/2, CCRIS, DART/ETIC, GENETOX, HSDB, RTECS, and Current Contents (prior 6 months). Vanadium pentoxide (CASRN 1314-62-1) was excluded from the search because it has both an IRIS record and a separate PPRTV document. In addition to searching for vanadium and its subheadings in these databases, the following vanadium compounds were specifically included as search terms: vanadyl sulfate (CASRN 27774-13-6), sodium metavanadate (CASRN 13718-26-8), sodium orthovanadate (CASRN 13721-39-6), ammonium vanadate (CASRN 7803-55-6), vanadium sulfate (CASRN 16785-81-2), sodium hexavanadate (CASRN 12436-28-1), sodium tetravanadate (CASRN 1258-74-1), vanadious (4+) acid, disodium salt (CASRN 64082-34-4), vanadium dichloride (CASRN 10580-52-6), vanadium trioxide (CASRN 1314-34-7), and vanadium tetrachloride (CASRN 7632-51-1). Review documents by U.S. EPA (1987), ATSDR (1992), the World Health Organization (WHO, 1988, 2001), and Rydzynski (2001) were also consulted for relevant information. An updated literature search on PubMed was performed on August 17, 2009.

REVIEW OF PERTINENT DATA

Vanadium Compounds Assessed

As noted above, vanadium pentoxide is the subject of both an IRIS record and a separate PPRTV document, which should be used in the toxicity assessment of this particular vanadium compound.

Although vanadium has six oxidation states (-1, 0, +2, +3, +4, and +5), the most stable oxidation state is +4 (Rydzynski, 2001). In the environment, vanadium is bound to a variety of elements including oxygen, sodium, sulfur, and chloride; in commerce, vanadium is often used in an iron alloy (ferrovanadium) (Rydzynski, 2001). The literature searches identified toxicity data for the following inorganic compounds: vanadyl sulfate (+4), sodium metavanadate (+5), sodium orthovanadate (+5), and ammonium metavanadate (+5). Table 1 shows the CASRNs, molecular formulas, molecular weights, and vanadium mass fractions for these compounds. These compounds all exhibit some solubility in water (Rydzynski, 2001; ATSDR, 1992) and, thus, can be considered representative of soluble tetravalent and pentavalent vanadium compounds.

Table 1. Soluble Inorganic Vanadium Compounds Considered in this PPRTV

Compound	Chemical Formula	Vanadium Valence	Molecular Weight (g/mol)	Vanadium Mass Fraction[a]
Vanadium	V	various	50.94	1.0
Vanadyl sulfate trihydrate	$VOSO_4 \cdot (H_2O)_3$	+4	217.06	0.235
Vanadyl sulfate pentahydrate	$VOSO_4 \cdot (H_2O)_5$	+4	253.10	0.201
Ammonium metavanadate or ammonium vanadate	NH_4VO_3	+5	116.99	0.435
Sodium metavanadate or sodium vanadate	$NaVO_3$	+5	121.93	0.418
Sodium orthovanadate or sodium vanadium oxide	Na_3VO_4	+5	183.91	0.277

[a]Molecular weight of vanadium divided by molecular weight of compound.

In recent years, organic vanadium compounds have been synthesized in an effort to enhance the lipophilicity and biological uptake of vanadium for use in treating diabetes and/or cancer. Toxicity data for three organic vanadium compounds were located: bis(maltolato)oxyvanadium(IV) (BMOV), bis(ethylmaltolato)oxyvanadium(IV) (BEOV), and vanadyl acetyl acetonate. Because these compounds have been developed as pharmaceutical agents and are believed to have different absorption and/or toxicokinetic properties than soluble inorganic vanadium salts, they are not considered in this review.

There are three early studies of human exposure to vanadium (Curran et al., 1959; Dimond et al., 1963; and Sommerville and Davies, 1962) that employed compounds reported as "ammonium vanadyl tartrate" and "diammonium oxy-tartrato vanadate" or "diammonium vanado-tartrate." Information provided on the chemical form in the studies is limited to the names and the valence state (+4) for the latter compound (reported by Sommerville and Davies, 1962). Reliable chemical structures and valence states for these compounds have not been located; however, the tartrate component is an organic moiety. Given that the compounds administered in these studies are unknown, it is difficult to estimate vanadium doses from the reported doses of the compounds. Further, because the compounds used in these studies were likely organic in nature and may have exhibited different bioavailability than inorganic vanadium salts, these studies have been excluded from consideration in this review.

Oral exposures to either vanadyl or vanadate result in internal exposures to a mixture of vanadyl and vanadate complexes as a result of reduction/oxidation (redox) reactions that occur in the gastrointestinal tract as well as in the blood and tissues (Rydzynski, 2001; Etcheverry and Cortizo, 1998). Available information suggests that conditions in extracellular fluid favor the formation of vanadate, while intracellular (cytosolic) conditions favor the vanadyl redox state (Rydzynski, 2001). As a result of these physiological interconversions, there is no firm toxicological basis for distinguishing dose-response relationships for these two forms given the currently available data: while toxicology studies can be categorized based on whether humans or animals were exposed to vanadyl or vanadate compounds, target organs and tissues are likely exposed to a mix of these ions. For the purpose of this review, exposure to either the vanadyl or vanadate form is treated as biologically equivalent. Therefore, exposure estimates in all of the toxicity studies have been converted to equivalent vanadium doses for the purpose of dose-response assessment.

In summary, this PPRTV document applies to soluble inorganic vanadyl (+4) and vanadate (+5) compounds other than vanadium pentoxide, which is the subject of an IRIS review and separate PPRTV document. Data are not available to assess the toxicity of insoluble compounds or compounds in which vanadium exists in higher or lower valence states. Organic vanadium compounds are expected to exhibit different toxicokinetic properties than inorganic compounds and should be assessed independently if necessary. Finally, vanadyl and vanadate exposures are considered biologically equivalent (on the basis of equivalent vanadium dose) for the purpose of this review.

Human Studies

The possibility that vanadium may be an essential element for humans remains an unanswered question. Etcheverry and Cortizo (1998) reported that deficiencies in vanadium intake could be associated with alterations in bone structure and development, changes in plasma cholesterol, and changes in reproductive performance. However, WHO (2001) considered the issue unresolved and noted that, if vanadium is essential, required levels are very low (in the range of nanograms per day).

Oral Exposure

Fawcett et al. (1997) administered tablets of vanadyl sulfate trihydrate at a dose of 0.5 mg/kg-day (0.1 mg V/kg-day) for 12 weeks to weight trainers. The treatment and control groups each included 15 males and 5 females. The control group received a daily placebo. Subjects in the control and treatment groups were matched with respect to gender, age, height, weight, and weight-training program (e.g., intensity, schedule). Of those starting the study, 11 males and 4 females in the treatment group and 12 males and 4 females in the control group completed the study. There were two males that withdrew from the study because of self-reported side effects (tiredness and/or aggressiveness while weight training); these two subjects were unremarkable with respect to endpoints assessed in this study. There were four subjects that withdrew because of training-related injuries and three subjects withdrew for other reasons not related to health. Blood pressure was measured and blood samples collected periodically during the exposure period for evaluation of hematology (differential cell counts and blood viscosity tests) and serum chemistry (plasma alanine aminotransferase [ALT] and alkaline phosphatase [ALP], albumin, bilirubin, cholesterol, creatinine, high-density lipoprotein, total protein, triglyceride, and urea). No differences were observed between the treatment and control

groups for the following endpoints: body weight, systolic and diastolic blood pressure, hematology or serum chemistry (all data shown). Without corroborating information, the toxicological relevance of the self-reported symptoms of (tiredness and aggressiveness) is uncertain. The administered dose (0.1 mg V/kg-day) is considered a freestanding NOAEL with respect to the endpoints assessed in the study.

In a study designed to evaluate the safety of vanadyl sulfate as a diabetes treatment, Boden et al. (1996) administered 50 mg capsules of vanadyl sulfate twice daily (100 mg/day) for 4–8 weeks to four men and four women with noninsulin-dependent diabetes mellitus. The specific form of vanadyl sulfate was not reported; assuming vanadyl trihydrate, the corresponding dose of vanadium would be 0.34 mg V/kg-day in men and 0.39 mg V/kg-day in females of average body weight (70 kg and 60 kg, respectively). Of the eight patients, four men and two women were treated with placebo for 4 weeks after the end of vanadium treatment to provide reference data. Patients self-monitored their glucose using a glucometer and were examined weekly at a hospital, where blood was drawn for complete blood count, serum chemistry (glucose, insulin, blood urea nitrogen [BUN], fatty acids, vanadium content), liver and kidney function tests, and urinalysis (urinary nitrogen). Self-reported symptoms were recorded at that time. Glycemic control was assessed during and after the exposure period. Of the eight patients, four reported diarrhea with abdominal cramps and/or flatulence, one reported flatulence alone, and one reported slight nausea. Diarrhea lasted for 11 days in one patient but had abated after the first week in the others. Vanadyl sulfate treatment resulted in statistically significant ($p < 0.05$) decreases in fasting glucose concentration and hepatic glucose output during hyperinsulinemia. There were no effects on total body glucose uptake, glycogen synthesis, glycolysis, carbohydrate oxidation, or lipolysis during the euglycemic-hyperinsulenemic clamps. The study authors reported that weekly blood counts, urinalysis, and liver function tests were not affected by treatment (data not shown). A LOAEL of 0.34–0.39 mg V/kg-day is identified from these data based on gastrointestinal symptoms; no NOAEL is identified.

Goldfine et al. (2000) also investigated the use of vanadyl sulfate to treat noninsulin-dependent diabetes mellitus. Participants in the study were 16 diabetes patients (11 males and 5 females) between the ages of 18 and 65 who did not have active cardiovascular, pulmonary, renal, or hepatic disease. After 12 weeks of monitoring to derive baseline information, the subjects were given vanadyl sulfate by tablet at doses of 75, 150, or 300 mg/day for 6 weeks. Based on individual body weights reported in the study and assuming that the trihydrate form of vanadyl sulfate was used, doses are 0.12–0.23, 0.28–0.45, and 0.43–1.14 mg V/kg-day in the 75, 150, and 300 mg/day groups. Blood glucose was monitored throughout the study (other tests of glycemic control were also administered) and the patients were given physical examinations, blood tests (electrolytes, BUN, creatinine, complete blood count), liver and thyroid function tests and urine tests biweekly. To assess lipid peroxidation, levels of thiobarbituric acid-reactive substances in the serum were measured. Ambulatory blood pressure was measured 4 weeks after exposure was terminated. The patients were monitored for 2 additional weeks. Although patients exposed to the lowest dose range did not experience any gastrointestinal symptoms, several patients at the next dose reported complaints and all patients at the high dose reported cramping, abdominal discomfort, and/or diarrhea. The study authors reported that no other signs of toxicity were observed and blood tests and urinalysis did not indicate toxicity (data not shown). Systolic, diastolic, and mean arterial pressure were not changed by exposure nor was heart rate. Insulin sensitivity and glycemic control were not

dramatically improved in this study. A LOAEL of 0.28–0.45 mg V/kg-day is identified from this study based on gastrointestinal symptoms; the NOAEL is in the range of 0.12–0.23 mg V/kg-day.

Cusi et al. (2001) gave a group of 11 patients (four men and seven women, mean age 59 years) with type 2 diabetes doses of 150 mg vanadyl sulfate each day for 6 weeks after a 2-week period of exposure to increasing doses up to 150 mg/day (exposure regimen during run-up not reported). Assuming that vanadyl sulfate was in the trihydrate form, the estimated doses (during the 6-week period) are 0.5 mg V/kg-day in males and 0.6 mg V/kg-day in females (based on default body weights of 70 and 60 kg, respectively). Measures of glycemic control were assessed throughout the exposure period. Effects reported in the subjects included diarrhea (4/11) and abdominal discomfort (2/11). According to the authors, blood chemistry, complete blood count, and urinalysis were not affected by treatment (data not shown), nor was bone mineral density (measured in three subjects) or body weight. Measures of 24-hour ambulatory blood pressure and mean heart rate were not affected by treatment (data shown). Glycemic control was significantly improved. This study suggests a LOAEL of 0.5–0.6 mg V/kg-day based on gastrointestinal symptoms; a NOAEL could not be identified.

Inhalation Exposure

The few studies examining human exposure to vanadium compounds (other than vanadium pentoxide) via inhalation (Woodin et al., 2000; Sorensen et al., 2005; Zhou et al., 2007) do not specify the form of vanadium exposure; in these studies, coexposure to other compounds could not be ruled out. Woodin et al. (2000) found increases in self-reported upper and lower airway respiratory symptoms in 18 boilermaker workers exposed to vanadium compared with 11 utility worker control subjects. The study authors correlated these symptoms with estimated vanadium doses to the lung and upper airway in all but the highest exposure quartile; the authors attributed the high-dose reversal to a possible healthy worker effect. Sorensen et al. (2005) observed a positive association between levels of 7-hydro-8-oxo-2'-deoxyguanosine (a measure of DNA damage) in lymphocytes of 49 students in Copenhagen and concentrations of both vanadium and chromium in PM2.5 samples. Concentrations of platinum, nickel, copper, and iron were not related to the measures of DNA damage. Based on the English abstract of a paper published in Chinese, 106 workers with exposure to vanadium were reported to exhibit more negative moods as well as poorer performance on neurobehavioral tests (Santa Ana dexterity, Benton visual retention and pursuit aiming) than unexposed workers (Zhou et al., 2007). The average concentration of vanadium in the air of the exposed workers ranged from 0.034 to 0.805 mg/m^3; however, the form of vanadium is not specified. No further information is presented in the abstract.

A case report documented symptoms of metal-fume fever in a worker exposed to a vanadium catalyst, vanadyl pyrophosphate (Vandenplas et al., 2002). After exhibiting symptoms in the work environment, the individual was assessed by a physician under controlled conditions of exposure to the vanadium catalyst. Forced vital capacity and forced expiratory volume were decreased and fever and peripheral blood neutrophilia were observed. Concentrations of vanadium to which the individual was exposed in the workplace or under the challenge conditions were not reported.

Animal Studies

Only a few of the available laboratory animal studies provide information on the levels of vanadium in the basal diet and none of the studies considered dietary input to total vanadium dose. Kanisawa and Schroeder (1967), along with Schroeder et al. (1970), reported the concentration of vanadium in their basal diet as 3.2 mg V/kg food. Elfant and Keen (1987) reported a concentration of 1 mg V/kg in a "purified" diet. Finally, Scibior et al. (2006) measured the concentration of vanadium in their standard chow to be 0.45 mg V/kg. For a dietary concentration of 1 mg V/kg, the vanadium dose to rats and mice would be in the range of 0.1 to 0.2 mg V/kg-day (assuming default values for subchronic exposure in female Sprague-Dawley and B6C3F1 mice; U.S. EPA, 1988). This estimate may not be representative of all commercial laboratory animal feeds used in the studies included in this review. Because exposure to vanadium in the basal diet was not taken into account in any of the studies, doses reported in this review may be underestimated to some degree. Further, low-level exposure to vanadium among controls increases the uncertainty in findings of effect at doses near the estimated control dose.

Oral Exposure

Subchronic Studies—Domingo et al. (1985) exposed male Sprague-Dawley rats to sodium metavanadate for 12 weeks. A control group consisted of 10 rats given free access to drinking water without added vanadate. There were three treatment groups that consisted of 10 rats/group exposed to drinking water to which 5, 10, or 50 mg/L sodium metavanadate (2, 4, or 21 mg V/L) had been added. Vanadium doses estimated for this review based on reported water consumption and body weight (of the high-concentration group only) were 0.3, 0.6, and 3.0 mg V/kg-day. Body weight was measured weekly, while food consumption, water intake, and urine volume were assessed daily. At sacrifice, blood was collected from five rats for serum chemistry determinations (AST, ALT, total protein, bilirubin, creatinine, urea, uric acid, glucose, and cholesterol). Selected organs (liver, kidneys, heart, spleen, and lung) from all animals were weighed. Microscopic examination of the heart, kidney, liver, lung, spleen, and stomach was performed on 3 rats/group. Body-weight gain was significantly ($p < 0.05$) increased (42%) over controls in the high-dose group (3.0 mg V/kg-day) during the first 2 weeks of exposure, but not thereafter; actual body weights are not reported. Food and water intake were not affected in the high-dose group. The authors indicated that body weight, food consumption, and water intake were not affected in other treatment groups (data not shown). Urine volume was greater than controls in the high-dose group during the first month (58% to 2-fold higher; $p < 0.05$), but not during the remainder of the study. Compared to the control values, plasma protein, urea, and uric acid concentrations were significantly higher (31%, 28%, and 2-fold, respectively; $p < 0.05$) in the 3.0 mg V/kg-day treatment group but not in other treatment groups. Organ weights were not affected by treatment (data shown). The histopathology findings are summarized qualitatively as mild changes in the kidney (hemorrhagic foci in the corticomedullary region), spleen (hypertrophy and hyperplasia), and lungs (perivascular mononuclear cell infiltration). The authors reported that these changes occurred in all treatment groups, but they are described as "more evident" in the 3.0 mg V/kg-day treatment group. Incidences of these effects are not reported. Given the authors' report of histopathology and clinical chemistry findings in the low-dose group, even though only three animals were examined, 3.0 mg V/kg-day is considered to be a LOAEL.

A number of studies examined the beneficial effects of vanadium exposure on diabetic rats[1]. Most of the studies examined few or no toxicological endpoints and used doses of 10 mg V/kg-day or greater. Those studies that did examine a few toxicological endpoints, included a nondiabetic treatment group, and exposed the animals for at least 28 days are summarized in Table 2. The studies shown in the table indicate that doses of 12 mg V/kg-day and higher result in body weight reductions of at least 10%, often accompanied by marked reductions in fluid intake. The reduced fluid intake may reflect an organoleptic effect of vanadium compounds administered in drinking water. Although body-weight reductions can be related to reduced fluid intake, studies that have observed reduced body weight or body weight gain with dietary or gavage administration of vanadium (e.g., Sanchez et al., 1991, 1998, 1999; Paternain et al., 1990; Elfant and Keen, 1987) suggest that this may be a toxic effect of the element rather than resulting from reduced fluid intake. Thus, the body-weight decrement of at least 10% observed at a dose of 12 mg V/kg-day (Cam et al., 1993) indicates that this dose is a LOAEL.

Most of the studies that examined only effects in diabetic animals are not summarized here—primarily because the studies demonstrated improvements in diabetes-related effects, rather than any toxic effects of vanadium exposure. However, one study examining effects of vanadium exposure in diabetic animals bears special consideration because it identifies enhanced toxicity in the vanadium-treated animals when compared with both nondiabetic and diabetic controls. Domingo et al. (1991) exposed groups of 10 streptozotocin-induced diabetic male Sprague-Dawley rats to three different forms of vanadium: sodium metavanadate (150 mg/L), sodium orthovanadate (230 mg/L), and vanadyl sulfate pentahydrate (310 mg/L) in the drinking water for 28 days. Based on body weights and fluid intake measurements, the authors estimated vanadium doses of 22.7, 15.6, and 6.1 mg V/kg-day for vanadyl sulfate, sodium orthovanadate, and sodium metavanadate, respectively. Sodium chloride (80 mM) was added to the water to inhibit gastrointestinal effects of vanadium. Both diabetic and nondiabetic control groups (10/group) were included for comparison. Mortality, body weight, food and fluid intake and blood glucose were monitored throughout the exposure period. After exposure ended, blood samples were collected for analysis of hematocrit, glucose, urea, creatinine, AST and ALT.

[1]A chronic study that included a broader range of toxicological endpoints is discussed under Chronic Studies (published in three papers: Dai et al., 1994a,b; Dai and McNeill, 1994).

Table 2. Studies of Effects in Streptozotocin-induced Diabetic and Nondiabetic Rats Exposed to Vanadium

Reference	Number and Sex of Rats	Vanadium Compound Administered	Duration	Dose[a] Vanadium (mg V/kg-day)	Significant Adverse Effects
Cam et al., 1993	11–16 males per group	Vanadyl sulfate in drinking water	5 months	12[b] (nondiabetic) 18–20 (diabetic)	Decreased body weight (14%), fluid intake (40%) and food intake (up to 10%) in treated nondiabetic rats relative to control nondiabetic rats.
Thompson et al., 1993	10–16 males per group	Vanadyl sulfate in drinking water	Up to 12 weeks	36 (nondiabetic) 102 (diabetic)	Decreased body weight (30%), decreased fluid intake (54%) in treated nondiabetic rats relative to control nondiabetic rats. Decreased body weight (11%) in treated diabetic rats relative to diabetic controls.
Yao et al., 1997	5–6 males per group	Vanadyl sulfate in drinking water	7 weeks	13 (nondiabetic) 24 or 29 (diabetic)	Decreased body-weight gain (14%), decreased fluid intake (34%) in treated nondiabetic rats relative to control nondiabetic rats.
Tunali and Yanardag, 2006; Akgün-Dar et al., 2007	5–13 males per group	Vanadyl sulfate via daily gavage	60 days	24 [b]	Lower body weight (11%), increased serum glucose and phospholipids, increased aortic lipid peroxidation, decreased stomach and aortic glutathione, decreased aortic diameter and aortic *tunica intima* thickness in treated nondiabetic rats relative to control nondiabetic rats. Decreased tunica muscularis thickness (in aorta) in treated diabetic rats relative to both diabetic and nondiabetic controls.

[a]Doses estimated by authors except where indicated.
[b]Doses estimated for this review based on default body weight and fluid intake (U.S. EPA, 1988). Cam et al. (1993) reported using the trihydrate form of vanadyl sulfate. Tunali and Yanardag (2006) and Akgün-Dar et al. (2007) did not report the form administered; it was assumed to be the trihydrate for the purpose of dose estimation.

In each of the groups exposed to sodium metavanadate and vanadyl sulfate, 3/10 rats died, while 2/10 diabetic rats treated with sodium orthovanadate died (Domingo et al., 1991). By comparison, no control nondiabetic rats died and 1/10 control diabetic rats died. Food and fluid intake in the groups exposed to sodium metavanadate and vanadyl sulfate were increased relative to the nondiabetic controls, but were lower than those of diabetic controls. Relative weight gain was significantly lower in diabetic controls than in nondiabetic controls (8.2% vs. 24% over study duration). However, the vanadium-treated rats lost weight over the exposure period (3.2%, 4.8%, and 7.2% losses in the groups exposed to vanadyl sulfate, sodium orthovanadate and sodium metavanadate, respectively; $p < 0.05$ relative to both diabetic and nondiabetic control groups). Thus, in this study, vanadium treatment enhanced the adverse effect of diabetes on body-weight gain. In addition, vanadium treatment (all forms) resulted in significantly ($p < 0.05$) higher serum urea concentrations relative to both diabetic and nondiabetic control groups. Treatment with vanadyl sulfate also increased the serum creatinine level relative to both control groups. This study suggests a LOAEL of 6.1 mg V/kg-day for body-weight losses in diabetic rats. Although mortality was observed in diabetic rats treated with vanadium (3/10 in the group exposed to 6.1 mg V/kg-day), it is not clear whether the deaths were attributable to the disease or the treatment; one death also occurred in the untreated diabetic group. A NOAEL cannot be determined.

A follow-up study assessing whether Tiron (sodium 4,5-dihydroxybenzene-1,3-disulfonate, a chelating agent) would mitigate the toxicity of vanadium in diabetic rats, provided some confirmation of these findings (Domingo et al., 1992). A group of 10 streptozotocin-induced diabetic rats was given sodium metavanadate at a concentration of 200 mg/L in the drinking water for 5 weeks, with or without Tiron; nondiabetic and diabetic control groups were included. The same parameters as in the earlier study were monitored. The authors estimated a vanadium dose of 23.2 mg V/kg-day in the group without Tiron exposure. As with the previous study, exposure to sodium metavanadate in diabetic rats resulted in body-weight loss (5%) while weight gains of 28% and 8.1% were seen in untreated nondiabetic and diabetic groups (respectively). The decrement was significantly different from both untreated groups at $p < 0.01$. In addition, serum urea was increased relative to both control groups (10.9 mmol/L vs. 6.3 and 8.2 mmol/L in nondiabetic and diabetic controls), while serum creatinine was not. Tiron administration did not ameliorate the effect of vanadium on body-weight gain, but did reduce serum urea concentrations. A LOAEL of 23.2 mg V/kg-day is identified from this study based on body-weight losses in treated diabetic rats.

A series of papers reported hematological effects of exposure to ammonium metavanadate (Gorski and Zaporowska, 1982; Zaporowska and Wasilewski 1989, 1990, 1991, 1992a,b; Zaporowska and Scibior, 1999). With few exceptions, the study protocols are largely the same. In most studies, 2-month old Wistar rats (either male or male and female) were exposed to ammonium metavanadate in drinking water provided ad libitum, typically for 4 weeks. Some studies examined the interaction of vanadium with another toxicant (ethanol or zinc), but some also provided data on exposure to the vanadium compound alone; in all cases, a single concentration of ammonium vanadate was used. Vanadium concentrations in the drinking water ranged from 50–300 mg/L, resulting in doses ranging from 7–29 mg V/kg-day in the various studies. Body weight, fluid intake, and food consumption were monitored during the exposure period. At sacrifice (at the end of exposure), the following hematological parameters were assessed: erythrocyte, reticulocyte, and total and differential leukocyte counts, hematocrit

[Hct], hemoglobin [Hgb], leukocyte composition in bone marrow and frequency of polychromatophilic erythrocytes in peripheral blood and bone marrow. A few other evaluations were conducted in individual studies. Zaporowska and Wasilewski (1992a) also examined the osmotic resistance of erythrocytes and the activities of glucose-6-phosphate dehydrogenase and lactate dehydrogenase in erythrocytes. Zaporowska and Scibior (1999) assessed the phagocytic activity of neutrophils and the activities of myeloperoxidase and alkaline phosphatase in the neutrophils. Based on the abstracts of papers published in Polish, Gorski and Zaporowska (1982) also examined the histopathology of liver and kidneys, and Zaporowska (1987) evaluated kidney histopathology.

Table 3 provides an overview of the study designs and results. Mortality occurred at doses of 13 mg/kg-day and higher in this series of papers. In general, the studies consistently demonstrated significantly depressed body-weight gain, food intake and fluid intake, decreased erythrocyte counts and hemoglobin concentrations and increased reticulocytes and polychromatophilic erythrocytes in exposed animals. Sporadic effects were observed on leukocytes or leukocyte composition and no effects on erythrocyte enzyme activities were reported. Abstracts from two studies (Gorski and Zaporowska, 1982; Zaporowska, 1987, both published in Polish) reported renal histopathology (parenchymatous degeneration with vacuolar degeneration and tubular casts) at doses of 9–29 mg V/kg-day, but the incidences of the renal effects are not given. Gorski and Zaporowska (1982) also reported parenchymatous degeneration of the liver. Neither study has been translated for this review. Taken together, these studies identify a FEL of 13 mg/kg-day based on mortality (Zaporowska and Wasilewski, 1992a).

In contrast to the other publications in this series, Zaporowska et al. (1993) used more than one concentration of ammonium metavanadate and also used lower doses that were not associated with mortality. Groups of 15–16 Wistar rats of each sex were given concentrations of 0, 10, or 50 mg V/L as ammonium metavanadate in drinking water for 4 weeks. Fluid intake was measured daily and body weight recorded weekly; based on these measures, the authors estimated doses of 1.2 or 5 mg V/kg-day in males and 1.5 or 7 mg V/kg-day in females. Food intake was also monitored daily during exposure. Blood was drawn (presumably at sacrifice at the end of exposure, although this is not specified) for hematology (erythrocyte count [RBC], leukocyte count [WBC], Hgb, Hct, leukocyte composition, polychromatophilic erythrocytes, and reticulocytes in peripheral blood) and erythrocyte enzyme activity determinations (catalase,glucose-6-phosphate dehydrogenase, lactate dehydrogenase and δ-aminolevulinic acid dehydratase). Malondialdehyde (MDA), glutathione (GSH) and L-ascorbic acid content of erythrocytes were also measured. At these doses, there was no mortality. Although body-weight gain was lower in exposed groups than in controls (as much as 9% lower at the high dose), the differences are not statistically significant. Food intake was not affected by treatment and fluid intake was decreased only in high-dose males (14% lower than controls, $p < 0.001$). Statistically significant—but modest—changes in erythrocyte count, hemoglobin concentration, and hematocrit are shown in Table 4. In addition to these changes, the percentage of reticulocytes was significantly increased at the high dose in both sexes (data presented graphically, $p < 0.05$). There was no effect on leukocyte composition or enzyme activity in erythrocytes. While MDA tended to be increased and GSH decreased in exposed animals, the changes are not statistically significant. However, the concentration of L-ascorbic acid in the plasma of male rats was reduced at both doses (24% and 37% below controls; $p < 0.05$). The high dose in this study is

Table 3. Studies of Hematologic Effects in Rats Exposed to Ammonium Metavanadate in Drinking Water

Reference	Number and Sex of Rats	Conc. Vanadium (mg V/L)	Duration	Dose[a] (mg V/kg-day)	Significant Effects
Gorski and Zaporowska, 1982 Published in Polish.	5–13 males per group	0, 200	1, 2, or 3 months	29[b]	Based on English abstract and tables only: decreased body-weight gain, decreased erythrocyte count, hemoglobin, and hematocrit; in "single cases," parenchymatous degeneration of liver and kidney, with vacuolar degeneration of kidney and tubular casts.
Zaporowska, 1987 Published in Polish.	15 (sex not given) per group	0, 50, 100, 200	4 weeks	9, 12, 23[b]	Based on English abstract and tables only: decreased body-weight gain at high dose; "renal tubule cylinders" at mid- and high doses.
Zaporowska and Wasilewski, 1989	10–18 per sex per group	0, 300	2, 4, or 8 weeks	21–29	Mortality[c] (6/16 and 2/14 males after 4 and 8 weeks; 2/13, 4/16, and 2/13 females after 2, 4, and 8 weeks), transient diarrhea in "some" rats, decreased body-weight gain, decreased food and water intake, decreased erythrocyte count and hemoglobin concentration, increased number polychromophilic erythroblasts.
Zaporowska and Wasilewski, 1990	10–21 per sex per group	0, 300	4 weeks	22–27	Mortality[c] (6/21 males and 6/21 females), diarrhea, decreased body-weight gain, decreased food and water intake, decreased erythrocyte count, increased reticulocyte count, increased number polychromatophilic erythrocytes, decreased lymphocytes and plasma cells in bone marrow.
Zaporowska and Wasilewski, 1991	10–11 males per group	0, 300	4 weeks	20	Decreased body-weight gain, fluid intake, food intake, erythrocyte count, and hemoglobin concentration. Increased reticulocytes and polychromatophilic erythrocytes in peripheral blood.
Zaporowska and Wasilewski, 1992a	12–13 per sex per group	0, 150	4 weeks	13	Mortality[c] (1/12 males); transient diarrhea (2 rats); decreased body-weight gain, food intake, fluid intake, erythrocytes, hemoglobin count; increased leukocyte count; decreased osmotic resistance of erythrocytes; increased reticulocytes, polychromatophilic erythrocytes, neutrophils and lymphocytes in peripheral blood.
Zaporowska and Wasilewski, 1992b	12–14 per sex per group	0, 300	4 weeks	20–26	Mortality[c] (2/13 males and 3/14 females); frequent diarrhea; decreased body-weight gain, food intake and fluid intake; decreased erythrocyte count and hemoglobin concentration; increased reticulocytes and polychromatophilic erythrocytes in peripheral blood and/or bone marrow.
Zaporowska and Scibior, 1999	10–13 males per group	0, 150	4 weeks	12	Decreased body-weight gain, food intake and fluid intake; decreased phagocytic activity of neutrophils.

[a]Doses estimated by authors based on fluid intake and body weight except where indicated
[b]Doses estimated for this review based on default body weight and fluid intake (U.S. EPA, 1988)
[c]No control animals died in any study

considered a LOAEL (5 mg V/kg-day in males and 7 mg V/kg-day in females) based on a 9% decrease in body-weight gain (albeit not significantly decreased from controls, and possibly related to reduced fluid intake) and modest hematology changes. The low dose (1.2 mg V/kg-day in males and 1.5 mg V/kg-day in females) is considered a NOAEL; the statistically significant hematology changes observed at this dose are not considered toxicologically significant.

Table 4. Hematologic Effects in Rats Exposed to Ammonium Metavanadate for 4 Weeks[a]

Parameter	Control	10 mg V/L	50 mg V/L
Males		**1.2 mg V/kg-day**	**5 mg V/kg-day**
Erythrocytes ($\times 10^{12}$/dm^3)	8.32 ± 0.17	7.38 ± 0.20 [b]	7.47 ± 0.27 [c]
Hemoglobin (mmol/L)	9.37 ± 0.19	8.94 ± 0.28	8.65 ± 0.26 [c]
Hematocrit (%)	0.48 ± 0.001	0.47 ± 0.004 [c]	0.47 ± 0.003 [b]
Females		**1.5 mg V/kg-day**	**7 mg V/kg-day**
Erythrocytes ($\times 10^{12}$/dm^3)	8.24 ± 0.10	7.38 ± 0.14 [d]	7.12 ± 0.17 [d]
Hemoglobin (mmol/L)	9.41 ± 0.12	8.76 ± 0.30	8.72 ± 0.20 [c]

In recent papers by the same group of investigators, sodium metavanadate was used as the test material in studies comparing the effects of vanadium alone or in combination with chromium or magnesium. Scibior (2005) administered sodium metavanadate in the drinking water to a group of 11 male Wistar rats at a concentration of 100 mg V/L; a group of 16 untreated rats served as controls. Food and fluid intake were measured daily and body weight recorded weekly during the 6-week exposure period. After exposure ended, blood was collected for hematology (RBC, Hct, Hgb, mean corpuscular volume [MCV], mean corpuscular hemoglobin [MCH], mean corpuscular hemoglobin concentration [MCHC], and WBC) and assessment of the total antioxidant status of erythrocytes. Based on measured body weight and fluid intake, the authors estimated the vanadium intake to be 8 mg V/kg-day. While total body-weight gain was reduced in the vanadium-exposed group (about 9% less than controls), the difference is not statistically significant. In treated rats, both food and fluid intake were reduced compared to controls (13% and 32% less than controls, respectively; $p < 0.05$). Modest—but statistically significant ($p < 0.05$)—effects observed with exposure include the following: increased erythrocyte count (in contrast to earlier studies that showed a decrease; 10% higher than controls) and decreased MCH (12% lower) and MCHC (4% lower). No other statistically significant effects were observed in the parameters evaluated. A LOAEL of 8 mg V/kg-day is identified for these data based on a 9% decrease in body-weight gain (albeit not significantly decreased from controls, and possibly related to reduced food and fluid intake) and hematology changes; no NOAEL can be determined.

Scibior et al. (2006) exposed male Wistar rats (12/group) to sodium metavanadate at a concentration of 0 or 125 mg V/L in the drinking water for 6 weeks. Based on fluid intake and body weight measurements, the authors estimated the average vanadium intake to be 11 mg V/kg-day in the exposed group. Evaluations were similar to those of previous studies and included body-weight gain, food and fluid intake, hematology (RBC, WBC, Hgb, Hct, MCV,

MCH, MCHC, and red-cell distribution width), leukocyte composition of peripheral blood smears, phagocytic activity of neutrophils in whole blood, erythrocyte concentrations of L-ascorbic acid and malondialdehyde, and the total antioxidant status of the plasma. In this study, significant ($p < 0.05$) effects of treatment included a 15% decline in body-weight gain, along with 6% and 30% decreases in food and fluid intakes (respectively). Erythrocyte count was decreased by 6%, while hemoglobin concentration was depressed by 10.6% compared to controls ($p < 0.05$). MCV and MCH were reduced by 4% and 6%, respectively ($p < 0.05$). Leukocyte count and leukocyte composition of peripheral blood were not affected by treatment. The plasma concentration of L-ascorbic acid was decreased (26%, $p < 0.05$), while malondialdehyde content of erythrocytes was increased (78%, $p < 0.05$). Based on data presented in tables, there are no statistically significant changes in Hct, MCHC, red-cell distribution width, or phagocytic activity of neutrophils with exposure. A LOAEL of 11 mg V/kg-day is identified for these data based on a 15% decrease in body-weight gain (possibly related to reduced food and fluid intake) and hematology changes; no NOAEL can be determined.

In contrast to the studies published by Zaporowska and collaborators, Dai et al. (1995) observed no effects on hematology parameters in groups of eight male Wistar rats exposed to ammonium metavanadate (140 mg/L) and vanadyl sulfate (260 mg/L) in the drinking water for 12 weeks. An additional group of eight rats received untreated water. Body weight, food intake, and fluid intake were measured before exposure and on Weeks 1, 2, 4, 8, and 12 of treatment. These data were used by the authors to estimate vanadium doses of 0.19 and 0.15 mmol V/kg-day for ammonium metavanadate and vanadyl sulfate, respectively; these values correspond to dose estimates of 9.7 and 7.6 mg V/kg-day, respectively. Blood samples were collected on the same schedule as body weight measurements for evaluation of Hct, Hgb, RBC, WBC, platelet count, differential leukocyte count, reticulocyte percentage and erythrocyte osmotic fragility tests. No other evaluations were performed. Vanadium in the drinking water led to significantly ($p < 0.05$) reduced fluid intake, regardless of the compound administered (data presented graphically). However, food intake and body weight were not affected by exposure and there was no statistically significant effect on any hematology parameter at any time (data shown graphically). This study identifies freestanding NOAELs of 9.7 and 7.6 mg V/kg-day (for ammonium metavanadate and vanadyl sulfate, respectively) for hematologic effects in male rats.

Adachi et al. (2000) exposed groups of seven female Wistar rats to sodium metavanadate in the diet for 10 weeks. Concentrations of 0, 50, or 100 ppm (0, 21, or 42 ppm V) were incorporated into the diet. Food intake and body weight were measured weekly; vanadium doses calculated for this review based on food intake (14 g/day) and body weight (0.260 kg) roughly estimated from graphical presentation of these data are 1.1 and 2.3 mg V/kg-day. After exposure was terminated, the animals were sacrificed and blood was collected for hematology (RBC, WBC, platelet count, reticulocyte count, Hgb, cell number, immunoglobulin levels) and serum chemistry (AST, ALT, cholinesterase [ChE], ALP). Thiobarbituric acid levels (a measure of lipid peroxidation) were determined in the liver, kidney, and spleen, while vanadium and metallothionein (a metal-binding protein) contents of the liver and kidney were also assayed. Histopathology was not assessed. Statistically significant decreases ($p < 0.05$) in body weight were observed at both doses after 3 weeks of exposure; however, the body-weight decrements at termination were less than 10% (approximately 5% and 7% lower than controls) at both doses.

Food intake was not affected by exposure. Hematology and serum chemistry data were presented graphically with statistical analysis of differences from control. ALT, ChE, and ALP levels were significantly ($p < 0.05$) decreased at both doses. Although AST levels were reduced by more than half at both doses, the difference was significantly different from control only at the high dose. A decrease in serum liver enzymes is not considered to be of toxicological significance. Hemoglobin content and hematocrit were slightly reduced at both doses ($p < 0.05$), but erythrocyte count was not affected. Based on visual inspection of the graphs, the Hgb decrease was about 4% at both doses, and Hct was decreased from about 51% to about 49%. Platelet and reticulocyte counts were increased, while leukocyte counts were decreased at the high dose only. The decrease in leukocytes was primarily a result of reduced lymphocyte counts, specifically B cells. Plasma levels of immunoglobulin G (IgG) and IgM were also reduced at the high dose. Lipid peroxidation, as measured by thiobarbituric acid content, was increased in the kidney at the high dose only. Metallothionein content of the kidney is very slightly statistically significantly ($p < 0.05$) higher in the exposed groups relative to controls; there was no difference in the liver. Given the minimal changes in hematology and small body-weight decrease (~7%), the high dose (2.3 mg V/kg-day) is considered a NOAEL.

Kasibhatla and Rai (1993) administered vanadium in drinking water to rabbits (strain and sex not given) in a study evaluating limited hematology parameters. Rabbits (4/dose) were exposed to concentrations of 0, 20, 40, or 80 ppm vanadium for 171, 171, 129, or 24 days, respectively. The test material was characterized as "metavanadate." These exposure levels correspond to doses of about 3.3, 6.7, and 13.8 mg V/kg-day based on measured body weights and default values for water intake (U.S. EPA, 1988). An untreated control group received tap water. Body weights were recorded at irregular intervals. Blood samples were collected periodically for evaluation of erythrocyte and leukocyte counts, hemoglobin concentration and packed cell volume. The authors reported clinical signs including diarrhea, conjunctivitis, weakness, white nasal secretions, and loss of appetite in exposed rabbits, but no information on incidences or doses is provided. Body weights were generally lower in the treated groups, but the authors' statistical analysis indicated significantly reduced body weights only in the low-dose group; thus, this finding appears to be spurious. The authors also reported statistically significant ($p < 0.05$) reductions in erythrocyte count, hemoglobin concentration, and packed cell volume in the treated animals. However, the hematology data show decreasing numbers of treated rabbits over time, without explanation. It is not clear whether the missing animals died or were otherwise removed from the study. The poor reporting in this study precludes determination of effect levels.

Steffen et al. (1981) observed increased blood pressure in renally compromised rats exposed to vanadium. Groups of 20 adult male uninephrectomized Sprague-Dawley rats were given rat chow containing 100-ppm vanadium and either tap water or a 1% solution of sodium chloride to drink for 9 weeks. Based on default values for food intake and body weight (U.S. EPA, 1988), the dose for this experiment was estimated to be 9 mg V/kg-day. Control groups of the same size were given untreated rat chow (which contained 0.3-ppm vanadium) with one of the two fluid options. Fluid intake, urine volume, and urinary sodium concentration were measured daily. Body weights and systolic blood pressure (measured by tail cuff) were measured weekly. Upon sacrifice at the end of exposure, heart weights were recorded. There was one rat exposed to vanadium and sodium chloride that died at Week 3 of exposure; cause of death was not noted. Body-weight gain was lower in the vanadium-treated groups than in the

corresponding control groups, with statistically significant ($p < 0.05$) reductions after the 4th week of treatment. Based on visual examination of the data presented graphically, body weights of the treated groups at termination were about 12% lower than corresponding control body weights. The authors reported that vanadium treatment did not alter water consumption, urine volume, or urinary excretion of sodium (data on sodium excretion shown) compared with corresponding control groups. In the vanadium-exposed group consuming tap water, blood pressure was increased over the tap-water control group after the 3rd week of exposure ($p < 0.05$). Blood pressure data are presented graphically; based on visual examination of the data, systolic blood pressure approached 150 mm Hg in the vanadium-tap water group, compared with a value of <130 mm Hg in the tap-water controls. Though blood pressure measures were higher in vanadium-treated rats consuming sodium chloride, the difference from the sodium chloride control group is not statistically significant. Heart weight was not affected by vanadium treatment (data not shown). These data suggest a LOAEL of 9 mg V/kg-day based on decreased body weight. Although one rat died in the first experiment, there are no other indications of severe toxicity that would suggest that the death was related to treatment.

Susic and Kentera (1986) assessed the effects of vanadium administration on pulmonary circulation in adult male Long-Evans rats. After 2 months of exposure to ammonium vanadate in the diet (300 ppm or about 130-ppm vanadium assuming that the administered form was ammonium metavanadate), pulmonary and systemic blood pressure and cardiac output were measured and pulmonary and systemic vascular resistances were calculated from these measurements. Blood pressure was measured directly using a femoral artery cannula in anaesthetized animals. Using default values for food consumption and body weight (U.S. EPA, 1988), this dietary concentration is estimated to result in a dose of about 12 mg V/kg-day. Arterial blood was collected for assessment of hematocrit (timing not reported), but the results are not reported. After the exposure period, the rats were sacrificed and hearts removed for determination of left and right ventricular weights. Body weight, heart rate, mean femoral artery pressure, cardiac output, and total peripheral resistance were not affected by exposure (data shown). Significant ($p < 0.05$) increases in right ventricular systolic and mean pressures, as well as the calculated pulmonary vascular resistance, were observed with exposure (data presented graphically). The right ventricles of exposed rats were slightly enlarged, as shown by increased relative weight compared to controls (5%, $p < 0.05$). These data suggest a LOAEL of 12 mg V/kg-day based on pulmonary hypertension.

Susic and Kentera (1988) compared the hypertensive effects of sodium metavanadate in normal and partially nephrectomized Long-Evans rats. Groups of 18–24 male rats were fed diets containing 0-, 300-, or 3000-ppm sodium metavanadate for 24 weeks. The authors estimated doses of 5 and 47 mg sodium metavanadate per rat per day, corresponding to doses of approximately 4.4 and 42 mg V/kg-day (assuming a body weight of 0.472 kg for male Long-Evans rats [U.S. EPA, 1988a]). A separate group of 38 rats was subjected to partial nephrectomy followed by exposure to either the control diet or a diet with 300-ppm sodium vanadate (calculated to deliver a dose of 4.5-mg sodium metavanadate per rat per day, or 4.0 mg V/kg-day). Measurements of systolic blood pressure, heart rate, and body weight were recorded biweekly and renal function (plasma creatinine concentration, 24-hour creatinine clearance, urinary sodium excretion, and urinary output) was assessed in eight randomly chosen rats per group during Weeks 5 and 6. After exposure was terminated, groups of six randomly selected rats per group were selected for determination of hematocrit as well as plasma and extracellular fluid volumes. The remaining animals were used for measurement of blood

pressure, cardiac output, and total peripheral resistance. The animals were then sacrificed for removal of hearts and measurement of left and right ventricular weights. Body weights were significantly lower at both doses in the nonnephrectomized rats ($p < 0.001$ by t-test performed for this review), but they did not exceed a 7% decrease from control body weight in either group. The authors indicated that food intake was not affected by exposure (data not shown). Graphical and tabular presentation of data indicated that systolic blood pressure, heart rate, and mean arterial pressure were unchanged by vanadium treatment in nonnephrectomized rats. Statistically significant ($p < 0.05$) changes observed in nonnephrectomized rats at the end of exposure included decreased cardiac output and increased total peripheral resistance at both doses and increased hematocrit and decreased extracellular fluid volume at the high dose (see Table 5). In partially nephrectomized rats, systolic blood pressure, mean arterial pressure, and total peripheral resistance were significantly increased by exposure; other parameters were not affected by exposure. The authors indicated that the increase in resistance resulted from a vasoconstrictive effect of vanadium. In rats with intact kidneys, the increased peripheral resistance was offset by a reduction in cardiac output and blood pressure remained stable. In partially nephrectomized rats, there was no compensatory reduction in cardiac output; thus, an increase in blood pressure was observed. Renal function was not modified by vanadium exposure in any of the groups of rats, based on the parameters measured (data shown). These data indicate a LOAEL of 4 mg V/kg-day based on increased blood pressure in partially nephrectomized rats. A NOAEL cannot be determined.

Table 5. Significant Changes in Cardiovascular Parameters in Rats Exposed to Sodium Metavanadate for 24 Weeks[a]

Parameter	Control	4 mg V/kg-day (300 ppm)	47 mg V/kg-day (3000 ppm)
Nonnephrectomized rats			
Cardiac output (mL/min per 100 g)	25.6 ± 1.2	22.2 ± 0.6[b]	21.2 ± 0.9[b]
Total peripheral resistance (mm Hg/mL per min per 100g)	4.44 ± 0.12	5.41 ± 0.23 [c]	5.82 ± 0.31 [c]
Hematocrit	41.9 ± 0.7	43.5 ± 0.5	45.5 ± 1.3[b]
Extracellular fluid volume (mL/100g)	17.0 ± 0.3	15.9 ± 0.4	12.9 ± 0.3[d]
Partially nephrectomized rats			
Mean arterial pressure (mm Hg)	112 ± 4	134 ± 3[d]	NA
Total peripheral resistance (mm Hg/mL per min per 100g)	4.11 ± 0.29	5.15 ± 0.25[b]	NA

[d]$p < 0.001$

Van Vleet et al. (1981; Van Vleet and Boon, 1980) exposed groups of six male pigs to ammonium metavanadate in feed (0 or 200 mg V/kg) for 10 weeks. The dose estimated for this review was 10 mg V/kg-day based on the average body weight reported in the study (12 kg) and assuming a feed consumption rate of 0.6 kg feed/day (Brooks et al., 1984; U.S. EPA, 1988). The authors indicated that food consumption was decreased in the treatment group relative to controls (data not reported); therefore, the calculated dose may overestimate the actual dose in the treatment group. Endpoints assessed include clinical signs, weekly body weight measurements, blood glutathione peroxidase activity, gross necropsy, and microscopic histopathology assessment of heart, kidney, liver, lung, skeletal muscle, stomach, and "other organs with lesions." There were two deaths in the treatment group (33% mortality): one death on Day 60 of

exposure and one on Day 65. Clinical signs observed in treated pigs (and not in controls) were emaciation, rough hair coats, diarrhea, and blood in feces (incidences not reported). Body weights were markedly lower in the treatment group compared to the control group (one-third to one-half of control values; significantly lower at $p < 0.05$) throughout the exposure period; this decrease may have been associated with the reduction in food consumption. Blood glutathione peroxidase concentrations were not different from controls. The histopathology assessment revealed no abnormalities in the control group and the following findings in the treatment group: ulceration of the large intestine (4/4 surviving pigs), bladder cystitis (2/4), periportal infiltration of mononuclear leukocytes in liver (3/4) and necrosis of the heart atria (2/4). The dose used in this study (10 mg V/kg-day) is a FEL based on mortality and emaciation.

Chronic Studies—There were three multiyear bioassays of vanadium published in the 1960s and 1970s that have been identified in the literature searches; none of the studies met current standards for assessment of chronic toxicity and/or carcinogenicity.

Kanisawa and Schroeder (1967) exposed white Swiss mice (53 treated, 198 controls; sex not specified) to vanadyl sulfate in the drinking water at a concentration of 5 mg V/L from birth until natural death. The dose estimated for this review is 1 mg V/kg-day based on default values for body weight and water intake (U.S. EPA, 1988). The group sizes are not specified. Survival and body weight were monitored. Upon death, the animals were examined for gross lesions and the heart, lung, kidney, liver, spleen, and abnormal organs were examined microscopically. The authors emphasized that the tumor data reflected only tumors visible under a magnifying lens since serial sections for histopathology evaluation were not performed. The authors reported that neither survival nor body weight were affected by vanadium treatment (data not shown). Tumor incidences were grouped across sex for reporting. Based on the tabulated results, exposure to vanadium did not increase the incidence of any individual tumor type or the total incidences of "pre-tumorous lesions," benign, or malignant tumors (grouped across target organ). However, statistical analysis of the individual tumor data is precluded by the absence of group size information. These data are not adequate to define effect levels for chronic exposure.

Schroeder et al. (1970) exposed Long-Evans rats to vanadyl sulfate in drinking water from weaning through natural death (up to 45 months in this study). The treatment group consisted of 61 female and 52 male rats that had free access to drinking water to which 5 mg/L vanadium was added. Controls (54 female, 52 males) were exposed to water without added vanadium. Doses estimated for this review based on reported body weights and default fluid intakes (U.S. EPA, 1988) are 0.7 and 0.9 mg V/kg-day in males and females, respectively. Body weight was measured weekly until 6 weeks of age and then monthly thereafter; at the same times, blood pressure was recorded and blood collected for assessment of serum glucose levels. Upon death, animals were necropsied, hearts were removed and weighed, and grossly visible tumors and other lesions were described. An outbreak of pneumonia during this study led to the deaths of 17 treated males, 17 treated females, 19 control males, and 12 control females; the timing of the outbreak was not reported. No differences were observed in the following endpoints: life span and longevity, body weight, blood pressure (measured with arterial cannula in anesthetized animals), urine protein and glucose, and gross tumor incidence (all data other than urine protein were shown). This study found significant ($p < 0.05$) differences between the treatment and control groups in the following endpoints: increased fasting plasma glucose concentrations (21%) in treated females, increased fasting plasma cholesterol concentrations

(18%) in treated males and decreased fasting cholesterol concentrations (41%) in treated females. Absolute and relative heart weights were 18 and 15% lower (respectively) in treated males relative to controls, while female heart weights were higher (4 and 5% higher for absolute and relative weights, respectively). No treatment-related increases in tumor formation were found. Microscopy was performed on "some" tissues; however, a comprehensive microscopy evaluation apparently was not performed or not reported. No microscopic lesions were reported for any animals, although the histological evaluations performed in this study were not adequate to detect any but the most severe lesions. However, a LOAEL of 0.7 mg V/kg-day can be established for increased fasting plasma glucose and cholesterol levels and decreased heart weights.

Using a study design similar to that above, Schroeder and Michener (1975) exposed groups of Swiss mice (54/sex) to vanadyl sulfate in drinking water (5 mg V/L) for their lifetimes; controls (54/sex) were given untreated water. The dose estimated for this review based on reported body weights and default estimates of fluid intake (U.S. EPA, 1988) was 1 mg V/kg-day in both sexes. The toxicological evaluations are the same as reported by Schroeder et al. (1970). Significant differences between the treatment and control groups included increased body weight in treated males and increased life span and longevity in treated males and females. A gross assessment of tumors and microscopy of "some" tissues revealed no treatment-related increases in tumor incidence. The limitations in the histological evaluations performed in this study preclude the identification of effect levels from these data.

Steffen et al. (1981) exposed groups of uninephrectomized rats (group sizes not reported) to dietary concentrations of 100- or 200-ppm vanadium (as sodium orthovanadate) for 56 weeks. Based on default values for food intake and body weight (U.S. EPA, 1988), the doses for this experiment are estimated to be 7 and 14 mg V/kg-day. Body weights and systolic blood pressure (measured by tail cuff) were measured weekly. Upon sacrifice at the end of exposure, heart weights were recorded, and tail artery norepinephrine content was measured. There were two rats given 14 mg V/kg-day that died "early in the experiment"; neither timing nor cause of death was reported (Steffen et al., 1981). In the 14 mg V/kg-day group, body weights were significantly ($p < 0.05$) below controls beginning at Week 20 of treatment; based on graphical presentation of the data, terminal body weight in this group was about 13% below that of controls. Body weight was not significantly different from controls in the low-dose group. In both groups of vanadium-treated rats, systolic blood pressure was significantly ($p < 0.05$) increased over controls, in a dose-dependent fashion, after the first 1–2 months of treatment. Increases of up to 10 and 25 mm Hg were seen in the low- and high-dose groups, respectively. Plasma vanadium concentration measured at sacrifice correlated strongly with the last measure of systolic blood pressure ($r = 0.71$, $p < 0.001$), bolstering evidence for the apparent relationship with exposure. The low dose (7 mg V/kg-day) is a freestanding LOAEL for increased blood pressure in uninephrectomized rats.

Dai et al. (1994a,b; Dai and McNeill, 1994) exposed groups of nondiabetic and diabetic (streptozocin-induced) male Wistar rats to vanadyl sulfate in drinking water for 1 year. The three publications each reported findings of different endpoints. A control group consisted of eight rats given free access to water without added vanadate. There were three treatment groups that consisted of 8 rats/group exposed to water to which vanadyl sulfate was added; the exposures (mg vanadyl sulfate/L) were as follows: treatment group 1500 mg/L for 52 weeks; treatment group 2500 mg/L for 1 week followed by 750 mg/L for 51 weeks; treatment group

3500 mg/L for 1 week followed by 750 mg/L for 1 week, followed by 1250 mg/L for 50 weeks. Food intake, fluid intake, and body weight were recorded every 3–5 weeks throughout the treatment period. On the basis of these measures, the authors estimated the doses of vanadyl sulfate to be 34, 54, and 90 mg/kg-day (8, 13, and 21 mg V/kg-day, using the molecular weight for the trihydrate form) in nondiabetic rats. In diabetic rats, vanadyl sulfate treatment was adjusted up or down in order to control blood glucose or prevent diarrhea and weight loss. The authors estimated vanadyl sulfate doses of 73 to 165 mg/kg-day (17 to 39 mg V/kg-day) at different time points in the diabetic rats. The general condition of the animals—especially the occurrence of diarrhea or cataracts—was assessed during treatment. Nonfasting blood glucose was measured weekly for the first month and then every 2–4 weeks thereafter. Fasting blood glucose, insulin, triglycerides and cholesterol were measured every 3 months during treatment. The following measurements were made after 3, 6, 9, and 12 months of exposure: blood pressure (measured with a tail cuff sensor in conscious animals), pulse rate, hematocrit and plasma concentrations of AST, ALT, and urea. Most animals were sacrificed after the exposure period; however, three control nondiabetic rats, eight treated nondiabetic rats, and five treated diabetic rats were monitored for 16 untreated weeks prior to sacrifice. At sacrifice, a hematology assessment (Hgb, RBC, total and differential WBC, platelet count, reticulocyte count) was conducted and the following organs were weighed and examined microscopically: adrenal, brain, heart, kidney, liver, lung, pancreas, spleen, testis, and thymus.

In nondiabetic rats, 1/8 animals treated at the highest dose died of unknown causes after 18 weeks of exposure (Dai et al., 1994a). Neither food nor fluid intake was significantly affected by exposure to vanadyl sulfate (data shown graphically). However, body weight gain was reduced in a dose-related manner in treated nondiabetic animals relative to control nondiabetic animals. Based on visual inspection of data presented graphically, the body weight decrements at termination were approximately 10% in the low- and mid-dose groups and 20% in the high-dose group; statistical analysis of the data was not presented. Other than body weight data, most information on the nondiabetic treated rats was pooled across the three treatment groups (the authors indicated that there were no differences among the three groups). Vanadyl sulfate treatment did not affect blood or plasma glucose levels, plasma triglycerides, or cholesterol levels, but significantly lowered plasma insulin levels compared with controls at Weeks 12 and 25 (data presented graphically; *p*-value not reported). No significant changes were observed in the treatment group relative to the control group for the following endpoints: systolic blood pressure, pulse rate, hematology endpoints and relative organ weights (Dai et al., 1994a; Dai and McNeill, 1994). Plasma ALT and urea concentrations are significantly ($p < 0.05$) higher (<2-fold higher based on data presented graphically) in the nondiabetic treatment group relative to the corresponding control group after 3 months of exposure but not after 6, 9, 12, or 16 months of exposure (data presented graphically).

Histopathology findings included a high incidence of glomerular and tubular degeneration and interstitial cell infiltration and fibrosis of the kidney in the nondiabetic control group: 3/5 (60%) at the end of exposure and 2/3 (66%) at 16 weeks postexposure, for a combined incidence of 5/8 (63%) for the two assessment times (Dai et al., 1994b). Despite this high incidence in controls, which was probably age- and/or husbandry-related, the treated animals (all three treatment groups pooled) had a higher incidence: 15/15 (100%, $p = 0.053$) at the end of the exposure, 7/8 (88%, $p = 0.049$) 16 weeks postexposure and a combined incidence of 22/23 (96%; $p = 0.043$) (based on Fisher exact test performed for this review). These results are consistent

with the higher plasma urea concentrations in the treatment group. No other histopathology findings are significantly increased with exposure to vanadyl sulfate. Based on the reduced body weight in the low-dose group (~10% lower than controls at termination), and possibly renal pathology, a LOAEL of 8 mg V/kg-day is identified for nondiabetic rats; no NOAEL can be determined.

Vanadyl sulfate treatment of diabetic rats improved or prevented a number of adverse effects seen in untreated diabetic rats, including: mortality; increased food and fluid intake; hypoinsulinemia; polydipsia; cataract formation; elevations of serum glucose, ALT, urea, triglycerides and cholesterol; bradycardia; decreased leukocyte count; increased relative organ weights and occurrence of megacolon (Dai et al., 1994a,b; Dai and McNeill, 1994). No improvement was seen in body-weight gain, which was markedly lower in both untreated and vanadyl sulfate-treated rats than in both control and treated nondiabetic rats. At the end of exposure, body weights were about 30% lower in both groups of diabetic rats when compared with nondiabetic controls (based on graphical presentation of data). Likewise, renal effects that were significantly increased in diabetic controls (compared with nondiabetic controls), including vacuolation of tubular epithelial cells and renal cell tumors, occurred at similar frequency in vanadyl sulfate-treated diabetic rats. As vanadium treatment was not associated with adverse effects in diabetic rats, the dose to this group (17 to 39 mg V/kg-day) is considered a NOAEL in diabetic rats.

Carmignani et al. (1991) exposed male Sprague-Dawley rats to sodium metavanadate in drinking water for 7 months beginning at weaning. Groups of 10 rats were exposed to water to which 0 or 100 mg V/L was added. The calculated dose was 12 mg V/kg-day, based on default values for fluid intake and body weight (U.S. EPA, 1988). At the end of exposure, blood pressure was measured (with an arterial cannula in anesthetized animals), urinalysis was performed on a 24-hour urine collection and both light and electron microscopic evaluation of the heart and kidney were performed. Systolic and diastolic blood pressure were significantly ($p < 0.05$) elevated in the treatment group compared to the control group (systolic: control 122 mmHg, treatment group 144 mmHg; diastolic: control 95 mmHg, treatment 115 mmHg), as was heart rate (control 239 beats per minute, treatment 288 beats per minute). According to the authors, the urinalysis revealed no difference in urine osmolarity, nitrogen, protein, or ionized calcium between the treatment and control group (data not shown). Urinary sodium and potassium excretion were significantly elevated (83% and >3-fold higher, respectively; $p < 0.05$) in the treatment group compared to the control group. The histopathology assessment revealed narrowing of the renal proximal tubules, which contained amorphous protein material and swollen mitochondria, in the treatment group. The incidences of these changes in treated and control animals are not reported. No changes were noted in the hearts of the treatment group relative to the control group. A LOAEL of 12 mg V/kg-day is identified based on the increased blood pressure and kidney histopathology. A NOAEL cannot be identified.

Investigators from the same laboratory (Boscolo et al., 1994) conducted further experiments with male Sprague-Dawley rats exposed to sodium metavanadate in drinking water. Groups of six rats were exposed to water containing 1, 10, or 40 mg V/L for 180, 210, and 210 days, respectively, in two experiments. Each experiment had a separate control group receiving untreated water for the same duration. Doses estimated for this review based on default estimates of fluid intake and body weight (U.S. EPA, 1988) were 0.12, 1.2, or 4.7 mg V/kg-day. The following endpoints were assessed: blood pressure (measured with an

arterial cannula in anesthetized animals); heart rate; plasma renin activity, plasma aldosterone, urinary kallikrein activity and urinary Kininase I and II activities (indicators of status of the renin-angiotensin-aldosterone system); urinalysis (creatinine, total nitrogen, proteins, sodium, potassium, and calcium); and microscopic examination of blood vessels, brain, heart, kidney, liver, and lung. Histochemical analysis of the Na+, K+-ATPase activity was assessed in the kidneys of high dose and control rats. Statistically significant changes in the measured parameters are shown in Table 6. Significantly higher ($p < 0.05$) systolic and diastolic blood pressures were observed in all treatment groups relative to the control group. The magnitude of the increase did not appear to be dependent on dose level. Plasma renin activity, plasma aldosterone concentration, and urinary kallikrein, Kininase I, and Kininase II were significantly elevated in the 1.2 and 4.7 mg V/kg-day treatment groups relative to controls, suggesting stimulation of the renin-angiotensin-aldosterone system at these exposure levels. In addition, Kininase I activity was doubled at 0.12 mg V/kg-day, although not statistically significant. In contrast, Kininase II activity and plasma aldosterone were significantly reduced at the low dose. The histological assessment revealed narrowing of the lumen and amorphous casts in renal proximal tubules and a decrease in histochemically detected Na^+, K^+-ATPase activity in injured tubules in the 4.7 mg V/kg-day treatment group. The authors also reported hydropic degeneration (swelling of the cells) in proximal, distal, and straight tubules. The incidences of the latter effect were not reported; however, the authors indicated that these changes were "less evident" at 1.2 mg V/kg-day and absent at 0.12 mg V/kg-day. These data suggest a LOAEL of 0.12 mg V/kg-day based on increased blood pressure (>20 mm Hg increase in both systolic and diastolic measures) and stimulation of the renin-angiotensin-aldosterone system. A NOAEL for increased blood pressure cannot be determined. However, a NOAEL for kidney effects (histopathology) is established at 0.12 mg V/kg-day, with a LOAEL at 1.2 mg V/kg-day.

Table 6. Significant Effects on Cardiovascular Parameters in Male Rats Exposed to Sodium Metavanadate[a]

Parameter	Control[b]	0.12 mg V/kg-day (180 days)	1.2 mg V/kg-day (210 days)	4.7 mg V/kg-day (210 days)

Reproductive Studies—Effects on reproductive success have been reported with preconception exposure to vanadium compounds. Domingo et al. (1986) administered daily gavage doses of 0, 5, 10, or 20 mg/kg-day sodium metavanadate (2.1, 4.2, or 8.4 mg V/kg-day) to male and female Sprague-Dawley rats (20/sex/dose). Male rats received daily doses for 60 days after which they were mated to female rats that had received the same doses 14 days prior to mating. Dosing of females continued through gestation. Half of the females were sacrificed on gestation day (GD) 14 for assessment of the number of corpora lutea, total implantations, resorptions, and living and dead fetuses. The remaining dams were continued on the exposure regimen through weaning of their pups (postnatal day [PND] 21). Evaluations of offspring included viability, body-weight gain, body and tail lengths and clinical signs on PND 1, 4, and 21. Results for pups were pooled across litters. Upon sacrifice of pups at weaning, the weights of heart, lungs, spleen, liver, kidneys, and testicles were recorded. The authors reported that maternal toxicity was not evident in the treated dams, but did not specify the endpoints measured to assess maternal effects. No significant differences between the treatment and control groups were observed in the various indicators of reproductive success assessed at sacrifice on GD 14 (data shown). A significant decrease ($p < 0.05$) in pup growth occurred in all treatment groups compared to the control group, as indicated by deficits in whole litter weight and pup body weight, head-to-rump length, tail length, and relative kidney and liver weights (organ-/body-weight ratios). Body weight per litter was significantly decreased in the high-dose group on PND 4 and the mid- and high-dose groups on PND 21. Table 7 shows the changes in pup growth parameters (pooled across litters) observed on PND 1, 4, and 21. At the

high dose, significant ($p < 0.05$) decreases in relative heart (males only) and spleen weights (both sexes) were also observed. These data suggest a developmental toxicity LOAEL of 2.1 mg V/kg-day based on growth retardation in pups; a developmental NOAEL was not identified. Due to the lack of information on maternal endpoints evaluated, effect levels for systemic toxicity cannot be determined

Table 7. Significant Effects on Growth Parameters (Pooled Across Litters) in Pups of Dams Exposed to Sodium Metavanadate[a]

Llobet et al. (1993) exposed male Swiss mice to sodium metavanadate in drinking water for 64 days prior to mating for 4 days with unexposed females. There were four treatment groups that consisted of 24 mice per group given water to which 100, 200, 300, or 400 mg/L sodium metavanadate was added. The authors reported the doses as 20, 40, 60, or 80 mg/kg-day sodium metavanadate, which correspond to calculated vanadium doses of 8.4, 17, 25, or 33 mg V/kg-day. The control group consisted of 24 mice given water without added vanadate. Dams were killed 10 days after mating (GD 10–14) and their uteri were examined to evaluate pregnancy outcomes. Endpoints assessed included body weights; reproductive success, including the number of implantations, early or late resorptions and dead or live fetuses; testis and epididymis weights; and sperm counts, motility, and morphology. Body weights in the 33 mg V/kg-day group were significantly lower than in the control group (13%, $p < 0.05$). The absolute (but not relative) epididymis weight was reduced by treatment (12%, $p < 0.01$). There was no difference in the absolute or relative testis weight between the control and treatment groups. A lower number of successful impregnations occurred in the 25 and 33 mg V/kg-day dose groups compared to the control group (43.8% and 62.5%, respectively, compared with

81.3% in controls; $p < 0.01$). There were no differences in the number of resorptions or fetal mortality. Outcomes related to sperm included: lower spermatozoa counts in the 25 and 33 mg V/kg-day groups relative to the control group (44% and 31% lower, respectively); a lower spermatid count in the 33 mg V/kg-day group (30%, $p < 0.01$) and no significant difference in sperm motility or morphology between control and treatment groups. These data indicate a LOAEL of 25.1 mg V/kg-day based on reproductive effects in treated male mice (decreased spermatozoa counts and reduced fecundity); the NOAEL is 17 mg V/kg-day.

In a study comparing reproductive effects of vanadium in diabetic and nondiabetic rats, Ganguli et al. (1994a) administered concentrations of 0, 250, or 500 mg/L sodium orthovandate (~69 or 138 mg V/L) with 0.45% normal saline in the drinking water of female Sprague-Dawley rats. There were six groups of 15 rats/dose that were used (three groups each of nondiabetic and streptozocin-induced diabetic rats). The authors reported that the animals were mated to untreated males at the commencement of treatment (Day 1); however, the balance of the treatment regimen was not described, so the duration of treatment is not known. Body weight, fluid intake, and urine glucose were measured daily; however, data on body weight and fluid intake are not reported or described. In the absence of information on the treatment schedule, it is not possible to estimate doses with any degree of confidence. Pregnant dams were sacrificed one day after giving birth; those treated females that did not become pregnant or failed to deliver were sacrificed for examination of uteri and ovaries. At birth, the total number of pups and total body weight were recorded. In contrast to the findings discussed previously (Dai et al., 1994a,b; Dai and McNeill, 1994), vanadium was severely toxic to diabetic rats; 7/15 females exposed to 500 mg/L died before Day 15 of treatment and the remainder had severe diarrhea and lack of appetite; these animals were sacrificed humanely. Mortality also occurred at the low dose in diabetic rats (3/15). No deaths occurred in controls. In high-dose nondiabetic rats, moderate-o-severe diarrhea was observed in 12/15 rats; this effect was not reported in low-dose nondiabetic rats. The rate of conception was significantly ($p < 0.05$) reduced by vanadium exposure in both diabetic and nondiabetic rats. When compared with nondiabetic controls, the rate of conception is reduced by 13% and 20% at 250 and 500 mg/L (respectively) in nondiabetic rats and by 7%, 33%, and 47% in 0, 250, and 500 mg/L (respectively) diabetic groups. Ability to carry a pregnancy to term was also compromised by vanadium exposure, significantly so in the diabetic animals. Compared with nondiabetic controls, nondiabetic treated animals exposed to 250 and 500 mg/L were 30% and 84% (respectively) less likely to carry pregnancy to term. In diabetic animals, fewer than 10% of animals at the low dose carried pregnancy to term; as the high-dose group was sacrificed early, there are no data on this endpoint. Effect levels cannot be determined from these data since duration of treatment is unknown and doses could not be estimated.

Faria de Rodriguez et al. (1998a) conducted three experiments to evaluate the effects of exposure to vanadium on the development of the central nervous system in albino rats. This study was published in Spanish and translated for this review. Groups of four female rats were used in all experiments. In the first experiment, three groups were exposed to 0, 100, or 200 ppm ammonium metavanadate (43.5 or 87 ppm V) in the drinking water from weaning until mating; treatment was discontinued during mating and gestation. Doses estimated for this review based on default values of water intake and body weight (U.S. EPA, 1988) were 7 and 15 mg V/kg-day. From each group, two dams were sacrificed at GD 20, while the other two were allowed to deliver. Litters were sacrificed at birth for gross examination of external and

internal malformations and the CNS was removed for microscopic examination and histochemical assessment of glycosaminoglycans. In another experiment, two groups of neonates whose mothers had been exposed to 100-ppm ammonium metavanadate from 37 days of age until mating were exposed to concentrations of 0 or 100 ppm via lactation until weaning and then via drinking water until mating. As with the first experiment, half of each group was sacrificed at GD 20 and half after delivery; evaluation of litters was also the same. In the final experiment, newborn rats of untreated mothers were exposed via lactation and then via drinking water to 0 or 200 ppm ammonium metavanadate. All rats of the final experiment were permitted to deliver. Females in all of the control groups delivered litters averaging from 5–11 offspring each. All four rats exposed to 7 mg V/kg-day in the first experiment became pregnant, delivering an average of 11 offspring per litter. At 15 mg V/kg-day, one rat died, one delivered a litter of 11 offspring, and the other 2 did not become pregnant. In the second experiment, of four rats exposed to 7 mg V/kg-day from birth to mating, only two became pregnant and delivered litters, averaging six offspring each. Similarly, in the third experiment, exposure to 15 mg V/kg-day resulted in only 2/4 females delivering litters (4 and 10 offspring each). No gross external malformations were observed in any of the groups. Data on the microscopic examination of brains were grouped across the experiments, so a dose-response relationship could not be discerned. Of the 81 brains obtained from the offspring of treated animals, 13 exhibited unilateral hypoplasia of the olfactory bulb and one exhibited unilateral hypoplasia of the cerebral hemisphere; the remaining brains were characterized as normal. Microscopic effects on the olfactory bulbs (for example, thinning or disorganization of the glomerular layer) were also seen in the brains of animals with grossly observable effects; the incidences of specific effects were not reported. All brains of control offspring were normal both macroscopically and microscopically. Histochemical studies indicate that exposure to 15 mg V/kg-day increased the glucosaminoglycan content—specifically those of a low grade of sulfation. Effect levels cannot be determined from these data due to the lack of incidence data, the grouping of effect information across treatment groups, and incomplete reporting.

Faria de Rodriguez et al. (1998b) exposed male and female Swiss albino mice to ammonium metavanadate from birth until the animals were mated. This study was published in Spanish and translated for this review. The test compound was administered in drinking water to mothers so that the offspring were exposed via lactation until weaning, when they were continued on the same exposure via drinking water (0, 100, or 200 ppm) until mating. These concentrations correspond to 43.5 and 87 ppm vanadium or dose estimates of 15 and 30 mg V/kg-day (males) and 14 and 28 mg V/kg-day (females) based on default values[2] for body weight and water intake (U.S. EPA, 1988). The animals' body weight, body length, and tail length were measured weekly. At maturity, the males and females of each exposure group were mated with same-treated mice or cross-mated with untreated mice to evaluate separately the effects on each gender. Numbers of offspring, as well as weight and length of offspring, were assessed after successful mating. The authors reported the results of statistical analysis of the parameters, but did not report the data for any endpoints. In addition, results for the same exposure level were grouped across sex. The authors reported that there were no treatment-related differences in body weight of the parents. Body length of treated mice was significantly ($p < 0.05$) reduced with exposure to 28–30 mg V/kg-day, and tail length was significantly lower at both exposure levels when compared with control animals. In contrast, neither weight nor length of offspring was affected in any of the matings. Further, the number of

[2]Assuming body weight and water intake at weaning.

offspring was higher in the exposure groups than in the control group. Effect levels cannot be determined from these data due to inconsistent outcomes and poor reporting.

The same group of investigators conducted additional experiments on female Swiss albino mice (Nava de Leal et al., 1998). This study was also published in Spanish and translated for this review. Ammonium metavanadate was administered in drinking water at concentrations of 0, 100, or 200 ppm (0, 43.5, or 87 ppm vanadium) at various times as shown in Table 8. Dose estimates calculated for this review are 11 or 23 mg V/kg-day based on default values[3] for body weight and water intake (U.S. EPA, 1988). In each experiment, exposure was suspended during 8 days of mating with untreated males (ratio of 1 female to 2 males) and during gestation. After mating, the mice were housed individually and weighed twice weekly. Pregnant mice were allowed to deliver; pregnancy rates and number of offspring were recorded. Those mice that failed to become pregnant were sacrificed 21 days after mating for evaluation of the following parameters: uterine and ovarian weights; corpora lutea counts and histopathology examination of the ovaries. The reporting of results was limited by some inconsistencies and apparent typographical errors. As Table 8 shows, the pregnancy rate was significantly reduced from controls in 2/3 groups (C1 and F1C, but not A2) exposed to 23 mg V/kg-day but not in any group exposed to 11 mg V/kg-day. The absence of an effect on pregnancy rate in Group A2 (exposed to 23 mg V/kg-day from weaning until mating) contrasts with the findings in Group C1 (exposed to 11 mg V/kg-day until first mating and then to 23 mg V/kg-day from parturition until second mating) and suggests that cumulative exposure may be an important factor in the effects of vanadium on mating success. In the statistical analysis of litter sizes, groups exposed for different time periods to the same concentration were combined (details unclear). The results shown in Table 8 indicate that litter size is significantly smaller in mice exposed to 23 mg V/kg-day compared with controls (*p*-value not given). A similar approach was used to compare the numbers of corpora lutea; this analysis also showed a reduced average number of corpora lutea in mice exposed to 23 mg V/kg-day compared with untreated controls. Corpora lutea were counted only in mice that failed to become pregnant, which may have biased the findings.

[3]Assuming body weight and water intake for subchronic exposure.

Table 8. Exposures, Group Sizes, and Pregnancy Outcomes Among Mice Exposed to Ammonium Metavanadate[a]

Group	Exposure Period	Dose (mg V/kg-day)	No. Mice	Pregnancy Rate (%)	Average Litter Size
A1	Weaning to adulthood (mating)	0 11	8 12	NR[b] 50	13 13
A2	Weaning to adulthood	0 23	8 12	50 66.6	9 8
B	Weaning to adulthood	0 11	8 12	75 83.3	11 9
B1	Second mating of Group B; no exposure between matings	0 11	6 10	100 100	10 10
F1B	Offspring of Group B	0 11	9 26	66.6 73	NR NR

C1	Mice Group C that successfully became pregnant; exposed from parturition until second mating	0 23	6 10	100 20[c]	9 3
F1C	Offspring of Group C; exposed via lactation until weaning and drinking water until adulthood	0 23	8 24	65 0[c]	12 0

[a]Nava de Leal et al., 1998
[b]Not reported
[c]Significantly different from control, $p < 0.0001$

Microscopic examination of the ovaries from mice that failed to become pregnant showed histopathology associated with exposure to vanadium (Nava de Leal et al., 1998). Most (94%) samples of ovaries from control mice that failed to become pregnant were reportedly normal. In contrast, ovaries of mice exposed to 11 mg V/kg-day (Groups A1 and B) exhibited fewer follicles and/or follicular atresia (absence of follicles due to degeneration); the follicles that were seen were enlarged and conferred a "polycystic aspect" on the ovaries. Histopathology findings in the ovaries of mice exposed to 23 mg V/kg-day (Groups A2, C1, and F1C) were more pronounced, including absence of mature follicles and corpora lutea, marked follicular atresia, thickening of the external theca, loss of ovarian parenchymal architecture, cellular disaggregation, and cytoplasmic vacuolation in granulosa lutein cells. The authors reported the incidences of these findings in the ovaries of mice that did not become pregnant; however, the overall incidences of these effects in treated mice were not available, as histopathology was not assessed in mice that became pregnant. Ovarian histopathology changes in mice exposed to 11 mg V/kg-day suggest that this dose may be a LOAEL, despite the lack of effect on pregnancy success; however, the absence of data on overall incidences in the treated and control groups (including those that became pregnant), in addition to reporting problems, precludes definition of reliable effect levels for this study.

Morgan and El-Tawil (2003) also assessed the effects of vanadium exposure on reproductive success. Groups of 10 male and 20 female Sprague-Dawley rats were given ammonium metavanadate at concentrations of 0 or 200 mg/L (87 mg V/L) in the drinking water. Based on default values of water intake and body weight (U.S. EPA, 1988), the dose is estimated to be 28 and 30 mg V/kg-day in males and females, respectively. Exposed male rats were treated

for 70 days prior to mating with untreated females; exposed females were treated for 14 days premating and during mating, gestation, and lactation (total of 61 days). During premating, the estrous cycles of females were monitored. Maternal body weights were recorded at the end of gestation. Half of each group of females was sacrificed on GD 20, while the other half, along with their pups, was sacrificed after weaning on PND 21. Gravid uterine and placental weights were recorded. Males were sacrificed after mating for assessment of body, testes, epididymis, prostate, and seminal vesicle weights. Reproductive parameters assessed in the study included: gestation duration; signs of dystocia; numbers of corpora lutea, implantation sites, resorptions, pre- and postimplantation losses; live and dead fetuses; fetal body weight at birth and on PND 4, 7, 14, and 21 and fetal survival during lactation. During lactation, pups were examined for learning and memory responses; however, the specific methods and endpoints were not described. All pups were examined for gross malformations at sacrifice; two-thirds were examined for skeletal abnormalities and the remainder for visceral abnormalities. Exposure to ammonium metavanadate resulted in profound effects on reproductive success and offspring development, regardless of whether males or females were treated. Statistically significant adverse effects are reported for nearly every reproductive parameter assessed, including maternal body, uterine and placental weights; litter parameters; viability of offspring at birth; pup body weight during lactation and incidences of gross, visceral and skeletal malformations. In addition, fewer treated females exhibited normal estrous cycles; treatment of females also resulted in reduced survival and viability indices of offspring. Body weight of treated males was not affected, but testes, epididymis, prostate gland and seminal vesicle weights were significantly ($p < 0.05$) reduced by exposure. Few offspring were produced in the treated groups (20 and 35 in the offspring of treated males and females, respectively, compared with 216 controls). Those that were produced had a high frequency of gross, visceral, and skeletal anomalies. Data were reported using the fetus, rather than the litter, as the unit of statistical analysis, so it is not possible to assess the litter distribution of effects. These data suggest a freestanding LOAEL of 28 mg V/kg-day for reproductive toxicity in rats.

Developmental Studies—Elfant and Keen (1987) exposed groups of at least 14 pregnant Sprague-Dawley rats to diets containing 0- or 75-ppm vanadium (as sodium metavanadate) throughout pregnancy and lactation. Based on default values for body weight and food intake[4] (U.S. EPA, 1988), the dose of vanadium was around 7 mg/kg-day. Maternal weight and food intake were recorded daily. When the dams gave birth, live and dead pups were counted. Pup weights were recorded at birth and every second day thereafter until PND 21. Sacrifice of both dams and pups was performed at PND 21, whereupon brain, kidney, spleen, pancreas, heart, thymus, and testes were weighed. Liver samples were collected for analysis of lipid peroxidation products (reduced glutathione, thiobarbituric acid reactivity, and superoxide dismutase activity).

The authors reported that both food intake and body-weight gain were lower in the exposed dams (statistical analysis not reported); at parturition, the cumulative weight gain appeared to be about 25% lower in exposed animals relative to controls based on visual examination of body-weight gain data presented graphically (Elfant and Keen, 1987). Data on food intake are not reported. The percentage of pups born alive was smaller in exposed dams (about 80%) than in controls (about 90%) and survival to weaning was also lower (about 40% vs. about 70% in controls based on visual examination of data presented graphically and without

[4]Default values for body weight and food intake are uncertain estimates of weight and intake for pregnant animals, but they do provide an approximate estimate of dose in the absence of study-specific data on these parameters.

statistical analysis). The cumulative weight gain of the surviving pups was lower in exposed offspring; at weaning, mean body weights of exposed pups were about 34% lower than controls (data shown graphically and without statistical analysis). Pups of exposed dams were reported to exhibit diarrhea, seborrhea, lethargy, staggered gaits, and ocular exudate (incidences not reported). The relative weights of the liver, brain, and testes were higher in exposed vs. control pups (18%, 36%, and 15%, $p < 0.05$). Reductions in body-weight gain among exposed pups complicate the interpretation of these organ weight changes. Thiobarbituric acid reactivity was elevated in whole cell homogenates from the livers of both dams and pups exposed to vanadium; reduced glutathione was lower in exposed pups than in control pups but was not affected in dams. The latter findings suggest increases in lipid peroxidation with vanadium exposure that may contribute to developmental toxicity. These data indicate a maternal and developmental LOAEL of about 7 mg/kg-day based on reduced maternal food intake and weight gain, as well as reduced pup survival, body weight, growth and clinical signs in pups. A NOAEL cannot be identified.

The effects of sodium metavanadate on development were further studied by Paternain et al. (1987). Groups of 20 pregnant Sprague-Dawley rats were treated with sodium metavanadate via gavage at doses of 0, 5, 10, or 20 mg/kg-day during GD 6–15. Equivalent doses of vanadium were 2, 4, and 8 mg V/kg-day. On GD 20, the uteri were opened by Caesarean section for examination of corpora lutea, implantations, live and dead fetuses, and resorptions. Placental weights were recorded and fetal body weight, body length, and tail length were measured. Gross abnormalities were assessed in all fetuses; half were examined for skeletal abnormalities and half were examined for visceral anomalies. The paper does not report any evaluation of maternal toxicity parameters. At the high dose, fewer litters were produced than in controls or in other dose groups (14, 14, 12, and 8 in control, 2, 4, and 8 mg V/kg-day groups, respectively), but the decrease is not statistically significant. The numbers of resorptions were increased and numbers of live fetuses decreased at both 4 and 8 mg V/kg-day; however, these differences were also not statistically significant. A slight—but statistically significant—decrease in tail length was observed at 2 and 8 mg V/kg-day (4–5%, $p < 0.01$), but not at 4 mg V/kg-day; there was no apparent dose-response relationship. The authors reported that the incidences of skeletal and visceral abnormalities were not affected by treatment (data not shown). A higher percentage of fetuses in the high-dose group exhibited facial (18%) and dorsal (10%) hemorrhages when compared with controls (2% for facial and 2% for dorsal); however, a litter-based comparison between the groups is not presented. The authors characterized the 4 mg V/kg-day dose as a NOAEL for developmental effects on the basis of the hemorrhages observed at the high dose. However, the lack of information on the litter distribution of fetuses with hemorrhages precludes a reliable determination of effect levels from these data. Further, as maternal parameters were not evaluated, no determination of maternal effect levels can be made.

Paternain et al. (1990) administered gavage doses of 0, 37.5, 75, or 150 mg/kg-day vanadyl sulfate pentahydrate (7.5, 15, or 30 mg V/kg-day) to female Swiss mice on GD 6–15. The control group included 20 mice and the treatment groups consisted of 16 or 20 mice per group. Body weight and food consumption were recorded daily and observations for morbidity and mortality were also made daily. Dams were killed on GD 18 and fetuses harvested by Caesarean section; dams were then examined for gross pathology. The following litter parameters were evaluated: number of implants, number of resorptions, and number of live and dead fetuses. Fetal sex, weight, and length were noted. Pups were examined for external,

visceral, and skeletal abnormalities. Treatment did not result in mortality or clinical signs, and food consumption was not different between the treatment and control groups. A significant ($p < 0.05$) decrease in body-weight gain of the dams occurred in all treatment groups during the treatment period (46%, 53%, and 59% below controls at low, mid-, and high doses, respectively). At termination, body weights corrected for gravid uterine weights were reduced at 15 and 30 mg V/kg-day (16% below controls at both doses; $p < 0.05$). At these doses, absolute liver and kidney weights were also reduced proportionate to the body weight decrements. A significant ($p < 0.05$) increase in early resorptions occurred in all treatment groups relative to the control group (2–6 fold higher, without a clear dose-response relationship). Fetal body weights were significantly lower (13–21%, $p < 0.001$) in all treatment groups compared to the control group. The following external and internal soft-tissue abnormalities were observed at significantly elevated incidences (with litter as unit of statistical measure, $p < 0.05$) in fetuses of treated dams: hematomas of the dorsal area (all dose levels), hematomas of the facial area and neck (15 and 30 mg V/kg-day only), anophthalmia/microphthalmia (15 mg V/kg-day), cleft palate, and micrognathia (30 mg V/kg-day). The incidences of litters with external defects (grouped across type) were 2/20, 8/20, 11/20, and 17/20 in control, low, mid-, and high doses, respectively; these were significantly ($p < 0.05$) elevated above control at all dose levels. While the incidences of soft tissue abnormalities (exclusively hydrocephaly) were increased at the mid- and high-dose, the increases were not statistically significant. However, the incidence of skeletal defects were increased at all doses (4/20, 9/16, 15/20, 20/20 affected litters in control through high dose; $p < 0.05$ for all treatment groups). The skeletal abnormalities consisted of poorly ossified supraoccipital bone, carpus, tarsus and sternebrae, as well as bipartite sternebrae and irregular ribs. These data indicate a freestanding LOAEL of 7.5 mg V/kg-day for both maternal toxicity (reduced body-weight gain during treatment) and developmental toxicity (increased resorptions, skeletal malformations, and growth delays).

In a later study by the same laboratory, Sanchez et al. (1991) administered daily gavage doses of 0, 7.5, 15, 30, or 60 mg/kg-day sodium orthovanadate (equivalent to 0, 2.1, 4.2, 8.3, or 17 mg V/kg-day) to groups of 14–20 pregnant Swiss mice on GD 6–15. Maternal appearance, body weight and food consumption were recorded daily. The dams were sacrificed on GD 18 for evaluation of body weight, liver and kidney weights, gravid uterine weight, and uterine parameters (numbers of implants, early and late resorptions, live and dead fetuses). Live fetuses were weighed, sexed, and examined grossly for abnormalities; two-thirds were then prepared for skeletal examination and one-third for visceral examination. Exposure to doses of 8.3 or 17 mg V/kg-day proved to be lethal; 4/18 dams dosed at 8.3 mg V/kg-day died, while 17/19 given the high dose died. Body-weight gain during treatment was reduced at 8.3 mg V/kg-day (30% less than controls, $p < 0.01$) and not at lower doses. Food consumption was significantly ($p < 0.05$) reduced at the beginning of treatment at both 4.2 and 8.3 mg V/kg-day. Body weight at termination, corrected for gravid uterine weight, was unaffected at any dose. Relative kidney weight was slightly—but statistically significantly—increased at 8.3 mg V/kg-day; however, the body-weight reduction at this dose may have contributed to the increased relative kidney weight. Litter parameters were not affected by exposure; at 8.3 mg V/kg-day, one litter contained no viable implants, but the incidence of litters with resorptions was not significantly increased. External and visceral malformations were not increased in exposed groups relative to controls; however, the numbers of litters containing fetuses with incompletely ossified sacrococcygeal vertebrae, forelimb and hindlimb proximal phalanges were increased at 8.3 mg V/kg-day. The authors identified the low dose (2.1 mg V/kg-day) as a NOAEL for maternal toxicity,

presumably considering the decreased food consumption at 4.2 mg V/kg-day. Given the evidence for frank effects at the next higher dose (mortality at 8.3 mg V/kg-day), the decrease in food consumption is considered potentially indicative of toxicity and is used to define the 4.2 mg V/kg-day dose as a LOAEL. The authors considered the 4.2 mg V/kg-day dose to be a NOAEL for developmental effects. For the purpose of this review, the LOAEL for developmental toxicity is 8.3 mg V/kg-day based on increases in the incidence of litters with incomplete skeletal ossification.

Ganguli et al. (1994b) exposed female Sprague-Dawley rats to 250 mg/L sodium orthovanadate (~69 mg V/L) added to drinking water on GD 10–20. The study compared the effects of treatment in diabetic (streptozocin-induced) and nondiabetic rats. The doses (calculated for this review based on reported fluid intakes and estimated body weight[5] of 250 g) were 7.5 and 17 mg V/kg-day in the nondiabetic and diabetic treatment groups, respectively. The treatment groups consisted of 11 diabetic and 7 nondiabetic pregnant females; the control groups consisted of 6 diabetic and 5 nondiabetic pregnant females given water without the addition of vanadate. Endpoints examined in dams included blood and urine glucose concentrations and fluid intake. On GD 20, the animals were sacrificed; the number of live pups and the pups' weights were recorded. Maternal uteri, ovaries, and placentas were examined grossly. Vanadium treatment was lethal in diabetic pregnant rats; only 6/11 dams survived until termination. No deaths occurred in other groups. Intake of drinking water was significantly decreased by vanadium treatment in both nondiabetic and diabetic rats. Fluid intake in the nondiabetic treatment group was approximately half that of the corresponding control group; in diabetic treated rats, fluid intake was about one-third that of the diabetic controls, who had significantly higher water intake than nondiabetic controls. Blood glucose was significantly decreased in vanadium-treated diabetic rats ($p = 0.006$), but the levels were still above those of nondiabetic rats. Urine glucose was not affected by vanadium exposure. Statistical analysis is not reported, and only data on pooled litters are reported; thus, a statistical group comparison cannot be made. Nevertheless, the outcomes included a lower average number of live fetuses on GD 20 (6.71 vs. 9.6 in treated vs. control nondiabetic rats and 5.5 vs. 11.3 in treated vs. control diabetic rats) and lower average pup mass in nondiabetic rats (3.60 vs. 4.02 g in treated vs. control) but not in diabetic rats (statistical analysis not reported). These data suggest that 17 mg V/kg-day is an FEL based on maternal mortality in the treated diabetic rats. Other effect levels cannot be determined due to poor reporting of data and limited endpoints evaluated.

Poggioli et al. (2001) assessed the effects of prenatal and postnatal exposure to vanadyl sulfate on the growth and behavior of Wistar rats. Concentrations of 0 or 300 mg/L of vanadyl sulfate (corresponding to 70 mg V/L according to the authors) were administered in the drinking water along with 5 g/L NaCl to reduce gastrointestinal effects of vanadium. An untreated control group received water without vanadyl sulfate or NaCl. Dams were exposed beginning three days before the last day of pregnancy and continued until weaning; thus, the pups were exposed during 3 days of gestation and via lactation until weaning. Litters were culled to 8–10 pups 1 day after birth and at weaning the groups were again reduced to 10/sex/dose. After weaning, the pups were given the same drinking water as their mothers until they were 100 days of age. Body weight was recorded at regular intervals and food and water intake were measured at 2 months of age. Based on recorded water intake, the vanadium dose was estimated by the authors to be about 10 mg V/kg-day. Neurobehavioral assessments were performed at 1 month

[5]The starting weights were 210–230 g; however, ending body weights were not reported.

of age (locomotor activity and open field evaluation of ambulation, rearing, grooming and defecation) and 100 days of age (memory test assessing time spent exploring new and familiar objects). Survival to weaning was significantly reduced by vanadyl sulfate treatment when compared with either the NaCl or untreated controls (61% in treated vs. 100% and 94% in NaCl and untreated controls, respectively; $p < 0.0001$). Neither food nor water intake was affected by exposure. Body weights were significantly lower than untreated controls beginning at weaning (PND 25) in the vanadyl sulfate group. However, body weights were also reduced in the NaCl group, so the effect of vanadium exposure cannot be distinguished. Locomotor activity was not different among the groups (data shown). In contrast, the open field evaluation revealed significantly ($p < 0.05$) fewer outer ambulation (ambulation in the outer area of the cage), rearing and grooming events and increased defecation in treated male rats when compared with the NaCl group; the treated males also exhibited reduced rearing events compared with untreated controls. The memory test revealed similar impairment in both the NaCl and vanadium exposure groups, which the authors attributed to NaCl exposure rather than vanadium (as the effect was similar in both). A LOAEL of 10 mg V/kg-day is identified based on reduced survival to weaning; a NOAEL cannot be identified.

Neurotoxicity

Sanchez et al. (1998) exposed male Sprague-Dawley rats to daily gavage doses of sodium metavanadate at dose levels of 0, 1.7, 3.4, or 6.8 mg V/kg-day for 8 weeks (12 animals per group). Endpoints assessed include body-weight gain and two neurobehavioral assessments: open-field activity and active avoidance (electric shock with auditory and light stimulus as the conditioned stimulus). Body-weight gains were significantly lower (10% below controls at the end of the exposure period, $p < 0.05$) in the 6.8 mg V/kg-day group relative to the control group. Open-field activity was lower in the 3.4 and 6.8 mg V/kg-day groups relative to the control group—but only during the first of three testing sessions ($p < 0.05$, data presented graphically). Similarly, acquisition of the avoidance response to the conditioned stimulus was significantly lower in all treatment groups ($p < 0.05$; about one-half as many avoidance responses and latencies about twice that of the control group based on graphical presentation of the data)—but only during the last of three sessions. Neither parameter exhibited a clear dose-response relationship; the magnitude of change from control was similar at all doses.

These investigators also conducted a follow-up study designed to evaluate whether the chelating agent Tiron would ameliorate the effects of vanadium exposure on behavior (Sanchez et al., 1999). Groups of 10 male Sprague-Dawley rats were given daily gavage doses of water or aqueous sodium metavanadate at a dose of 6.84 mg V/kg-day for 8 weeks. There were two groups that were also given Tiron via i.p. injection at two different doses. Body weight was measured daily. After the end of exposure, open-field activity and active avoidance were assessed as in the previous study. The authors indicated that body weight was not affected by treatment (data not shown). Graphical presentation of the data indicated no effect of exposure on open field motor activity but significant ($p < 0.05$) inhibition of active avoidance. Administration of Tiron mitigated the effects of sodium metavanadate on both of these endpoints.

Immunotoxicity

The limited data on immunotoxicity of vanadium suggest little or no adverse effect on this endpoint. Alexandrova et al. (2002) assessed humoral and cellular immune responses in

BALB/c mice and Wistar rats (both sexes) exposed to ammonium vanadate. Exposure to ammonium vanadate in the drinking water (0.5 mg/L or 0.2 mg V/L) for 40 or 200 days (about 6 or 28 weeks) stimulated both humoral and immune responses, as measured by increases (above control values) in the number of antibody-synthesizing cells in the spleen after challenge with sheep erythrocytes, the titers of serum agglutinins and haemolysins (humoral response) and the migration of spleen cells and peritoneal macrophages in vitro (cellular response). In contrast to the results of Alexandrova et al. (2002), Sharma et al. (1981) observed a decrease (albeit not statistically significant) in antibody-producing cells in the spleen of male Swiss-Webster mice exposed to concentrations of 0, 1, 10, or 50 mg/L vanadium (as sodium orthovanadate) in the drinking water for up to 13 weeks. No treatment-related effects were observed on delayed hypersensitivity reaction and immunoglobulin levels (IgG, IgA, and IgM) were not affected by exposure. Both Alexandrova et al. (2002) and Sharma et al. (1981) observed increased DNA synthesis in splenic lymphocytes treated with vanadium and cultured in the presence of some mitogens (phytohemagglutinin and pokeweed) but not others (bacterial lipopolysaccharide), when compared with cells not treated with vanadium.

Inhalation Exposure

No subchronic or chronic animal studies of inhalation exposure to vanadium compounds (other than vanadium pentoxide) have been identified in the literature search.

Other Studies

Toxicokinetics

In the United States, exposure to vanadium primarily occurs through dietary sources. Estimates of the daily intake of vanadium in the diet are in the range of 10–30 μg V/day or 0.0001 to 0.0004 mg V/kg-day for an adult man (WHO, 2001). Few studies are available on the absorption of vanadium from the gastrointestinal tract in humans or experimental animals; however, existing data suggest a relatively low fractional absorption. WHO (2001) estimated the gastrointestinal absorption of vanadium to be about 3% of the administered dose based on animal studies. Therefore, a relatively small absolute difference in gastrointestinal absorption between rodents and humans could result in a large error in the equivalent dose extrapolation. There are no studies that allow a direct comparison of the absorption of vanadium when administered as vanadyl or vanadate compounds.

Once absorbed, vanadium is distributed primarily to the bone, with smaller amounts distributing to the kidney, liver, spleen, muscle, and testes (ATSDR, 1992; WHO, 2001; Rydzynski, 2001). Vanadium stored in bone is retained much longer than in other tissues, from which vanadium is rapidly excreted (ATSDR, 1992; Rydzynski, 2001). Urine appears to be the major excretory route for absorbed vanadium, while unabsorbed vanadium is excreted in the feces (ATSDR, 1992; WHO, 1988, 2001).

In blood, vanadyl and vanadate ions are interconverted through redox reactions that may involve glutathione, cysteine, ascorbate, and possibly other components of plasma and cytosol (Rehder and Jantzen, 1998). Vanadium in blood partitions between plasma and erythrocytes. In beagle dogs administered single intravenous injections of vanadyl sulfate or ammonium vanadate, approximately 30–45% of the vanadium in blood was associated with erythrocytes and approximately 80% of vanadium in serum was associated with transferrin (Harris et al., 1984). Albumin also participates as a protein ligand for vanadyl and vanadate in plasma

(Chasteen et al., 1986a,b). Vanadyl and vanadate form complexes with a variety of intracellular proteins including ATPases, calmodulin, kinases and phosphatases, ribonucleases and nucleic acids (Rehder and Jantzen, 1998). The redox state of the cytosol favors the intracellular reduction of vanadate to vanadyl, whereas the oxidation of vanadyl to vanadate is favored in plasma; the interconversion occurs in minutes (Etcheverry and Cortizo, 1998).

Antineoplastic Studies

Vanadium has been tested as an antineoplastic agent in animal models of colon, liver, and mammary carcinogenesis. All of the studies of this effect that were identified in the literature searches were conducted by a single laboratory. In all of the studies, vanadium was administered as ammonium monovanadate to rats at a concentration of 0.5 ppm in drinking water. Vanadium coadministration reduced the number of aberrant crypt foci (a preneoplastic lesion in colon cancer) in rats treated with 1,2-dimethylhydrazine and resulted in fewer colon tumors (Kanna et al., 2003, 2004, 2005). Mechanistic data collected in these studies showed that vanadium treatment reduced the number of DNA-protein cross-links and evidence of DNA damage in colon cells, reduced the PCNA index, decreased the frequency of chromosomal aberrations and increased glutathione S-transferase and cytochrome p450 levels when compared with rats treated with carcinogen alone (Kanna et al., 2003, 2004, 2005). Similar findings were observed in rat models of hepatocarcinogenesis. In rats treated with 2-acetylaminofluorene (2-AAF) or diethyl nitrosamine (DEN) and subsequently given vanadium, relative liver weight, incidence of gamma glutamyl transpeptidase (GGT)-positive foci, nodular incidence, number of liver nodules and multiplicity of nodules were reduced compared with treatment with the carcinogen alone (Chakraborty et al., 2005; 2006a,b,c; 2007a,b). Vanadium treatment reduced the frequency of modified DNA bases, DNA damage, and chromosomal aberrations; reduced the expression of metallothionein (a metalloprotein associated with neoplastic cell growth) and Ki-67 nuclear antigen; and increased the expression of p53 tumor suppressor (Chakraborty et al., 2005; 2006a,b,c; 2007a,b). Further evidence of a potential antineoplastic effect of vanadium was provided in studies of rat mammary carcinogenesis. Vanadium treatment reduced the incidence, total number, multiplicity and size of mammary tumors in rats pretreated with 7,12-dimethylbenz(a)anthracene (Ray et al., 2004; 2005a,b; 2006). Ray et al. (2006) used immunohistochemical analysis to show that vanadium exposure increased apoptosis in mammary tissues; p53 and Bax genes were upregulated, while the antiapoptotic protein Bcl2 was downregulated by vanadium. In studies performed in another laboratory, a vanadium-cysteine complex was effective in prolonging survival, reducing the rate of benzo(a)pyrene-induced leiomyosarcoma growth, and inducing some tumor remission when given to male rats beginning on the day a palpable tumor was observed (Evangelou et al., 1997; Liasko et al., 1998).

Mechanistic

Etcheverry and Cortizo (1998) reviewed the action of vanadium on cells in culture. Their review indicated that vanadate acts as an analogue of phosphate, resulting in the modification (stimulation or inhibition) of several enzymes involved in phosphate metabolism. In in vitro systems, vanadium compounds have been shown to inhibit Na+K+ ATPase, Ca2+ ATPase, H+K+ ATPase, H+-ATPase, K+ATPase, Ca+Mg+ATPase, dynein ATPase, actomysosin ATPase, protein tyrosine phosphatase, glutamine dehydrogenase, acid and alkaline phosphatases, glucose-6-phosphatase, phosphofructokinase, alanine aminotransferase, aspargine aminotransferase, ribonuclease, phosphodiesterase, phosphotyrosyl-phosphatase, while stimulating phospholipase C, adenyl cyclase, mitogen-activated protein kinases,

phosphatidylinositol 3-kinase, NADPH oxidase, glycogen synthase, lipoprotein lipase, and tyrosine kinase phosphorylase (Etcheverry and Cortizo, 1998; Rydzynski, 2001). In addition, vanadium is a strong mitogen, inducing cell proliferation in a number of different systems (including fibroblasts, Leydig cells, and bone cells); the mechanism for this effect may be related to the inhibition of protein tyrosine phosphatases (Etcheverry and Cortizo, 1998). The effects of vanadium on various enzymes, which, in turn, affect many systems, may be responsible for the diverse effects seen in vivo—including modulation of diabetes, renal effects, reproductive and developmental toxicity and cardiovascular effects. In a recent review, Coderre and Srivastava (2004) proposed a potential mechanism of action for the cardiovascular effects of vanadium. In the proposed scheme, vanadium inhibition of protein tyrosine phosphatases results in the intracellular release of calcium and activation of phosphatidylinositol 3-kinase (PI3K) and p38-mitogen activated protein kinase (p38 MAPK) signaling pathways; these effects, in turn, stimulate smooth muscle contraction and glucose uptake (Coderre and Srivastava, 2004). Vanadium causes contraction of several types of smooth muscles, including gastric and vascular smooth muscle (Coderre and Srivastava, 2004). The effects of vanadium on smooth muscle contraction and glucose uptake may help to explain the in vivo modulation of blood pressure by vanadium. The authors noted that vanadium has exerted both vasodilation and vasoconstriction effects in different systems; thus, the action of vanadium on blood pressure may vary with dose, duration, and model system (Coderre and Srivastava, 2004).

Genotoxicity

Genotoxicity testing of soluble inorganic vanadium salts have primarily given positive results for mutagenicity and clastogenicity (especially numerical chromosomal aberrations). In the *Bacillis subtilis* Rec^- mutagenicity screening assay, ammonium metavanadate gave a positive result (greater inhibition of the Rec^- strain than the wild type Rec^+ strain) at a concentration of 0.3 M (Kanematsu et al., 1980). However, spot mutation tests with *Escherichia coli* (B/r WP2 and WP2) and *Salmonella typhimurium* (TA1535, TA100, TA98, TA1537, and TA1538) were negative for this compound (Kanematsu et al., 1980). Ammonium metavanadate induced mitotic gene conversion and reverse point mutations in *Saccharomyces cerevisia* (strain D7) when tested at concentrations from 80–210 nM with and without S9 (Bronzetti et al., 1990). Greater numbers of conversions and mutations were observed in the absence of S9, suggesting that the metabolism of ammonium metavanadate may detoxify the compound. In a study of cultured Chinese hamster V79 and V79-derived $hprt^-/gpt^+$ transgenic G12 cells, ammonium metavanadate exposure resulted in weak, but concentration-related increases in *hprt* mutations in V79 cells and in *gpt* mutations in G12 variants when the cells were exposed for 24 hours at concentrations from 5–50 µM (Cohen et al., 1992; Klein et al., 1994). Owusu-Yaw et al. (1990) reported that vanadyl sulfate and ammonium metavanadate both induced significant ($p < 0.01$) increases in the frequency of sister chromatid exchanges (SCE) in Chinese hamster ovary (CHO) cells treated with and without S9. Concentrations resulting in increases in SCE were about 6 and 2 µg V/mL for vanadyl sulfate and ammonium metavanadate, respectively. These compounds also induced dose-related increases in the frequency of chromosomal aberrations at concentrations near those causing cytotoxicity. Cytotoxic concentrations (TC_{50}s) were 23 and 16 µg V/mL for vanadyl sulfate and ammonium metavanadate, respectively (Owusu-Yaw et al., 1990). In human lymphocytes cultured in vitro, sodium metavanadate, sodium orthovanadate and ammonium metavanadate and vanadyl sulfate resulted in increased frequencies of micronuclei and numerical chromosomal aberrations (primarily hypoploidy) at doses as low as 5 uM (Migliore et al., 1993). SCEs were induced at higher doses (Migliore et al., 1993).

In vivo studies in mice indicated that vanadyl sulfate (100 mg/kg body weight), sodium orthovanadate (75 mg/kg) and ammonium metavanadate (50 mg/kg) administered by gavage all increased the frequency of micronucleated polychromatic erythrocytes (2- to 3-fold increase over controls) (Ciranni et al., 1995). The frequencies of hypoploid (missing chromosomes) and hyperploid (having an excess of chromosomes) cells were also increased by both compounds. Only vanadyl sulfate exposure resulted in a statistically significant ($p < 0.05$) increase (up to 7-fold above control values) in structural chromosomal aberrations (Ciranni et al., 1995). Mice exposed for 5 months to sodium orthovanadate in drinking water were observed to exhibit statistically significant increases in bone marrow micronuclei (at exposure concentrations of 750 or 1500 mg/L) as well as evidence of DNA damage in splenocytes (measured by comet assay, at a concentration of 1500 mg/L)—but not in bone marrow cells, testis cells or epididymal sperm (Leopardi et al., 2005). In another study, oral exposure to drinking water containing vanadyl sulfate (2–1000 mg/L) did not increase the frequency of micronuclei in bone marrow polychromatic erythrocytes in male CD-1 mice exposed for 5 weeks (Villani et al., 2007). In reticulocytes from these same mice, the frequency of micronuclei was slightly increased at some exposure levels, but there was no dose-response relationship (Villani et al., 2007).

DERIVATION OF PROVISIONAL SUBCHRONIC AND CHRONIC ORAL RfD VALUES FOR VANADIUM AND COMPOUNDS

Equal intakes of vanadium in any of the forms considered (vanadyl sulfate, sodium metavanadate, sodium orthovanadate, and ammonium metavanadate) were treated as toxicologically equivalent for the purpose of deriving provisional oral toxicity values on the following basis: (1) there is very little quantitative information about the gastrointestinal absorption of vanadium and no evidence that the absorption of vanadium will be substantially affected by the form of vanadium ingested for this set of compounds and (2) although there is evidence for pharmacologic specificity of the actions of vanadate and vanadyl ions in various biochemical systems, these forms are rapidly (within minutes) interconverted in the body in oxidation-reduction reactions that take place in the intracellular and extracellular compartments (Etcheverry and Cortizo, 1998; Mendz, 1998; Rydzynksi, 2001).

A total of four studies of humans exposed to vanadium compounds for brief durations (up to 12 weeks) are available; Table 9 provides an overview of the findings in these studies. Of these, three studies were of patients with diabetes. All of the studies used vanadyl sulfate in tablet form. Endpoints assessed in the studies included body weight, gastrointestinal symptoms, hematology, glycemic control, serum chemistry parameters, urinalysis, liver, kidney or thyroid function tests, and blood pressure. None of the studies reported significant effects on any endpoint other than gastrointestinal symptoms. Of particular note is the apparently normal kidney function and the absence of a blood pressure effect at daily doses as high as 0.5 to 1.1 mg V/kg-day. However, the exposure groups were small, no histopathology was possible, and often no referent population is included. While the individual studies are limited, the human studies collectively provide a short-term human LOAEL of approximately 0.3 mg V/kg-day in humans based on symptoms of gastrointestinal distress, including diarrhea, cramping, and discomfort. The NOAEL for these effects is approximately 0.1 mg V/kg-day based on the available studies. Gastrointestinal effects (severe diarrhea) have also been observed in rats

exposed to vanadium in drinking water (Zaporowska and Wasilewski, 1989, 1990, 1992a,b; Ganguli et al., 1994b); in rabbits exposed via drinking water (Khasibhatla and Rai, 1993) and in pigs exposed via the diet (Van Vleet et al., 1981; Van Vleet and Boon, 1980), providing support for the observed relationship between vanadium exposure and diarrhea in humans. The doses resulting in diarrhea in laboratory animals were in the 5–20 mg V/kg-day range. Studies in rats and mice indicate that vanadium exposure may be associated with effects on body weight, hematology, kidney function, blood pressure and reproduction. Animal studies that meet minimum criteria for possible use in deriving subchronic or chronic provisional RfDs (e.g., effect levels could clearly be identified) are summarized in Table 10. It should be noted that some of the LOAELs shown in Table 10 were identified for effects in partially nephrectomized rats (Steffen et al., 1981; Susic and Kentera, 1988) or in diabetic rats (Domingo et al., 1991, 1992).

Table 9. Human Studies of Oral Exposure to Vanadium Compounds

Study Description	Dose (mg V/ kg-day)	Vanadium Form Administered	NOAEL (mg V/ kg-day)	LOAEL (mg V/ kg-day)	Responses at the LOAEL	Comments	Reference
Human, 4 M and 7 F Tablet, daily for 6 weeks after 2-week run-up	0.5 (M) 0.6 (F)	Vanadyl sulfate (assumed trihydrate)	NA	0.5 (M) 0.6 (F)	Gastrointestinal symptoms	Patients with type 2 diabetes	Cusi et al., 2001
Human, 11 M and 5 F Tablet, daily for 6 weeks	0.12–0.23 0.28–0.45 0.43–1.14	Vanadyl sulfate (assumed trihydrate)	0.12–0.23	0.28–0.45	Gastrointestinal symptoms	Patients with type 2 diabetes	Goldfine et al., 2000
Human, 12–13 M and 4 F Tablet, daily for 12 weeks	0, 0.1	Vanadyl sulfate trihydrate	0.1	NA	None	Weight trainers	Fawcett et al., 1997
Human, 4 M and 4 F Tablet, daily for 4–8 weeks	0.34 (M) 0.39 (F)	Vanadyl sulfate (assumed trihydrate)	NA	0.34 (M) 0.39 (F)	Gastrointestinal symptoms	Patients with type 2 diabetes	Boden et al., 1996

Effects on blood pressure have been associated with vanadium exposure, although the available studies provide conflicting results. Boscolo et al. (1994) found a significant increase in systolic and diastolic blood pressure in rats exposed to 0.12, 1.2, or 4.7 mg V/kg-day as sodium metavanadate in the drinking water for 6 months. Carmignani et al. (1991) reported similar findings at a dose of 12 mg V/kg-day (as sodium metavanadate in drinking water). The increases in blood pressure are not corroborated by the Schroeder et al. (1970) chronic rat study or the Dai et al. (1994b) 52-week study in rats. Steffen et al. (1981) and Susic and Kentera (1988) reported increases in blood pressure in partially nephrectomized rats exposed to sodium orthovanadate and sodium metavanadate (respectively). In addition to these subchronic and chronic studies, a shorter-term study reported increased blood pressure in lean Zucker rats exposed to vanadium in the drinking water (about 10 mg V/kg-day) for 25 days (Hopfner et al., 1999). Several differences in the studies need to be taken into consideration in cross-study comparisons; Table 11 shows the major differences, which include the form of vanadium

Table 10. Animal Studies of Oral Exposure to Vanadium Compounds

Study Description	Dose (mg V/kg-day)	Vanadium Form Administered	NOAEL (mg V/kg-day)	LOAEL (mg V/kg-day)	Responses at the LOAEL	Comments	Reference
Shorter-term							
Male Sprague-Dawley rats (10/group) were exposed via drinking water for 28 days	0, 6.1, 15.6, 22.7	Sodium metavanadate, sodium orthovanadate, vanadyl sulfate	NA	6.1	Body-weight loss in diabetic rats	No nondiabetic treatment group	Domingo et al., 1991
Male Sprague-Dawley rats (10/group) were exposed via drinking water for 5 weeks	0, 23.2	Sodium metavanadate	NA	23.2	Body-weight loss in diabetic rats	No nondiabetic treatment group	Domingo et al., 1992
Male and female Wistar rats (15–16/sex/group) were exposed via drinking water for 4 weeks	0, 1.2, 5 (males) 0, 1.5, 7 (females)	Ammonium metavanadate	1.2 (males); 1.5 (females)	5 (males); 7 (females)	Reduced body weight (with reduced fluid intake) and hematology changes		Zaporowska et al., 1993
Subchronic							
Male Sprague-Dawley rats (20/group) were exposed via the diet for 9 weeks	0, 9	Sodium orthovanadate	NA	9	Decreased weight gain and increased blood pressure in uninephrectomized rats		Steffen et al., 1981
Male weanling pigs (6) were exposed via drinking water for 12 weeks	0, 10	Ammonium metavanadate	NA	10 (FEL)	Emaciation and mortality		Van Vleet, 1981
Male Sprague-Dawley rats (10/group) were exposed via drinking water for 12 weeks	0, 0.3, 0.6, 3.0	Sodium metavanadate	NA (0.6, ATSDR, 1992)	0.3 – 3.0 (indeterminate)	Mild changes in the kidney (hemorrhagic foci in the corticomedullary region), spleen (hypertrophy and hyperplasia) and lungs (perivascular mononuclear cell infiltration)	Occurring in all treatment groups, but "more evident" in the high-dose group. Clear AEL at 3 mg/kg-day.	Domingo et al., 1985
Male Long-Evans rats (15/group) were exposed via the diet for 2 months	0, 12	Ammonium metavanadate	NA	12	Pulmonary hypertension		Susic and Kentera, 1986
Male Wistar rats (8/group) were exposed via drinking water for 12 weeks	0, 7.7, 9.7	Ammonium metavanadate, vanadyl sulfate	7.7, 9.7	NA	No effects on food intake, body weight, hematology	Fluid intake was reduced at this dose	Dai et al., 1995

Table 10. Animal Studies of Oral Exposure to Vanadium Compounds

Study Description	Dose (mg V/kg-day)	Vanadium Form Administered	NOAEL (mg V/kg-day)	LOAEL (mg V/kg-day)	Responses at the LOAEL	Comments	Reference
Female Wistar rats (7/group) were exposed via the diet for 10 weeks	0, 1.1, or 2.3	Sodium metavanadate	2.3	NA	Small changes in hematology and body weight were not considered toxicologically significant		Adachi et al., 2000
Male Wistar rats (11–16/group) were exposed via drinking water for 6 weeks	0, 8	Sodium metavanadate	NA	8	Reduced body weight gain (possibly related to reduced food and fluid intake); hematologic effects		Scibior, 2005
Male Wistar rats (12/group) were exposed via drinking water for 6 weeks	0, 11	Sodium metavanadate	NA	11	Reduced body weight gain (possibly related to reduced food and fluid intake); hematologic effects		Scibior et al., 2006
Intermediate							
Male Long-Evans rats (12–24/group) were exposed via the diet for 24 weeks	0, 4.4, 42	Sodium metavanadate	NA	4.4	Increased blood pressure in partially nephrectomized rats	Blood pressure not affected in rats with intact kidneys	Susic and Kentera, 1988
Male Sprague-Dawley rats (10/group) were exposed via drinking water for 7 months	0, 12	Sodium metavanadate	NA	12	Increased blood pressure, kidney histopathology		Carmignani et al., 1991
Male Wistar rats (12/group) were exposed via drinking water for 5 months	0, 12	Vanadyl sulfate	NA	12	Decreased body weight in treated nondiabetic rats relative to nondiabetic controls		Cam et al., 1993
Male Sprague-Dawley rats (6/group) were exposed via drinking water for 180 or 210 days	0, 0.12, 1.2, 4.7	Sodium metavanadate	NA	0.12	Increased blood pressure, stimulation of the renin-angiotensin-aldosterone system, and kidney histopathology		Boscolo et al., 1994

Table 10. Animal Studies of Oral Exposure to Vanadium Compounds

Study Description	Dose (mg V/kg-day)	Vanadium Form Administered	NOAEL (mg V/kg-day)	LOAEL (mg V/kg-day)	Responses at the LOAEL	Comments	Reference
Chronic							
Long-Evans rats were exposed via drinking water from weaning through natural death (up to 45 months)	0, 0.7 (males), d 0.9 (females)	Vanadyl sulfate	NA	NA	No effects observed	Histological evaluations inadequate to detect any but the most severe lesions; effect levels cannot be determined	Schroeder et al., 1970
Male Sprague-Dawley rats (>20/group) were exposed via diet for 56 weeks	0, 7, 14	Sodium orthovanadate	NA	7	Increased blood pressure in uninephrectomized rats		Steffen et al., 1981
Male Wistar rats (8/group) were exposed via drinking water for 52 weeks	0, 8, 13 or 21	Vanadyl sulfate	NA	8	Reduced body-weight gain	Diabetic and nondiabetic rats	Dai et al., 1994a,b; Dai and McNeill, 1994
Reproductive							
Male and female Sprague-Dawley rats (20/sex/group) were exposed via drinking water for 60 (M) or 14 (F) days premating and during gestation and lactation (F)	0, 2.1, 4.2, 8.4	Sodium metavanadate	NA	2.1 (offspring)	Growth retardation in pups	Maternal effect levels could not be identified due to lack of information on endpoints assessed	Domingo et al., 1986
Male and female Sprague-Dawley rats (10 M and 20 F/group) were exposed via drinking water for 70 days (M) or through premating, mating, gestation and lactation (61 days, F)	0 or 28 (M) or 30 (F)	Ammonium metavanadate	NA	28	Effects on reproductive success, litter parameters, postnatal growth, male reproductive organ weights and skeletal malformations		Morgan and El-Tawil, 2003
Male Swiss mice (24/group) were exposed via drinking water for 64 days prior to mating	8.4, 17, 25.1 or 33.4	Sodium metavanadate	17	25.1	Decreased spermatozoa counts and reduced fecundity		Llobet et al., 1993

Developmental							
Pregnant Sprague-Dawley rats (14/group) were exposed via the diet throughout pregnancy and lactation	0, 7	Sodium metavanadate	NA	7 (maternal and develop-mental)	Reduced food intake and weight gain (maternal); reduced pup survival, body weight, growth and clinical signs (developmental)		Elfant and Keen, 1987
Pregnant Swiss mice (16–20/group) were exposed via daily gavage on GD 6–15	0, 7.5, 15.1 or 30.2	Vanadyl sulfate pentahydrate	NA	7.5 (maternal and develop-mental)	Reduced body-weight gain (maternal) Increased resorptions, growth deficits, external and skeletal abnormalities (developmental)		Paternain et al., 1990
Pregnant Swiss mice (14–18/group) were exposed via daily gavage on GD 6–15	0, 2.1, 4.2, 8.3 or 16.6	Sodium orthovanadate	2.1 (maternal) 4.2 (develop-mental)	4.2 (maternal) 8.3 (develop-mental)	Reduced food consumption (maternal) Delayed skeletal ossification (developmental)	Maternal deaths occurred at 8.3 mg V/kg-day	Sanchez et al., 1991
Male and female Wistar rats, (8–10/group) were exposed via drinking water from 3 days before birth until 100 days of age	0, 10	Vanadyl sulfate	NA	10	Reduced survival to weaning		Poggioli et al., 2001

administered, the method of administration, the renal status of the affected animals, the strain of the affected animals and the method by which blood pressure was measured. All the blood pressure increases were from exposure to the vanadate; there were no blood pressure increases in the only two studies that used the vanadyl salt. Given the rapid interconversion of the two forms in plasma and cytosol, this discrepancy cannot be explained. Blood pressure was generally increased by 20–25 mm Hg over a 100-fold dose range within and among studies; this is particularly noted for the companion studies of Carmignani et al. (1991) and Boscolo et al. (1994) in which an interaction with thiopentane cannot be ruled out. Except for the shortest study of 25 days (Hopfner et al., 1999), there is no apparent exposure-duration effect on the magnitude of the blood pressure increase from exposure to vanadium for 9 to 56 weeks. No effects on blood pressure were observed in the human studies at doses as high as 0.5–1 mg V/kg-day (Boden et al., 1996; Fawcett et al., 1997; Goldfine et al., 2000; Cusi et al., 2001). Overall, these studies establish a NOAEL of at least 0.3 mg V/kg-day for blood pressure effects in humans for short-term exposure (6 weeks).

Table 11. Comparison Among Studies in which Blood Pressure was Measured

Study	Observed Effect on Blood Pressure[a]	Magnitude of Effect (mm Hg)	Form and Method of Vanadium Administration	Renal Status and Strain of Affected Animals	Method of Blood Pressure Measurement
Boscolo et al., 1994	Increase at ≥0.12 mg V/kg-day	25 (not dose-related)	Na metavanadate in drinking water for 6 months	Intact Sprague-Dawley rats	Arterial cannula under thiopentane anesthesia
Carmignani et al., 1991	Increase at 12 mg V/kg-day	22	Na metavanadate in drinking water for 7 months	Intact Sprague-Dawley rats	Arterial cannula under thiopentane anesthesia
Steffen et al., 1981	Increase at 9 mg V/kg-day	20	Na metavanadate in diet for 9 weeks	Uninephrectomized Sprague-Dawley rats	Tail cuff in conscious animals
Steffen et al., 1981	Increase at 7, 14 mg V/kg-day	10, 25	Na metavanadate in diet for 56 weeks	Uninephrectomized Sprague-Dawley rats	Tail cuff in conscious animals
Hopfner et al., 1999	Increase at 10 mg V/kg-day	15	Na orthovanadate in drinking water for 25 days	Intact lean Zucker rats	Tail cuff in conscious animals
Susic and Kentera, 1988	Increase at 4.4 mg V/kg-day	22	Na orthovanadate in diet for 24 weeks	Partially nephrectomized Long-Evans rats	Arterial cannula under nembutal anesthesia
Susic and Kentera, 1988	None at 42 mg V/kg-day	0	Na orthovanadate in diet for 24 weeks	Intact Long-Evans rats	Arterial cannula under nembutal
Dai et al., 1994b	None at 21 mg V/kg-day	0	Vanadyl sulfate in drinking water for 1 year	Intact Wistar rats	Tail cuff in conscious animals
Schroeder et al., 1970	None at 0.7 mg V/kg-day	0	Vanadyl sulfate in drinking water for 45 months	Intact Long-Evans rats	Anaesthetized animals; method not specified

[a]Effect observed at lowest dose tested in all positive studies

Studies conducted by Susic and Kentera (1988) in which several cardiovascular endpoints were assessed provide some information as to why vanadium exposure may increase blood pressure in some animals and not in others. In rats with intact kidneys exposed to doses up to 42 mg V/kg-day, a vanadium-related increase in peripheral resistance was offset by a reduction in cardiac output and blood pressure remained stable (no effect on blood pressure was observed). In partially nephrectomized rats, there was no compensatory reduction in cardiac output; thus, an increase in blood pressure was observed (Susic and Kentera, 1988). Thus, one potential explanation as to why blood pressure was not increased in every study is that compensatory mechanisms may serve to modulate the effect on blood pressure. If so, then individuals with health conditions that compromise these compensatory mechanisms (e.g., impaired renal function) may be at greater risk from vanadium exposure, although this hypothesis must be considered somewhat speculative.

Limited mechanistic information also supports a potential relationship between vanadium exposure and blood pressure changes. Boscolo et al. (1994) showed that vanadium exposure can modify plasma levels of proteins involved in blood pressure homeostasis. In this study, exposure to sodium metavanadate at doses of 1.2 or 4.7 mg V/kg-day resulted in increases in plasma renin activity (an enzyme that converts angiotensin to angiotensin I, a precursor to the vasoconstrictor angiotensin II) and aldosterone (a hormone involved in salt:water balance), as well as increases in urinary excretion of kallikrein (an enzyme that releases vasodilating kinins from plasma proteins) and kininases I and II (enzymes that break down kinins). The effects on the renin-angiotensin-aldosterone system are consistent with the observed increases in blood pressure.

Several studies (Domingo et al., 1985; Gorski and Zaporowska, 1982; Zaporowska, 1987; Dai et al., 1994a,b; Dai and McNeill, 1994) have indicated that the kidney is a primary target organ of vanadium toxicity in male rats. Among these, the study identifying effects at the lowest dose was Domingo et al. (1985). This study reported histopathologic changes in kidneys of rats exposed to sodium metavanadate in drinking water at dosages of 0.3 mg V/kg-day and higher. However, as previously noted, this study is limited in that only three animals per exposure group were actually subjected to a histopathological assessment and the results are summarized without a qualitative or quantitative reporting of incidence and severity. As a result, it is difficult to verify that the observed effects were clearly increased by exposure. Boscolo et al. (1994) reported hydropic degeneration in the kidneys of rats exposed to sodium metavanadate at a dose of 1.2 mg V/kg-day (in drinking water) for 1 year, with additional histopathologic changes (narrowing of the lumen and appearance of amorphous casts in the renal proximal tubules) at the next higher dose (4.7 mg V/kg-day). The latter changes were also observed by Carmignini et al. (1991) at a drinking water dose of 12 mg V/kg-day for 1 year. Dai et al. (1994a,b; Dai and McNeill, 1994) reported an increased incidence of glomerular and tubular degeneration, with interstitial cell infiltration and fibrosis in the kidneys of rats exposed to vanadyl sulfate in the drinking water at doses of 8–21 mg V/kg-day for a year. Limited information provided in English abstracts of two Polish studies (Gorski and Zaporowska, 1982; Zaporowska, 1987) suggested renal histopathology in rats exposed to 12–29 mg V/kg-day as ammonium metavanadate. Of all of these studies, only Boscolo et al. (1994) identified an unequivocal NOAEL for kidney effects.

Clinical chemistry changes indicative of renal effects have also been reported in a number of animal studies, although similar changes have not been observed in human studies (Fawcett et al., 1997; Boden et al., 1996). Increases in plasma urea concentrations have been observed at a dose of 3.0 mg V/kg-day in rats treated with sodium metavanadate (Domingo et al., 1985) and at higher doses in a number of studies (Domingo et al., 1991, 1992; Dai et al., 1994a,b; Dai and McNeill, 1994). Serum creatinine was higher in diabetic rats exposed to 6.1–22.7 mg V/kg-day as sodium metavanadate (Domingo et al., 1991) but not in a follow-up study in which diabetic rats were exposed to 23.2 mg V/kg-day as sodium metavanadate (Domingo et al., 1992). Susic and Kentera (1988) observed no changes in indicators of renal function (plasma creatinine, 24-hour creatinine clearance, urinary sodium excretion, and urine output) in normal and partially nephrectomized Long-Evans rats exposed to 4.4 or 42 mg V/kg-day as sodium metavanadate. Boscolo et al. (1994) observed increased potassium excretion after rats were exposed to sodium metavanadate at 1.2 and 4.7 mg V/kg-day, but no changes in urinary creatinine, nitrogen, proteins, sodium, or calcium. It should be noted vanadium was administered in drinking water in all of the studies that indicated clinical chemistry changes related to renal function. A number of studies have shown reductions in fluid intake, including marked reductions at doses of ≥10 mg V/kg-day, when vanadium is incorporated into the drinking water of rats. Thus, the changes in renal function parameters may have been influenced to an unknown degree by decreases in fluid intake, particularly at the higher exposure levels. No changes in renal function were observed in the human studies at doses as high as 0.5–1 mg V/kg-day (Boden et al., 1996; Fawcett et al., 1997; Goldfine et al., 2000; Cusi et al., 2001). Overall, these studies establish a NOAEL of at least 0.3 mg V/kg-day for overt kidney effects in humans for short-term exposure (6 weeks).

Limited mechanistic information in animals also provides some support for potential renal toxicity after vanadium exposure. Adachi et al. (2000) measured higher levels of lipid peroxidation products in the kidneys of rats exposed to 2.3 mg V/kg-day. Boscolo et al. (1994) reported reductions in Na+ K+ ATPase in the kidneys of rats exposed to 4.7 mg V/kg-day as sodium metavanadate; vanadium is known to inhibit the sodium-potassium ATPase (Etcheverry and Cortizo, 1998; Rydzynski, 2001). In addition, studies of vanadium distribution after oral exposure indicate that higher levels of vanadium are observed in the kidneys than in other organs, providing support for this organ as a potential target of vanadium toxicity.

Available data also supports a finding of reproductive and developmental toxicity associated with vanadium exposure. Effects observed in the available studies (see Table 10), conducted in both rats and mice, include diminished fertility, reduced offspring viability, growth retardation of offspring and skeletal malformations (Morgan and El-Tawil, 2003; Poggioli et al., 2001; Llobet et al., 1993; Sanchez et al., 1991; Paternain et al., 1990; Elfant and Keen, 1987; and Domingo et al., 1986). In addition to the studies shown in the table, several other studies are not suitable for derivation of provisional toxicity values, but they do contribute to the overall database for reproductive and developmental toxicity. There were three studies published in Spanish that provide suggestive evidence that vanadium exposure (as ammonium metavanadate) may result in histopathologic changes in the ovaries (Nava de Leal et al., 1998), effects on the developing central nervous system (especially the olfactory bulbs; Faria de Rodriguez et al., 1998a) and growth delays (Faria de Rodriguez et al., 1998b). In a study with poorly-reported information on the treatment regimen,

Ganguli et al. (1994b) reported reduced rate of conception and reduced ability to carry pregnancy to term in rats exposed to sodium orthovanadate.

Subchronic p-RfD

Data pertinent to the derivation of a subchronic p-RfD for vanadium include short-term human studies, short-term (4–5 weeks) and subchronic animal studies, and reproductive and developmental toxicity studies. In addition, several studies of slightly longer duration (5–7 months) have some bearing on the subchronic p-RfD because of the kidney and blood pressure endpoints. Blood pressure and kidney effects were fairly common among the rat studies. Kidney toxicity was implied in the Domingo et al. (1985) 3-month study at doses as low as 0.3 mg/kg-day, although it was not clear as to whether this was a LOAEL; ATSDR (1992) determined that the 0.6 mg/kg-day exposure level was a NOAEL. Subsequent to that determination, Boscolo et al. (1994) found mild kidney lesions in rats after a 6-month exposure to 1.2 mg/kg-day, but none at 0.12 mg/kg-day. The most sensitive effect found by Boscolo et al. (1994) was increased blood pressure at 0.12 mg/kg-day; although a 6-month study is somewhat longer than subchronic, the findings are relevant to the subchronic p-RfD assessment because they establish a much lower LOAEL for this effect. All the kidney and blood-pressure effects occurred in male rats, but there was no direct indication that the kidney toxicity in any of these studies was a result of α_{2u}-globulin accumulation. The relevant studies apparently did not test for the presence of α_{2u}-globulin. However, as vanadium binds readily to proteins and is a protease inhibitor, accumulation of α_{2u}-globulin in the proximal tubule cells, leading to tissue necrosis, is plausible. The hemorrhagic foci in the corticomedullary region described by Domingo et al. (1985) could indicate proximal tubule necrosis. However, the criteria for establishing an α_{2u}-globulin mode of action have not been met. The human studies collectively identify a NOAEL of at least 0.3 mg V/kg-day for increased blood pressure and overt kidney toxicity, the most sensitive effects in rats; neither of these effects was observed for some subjects at dose levels of 0.5 to 1.1 mg V/kg-day. The human studies, however, were not considered for use in deriving the subchronic RfD. These studies are of short duration, used small numbers of subjects, and are not capable of detecting sub-clinical kidney damage—identifying a portal-of-entry effect (gastrointestinal distress) as the only adverse effect. Given no evidence of systemic effects in the human subjects, many of which were diabetic, the male rat may be particularly susceptible to kidney and blood pressure effects from vanadium exposure. Accordingly the increased blood pressure reported by Boscolo et al. (1994) at the lowest dose level (0.12 mg V/kg-day) is discounted as a basis for the pRfD, but the kidney effects remain relevant for consideration as the basis for the subchronic p-RfD.

The lowest reproductive/developmental toxicity LOAEL is 2.1 mg V/kg-day for growth retardation in the offspring of rats exposed prior to mating (Domingo et al., 1986); a NOAEL is not established. A clear dose-response relationship is reported in both sexes of offspring for a number of growth-related endpoints measured at several postnatal times. Benchmark dose modeling is rejected because the data were pooled across litters, BMD models could not be fit to most of the data, and it is not clear whether those endpoints that were fit successfully were the most sensitive. Therefore, only the LOAEL of 2.1 mg V/kg-day is considered as a potential POD for the subchronic p-RfD.

The NOAEL of 0.12 mg V/kg-day based on kidney histopathology at 1.2 mg V/kg-day in the 6-month rat study of Boscolo et al. (1994) provides the most appropriate basis for the

subchronic p-RfD. However, given exposure to vanadium in the diet, the NOAEL is adjusted upward by 0.1 mg/kg-day, which is the lower end of the range of likely dietary exposure discussed previously in this document. The subchronic p-RfD is derived as follows:

Subchronic p-RfD = NOAEL ÷ UF
= 0.22 mg V/kg-day ÷ 300
= **0.0007 mg V/kg-day or 7×10^{-4} mg/kg-day**

The composite UF of 3000 is composed of the following:

- A full UF of 10 is used to account for interspecies extrapolation to account for potential pharmacokinetic and pharmacodynamic differences between rats and humans.
- A full UF of 10 is used to account for potentially susceptible individuals in the population in the absence of information on the variability of response to vanadium developmental toxicity in humans.
- A partial UF of 3 ($10^{0.5}$) is used to account for database deficiencies—in particular the lack of a reproductive toxicity study.

Confidence in the key study (Boscolo et al., 1994) is low. The study does not examine the factors that would determine whether the kidney effects in male rats were a result of α_{2u}-globulin accumulation. Confidence in the database is medium. The toxicological database for oral exposure to vanadium includes human studies, several subchronic studies, several reproductive and developmental toxicity studies and limited studies of immunotoxicity and neurotoxicity. However, the majority of the subchronic studies evaluate limited endpoints; there are no comprehensive bioassays of subchronic duration. Although several studies reported kidney and blood pressure effects in male rats, none of them examined the factors that would determine whether the kidney effects were a result of α_{2u}-globulin accumulation. The reproductive toxicity database does not include any adequate standard multigeneration studies. The available 2-generation studies (Faria de Rodriguez et al., 1998a; Nava de Leal et al., 1998) were limited by poor reporting or pooling of data across treatment groups; however, the results provided suggestive evidence for reproductive toxicity. Likewise, two short-term studies of neurotoxicity (Sanchez et al., 1998, 1999) provide suggestive evidence for an effect of vanadium exposure on avoidance response, but neither study conducted comprehensive tests of neurobehavioral endpoints. Low confidence in the subchronic p-RfD follows.

Chronic p-RfD

Kanisawa and Schroeder (1967) and Schroeder et al. (1970; Schroeder and Michener, 1975) conducted chronic mouse and rat studies; however, the histopathologic assessment in these studies included only gross morphologic evaluations after natural deaths of the animals and would not have detected more subtle histopathologic lesions, particularly kidney lesions. Thus, these studies are inappropriate as critical studies for the chronic p-RfD. The lowest LOAEL of the remaining relevant endpoints is 1.2 mg V/kg-day for kidney pathology in male rats after a 6-month exposure to sodium metavanadate in drinking water (Boscolo et al., 1994), the basis for the subchronic p-RfD. As the human studies would not have revealed subclinical tissue damage and were of short duration, chronic kidney damage would be of concern. Therefore, kidney toxicity is selected as the critical effect, with a LOAEL of

1.2 mg V/kg-day and NOAEL of 0.12 mg V/kg-day established in the Boscolo et al. (1994) rat study. As for the subchronic p-RfD, the NOAEL is adjusted to 0.22 mg/kg-day to account for dietary exposure. The chronic p-RfD is derived as follows:

Chronic p-RfD = NOAEL ÷ UF
= 0.22 mg V/kg-day ÷ 3000
= **0.00007 mg V/kg-day or 7×10^{-5} mg/kg-day**

The composite UF of 3000 is composed of the following:

- A full UF of 10 is used to account for interspecies extrapolation to account for potential pharmacokinetic and pharmacodynamic differences between rats and humans.
- A full UF of 10 is used to account for potentially susceptible individuals in the population in the absence of information on the variability of human response to vanadium.
- A partial UF of 3 ($10^{0.5}$) is used to account for database deficiencies as per the subchronic p-RfD.
- A full UF of 10 is used to account for extrapolation to chronic exposure duration from a subchronic study.

Confidence in the key study (Boscolo et al., 1994) is low. The study focused on the blood pressure and kidney effects of vanadium; it did not address a comprehensive suite of endpoints. In addition, the issue of α_{2u}-globulin accumulation was not addressed. Confidence in the database is medium as for the subchronic p-RfD. The chronic studies are of limited utility. Low confidence in the chronic p-RfD follows.

FEASIBILITY OF DERIVING PROVISIONAL SUBCHRONIC AND CHRONIC INHALATION RfC VALUES FOR VANADIUM AND COMPOUNDS

There are no inhalation data with which to derive subchronic or chronic p-RfCs for vanadium compounds.

PROVISIONAL CARCINOGENICITY ASSESSMENT FOR VANADIUM AND COMPOUNDS

There are no human data on the potential carcinogenicity of soluble inorganic vanadium compounds, nor are there adequate animal carcinogenicity bioassays; thus, under the U.S. EPA (2005) *Guidelines for Carcinogen Risk Assessment*, there is "*Inadequate Information to Assess* [the] *Carcinogenic Potential"* of vanadium. In early carcinogenicity bioassays of vanadium, no increases in tumor incidence were observed in rats or mice exposed chronically (Kanisawa and Schroeder, 1967; Schroeder et al., 1970; Schroeder and Michener, 1975). However, these studies are limited in several ways: there is limited histopathology evaluation,

and tumor findings are not reported by target organ. In addition, the study in rats (Schroeder et al., 1970) is hampered by significant animal loss due to a pneumonia outbreak. A number of studies in rats have indicated that vanadium may exert an antineoplastic effect in chemical carcinogenesis, reducing the number and/or incidence of leiomyosarcomas and tumors of the liver, colon, and mammary glands in rats (Evangelou et al., 1997; Liasko et al., 1998; Ray et al., 2004, 2005a,b, 2006; Chakraborty et al., 2005, 2006a,b,c, 2007a,b; Kanna et al., 2003, 2004, 2005). Mechanistic information supporting the potential antineoplastic effect includes evidence that vanadium can induce apoptosis in mammary tumor cells both in vitro and in vivo (Ray et al., 2006). Limited genotoxicity data have shown that vanadium can induce mutations in yeast and mammalian cells (Bronzetti et al., 1990; Cohen et al., 1992; Klein et al., 1994). In mammalian cells cultured in vitro, vanadium increased the SCE frequency at noncytotoxic concentrations (Owusu-Yaw et al., 1990). Vanadium has induced micronuclei and/or numerical chromosomal aberrations (hypoploidy or hyperploidy) in mice treated in vivo (Ciranni et al., 1995; Leopardi et al., 2005; Villani et al., 2007).

EPA Document Number: 822-R-16-003
May 2016

BACKGROUND

The Safe Drinking Water Act (SDWA), as amended in 1996, requires the Administrator of the U.S. Environmental Protection Agency (EPA) to periodically publish a list of unregulated chemical contaminants known or anticipated to occur in public water systems and that may require regulation under SDWA. The SDWA also requires the Agency to make regulatory determinations on at least five contaminants on the Contaminant Candidate List (CCL) every 5 years. For each contaminant on the CCL, before EPA makes a regulatory determination, the Agency needs to obtain sufficient data to conduct analyses on the extent to which the contaminant occurs and the risk it poses to populations via drinking water. Ultimately, this information will assist the Agency in determining the most appropriate course of action in relation to the contaminant (e.g., developing a regulation to control it in drinking water, developing guidance, or deciding not to regulate it).

The PFOA health assessment was initiated by the Office of Water, Office of Science and Technology in 2009. The draft *Health Effects Support Document for Perfluoroctanoic Acid (PFOA)* was completed in 2013 and released for public comment in February 2014. An external peer-review panel meeting was held on August 21 and 22, 2014. The final document reflects input from the panel as well as public comments received on the draft document. Both the peer-reviewed draft and this document include only the sections of a health effects support document (HESD) that cover the toxicokinetics and health effects of PFOA. If a decision is made to regulate the contaminant, this document will be expanded.

One of the challenges inherent in conducting this assessment was the wealth of experimental data published before and during its development. This section provides a synopsis of the approach used in identifying and selecting the publications reflected in the final assessment.

Data were identified through the following:

- Monthly/bimonthly literature searches conducted by EPA library staff (2009–2015) and New Jersey Department of Environmental Protection library staff (2012–2015).
- Papers identified by EPA internal and external peer reviewers.
- Papers identified through public comments on the draft assessments.
- Papers submitted to EPA by the public.

In mid-2013, the EPA library searches were expanded to cover all members of the perfluoroalkane carboxylate family (C4 through C12). Appendix A describes the literature search strategy used by the libraries. Through the literature search, documents were identified for retrieval, review, and inclusion in the HESD using the following criteria:

- The study examines a toxicity endpoint or population not examined by studies already included in the draft document.
- Aspects of the study design such as the size of the population exposed or quantification approach make it superior to key studies already included in the draft document.
- The data contribute substantially to the weight of evidence for any of the toxicity endpoints covered by the draft document.
- Elements of the study design merit its inclusion in the draft document based on its contribution to the mode of action (MoA) or the quantification approach.

- The study elucidates the MoA for any toxicity endpoint or toxicokinetic property associated with PFOA exposure.
- The effects observed differ from those in other studies with comparable protocols.

In addition to each publication being evaluated against the criteria above, the relevance of the study to drinking water exposures and to the U.S. population also were considered.

The studies included in the final draft were determined to provide the most current and comprehensive description of the toxicological properties of PFOA and the risk it poses to humans exposed to it in their drinking water. Appendix B summarizes the studies evaluated for inclusion in the HESD following the August 2014 peer review and identifies those selected for inclusion in the final assessment. Appendix B includes epidemiology data that provide a high-level summary of the outcomes across the studies evaluated.

Development of the hazard identification and dose-response assessment for PFOA has followed the general guidelines for risk assessment forth by the National Research Council (1983) and EPA's *Framework for Human Health Risk Assessment to Inform Decision Making* (USEPA 2014a). Other EPA guidelines used in the development of this assessment include the following:

- *Guidelines for the Health Risk Assessment of Chemical Mixtures* (USEPA 1986a)
- *Guidelines for Mutagenicity Risk Assessment* (USEPA 1986b)
- *Recommendations for and Documentation of Biological Values for Use in Risk Assessment* (USEPA 1988)
- *Guidelines for Developmental Toxicity Risk Assessment* (USEPA 1991)
- *Interim Policy for Particle Size and Limit Concentration Issues in Inhalation Toxicity Studies* (USEPA 1994a)
- *Methods for Derivation of Inhalation Reference Concentrations and Application of Inhalation Dosimetry* (USEPA 1994b)
- *Use of the Benchmark Dose Approach in Health Risk Assessment* (USEPA, 1995)
- *Guidelines for Reproductive Toxicity Risk Assessment* (USEPA 1996)
- *Guidelines for Neurotoxicity Risk Assessment* (USEPA 1998)
- *Science Policy Council Handbook: Peer Review (2nd edition)* (USEPA 2000a)
- *Supplemental Guidance for Conducting Health Risk Assessment of Chemical Mixtures* (USEPA 2000b)
- *A Review of the Reference Dose and Reference Concentration Processes* (USEPA 2002a)
- *Guidelines for Carcinogen Risk Assessment* (USEPA 2005a)
- *Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens* (USEPA 2005b)
- *Science Policy Council Handbook: Peer Review (3rd edition)* (USEPA 2006a)
- *A Framework for Assessing Health Risks of Environmental Exposures to Children* (USEPA 2006b)
- *Exposure Factors Handbook* (USEPA 2011)
- *Benchmark Dose Technical Guidance Document* (USEPA 2012)
- *Child-Specific Exposure Scenarios Examples* (USEPA 2014b)

VLDL	very low-density lipoprotein
VOC	volatile organic compound
WHO	World Health Organization
WRF	Water Research Foundation

EXECUTIVE SUMMARY

Perfluorooctanoic acid (PFOA) is a synthetic, fully fluorinated, organic acid used in a variety of consumer products and in the production of fluoropolymers and generated as a degradation product of other perfluorinated compounds. Because of strong carbon-fluorine bonds, PFOA is stable to metabolic and environmental degradation. PFOA is one of a large group of perfluoroalkyl substances (PFASs) that are used to make products more resistant to stains, grease, and water. These compounds have been widely found in consumer and industrial products as well as in food items. Major U.S. manufacturers voluntarily agreed to phase out production of PFOA by the end of 2015. Exposure to PFOA in the United States remains possible due to its legacy uses, existing and legacy uses on imported goods, degradation of precursors, and extremely high persistence in the environment and the human body.

Extensive data on humans and animals indicate ready absorption of PFOA and distribution of the chemical throughout the body by noncovalent binding to plasma proteins. Studies of postmortem human tissues identify its presence in liver, lung, kidney, and bone. PFOA is not readily eliminated from the human body as evidenced by the half-life of 2.3 years among members of the general population. In contrast, half-life values for the monkey, rat, and mouse are 20.8 days, 11.5 days, and 15.6 days, respectively.

Human epidemiology data report associations between PFOA exposure and high cholesterol, increased liver enzymes, decreased vaccination response, thyroid disorders, pregnancy-induced hypertension and preeclampsia, and cancer (testicular and kidney). Epidemiology studies examined workers at PFOA production plants, a high-exposure community population near a production plant in the United States (i.e., the C8 cohort), and members of the general population in the United States, Europe, and Asia. These studies examined the relationship between serum PFOA concentration (or other measures of PFOA exposure) and various health outcomes. Exposures in the highly exposed C8 community are based on the concentrations in contaminated drinking water and serum measures. Exposures among the general population typically included multiple PFASs as indicated by serum measurements. The correlation among eight carbon PFASs is often moderately strong (e.g., Spearman $r > 0.6$ for PFOA and perfluorooctane sulfonate (PFOS) in the general population). Mean serum levels among the occupational cohorts ranged from approximately 1 to 4 micrograms per milliliter (μg/mL) and in the C8 cohort ranged from 0.01 to 0.10 μg/mL. Geometric mean serum values for the National Health and Nutrition Examination Survey (NHANES) general population (≥ age 12; 2003–2008) were 0.0045 μg/mL for males and 0.0036 μg/mL for females.

These epidemiology studies have generally found positive associations between serum PFOA concentration and total cholesterol (TC) in the PFOA-exposed workers and the high-exposure community (i.e., increasing lipid level with increasing PFOA); similar patterns are seen with low-density lipoproteins (LDLs) but not with high-density lipoproteins (HDLs). These associations were seen in most of the general population studies, but similar results also were seen with PFOS, and the studies did not always adjust for these correlations. Associations between serum PFOA concentrations and elevations in serum levels of alanine aminotransferase (ALT) and gamma-glutamyl transpeptidase (GGT) were consistently observed in occupational cohorts, the high-exposure community, and the U.S. general population. The associations are not large in magnitude, but indicate the potential for PFOA to affect liver function.

Diagnosed thyroid disease in females and female children was increased both in the high-exposure C8 study population and in females with background exposure; thyroid hormones are not consistently associated with PFOA concentration. Associations between PFOA exposure and risk of infectious diseases (as a marker of immune suppression) were not identified, but a decreased response to vaccines in relation to PFOA exposure was reported in studies in adults in the high-exposure community population and in studies of children in the general population; in the latter studies, it is difficult to distinguish associations with PFOA from those of other correlated PFASs. Studies in the high-exposure community reported an association between serum PFOA and risk of pregnancy-related hypertension or preeclampsia, conditions related to renal function during pregnancy; this outcome has not been examined in other populations. An inverse association between maternal PFOA (measured during the second or third trimester) or cord blood PFOA concentrations and birth weight was seen in several studies. It has been suggested that low glomerular filtration rate (GFR) can impact fetal birth weight (Morken et al. 2014). Pharmacokinetic (PK) analyses have shown, however, that in individuals with low GFR, there are increased levels of serum PFOA and lower birth weights. Thus, the impact on body weight is likely due to a combination of the low GFR and the serum PFOA.

The epidemiology studies did not find associations between PFOA and diabetes, neurodevelopmental effects, or preterm birth and other complications of pregnancy. Developmental outcomes including delayed puberty onset in girls also have been reported; however, in the two studies examining PFOA exposure in relation to menarche, conflicting results were observed: either no association or a possible indication of an earlier menarche seen with higher maternal PFOA levels in one study and a later menarche seen with higher maternal PFOA levels in the other study. Increased risk of ulcerative colitis was reported in the high-exposure community study as well as in a study limited to workers in that population.

For PFOA, oral animal studies of short-term subchronic and chronic duration are available in multiple species including monkeys, rats, and mice. These studies report developmental effects, liver and kidney toxicity, immune effects, and cancer (liver, testicular, and pancreatic). Developmental effects observed in animals include decreased survival, delayed eye opening and reduced ossification, skeletal defects, altered puberty (delayed vaginal opening in females and accelerated puberty in males), and altered mammary gland development.

In most animal studies, changes in relative and/or absolute liver weight appear to be the most common effect observed with or without other hepatic indicators of adversity, identifying increased liver weight as a common indicator of PFOA exposure. The liver also contains the highest levels of PFOA when analyzed after test animal sacrifice. The increases in liver weight and hypertrophy, however, also can be associated with activation of cellular peroxisome proliferator-activated receptor α (PPARα) receptors, making it difficult to determine if this change is a reflection of PPARα activation or an indication of PFOA toxicity. The PPARα response is greater in rodents than it is in humans. The U.S. Environmental Protection Agency (EPA) evaluated liver disease and liver function resulting from PFOA exposure in studies where liver weight changes and other indicators of adversity such as necrosis, inflammation, fibrosis, and/or steatosis (fat accumulation in the liver) or increases in liver or serum enzymes indicative of liver damage were observed.

In repeat PFOA dosing studies, rats given 0.64 milligrams per kilogram per day (mg/kg/day) for 13 weeks and monkeys given 3 mg/kg/day for 26 weeks had increased liver weight accompanied by hepatocellular hypertrophy. As part of a two-generation study, male rats had increased liver and kidney weights as well as decreased body weight at 1 mg/kg/day. In shorter term studies, slightly higher or lower doses to rats resulted in increased liver weight, liver necrosis, and developmental delays. In mice, developmental toxicity and increased spleen weight was observed at a dose of 1 mg/kg/day accompanied by increased liver weight. Other doses of similar magnitudes in mice were associated with developmental delays and liver necrosis. Slightly higher doses resulted in decreased immunoglobulin levels. As supported by the epidemiology data, suppression of the immune system in response to PFOA exposure is an area of concern for humans as well as animals.

PFOA is known to activate PPAR pathways by increasing transcription of mitochondrial and peroxisomal lipid metabolism, sterol, and bile acid biosynthesis and retinol metabolism genes. Based on PFOA-induced transcriptional activation of many other genes in PPARα-null mice, however, other receptors such as the constitutive androstane receptor (CAR), farnesoid receptor (FXR), and pregnane X receptor (PXR) could be involved in PFOA-induced toxicity.

EPA used a peer-reviewed PK model to calculate the average serum concentrations associated with candidate no observed adverse effect levels (NOAELs) and lowest observed adverse effect levels (LOAELs) from six studies for multiple effects to calculate corresponding human equivalent doses (HEDs) for the derivation of candidate reference doses (RfDs). Overall, the toxicity studies available for PFOA demonstrate that the developing fetus is particularly sensitive to PFOA-induced toxicity. In addition to the critical developmental effects described above, other adverse effects include decreased survival, delays in eye opening and ossification, skeletal defects, delayed vaginal opening in females, and altered mammary gland development.

The EPA Office of Water (OW) selected an RfD of 0.00002 mg/kg/day based on effects observed in a developmental toxicity study in mice for PFOA (Lau et al. 2006). The RfD is based on reduced ossification and accelerated puberty (in males). The total uncertainty factor (UF) applied to the HED LOAEL from Lau et al. (2006) is 300 and includes a UF of 10 for intrahuman variability, a UF of 3 to account for toxicodynamic differences between animals and humans, and a UF of 10 to account for use of a LOAEL as the point of departure (POD).

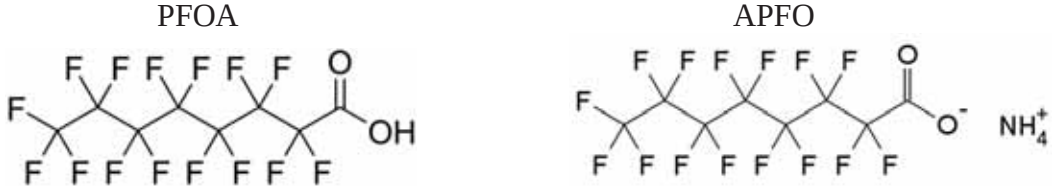
Decreased pup body weights also were observed in studies conducted in mice receiving external doses within the same order of magnitude (1, 3, and 5 mg/kg/day, respectively) as those chosen for the RfD. These studies, however, lacked serum levels and were not amenable to modeling. Overall, the developmental and reproductive toxicity studies available for PFOA demonstrate that the developing fetus is particularly sensitive to PFOA-induced toxicity. The selected RfD is supported by the other candidate RfDs (also 0.00002 mg/kg/day) based on effects on the immune system in a 15-day short-term study by DeWitt et al. (2008) and on the kidneys of F0 and F1 males in a two-generation study of developmental and reproductive toxicity.

Under EPA's *Guidelines for Carcinogen Risk Assessment* (USEPA 2005a), there is "suggestive evidence of carcinogenic potential" for PFOA. Epidemiology studies demonstrate an association of serum PFOA with kidney and testicular tumors among highly exposed members of the general population. Two chronic bioassays of PFOA support a positive finding for its ability to be tumorigenic in one or more organs of rats, including the liver, testes, and pancreas. EPA estimated a cancer slope factor (CSF) of 0.07 $(mg/kg/day)^{-1}$ based on testicular tumors. As a

comparative analysis, the concentration of PFOA in drinking water that would have a one-in-a-million increased cancer risk was calculated using the oral slope factor for testicular tumors, assuming a default adult body weight of 80 kg and a default drinking water intake (DWI) rate of 2.5 liter per day (L/day) (USEPA 2011). This concentration is lower than the concentration for cancer (also derived with adult exposure values), indicating that a guideline derived from the developmental endpoint will be protective for the cancer endpoint.

1 IDENTITY: CHEMICAL AND PHYSICAL PROPERTIES

Perfluorooctanoic acid (PFOA) is a completely fluorinated organic synthetic acid used to produce fluoropolymers. It is manufactured by the Simons electrochemical fluorination (ECF) process or by telomerization. In the ECF process, the carbon-hydrogen bonds on molecules of organic feedstock are replaced with carbon-fluorine bonds when an electric current is passed through a solution of hydrogen fluoride and the organic feedstock. In the telomerization process, fluorine-bearing chemicals and tetrafluoroethylene react to produce fluorinated intermediates that are converted into PFOA (HSDB 2006). The telomerization process produces linear chains (Beesoon et al. 2011). Ammonium perfluorooctanoate (APFO) is the salt of PFOA and is a processing aid in the manufacture of certain fluoropolymers, especially as an emulsifier in aqueous solution during the emulsion polymerization of tetrafluoroethylene (see Figure 1-1). APFO is not consumed during the polymerization process (SPI 2005). Some sources of PFOA in the atmosphere result from the atmospheric degradation or transformation or surface deposition of precursors, including related fluorinated chemicals (e.g., fluorotelomer alcohols, olefins, and perfluoroalkyl sulfonamide substances) (Wallington et al. 2006).



Source: SIAR 2006

Figure 1-1. Chemical Structures of PFOA and APFO

Although PFOA is not a polar molecule, each of the carbon fluoride bonds is a dipole as a result of the electronegativity difference between fluoride (4.1) and carbon (2.5), placing a partial negative charge on each of the covalently bound fluorines and a partial positive charge on each of the fluorinated carbons. Charge repulsion of the partially negative fluorines and steric factors favor a PFOA conformation in which carbons 2 through 7 adopt an *anti* arrangement of substituents resulting in a fairly linear molecular shape as the lowest energy conformer (see Figure 1-2 and Figure 1-3).

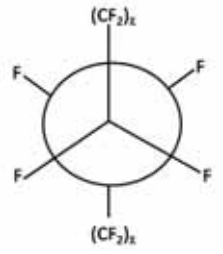


Figure 1-2. PFOA Anti-Conformer

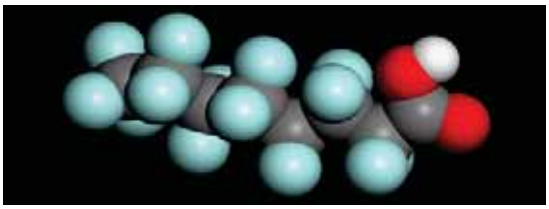

Figure 1-3. PFOA Lowest Energy Conformer

The favored PFOA conformer is very similar to the preferred conformation of the eight-carbon fatty acid, octanoic acid (also known as caprylic acid) except for the sphere of partial negative charge on the fluorines of the exterior surface. The ionized carboxylate grouping and the fluorine's partial negative charges favor electrostatic interactions between PFOA and positively charged surfaces on proteins and other macromolecules.

The ECF process produces branched chain isomers, about 80% linear and 20% branched (Loveless et al. 2008). The samples studied by Loveless et al. (2008) had the following mole (mol) percents of branched chain isomers: 12.6% internal monomethyl (nonalpha), 9% isopropyl, 0.2%, *tert*-butyl, 0.1 gem-dimethyl, and 0.1 alpha monomethyl. A study by Yoshikane et al. (2010) reported finding perfluoro-6-methylheptanoic acid (the isopropyl isomer) using mass spectroscopy analysis of environmental fluorosurfactants in Japan. Branched chain samples evaluated by Beesoon and Martin (2015) had a 7 carbon linear chain with methyl groups on carbons 3, 4, 5, or 6, designated as 3m, 4m, 5m, or 6m (iso), respectively. The composition of a PFOA product is important because the toxicokinetic and physiological properties of the linear and branched chain isomers are different. The nomenclature for the branched chain isomers varied between authors and indicates that differences exist in the composition of the commercial products that were evaluated.

The physical and chemical properties and other reference information for PFOA and its salt APFO are provided in Table 1-1. These properties help to define the behavior of PFOA in living systems and the environment. PFOA and its salt are highly stable compounds. They are solids at room temperature with low vapor pressures. The melting point for PFOA is identified as 54.3 degrees Celsius, and vapor pressures increase at temperatures near the melting point.

PFOA is moderately soluble in water and APFO is even more soluble. Both compounds are considered insoluble in nonpolar solvents, which results in their being described as olephobic. Water solubility is increased by the presence of other ions and is an important factor governing solubility in body fluids. As the concentration of PFOA in aqueous solution increases, it forms colloidal micelles with the carboxyl functional groups on the exterior and the fluorocarbon chain on the interior. The critical micelle concentration has been identified as 3.6–3.7 g/L. Once the critical concentration has been reached, micelles will form and the PFOA molecules will colloidally distribute in the aqueous environment. At levels below the critical micelle concentration, the individual molecules are individually distributed in the solvent.

The acid dissociation constant (pKa) for PFOA has been reported as 2.8. As a result, it will be present in most biological fluids (gastric secretions excluded) primarily as the perfluorooctanoate anion. This is an important feature in governing absorption and membrane transport.

Table 1-1. Chemical and Physical Properties of PFOA

Property	Perfluorooctanoic Acid	Source
Chemical Abstracts Service Registry No. (CASRN) [a]	335-67-1	
CA Index Name	2,2,3,3,4,4,5,5,6,6,7,7,8,8,8-pentadecafluorooctanoic acid	
Synonyms	PFOA; Pentadecafluoro-1-octanoic acid; Pentadecafluoro-n-octanoic acid; Octanoic acid, pentadecafluoro-; Perfluorocaprylic acid; Pentadecafluorooctanoic acid; Perfluoroheptanecarboxylic acid	
Chemical Formula	$C_8HF_{15}O_2$	
Molecular Weight (g/mol)	414.09	(HSDB 2012); (Lide 2007); (SRC 2016)
Color/Physical State	White powder (ammonia salt)	(HSDB 2012); (Lewis 2004)
Boiling Point	192.4 ºC; Stable when bound	(HSDB 2012); (Lide 2007); (SRC 2016)
Melting Point	54.3 ºC	(HSDB 2012); (Lide 2007); (SRC 2016)
Vapor Pressure	0.525 mm Hg at 25 ºC (measured) 0.962 mm Hg at 59.25 °C (measured)	(Hekster et al. 2003); (HSDB 2012); (SRC 2016) (ATSDR 2015); (Kaiser et al. 2005)
Henry's Law constant	Not measureable	(ATSDR 2015)
pKa	2.80	(SRC 2016)
K_{oc}	2.06	(Higgins and Luthy 2006)
K_{ow}	Not measurable	(ATSDR 2015); (EFSA 2008)
Solubility in water	9.50×10^3 mg/L at 25 ºC (estimated)	(ATSDR 2015); (Hekster et al. 2003); (HSDB 2012); (Kauck and Diesslin 1951); (SRC 2016)
Half-life in water (25ºC)	Stable	(UNEP 2015)
Half-life in air	Stable when bound	(UNEP 2015)

Note: [a]This CASRN is for linear PFOA, but the toxicity studies are based on a mixture of linear and branched and the RfD applies to both.

2 TOXICOKINETICS

PFOA is stable to metabolic and environmental degradation because of strong carbon-fluorine bonds. It also is resistant to metabolic biotransformation. Thus, the toxicity of the parent compound is the concern. Because of its impact on cellular receptors and proteins, it possesses the ability to impact the biotransformation of dietary constituents, intermediate metabolites, and other xenobiotic chemicals by altering enzyme activities and transport kinetics. PFOA is known to activate PPAR pathways by increasing transcription of mitochondrial and peroxisomal lipid metabolism, sterol, and bile acid biosynthesis and retinol metabolism genes. Based on transcriptional activation of many genes in PPARα-null mice, however, the effects of PFOA involve far more than activation of PPAR and consequent peroxisome proliferation. The data indicate that it also can activate the CAR, FXR, and PXR and metabolic activities linked to these nuclear receptors.

PFOA is not readily eliminated from humans and other primates. Toxicokinetic profiles and the underlying mechanism for half-life differences are not completely understood, although many of the differences appear to be related to elimination kinetics and factors that control membrane transport. Thus far, three transport families appear to play a role in PFOA absorption, distribution, and excretion: organic anion transporters (OATs), organic anion transporting polypeptides (OATPs), and multidrug resistance-associated proteins (MRPs) (Klaassen and Aleksunes 2010; Launay-Vacher et al. 2006). The transporters are critical for gastrointestinal absorption, uptake by the tissues, and excretion via bile and the kidney. These transport systems are located at the membrane surfaces of the intestines, liver, lungs, heart, blood brain barrier, blood placental barrier, blood testes barrier, and mammary glands where they function to protect the organs, tissues, and fetus from foreign compounds (Ito and Alcorn 2003; Klaassen and Aleksunes 2010, Zaïr et al. 2008).

There are differences in transporters across species, genders, and individuals. For example, more PFOA-specific information is available about the OAT and OATP families than about the MRPs. These limitations have hindered the development of PK models for use in predicting effects in humans based on the data from animal studies. Abbreviations for the various transporters are not totally standardized, and there are inconsistencies across individual publications. The current convention for distinguishing between the transporters in humans and those in animals is to use uppercase letters for humans and lowercase letters for animals. In this document, uppercase letters are used uniformly, thus, the abbreviations indicate the transporter family and not the species studied.

2.1 Absorption

Absorption data are available for oral, inhalation, and dermal exposure in laboratory animals, and extensive data are available from humans demonstrating the presence of PFOA in serum. These data demonstrate absorption by one or more routes but do not quantify the amounts absorbed relative to dose.

The absorption process requires transport across the interface of the gut, lung, and skin with the external environment. Since PFOA is moderately soluble in aqueous solutions and oleophobic (i.e., minimally soluble in body lipids), movement across the apical and basal membrane surfaces of the lung, gastrointestinal tract, and skin involves transporters or mechanisms other than simple diffusion across the lipid bilayer. As discussed above, there are

data that identify involvement of OATs, OATPs, and MRPs in enterocytes in uptake of PFOA (Klaassen and Aleksunes 2010; Zaïr et al. 2008). OAT2, OAT3, OATP2b1, and MRP2 are located in the apical membrane of the microvilli, and MRP1, 3, and 4 are located along the basolateral membrane. Together they function in the uptake of organic anions from gastrointestinal contents and transport of those anions into the portal blood supply (Zaïr et al. 2008). Few studies have been conducted of the intestinal transporters for PFOA in humans or laboratory animals. Most of the research has focused on the kidney and has been carried out using cultured carrier cells transfected with the transporter proteins.

2.1.1 Oral Exposure

Based on animal data, PFOA is well absorbed following oral exposure. Gibson and Johnson (1979) administered a single dose of ^{14}C-PFOA averaging 11.4 mg/kg by gavage to groups of three male 10-week-old CD rats. Twenty-four hours after administration, at least 93% of total carbon-14 was absorbed. In another study, Cui et al. (2010) exposed male Sprague-Dawley rats (10 per group) to PFOA (96% active ingredient) at 0, 5, and 20 mg/kg/day once daily by gavage for 28 days. The percent of the dose absorbed was 92.8% and 92.3% for the low and high dose, respectively, under the assumption that fecal excretion over the first 24 hours after dosing was estimated to be unabsorbed material and did not include biliary loss.

The data from studies of adverse effects on monkeys, rats, and mice receiving PFOA in capsules, food, or drinking water demonstrate gastrointestinal absorption. In cynomolgus monkeys, steady-state serum PFOA levels were reached within 4–6 weeks after dosing with capsules containing 3, 10, and 20 mg/kg PFOA for 6 months (Butenhoff et al. 2004b). Urine steady-state levels were reached after 4 weeks. Serum PFOA concentration in male rats fed diets containing 0.06, 0.64, 1.94, and 6.5 mg PFOA/kg for 90 days was 7.1, 41, 70, and 138 μg/mL, respectively (Perkins et al. 2004). Peak blood levels of PFOA were attained 1–2 hours following a 25-mg/kg dose to male and female rats (Kennedy et al. 2004). Blood levels of PFOA over time were similar in female rats given a single dose of 25 mg PFOA/kg to a female rat given 10 daily doses of 25 mg PFOA/kg (Kennedy et al. 2004). Plasma PFOA concentrations in male Sprague-Dawley rats fed a diet containing 300 parts per million (ppm) PFOA for 1, 7, and 28 days were 259, 234, and 252 μg/mL, respectively (Elcombe et al. 2010).

In rats, a marked gender difference in serum and tissue levels exists following PFOA administration. Males consistently have much higher levels than females with the difference maintained and becoming more pronounced over time. Female rats show much greater urinary excretion of PFOA than do male rats with serum half-life values in hours for females compared with days for males. These differences account for variability in postexposure serum concentrations between males and females.

2.1.2 Inhalation Exposure

Hinderliter (2003) measured the serum concentrations of PFOA following single and repeated inhalation exposures in Sprague-Dawley rats. For the single-exposure study, male and female rats (3/gender/group) were exposed to a single nose-only exposure of an aerosol of 0, 1, 10, and 25 mg/m^3 PFOA. Preliminary range-finding studies demonstrated that aerosol particle sizes were 1.8–2.0 μm mass median aerodynamic diameter (MMAD) with geometric standard deviations (GSDs) ranging from 1.9 to 2.1 μm. Blood samples were collected before exposure; at 0.5, 1, 3, and 6 hours during exposure; and at 1, 3, 6, 12, 18, and 24 hours after exposure. Plasma

was analyzed by liquid chromatography-mass spectrometry (LC-MS). PFOA plasma concentrations increased proportional to aerosol exposure concentrations.

The male plasma C_{max} values were approximately 2–3 times higher than the female C_{max}. The female C_{max} occurred approximately 1 hour after the exposure period with plasma concentrations then declining. In males, Cm_{ax} was observed immediately after the exposure period ended and persisted for up to 6 hours. The data are illustrative of absorption of PFOA via inhalation and are consistent with the gender differences in rate of excretion.

2.1.3 Dermal Exposure

There is evidence that PFOA is absorbed following dermal exposure. Kennedy (1985) treated rabbits and rats dermally with a total of 10 applications of PFOA at doses of 0, 20, 200, and 2,000 mg/kg. Treatment resulted in elevated blood organofluorine levels that increased in a dose-related manner. Organofluorine was measured because, at the time of the study, reliable analytical techniques for measuring serum or plasma PFOA were still under development. O'Malley and Ebbens (1981) treated groups of two male and two female New Zealand White rabbits dermally with doses of 100, 1,000, and 2,000 mg/kg PFOA for 14 days. Mortality among the exposed animals demonstrated dermal uptake. All of the animals died at the highest dose, three of four died in the mid-dose group, and none in the low-dose group. Although these data demonstrate dermal absorption, they do not provide quantitative dose-response data for effects other than mortality.

The results of *in vitro* percutaneous absorption studies of PFOA through rat and human skin have been reported (Fasano et al. 2005). The permeability coefficient for PFOA was calculated to be $3.25 \pm 1.51 \times 10^{-5}$ centimeters per hour (cm/h) and $9.49 \pm 2.86 \times 10^{-7}$ cm/h in rat and human skin, respectively.

2.2 Distribution

Distribution of absorbed material requires vascular transport from the portal of entry to receiving tissues. It has been suggested that PFOA circulates in the body by noncovalently binding to plasma proteins. Several studies have investigated the binding of PFOA to plasma proteins in rats, humans, or monkeys to gain an understanding of its absorption, distribution, and elimination as well as information on species and gender differences.

Protein Binding. Protein binding in plasma from cynomolgus monkeys, rats, and humans was tested with PFOA via *in vitro* methods (Kerstner-Wood et al. 2003). The results are summarized in Table 2-1. Rat, human, and monkey plasma proteins were able to bind 97–100% of the PFOA added at concentrations ranging from 1 to 500 ppm. Human serum albumin (HSA) carried the largest portion of the PFOA among the protein components of human plasma. Serum albumin is a common carrier of hydrophobic materials in the blood, including short- and medium-chain fatty acids, thyroxine (T4), heme, inorganic ions, and some pharmaceuticals (Fasano et al. 2005). Approximately 60% of the serum protein in humans and rats is albumin (Harkness and Wagner 1983; Saladin 2004). At 68%, the percentage bound to albumin in mice is slightly higher than in humans and rats (Harkness and Wagner 1983).

Table 2-1. Protein Binding in Rat, Human, and Monkey Plasma

PFOA Concentration (ppm)	Rat (%)	Monkey (%)	Human (%)
1	~100	~100	~100
10	99.5	99.8	99.9
100	98.6	99.8	99.9
250	97.6	99.8	99.6
500	97.3	99.5	99.4

Source: Kerstner-Wood et al. 2003
Note: % binding values reported as "~100" reflect a nonquantifiable amount of test article in the plasma water below the quantifiable limit <6.25 ng/mL.

Han et al. (2003) investigated the binding of PFOA to rat and human plasma proteins *in vitro*. The authors concluded that there was no correlation between the PFOA persistence and binding of the PFOA to rat serum. The primary PFOA binding protein in plasma was serum albumin. However, the method used (ligand blotting) would not theoretically allow the identification of low-abundance proteins with high affinity for PFOA. Further investigation of purified rodent and HSA binding using labeled ^{19}F nuclear magnetic resonance (NMR) allowed the calculation of disassociation constants for PFOA binding to rodent and HSA. No significant difference in binding to the serum albumin of rat versus human was detected (Table 2-2).

Male and female rats treated *in vivo* showed no gender difference in the binding of PFOA to serum proteins though the persistence of PFOA *in vivo* is much greater in male than female rats.

Table 2-2. Dissociation Constants (K_d) of Binding Between PFOA and Albumin

Parameter	Method	RSA	HSA
K_d (mM)	NMR[a]	0.29 ± 0.10[c]	
K_d (mM)	micro-SEC[b]	0.36 ± 0.08[c]	0.38 ± 0.04
Number of Binding Sites	micro-SEC[b]	7.8 ± 1.5	7.2 ± 1.3

Source: Han et al. 2003
Notes:
RSA = rodent serum albumin; HSA= human serum albumin
a = Average of the two K_d values (0.31 ± 0.15 and 0.27 ± 0.05 mM) obtained by NMR.
b = Values were obtained from three independent experiments and their SDs are shown.
c = On the basis of the result of unpaired t-test at 95% confidence interval, the difference of K_d values determined by NMR and micro-SEC is statistically insignificant.

Wu et al. (2009) examined the interaction of PFOA and HSA. The authors tested their hypothesis that PFOA, after absorption, was transported bound to albumin by dialyzing PFOA solutions in the presence and absence of HSA. In the absence of HSA, 98% of the dissolved PFOA crossed the dialysis membrane into the dialysate within 4 hours. In the presence of HSA, the amount of PFOA found in the dialysate after 4 hours decreased in direct proportion to the albumin concentration, demonstrating binding to the protein. No albumin was identified in the dialysate.

Using the dialysis data and thermodynamic considerations, the authors concluded that albumin could bind up to 12 PFOA molecules on its surface via chemical monolayer absorption with a 13th molecule bound noncovalently in the more hydrophobic interior of the protein. The surface nature of the binding could well indicate potential binding to other serum proteins as well. Circular dichroism measurements of the albumin/PFOA complex suggested a conformational change in the protein as a result of the PFOA binding. The beta-pleated sheet

content of the albumin decreased, and the alpha-helix content increased by 15%. These conformational changes could interfere with the functional properties of serum albumin or other serum proteins impacted by surface monolayers of PFOA. For example, albumin's ability to transport its natural ligands could be decreased by the presence of PFOA on the protein surface. The interaction of albumin with target cellular receptors also could be altered.

MacManus-Spencer et al. (2010) used a variety of approaches to quantify the binding of PFOA to serum albumin (e.g., surface tension measurements, ^{19}FNMR spectroscopy, and fluorescence spectroscopy). When taken together, the results from these analyses suggest the presence of primary and secondary binding sites on albumin. The PFOA-albumin association constants for the primary site (K_1^a) was about 1.5 ± 0.2 x 10^5/mol bovine serum albumin (BSA) while the association constant for the secondary site (K_2^a) was 0.8 ± 0.1 x 10^2/mol BSA at a concentration of 1µmol. When the concentration of BSA increased to 10 µmol, the binding per mol of BSA decreased K_1^a = 0.33 ± 0.004 and K_2^a = 0.53 ± 0.1. Qin et al. (2010) also used fluorescence spectroscopy quenching analysis to study PFOA binding to BSA and concluded that van der Waals forces and hydrogen bonds were the dominant intermolecular binding forces.

The results of the fluorescence spectroscopy suggested a conformational change in BSA following binding of PFOA that moved a tryptophan residue (#214) from a slightly polar region of the protein to a less polar region. The shift in a tryptophan position is consistent with the observations of Wu et al. (2009) and Qin et al. (2010), who reported that BSA underwent a conformational change following the binding of PFOA. The authors considered the results from the fluorescence spectroscopy to be relevant to the potential physiological impact of PFOA at levels found in the environment. Because serum albumin is a carrier for a variety of endogenous and exogenous substrates, a change in conformation can alter the bonding constants between albumin and other serum constituents.

A modeling study by Salvalaglio et al. (2010) was conducted to determine the binding sites of PFOA on HSA and classify them by their interaction energy using molecular modeling; this study builds on the binding studies of Wu et al. (2009) and MacManus-Spencer et al. (2010). It was estimated that the maximum number of PFOA binding sites on HSA was nine. The site locations were common to the natural binding sites for fatty acids, T4, Warfarin, indol, and benzodiazepine (see Figure 2-1) (Salvalaglio et al. 2010). The binding site closest to tryptophan residue #214 had the highest binding affinity (-8.0 kilocalorie/mol).

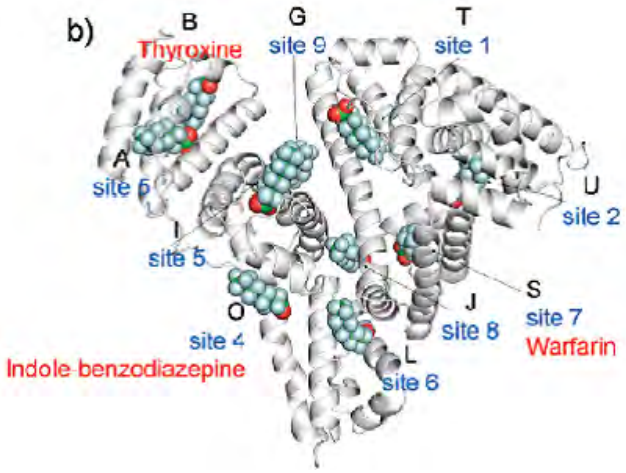

Figure 2-1. PFOA Binding Sites on HSA

Weiss et al. (2009) screened several perfluorinated compounds (n = 30), differing by carbon chain length C4–18, fluorination degree, and functional groups for potential binding to the serum thyroid hormone transport protein, transthyretin (TTR), using a radioligand-binding assay. The natural ligand of TTR is T4. PFOA was one of the chemicals evaluated. Human TTR was incubated overnight with ^{125}I-labeled T4, unlabeled T4, and 10-10,000 nanomolar (nmol) PFOA as a competitor for the T4 binding sites. The unlabeled T4 was used as a reference compound. The levels of T4 in the assay were close to the lower range for total T4 measured in healthy adults. The authors concluded that binding affinity for TTR was highest for the fully fluorinated compounds tested and those having at least an eight carbon length chain, characteristics that apply to PFOA. PFOA demonstrated a high binding affinity for TTR with 949 nmol, causing a 50% inhibition of T4 binding to the TTR.

Beesoon and Martin (2015) examined differences in the binding of the linear and branched chain isomers to serum albumin and human serum proteins. The linear PFOA molecule was found to bind more strongly to calf serum albumin than the branched chain isomers. When arranged in order of increasing binding, the order was 4m < 3m <5m < 6m (iso) <linear. In the isomer-specific binding to spiked total human serum protein, the linear molecule clearly had the strongest binding potential with about 7–10% free. The relationship for the other isomers was 5m > 6m >4m> 3m (15–30% free). Binding was estimated based on the concentrations in the ultrafiltrate after spiking with 5–60 mg/L of technical PFOA. The human serum was diluted tenfold before spiking.

When incubated with separate human-derived plasma protein fractions (Kerstner-Wood et al. 2003), PFOA was highly bound (99.7%) to albumin and showed some affinity for LDLs, formerly beta-lipoproteins (9.6%) with limited binding to alpha-globulins (11.0%) and gamma-globulins (3.0%). Low levels of binding to alpha-2-macroglobulin and transferrin were measured when the protein concentrations were approximately 10% of physiological concentration (see Table 2-3).

Table 2-3. Percent (%) Binding of PFOA to Human Plasma Protein Fractions

Fraction	~10% Physiological Conc.	100% Physiological Conc.
Albumin	96.4	99.7
Gamma-globulin	3.5	3.0
Alpha-globulin	28.5	11.0
Fibrinogen	5.4	<0.1
Alpha-2-macroglobulin	7.9	<0.1
Transferrin	1.0	2.1
LDLs	19.6	39.6

Source: Kerstner-Wood et al. 2003

It also is possible that PFOA will display nonspecific binding to proteins within the cellular matrix as well as in the serum but little work has been done to investigate that probability.

Luebker et al. (2002) conducted *in vitro* studies of the ability of a variety of perfluorinated chemicals to displace a fluorescent substrate (11-(5-dimethylamino-napthalenesulphonyl)-undecanoic acid) from liver fatty acid binding protein (L-FABP). L-FABP is an intracellular lipid carrier protein that reversibly binds long-chain fatty acids, phospholipids, and an assortment of peroxisome proliferators (Erol et al. 2003). It constitutes 2–5% of the cytosolic protein in hepatocytes. Luebker et al. (2002) reported that PFOA (IC_{50}>10µmol) exhibited some binding to

L-FABP, but the binding potential was only about 50% of that for PFOS (IC_{50} = 4.9 μmol) and far less than that of oleic acid (IC_{50} = 0.01 μmol).

L. Zhang et al. (2013) cloned the human L-FABP gene and used it to produce purified protein for evaluation of the binding of PFOA and other PFASs. Nitrobenzoxadiazole-labeled lauric acid was the fluorescent substrate used in the displacement assays. IC_{50} values and dissociation constants were generated for the PFASs studied. Oleic and palmitic acids served as the normal substrates for L-FABP binding. The nitrobenzoxadiazole-labeled lauric acids indicated that there were two distinct binding sites for fatty acids in human FABP with the primary site having a twentyfold higher affinity than the secondary site. The IC_{50} value for PFOA was 9.0 ± 0.7 μmol, suggesting that it has a lower binding affinity than PFOS (IC_{50}=3.3 ± 0.1 μmol). A similar approach was used to compare perfluorohexanoic acid (PFHxA, perfluorohexanesulfonic acid (PFHxS), PFOA, and perfluorononanoic acid (PFNA). The affinity of PFNA for human L-FABP was found to be greater than that for PFOA. The affinities of PFHxA and PFHxS for the protein were much lower. Both PFOA and PFNA bound to the carrier protein in a 1:1 ratio and the interaction was mediated by electrostatic interactions and hydrogen binding of the PFAS with the fatty acid binding site.

2.2.1 Oral Exposure

Tissue Distribution

Human. No clinical studies are available that examined tissue distribution in humans following administration of a controlled dose of PFOA. However, samples collected in biomonitoring and epidemiology studies provide data showing distribution of PFOA. Olsen et al. (2001a) analyzed human sera and postmortem liver samples and found that more than 90% of the liver samples (n = 30) were < limit of quantitation (LOQ). Serum levels ranged from <LOQ–7.0 nanograms per milliliter (ng/mL). PFOA concentrations above the LOQ were detected in 5/6 postmortem liver samples from males in Catalonia, Spain. In females, only 1/6 liver samples was above LOQ (Kärrman et al. 2009). Pirali et al. (2009) measured intrathyroidal PFOA levels (0.4–6.0 ng/g) in thyroid surgical patients and found no correlation between serum and thyroid PFOA concentration. PFOA has been detected in breast milk samples (Tao et al. 2008; Völkel et al. 2008) and cord blood samples (Apelberg et al. 2007; Monroy et al. 2008) at concentrations above the LOQ. These studies indicate that PFOA is distributed within the body and that maternal transfer to offspring can occur.

Pérez et al. (2013) collected tissue samples from 20 adult subjects (aged 28–83) who had been living in Catalonia, Spain, for 10 years and died of a variety of causes. Autopsies and tissue collection (liver, kidney, brain, lung, and bone) were carried out in the first 24 hours after death. The tissues were analyzed for 21 perfluorinated compounds. PFOA was present in 45% of the samples but could be quantified in only 20% (median 1.9 ng/g). PFOA accumulated primarily in the bone (60.2 ng/g), lung (29.2 ng/g), liver (13.6 ng/g), and kidney (2.0 ng/g), with levels below detection in brain based on the mean wet weight tissue concentrations. Detection levels varied with the tissue evaluated.

Animal. Studies of tissue distributions are available for several species including monkeys, rats, and mice. The data are categorized by species in the sections that follow. The distribution data derived from studies during pregnancy and lactation follow the data on nonpregnant animals.

Monkey. Butenhoff et al. (2002, 2004b) studied the fate of PFOA in cynomolgus monkeys in a 6-month oral exposure study. Groups of four to six male monkeys each were administered PFOA daily via oral capsule at dose rates (DRs) of 0, 3, 10, or 20 mg/kg. The highest dose was initially 30 mg/kg, but due to its toxicity, it was suspended after 12 days. Dosing was resumed on test day 22 using the 20 mg/kg/day dose for the remainder of the 6-month period, resulting in a normalized dose of 20 mg/kg/day for the study. Serum, urine, and fecal samples were collected at 2-week intervals and were analyzed for PFOA concentrations. Liver samples were collected at time of sacrifice.

Serum concentrations reached steady-state levels within 4–6 weeks in all dose groups. Steady-state concentrations of PFOA in serum were 77 ± 39, 86 ± 33, and 158 ± 100 μg/ml after 6 weeks and 81 ± 40, 99 ± 50, and 156 ± 103 μg/ml after 6 months for the 3-, 10-, and 20-mg/kg dose groups, respectively (Butenhoff et al. 2002, 2004b). The mean serum concentration of PFOA in control monkeys was 0.134–0.203 μg/ml. Urine PFOA concentrations reached steady state after 4 weeks and were 53 ± 25, 166 ± 83, and 181 ± 100 μg/ml in the 3, 10, and 20-mg/kg dose groups, respectively, for the duration of the study. Liver PFOA concentrations at terminal sacrifice in the 3-mg/kg and 10-mg/kg dose groups were similar and ranged from 6.29 to 21.9μg/g. Liver PFOA concentrations in two monkeys exposed to 20 mg/kg were 16.0 and 83.3 μg/g. Liver PFOA concentrations in two monkeys dosed with 10 mg/kg/day at the end of a 13-week recovery period were 0.08 and 0.15 μg/g (Butenhoff et al. 2004b).

Rat. Ylinen et al. (1990) administered newly weaned Wistar rats (18/gender/group) doses of 3, 10, and 30 mg/kg/day PFOA by gavage for 28 days. At necropsy, serum was collected as well as brain, liver, kidney, lung, spleen, ovary, testis, and adipose tissue. The concentration of PFOA in the serum and tissues was determined with capillary gas chromatography equipped with a flame ionization detector (FID). A mass spectrometer was used in the selected ion monitoring mode when the PFOA concentration was below the LOQ of the FID (1 μg/ml).

The concentration of PFOA in the serum and tissues following 28 days of administration is presented in Table 2-4. PFOA was not detected in the adipose tissue. The concentrations of PFOA in the serum and tissues were much higher in males than in females. In the males, the levels of PFOA in the serum were generally lower in the 30 mg/kg/day dose group than in the 10 mg/kg/day dose group due to increased urinary elimination in the 30 mg/kg/day group. The tissue levels were similar for the 10 and 30 mg/kg/day doses. In females, there was a dose-related increase in tissue levels while the serum levels were comparable for the 10 and 30 mg/kg/day dose groups. Among solid tissues, the liver had the highest tissue concentration followed by the testis, spleen, lung, kidney, and brain, respectively. In females, the concentration in the kidneys exceeded that in the liver for the 10 and 30 mg/kg/day doses but not at the lowest dose. Ovary and spleen tissue had similar concentrations followed by lower levels in the lung and brain.

Table 2-4. Tissue Distribution of PFOA in Wistar Rats After 28 Days of Treatment

Tissue	Dose (Males[a]) mg/kg/day			Dose (Females[a]) mg/kg/day		
	3	10	30	3	10	30
Serum	48.6 ± 10.3	87.27 ± 20.09	51.65 ± 1.47	2.4[b]	12.47 ± 4.07	13.92 ± 6.06

Kemper (2003) examined the distribution of PFOA in tissues of male and female Sprague-Dawley rats following administration by gavage. Rats were administered 1, 5, and 25 mg/kg ^{14}C-PFOA by oral gavage. Tissue concentrations were determined at the time of maximum plasma concentration (T_{max}) and at the time that plasma concentration had fallen to one half the maximum ($T_{max/2}$). Values for T_{max} and $T_{max/2}$ for male and female rats were determined from PK experiments. In those experiments, plasma was collected over the course of several days and PFOA concentration was analyzed. Noncompartmental PK models were applied to identify T_{max} and elimination half-time ($T_{1/2}$) from the data. The $T_{max/2}$ was calculated as the time (hr) for the maximum plasma concentration plus the elimination half-time (hr) ($T_{max} + T_{1/2}$). In some cases, elimination could occur in a rapid phase followed by a slower elimination phase. For cases in which biphasic elimination was evident, the rapid phase $T_{1/2}$ was used for calculation of $T_{max/2}$.

Tissues from male rats were collected at 10.5 hours (T_{max}) and 171 hours ($T_{max/2}$) after dosing. Tissues from female rats were collected at 1.25 hours (T_{max}) and 4 hours ($T_{max/2}$) after dosing. The results are summarized in Table 2-5 for males and Table 2-6 for females. Liver, blood, skin, muscle, bone, G.I. tract, and fat were the primary tissues for distribution of ^{14}C-PFOA. In males, the fraction of the dose found in the liver increased between T_{max} and $T_{max/2}$, but remained constant or decreased in other tissues. In females, the fraction of the dose present in all tissues remained constant or decreased between T_{max} and $T_{max/2}$. Liver-to-blood concentration ratios for ^{14}C at T_{max} in males were greater than 1 and increased between T_{max} and $T_{max/2}$. In females distribution levels in blood were between 1 and 2 at all dose levels and remained relatively constant between T_{max} and $T_{max/2}$. In males, the blood distributions levels were tenfold or higher than kidney levels at T_{max} and declined slightly at $T_{max/2}$.

Examination of the residuals from the administered PFOA in the male tissues at $T_{max/2}$ (171 hours) indicate that 40–60% of the dosed PFOA retained was present in the liver, blood, skin, and muscle tissues in decreasing amounts (Table 2-5). In males, about 1% of the label was present in the gastrointestinal tissues and contents at $T_{max/2,}$ while the value for females was about 10%. However, the samples were collected at 1.25 and 4 hours in females and 10.5 and 171 hours in males, providing more time for absorption in the males.

Notes: Percent of dose recovered at T_{max} and $T_{max/2}$ in tissues.

[a] Percent recovery scaled to whole animal assuming the following: skin=19%, whole blood=7.4%, fat=7%, muscle=40.4%, bone=7.3% of body weight.

[b] Totals are calculated from individual animal data.

In the female tissues at $T_{max/2}$ (4 hours), approximately 30% of the dosed PFOA retained was present in the liver, blood, kidney, muscle, and skin tissues in decreasing amounts (Table 2-6). About 14% of the administered dose remained in the gastrointestinal tissues and contents. Based on the timing of the measurements and the results, females appear to absorb and excrete PFOA more rapidly than males.

Lau et al. (2006) studied PFOA's toxicokinetic properties in rats as part of a larger study. The authors gavage-dosed adult male and female Sprague-Dawley rats (n = 8) with 10 mg/kg for 20 days and sacrificed them 24 hours after the last treatment. After 20 days of treatment, male rats had serum PFOA levels of 111 µg/mL compared to 0.69 µg/mL in female rats.

Martin et al. (2007) administered 20 mg PFOA/kg to adult male Sprague-Dawley rats (n = 4 or 5) for 1, 3, and 5 days by oral gavage and determined the liver and serum levels of PFOA. Blood was collected via cardiac puncture and PFOA concentration was determined by high-performance liquid chromatography-electrospray tandem mass spectrometry (LC-MS/MS). The mean liver PFOA concentration was 92 ± 6, 250 ± 32, and 243 ± 23 µg/g after 1, 3, and 5 daily doses of 20 mg PFOA/kg/day, respectively. The mean serum concentration was 245 ± 41 µg/mL after 3 daily doses of 20 mg PFOA/kg/day. Serum PFOA concentration was not determined after 1 day and 5 days of dosing due to sample availability.

Notes: Percent of dose recovered at T_{max} and $T_{max/2}$ in tissues.

[a] Percent recovery scaled to whole animal assuming the following: skin=19%, whole blood=7.4%, fat=7%, muscle=40.4%, bone=7.3% of body weight.

[b] Totals are calculated from individual animal data.

Mouse. Lau et al. (2006) gavage-dosed adult male and female CD-1 mice (5–7/group) with 20 mg/kg for 7 and 17 days. The animals were sacrificed 24 hours after the last treatment. After 7 days of treatment, male mice had serum PFOA levels of 181 µg/mL and females had levels of 178 µg/mL. After 17 days of treatment, male mice had serum PFOA levels of 199 µg/mL and females had levels of 171 µg/mL. These data suggest that the gender difference observed by Lau et al (2006) in rats was not seen in the mice under the conditions of this study.

As part of a physiologically based pharmacokinetic (PBPK) modeling exercise, Lou et al. (2009) administered single doses of 1 and 10 mg/kg to groups of three male and three female CD-1 mice. The mice were sacrificed for analysis of plasma, liver, and kidney tissues after 4, 8, and 12 hours and at 1, 3, 6, 9, 13, 20, 27, 34, and 48 days after dosing. This study was repeated for a second analysis that extended the sacrifice times to 55, 62, 70, and 80 days.

Measures of PFOA in serum were presented graphically and indicate that the order of magnitude difference between the doses led to a comparable order of magnitude difference in serum concentrations for both males and females across the 80-day observation period. [The study procedures indicated that *serum* was collected and analyzed, but the graphic presentation described the values as *plasma* values. Contact with one of the authors confirmed that the values should have been listed as *serum* rather than *plasma*.] The peak serum concentrations were

10 and 100 mg/L for the 1 and 10 mg/kg/day doses, respectively. Declines in serum concentrations for females over time were roughly parallel reaching concentrations of about 2 mg/L and <0.2 mg/L for the high and low doses, respectively, at the end of 80 days. Peak serum concentrations were slightly lower in the males (~8 and 80 mg/L) than in the females, and final serum concentrations were higher in the males (~0.5 and 8 mg/L). Liver and kidney concentrations also were higher in males than in females for each of the two doses. These data suggest a longer half-life in males than in females.

Lou et al. (2009) also collected serum data for up to 28 days after administration of a 60-mg/kg dose to groups of three female mice. Based on the graphic presentation of the data, the 60-mg/kg dose was cleared from the serum much more rapidly than the 1- and 10-mg/kg doses. For example, a serum concentration of about 0.4 mg/L was reached in about 28 days for the 60-mg/kg dose, 61 days for the 10-mg/kg dose, and 70 days for the 1-mg/kg dose (values estimated from Figure 3 in Lou et al. [2009]). No measurements were made for liver or kidney in the high-dose animals.

In the final experimental portion of the study, Lou et al. (2009) exposed groups of five female CD-1 mice to 20 mg/kg/day for 17 days. Serum samples were collected 24 hours after the final dose and analyzed for PFOA. The mean serum concentration was 130 ± 23 mg/L, which is comparable to that of 171 µg/mL reported by Lau et al. (2006).

Minata et al. (2010) orally administered 0, 12.5, 25, and 50 micromole per kilogram (µmol/kg) PFOA (~0, 5.4, 10.8, and 21.6 mg/kg PFOA) to groups of male wild-type 129S4/SvlmJ mice (n = 39) and PPARα- null 129S4/SvJae-Pparα^{tm1Gonz}/J mice (n = 40) for 4 weeks. Blood, liver, and bile were collected for determination of PFOA concentration at the end of 4 weeks, as shown in Table 2-7. The PFOA concentration in whole blood and the liver were similar between wild-type and PPARα-null mice at the same dose level and appeared to increase in proportion to dose. In bile, PFOA concentration in wild-type mice increased by a factor of 13.8 from 12.5 to 25 µmol/kg and by a factor of 2.8 from 25 to 50 µmol/kg. In the bile of PPARα-null mice, PFOA concentration increased by a factor of 3.2 from 12.5 to 25 µmol/kg and by a factor of 19.5 from 25 to 50 µmol/kg. The data suggested saturation of PFOA transport from the liver to bile ducts in wild-type mice, but not PPARα-null mice. This may indicate that PPARα plays a role in the clearance of PFOA.

Table 2-7. PFOA Concentrations in Wild-type and PPARα-null Mice (µg/mL)

Dose µmol/kg	Whole Blood		Bile		Liver	
	Wild-type	PPARα-null	Wild-type	PPARα-null	Wild-type	PPARα-null

Tissue Transporters. As identified earlier, protein transporters from a number of families play a role in the tissue uptake of orally ingested PFOA. The transporters are located at the interface between the serum and the liver, kidneys, lungs, heart, brain, testes, ovaries, placenta, and uterus (Klaassen and Aleksunes 2010). The liver is an important uptake site for PFOA. OATPs and MRPs, at least one OAT, and the sodium-taurocholate cotransporting polypeptide (NTCP), a

hepatic bile uptake transporter, have been identified at the interface of the liver with the portal blood and/or the canalicular membranes within the liver (Kim 2003; Kusuhara and Sugiyama 2009; Zaïr et al. 2008).

The impact of PFOA on several membrane transporter systems linked to biliary transport was studied by Maher et al. (2008) as part of a more detailed study of perfluorodecanoic acid (PFDA). A dose of 80 mg/kg by intraperitoneal (i.p.) injection (propylene glycol: water vehicle) was found to significantly increase ($p<0.05$) the expression of MRP3 and MRP4 in the livers of C57BL/6 mice 2 days after treatment as reflected in quantification of their deoxyribonucleic acid (DNA) transcripts. MRP3 and MRP4 are believed to protect the liver from accumulation of bile acids, bilirubin, and potentially toxic exogenous substances by promoting their excretion in bile. There were significant increases in serum bilirubin and bile acids after PFDA exposure, signifying increased export. Conversely, there were significant decreases ($p<0.05$) in the protein levels for OATP1a1, OATP1a4, and OATP1b2 as determined by Western Blot analysis and messenger ribonucleic acid (mRNA) measurements following exposure to 40 mg PFOA/kg (Cheng and Klaassen 2008). There was no significant impact on NTCP protein or the serum levels of bile acids. The OATPs are transporters responsible for the uptake of bile acids and other hydrophobic substances such as steroid conjugates, ecosinoids, and thyroid hormones into the liver.

These studies, all by the same laboratory, were carried out at high, single-dose exposures, which limit their value in extrapolating to low- and repeat-dose scenarios. The results suggest a decrease in the uptake of favored substrates into the liver and an increase in removal of favored substrates from the liver via bile. Upregulation of MRP3 and MRP4, coupled with decreased OATp levels, could be beneficial due to increased biliary excretion of bile acids, bilirubin, and conjugated metabolites of toxic chemicals, including PFOA. Based on the results with the more extensive evaluation of PFDA including mouse strains null for several receptors (PPARα, CAR, PXR, and FXR), the authors concluded that the changes in receptor proteins were primarily linked to activation of PPARα.

Impact of Developmental Age. Han (2003) administered groups of 4–8-week-old Sprague-Dawley rats (10 per gender per age) a single dose of 10 mg/kg/day PFOA by oral gavage. Blood samples were collected 24 hours after dosing and the plasma concentration of PFOA was measured by high-performance liquid chromatography mass spectrometry (HPLC/MS). In the 4-week-old rats, the concentration of plasma PFOA was approximately 2.7 times higher in males than in the females (Table 2-8). In the 5- and 6-week-old female rats, the plasma PFOA concentrations were about twofold lower than in the 4-week-old rats. However, in the 5-week-old males, the concentration of plasma PFOA was about fivefold higher than in the 4-week-old group, suggesting a developmental change in excretion rate. Plasma concentrations did not differ appreciably among 5-, 6-, 7-, and 8-week-old rats within each gender but did differ between genders. In fact, PFOA plasma concentrations were 35–65-fold higher in males than in females at every age except at 4 weeks. Thus, it appears that maturation of the transport features responsible for the gender difference in elimination occurs between the ages of 4 and 5 weeks in the rat.

Table 2-8. Plasma PFOA Concentrations (µg/ml) in Postweaning Sprague-Dawley Rats

Age (weeks)	Males	Females
4	7.32 ± 1.01[a]	2.68 ± 0.64
5	39.24 ± 3.89	1.13 ± 0.46
6	43.19 ± 3.79	1.18 ± 0.52
7	37.12 ± 4.07	0.57 ± 0.29
8	38.55 ± 5.44	0.81 ± 0.27

Notes:
[a] Mean ± SD; samples from 10 animals/gender/group

Hinderliter (2004) and Hinderliter et al. (2006a) continued the investigation of the relationship between age and plasma PFOA in male and female Sprague-Dawley rats. Immature rats at 3, 4, and 5 weeks of age were administered PFOA via oral gavage at a single dose of 10 or 30 mg/kg. Rats were not fasted prior to dosing. Two hours after dosing, five rats per gender per age group and dose group were sacrificed and blood samples were collected. The remaining five rats per gender per age and dose group were placed in metabolism cages for 24-hour urine collection. These rats were sacrificed at 24 hours and blood samples were collected.

In the male rats, plasma PFOA concentrations for either the 10- or 30-mg/kg dosage groups did not differ significantly by sample time (at 2 and 24 hours) or by animal age (3, 4, and 5 weeks), except at 2 hours for the 5-week-old group ($p<0.01$), which showed the lowest PFOA level (Table 2-9). PFOA plasma concentrations following a 30-mg/kg dose were 2–3 times higher than those following a 10-mg/kg dose. These data do not demonstrate a difference between the 5-week-old rats and the younger 3- and 4-week-old groups at 24 hours after dosing, and thus do not support the observations from the Han study (2003).

Table 2-9. Plasma PFOA Concentrations in Male Rats

Age (weeks)	Dose (mg/kg)	Plasma PFOA (µg/ml)			
		2 Hours Post-Dose		24 Hours Post-Dose	
		Mean	SD	Mean	SD
3	10	41.87	4.01	34.22	7.89
4	10	39.92	4.45	42.94	5.33
5	10	26.32*	6.89	40.60	3.69
3	30	120.65	12.78	74.16	18.23
4	30	117.40	18.10	100.81	13.18
5	30	65.66*	15.53	113.86	23.36

Source: Hinderliter 2004
Note: *Statistically significantly different by sample time and animal age ($p<0.01$).

In the female rats, plasma PFOA concentrations were significantly lower in the 5-week-old group than in the 3- or 4-week-old groups at the 24-hour time period for both doses and for the 30-mg/kg dose group at 2 hours (Table 2-10). Plasma PFOA concentrations following a 30-mg/kg dose were approximately one and one half to four times higher than those observed following a 10-mg/kg dose.

At 24 hours post-dose, plasma PFOA levels in the female rats were significantly lower than the plasma PFOA levels in male rats, especially at 5 weeks of age. The data for the 5-week-old female rats compared to the 3- and 4-week-old groups at 24 hours are consistent with the Han (2003) data

in that they demonstrate a decline in plasma levels compared to their earlier measurements. Thus, the developmental change is one that appears to be unique to the female rat.

Table 2-10. Plasma PFOA Concentrations in Female Rats

Age (weeks)	Dose (mg/kg)	Plasma PFOA (μg/ml)			
		2 Hours Post-Dose		24 Hours Post-Dose	
		Mean	SD	Mean	SD
3	10	37.87	5.77	13.55 [b]	3.83
4	10	29.88	12.15	18.98 [b]	7.01
5	10	33.23	7.41	1.36 [a, b]	0.87
3	30	84.86	10.51	51.43 [b]	13.61
4	30	80.67	14.10	28.01 [b]	9.90
5	30	56.90 [a]	29.66	3.42 [a, b]	1.95

Source: Hinderliter 2004
Notes:
[a] Statistically significantly different from the 3- and 4-week values ($p < 0.01$).
[b] Statistically significantly different from 2-hour values ($p < 0.01$).

The data demonstrate that both dose and gender influence plasma levels. Post-dosing clearance (CL) is slow for both doses at 2 and 24 hours in males and females at postnatal weeks 3 and 4. At 5 weeks, however, the plasma levels after 24 hours are greater than those at 2 hours in males. In females, for the high dose at 2 hours, plasma levels are similar to those in males, while at 24 hours they are only 3% of the value for males. This suggests that uptake from the intestines is similar while the rate of excretion at 5 weeks and beyond is considerably greater for female rats than males. They are comparable for postnatal weeks 3 and 4.

In a supplemental study to determine the effect of fasting (Hinderliter [2004] and Hinderliter et al. [2006a]), 4-week-old rats, 4 rats per gender, were administered 10 mg/kg PFOA via oral gavage. Animals (two per gender) were fasted overnight for 12 hours before dosing with PFOA. All the rats were sacrificed at 24 hours post dosing and blood was collected for analysis of PFOA in plasma. Plasma PFOA concentrations in male rats were 64.95 and 30.00 μg/ml for the fasted and nonfasted animals, respectively. Plasma PFOA concentrations in the female rats were 68.16 and 26.54 μg/ml for the fasted and nonfasted animals, respectively. Given the consistency in the 4-week-old rat plasma PFOA concentrations, the authors concluded that age-dependent changes in female PFOA elimination are observable between 3 and 5 weeks of age. PFOA uptake was greater in the fasted animals than the fed animals, suggesting competition for uptake in the presence of food components that share common transporters and/or decreased contact of PFOA with the intestinal epithelium in the presence of dietary materials.

Distribution during Pregnancy and Lactation

Humans. T. Zhang et al. (2013) recruited pregnant females for a study to examine the distribution of PFOA between maternal blood, cord blood, the placenta, and amniotic fluid. Thirty-two females from Tianjin, China, volunteered to take part in the study. Samples were collected at time of delivery. Maternal ages ranged from 21 to 39 years, gestation periods ranged from 35 to 37 weeks. It was the first child for 26 of the females and a second child for 6. The study yielded 31 maternal whole blood samples, 30 cord blood samples, 29 amniotic fluid samples, and 29 placentas. The maternal blood contained variable levels of 10 PFASs, eight acids, and two sulfonates. The mean maternal blood concentration was highest for PFOS

(14.6 ng/mL) followed by PFOA (3.35 ng/mL). In both cases, the mean was greater than the median, indicating a distribution skewed toward the higher concentrations.

PFOA was found in all fluids/tissues sampled. PFOA was transferred to the amniotic fluid to a greater extent than PFOS, based on their relative proportions in the maternal blood and cord blood. Compared to the mean PFOA blood levels in the pregnant females, the mean levels in the cord blood, placenta, and amniotic fluid were 47%, 59%, and 1.3%, respectively, of those in the mother's blood. The correlation coefficients between the maternal PFOA blood levels and placenta, cord blood, and amniotic fluid levels were good (0.7–0.9) and the relationships statistically significant ($p<0.001$).

Rat. An oral two-generation reproductive toxicity study of PFOA in rats was conducted (Butenhoff et al. 2004a). Five groups of rats (30 gender/group) were administered PFOA by gavage at doses of 0, 1, 3, 10, and 30 mg/kg/day. At scheduled sacrifice, after completion of the cohabitation period in F0 male rats and on lactation day (LD) 22 in F0 female rats, blood samples (3/gender/group-control; 10/gender/group-treated) were collected from animals dosed with 0, 10, and 30 mg/kg for analysis of PFOA. Serum analysis for the F0 generation males in the control, 10-, and 30-mg/kg/day groups sampled at the end of cohabitation showed that PFOA was present in all samples tested, including controls. Control males had an average concentration of 0.0344 ± 0.0148 μg/ml PFOA. Levels of PFOA were similar in the two male dose groups; treated males had 51.1 ± 9.30 and 45.3 ± 12.6 μg/ml, respectively, for the 10- and 30-mg/kg/day dose groups. In the F0 female controls, serum PFOA was below LOQ (0.00528 μg/ml). Levels of PFOA found in female sera increased between the two dose groups; treated females had an average concentration of 0.37 ± 0.0805 and 1.02 ± 0.425 μg/ml, respectively, for the 10- and 30-mg/kg/day dose groups.

PFOA levels during gestation and lactation were studied by Hinderliter et al. (2005) and Mylchreest (2003). Groups of 20 pregnant Sprague-Dawley rats were dosed with 0, 3, 10, and 30 mg/kg/day of PFOA during days 4–10, 4–15, and 4–21 of gestation, or from gestation day (GD) 4 to LD 21. Maternal blood samples were collected at 2 hours ± 30 minutes (mins) post-dose on a daily basis. Clinical observations and body weights were recorded daily. Five animals per dose group were sacrificed at specific time periods to harvest the conceptus and/or placenta and amniotic fluid. On GD 10, only embryos were recovered, and on GDs 15 and 21, the placentas, amniotic fluid, and embryos/fetuses were collected.

The remaining five rats per group were allowed to deliver their pups. On LDs 0, 3, 7, 14, and 21, the pups were counted, weighed (genders separate), and examined for abnormal appearance and behavior. Randomly selected pups were sacrificed and blood samples were collected. On LDs 3, 7, 14, and 21, the dams were anesthetized and milk and blood samples were collected; dams were removed from their litters 1–2 hours prior to collection.

Plasma, milk, amniotic fluid extract, and tissue homogenate (placenta, embryo, and fetus) supernatants were analyzed for PFOA concentrations by HPLC/MS. Maternal PFOA plasma levels during gestation and lactation are presented in Table 2-11. Maternal plasma levels at 2 hours post-dosing (approximately the time of peak blood levels following a gavage dose) were fairly similar during the course of the study with a mean level of 11.2, 26.8, and 66.6 μg/ml in the 3-, 10-, and 30-mg/kg/day groups, respectively; PFOA levels in the control group were below the LOQ (0.05 μg/ml).

Table 2-11. Maternal Plasma PFOA Levels (µg/ml) in Rats During Gestation and Lactation

Exposure Period	Sample Time	Dose		
		3 mg/kg/day	10 mg/kg/day	30 mg/kg/day
GD 4 - GD 10	GD 10 plasma	8.53 ± 1.06	23.32 ± 2.15	70.49 ± 8.94

Notes: Mean ± SD; samples were from five dams/group/time point and were collected 2 hours post-dosing.

PFOA levels in the placenta, amniotic fluid, and embryo/fetus are presented in Table 2-12. The levels of PFOA in the placenta on GD 21 were approximately twice the levels observed on GD 15, and the levels of PFOA in the amniotic fluid were approximately four times higher on GD 21 than on GD 15. The concentration of PFOA in the embryo/fetus was highest in the GD 10 embryo and lowest in the GD 15 embryo; PFOA levels in the GD 21 fetus were intermediate.

Table 2-12. Placenta, Amniotic Fluid, and Embryo/Fetus PFOA Concentrations in Rats (µg/ml)

Exposure Period	Tissue	Dose		
		3 mg/kg/day	10 mg/kg/day	30 mg/kg/day
GD 4–GD 10	GD 10—embryo	1.40 ± 0.30	3.33 ± 0.81	12.49 ± 3.50

Note: Mean ± SD; samples were pooled by litter and were collected 2 hours post-dosing.

The concentrations of PFOA in the plasma of the GD 21 fetus were approximately half the levels observed in the maternal plasma (Table 2-11). The values were about twice as high in the dams as in the pups with mean values of 14.04, 34.20, and 76.36 µg/ml, respectively, in the 3-, 10-, and 30-mg/kg/day groups for the dams and 5.88, 14.48, and 33.11 µg/ml, respectively, for the pups. Pup plasma levels decreased between birth and LD 7 (Table 2-13) and were, thereafter, similar to the levels observed in the milk (Table 2-14). The pups were not separated by gender.

The concentration of PFOA in the milk also was fairly similar throughout lactation and was approximately one-tenth of the PFOA levels in the maternal plasma (see Table 2-11); the mean values for maternal milk were 1.1, 2.8, and 6.2 µg/ml in the 3-, 10-, and 30-mg/kg/day groups, respectively (Table 2-14).

Table 2-13. Fetus/Pup PFOA Concentration (µg/ml) in Rats During Gestation and Lactation

Exposure Period	Tissue	Dose		
		3 mg/kg/day	10 mg/kg/day	30 mg/kg/day

Source: Hinderliter et al. 2005; Mylchreest 2003
Notes: Mean ± SD; samples were from 5 dams/group/time point and were collected 2 hours post-dosing.

Mouse. Fenton et al. (2009) orally dosed pregnant CD-1 mice (n = 25/group) with 0, 0.1, 1, and 5 mg PFOA/kg on GD 17. On GD 18, five dams/group were sacrificed and trunk blood, urine, amniotic fluid, and the fourth and fifth mammary glands were collected. One fetus/dam was euthanized and retained for whole-pup analysis. The remaining dams were allowed to litter. Biological samples as described above excluding amniotic fluid also were collected on postnatal days (PNDs) 1, 4, 8, and 18. As before, at each time-point, a single pup was euthanized and retained for whole-pup analysis. Blood from the remaining pups was collected and pooled. Milk was collected from dams on PNDs 2, 8, 11, and 18 following a 2-hour separation of the pups from the dam.

The concentration of PFOA in dam serum was approximately twice that detected in amniotic fluid (Table 2-15). Compared to the amniotic fluid, the concentration of PFOA in the fetuses was increased by 2.3-, 3.1-, and 2.7-fold at 0.1, 1, and 5 mg/kg, respectively. The highest concentration of PFOA was detected in the serum of nursing dams. In the dams, the concentration of PFOA in the serum exhibited a U-shaped response curve; the lowest serum concentration was observed at the time of peak lactation. Dam mammary tissue and milk PFOA concentrations showed a U-shaped response that mirrored that found in the dam's serum. The concentration of PFOA in pup's serum was significantly higher than PFOA concentration in dam's serum and appeared to decrease as the time for weaning approached. When pup PFOA concentration was calculated with consideration for pup body weight gain, PFOA body burden increased through the peak of lactation and began to decrease by PND 18, showing an inverse U-shaped response curve.

Source: Fenton et al. 2009

Pregnant C57BL/6/Bkl mice were fed diets containing 0.3 mg PFOA/kg/day from GD 1 through the end of pregnancy. At birth, the PFOA concentrations in the offspring were 0.7 ± 0.1 μg/g in the brain and 16.3 ± 4.1 μg/g in the liver (Onishchenko et al. 2011).

Macon et al. (2011) gavage-dosed CD-1 mice with 0, 0.3, 1.0, or 3.0 mg PFOA/kg from GD 1 to GD 17 or with 0, 0.01, 0.1, and 1.0 mg PFOA/kg from GD 10 to GD 17. In the full gestation experiment (GD 1–17), offspring were sacrificed on PNDs 7, 14, 21, 28, 42, 63, and 84, and in the half gestation experiment (GDs 10–17), female offspring were sacrificed on PNDs 1, 4, 7, 14, and 21. Serum, liver, and brain from the offspring were analyzed for PFOA by HPLC/MS/MS.

At the lowest dose, PFOA concentration in the serum peaked at or before PND 7, but the two higher doses peaked around PND 14 (Table 2-16). Calculated blood burdens which take into account the increasing blood volumes and body weights for females showed an inverted U-shaped curve peaking at PND 14 for all doses. In the liver, PFOA concentration decreased over time with the highest concentration observed at PND 7. Lower concentrations of PFOA were detected in the brain of the offspring on PND 7 and 14.

Table 2-16. Female Offspring PFOA Levels (ng/ml) in Mice After GD 1-17 Exposure

Tissue	Day	Dose		
		0.3 mg/kg	**1.0 mg/kg**	**3.0 mg/kg**

LOQ: serum full gestation = 10-20 ng/g; liver = 35 ng/g; brain = 35 ng/g; late gestation serum = 5 ng/mL

After an exposure to low doses of PFOA from GD 10 to GD 17, serum PFOA concentration in the female offspring declined from PND 1 through the end of the experiment (Table 2-17). Calculated blood burden showed a gradual increase from PND 1 to PND 14, followed by a decline through PND 21.

Table 2-17. Female Offspring Serum PFOA Levels (ng/ml) in Mice After GD 10-17 Exposure

White et al. (2011) measured serum PFOA concentrations in three generation of CD-1 mice (Table 2-18). Pregnant mice (F0, n = 10–12 dams/group) were gavage-dosed with 0, 1, and 5 mg PFOA/kg from GD 1–17. A separate group of pregnant mice (n = 7–10 dams/group) were gavage-dosed with either 0 or 1 mg PFOA/kg from GD 1–17 and received drinking water containing 5 parts per billion (ppb) PFOA beginning on GD 7 and continuing until the end of the study for their offspring, except during breeding and early gestation, to simulate a chronic low-dose exposure. An increase in serum PFOA concentration was observed in the control + 5 ppb PFOA groups in the F1 and F2 generations and in the 1-mg/kg + 5-ppb PFOA group of the F2 generation. A decrease was observed for the remaining groups.

Table 2-18. Serum PFOA Levels (ng/ml) in Mice Over Three Generations

	Generation/ Day	Dose			
		0 mg/kg + 5 ppb	1 mg/kg	1 mg/kg + 5 ppb	5 mg/kg

Subcellular Distribution. Han et al. (2005) examined the subcellular distribution of PFOA in the liver and kidney of male and female rats. Male and female Sprague-Dawley Crl:CD (SD)IGS BR rats were gavage-dosed with 25 mg/kg [^{14}C] PFOA and sacrificed 2 hours after dosing. Blood was collected and the liver and kidneys were removed. Five subcellular fractions (nuclei

and cell debris, lysosome and mitochondria, microsome, light microsome and ribosome, and membrane-free cytosol) were obtained by differential centrifugation. The radioactivity per gram (g) of each fraction and the total radioactivity were measured.

In the male liver, the highest proportion of total reactive residues (TRR) of PFOA was located in the nuclei and cell debris (40%). The TRR for the other subcellular fractions were as follows: membrane-free cytosol 26 percent% TRR, lysosome and mitochondria ~14% TRR, and microsome ~16% TRR. The level of PFOA in the light microsome and ribosome was ~1% TRR. In the female liver, the highest proportion of PFOA was found in the membrane-free cytosol, 48% TRR. The TRR were nuclei and cell debris ~31% TRR, lysosome and mitochondria ~12% TRR, and microsome ~8% TRR. As observed in the males, the level of PFOA in the light microsome and ribosome was ~1% TRR (Han et al. 2005).

In the male kidney, the level of PFOA was 79% TRR in the membrane-free cytosol, 15% TRR in the nuclei and cell debris, and 4% TRR in the lysosome and mitochondria/microsome/ light microsome and ribosome (combined). In the female kidney, the level of PFOA was 71% TRR in the cytosol, 21% TRR in the nuclei and cell debris, and 8% TRR in the lysosome and mitochondria/ microsome/light microsome and ribosome (combined). Further examination showed that in both genders, 98% of PFOA in the plasma was protein bound. The protein-bound fraction of PFOA in the liver cytosol was 56% TRR. In the kidney, the protein-bound fraction of PFOA in males was 42% TRR and 17% TRR in females (Han et al. 2005).

Based on the results, the authors concluded that subcellular distribution of PFOA in the rat liver was gender-dependent because the proportion of PFOA in the liver cytosol of female rats was almost twice that of the male rats. They hypothesized that the female might have a greater amount than the male of an unknown liver cytosolic binding protein with an affinity for perfluorinated acids. They also hypothesized that the unknown protein or protein complex might normally aid in transport of fatty acids from the liver. In the kidney, the subcellular distribution did not show the gender difference seen with the liver; however, the protein-bound fraction for the males (42%) was about twice that for the females (17%) (Han et al. 2005).

Inhalation Exposure

In a repeated exposure study, Hinderliter (2003) and Hinderliter et al. (2006b) exposed 6–8-week-old male and female rats (5 per gender per group) to 0-, 1-, 10-, and 25-mg/m^3 aerosol concentrations of PFOA for 6 hours/day, 5 days/week for 3 weeks. Blood was collected immediately before and after the daily exposure period 3 days/week. The aerosols had MMADs of 1.3–1.9 μm with GSDs of 1.5–2.1. PFOA plasma concentrations were proportional to the inhalation exposure concentrations, and repeated exposures produced little plasma carryover in females, but significant day-to-day carryover in males. Male rats reached steady-state plasma levels of 8, 21, and 36 μg/ml for the 1-, 10-, and 25-mg/m^3 groups, respectively, by 3 weeks. In females, the post-exposure plasma levels were 1, 2, and 4 μg/ml for the 1-, 10-, and 25-mg/m^3 groups, respectively. When measured immediately before the next daily exposure, plasma levels had returned to baseline in females, demonstrating CL within 24 hours of each daily dose.

Dermal Exposure

No data were identified on tissue distribution following dermal exposures.

2.3 Metabolism

Several studies have examined metabolism of PFOA. However, no studies show clear evidence of metabolism. Ophaug and Singer (1980) found no change in fluoride ion level in the serum or urine following oral administration of PFOA to female Holtzman rats. Ylinen et al. (1989) found no evidence of phase II metabolism of PFOA following a single intraperitoneal PFOA dose (50 mg/kg) in male and female Wistar rats. The free anionic and possible conjugated forms of PFOA in the urine were separated using BondElut tubes. The tubes contain NH_2, which is a weaker anion exchange sorbent and a good choice for retaining strong anions. The samples were aspirated through the tube, washed with water, and eluted with sodium bicarbonate/carbonate-buffer. The aspirate and eluate from the separation method were analyzed by gas chromatography. PFOA was not detected in the aspirate, but was retained with the cationic amino phase found in the eluate. This also occurred in control blanks spiked with PFOA. The authors concluded that because the PFOA anion was completely bound to the weak cationic amino phase in both the spiked controls and urine samples, PFOA in urine is not altered by phase II metabolism (Ylinen et al. 1989).

2.4 Excretion

Excretion data are available for oral exposure in humans and laboratory animals. Several studies have investigated the elimination of PFOA in humans, cynomolgus monkeys, and rats. In human females, elimination pathways include pregnancy (cord blood) and lactation (breast milk) (Apelberg et al. 2007; Tao et al. 2008; Thomsen et al. 2010; Völkel et al. 2008; von Ehrenstein et al. 2009).

Elimination half-lives differ among species. There are also significant gender differences in humans and some laboratory animal species. Information from humans does not, at this time, provide sufficient data to determine the magnitude of interindividual and gender differences in excretory half-lives. The transporters appear to play an important role in renal excretion of PFOA and possibly its biliary elimination as well.

Humans. The urinary excretion of PFOA in humans is impacted by the isomeric composition of the mixture present in blood and the gender/age of the individuals. The half-lives of the branched-chain PFOA isomers are shorter than those for the linear molecule, an indication that renal resorption is less likely with the branched chains.

Y. Zhang et al. (2013) determined half-lives for PFOA isomers based on paired serum samples and early morning urine samples collected from healthy volunteers in two large Chinese cities. Half-lives were determined using a one compartment model and an assumption of first order CL. The V_d applied in the analysis as determined by Thompson et al. (2010) was 170 mL/kg. CL was estimated from the concentration in urine normalized for creatinine and assuming excretion of 1.2 and 1.4 L/day of urine and 0.9 and 1.1 mg creatinine/day for males and females, respectively. The mean half-life for the sum of all PFOA isomers in younger females (n = 12) was 2.1 years (range 0.19–5.2 years) while that for all males and older females (n = 31) was 2.6 (range 0.0059–14 years); the medians were 1.8 and 1.7 years, respectively. The mean values for the four branched-chain isomers of PFOA were lower than the value for the linear chain, suggesting that resorption transporters might favor uptake of the linear chain over the branched-chain isomers. Older females and males have longer half-lives than young females, suggesting the importance of monthly menstruation as a pathway for excretion (Y. Zhang et al. 2013).

T. Zhang et al. (2014) derived estimates for PFOA's urinary excretion rate using paired urine and blood samples from 54 adults (29 males and 25 females) in the general population and 27 pregnant females in Tainjin, China. The age range for the general population was 22–62 years and for the pregnant females was 21–39 years. Urinary excretion was calculated based on the concentration in the urine times volume of urine wherein a urinary volume of 1,200 mL/day was applied to all females and 1,600 mL/day for all males. Urine samples were first-draw morning samples. Total daily intakes for PFOA were calculated from the concentration in blood using first order assumptions, a half-life of 2.3 years (Bartell et al. 2010) and a V_d of 170 mL/kg (Lorber and Egeghy 2011; Thompson et al. 2010). PFOA was detected in the blood samples for all participants but for only 76% of the urine samples from the general population and 30% for the pregnant females. There was a direct correlation between the PFOA concentrations in blood and creatinine adjusted urine ($r = 0.348$ $p = 0.013$) for the general population but not for the pregnant females. When limited to the eight females who had detectable levels in both blood and urine, there was a significant correlation ($r= 0.724$, $p = 0.042$).

Among the general population, the daily urinary excretion rate accounted for 25% of the estimated intake with the excretion higher in males (31%) than in females (19%). The urine: blood ratio was lower for pregnant females than for nonpregnant females (0.0011 versus 0.0029), suggesting other removal pathways such as placenta and cord blood. There was little difference between the younger menstruating females (21–50 years versus 51–61 years), but there is no indication that data were collected from the participants relative to menstruation status on the day of blood and urine collection.

Wong et al. (2014) looked at the role of menstrual blood as an excretory pathway to explain the shorter half-life of PFOS in females than in males. They fit a population-based PK model to six cross-sectional NHANES data sets (1999–2012) for males and females. They concluded that menstruation could account for about 30% of the PFOS elimination half-life difference between females and males. Although Wong et al. (2014) studied PFOS and not PFOA, their findings are relevant to both chemicals.

Elimination of PFOA by way of the gastrointestinal tract was reported in a case history of a single human male with high serum levels of perfluorinated chemicals that appeared to originate from household dust following the installation of new carpeting (Genuis et al. 2010). Treatment with cholestyramine, a bile acid sequestrant for 20 weeks (4g/day, three times a day), lowered his serum PFOA concentration from 5.9 ng/g serum to 4.1 ng/g serum. More dramatic decreases were observed with serum PFOS (23–14.4 ng/g serum) and PFHxS (58–46.8 ng/g serum), which were present at higher levels in the serum. This observation suggests that excretion with bile and possible enterohepatic resorption via intestinal transporters limits the loss of absorbed PFOA via feces in the absence of a binding agent such as cholestyramine.

2.5 Animal Studies

Oral Exposure

Monkey. Butenhoff et al. (2004b) studied the fate of PFOA in cynomolgus monkeys in a 6-month oral exposure study. Groups of four to six male monkeys each were administered PFOA daily via oral capsule at DRs of 0, 3, 10, and 30/20 mg/kg for 6 months. Two monkeys exposed to 10 mg/kg and three monkeys exposed to 20 mg/kg were monitored for 21 weeks (recovery period) following dosing. Urine and fecal samples were collected at 2-week intervals and were analyzed for PFOA concentrations.

Urine PFOA concentrations over the duration of the study were 53 ± 25, 166 ± 83, and 181 ± 100 μg/ml in the 3-, 10-, and 30-/20-mg/kg dose groups, respectively, and reached steady-state after 4 weeks. Within two weeks of recovery, urine PFOA concentrations were <1% of the value measured during treatment and decreased slowly thereafter. Fecal PFOA concentrations were 6.8 ± 5.3, 28 ± 20, and 50 ± 33 μg/g in the 3-, 10-, and 20-mg/kg dose groups, respectively. Within two weeks of recovery, fecal PFOA concentrations dropped to less than 10% of the last value during treatment, and then declined slowly. These results are consistent with both renal and biliary excretion in male monkeys.

Rat. There have been a number of studies of excretion in rats because of the gender differences noted in serum levels. Hinderliter (2004) and Hinderliter et al. (2006a) investigated the relationship between age and urine PFOA concentrations in male and female Sprague-Dawley rats. Immature rats 3, 4, or 5 weeks of age were administered PFOA via oral gavage as a single dose of 10 or 30 mg/kg. Two hours after dosing, five rats per gender per age group and dose group were sacrificed and blood samples were collected (see section 2.2.1). The remaining five rats per gender per age and dose group were placed in metabolism cages for 24-hour urine collection. Urinary output (volume) was not quantified or standardized for creatinine levels.

Urine PFOA concentrations differed significantly with age, dose, and gender ($p<0.01$, Table 2-19). Urinary excretion of PFOA was substantially higher in females than in males, and the female urine PFOA concentrations increased with age. In male rats, 24-hour urine PFOA concentrations decreased with age up to five weeks. In both genders, urine PFOA was higher (2.5 to 6.5 times) at the 30-mg/kg dose as compared to the 10-mg/kg dose.

There was a difference in urinary excretion between the 3-week-old and 4/5-week-old male rats, with the older rats excreting ~50% less PFOA in the urine than the younger rats at 10 mg/kg and 30 mg/kg. If the data from urine are integrated with the plasma data in the same study (Table 2-9), the male plasma levels increased from the 3-week value and were relatively stable for weeks 4 and 5. In the females, urine excretion increased gradually with age (Table 2-19) and plasma concentrations decreased (Table 2-10).

Table 2-19. Urine PFOA Concentrations in Male and Female Rats

Age (weeks)	Dose (mg/kg)	Urine PFOA (μg/ml at 24 hours post-dose)			
		Male		Female	
		Mean	SD	Mean	SD
3	10	9.57	4.86	21.17	8.95
4	10	4.53	2.45	23.26	15.27
5	10	4.03	2.36	49.77	24.64
3	30	51.76	28.86	94.89	26.26
4	30	28.70	18.84	104.12	28.97
5	30	15.65	6.24	123.16	51.56

Source: Hinderliter 2004

Hundley et al. (2006) examined excretion of PFOA in one male and one female CD rat (sexually mature). Each was given a single dose of 10 mg/kg ^{14}C-PFOA and housed in a metabolism cage. Urine and feces were collected at 12, 24, 48, 72, 96, and 120 hours post-dose. The female rat excreted more PFOA over the 120-hour collection period than the male rat. In the male rat, 25.6% and 9.2% ^{14}C-PFOA were excreted in the urine and feces, respectively. In the female rat, 73.9% and 27.8% ^{14}C-PFOA were excreted in the urine and feces, respectively. The

female rat excreted almost all of the PFOA by 48 hours compared with only 19% of the dose excreted by the male rat over the same amount of time. The cumulative percent of the dose excreted is shown in Table 2-20.

Table 2-20. Cumulative Percent ^{14}C-PFOA Excreted in Urine and Feces by Rats

Rat	Hours After Dosing					
	12	24	48	72	96	120
Male	0.6	8.7	19.2	23.4	30.2	34.3
Female	52.5	96.4	99.8	100.0	100.0	100.0

Source: Hundley et al. 2006

Adult male Sprague-Dawley rats (n = 7) were given a single gavage dose of 0.5 mg PFOA/kg and monitored for 38 days (Benskin et al 2009). Over the course of the study, the rats were held in metabolic cages and urine and feces were collected. The mean blood PFOA concentration was 1.1 µg/mL 24 hours post-dose. During the first 24 hours post-dose, 65% of PFOA was excreted in the urine; most of the PFOA that was not absorbed was excreted in the feces. After that time period, 91–95% of the daily excreted PFOA was eliminated in the urine. On day 3, the mean PFOA concentration in urine and feces were 265 ng/g and 28 ng/g. The half-life for elimination from plasma in male rats was 13.4 days.

Cui et al. (2010) exposed 2-month-old male Sprague-Dawley rats (10 per group) to PFOA (96% active ingredient) at 0, 5, and 20 mg/kg/day once daily by gavage for 28 days. Urine and fecal samples were collected through use of metabolism cages at 24-hour intervals immediately following dosing on days 1, 2, 5, 7, 10, 14, 18, 21, 24, and 28 of the study. Daily urine volume and fecal weight were comparable across all groups throughout the study. As measured by excretion 24-hours after the first dose, 17.9% of the applied dose was excreted in the urine of the low-dose group and 22% for the high-dose group. The percent of the absorbed dose was 92.8% and 92.3% for the low and high doses, respectively, when the fecal excretion over the 24 hours following dosing was estimated to be unabsorbed material. During week 1, a sharp increase in urinary and fecal excretion expressed as percent of dose/day was observed in rats of both groups. The excretion rate leveled off at about 50% for the low-dose animals for the remainder of the 28 days. In the case of the high-dose animals, the urinary excretion remained level at about 80% for the second and third weeks and then increased sharply to about 140% at 28 days. The fecal excretion rates were 7.2% and 7.7% for rats in the 5- and 20-mg/kg groups, respectively, during the first 24 hours post-dosing and continued an upward trend throughout the 28 days with the terminal percent/day about 25% for the low-dose group and 40% for the high-dose group.

Dose is an important variable that impacts excretion. Rigden et al. (2015) exposed groups of five male Sprague-Dawley rats to doses of 0, 10, 33, and 100 mg/kg/day for 3 days and maintained them for 3 additional days; overnight urine was collected and body weight was measured daily. Of greatest interest relative to the limitations on renal resorption, is the dose-related increase in urine PFOA concentration and urine PFOA concentration per mg creatinine for the 33- and 100-mg/kg/day groups compared to the 10-mg/kg/day group. The peak in PFOA excretion normalized to creatinine occurred on day 3 after the cessation of dosing. The concentration at 33 mg/kg/day was 500 times greater than that at 10 mg/kg/day. At the 100-mg/kg/day dose, the peak concentration was about 3,200 times greater than for the low dose. The low-dose excretion was only slightly greater than the controls. The urine results support the renal resorption hypothesis concept and suggest that there is a threshold limit on resorption that,

once exceeded, dramatically increases PFOA loss in urine. As a consequence, half-life for continuous low-dose exposures will be longer than for single or short-term high-dose exposures.

Other Species. Hundley et al. (2006) examined excretion of PFOA in CD mice, BIO-15.16 hamsters, and New Zealand White rabbits. One male and one female of each species was given a single dose of 10-mg/kg ^{14}C-PFOA and housed in metabolism cages. Urine and feces were collected at 12, 24, 48, 72, 96, and 120 hours post-dose. Additional samples were collected from rabbits at 144 and 168 hours post-dose.

Over 120 hours, the male mouse excreted 3.4% ^{14}C-PFOA in urine and 8.3% ^{14}C-PFOA in feces, and the female mouse excreted 6.7% ^{14}C-PFOA in urine and 5.7% ^{14}C-PFOA in feces. The mice were similar in the amounts excreted. The male hamster excreted 90.3% and 8.2% ^{14}C-PFOA in urine and feces, respectively, and the female hamster excreted 45.3% and 9.3%^{14}C-PFOA. The male hamster excreted a greater amount of ^{14}C-PFOA than the female hamster. Over 84% of ^{14}C-PFOA was excreted 24 hours after dosing by the male hamster compared to less than 25% of ^{14}C-PFOA excreted by the female hamster at 24 hours after dosing. Over 168 hours, the male rabbit excreted 76.8% and 4.2% ^{14}C-PFOA in urine and feces, respectively, and the female rabbit excreted 87.9% and 4.6% ^{14}C-PFOA. Both rabbits excreted most of the dose by 24 hours. The cumulative percentage of ^{14}C-PFOA excreted is shown in Table 2-21.

Table 2-21. Cumulative Percent ^{14}C-PFOA Excreted in Urine and Feces

		Hours After Dosing						
Species	**Gender**	**12**	**24**	**48**	**72**	**96**	**120**	**168**
Mouse	Male	0.4	4.1	6.7	8.6	9.1	10.8	-
	Female	0.2	4.1	6.5	8.4	9.0	11.0	-
Hamster	Male	67.3	84.5	96.1	97.4	98.2	98.4	-
	Female	11.3	24.6	36.4	43.9	50.1	54.0	-

	Female	86.7	90.5	92.0	92.2	92.7	92.9	93.0

Source: Hundley et al. 2006

When the data in Table 2-21 are integrated with the data from rats, the gender differences in PFOA excretion rate appear to be species-specific. Female rats, male hamsters, and both genders of rabbits appear to be good excreters based on their response to a radiolabeled dose of 10 mg/kg. Most of the dosed material is excreted within 24 hours after dosing. Female hamsters apparently are moderate excreters. Males and female mice excreted only about 10% of the dose over the 120 hours (5 days) after dosing. Mice do not show a gender difference but retain more of the dose than do hamsters, rabbits, and female rats. The long half-lives in humans suggest that their excretion rates are more like mice or male rats.

Inhalation Exposure

Although no data were identified on urine or fecal excretion of PFOA following inhalation exposures, the Hinderliter study (2003) provides evidence of CL following single and repeated inhalation exposures in Sprague-Dawley rats. Plasma PFOA concentrations following a single exposure to 1, 10, and 25 mg/m^3 PFOA declined 1 hour after exposure in females and 6 hours after exposure in males. In females, the elimination of PFOA was rapid at all exposure levels and, by 12 hours after exposure, their plasma levels had dropped below the analytical LOQ (0.1 µg/ml). In males, the plasma elimination was much slower and, at 24 hours after exposure, the plasma concentrations were approximately 90% of the peak concentrations at all exposure

levels. In the repeated exposure study, male and female rats were exposed to the same concentrations for 6 hours/day, 5 days/week for 3 weeks. Steady-state plasma levels were reached in males by 3 weeks, but plasma PFOA levels in females returned to baseline with 24 hours of each dose. The data are illustrative of distinct toxicokinetic differences between male and female rats in their response to PFOA exposure (Hinderliter 2003).

Dermal Exposure

No data were identified on excretion following dermal exposures. Minimal fecal excretion is anticipated for the dermal route of exposure although the biliary pathway can be a route for excretion of material absorbed through the skin, distributed to the liver, and discharged to the gastrointestinal tract.

2.5.1 Mechanistic Studies of Renal Excretion

Several studies have been conducted to elucidate the cause of the gender difference in the elimination of PFOA by rats. Many of the studies have focused on the role of transporters in the kidney tubules. Most studies have examined the OATs located in the proximal portion of the descending tubule. OATs are found in other tissues as well and were discussed earlier for their role in absorption and distribution. In the kidney, they are responsible for delivery of organic anions, including a large number of medications from the serum into the kidney tubule for excretion as well as reabsorption of anions from the glomerular filtrate. The transporters are particularly important in excretion of PFOA because it binds to surfaces of serum proteins (particularly albumin), which makes much of it unavailable for removal during glomerular filtration. Other transporter families believed to be involved in renal excretion are the OATPs and the MRPs. However, they have not been evaluated as extensively as the OATs for their role in renal excretion.

OATs are located on both the basolateral (serum interface) and apical surfaces of the brush boarder of the proximal tubule inner surface. At the basolateral surface, the OATs transport the perfluorooctanoate anion from the serum to the tubular cells (Anzai et al. 2006; Cheng and Klaassen 2008; Klaassen and Aleksunes 2010; Klaassen and Lu 2008; Nakagawa et al. 2007, 2009). OAT1, 2, and 3 are located on the basolateral membrane surface. OAT4 and OAT5 are located on the apical surface of the tubular cells, where they reabsorb the PFOA anions from the glomerular filtrate. Figure 2-2 diagrams the flow of organic anions such as the PFOA anion from serum to the glomerular filtrate for excretion and resorption of organic acids from the glomerular filtrate with transport back to serum. OATs can function for uptake into the cell across both the basolateral and apical surfaces.

Several MRP transporters also appear to function in the kidney and move organic anions in and out of cells at both the basolateral surface (e.g., MRP2/4) and the apical surface (e.g., MRP1) as well as one or more OATPs on each surface (Cheng and Klaassen 2009; Klaassen and Aleksunes 2010; Klaassen and Lu 2008; Kusuhara and Sugiyama 2009; Launay-Vacher et al. 2006; Yang et al. 2009). Bidirectional movement of PFOA across both the basolateral and apical surfaces is driven by concentration gradients and/or active transport. Far more data exist on PFOA and OATs in the kidneys than on OATPs and MRPs. Abbreviations for individual transporters on the basolateral and apical surfaces differ across publications. The accepted convention is to use uppercase letters to refer to human transporters and lowercase letters to refer to animal transporters. For this report, the data are not reported by species but by transporter family and the uppercase letters are used.

Figure 2-2. Localization of Transport Proteins

Knowledge about specific OAT, OATP, and MRP transporters in the kidneys is rapidly evolving. A low membrane density or blockage of basolateral OATs will decrease PFOA excretion while low membrane densities or blockage of apical OATs will increase excretion because they decrease resorption of anions from the glomerular filtrate.

The earliest studies of the impact of gender on urinary excretion were conducted by Hanhijarvi et al. (1982) using probenecid, an inhibitor of renal excretion of organic acids on PFOA excretion in male and female Holtzman rats. The female rats that had not received the probenecid excreted 76% of the administered dose of PFOA over a 7-hour period, while males excreted only 7.8% of the administered dose over the same period of time. Probenecid administration modified the cumulative excretion curve for males only slightly. In females, however, probenecid markedly reduced PFOA elimination to 11.8%. The authors concluded that the female rat possesses an active secretory mechanism that rapidly eliminates PFOA from the body that male rats do not possess.

Kudo et al. (2002) examined the role of sex hormones and OATs on the renal clearance (CL_R) of PFOA. Renal mRNA levels of specific OATs in castrated male and ovariectomized (OVX) female Wistar rats also were determined. Castration of male rats caused a 14-fold increase in CL_R of PFOA. The elevated PFOA CL_R in castrated males was reduced by treating them with testosterone. Treatment of male rats with estradiol increased the CL_R of PFOA. In female rats, ovariectomy caused a significant increase in CL_R of PFOA (a twofold increase), but the administration of estradiol to OVX female rats returned CL_R of PFOA to normal values. Treatments of female rats with testosterone reduced the CL_R of PFOA.

Treatment with probenecid, a known inhibitor of OAT1–6 and OAT8, markedly reduced the CL_R of PFOA in male rats, castrated male rats, and female rats (Kudo et al. 2002). Accordingly, the male sex hormones appear to decrease the presence of OATs in the renal basolateral membranes while the female sex hormones appear to increase the transporters.

To identify the transporter molecules responsible for PFOA transport in the rat kidney, renal mRNA levels of specific OATs were determined in male and female rats under various hormonal states and compared with the CL_R of PFOA. The level of OAT2 mRNA in male rats was only 13% of the level in female rats. Castration or estradiol treatment increased the level of OAT2 mRNA whereas treatment of castrated male rats with testosterone reduced it. Ovariectomy of female rats significantly increased the level of OAT3 mRNA. Multiple regression analysis of the data suggested that OAT2 and OAT3 are responsible for urinary elimination of PFOA in the rat; however, the possibility of a resorption process mediated by OATP1 was mentioned as a possible factor in male rat retention of PFOA. OAT2 and OAT3 are located on the basolateral cell surface. OATP1 is located on the apical surface of the renal tubule cells (Kudo et al. 2002).

Cheng et al. (2006) examined whether sex hormones influenced gender-specific OATP expression in the kidneys of adult male and female C57BL/6 mice. Gonadectomized mice were used for the studies in conjunction with hormone replacement measures (5α-dihydroxy-testosterone [DHT] or 17-β estradiol [E2]). OATP1a1 and OATP3a1 were evaluated. Treatment with DHT resulted in significant increase in both OATPs in the kidneys of male and female gonadectomized mice. In both cases, the change in males was greater than the change in females. Treatment with E2 almost abolished the expression of OATP1a1 in the kidneys but caused no significant change in OATP3a1. In the intact control animals, almost no expression of OATP1a1 occurred in the kidneys of females and a significantly lower expression of OATP3a1 ($p<0.05$) occurred. In the gonadectomized control animals, little or no expression of OATP1a1 occurred in either gender, and expression of OATP3a1 was equivalent in both genders.

Nakagawa et al. (2007) investigated the role of OATs in the renal excretion of PFOA using *in vitro* methods. HEK293-transformed cells, derived from human embryonic kidney (HEK), were transfected with human or rat OAT1, OAT2, or OAT3 constructs. Cells from the S2 segment of the proximal tubule were transfected with human or rat OAT2 constructs. HEK293 and S2 cells transfected with the vector served only as control cells. The transfected HEK293 cells were incubated for 1 min with or without 0, 10, and 100 µmol [^{14}C]PFOA and/or varying concentrations of favored OAT substrates to determine inhibitory effects of PFOA as follows: 5 µmol [^{14}C]para-aminohippuric acid (OAT1), 20 nmol [^{14}C]estrone sulfate (OAT3), and 10 nmol [^{14}C]prostaglandin $F_{2\alpha}$ (OAT2).

PFOA significantly inhibited para-aminohippuric acid and estrone sulfate uptake mediated by OAT1 and OAT3, respectively. At 10 µmol PFOA, uptake of 5 µmol [^{14}C] para-aminohippuric acid was 75–85% of the control level and, at 100 µmol PFOA, uptake was reduced to 35–45% of control. Estrone sulfate uptake by human OAT3 was 65% of the control level at 10 µmol PFOA and 40% of control at 100 µmol PFOA. Estrone sulfate uptake by rat OAT3 was 15% of the control level in the presence of 10 µmol PFOA and was almost completely inhibited at 100 µmol PFOA. Prostaglandin $F_{2\alpha}$ uptake by OAT2 was inhibited moderately by PFOA, 75–85% of control at 10 µmol PFOA, and 65% of control at 100 µmol PFOA.

In the second part of their study, Nakagawa et al. (2007) incubated HEK293 and S2 transfected cells with 10 µmol [^{14}C]PFOA for 1 min to determine uptake. Time-dependent uptake of 5 µmol [^{14}C]PFOA from 0 to 30 mins was conducted in the HEK293 cells transfected with human or rat OAT1, OAT2, or OAT3. Experiments were conducted in triplicate. Uptake of PFOA was stimulated ($p<0.001$) in cells transfected with human or rat OAT1 or OAT3, while no uptake was stimulated in cells transfected with OAT2 in either cell line. In the time-dependent experiments, uptake by human or rat OAT1 or OAT3 increased linearly up to 2 mins and reached a plateau in about 15 mins. Kinetic evaluations resulted in substrate concentration at which the

initial reaction rate is half maximal (K_m) values of 48.0, 51.0, 49.1, and 80.2 μmol for human OAT1, rat OAT1, human OAT3, and rat OAT3, respectively. The authors showed that both human and rat OAT1 and OAT3 transport PFOA in the kidney while human and rat OAT2 do not (Nakagawa et al. 2007).

Yang et al. (2009) investigated the role of OAT polypeptide 1a1 (OATP1a1) in the renal elimination of PFOA. The polypeptide is located on the apical side of proximal tubule cells and could be the mechanism for renal reabsorption of PFOA in rats. The level of mRNA of OATP1a1 in male rat kidney is 5–20-fold higher than in female rat kidney, OATP1a1 protein expression is higher in male rat kidneys, and it is regulated by sex hormones. One of its known substrates is estrone-3-sulfate (E3S). A substantial presence of OATP1a1 in male rats would favor resorption of PFOA in the glomerular filtrate and reduce excretion.

Chinese hamster ovary (CHO) cells were transfected with rat OATP1a1 complementary DNA. The transfected CHO cells were incubated with 4 μmol [^{14}C]PFOA for up to 10 mins or with 0–1,000 μmol [^{14}C]PFOA for 2 mins to determine uptake. The difference between the uptake velocities of CHO OATP1a1-transfected cells and CHO vector-transfected cells was defined as active PFOA uptake by the tubular epithelium. The transfected CHO cells were incubated with 5 μmol [^{14}C]PFOA for 2 mins in the absence or presence of inhibitors (e.g., BSP, taurocholate, probenecid, *p*-aminohippurate, and naringin [a flavonoid found in grapefruit]) for inhibition studies. The transfected CHO cells were incubated with 2 μmol E3S and 0, 0.1, or 1 mM perfluorocarboxylates with carbon chain lengths ranging from 4 to 12, including PFOA (C8) for 30 seconds for E3S inhibition studies.

In time-dependent uptake experiments, uptake of PFOA by OATP1a1-transfected cells increased proportionally to time during the first 2 mins of incubation. Vector-transfected cells had a significant level of uptake of PFOA attributed to nonspecific passive diffusion. In the concentration-dependent uptake experiments, uptake velocity of PFOA in OATP1a1-transfected cells increased with increasing concentration and saturation levels were not reached. In vector-transfected cells, uptake velocities increased linearly with increasing concentration of PFOA, demonstrating a passive diffusion mechanism. Active PFOA uptake—the difference between the uptake of the OATP1a1 cells and the vector-transfected cells—could be described by the Michaelis-Menton equation and exhibited saturable kinetics.

Inhibition experiments with substrates of OATs and OATPs showed that BSP, taurocholate, and naringin inhibited PFOA uptake to 10–30% of control and *p*-aminohippurate inhibited PFOA uptake to 62% of control. Probenecid, an OAT inhibitor, did not inhibit PFOA uptake at all. In OATP1a1-transfected cells, uptake of E3S was inhibited to less than 10% of control uptake following incubation with 1 mM [^{14}C]PFOA. Inhibition of E3S was less than 50% of control uptake after incubation with 0.1 mM [^{14}C]PFOA. Based on the results of the uptake and inhibition experiments, the authors suggested that passive diffusion could be an important route of PFOA distribution and that renal reabsorption in the male rat could be mediated by OATP1a1.

Nakagawa et al. (2009) investigated the role that the human organic acid transporter (OAT4) plays in transporting PFOA. Human OAT4 is located on the apical side of proximal tubule cells and mediates reabsorption of organic anions. Transformed cells derived from HEK cells, HEK293, were transfected with human OAT1, OAT3, or OAT4 constructs. HEK293 cells transfected with only the vector served as control cells. The transfected HEK293 cells were incubated with 10 μmol [^{14}C]PFOA for 15 mins to determine uptake. Transfected cells also were incubated with 10 μmol [^{14}C]PFOA for 15 mins and then washed with incubation medium

containing 1%, 3%, and 5% BSA to investigate the contribution of nonspecific binding of PFOA on the cell membrane. Experiments were conducted in triplicate.

Uptake of PFOA was significantly stimulated ($p<0.01$) in cells transfected with human OAT1, OAT3, and OAT4. Uptake of PFOA in human OAT1 transfected cells was 1.6-fold higher than in control cells. In human OAT3 transfected cells, PFOA uptake was ~2.4-fold higher than in control cells. In human OAT4 transfected cells, PFOA uptake was 2.7-fold higher than in control cells. Accumulation of PFOA in transfected human OAT4 cells also was significantly greater than in human OAT1 cells ($p<0.01$). Washing the cells with BSA reduced PFOA uptake by 30% at most, suggesting mediation by the transporters into the transfected cells. The experiments showed that human OAT4 transports PFOA and that human OAT4 activity might play a role in reabsorption of PFOA from the tubule, resulting in poor urinary excretion.

Yang et al. (2010) examined cellular uptake of PFOA by OATP1A2, OAT4, and urate transporter 1 (URAT1) to determine their roles in mediating human renal reabsorption. CHO and HEK293 cells were transfected with OATP1A2, OAT4, and URAT1 plasmid DNA or vector DNA (control). In uptake studies, PFOA incubation times were 10 seconds (OAT4) and 30 seconds (URAT1). Cells transfected with OAT4 were incubated with 5 µmol PFOA for up to 1 min in time-dependent uptake experiments. In inhibition studies, cells transfected with OAT4 were incubated with 5 µmol [^{14}C]PFOA for 10 seconds in the presence and absence of 100 µmol sulfobromophthalein (BSP), probenecid, glutarate, or polycyclic aromatic hydrocarbon (PAH). Perfluorinated carboxylates with differing chain lengths (C4–C12) were used in chain length-dependent inhibition experiments. Incubations with ^{3}H-E3S (OAT4 and OATP1A2) or 6 µmol C^{14}-uric acid (URAT1) in the presence and absence of 100 µmol perfluorinated carboxylate lasted 10 seconds (OAT4), 30 seconds (OATP1A2), and 1 min (URAT1).

PFOA uptake in OATP1A2-transfected HEK293 cells was no different than uptake in control cells. At 100 µmol, E3S uptake was inhibited ~30% by PFOA (C8), ~62% by C9, ~70% by C10, ~42% by C11, and ~18% by C12. E3S uptake was not inhibited by C4–C7. In CHO cells transfected with OAT4, time-dependent uptake experiments showed a saturation phase after an incubation time of approximately 10 seconds. A pH-dependent increase in PFOA uptake was observed with approximately 90% uptake at pH 8 and 250% at pH 5.5.

In concentration-dependent uptake experiments, uptake increased with increasing PFOA concentration (0–1000 µmol) in OAT4-transfected CHO cells at pH 7.4 and 6. PFOA uptake was cis-inhibited by BSP and probenecid and trans-stimulated by PAH and glutarate at pH 7.4. A chain length-dependent effect was observed in E3S inhibition on OAT4-expressing cells in the presence of C7 (30%) through C10 (~80%). Inhibition in the presence of C11 and C12 were ~52% and ~30%, respectively. Inhibition of E3S in the presence of C4, C5, and C6 was less than 20% for each.

PFOA uptake in HEK293 cells transfected with URAT1 was not statistically different from control cells in the presence and absence of Cl^-. Under both conditions, PFOA intake was enhanced especially in the absence of Cl^- in which PFOA uptake was greater than fourfold compared to uptake in control cells. Time-dependent PFOA (5 µmol) uptake by URAT1 increased with time during the 5-min incubation period, and a concentration-dependent increase in PFOA uptake was observed (0–700 µmol). Urate uptake was inhibited in a chain length-dependent manner. Inhibition in the presence of C7–C10 was ~70% each, ~60% in the presence of C6 and C11, ~50% in the presence of C5, ~30% in the presence of C12, and ~25% in the presence of C4. Based on the results, Yang et al. (2010) concluded that PFOA was not a

substrate for OATP1A2, but that OAT4 and URAT1 were probably involved in the renal reabsorption of PFOA.

Weaver et al. (2010) published *in vitro* studies on the transport activities of the rat renal transporters OAT1, OAT2, OAT3, OATP1a1, and URAT1. The transporters were transfected into one of several cell lines and exposed to a series of perfluorinated carboxylates having chain lengths ranging from 2 to 18 carbons (C). The activity of the perfluorinated carboxylate on the transporters was quantified on the basis of its ability to inhibit the transport of a favored radiolabeled substrate. The PFAS inhibition of the individual transporters varied with chain length. The perfluorinated carboxylate with 6, 7, and 8 carbon chains caused a significant decrease in OAT1 transport of tritiated p-aminohippurate, with the C7 acid having the strongest effect. The perfluorinated carboxylates with 5 through 10 carbon chains caused a significant decrease in transport of tritiated E3S by OAT3, with C8 and C9 acids having the strongest effect. The transport of tritiated estadiol-17β-glucuronide by OATP1a1 was significantly inhibited by perfluorinated carboxylates with 6 through 11 carbon chains, with C10 acid having the strongest effect. The perfluorinated carboxylate did not inhibit OAT2 or URAT1 transport of favored substrates.

The kinetic response of the OAT1, OAT3, and OATP1a1 transporters to increasing concentrations of selected perfluorinated carboxylates also was evaluated by Weaver et al. (2010). The change in transport velocity (ng/mg protein/min) with increasing concentrations of the perfluorinated carboxylate exhibited a Michaelis-Menton-type response. The kinetic data were analyzed to determine the K_m and V_{max}, and the results are summarized in Table 2-22 below.

Table 2-22. Kinetic Parameters of Perfluorinated Carboxylate Transport by OAT1, OAT3, and OATP1a1

Transporter	PFAS	K_m (µmol)	Vmax (nmol/mg protein/min)
OAT1	C7	50.5 ± 13.9	2.2 ± 0.2
	C8	43.2 ± 15.5	2.6 ± 0.3
OAT3	C8	65.7 ± 12.1	3.8 ± 0.5
	C9	174.5 ± 32.4	8.7 ± 0.7
OATP1a1	C8	126.4 ± 23.9	9.3 ± 1.4
	C9	20.5 ± 6.8	3.6 ± 0.5
	C10	28.5 ± 5.6	3.8 ± 0.3

Source: Weaver et al. 2010

The Michaelis-Menton kinetic data (K_m and V_{max} [maximum initial rate of an enzyme catalyzed reaction]) indicate that there are substantial differences in the affinity of the perfluorinated carboxylate with 8 and 9 carbon chains for OAT3, with the C8 acid favored over the C9 acid. OAT3 is an export transporter located on the basolateral side of the tubular cells; thus, when present in a mixture consisting of comparable concentrations of both, renal tubular excretion of the C8 acid would tend to decrease excretion of the C9 acid. For OATP1a1, a resorption transporter located on the apical side of the renal tubular cells, the C9 and C10 acid have a greater affinity for the transport protein than the C8 acid. The kinetic data suggest that the net impact of these relationships would be to favor excretion of the C8 acid over the C9 acid and possibly the C10 acid when all three fluorocarbons are present in the exposure matrix at approximately equal concentrations. There were minimal kinetic differences between transport

of the C7 and C8 acids by OAT1, an export transporter on the basolateral surface of the renal tubular cells.

Based on the Hinderliter study (2004), a developmental change in renal transport occurs in female rats between 3 and 5 weeks of age that allows for expedited excretion of PFOA. When the transporters become active, there is a decrease in plasma PFOA levels and an increase in urinary excretion (Table 2-23). The developmental change in male rats appears to have the opposite effect. Sexual maturity appears to influence these events because castrated male rats become more like females and OVX females become more like males in their PFOA excretion capabilities. The change in female rats seems to involve the OATs (Kudo et al. 2002) while the change in males seems to involve the OATPs (Cheng et al. 2006).

Table 2-23. Plasma and Urine PFOA Concentration 24-hr After Treatment with 30 mg/kg PFOA

Age (weeks)	Female		Male	
	Plasma (µg/ml)	Urine (µg/ml)	Plasma (µg/ml)	Urine (µg/ml)
3	51.43 ± 13.61	94.89 ± 26.26	74.16 ± 18.23	51.76 ± 28.86
4	28.01 ± 9.90	104.12 ± 28.97	100.81 ± 13.18	28.70 ± 18.84
5	3.42 ± 1.95	123.16 ± 51.56	113.86 ± 23.36	15.65 ± 6.24

Source: Hinderliter 2004

When considered together, the studies of the transporters suggest that female rats are efficient in transporting PFOA across the basolateral and apical membranes of the proximal kidney tubules into the glomerular filtrate, but male rats are not. Males, on the other hand, have a higher rate of resorption than females for the smaller amount they can transport into the glomerular filtrate via OATP1a1 in the apical membrane. This scenario might explain the inverse relationship between the levels of PFOA in female urine and plasma and the plateau of plasma PFOA in male rats compared to their losses via urine.

Unfortunately, much work remains to be done to explain the gender differences between male and female rats and to determine whether it is relevant to humans. Similarities are possible because the long half-life in humans suggests that they might be more like the male rat than the female rat. There is a broad range of half-lives in human epidemiology studies suggesting a variability in the unbound fraction of PFOA in serum or in human transport capabilities resulting from genetic variations in structures and consequently in function. Genetic variations in human OATs and OATPs are described in a review by Zaïr et al. (2008).

2.6 Toxicokinetic Considerations

2.6.1 PK Models

One of the earliest PK models was done using the post-dosing plasma data from the Butenhoff et al. study (2004b) in cynomolgus monkeys (Andersen et al. 2006). In this study, groups of six monkeys (three per gender per group) were dosed for 26 weeks with 0, 3, 10, and 20 mg/kg PFOA (high-dose =30 mg/kg PFOA for the first 12 days), followed for >160 days after dosing. Metabolism cages were used for overnight urine collection. Since urine specimens could account for only overnight PFOA excretion, the total volume and total PFOA were extrapolated to 24-hour values based on the excretion rate (volume/hour) for the volume collected and the hours of collection.

The Andersen et al. model (2006) was based on the hypothesis that saturable resorption capacity in the kidney would possibly account for the unique half-life properties of PFOA across species and genders. The model structure, shown in Figure 2-3, was derived from a published model for glucose resorption from the glomerular filtrate via transporters on the apical surface of renal tubule epithelial cells (Andersen et al. 2006).

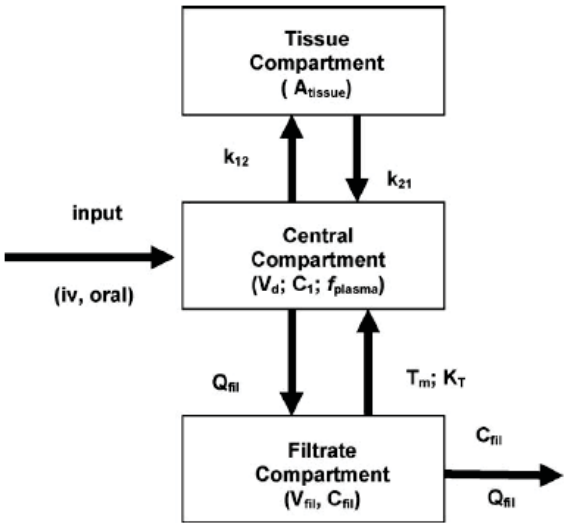

Figure 2-3. Schematic for a Physiologically Motivated Renal Resorptions PK Model

The renal-resorption model includes a central compartment that receives the chemical from the oral dose and a filtrate compartment for the glomerular filtrate from which resorption and transfer to the central compartment can occur. Transfer from the filtrate compartment to the central compartment decreases the rate of excretion. The resorption in the model was saturable, meaning that there was less resorption and greater excretion at high serum PFOA concentrations than at low concentrations.

The model was parameterized using the body weight and urine output of cynomolgus monkeys (Butenhoff et al. 2004b) and a cardiac output of 15 L/h-kg from the literature (Corley et al. 1990). A 20% blood flow rate to the kidney was assumed based on data from humans and dogs. Other parameters were optimized to fit the data for plasma and urine at lower concentrations and then applied for the 20 mg/kg/day dose, which was assumed to represent a concentration at which renal resorption was saturated. Based on the data for the dose of 20 mg/kg/day, the model was able to predict the decline in plasma levels after the cessation of dosing. The predictions were fairly adequate for one of the three modeled monkeys; for the other two monkeys, the model predicted higher levels than were observed. That result could have occurred because the model did not allow for efflux of PFOA into the glomerular filtrate through transporters on the basolateral surface of the tubular cells. The authors observed that three monkeys had faster CL_R of PFOA than the other three monkeys.

Tan et al. (2008) divided the second compartment in the Andersen et al. model (2006) into a liver compartment and a tissue compartment. A storage compartment was added between the filtrate compartment and urinary excretion (Figure 2-4) (Tan et al. 2008).

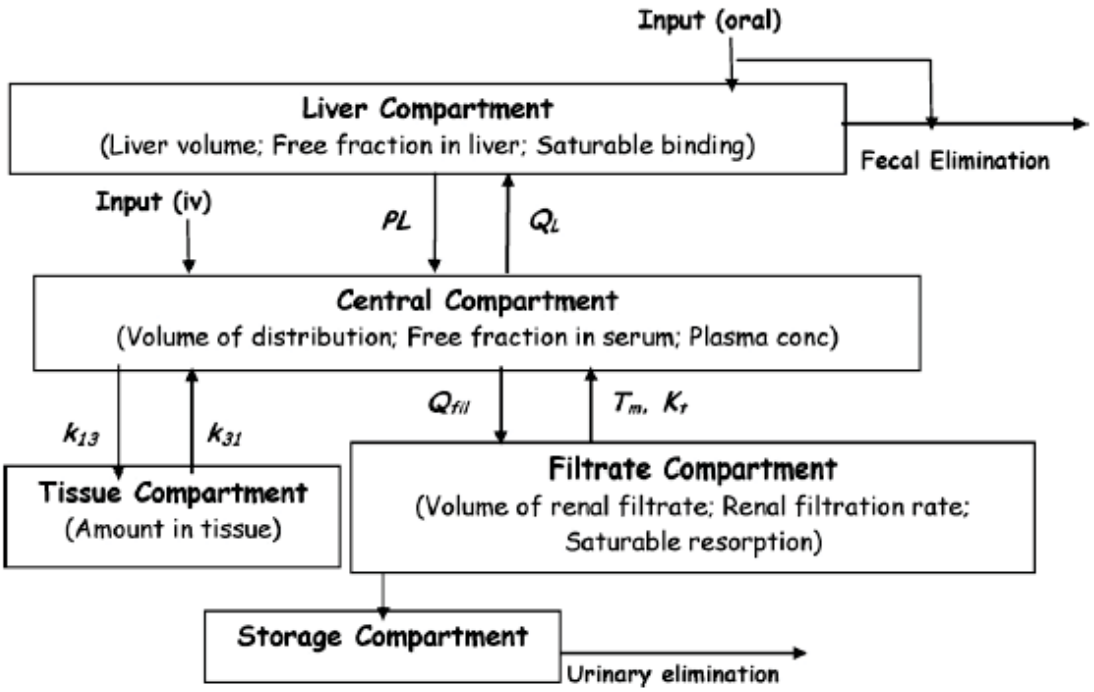

Figure 2-4. Physiologically Motivated Pharmacokinetic Model Schematic for PFOA-Exposed Rats

The models were parameterized and applied to the Kemper data (2003) for male and female CD rats given doses of 1, 5, and 25 mg/kg/day. The model did not provide a satisfactory fit between the predictions of plasma concentration or urine + fecal excretion and experimental data for either gender.

Lou et al. (2009) used the data they collected on the serum, liver, and kidney PFOA concentration (see section 2.2.1) in CD-1 mice to examine if one- or two-compartment PK models would fit the experimental data for 1, 10, and 60 mg/kg/day single gavage doses (see Figure 2-5 for the one-compartment model). Both models assumed first order absorption and elimination. The two-compartment model included a central compartment that received PFOA after absorption and transferred it to a second compartment for excretion. The excretion compartment was coupled with bidirectional flow between the two compartments. The net loss from the central compartment differed during and after distribution. The models were fit using a general nonlinear least squares approach. A likelihood ratio squared approach was applied to determine which model achieved the best fit to the data.

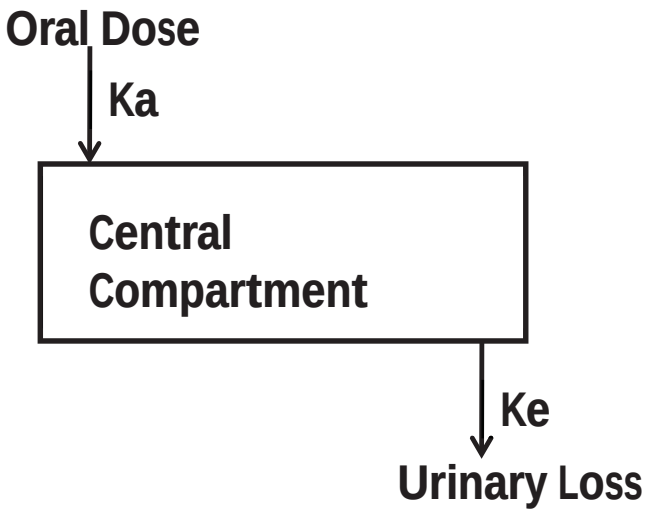

Figure 2-5. Schematic for One-Compartment Model.

The one compartment model performed well for serum, liver, and kidney in this analysis, and output was not significantly improved with use of a two-compartment model. The input parameters for the one-compartment model included V_d, serum half-life, and absorption rate constant (K_a) and elimination rate constant (K_e) for serum, liver, and kidney. There were slight differences in the fitted values between males and females for some parameters. The K_e values were consistently higher in the female mice (Table 2-24). The quantitative measures for liver and kidney were only available for the 1- and 10-mg/kg/day doses.

Table 2-24. Model Parameters for 1 and 10 mg/kg Single Doses of PFOA to CD1 Mice

Tissue	Parameter (abbreviation)	Females	Males
Serum	Volume of distribution (V_d)	0.135 L/kg	0.266 L/kg
	Absorption rate constant (K_a)	0.537 L/hr	
	Elimination rate constant (K_e)	0.00185 L/hr	0.00133 L/hr
	Half-life ($T_{½}$)	15.6 days	21.7 days
Liver	Volume of distribution (V_d)	0.161 L/kg	0.120 L/kg
	Absorption rate constant (K_a)	0.5170 L/hr	
	Elimination rate constant (K_e)	0.00161 L/hr	0.00129 L/hr
Kidney	Volume of distribution (V_d)—1 mg/kg	0.822 L/kg	1.280 L/kg
	Volume of distribution (V_d)—10 mg/kg	1.092 L/kg	1.170 L/kg
	Absorption rate constant (K_a)	0.527 L/hr	
	Elimination rate constant (K_e)	0.00151 L/hr	0.00113 L/hr

Source: Lou et al. 2009

The one-compartment model described above was not able to predict serum concentration in female mice given a single 60-mg/kg dose, suggesting a change in kinetics with the 60-mg/kg dose compared to the 1- and 10-mg/kg doses. This conclusion is supported by comparison of the serum measurements made during the 30-day post-dosing period for all three doses. The serum PFOA concentration at the 60-mg/kg dose declined more rapidly with time than serum PFOA concentrations at the 1- and 10-mg/kg doses. For example, a serum concentration of about 0.4 mg/L was reached in about 28 days at the 60-mg/kg dose, 61 days at the 10-mg/kg dose, and 70 days at the 1-mg/kg dose (values estimated from Figure 3, Lou et al. 2009). The one-

compartment model also produced a poor fit for the serum level measurements taken 24 hours after the cessation of a 17-day exposure to 20 mg/kg/day. The two-compartment model provided a better fit with experimental serum concentration data for the single 60-mg/kg dose and the repeat 20-mg/kg/day dose, but the fit was still unsatisfactory.

Lou et al. (2009) also tried the Andersen et al. renal-resorption model (2006) to determine if it provided an improved fit for the data. The Andersen et al. model (2006) fit to the data was superior to that of the one- and two-compartment models of Lou et al. (2009) for the 60-mg/kg single-dose and the 20-mg/kg/day repeat-dose scenarios.

The Andersen et al. model (2006) includes a second tissue compartment that articulates with the central compartment but not the filtrate compartment. In addition to values for V_d, K_a, and K_e, the model includes values for cardiac output, volume for the renal filtrate, renal blood filtration rate, intercompartmental CL, transport maximum, transport affinity constant (K_t), and the proportion of free PFOA in serum. With the exception of body weight and cardiac output, the input parameters for the model were either assumed (i.e., volume of renal filtrate and proportion of free serum PFOA) or optimized for the model. The wide confidence bounds around the optimized values are indicative of considerable parameter uncertainty.

The Lou et al. parameter estimates (2009) indicate that there may be several biological limitations to the Andersen et al. (2006) PK model for adult mice including the fact that it requires an unreasonably high portion of the cardiac output to pass through the kidneys to optimize fit to the experimental data. It also does not include excretion via export transporters in the renal tubular cells or consider that the bound fraction in the serum could vary with the magnitude of the dose and duration of dosing. Much of the emerging data is consistent with a variety of tubular transporters functioning in both efflux and resorption from the glomerular filtrate. In addition, there are opportunities for protein binding within organs that could function to retard distribution to the cytosol, especially at low doses. The binding of PFOA with L-FABP is an example. Once binding sites are saturated, the concentration in the cytosol will increase.

A model also has been developed that applied to female CD-1 mice during gestation and lactation (Rodriguez et al. 2009). The gestational model includes two compartments, one for the dam and the other for the litter. They are linked by placental blood flow. The biological data used to set the parameters for the two compartments were based on the data from the Lau et al. (2006) and Abbott et al. (2007) studies in CD-1 and 129S1/SvlmJ mice, respectively. Exposure was assumed to be limited by blood flow, and only the experimental doses that did not impact litter size (i.e., 0.1–1.0 mg/kg/day for CD-1 mice and 1–10 mg/kg/day for 129S1/SvlmJ mice) were used in model development.

Lactational exposure was modeled as a dynamic relationship between the dam (n = 10) and the litter, and they were connected by a milk compartment. Milk yield information was obtained from the literature. Milk was assumed to be consumed as it was produced without any circadian impact on consumption patterns. PFOA excreted in pup urine was routed back to the dam.

Both absorption and excretion were assumed to be first order processes as was lactation transfer from the dam to the litter (Figure 2-6) (Rodriguez et al. 2009). Resorption of a portion of the PFOA urinary efflux was included in the model. The renal excretion/resorption was parameterized for cardiac output, kidney blood flow, GFR, urine flow rate, volume of renal plasma (fraction of body weight), and volume of renal filtrate (fraction of body weight). The fraction of free PFOA in serum reaching the glomerulus was assumed to be 0.01 based on

protein binding information. As was the case with the Lou et al. model (2009), Rodriguez et al. (2009) did not include parameters to adjust for transporter-mediated efflux from the renal tubular cells into the glomerular filtrate.

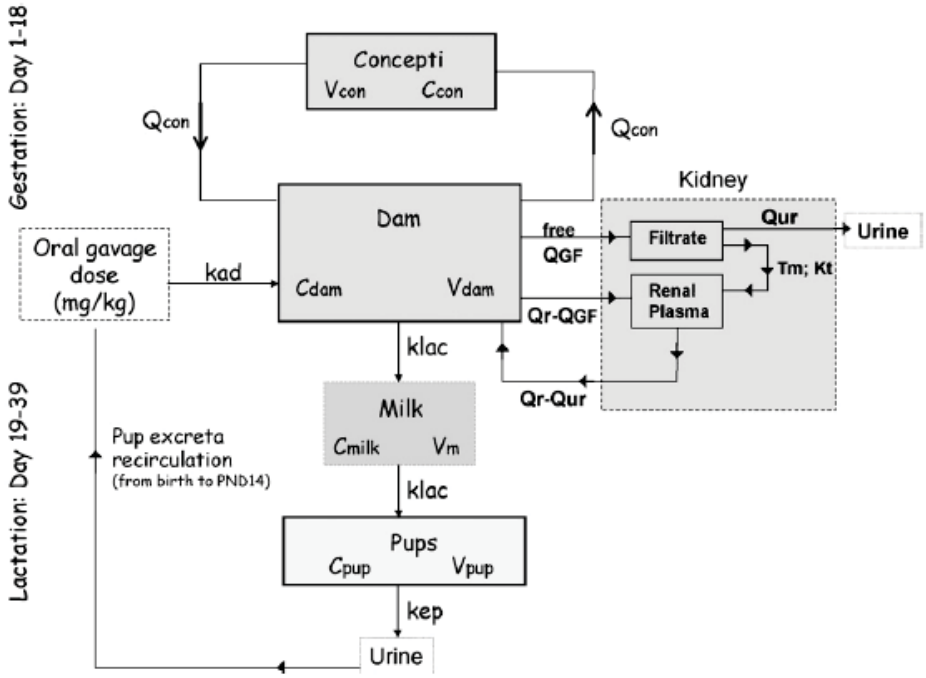

Figure 2-6. PK Model of Gestation and Lactation in Mice

One of the limitations of the Rodriguez et al. modeling effort (2009) was the limited amount of laboratory data against which to evaluate projections. Serum measures from the Lau et al. (2006) and Abbott et al. (2007) studies were available for only a few time points. Nevertheless, the authors reached several conclusions based on the model projections as follows:

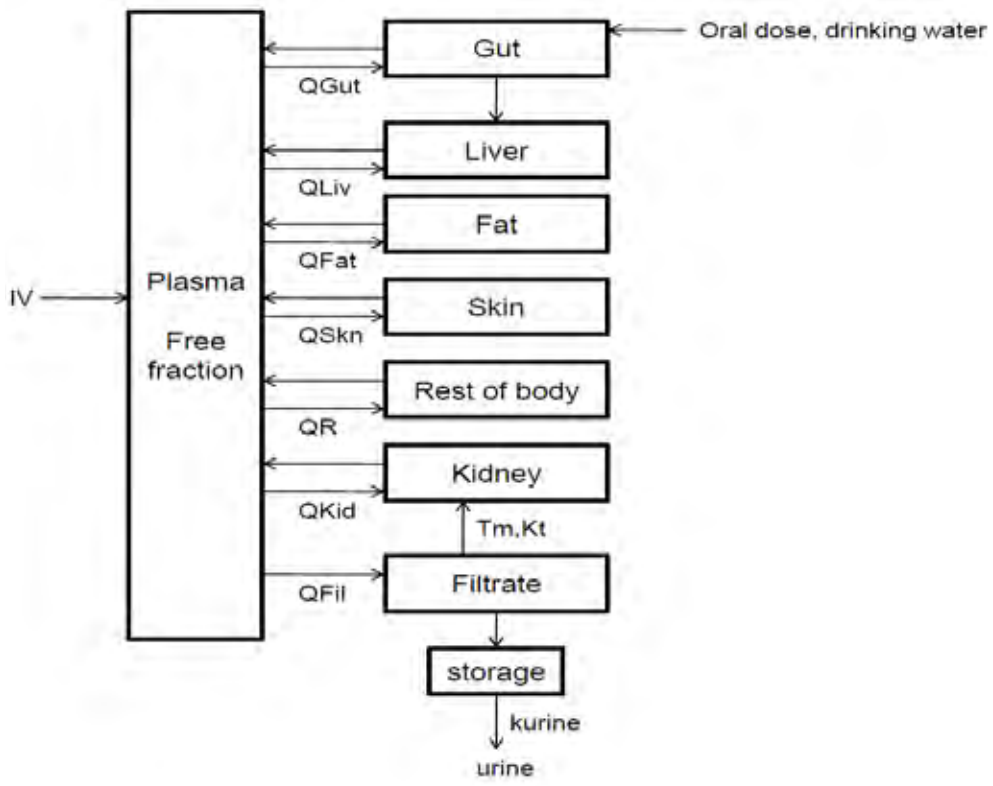
- The model had a tendency to overestimate serum levels, suggesting nonlinearity as doses increased.
- Gestation and lactation as a source of exposure contributed about equally to the pups of 129S1/SvlmJ dams exposed only during gestation.
- The contributions to the pups from gestation exceeded those from lactation in the CD-1 mice.
- Exposure to the pups via lactation increased over time.
- Lactation is a CL pathway for the dam.

A number of uncertainties accompany the model because of the assumptions regarding the flow limitation on transport to the fetus and to maternal milk: the first order K_e for the pups and, for the milk, the maternal serum partition coefficient and the limited knowledge regarding the renal tubular transporters. They caution that the model should not be applied for cross-species or high-to-low dose extrapolation.

Loccisano et al. (2011) developed a PFOA PBPK model for monkeys based on the Andersen et al (2006) and Tan et al. (2008) models, and then extrapolated it for use in humans (Figure 2-7). The model reflects saturable renal absorption of urinary PFOA by the proximal tubule of

the kidney. This is represented in Figure 2-7 by the interactions between the plasma and kidney plus the interaction of the filtrate compartment with both plasma and kidney.

The fraction of PFOA free in plasma and available for glomerular filtration was based on data fit and estimated to be less than 10% because of binding to serum proteins, especially albumin. Lacking the kinetic data on tubular resorption, the rate was based on the best fit to the plasma/urine data. A storage compartment was added to the model between filtrate and urine. Tissue plasma partition coefficients were derived from the data by Kudo et al. (2007) following the disposition pattern of a single intravenous (IV) dose to male Wistar rats.



Notes:
T_m = transporter maximum, K_t = affinity constant, and Q = flow in and out of tissues.

Figure 2-7. Structure of the PFOA PBPK Model in Monkeys and Humans

Existing IV and oral data sets from Butenhoff et al. (2004b) for the cynomolgus monkey were used to develop the monkey model. In the oral study (section 2.2.1), animals were dosed for 6 months and followed for 90 days after dosing. Plasma and urine samples were analyzed periodically during dosing and recovery. The model projections for the oral study were in good agreement with the Butenhoff et al. data (2004b) for the 10-mg/kg dose, showing a rapid rise to plasma steady state and a slow terminal half-life. The model performance for the high dose (30/20 mg/kg/day) did not fit as well, partially as a consequence of the observed toxicity with the initial 30 mg/kg/day dose that necessitated cessation of dosing on study day 12, followed by resumption of dosing at 20 mg/kg/day on study day 22.

The structure of the human model was similar to that used for the monkeys. Human serum data (means with standard deviations [SDs] or medians) for PFOA are available for occupational and general populations (Bartell et al. 2010; Calafat et al. 2007a, 2007b; Emmett et al. 2006;

Hölzer et al. 2008; Olsen et al. 2005; Steenland et al. 2009). The fact that the serum data were the results from measurements made following uncertain routes and uncertain exposure durations presented a challenge in the assessment of model fit. The human half-lives used for the model (3.8 and 2.3 years) came from an occupational study (Olsen et al. 2005) and a study of the Little Hocking, Ohio, population after reduction of the PFOA in drinking water as a result of treatment (Bartell et al. 2010). See section 2.6.2. Both half-life values were used in evaluating the model's ability to predict serum concentration at the time the serum samples were collected.

The model produced results that can be characterized as fair to good when compared to the reported average serum measurements. For the Little Hocking population studied by Emmett et al. (2006), the model indicated the need for a 30-year exposure to reach steady-state concentrations. The model indicated that both half-life values provided reasonable results when compared to the measured serum values. The authors concluded that more data are needed on the kinetics of renal transporters and intrahuman variability, plus more definitive information on exposures to further refine the human model.

Fàbrega et al. (2014) adapted the Loccisano et al. model (2011) to include compartments for the brain and lung, and to remove the skin. They applied the adjusted model to humans by using intake and body burden data from residents in Tarragona County, Spain. Food and drinking water were the major sources of exposure. Body burden information came from blood samples from 48 residents; tissue burdens came from 99 samples of autopsy tissues. The adjusted model overpredicted PFOA serum levels by a factor of about 9, the liver by a factor of 4.5, and the kidney by a factor of about 18. Model predictions for PFOS were far more consistent with the tissue concentration experimental data.

The authors also looked at the impact of using data for partition coefficients from human tissues in place of the Loccisano et al. rat data (2011) for the estimation of steady-state tissue concentrations. The PFOA simulation values were closer to the human experimental data when using the human partition coefficient values for the brain and lung, but not for the liver. In the case of the kidney, the simulated projections were generally equivalent with both the human and rat partition coefficients. The authors suggested that both saturable resorption and variations in protein binding are important parameters for PK models. With the exception of serum albumin, the existing models have not considered protein-binding constants within tissues. Even though the use of human partition coefficients improved the steady-state predictions for tissues, overall there were still considerable differences between the experimental values and the predictions with both models.

Loccisano et al. (2012a) also used the saturable resorption hypothesis when developing a model for adult Sprague-Dawley rats (Figure 2-8). The structure of the model is similar to that for the monkey/human model depicted in Figure 2-7, but lacks the fat and skin compartments and includes a storage compartment to accommodate fecal loss of unabsorbed dietary PFOA as well as loss from biliary secretions. Oral and IV data used in model development came from studies by Kemper (2003), Kudo et al. (2007) and Perkins et al. (2004). Partition coefficients for liver:plasma, kidney:plasma, and rest of the body:plasma were derived from unpublished data on mice by DePierre (2009) through personal communication with the authors (Loccisano et al. 2012a). Most of the other kinetic parameters were based on values providing the best fit to the experimental data. Because a number of the renal transporters involved with PFOA resorption are known, available kinetic information was used where appropriate. Model performance was evaluated primarily based on its ability to predict plasma and liver concentrations from the

studies identified above. Performance was generally good given the limitations in the primary data sources, as was the case for the monkey model.

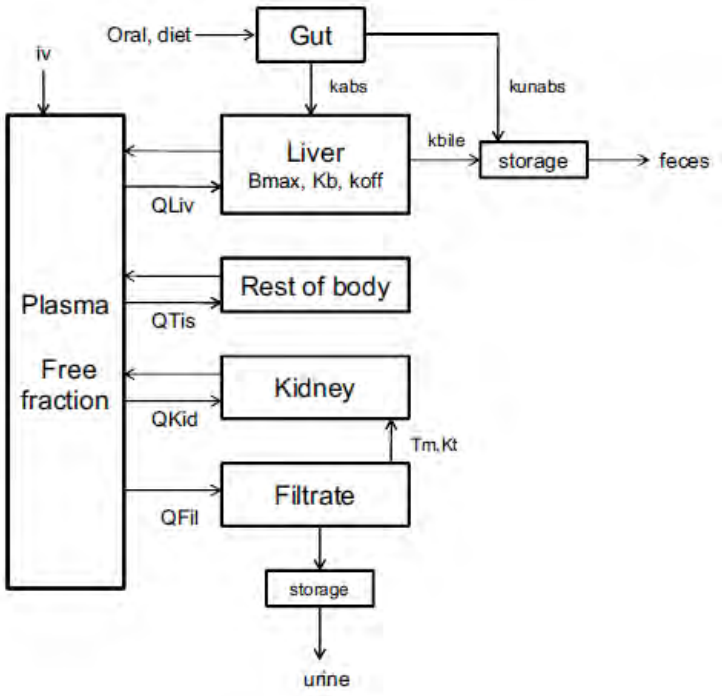


Figure 2-8. Structure of the PBPK Model for PFOA in the Adult Sprague-Dawley Rat

Loccisano et al. (2012b) expanded the adult Sprague-Dawley rat model to cover gestational and lactational exposure to the fetus and pups through their dams. The data from Hinderliter et al. (2005) were used in model development for both the gestation and lactation periods. The gestational model structure for the dams is similar to the model structure shown in Figure 2-8. The model was expanded to include the fetuses linked to the dams by way of the placenta. Uptake from the placenta was described by simple diffusion; the fetal plasma compartment was separate from the dams as was distribution to fetal tissues and amniotic fluid. Based on the transporter data for PFOA, elimination differed for male and female rats and was considered to be developmentally regulated, resulting in faster elimination for female rats than for male rats after sexual maturation. The lactation model linked the pups to their dams through mammary gland secretions. Pup compartments included the gut, liver, kidney, renal filtrate, plasma, and rest of the body.

Model performance was judged by its ability to predict concentrations in maternal and fetal plasma, amniotic fluid, and milk. The predictive capability of the model ranged from fair to good, depending on the medium. The fit of the projections to the data was weakest for the whole embryo during gestation, for which measured levels were greater than projection for two of three data points and for neonate plasma during lactation, for which all data points fell below the predictions.

Loccisano et al. (2013) extended their model development to cover humans during pregnancy and lactation, building on the work done with rodents and recognizing the limitations of the human data available for evaluating the model predictions. Figure 2-9 illustrates the structure of

the model used. The basic structure was derived from the rat model discussed above. Following are some of the key features of the model:

- The fetus is exposed via the placenta through simple bidirectional diffusion.
- Transfer rates to the fetus from the amniotic fluid are governed by bidirectional diffusion.
- Transfer from the fetal plasma to tissues is flow-limited.
- Maternal plasma is directly linked to the milk compartment and considered to be flow-limited; only the free fraction in plasma is transferred to maternal milk.
- The neonate is exposed to PFOA only via maternal milk for the first 6 months postpartum.
- The infant in the model is treated as a single compartment with a V_d.

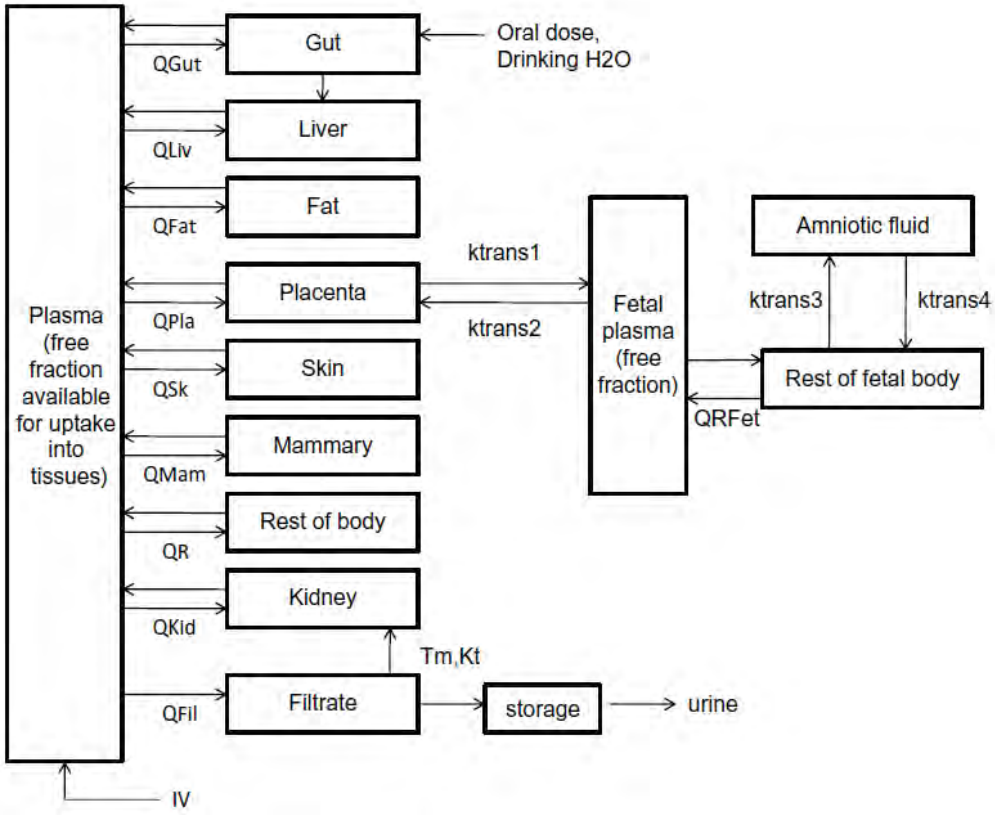

Figure 2-9. PBPK Model Structure for Simulating PFOA and PFOS Exposure During Pregnancy in Humans (Maternal, Left; Fetal, Right)

Limitations to the model are acknowledged and attributed primarily to lack of data to support a more mechanistic approach. Physiological parameters applicable to a pregnant or lactating woman, the fetus, and the nursing infant were obtained from a variety of referenced publications.

To obtain a plasma value at the time of conception, the model was run until it reached a prepregnancy steady-state concentration. The model predicted 30 years as the exposure necessary to reach steady state for the general female population (1 E-4 to 2 E-3 µg/kg body weight [bw] /day). The model performance simulations for PFOA were run using an exposure of 1.5×10^{-4} µg/kg bw/day. Projections were developed for maternal plasma, fetal plasma, infant plasma, and maternal milk. Agreement between the observed concentrations (µg/L) and the predicted values was considered satisfactory if the predicted value was within 1% of the

observed value. Model output was compared to maternal and fetal plasma values at delivery or at specific time points, and for the infant plasma and milk data where available. Predicted maternal:fetal plasma (cord blood) concentration ratios were more consistent for PFOA than for PFOS when compared to the published data. The projections for fetal internal dose were reasonable, and there was good agreement between the model and the available human lactation data. The modeled maternal plasma was 2.4 μg/L at the time of conception; it slowly decreased across the gestation period and increased slightly at delivery. For the most part, the modeled results fell within ± 1 SD of the observed data.

During lactation, there was a decline in maternal plasma across the 6 months of lactation (a change of 1μg/L). Thereafter, plasma values slowly increased and stabilized at about 1.5 μg/L at 6 months postpartum. The fetal plasma concentration was about 2.3 μg/L at the start of gestation and declined to about 1.8 μg/L at the time of delivery. Maternal plasma values are about the same as those for the fetus. During the lactation period, the infant plasma increased in a linear fashion to a terminal value of about 5 μg/L. Milk concentrations declined very slightly across the lactation period with an initial concentration of 0.07 μg/L and a final value of 0.05 μg/L. These concentrations were estimated from the graphic data presentation. Breast milk appears to be an important excretory route for the dam.

The projections for PFOA differed from those for PFOS in several respects. Most importantly, maternal and fetal plasma values were similar for PFOA but for PFOS, maternal levels were approximately twofold higher than fetal levels. Compared with PFOS, there was a much greater decline in maternal PFOA plasma values during lactation accompanied by a comparable decline in the PFOA concentration in milk. The increase in infant plasma across the lactation period was comparable for PFOA and PFOS, with the concentration at 6 months postpartum about 2.5 times higher than at 1 month.

Loccisano et al. (2011, 2012a, 2012b, 2013) determined that the human pregnancy lactation model results, when compared to published data, identified the following important research needs:

- Are there differences in the transporter preferences and transfer rates for the individual PFASs? Do those differences correlate with half-life differences?
- Are there qualitative or quantitative differences between the transporters favored by PFOA and those favored by PFOS?
- What physiological factors influence CL for the mother, the fetus, and the infant during gestation and lactation?
- Are placental transport processes active, facilitated, or passive?

These research needs are more pronounced for PFOS than PFOA because the information supporting renal resorption and tissue uptake via membrane transporters for PFOS is very limited. Most models infer that PFOS and PFOA are similar based on their half-lives rather than on published research on PFOS transporter kinetics.

Building on the work of other researchers, Wambaugh et al. (2013) developed and published a PK model to support the development of an EPA RfD for PFOA. The model was applied to data from studies conducted in monkeys, rats, and mice that demonstrated an assortment of systemic, developmental, reproductive, and immunological effects. A saturable renal resorption PK model was used. This concept has played a fundamental role in the design of all of the published PFOA models summarized in this section. In this case, an oral dosing version of the

original model introduced by Andersen et al. (2006) and summarized early in section 2.6.1 was selected for having the fewest number of parameters that would need to be estimated. A unique feature of the Wambaugh et al. approach was to use a single model for all species in the toxicological studies to examine the consistency in the average serum values associated with effects and with no effects from nine animal studies of PFOA. The model structure is depicted in Figure 2-3, with minor modifications.

Wambaugh et al. (2013) placed bounds on the estimated values for some parameters of the Andersen et al. model (2006) to support the assumption that serum carries a significant portion of the total PFOA body load. The Andersen et al. model is a modified two-compartment model in which a primary compartment describes the serum and a secondary deep tissue compartment acts as a specified tissue reservoir. Wambaugh et al. (2013) constrained the total V_d to a value of not more than 100 times that in the serum. As a result, the ratio of the two volumes (serum versus total) was estimated in place of establishing a rate of transfer from the tissue to serum.

A nonhierarchical model for parameter values was assumed. Under this assumption, a single numeric value represents all individuals of the same species, gender, and strain. The gender assumption was applied to monkeys and mice while male and female rats were treated separately because of the established gender-related toxicokinetic differences. Body weight, number of doses, and magnitude of the doses were the only parameters to vary. In place of external doses, serum concentrations as measured at the time of euthanasia were used as the metric for dose magnitude. Measurement errors were assumed to be log-normally distributed. Table 2-25 provides the estimated and assumed PK parameters applied in the Wambaugh et al. model (2013) for each of the species evaluated.

The PK data that supported the analysis were derived from two PFOA PK *in vivo* studies. The monkey PK data were derived from Butenhoff et al. (2004b), and the data for the rats (M/F) were from Kemper (2003). Two strains of female mice were analyzed separately, with CD1 information derived from Lou et al. (2009) and C57Bl/6 information derived from DeWitt et al. (2008). The data were analyzed within a Bayesian framework using Markov Chain Monte Carlo sampler implemented as an R package developed by EPA to allow predictions across species, strains, and genders and to identify serum levels associated with the NOAEL and LOAEL external doses. The model chose vague, bounded prior distributions on the parameters being estimated, allowing them to be significantly informed by the data. The values were assumed to be log-normally distributed, constraining each parameter to a positive value.

The model predictions were evaluated by comparing each predicted final serum concentration to the serum value in the supporting animal studies. The predictions were generally similar to the experimental values. There were no systematic differences between the experimental data and the model predictions across species, strain, or gender, and median model outputs uniformly appeared to be biologically plausible despite the uncertainty reflected in some of the 95^{th} percentile credible intervals. The application of the model outputs in deriving a human RfD is the focus of section 4.0 of this document.

Table 2-25. Pharmacokinetic Parameters from Wambaugh et al. (2013) Meta-Analysis of Literature Data

Parameter	Units	CD1 Mouse (f)[a]	C57Bl/6 Mouse (f)[a]	Sprague-Dawley Rat (f)[a]	Sprague-Dawley Rat (m)[a]	Cynomolgus Monkey (m/f)[a]

Notes:
Means and 95% confidence interval (in parentheses) from Bayesian analysis are reported. For some parameters, the distributions are quite wide, indicating uncertainty in that parameter (i.e., the predictions match the data equally well for a wide range of values).
m = male, f = female
[a] Data sets modeled for the CD1 mouse were from Lou et al. (2009), for the C57Bl/6 mouse were from DeWitt et al. (2008), for the rat were from Kemper (2003), and for the monkey from Butenhoff et al. (2004b).
[b] Estimated average body weight for species used except with Kemper study (2003) where individual rat weights were available and assumed to be constant.
[c] Cardiac outputs obtained from Davies and Morris (1993).

2.6.2 Half-Life Data

Human. There have been several studies of half-lives in humans and all support a long residence time for serum PFOA with estimates measured in years rather than months or weeks. Bartell et al. (2010) determined an average half-life of 2.3 years based on a study of the decreases in human serum levels after treatment of drinking water for PFOA removal was instituted by the Lubeck Public Services District in Washington, West Virginia, and the Little Hocking Water Association (LHWA) in Ohio. Source waters for these systems had become contaminated with PFAS from the DuPont Works Plant in Washington, West Virginia, between 1951 and 2000.

The Bartell et al. study (2010) was based on a series of serum measurements (eight over 4 years) from 200 individuals who agreed to participate in the study. Inclusion criteria for the participants included: serum PFOA concentrations ≥ 50 ng/mL, residential water service provided by one of the two treatment plants, never employed at the DuPont plant, not growing their own vegetables, and signed acceptance of the study consent form. The participants were almost equally divided between males and females with an average age of about 50 years (range of 18–89 years). Most of the participants consumed public tap water (172) as their primary source, but a small number (28) consumed bottled water as their source.

The participants were required to report that they primarily used home tap water for cooking, bathing, and showering for the years between 2005 and 2007. The tap water users had to report public water as their primary source of residential water consumption, and bottled water users had to report the use of bottled water as their primary source of residential water consumption. The initial blood draw for serum occurred in June 2007, with subsequent samples at 1, 2, 3, 6, and 12 months after the initial sample. Samples were analyzed by the Centers for Disease Control and Prevention. Nineteen samples from the 2-month blood draw were not analyzed due to mislabeling.

A linear mixed model was used to determine the decline in serum PFOA concentration over time. With these models, the decline from baseline by the participants was essentially first order. The serum PFOA concentration was the only time-varying measurement entered into the model. Serum concentrations were log-normally distributed, as described by the following equation:

$$\ln C = \ln C0 - k t$$

where:

C= serum concentration at time *t*
C0 = baseline serum concentration
k = elimination rate constant
t = time point for the measurement

The results of this assessment showed a 26% decrease in PFOA concentration per year after adjustment for covariates and a half-life of 2.3 years [confidence interval (CI) = 2.1-2.4]. The covariates considered included the water treatment system, the time exposed before and after filtration, public versus bottled water, gender, age, consumption of local or homegrown vegetables, and exposure to the public water supply at work. The only potential confounders determined to be significant were the treatment plant ($p = 0.03$) and homegrown vegetable consumption ($p<0.001$).

Identification of consumption of homegrown vegetables as a significant confounder revealed a weakness in the study design because it had been an exclusion factor, yet was identified as an exposure source at the 12-month interview of the study participants. The researchers concluded that this problem was a result of the way the exclusion question was phrased for the original interview, “Do you grow your own vegetables?” When the question was asked later in the study, it was rephrased, “Do you eat any fruits and vegetables grown at your own home?” Some people who answered “no” to the original questions answered “yes” to the second question.

Changes in the source of drinking water during the study could also have impacted the results. When baseline interview data were compared with the results from the 12-month interview, 39% of the bottled water group reported using public water at home. Some of the public water drinkers (10%) reported using primarily bottled water at the 6-month interview.

In another study, the drinking water supply was contaminated with a mixture of perfluorinated chemicals when a soil-improver mixed with industrial waste was applied upriver to agricultural lands in Arnsberg, Germany (Brede et al. 2010). The PFOA levels in the finished drinking water were measured as 500–640 ng/L in 2006. PFOS and PFHxS also were present. The plasma PFOA levels in the Arnsberg population were 4.5 to 8.3 times higher than those in a reference community at the time the problem was discovered. Charcoal filtration was added to the potable treatment train and succeeded in reducing concentrations in the drinking water.

The authors used the differences in plasma 2008 PFOA measurements from a subset of the participants (children and adults) initially exposed in 2006 to determine the PFOA half-life. The 2008 subjects included 66 males, females, and children from Arnsberg and 73 from the reference community in the evaluation. The drinking water concentration monitoring results (nondetects estimated as one-half of the limit of detection [LOD], 10 ng/L) and DWI estimates obtained by questionnaire and interview were used to estimate PFOA exposures. Plasma PFOA samples were collected during a 2-month period in late 2008. Plasma PFOA had declined in the serum for both the Arnsberg residents (39.2%) and those from the reference community (13.4%). In Arnsberg, the decrease was greater for the exposed females and children than for the males when compared to the reference community, an observation that appeared to reflect the reported lower DWIs of the Arnsberg females and children (0.3 ± 0.2 and 0.8 ± 0.6 L/day compared to 0.7 ± 0.5 and 1.6 ± 0.8 L/day, respectively). The estimate for the human half-life was 3.26 years (geometric mean; range 1.03–14.67 years). Regression analysis of the data also suggested that the elimination rate might have been greater in younger subjects and older subjects.

Seals et al. (2011) determined half-life estimates for 602 residents of Little Hocking, Ohio, and 971 residents of Lubeck, West Virginia, who were part of the C8 study but had relocated to a different area of the country. The half-life estimate was based on the decline in serum PFOA levels after the time of the initial measurement and the years since the change in residential location occurred. A background estimate (5 ng/mL) was subtracted from the serum measurements before analysis. On average, the initial serum PFOA concentrations were higher in Little Hocking (60.6 ng/mL) than in Lubeck (31.0 ng/mL). Due to the nonlinearity in scatter plots of the natural log for adjusted serum PFOA concentrations versus the years elapsed since relocation, the authors used a two-segment linear spline regression approach in their analysis of the data (i.e., Little Hocking—4 years, Lubeck—9 years). The slope of the line decreased for the second time segment compared to the first. In former residents of Little Hocking, a -21.4%-change in serum PFOA was observed in the first 4 years after leaving Little Hocking, and a -7.6%-change was observed beyond 4 years. In former Lubeck residents, the serum PFOA change was -7.8% for the first 9 years and 0.2% (a slight increase) afterwards. The half-life estimates for Little Hocking ranged from 2.5–3.0 years (average 2.9 years) and for Lubeck ranged from 5.9–10.3 years (average 8.5 years).

Based on their analysis, the authors suggested that, if their assumptions were correct, a simple first order elimination model might not be appropriate for PFOA given that the rate of elimination appeared to be influenced by both concentration and time. There was a difference in the CL for the two locations even though the range of years elapsed since relocation was the same for both communities. The authors identified three potential limitations of their analysis: the cross-sectional design, the assumption that exposure was uniform within a water district, and a potential bias introduced by exclusion of individuals with serum values <15 ng/mL.

3M (Burris et al. 2000, 2002) conducted a half-life study on 26 retired fluorochemical production workers from their Decatur, Alabama, (n = 24) and Cottage Grove, Minnesota, (n = 3) plants. Blood was collected from the subjects between 1998 and 2004, a period during which serum samples were drawn every 6 months over a 5-year period, depending on the facility at which the subject had worked. Responses on questionnaires determined whether any of the retirees had occupational exposures after retirement. The average number of years that participants worked was 31 (range 20–36 years) and they had been retired an average of 2.6 years at study initiation (range 0.4–11.5 years). The mean age of the retirees was 61 years (range 55–75) at the beginning of the study.

The initial mean serum PFOA concentration of all of the subjects was 0.691 µg/ml (range 0.072–5.1 µg/mL). At the completion of the study, the mean PFOA concentration was 0.262 µg/mL (range 0.017–2.435 µg/mL). Two of the retirees died during the study period; therefore, they were only followed for 4.2 years. The mean serum elimination half-life of PFOA in these workers was 3.8 years (1378 days, 95% CI, 1131-1624 days) and the median was 3.5 years (Olsen et al. 2005). The range was 1.5–9.1 years (561–3334 days). No association was reported between the serum elimination half-life and with initial PFOA concentrations, age, or gender of the retirees, the number of years retired or working at the production facility, or medication use or health conditions.

Harada et al. (2005) studied the relationship between age, gender, and serum PFOA concentration in residents of Kyoto, Japan. They found that females in the 20–50-year-old age group (all with regular menstrual cycles) had serum PFOA concentrations that were significantly lower than those in females over age 50 (all postmenopausal). Mean serum PFOA concentration in the younger females was 7.89 ± 3.61 ng/ml versus 12.63 ± 2.42 ng/mL in the older females. This age difference in serum PFOA concentrations was not seen in males, and serum PFOA concentrations in males were comparable to those of the older females.

Harada et al. (2005) also estimated the CL_R rate of PFOA in humans and found it to be only about 0.001% of the GFR. There was no significant difference in CL_R of PFOA with respect to gender or age group, and the mean value was 0.03 ± 0.013 ml/day/kg.

Animal. Kemper (2003) examined the plasma concentration profile of PFOA following gavage administration in sexually mature Sprague-Dawley rats. Male and female rats (four per gender per group) were administered single doses of PFOA by gavage at DRs of 0.1, 1, 5, and 25 mg PFOA/kg. After dosing, plasma was collected for 22 days in males and 5 days in females. Plasma concentration versus time data were then analyzed using noncompartmental PK methods (see Table 2-26 and Table 2-27). To further characterize plasma elimination kinetics, animals were given oral PFOA at a rate of 0.1 mg/kg, and plasma samples were collected until PFOA concentrations fell below quantitation limits (extended time).

Plasma elimination curves were linear with respect to time in male rats at all dose levels. In males, plasma elimination half-lives were independent of dose level and ranged from approximately 138 hours to 202 hours. To further characterize plasma elimination kinetics, particularly in male rats, animals were given oral PFOA at a dose of 0.1 mg/kg, and plasma samples were collected until PFOA concentrations fell below quantitation limits (2,016 hours in males). The estimated plasma elimination half-life in this experiment was approximately 277 hours (11.5 days) in male rats.

Plasma elimination curves were biphasic in females at the 5-mg/kg and 25-mg/kg dose levels. In females, terminal elimination half-lives ranged from approximately 2.8 hours at the lowest dose to approximately 16 hours at the high dose. The estimated plasma elimination half-life in the extended time experiment was approximately 3.4 hours in females.

Table 2-26. PK Parameters in Male Rats Following Administration of PFOA

Parameter	Dose					
	0.1 mg/kg	1 mg/kg	5 mg/kg	25 mg/kg	1 mg/kg (IV)	0.1 mg/kg extended time

Gibson and Johnson (1979) administered a single dose of ^{14}C-PFOA averaging 11.4 mg/kg by gavage to groups of three male 10-week-old CD rats. The elimination half-life of ^{14}C from the plasma was 4.8 days. NRC ([2005], cited in Butenhoff et al. [2004b]) reported half-lives of 4–6 days for male rats and 2–4 hours for female rats; there was no mention of the strains studied.

Kemper (2003) reported half-lives of 6–8 days for male Sprague-Dawley rats (Table 2-26) and 3–16 hours for females (Table 2-27).

Lou et al. (2009) determined values of 21.7 days (95% confidence interval: 19.5–24.1) for male CD1 mice and 15.6 days (95% confidence interval: 14.7–16.5) for females for use in their pharmacokinetic model (see section 2.6.1). NRC ([2005], cited in Butenhoff et al. [2004b]) provided values of 12 days for males and 20 days for females without any information on strains.

Butenhoff et al. (2004b) looked at the elimination half-life in monkeys treated for 6 months with 0, 3, 10, and 20 mg/kg/day via capsules. Elimination of PFOA from serum after cessation of dosing was monitored in recovery monkeys from the 10- and 20-mg/kg dose groups. For the two monkeys exposed to 10 mg/kg, serum PFOA elimination half-life was 19.5 (R^2=0.98) days and indicated first-order elimination kinetics. For three monkeys exposed to 20 mg/kg, serum PFOA elimination half-life was 20.8 days (R^2=0.82) and also indicated first-order elimination kinetics, although dosing was suspended at different time points because of weight loss. The data from NRC (2005), which were provided by Butenhoff et al. (2004b), were about 21 days for females and 30 days for males.

2.6.3 Volume of Distribution Data

Several researchers have attempted to characterize PFOA exposure and intake in humans through PK modeling (Lorber and Egeghy 2011; Thompson et al. 2010). As an integral part of model validation, the parameter for V_d of PFOA within the body was calibrated from the available data. In the models discussed below, V_d was defined as the total amount of PFOA in the body divided by the blood or serum concentration.

Two groups of researchers defined a V_d of 170 ml/kg body weight for humans for use in a simple, single compartment, first-order PK model (Lorber and Egeghy 2011; Thompson et al. 2010). The models developed by these groups were designed to estimate intakes of PFOA by young children and adults (Lorber and Egeghy 2011) and the general population of urban areas on the east coast of Australia (Thompson et al. 2010). In both models, the V_d was calibrated using human serum concentration and exposure data from the NHANES and assumes that most PFOA intake is from contaminated drinking water. Thus, in using the models to derive an intake from contaminated water, the V_d was calibrated so that model prediction of elevated blood levels of PFOA matched those seen in residents.

Butenhoff et al. (2004b) calculated a V_d from noncompartmental PK analysis of data from cynomolgus monkeys. Three males and three females were administered a single IV dose of 10 mg/kg, and serum PFOA concentrations were measured in samples collected up to 123 days post-dosing. The V_d of PFOA at steady state ($V_d$ss) were similar for both genders at 181 ± 12 ml/kg for males and 198 ± 69 ml/kg for females.

2.6.4 Toxicokinetic Summary

Uptake and egress of PFOA from cells is largely regulated by transporters in cell membranes. It is absorbed from the gastrointestinal tract as indicated by serum measurements in humans and treated animals. In serum, PFOA is electrostatically bound to albumin occupying up to nine to twelve sites and sometimes displacing other substances that normally would occupy a site. Linear PFOA chains display stronger binding than branched chains. PFOA binding causes a

change in the conformation of serum albumin, altering its ability to bind with some endogenous and exogenous materials it normally transports.

PFOA is distributed to tissues by a process requiring membrane transporters. Accordingly, the tissue levels vary from organ to organ. The highest tissue concentrations are usually in the liver. Liver accumulation in males is greater than in females. Other tissues with a tendency to accumulate PFOA are the kidneys, lungs, heart, and muscle, plus the testes in males and uterus in females. Post-mortem studies in humans have found PFOA in liver, lungs, bone, and kidneys, but only low levels in brain. PFOA is not metabolized, thus, any effects observed in toxicological studies are the result of parent compound, not metabolites.

Electrostatic interactions with proteins are an important toxicokinetic feature of PFOA. Studies demonstrate binding or interactions with membrane receptors (e.g., PPARα, T3), transport proteins, and enzymes. Saturable renal resorption of PFOA from the glomerular filtrate via transporters in the kidney tubules is a major contributor to the long half-life of this compound. Branched-chain PFOAs are less likely to be resorbed than the linear molecules based on half-life information in humans. All toxicokinetic models for PFOA are built on the concept of saturable renal resorption first proposed by Andersen et al. (2006). Some PFOA is removed from the body with bile, a process that also is transporter-dependent. Accordingly, the levels in fecal matter represent both unabsorbed material and that discharged with bile.

During pregnancy, PFOA is present in the placenta and amniotic fluid in both animals and humans. Post-delivery, PFOA is transferred to offspring through lactation in a dose-related manner. Maternal serum levels decline as those in the pups increase. This also occurs in humans as demonstrated in a study of females breast-feeding their infants in Little Hocking, Ohio.

The half-life in humans for occupationally exposed workers was 3.8 years (95% CI, 1.5-9.1). The average half-life was 2.3 years among people in the Lubeck Public Services District in West Virginia and the LHWA in Ohio, based on changes in serum levels for the general population after treatment of drinking water was implemented. This half-life value reflects humans whose exposure came primarily from their public water system. Half-lives from animals included 21 days (females) and 30 days (males) for monkeys Butenhoff et al. (2004b); 11.5 days (males) and 3.4 hours (females) in Sprague-Dawley rats (Kemper 2003); and 27.1 days (male) and 15.6 days (female) CD1 mice (Lau et al. 2006). The gender difference between male and female rats is not seen in mice. In early life, the half-lives are nearly the same for both genders of rats, but once the animals reach sexual maturity, resorption increases in males, prolonging the half-life (Hinderliter 2004; Hundley et al. 2006). This change appears to be under the control of hormones in both males and females (Cheng et al. 2006; Kudo et al. 2002).

3 HAZARD IDENTIFICATION

This section provides a summary and synthesis of the data from a large number of human epidemiology studies accompanied by studies in laboratory animals designed to identify both the dose response and critical effects that result from exposures to PFOA and to examine the MoA leading to toxicity.

3.1 Human Studies

Epidemiology studies of effects of PFOA have been conducted in three types of populations: workers exposed in chemical plants producing or using PFOA, high-exposure communities (i.e., an area in West Virginia and Ohio that experienced water contamination over a period of more than 20 years), and general population studies with background exposures. These populations differ with respect to exposure levels. The approximate range in serum PFOA concentrations is 0.010–> 2.0 (means around 1–4 μg/mL) in the PFOA-exposed workers, and 0.010–0.100 μg/mL and below LOD to < 0.010 μg/mL in the high-exposure community and general population settings, respectively. Although moderate-to-high correlations between PFOA and PFOS are often seen in general populations ($r > 0.5$), the correlation is lower in the West Virginia and Ohio high-exposure area ($r=0.3$). In evaluating and synthesizing results from these studies, it is important to consider differences in the exposure range within the study population and the exposure level within the referent group, as differences (or inconsistencies) can be expected depending on the shape of the exposure-response curve and the exposure range encompassed by different studies. In addition, the optimal choice of an exposure metric (e.g., cumulative or a time-specific) depends on the specific outcome being examined.

Occupational studies. Large-scale production of PFOA occurred in the United States for several decades. Both 3M (in Alabama and Minnesota) and DuPont (in West Virginia) have been the primary U.S. producers and users of perfluorinated compounds, and both companies have offered voluntary fluorochemical medical surveillance programs to workers at plants that produced or used perfluorinated compounds. The monitoring data collected by 3M and DuPont were used in conjunction with mortality and health effects information in a number of epidemiology studies of cancer and noncancer outcomes in the worker populations. 3M discontinued manufacturing PFOA in 2000, but a subsidiary in Europe (Antwerp, Belgium) continued to manufacture and sell it through 2008.

High-exposure community studies. Members of the general population living in the vicinity of the DuPont Washington Works PFOA production plant in Parkersburg, West Virginia, are the focus of a large-scale, community-based study titled the C8 Health Project. Releases from the Washington Works plant, where PFOA (C8) was used as a processing aid in the manufacture of fluoropolymers, contaminated the ground water of six water districts near the plant resulting in exposures to the general population. The plant began production in the 1950s, with PFOA use and emission from the plant increasing in the 1980s. Study participants from the affected areas ($n = 69,030$; 33,242 males, 35,788 females; <10–70+ years) were identified in 2005–2006, and a series of studies were conducted. The participants all received compensation and provided a blood sample and filled out an extensive questionnaire that included information on drinking water sources, use of home-grown produce, and health information. A variety of approaches to exposure assessment have been used in these studies, with the most detailed incorporating individual residential history and water consumption and source data, emissions data,

environmental characteristics, water pipe installation, PK data, and workplace exposures (Barry et al. 2013; Shin et al. 2011; Vieira et al. 2013). The methods allow the estimation of cumulative and of current exposure at different time periods or ages for individual study participants. Details of the specific analyses undertaken to estimate historical exposures and to ascertain different types of outcomes (retrospective and prospective analyses) are described in detail below. Drinking water concentrations were based on PFOA releases from the DuPont plant and residential address history of the participants (C8 Science Panel 2012).

The C8 Health Project also involved a review of evidence of health effects, considering their own studies and studies conducted by others and in other populations. The conclusions for each health endpoint assessed—"probable link" or "not a probable link"—are available on the C8 Science Panel website in a series of reports completed in 2011–2012 (see http://www.c8sciencepanel.org/index.html).

General population studies. Studies investigating the association between PFOA levels and health effects in the U.S. general population have been conducted using the NHANES data set. NHANES examined representative members of the U.S. population (~5000 adults and children/year) through surveys focusing on different health topics. The study consists of an interview (demographic, socioeconomic, dietary, and medical questions) and examination (medical including blood and urine collection, and dental and physiological parameters). Biomonitoring included a number of PFAS, predominantly PFOA and PFOS.

A study by Jain (2014) examined the influence of diet and other factors on the levels of serum PFOA and other PFAS using NHANES 2003–2004, 2005–2006, and 2007–2008 data. Significantly higher serum PFOA levels were found in males (0.0047 μg/mL) than in females (0.035 μg/mL) and in smokers (0.043 μg/mL) than in nonsmokers (0.040 μg/mL). No significant differences in PFOA serum concentration were seen during the time periods evaluated. There was a positive association of PFOA with increases in serum cholesterol ($p<0.001$), serum albumin ($p<0.001$), and body mass index (BMI) ($p<0.04$) based on the 5,591 records used in the assessment. Intakes of nonalcoholic beverages were positively associated with serum PFOA ($P<0.001$), but no associations were found for other dietary food groupings.

The results of these studies along with other population studies are described in the following sections. In the studies of worker cohorts, the data collected focused on measures of cardiovascular risk, signs of organ damage, standard hematological endpoints, and cancer (primarily cancer-related mortality). Within the general population, data were focused on cardiovascular risk factors and diabetic or prediabetic conditions as well as reproductive and developmental endpoints. The following summary focuses on measures of lipids (e.g., cholesterol, LDL); liver, kidney, and thyroid effects; reproductive effects (e.g., pregnancy-related outcomes, specifically pregnancy-related hypertension and preeclampsia, measures of fetal growth, and pubertal development); and cancer (specifically kidney and testicular cancer). These outcomes were selected either because of the availability of studies in a variety of settings with some indications of effects (e.g., as noted in the C8 Science Panel reports), or to allow comparison with results from studies in animals. Summary tables are included to support evaluation of the weight of evidence and facilitate comparison of the serum concentrations in the epidemiology studies to those in the animals studies summarized in section 3.2.

3.1.1 Noncancer

3.1.1.1 Serum Lipids and Cardiovascular Diseases

Serum Lipids

Occupational studies. Four cross-sectional studies are described in this section and in Table 3-1. Olsen et al. (2000) analyzed data from voluntary medical surveillance examinations of PFOA production workers at a 3M plant in 1993, 1995, and 1997. Cholesterol, LDL, HDL, and triglycerides were measured in male workers (n = 111 in 1993, n = 80 in 1995, and n = 74 in 1997). Multivariable regression analyses, conducted separately by year (cross-sectional), were adjusted for age, BMI, alcohol consumption, and cigarette use. Employees' serum PFOA levels were stratified into three categories—<1, 1- <10, and ≥10 μg/mL. The sample size in the highest category ranged from 11 to 15 in the three examination years. There was little variation by exposure category in mean or median TC, LDL, HDL, or triglycerides across the workers in 1993, 1995, or 1997.

Olsen and Zobel (2007) examined data from the 2000 medical surveillance program at the three 3M plants, which is an expanded and refined analysis of the data reported in Olsen et al. (2003). The fluorochemical workers consisted of males (age 21–67) from the Antwerp, Belgium (n = 196); Cottage Grove, Minnesota (n = 122); and Decatur, Alabama (n = 188) production facilities who volunteered to participate in the medical surveillance program and did not take cholesterol-lowering medication. Blood was collected for fluorochemical concentration determination and serum lipid parameters including cholesterol, LDL, HDL, and triglycerides. Analysis of variance (ANOVA), analysis of covariance, logistic regression, and multiple regression models were used to analyze the data with age, BMI, and alcohol consumption as covariates. Potential associations with PFOS levels were not evaluated because a previous analysis had shown no association between PFOS and the selected outcomes. Serum PFOA concentrations ranged from 0.01 to 92.03 μg/mL for the male workers (all sites combined), with a mean serum PFOA concentration of 2.21, 1.02, 4.63, and 1.89 μg/mL for all sites combined, and the Antwerp, Cottage Grove, and Decatur sites, respectively. Serum PFOA (all sites combined) was not associated with TC or LDL. A negative association was observed between serum PFOA concentration (all sites combined) and HDL. Serum triglyceride was positively associated with serum PFOA at all sites combined and independently at the Antwerp site. Nonadherence to the fasting requirement for blood collection, especially for night-shift workers, and potential binding of PFOA to albumin and LDL, were identified by the authors as possible factors that influenced the triglyceride results.

Sakr et al. (2007a) conducted a cross-sectional analysis of PFOA and lipids among active employees at the DuPont Washington Works fluoropolymer production plant in West Virginia. The employees who volunteered to participate in the study (n = 1025, 782 males, 243 females) each had a physical examination, provided a fasting blood sample, and answered a medical and occupation history questionnaire in 2004. The association between PFOA and lipid levels was evaluated by ANOVA, χ^2 test, student's t-test, and linear regression models. Confounders including age, BMI, gender, alcohol consumption, and parental heart attack were considered in the models. Mean serum PFOA concentration in the workers was 0.428 ± 0.189 μg/mL (interquartile range 0.099–0.381). For those with current occupational exposure to PFOA, the range was 0.0174–9.55 μg/mL and for workers with intermittent occupational exposure, the range was 0.0081–2.07 μg/mL. The range was 0.0086–2.59 μg/mL for workers with past occupational exposure and the 0.0046–0.963 μg/mL for workers with no occupational exposure.

Serum PFOA was positively associated with cholesterol, very low-density lipoprotein (VLDL), and LDL ($p<0.03$) in the participating workers, whether or not they were taking lipid-lowering medication. No association was observed between serum PFOA and HDL or triglycerides. PFOS was not included in the study.

Costa et al. (2009) examined serum lipid data using 30 years of medical surveillance data from workers of a PFOA production plant in Italy. The workers (n = 53 males, 20–63 years of age) participated in the medical surveillance program yearly from 1978 to 2007. The length of work exposure was 0.5–32.5 years. In 2007, 37 males were active workers and 16 males were retired or had transferred to other departments and were no longer being exposed. Unexposed male workers (n = 107, 12 executives and 95 blue collar workers) from different departments also participated in the medical surveillance program and served as controls. Beginning in 2000, serum PFOA was monitored yearly except in 2005. Serum PFOA concentrations in the workers decreased after plant renovations partially automated the PFOA production process and procedures for the use of protective devices were instituted in 2002. In 2007, the geometric mean serum PFOA was 4.02 and 3.76 μg/mL, respectively, in currently exposed and retired workers. Three analyses were conducted: a t-test comparing 34 exposed workers matched to 34 unexposed workers by age, work seniority, day/shift work, and living conditions; linear regression with 34 exposed workers and 107 unexposed workers adjusting for age, work seniority, BMI, smoking, and alcohol consumption; and a repeated measures analysis with a total of 56 individuals with more than one measure, adjusting for age, work seniority, BMI, smoking, alcohol consumption, and year of observation. TC and uric acid were significantly increased ($p<0.05$) in relation to PFOA exposure in each of these analyses. No correlations were observed between serum PFOA concentration and Apo-A (HDL-associated) or Apo-B (LDL-associated) proteins, HDL, or triglycerides in any of the analyses. PFOS was not included in this study.

Three other studies included analyses with multiple measures over time (Table 3-1). Olsen et al. (2003) conducted a longitudinal analysis of the 2000 medical surveillance data from the 3M workers in conjunction with 1995 and 1997 data. This analysis included 175 male employees with data from 2000 and at least one of the other survey dates. Only 41 employees were participants in all three surveillance periods. Mean serum levels for the group sampled in 1995 and 2000 (n = 64) were 1.36 μg/mL and 1.59 μg/mL, respectively. Mean serum levels for the group sampled in 1997 and 2000 (n = 69) were 1.22 μg/mL and 1.49 μg/mL, respectively. Finally, mean serum levels for the group sampled in 1995, 1997, and 2000 (n = 41) were 1.41 μg/mL, 1.90 μg/mL, and 1.77 μg/mL, respectively. When serum levels were analyzed using a repeated measures mixed-model multivariable regression, adjusting for age, BMI, smoking, alcohol consumption, location, year at first entry, years worked (at baseline), and years of follow-up, there was a statistically significant positive association between PFOA and serum cholesterol (Beta[1] = 0.032, 95% CI 0.013, 0.015) and triglycerides (Beta = 0.094, 95% CI 0.045, 0.144) ($p = 0.0002$). PFOS levels were not associated with changes in serum lipids over time.

Sakr et al. (2007b) conducted a longitudinal analysis among the workers at the DuPont Washington Works plant in West Virginia using data from 1979 to 2004. Employee medical records from the medical surveillance program were used to obtain blood lipid (e.g., TC, LDL, HDL, triglycerides), height, and weight data. As part of the medical surveillance program, each employee gave a detailed medical history and had a physical examination at least every 3 years. Serum PFOA concentration was measured every 1–2 years in PFOA-exposed workers and every

[1] The beta coefficient from the regression analysis.

3–5 years in non-PFOA-exposed workers on a volunteer basis. This study included 454 workers who had two or more serum PFOA measurements. The study population included 334 males and 120 females ranging in age from 24 to 66 years who had worked at the plant for at least 1 year since 1979. A linear mixed effects regression model was used to analyze the data and accounted for age (and age-squared), gender, BMI, and decade of hire as potential confounders. Serum PFOA concentrations ranged from 0 to 22.66 μg/mL, with a mean of 1.13 μg/mL over the 23-year monitoring period in the study population. For employees with two or more PFOA measurements, the mean of the first and last sample was 1.04 μg/mL and 1.16 μg/mL, respectively, with an average of 10.8 years between samples. Serum PFOA concentration was positively associated with TC after age, BMI, gender, and decade of hire adjustment in the model (Beta = 1.06, 95% CI 0.24, 1.88) per ppm increase in PFOA. Information on lipid-lowering medications and alcohol intake by the participants was not available. PFOS was not included in this study.

Steenland et al. (2015) conducted an analysis of the incidence of several conditions, including high cholesterol (based on prescription medication use) among 3,713 workers at the Washington Works plant in West Virginia who participated in the C8 Health Project. Yearly serum estimates were modeled from work history information and job-specific concentrations. Cox proportional hazard models, stratified by birth year, were used to assess self-reported incidence of high cholesterol in relation to time-varying cumulative estimated PFOA serum concentration, controlling for gender, race, education, smoking, and alcohol consumption. No association was seen when analyzed without a lag (HRs by quartile 1.0, 1.11, 1.06, 1.05; trend p = 0.56 for log cumulative exposure), or when using a 10-year lag (HRs by quartile 1.0, 0.93, 1.01, 0.96; trend p = 0.62).

High-exposure community studies. Several studies examined serum lipids in populations serviced by water districts contaminated by the Washington Works PFOA production plant in Ohio and West Virginia (Table 3-2). Emmett et al. (2006) is a small study (n = 371) with limited analysis (t-tests comparing PFOA levels in people with abnormal versus normal TC); the larger studies were conducted as part of the C8 Health Project. This collection of studies includes analyses of current serum PFOA levels in relation to serum lipids in adults (Steenland et al. 2009) and children (Frisbee et al. 2010), longitudinal analysis of the change in lipids seen in relation to a change in serum PFOA (Fitz-Simon et al. 2013), and analyses of the incidence of hypercholesteremia in relation to modeled exposure (Winquist and Steenland 2014a). With the exception of one set of analyses within the Winquist and Steenland study (2014a), these data provide consistent evidence of positive associations between PFOA exposure (measured directly in blood or modeled based on environmental and drinking water data) and TC.

Emmett et al. (2006) examined the association of serum PFOA concentration with serum TC in residents of the Little Hocking water district in Ohio. The study population (n = 371, 2–>60 years of age) was a random sample of the population served by LHWA. The subjects completed questionnaires (e.g., demographic, occupational, health conditions, and so forth) and provided blood samples. PFOA concentration was determined by HPLC/MS/MS; no other PFASs were measured. Regression models were used to analyze the data. The median serum PFOA concentration was 0.354 μg/mL. No association was observed between serum PFOA and TC.

Steenland et al. (2009) examined the association of PFOA with serum lipids in adult participants of the C8 Health Project (n = 46,294; 18–≥80 years). Serum samples were separated into deciles or quartiles for analysis. TC, HDL, triglycerides, LDL, and non-HDL (TC minus HDL cholesterol) were measured or calculated from blood samples. The data were analyzed by linear regression using the log-transformed values for all variables. Covariates of the model

included age, gender, quartile BMI, education, smoking, regular exercise, and alcohol consumption. A logistic model was used to analyze high cholesterol and serum PFOA concentration (quartiles). The mean serum PFOA concentration was 0.080 μg/mL. All lipid outcomes, except for HDL, showed significant increasing trends with increasing serum PFOA decile. There was a positive association between mean levels of serum PFOA and TC, LDL cholesterol, triglycerides, TC/HDL ratio, and non-HDL. The predicted increase in TC from lowest to highest serum PFOA concentration decile was 11–12 milligrams per deciliter (mg/dL). The odds ratio (OR) for high cholesterol (≥240 mg/dL) increased from the lowest to the highest quartile of serum PFOA concentrations: 1.00, 1.21 (95% CI: 1.12–1.31), 1.33 (95% CI: 1.23–1.43), and 1.38 (95% CI: 1.28–1.51). No association was observed between mean level of serum PFOA and HDL cholesterol. PFOS also was positively associated with TC, LDL cholesterol, and triglycerides. The results of the study were consistent with occupational studies that found a positive association between PFOA exposure and serum lipids.

The study by Frisbee et al. (2010) used a design and analysis strategy similar to that of Steenland et al. (2009), but it was conducted among children (n = 6536; 1–11.9 years) and adolescent (n = 5934; 12.0–17.9 years) participants of the C8 Health Project. The mean serum PFOA concentration was 0.0777 μg/mL and 0.0618 μg/mL, respectively, for children and adolescents. TC, LDL, and triglycerides were positively associated ($p \leq 0.02$) with serum PFOA concentration, adjusting for age, gender, BMI, exercise, and length of fast. Assessment of the quintile trends showed significant differences ($p \leq 0.02$) between the first and fifth quintile for TC and LDL for children and adolescents of both genders combined and separated. A significant difference ($p = 0.04$) was observed for fasting triglycerides in female children only. An increased risk of abnormal TC and LDL were positively associated with serum PFOA. The ORs were 1.0 first (reference), 1.1 (95% CI: 1.0–1.3, second), 1.2 (95% CI: 1.0–1.4, third), and 1.2 (95% CI: 1.1–1.4, fourth and fifth) for TC, and 1.0 (reference, first), 1.2 (95% CI: 1.0–1.5, second), 1.2 (95% CI: 1.0–1.4, third and fourth), and 1.4 (95% CI: 1.2–1.7, fifth) for LDL. An increased risk of abnormal fasting triglyceride and HDL was not associated with serum PFOA. PFOS also was positively associated with TC, LDL cholesterol, and HDL cholesterol.

The C8 Science Panel (2012) used data from the C8 general population cohorts as well as from combined general population and worker cohorts to evaluate the association between PFOA and a medical diagnosis of high cholesterol. Despite inconsistent evidence between studies, they concluded that there is a probable link between PFOA and diagnosed high cholesterol. The worker cohort was not evaluated separately in this analysis.

A cohort of 521 members of the C8 Health Project was evaluated for an association between changes in serum PFOA levels and changes in serum LDL-cholesterol, HDL-cholesterol, TC, and triglycerides over a 4.4-year period (Fitz-Simon et al. 2013). Linear regression models were fit to the logarithm (base 10) of ratio change in each serum lipid measurement in relation to the logarithm of ratio change in PFOA. Mean serum PFOA concentration decreased by approximately one-half between baseline (0.140 ± 0.209 μg/mL) and follow-up (0.068 ± 0.144 μg/mL). No corresponding changes in serum lipids were found. However, those individuals with the greatest declines in serum PFOA had a larger decrease in LDL cholesterol.

Incidence of Hypercholesterolemia					
Winquist and Steenland 2014a n = 32,254 (including 3,713 workers) Data collected in 2005-2006 and 2008-2011 n = 9,653 cases in primary analysis (all diagnoses) n = 1,825 cases in prospective analysis (diagnoses after 2005-2006)	In 2005-2006: mean 0.0866 µg/mL, median 0.0261 µg/mL	HR (95% CI), self-reported use of cholesterol-lowering medications, primary analysis Cumulative exposure quintiles: 1.00 (referent) 1.24 (1.15, 1.33) 1.17 (1.09, 1.26) 1.19 (1.11, 1.27) 1.19 (1.11, 1.28) (P_{trend} = 0.005) Year exposure quintiles: 1.00 (referent) 1.07 (1.01, 1.15) 1.11 (1.04, 1.19) 1.05 (0.99, 1.13) 1.20 (1.12, 1.28) (P_{trend} = 0.001) Diagnoses after 2005: no association with PFOA with either exposure metric			

More recently, participants in the C8 Health Project were examined for an association between PFOA levels and incidence of several conditions, including high cholesterol (based on prescription medication use) (Winquist and Steenland 2014a). The cohort included 28,541 community members and 3,713 workers who had completed study questionnaires during 2008–2011. The median serum PFOA level at enrollment in 2005–2006 was 0.0261 μg/mL for the combined cohort, 0.0242 μg/mL for the community members, and 0.1127 μg/mL for the workers. Retrospective serum levels for the community cohort were estimated from air and water concentrations, residential history, and water consumption rates. For the workers, yearly serum estimates were modeled from work history information and job-specific concentrations. Cox proportional hazard models, stratified by birth year, were used to assess self-reported adult heart disease hazard in relation to time-varying yearly or cumulative (sum of yearly estimates) estimated PFOA serum concentration, controlling for gender, race, education, smoking, and alcohol consumption. Using the cumulative exposure metric, the HRs for hypercholesterolemia for quintiles 2–5 versus quintile 1 were 1.24, 1.17, 1.19, and 1.19 (P_{trend} = 0.005). Using the yearly exposure metric, the HRs for high cholesterol for quintiles 2–5 versus quintile 1 were 1.07, 1.11, 1.05, and 1.20 (P_{trend} = 0.001). The strongest association was in males aged 40–59. No associations were found between PFOA level and hypertension or coronary artery disease incidence. (The analysis of these data restricted to the worker population by Steenland et al. [2015] is described in the previous section).

A subset of 290 individuals in the C8 Health Project was evaluated for evidence that PFOA exposure can influence the transcript expression of genes involved in cholesterol metabolism, mobilization, or transport (Fletcher et al. 2013). RNA was extracted from whole blood samples taken from 144 males and 146 females aged 20–60 years; serum collected at the same time was used to measure PFOA concentration. The association between candidate gene expression levels and PFOA levels was assessed by multivariable linear regression with adjustments for confounders. Inverse associations were found between PFOA levels and expressions of transcripts involved in cholesterol transport (NR1H2, NPC1, and ABCG1; p = 0.002, 0.026, and 0.014, respectively). When genders were analyzed separately, PFOA was negatively associated with expression of genes involved in cholesterol transport in males (NPC1, ABCG1, PPARα) and females (NCEH1). Similar associations were found with PFOS.

General population studies. Several studies examined serum lipids in the general population (Table 3-3). Nelson et al. (2010) examined the relationship between polyfluoroalkyl chemical serum concentration, including PFOA, and lipid and weight outcomes in the general population of the United States by analyzing data from the 2003–2004 NHANES. The population (n = 860) included persons aged 20–80 years with no missing covariate information who were not pregnant, breast-feeding, taking insulin or cholesterol medicine, or undergoing dialysis. Cholesterol (TC, HDL, LDL) was measured from serum samples. Data for covariates predicting cholesterol and body weight including age, gender, race/ethnicity, socioeconomic status, saturated fat intake, exercise, alcohol consumption at ≥ 20 years of age, smoking, and parity were obtained from the questionnaires. Regression analyses were performed for gender and the age groups 12–19 years, 20–59 years, and 60–80 years. The mean PFOA concentration was 0.0046 ± 0.003 μg/mL. A positive association was found between TC and non-HDL (TC-HDL, ~70–80% TC) cholesterol and serum PFOA (effect estimate 9.8; 95% CI, -0.2–19.7). No association was found between serum PFOA concentration and HDL, or LDL. No association was found between serum PFOA concentration and body weight. Similar results were found with PFOS. A similar analysis using 1999–2008 NHANES data for 815 adolescents (aged 12–18 years) by Geiger et al. (2014a) found an association between serum PFOA and TC

(Beta 4.55, 95% CI 0.90, 8.20, per ln-unit increase in PFOA) and LDL (Beta 5.75, 95% CI 2.16, 9.33, per ln-unit increase in PFOA).

Eriksen et al. (2013) examined the association between plasma PFOA (and PFOS) levels and TC levels in a middle-aged Danish population. This cross-sectional study included 663 males and 90 females aged 50–65 years who were enrolled in the Danish Diet, Cancer and Health cohort. Generalized linear models were used to analyze the association between PFOA and TC levels, adjusted for age, gender, education, BMI, smoking, alcohol consumption, egg intake, animal fat intake, and physical activity. The mean plasma PFOA level was 0.0071 μg/mL. A significant, positive association was found between PFOA (and PFOS) and TC such that, in the fully adjusted model, a 4.4-mg/dL (95% CI 0.8, 8.5) higher concentration of TC was found per interquartile range of plasma PFOA (quartile cut-points were not reported).

Fisher et al. (2013) examined the association of plasma PFAS levels, including PFOA, with metabolic function and plasma lipid levels. This population-based sample included 2,700 participants aged 18–74 years (~50% male) in the Canadian Health Measures Survey. The geometric mean PFOA concentration was 0.0025 ± 0.0018 μg/mL. In analyses that included sampling weights, no associations were found between PFOA (or PFOS) and TC, HDL- and LDL-cholesterol, and metabolic syndrome and glucose homeostasis parameters. Covariates considered included age, gender, marital status, income adequacy, race, education, BMI, physical activity, smoking, and alcohol consumption.

Starling et al. (2014) examined the association between PFOA (and six other PFASs) and serum lipids in pregnant females in the Norwegian Mother and Child Cohort Study. Most of the blood samples were drawn during weeks 14–26 of gestation. Weighted multiple linear regression was used to estimate the association between PFOA level and each lipid level. Covariates considered included age, prepregnancy BMI, nulliparous or interpregnancy interval, breast-feeding duration, education, current smoking, gestation week at blood draw, oily fish consumption, and weight gain during pregnancy. The median plasma PFOA level was 0.00225 μg/mL. No association was observed between PFOA and triglycerides, TC, or LDL-cholesterol. PFOA was positively associated with HDL-cholesterol, although the CI was large for the association. With HDL-cholesterol, each interquartile range- (IQR-) unit increase in ln-PFOA was associated with an increase of 1.28 mg/dL (95% CI: -0.15, 2.71). Five of the seven PFASs studied were positively associated with HDL cholesterol and all seven had elevated HDL associated with the highest quartile.

Table 3-3. Summary of General Population Epidemiology Studies of PFOA with Serum Lipids

Reference and Study Details	PFOA level	TC	LDL	HDL	Triglycerides
All Adults					
Nelson et al. 2010 United States, NHANES (2003–2004) n = 860, aged 20-80 yrs (451 men, 409 women) Linear regression, PFOA in quartiles and continuous PFOA, adjusted PFOA-PFOS correlation Spearman r = 0.65	Mean 0.0046 µg/mL, median 0.0038 µg/mL	Beta = 1.22 (95% CI 0.04, 2.40) 9.8 mg/dl increase in top versus bottom quartile (PFOS results similar)	Beta = -0.21 (95% CI -1.91, 1.49) (PFOS results similar)	Beta = -0.12 (95% CI -0.41, 0.16) Different pattern seen with PFOS	Not measured
Eriksen et al. 2013 Denmark n = 753, aged 50-65 yrs (663 men, 90 women) Linear regression, continuous PFOA, adjusted PFOA-PFOS correlation not reported	Mean 0.0071 µg/mL	4.4 mg/dl increase per IQR (PFOS results similar)	Not measured	Not measured	Not measured
Fisher et al. 2013 Canada, Canadian Health Measures Survey n = 2,700, aged 18-74 yrs Linear regression, continuous PFOA (log-transformed PFOA and lipids) PFOS correlation r = 0.36	Mean 0.0025 µg/mL Quartiles: 0.00015-0.00185 0.00186-0.00258 0.00259-0.00355 ≥ 0.0036	Beta = 0.03 (95% CI -0.017, 0.07) [log PFOA and lipids]	Beta = 0.02 (95% CI -0.06, 0.091) [log PFOA and lipids]	Beta = 0.0009 (95% CI -0.04, 0.04) [log PFOA and lipids]	Not measured
Pregnant Women					
Starling et al. 2014 Norway n = 891 pregnant women Plasma PFOA (collected in 2nd trimester) Linear regression, continuous PFOA (log-transformed PFOA), adjusted PFOS correlation Spearman r = 0.64	Median 0.00225 µg/mL	Beta = 2.58 (95% CI -4.32, 9.47) [per ln-unit increase in PFOA]	Beta = 2.25 (95% CI -3.97, 8.48) [per ln-unit increase in PFOA]	Beta = 2.13 (95% CI -0.26, 4.51) [per ln-unit increase in PFOA]	Beta = 0.00 (95% CI -0.07, 0.06) [per ln-unit increase in PFOA]
Adolescents					
Geiger et al. 2014a United States, NHANES (1999-2008) n = 815, aged 12-18 yrs Linear regression, continuous PFOA (log-transformed PFOA), adjusted	Mean 0.0042 µg/mL	Beta = 4.55 (95% CI 0.90, 8.20) [per ln-unit increase in PFOA] (PFOS results similar)	Beta = 5.75 (95% CI 2.16, 9.33) [per ln-unit increase in PFOA] (PFOS results similar)	Beta = -1.52 (95% CI -3.02, -0.03 [per ln-unit increase in PFOA] Attenuated results when adjusted for PFOS	Beta = 1.74 (95% CI -2.88, 6.36) Different pattern seen with PFOS

The association between PFOA and serum lipids has been examined in several studies in different populations. Cross-sectional and longitudinal studies in occupational settings (Costa et al. 2009; Olsen et al. 2000, 2003; Olsen and Zobel 2007; Sakr et al. 2007a, 2007b; Steenland et al. 2015) and in the high-exposure community (the C8 Health Project study population) (Fitz-Simon et al. 2013; Frisbee et al 2010; Steenland et al. 2009; Winquist and Steenland 2014a) generally observed positive associations between serum PFOA and TC in adults and children (aged 1–< 18 yrs); most of the effect estimates were statistically significant. Although exceptions to this pattern are present (i.e., some of the analyses examining incidence of self-reported high cholesterol based on medication use in Winquist and Steenland [2014a] and in Steenland et al. [2015]), the results are relatively consistent and robust. Similar associations were seen in analyses of LDL, but were not seen with HDL. The range of exposure in occupational studies is large (with means varying between 0.4 and > 12 μg/mL), and the mean serum levels in the C8 population studies were around 0.08 μg/mL. Positive associations between serum PFOA and TC (i.e., increasing lipid level with increasing PFOA) were observed in most of the general population studies at mean exposure levels of 0.002–0.007 μg/mL (Eriksen et al. 2013; Fisher et al. 2013; Geiger et al. 2014a; Nelson et al. 2010; Starling et al. 2014). The interpretation of these general population results is limited, however, by the moderately strong correlations (Spearman r > 0.6) and similarity in results seen for PFOS and PFOA.

3.1.1.2 Cardiovascular Diseases

Occupational exposure studies. Several studies examined cardiovascular-related cause of death among PFOA-exposed workers at the West Virginia Washington Works plant (Leonard et al. 2008; Sakr et al. 2009; Steenland and Woskie 2012) and the 3M Cottage Grove plant in Minnesota (Lundin et al. 2009; Gilliland and Mandel 1993). This type of mortality is of interest because of the relation between lipid profiles (e.g., LDL) and the risk of cardiovascular disease. The most recent West Virginia study included 5,791 individuals who had worked at the plant for at least 1 year between 1948 and 2002, with mortality follow-up through 2008. No associations were found between cumulative PFOA levels and ischemic heart disease (IHD) mortality (standardized mortality ratio [SMR] 1.07, 1.02, 0.87, and 0.93 across four quartiles of cumulative exposure, compared to U.S. referent group). Based on these data from the worker cohorts, the C8 Science Panel (2012) concluded that there is no probable link between PFOA and stroke and coronary artery disease.

The analysis of the Minnesota plant (n = 3,993 workers who began work between 1983 and 1997, with follow-up through 2002) also found no association between cumulative PFOA exposure and IHD risk, but an increased risk of cerebrovascular disease mortality was seen in the highest exposure category (HR 2.1, 95% CI 1.0, 4.6). These studies are limited by the reliance on mortality (rather than incidence) data, which can result in a substantial degree of under ascertainment and misclassification.

3.1.1.3 Liver Enzymes and Liver Disease

Cross-sectional studies and longitudinal studies of PFOA and liver enzymes in various populations are described in this section and summarized in Table 3-4.

Table 3-4. Summary of Epidemiology Studies of PFOA and Liver Enzymes

Reference and Study Details	PFOA level	Results
Cross-sectional: Occupational Exposure Studies		
Olsen et al. 2000 n = 111 in 1993, 80 in 1995, 74 in 1997; 50-70% participation rate Mean age: ~ 40 yrs Mean duration: not reported ANOVA and linear regression adjusted for age, BMI, and alcohol and cigarette use	Mean (range) µg/mL 1993: 5 (0-80) 1995: 6.8 (0-114) 1997: 6.4 (0.1-81)	ALT: Year β (±SE) (p value) 1993: 0.89 (2.88) (p = 0.76) 1995: 0.81 (2.62) (p = 0.75) 1997: 2.77 (1.27) (p = 0.03) Change per 10 µg/mL increase in serum PFOA; stronger association in individuals with BMI< 30. No associations for ALP, GGT, AST, total bilirubin, direct bilirubin.
Olsen and Zobel 2007 3M. Antwerp, Cottage Grove, Decatur combined; 50-65% participation rate n = 506 (men, not taking lipid-lowering medications) Mean age: 40 yrs Mean duration: not reported Linear regression adjusting for ln age, ln BMI, ln alcohol [Related reference: Olsen et al. 2003)	Mean (range) 2.21 (0.01 – 92.03) µg/mL	β change per ln PFOA (±SE) p value ln ALP: All 0.009 (± 0.008) (p = 0.25) Decatur: 0.08 (0.34) (p = 0.02) ln AST: All -0.005 (± 0.009) (p = 0.55) Decatur: 0.011 (0.02) (p = 0.57) ln ALT: All 0.025 (± 0.013) (p = 0.06) Decatur: 0.08 (0.034) (p = 0.02) ln GGT: All 0.033 (± 0.017) (p = 0.05) Decatur: 0.08 (0.034) (p = 0.02) ln total bilirubin: All -0.033 (± 0.01) (p = 0.001) Decatur: -0.054 (± 0.021) (p = 0.01) Replacement of ln BMI with triglycerides in the model resulted in reduced associations for ALT and GGT.
Sakr et al. 2007a Washington Works (West Virginia) n = 1025 (782 men, 243 women), 55% participation rate Mean age: 46.5 and 44.4 yrs, respectively for men and women Mean duration: 19.6 and 15.9 yrs, respectively for men and women Linear regression, adjusting for age, BMI, alcohol consumption, gender, history of heart attack in parent, use of lipid-lowering medications	0.428 µg/ml LOQ 0.0005 µg/ml range 0.005 – 9.55 µg/mL	β (±SE) p value: Full sample / Excluding 178 men on lipid-lowering medications ln AST: 0.012 (± 0.012) (p = 0.317) / ln AST: 0.023 (±0.013) (p = 0.079) ln ALT: 0.023 (± 0.015) (p = 0.124) / ln ALT: 0.031 (±0.017) (p = 0.071) ln GGT: 0.048 (± 0.02) (p = 0.016) / ln GGT: 0.05 (±0.023) (p = 0.03) ln bilirubin: 0.008 (± 0.014) (p = 0.59) / ln bilirubin: 0.1 (±0.017) (p = 0.637)
Costa et al. 2009 Italy Cross-sectional 56 male workers (currently and formerly exposed and unexposed) with concurrent serum PFOA and clinical parameters measured in last 7 yrs GEE models adjusting for age, years of exposure, year of PFOA sampling, BMI, smoking, and alcohol consumption	Currently exposed: mean 12.9, geometric mean 4.02, range 0.2-47 Formerly exposed: mean 6.81 geometric mean 3.76, range 0.53-18 µg/mL	β change per µg PFOA/mL (95% CI) AST: 0.038 (-0.003, 0.080) ALT: 0.116 (0.054, 0.177) GGT: 0.177 (0.076, 0.278) ALP: 0.057 (0.007, 0.107) Total bilirubin: -0.080 (-0.137, -0.024) Conj. bilirubin: -0.034 (-0.09, 0.031)

Reference and Study Details	PFOA level	Results
Longitudinal: Occupational Exposure Studies		
Olsen et al. 2003 3M, Antwerp and Decatur combined ~5 yr follow-up period n = 174 (measure in 1995 or 1997, and in 2000) Mean age: not reported Mean duration: not reported Linear mixed effects regression for repeated measures, adjusted	1995 baseline: 1.36-1.41 µg/mL 2000 follow-up: 1.49-1.77 µg/mL	No associations observed; however, data not provided
Sakr et al. 2007b Washington Works (West Virginia) n = 454 23-yr follow-up (mean 3.7 PFOA measures) Mean age: 27 yrs (at hire) Mean duration: 27 yrs Linear mixed effects regression for repeated measures, adjusted	1.04 µg/mL (first) 1.16 µg/mL (last) Used PFOA measurement from same year as biomarker test or interpolated using two surrounding values	β IU/L change per 1 µg/mL PFOA (95% CI) ALP: (n = 1327) -0.21 (-0.60, 0.18) AST: (n = 1326) 0.35 (0.10, 0.60) ALT: (n = 231) 0.54 (-0.46, 1.54) GGT: (n = 233) 1.24 (-1.09, 3.57) Total bilirubin: (n = 1327) 0.008 (-0.0139, -0.0021)

Emmett et al. 2006 n= 371, aged 2–89 yrs, median 50 yrs (317 from stratified random population sample) Linear regression (continuous PFOA) and t-test, PFOA, abnormal versus normal enzyme levels	Median 0.354 µg/mL (IQR 0.184 – 0.571 µg/mL); nonfasting blood sample	Linear regression, Beta (p-value) n (%) abnormal,(t-test p-value) ALP: -0.00416 (p = 0.65) 6 (2%) (p = 0.63) AST: -0.0007586 (p = 0.76) 9 (2%) (p = 0.03) ALT: -0.00183 (p = 0.65) 28 (8%) (p = 0.30) GGT: 0.00057711 (p = 0.89) 11 (3%) (p = 0.50)
Gallo et al. 2012 West Virginia, United States; C8 Health Project, 46,452 of 56,554 (82.1%) adults Adjusting for age, gender, physical activity, BMI, average household income, educational level, fasting status, month of blood sample collection, race, insulin resistance, alcohol consumption, and cigarette smoking	Median 0.028 µg/mL (IQR 0.135 – 0.71 µg/mL) nonfasting blood sample; LOD 0.0005 µg/mL, n = 32 below LOD	Linear regression, Logistic regression of abnormal values β per 1 unit increase PFOA (95% CI) OR (95% CI) Ln ALT: 0.022 (0.018 – 0.025) ALT: 1.10 (1.07, 1.13) ln GGT: 0.015 (0.01 – 0.019) GGT: 1.01 (0.99, 1.04) n Direct (conjugated) bilirubin: 0.001 (-0.002 – 0.004) Direct bilirubin 0.97 (0.90, 1.05) Analysis of Ln ALT or Ln GGT by decile showed increase from 0.005 to 0.030 µg/mL, then leveling; p value for trend < 0.001; Direct bilirubin showed a U-shaped relation increasing to 0.030 µg/mL, then declining.
Cross-sectional: General Population Studies		
Lin et al. 2010 United States, NHANES (1999-2000; 2003-2004) 1,076 men, 1,140 women of 10,224 enrolled, excluding < 6-hr fast n = 1,802), and missing covariate or no serum PFOA or liver function of metabolic syndrome data Adjusting for age, gender, race/ethnicity, smoking, alcohol consumption, education level, BMI, metabolic syndrome, and iron saturation status	Geometric mean 0.00505 µg/mL 0.00406 µg/mL; 0.4% of samples below LOD (LOD 0.0002 and 0.0001 µg/mL in 1999-2000 and 2003-2004)	β per unit (ng/ml) increase in log serum PFOA (95% CI) ALT: (U/l) 1.86 (1.24, 2.48) Log GGT: (U/l) 0.08 (0.05, 0.11) β per unit (ng/ml) increase in log serum PFOA (95% CI); Same model as above, also controlling for other PFASs ALT: (U/l) 2.19 (1.4, 2.98) Log GGT: (U/l) 0.15 (0.11, 0.19)

Liver Enzymes

Occupational exposure studies. Olsen et al. (2000) analyzed alkaline phosphatase (ALP), GGT, aspartate aminotransferase (AST), ALT, and total- and direct bilirubin data from voluntary medical surveillance examinations of PFOA production workers at a 3M plant in 1993, 1995, and 1997. No association was observed between serum PFOA concentration and the parameters explored in cross-sectional analyses in the workers in 1993 or 1995; although in 1997 increases in AST per unit increase in serum PFOA concentration were observed. When measurements for all years were combined in longitudinal analyses (Olsen et al. 2003), the authors reported that no associations were observed with serum PFOA levels. Other than the analyses of AST, however, quantitative results were not provided.

A subsequent analysis involving these fluorochemical workers and an additional plant (Cottage Grove, Minnesota) that used medical surveillance data collected in 2000 examined the association between serum PFOA concentration and liver enzymes (Olsen and Zobel 2007). Serum samples were analyzed for ALP, GGT, AST, ALT, and bilirubin concentrations. Ln serum PFOA was marginally associated with ln ALT and ln GGT in regression models adjusting for ln age, ln BMI, and ln alcohol consumption, although the association was reduced when ln triglycerides replaced ln BMI in the model. An inverse association between total bilirubin and serum PFOA concentration ($p<0.05$) was observed at all sites combined.

Sakr et al. (2007a) examined the relationship between serum PFOA and several clinical chemistry parameters in workers at the Washington Works plant in West Virginia. A complete blood count, metabolic panel (glucose, blood urea nitrogen [BUN], creatinine, iron, uric acid, electrolytes, creatinine kinase, lactic dehydrogenase [LDH], ALP, protein, albumin, C-reactive protein), liver enzyme panel (AST, ALT, GGT, bilirubin), and serum PFOA concentration were determined from the blood samples. Serum PFOA was associated ($p<0.05$) with increasing GGT in all of the participating workers. It was stated that an association was observed between serum PFOA concentration and iron, LDH, calcium, and potassium, but quantitative results were not included and the direction of association was not specified.

Costa et al. (2009) also examined associations between serum PFOA concentration and liver enzymes in workers at a fluorochemical production plant in Italy. Serum PFOA concentration was associated with increasing ALT, GGT, and ALP levels ($p<0.05$), and inversely associated with total bilirubin ($p<0.01$) in 56 workers with PFOA and liver enzymes measured concurrently over the last 7 years. This subset of 56 workers included currently, formerly, and never exposed.

Sakr et al. (2007b) also conducted a longitudinal study of liver enzymes among workers at the Washington Works plant with two or more PFOA measurements as described previously. Hepatic clinical chemistry (GGT, AST, ALT, ALP, total bilirubin), height, and weight data were analyzed. Serum PFOA concentration was associated in the model with increasing AST levels ($p = 0.009$) and inversely associated with total bilirubin ($p = 0.006$) after adjustment for age, BMI, gender, and decade of hire. No association was observed between serum PFOA concentration and GGT, ALT, and ALP. The regression models did not adjust for alcohol consumption, a potential limitation.

High-exposure community studies. A small study (n = 371) of residents of the Little Hocking water district in Ohio found inconsistent results in different analyses of liver enzymes: An association with AST but not with ALP or ALT was seen when comparing serum PFOA levels between groups with abnormal compared to normal enzyme levels, but no association with any

enzyme was seen in regression analyses with PFOA as a continuous variable (Emmett et al. 2006). A subsequent study, which included a wider set of communities in the contaminated area, investigated the correlation between serum PFOA levels and liver enzymes in a total of 47,092 samples collected from members enrolled in the C8 Health Project (Gallo et al. 2012). The association of ALT, GGT, and direct bilirubin with PFOA was assessed using linear regression models adjusted for various confounders. The median PFOA level was 0.028 μg/mL. The ln-transformed values of ALT were significantly associated with ln-PFOA (and PFOS). There was a steady increase in fitted levels of ALT per decile of PFOA, leveling off after approximately 0.030 μg PFOA/mL. Fitted values of GGT by deciles of PFOA showed a slight positive trend when adjusted for insulin resistance and BMI, but this was not confirmed in the logistic model analysis of elevated enzyme levels. Direct bilirubin levels appeared to increase at lower concentrations and then decline in a U-shaped pattern at 0.030 μg PFOA/mL.

General population studies. Lin et al. (2010) investigated the association between serum PFOA (plus three other PFASs) and liver enzymes in the adult population of the United States by analyzing data from the 1999–2000 and 2003–2004 NHANES. The study population included 2,216 adults (1076 males, 1140 females) older than 20 years who were not pregnant or nursing; had fasted more than 6 hours at the time of examination; were negative for hepatitis B or C virus; had body weight, height, educational attainment, and smoking status data available; and had serum tests for PFAS, liver function, or the five physiological measures associated with metabolic syndrome. Regression models were used to analyze the data and adjust for confounders. Mean PFOA levels were 0.00505 μg/mL and 0.00406 μg/mL for males and females, respectively. Serum PFOA concentration was divided into quartiles (Q1 = ≤ 0.0029; Q2 = ≤ 0.0042; Q3 = ≤ 0.00595; Q4 = > 0.00595 μg/ml). In the univariate regression models, liver enzymes, serum ALT, and log-GGT increased across quartiles of PFOA ($p \leq 0.012$), but total bilirubin showed no trend. The linear regression models were adjusted for (1) age, gender, and race/ethnicity; (2) age, gender, race/ethnicity, and lifestyle (smoking status, drinking status, education level), and (3) additional data for BMI, metabolic syndrome biomarkers, iron saturation status, and insulin resistance. An association was found between serum log-PFOA concentration and increasing serum ALT and log-GGT. One unit increase in serum log-PFOA was associated with an increase of 1.86 units in serum ALT measurements and a 0.08-unit increase in log-GGT measurements. Effect modification was seen: For example, stronger associations between serum PFOA concentration and serum ALT (or GGT) were found among non-Hispanic Caucasians. PFOS also was positively associated with ALT in the fully adjusted model.

The results of the occupational studies provide evidence of an association with increases in serum AST, ALT, and GGT, with the most consistent results seen for ALT. The associations were not large and they might depend on the covariates in the models such as BMI, use of lipid-lowering medications, and triglycerides (Costa et al. 2009; Olsen et al. 2000, 2003; Olsen and Zobel 2007; Sakr et al. 2007a, 2007b). Two population-based studies of highly exposed residents in contaminated regions near a fluorochemical industry in West Virginia have evaluated associations with liver enzymes, and the larger of the two studies reported associations of increasing serum ln ALT and ln GGT levels with increasing serum PFOA concentrations (Emmett et al. 2006; Gallo et al. 2012). A cross-sectional analysis of data from NHANES, representative of the U.S. national population, also found associations with ln PFOA concentration with increasing serum ALT and ln GGT levels. Serum bilirubin was inversely associated with serum PFOA in the occupational studies. A U-shaped exposure-response pattern for serum bilirubin was observed among the participants in the C8 Health Project, which might explain the inverse associations reported for occupational cohorts. Overall, an association of

serum PFOA concentration with elevations in serum levels of ALT and GGT has been consistently observed in occupational and highly exposed residential communities, and the U.S. general population. The associations are not large in magnitude, but indicate the potential of PFOA to affect liver function.

Liver Diseases

High-exposure community studies. Few studies of the relationship between PFOA and liver disease are available, but the C8 Health Project did not observe associations with hepatitis, fatty liver disease, or other types of liver disease in their initial studies. The most recent update of disease incidence in the workers identified 35 cases of nonhepatitis liver disease (with medical validation) (Steenland et al. 2015); no association was seen with cumulative exposure when analyzed without a lag (HRs by quartile 1.0, 0.58, 1.43, 1.20; trend p = 0.86 for log cumulative exposure), but there was a possible trend in the analysis using a 10-year lag (HRs by quartile 1.0, 1.46, 2.13, and 2.02; trend p = 0.40).

3.1.1.4 Biomarkers of Kidney Function and Kidney Disease

Kidney Function

PFOA has the potential to affect the kidney's function of tubular resorption because of it uses tubular transporters for excretion and resorption (see section 2.4). Since PFOA is removed from the blood by the kidney, cross-sectional analyses using serum PFOA as the exposure measure are problematic if individuals with compromised kidney function are included: PFOA concentrations could be increased in those individuals and an apparent association with GFR would be observed, even if one did not exist. Studies examining measures of kidney function are described in this section and summarized in Table 3-5.

Table 3-5. Summary of Epidemiology Studies of PFOA and Measures of Kidney Function

Reference and Study Details	PFOA Level	Results
Sakr et al. 2007a Washington Works plant Cross-sectional; all active, nonpregnant employees enrolled over 12 days in 2004 1,025 of 1,863 eligible (55%)	0.428 µg/ml LOQ 0.0005 µg/ml range 0.005–9.55 µg/mL	Reported association with uric acid but quantified results were not provided
Costa et al. 2009 Italy Cross-sectional 56 male workers (currently and formerly exposed and unexposed) with concurrent serum PFOA and clinical parameters measured in last 7 yrs	Currently exposed: mean 12.9, geometric mean 4.02, range 0.2–47 µg/mL Formerly exposed: mean 6.81 geometric mean 3.76, range 0.53–18 µg/mL	β change per µg PFOA/mL (95% CI) Uric acid 0.026 (0.001, 0.053) GEE models adjusting for age, years of exposure, year of PFOA sampling, BMI, smoking, and alcohol consumption

Reference and Study Details	PFOA Level	Results
Steenland et al. 2010 C8 Health Project, West Virginia Cross-section; adult subjects (n = 53,458; 20–≥80 years of age) participating in the C8 Health Project from 2005-2006 Subjects had consumed water for at least 1 year prior to 2004	0.0864 µg/mL, measured in 2005–2006	Increased predicted uric acid of 0.2–0.3 µg/dL with increasing deciles of PFOA or PFOS
Shankar et al. 2011 United States, NHANES Uric acid analysis: 1999–2000, 2003–2004 and 2005–2006 cycles 3,883 out of 3,974 participants ≥ 20 years of age with serum PFOA measurements; excluded subjects with missing data (n = 91); 48.3% male, mean age 46.4 years eGFR analysis: 1999–2000, 2003–2004, 2005–2006, and 2007–2008 cycles 4,587 out of 5,717 (80%) eligible 20 years or older with PFOA measures; excluded self-reported CVD (n = 572), missing data on serum creatinine or covariates (n = 558)	0.0059 µg/mL; LOD 0.1 ng/mL Quartiles, µg/mL, n 1 < 0.0028 µg/mL, 1,176 2 0.0028–0.0041 µg/mL, 1,141 3 0.0042–0.0059 µg/mL, 1,141 4 > 0.0059 µg/mL, 1,129	Mean change in uric acid, mg/dL (95% CI) by quartile 1 referent 2 0.14 (0.04–0.25) 3 0.37 (0.25–0.49) 4 0.44 (0.32–0.56), p trend 0.0001 Mean change in uric acid, mg/dL (95% CI) by ln PFOA: 0.22 (0.15–0.30) Multivariate regression adjusting for age, gender, race/ethnicity, education, smoking, alcohol consumption, BMI, hypertension, diabetes, and serum total cholesterol Hyperuricemia risk by quartile, OR (95% CI) 1 referent 2 1.14 (0.78–1.67) 3 1.90 (1.35–2.69) 4 1.97 (1.44–2.70), p trend 0.0001 Hyperuricemia risk per unit increase in ln PFOA, OR (95% CI): 1.43 (1.16–1.76) Logistic regression adjusting for age, gender, race/ethnicity, education, smoking, alcohol consumption, BMI, hypertension, diabetes, and serum total cholesterol Chronic kidney disease defined as eGFR < 60 mL/min/1.73 m^2 Quartile, OR (95% CI) 1 referent 2 0.83 (0.55–1.24) 3 1.24 (0.75–2.05) 4 1.73 (1.04–2.88) Logistic regression adjusting for age, gender, race/ethnicity, education, smoking, alcohol consumption, BMI, systolic blood pressure, diastolic blood pressure, diabetes, serum TC, and glycohemoglobin Adjustment for PFOS did not alter association with PFOA Multivariate regression of association PFOA with eGFR among subjects with and without chronic kidney disease β (SE) with -1.6 (0.8) and without -2.8 (0.6) chronic kidney disease

Reference and Study Details	PFOA Level	Results
Watkins et al. 2013 West Virginia Cross-sectional population-based survey, residents near the Washington Works plant (C8 Health Project) 9,660 (children < 18 yrs) out of 9,783 eligible with complete data for serum creatinine, height, and serum PFOA	Median measured PFOA 0.0283 µg/mL; range 0.0007–2.071; yearly serum PFOA estimated for each individual from model used to predict serum PFOA at time of enrollment, historical serum PFOA during the first 10 years of life, 3 years before enrollment or at birth	β (95% CI) change in unit eGFR (mL/min/1.73 m^2) per ln serum PFOA, -0.75 (-1.41–-0.010) Linear regression adjusting for age, gender, race, smoking, and household income; additional adjustment for regular exercise, BMI z-score, and TC did not alter association No associations of predicted serum PFOA (modeled) with eGFR

Uric Acid (risk factor for hypertension)

Occupational exposure studies. Costa et al. (2009) examined associations between serum PFOA concentration and uric acid levels in serum in workers at a fluorochemical production plant in Italy. Serum PFOA concentration was associated with uric acid levels ($p<0.05$) in 56 workers assessed concurrently over the previous 7 years. This subset of 56 workers included currently, formerly, and never exposed with relatively high serum PFOA concentrations.

High-exposure community studies. Steenland et al. (2010) examined the association of serum PFOA concentrations with uric acid levels in adult subjects (n = 53,458; 20–≥80 years) participating in the C8 Health Project from 2005–2006. The reference range for uric acid is 2.0–8.5 mg/dL. Serum samples were separated into deciles or quintiles for analysis. The data were analyzed by linear and logistic regression with uric acid as the outcome and PFOA as the exposure variable. Covariates of the model included age, gender, BMI, education, smoking, alcohol consumption, and serum creatinine. The mean serum PFOA concentration was 0.0864 µg/mL. The mean uric acid level was 5.58 mg/dL with an IQR of 4.5–6.6 mg/dL. The increase in uric acid from lowest to highest serum PFOA concentration decile was 0.2–0.3 mg/dL. The OR for high serum uric acid levels increased from the lowest to the highest quintile of PFOA serum concentrations: 1.00, 1.33 (95% CI: 1.24–1.43), 1.35 (95% CI: 1.26–1.45), 1.47 (95% CI: 1.37–1.58), and 1.47 (95% CI: 1.37–1.58). The study showed that higher serum PFOA concentrations were associated with higher incidence of high serum uric acid levels. The serum of C8 study participants included several PFASs; PFOA appeared to have a greater influence on uric acid trends than PFOS in the models employed by Steenland et al. (2010).

The C8 Science Panel (2012) combined the data from the C8 general population cohort with data from worker cohorts and concluded that there is no probable link between PFOA and stroke, hypertension, and coronary artery disease. The general population cohorts were not evaluated separately in these analyses.

General population studies. Shankar et al. (2011) investigated the association between serum PFOA (and PFOS) and uric acid concentration in the adult population of the United States by analyzing data from the 1999–2000, 2003–2004, and 2005–2006 NHANES evaluations. The study population included 3,883 adults (48.3% male) older than 20 years with data available for serum PFOA, plasma uric acid, and important covariates. Regression models were used to analyze associations with serum PFOA as a continuous variable and in quartiles. Logistic regression models analyzed risk for hyperuricemia defined as plasma uric acid > 6.8 mg/dL in males and > 6.0 mg/dL in females. Ln PFOA concentration was associated with increasing uric

acid concentration in multivariate models adjusting for age, gender, race/ethnicity, education, smoking, alcohol consumption, BMI, hypertension, diabetes, and serum TC. Mean uric acid concentration increased by 0.22 (95% CI 0.15–0.30) mg/dL per unit change in ln PFOA. A concentration-response relationship was indicated across all quartiles. In addition, an elevated hyeruricemia risk was observed with increasing serum PFOA concentration (OR 1.43, 95% CI 1.16–1.76).

Glomerular Filtration Rate

High-exposure community studies. Watkins et al. (2013) evaluated the cross-sectional association between PFOA exposure and kidney function among children aged 1<18 years (mean 12.4 ± 3.8 years) enrolled in the C8 Health Project. A total of 9,660 participants had data available on serum PFOA (median 0.0283 μg/mL), as well as serum creatinine and height, which were used to calculate an estimated glomerular filtration rate (eGFR). Linear regression was used to evaluate the association between quartiles of measured serum PFOA concentration and eGFR. A shift from the lowest to the highest quartile of measured, natural log-transformed concentrations of PFOA in serum [IQR ln (PFOA) = 1.63] was associated with a decrease in eGFR of 0.75 mL/min/1.73 m^2 (95% CI: –1.41, –0.1; p = 0.02) adjusting for age, gender, race, smoking status, and household income. With increasing quartile of serum PFOA concentrations, eGFR decreased monotonically, although the change was slight and did not attain statistical significance (p for trend across quartiles = 0.30). PFOS also was associated with a decrease in eGFR and showed a dose-related trend. Modeled predicted serum PFOA and PFOS concentrations were not associated with eGFR.

General population studies. Shankar et al. (2011) also used data from the NHANES to determine whether there was a relationship between serum PFOA levels and chronic kidney disease defined as eGFR (determined from serum creatinine) of less than 60 mL/min/1.73 m^2. Serum PFOA levels were categorized into quartiles: Q1 = <0.0028 μg/mL; Q2 = 0.0028–0.0041 μg/mL; Q3 = 0.0042–0.0059 μg/mL; Q4 = >0.0059 μg/mL. The adjusted OR for chronic kidney disease for individuals in Q4 was 1.73 (95% CI: 1.04, 2.88; p for trend = 0.015) compared with individuals in Q1. The logistic regression model was adjusted for age, gender, race/ethnicity, education, smoking, alcohol consumption, BMI, systolic blood pressure, diastolic blood pressure, diabetes, serum TC, and glycohemoglobin. Although a similar increase in OR was seen for PFOS, additional adjustment for serum PFOS did not alter the association with PFOA. In addition, the inverse association of eGFR with serum PFOA was observed over all quartiles of PFOA, as well as among individuals both with and without chronic kidney disease. Although the possibility of reverse causality could not be excluded, the association between serum PFOA and eGFR among participants without chronic kidney disease suggests a PFOA-related effect on kidney function.

Overall, studies of occupational cohorts (Costa et al. 2009), a highly exposed community (Steenland et al. 2010; Watkins et al. 2013), and the U.S. general population (Shankar et al. 2011) that evaluated uric acid levels or eGFR as a measure of kidney function found associations with decreased function, although reverse causality as an explanation cannot be ruled out. Since the URAT transporter functions in the renal resorption of PFOA, the increase in serum uric acid could be a reflection of systemic transport pharmacodynamics rather than formation biochemistry.

Kidney Disease

The occupational mortality studies have produced generally negative results with respect to the association between PFOA and mortality due to chronic kidney disease (Steenland et al. 2015; Steenland and Woskie 2012; Raleigh et al. 2014). The most recent update of incidence of chronic kidney disease in the workers in the C8 West Virginia community identified 43 cases (with medical validation) (Steenland et al. 2015); no association was seen with cumulative exposure when analyzed without a lag (HRs by quartile 1.0, 0.50, 0.69, 0.67; trend p = 0.92 for log cumulative exposure), or using a 10-year lag (HRs by quartile 1.0, 1.32, 0.50, and 0.67; trend p = 0.99).

In 2012, the C8 Science Panel concluded that there is no probable link between PFOA and chronic kidney disease. Their conclusion was based on findings in combined general population and worker cohorts, data on children enrolled in the C8 Health Project, and published data from NHANES.

3.1.1.5 Immunotoxicity

Immune suppression

Immune function—specifically immune system suppression—can affect numerous health outcomes, including risk of common infectious diseases (e.g., colds, flu, otitis media) and some types of cancer. The World Health Organization (WHO) guidelines for immunotoxicity risk assessment recommend measures of vaccine response as a measure of immune effects, with potentially important public health implications (WHO 2012).

Associations between prenatal PFOA exposure and risk of infectious diseases (as a marker of immune suppression) were not seen in two studies, although there was some indication of effect modification by gender (i.e., associations seen in females but not in males). Fei et al. (2010a) examined hospitalizations for infectious diseases in early childhood in a Danish birth cohort. Mean maternal PFOA concentration was 0.0056 µg/mL. A slightly higher risk for hospitalizations was observed in females with higher maternal PFOA concentrations (incidence rate ration [IRR] = 1.00, 1.20, 1.63, 1.74 for Q1, Q2, Q3, and Q4, respectively), and the risk for males was below 1.0 for each quartile. Overall, there was no association between hospitalizations due to infectious diseases and maternal PFOA exposure; similar results were found with PFOS.

Okada et al. (2012) examined history of otitis media (and of allergic conditions) in children up to the age of 18 months. Mean maternal PFOA concentration was 0.0014 µg/mL. Cord blood immunoglobulin E (IgE) level decreased significantly with high maternal PFOA concentration among female infants, but not male infants. No significant associations were observed between maternal PFOA levels (and PFOS) with the incidence of otitis media (or specific types of allergies or wheeze). Two other studies, described below, examined reported history of colds and gastroenteritis in children up to age 3 years (Granum et al. 2013) or colds and flu in adults (Looker et al. 2014). Granum et al. (2013) observed associations between prenatal PFOA exposure and frequency of colds or gastroenteritis episodes, but not with a variable based on “ever had” this condition in the past year. Looker et al. (2014) did not observe associations between serum PFOA and “ever had” or frequency of colds or flu in the past year.

In 2012, the C8 Science Panel (2012) concluded that there is no probable link between PFOA and common infections, including influenza, in children or adults. The panel based their

conclusions on a subset of adult members of the cohort, a subset of mother-child pairs, and published data from other researchers.

Three studies have examined response to one or more vaccine (e.g., measured by antibody titer) in relation to higher exposure to PFOA in children (Grandjean et al. 2012; Granum et al. 2013) or adults (Looker et al. 2014); the latter study was conducted in the high-exposure C8 community population (Table 3-6).

Table 3-6. Summary of Epidemiology Studies of PFOA and Immune Suppression (Vaccine Response)

A cohort of 411 adult members of the C8 Health Project was evaluated in 2010 for an association between serum PFOA levels and antibody response following vaccination with an inactivated trivalent influenza vaccine (Looker et al. 2014). A prevaccination serum sample was collected at the time of vaccination and the postvaccination serum sample was collected 21 ± 3 days later. The geometric mean serum PFOA level was 0.0337 μg/mL (95% CI 0.0298, 0.0382) and participants were divided into quintiles for analyses. PFOA was negatively associated with geometric mean A/H3N2 antibody titer rise, but no association was found with antibody titers for A/H1N1 and influenza type B. No association was found between antibody titers and PFOS levels.

Antibody responses to diphtheria and tetanus toxoids following childhood vaccinations were assessed in context of exposure to five perfluorinated compounds (Grandjean et al. 2012). The prospective study included a birth cohort of 587 singleton births during 1999–2001 from the National Hospital in the Faroe Islands. Serum antibody concentrations were measured in children at age 5 years prebooster, approximately 4 weeks after the booster, and at age 7 years. Prenatal exposures to perfluorinated compounds were assessed by analysis of serum collected from the mother during week 32 of pregnancy (PFOA geometric mean 0.0032 μg/mL; IQR 0.00256–0.00401); postnatal exposure was assessed from serum collected from the child at 5 years of age (PFOA geometric mean 0.00406 μg/mL; IQR 0.00333–0.00496). Multiple regression analyses with covariate adjustments were used to estimate the percent difference in specific antibody concentrations per twofold increase in PFOA concentration in both maternal and 5-year serum. Maternal PFOA serum concentration was negatively associated with antidiphtheria antibody concentration (-16.2%) at age 5 before booster. The biggest effect was found in comparison of antibody concentrations at age 7 with serum PFOA concentrations at age 5 where a twofold increase in PFOA was associated with differences of -36% (95% CI, -52%–-14%) and -25% (95% CI, -43%–-2%) for tetanus and diphtheria, respectively. Additionally at age 7, a small percentage of children had antibody concentrations below the clinically protective level of 0.1 international unit (IU) /mL. The ORs of antibody concentrations falling below this level were 4.20 (95% CI, 1.54–11.44) for tetanus and 3.27 (95% CI, 1.43–7.51) for diphtheria when age 7 antibody levels were correlated with age 5 PFOA serum concentrations. Maternal and child PFOS levels also were negatively associated with antibody titers in children.

The effects of prenatal exposure to perfluorinated compounds on vaccination responses and clinical health outcomes in early childhood were investigated in a subcohort of the Norwegian Mother and Child Cohort Study (Granum et al. 2013). A total of 56 mother-child pairs, for whom both maternal blood samples at delivery and blood samples from the children at 3 years of age, were evaluated. Antibody titers specific to measles, rubella, tetanus, and influenza were measured as these vaccines are part of the Norwegian Childhood Vaccination Program. Serum IgE levels also were measured. Clinical health outcomes, including common colds and gastroenteritis, at ages 1, 2, and 3 years were assessed by means of a questionnaire sent to participants. Mean maternal plasma PFOA concentration was 0.0011 μg/mL at delivery; the PFOS level was 0.0056 μg/mL and PFNA and PFHxS were below the LOQ. PFOA levels in the children were not measured. No associations were found with PFOA or any perfluorinated compound and antibody levels to the vaccines with one exception. A slight, but significant, inverse relationship between maternal PFOS level and anti-rubella antibodies in children at 3 years was found (β = -0.8 [95% CI -0.14, -0.02]). Maternal PFOA levels were not associated with adverse childhood health outcomes.

In summary, three studies have reported decreases in response to one or more vaccines (e.g., measured by antibody titer) in relation to higher exposure to PFOA in children (Grandjean

et al. 2012; Granum et al. 2013) and adults (Looker et al. 2014). In the two studies examining exposures in the background range (i.e., general population exposures, < 0.010 μg/ml), the associations with PFOA also were seen with other correlated PFASs. This limitation was not present in the study in adults in the high-exposure C8 community population. Serum PFOA levels in this study population were approximately 0.014–0.090 μg/mL.

Asthma

The association between serum levels of perfluorinated compounds and childhood asthma was investigated by Dong et al. (2013). The cross-sectional study included a total of 231 children aged 10–15 years with physician-diagnosed asthma and 225 age-matched nonasthmatic controls. Between 2009 and 2010, asthmatic children were recruited from two hospitals in Northern Taiwan, while the controls were part of a cohort population in seven public schools in Northern Taiwan. Serum was collected for measurement of 10 perfluorinated compounds, absolute eosinophil counts, total IgE, and eosinophilic cationic protein. A questionnaire was administered to asthmatic children to assess asthma control and to calculate an asthma severity score (e.g., frequency of attacks, use of medicine, and hospitalization) during the previous 4 weeks. Associations of perflourinated compound quartiles with concentrations of immunological markers and asthma outcomes were estimated using multivariable regression models. Nine of 10 perfluorinated compounds were detectable in ≥84.4% of all children with levels generally higher in asthmatic children than in nonasthmatics. Serum concentrations of PFOA in asthmatic and nonasthmatic children were 0.0015 ± 0.0013 μg/mL and 0.0010 ± 0.0011 μg/mL, respectively; four other compounds were measured at higher concentrations with the highest levels for PFOS and perfluorotetradecanoic acid. The adjusted ORs for asthma association with the highest versus lowest quartile levels were significantly elevated for seven of the compounds. For PFOA, the OR was 4.05 (95% CI: 2.21, 7.42). In asthmatic children, absolute eosinophil counts, total IgE, and eosinophilic cationic protein concentration were positively associated with PFOA levels with a significant monotonic trend with increasing serum concentration. None of these biomarkers were significantly associated with PFOA levels in nonasthmatic children. Serum PFOA levels were not significantly associated with asthma severity scores among the children with asthma, although four other compounds did show an association.

Humblet et al. (2014) evaluated a cohort from NHANES to investigate children's PFAS serum levels, including PFOA, and their association with asthma-related outcomes. Sera were analyzed for 12 PFASs with focus on PFOA, PFOS, PFHxS, and PFNA. A total of 1,877 children aged 12–19 years with at least one serum sample available were included. Asthma and related outcomes were self-reported. Median serum PFOA levels were 0.0043 μg/mL for those ever having asthma and 0.0040 μg/mL for children without asthma. In the multivariable adjusted model, a doubling of PFOA level was associated with an increased odds of ever having asthma (OR=1.18, 95% CI 1.01, 1.39). PFOS was inversely associated with asthma and no associations were found between the other PFAS and outcome.

On the basis of epidemiological and other data available, the C8 Science Panel (2012) found no probable link between PFOA and asthma in children and adults and chronic obstructive pulmonary disease (COPD) in adults.

Autoimmune conditions

The most recent report on the worker cohort initially described by Leonard et al. (2008) included 6,026 workers evaluated for disease incidence, not just mortality (Steenland et al.

2015). Lifetime serum cumulative dose was estimated by combining occupational and nonoccupational exposures. Median measured serum level was 0.113 μg/mL based on samples collected in 2005. Statistically significant positive trends were found between log of cumulative exposure and ulcerative colitis and rheumatoid arthritis. Rate ratios for the highest quartile compared to the lowest quartile were 2.74 (95% CI 0.78, 9.65) for ulcerative colitis and 4.45 (95% CI 0.99, 19.9) for rheumatoid arthritis.

The C8 Science Panel (2012) combined these data with findings from the C8 general population cohort and concluded that there is a probable link between PFOA and ulcerative colitis. Using historical estimates for serum PFOA, the C8 Science Panel found a significant positive, dose-response trend with a relative risk (RR) for the highest quartile compared to the lowest of 3.18 (95% CI 1.84, 5.51). The panel concluded that there was no probable link between PFOA and autoimmune diseases, including rheumatoid arthritis, lupus, type1 diabetes, Crohn's disease, or multiple sclerosis. The C8 Science Panel also concluded that there is no probable link between PFOA and osteoarthritis. These analyses by the panel included both worker and general population cohorts.

3.1.1.6 Thyroid Effects

Several epidemiology studies have evaluated thyroid function and/or thyroid disease and its association with serum PFOA concentrations. Thyroid disease is more common in females than in males. Among the PFOA studies, the three most highly powered studies with the largest number of participants are one from the general U.S. population (Melzer et al. 2010) and two from highly exposed individuals within the C8 population (Lopez-Espinosa et al. 2012; Winquist and Steenland 2014b). Two of these studies are of adults (Melzer et al. 2010; Winquist and Steenland 2014b) and one is of children/adolescents (Lopez-Espinosa et al. 2012). Hypothyroidism is characterized by elevated thyroid stimulating hormone (TSH) and low T4; elevated TSH in conjunction with normal T4 and triiodothyronine (T3) is defined as subclinical hypothyroidism. Hyperthyroidisim is characterized by elevated T4 and low TSH; low levels of TSH in conjunction with normal T4 and T3 is defined as subclinical hyperthyroidism. Some studies focused on the prevalence of clinically defined disease (or the subclinical state), and others examined variations in TSH, T4, and T3 measurements among people who have not been diagnosed with a thyroid disease. Both hypothyroidism and hyperthyroidism can result from an autoimmune pathogenesis involving destruction of thyroid tissue. A summary of the studies on PFOA's association with thyroid disease or changes in thyroid hormones follows, and is depicted in Table 3-7 (studies in adults) and Table 3-8 (studies in special populations—children and pregnant females).

Occupational exposure studies. Serum PFOA levels were obtained from volunteer workers of the Cottage Grove, Minnesota, PFOA plant in 1993 (n = 111) and 1995 (n = 80) as part of the medical surveillance program and analyzed to determine a relationship between TSH and PFOA concentration (Olsen et al. 1998). Employees were placed into four exposure categories based on their serum PFOA levels: 0–1 μg/mL, 1– < 10 μg/mL, 10– < 30 μg/mL, and >30 μg/mL. Statistical methods used to compare PFOA levels and hormone values included multivariable regression analysis, ANOVA, and Pearson correlation coefficients. TSH was significantly ($p = 0.002$) elevated in 10–<30 μg/mL exposure category for 1995 only (mean serum TSH level was 2.9 ppm). However, mean TSH levels for the other exposure categories, including the ≥30 μg/mL category, were all the same (1.7 ppm). In 1993, TSH was elevated in this same exposure category, but was not statistically significant ($p = 0.09$) when compared to the other exposure categories.

Table 3-7. Summary of Epidemiology Studies of PFOA and Thyroid Effects in Adults

In an expanded and refined analysis of the data reported in Olsen et al. 2003, Olsen and Zobel (2007) looked at the relationship between serum PFOA concentration and TSH, serum and free T4, and T3 levels in workers at the Decatur, Antwerp, and Cottage Grove production plants. The fluorochemical workers consisted of males (aged 21–67) from the Antwerp, Belgium (n = 196); Cottage Grove, Minnesota (n = 122); and Decatur, Alabama (n = 188) production facilities who volunteered to participate in the medical surveillance program in 2000. The mean serum PFOA concentration was 2.21 μg/mL for all sites combined. No association between TSH, serum T4, and PFOA concentration was observed. A negative association ($p<0.01$) between free T4 and serum PFOA concentration was observed in the unadjusted and adjusted (age, BMI, and alcohol consumption) models for all locations combined; no association was observed for the individual locations. A positive association ($p<0.05$) was observed between T3 and serum PFOA concentration in the unadjusted and adjusted models for all locations combined, the Antwerp plant, and the Decatur plant. The authors noted that the results were not considered clinically relevant because the results were within normal reference range. Steenland et al. (2015) did not find an association between self-reported thyroid disease and PFOA levels among 3,713 workers at the Washington Works plant in West Virginia who participated in the C8 Health Project.

Two studies measured thyroid hormones in PFOA-exposed workers, but did not present an analysis of the relation between PFOA exposure and hormone levels. Both studies noted that the thyroid hormone values were in the normal range (Costa et al. 2009; Sakr et al. 2007a).

High-exposure community studies. Emmett et al. (2006) examined the association of serum PFOA with thyroid disease in 371 residents of the Little Hocking, Ohio, water district as described previously. No association was observed between serum PFOA and thyroid disease. Serum PFOA was decreased (not significantly different) in subjects with self-reported disease (e.g., hyperthyroidism, goiter or enlarged thyroid, hypothyroidism) (0.387 μg/mL; n = 40) compared to subjects without thyroid disease (0.451 μg/mL; n = 331). No association was seen between serum PFOA and TSH when analyzed with linear regression or by t-test comparison of PFOA in the abnormal TSH (n = 24, 6%) and normal TSH groups ($p = 0.59$).

Participants in the C8 Health Project were examined for an association between PFOA levels and thyroid disease (Winquist and Steenland 2014b). The cohort included 28,541 community members and 3,713 workers who had completed study questionnaires during 2008–2011. The median serum PFOA level at enrollment in 2005–2006 was 0.0261 μg/mL for the combined cohort, 0.0242 μg/mL for the community members, and 0.1127 μg/mL for the workers. Retrospective serum levels for the community cohort, estimated from air and water concentrations, residential history, and water consumption rates, were used to estimate yearly intakes. For the workers, yearly serum estimates were modeled from work history information and job-specific concentrations. Cox proportional hazard models, stratified by birth year, were used to assess self-reported adult thyroid disease hazard in relation to time-varying yearly or cumulative (sum of yearly estimates) estimated PFOA serum concentration, controlling for gender, race, education, smoking, and alcohol consumption. For the combined cohort, quintiles for yearly exposure were 0.00011–<0.0047, 0.0047–<0.00849, 0.00849–<0.0216, 0.0216–<0.100, and 0.100–3.303 μg/mL; quintiles for cumulative exposure were 0.0001–<0.115, 0.115–<0.202, 0.202–<0.497, 0.497–2.676, and 2.676–97.396 μg/mL·year. As expected, the number of thyroid disease cases was higher among females than among males. Positive associations were seen with the cumulative exposure and the per-year exposure metrics for incidence of all thyroid disease (as well as for specific subtypes), with the observations seen primarily in females

(Table 3-7). When limited to disease occurring after the 2005–2006 serum collection, the number of incident cases was reduced from 2,008 to 454, and the patterns of associations were more variable. No associations between estimated serum PFOA level and thyroid disease were found in the analysis limited to workers in this study population (Steenland et al. 2015).

The C8 Science Panel (2012) used data from the C8 general population cohort and concluded that there is a probable link between PFOA and thyroid disease.

General population studies. Bloom et al. (2010) investigated the associations between serum PFAS, including PFOA, and TSH and free thyroxine (FT4). The serum samples came from 31 participants (27 males, 4 females; mean age 39 years) of the 1995–1997 New York State Angler Cohort Study Dioxin Exposure Substudy. The study subjects each completed a questionnaire and provided a blood sample for serum analysis. The questionnaire contained questions about sport-fish and game consumption, lifestyle, demographic factors, and medical history. The serum samples were analyzed for TSH and FT4 in 2003 by immunometric chemiluminescent sandwich assay and for PFAS in 2006 by ion pair extraction high-performance LC-MS/MS. Regression models were used to analyze the data and adjust for confounders. No subjects reported use of thyroid medication or physician-diagnosed goiter or thyroid conditions. Mean TSH concentration (range 0.43–15.70 μIU/mL) was within normal range (0.40–5.00 μIU/mL) with the exception of one subject. Mean FT4 (0.90–1.55 ng/dL) was within normal range (0.80–1.80 ng/dL) for all subjects. The mean serum PFOA concentration was 0.00133 μg/mL and ranged from 0.00057 to 0.00258 μg/mL. The males had a significantly higher serum PFOA concentration than the females (0.00147 μg/mL versus 0.00105 μg/mL; $p = 0.047$). There was no association between serum PFOA concentration (or PFOS) and TSH or FT4.

The relationship between serum levels of PFOA, PFOS and other persistent organic pollutants and thyroid biomarkers was investigated in older adults (Shrestha et al. 2015). Levels of TSH, FT4, T4, and T3 were measured in 51 males and 36 females with a mean age of 63.6 years. None of the participants had thyroid disease or were taking thyroid medication. Covariates in the analysis included age, gender, education level, the sum of polychlorinated biphenyls (∑PCBs) and polybrominated diphenyl ethers (∑PBDEs), smoking status, and alcohol consumption. The mean PFOA serum level was 0.0104 ± 0.0057 μg/mL for all participants. In both unadjusted and adjusted models, PFOA was significantly ($p<0.05$ or 0.01) and positively associated with T4 and T3; a possible dose-response was not evaluated in this small sample. A statistical interaction was detected between age and PFOA for effects on FT4 and T4 suggesting that the positive associations of PFOA were potentiated by age. PFOS was also positively associated with FT4 and T4.

Melzer et al. (2010) examined the association between serum PFOA concentration and thyroid disease in the general population of the United States by analyzing data from the 1999–2000, 2003–2004, and 2005–2006 NHANES The population included 3,966 adults (2,066 females, 1,900 males) older than 18 years. Each of the participants answered a questionnaire, had a physical examination, and provided blood and urine samples for analysis. Serum samples were analyzed for PFOA concentration by solid-phase extraction coupled to isotope dilution/high-performance LC-MS/MS. Data on diseases diagnosed by a physician and confounding factors, including year of NHANES, age, gender, race/ethnicity, education, smoking status, BMI, and alcohol consumption were obtained from the questionnaire. Individuals were considered to have thyroid disease if they responded on the questionnaire to having a physician-diagnosed disease or if they were taking medication for either hypothyroidism or hyperthyroidism.

Regression models were used to analyze the data and adjust for confounders. Serum PFOA concentration was divided into quartiles for each gender. In females, serum PFOA concentration ranged from 0.0001–0.123 μg/mL (Q1 = 0.0001–0.0026; Q2 = 0.0027–0.004; Q3 = 0.0041–0.0057; Q4 = 0.0057–0.123), and in males, serum PFOA concentration ranged from 0.0001–0.0459 μg/mL (Q1 = 0.0001–0.0036; Q2 = 0.0037–0.0052; Q3 = 0.0053–0.0072; Q4 = 0.0073–0.0459). Females in PFOA Q4 were more likely to report current thyroid disease [OR = 2.24, 95% CI: 1.38–3.65, p = 0.002] compared to females in Q1 and Q2. No association between serum PFOA concentration and thyroid disease was observed in males. With PFOS, the opposite was found, with males in the highest quartile, but not females, more likely to report thyroid disease. Data interpretation was limited by the cross-sectional study design, lack of information on the specific thyroid disorder diagnosis in the questionnaire responses, and single serum samples for PFOA measurements taken at the same time disease status was ascertained through the questionnaire. Thus, the possibility of reverse causality cannot be eliminated.

Another study of 1,181 members of NHANES for survey years 2007–2008 and 2009–2010 examined the association between serum PFOA levels (and 12 other PFASs) and thyroid hormone levels (Wen et al. 2013). Multivariable linear regression models were used with serum thyroid measures as the dependent variable and individual natural log-transformed PFAS concentration as a predictor along with confounders. The geometric mean serum PFOA level was 0.00415 μg/mL. A positive association between PFOA level and free T3 (FT3) was found in females as a 1-unit increase in natural log-serum PFOA increased serum total T3 concentration by 6.628 ng/dL (95% CI 0.545, 12.712, p = .035). However, the association was no longer significant when PFOS, PFNA, and PFHxS levels were included in the model.

A different type of examination was undertaken by Pirali et al. (2009). The study measured intrathyroidal levels of PFOA (and PFOS) in thyroid surgical specimens to determine if a relationship existed between PFOA and the clinical, biochemical, and histological phenotype of thyroid disease patients. Serum PFOA concentration also was measured to determine if a relationship existed between thyroid tissue and serum PFOA levels. Patients (n = 28; 8 males, 20 females; 33–79 years) with benign multinodular goiters (n = 15), Graves' disease (n = 7), malignant papillary carcinoma (n = 5), and malignant follicular carcinoma (n = 1) were included in the study. Informed consent, clinical examination, work history, thyroid hormone and antibody measurements, thyroid ultrasound, fine-needle aspiration of nodules greater than 1 cm, and serum samples (n = 21) were performed or collected prior to surgery. The control group consisted of thyroid tissues collected at autopsy from subjects with no history of thyroid disease (n = 7; 5 males, 3 females; 12–83 years) and serum samples from 10 subjects with no evidence of thyroid disease. The student's t-test, Mann-Whitney U-test, Pearson and Spearman's correlation tests, and chi-square test with Fisher's correction were used to compare group results. Regression analysis was used to test the effect of different variables independently of a covariate.

The median concentration of PFOA in thyroid tissue was 2.0 ng/g (range = 0.4–4.6 ng/g). The patients were divided into three different groups: group I (toxic and nontoxic multinodular goiter, n = 12), group II (differentiated thyroid cancer, n = 6), and group III (Hashimoto's thyroiditis or Graves' disease, n = 10). Thyroid PFOA concentration for the control group, group I, group II, and group III ranged from 1.0–6.0, 0.4–4.4, 1.4–4.0, and 1.0–4.6 ng/g, respectively. Serum PFOA concentration for the control group, group I, group II, and group III ranged from 0.004–0.0137, 0.0012–0.0166, 0.0051–0.0096, and 0.0039–0.0125 μg/ml, respectively. The concentration of PFOA in the thyroid and serum was similar between control and thyroid patients at the time of measurement. Age, gender, residence, working activity, malignant /

nonmalignant conditions, antibodies, thyroid hormone concentrations, and ultrasound parameters were not associated with thyroid or serum PFOA concentration. There also was no correlation between serum and thyroid PFOA concentration. Similar results were obtained with PFOS.

Children. Three studies evaluated thyroid function in children (or children and young adults) (Table 3-8). In the children from the C8 cohort who were highly exposed to PFOA, Lopez-Espinosa et al. (2012) observed positive associations between prenatal PFOA (modeled maternal levels) and any thyroid disease or clinical hypothyroidism; similar results were seen with the child's PFOA level. Associations were not seen with subclinical hypothyroidism or hyperthyroidism, or TSH or total T4 levels among children without thyroid disease. In a study from the Netherlands of 52 males and 31 females, increasing T4 levels in females were associated with increasing prenatal PFOA concentrations (as measured in cord blood samples) (de Cock et al. 2014); no associations were reported in males. A study of adolescents and young adults (aged 12–30 years) from Taiwan did not observe associations between serum PFOA concentrations and TSH or T4 levels (Lin et al. 2013).

Pregnant females. Several studies of thyroid have been conducted in pregnant females (Table 3-8), mostly reporting null associations between maternal PFOA concentration and thyroid status during pregnancy (Berg et al. 2015; Chan et al. 2011; Wang et al. 2013). The exception to these results is the only study that included an analysis stratified by presence of antithyroid peroxidise (anti-TPO) antibodies (Webster et al. 2014), in which associations between PFOA and TSH were seen only among females with high autoantibody levels. This finding supports the importance of further research into the association between PFOA and autoimmunity and autoimmune conditions.

Chan et al. (2011) examined the association between hypothyroxinemia and serum PFOA concentration (and PFOS) in pregnant Canadian females (n = 271; 20.1–45.1 years of age, ≥22 weeks of gestation) in a matched case-control study. Maternal serum from the second trimester was collected between December 15, 2005, and June 22, 2006, as part of an elective prenatal screen for birth defects. Serum samples were analyzed for TSH and FT4 concentrations and PFOA. The cases of hypothyroxinemia (n = 96) had normal TSH concentrations and FT4 concentrations in the lowest 10^{th} percentile (≤8.8 pmol/L). The controls (n = 175) had normal TSH concentrations and FT4 concentrations between the 50^{th} and 90^{th} percentiles (12–14.1 pmol/L). Maternal age, weight, and gestational age at blood draw and dichotomized at 50^{th} percentiles were included as confounders, and race was included as a covariate. Chi-square tests and regression models were used to analyze the data. Overall, the geometric mean PFOA level was 0.00135 µg/mL. Statistical comparisons used the geometric mean serum PFOA concentration in the cases of 3.10 nmol/L and 3.32 nmol/L in the controls. There was no association between serum PFOA concentration (or PFOS) and hypothyroxinemia in pregnant females.

A cross-sectional study of 903 pregnant females evaluated the association between plasma PFOA levels and plasma TSH (Wang et al. 2013). Twelve other PFASs also were quantified and evaluated. The females were a cohort of the Norwegian Mother and Child Cohort Study and the blood samples were drawn at approximately week 18 of gestation. The median PFOA concentration was 0.0022 µg/mL with an interquartile range of 0.00157–0.00295 µg/mL. No association was found between plasma levels of PFOA and TSH. PFOS was associated with higher TSH levels, but plasma levels of other PFASs were unrelated to TSH.

Expanding on the above study, Berg et al. (2015) investigated the association between a number of PFASs, including PFOA, and TSH, T3, T4, FT3, and FT4. A subset of 375 females in the Norwegian Mother and Child Cohort Study with blood samples at about gestational week 18 and at 3 days and 6 weeks after delivery were included. Seven compounds were detected in more than 80% of the blood samples, with PFOS present in the highest concentration followed by PFOA. The median PFOA level was 0.00153 µg/mL, and the females were assigned to quartiles based on the first blood sample at week 18 of gestation. Females in the highest quartile had significantly higher mean TSH than females in the first quartile; however, when PFOS concentration was included as a covariate, the association was not significant.

A study of Canadian females (n = 152) evaluated maternal serum PFOA levels (and PFHxS, PFNA, and PFOS) for associations with thyroid hormone levels during the early second trimester of pregnancy, weeks 15–18 (Webster et al. 2014). Mixed effects linear models were used to examine associations between PFOA levels and FT4, total T4, and TSH; associations were made for all females and separately for females with high levels of TPO antibody, a marker of autoimmune hypothyroidism. Median serum PFOA was 0.0017 µg/mL. No associations were found between levels of PFOA (or PFOS and PFHxS), and thyroid hormone levels in females with normal antibody levels. PFNA was positively associated with TSH. Clinically elevated TPO antibody levels were found in 14 (9%) of the study population. In the females with high antibody levels, PFOA, as well as PFNA and PFOS, was strongly and positively associated with TSH. An IQR increase in maternal PFOA concentrations was associated with a 54% increase in maternal TSH compared to the median TSH level. PFNA and PFOS concentrations were associated with 46% and 69% increases, respectively, in maternal TSH.

As illustrated above, numerous epidemiology studies have evaluated thyroid function and/or thyroid disease in association with serum PFOA concentrations (Tables 3-7 and 3-8). As noted previously, thyroid disease is more common in females. Several studies provide support for an association between PFOA exposure and incidence or prevalence of thyroid disease, and include large studies of representative samples of the general U.S. population (Melzer et al. 2010) and the high-exposure C8 community population (Lopez-Espinosa et al. 2012; Winquist and Steenland 2014b). Two of these studies are of adults (Melzer et al. 2010; Winquist and Steenland 2014b) and one is of children/adolescents (Lopez-Espinosa et al. 2012). The trend for an association with thyroid disease was seen in females in the C8 population (Winquist and Steenland 2014b) and the general population (Melzer et al. 2010), and in children (Lopez-Espinosa et al. 2012); this was most often hypothyroidism. Association between PFOA and TSH also was seen in pregnant females with anti-TPO antibodies (Webster et al. 2014). In contrast, generally null associations were found between PFOA and TSH or thyroid hormones (T3 or T4) in people who have not been diagnosed with thyroid disease.

3.1.1.7 Diabetes and Related Endpoints

Occupational exposure studies. Leonard et al. (2008) examined cause of death among former workers at the DuPont Washington Works plant in West Virginia. The cohort consisted of 6,027 employees (4,872 males and 1,155 females) who had worked at the plant from 1948 through 2002. The DuPont Epidemiology Registry and U.S. National Death Index were used to obtain causes of death. SMRs were estimated using three reference populations; the populations of the United States and West Virginia and the DuPont regional worker reference population excluding workers at the Washington Works plant. A significant increase in diabetes mortality was observed for Washington Works plant workers compared to the DuPont regional worker

reference population [SMR = 197, 95% CI: 123, 298]. However, no regression analyses were done with PFOA levels.

The Leonard et al. study (2008) was updated in a cohort mortality study conducted by Steenland and Woskie (2012) to include 5,791 individuals who had worked at the DuPont West Virginia plant for at least 1 year between 1948 and 2002. Mean duration of employment was 19 years. Deaths through 2008 were ascertained through either the National Death Index or death certificate data. Exposure quartiles were assessed by estimated cumulative annual serum levels based on blood samples from 1,308 workers taken during 1979–2004 and time spent in various job categories (ppm-years). Referent groups included both nonexposed DuPont workers in the same region and the U.S. population. Overall, the mean cumulative exposure was 7.8 ppm-years and the estimated average annual serum level was 0.35 μg/mL. Compared to the referent rates from other DuPont workers, cause-specific mortality rates were elevated for diabetes (n = 38; SMR=1.90; 95% CI 1.35, 2.61). These data are limited by the small number of cases and the restriction to mortality as an outcome.

The most recent report on the above cohort included 6,026 workers evaluated for disease incidence, not just mortality (Steenland et al. 2015). Lifetime serum cumulative dose was estimated by combining occupational and nonoccupational exposures. Median measured serum level was 0.113 μg/mL based on samples collected in 2005. No association was found between PFOA level and type II diabetes incidence rate.

High-exposure community studies. MacNeil et al. (2009) examined the association of PFOA with type II diabetes in adult participants of the C8 Health Project (n = 54,468; age 20 to >80 years). Serum PFOA concentration was divided into deciles using the population distribution. Other PFAS were not evaluated in this study. Serum PFOA (deciles), BMI, gender, family history of diabetes, race, use of cholesterol-lowering medicine, and use of blood pressure-lowering medicine were used to analyze the data in categorical and logistic regression models for the outcome of type II diabetes. Serum fasting glucose levels were the focus for a linear regression analysis of the study population (n = 21,643) excluding type II diabetics and those who had provided nonfasting blood samples. The mean serum PFOA concentration for the entire study population was 0.0868 μg/mL and 0.0913 μg/mL for subjects with type II diabetes validated by medical review (n = 3,539).

There was no association between serum PFOA concentration and fasting serum glucose level in subjects characterized as nondiabetic. The mean serum PFOA concentration was 0.0929 μg/mL in subjects who self-reported type II diabetes (n = 4,278) and 0.1227 μg/mL in subjects diagnosed in the last 10 years (n = 1,055). No association was observed between type II diabetes and serum PFOA concentration. The OR by decile was 1.00, 0.71, 0.60, 0.72, 0.65, 0.65, 0.87, 0.58, 0.62, and 0.72. The results of the analysis indicated that PFOA exposure is not associated with type II diabetes among the population studied. Data interpretation was limited by the cross-sectional study design, which made it difficult to determine if PFOA exposure preceded disease.

The C8 Science Panel (2012) combined these data from the C8 general population cohort with follow-up data and data from worker cohorts, and concluded that there is no probable link between PFOA and type II diabetes.

General population studies. Preconception serum levels of PFOA (and other PFASs) were evaluated in females attempting pregnancy in relation to risk of developing gestational diabetes

(Zhang et al. 2015). The 258 participants were members of the Longitudinal Investigation of Fertility and the Environment (LIFE) study with blood samples taken during 2005–2009. The ORs and 95% CIs of gestational diabetes associated with each SD increment of preconception serum PFOA concentration (log-transformed) (and six other PFASs) were estimated with the use of logistic regression after adjusting for confounders. Preconception mean serum PFOA levels were 0.0033 μg/mL for the entire cohort, 0.00394 μg/mL in females with gestational diabetes and 0.00307 μg/mL in females without gestational diabetes. A significant positive association was found between PFOA and risk of gestational diabetes in the fully adjusted model (OR=1.86; 95% CI 1.14, 3.02). Associations for six other PFAS were slightly increased (e.g., PFOS OR=1.13), but did not attain statistical significance.

Metabolic syndrome is a combination of medical disorders and risk factors that increase the risk of developing cardiovascular disease and diabetes. Lin et al. (2009) investigated the association between serum PFOA (plus three other PFASs) and glucose homeostasis and metabolic syndrome in adolescents (aged 12–20 years) and adults (aged >20 years) by analyzing the 1999–2000 and 2003–2004 NHANES data. The National Cholesterol Education Program Adult Treatment Panel III guidelines were used to define adult metabolic syndrome and the modified guidelines were used to define adolescent metabolic syndrome. The study population included 1,443 subjects (474 adolescents, 969 adults) at least 12 years of age who had a morning examination and triglyceride measurement. There were 266 male and 208 female adolescents and 475 male and 493 female adults. Multiple linear regression and logistic regression models were used to analyze the data. Covariates included age, gender, race, smoking status, alcohol intake, and household income. Log-transformed PFOA concentration was 1.51 and 1.48 ng/mL for adolescents and adults, respectively. In adults, serum PFOA concentration was associated with increased β-cell function (β coefficient 0.07, $p<0.05$). Serum PFOA concentration was not associated with metabolic syndrome, metabolic syndrome waist circumference, glucose concentration, homeostasis model of insulin resistance, or insulin levels in adults or adolescents. Both PFOS and PFNA were positively associated with some of the endpoints associated with metabolic syndrome.

Nelson et al. (2010) examined the relationship between polyfluoroalkyl chemical serum concentration, including PFOA, and insulin resistance as previously described for data from NHANES. Fasting insulin and fasting glucose were used to determine the homeostatic model assessment for insulin resistance. No association was found between serum PFOA concentration, or any other PFAS, and insulin resistance.

Overall, these studies show a lack of association of PFOA with diabetes, metabolic syndrome, and related endpoints.

3.1.1.8 Reproductive and Developmental Endpoints

Several studies have examined the relationship between PFOA exposures and reproductive, gestational, and developmental endpoints as well as postnatal growth and maturation in humans. Pregnancy-related endpoints include gestational age (Nolan et al. 2009), measures of fetal growth (Apelberg et al. 2007; Fei et al. 2007, 2008a; Monroy et al. 2008; Nolan et al. 2009; Stein et al. 2009; Washino et al. 2009), miscarriage or preterm birth (Stein et al. 2009), birth defects (Stein et al. 2009), hypertension and preeclampsia (Darrow et al. 2013; Savitz et al. 2012a, 2012b; Stein et al. 2009), and fecundity (Fei et al. 2009; Vélez et al. 2015). Infant growth and development during the first 7 years (Andersen et al. 2010, 2013; Fei et al. 2008b, 2010a, 2010b; Høyer et al. 2015b) and postnatal growth and maturation, including neurodevelopment (Fei and

Olsen 2011; Hoffman et al. 2010; Høyer et al. 2015a; Liew et al. 2014; Stein et al. 2013) and risk of adult obesity (Halldorsson et al. 2012) also have been studied. Male reproductive endpoints evaluated in humans include sperm count and semen quality (Buck Louis et al. 2015; Joensen et al. 2009, 2013; Vested et al. 2013). Female pubertal development was examined in three studies (Christensen et al. 2011; Kristensen et al. 2013; Lopez-Espinosa et al. 2011). As noted previously, the focus of this review is on pregnancy-related outcomes, specifically pregnancy-related hypertension and preeclampsia, measures of fetal growth, and pubertal development. Within each section, the discussion is divided into occupational exposure studies (if applicable), the C8 high-exposure community studies, and general population studies.

Several analyses are based on the Danish National Birth Cohort (Andersen et al. 2010, 2013; Fei et al. 2007, 2008a, 2008b, 2009, 2010a, 2010b; Fei and Olsen 2011). The females (n = 1,400) and their infants were randomly selected, and the study included those who provided their first blood samples between gestational weeks 4 and 14 and gave birth to a single live-born child without congenital malformation. The females participated in telephone interviews—at 12 and 30 weeks gestation, when the children were 6 and 18 months of age, and when the children were 7 years of age—and filled out a food frequency questionnaire. As the children aged, more questionnaires were completed by the mothers with regard to behavioral health and motor coordination. Highly structured questionnaires were used to gather information on possible confounders, including infant gender, maternal age, parity, socio-occupational status, prepregnancy BMI, and smoking during pregnancy. The National Hospital Discharge Register was used to obtain birth weight, gestational age, placental weight, birth length, head and abdominal circumference data, Apgar scores based on heart rate, respiratory effort, reflex, irritability, muscle tone, and skin color. Plasma PFOA concentration was determined from the first blood samples of 1,399 females, from the second blood samples of 200 females, and from cord blood samples of 50 infants by solid-phase extraction high-performance LC-MS/MS. PFOA concentrations were divided into quartiles (Fei et al. 2009, 2010b), with the lowest quartile designated as the reference group, as follows: <lower limit of quantification– (LLOQ–) 0.00390, 0.00391–0.00520, 0.00521–0.00696, and ≥ 0.00697 μg/mL. Regression models were used to analyze the data. Results of these studies are included in the following discussion of results for specific endpoints.

Pregnancy-related hypertension and preeclampsia. There are no occupational exposure and general population studies examining pregnancy-related hypertension and preeclampsia in relation to PFOA exposure. The only data available come from the high-exposure C8 Health Project study population (Table 3-9).

Several studies, using different designs and exposure measures, have examined birth outcomes, including pregnancy-induced hypertension or preeclampsia in infants born to mothers in the high-exposure C8 community population in West Virginia and Ohio (information obtained from questionnaire-based pregnancy histories or from linkage to birth records) (Table 3-9). Stein et al. (2009) used an exposure measure based on individual serum PFOA levels obtained in the 2005–2006 baseline survey to examine birth outcomes (based on self-report) in 1,845 births in the 5 years preceding the PFOA measurement. Savitz et al. (2012a, 2012b) included births from 1990 to 2004, modeling exposure based on the serum measurements in 2005, information obtained in the 2005 baseline questionnaire regarding residential history, information on historical environmental releases, and PKs. In one of the analyses (study II in Savitz et al. 2012b), linkage with birth records was used to verify the preeclampsia outcome.

Table 3-9. Summary of Epidemiology Studies of PFOA and Pregnancy-Induced Hypertension or Preeclampsia

Study	PFOA Level	Results
Stein et al. 2009 United States (C8 Health Project) n = 1,845 pregnancies in the 5 years before enrollment Exposure based on serum collected in 2005 Outcome based on pregnancy history collected in 2005	Median 0.0212 µg/mL	OR (95% CI), preeclampsia per IQR (lnPFOA) increase in PFOA: 1.1 (0.9, 1.3) [IQR(lnPFOA)=0.0395 µg/mL] < 50th percentile 1.0 (referent) ≥ 50th 1.3 (0.9, 1.9) < 50th percentile 1.0 (referent) 50-75th 1.5 (1.0, 2.3) 75-90th 1.2 (0.7, 2.1) > 90th 0.9 (0.5, 1.8)
Savitz et al. 2012a United States (C8 Health Project) n = 11,737 pregnancies in 1990-2006 Modeled exposure based on serum collected in 2005, residential history, and other data Outcome based on pregnancy history collected in 2005		OR (95% CI), preeclampsia per IQR(lnPFOA) increase in PFOA: 1.13 (1.00–1.28) [IQR (lnPFOA)=0.00219 µg/mL] per 0.100 µg/mL increase in PFOA: 1.08 (1.01–1.15) < 40th percentile 1.0 (referent) 40-60th 1.2 (1.0, 1.5) 60-80th 1.1 (0.9, 1.4) ≥ 80th 1.2 (1.0, 1.6) Also noted stronger associations with Bayesian calibration of exposure and among women with highest quality residential history
Savitz et al. 2012b United States (C8 Health Project) n = 4,547 pregnancies in 1990-2004 Modeled exposure based on serum collected in 2005, residential history, and other data Outcome based on linkage to birth records	Median 0.0134 µg/mL	With Bayesian calibration of exposure: OR (95% CI) per IQR (lnPFOA) increase in PFOA: 1.13 (0.92, 1.37) [IQR (lnPFOA)=0.00192 µg/mL] per 0.100 µg/mL increase in PFOA: 0.97 (0.85, 1.11) < 40th percentile 1.0 (referent) 40-60th 1.0 (0.7, 1.4) 60-80th 1.5 (1.1, 2.1) ≥ 80th 1.2 (0.8, 1.7)
Darrow et al. 2013 United States (C8 Health Project) n = 1,330 pregnancies in 2005-2010; 770 first pregnancies after PFOA measures; 947 (pregnancies in 2005-2007) Exposure based on serum collected in 2005	Geometric mean 0.016 µg/mL Mean 0.031	OR (95% CI) per log unit increase in PFOA Full analysis: 1.27 (1.05, 1.55) (adjusted for PFOS) 1.22 (0.99, 1.51) By quintile: Q1 up to 0.0069 µg/mL 1.0 (referent) Q2 0.0069 – < 0.0111 2.39 (1.05, 5.46) Q3 0.0111 – < 0.0189 3.43 (1.50 (7.82) Q4 0.0189 – < 0.0372 3.12 (1.35, 7.18) Q5 ≥ 0.0372 3.16 (1.35, 7.38) First pregnancy after PFOA measure 1.23 (0.92, 1.64) Pregnancies in 2005-2007: 1.35 (1.04, 1.76)

Darrow et al. (2013) examined birth outcomes in births that occurred in the 5 years after the PFOA measurement. In this study, reproductive history in a follow-up interview in 2010 was collected from females who had provided serum for PFOA measurement in 2005–2006. Singleton live births among 1,330 females after January 1, 2005, were linked to birth records to identify outcomes of pregnancy-induced hypertension and other outcomes (e.g., preterm birth, low birth weight, and birth weight among full-term infants). Thus there is a progressively greater refinement and reduction in misclassification (or exposure and outcome) among this set of

studies. Each of these studies provides some evidence of an association between PFOA exposure and risk of pregnancy-induced hypertension or preeclampsia, with the most robust findings from the methodologically strongest study (Darrow et al. 2013). Maternal serum PFOA levels were positively associated with pregnancy-induced hypertension, with an adjusted OR per log unit increase in PFOA of 1.27 (95% CI: 1.15, 1.55). PFOS also was positively associated with pregnancy-induced hypertension.

The C8 Science Panel (2012) considered both hypertension and preeclampsia together in determining a link between PFOA and pregnancy-induced hypertension. Some studies conducted by the panel found no associations while others showed positive associations. Among the studies with positive associations, no clear dose response was indicated. However, the panel decided that the evidence was sufficient to conclude that PFOA has a probable link to pregnancy-induced hypertension.

Fetal growth. Many different measures of fetal growth can be used in epidemiology studies. Birth weight is widely available (as it is routinely collected in medical records and birth certificates). Low birth weight (defined as < 2,500 g) can be a proxy measure for preterm birth (particularly when accurate gestational age dating is not available). Other measures of fetal growth such as small for gestation age might more accurately reflect fetal growth retardation.

Both birth weight and gestational age are characterized as two-part distributions, with a larger Gaussian portion representing term births and a longer tail representing preterm births. Increased risks of complications, including infant mortality, are seen in preterm births (or low birth-weight births). When analyzed as a continuous measure, changes in birth weight might not be clinically significant, as small changes in the distribution among term infants do not result in a shift into the distribution seen in preterm infants (Savitz 2007; Wilcox 2010). This consideration differs from that of some other types of continuous measures, such as neurodevelopment scales, blood pressure, or cholesterol, in which shifts in the distribution are expected to move a greater proportion of the population into an “at risk” or “abnormal” level.

High-exposure community studies. As noted in the previous discussion of preeclampsia, several studies using different designs and exposure measures have examined birth outcomes in infants born to mothers in the high-exposure C8 community population in West Virginia and Ohio (Darrow et al. 2013; Nolan et al. 2009; Savitz et al. 2012a, 2012b; Stein et al. 2009). These studies include analyses of birth weight and of low birth weight, and have not observed associations between PFOA and either birth weight among term births or the risk of low birth weight among all (singleton) births (Table 3-10).

Based on these data, as well as continued follow-up of the community cohort, the C8 Science Panel (2012) concluded that there is no probable link between PFOA and low birth weight.

General population studies. Two studies examined associations between maternal PFOA levels and birth weight among term infants (Fei et al. 2007; Monroy et al. 2008). The larger of these is from the Danish National Birth Cohort by Fei et al. (2007) (Table 3-10). In this study of 1,207 term births, the change in birth weight per log unit increase in PFOA was -9 g (95% CI: -20, 2 g).

Table 3-10. Summary of Epidemiology Studies of PFOA and Birth Weight

Study	PFOA Level	Results
High-Exposure Community		
Darrow et al. 2013 United States (C8 Health Project) n = 1,629 pregnancies in 2005-2010; 770 first pregnancies after PFOA measures; 947 (pregnancies in 2005-2007) Exposure based on serum collected in 2005	Geometric mean 0.0162 µg/mL Mean 0.031 µg/mL	Change in birth weight per log unit increase (95% CI) Full analysis: -8 (-28, 12) g (adjusted for PFOS) -4 (-25, 17) g First pregnancy after PFOA measure 5 (-22, 33) g Pregnancies in 2005-2007: -10 (-34, 14) g OR (95% CI) for low birth weight (< 2500 g) per log unit increase Full analysis: 0.94 (0.75, 1.17) (adjusted for PFOS) 0.91 (0.72, 1.16) First pregnancy after PFOA measure 1.07 (0.78, 1.47) Pregnancies in 2005-2007: 0.91 (0.70, 1.17) [Similar results in Nolan et al. 2009; Savitz et al. 2012a, 2012b; Stein et al. 2009]
General Population: Birth Weight Among Term Births		
Fei et al. 2007 Denmark n = 1,207 (term births) Blood sample at 4-14 weeks	0.0056 µg/mL	Change in birth weight per unit increase (95% CI) -8.7 (-19.5, 2.1)
Monroy et al. 2008 Canada n = 101 Cord blood sample	0.0019 µg/mL (cord blood)	Change in PFOA per g change in birth weight: Beta = 0.000171 (p = 0.65)
General Population: Birth Weight or Low Birth Weight Among All Births (by time of blood collection)		
Fei et al. 2007 Denmark Blood sample at 4-14 weeks n = 1,399 (full sample) 3.8% preterm	0.0056 µg/mL	Change in birth weight per unit increase (95% CI) -10.6 (-20.8, -0.47) g OR (95% CI) for low birth weight (< 2500 g) by quartile Q1 up to 0.00390 µg/mL 1.0 (referent) Q2 0.00391-0.00520 4.3 (0.51, 37) Q3 0.00521-0.00696 3.7 (0.42, 32) Q4 ≥ 0.00697 2.4 (0.27, 22) (Trend p = 0.94)
Hamm et al. 2010 Canada n = 252 Blood sample at 15-16 weeks 8.3% preterm	0.0021 µg/mL	Change in birth weight per ln unit increase (95% CI) -37.4 (-86.0, 11.2) g
Whitworth et al. 2012 Norway n = 849 Blood sample at around 17 weeks 3.9% preterm	0.0021 µg/mL	Change in birth weight z-score per unit increase (95% CI) -0.03 (-0.10, 0.04)
Maisonet et al. 2012 United Kingdom n = 395 Blood sample at 10-28 weeks 3.1% preterm	0.0037 µg/mL	Change in birth weight per log unit increase -34.2 (-54.8, -13) g
Washino et al. 2009 Japan n = 428 Blood sample at 23-35 weeks % preterm not reported	0.0014 µg/mL	Change in birth weight per log unit increase (95% CI) -75 (-191, 42) g

Study	PFOA Level	Results
Apelberg et al. 2007 United States (Baltimore) n = 293 Cord blood sample 13% preterm	0.0016 µg/mL (cord blood)	Change in birth weight per log unit increase (95% CI) -104 (-213, 5) g
Chen et al. 2012 Taiwan n = 429 Cord blood sample 9.3% preterm	0.0018 µg/mL (cord blood)	Change in birth weight per log unit increase (95% CI) -19 (-63, 25) g

Fei et al. (2007, 2008a), and other studies in the general population have examined PFOA in relation to birth weight or risk of low birth weight (or other measures of fetal growth), without restriction to term births (Table 3-10). These studies vary in size from approximately 250 to 1,400 births, and also in terms of timing of exposure measure. Fei et al. (2007, 2008a) used blood samples collected early in pregnancy (4–14 weeks), three studies used samples collected in the second trimester (Hamm et al. 2010; Maisonet et al. 2012; Whitworth et al. 2012), Washino et al. (2009) used samples collected in the third trimester, and two studies used cord blood samples (Apelberg et al. 2007; Chen et al 2012). These studies also differed in the percent of births that were preterm (ranging from approximately 3% to 13%), and presented results using different types of analyses (i.e., the form of the exposure and outcome variables, continuous, ln-transformed, categorical, etc). Each of the analyses indicates a negative association between PFOA levels and birth weight (i.e., a decrease in birth weight with increase in PFOA), although CIs were wide.

In a systematic review based on the Navigation Guide methods (Woodruff and Sutton 2014), Johnson et al. (2014) identified the general population studies shown in Table 3-10 and the high-exposure C8 Health Project studies published through 2012. The results from the meta-analysis showed that a 0.001 µg/mL increase in serum or plasma PFOA was associated with a -18.9 g (95% CI -29.8, -7.9) difference in birth weight.

Preeclampsia is a condition that causes the pregnant female to be hypertensive because of reduced renal excretion associated with a decrease in GFR. Preeclampsia is often accompanied by low birth weight (Whitney et al. 1987). Morken et al. (2014) used a subset of the Norwegian Mother and Child Cohort to evaluate the relationship between GFR and fetal size. Participants included 470 preeclamptic patients and 483 nonpreeclamptic females; plasma creatinine measured during the second trimester was used to estimate GFR. For the overall cohort, for each mL/min increase in GFR, infant weight at birth increased 0.73–0.83 g, depending on the method used to calculate GFR. The increases were greater and statistically significant in females with preeclampsia. Differences were not statistically significant for the nonpreeclamptic group. Morken et al. (2014) was not a study of perfluorochemicals and there were no serum measurements of any PFASs. However, because PFOA/PFOS serum levels are expected to be higher with a lower GFR, the finding stimulated examination of the GFR as it relates to serum PFAS levels and the low birth weight identified in the epidemiology studies (Verner et al. 2015; Vesterinen et al. 2014).

The evidence for an inverse association between PFOA levels and birth weight raised the question of whether reverse causality linked to maternal GFR played a role in the association of low birth weight with serum PFOA. PFOA excretion by the kidney is dependent, in part, on the

GFR. Conditions that result in impairment of GFR (and thus increased serum PFOA) also could be related to fetal growth restriction, confounding the association between serum PFOA and decreased birth weight. Vesterinen et al. (2014) examined evidence pertaining to the relationship between fetal growth and maternal GFR using Navigation Guide systematic review methods. They identified 35 relevant studies published between 1954 and 2012 that met the Navigation Guide criteria for inclusion in the analysis. All studies were rated as "low" or "very low" quality due to inconsistency of findings among studies, small sample sizes resulting in large CIs around a mean, and high risk of bias in conduct of the study. The quality rating led to the conclusion that data were "inadequate" to determine an association between fetal growth and GFR. However, a more recent publication described below, expanded the database on the relationship between GFR and fetal size.

Verner et al. (2015) modified the human pregnancy/lactation PK model of PFOA by Loccisano et al. (2013) described in section 2.6.1 to evaluate the association between GFR, serum PFOA levels, and birth weight. When GFR was accounted for in the model simulations, the reduction in birth weight associated with increasing serum PFOA was less than that found by the author's meta-analysis of the same data. This finding suggests that a portion of the association between prenatal PFOA and birth weight is confounded by maternal GFR differences within the populations studied. The true association for each 1 ng/mL increase in PFOA could be closer to a 7-g reduction (95% CI -8, -6) compared to the 14.72-g reduction (95% CI: -8.92, -1.09) predicted by meta-analysis of the epidemiology data without a correction for low GFR as observed in individuals with pregnancy-induced hypertension or evidence of preeclampsia.

Other pregnancy outcomes. Gestational age and preterm birth and risk of miscarriage were not associated with PFOA in the studies examining pregnancy outcomes in the high-exposure community (Darrow et al. 2014; Nolan et al. 2009, 2010). In contrast, PFOS was positively associated with miscarriage (Darrow et al. 2014).

Congenital anomalies were diagnosed in 1.8%, 1.9%, and 2.0% of the mothers with water provided completely, partially, or not at all by LHWA, respectively (Nolan et al. 2010). When adjusted for confounders, no statistically significant differences were found. Complications with labor and delivery were observed in 32.5%, 35.9%, and 41.9% of the mothers with water provided completely, partially, or not at all by LHWA, respectively. Mothers with water provided by LHWA did have in increased likelihood of having dysfunctional labor, but the number of reported cases was low. Mothers with one or more maternal risk factors were 37.5%, 34.4%, and 39.3% of the populations with water provided completely, partially, or not at all by LHWA, respectively. Adjusted regression models showed no statistical differences across water service status. An increased likelihood of anemia (crude OR 11, 95% CI: 1.8–64) and dysfunctional labor (crude OR 5.3, 95% CI: 1.2–24) in mothers with water provided by LHWA was found, but the number of reported cases was low. No association was found between PFOA and increased incidence of congenital anomalies, other labor and delivery complications, or maternal risk factors.

The C8 Science Panel (2012) concluded that there is no probable link between PFOA and birth defects, miscarriage, preterm birth, or stillbirth. Their conclusion was based on findings in Nolan et al. (2010), Stein et al. (2009), and other data available to the panel. These other data included historical estimates of serum PFOA generated by the panel based on amounts released from the plant and an individual's residential history.

Fei et al. (2009) examined the association between plasma PFOA concentration and longer time to pregnancy (TTP) as a measure of fecundity in 1,240 females. TTP was categorized as follows: immediate pregnancy (<1 month), 1–2, 3–5, 6–12, and >12 months. Having >12 months TTP or having used fertility treatment to get pregnant were used to define infertility. A total of 620 females had a TTP within the first 2 months of trying to conceive and 379 had a TTP of ≥6 months with 188 of those females having a TTP of >12 months. The mean plasma PFOA concentration was 0.0056 μg/mL for females who planned their pregnancies, and 0.0054, 0.0060, and 0.0063 μg/mL for TTPs <6 months, 6–12 months, and >12 months, respectively. Plasma PFOA concentration was significantly greater ($p<0.001$) in females who had TTPs >6 months than those with TTPs <6 months. The females with TTPs >6 months were more likely to be older, have middle socio-occupational status, and have a history of spontaneous miscarriage or irregular menstrual cycles. The adjusted odds for infertility increased 60–154% among females with >0.00391 μg/mL plasma PFOA concentration compared to females with <0.00391 μg/mL plasma concentration. The fecundity OR was 0.72, 0.73, and 0.60 for the three highest PFOA concentration quartiles. In the likelihood ratio test, the trend was significant ($p<0.001$). Both TTP and infertility also were positively associated with serum PFOS levels in this study. Although the results of the study suggest that plasma PFOA concentration could reduce fecundity, the authors noted that selection bias, the unknown quality of the sperm, unknown frequency and timing of intercourse, and abnormal hormone levels might have an impact on the results and fecundity.

Participants enrolled in the Maternal-Infant Research on Environmental Chemicals Study, a Canadian pregnancy and birth cohort, were evaluated for an association between serum PFOA levels (as well as PFOS and PFHxS) and TTP (Vélez et al. 2015). A total of 1,743 females, enrolled between 2008 and 2011 and having a blood sample collected during the first trimester were included. Infertility was defined as having a TTP of >12 months or requiring infertility treatment for the current pregnancy. The geometric mean plasma PFOA level was 0.00166 μg/mL. The crude fecundity OR per one SD increase in log-transformed serum concentration was significantly lower for PFOA (OR=0.91, 95% CI 0.86, 0.96) (and for PFHxS). In fully adjusted models, PFOA (and PFHxS) was associated with an 11% reduction in fecundability per one SD increase in log-transformed serum concentration (OR=0.89; 95% CI 0.83, 0.94). The adjusted odds of infertility increased by 31% per one SD increase of PFOA (OR=1.31; 95% CI 1.11–1.53) (and of PFHxS). No significant associations were observed for PFOS.

Fei et al. (2010b) reported on the effects of PFOA and PFOS on the length of breast-feeding. Self-reported data on the duration of breast-feeding were collected during the telephone interviews with each mother at 6 and 18 months after birth of the child. Higher levels of PFOA were significantly associated with a shorter duration of breast-feeding. In multiparous females, the adjusted OR for weaning before 6 months was 1.23 (95% CI, 1.13–1.33) for each 1-ng/mL increase in PFOA concentration in the maternal blood and the increase was dose-related. A similar association was observed with PFOS levels. No association was found between length of breast-feeding and PFOA levels in females having their first child. The authors speculate that the observed associations might be noncausally related to previous length of breast-feeding or to reduction of PFOA and PFOS through lactation.

Pubertal development. Two studies examined development of puberty in females in relation to prenatal exposure to PFOA as measured through maternal or cord blood samples (Christensen et al. 2011; Kristensen et al. 2013), and another study examined PFOA exposure measured concurrently with the assessment of pubertal status in females and in males (Lopez-Espinosa et al. 2011) (Table 3-11).

Table 3-11. Summary of Epidemiology Studies of PFOA and Pubertal Development

Study	PFOA Level	Results
Prenatal Exposure: General Population		
Christensen et al. 2011 United Kingdom Pregnancy cohort, with case-control of early menarche in follow-up n = 218 cases (menarche before age 11.5 yrs) and 230 controls	0.0036-0.0039 µg/mL (maternal)	Median (75th percentile) in cases: 3.9 (5.0) controls: 3.6 (4.7) (p = 0.15) OR (95% CI) above versus below median 1.29 (0.86, 1.93) per ln-unit increase in PFOA 1.01 (0.61, 1.68)
Kristensen et al. 2013 Denmark Pregnancy cohort, with follow-up of 343 (79% of eligible) daughters at age 20 Health questionnaire and exams/hormone measurements (for n = 254)	0.0036 µg/mL (maternal)	Difference in age at menarche (months) by exposure group low (0.001–0.003 µg/mL) 0.0 (referent) medium (0.003–0.0043 µg/mL) 0.9 (-3.0, 4.8) high (0.0044–0.0198 µg/mL) 5.3 (1.3, 9.3) continuous 1.01 (0.22, 1.89)
Peripubertal Exposure: High-Exposure Community		
Lopez-Espinosa et al. 2011 United States (C8 Health Project) n = 2,931 girl and 3,076 boy, aged 8-18 yrs Self-reported menarche (girls) and free or total testosterone (boys)	Median 0.058 µg/mL	Prevalence of menarche in girls OR / 95% CI / days delay Q1: 1.0 (referent) Q2: 1.01 (0.65-1.58) -4 Q3: 1.00 (0.64-1.58) -1 Q4: 0.75 (0.49-1.15) 69 Prevalence of delayed puberty in boys OR / 95% CI / days delay Q1: 1.0 (referent) Q2: 0.54 (0.35-0.84) 142 Q3: 0.50 (0.32-0.87) 163 Q4: 0.57 (0.37-0.89) 130 Results were broadly similar when the analysis was based on estradiol levels to define menarche or when the models included PFOA and PFOS jointly, though significance was reduced in some comparisons.

Christensen et al. (2011) used data from a prospective cohort study in the United Kingdom to perform a nested case-control study examining the association between age at menarche and gestational exposure to perfluorinated chemicals, including PFOA and PFOS. The study population from the Avon Longitudinal Study of Parents and Children included single-birth female subjects who had completed at least two puberty staging questionnaires between the ages of 8 and 13 years and whose mothers provided at least one analyzable prenatal serum sample. If more than one serum sample was available, the earliest sample provided was used for analysis. The study does not provide information as to when samples were collected. The females were divided into two groups: those who experienced menarche prior to age 11.5 years (n = 218) and a random sample of those who experienced menarche after age 11.5 (n = 230). Confounders such as the mother's prepregnancy BMI, age at delivery, age at menarche, educational level, and the child's birth order and ethnic background were included in linear and logistic regression models used to analyze the data. The median maternal serum PFOA concentrations were 0.0039 and 0.0036 µg/mL for the early menarche and nonearly menarche groups, respectively. The authors noted a modest nonsignificant association between the odds of earlier menarche and prenatal serum PFOA concentrations above the median. For all models, the CIs included the null value of 1.0. Similar results were obtained for PFOS.

Effects of prenatal exposure to PFOA (and PFOS) on female and male reproductive function was evaluated in 343 females and 169 males whose mothers participated in a cohort in 1988–1989 (Kristensen et al. 2013; Vested et al. 2013). Maternal blood samples were collected during week 30 of gestation. Follow-up was initiated in 2008 when the offspring were ~20 years old. Median serum PFOA level was 0.0036 μg/mL for the mothers with daughters evaluated. In adjusted regression analysis, daughters from mothers in the highest PFOA tertile had a 5.3-month later age at menarche (95% CI 1.3, 9.3) than those in the lowest tertile. No association was found between prenatal exposure to PFOS and age of menarche. No statistically significant relationships were found between PFOA (or PFOS) exposure and cycle length, reproductive hormone levels, or number of follicles assessed by ultrasound (Kristensen et al. 2013).

Lopez-Espinosa et al. (2011) examined the association of serum PFOA concentration and the age of puberty in exposed children of the Mid-Ohio Valley. Data from the C8 Health project (e.g., sex steroid hormone levels, self-reported menarche status) along with detailed date of birth information were used to determine age of puberty in males (n = 3,076) and females (n = 2,931) aged 8–18 years. Serum PFOA concentrations were divided into quartiles: <0.0114, 0.0114–0.023, >0.023–0.058, and >0.058 μg/mL. Confounders such as age at survey, BMI, BMI *z*-score, height, family income, ethnicity, smoking status, alcohol consumption, and date and time of sample collection were included in the logistic regression models used to analyze the data. The median PFOA concentrations were 0.026 and 0.020 μg/mL in males and females, respectively. No association between PFOA concentration and puberty was observed for males. Reduced odds of having reached puberty was associated with higher PFOA exposure in females (OR=0.57, 95% CI 0.37–0.89). There were 130 days of delay between the highest and lowest quartile. Reduced odds of experiencing menarche at a younger age (10–15 years) also was observed (OR 0.83, 95% CI 0.74–0.93). The results suggested that PFOA was associated with a later age of menarche. PFOS was associated with delayed puberty in both males and females. The authors expressed caution in interpretation of the data because of lack of serum PFOA concentration prior to puberty, PFOA concentration having been measured after the attainment of puberty, and lack of secondary sexual maturation data (i.e., physical, Tanner criteria, and biomarker measurements).

Male reproductive effects. Joensen et al. (2009) examined the association between PFASs, including PFOA, and testicular function in 105 Danish males who provided semen and blood samples as part of reporting for the military draft in 2003. The males chosen for the study had the highest testosterone concentrations (ranging from 30.1 to 34.8 nmol/L; n = 53; 18.2–24.6 years) and lowest testosterone concentrations (ranging from 10.5 to 15.5 nmol/L; n = 52; 18.2–25.2 years). Regression models were used to analyze associations between PFOA and testicular function. Median serum PFOA concentration was 0.0044, 0.0050, and 0.0049 μg/mL in the high testosterone, low testosterone, and combined groups, respectively. A nonsignificant negative association was observed between serum PFOA concentration and semen volume, sperm concentration, sperm count, sperm motility, or sperm morphology. No association was observed between serum PFOA concentration and testosterone, estradiol, sex hormone-binding globulin (SHBG), luteinizing hormone (LH), follicle-stimulating hormone (FSH), and inhibin B. However, significantly fewer ($p<0.05$) morphologically normal sperm were seen in males with high combined levels of PFOA/PFOS (6.2 million spermatozoa) than in males with low PFOA/PFOS levels (15.5 million spermatozoa).

In a slightly expanded study, Joensen et al. (2013) investigated the associations between PFASs, including serum PFOA concentration, and reproductive hormones and semen quality in

247 healthy young Danish males (mean age 19.6 years). Serum samples were analyzed for PFOA as well as total testosterone (T), estradiol, SHBG, LH, FSH, and inhibin-B. The mean PFOA level was 0.0035 μg/mL. No associations were found between PFOA levels (or 12 other PFAS) and any hormone level or semen quality parameters. PFOS levels were negatively associated with testosterone.

An association between serum levels of seven PFASs and 35 semen quality parameters was evaluated in 462 males enrolled in the LIFE study cohort (Buck Louis et al. 2015). The males were from Michigan and Texas with a mean age of 31.8 years and mean PFOA levels 0.00429–0.00509 μg/mL. PFOA was significantly associated with a lower percentage of sperm with coiled tails, an increased curvilinear velocity, and a slightly larger acrosome area of the head. In total, six PFASs (including PFOA) were associated with changes in 17 semen quality endpoints.

Effects of prenatal exposure to PFOA (and PFOS on male reproductive function was evaluated in 169 males whose mothers participated in a cohort in 1988–1989 (Vested et al. 2013). Maternal blood samples were collected during week 30 of gestation. Follow-up was initiated in 2008 when the offspring were ~20 years old. Median serum PFOA level was 0.0038 μg/mL for mothers with sons evaluated. Multivariable regression models showed significant negative trends for sperm concentration and total sperm count in association with *in utero* exposure to PFOA. A 34% reduction in sperm concentration (95% CI 58, 5%) and a 34% reduction in total count (95% CI 62, 12%) were estimated for the highest exposure tertile compared with the lowest tertile. Maternal PFOA level also was positively associated with higher FSH and LH levels in the sons. No associations were found between PFOA level and percentage of progressive sperm, sperm morphology, semen volume, or testicular volume. PFOS was not associated with any outcome (Vested et al. 2013).

3.1.1.9 Steroid Hormones

Occupational exposure studies. Olsen et al. (1998) examined several hormones, including cortisol, estradiol, FSH, dehydroepiandrosterone sulfate, 17 gamma-hydroxyprogesterone (a testosterone precursor), free testosterone, T, LH, prolactin, and SHBG in male workers at the Cottage Grove, Minnesota, production plant for 1993 and 1995. This was the same population used for the thyroid hormone study described above for 111 workers in 1993 and 80 in 1995. Employees were placed into four exposure categories based on their serum PFOA levels: 0–1 μg/mL, 1– < 10 μg/mL, 10– < 30 μg/mL, and >30 μg/mL. Statistical methods used to compare PFOA levels and hormone values included multivariable regression analysis, ANOVA, and Pearson correlation coefficients. No association between serum PFOA and any hormone was observed, but some trends were observed. When the mean measures of the various hormones were compared by exposure categories, there was a statistically significant elevation in prolactin ($p = 0.01$) in 1993 only for the 10 workers whose serum PFOA levels were between 10 and 30 μg/mL compared to the lower two exposure categories.

Estradiol levels in the >30 μg/mL PFOA group in both years were 10% higher than in the other PFOA groups, but the difference was not statistically significant. These results were confounded by estradiol being correlated with BMI ($r = 0.41$, $p<0.001$ in 1993, and $r = 0.30$, $p<0.01$ in 1995). The authors postulated that the study might not have been sensitive enough to detect an association between PFOA and estradiol because measured serum PFOA levels were likely below the observable effect levels suggested in animal studies (e.g., 55 μg/mL PFOA in the CD rat). Only three employees in this study had PFOA serum levels that high. They also

suggest that the higher estradiol levels in the highest exposure category could suggest a threshold relationship between PFOA and estradiol.

In the Sakr et al. study (2007a) of 1,025 workers at the DuPont Washington Works facility in West Virginia, an association was observed between serum PFOA and serum estradiol ($p = 0.017$) and testosterone ($p = 0.034$) in male workers; however, circadian variations of hormones were not taken into consideration during analysis. The biological significance of the results is unknown.

Costa et al. (2009) found no association between serum PFOA concentration and estradiol or testosterone in 53 male workers at a PFOA production plant in Italy based on medical surveillance data collected between 2000 and 2007.

High-exposure community studies. Knox et al. (2011) examined the endocrine disrupting effects of perfluorocarbons in females from the C8 Health Project by analyzing the relationship between serum PFOA, serum estradiol concentration, and menopause onset. The population included females over age 18 years (n = 25,957). Serum PFOA and estradiol concentrations were determined from blood samples. Females who were pregnant; had had full hysterectomies; and were taking any prescription hormones, selective estrogen receptor modulators, and/or fertility agents were excluded from estradiol analysis. Serum PFOA concentrations were grouped into quintiles (natural log-transformation)—Q1 = 0.00025–0.0112; Q2 = 0.0113–0.0198; Q3 = 0.0199–0.0367; Q4 = 0.0368–0.0849; and Q5 = 0.0850–22.412 μg/mL. Estradiol analysis was calculated by age group—18–42 years, >42 ≤ 51 years, and >51 ≤ 65 years. Menopause was determined by questionnaire. Menopause analysis was calculated by age group—30–42 years, >42 ≤ 51 years, and >51 ≤ 65 years—and excluded those who reported having had hysterectomies. Logistic regression models were adjusted for smoking, age, BMI, alcohol consumption, and regular exercise. PFOA concentration in females who had had hysterectomies was significantly higher than in females who had not had hysterectomies. Serum PFOA and estradiol concentrations were not associated, while PFOS levels were negatively associated with estradiol. The odds of attaining menopause analysis in the oldest group of females, showed that all quintiles were significantly higher for all quintiles than the lowest, and in females between the ages of 42 and 51 years, Q3, Q4, and Q5 were significantly higher than the lowest. PFOS also was associated with increased odds of attaining menopause in women 42–51 years and >51 years. Data interpretation was limited by the cross-sectional study design and survey-reported menopause without age or independent confirmation.

3.1.1.10 Neurodevelopment

High-exposure community studies. A subset of 321 children enrolled in the C8 Health Project was assessed for neurobehavioral development 3–4 years after enrollment (Stein et al. 2013). The children had serum samples collected at enrollment in 2005–2006 with the current follow-up evaluation conducted in 2009–2010, when the children were 6–12 years old. Both the mother and teacher completed surveys to elicit information on each child's executive function, attention deficit hyperactivity disorder- (ADHD-) like behavior, and behavioral problems. Information on family demographics and other health conditions of the child were included as confounders. Linear regression was used to determine the association between PFOA levels and mother and teacher reports.

The median PFOA level was 0.0351 µg/mL with an IQR of 0.0158–0.0941 µg/mL. When comparing the highest to the lowest PFOA quartile, survey results from the mother for both executive function and ADHD showed a favorable association for males, but an adverse association for females. These findings were not replicated when males and females were analyzed together or with results from the teacher surveys. No association was found between PFOA levels and either mother or teacher scores for behavioral problems in females and males.

In 2012, the C8 Science Panel concluded that there is no probable link between PFOA exposure and neurodevelopmental disorders in children, including attention deficit disorders and learning disabilities. Their conclusion was based on epidemiology studies conducted by the panel and other data available.

General population studies. Fei et al. (2008b) examined the association between plasma PFOA concentration in pregnant females and motor and mental developmental milestones of their children. The mothers self-reported the infant's fine and gross motor skills and mental development at 6 and 18 months of age. There was no association between maternal plasma PFOA concentration and Apgar score or between maternal plasma PFOA concentration and fine motor skills, gross motor skills, or cognitive skills at 6 and 18 months of age. The children born to females having higher plasma PFOA concentrations reached developmental milestones at the same times as children born to females having lower plasma PFOA concentrations. The authors concluded that there was no association between maternal early pregnancy levels of PFOA and motor or mental developmental milestones in offspring. However, in children at 18 months, mothers with higher PFOS levels were slightly more likely to report that their babies started sitting without support at a later age.

A subset of the Danish National Birth Cohort was evaluated for an association between prenatal PFAS exposure and the risk of cerebral palsy (Liew et al. 2014). A total of 156 cases of cerebral palsy were identified and matched to 550 randomly selected controls. Stored maternal plasma samples were analyzed for 16 PFAS and six compounds were quantifiable in >90% of the samples. For the cerebral palsy cases and matched controls, median maternal PFOA levels were 0.00456 and 0.00400 µg/mL, respectively, for males and 0.00390 and 0.00404 µg/mL, respectively, for females. Per natural-log unit increase in maternal PFOA level, the risk of developing cerebral palsy in males was significantly increased (RR=2.1; 95% CI 1.2, 3.6). Positive associations were also found with PFOS and perfluoroheptane sulfonate. No association was found between any PFAS level and risk of cerebral palsy in females.

Fei and Olsen (2011) examined the association between prenatal PFOA (and PFOS) exposure and behavior or coordination problems in children at age 7. The children and their mothers were part of the Danish National Birth Cohort. Behavioral problems were assessed using the Strengths and Difficulties Questionnaire (SDQ), and coordination problems were assessed using the Developmental Coordination Disorder Questionnaire (DCDQ) completed by the mothers. A total of 787 mothers completed the SDQ and 537 completed the DCDQ for children aged 7.01–8.47 years (mean age 7.15 years). The mean maternal PFOA concentration was 0.0057 µg/mL, and PFOA levels were divided into quartiles: <LLOQ-0.00395, 0.00396–0.00532, 0.00535–0.00711, and 0.00714–0.02190 µg/mL. A child having higher scores in total difficulties, emotional symptoms, and hyperactivity was negatively associated with the second or third PFOA quartiles (OR=0.56, 95% CI 0.27–1.19; $p<0.05$ and OR=0.36, 95% CI 0.15–0.82; $p<0.05$, respectively) when compared with females in the lowest quartile. ORs adjusted for parity, maternal age, prepregnancy BMI, pregnancy smoking and alcohol consumption, socio-occupational status, child gender, breast-feeding, birth year, home density, gestational age at blood draw, and

parental behavior problem as children did not show a positive association between prenatal PFOA exposure and behavior or coordination problems. Overall, no significant association between behavioral or coordination problems in children 7 years of age and prenatal PFOA (and PFOS) exposure was found.

Similar to the above study, the association between maternal PFOA (and PFOS) levels and offspring behavior and motor development was investigated in a subset of the Biopersistent Organochlorines in Diet and Human Fertility study (INUENDO) birth cohort (Høyer et al. 2015a). Pregnant females were enrolled between May 2002 and February 2004 with a total of 1,106 mother-child pairs at follow-up between January 2010 and May 2012, when the children were 7–9 years old. The study population consisted of 526 pairs from Greenland, 89 pairs from Poland, and 491 pairs from Ukraine. Maternal blood samples for measurement of plasma PFOA levels were taken any time during pregnancy. Behavior of children was assessed with SDQ score, and logistic regression models were used in the analyses of PFOA tertile levels and behavioral problems. Motor development was assessed with DCDQ score, and linear regression was used for analyses. All analyses were performed on the entire cohort as well as by country, except that not all analyses could be performed on the Polish subset because of the small number of cases. The median maternal plasma PFOA level was 0.0014 μg/mL for the combined population and 0.0018, 0.001, and 0.0027 μg/mL for the pregnant females from Greenland, Ukraine, and Poland, respectively.

No associations were found between PFOA (and PFOS) levels and motor development score. Total SDQ score was not associated with PFOA levels; however, the OR of having an abnormal total SDQ score was 2.7 (95% CI 1.2, 6.3) for all groups combined. PFOS levels were associated with higher total SDQ score only in Greenland. The highest PFOA tertile was associated with a 0.5-point higher hyperactivity score in both the combined analysis and in Greenland, but no associations were found in Poland and Ukraine. The OR for hyperactive behavior in the combined analysis was 3.1 (95% CI 1.3, 7.2) for the highest tertile compared to the lowest PFOA tertile. In Greenland, the ORs for hyperactivity were increased for the middle (OR=5.4, 95% CI 1.1, 25.6) and highest (OR=6.3, 95% CI 1.3, 30.1) tertiles (Høyer et al. 2015a).

Hoffman et al. (2010) examined the associations between perfluorochemicals, including PFOA, and diagnosis of ADHD using the NHANES data from 1999–2000 and 2003–2004. The study population comprised 571 children aged 12–15 years, including those who had been diagnosed as having ADHD (n = 48) and/or were taking ADHD medications (n = 21). Age, gender, and race/ethnicity were included as covariates; and socioeconomic status, health insurance coverage and having a routine health care provider, living with someone who smokes, birth weight, admittance to a neonatal intensive care unit, maternal smoking, and preschool attendance were confounders. Regression models were used to analyze the data. The median serum PFOA level was 0.0044 μg/mL and ranged from 0.0004 to 0.0217 μg/mL. Serum PFOA was positively associated with parental report of ADHD (OR=1.12, 95% CI 1.01–1.23). The OR for serum PFOA and parental report of ADHD and ADHD medication use was 1.19 (95% CI 0.95–1.49). Both PFOS and perfluorohexane sulfonate also were positively associated with parentally reported ADHD. Data interpretation was limited by the cross-sectional study design, random misclassification error resulting from using current PFOA levels as proxy measures of etiologically relevant exposures, and other confounders not included in the available data.

3.1.1.11 Postnatal Development

General population studies. Andersen et al. (2010) examined the association between maternal plasma PFOA concentration and offspring weight, length, and BMI at 5 and 12 months of age. The mothers (n = 1,010) reported the information during an interviews, and weight and length measurements were used to calculate BMI. The median PFOA level was 0.0052 µg/mL with a range of 0.0005–0.0219 µg/mL. Maternal plasma PFOA concentration was inversely associated with weight at 5 months (β -30.2, 95% CI -59.3–-1.1), BMI at 5 months (β -0.067, 95% CI -0.129–-0.004), weight at 12 months (β -43.1, 95% CI -82.9–-3.3), and BMI at 12 months in male children (β -0.078, 95% CI -0.144–-0.011) in models adjusted for maternal age, parity, prepregnancy BMI, smoking, gestational age at blood draw, socioeconomic status, and breast-feeding. Similar inverse associations were found with PFOS. No associations were observed between maternal plasma PFOA concentration and the endpoints for female children in the adjusted models.

The latest report on the Danish National Birth Cohort evaluated an association between maternal plasma PFOA levels and the children's BMI, waist circumference, and risk of being overweight at 7 years of age (Andersen et al. 2013). From the subset of 1,400 females who provided blood samples during their first trimester, children were included if they had weight and height information (n = 811) or waist measurements (n = 804) at age 7 years. The median PFOA level was 0.0053 µg/mL with a range of 0.0005–0.0219 µg/mL. Maternal PFOA levels were inversely associated with all of the children's anthropomorphic endpoints, but statistical significance was not attained and a dose response was not observed. Maternal PFOA (or PFOS) did not affect the risk of being overweight in either males or females.

The association between maternal PFOA (and PFOS) levels and prevalence of offspring that are overweight plus waist-to-height ratio >0.5 was investigated in a subset of the INUENDO birth cohort (Høyer et al. 2015b). Pregnant females were enrolled between May 2002 and February 2004 with a total of 1,022 mother-child pairs at follow-up between January 2010 and May 2012, when the children were 7–9 years old. The study population consisted of 531 pairs from Greenland and 491 pairs from Ukraine. Maternal blood samples for measurement of plasma PFOA levels were taken at a mean gestational age of 24 weeks. Each child's weight and height were measured and BMI calculated. All analyses were performed on the entire cohort as well as by country.

The median maternal plasma PFOA level was 0.0018 µg/mL in pregnant females from Greenland and 0.0010 µg/mL in pregnant females from Ukraine. No associations were found between PFOA (and PFOS) levels and risk of being overweight in the combined analysis or in Ukraine. In Greenland, the risk of being overweight was slightly increased only for females (RR=1.81, 95% CI 1.04, 3.17). PFOA association with risk of having waist-to-height ratio >0.5 was slightly increased for the combined analysis (RR=1.30, 95% CI 0.97, 1.74), but statistical significance was not attained. PFOS levels were significantly associated with waist-to-height ratio >0.5 in the combined analysis (Høyer et al. 2015b).

Halldorsson et al. (2012) examined prenatal exposure to PFASs, including PFOA, and the risk of being overweight at 20 years of age in a prospective study. A birth cohort consisting of 665 mother-offspring pairs was recruited from a midwife center in Aarhus, Denmark. Maternal PFOA levels were measured in serum samples collected during week 30 of gestation for assessment of *in utero* PFOA exposure and offspring anthropometry at 20 years. The median PFOA concentration was 0.0037 ± 0.0020 µg/mL with quartiles of 0.0024 ± 0.0006, 0.0033 ±

0.0004, 0.0042 ± 0.0005, and 0.0058 ± 0.0019 μg/mL. Three PFASs, including PFOS, perfluorooctane sulphonamide, and perfluorononanoate, increased across quartiles of PFOA concentration, but eight other PFASs did not. In covariate-adjusted analyses, female offspring whose mothers were in the highest quartile had 1.6 kg/m^2 higher BMI (95% CI: 0.6, 2.6) and 4.3 cm larger waist circumference (95% CI: 1.4, 7.3) than offspring whose mothers were in the lowest quartile. Female offspring of mothers in the highest versus lowest PFOA quartile were also more likely to be overweight [RR 3.1 (95% CI: 1.4, 6.9)] and to have a waist circumference >88 cm at 20 years of age [3.0 (95% CI: 1.3, 6.8)]. Among female participants who provided blood samples at clinical examination (n = 252), maternal PFOA concentration was positively associated with insulin, leptin, and the leptin-adiponectin ratio; and inversely associated with adiponectin levels. PFOA was not associated with being overweight or obesity in male offspring. The other PFASs were not significantly associated with any endpoint after adjustment for PFOA.

Geiger et al. (2014b) used data from the NHANES to determine whether there was a relationship between serum PFOA levels and hypertension in children. A total of 1,655 participants (aged 12–18 years) from the 1999–2000 and 2003–2008 cycles of the survey who had PFOA measurements available were examined. Blood pressure was measured to determine the presence of hypertension, and linear regression modeling was used to study the association between increasing quartiles of serum PFOA and mean changes in systolic and diastolic blood pressures. Mean PFOA level was 0.0044 ± 0.0001 μg/mL. No association was found between serum PFOA (or PFOS) levels and hypertension in either unadjusted or multivariable-adjusted analyses. Compared with the lowest quartile, the multivariable-adjusted OR (95% CI) of hypertension in the highest quartile of exposure was 0.69 (0.41–1.17) (*P*-trend >0.30).

3.1.1.12 Summary and Conclusions from the Human Epidemiology Studies

Numerous epidemiology studies have been conducted of workers, a large highly exposed community (the C8 Health Project), and the general population to evaluate the association of PFOA exposure to a variety of health endpoints. Health outcomes assessed include blood lipid and clinical chemistry profiles, thyroid effects, diabetes, immune function, birth and fetal and developmental growth measures, and cancer.

Serum lipids. The association between PFOA and serum lipids has been examined in several studies in different populations. Cross-sectional and longitudinal studies in occupational settings (Costa et al. 2009; Olsen et al. 2000, 2003; Olsen and Zobel 2007; Sakr et al. 2007a, 2007b; Steenland et al. 2015) and in the high-exposure community (the C8 Health Project study population) (Fitz-Simon et al. 2013; Frisbee et al. 2010; Steenland et al. 2009; Winquist and Steenland 2014a) generally observed positive associations between serum PFOA and TC in adults and children (aged 1–< 18 yrs); most of these effect estimates were statistically significant. Although exceptions to this pattern are present (e.g., some of the analyses examining incidence of self-reported high cholesterol based on medication use [Steenland et al. 2015; Winquist and Steenland 2014a]), the results are relatively consistent and robust. Similar associations were seen in analyses of LDL, but were not seen with HDL. The range of exposure in occupational studies is large (with means varying between 0.4 and > 12 μg/mL), and the mean serum levels in the C8 population studies were around 0.08 μg/mL. Positive associations between serum PFOA and TC (i.e., increasing lipid level with increasing PFOA) were observed in most of the general population studies at mean exposure levels of 0.002–0.007 μg/mL (Eriksen et al. 2013; Fisher et al. 2013; Geiger et al 2014a; Nelson et al. 2010; Starling et al. 2014). The interpretation of results for these general population studies is limited, however, by the moderately strong correlations (Spearman r > 0.6) and similarity in results seen for PFOS and

PFOA. Additionally, many of the C8 studies do not appear to have controlled for the impact of diet on serum lipids.

Liver disease and liver function. Few studies of the relationship between PFOA and liver disease are available, but the C8 Health Project did not observe associations with hepatitis, fatty liver disease, or other types of liver disease. In the studies of PFOA exposure and liver enzymes (measured in serum), positive associations were seen. The results of the occupational studies provide evidence of an association with increases in serum AST, ALT, and GGT, with the most consistent results seen for ALT. The associations were not large and might depend on the covariates in the models, including BMI, use of lipid lowering medications, and triglycerides (Costa et al. 2009; Olsen et al. 2000, 2003; Olsen and Zobel 2007; Sakr et al. 2007a, 2007b). Two population-based studies of highly exposed residents in contaminated regions near a fluorochemical industry in West Virginia have evaluated associations with liver enzymes, and the larger of the two studies reported associations of increasing serum ln ALT and ln GGT levels with increasing serum PFOA concentrations (Emmett et al. 2006; Gallo et al. 2012). A cross-sectional analysis of data from the NHANES, representative of the U.S. national population, also found associations with ln PFOA concentration with increasing serum ALT and ln GGT levels. Serum bilirubin was inversely associated with serum PFOA in the occupational studies. A U-shaped exposure-response pattern for serum bilirubin was observed among the participants in the C8 Health Project, which might explain the inverse associations reported for occupational cohorts. Overall, an association of serum PFOA concentration with elevations in serum levels of ALT and GGT has been consistently observed in occupational, highly exposed residential communities, and the U.S. general population. The associations are not large in magnitude, but indicate the potential of PFOA to affect liver function.

Immune function. Associations between prenatal, childhood, or adult PFOA exposure and risk of infectious diseases (as a marker of immune suppression) have not been consistently seen, although there was some indication of effect modification by gender (i.e., associations seen in female children but not in male children) (Fei et al. 2010a; Granum et al. 2013; Looker et al. 2014; Okada et al. 2012). Three studies have examined associations between maternal and/or child serum PFOA levels and vaccine response (measured by antibody levels) in children (Grandjean et al. 2012; Granum et al. 2013) and in adults (Looker et al. 2014). The study in adults was part of the high-exposure community C8 Health Project. A reduced antibody response to one of the three influenza strains tested after subjects received the flu vaccine was seen with increasing levels of serum PFOA; these results were not seen with PFOS. The studies in children were conducted in general populations in Norway and in the Faroe Islands. Decreased vaccine response in relation to PFOA levels was seen in these studies, but similar results also were seen with correlated PFASs (e.g., PFOS).

Thyroid. Three large studies provide support for an association between PFOA exposure and incidence or prevalence of thyroid disease in women or children, but not in men (Lopez-Espinosa et al. 2012; Melzer et al. 2010; Winquist and Steenland 2014b). In addition, associations between PFOA and TSH were seen in pregnant females with anti-TPO antibodies (Webster et al 2014). In contrast, generally null associations were found between PFOA and TSH in people who had not been diagnosed with thyroid disease.

Diabetes. No associations were observed between serum PFOA levels and type II diabetes incidence rate in general or worker populations with mean serum PFOA up to 0.0913–0.113 μg/mL (MacNeil et al. 2009; Steenland et al. 2015). PFOA was not associated with measures of metabolic syndrome in adolescents or adults (Lin et al. 2009). However, one study found an

increased risk for developing gestational diabetes in females with mean serum PFOA (measured preconception) of 0.00394 μg/mL (Zhang et al. 2015).

Fertility, pregnancy, and birth outcomes. There are no occupational exposure or general population studies examining pregnancy-related hypertension and preeclampsia in relation to PFOA exposure. The only data available come from the high-exposure C8 Health Project study population. Several studies, using different designs and exposure measures, have examined that outcome in this population (Darrow et al. 2013; Savitz et al. 2012a, 2012b; Stein et al. 2009). There is a progressively greater refinement and reduction in misclassification (or exposure and outcome) among this set of studies. Each of the studies provides some evidence of an association between PFOA exposure and risk of pregnancy-induced hypertension or preeclampsia, with the most robust findings from the methodologically strongest study (Darrow et al. 2013).

The association between PFOA and birth weight was examined in numerous studies. Most studies measured PFOA using maternal blood samples taken in the second or third trimester or in cord blood samples. Studies on the high-exposure C8 community population did not observe associations between PFOA and either birth weight among term births or the risk of low birth weight among all (singleton) births (Darrow et al. 2013; Nolan et al. 2009; Savitz et al. 2012a, 2012b; Stein et al. 2009). In contrast, several analyses of general populations indicate a negative association between PFOA levels and birth weight (Apelberg et al. 2007; Fei et al. 2007; Maisonet et al. 2012), while others did not attain statistical significance (Chen et al. 2012; Hamm et al. 2010; Monroy et al. 2008; Washino et al. 2009). A meta-analysis of many of these studies found a mean birth weight reduction of 19 g (95% CI: -30, -9) per each one unit (ng/mL) increase in maternal or cord serum PFOA levels (Johnson et al. 2014). It has been suggested that GFR can impact birth weight (Morken et al. 2014). Verner et al (2015) conducted a meta-analysis based on PBPK simulations and found that some of the association reported between PFOA and birth weight is attributable to GFR and that the actual association could be closer to a 7-g reduction (95% CI: -8, -6). Verner et al. (2015) showed that, in individuals with low GFR, there are increased levels of serum PFOA and lower birth weights. While there is some uncertainty in the interpretation of the observed association between PFOA and birth weight given the potential impact of low GFR, the available information indicates that the association between PFOA exposure and birth weight for the general population cannot be ruled out. In humans with low GFR (which includes females with pregnancy-induced hypertension or preeclampsia), the impact on body weight is likely due to a combination of the low GFR and the serum PFOA.

Two studies examined development of puberty in females in relation to prenatal exposure to PFOA as measured through maternal or cord blood samples in follow-up of pregnancy cohorts conducted in England (Christensen et al. 2011) and in Denmark (Kristensen et al. 2013). The results of these two studies are conflicting, with no association (or possible indication of an earlier menarche seen with higher PFOA) in Christensen et al. (2011), and a later menarche seen with higher PFOA in Kristensen et al. (2013). Another study examined PFOA exposure measured concurrently with the assessment of pubertal status (Lopez-Espinosa et al. 2011). An association between later age at menarche and higher PFOA levels was observed, but the interpretation of this finding is complicated by the potential effect of puberty on the exposure biomarker levels (i.e., reverse causality).

Studies found a positive association with ADHD in children in the highly exposed community (Stein et al. 2013) and the general population (Hoffman et al. 2010). No other behavior endpoints in children were associated with maternal PFOA levels in either population.

Limited data suggest a correlation between higher PFOA levels (>0.02 μg/mL) in females and decreases in fecundity and fertility (Fei et al. 2009; Vélez et al. 2015), but there are no clear effects of PFOA on male fertility endpoints (0.0035–0.005 μg/mL) (Joensen et al. 2009, 2013).

C8 Science Panel conclusions. As part of the C8 Health Project, the C8 Science Panel used epidemiological and other data available to them to assess probable links between PFOA exposure and disease (C8 Science Panel 2012). Analyses conducted by the C8 Science Panel used historical serum PFOA estimates over time, which were developed based on estimated intake of contaminated drinking water. The panel concluded that a probable link existed between PFOA exposure and ulcerative colitis, high cholesterol, pregnancy-induced hypertension, and thyroid disease.

The C8 Science Panel found no probable link between PFOA exposure and multiple other conditions, including birth defects, other autoimmune diseases (e.g., rheumatoid arthritis, lupus, type 1 diabetes, Crohn's disease, MS), type II diabetes, high blood pressure, coronary artery disease, infectious disease, liver disease, Parkinson's disease, osteoarthritis, neurodevelopmental disorders in children (e.g., ADHD, learning disabilities), miscarriage or stillbirth, chronic kidney disease, stroke, asthma or COPD, and preterm birth or low birth weight (C8 Science Panel 2012).

3.1.2 Cancer

Occupational exposure studies. Several occupational studies examining cancer mortality have been conducted at 3M's Cottage Grove facility in Minnesota and at the DuPont Washington Water Works plant in West Virginia. These studies have focused on kidney, bladder, liver, pancreatic, testicular, prostate, thyroid, and breast cancers. For cancers with a high survival rate (i.e., bladder, kidney, prostate, testicular, thyroid, and breast cancer), studies that use mortality data provide a more limited basis for drawing conclusions than studies that use incidence data. The discussion in this section summarizes the design and results of the available studies, focusing on the most recent update of occupational cohorts. Table 3-12 presents results for studies of kidney and testicular cancer.

Raleigh et al. (2014) is the latest update of the analyses of mortality in the 3M Cottage Grove workers, previously analyzed in Lundin et al. (2009) and Gilliland and Mandel (1993). Raleigh et al. (2014) followed 4,668 Cottage Grove workers through 2008, using an improved exposure reconstruction method and adding a nonexposed worker referent group from a different 3M plant. In addition to the mortality data, incidence data based on state cancer registries also were included. Exposure estimates for inhalation exposures were calculated from work history records and industrial hygiene monitoring data; blood levels were not included. No associations were found between PFOA exposure and the risk of dying from any cancer type (see Table 3-12 for bladder, kidney, and testicular cancer results). The mean age of the workers was 29 years at the start of employment and 63 years at the end of follow-up.

Table 3-12. Summary of PFOA Epidemiology Studies of Kidney and Testicular Cancer

Steenland and Woskie (2012) updated the cohort study by Leonard et al. (2008) of employees at the DuPont Washington Works plant in West Virginia (see Table 3-12 for bladder, kidney, and testicular cancer results). This study included 5,791 individuals who had worked at the DuPont West Virginia plant for at least 1 year between 1948 and 2002. Mean duration of employment was 19 years. Deaths through 2008 were ascertained through either the National Death Index or death certificate data. Exposure quartiles were assessed by estimated cumulative annual serum levels based on blood samples from 1,308 workers taken during 1979–2004 and time spent in various job categories (ppm-years). Referent groups included both nonexposed DuPont workers in the same region and the U.S. population. Overall, the mean cumulative exposure was 7.8 ppm-years and the estimated average annual serum level was 0.35 μg/mL. A significant positive trend was found for kidney cancer with the SMR=2.66 (n = 8; 95% CI 1.15, 5.24) for workers in the highest quartile. The most recent report on the same cohort included 6,026 workers evaluated for disease incidence, based on self-report with validation from medical records (Steenland et al. 2015). Lifetime serum cumulative dose was estimated by combining occupational and nonoccupational exposures. Median measured serum level was 0.113 μg/mL based on samples collected in 2005. Bladder cancer incidence (n = 29 cases) decreased with increased PFOA levels (RR 1.0, 0.55, 0.47, and 0.31 across quartiles, trend p = 0.03). Prostate cancer risk increased in Q1 compared to Q2 (n = 1.92), and remained at this level in the remaining quartiles (RR 1.89 and 2.15 in Q3 and Q4, respectively, trend p = 0.10).

Cholecystokinin (CCK) is a peptide hormone that stimulates the digestion of fat and protein, causes the increased production of hepatic bile, and stimulates contraction of the gall bladder. Research in rats suggests that pancreas acinar cell adenomas observed in rodents might be the result of increased CCK levels secondary to blocked bile flow (Obourn et al. 1997). CCK was measured in male workers (n = 74 males) at the 3M's Cottage Grove plant in 1997 as part of the medical surveillance program (Olsen et al. 1998, 2000). Employees' serum PFOA levels were stratified into three categories (<1, 1– <10, and ≥10 ppm). The mean CCK values for the three PFOA categories were 33.4, 28.0, and 17.4 pg/mL, respectively. The means in the two serum categories < 10 ppm were at least 50% higher than in the ≥ 10 ppm category. A statistically significant negative association between mean CCK levels and the three PFOA categories was observed (p = 0.03). A multiple regression model of the natural log of CCK and serum PFOA levels continued to display a negative association after adjusting for potential confounders. As stated previously (Olsen et al. 2000), no abnormal liver function, hypolipidemia, or cholestasis was observed in the workers. The authors suggested that the lack of a positive association between PFOA and CCK in workers could have resulted from serum PFOA levels too low to cause an increase in CCK provided that the same mechanism that increases CCK levels in rodents exists in humans.

High-exposure community studies. Vieira et al. (2013) investigated the relationship between PFOA exposure and cancer among the residents living near the DuPont plant in Parkersburg, West Virginia. This analysis included incident cases of 18 cancers diagnosed from 1996–2005 in five Ohio counties and eight West Virginia counties that included public water districts contaminated with PFOA. The dataset included 7,869 cases from Ohio geocoded to residence and 17,238 cases from West Virginia linked to water district. Exposure levels and serum PFOA concentrations were estimated based on residence at time of diagnosis, using modeled data based on previous work in the C8 study population (Shin et al. 2011). Individual-level exposure was categorized as very high, high, medium, low, or unexposed based on serum concentrations of >0.110 μg/mL, 0.0308–0.109 μg/mL, 0.0129–0.0307 μg/mL, 0.0037–0.0129 μg/mL, and unexposed (background levels not given), respectively. Logistic regression was applied to

individual-level data to calculate ORs and CIs for each cancer category. Data were first analyzed by water district. The adjusted ORs were increased for testicular cancer and for kidney cancer (OR: 5.1, 95% CI: 1.6, 15.6; n = 8 and OR: 1.7, 95% CI: 0.4, 3.3; n = 10, respectively) in the Little Hocking water district and for kidney cancer (OR: 2.0, 95% CI: 1.3, 3.1; n = 23) in the Tuppers Plains water district. Both districts are in Ohio. Residents of Little Hocking also had increased OR for non-Hodgkin lymphoma (OR: 1.6, 95% CI: 0.9, 2.8; n = 14) and prostate cancer (OR: 1.4, 95% CI: 0.9, 2.3; n = 36). The analysis by exposure level for kidney and testicular cancers is shown in Table 3-12. Kidney cancer was positively associated with very high and high exposure categories (OR: 2.0, 95% CI: 1.0, 3.9; n = 9 and OR: 2.0, 95% CI: 1.3, 3.2; n = 22, respectively), while ORs for medium and low exposure categories were close to the null when compared to the unexposed category. The largest OR was for testicular cancer with the very high exposure category (OR: 2.8, 95% CI: 0.8, 9.2; n = 6), but the estimate was imprecise because of the small numbers. ORs for the other exposure categories were all <1.0. Ovarian cancer, non-Hodgkin's lymphoma, and prostate cancer were positively associated with the very high exposure category, but showed weaker or negative associations for the other exposure categories (Vieira et al. 2013).

Barry et al. (2013) extended the study of cancer incidence in the C8 Health Project population in an analysis of data from 32,254 study participants; there is some overlap in the cases included in Vieira et al (2013) and in Barry et al. (2013). The cohort included 3,713 current and former DuPont Washington Works employees, but results for this subset were limited by the small sample size for cancers of interest. Median serum PFOA levels, measured in 2005–2006 at enrollment in C8, were 0.024 and 0.113 µg/mL for community and worker populations, respectively. A proportional hazard regression model was run for each cancer type with the cancer as the outcome, time-varying cumulative PFOA serum concentration as the independent variable, and age as the time scale. Cumulative PFOA serum concentrations were estimated based on historical regional monitoring data and individual residential histories. Self-reported cancers were validated through a cancer registry or medical record. Confounders included smoking, alcohol consumption, gender, education, and 5-year birth year period. Testicular cancer risk was significantly increased with an increase in the log of estimated cumulative PFOA serum level (HR: 1.34, 95% CI: 1.00, 1.79; n = 17). Using estimated cumulative PFOA serum concentration quartiles, a significant monotonic trend was found for testicular cancer. Slight nonsignificant increases were seen for kidney cancer (HR: 1.10, 95% CI: 0.98, 1.24; n = 105) and for thyroid cancer (HR: 1.10, 95% CI: 0.95, 1.26; n = 86) (Barry et al. 2013).

Members of the C8 Health Project were evaluated for an association between serum PFOA levels and incidence of colon or rectal cancer (Innes et al. 2014). This cross-sectional study compared serum PFOA (and PFOS) levels at enrollment with diagnosis of primary colorectal cancer; 47,151 cancer-free adults and 203 cases were included. Serum PFOA levels ranged from <0.0005 to 22.4 µg/mL, with an average of 0.0866 µg/mL. An inverse relationship was found between PFOA level and diagnosis of colorectal cancer with OR = 0.64 (95% CI 0.44, 0.94; highest to lowest quartile, p for trend = 0.002). A concentration-related inverse association also was found between PFOS and colorectal cancer.

In 2012, the C8 Science Panel concluded that there is a probable link between exposure to PFOA and testicular and kidney cancer, but no other types of cancers. Their conclusion was based on the studies presented above, other epidemiology studies on cancer incidence in the mid-Ohio population, worker cohorts, and published data. Panel studies addressed 21 different

categories of cancer and looked for positive trends with increasing exposure as measured by cumulative serum levels.

General population studies. Eriksen et al. (2009) examined the association between plasma PFOA concentration and the risk of cancer in the general Danish population. The study population was chosen from individuals (aged 50–65 years) who had enrolled in the prospective Danish cohort Diet, Cancer and Health study between December 1, 1993, and May 31, 1997. The Danish Cancer Registry and Danish Pathology Data Bank were used to identify cancer patients diagnosed between December 1, 1993, and July 1, 2006. The cancer patients (n = 1,240) consisted of 1,111 males and 129 females whose median age was 59 years and who had prostate cancer (n = 713), bladder cancer (n = 332), pancreatic cancer (n = 128), or liver cancer (n = 67). The individuals (n = 772) in the subcohort comparison group were randomly chosen from the cohort study and consisted of 680 males and 92 females whose median age was 56 years. The participants each answered a questionnaire upon enrollment in the cohort study, and data on known confounders were obtained from the questionnaires. The plasma PFOA concentrations, based on blood samples provided by cancer patients at enrollment (1993–1997) were as follows: males 0.0068 μg/mL, females 0.0060 μg/mL, prostate cancer 0.0069 μg/mL, bladder cancer 0.0065 μg/mL, pancreatic cancer 0.0067 μg/mL, and liver cancer 0.0054 μg/mL. The plasma PFOA concentrations for the subcohort comparison group were 0.0069, 0.0054, and 0.0066 μg/mL for males, females, and combined, respectively. IRRs, crude and adjusted for confounders, did not indicate an association between plasma PFOA concentration and prostate, bladder, pancreatic, or liver cancer (see Table 3-12 for bladder cancer results). The plasma PFOA levels in the population were lower than those observed in occupational cohorts. This study is novel in that it is the first to examine PFOA levels and cancer in the general population.

A subset of females enrolled in the Danish National Birth Cohort was evaluated for an association between plasma PFOA levels (as well as 15 other PFASs) measured during pregnancy and risk of breast cancer during a follow-up period of 10–15 years (Bonefeld-Jørgensen et al. 2014). A total of 250 females diagnosed with breast cancer were matched for age and parity with 233 controls. The mean PFOA level in the controls was 0.0052 μg/mL while levels in the cases were divided into quintiles ranging from <0.0037 up to >0.0065 μg/mL. No association was found between PFOA levels and breast cancer risk. A weak positive association was found only with perfluorooctane sulfonamide.

Hardell et al. (2014) investigated an association between prostate cancer and levels of perfluoroalkyl acids (PFAAs) in whole blood. Patients with newly diagnosed prostate cancer (n = 201) had median PFOA levels of 0.002 μg/mL while the case-control group (n = 186) had a median level of 0.0019 μg/mL. PFOA levels were not associated with higher risks of prostate cancer when compared to controls or when analyzed according to Gleason score (pathology grade) and prostate-specific antigen. A significantly higher risk for prostate cancer was found for PFOA levels above the median combined with a first-degree relative with prostate cancer, indicating a genetic risk factor.

Two studies found no differences in blood and tissue PFOA levels between cancer and noncancer patients; the types of cancer in the patients were not defined. Vassiliadou et al. (2010) found that median serum PFOA concentrations among 40 cancer patients (0.00227 μg/mL in males; 0.00185 μg/mL in females) were similar to two control groups (0.00314 and 0.00181 μg/mL in males; 0.0017 and 0.00171 μg/mL in females). Yeung et al. (2013) found similar PFOS levels in serum and liver tissue between controls and those with hepatocellular carcinoma. Median serum levels in controls (n = 25) and patients with liver cancer (n = 24) were 0.00234

and 0.0025 µg/mL, respectively, and liver tissue were 0.506 (n = 9) and 0.495 (n = 12) ng/g, respectively.

3.1.2.1 Summary and Conclusions from the Human Cancer Epidemiology Studies

Evidence of carcinogenic effects of PFOA in epidemiology studies is based on studies of kidney and testicular cancer. These cancers have relatively high 5-year survival rates of 73% for kidney cancer and 95% for testicular cancer (based on National Cancer Institute [NCI] Surveillance, Epidemiology, and End Results data for 2005–2011). Thus studies that examine cancer incidence are particularly useful for these types of cancer. The high-exposure community studies also have the advantage for testicular cancer of including the age period of greatest risk, as the median age at diagnosis is 33 years. The two occupational cohorts in Minnesota and West Virginia (most recently updated, respectively, in Raleigh et al. 2014 and Steenland and Woskie 2012) do not support an increased risk of these cancers, but each of them is limited by a small number of observed deaths and incident cases. Two studies involving members of the C8 Health Project showed a positive association between PFOA levels (mean at enrollment of 0.024 µg/mL) and kidney and testicular cancers (Barry et al. 2013; Vieira et al. 2013). There is some overlap in the cases included in these studies. None of the general population studies examined kidney or testicular cancer, but no associations were found in the general population between mean serum PFOA levels up to 0.0866 µg/mL and colorectal, breast, prostate, bladder, or liver cancer (Bonefeld-Jørgensen et al. 2014; Eriksen et al. 2009; Hardell et al. 2014; Innes et al. 2014).

As part of the C8 Health Project, the C8 Science Panel (2012) concluded that a probable link existed between PFOA exposure and testicular and kidney cancer.

A group of independent toxicologists and epidemiologists critically reviewed the epidemiological evidence for cancer based on 18 studies of occupational exposure to PFOA and general population exposure with or without coexposure to PFOS. The project was funded by 3M, but the company was not involved in the preparation or approval of the report. The authors evaluated the published studies based on the study design, subjects, exposure assessment, outcome assessment, control for confounding, and sources of bias. They followed the Bradford Hill guidelines on the strength of the association, consistency, plausibility, and biological gradient in reaching their conclusion. They found a lack of concordance between community exposures and occupational exposures one or two magnitudes higher than those for the general population. The discrepant findings across the study populations were described as likely due to chance, confounding, and/or bias (Chang et al. 2014).

3.2 Animal Studies

Acute and short-term studies in monkeys, rats, and mice provide data on systemic toxicity and MoA. Subchronic studies in monkeys and rats found decreased body weight, increased liver weight accompanied by microscopic lesions, and decreased serum cholesterol. The most prominent microscopic lesion of the liver in both monkeys and rats was centrilobular hepatocellular hypertrophy. Data from studies of inhalation and dermal exposures are limited.

Chronic exposure studies were conducted in monkeys, rats, and mice providing information on tumor incidences for both rats and mice. Effects on development and reproduction were found in both rats (a 2-generation study) and mice (male fertility) and included developmental delays and increased neonatal mortality. Many developmental studies focused on the impact of

gestational/lactational exposure on mammary gland development and effects observed in offspring at maturity.

3.2.1 Acute Toxicity

Oral Exposure

Dean and Jessup (1978) reported an oral lethal dose for 50% of animals (LD_{50}) of 680 mg/kg and 430 mg/kg PFOA for male and female CD rats, respectively. Glaza (1997) reported an oral LD_{50} of greater than 500 mg/kg in male Sprague-Dawley rats and between 250 and 500 mg/kg in females. Gabriel (1976a) reported an oral LD_{50} of less than 1,000 mg/kg for male and female Sherman-Wistar rats. According to the Hodge Sterner Scale, these LD_{50} values suggest that PFOA can be classified as moderately toxic after acute oral exposures.

Rigden et al. (2015) exposed groups of five male Sprague-Dawley rats to doses of 0, 10, 33, and 100 mg/kg/day for 3 days and maintained them for 4 additional days with daily body weight measurement and overnight collection of urine. Following the recovery period, the animals were sacrificed with collection of serum samples for analysis. Major organs were weighed, and the liver homogenized. The serum samples, liver homogenate, and supernatant were kept frozen at -80°C until they were analyzed. Phase I and II drug metabolizing enzymes and palmitoyl-coenzyme A (-CoA) oxidase were measured in the liver homogenate. Urine was analyzed for malondialdehyde (MDA) and 8-hydroxydeoxyguanine. The results for PFOA were compared with those for 100-mg/kg/day doses of di(2-ethylhexyl) phthalate (DEHP) and fenofibrate, known inducers of PPARα.

There was a dose-related statistically significant increase in palmitoyl-CoA oxidase and liver weight at all PFOA doses. The palmitoyl-CoA increase was not significant for DEHP and fenofibrate with 100-mg/kg doses; liver weight increased significantly for fenofibrate but not DEHP. The only serum parameter that showed a significant dose-related response with PFOA was a decrease in uric acid compared to controls. Serum was analyzed for several minerals, proteins, enzymes (e.g., ALP, AST, ALT), glucose, cholesterol, and triglycerides. Phase I drug metabolizing enzyme activities (ethoxyresorufin-O-deethylase [EROD] and pentoxyresorufin-O-dependentilase [PROD]) were significantly increased at the 100-mg PFOA/kg/day dose, and glutathione-S-transferase (GST) activity was significantly decreased at the two highest doses, but not in a dose-related fashion. UDP-glucuronyltransferase (UDP-GT) was significantly lower than controls at all doses, but the changes did not demonstrate a dose-related response. There were no dose-related significant changes for the other analytes. The 10-mg PFOA/kg/day dose administered for 3 days was a LOAEL for effects on the liver associated with PPARα activation and for a decrease in serum uric acid. PFOA at 10 mg/kg/day for 3 days had a stronger impact on liver weight and palmitoyl-CoA activation than 100 mg/kg/day of DEHP and fenofibrate for the same exposure duration (Table 3-13). The 10-mg/kg/day dose was a LOAEL for liver effects usually associated with PPARα activation. The PFOA response was stronger than that for a 100-g/kg/day dose for the two known activators of PPAR-α.

Table 3-13. Comparison of PPAR-α Related Effects in Rats for PFOA, DEHP, and Fenofibrate after a 3-day Exposure

Chemical	Dose mg/kg/day	Liver wt. g	Palm. CoA abs/min/g prot	EROD nmol/min/mg prot	PROD nmol/min/mg prot	UDP-GT nmol/min/mg prot	GST nmol/min/mg prot

Inhalation Exposure

Rusch (1979) reported no mortality in male or female Sprague-Dawley rats following inhalation exposure to 186,000 mg/m^3 PFOA for 1 hour. Kennedy et al. (1986) reported a 4-hour lethal concentration for 50% of animals (LC_{50}) of 980 mg/m^3 for groups of six male rats exposed to PFOA as a dust in air. As reported in a later publication (Kennedy et al. 2004), body weight loss, irregular breathing, and red discharge around the nose and eyes were observed. Corneal opacity and corrosion were seen at concentrations greater than or equal to 810 mg/m^3.

Dermal/Ocular Exposure

The dermal LD_{50} in New Zealand White rabbits was determined to be greater than 2,000 mg/kg (Glaza 1995). Kennedy (1985) determined a dermal LD_{50} of 4,300 mg/kg for rabbits, 7,000 mg/kg for male rats, and 7,500 mg/kg for female rats. The animals lost body weight and exhibited lethargy, labored breathing, diarrhea, and severe skin irritation (Kennedy et al. 2004). PFOA is an ocular irritant in rabbits when the compound is not washed from the eyes (Gabriel 1976b), but is not an irritant in rabbits when washed from the eye (Gabriel 1976c). Markoe (1983) found PFOA to be a skin irritant in rabbits, while Gabriel (1976d) did not conclude that PFOA is a skin irritant.

3.2.2 Short-Term Studies

Oral Exposure

Monkey. In a range-finding study, Thomford (2001) administered PFOA to male cynomolgus monkeys as an oral capsule containing 0, 2, and 20 mg/kg/day PFOA for 4 weeks. There were three monkeys in the 2- and 20-mg/kg/day groups and one monkey in the control group. Animals were observed twice daily for mortality and moribundity and were examined at least once daily for signs of poor health or abnormal behavior. Body weights were recorded weekly and food consumption was assessed qualitatively. The monkeys were fasted overnight and blood samples were collected 1 week prior to the start of the study and on day 30 for measurement of serum PFOA, clinical hematology, and clinical chemistry, plus analysis for hormones (estradiol, estrone, estriol, TSH, total and FT3, and total and FT4). Blood samples also were collected from each animal on day 2 (approximately 24 hours after the first dose) for clinical chemistry measurements.

At scheduled necropsy, liver samples were collected for palmitoyl-CoA oxidase activity (a biomarker for peroxisome proliferation) and serum PFOA. Liver, testes, and pancreas were collected and assayed for cell proliferation using antibodies to proliferating cell nuclear antigen (PCNA). Bile was collected from each animal for measurement of bile acid. The adrenals, liver, pancreas, spleen, and testes from each animal were examined microscopically.

All animals survived to scheduled sacrifice. There were no clinical signs of toxicity in the treated groups and there was no effect on body weight. Low or no food consumption was observed for one animal given 20 mg/kg/day. There were no effects on the hormones measured with the exception of estrone, which was notably lower in the 2- and 20-mg/kg/day PFOA groups. There was no evidence of peroxisome proliferation or cell proliferation in the liver, testes, or pancreas of the treated monkeys. No adverse effects were noted in either the gross or clinical pathology evaluations. Under the conditions of this study, the NOAEL was 20 mg/kg and no LOAEL was established.

Rat. Pastoor et al. (1987) dosed male Crl:CD (SD) BR rats (n = 6 per group) for 1, 3, and 7 days with 0 and 50 mg PFOA/kg. Liver sections were collected at necropsy and stained with hematoxylin and eosin. Sections also were examined by electron microscopy. DNA content was also determined for the livers of rats dosed for 7 days. Treatment with 50 mg PFOA/kg for 7 days caused a 17% decrease ($p<0.05$) in mean body weight. Pair-fed control rats had a 24% decrease in body weight. Body weight was no different in the rats treated for 1 and 3 days than in the control rats. Liver weight of rats treated for 1 day was no different than control liver weight. The relative liver weight of rats treated for 3 days was significantly increased ($p<0.05$) compared to control relative liver weight. Absolute and relative liver weights were significantly increased ($p<0.05$) after the 7-day treatment with PFOA. A 57% decrease ($p<0.05$) was observed in relative hepatic DNA/g liver, but no difference was observed between total amount of hepatic DNA/liver and total amount of DNA/liver in control rats.

The hepatocytes of rats treated with PFOA for 3 days were enlarged with partially occluded sinusoids, and had numerous basophilic granules, eosinophilic granular material in the cytoplasm, and fewer perinuclear glycogen vacuoles compared to control hepatocytes. Enlarged hepatocytes with hyperplastic smooth endoplasmic reticulum (ER), increased mitochondria, increased peroxisomes, decreased rough ER, and increased autophagosomes with electron-dense material also were observed in the hepatocytes.

Loveless et al. (2008) administered 0, 0.3, 1, 10, and 30 mg linear PFOA/kg by oral gavage to groups of male CD rats (n = 10 per group) for 29 days. Body weight was recorded on days 0, 3, and 6–28. At necropsy, blood was collected for hematology, clinical chemistry, and corticosterone (CORT) measurements. Tissues were collected for weight and microscopic examination. Body weight, weight gain, hematocrit, and hemoglobin were reduced at ≥10 mg PFOA/kg/day. Increased reticulocytes and hematopoieses were observed in the rats dosed with 30 mg PFOA/kg/day. Total and non-HDL cholesterol were significantly reduced at 0.3 and 1 mg/kg/day compared to control. HDL cholesterol was significantly decreased at 0.3, 1, and 10 mg/kg/day. Triglyceride levels were significantly decreased at all doses except 1 mg/kg. Absolute liver weight (≥1 mg/kg/day) and relative liver weight (≥10 mg/kg/day) were significantly increased. Hepatocellular hypertrophy was graded as minimum to mild (0.3–1 mg/kg/day) and moderate (≥10 mg/kg/day), and focal necrosis was present at doses ≥ 10 mg/kg/day. Although not statistically significant, serum CORT was increased at ≥ 10 mg/kg/day. The decrease in cholesterol and triglycerides at the lowest dose are not necessarily adverse. The 1-mg/kg/day dose is classified as the NOAEL and the 10-mg/kg/day

dose as the LOAEL based on the observations of increased liver weight, hepatocellular hypertrophy, and hepatic necrosis at that dose. Data on several immunological endpoints were reported as part of the Loveless et al. (2008) publication. The immunological data from that study are included in section 3.3.2 of this report.

Cui et al. (2009) exposed male Sprague-Dawley rats (10 per group) to PFOA (96% active ingredient) at 0, 5, and 20 mg/kg/day for 28 days by gavage once daily. The activity of the rats was observed over the course of the study. All rats were sacrificed after the final exposure. The rats dosed with 5 mg/kg/day exhibited hypoactivity, decreased food consumption, cachexia, and lethargy during the third week of the study. Rats dosed with 20 mg/kg/day also exhibited sensitivity to external stimuli. The visceral index (i.e., hepatic, renal, gonad weight/animal's body weight) used to evaluate hyperplasia, swelling, or atrophy was significantly increased in the treated animals compared to control animals. In the liver, treatment with 5 or 20 mg PFOA/kg caused hepatic hypertrophy, fatty degeneration, and acidophilic lesions as well as angiectasis (gross dilation) and congestion in the hepatic sinusoid or central vein. In the lung, treatment with 5 or 20 mg PFOA/kg caused pulmonary congestion and focal or diffuse thickened epithelial walls. No histopathologic lesions were observed in the kidneys of the low-dose animals, but turbidness and swelling in the epithelium of the proximal convoluted tubule were observed at 20 mg PFOA/kg. Under the conditions of this study, the LOAEL was 5 mg/kg/day based on increased visceral indices, and liver and pulmonary lesions; no NOAEL was established.

Male Sprague-Dawley rats (n = 10 per group) were fed diets containing 0 and 300 ppm PFOA for 1, 7, and 28 days in two studies (Elcombe et al. 2010). The mean daily intake for study 1 and study 2 were 19 and 23 mg/kg/d, respectively. A group of rats was fed diets containing 50 ppm Wyeth 14,643, a PPARα agonist, as a positive control. The animals were observed daily and body weights and food consumption were recorded. At necropsy, day 2, day 8, or day 29, the organs were weighed, examined for gross pathology and preserved for histopathology. In study 1, liver DNA content and concentration were determined, and plasma was collected for analysis of liver enzymes, cholesterol, triglycerides, and glucose. Hepatic cell proliferation and apoptosis also were determined.

In both studies, body weight significantly decreased ($p<0.05$) after 7 and 28 days on the PFOA diet. Body weight was not affected by Wyeth 14,643. Absolute liver weight was significantly increased ($p<0.05$) in rats fed PFOA diets for 7 days in the first study and in rats treated for 7 and 28 days in the second study (Table 3-14). The liver-to-body-weight ratio was significantly higher in rats fed PFOA diets for 7 and 28 days in both studies. Absolute liver weight and liver-to-body-weight ratios were significantly increased in rats fed the Wyeth 14,643 diet in both studies.

After 1 day of eating the PFOA diet, subjects' plasma AST was significantly decreased and triglycerides were significantly increased. After 7 and 28 days on the PFOA diet, TC, triglycerides, and glucose levels were significantly decreased. The AST response did not show a duration-related response because there was a significant decrease at 1 and 28 days, but not at 7 days on the PFOA diet. Liver DNA concentration was significantly decreased ($p<0.05$) in all PFOA-exposed rats except those treated for 1 day in the second study, but liver DNA content was not altered by PFOA, suggesting that the increase in volume was responsible for the change in concentration.

Table 3-14. Hepatic Effects of Rats Exposed to PFOA

		Study 1			Study 2		
	Day	Control	300 ppm PFOA (19 mg/kg/day)	50 ppm Wyeth 14,643	Control	300 ppm PFOA (32 mg/kg/day)	50 ppm Wyeth 14,643
Liver weight (g)	1	13.6 ± 1.3	14.1 ± 2.4	15.7 ± 1.2	15.2 ± 1.9	14.4 ± 0.9	15.8 ± 1.4
	7	15.3 ± 1.3	19.2 ± 3.1*	23.1 ± 3.1*	16.6 ± 1.7	22.8 ± 2.6*	23.4 ± 2.5*
	28	18.3 ± 2.5	20.8 ± 3.2	30.6 ± 3.2*	17.2 ± 2.0	24.6 ± 2.2*	29.2 ± 4.0*
Liver-to-bw (g/kg)	1	4.25 ± .34	4.39 ± 0.44	4.64± 0.17*	4.39 ± 0.36	4.27 ± 0.14	4.49 ± 0.23
	7	4.10 ± 0.26	5.83 ± 0.55*	6.26 ± 0.48*	4.28 ± 0.24	6.56 ± 0.38*	6.34 ± 0.33*

Notes: *Significantly different from control ($p < 0.05$); ND = No Data.

After 1 day on the Wyeth 14,463 diet, subjects'AST and TC were significantly decreased. After 7 and 28 days on the Wyeth 14,643 diet, subjects' ALT, TC, triglycerides, and glucose levels were significantly decreased. AST was not significantly decreased in rats fed Wyeth 14,643 diets for 28 days, but it was after 7 days. In the Wyeth 14,643 rats, liver DNA concentration was significantly decreased after 1 and 7 days in the first study and 7 and 28 days in the second study. Total liver DNA content in the Wyeth 14,643-treated rats was significantly increased after 7 and 28 days in both studies.

Labeling indices for hepatic cell proliferation, as measured by bromodeoxyuridine (5-bromo-2-deoxyuridine, BrdU) incorporation, was significantly increased after day 1 and 7 in study 1 in both PFOA ($p<0.05$) and Wyeth 14,643 ($p<0.01$) diet-fed rats. Samples from control livers at day 29 were not available for comparison. In study 2, labeling was significantly increased ($p<0.05$) at all time points in both groups of rats compared to labeling in control rats (Table 3-14). Apoptosis of hepatic cells was not altered by treatment with PFOA at any time point. In rats fed diets containing Wyeth 14,643 for 28 days, hepatic apoptosis was significantly decreased ($p<0.01$) compared to apoptosis observed in control livers.

Histological examination of the livers of PFOA and Wyeth 14,643 diet-fed rats showed decreased glycogen after 1, 7, and 28 days. An increase in hepatocellular hypertrophy was observed after 7 and 28 days on the diets, fatty vacuolation was observed after 7 days on the diets, and increased hepatocellular hyperplasia was observed after 28 days on the diets. The hepatic observations were similar in both studies, and findings in Wyeth 14,643 diet-fed rats were generally more pronounced or severe than those in PFOA diet-fed rats. Although there were many similarities in response to the PFOA and Wyeth 14,463 diets, the body weight and apoptosis responses differed.

Mouse. Kennedy (1987) fed male and female Crl:CD-1 mice diets containing 0, 30, 300, and 3,000 ppm PFOA for 14 days. At necropsy body weight and liver weight were recorded and analyzed. No histological evaluations were conducted. All mice died at 3,000 ppm. At 300 ppm, body weight was decreased and one female died. Both male and female mice had significantly increased absolute and relative liver weights at all doses ($p<0.05$) compared to the control. The

LOAEL was 30 ppm based on increased liver weight, and no NOAEL was established. Kennedy (1987) used lower doses in a follow-up study lasting 21 days. Male and female mice were fed diets containing 0, 0.01, 0.03, 0.1, 0.3, 1, 3, 10, and 30 ppm PFOA. Absolute and relative liver weights for male and female mice were significantly increased ($p<0.05$) at ≥ 3 ppm PFOA. The LOAEL was 3 ppm based on increased liver weight, and the NOAEL was 1 ppm.

Loveless et al. (2008) administered 0, 0.3, 1, 10, and 30 mg linear PFOA/kg by oral gavage to groups of male CD-1 mice (n = 20 per group) for 29 days. Body weight was recorded on days 0, 3, and 6–28. At necropsy, blood was collected for hematology, clinical chemistry, and CORT measurements. Tissues were collected for weight and microscopic examination. Body weight was significantly reduced at 10 and 30 mg/kg/day. An increase in neutrophils and monocytes was observed at ≥10 mg/kg/day along with a decrease in eosinophils. Serum CORT levels were significantly increased in mice dosed with 10 mg/kg and elevated in those dosed with 30 mg/kg/day. Total serum cholesterol and triglycerides were significantly decreased at ≥10 mg/kg/day. HDL was significantly reduced at ≥1 mg/kg/day. In mice treated with 30 mg/kg and water, triglycerides and HDL levels were significantly decreased compared to control levels. Absolute and relative liver weights were significantly increased at ≥1 mg PFOA/kg/day. Increased incidences of microscopic lesions in the liver included mild hepatocellular hypertrophy at 0.3 mg/kg/day, moderate-to-severe hypertrophy and individual cell necrosis at ≥1 mg/kg/day, and increased hepatocellular mitotic figures, fatty changes, and bile duct hyperplasia at ≥10 mg/kg/day. The LOAEL for this study was 1 mg/kg/day based on increased liver weight, hepatocellular hypertrophy, and cell necrosis; the NOAEL was 0.3 mg/kg/day. Data on several immunological endpoints were reported as part of the Loveless et al. (2008) publication. The immunological data are included in section 3.3.2 of this report.

Some of the epidemiology studies report that evaluated serum lipids demonstrate a positive correlation between total serum cholesterol and triglycerides and serum PFOA. Tan et al. (2013) used male C57BL/6N mice to determine if dietary fat content could be an important variable influencing the impact of PFOA on serum lipids. Groups of seven or eight 4-month-old male mice were given either a liquid regular fat diet (RFD) or a high-fat diet (HFD), with or without PFOA, for 3 weeks. The RFD provided 12% and the HFD provided 35% of their calories from fat. Calories from protein (18%) were equivalent in both diets. The RFD provided 60% and the HFD provided 40% of their calories from carbohydrate. The fats were primarily monounsaturated (olive oil) or polyunsaturated (safflower and corn oil). PFOA was added to both diets for 3 weeks at a level that maintained a dose of 5 mg/kg/day to the mice. The PFOA-treated groups were fed *ad libitum*, and the control groups were given the amount consumed by the PFOA-treated groups the previous day. Body weight; liver weight; plasma ALT, AST, and ALP; total and direct bilirubin; free fatty acids and liver triglycerides; as well as subcutaneous and epididymal white adipose tissue were monitored. Statistical differences between groups ($p<0.05$) were determined using one-way ANOVA. Liver and epididymal white fat tissue samples were examined histologically.

The fat content of the diets alone resulted in significant differences in body weight and subcutaneous white adipose tissue, but not in liver weight. The addition of PFOA to the RFD resulted in significant increases in body weight, liver weight, ALT, ALP, and plasma free fatty acids, but not in AST or bilirubin. The addition of PFOA to both the RFD and HFD resulted in decreases in the mass of both epididymal and subcutaneous white fat deposits.

The HFD alone did not result in definitive alterations in liver histopathology. When PFOA was added to the RFD, indications of hepatocyte hypertrophy, necrosis, and inflammatory cell

infiltration were observed. The liver damage in the animals being fed the HFD with PFOA was increased more than in the RFD-PFOA animals, as indicated by higher levels of necrosis and inflammation accompanied, in this case, by lipid droplet accumulation and significantly increased liver triglycerides, but not liver cholesterol or free fatty acids. In the epididymal adipose tissues, adipocyte size was increased in the HFD control compared to the RFD control but decreased with the addition of PFOA compared to both the RFD and HFD controls. Inflammatory cell infiltration was observed in the epididymal adipose tissues when PFOA was added to the HFD but not the RFD. No data for the subcutaneous white fat tissues was provided.

The authors evaluated the hepatic expression of 84 genes involved in the regulation of fatty acid metabolism using RT^2 Profiler PCR Arrays. HFD and/or PFOA altered the expression of 33 genes (> 1.5 fold). PFOA alone upregulated 13 genes (>1.5) and downregulated 4 (>1.5) genes with fatty acid and triglyceride catabolism. Eight fatty acid transport-related genes were upregulated by PFOA and one was downregulated. The study demonstrates the importance of the fat content of the diet as a modulator of the effects of PFOA on the liver in animals. Damage to the liver tissues was intensified in the presence of the HFD.

Son et al. (2008) administered 0, 2, 10, 50, and 250 mg/L PFOA (0, 0.49, 2.64, 17.63, and 47.21 mg/kg PFOA, respectively) in the drinking water to 4-week-old male imprinting control region (ICR) mice for 21 days. Food and water consumption, and body weight were recorded daily. At sacrifice, blood was collected and the liver and kidneys were removed and weighed. Plasma from the blood was used to determine levels of ALT, AST, BUN, and creatinine. Sections of the liver and kidney were processed and stained with hematoxylin and eosin or stained for caspase 3 (a biomarker for apoptosis). Expression of mRNA for tumor necrosis factor-α, interleukin-1β, and transforming growth factor-β were determined using reverse transcription polymerase chain reaction (RT-PCR).

The mice exposed to 250 mg/L PFOA (47.21 mg/kg/day) had significantly reduced food and water consumption ($p<0.05$), and body weight gain ($p<0.05$) compared to the control mice. Body weight gain also was significantly reduced ($p<0.05$) in mice receiving 50 mg/L PFOA in the drinking water. In all PFOA-exposed mice, relative liver weight was significantly increased in a dose-dependent manner ($p<0.05$) compared to liver weight of the control mice. Relative kidney weight was not affected by PFOA exposure. At ≥ 10 mg/L PFOA (2.64 mg/kg/day), plasma ALT activity was significantly increased, and at ≥ 50 mg/L PFOA (17.63 mg/kg/day), plasma AST activity was significantly elevated compared to the activity level in the control mice. Exposure to PFOA did not affect BUN or creatinine.

The livers of mice exposed to ≥50 mg/L PFOA were characterized by enlarged hepatocytes with acidophilic cytoplasm and the presence of eosinophils. No apoptotic bodies were observed in the liver with staining for caspase 3. Exposure to PFOA did not affect kidney morphology and did not cause toxic damage or necrosis in the kidney. In the liver, tumor necrosis factor-α expression was significantly reduced at ≥ 50 mg/L PFOA, interleukin-1β expression was significantly reduced at 250 mg/L PFOA, and transforming growth factor-β expression was significantly elevated at ≥ 50 mg/L PFOA. Under the conditions of this study, the LOAEL was 2 mg/L (0.49 mg/kg/day) based on increased liver weight, and no NOAEL was established. The LOAEL for increased plasma ALT was 2.64 mg/kg/day.

Wolf et al. (2008a) gavage-dosed wild-type 129S1/SvlmJ mice (n = 7–8 per group) and PPARα-null mice (129S4/SvJae-$PPAR\alpha^{tm1Gonz}$/J, n = 6–8 per group) with 0, 1, 3, or 10 mg PFOA/kg or 50 mg Wyeth 14,643, a PPARα agonist, and wild-type CD-1 (n = 7–8 per group)

with 0, 1, and 10 mg PFOA/kg for 7 days to characterize hepatic effects resulting from exposure. The mice were sacrificed 24 hours following the last dosing. Blood was collected for serum, and the livers were removed and weighed. Liver sections were stained with hematoxylin and eosin for examination by light microscopy and with uranyl acetate for transmission electron microscopy. Liver sections were also processed for immunohistochemistry of PCNA. Hepatocyte hypertrophy and vacuolation, observed in both strains of wild-type mice, were assigned a score from 0 to 4 based on severity, with 0 being no lesions observed and 4 being panlobular hypertrophy with cytoplasmic vacuolation. Hepatic lesions in PPARα-null were assigned a score (0–4) based on cytoplasmic vacuolation as no hypertrophy was observed. The percentage labeling index was obtained by counting the number of positive PCNA cells in 900–1,000 hepatocyte nuclei per animal. Slides were read blind to treatment but with knowledge of genetic status.

Compared to control values, the absolute and relative liver weights, lesion score, and labeling index were significantly increased ($p<0.05$) in a dose-dependent manner in both strains of wild-type mice exposed to PFOA and also were significantly increased ($p<0.05$) in the wild-type 129S1/SvlmJ mice exposed to Wyeth 14,643 (see Table 3-15). The absolute and relative liver weights and lesion score were significantly increased ($p\leq0.05$) in a dose-dependent manner in all PFOA-exposed PPARα-null mice. The labeling index was significantly increased ($p<0.05$) in PPARα-null mice exposed to 10 mg PFOA/kg. Absolute and relative liver weights, lesion score, and labeling index of PPARα-null mice exposed to Wyeth 14,643 were no different from control values.

Table 3-15. Hepatic Effects in PFOA-Treated Mice

Group	Liver Weight (g)	Relative Liver Weight (%)	Lesion Score	Labeling Index
Wild-type CD-1 Mice				
Control	1.53 ± 0.14	4.5 ± 0.4	0.3 ± 0.5	0.6 ± 0.4
1 mg/kg/day PFOA	2.26 ± 0.24*	6.5 ± 0.5*	2.1 ± 0.9	0.7 ± 0.5
10 mg/kg/day PFOA	3.48 ± 0.54*	10.5 ± 0.8*	3.0 ± 0*	7.7 ± 3.0*
Wild-type 129S1/SvlmJ Mice				
Control	0.87 ± 0.08	3.3 ± 0.4	0.3 ± 0.5	0.3 ± 0.2
1 mg/kg/day PFOA	1.22 ± 0.22*	1.6 ± 0.2*	2.0 ± 0.0*	0.7 ± 0.6
3 mg/kg/day PFOA	1.70 ± 0.12*	6.4 ± 0.4*	2.0 ± 0.0*	1.0 ± 0.4
10 mg/kg/day PFOA	2.20 ± 0.23*	8.3 ± 0.2*	4.0 ± 0.0*	2.4 ± 0.9*
50 mg/kg/day Wyeth 14,643	1.5 ± 0.13*	5.6 ± 0.1*	3.3 ± 0.5*	2.1 ± 1.2*
PPARα-null Mice				
Control	0.92 ± 0.08	3.4 ± 0.4	1.1 ± 0.4	0.2 ± 0.2
1 mg/kg/day PFOA	1.2 ± 0.14*	4.5 ± 0.2*	1.9 ± 0.6*	0.6 ± 0.4
3 mg/kg/day PFOA	1.46 ± 0.21*	5. 8 ± 0.3*	3.0 ± 0.0*	0.6 ± 0.3
10 mg/kg/day PFOA	2.8 ± 0.18*	9.4 ± 0.6*	4.0 ± 0.0*	7.7 ± 3.0*

Source: Wolf et al. 2008a
Note: * Statistically different from control, $p < 0.05$.

Ultrastructure evaluations were done on liver sections from wild-type 129S1/SvlmJ mice and PPARα-null mice, but not from CD-1 mice. There were the expected differences in the characteristics of hepatocytes from the control wild-type mice when compared to both the PFOA-treated and Wyeth 14,643 wild-type mice. In the PPARα-null mice, the responses of the control and Wyeth 14,643-dosed animals were similar, but the response of the PFOA-dosed animals differed. Table 3-16 summarizes the cellular characteristics of the hepatocytes for the control, POFA-treated, and Wyeth 14,643-treated wild-type and PPARα-null mice on the basis of their glycogen content, Golgi bodies and associated rough ER, mitochondria, peroxisomes, and lipid-like cytoplasmic vacuoles.

Table 3-16. Mouse Hepatocyte Ultrastructure After PFOA or Wythe 14,643 Treatment

	Characteristics				
Mouse/Treatment	**Glycogen**	**Golgi/ Rough ER**	**Mitochondria**	**Peroxisomes**	**Lipid-like Vacuoles**
Wild-type/Control	Prominent	Prominent	Numerous	Few	Rare
Wild-type/PFOA (10 mg/kg)	Negative	Nominal/ scarce ER	Numerous	Numerous	Scattered
Wild-type/Wyeth	Negative	Nominal/ scarce ER	Numerous	Numerous	Scattered
PPARα-null/Control	Prominent	Prominent	Numerous	Absent	Scattered
PPARα-null/PFOA (10 mg/kg)	Limited	Limited	Not reported	Not reported	Numerous[a]
PPARα-null/Wyeth	Prominent	Prominent	Numerous	Absent	Scattered

Source: Wolf et al. 2008a

Note: [a] Described as electron-dense, nonmembrane-bound spaces morphologically consistent with lipids ranging from the size of mitochondria to the size of nuclei. The vacuoles were believed to be an accumulation of PFOA.

It is apparent from the data in Table 3-16 that PFOA and Wyeth 14,643 behaved similarly in the wild-type strains but differently in the PPARα-null mice. The hepatocytes of PFOA-dosed PPARα-null mice exhibited lower glycogen content, Golgi bodies, and associated rough ER than both the control and Wyeth 14,643 PPARα-null mice. In addition, the PFOA-dosed PPARα-null mice had numerous large nonmembrane-bound lipid-like vacuoles throughout the cytoplasm. At the high dose (10 mg/kg/day), there was an increase in the labeling index that was not observed with Wyeth 14,643. The authors concluded that the large lipid-like vacuoles in the hepatocytes of PFOA-dosed PPARα-null mice were likely accumulations of PFOA. Under the conditions of this study, the LOAEL was 1 mg/kg/day based on increased absolute and relative liver weight and hepatic morphology changes; no NOAEL was established.

Nakamura et al. (2009) investigated the functional difference in PFOA response between mice and humans using a humanized PPARα transgenic mouse strain (hPPARα). Humanized PPARα mice express a high level of human PPARα protein in the liver. Male 8-week-old wild-type (mPPARα) mice, PPARα-null mice, and hPPARα mice were gavage-dosed with 0, 0.1, and 0.3 mg/kg/day PFOA (n = 4–6 per group) for 2 weeks and sacrificed 18–20 hours following the last dose. Blood was collected and analyzed for triglyceride and cholesterol concentrations, and ALT measurements. Livers were collected and analyzed for triglyceride and cholesterol concentrations, plus histopathological changes. The differences in the observations for the three strains of mice are summarized in Table 3-17.

Table 3-17. Relative Response of hPPARα, mPPARα, and PPARα-null Mice to PFOA

Parameter	hPPARα	mPPARα	PPARα-null
Liver weight	ND	↑ compared to control (0.3 mg/kg/day)	↓ compared to control (0.1 mg/kg/day)
Liver/body weight ratio	ND	↑ compared to control (0.3 mg/kg/day)	ND
Hepatocyte hypertrophy	Mild (0.3 mg/kg/day)	Mild (0.3 mg/kg/day)	ND
ALT	ND	ND	ND
Plasma cholesterol	↑ compared to mPPARα (all doses)	ND	ND
Liver cholesterol	↓ compared to PPARα-null (0.1, 0.3 mg/kg/day), mPPARα (0.3 mg/kg/day)	↑ compared to control (0.3 mg/kg/day)	ND
Plasma triglyceride	ND	ND	ND
Liver triglyceride	↓ compared to PPARα-null (0.3 mg/kg/day)	↓ compared to PPARα-null (0.1, 0.3 mg/kg/day; ↑ compared to control (0.3 mg/kg/day)	↑ compared to mPPARα (all doses)

Source: Nakamura et al. 2009
Notes:
hPPARα: transgenic mice (that express a high level of human PPARα protein in the liver); mPPARα: wild-type mice.
↑ = significant increase ($p < 0.05$).
↓ = significant decrease ($p < 0.05$)
ND = no differences.

Body weight of the hPPARα mice was slightly lower than the mPPARα and PPARα-null mice prior to PFOA treatment and remained lower throughout the dosing regimen. Treatment with PFOA did not affect plasma ALT or triglyceride concentrations in any group. The hPPARα mice differed from the wild-type mice in that their plasma cholesterol was significantly increased and their liver cholesterol and triglycerides significantly decreased at the highest dose (Table 3-17). In addition, the increases in absolute and relative liver weights were less than those observed in the wild-type mice. The PPARα-null mice differed from the wild-type in that liver triglycerides were significantly increased. Comparable to the Wolf et al. (2008a) report, the cytoplasmic vacuoles were larger in the PPARα-null mice than in the wild-type and hPPARα mice. There were no other significant differences between PPARα-null mice and wild-type mice.

Under the conditions of the study, the LOAEL for mPPARα mice was 0.3 mg/kg/day of PFOA based on increased liver weight and increased liver triglyceride and cholesterol concentrations. The NOAEL for mPPARα mice was 0.1 mg/kg/day of PFOA. The NOAEL for PPARα-null mice was 0.3 mg/kg/day because the changes in absolute liver weight were not dose-related and the increase in relative liver weight was not significantly different from the control. The NOAEL for hPPARα mice was 0.3 mg/kg/day of PFOA, the highest dose tested. However, a nonsignificant but dose-related increase was observed in plasma cholesterol.

Minata et al. (2010) examined hepatobiliary injury in mice treated with PFOA. Male wild-type 129S4/SvlmJ mice (n = 39) and PPARα-null (129S4/SvJae-Pparα^{tm1Gonz}/J mice (n = 40) were orally dosed with 0, 12.5, 25, and 50 μmol/kg/day of PFOA (equivalent to ~0, 5.4, 10.8, and 21.6 mg/kg/day of PFOA) for 4 weeks. At the end of 4 weeks, animals were sacrificed and blood, liver, and bile were collected for clinical chemistry analysis and determination of PFOA concentration. Sections of the liver were processed for histological examination, oxidative DNA damage, and multidrug resistance protein 2 (Mdr2) and tumor necrosis factor α (TNF-α) mRNA

expression. Bile acid and phospholipid contents in bile were determined as well as the protein expression of canalicular bile salt export pump (BSEP) and canalicular MRP2.

Absolute and relative liver weights in all PFOA treated wild-type and PPARα-null mice were significantly increased ($p<0.05$) at sacrifice compared to control liver weight. Plasma AST was significantly increased in wild-type mice at 25 and 50 μmol/kg/day (equivalent to 10.8 and 21.6 mg/kg/day) and in PPARα-null mice at 50 μmol/kg/day compared to the concentrations of their respective controls. Plasma ALT was no different from control in the treated mice. In wild-type mice, total bilirubin was significantly decreased at 12.5 μmol/kg/day and significantly increased at 50 μmol/kg/day. In PPARα-null mice, total bilirubin was significantly increased at 50 μmol/kg/day. Total bile acid was significantly increased at 50 μmol/kg/day in PPARα-null mice. TC was significantly decreased in wild-type mice at 25 and 50 μmol/kg/day, and total triglyceride was significantly increased at 12.5 and 25 μmol/kg/day. TC was significantly decreased at 12.5 and 25 μmol/kg/day and significantly increased at 50 μmol/kg/day in PPARα-null mice. In PPARα-null mice, total triglycerides were significantly increased at all doses.

Hepatocellular hypertrophy was observed in wild-type mice treated with 12.5, 25, and 50 μmol/kg/day (equivalent to 5.4, 10.8 and 21.6 mg/kg/day). A dose-dependent increase in eosinophilic cytoplasmic changes consistent with peroxisome proliferation was observed in liver parenchyma, but no fat droplets or focal necrosis were observed in wild-type mice. An increase in bile duct epithelium thickness suggested slight cholangiopathy in wild-type mice at 25 and 50 μmol/kg/day. Increased apoptosis in hepatic cells, hepatic arterial walls, and bile duct epithelium was observed at 25 and 50 μmol/kg/day in wild-type mice. Ultrastructure examination of livers from PFOA-treated wild-type mice showed decreased glycogen granules, degranulated or disrupted rough ER, nuclear vacuoles, extensive peroxisome proliferation, and slight mitochondria proliferation.

In PPARα-null mice treated with 12.5, 25, and 50 μmol/kg/day of PFOA (equivalent to 5.4, 10.8 and 21.6 mg/kg/day), hepatocellular hypertrophy, cytoplasmic vacuolation, and increased microvesicular steatosis were observed. These observations are consistent with Wolf et al. (2008a). At 50 μmol/kg/day, focal necrosis was observed. Areas of bile fibrosis and bile plaque and few inflammatory cells were observed in the bile ducts of PPARα-null mice at 25 and 50 μmol/kg/day. Increased apoptosis was observed in bile duct epithelium at 25 and 50 μmol/kg/day in PPARα-null mice. Ultrastructure examination of livers from PFOA-treated PPARα-null mice showed decreased glycogen granules, degranulated or disrupted rough ER, increased cytoplasmic lipid accumulation, mitochondria proliferation, and mitochondrial changes (e.g., swelling and decreased matrix density). Peroxisome proliferation was not observed. Ultrastructure of bile duct showed degradation of cytoplasmic structure, vacuolization, disintegration of nuclei and organelles, periductal infiltration of fibroblasts and macrophages, and fibrosis.

The marker for oxidative damage, 8-hydroxydeoxyguanosine (8-OH-dG), and TNF-α were not elevated or upregulated in wild-type mice. In PPARα-null mice, 8-OH-dG was elevated in the liver at 21.6 mg/kg/day and TNF-α mRNA was significantly increased at 10.8 and 21.6 mg/kg/day. The transporter Mdr2 moves biliary phospholipids from hepatocytes to bile and was significantly upregulated in wild-type mice at all doses, but only at 5.4 mg/kg/day in PPARα-null mice. The BSEP transports bile acid from hepatocytes to bile and was significantly decreased in wild-type mice at 21.6 mg/kg/day, significantly increased in PPARα-null mice at 5.4 mg/kg/day, and significantly decreased at 21.6 mg/kg/day. The transporter MRP2 also transports bile acid and was significantly decreased at 21.6 mg/kg/day in both groups of mice.

Under the conditions of the study, the LOAEL for male wild-type and PPARα-null mice was 5.4 mg/kg/day of PFOA based on increased liver weight. A NOAEL was not established. At the LOAEL, the difference between the PPARα-null mice and the wild-type mice was the presence of cytoplasmic vacuoles and microvesicular steatosis in addition to hypertrophy in the PPARα-null mice.

The effects of gavage exposure on groups of six male Klunming mice (8 weeks old) to doses of 0, 2.5, 5, and 10 mg PFOA/kg/day for 14 days on the testes and epididymis was examined by Liu et al. (2015). The lowest dose tested was a LOAEL for dose-related effects on decreased sperm count, testicular superoxide dismutase (SOD), catalase, nuclear respiratory factor 2 (NRF2), and BAX expression ($0<0.05$) plus increases in MDA, hydrogen peroxide, BAX and BCL expression ($p<0.05$). There was no effect on relative testes weight at any dose. Some effects were observed on testicular morphology at the lowest dose, including atrophy of the seminiferous tubules, depletion of spermatogonial cells, detachment of germ cells from the seminiferous epithelium, and decreased sperm production. The severity of the testicular morphological changes increased with dose. Six animals per dose group were used for the evaluation of testicular weight and 4 animals per dose group were used for the other assays. The increase in MDA and hydrogen peroxide accompanied by the decrease in SOD and carnitine acyltransferase (CAT) activity and NRF2 expression indicate that oxidative stress played a major role in the observed toxicity. NRF2 plays an important role as a messenger that upregulates genes involved in response to oxidative stress.

Lu et al. (2015) reported on the testicular effects of PFOA on the blood testes barrier after a 28-day exposure of BALBL/c male mice (14 days old) to gavage doses of 0. 1.25, 5, and 20 mg/kg/day (3–5 animals per dose group). The blood testes barrier divides the seminiferous epithelium into apical and basolateral compartments and plays an important role in germinal cell development and male fertility. The barrier prevents the passage of large molecules from one compartment to the other. At termination of the exposure, the animals were sacrificed and the testes recovered for analysis. A second component of this study examined the impact of the PFOA treatment on male fertility and is reported in section 3.2.6.

The blood testes barrier integrity was weakened at the lowest dose tested and in a dose-dependent manner as indicated by the passage of a red fluorescent dye injected into the interstitium and concentrations of IgG measure in gel electrophoresis columns visualized by chemiluminescence (three per dose group). Membrane integrity is dependent on coexisting tight junctions, basal ectoplasmic specializations, and gap junctions. Accompanying *in vitro* assays of cultured sertoli cells demonstrated downregulation of key proteins associated with the tight junction and gap junction intercellular communication (GJIC) and regulation of the ectoplasmic specialization protein N-cadhedran. Tumor necrosis factor actin protein in the testes increased in a dose-related fashion at 5 and 20 mg/kg/day on observation of three per dose group. The authors identified the 5-mg/kg/day dose as a LOAEL for PFOA effects on the blood testes barrier and the 1.25-mg/kg/day dose as a NOAEL, apparently based on the results for the key protein biomarkers for cellular intercommunication rather than the IgE and fluorescence results where 1.25 mg/kg/day was a LOAEL.

Li et al. (2011) investigated the involvement of mouse and human PPARα in PFOA-induced testicular toxicity. Wild-type, PPARα-null, and humanized PPARα male 129/Sv mice were given PFOA daily by gavage at doses of 0, 1, and 5 mg/kg/day for 6 weeks. Body weight and testis weight were not affected by treatment in any group. Absolute and relative-to-body weights of the epididymis and seminal vesicle plus prostate gland were decreased only in high-dose wild-type

mice compared to the wild-type controls. No effects on sperm count and motility were seen in any group. Sperm abnormalities were significantly increased in both treated groups of wild-type and humanized PPARα mice, but not in the PPARα-null mice. Plasma testosterone levels were slightly decreased in low-dose wild-type mice, and significantly decreased in high-dose wild-type and low- and high-dose humanized PPARα mice compared to the control groups. Testosterone levels were slightly reduced in a dose-related manner in the PPARα-null mice, but statistical significance was not attained.

Using real-time quantitative PCR, the mRNA levels for several genes associated with testicular cholesterol synthesis, transport, and testosterone biosynthesis were examined. Levels of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) synthase, HMG-CoA reductase, and aromatase were not changed after treatment in any group. Expression of steriodogenic acute regulatory protein (which transports cholesterol into mitochondria) was inhibited in wild-type mice at the high dose and in humanized PPARα mice at both doses; peripheral benzodiazepine receptor level was decreased only in high-dose humanized PPARα mice; cytochrome P450 side-chain cleavage enzyme was decreased in both groups of wild-type mice; cytochrome P450 17α-hydroxylase/C17-20 lyase was inhibited at the high dose in both wild-type and humanized PPARα mice; and 3β-hydroxysteroid dehydrogenase was decreased in both treated groups of humanized PPARα mice. Decreased expression of 17β-hydroxysteroid dehydrogenase was the only change found in treated PPARα-null mice.

In the mitochondria, carnitine palmitoyltransferase (CPT) was decreased in both groups of wild-type and high-dose humanized PPARα mice, and SOD levels were reduced in all treated wild-type and humanized PPARα mice. Histopathological lesions of the testes, including abnormal seminiferous tubules, lack of germ cells, or necrotic cells, were observed in high-dose wild-type and humanized PPARα mice. No morphological changes were observed in the testes from PFOA treatment in PPARα-null mice. The 1-mg/kg/day dose was the LOAEL for significant ($p<0.05$) sperm abnormalities, decreased testosterone, and several biochemical alterations in the PPARα and hPPARα mice, but not in the PPARα-null mice. There were dose-related decreases in testosterone in the PPARα-null mice, but they did not achieve statistical significance.

Inhalation Exposure

No data on the effects of short-term inhalation exposures to PFOA were identified in the literature.

Dermal Exposure

Fairley et al. (2007) investigated the role of dermal exposure to PFOA in an experiment to evaluate toxicity in BALB/c mice. The mice were exposed to 0, 0.01%, 0.1%, 0.25%, 0.5%, 1.0%, and 1.5% PFOA (equivalent to 0, 0.25, 2.5, 6.25, 12.5, 25, and 50 mg/kg PFOA). It was applied to the dorsal surface of both ears daily for 4 days. The mice were sacrificed 6 days later. Dermal PFOA exposure did not cause reductions in body weight or signs of inflammation at the application site. A significant increase in liver weight was observed in mice dosed with $\geq$ 6.25 mg/kg PFOA ($p<0.01$) compared to control liver weight. Under the conditions of the study, the LOAEL was 6.25 mg/kg PFOA based on increased liver weight, and the NOAEL was 2.25 mg/kg PFOA.

3.2.3 Subchronic Studies

Oral Exposure

Monkey. Goldenthal (1978) administered rhesus monkeys (two per gender per group) doses of 0, 3, 10, 30, and 100 mg/kg/day PFOA by gavage for 90 days. Animals were observed twice daily and body weights were recorded weekly. Blood and urine samples were collected once during a control period, and at 1 and 3 months for hematology, clinical chemistry, and urinalysis. Organs and tissues from animals that were sacrificed at the end of the study and from animals that died during the treatment period were weighed, examined for gross pathology, and processed for histopathology.

All monkeys in the 100-mg/kg/day group died between weeks 2–5 of the study. Signs and symptoms that first appeared during week 1 included anorexia, frothy emesis, swollen face and eyes, decreased activity, prostration, and body trembling. Three monkeys from the 30-mg/kg/day group died during the study. Beginning in week 4, all four animals showed slight to moderate, and sometimes severe, decreased activity. One monkey had emesis and ataxia, swollen face, eyes, and vulva. Beginning in week 6, two monkeys had black stools and one monkey had slight-to-moderate dehydration. No monkeys in the 3- or 10-mg/kg/day groups died during the study. One monkey in the 10-mg/kg/day group was anorexic during week 4, had a pale and swollen face in week 7, and had black stools for several days in week 12. Animals in the 3-mg/kg/day group occasionally had soft stools or moderate-to-marked diarrhea and frothy emesis.

Changes in body weight were similar to the controls for animals from the 3- and 10-mg/kg/day groups. Monkeys from the 30- and 100-mg/kg/day groups lost body weight after week 1. At the end of the study, this loss was statistically significant for the one surviving male in the 30-mg/kg/day group and reflected in body weight (2.30 kg versus 3.78 kg for the control). The results of the urinalysis, and hematological and clinical chemistry analyses were comparable for the control and the 3- and 10-mg/kg/day groups at 1 and 3 months.

At necropsy, there were significant decreases in the absolute heart and brain weight and relative liver weight in 10-mg/kg/day females. At 3 mg/kg/day, the relative pituitary weight in males was significantly increased. The biological significance of these weight changes is difficult to assess, as they were not accompanied by morphologic changes.

In animals that died, one male and two females from the 30-mg/kg/day group and all animals from the 100-mg/kg/day group had marked diffuse lipid depletion in the adrenal glands. All males and females from the 30- and 100-mg/kg/day groups also had slight to moderate hypocellularity of the bone marrow and moderate atrophy of lymphoid follicles in the spleen. One female from the 30-mg/kg/day group and all animals in the 100-mg/kg/day group had moderate atrophy of the lymphoid follicles in the lymph nodes.

The one male in the 30-mg/kg/day group that survived until terminal sacrifice had slight-to-moderate hypocellularity of the bone marrow and moderate atrophy of lymphoid follicles in the spleen. Under the conditions of this study, the male LOAEL was 3 mg/kg/day based on increased relative pituitary weight, and no NOAEL was established. The female LOAEL was 10 mg/kg/day based on decreased heart and brain weight, and the NOAEL was 3 mg/kg/day.

Rat. In a dietary study reported by Perkins et al. (2004), male ChR-CD rats (45–55 per group) were administered concentrations of 1, 10, 30, and 100 ppm PFOA for 13 weeks. These doses are equivalent to 0.06, 0.64, 1.94, and 6.50 mg/kg/day. There were two control groups—a nonpair-fed control group and a pair-fed control group for the 100-ppm dose group); both were fed the basal diet. Following the 13-week exposure period, 10 animals per group were fed basal diet for an 8-week recovery period. The animals were observed twice daily for clinical signs of toxicity, and body weights and food consumption were recorded weekly. Food consumption was recorded daily for the pair-fed animals.

A total of 15 animals per group were sacrificed following 4, 7, and 13 weeks of treatment; 10 animals per group were sacrificed after 13 weeks of treatment and an 8-week recovery period. Serum samples collected from 10 animals per group at each scheduled sacrifice during treatment and from five animals per group during recovery were analyzed for estradiol, T, LH, and PFOA. The level of palmitoyl-CoA oxidase was analyzed from a section of liver that was obtained from five animals per group at each scheduled sacrifice. Weights of the brain, liver, lungs, testis, seminal vesicle, prostate, coagulating gland, and urethra were recorded, and these tissues also were examined histologically. In addition, the brain, liver, lungs, testis, seminal vesicle, and prostate were preserved in glutaraldehyde for electron microscopic examination.

In the analysis of the data, animals exposed to 1, 10, 30, and 100 ppm PFOA were compared to the control animals in the nonpair-fed group, while the data from the pair-fed control animals were compared to animals exposed to 100 ppm PFOA. At 100 ppm, significant reductions in body weight and body weight gain were seen compared to the pair-fed control group during week 1 and the nonpair-fed control group during weeks 1–13. Body weight data in the other dosed groups were comparable to controls. At 10 and 30 ppm, mean body weight gains were significantly lower than for the nonpair-fed control group at week 2. These differences in body weight and body weight gains were not observed during the recovery period. Animals fed 100 ppm consumed significantly less food during weeks 1 and 2 than the nonpair-fed control group. Overall, there was no significant difference in food consumption. There were no significant differences among the groups for any of the hormones evaluated, although there was some indication of elevated estradiol for the 100 ppm group at week 4. The elevated estradiol for the high-dose group at week 4 should be interpreted with caution because most of the measurements for control and treated groups were below the level of detection at all other timepoints (Perkins et al. 2004).

Significant dose-related increases in absolute and relative liver weights and hepatocellular hypertrophy were observed at weeks 4, 7, and 13 in the 10, 30, and 100 ppm groups (Table 3-18). There was no significant evidence of any dose-related degenerative changes. Hepatic palmitoyl-CoA oxidase activity was significantly increased at weeks 4, 7, and 13 in the 30 and 100 ppm groups. At 10 ppm, hepatic palmitoyl-CoA oxidase activity was significantly increased at week 4 only. At 13 weeks, the palmitoyl-CoA oxidase activity was lower than it was at weeks 4 and 7 for the 10, 30, and 100 ppm dose groups, possibly suggesting attenuation of the peroxisomal response. Histologically, liver effects were limited to minimal or slight coagulative necrosis observed in 0/45, 1/45, 0/45, 2/45, and 3/44 in the control, 1, 10, 30, and 100 ppm groups, respectively.

Table 3-18. Liver Effects in Male Rats

Parameter	Week	Dose (mg/kg/day)					
		0 [a]	0 [b]	0.06 (1 ppm)	0.64 (10 ppm)	1.94 (30 ppm)	6.5 (100 ppm)

Under the conditions of this study, the authors identified the LOAEL as 10 ppm (0.64 mg/kg/day) based on increases in absolute and relative liver weight and hepatocellular hypertrophy (Perkins et al. 2004). The NOAEL identified was 1.0 ppm (0.06 mg/kg/day). However, the liver weight and palmitoyl-CoA responses were associated with the activation of PPARα and were not accompanied by significant dose-related changes that would classify them as adverse for humans (e.g., fibrosis, macrovesicular steatosis, inflammation) as enumerated by Hall et al. (2012). Therefore, for the current assessment, the LOAEL is identified as 1.94 mg/kg/day based on a slight increased incidence of coagulative necrosis in the liver. The NOAEL is 0.64 mg/kg/day.

Serum samples were collected from 8 to 10 animals prior to each sacrifice. PFOA concentrations in serum increased with the dose, but all dose levels appeared to have reached steady state by the first sacrifice at week 4. Following the 8-week recovery period, serum levels were below detection for many animals and consistent with a half-life of about seven days in male ChR-CD rats.

Inhalation and Dermal Exposure

No data on the effects of subchronic inhalation or dermal exposures to PFOA were identified in the literature.

3.2.4 Neurotoxicity

Johansson et al. (2008) gave male neonatal Naval Medical Research Institute (NMRI) mice (3–4 litters, ~5–6 male pups per litter) a single gavage dose of 0, 0.58, and 8.7 mg PFOA/kg in a lecithin/peanut oil emulsion on PND 10, the approximate peak time of rapid brain growth in mice. Spontaneous behavior (e.g., locomotion, rearing, and total activity) and habituation in response to a placement in unfamiliar environment were tested in 10 mice in each group at ages 2 and 4 months. Each test period was divided into three 20-min periods. The habituation ratio was determined by dividing the activity for the third 20-min period by the activity for the first period. A high habituation ratio indicated that movement patterns of the exposed animals when placed in an unfamiliar test chamber differed from control by displaying comparatively low activity for the first 20 mins and comparatively higher activity for the last 20 mins.

Exposure to PFOA did not affect body weight or body weight gain in male NMRI mice following treatment. Compared to controls, the habituation ratio for rearing and locomotion in the high-dose animals was elevated compared to controls at 2 and 4 months, with a significantly higher ratio ($p<0.01$) at 4 months than at 2 months. At 4 months, the changes in activity patterns for the high dose were significant ($p<0.01$) compared to controls for locomotion, rearing, and total activity. The results at the low dose were less pronounced, with a significant impact on locomotion and slight changes in rearing behavior.

At 4 months of age, mice were tested for nicotine-induced behavior and behavior in the elevated plus maze. Increased activity is the expected response to nicotine injection (80 μg) as a result of stimulation of the cholinergic receptors in the brain. The activity responses of the PFOA-exposed animals to nicotine stimulation were significantly less than the response of the controls, but the differences were most pronounced in the high-dose animals.

The mice also were tested in an elevated plus maze, which determined whether they would select an enclosed environment (the expected response) over an open environment. No significant differences were observed in the PFOA-exposed mice in this test. Under the conditions of this study, the clear LOAEL was 8.7 mg/kg based on locomotion, rearing, and total activity; habituation ratio; and response to nicotine at 2 and 4 months after receiving a single gavage dose on PND 10. There were significant differences in locomotion and total activity at 4 months in the low-dose animals, which supports identifying the 0.58-mg/kg dose as a marginal LOAEL. However, the data at the low dose are less compelling than those at the high dose.

In a follow-up to their original study, Johansson et al. (2009) gave male neonatal NMRI mice (3–4 litters, ~5–6 male pups per litter) a single gavage dose of 0 and 8.7 mg PFOA/kg on PND 10. Protein levels of calcium/calmodulin-dependent protein kinase II (CaMKII), growth-associated protein-43 (GAP-43), synaptophysin, and tau protein were determined in the cerebral cortex and hippocampus. CaMKII regulates synapotogenesis and synaptic plasticity, GAP-43 modulates axon sprouting and growth, synaptophysin is a membrane glycoprotein in presynaptic vesicles, and tau protein is responsible for outgrowth of neuronal processes and microtubule assembly and maintenance.

Levels of CaMKII protein in the hippocampus were significantly higher (58%, $p\leq0.05$) in mice exposed to PFOA than levels in control mice, but unchanged in the cerebral cortex. Levels of GAP-43 protein in the hippocampus were significantly higher (17%, $p\leq0.05$) in PFOA-exposed mice than levels in control mice, but unchanged in the cerebral cortex. Synaptophysin levels in mice exposed to PFOA were significantly increased in the hippocampus (52%) and

cerebral cortex (82%). Tau protein levels in PFOA-exposed mice were increased 92% and 142% ($p \leq 0.001$) in the hippocampus and cerebral cortex, respectively, above levels in the control mice. The authors concluded that alterations of these proteins could be a factor in the altered behavior of adult mice that were exposed to PFOA as neonates because they are required for normal brain development.

Onishchenko et al. (2011) exposed pregnant C57BL/6/Bkl mice (n = 6 per group) to 0 and 0.3 mg PFOA/kg/day in the diet from GD 1 to the end of pregnancy. The behavior of the weaned offspring was analyzed in locomotor, circadian activity, elevated plus maze, and forced swim tests at 5–8 weeks of age. Muscle strength and motor coordination tests were given at 3–4 months of age. The distance traveled over 30 mins was registered in 5-min intervals in the locomotor test. For the circadian activity test, the activity of the mice in social groups was monitored for 48 hours after placement in new cages. Anxiety-like behavior was determined using the elevated plus maze. Depression-like behavior was determined in the forced swim test by tracking the time spent floating passively for 2 seconds or longer. Muscle strength (three trials) was measured by how long within 60 seconds it took the mouse to fall off an upside-down lid onto the cage floor. Motor coordination (four trials) was measured by how long the mice remained on a rotating drum as a rotarod accelerated from 4 to 40 rpm over 5 mins.

Prenatal exposure to PFOA did not alter offspring locomotor activity, anxiety-related behavior, depression-like behavior, or muscle strength. In the circadian activity tests, male offspring exposed to PFOA were significantly more active ($p = 0.013$) and the female offspring were significantly less active ($p = 0.036$) than control offspring during the first hour of the test. PFOA-exposed male offspring were significantly more active ($p<0.05$) than control males from the dark phase of day 1 through the dark phase day 2. Both male and female offspring exposed to PFOA had significantly less inactive periods ($p<0.05$) during the light phase compared to their respective controls. In the accelerating rotarod test, female offspring exposed to PFOA exhibited decreased fall latency over the four trials compared to control females, but no effect of treatment was observed in male offspring. The authors concluded that prenatal exposure to 0.3 mg/kg/day of PFOA resulted in gender-related postnatal alterations in offspring behavior and motor function at 3–4 months of age.

In vitro. Slotkin et al. (2008) characterized the neurotoxicity of PFOA using PC12 cells. The cells were derived from a neuroendocrine tumor of the rat adrenal medulla and serve as a model for neuronal development and differentiation. Exposure to nerve growth factors causes PC12 cells to differentiate into cells expressing either dopamine or acetylcholine phenotypes. The cells were incubated with 10, 50, 100, and 250 µmol PFOA. Synthesis of DNA, cell viability, cell growth, and lipid peroxidation were measured to determine if PFOA targets specific events in neural cell differentiation. Differentiation shifts towards or away from the dopamine and acetylcholine phenotypes were measured by assessing the activities of tyrosine hydroxylase (TH, dopamine) and choline acetyltransferase (ChAT, acetylcholine). The undifferentiated cells were evaluated after a 24-hour exposure to PFOA, and differentiating cells were evaluated after 4–6 days of exposure to PFOA.

Significant inhibition of DNA synthesis ($p<0.0001$) occurred in the undifferentiated cells after exposure to 250 µmol PFOA with no change in DNA content. Lipid peroxidation was significantly increased ($p<0.02$) after exposure to 10 µmol PFOA, and cell viability was significantly decreased ($p<0.03$) after a 24-hour exposure to 100 and 250 µmol PFOA.

In differentiating PC12 cells, exposure to 250 μmol PFOA caused decreased DNA content with no change in total protein/DNA content ratio or the membrane/total protein ratio. The lowest and highest PFOA concentrations caused a significant increase in lipid peroxidation ($p<0.007$), but no effect was observed in cell viability. TH activity was decreased ($p<0.05$) after exposure to 10 and 250 μmol PFOA, and the TH/ChAT ratio was decreased ($p<0.05$) at 10 μmol PFOA. The results suggest that PFOA exposure caused the differentiating cells to shift slightly to favor the acetylcholine phenotype.

3.2.5 Developmental/Reproductive Toxicity

Reproductive Effects

A comprehensive two-generation reproductive toxicity study was conducted in Sprague-Dawley Rats with publication of the results by Butenhoff et al. (2004a). A subsequent study by York et al. (2010) provided details of male reproductive organ histopathology. One study in mice examined the impact of mating exposed males with unexposed females on fertility and neonatal body weight (Lu et al. 2015).

Rat. A standard oral two-generation reproductive toxicity study of PFOA in Sprague-Dawley rats was conducted (Butenhoff et al. 2004a). Five groups of male and female SD rats (30 per gender per group) were administered PFOA by gavage at doses of 0, 1, 3, 10, and 30 mg/kg/day. The parental generation (F0) rats (n = 30 per gender per group) were dosed for 10 weeks prior to mating and until sacrificed (after mating for males; after weaning for females). F1 generation rats (n = 60 per gender per group) were dosed similarly, beginning at weaning. The F2 generation rats were maintained through LD 22. Reproductive parameters evaluated in the F0 and F1 generations included estrus cyclicity, sperm number and quality, mating, fertility, natural delivery, and litter viability and growth. Age at sexual maturation in F1 pups, anogenital distance in F2 pups, and presence of nipples (males) in F2 pups also were determined. Food consumption, body-weight gain, selected organ weights, gross pathology, and appropriate histopathology of reproductive organs were evaluated.

F0 Male Rats

One F0 male rat in the 30 mg/kg/day dose group was sacrificed on day 45 of the study because of adverse clinical signs. Statistically significant increases in clinical signs also were observed in male rats in the high-dose group, including dehydration, urine-stained abdominal fur, and ungroomed coat. Significant reductions in body weight were reported beginning on post-weaning day 50 at 3 mg/kg/day and for most of the study until termination in 10 and 30 mg/kg/day dose groups (6%, 11%, and 25% decrease from controls, respectively, at the end of premating; $p\leq0.05$). Absolute food consumption was significantly reduced to approximately 91% of the control level during the study in the 30-mg/kg/day dose group but not for the lower dose groups. Mean food consumption relative to body weight was increased in a dose-related manner for all treated males with statistical significance at ≥3 mg/kg/day; overall relative food consumption was 101, 105, 110, and 118% of the controls in the 1, 3, 10, and 30 mg/kg/day groups, respectively. The body weight and food consumption effects were not observed in female rats at any dose.

Organ weight data for the F0 male rats is shown in Table 3-19. The absolute and relative-to-body and -brain weights of the liver were statistically significantly increased in all dose groups. Absolute kidney weights were statistically significantly increased in the 1-, 3-, and 10-mg/kg/day dose groups, but significantly decreased in the 30-mg/kg/day group. Organ weight-to-terminal body weight ratios for the left and right kidney were statistically significantly increased in all treated groups. Kidney weight-to-brain weight ratios were significantly increased at 1, 3, and 10 mg/kg/day, but decreased at 30 mg/kg/day, following the trends in absolute weights. In the high-dose group, absolute and relative kidney weight changes occurred in a pattern typically associated with decrements in body weight. However, in the lower dose groups, consistent significant increases in absolute kidney weight and relative-to-body and -brain weights are a response to the challenge of providing transporters for renal removal of the foreign molecule. Increased kidney weight can be regarded as an adaptive response to the transport challenge. It is beneficial for the individual but adverse in the sense that it signifies the need to upregulate tubular transporters in the kidney to excrete the foreign material and a reflection of PFOA bioaccumulation in serum and tissues.

Table 3-19. Organ Weight Data from F0 Male Rats

	0 mg/kg/day	1 mg/kg/day	3 mg/kg/day	10 mg/kg/day	30 mg/kg/day
Body weight (g)	581 ± 40	575 ± 48	542 ± 47**	513 ± 54**	432 ± 64**

Source: Butenhoff et al. 2004a
Not*es*: Mean±SD; n = 29–30; significantly different from control: *p < 0.05, **p < 0.01.

The only histologic finding was increased thickness and prominence of the zona glomerulosa and vacuolation in the cells of the adrenal cortex observed in 2/10 males in the 10-mg/kg/day dose group and 7/10 males in the 30-mg/kg/day dose group.

No treatment-related effects were reported at any dose level for any of the male reproductive parameters assessed. There was no evidence of altered testicular and sperm structure and function in PFOA-treated F0 rats with mean group serum PFOA concentrations of up to approximately 45 µg/mL (York et al. 2010). There was a significant dose-related increase in seminal vesicle weight ($p<0.05$) with and without fluid in the F1 males, but fertility of the exposed males in all generations was comparable to the controls.

No treatment-related effects were seen at necropsy or upon microscopic examination of the reproductive organs.

Under the conditions of the study, the LOAEL for F0 parental male rats is 1 mg/kg/day, the lowest dose tested, based on significant increases in absolute and relative liver and kidney weights. A NOAEL for the F0 parental males could not be determined.

F0 Female Rats

There were no treatment-related effects on clinical signs, body weight, food consumption, organ weights, or histology of the organs. There were no treatment-related effects on any of the reproductive parameters assessed, and no treatment-related effects were seen at necropsy other than slightly decreased liver weights ($p<0.05$) at doses of 3 and 10 mg/kg/day, but not 30 mg/kg/day. No abnormalities were seen with microscopic examination of the reproductive organs. The NOAEL for F0 parental females is 30 mg/kg/day, the highest dose tested.

F1 Generation

Pup body weight on a per-litter basis (genders combined) was significantly reduced ($p\leq0.01$) by 8–10% throughout the first 2 weeks of lactation in the 30-mg/kg/day group; at weaning, the mean body weight was reduced 4.5%, but the difference was not statistically significant. Although there were no effects on the viability and lactation indices, the total number of dead pups during lactation was increased in the 30-mg/kg/day groups; the difference was statistically significant on LDs 6–8. No other effects were noted, and there were no treatment-related findings for the pups necropsied at weaning. The offspring toxicity LOAEL is 30 mg/kg/day based on decreased body weight and an increase in the number of dead pups; the NOAEL is 10 mg/kg/day.

F1 Male Rats

Significant increases in treatment-related deaths (5/60 animals) were reported in F1 males in the high-dose group between days 2–4 postweaning. One rat was moribund sacrificed on day 39 postweaning and another was found dead on day 107 postweaning. Clinical signs included a significant increase in emaciation at 10 and 30 mg/kg/day, and in urine-stained abdominal fur, decreased motor activity, and abdominal distention at 30 mg/kg/day.

Mean body weight was significantly reduced in the 30-mg/kg/day group beginning on postweaning day 8, in the 10-mg/kg/day group beginning on postweaning day 36, and towards the end of the study in the 1- and 3-mg/kg/day groups. Terminal mean body weight was reduced in all treated groups at the time of sacrifice. For all groups, there was a significant, dose-related reduction in mean body weight gain for the entire dosing period (days 1–113). Absolute food consumption values were significantly reduced at 10 and 30 mg/kg/day during the entire precohabitation period (days 1–70 postweaning), while relative food consumption values were significantly increased.

Statistically significant delays in the average day of preputial separation ($p\leq 0.01$) were observed in high-dose animals versus concurrent controls (52.2 days of age versus 48.5 days of age, respectively). There were no other effects on any of the reproductive parameters assessed, and at necropsy no effects on reproductive organs or fertility were noted (York et al. 2010).

The absolute and relative weights of the liver were statistically significantly increased in all treated groups ($p \leq 0.01$). Treatment-related microscopic changes were described as diffuse hepatocellular hypertrophy in rats receiving doses of ≥ 3 mg/kg/day. At the same dose levels, there were scattered incidences of focal-to-multifocal necrosis and inflammation in the livers of the F1 male rats. As in the F0 males, the relative weight of the left and/or right kidneys was statistically significantly increased compared to controls for all dose groups, except for the right kidney at the high dose in which it was lower than for the controls (Table 3-20). Organ weight-to-terminal body weight and brain weight ratios for the kidney were statistically significantly

increased in all treated groups. All other organ weight changes observed (i.e., thymus, spleen, left adrenal, brain, prostate, seminal vesicles, testes, and epididymis) were probably due to decrements in body weight and not a reflection of target organ toxicity. Treatment-related microscopic changes were observed in the adrenal glands of high-dose animals (i.e., cytoplasmic hypertrophy and vacuolation of the cells of the adrenal cortex) and in the liver of rats treated with 3, 10, and 30 mg/kg/day (hepatocellular hypertrophy).

Table 3-20. Organ Weight Data from F1 Male Rats

	0 mg/kg/day	1 mg/kg/day	3 mg/kg/day	10 mg/kg/day	30 mg/kg/day

Source: Butenhoff et al. 2004a
Notes: Mean±SD; n = 29-30; significantly different from control: *p<0.05, **p<0.01.

The LOAEL for adult systemic toxicity in the F1 males is 1 mg/kg/day based on significant, dose-related decreases in body weights and body weight gains, and in terminal body weights; and significant increases in absolute and relative kidney weights. A NOAEL for adult systemic toxicity in the F1 males could not be determined. Liver weights were significantly increased at all doses, but only accompanied by microscopic lesions at doses ≥ 3 mg/kg/day.

F1 Female Rats

A statistically significant increase in treatment-related mortality (6/60 animals) was observed in F1 females on postweaning days 2–8 at the highest dose of 30 mg/kg/day. No adverse clinical signs of treatment-related toxicity were reported. Statistically significant decreases in body weight were observed in high-dose rats on days 8, 15, 22, 29, 50, and 57 postweaning, during precohabitation (recorded on the day cohabitation began, when F1 generation rats were 92–106 days of age), and during gestation and lactation. Body weight gain was significantly reduced during days 1–8 and 8–15 postweaning. Statistically significant decreases in absolute food consumption were observed during days 1–8, 8–15, and 15–22 postweaning, during precohabitation, and during gestation and lactation in animals treated with 30 mg/kg/day. Relative food consumption values were comparable across all treated groups.

Statistically significant delays ($p \leq 0.01$) in sexual maturation (the average day of vaginal patency) were observed in high-dose animals versus concurrent controls (36.6 days of age versus 34.9 days of age, respectively). Prior to the rats mating, the study authors noted a statistically significant increase in the average numbers of estrous stages per 21 days in high-dose animals (5.4 versus 4.7 in controls). For this calculation, the number of independent occurrences of estrus in the 21 days of observation was determined. This calculation can be used as a screen for effects on the estrous cycle, but should be followed by a more detailed analysis.

Both 3M (2002, cited in USEPA [2005c]), and EPA (USEPA 2002b) conducted a more detailed analysis of the estrous cycle data. The 3M analysis of the data concluded that there were no differences in the number of females with ≥3 days of estrus or with ≥4 days of diestrus in the control and high-dose groups. This conclusion is consistent with that of EPA (USEPA 2002b). The cycles were evaluated as having either regular 4–5-day cycles, uneven cycling (defined as brief periods with irregular pattern) or periods of prolonged diestrus (defined as 4–6-day diestrus periods), extended estrus (defined as 3–4 days of cornified smears), possible pseudopregnancy (defined as 6 or more days of leukocytes), or persistent estrus (defined as 5 or more days of cornified smears). The two groups were not different in any of the parameters measured. Thus, the increase in the number of estrus stages per 21 days noted by the study authors was an outcome of the approach used for the calculations and is not biologically meaningful. There were no effects on the other reproductive parameters assessed, and at necropsy no effects on reproductive organs were noted.

No treatment-related effects were observed in the terminal body weights of the F1 female rats. The absolute weight of the pituitary, the pituitary weight-to-terminal body weight ratio, and the pituitary weight-to-brain weight ratio were statistically significantly decreased at 3 mg/kg/day and higher. Since there is not a clear dose-response relationship and histologic examination reveal no lesions, the biological significance of the pituitary weight data is problematic. No other differences were reported for the absolute weights or ratios for other organs evaluated. No treatment-related effects were reported following macroscopic and histopathologic examinations.

For F1 females, the LOAEL for developmental/reproductive toxicity was considered to be 30 mg/kg/day based on significantly reduced body weight and body weight gain during lactation, a delay in sexual maturation, and increased mortality during postweaning days 2–8; the NOAEL was 10 mg/kg/day. The NOAEL and LOAEL for adult systemic toxicity in F1 females are 10 and 30 mg/kg/day, respectively, based on statistically significant decreases in body weight and body weight gains.

F2 Generation Rats

There was a statistically significant increase ($p \leq 0.01$) in the number of pups found dead on LD 1 in the 3- and 10-mg/kg/day groups. An independent statistical analysis was conducted by EPA (USEPA 2002c), and no significant differences were observed between dose groups and the response did not have any trend in dose. There were no treatment-related effects on any of the developmental parameters assessed, and at necropsy, no treatment-related effects were noted. The NOAEL for developmental/reproductive toxicity in the F2 offspring was 30 mg/kg/day.

Mouse. In a follow-up to the 28-day component of the Lu et al. study (2015) of the impact on PFOA on the blood testes barrier (section 3.2.2), the authors examined the impact exposure to 0 and 5 mg/kg/day PFOA had on the fertility of the treated male mice (6–8 weeks old; 15 per dose group). Each treated male was mated with three virgin ICR females (8–10 weeks old). Successful mating was determined by the presence of a vaginal plug in the morning. The pregnant females were separated from the males and caged alone throughout the pregnancy; they were not dosed with PFOA. At parturition, the pups were counted and the litter body weight recorded. There was a statistically significant decrease in the number of mated females per male mouse and pregnant females per male mouse ($p<0.001$) for the exposed males compared to the controls. The average number of pups per litter was smaller for the exposed group (10.20 ± 0.72 versus 11.89 ± 0.54), but the difference was not significant. The average litter weight was

significantly lower for the offspring of the paternally exposed mice than of the paternal controls (16.17 ± 1.63 g versus 19.95 ± 0.80 g; $p<0.05$). The 5-mg/kg/day dose was a LOAEL for effects on male fertility and the significantly lower body weight of their progeny.

Developmental Effects

Standard developmental studies in rats and mice found impacts on pup body weight and developmental delays. Most studies used the oral route of exposure; one study used inhalation exposure to PFOA particulate matter. Some examined the developmental impact of PFOA associated with exposures that occurred only during gestation and lactation or during the prepubertal period and the association of PPARα with the developmental effect spectrum. A substantial number of studies in mice focused on PFOA's impact on mammary gland development.

3.2.6 Prenatal Development

Rat. Pregnant Sprague-Dawley rats were gavage-dosed with 0, 3, 10, and 30 mg/kg/day PFOA during days 4–10, 4–15, and 4–21 of gestation, or from GD 4 to LD 21 (Hinderliter et al. 2005; Mylchreest 2003). Clinical observations and body weights were recorded daily. On GDs 10, 15, and 21, five rats per group per time-point were sacrificed and the number, location, and type of implantation sites were recorded. Embryos were collected on day 10, and placentas, amniotic fluid, and embryos/fetuses were collected on days 15 and 21. Maternal blood samples were collected at 2 hours ± 30 mins post-dose. The remaining five rats per group were allowed to deliver. On LDs 0, 3, 7, 14, and 21, the pups were counted, weighed (genders separate), and examined for abnormal appearance and behavior. Randomly selected pups were sacrificed and blood samples were collected. On LDs 3, 7, 14, and 21, the dams were anesthetized and milk and blood samples were collected; dams were removed from their litters 1–2 hours prior to collection. Plasma, milk, amniotic fluid extract, and tissue homogenate (i.e., placenta, embryo, and fetus) supernatants were analyzed for PFOA concentrations by HPLC/MS.

All dams survived and there were no clinical signs of toxicity. In the 30-mg/kg/day group, mean body weight gain was approximately 10% lower than in the control group during gestation, and mean body weight was approximately 4% lower than for controls throughout gestation and lactation. The number of implantation sites, resorptions, and live fetuses were comparable among groups on days 10, 15, and 21 of gestation. One dam in the 3-mg/kg/day group and two dams in the 30-mg/kg/day group delivered small litters (3–6 pups per litter compared to 12–19 pups per litter in the control group); however, given the small sample size, the biological significance of this finding is unclear. There were no clinical signs of toxicity in the pups, and pup survival and body weights were comparable among groups. Under the conditions of this study, the maternal LOAEL was 30 mg/kg/day for decreased body weight gain during gestation, and the NOAEL was 10 mg/kg/day. The developmental NOAEL was 30 mg/kg/day.

Mouse. Lau et al. (2006) conducted a developmental toxicity study of PFOA in mice to ascertain whether there was a gender-related difference in the bioaccumulation of PFOA in the mouse and to evaluate the effects of PFOA on prenatal and postnatal development in offspring exposed during pregnancy. In that study, groups averaging 9–45 timed-pregnant CD-1 mice were given 0, 1, 3, 5, 10, 20, and 40 mg/kg PFOA daily by oral gavage on GDs 1–17. Maternal weight was monitored during gestation. Dams were divided into two groups. In the first group, dams were sacrificed on GD 18 and underwent maternal and fetal examinations that included measure of maternal liver weight and examination of the gravid uterus for numbers of live and dead fetuses

and resorptions. Maternal blood was collected and analyzed for PFOA serum concentration. PFOA levels in the fetuses were not examined. Live fetuses were weighed and subjected to external gross necropsy and skeletal and visceral examinations. In the second group of dams, an additional dose of PFOA was administered on GD 18. Dams were allowed to give birth on GD 19.

The day following parturition was designated as PND 1. Time of parturition, condition of newborns, and number of live offspring were recorded. The number of live pups in each litter and pup body weight were noted for the first 4 days after birth and then at corresponding intervals thereafter. Eye opening was recorded beginning at PND 12. Pups were weaned on PND 23 and separated by gender. The time to sexual maturity was determined by monitoring vaginal opening and preputial separation beginning on PND 24. Two to four pups per gender per litter were randomly selected for observation of postnatal survival, growth, and development. Estrous cyclicity was determined daily by vaginal cytology. After weaning, dams were sacrificed and the contents of the uteri examined for implantation sites. Postnatal survival was calculated based on the number of implantations for each dam.

Signs of maternal toxicity were observed following exposure to PFOA during pregnancy. Statistically significant dose-related increases ($p \leq 0.05$) in maternal liver weight also were observed, beginning at 1 mg/kg/day. Dose-related decreases in maternal weight gain during pregnancy were observed beginning at 5 mg/kg/day, with statistical significance ($p \leq 0.05$) seen in the 20- and 40-mg/kg/day dose groups. Under the conditions of the study, a maternal LOAEL of 1 mg/kg was indicated based on increased liver weight, and a NOAEL was not established. Signs of developmental toxicity were observed following *in utero* exposure to PFOA. The number of implantations in treated mice was comparable to control mice. Statistically significant increases ($p \leq 0.05$) in full-litter resorptions were reported at doses of ≥ 5 mg/kg/day, with complete loss of pregnancies at the highest dose group of 40 mg/kg/day. A 20% reduction ($p \leq 0.05$) in live fetal body weight at term was reported at 20 mg/kg/day. A statistically significant increase in prenatal loss was observed in the 20-mg/kg/day dose group. Ossification (number of sites) of the forelimb proximal phalanges was significantly reduced at all doses except 5 mg/kg. Ossification of hindlimb proximal phalanges was significantly reduced at all doses except 3 and 5 mg/kg. Reduced ossification ($p \leq 0.05$) of the calvaria and enlarged fontanel was observed at 1, 3, and 20 mg/kg and at ≥ 10 mg/kg in the supraoccipital bone. Statistically significant increases ($p \leq 0.05$) in minor limb and tail defects were observed in the fetuses at doses ≥ 5 mg/kg/day. Under the conditions of the study, a prenatal developmental LOAEL of 1 mg/kg was indicated based on increased skeletal defects, and the NOAEL was not established.

Slight, but statistically significant, increases ($p \leq 0.05$) in the average time to parturition were observed at 10 and 20 mg/kg/day. Increases ($p \leq 0.05$) in stillbirths and neonatal mortality (or decreases in postnatal survival) were observed at doses ≥ 5 mg/kg/day, with as much as a 30% increase in these effects seen in the 10- and 20-mg/kg/day dose groups. Postnatal survival and viability in the 1- and 3-mg/kg/day dose groups were comparable to controls. At doses ≥ 3 mg/kg/day, a trend in growth retardation (body weight reductions of 25–30%; $p \leq 0.05$), was observed in the neonates at weaning. Body weights were at control levels by 6 weeks of age for females and by 13 weeks of age for males. A trend for increasing body weight (~6–10% greater than controls) was observed in animals dosed with 5 mg/kg at 13 weeks and in animals dosed with 1 and 3 mg/kg at 48 weeks. Deficits in early postnatal growth and development also were manifested by significant delays ($p \leq 0.05$) in eye opening at doses ≥ 5 mg/kg/day. Slight delays

($p \leq 0.05$) in vaginal opening and in time to estrous were observed at 20 mg/kg/day in females; in contrast, significant accelerations ($p \leq 0.05$) in sexual maturation were observed in males, with preputial separation occurring 4 days earlier than controls at the 1-mg/kg/day dose and 2–3 days earlier in the 3–10-mg/kg/day dose groups, but the 20-mg/kg/day dose group was only slightly delayed compared to controls. Under the conditions of the study, a LOAEL for developmental toxicity of 1 mg/kg/day for males was indicated based on accelerated pubertal development, and a NOAEL was not established. For females, the developmental LOAEL was 3 mg/kg/day based on growth retardation, and the NOAEL was 1 mg/kg/day.

Values for the benchmark dose (BMD) and the lower 95th percentile confidence bound on the BMD (BMDL) for the maternal and developmental endpoints (BMD_5 and $BMDL_5$) were calculated by the study authors and reported in Lau et al. (2006). For maternal toxicity, BMD_5 and $BMDL_5$ estimates for decreases in maternal weight gain during pregnancy were 6.76 and 3.58 mg/kg/day, respectively. For increases in maternal liver weight at term, BMD_5 and $BMDL_5$ estimates were 0.20 mg/kg/day and 0.17 mg/kg/day, respectively. BMD_5 and $BMDL_5$ estimates for the incidence of neonatal mortality (determined by survival to weaning) at 5 mg/kg/day were 2.84 and 1.09 mg/kg/day, respectively. Significant alterations in postnatal growth and development were observed at 1 and 3 mg/kg/day, with BMD_5 and $BMDL_5$ estimates of 1.07 and 0.86 mg/kg/day, respectively, for decreased pup weight at weaning; and 2.64 and 2.10 mg/kg/day, respectively, for delays in eye opening. The BMD_5 and $BMDL_5$ estimates for reduced phalangeal ossification were < 1 mg/kg/day. BMD_5 and $BMDL_5$ estimates for reduced fetal weight at term were estimated to be 10.3 and 4.3 mg/kg/day, respectively.

Male and female 129S1/SvImJ and PPARα-null mice were used in studies to determine if PFOA-induced developmental toxicity was mediated by PPARα (Abbott et al. 2007). Pregnant 129S1/SvlmJ wild-type and PPARα-null mice were orally dosed from GD 1–17 with 0, 0.1, 0.3, 0.6, 1, 3, 5, 10, and 20 mg PFOA/kg/day. Heterozygous (HET) litters also were produced by mating wild-type and PPARα-null males with wild-type and PPARα-null dams to determine if genetic background affected survival. The HET litters were sacrificed on PND 15. Survival at birth was recorded and live offspring counted and weighed by gender. Litters were counted and offspring weighed on PND 1–10, 14, 17, and 22. Weaning occurred on PND 22, and all dams and one pup per litter were sacrificed. Blood was collected and the uteri were stained for implantation counts.

There was no effect of treatment on maternal weight or maternal weight gain (excluding nonpregnant females and those with full-litter resorptions), number of implants, or pup weight at birth. Wild-type dams exposed to ≥0.6 mg/kg/day and PPARα-null dams exposed to ≥5 mg/kg/day had a significantly greater percentage of litter loss compared to their respective controls. At ≥5 mg/kg/day in wild-type dams and 20 mg/kg/day in PPARα-null dams, 100% litter loss occurred. Relative liver weight was significantly increased in wild-type adult females dosed with ≥1 mg/kg/day and in PPARα-null adult females dosed with ≥3 mg/kg/day.

Body weight in wild-type offspring born of dams dosed with 1.0 mg/kg/day was significantly reduced ($p<0.05$) compared to control offspring body weight gain on PND 9, 10, and 22 (males) and PND 7–10 and PND 22 (females). No differences were observed between PPARα-null offspring body weight and control offspring body weight. Survival of pups from birth to weaning was significantly reduced ($p<0.05$) in wild-type litters exposed to ≥0.6 mg/kg/day, but was not affected in PPARα-null litters. Survival was significantly decreased ($p<0.05$) for wild-type and HET pups born to wild-type dams dosed with 1 mg/kg/day and for HET pups born to PPARα-null dams dosed with 3 mg/kg. Offspring born of wild-type dams showed a dose-related trend for

delayed eye opening compared to control offspring (significantly delayed at 1 mg/kg/day, $p<0.05$), but no difference in day of eye opening was observed in the offspring born of PPARα-null dams. At weaning, relative liver weight was significantly increased ($p<0.05$) in wild-type offspring gestationally exposed to ≥0.1 mg/kg/day and in PPARα-null offspring gestationally exposed to 3 mg/kg/day.

The authors concluded that survival of PPARα-null pups and deaths of HET pups born to PPARα-null dams indicates that expression of PPARα is required for PFOA-induced postnatal lethality; however, early prenatal lethality was independent of PPARα. Delayed eye opening and reduced postnatal weight gain appeared to be mediated by PPARα, but other mechanisms might also contribute. Under the conditions of the study, the maternal/reproductive LOAEL for wild-type mice was 0.6 mg/kg/day based on increased percentage of litter loss, and the NOAEL was 0.3 mg/kg/day. The developmental LOAEL for wild-type offspring was 0.1 mg/kg/day based on increased liver weight, and the NOAEL was not established. The maternal LOAEL for PPARα-null mice was 3 mg/kg/day based on increased liver weight, and the NOAEL was 1 mg/kg/day. The developmental LOAEL for PPARα-null offspring was 3 mg/kg/day based on increased liver weight, and the NOAEL was 1 mg/kg/day.

To further evaluate the developmental effects potentially mediated by PPARα, groups of female wild-type, PPARα-null, and PPARα-humanized mice were given 0 and 3 mg PFOA/kg on GDs 1–17 by oral gavage (Albrecht et al. 2013). Controls received the water vehicle. Females were either sacrificed on GD 18 (n = 5–8 per group) or allowed to give birth and then sacrificed, along with their litters (n = 8–14), on PND 20. Livers from dams, fetuses, and pups were weighed and collected for histopathological evaluation and RNA analysis. Gene expression results are given in section 3.3.4. Mammary gland whole mounts were prepared from female pups on PND 20 for quantification of ductal length and number of terminal end buds; these results are described below with other studies evaluating the effects of PFOA on mammary gland development.

Evaluation on GD 18 showed no effects of PFOA administration on maternal body weight, body weight gain, gravid uterine weight, number of implantations per dam, or number of resorptions per litter in dams of any genotype. For animals allowed to litter, the average day of parturition was slightly later in PFOA-treated humanized mice than in the controls. Body weight of dams during lactation, the number of pups born per litter, pup body weight during lactation, and the onset of pup eye opening were similar between treated and control groups for all genotypes. Offspring survival during PNDs 1–5 was significantly reduced in the wild-type PFOA-treated group, but not in the other genotypes.

Maternal liver weight was significantly increased in the treated groups of all genotypes on GD 18 and in wild-type animals on PND 20. Maternal liver weight was not affected on PND 20 in the PPARα-null or PPARα-humanized mice. Relative fetal liver weight on GD 18 was significantly increased in fetuses from treated wild-type and humanized dams. On PND 20, relative liver weight was increased only in pups from treated wild-type dams. Microscopic evaluation of the maternal liver showed centrilobular hepatocellular hypertrophy in all PFOA-treated groups on GD 18 and PND 20, with decreased incidence and severity by PND 20. On GD 18, the liver lesions were graded as mild in the wild-type mice, minimal-to-mild in the humanized mice, and minimal in the null mice. The morphological features of the liver lesions differed slightly between genotypes and are described in more detail in section 3.4.1. Only wild-type fetuses and pups from treated dams showed similar liver lesions.

Yahia et al. (2010) gavage-dosed pregnant ICR mice (n = 5 per group) with 0, 1, 5, and 10 mg PFOA/kg/day from GDs 0–17 or 0–18. The dams dosed from GDs 0–17 were sacrificed on GD 18, and the fetal skeletal morphology was evaluated. Dams dosed from GDs 0–18 were allowed to give birth and their offspring were either processed for pathological examination or observed for 4 days for neonatal mortality. Maternal liver, kidney, brain, and lungs were histologically examined after necropsy. Serum was collected for clinical chemistry and lipid analysis. Body weight was significantly decreased in dams receiving 10 mg/kg/day. Maternal absolute liver weight was significantly increased ($p<0.05$) at doses ≥ 5 mg/kg/day and relative liver and kidney weights were significantly increased at all doses. Hepatic hypertrophy was localized to the centrilobular region at the two lower doses and was diffuse at the highest dose. Renal cells in the outer medullar and proximal tubule were slightly hypertrophic at all doses. Treatment with 10 mg/kg/day caused a significant increase in AST, ALT, GGT, and ALP and a significant decrease in total serum protein, albumin, globulin, triglycerides, phospholipids, TC, and free fatty acids. At 5 mg/kg/day, total serum protein and globulin were significantly decreased, and phosphorus was increased. At 1 mg/kg/day, BUN and phosphorus were significantly increased. The maternal LOAEL was 1 mg/kg/day based on significantly increased relative liver and kidney weight, and no NOAEL was established.

Live fetal birth weight was significantly decreased at the two highest doses. There was no difference in the percentage of live fetuses between treated and control groups. At 10 mg/kg/day, increased incidence of cleft sternum, reduced phalanges ossification, and delayed eruption of incisors was observed. Delayed parturition was observed in dams treated with 10 mg/kg/day, and ~58% of all pups born to those dams were stillborn. Death occurred within 6 hours of delivery in the remaining pups, and whole body edema was observed in some of the pups. The body weight of the live pups born to dams treated with 5 or 10 mg/kg/day was significantly reduced compared to control pup body weight. By PND 4, 16% of offspring born to dams dosed with 5 mg/kg/day had died. No pathological differences were observed in the lungs or brains of treated and control offspring. The developmental LOAEL was 5 mg/kg/day based on decreased body weight and decreased survival rate, and the NOAEL was 1 mg/kg/day.

Suh et al. (2011) examined placental prolactin-family hormone and fetal growth retardation in mice treated with PFOA. Pregnant CD-1 mice (n = 10 per group) were treated with 0, 2, 10, and 25 mg/kg/day PFOA from GDs 11–16. Dams were sacrificed on GD 16 and uteri were removed and examined. Three placentas per group were analyzed histochemically and the numbers of glycogen trophoblast cell (GlyT) in the junctional zone plus sinusoidal trophoblast giant cells (S-TGC) in the labyrinth zone were counted and compared. Trophoblast cells express prolactin-family genes. mRNA from three placentas per group were analyzed using situ hybridization, northern blot hybridization, and RT-PCR for mouse placental lactogen- (mPL-) II, mouse prolactin-like protein- (mPLP-) E and F, Pit-1α, and β isotype (transacting factors of mPL and mPLP genes).

A significant difference in maternal body weight was observed from GD 13–16 in dams treated with 25 mg/kg/day of PFOA compared to controls. At ≥2 mg/kg/day of PFOA, placental weight was significantly decreased and the number of resorptions and dead fetuses was significantly increased. At ≥10 mg/kg/day of PFOA, fetal weight and the number of live fetuses were significantly decreased. There were no differences in the number of implantation sites among the groups, and postimplantation loss was 3.87, 8.83, 30.98, and 55.41% for the 0, 2, 10, and 25 mg/kg/day PFOA groups, respectively.

The placentas of dams dosed with ≥10 mg/kg/day of PFOA displayed necrotic changes. Parietal and S-TGC and GlyT cell frequency in the placental junctional and labyrinth zones was significantly decreased ($p<0.05$) in a dose-dependent manner in treated dams. At 25 mg/kg/day of PFOA, S-TGCs showed signs of atrophy with crushed cell nucleus. A significant dose-dependent decrease in mPL-II, mPLP-E, mPLP-F, and Pit-1α and β isotype mRNA and expression was observed. Correlation coefficients between fetal weight and maternal mPL-II, mPLP-E, and mPLP-F mRNA levels were positive ($p<0.001$). Based on the results, the authors suggested that inhibited prolactin-family gene expression could be secondary to insufficient trophoblast cell differentiation and increased cell necrosis. These effects reduced placental efficiency and contributed in part to fetal growth retardation. The 2-mg/kg/day dose was a LOAEL for increases in resorption and dead fetuses plus decreased placental weight. There was no NOAEL.

A meta-analysis was conducted to determine whether developmental exposure to PFOA was associated with fetal growth effects in animals (Koustas et al. 2014). Eight studies identified in the published literature met the criteria of the Navigation Guide systematic review methodology for inclusion in the analysis (Woodruff and Sutton 2014). The data sets included mouse gavage studies with offspring body weight at birth. Maternal PFOA doses ranged from 0.01 to 20 mg/kg/day. The results from the meta-analysis showed that a 1-mg/kg/day increase in PFOA dose was associated with a -0.023 g (95% CI -0.029, -0.016) difference in pup birth weight. All of the studies included in the analysis are described either above with the developmental toxicity studies or with the specialized developmental studies that follow.

3.2.7 Mammary Gland Development and Other Specialized Developmental Studies

The following studies used experimental study designs and/or examined endpoints not typically included in standard developmental toxicity studies. The studies were conducted to determine critical periods of exposure for outcomes that occurred later in life. A number of the studies focused on mammary gland development in dams and female offspring. Researchers focused on effects resulting from indirect exposure of offspring via treatment of pregnant animals and/or direct exposure of peripubertal animals starting about the time of weaning.

Indirect gestational and/or lactational exposures

Many studies evaluating indirect gestational and/or lactational exposure to PFOA are available and Table 3-21 provides an overview of experiments designed to assess the developmental effects of PFOA following exposures during gestation. Most of the studies focus on mammary gland effects as a consequence of gestational and lactational or prepubertal exposures in CD-1 mice. Some have included postnatal assessment of the liver. Additional details of the studies are described in the section following the table.

Timed pregnant CD-1 mice were given PFOA by gavage at doses of 0, 0.01, 0.1, 0.03, and 1 mg/kg/day from GD 1 through the end of lactation (PND 21) in a study by Quist et al. (2015). The litters were equalized on PND 4 to four females and six males. Only the females continued in the study after weaning. At the end of lactation, litters with less than four females were removed from the study. On PND 21, seven to 10 female pups per dose group were sacrificed by decapitation. The livers were removed for analysis.

Table 3-21. Studies of Pregnant CD-1 Mice Following Administration of PFOA

Dose (mg PFOA /kg/day)	Timing	Endpoints	Reference
0, 0.01. 0.1, 0.3, 1	GD 1 to PND 21	Liver histopathology; periportal inflammation; clinical chemistry; impact of postweaning HFD	Quist et al. 2015
0, 5	GD 1-17, 8-17, or 12-17	Body weight; mammary gland morphology GD 18 (dams) and PNDs 10 and 20 (dams, female pups)	White et al. 2007
0, 5 20	GD 7-17, 10-17, 13-17, 15-17 GD 15-17	Body weight; developmental landmarks and growth to PND 189; mammary gland morphology of female pups up to 18 months	White et al. 2009; Wolf et al. 2007
0, 3, 5	GD 1-17 Cross-fostered at birth	Body weight; developmental landmarks and growth to PND 245; mammary gland morphology of female pups up to 18 months	White et al. 2009; Wolf et al. 2007;
0, 5	GD 8-17 Cross-fostered at birth	Mammary gland morphology of dams and female pups on PNDs 1, 3, 5, and 10	White et al. 2009
0, 0.3, 1.0, 3	GD 1-17	Liver weight; mammary gland morphology of female pups on PNDs 7, 14, 21, 28, 42, 63, and 84	Macon et al. 2011
0, 0.01, 0.1, 1	GD 10-17		
0, 1, 5	GD 1-17	Body weight; reproductive parameters; mammary gland morphology of F0, F1, and F2 females	White et al. 2011
0, 1 + 5 ppb in drinking water to both groups	GD 1-17 Drinking water started on GD 7 and continued to F2 generation		
0, 3	GD 1-17	Wild-type, PPARα-null, and hPPARα vv/129 mice; pup body weight at PNDs 14 and 20 plus mammary gland structure	Albrecht et al. 2013
0, 0.01, 0.1, 0.3, 1	GD 1-17 Study included both CD-1 and C57BL/6 mice	Body weight; net body weight; absolute and relative liver weight on PNDs 21, 35, and 56; serum estradiol and progesterone; mammary gland morphology	Tucker et al. 2015

During the lactation period all pups received a Purina control diet with a normal fat content. At sacrifice on PND 21, there was a dose-related increase in relative liver weight at doses ≥0.3 mg/kg/day. When the animals from the same dose group were sacrificed on PND 91, there was no observed impact on relative liver weight.

Starting on PND 35, one pup from each of 20 dams was placed on a HFD (with 60% of the calories from fat) until sacrificed on PND 91. Half were fasted for 4 hours before blood collection and sacrifice. Another seven to 10 pups per dose group received the Purina control diet with lower fat content until their sacrifice on PND 91. Blood samples were collected at sacrifice for determination of ALP, AST, ALT, SDH, LDL, HDL, cholesterol, triglycerides, total bile acid (TBA), glucose, leptin and insulin. Liver sections were collected for histological analysis and graded 1 to 4 for lesion severity (1 = minimal; 4 = severe). Selected samples of the liver tissues (four from the HFD groups and four from the PFOA-exposed control diet group) were fixed in osmium trioxide and prepared for evaluation using transmission electron microscopy.

At PND 91, the animals on the PFOA + HFD weighed more than the Purina controls. The body weight for the group that received PFOA and the control diet did not differ from the untreated controls on the same diet. Serum samples from the PFOA-treated Purina controls, and the fasted high-fat and nonfasted high-fat groups were analyzed for LDL, HDL, TC, and leptin.

At PFOA doses < 0.3 mg/kg/day, the LDL and TC levels in the fasted and nonfasted HFD animals were greater than in the untreated Purina controls. There was no impact of PFOS on either parameter in animals on the PFOA plus Purina control diet, but both LDL and TC were statistically lower at the high PFOA dose than they were at the low doses for both parameters. A similar pattern was seen for the HDL levels.

The impact of PFOA dose on leptin was variable and not significant for the PFOA plus Purina control animals and the high-fat, fasted animals. For the high-fat, nonfasted animals, there was a trend towards decreasing leptin as the PFOA dose increased, which was significant at the high dose of 1 mg/kg/day ($P< 0.01$). In those animals, the liver showed chronic periportal inflammation and microvescicular intracytoplasmic lipid droplets. The transmission electron microscopy slides showed that the hypertrophic liver cells presented evidence of cellular damage and changes in both mitochondrial morphology and numbers. The observed mitochondrial abnormalities were not those generally associated with PPARα activation. The 0.01 mg/kg/day dose was a NOAEL. The LOAEL was 0.3 mg/kg/day for the effects on TC for animals receiving a HFD, but not for those receiving the PFOA plus Purina control diet.

Effects of PFOA exposure on mammary gland morphology of CD-1 mice were evaluated in a series of studies by the same researchers (Macon et al. 2011; Tucker et al. 2015; White et al. 2007, 2009, 2011). The focus was on mammary gland development of female pups, although limited evaluations were conducted on the dams. Mammary gland whole mounts were scored on a 1 to 4 subjective, age-adjusted, developmental scale (1 = poor development/structure; 4 = normal development/structure). Tissue was assessed qualitatively for the gross presence of several histological criteria by two independent scorers and a mean score calculated. Neither standardization of these subjective measures nor training of the scorers was described in the publications. Quantitative measures of longitudinal growth, lateral growth, and number of terminal end buds also were made in the Macon et al. (2011) and Albrecht et al. (2013) studies.

White et al. (2007) orally dosed pregnant CD-1 mice with 0 and 5 mg PFOA/kg/day on GD 1–17 (n = 14), 8–17 (n = 16), and 12–17 (n = 16) to determine if decreased neonatal body weights and survival were linked to gestational exposure or lactational changes in milk quantity or quality. The control mice (n = 14) were dosed with vehicle on GD1–17. A subset of dams was sacrificed on GD 18. The remaining dams were allowed to give birth, and pups were pooled and randomly redistributed among the dams of the respective treatment groups. Litters were equalized to 10 pups per litter. Half of the dams and litters were sacrificed on PND 10, and the remaining dams and litters were sacrificed on PND 20. Mammary glands were collected from dams and female pups at time of sacrifice.

Treatment with PFOA did not affect maternal weight gain, number of implants, or the number of live fetuses. There was a significant increase ($p<0.05$) in prenatal loss in dams exposed during GD1–17. Body weight of pups exposed gestationally to PFOA was significantly decreased ($p<0.05$) at all time points measured and for all dosing regimens. On GD 18, stunted alveolar development was observed in the mammary gland of dams treated with PFOA on GD 1–17 compared to the mammary glands of the control dams, which were saturated with milk-filled alveoli. Dams treated with PFOA on GD 1–17 or 8–17 exhibited significant mammary gland epithelial differentiation delays on PND 10 as evidenced by an excessive amount of adipose tissue. In comparison, mammary glands from control dams on PND 10 were well differentiated, full of alveoli filled with milk, and contained few apoptotic bodies and little adipose tissue. The mammary gland developmental score in dams treated on GD 12–17 was not

statistically different from control dams on PND 10. At PND 20, the mammary gland scores from all PFOA-treated dams were not significantly different from those of the control group.

The pups were impacted by their *in utero* PFOA exposure over all dosing intervals. Their mammary glands exhibited significantly stunted epithelial branching and longitudinal growth at PNDs 10 and 20; the resulting developmental scores were significantly less than those of controls. Very little mammary gland development occurred between PND 10–20 in the offspring of dams exposed to PFOA, even though postnatal growth and body weight gain increased in parallel to that of the controls. Thus, at the only dose tested, 5 mg/kg/day, effects were observed on the dam and pup mammary gland, accompanied by decreased pup body weight and decreased survival for the pups exposed during GD 1–17.

In the study by Wolf et al. (2007), CD-1 mice were orally dosed with 0 and 5 mg PFOA/kg/day on GD 7–17 (n = 14), 10–17 (n = 14), 13–17 (n = 12), and 15–17 (n = 12) or with 20 mg/kg on GD 15–17 (n = 6) to determine if there was a specific window during which PFOA exposure produced developmental effects. The developmental results from this study were published by Wolf et al. (2007) and the mammary gland effects were published by White et al. (2009). On PND 22, all dams and one male and female pup from each litter were necropsied. Blood samples were collected and livers from dams and offspring were removed and weighed. Uterine implantation sites were counted. The fourth and fifth inguinal mammary glands were removed from female offspring and analyzed at various intervals up to 18 months of age (White et al. 2009). Mammary gland whole mounts from female offspring between PNDs 22 and 32 were scored as described above; whole mounts from lactating dams and female offspring at 18 months were qualitatively examined with respect to concurrent controls.

Maternal weight gain was increased in dams exposed to PFOA beginning on GDs 7 and 10, but there was no effect on number of uterine implantation sites, litter loss, or number of pups per litter at birth. Male pup weight at birth was significantly decreased ($p<0.05$) in dams dosed with 5 mg/kg/day on GD 7–17 or 10–17 or with 20 mg/kg/day on GD 15–17. By PND 78, all male offspring had recovered to control body weight levels. On PND 161, the offspring of dams dosed during GD 13–17 weighed significantly more than control. Litters exposed to 20 mg/kg/day on GD 15–17 experienced decreased survival ($p<0.01$) during PND 1–22. Maternal relative liver weight was significantly increased in all PFOA-treated dams except those treated during GD 15–17. Relative liver weight in all male and female pups was significantly increased ($p<0.01$). Eye opening and growth of body hair were delayed in pups exposed GD 7–17 and 10–17 (Wolf et al. 2007).

Mammary gland developmental scores for all offspring of dams exposed to PFOA were significantly lower compared to scores from offspring of control dams at PND 29 and 32. Delayed ductal elongation and branching and delayed appearance of terminal end buds were characteristic of delayed mammary gland development at PND 32. At 18 months of age, mammary tissues were not scored due to a lack of a protocol applicable to mature animals. However, there were dark foci (composition unknown) in the mammary tissue that occurred at a higher frequency in the exposed animals compared to controls, but did not display a consistent response with dosing interval. Qualitatively, mammary glands from treated dams on LD 1 appeared immature compared with control dams (White et al. 2009). The 5-mg/kg/day dose was associated with increased maternal and pup liver weight, altered pup mammary gland development, and delayed pup eye opening and growth of body hair. The 20-mg/kg/day dose was associated with decreased postnatal pup survival.

The objective of a second component of the study by Wolf et al. (2007) and White et al. (2009) was to determine if postnatal body weight deficits, neonatal lethality, and developmental delays caused by PFOA exposure were the result of gestational exposure, lactational exposure, or a combination of gestational and lactational exposure. Pregnant CD-1 mice were orally dosed with 0 (n = 48), 3 (n = 28), and 5 (n = 36) mg PFOA/kg/day on GD 1–17 and their offspring cross-fostered at birth to create seven treatment groups: control, *in utero* exposure only (3U and 5U), lactation exposure only (PFOA stored in milk during gestation and released during lactation; 3L and 5L), and *in utero* and lactation exposure (3U+L and 5U+L). On PND 22, all dams and one male and female pup from each litter were necropsied. Blood samples were collected and the liver was removed from dams and offspring and weighed. Implantation sites were counted from the uteri of dams. The fourth and fifth inguinal mammary glands were removed from female offspring and analyzed at various intervals up to 18 months of age (White et al. 2009). Mammary gland whole mounts from female offspring between PND 22 and 63 were scored as described above; whole mounts from female offspring at 18 months were qualitatively examined with respect to concurrent controls due to lack of an applicable protocol for mature animals.

Maternal weight and weight gain were higher in PFOA-treated dams compared to control dams. Whole litter loss was significantly increased ($p<0.05$) at 5 mg/kg/day, but no differences in the number of implantation sites were observed between the treated and control mice. Absolute and relative liver weights of PFOA-treated dams from both dose groups were significantly increased ($p<0.001$) compared to absolute and relative liver weights of control dams 23 days after the last dose (PND 22). No difference in the number of live pups born per litter was found between treated and control mice, but male and female pup birth weight was reduced ($p<0.01$) in dams receiving 5 mg/kg/day (Wolf et al. 2007). The 3-mg/kg/day dose was a LOAEL for increases in liver weight in the dams while 5 mg/kg/day was a LOAEL for the pups, based on whole litter loss and significantly reduced male and female birth weight.

A dose-dependent increase of PFOA was observed in the serum of dams treated with PFOA, providing a reservoir for lactational transfer. The control dams that nursed offspring exposed *in utero* (3U and 5U) had low concentrations of PFOA in their serum that originated from maternal grooming behavior of the pups and allowed for low-level lactational transfer.

Body weight of male and female pups (3U+L, 5U, and 5U+L) was significantly reduced as early as PND 2 and 1, respectively, and remained reduced throughout the lactation period. Body weight recovery to control levels was reached by male offspring within 2 weeks of weaning, but recovery in female offspring in the 5U and 5U+L groups did not occur until after PND 85.

Postnatal survival in 5U+L pups was significantly decreased compared to control survival beginning at PND 4 and continuing throughout lactation. Survival in the other groups was no different than control survival. Eye opening and body hair growth were significantly delayed in the 3U+L, 5U, and 5U+L offspring. The relative liver weight was significantly increased in all offspring regardless of exposure scenario (Wolf et al. 2007).

All female offspring of PFOA-exposed dams had reduced mammary gland developmental scores at PND 22, except for females in the 3L group. At PND 42, mammary gland scores from females in the 3U+L group were the only ones not statistically different from control scores. This might have been due to interindividual variance and multiple criteria used to calculate mammary gland development scores. All offspring of dams exposed to PFOA exhibited delayed mammary gland development at PND 63, including those exposed only through lactation (3L and 5L). A

higher density of dark staining foci was observed in the mammary glands of these animals at 18 months of age (White et al. 2009).

White et al. (2009) also reported the results from pregnant CD-1 mice orally dosed with 0 (n = 56) and 5 (n = 56) mg PFOA/kg/day from GD 8–17 to determine the timing of the mammary gland development deficits observed following gestational or lactational exposure to PFOA. The groups were cross-fostered at birth to create four treatment groups: control, *in utero* exposure only (5U), lactation exposure only (5L), and *in utero* and lactation exposure (5U+L). Dams and litters were sacrificed on PNDs 1, 3, 5, and 10. Blood and liver samples were collected for PFOA analysis. The fourth and fifth inguinal mammary glands were collected from dams and female offspring and analyzed as described above; whole mounts from lactating dams were qualitatively examined with respect to concurrent controls.

Maternal weight gain in treated dams was significantly higher than control weight gain, but there were no effects of treatment on litter size or pup birth weight at PND 1. Significantly decreased body weight occurred in the pups of the 5U+L group on PND 3 and in all PFOA-exposed pups on PNDs 5 and 10. Relative liver weight of the treated dams was significantly increased ($p<0.05$) compared to relative liver weight of control dams. On PND 1, liver-to-body weight ratios were significantly increased ($p<0.05$) in pups exposed *in utero* (5U, 5U+L); serum PFOA levels were 65,000–70,000 ng/mL. The liver-to-body weight ratio was increased in pups exposed lactationally by PND 5; serum PFOA levels were approximately 15,000 ng/mL (White et al. 2009).

On PND 1, the mammary glands of PFOA-exposed dams were qualitatively similar to glands seen in late pregnancy, prior to parturition. In control dams nursing offspring from PFOA-exposed dams, reduced alveolar filling was noted as early as PND 3, presumably a result of exposure of the dam from maternal grooming behavior. The delayed lactational morphology in dams treated with PFOA and control dams nursing offspring from PFOA-treated dams was persistent up to PND 10 (terminal sacrifice). Reduced mammary gland developmental scores were observed as early as PND 1 in all female offspring from PFOA-exposed dams, including those exposed through lactation only (5L). Delayed mammary gland development persisted throughout the study duration (White et al. 2009).

Macon et al. (2011) gavage-dosed CD-1 mice with 0, 0.3, 1.0, and 3.0 mg PFOA/kg/day from GD 1–17 (n = 13 dams per group). Six offspring per group were sacrificed on PNDs 7, 14, 21, 28, 42, 63, and 84, and blood, liver, brain, and the fourth and fifth mammary glands were collected from female pups. Mammary gland developmental scores were not included in the published article, but were available in supplemental materials.

Body weight in male and female offspring was not affected through PND 84. Absolute liver weight was significantly increased at ≥0.3 mg/kg/day in females and at ≥1.0 mg/kg/day in males on PND 7, and at 3.0 mg/kg in females at PND 14. Relative liver weight was significantly increased at ≥0.3 mg/kg/day in males and females on PND 7, at ≥1.0 mg/kg/day in females on PND 14, and at 3.0 mg/kg/day in males and females on PNDs 14, 21, and 28. No dose-related differences were observed in absolute and relative brain weights.

Delayed mammary gland development of female pups was observed as early as PND 7 at ≥1.0 mg/kg/day and PND 14 at ≥0.3 mg/kg/day and persisted until the end of the study. However, the developmental scores did not show dose-related trends at each interval. The delayed development was characterized by reduced epithelial growth and the presence of

numerous terminal end buds. Photographs of the mammary gland whole mounts at PNDs 21 and 84 show differences in the duct development and branching pattern of offspring from dams given 0.3 and 1 mg/kg/day (offspring from high-dose dams not pictured). The LOAEL was 0.30 mg/kg/day based on significantly increased liver weight and delayed mammary gland development. No NOAEL was established. The lowest dose tested was a NOAEL at PND day 7 and is a LOAEL at day PND 14.

Macon et al. (2011) also gavage-dosed CD-1 mice with 0, 0.01, 0.1, and 1.0 mg PFOA/kg/day from GD 10–17 (n = 5–8 dams per group) to examine the effects of low doses of PFOA on mammary gland development. Female offspring (one from at least three litters per group) were sacrificed on PNDs 1, 4, 7, 14, and 21, and blood, liver, and the fourth and fifth mammary glands were collected. In addition to the qualitative mammary gland developmental scores, quantitative measurements of longitudinal growth, lateral growth, and numbers of terminal end buds and terminal ends were recorded. These data were presented only for animals sacrificed on PND 21.

No differences in body weight or brain weight were observed for male or female offspring. At 1 mg/kg, absolute and relative liver weights were significantly increased at PNDs 4 and 7. Relative liver weight also was significantly increased at PND 14. Mammary gland development was delayed by exposure to PFOA, especially longitudinal epithelial growth. At PND 21, all treatment groups had significantly lower developmental scores. At the highest dose, poor longitudinal epithelial growth and decreased number of terminal end buds were observed. As seen in Table 3-22, the quantitative measures were statistically significant only for the high dose compared to the controls, while the qualitative scores were significantly different from controls at all doses. The LOAEL was 0.01 mg PFOA/kg/day based on the qualitative / quantitative developmental score for mammary gland development and 1 mg/kg/day based on the quantitative score in the absence of the qualitative component. No NOAEL was established.

White et al. (2011) examined the extended consequences of PFOA-induced altered mammary gland development in a multigenerational study in CD-1 mice. Pregnant mice (F0, n = 10–12 dams per group) were gavage-dosed with 0, 1, and 5 mg PFOA/kg/day from GD 1–17. A separate group of pregnant mice (n = 7–10 dams per group) was gavage-dosed with either 0 or 1 mg PFOA/kg/day from GD 1–17 and received drinking water containing 5 ppb PFOA beginning on GD 7. F1 females and F2 offspring from the second group continued to receive drinking water that contained 5 ppb PFOA until the end of the study, except during F1 breeding and early gestation, to simulate a chronic low-dose exposure. Only the F0 dams were given

PFOA by gavage. Total doses were not calculated for the groups receiving drinking water with 5 ppb PFOA. Table 3-23 shows the array of dosing regimens used in the study and the estimated average daily PFOA intake by F0 dams. The average daily intake from the chronic water exposures were calculated from total weekly water consumption, divided by the number of days per week (values given in supplemental materials; intake by the F1 animals was not calculated).

Table 3-23. Dosing Regimens Used in the Multigeneration Study of CD-1 Mice

	F0 Dams	F0 Dams → F1 Offspring		F1 Dams → F2 Offspring	F2 Offspring
Treatment	Gavage	Drinking water	Gavage + drinking water	Drinking water	Drinking water
Dose	0, 1, or 5 mg/kg/day	0+5 ppb	1+5 ppb	5 ppb	5 ppb
Duration Gavage Drinking water	 GD 1-17 None	 GD 1-17 GD 7-LD 22	 GD 1-17 GD 7-LD 22	 None Through LD 22	 None Through PND 63

F0 females were sacrificed on PND 22. F1 offspring were weaned on PND 22 and bred at 7–8 weeks of age. F2 litters were maintained through PND 63. Groups of F1 and F2 offspring (n = 1–2 offspring per litter from 5–7 litters per group) were sacrificed on PND 22, 42, and 63. A group of F2 offspring (n = 6–10 per group) also was sacrificed on PND 10. A lactational challenge experiment was performed on PND 10 with F1 dams and F2 offspring. Mammary glands were evaluated from F0 dams on PND 22, from F1 dams on PNDs 10 and 22, and from F1 and F2 female offspring on PNDs 10 (F2 only), 22, 42, and 63. Mammary gland whole mounts were scored qualitatively as described above.

Exposure to 5 mg PFOA/kg/day significantly increased prenatal loss in F0 mice and significantly decreased the number of live offspring and the postnatal survival of the viable pups. Maternal weight gain and number of implants did not differ among F0 the groups. There was no indication of toxicity in F1 adult females. Exposure to PFOA did not affect prenatal loss or postnatal survival, although F1 females that had been exposed *in utero* to 5 mg/kg/day had significantly fewer implants.

On PND 22, F1 pup body weight was similar across all treated and control groups. F1 offspring body weight at PND 42 was significantly reduced for those whose dams received 5 mg/kg/day; at PND 63, body weight was significantly reduced for offspring from dams given 1 mg/kg/day plus 5 ppb in the drinking water compared to offspring from dams given 1 mg/kg/day. Liver-to-body weight ratios were significantly increased at 1 mg/kg/day on PND 22 and at 5 mg/kg on PNDs 22 and 42. For the F2 pups, a significant reduction in body weight was observed in control plus 5 ppb drinking water PFOA offspring on PND 1, but there was no difference by PND 3. F2 offspring from the 1 mg/kg/day and 1 mg/kg/day plus 5-ppb drinking water PFOA groups had increased body weight compared to controls on PNDs 14, 17, and 22. Liver-to-body weight ratios were no different across the groups.

Mammary gland developmental scores for the three generations of females are summarized in Table 3-24. At PND 22, control F0 dams displayed weaning-induced mammary involution. At PND 22, the mammary glands of all PFOA-exposed F0 dams, including the control dams receiving 5 ppb PFOA in drinking water, resembled glands of mice at or near the peak of lactation (~PND 10). The F1 dams examined on PNDs 10 and 22 had significantly lower developmental scores on PND 10, but that was no longer evident at PND 22, except for those exposed *in utero* to 5 mg/kg/day.

Table 3-24. Mammary Gland Scores from Three Generations of CD-1 Female Mice

Group	Control	Control +5 ppb	1 mg/kg/day	1 mg/kg/day + 5 ppb	5 mg/kg/day
F0 dams on PND 22	2.4 ± 0.2	3.4 ± 0.1*	3.0 ± 0.2*	3.2 ± 0.2*	3.9 ± 0.1*
F1 as pups PND 63	3.8 ± 0.2	2.6 ± 0.4*	2.9 ± 0.2*	2.0 ± 0.3*#	2.2 ± 0.2*
F1 as dams on PND 10	4.0 ± 0.0	2.8 ± 0.5*	2.5 ± 0.2*	2.0 ± 0.2*	2.5 ± 0.2*
F1 as dams on PND 22	2.1 ± 0.3	2.2 ± 0.2	1.9 ± 0.4	1.5 ± 0.2*	3.2 ± 0.3*
F2 PND 10	2.8 ± 0.3	3.0 ± 0.2	1.9 ± 0.3	2.6 ± 0.2	2.0 ± 0.2
F2 PND 22	3.1 ± 0.4	1.9 ± 0.3	2.3 ± 0.1	2.3 ± 0.2	2.0 ± 0.2
F2 PND 42	3.5 ± 0.2	2.5 ± 0.4*	3.4 ± 0.2	2.4 ± 0.2*#	3.3 ± 0.4
F2 PND 63	3.4 ± 0.2	3.5 ± 0.2	2.4 ± 0.2*	2.6 ± 0.5	2.6 ± 0.4

Notes: n = 4–11.
* $p<0.05$ compared with control.
# $p<0.05$ compared with 1 mg/kg/day.
F1 and F2 animals represented in each data set are different. They represent members of litters within each group at different stages of development.

In the F1 female offspring not used for breeding, the mammary glands of all mice exposed to PFOA were significantly delayed in development on PNDs 22, 42, and 63. For the F2 female offspring, some differences in mammary gland scores were observed between the groups, but most were not significantly different from controls.

In the lactational challenge experiment, dams were removed from their litters for 3 hours, then returned to their litters and allowed to nurse for 30 mins. The time from the dam's return to the litter and nursing initiation was recorded. The litters were weighed before and after nursing to estimate volume of milk produced. The results from the lactational challenge on PND 10 for the F1 dams showed a slight dose-related trend for decreased milk production (measured in grams) over a 30-min period (differences from controls not identified as significant), but no clear differences in time to initiate nursing (measured in seconds). As discussed above, morphological differences were seen in developmental scores for the treated F1 dams on PND 10 and were generally no longer evident at PND 22.

White et al. (2011) demonstrated that no significant dose-related differences were found in the ability of the CD-1 mice given 1 mg/kg/day to provide nourishment to their young as reflected in measurements of body weight in F1 and F2 pups across a 63-day postnatal period. There were body weight effects in the pups from dams given 5 mg/kg/day and in pups from dams that received 1 mg/kg/day by gavage with 5 ppb in the drinking water.

In the study by Albrecht et al. (2013) discussed earlier, groups of female wild-type, PPARα-null, and PPARα-humanized mice on a SV/129 genetic background were given 0 and 3 mg PFOA/kg on GD 1–17 by oral gavage. Controls received the water vehicle. The study was

designed with the goal of identifying the contribution of PPARα activation to the responses evaluated. Mammary gland structure was one of the endpoints evaluated. Females were either sacrificed on GD 18 (n = 5–8 per group) or allowed to give birth and then sacrificed, along with their litters (n = 8–14), on PND 20. The left and right fourth and fifth mammary glands were removed, spread on a glass slide, and stained. Ductal length and terminal end buds were quantified in the offspring of from three to nine dams. There was no significant difference in the measurements for either parameter at either timepoint for the offspring of PFOA-treated animals compared to the controls. In the case of the wild-type mice, the terminal end bud measurements were 2.1 ± 0.01 terminal end buds/gland for the control and 2.2 ± 0.2 terminal end buds/gland based on the mean for three control litters and four PFOA-exposed litters. For the ductal lengths, the values were 2.4 ± 0.3 millimeter (mm) for the control and 2.4 ± 0.4 mm for the PFOA-exposed animals. There was no qualitative component of the scoring approach used by Albrecht et al. (2013). The fewest number of terminal end buds and the longest ductal length measurement were those for the animals with the hPPARα.

To examine the impact of differences in mouse strains, Tucker et al. (2015) conducted a study of the effects of gestational exposure on mammary gland development as measured at prepubertal time points. Doses of 0, 0.01, 0.1, 0.3, and 1 mg/kg/day were administered to timed pregnant CD-1 and C57Bl/6 mice by gavage on GD 1–17. After parturition, the number of pups was reduced so that there were ultimately four to eight CD-1 litters per treatment block and three to seven B57BL/6 litters per treatment. Endpoints monitored included body weight; net body weight; absolute and relative liver weight on PNDs 21, 35, and 56; neonatal developmental endpoints (e.g., vaginal opening, first estrus); and serum estradiol and progesterone (P) measurement; and as well as mammary gland development scores. Qualitative assessment of mammary gland scores was as described above. Different treatment blocks monitored different endpoints at different times. Serum POA levels were measured at PNDs 21, 35, and 56 for the CD-1 mice (n = 4–12) and at PND 21 and 61 for the C57BL/6 mice (n = 2–6). At each time point, the serum concentration increased with dose and decreased with duration.

There were no measures that were significantly ($p<0.05$) different from controls for the CD-1 anthropometric parameters, except relative liver weight on PND 56 at 0.3 mg/g/day and on PND 21 at 1 mg/kg/day. Net body weight was significantly increased ($p<0.05$) at PNDs 21 and 35 in the 1-mg/kg/day group. No significant differences were observed in the C57Bl/6 mice at any dose or duration. There were no significant differences for postnatal developmental endpoints, estradiol, or P in either mouse strain. There was a trend towards decreasing mammary gland developmental scores with dose for both strains of mice. In the CD-1 mice, mammary gland developmental scores were significantly reduced at ≥0.01 mg/kg/day on PND 35 and at ≥0.1 mg/kg/day on PND 21 compared to scores in the controls. However, in the C57Bl/6 mice, mammary gland developmental scores were significantly reduced only at 0.3 and 1.0 mg/kg/day on PND 21 compared to scores in the controls.

Serum P was higher in the control and treated CD-1 mice on PND 56 than at the other two time points but lacked dose response; estradiol was relatively consistent across time points. For the C57BL/6 mice, the estradiol levels at PND 61 were higher in all treated groups but lacked dose-response; P changed little with time and was similar between treated and control groups. The LOAEL was 0.01 mg/kg/day for aberrant mammary gland development in the CD-1 mice and 0.3 mg/kg/day for the C57BL/6 mice. The CD-1 mice lacked a NOAEL. The NOAEL for the C57/BL/6 mice was 0.1 mg/kg/day. Although both strains experienced delayed prepubertal mammary gland development, there were no significant changes in other postnatal

developmental events. The relevance of the mammary gland changes at maturity in the absence of any postlactational PFOA exposure is uncertain, especially as it relates to humans.

Direct peripubertal exposures

C. Yang et al. (2009) gavage-dosed 21-day-old female BALB/c mice (5 per group) with 0, 1, 5, and 10 mg PFOA/kg/day for 5 days per week for 4 weeks to determine the effects of peripubertal PFOA exposure on puberty and mammary gland development. At necropsy, uteri and livers were weighed and processed for histological examination. Mammary glands were collected and processed for histological and whole-mount examination. A significant decrease in body weight was observed following exposure to 10 mg/kg/day. The mammary glands of female BALB/c mice treated with 5 or 10 mg/kg/day had reduced ductal length, decreased number of terminal end buds, and decreased stimulated terminal ducts compared to the mammary glands of control mice. BrdU incorporation into the mammary gland revealed a significantly lower number of proliferating cells in the ducts and terminal end buds/terminal ducts at 5 mg/kg/day (not tested at 10 mg/kg/day). Absolute and relative liver weight was significantly increased in all treated BALB/c mice. The absolute and relative uterine weight was significantly decreased in all treated mice compared to uterine weight in control mice. Vaginal opening was significantly delayed in mice dosed with 1 mg/kg/day and did not occur at 5 or 10 mg/kg/day. The LOAEL was 1 mg/kg/day based on delayed vaginal opening, increased liver weight, and decreased uterine weight; and no NOAEL was established.

C. Yang et al. (2009) also dosed 21-day-old female C57BL/6 mice in the same manner as the BALB/c mice and examined the effects of PFOA on mammary gland development and vaginal opening. The body weight effects were similar in both strains with 10 mg/kg/day causing significantly reduced body weight. At 5 mg/kg/day, PFOA had a stimulatory effect on the mammary glands. There was a significant increase in the number of terminal end buds and stimulated terminal ducts. Ductal length was not affected. Mammary gland development was inhibited in mice dosed with 10 mg/kg/day, with no terminal end buds or stimulated terminal ducts present and very little ductal growth. Absolute and relative liver weight was significantly increased in all treated mice. The absolute and relative uterine weight was significantly increased in C57BL/6 mice dosed with 1 mg/kg/day and significantly decreased in C57BL/6 mice dosed with 10 mg/kg/day. There was no difference in uterine weights between mice treated with 5 mg/kg/day and control mice. Vaginal opening was delayed in C57BL/6 mice dosed with 5 mg/kg/day and did not occur in mice dosed with 10 mg/kg/day. The LOAEL was 1 mg/kg/day based on increased liver and uterine weights, and no NOAEL was established.

Y. Zhao et al. (2010) conducted several experiments in C57BL/6 mice to determine the potential mechanism by which peripubertal PFOA exposure resulted in the stimulation of mammary gland development observed by C. Yang et al. (2009). In experiments to determine if PFOA has a hormonal effect on mammary gland development, C57BL/6 mice (n = 10 per group) were OVX at 3 weeks of age, allowed 1 week to recover, and treated with 0 and 5 mg PFOA/kg bw/day for 4 weeks. Abdominal and inguinal mammary glands were collected at sacrifice, prepared as whole mounts, and scored for growth and development. The mammary glands of the OVX control and PFOA-treated OVX mice were similarly stunted in growth as evidenced by no outgrowth of ducts or presence of terminal end buds. This was in contrast to the stimulatory effect of PFOA observed by C. Yang et al. (2009) in intact mice.

In experiments to determine if PFOA-affected mammary glands respond to hormone treatment, intact C57BL/6 mice were dosed with 0 or 5 mg/kg bw/day of PFOA for 4 weeks

starting at 21 days of age. After the last dose, the mice were OVX, allowed to recover for 1 week, and injected subcutaneous for 5 days with E2 (1 μg/0.2 ml per mouse), P (1 mg/0.2 ml per mouse), or both (E+P, 1 μg+1 mg/0.2 ml per mouse). The mice were sacrificed 24 hours after the last hormone injection. Abdominal and inguinal mammary glands were collected at sacrifice, prepared as whole mounts, and scored for growth and development. In the mammary glands of mice treated with PFOA and estradiol, stimulated terminal ducts were observed, and in PFOA-treated mice given P or E+P, stimulated terminal ducts and an increased number of side branches were observed. The results showed that PFOA increased the mouse mammary gland response to exogenous estrogen and P.

In experiments to determine if PFOA-induced mammary gland development stimulation is related to PPARα expression and the impact of PFOA on steroid hormones and growth factors, female C57BL/6 and PPARα-null C57BL/6 mice (n = 5–10 mice per group) were gavage-dosed with 0 or 5 mg/kg bw/day of PFOA 5 days per weeks for 4 weeks starting at 21 days of age (Y. Zhao et al. 2010). Vaginal opening was monitored daily and estrous cycle state was determined at sacrifice after 4 weeks of treatment. At necropsy, blood was collected for measurement of serum steroid hormones and binding proteins. Portions of the mammary glands, ovaries, and livers were collected and processed for histological examination. RNA was extracted from the livers for quantitative RT-PCR and PCR array for selected genes related to metabolism of drugs, toxic chemicals, hormones, and micronutrients. Portions of mammary glands were used in western blot analysis of several enzymes, local growth factors, and receptors, including aromatase—which aids in converting testosterone to estradiol and androstenedione to estrone, hydroxysteroid 17β dehydrogenase 1 (HSD17β1)—which aids in converting estrone to estradiol, and hydroxysteroid 3β dehydrogenase 1 (HSD3β1)—which aids in converting pregnenolone to P and androstenedione to testosterone. Growth factors critically involved in mammary gland development, including amphiregulin (Areg), insulin like growth factor I (IGF-I), and hepatocyte growth factor (HGFα), and markers of cell proliferation (e.g., cyclin D1 and PCNA) were analyzed by western blot. Areg mediates estrogen receptor α (ERα) function and is a ligand for the epidermal growth factor receptor (EGFR). These receptors also were analyzed by western blot.

The mammary glands of PPARα-null mice treated with PFOA had an increased number of terminal end buds and stimulated terminal ducts compared to control PPARα-null mice. Protein levels of Areg, IGF-I, HGFα, ERα, and EGFR were significantly increased ($p<0.05$) in PFOA-treated C57BL/6 mice; and Areg, HGFα, ERα, and EGFR were significantly increased ($p<0.05$) in PFOA-treated PPARα-null mice. Cyclin D1 and PCNA were significantly increased ($p<0.05$) in C57BL/6 and PPARα-null mice treated with PFOA compared to levels in control mice. Immunofluorescent staining of the mammary glands for ERα and Areg showed a significant increase ($p<0.05$) in Areg positive luminal epithelial cells and Areg and ERα double positive staining cells in C57BL/6 and PPARα-null mice treated with PFOA compared to control mice. The results show that the stimulatory effect of PFOA on mammary gland development is independent of PPARα expression and suggest that PFOA increases the levels of steroid hormones, growth factors, and receptors, which promote mammary gland cell proliferation.

Estradiol levels were similar between intact control and treated wild-type mice, but P levels were significantly increased ($p<0.05$) in PFOA-treated mice in proestrus and estrus compared to control mice in the same stages of the estrous cycle. Serum SHBG and albumin levels were not significantly changed by treatment with PFOA.

The effect of PFOA on aromatase, HSD17β1, and HSD3β1 activity in the ovaries of C57BL/6 PPARα-null mice was examined. In C57BL/6 mice, HSD17β1 and HSD3β1 proteins were significantly increased ($p<0.05$), and in PPARα-null mice, HSD17β1 protein was significantly increased. Aromatase levels were not affected by PFOA. The results suggest that PFOA might increase serum steroid hormone levels in the ovaries.

Due to the increased P levels observed in PFOA-treated mice, the expression of liver metabolic enzymes was analyzed. Liver metabolic function might affect steroid hormone serum levels, which play a role in mammary gland development. In PPARα-null and C57BL/6 mice treated with PFOA, detoxification enzymes in the liver, including glutathione s-transferase α1, μ3, and μ4, were upregulated ($p<0.05$). Expression of liver drug metabolic enzymes, including CYP1a1, CYP1a2, and HSD17β2, was significantly downregulated ($p<0.05$) in C57BL/6 mice treated with PFOA, but expression in PFOA-treated PPARα-null mice was comparable to that in control mice. Hydroxysteroid 17β dehydrogenase 4, an enzyme that converts estradiol to estrone, was significantly upregulated ($p<0.05$) in C57BL/6 mice treated with PFOA. The results suggested that PFOA-induced expression changes in liver enzymes might not contribute to PFOA-induced mammary gland development stimulation.

Inhalation Exposure

Staples et al. (1984) exposed Sprague-Dawley rats to PFOA using whole-body dust inhalation for 6 hours per day on GD 6–15. The MMAD of the particles ranged from 1.4 to 3.4 μm and the GSD ranged from 4.3 to 6.0. The study was carried out in two trials with each trial including two experiments. In experiment 1, the dams were sacrificed on GD 21 prior to parturition, and in experiment 2, the dams were allowed to litter and were sacrificed on PND 23; offspring were sacrificed on PND 35. In the trial 1 (both experiments), dams (n = 12) were exposed to 0, 0.1, 1, and 25 mg/m^3. In trial 2, the high dose was reduced to 10 mg/m^3. In experiment 1 of trial 2, dams numbered 12–15 per group and two additional groups (6 dams per group) were added and were pair-fed at 10 and 25 mg/m^3. In experiment 2 of trial 2, only six control and six dams dosed at 10 mg/m^3 were allowed to litter.

In experiment 1, the dams were weighed on GDs 1, 6, 9, 13, 16, and 21 and observed daily for abnormal clinical signs. On GD 21, the dams were sacrificed by cervical dislocation and examined for any gross abnormalities, liver weights were recorded, and the reproductive status of each animal was evaluated. The ovaries, uterus, and contents were examined for the number of corpora lutea, live and dead fetuses, resorptions, and implantation sites. Pups (live and dead) were counted, weighed and sexed, and examined for external, visceral, and skeletal alterations. The heads of all control and high-dosed group fetuses were examined for visceral alterations and macroscopic and microscopic evaluations were conducted of the eyes.

Treatment-related clinical signs of maternal toxicity occurred at 10 and 25 mg/m^3 and consisted of wet abdomens, chromodacryorrhea, chromorhinorrhea, a general unkempt appearance, and lethargy in four dams at the end of the exposure period (high-concentration group only). Three out of 12 dams died during treatment at 25 mg/m^3 (on GDs 12, 13, and 17). Food consumption was significantly reduced at 10 and 25 mg/m^3; however, no significant differences were noted between treated and pair-fed groups. Significant reductions in body weight also were observed at these concentrations, with statistical significance at the high concentration only. Likewise, statistically significant increases in mean liver weights ($p<0.05$) were seen in the high-concentration group. The NOAEL and LOAEL for maternal toxicity were 1 and 10 mg/m^3, respectively.

No effects were observed on the maintenance of pregnancy or the incidence of resorptions. Mean fetal body weights were significantly decreased in the 25 mg/m^3 PFOA group ($p = 0.002$) and in the pair-fed control group ($p = 0.001$). Interpretation of the decreased fetal body weight is difficult given the high incidence of mortality in the dams. The NOAEL and LOAEL for developmental toxicity were 10 and 25 mg/m^3, respectively.

In experiment 2, in which the dams were allowed to litter, the procedure was the same as for experiment 1 until GD 21. Two days before the expected day of parturition, each dam was housed in an individual cage. The date of parturition was noted and designated PND 1. Dams were weighed and examined for clinical signs on PNDs 1, 7, 14, and 22. On PND 23 all dams were sacrificed. Pups were counted, weighed, and examined for external alterations. At birth, each pup was subsequently weighed and then inspected for adverse clinical signs on PNDs 4, 7, 14, and 22. The eyes of the pups were also examined on PNDs 15 and 17. Pups were sacrificed on PND 35 and examined for visceral and skeletal alterations.

Clinical signs of maternal toxicity seen at 10 and 25 mg/m^3 were similar in type and incidence to those described for trial 1. Maternal body weight gain during treatment at 25 mg/m^3 was less than controls, although the difference was not statistically significant. In addition, two out of 12 dams died during treatment at 25 mg/m^3. No other treatment-related effects were reported, nor were any adverse effects noted for any of the measurements of reproductive performance. The NOAEL and LOAEL for maternal toxicity were 1 and 10 mg/m^3, respectively.

Signs of developmental toxicity in this group consisted of statistically significant reductions in pup body weight on PND 1 (6.1 g at 25 mg/m^3 versus 6.8 g in controls, $p = 0.02$). On PNDs 4 and 22, pup body weight continued to remain lower than controls, although the difference was not statistically significant. No significant effects were reported following external examination of the pups or with ophthalmoscopic examination of the eyes. The NOAEL and LOAEL for developmental toxicity were 10 and 25 mg/m^3, respectively.

Dermal Exposure

No data on the developmental effects of dermal exposures to PFOA were identified in the literature.

3.2.8 Chronic Toxicity

Oral Exposure

Monkey. Male cynomolgus monkeys (n = 4 or 6 per dose) were administered PFOA by oral capsule containing 0, 3, 10, or 30/20 mg/kg/day for 26 weeks (Butenhoff et al. 2002). Dosing of animals in the 30-mg/kg/day dose group ceased after 12 days and decreased to 20 mg/kg/day when reinstated on day 22 because of low food consumption, decreased body weight, and decreased feces. Sacrifice of the surviving monkeys, except for two control monkeys and two monkeys from the mid-dose group (recovery animals) occurred at 26 weeks. The animals in the recovery groups were sacrificed 13 weeks later.

Animals were observed twice daily for mortality and moribundity and were examined at least once daily for signs of poor health or abnormal behavior. Ophthalmic examinations were performed before treatment began and at weeks 26 and 40. Body weight, food consumption, clinical hematology, clinical chemistry, urinalysis, serum hormone levels, and PFOA levels in

blood and tissue were assessed throughout the study. One animal from the 30/20-mg/kg/day dose group was sacrificed in moribund condition on day 29 with signs of dosing injury and liver lesions. One animal from the 3-mg/kg/day dose was sacrificed (day 137) with signs of hind limb paralysis, ataxia and hypoactive behavior, few feces, and no food consumption. Treatment of the remaining three animals given 30/20 mg/kg/day was halted on days 43, 66, and 81, respectively, because of thin appearance, few or no feces, low or no food consumption, and weight loss, but the animals appeared to recover from compound-related effects within 3 weeks after cessation of treatment. No significant changes in mean body weight were observed at doses of 3 or 10 mg/kg/day.

Serum hormone levels (i.e., estrone, estradiol, estriol, testosterone, TSH, FT4, total T4, and CCK) were not significantly altered throughout the study. However, FT3 and total T3 levels were significantly decreased ($p<0.05$) from weeks 5 to 10 and at week 27 in the 30/20-mg/kg/day dose group compared to controls.

At terminal sacrifice (26 weeks), mean absolute liver weight was significantly increased in all dose groups and the relative liver-to-body weight ratio was significantly increased for the High-Dose Group. Final Body Weight And Liver Weight Data Are Presented In Table 3-25.

Table 3-25. Liver Weight Data in Monkeys Administered PFOA for 6 Months

Dose	Body Weight	Absolute Liver Wt (g)	Relative Liver Wt (%)
0 mg/kg (n = 4)	3947 ± 591	60.2 ± 6.9	1.5 ± 0.1
3 mg/kg (n = 3)	4486 ± 30	81.8 ± 2.8*	1.8 ± 0.1
10 mg/kg (n = 4)	4447 ± 498	83.2 ± 9.7*	1.9 ± 0.1
30/20 mg/kg (n = 2)	3925 ± 583	90.4 ± 4.2*	2.4 ± 0.5*

Note: * Significantly different from control, $p<0.01$.

The cause of the increase in liver weight was suggested to be hepatocellular hypertrophy (indicated by decreased hepatic DNA content), which was hypothesized to result from mitochondrial proliferation based on an increase in hepatic succinate dehydrogenase activity. The two animals given 20 mg/kg/day had significantly decreased hepatic DNA content, and increased succinate dehydrogenase and palmitoyl-CoA oxidase activities; glucose-6-phophatase activity was slightly decreased in all treated groups, but a dose-response was not shown. These data are shown in Table 3-26. Succinate dehydrogenase activity was highly variable in animals given 3 mg/kg/day despite this group having the most consistent liver PFOA concentrations. Although serum steady-state had been attained by 4-6 weeks of dosing (Table 3-26 (see section 2.2, Distribution), liver PFOA levels ranged from 11.3-18.5, 6.29-21.9, and 16-83.3 μg/g tissue in the 3, 10, and 20 mg/kg/day groups, respectively.

Because administration of PFOA to rats has been shown to result in liver, Leydig cell tumors (LCTs), and pancreatic acinar cell tumors (PACTs), Butenhoff et al. (2002) analyzed markers of tumor formation in the monkey study just described. In the liver, a twofold increase in hepatic palmitoyl-CoA oxidase activity was observed in the 30/20-mg/kg/day group, consistent with reports for species that are not particularly responsive to PPARα agonists. Replicative DNA synthesis in the liver, an indication of cell proliferation, was not altered in the treated animals. It also has been proposed that changes associated with the PACTs in rats include increased serum CCK concentrations and indications of cholestasis, including increases in ALP, bilirubin, and bile acids. None of these changes were observed in the cynomolgus monkeys. There were also no significant changes in estradiol, estriol, or testosterone in the monkeys. Each of these factors

is associated with LCTs in rats. There were no changes in replicative DNA synthesis in the pancreas or testes.

Table 3-26. Subcellular Liver Enzyme Activities and Liver PFOA Concentrations

Endpoint	0 mg/kg/day	3 mg/kg/day	10 mg/kg/day	20 mg/kg/day
DNA (mg/g liver)	1.44 ± 0.28	1.23 ± 0.89	1.25 ± 0.37	1.02 ± 0.17*
Succinate dehydrogenase (µmol cytochrome c reduced/min/g liver)	0.21 ± 0.15	1.77 ± 1.59	0.55 ± 0.14	1.37 ± 0.73*
Palmitoyl-CoA oxidation (µmol/min/g liver)	0.53 ± 0.12	0.47 ± 0.13	0.90 ± 0.29	1.36 ± 0.34*

Notes:
* Significantly different from control, $p<0.05$.
<LOQ: less than the lower LOQ of 0.019 µg/g.

After a 13-week recovery period, there were no treatment-related effects on terminal body weights or on absolute or relative organ weights, suggesting that the treatment-related liver weight changes were reversible. There were no treatment-related macroscopic or microscopic changes at the recovery sacrifice. Toxicological significance of the parameters in Table 3-26 are difficult to evaluate because of the small number of animals and the high variability in the enzyme measurements and the liver PFOA levels.

Rat. The chronic toxicity of PFOA was investigated in a 2-year study in rats by Butenhoff et al. (2012); this study was conducted from April 1981 through May 1983. Sprague-Dawley (Crl:CD BR) rats (50 per gender) were fed diets containing 0, 30, and 300 ppm PFOA (0, 1.3, and 14.2 mg/kg/day for males; 0, 1.6, and 16.1 mg/kg/day for females). Groups of 15 additional rats per gender were fed 0 or 300 ppm PFOA and evaluated at the 1-year interim sacrifice. All animals were observed daily throughout the 2-year dosing period. Periodic observations included body weights and feed consumption, hematology, serum chemistry, urinalysis, gross pathology, organ weights, and histopathology. Animals were sacrificed after 1 and 2 years of dosing. Organ weights were determined after each sacrifice and tissues subjected to histological examination.

No dose- or treatment-related clinical signs of toxicity were observed in males or females. Significantly decreased body weight gains occurred in high-dose male and female rats compared to the controls. The body weight changes correlated with slight decreases in feed consumption during the study. Survival rate was increased for high-dose males and females compared with their respective controls, likely because of the lower body weights for these treated groups. No consistent dose-related changes over time were observed in hematology parameters of males and females. Clinical chemistry changes included slight (less than twofold) but significant increases in ALT, AST, and ALP in both treated male groups from 3 to 18 months, but only in the high-dose males at 24 months (Table 3-27); no differences were observed in females. No dose- or treatment-related differences in absolute and relative organ weights were found between the treated and control groups at 2 years.

Table 3-27. Clinical Chemistry Values from Male Rats Given PFOA for 2 Years

Endpoint	Diet Level (ppm)	3 Months	6 Months	12 Months	18 Months	24 Months
ALT (IU/L)	0	21.4 ± 2.67	24.1 ± 3.75	33.5 ± 19.45	34.1 ± 10.68	33.4 ± 8.1
	30	34.5 ± 15.33*	53.3 ± 29.34*	77.6 ± 56.59*	59.7 ± 33.41*	42.5 ± 10
	300	31.9 ± 21.94*	54.8 ± 29.26*	106.1 ± 70*	84.3 ± 55.95*	61.8 ± 20.13*
AST (IU/L)	0	45.3 ± 7.26	49.7 ± 14.98	79.1 ± 44.61	99.1 ± 68.14	64.9 ± 25.76
	30	59.7 ± 22.47	92.1 ± 45.6*	124.4 ± 94.04*	116.4 ± 57.99	68.0 ± 17.64
	300	58.2 ± 27.23	87.8 ± 34.83*	132.7 ± 76.84*	123.3 ± 62.98	95.7 ± 29.76*
ALP (mg/dL)	0	91.1 ± 26.22	97.1 ± 40.41	150.8 ± 43.94	85.2 ± 33.76	70.1 ± 25.53

Note:
* Significantly different from control, $p \leq 0.05$.

Incidence of selected microscopic lesions is detailed in Table 3-28; severity scores were not given for any type of lesion. Significantly increased incidence of lesions in the liver was observed in the high-dose male group. At 1 year, diffuse hepatocellular hypertrophy, portal mononuclear cell infiltration, and hepatocellular necrosis were seen. At 2 years, significant increases in hepatocellular hypertrophy were observed in the males and females in the high-dose group. Hepatic cystoid degeneration, a condition characterized by areas of multilocular microcysts in the liver parenchyma, also was significantly increased in high-dose males. The incidence of hepatocellular necrosis did not increase for the high-dose males at the end of the study compared with the interim rate.

Among the high-dose males, histological changes were noted in tissues other than the liver. Small but statistically significant increases in vascular mineralization of the testes and of pulmonary hemorrhage probably were not caused by treatment with PFOA. In the lung, while the incidence of alveolar macrophages was increased, that of perivascular mononuclear infiltrate and of pneumonia were decreased and vascular mineralization was a common finding in treated and control animals.

The LOAEL for male rats is 300 ppm (14.2 mg/kg/day) based on a decrease in body weight gain and histological changes in the liver. The LOAEL for female rats is 300 ppm (16.1 mg/kg/day) based on decreased body weight gain. The NOAEL for both genders is 30 ppm (1.3 mg/kg/day for males and 1.6 mg/kg/kg for females).

Biegel et al. (2001) conducted a 2-year mechanistic study in which male Crl:CD BR (CD) rats (n = 156 per group) were fed a diet containing 0 or 300 ppm PFOA (0 or 13.6 mg/kg/day). Interim sacrifices were conducted every 3 months up to 21 months for measurements of liver and testes weights, peroxisome proliferation, and cell replication. Serum samples were collected and reproductive hormones measured.

Table 3-28. Incidence of Nonneoplastic Lesions in Rats Given PFOA for 2 Years

Lesion	0 ppm	30 ppm	300 ppm
Males			
Liver			
Cystoid degeneration	4/50	7/50	28/50*
Hepatocellular hypertrophy	0/50	6/50	40/50*

Notes:
* Significantly different from control, $p \leq 0.05$.
- Not examined; interim sacrifice not done on animals at 30 ppm.

Body weight was significantly decreased from days 8 through 630 in PFOA-exposed rats. In the treated group, relative liver weights and hepatic β-oxidation activity were statistically significantly increased at all time points between 1 and 21 months when compared to the controls. Absolute testis weights were significantly increased only at 24 months. No hepatic or Leydig cell proliferation was observed at any sampling times. The incidence of Leydig cell hyperplasia was significantly increased in PFOA-exposed rats (46% versus 14% in the control group). Pancreatic acinar cell proliferation was significantly increased at 15, 18, and 21 months. The incidence of acinar cell hyperplasia was 30/76 (39%) compared to the incidence in the control group of 14/80 (18%). There were no significant differences in serum testosterone or prolactin in the PFOA-treated rats when compared to the controls. Serum FSH was significantly increased at 6 months, and LH was significantly increased at 6 and 18 months. There were significant increases in serum estradiol concentrations in the treated rats at 1, 3, 6, 9, and 12 months.

3.2.9 Carcinogenicity

Oral Exposure

Rat. Tissues from the animals in the Butenhoff et al. study (2012) were evaluated for neoplastic and preneoplastic formations; this study was conducted from April 1981 through May 1983. Hepatocellular carcinomas were observed at 6% (3/49), 2% (1/50), and 10% (5/50) in the control, low-, and high-dose male rats, respectively. None were observed in females in the control and low-dose groups, but a 2% (1/50) incidence was observed for female rats in the high-

dose group. The differences between the treated and control groups were not significantly different. No liver adenomas were observed.

At the 1-year sacrifice, testicular masses were found in 7/50 (14%) high-dose and 2/50 (4%) low-dose rats, but not in any of the controls. A significant increase ($p<0.05$) in the incidence of testicular (Leydig) cell adenomas was observed in the high-dose male rats at the end of the study. The LCT incidence in the control, low-, and high-dose groups was 0/50 (0%), 2/50 (4%), and 7/50 (14%), respectively. The increase also was statistically significant when compared to the historical control incidence of 0.82% observed in 1,340 Sprague-Dawley control male rats used in 17 carcinogenicity studies (Chandra et al. 1992). In a published workshop report on LCTs, Clegg et al. (1997) identified the spontaneous incidence of LCTs in 2-year-old Sprague-Dawley rats as approximately 5%.

A statistically significant, dose-related increase in the incidence of ovarian tubular hyperplasia was found in female rats at the 2-year sacrifice. The incidence of this lesion in the control, low-, and high-dose groups was 0%, 14%, and 32%, respectively. The biological significance of this effect at the time of the initial evaluation was unknown, as there was no evidence of progression to tumors.

Slides of the ovaries from the Butenhoff et al. study (2012)—originally conducted from April 1981 through May 1983—were reevaluated by Mann and Frame (2004) with emphasis placed on the proliferative lesions of the ovary. Using more recently published nomenclature, the ovarian lesions were diagnosed and graded as gonadal stromal hyperplasia and/or adenomas, which corresponded to the diagnoses of tubular hyperplasia or tubular adenoma by the original study pathologist. The data are summarized in Table 3-29. No statistically significant increases in hyperplasia (total number), adenomas, or hyperplasia/adenoma combined were seen in treated groups compared to controls. There was some evidence of an increase in size of stromal lesions observed at the 300-ppm group; however, adenomas occurred in greater incidence in the control group than in either of the treated groups. Results of this follow-up evaluation indicated that rats sacrificed at the 1-year interim sacrifice, as well as rats that died prior to the interim sacrifice, were not considered at risk for tumor development.

Table 3-29. Incidence of Ovarian Stromal Hyperplasia and Adenoma in Rats

Group	0 ppm	30 ppm	300 ppm
No. examined	45	47	46
Hyperplasia (Total)	8	16	15
Grade 1	6	7	5
Grade 2	2	3	1
Grade 3	0	5	6
Grade 4	0	1	3
Adenoma	4	0	2
Adenoma and/or Hyperplasia	12	16	17

Source: Mann and Frame 2004

Mammary gland tumors also were observed in the Butenhoff et al. (2012) bioassay. In the original analysis of mammary tissues from female rats, the incidence of fibroadenoma of the mammary gland in the female 300-ppm group (48%) was greater than that in either of the concurrent control groups (22%). It also was similar to the incidence in the 30-ppm group (42%), but considered to be within the norm for background variation of this lesion in Sprague-Dawley

rats based on the published literature. As a result of questions raised about this conclusion, a pathology working group (PWG) was commissioned to review the female mammary tumor findings, blinded to treatment status, using current diagnostic criteria (Hardisty et al. 2010). Table 3-30 compares the original mammary gland tumor findings to those of the PWG.

Table 3-30. Mammary Gland Tumor Incidence Comparison

	0 ppm		30 ppm		300 ppm	
	Butenhoff	**Hardisty**	**Butenhoff**	**Hardisty**	**Butenhoff**	**Hardisty**

Source: Hardisty 2005; Hardisty et al. 2010
Notes:
[a] Includes fibroadenoma, multiple counts.

The principal differences between the original reported findings and the PWG results relate to changes in the mammary gland that were initially reported as lobular hyperplasia, which the PWG felt had features more characteristic of mammary gland fibroadenoma (Table 3-30). As a result, the numbers of rats with benign tumors (adenoma and fibroadenoma) were reclassified from 13 to 19 in the control group, from 19 to 22 in the 30-ppm group, and from 21 to 23 in the 300-ppm group. Although the incidence of neoplasms varied among the control and treated groups, there were no statistically significant differences when evaluated using the Fisher's exact test for pairwise comparison for fibroadenoma, adenocarcinoma, total benign neoplasms, and total malignant neoplasms. The morphologic appearance, overall incidence, and distribution of the neoplasms observed in treated and control groups were similar, resulting in a conclusion that they are not related to compound administration.

A 2-year mechanistic study in male Crl:CD BR (CD) rats (Biegel et al. 2001; Cook et al. 1992) resulted in liver tumors, LCTs, and PACTs. The rats (n = 156 per group) were fed diets containing 0 ppm (*ad libitum* control and control pair-fed to the PFOA-exposed rats) or 300-ppm PFOA (13.6 mg/kg intake). Rats were euthanized at interim time points of 1, 3, 6, 9, 12, 15, 18, and 21 months. All rats surviving the 24-month test period were necropsied for microscopic examination of various organs (e.g., kidneys, liver, testes, brain, heart, spleen). The incidence of liver adenomas in the *ad libitum* control, pair-fed control, and treated groups was 3% (2/80), 1% (1/79), and 13% (10/76), respectively. In the Butenhoff et al. study (2012), no hepatic adenomas were observed. The incidence for liver carcinomas was 0% (0/80), 3% (2/79), and 0% (0/76) in the *ad libitum* control, pair-fed control, and treated groups, respectively.

There was a significant increase in the incidence of Leydig cell adenomas in the treated rats—11% (8/76) when compared to the pair-fed control rats (3%, 2/78)—supporting the observations from the Butenhoff et al. study (2012). The incidence in *ad libitum* control rats was 0% (0/80). In addition, the treated group had a significant increase in the incidence of liver adenomas and pancreatic acinar cell adenomas when compared to the pair-fed and *ad libitum* control groups. The incidence for the pancreatic acinar cell adenomas was 0% (0/80) in the

treated rats, 1% (1/79) in the pair-fed control rats, and 9% (7/76) in the control rats. The incidence of pancreatic acinar cell carcinoma was 1% (1/76) in the treated rats, 0% (0/79) in the pair-fed control rats, and 0% (0/80) in the control rats.

In Butenhoff et al. (2012), there was no reported increase in the incidence of PACTs. However, the incidence of pancreatic acinar hyperplasia in the male rats was 0/33, 2/34, and 1/43 in the control, 30-, and 300-ppm groups, respectively. To resolve this discrepancy, the histological slides from both studies were reviewed by independent pathologists. This review of the microscopic lesions of the pancreas in the two studies indicated that PFOA produced increased incidence of proliferative acinar cell lesions of the pancreas in the rats of both studies at the dietary concentration of 300 ppm. The differences observed were quantitative rather than qualitative; more and larger focal proliferative acinar cell lesions and greater tendency for progression of lesions to adenoma of the pancreas were observed in the Biegel et al. study (2001) than in the Butenhoff et al. study (2012). The difference between pancreatic acinar hyperplasia (Butenhoff et al. 2012) and adenomas (Biegel et al. 2001) in the rat was a reflection of arbitrary diagnostic criteria and nomenclature by different pathologists. The basis for the quantitative difference in the lesions observed is not known, but was believed most likely to have been caused by the difference in the diets used in the two laboratories (Frame and McConnell 2003).

Mouse. Filgo et al. (2015) reported on tumor development in females from three strains of mice (CD-1, SV-139, and SV-129 PPARα knock-out [KO]) at 18 months with exposures that occurred only during development (gestation and lactation). The animals were from separate experiments initially carried out by EPA and published as Hines et al. (2009) and Abbott et al. (2007). The Filgo et al. (2015) analysis focused on the mature offspring from the earlier publications and was carried out at the National Institute for Environmental Health Sciences (NIEHS). Dosing regimens differed for the individual strains as did the doses and the number of animals per dose group. Some of the animals in the original studies had died before the 18-month sacrifice at NIEHS. After sacrifice, the livers were recovered for analysis. The tissue sections were reviewed by a team of board-certified veterinary pathologists. Table 3-31 summarizes the tumor results.

Table 3-31. Liver Tumors in Three Strains of Mice at 18 Months with Exposure to PFOA Only during Gestation and Lactation

Strain	0 mg/kg/day	0.01 mg/kg/day	0.1 mg/kg/day	0.3 mg/kg/day	0.6 mg/kg/day	1 mg/kg/day	3 mg/kg/day	5 mg/kg/day
	Number of Tumors / Total Number Tested Tumor Type							
CD-1	1/29 L	1/29 HCA	1/37 HCA	6/26 HCA(4), HCC, L	NT	2/31 HcyS, L	NT	6/21 HmS(2), HCA, HCC, HcyS, L
SV-129	0/10	NT	1/10 HcyS	0/8	0/6	0/8	NT	NT
SV-129-PPARαKO	0/6	NT	1/10 HCA	2/10 HCA. ICT	NT	1/9 ICT	2/9 HCA	NT

Notes:
HCA = hepatocellular adenoma, HCC = hepatocellular carcinoma, HcyS = histocytic sarcoma, HmS = hemangeosarcomas, ICT = Ito cell tumor, L = lymphoma, NT = not tested.

It is difficult to draw conclusions regarding the carcinogenicity of PFOA in mice based on the data collected because of the small number of animals evaluated in both studies of SV-129 mice and the lack of PFOA exposure between PND 21 and 18 months for all dose groups. As was the case for liver tumors in the Butenhoff et al. study (2012), there is a lack of dose-response for total liver tumors, although the four hepatocellular adenomas seen at 0.3 mg/kg/day in CD-1 mice were significantly greater ($p<0.05$) than the control. Tumor types varied across the dose groups. The authors also reported on preneoplastic basophilic, and eosinophilic foci were observed in the CD-1 mice but did not show a response to dose.

An interesting histological finding in both the CD-1 and SV-129 mice was a trend for increased Ito cell atrophy and lesion severity across the doses (Filgo et al. 2015). Since Ito cells accumulate fat in the liver sinusoids, this observation provides additional support for hepatic steatosis as a condition of concern following developmental PFOA exposure. There was an increase in severity with dose for the Ito cell fat deposits for all but the high-dose group. The Ito cell lesion was present in the SV-129 mice, but was not associated with tumors. CD-1 mice had a significant increase in Ito cell hypertrophy at 5 mg/kg/day compared to controls, but there was a lack of dose-response. The authors concluded that liver damage from PFOA exposure occurring early in development is not totally linked to PPAR-α and could progress as animals aged without continued dosing, thus compromising liver function and possibly leading to tumor development.

Inhalation and Dermal Exposures

No data on the tumorigenic effects of chronic inhalation or dermal exposures to PFOA were identified in the literature.

3.3 Other Key Data

3.3.1 Mutagenicity and Genotoxicity

PFOA has been tested for genotoxicity in a variety of *in vivo* and *in vitro* assays. The data from the *in vitro* studies are summarized in Table 3-32.

PFOA was tested in a cell transformation and cytotoxicity assay conducted in $C_3H10T_{½}$ mouse embryo fibroblasts. The cell transformation was determined as both colony transformation and foci transformation. There was no evidence of transformation at any of the dose levels tested in either the colony or foci assay methods (Garry and Nelson 1981).

PFOA was tested twice (Lawlor 1995, 1996) for its ability to induce mutation in the *Salmonella – E. coli*/mammalian-microsome reverse mutation assay. The tests were performed both with and without metabolic activation. A single positive response seen in *S. typhimurium* TA1537 when tested without metabolic activation was not reproducible. PFOA did not induce mutation in either *S. typhimurium* or *E. coli* when tested either with or without metabolic activation. PFOA did not induce chromosomal aberrations in human lymphocytes when tested with and without metabolic activation up to cytotoxic concentrations (Murli 1996a; NOTOX 2000). Sadhu (2002) reported that PFOA did not induce gene mutation when tested with or without metabolic activation in the K-1 line of CHO cells in culture.

Table 3-32. Genotoxicity of PFOA *In Vitro*

Test System	End-point	With Activation	Without Activation	Reference
$C_3H10T_{½}$ mouse embryo fibroblasts	Cell Transformation	NA	-	Garry and Nelson 1981
$C_3H\ 10T_{½}$ mouse embryo fibroblasts	Cytotoxicity	NA	-	Garry and Nelson 1981
S. typhimurium TA1537	Gene Mutation	-	+ (not reproducible)	Lawlor 1995, 1996
E. coli	Gene Mutation	-	-	Lawlor 1995, 1996
CHO cells	Chromosomal Aberrations	+, +	+, -	Murli 1996b, 1996c
CHO cells	Polyploidy	+, +	+, -	Murli 1996b, 1996c
Human lymphocytes	Chromosomal Aberrations	-	-	Murli 1996c; NOTOX 2000
K-1 CHO cells	Gene Mutation	-	-	Sadhu 2002
S. typhimurium TA98, TA100, TA102, TA104	Gene Mutation	-	-	Freire et al. 2008

Note: NA= not applicable.

Murli (1996b, 1996c) tested PFOA twice for its ability to induce chromosomal aberrations in CHO cells. In the first assay, PFOA induced both chromosomal aberrations and polyploidy in both the presence and absence of metabolic activation. In the second assay, no significant increases in chromosomal aberrations were observed without activation. However, when tested with metabolic activation, PFOA induced significant increases in chromosomal aberrations and in polyploidy (Murli 1996b). The effects were observed only at toxic concentrations (EFSA 2008).

PFOA did not display mutagenic activity with or without metabolic activation in *S. typhimurium* strains TA98, TA100, TA102, or TA104 (Freire et al. 2008).

The data summarized in Table 3-32 suggest that PFOA is not a mutagen. A single positive result in *S. typhimurium* was not reproducible by the same authors and was not replicated in other studies. Potential chromosomal effects were found in CHO cells at toxic concentrations, but not in human lymphocytes.

Governini et al. (2015) collected semen samples from 59 healthy nonsmoking patients attending a Center for Couple Sterility conference at the University in Siena, Italy. The subjects were divided into those that were normozoospermic (13) and those that were oligoasthenoterato-zoospermic (46). PFOA was present in 75% of the seminal plasma samples and only 16% of the blood samples. Conversely, PFOS was present in 25% of the seminal plasma samples and 84% of the serum samples. Sperm were evaluated for the presence of aneuploidy and diploidy, and sperm DNA was evaluated for fragmentation using the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay. The frequencies of aneuploidy and diploidy were significantly greater in the PFAS-positive samples than in the PFAS-negative samples ($P<0.001$ and $P<0.05$, respectively), suggesting the possibility for errors in cell division. The levels of fragmented chromatin were significantly increased ($P<0.001$) for the PFAS-positive group compared with the PFAS-negative group.

PFOA was tested twice in the *in vivo* mouse micronucleus assay. PFOA did not induce any significant increases in micronuclei and was considered negative under the conditions of this assay (Murli 1995, 1996d).

G. Zhao et al. (2010) used A_L cells to determine the mutagenicity of PFOA to mammalian cells. A_L cells are a human-hamster hybrid containing CHO-K1 chromosomes and a single copy of human chromosome 11. The significance of human chromosome 11 is that it encodes for expression of the human cell surface protein CD59. A_L and mitochondria-deficient A_L cells were incubated with 0, 1, 10, 100, and 200 μmol PFOA for up to 16 days and used in the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) viability, mutation, or caspace assays. Reactive oxygen species (ROS), nitric oxide, and superoxide anion production were measured in the cells, and the effects of ROS/reactive nitrogen species quenchers [0.5% dimethyl sulfoxide (DMSO) and 0.2 mM NG-methyl-$_L$-arginine, respectively] on mutagenicity and caspace activities were determined. At 100 and 200 μmol PFOA, A_L cell viability was significantly decreased after incubation for 1, 4, 8, and 16 days. CD59 mutation frequencies were increased in A_L cells after a 16-day incubation with 200 μmol PFOA. There was no increase in mutations in mitochondria-deficient A_L cells after incubation with 100 or 200 μmol PFOA.

Production of ROS, nitric oxide, and superoxide anion was significantly increased at 100 and 200 μmol PFOA after incubation of A_L cells for 1, 4, and 16 days. Incubation with DMSO to inhibit ROS production significantly decreased the CD59 mutation frequency caused by 200 μmol PFOA after the 16-day incubation. In contrast, mitochondria-deficient A_L cells had no increase in ROS or superoxide production after incubation with up to 200 μmol PFOA for 16 days.

To assess whether PFOA could induce the apoptotic pathway, caspase-3/7 and caspase-9 were examined in intact A_L cells (mitochondria-deficient cells were not examined). The highest concentration significantly increased caspase 3/7 and 9 activities after 1- and 4-day incubations. Incubation with 0.5% DMSO and 0.2 mM NG-methyl-$_L$-arginine significantly decreased the increased caspace activity induced by 200 μmol PFOA. The results led the authors to suggest that mitochondrial-dependent ROS might play an important role in PFOA-induced mutagenicity and that induction of caspase activities might be mediated by reactive oxygen and nitrogen species.

3.3.2 Immunotoxicity

The impact of PFOA on the immune system has been the subject of considerable research, primarily in mice. A number of the early studies by Yang et al. (2000, 2001, 2002a) used high-dose exposures of 0.02% to 0.05% PFOA. Later studies by DeWitt et al. (2008, 2009, 2015) and Loveless et al. (2008) used a range of doses from < 1 mg/kg/day to 30 mg/kg/day. Most of the studies focused on responses associated with the spleen and thymus. Some of the effects observed were PPARα-associated, but others are totally or partially independent. There is evidence for full or partial reversal of effects in those studies that incorporated a recovery phase. One study of immunotoxicity used the dermal route of exposure (Fairley et al. 2007).

Rat. Loveless et al. (2008) administered 0, 0.3, 1, 10, and 30 mg linear PFOA/kg by oral gavage to groups of male CD rats (n = 10 per group) for 29 days. The animals received a dose of SRBC on day 23. A separate group of high-dose rats were injected with water instead of SRBC. Rat body weight was recorded on days 0, 3, and 6–28. At necropsy, blood was collected for evaluation of immune system parameters. Cell counts were determined for the thymus and

spleen. Total spleen and thymocyte cell counts and organ weights in exposed rats were comparable to control. Microscopic examination of the thymus, mesenteric lymph nodes, and popluteal lymph nodes revealed no effects in treated rats resulting from PFOA exposure. There was no difference observed in immunoglobulin (IgM) titers between treated and control rats. The immunological NOAEL was 30 mg/kg/day.

Mouse. Yang et al. (2000, 2001, 2002a, 2002b) completed a series of studies investigating the immunotoxic effects of PFOA. In the first study, Yang et al. (2000) examined the liver, spleen, and thymus effects of several known PPARα activators, including PFOA. The researchers administered 0.02% PFOA (~40 mg/kg/day) to male C57BL/6 mice in the diet for 2, 5, 7, and 10 days. At the end of the feeding period, mice were sacrificed and the liver, spleen, and thymus were weighed. Administration of PFOA resulted in a significant increase in liver weight relative to control even at day 2. Following 5 days of administration, significant decreases in thymus and spleen weight were noted.

A second component of the Yang et al. study (2000) examined the effect of 0.02% PFOA in the diet on the cellularity, cell surface phenotype, and cell cycle of thymocytes and splenocytes. After 7 days, significant decreases in the total number of thymocytes (85%) and splenocytes (80%) were observed. There is a pattern to the development of thymocytes that should be considered when evaluating the impact of chemicals on their differentiation. Early thymocytes formed in the bone marrow do not express CD4 or CD8 ($CD4^{-}CD8^{-}$). In the thymus, they differentiate and express both CD4 and CD8 ($CD4^{+}CD8^{+}$). They also undergo proliferation and downregulation of either the CD4 or CD8 protein expression to become either a CD4 or CD8 thymocyte (Yang et al. 2000). Following exposure to PFOA, the number of thymocytes expressing neither CD4 nor CD8 decreased by 57%; the number expressing both CD4 and CD8 decreased by 95%; the number expressing only CD4 decreased by 64% while those expressing only CD8 decreased by 72%. As detected by cell cycle flow cytometry analyses, thymocyte proliferation was inhibited based on the number of cells in each stage of the cell cycle.

T-cells ($CD3^{\pm}$) and B-cells ($CD19^{\pm}$) in the spleen decreased by 75% and 86%, respectively. Splenic T-cells are lymphocytes produced in the thymus that carry the $CD3^{+}$ surface protein marking them as T-cells for exportation to the spleen. There are several classes of T-cells that are characterized by surface proteins. Yang et al. (2000) found significant decreases in helper $CD3^{+}$T-cells with $CD4^{+}$ surface proteins (78%) and cytotoxic $CD3^{+}$T-cells with $CD8^{+}$ surface proteins (74%). The authors suggested that, unlike the $CD3^{+}$T-cells that originate in the thymus, the decrease in $CD19^{+}$B-cells of the spleen reflects decreased differentiation and maturation in the bone marrow where they are formed.

In the final phase of the Yang et al. study (2000), the effects of *in vitro* exposure of thymocytes and splenocytes to PFOA were examined. The *in vitro* studies showed spontaneous apoptosis occurring in splenocytes and thymocytes after 8 or 24 hours of culturing in the presence of varying concentrations of PFOA (50, 100, and 200 μmol). However, under the exposure conditions, PFOA did not appear to significantly alter the cell cycle. The only dose tested (~40 mg/kg/day) was a LOAEL for its effects on the immunoactive products of the thymus and spleen. Recovery can occur with the cessation of exposure as illustrated by the Yang et al. study (2001) described below.

Yang et al. (2001) reported on their examination of the immunosuppressive effects of PFOA. As was the case in their earlier publication (Yang et al. 2000), the 2001 report includes several components. A diet of 0.02% PFOA (~40 mg/kg/day) was fed to C57BL/6 mice for 2–10 days.

One group of animals was exposed to PFOA each day until day of sacrifice on days 2, 5, 7, and 10. At sacrifice, body, liver, and spleen weights were recorded. A second group of animals was dosed according to the same schedule, but dosing ceased after day 7, and the animals were fed normal diets for 2–10 days to monitor recovery from the effects of exposure. In the recovery group, animals were sacrificed after 2-, 5-, and 10-day recovery periods.

The mice that received 0.02% PFOA for up to 10 days experienced significant increases in liver weight compared to controls beginning at day 2. Significant decreases in thymus and spleen weights were observed starting on day 5. Body weight increased for the first 2 days of the study and decreased continuously for the remainder of the exposure period. The activity of palmitoyl-CoA and lauryl-CoA, biomarkers for PPARα activation and peroxisome proliferation, also were increased significantly and increasingly across the exposure period. The impact of PFOA exposure was similar to that observed in the Yang et al. study (2000). After administration for 7 days, the number of thymocytes expressing neither CD4 nor CD8 decreased by 65% following exposure to PFOA; the number expressing both CD4 and CD8 decreased by 95%; and the number expressing either CD4 or CD8 decreased by 65% and 75%, respectively. T-cell ($CD3^+$) splenocytes and B-cell ($CD19^+$) splenocytes decreased by 65% and 75%, respectively. As detected by cell cycle flow cytometry analyses, thymocyte but not splenocyte proliferation was inhibited.

The animals that participated in the recovery portion of this study rapidly regained their body weight starting on the second day after withdrawal of PFOA. However, the liver weight failed to recover even after 10 days. Thymus weight recovery started on day 2 and was completed by day 10. The spleen weights returned to normal by day 2 post-withdrawal. The increases in thymus and spleen weight during recovery were paralleled by increases in total thymocyte and splenocyte counts. Thymocyte recovery was apparent on day 5 and complete by day 10, although during the first two days of the recovery period, further decreases in the $CD4^+CD8^+$, $CD4^+$ and $CD8^+$ cells were observed. Flow cytometry evaluation of the distribution of the cells across the cell cycle in the recovery group animals demonstrated increases in cell proliferation following removal of PFOA from the diet. However, final cell counts did not reach the control values for the thymocyte ($CD4^+$ and $CD8^+$) or splenocyte ($CD3^+$ and $CD19^+$) populations evaluated.

In the second component of the Yang et al. study (2001), C57BL/6 mice were administered diets consisting of 0.001%–0.05% PFOA (w/w) for 10 days. These doses are equivalent to approximately 2.0–100 mg/kg/day. There was a dose-related decrease in spleen and thymus weights and a dose-related increase in liver weights accompanied by a corresponding increase of palmitoyl-CoA and lauryl-CoA activity. Enzyme activity was significantly increased for all doses. Spleen and thymus weights were significantly decreased at doses ≥ 0.01% and higher but not at the lower doses; the increases in liver weights were significantly increased for the 0.02% and 0.05% doses. With the testing of a broader range of doses, ~20 mg/kg/day was found to be a LOAEL for effects on the thymus and spleen and the ~6 mg/kg/day dose a NOAEL.

Yang et al. (2002a) examined the possible involvement of PPARα in the immunomodulation exerted by PFOA. This study made use of transgenic PPARα-null mice (Sv/129), which are homozygous with regards to a functional mutation in the PPARα gene. These mice do not exhibit peroxisome proliferation or hepatomegaly and hepatocarcinogenesis even after exposure to peroxisome proliferators. The mice were fed a diet consisting of 0.02% PFOA (w/w) (~40 mg/kg/day) for 7 days. At the end of the feeding period, mice were sacrificed and the liver, spleen, and thymus were removed and weighed. The effect of PFOA on peroxisome proliferation, cell cycle, and lymphoproliferation was ascertained.

The results showed that, in contrast to wild-type mice, feeding PPARα-null mice PFOA resulted in no significant decrease in body weight. Liver weight in PPARα-null mice fed the PFOA diet was significantly increased when compared to control PPARα-null mice, but not when compared to wild-type PFOA-exposed mice. Peroxisome proliferation, as measured by fatty acid oxidation, was totally lacking in PPARα-null mice. Also, in contrast to wild-type mice, feeding PPARα-null mice PFOA resulted in no significant decrease in the weight of the spleen or the number of splenocytes.

There was a decrease in weight and cellularity of the thymus in the PPARα-null mice compared to the PPARα-null control mice, but it was not as dramatic as that in the PFOA-exposed wild-type mice. In addition, the decreases in the size of the CD4+CD8+ population of thymus cells and the number of thymus cells in the S and G2/M phases of the cell cycle were lower in PPARα-null mice than they were in the PFOA-exposed wild-type mice, but higher than in the PPARα-null control mice. PFOA treatment caused no significant change in splenocyte proliferation in PPARα-null mice in response to mitogen exposure, but did show a response in the PFOA-exposed wild-type mice as described above.

The series of studies published by Yang et al. (2000, 2001, 2002a) link many of the effects of the liver, thymus, and spleen in PFOA-exposed mice to the activation of PPARα. However, there were some impacts on the thymus and liver that were independent of PPARα receptor activation. PPARα-null mice still showed increases in liver weight and effects on the thymus (small decrements in organ weight, thymocyte cellularity, and proliferative cell cycle) following a 7-day exposure to approximately 40 mg/kg/day PFOA that were independent of PPARα.

Yang and colleagues extended their studies of the immunotoxicity of PFOA in a feeding study designed to examine the effects of PFOA on specific humoral immune responses in mice (Yang et al. 2002b). For this study, 0.02 % PFOA was administered to male C57BL/6 mice for 10 days. The animals were then evaluated via plaque-forming cell (PFC) and serum antibody assays for their ability to generate an immune response to horse red blood cells (HRBCs). *Ex vivo* and *in vitro* splenic lymphocyte proliferation assays also were performed. The results showed that mice fed normal chow had a strong humoral response to challenge the HRBCs, as measured by the PFC assay. In contrast, mice fed PFOA responded to HRBC immunization with no increase in HRBC-specific PFCs, relative to unimmunized controls. However, in experiments where PFOA-treated mice received normal chow following HRBC immunization, there was a significant recovery of the numbers of specific PFCs stimulated. The suppression of the humoral immune response by PFOA was confirmed by analysis of the serum anti-HRBC response.

In *ex vivo* experiments, splenocytes isolated from control mice responded to both concanavalinA (ConA) and lipopolysaccharide (LPS) with lymphocyte proliferation, as measured by thymidine incorporation. However, treating mice with 0.02% PFOA for 7 days attenuated the proliferation. In a set of *in vitro* experiments, PFOA (1–200 μmol) added to the culture medium of splenocytes cultured from untreated mice did not cause an alteration of lymphocyte proliferation in response to LPS or ConA.

DeWitt et al. (2008) expanded the repertoire of studies of the immunological effects of PFOA by examining various aspects of humoral (antibody production) and cellular immunity. The first component of their publication had many similarities with the Yang et al. study (2001). Adult female C57BL/6J mice (n = 40 per endpoint and 8 per group) were exposed to a single daily dose of 30 mg PFOA/kg/day in distilled water by gavage for 10 continuous days. After 10 continuous days of exposure, half of the mice continued receiving PFOA from day 11 through

day 15 (constant group) while the other half received distilled water from day 11 through day 15 (recovery group). On day 11, 16 mice per group were immunized with sheep red blood cells (SRBC) and eight mice per group were injected with BSA. Sacrifices took place on day 16 (1 day postexposure period) and day 31 (15 days postexposure period). Vehicle and cage controls also were included in the study. All groups were monitored for the following effects:

- Body weight and organ weights (day 16, day 31)
- Serum IgM levels (day 16)
- Delayed-type hypersensitivity (DTH) foot-pad response to BSA (day 26)
- Serum IgG levels after booster immunization with SRBC on day 20 (day 31)

The results for body and organ weights were comparable to those in the Yang et al. study (2001). Body weight was significantly decreased from days 8–11 for both PFOA-treated groups and on day 16 for mice in the constant exposure group. By day 31, there were no body weight differences between the groups. Relative liver weight was significantly elevated in both PFOA-treated groups on days 16 and 31. Absolute and relative spleen and thymus weights of animals in both PFOA groups were significantly decreased compared to control groups on day 16. By day 31, thymus and spleen weights were not statistically different between control and treated mice. IgM levels following immunization with SRBC were reduced by up to 20% compared to controls on postexposure day 1 in both the recovery and constant exposure groups. There were no significant differences from controls for SRBC-specific IgG levels and for DTH foot-pad responses to the BSA challenge.

The C57BL/6 mice used for the continuous-dosing versus recovery component of the DeWitt et al. study (2008) were found to develop ulcerative dermatitis following the PFOA exposure. It was determined that this effect was a genetic susceptibility in the strain, and they were not used for the dose-response component of the study; the C57BL/6N strain was used in its place.

Two studies of dose-response were included in the DeWitt et al. (2008) publication. Groups of 16 female C57BL/6N mice were given 0, 3.75, 7.5, 15, and 30 mg PFOA/kg/day in the drinking water for 15 days during the first experiment. In the second experiment, the doses were 0, 0.94, 1.88, 3.75, and 7.5 mg PFOA/kg/day administered for 15 days in the drinking water. The immunological sensitization and postdose monitoring were identical to that used in the constant-dosing versus recovery experiment.

In the first experiment, body weight was significantly decreased from day 8–16 at 30 mg/kg PFOA and on day 16 at 15 mg/kg PFOA. As observed previously, liver weights were significantly elevated at day 16 and day 31 at all doses. Absolute and relative spleen and thymus weights were significantly decreased at ≥15 mg/kg PFOA on day 16. With the exception of the absolute thymus weight at 15 mg/kg PFOA, all spleen and thymus weights were similar to weights in controls 15 days after dosing. The IgM response to SRBC was significantly reduced at ≥3.75 mg/kg PFOA in a direct dose-related manner. The IgG response to SRBC challenge was slightly but significantly elevated at 3.75 and 7.5 mg/kg PFOA but similar to that of the control level at the higher doses. Thus, there was a direct response of IgM, but not IgG, to dose across the dose levels. There was no significant change in the DTH response at any dose. The LOAEL from the first experiment was 3.75 mg/kg/day dose based on decreased IgM and increased IgG response to SRBC immunization and increased liver weights ($p<0.05$).

The second dose-response experiment confirmed the 3.75 mg/kg/day dose as the immunological LOAEL on the basis of significantly decreased spleen weight, decreased IgM

levels on day 16, and increased IgG levels on day 31. The immunological NOAEL was 1.88 mg/kg/day. BMD analysis of IgM serum titer data gave a lower bound 95% confidence limit of 1.75 mg/kg/day on a BMD (one SD) of 3.06 mg/kg/day. Liver weight was significantly increased at all doses on days 16 and 31. The LOAEL for increased liver weight was 0.94 mg/kg PFOA.

As mentioned earlier, some of the immunological responses observed in the studies of immunotoxicity are linked to PPARα activation by PFOA. DeWitt et al. (2015) published results for a study in female PPARα KO mice (B6.129S4-*Ppar*^{tm1Gonz}N12 mice) and compared them to the response of female C57BL/6-Tac wild-type mice. Both T-cell-dependent and T-cell-independent antibody production were evaluated. The doses used in the study of the T-cell-dependent responses were 0, 7.5, and 30 mg PFOA/kg/day dissolved in deionized drinking water for 14 days. On day 11, the animals were injected with SRBCs to stimulate an immune response. PFOA dosing continued for 4 more days (15 days dosed); the following day, the animals were sacrificed. Body weight was significantly decreased only in wild-type mice at 30 mg/kg/day. Relative spleen weights were significantly decreased ($P<0.05$) in the wild-type but not the KO mice at 30 mg/kg/day of PFOA. Relative thymus weights were significantly decreased in the wild-type mice at 7.5 mg/kg/day, but not in the KO mice at either dose or the wild-type mice receiving 30 mg/kg/day. There was a significant ($P<0.05$) reduction in the IgM antibody response to the SRBC injection at 30 mg/kg/day for both the wild-type and KO animals ($n = 6$), indicating that the response was not totally related to PPAR-α activation. The NOAEL in wild-type and KO animals was 7.5 mg/kg/day and the LOAEL 30 mg/kg/day based on decreased T-cell-dependent IgM antibody response to SRBC.

To evaluate T-cell-independent responses to PFOA, groups of eight C57BL/6N mice were given doses of 0, 0.94, 1.88, 3.75, and 7.5 mg/kg/day in their drinking water. On day 11, they were injected with the T-cell-independent antigen dinitrophenyl ficol. At sacrifice (day 16), blood was collected for analysis of IgM antibody titers. There was a significant decrease ($p<0.05$) in the antibody response by 9.4–10.7% in the animals receiving doses ≥ 1.88 mg/kg/day of PFOA. The NOAEL for the T-cell-independent response to dinitrophenyl ficol was 0.94 mg/kg/day of PFOA and the LOAEL was 1.88 mg/kg/day. Thus, suppression of the T-cell-independent response occurred at a lower dose (1.88 mg/kg/day) than the dose resulting in suppression of the T-cell-dependent response (7.5 mg/kg/day).

The authors looked at changes in lymphocyte populations at 10, 13, and 15 days of exposure in the female C57BL/6N mice and saw no significant dose-dependent changes in lymphocyte cell types. They concluded that both sets of responses were due to changes in cellular function rather than lymphocytotoxicity (DeWitt et al. 2015).

Loveless et al. (2008) administered 0, 0.3, 1, 10, and 30 mg linear PFOA/kg by oral gavage to groups of male CD-1 mice ($n = 20$ per group) for 29 days. The animals received a dose of SRBC on day 24. A separate group of high-dose mice was injected with water instead of SRBC. Mice were weighed daily. At necropsy, blood was collected for evaluation of immunity parameters. Cell counts were determined for the thymus and spleen.

Absolute and relative spleen and thymus weights were significantly decreased at ≥10 mg/kg/day. The relative spleen weight of mice dosed with 1 mg/kg/day also was significantly decreased compared to control animals. Spleen and thymus cell counts were significantly decreased and minimal to severe lymphoid depletion/atrophy of the thymus was observed at ≥10 mg/kg/day. IgM titers were significantly decreased at ≥10 mg/kg/day. Serum

CORT was significantly increased at 10 mg/kg/day and elevated (not statistically significant) at 30 mg/kg/day. When IgM and CORT were plotted against each other, a negative correlation coefficient suggested that increasing CORT levels decreased the ability to make SRBC antibody. The LOAEL was 1 mg/kg/day based on decreased spleen weight, and the NOAEL was 0.3 mg/kg/day. Mice appeared to be more susceptible than rats to immunosuppression from PFOA.

Loveless et al. (2008) hypothesized that at least a portion of the thymic response to PFOA might be related to physiological stress and increased levels of CORT hormones. DeWitt et al. (2009) investigated this hypothesis by comparing the immunological response of adrenalectomized (ADX) C57BL/6N female mice to that of sham-operated female mice from the same strain. The animals were dosed with 0, 3.75, 7.5, and 15 mg PFOA/kg/day in the drinking water for 10 days. Body weight was recorded on dosing days 0, 4, and 8, plus 2 and 5 days postdosing. On exposure days 5 and 10, blood and serum were collected for analysis of a broad array of clinical chemistry parameters, including activity of liver enzymes indicative of cellular damage (e.g., ALP, AST, ALT, LDH, GGT, and SDH), serum lipids (cholesterol and triglycerides), and CORT. A baseline measure of CORT was determined from serum samples collected before dosing began. One day after cessation of exposure, the mice were immunized with SRBC. Four days later, serum was collected and the levels of CORT and IgM were determined.

Body weight in the sham-operated mice declined during dosing in the highest dose group but recovered by 5 days postdosing. In the ADX mice, body weight declined during dosing at 7.5 and 15 mg PFOA/kg/day, but recovered in mice receiving 7.5 mg PFOA/kg/day by 5 days postdosing. There were significant increases in ALT, AST, LDH, and SDH at the highest dose for the ADX mice indicative of damage to hepatic cell membranes (Table 3-33).

Serum levels of triglycerides significantly decreased compared to controls, with all doses for the sham-operated mice on day 5 of dosing but only for the 7.5- and 15-mg/kg/day doses in the ADX mice. Cholesterol levels were significantly decreased ($p<0.05$) in the sham-operated mice at the highest dose, but no differences in cholesterol levels were observed in the ADX mice.

Table 3-33. Selected Clinical Chemistry Parameters in Mice Treated with PFOA for 5 Days

Dose (mg/kg/day)	ALT	AST	LDH	SDH
Sham-Operated

Note: * = $p<0.05$ versus corresponding sham control or ADX control group.

After 10 days, there were no significant differences in liver enzymes for the ADX or sham mice. However, there was a dose-related trend towards increased levels of liver enzymes for the PFOA-exposed sham-operated animals and for LDH in the PFOA-exposed ADX animals (Table 3-34).

Table 3-34. Selected Clinical Chemistry Parameters in Mice Treated with PFOA for 10 Days

Dose (mg/kg/day)	ALT	AST	LDH	SDH

Source: DeWitt et al. 2009

At the end of dosing, corticosteroid levels in the sham-operated animals were greatly elevated compared to the levels in the control animals at all doses, and the difference was statistically significant at the highest dose. By 5 days postdosing, the CORT levels had declined for all doses but were still elevated compared to controls for the 7.5- and 15-mg/kg/day groups. In the animals lacking their adrenal glands, there were no statistically significant differences in the hormone levels. IgM levels were significantly lower than controls at the highest dose for the sham-operated animals and at the two highest dose groups for the ADX mice. However, when comparing the sham mice to the ADX mice, the only significant difference in IgM was found for the 7.5-mg/kg/day animals. On the basis of data, it appears that stress-related CORT production did not have a major impact on the IgM response to the SRBC inoculation.

Son et al. (2009) administered 0, 2, 10, 50, and 250 ppm PFOA (equivalent to 0, 0.49, 2.64, 17.63, and 47.21 mg/kg PFOA) in the drinking water to 4-week-old male ICR mice for 21 days to determine if PFOA alters T lymphocyte phenotypes and cytokine expression in mice. The spleen, thymus, and trunk blood were collected at sacrifice. Sections of the spleen and thymus were processed for histological examination. Splenic and thymic expression of mRNA from proinflammatory cytokines—including tumor necrosis factor-α, interleukin-1β, and interleukin-6, and the proto-oncogene c-myc—were analyzed using RT-PCR. Flow cytometry was used to phenotype the splenic and thymic lymphocyte populations.

Spleen and thymus weights were slightly decreased in mice treated with PFOA. Enlargement with marked hyperplasia of the white pulp and increased cellular density of the lymphoid follicles were observed in spleens at 250 ppm. In the thymus, decreased cortex and medulla thickness and densely arranged cortex lymphoid cells were observed at 250 ppm. Tumor necrosis factor-α, interleukin-1β, interleukin-6, and c-myc expression were significantly elevated at 250ppm in the spleen. Interleukin-1β expression also was elevated at 50 ppm in the spleen. In the thymus, c-myc expression was significantly elevated by treatment with 50 and 250 ppm PFOA.

The splenic and thymic lymphocyte population was altered by PFOA treatment, as shown in Table 3-35. A 50% decrease was observed in splenic $CD8^+$ lymphocytes at all PFOA doses, and increases in splenic $CD4^+$ lymphocytes of 43% and 106% at 50 and 250 ppm PFOA, respectively, were observed. In the thymus, a 110% increase was observed in thymic $CD8^+$ lymphocytes at 250 ppm, but thymic $CD4^+$ lymphocyte populations were not affected and $CD4^+CD8^+$ populations were decreased at 50 and 250 ppm PFOA. The lowest dose tested (0.49 mg/kg/day) was a LOAEL for $CD4^-$ and $CD8^+$ splenocytes.

Table 3-35. Impact of PFOA on Splenic and Thymic Lymphocyte Populations

	Dose (mg/kg/day)			
Spleen	0.49	2.64	17.63	47.21
$CD4^-CD8^-$	↑	-	-	↓
$CD4^+CD8^-$	-	-	↑	↑
$CD4^-CD8^+$	↓	↓	↓	↓
$CD4^+CD8^+$	↓	↓	-	-
Thymus				
$CD4^-CD8^-$	-	-	-	↑
$CD4^+CD8^-$	-	-	-	-
$CD4^-CD8^+$	-	-	-	↑
$CD4^+CD8^+$	-	-	↓	↓

Notes:
↑ Significantly increased compared to control ($p < 0.05$).
↓ Significantly decreased compared to control ($p < 0.05$).
- Not significantly different from control.

Qazi et al. (2009) investigated the impact of PFOA on the innate immune system. Adult male C57BL/6 ($H\text{-}2^b$) mice were administered 0.001% and 0.02% PFOA (~2 or 40 mg/kg) in the diet (w/w) for 10 days. After the last dose, all mice were sacrificed. Sacrifice was delayed for a subset of the animals until 2 hours after they had received an LPS injection to stimulate an immunological response. Blood, peritoneal exudate cells, liver, epididymal fat, spleen, thymus, and bone marrow were recovered. The blood, peritoneal exudate, bone marrow, and spleen were evaluated for total and differential white blood cell counts and concentrations of tumor necrosis factor (TNF-α) and interleukin 6 (IL-6).

Consistent with other studies of the 0.02% dose, there was a significant increase in liver weight after the 10-day exposure. Body weight, thymus weight, spleen weight, and epididymal fat depots were decreased. Food consumption in these animals was reduced by 35%, which might have played a role in the reduced body, organ, and tissue weights. Compared to the controls, there was a significant decrease in total white cells, lymphocytes, and neutrophils at 0.02% PFOA. This same dose was associated with a decrease in total white cell count in bone marrow and spleen, and an increase in the proportion found as macrophages in the bone marrow, spleen, and peritoneal cavity. Although the total number of macrophages was not reduced in the peritoneal cavity and spleen, it was reduced in the bone marrow. The increase in the proportion of macrophages reflects a decrease in other white cell populations. There was significant increase in the concentration of IL-6 in all of the 0.02 % dosed animals, but only those receiving the LPS injections showed a significant increase in TNF-α. The 0.001% dose (about 2 mg/kg/day) was a NOAEL.

The data available on immunological responses of animals following oral exposure to PFOA are extensive, especially as they apply to mice. A number of the studies used doses of about 40 mg/kg/day. However, studies conducted at lower doses find effects on the spleen and/or thymus at doses from 0.5 to 2 mg/kg/day. Activation of PPARα appears to augment the response based on studies in PPARα-null mice but is not necessary (Yang et al. 2002a). There are differences between mice and rats with mice showing a response at a lower dose (Loveless et al. 2008). Cessation of dosing can reverse some of the observed effects in mice (Yang et al. 2001).

Inhalation Exposure

No data on the effects of inhalation exposure on immunological endpoints were identified in the literature.

Dermal Exposure

Fairley et al. (2007) carried out a complex study of toxicity and respiratory hypersensitivity to ovalbumin (OVA) as impacted by dermal exposure to PFOA dissolved in acetone compared to acetone alone. There were several phases to the study. In the first phase, a range-finding study, PFOA was applied to each ear of female BALB/c mice (n = 5 per group) at doses of 0, 0.01%, 0.1%, 0.25%, 0.5%, 1.0%, and 1.5% PFOA (equivalent to 0, 0.25, 2.5, 6.25, 12.5, 25, and 50 mg/kg/day) for 4 days. Six days after last inoculation, the animals were sacrificed. The liver, spleen, and thymus were recovered and weighed. A significant increase in liver weight was observed at ≥6.25 mg/kg PFOA. Spleen weight was significantly decreased in mice dosed with 25 mg/kg and 50 mg/kg PFOA, and thymus weight was significantly decreased in mice at the highest dose ($p<0.05$). The cell counts in the spleen were significantly decreased compared to control at all doses and for the highest two doses in the thymus. The LOAEL was 6.25 mg/kg/day based on a statistically significant increase in liver weight ($p<0.01$), and the NOAEL was 2.5 mg/kg/day.

In the second phase of the Fairley et al. study (2007), groups of 5–15 animals were dosed dermally on the ears for 4 days with doses of 0, 0.5%, 0.75%, 1.0%, and 1.5% PFOA (equivalent to 0, 12.5, 18.75, 25, and 50 mg/kg/day). On days 1 and 10, they were injected i.p. with either 2.0 mg alum or 7.5 μg OVA and 2.0 mg alum in a phosphate-buffered saline solution (100μL). Four days after the last inoculation, the animals were sacrificed and blood was collected by cardiac puncture. Liver, spleen, and thymus were recovered and weighed; spleen and thymus cellularities were determined. A significant ($p<0.01$) increase in liver weight and decrease in spleen weight and spleen cellularity occurred at all doses. Thymus weight and cellularity were significantly decreased ($p<0.01$) at ≥18.75 and ≥ 25 mg/kg/day, respectively. There were no significant differences in the $CD4^+$, $CD8^+$, $CD4^-8^-$, or CD3e T-cells. CD3e protein is expressed by both thymocytes and mature T-cells.

Levels of IgE and OVA-specific IgE were measured in the control and dosed animals by enzyme-linked immunosorbent assay. IgE is the immunoglobulin that is best correlated with respiratory allergic responses. It functions to stimulate mast cells and basophils to release histamine and other mediators of inflammation (Saladin 2004). The IgE response was increased in a dose-related fashion compared to the OVA control for all the PFOA-treated animals; the increase was significant ($p<0.05$ or 0.01) at doses ≥18.75 mg/kg/day. The OVA-specific IgE response did not demonstrate a direct response to dose, but there was a significant increase ($p<0.05$) for the 18.75- and 25-mg/kg/day groups. The OVA-specific response for the three highest dose groups was practically indistinguishable from the OVA control.

The dermal LOAEL was 12.5 mg/kg/day based on increased liver weight and decreased spleen weight and cellularity. No NOAEL was established.

In the third part of the Fairley et al. study (2007), mice (n = 5) were dosed dermally via their ears for 4 days as described above (0, 12.5, 18.75, 25, and 50 mg/kg/day). On days 19 and 26 after the start of dosing, they were challenged by pharyngeal aspiration of 250 μg OVA in the phosphate-buffered saline vehicle and sacrificed 24 hours after the last challenge. There was a dose-related decrease in number of splenocytes carrying the $B220^{+}$ marker (expressed on B-cells, activated B-cells, and subsets of T- and natural killer- [NK-] cells) compared to the OVA controls. The changes were significantly different for the 25-mg/kg/day ($p<0.05$) and 37.5-mg/kg/day ($p<0.01$) groups.

After the day 19 challenge, the mice (n = 5) were placed in a plethysmography chamber for measurement of enhanced pause airway respiration (PenH) values. PenH values reflect volume of air in the lungs. Once in the chamber, they were challenged with nebulized methacholine for 3 mins followed by 2 mins of fresh air. The PenH measures were recorded every 30 seconds over the next 5 hours. The area under the plasma concentration time curve (AUC) for the PenH measures was determined after correction for baseline (acetone control, no OVA or PFOA). An AUC of 1.6 was considered to be a positive response. Twenty-four hours later, blood was drawn from the abdominal artery and the mice were sacrificed. The lungs were recovered for histological analysis. An increase in antigen-specific hyperactivity response to PFOA, in both the PenH values and the number of animals responding, was observed at doses up to about 25 mg/kg/day. The PenH AUC was significantly ($p<0.05$) increased in mice treated with 25 mg/kg/day PFOA and OVA compared to the OVA control mice, but there was no significant difference between the OVA control and the animals exposed to 50 mg/kg/day PFOA and OVA. The LOAEL for the PenH response was 25 mg/kg/day, and the NOAEL was 18.75 mg/kg/day.

Histopathological evaluation of the lungs revealed macrophage and eosinophil infiltration in response to the challenge with 250 μg OVA by pharyngeal aspiration. The severity of the response increased with increasing concentrations of PFOA. Eosinophils and macrophages were found in the interstitial, peribronchiole, and perivascular areas. Neutrophils, lymphocytes, and some multinucleated giant cells also were observed. Increased secretory matter, sloughing of epithelium, and secretory cell necrosis were observed in mice exposed to all concentrations of PFOA and OVA. The response was not observed in the mice exposed to only PFOA. The authors concluded that dermal exposure to PFOA was immunotoxic and enhanced the airway hypersensitivity response to OVA suggesting that PFOA may augment the IgE response to environmental allergens.

In vitro. In a pilot study, Brieger et al. (2011) examined the effects of PFOA on human leukocytes. Peripheral blood mononuclear cells (PBMCs) were obtained from the blood of 11 voluntary donors (n = 6 females, 5 males). PBMCs were incubated with varying concentrations of PFOA followed by assays for cell viability, proliferation, and NK cell activity. The human promyelocytic leukemia cell line, HL-60, was used in cell viability and monocyte differentiation assays. The various components of the assays employed are identified as follows:

- In the cell viability assay, the PBMCs were incubated with 0–500 μg/mL for 24, 48, and 72 hours, and HL-60 cells were incubated with 0–125 μg/mL PFOA for 24 hours.
- In the proliferation assay, the PBMCs were incubated with 0–100 μg/mL PFOA for 24 hours, labeled with 6-carboxyfluorescein succinimidyl ester (CFSE), stimulated with

ConA, a T-cell mitogen (5 μg/mL to half of all samples), and incubated for an additional 72 hours.

- For the NK assays, PBMCs were incubated with 0–100 μg/mL PFOA for 24 hours followed in incubation of 3 hours with K562 target cells (12.5:1 ratio) labeled with CFSE.
- In the monocyte differentiation assay, HL-60 cells were incubated with 0–100 μg/mL PFOA for 72 hours. Half of each sample was stimulated with 25 nmol calcitrol, 1α,25-dehydroxyvitamin D3 ($1,25D_3$) 24 hours into the incubation period. Expression of CD11b and CD14 were measured as markers of differentiation.
- Whole blood was incubated with 0–100 μg/mL PFOA in the presence or absence of 25 μg/mL phytohemagglutinin (PHA), T-cell cytokine secretion stimulator for 48 hours in quantification assays for the cytokines TNF-α and IL-6. LPS (0 or 250 ng/mL) was added to whole blood incubated with 0.1–100 μg/mL PFOA either 4 or 24 hours prior to the end of the 48-hour incubation period to determine TNF-α and IL-6 release.

The plasma concentrations of PFOA were 3.3, 1.56, and 4.19 ng/mL for all, female, and male volunteers, respectively. Exposure to 31.3 and 62.5 μg/mL PFOA significantly increased PBMC viability at the 72-hour endpoint, and 62.5 μg/mL PFOA significantly increased cell viability at 24 hours. Exposure to 250 and 500 μg/mL PFOA significantly decreased cell viability at all time endpoints. Exposure to PFOA did not affect HL-60 cell viability. A trend towards slightly augmented proliferation was observed following incubation with PFOA. Of the nine samples used, cells from six donors had slightly increased proliferation and t had no response. In cells incubated with ConA and 100 μg/mL PFOA, a nonsignificant decrease in the number of proliferating cells was observed. PFOA decreased NK cell activity approximately 16% (not statistically significant). In the presence of $1,25D_3$, 100 μg/mL PFOA significantly increased the percentage of HL-60 cells expressing CD11b and CD14. There were no differences in monocyte differentiation in the absence of $1,25D_3$.

In whole blood, exposure to PFOA for 48 hours caused a slight increase in TNF-α and IL-6 levels. In the presence of PHA, a slight dose-dependent decrease in TNF-α and IL-6 was observed. There was a slight dose-dependent decrease in TNF-α release when LPS was added 4 hours before the end of the incubation period and a slight dose-dependent increase in IL-6 release when LPS was added 24 hours prior to the end of incubation. The authors also looked at the correlation between basal PFOA concentration and cytokine release. A significant association was observed between PFOA concentration and the release of LPS-induced TNF-α and IL-6 by peripheral monocytes. The authors suggested that the trends observed at the lower concentrations might show an impact on human immunity with a larger population.

Ahuja et al. (2009) examined the effects of PFOA on the production and activation of human monocyte-derived dendritic cells. These cells are responsible for a primary immune system response by activating lymphocytes and secreting cytokines. Peripheral monocytes and immature dendritic cells were incubated with 200 μmol PFOA from day 0 to day 6 or 8 to determine the impact on phenotype and cytokine secretion. Maturation stimulus (i.e., prostaglandin E2, tumor necrosis factor, interleukin 1β, and IL-6) was added during the last 48 hours of incubation to induce dendritic cell maturation. Mixed leukocyte reaction assays were conducted to determine if immature dendritic cells could stimulate T-cells. Cytokine (HLA-DR, CD25, CD80, CD83, and CD86) expression was measured as a determination of maturity. HLA-DR is a cytokine that presents antigens to elicit T-cell response. CD25, 80, 83, and 86 are cell receptors that act as co-receptors in T-cell activation; and interleukin 12p40 and 10 stimulate T-cells. Mature cytokine-

activated dendritic cells secrete interleukin 12p40 and interleukin 10 as antiinflammatory cytokines.

In peripheral monocytes incubated with only PFOA from day 0–6 or day 0–8, expression of HLA-DR and CD86 was increased compared to expression in control cells, indicating that immature dendritic cells were present. In the mixed leukocyte reaction assay, the ability to stimulate T-cells was not different between immature dendritic cells generated in the absence or presence of PFOA.

To determine if PFOA impacted the differentiation of immature dendritic cells to mature dendritic cells, immature dendritic cells were incubated with 200 μmol of PFOA for 6 days and the maturation stimulus was added for the final 2 days of incubation. There were no differences in cytokine (CD25, CD80, CD83, and CD86) expression between cells incubated with PFOA and control cells. Expression of interleukin 12p40 and interleukin 10 was significantly inhibited by PFOA in mature cytokine-activated dendritic cells, even in the presence of maturation stimulus during the last 48 hours of incubation. The result suggested that exposure to PFOA during generation of dendritic cells affected the phenotype and cytokine production of human dendritic cells and could lead to immunomodulation in the development of the immune response.

3.3.3 Hormone Disruption

Thyroid. Martin et al. (2007) administered 20 mg PFOA/kg to adult male Sprague-Dawley rats (n = 4 or 5) for 1, 3, or 5 days by oral gavage and determined the impact of PFOA on hormone levels. Blood was collected via cardiac puncture and the serum was analyzed for cholesterol, testosterone, FT4 and total T4, and total T3. RNA extracted from the livers was used for gene expression profiling, genomic signatures, and pathway analyses to determine a mechanism of toxicity.

Following a 1-day, 3-day, and 5-day dose, a significant decrease ($p<0.05$) was observed in serum cholesterol (~↓45-72%), total T4 (~↓83%), FT4 (~↓80%), and total T3 (~↓25-48%). Serum testosterone was significantly decreased ($p<0.05$, ~↓70%) following a 3-day and 5-day PFOA dose. PFOA treatment was matched to hepatotoxicity-related genomic signatures, as well as signatures for hepatocellular hypertrophy, hypocholesterolemia, hypolipidemia, and peroxisome proliferation. PPARα nuclear regulated genes were induced by PFOA treatment. Genes associated with the thyroid hormone release and synthesis pathway including *Dio3,* which catalyzes the inactivation of T3, and *Dio1,* which deiodinates prohormone T4 to bioactivate T3, were affected by PFOA. Treatment with PFOA resulted in significantly upregulated expression of *Dio3* and downregulated expression of *Dio1* ($p<0.05$). Expression of HMG-CoA reductase (involved in cholesterol biosynthesis) was significantly upregulated and cholesterol biosynthesis was downregulated in a manner consistent with PPARγ agonists. The authors suggested a link between PFOA, PPAR, and thyroid hormone homeostasis based on work by Miller et al. (2001), who observed decreased serum T4 and T3 levels and increased hepatic proliferation following exposure to peroxisome proliferators. They also noted that PFOA exhibited similarities to compounds that induce xenobiotic metabolizing enzymes through PPARγ and CAR. The 20-mg/kg/day dose was a LOAEL for the effects monitored after a 5-day exposure.

Reproductive Hormones. Cook et al. (1992) gavage-dosed male CD rats (n = 15 per group) for 14 days with 0, 1, 10, 25, and 50 mg PFOA/kg/day to examine the possibility that an endocrine-related mechanism might explain Leydig cell adenomas observed in rats. A separate control group was pair-fed to the 50-mg/kg/day group. Blood and testicular interstitial fluid were

collected at necropsy for hormone analysis including testosterone, estradiol, and LH. A separate group of rats was dosed with 0 and 50 mg PFOA/kg/day for 14 days and challenged with 100 IUs of human chorionic gonadotropin (hCG) or 2 mg naloxone/kg 1 hour prior to necropsy to induce testosterone concentrations. Blood was collected and analyzed for testosterone and LH. Serum from rats challenged with 100 IUs hCG also was analyzed for P, 17 α-hydroxyprogesterone, and androstenedione.

The relative liver weight at 10, 25, and 50 mg PFOA/kg/day was significantly increased ($p<0.05$). The accessory sex organ unit relative weight was significantly decreased ($p<0.05$) at 25 and 50 mg PFOA/kg/day compared to those weights in control rats. The relative weights of the liver, accessory sex organ unit, and ventral prostate were significantly decreased at the highest dose compared to the pair-fed control.

Serum estradiol was significantly increased at ≥10 mg PFOA/kg compared to the control. No differences were observed in testosterone and LH between the treated rats and control. In the challenge experiment, serum testosterone was significantly decreased ($p<0.05$) by treatment with 50 mg PFOA/kg after challenge with 100 IUs hCG. No differences in testosterone concentration were observed in the naloxone-challenged rats, and no differences in LH were observed after either challenge. In the hCG-challenged rats, androstenedione was significantly reduced at 50 mg PFOA/kg, but no differences in concentrations were observed in P or 17 α-hydroxyprogesterone between control and treated rats. The authors suggested that the observed decreased serum testosterone levels could be due to decreased conversion of 17 α-hydroxyprogesterone to androstenedione as a result of increased serum estradiol levels. The LOAEL was 10 mg/kg based on increased liver weight and increased serum estradiol levels, and the NOAEL was 1 mg/kg.

Biegel et al. (1995) conducted *in vitro, in vivo,* and *ex vivo* studies to determine the effects of PFOA on Leydig cell function. In the *in vitro* study, Leydig cells were cultured with ± 2 IUs hCG (for final 3 hours) and 0, 100, 200, 250, 500, 700, and 1000 µmol PFOA for a total of 5 hours and then analyzed for testosterone concentration. Leydig cells also were incubated ±500 µmol PFOA and analyzed for testosterone and estradiol at 0, 0.5, 1, 3, 6, 12, 24, and 48 hours.

In the *in vitro* studies, there was no effect of PFOA treatment on testosterone in Leydig cells cultured without hCG. In cells cultured with hCG, PFOA caused a dose-dependent decrease in testosterone production. At 100 µmol PFOA plus hCG, the testosterone concentration was significantly increased compared to cells treated with only 100 µmol PFOA. Cytotoxicity occurred at ≥ 750 µmol PFOA. In the time course experiment, 500 µmol PFOA significantly inhibited hCG-stimulated release of testosterone at time points of at least 3 hours compared to control. Estradiol levels of PFOA-treated Leydig cells at 48 hours were statistically greater than the control.

Male CD rats were gavage-dosed for 14 days with 0, 0 pair-fed, or 25 mg PFOA/kg and necropsied on day 15. Blood and testicular interstitial fluid were collected for hormone analysis. Liver samples were collected for analysis of peroxisomal β-oxidation and microsomal aromatase activities. Serum estradiol was significantly increased ($p<0.05$) by 25 mg PFOA/kg when compared to the *ad libitum* and pair-fed control rats. Testicular interstitial fluid testosterone concentration was significantly decreased ($p<0.05$) and microsomal aromatase activity, and peroxisomal β-oxidation activity were significantly increased ($p<0.05$) in PFOA-treated rats compared to the pair-fed control rats.

Leydig cells from the treated rats in the *in vivo* study were isolated and cultured for analysis of testosterone concentration for the *ex vivo* study. An increase of 8.6-fold in testosterone production ($p<0.05$) was observed in Leydig cells isolated from PFOA-treated rats. The authors suggested that the increased serum estradiol levels resulted from liver aromatase induction by PFOA, and that PFOA could directly affect Leydig cell function.

Liu et al. (1996) treated adult male Crl:CD(BR) rats (n = 15 per group) with 0, 0 pair-fed, 0.2, 2, 20, and 40 mg PFOA/kg for 14 days by oral gavage to determine the impact of PFOA on aromatase activity. At necropsy on day 15, blood was collected for serum estradiol determination. Liver samples were collected for determination of microsomal aromatase activity and total P450 concentration. The testes were collected and testicular aromatase was determined.

The body weight of rats treated with ≥ 20 mg PFOA/kg was significantly decreased ($p<0.05$) compared to the control rats. Pair-fed control rats also had significantly decreased body weight compared to the control rats. Body weight was not different between the pair-fed control rats and rats dosed with 40 mg/kg PFOA. Absolute and relative liver weights were significantly increased ($p<0.05$) at ≥ 2 mg PFOA/kg. Relative testes weight was significantly increased at ≥20 mg PFOA/kg, but the differences were due to decreased body weight. There were no differences observed in testicular aromatase activity. In the remaining analysis, the pair-fed control group was similar to the *ad libitum* control group. The protein yield of hepatic microsomes was significantly increased at ≥0.2 mg PFOA/kg, and hepatic aromatase activity, total hepatic aromatase activity adjusted for liver and body weight effects, and serum estradiol were significantly increased ($p<0.05$) at ≥2 mg PFOA/kg. The maximum increase in total hepatic aromatase activity was 16-fold and the increase was twofold for serum estradiol. A significant correlation ($p<0.0001$) was observed between total hepatic aromatase activity and serum estradiol. The aromatase activity in liver microsomes isolated from control rats and incubated for 2 hours with PFOA was significantly decreased at ≥ 100 µmol. The authors estimated the half maximal effective concentration (EC_{50}) values for the outcomes, and they are shown in Table 3-36. Liu et al. (1996) concluded that the PFOA-increased protein yields suggested induction of the ER resulting in aromatase induction, which led to increased serum estradiol. However, PFOA also inhibited aromatase activity, which would explain why serum estradiol was only increased up to twofold.

Table 3-36. Estimated EC_{50} Values

Parameters	EC_{50} (mg PFOA/kg)
Hepatic microsome protein yield	0.53
Hepatic microsomal aromatase activity	0.76
Absolute liver weight	1.07
Relative liver weight	1.56
Serum estradiol	3.24
Terminal body weight	11.65

Source: Liu et al. 1996
Note: EC_{50}= half-maximum response.

A separate component of the Liu et al. study (1996) examined the effect of PFOA on aromatase activity in cultured hepatocytes and is discussed below. Aromatase is a cytochrome P450 enzyme localized to the ER that catalyzes the conversion of androgens to estrogens. The cultured hepatocytes isolated from control male CD rats were incubated with 0–1000 µmol PFOA and the aromatase activity was evaluated after 18, 42, and 66 hours (Liu et al. 1996).

Compared to aromatase activity in time-matched control cultures, PFOA caused a decrease in aromatase activity after 18 and 42 hours incubation with hepatocytes and an increase after the 66-hour incubation period.

In their study examining the impact of PFOA on aromatase activity, Liu et al. (1996) also examined the impact of PFOA on peroxisome β-oxidation and cytochrome P450 activities. Male Crl:CD BR (CD) rats (n = 15 per group) were orally dosed with 0, 0 pair-fed, 0.2, 2, 20, and 40 mg PFOA/kg for 14 days. Liver samples were collected for determination of microsomal total cytochrome P450 concentration and peroxisome β-oxidation activity. Total cytochrome P450 was significantly increased ($p<0.05$) at ≥20 mg PFOA/kg and β-oxidation activity was increased at ≥2 mg PFOA/kg. The estimated EC_{50}s for total cytochrome P450 and β-oxidation were 18.18 and 2.19 mg PFOA/kg, respectively. The LOAEL was 2 mg/kg based on increased liver weight, serum estradiol, and hepatic aromatase activity, and the NOAEL was 0.2 mg/kg.

Hines et al. (2009) examined the roles that exposure to PFOA and ovarian hormones might play in animals exposed during gestation compared to during their adult years. Timed-pregnant CD-1 mice were gavage-dosed in two blocks on GDs 1–17, but not thereafter. Block 1 animals were dosed with 0, 1, 3, and 5 mg PFOA/kg, and block 2 animals were dosed with 0, 0.01, 0.1, 0.3, 1, and 5 mg PFOA/kg/day. At birth, pups were pooled within each block and dose group and randomly redistributed among the dams (10 pups per litter). Offspring were weaned at 3 weeks, and a subset of females from each dose group (0, 0.01, 0.1, 0.3, 1, and 5 mg PFOA/kg/day) was OVX at weaning or the day after weaning. All animals were observed until they reached 18 months of age.

Body weight was recorded weekly for the first 9 months of age, followed by monthly body weight recordings over the next 9 months. As the animals matured, they were evaluated for the endpoints listed in Table 3-37. A group of naive 8-week-old adult mice were dosed for 17 days with 0, 1, and 5 mg PFOA/kg/day to compare the impact of exposure in adult animals to those occurring during gestation. At 18 months of age, the mice were sacrificed. Blood, retroperitoneal abdominal fat, interscapular brown fat, organs, and abnormal growths were collected at necropsy.

Table 3-37. Data Collection for Female Mice Gestationally Exposed to PFOA

Test	Age at Test	Dose (mg/kg/day)	Group
Glucose tolerance test	15-16 weeks	0, 1, 5	Intact
Serum leptin and insulin	21-33 weeks	0, 0.01, 0.1, 0.3, 1	Intact, OVX
Body mass composition	42 weeks	0, 0.01, 0.1, 0.3, 1	Intact
Glucose tolerance test	17 months	0, 0.1, 1, 5	Intact
Food consumption	17 months	0, 0.1, 1, 5	Intact
Serum estradiol	18 months	0, 0.01, 0.1, 0.3, 1, 5	Intact

Source: Hines et al. 2009

Body weight of offspring born to dams exposed to 5 mg PFOA/kg was significantly decreased ($p<0.05$) on PND 1 and through 18 months of age compared to control offspring body weight. At weaning, the body weight of offspring born to dams exposed to 1 mg PFOA/kg/day was significantly decreased ($p<0.05$) compared to control offspring body weight. A significant increase ($p<0.05$) in body weight, due to more rapid weight gain after week 10, compared to intact control body weight, was observed in intact mice exposed to 0.01–0.3 mg PFOA/kg/day

during gestation. Body weight of intact mice gestationally exposed to 0.01–0.3 mg PFOA/kg/day was comparable to body weight of control mice at 18 months.

Due to the increased weight gain observed in intact mice exposed to PFOA during gestation, glucose tolerance tests were carried out along with determination of serum insulin concentration. In cases of insulin resistance, plasma glucose and insulin levels are elevated and the insulin response is lessened. Insulin resistance also has been associated with excess abdominal fat. Serum leptin levels also were determined as increased leptin levels have been associated with a leptin-resistance mechanism of action (MOA) for increased weight gain in humans. Body mass composition was used to determine if there were differences in body fat between the intact groups, and feed consumption was recorded to determine if consumption played a role in body weight differences in intact control and intact gestationally exposed mice. Serum estradiol was measured to determine if PFOA impacted hormone levels at 18 months in intact control and intact gestationally exposed mice.

Glucose tolerance testing showed no statistically significant differences in baseline glucose or response to glucose challenge at 15–16 weeks or at 17 months. At 21 and 31 weeks of age, a significant increase in serum leptin and insulin levels was observed in intact mice exposed to 0.01 and 0.1 mg PFOA/kg/day. No statistically significant difference was observed between the fat-to-lean ratio of intact control and intact gestationally exposed animals at 42 weeks of age. No significant difference was observed in food consumption between intact control and intact gestationally exposed animals at 42 weeks of age. Serum estradiol levels were not different between intact control and intact gestationally exposed animals at 18 months.

Exposure to PFOA as an adult did not result in body weight differences among the groups at 18 months of age. The body weight of intact mice gestationally exposed to 1 mg PFOA/kg/day was significantly increased ($p<0.05$) compared to adult mice exposed to 1 mg PFOA/kg/day. No other differences in body weight among the groups were observed.

No significant differences among the groups were observed in survival during the 18-month study. At necropsy, abdominal white fat was significantly decreased ($p<0.05$) at 1 and 5 mg PFOA/kg/day in gestationally exposed intact mice compared to intact control mice. Interscapular brown fat was significantly increased ($p<0.05$) at 1 and 3 mg PFOA/kg/day in gestationally exposed intact mice and in gestationally exposed OVX mice at 1 mg PFOA/kg/day. Relative spleen weight was significantly decreased ($p<0.05$) at 3 mg PFOA/kg/day in gestationally exposed intact mice and at 1 and 5 mg PFOA/mg ($p = 0.05$-0.07) in gestationally exposed OVX mice. Relative liver weight was not different between the groups. No differences were observed at 18 months of age in tissue weight in mice exposed to PFOA as adults. At 1 mg PFOA/kg/day, white and brown fat weight was significantly increased in gestationally exposed intact mice compared to adult-exposed mice exposed to 1 mg PFOA/kg/day.

The authors concluded that developmental exposure to low doses and high doses of PFOA resulted in different phenotypes in mice. At low doses, increased weight, increased serum insulin, and increased serum leptin were observed in adult mice. At high doses the animals displayed decreased weight in early and late life, decreased white fat, increased brown fat, and decreased spleen weight. Under the conditions of the study, the developmental LOAEL was 0.01 mg PFOA/kg based on increased weight gain and increased serum insulin and leptin levels. No developmental NOAEL was established. The adult NOAEL was 5 mg PFOA/kg, and no LOAEL was established.

Adrenal Hormones. Thottassery et al. (1992) exposed intact or ADX male Sprague-Dawley rats to a single dose of 150 mg/kg PFOA in corn oil to determine the role of adrenal hormones on liver enlargement and peroxisomal proliferation. ADX rats were dosed 2 days after surgery with PFOA (ADX PFOA), CORT (ADX CORT), or both (ADX CORT PFOA). A group of intact and ADX rats received only the vehicle and served as controls. The animals were sacrificed 48 hours after dosing with PFOA or vehicle. Assays were conducted to determine DNA levels and changes in peroxisomal β-oxidation, catalase, and ornithine decarboxylase activities. An increase in ornithine decarboxylase activity has been associated with proliferation of many different cell types. An increase of ornithine decarboxylase in the livers of animals exposed to PFOA would suggest that the increased liver weight observed in PFOA-exposed animals was the result of hyperplasia. Ornithine decarboxylase was determined by measuring liberated CO_2 from DL-[1-^{14}C] ornithine hydrochloride in all animals except those in the ADX CORT PFOA group.

Relative liver weight in intact rats treated with PFOA was significantly increased compared to control (36%, $p<0.05$). Relative liver weight in rats in the ADX PFOA group was significantly increased compared to rats in the ADX vehicle group (16%, $p<0.05$). Relative liver weight in rats in the ADX CORT PFOA group was significantly increased compared to rats in the ADX CORT group (32%, $p<0.05$). Hepatic DNA levels were significantly decreased $p<0.001$) in intact rats treated with PFOA and in rats in the ADX CORT PFOA group.

Ornithine decarboxylase activity was significantly increased in the rats in the ADX PFOA group compared to rats in the ADX group (170.5 pmole CO_2/hr/mg protein, versus 30.5 pmole CO_2/hr/mg protein, $p<0.001$), but no different between the intact rats treated with PFOA and the intact rats treated with the vehicle.

PFOA increased whole liver peroxisomal β-oxidation activity by a similar amount and was not different among the groups. In intact rats and rats in the ADX CORT PFOA group, exposure to PFOA increased whole liver catalase activity, but exposure did not increase activity in the rats in the ADX PFOA group. Based on the results, the authors concluded that adrenal hormones were not required to induce peroxisomal β-oxidation activity in PFOA-exposed rats, but are required to increase catalase activity. They also concluded that the enlarged livers of PFOA-exposed animals were the result of hypertrophy rather than hyperplasia based on decreased hepatic DNA content and lack of increased ornithine decarboxylase activity.

3.3.4 Physiological or Mechanistic Studies

Gene Expression. Rosen et al. (2007) examined the gene expression profile in the lung and liver of mouse fetuses exposed to PFOA. Pregnant CD-1 mice were gavage-dosed with 0, 1, 3, 5, and 10 mg PFOA/kg/day on GD 1–17. Dams were sacrificed on GD 18, and three fetuses per litter were processed for total RNA from portions of the liver and lung. Global gene expression was analyzed using Affymetrix gene chips.

A dose-related increase was observed in the number of genes altered by PFOA exposure in both the liver and lung. A greater number of genes in the liver were altered compared the number of genes altered in the lung. Analysis of the genes by canonical pathway or biological function showed that most of the altered genes in both the liver and lung were associated with lipid homeostasis. In the fetal lung, the two highest doses of PFOA altered genes associated with fatty acid catabolism. In the fetal liver, all doses of PFOA were associated with genes involved in fatty acid catabolism, lipid transport, cholesterol biosynthesis, bile acid biosynthesis, lipoprotein metabolism, steroid metabolism, retinol metabolism, inflammation, phospholipid metabolism,

glucose metabolism, proteosome activation, and ketogenesis. Although PPARα is known to at least partly regulate the expression of genes for the pathways or biological functions involved in lipid homeostasis, PFOA might independently activate other nuclear receptors, influencing the metabolic responses observed.

Rosen et al. (2008a) described the gene profiles in liver tissue from wild-type 129S1/SvlmJ mice (7–8 per group) and PPARα-null mice (129S4/SvJae-PPARαt^{m1Gonz}/J, 6–8 per group) dosed for 7 days with 0, 1, and 3 mg PFOA/kg or 50 mg Wyeth 14,643, a PPARα agonist (Wolf et al. 2008a). RNA was isolated from the tissues and gene expression analyzed using Applied Biosystems Mouse Genome Survey Microarrays. RT-PCR was used to evaluate selected genes.

In both wild-type and PPARα-null mice exposed to PFOA, the number of significant and fully annotated genes used to evaluate the data for relevance to canonical pathway or biological function were fewer at 1 mg/kg than at 3 mg/kg PFOA. However, 85% of the altered genes at 1 mg/kg PFOA also were altered at 3 mg/kg PFOA.

PPARα target genes including acyl-CoA oxidase 1 (Acox1), Me1, Slc27a1, Hsd17b4, Hadha, Hadhb, and Pdk4 were upregulated in PFOA- and Wyeth 14,643-treated wild-type mice, but not in PPARα-null mice. Pdk4 was downregulated in PPARα-null mice exposed to PFOA but not in PPARα-null mice exposed to Wyeth 14,643. Principal components analysis showed that genes activated in PFOA-treated PPARα-null mice were similar to those in PFOA-treated wild-type mice at 3 mg PFOA/kg, suggesting that many of the responses were not completely linked to PPARα.

In wild-type PFOA- and Wyeth 14,643-treated mice, alterations were observed in genes associated with fatty acid metabolism (mostly upregulated), inflammatory response (mostly downregulated), cell cycle control (mostly upregulated), peroxisome biogenesis (mostly upregulated), and proteasome structure and organization (mostly upregulated). In genes associated with xenobiotic metabolism, the response was different between PFOA- and Wyeth 14,643-treated wild-type mice. Many of the Cyp2 genes were upregulated by PFOA and downregulated by Wyeth 14,643. In PPARα-null PFOA-treated mice, genes associated with fatty acid metabolism, inflammation, xenobiotic metabolism, and cell cycle control were altered in a manner similar to the changes observed in PFOA-treated wild-type mice.

RT-PCR generally revealed good agreement with microarray analysis. However, expression of Ehhadh, a PPARα-regulated gene, was upregulated in PFOA-treated wild-type mice but not in PFOA-treated PPARα-null mice in microarray analysis. In contrast, expression of Ehhadh was upregulated in all PFOA-treated mice in RT-PCR analysis. The authors concluded that PFOA induces transcriptional changes mediated through PPARα activation, and it also alters gene expression independently of PPARα. They noted that PFOA had multiple modes of action and can function as a biologically active xenobiotic in the absence of PPARα.

Rosen et al. (2008b) described the transcript profiles in the livers of adult mice exposed to PFOA. Tissues from several different studies were analyzed. The samples included liver tissue from:

- male wild-type (strain 129S1/SvlmJ) and PPARα-null (strain 129S4/SvJae) mice dosed with 3 mg/kg/day PFOA for 7 days (from Wolf et al. 2008a);
- male wild-type and PPARα-null mice (strain SV129/C57BL/6) gavage-dosed or fed diets containing Wyeth 14,643 (PPARα agonist);

- female wild-type and CAR-null (strain C57BL/6x129Sv) gavage-dosed with CAR activators phenobarbital (PB) or 1,4-bis[2-(3,5-dichloropyridyloxy)] benzene (TCPOBOP); and
- wild-type and Nrf-null ICR mice gavage-dosed with the Nrf activator dithiol-3-thione.

RNA was isolated from the tissues and gene expression was analyzed using Affymetrix full genome mouse chips. Rosetta Resolver software was used to identify significantly altered genes.

Exposure to 3 mg/kg PFOA for 7 days upregulated 641 genes and downregulated 451 genes in wild-type mice compared to 104 upregulated genes and 52 downregulated genes in PPARα-null mice. A total of 117 genes were regulated similarly in both strains, and 29 upregulated genes and 11 downregulated genes were unique to PPARα-null mice.

The gene expression profile of wild-type and PPARα-null mice exposed to PFOA for 7 days or Wyeth 14,643 for 12 hours, or 3 or 7 days were compared. Four groups of altered genes were identified based on their expression in wild-type and PPARα-null PFOA-exposed mice compared to genes from Wyeth 14,643-treated mice. The first group consisted of genes (397) regulated by both PFOA and Wyeth 14,643 in wild-type mice. They had a common direction and magnitude of change and were characterized as being involved in lipid homeostasis, inflammation, cell proliferation, or proteome maintenance genes. Group II consisted of genes in wild-type mice (51) regulated solely by PFOA; most were involved in amino acid metabolism. Of the 81 genes altered by PFOA exposure in PPARα-null mice (Group III), 62 had similar expression in wild-type mice and many were involved in lipid metabolism. Regulation of these genes also was observed in Wyeth 14,643 wild-type mice. Group IV genes (19) were altered by PFOA only in PPARα-null mice; most were xenobiotic metabolizing enzymes.

By comparing the gene expression patterns between PFOA and Wyeth 14,643, the authors concluded that:

- PPARα is required for a majority of the transcriptional changes observed in the mouse liver following PF also are regulated by other peroxisome proliferators in a PPARα-dependent manner; and
- PFOA impacts some PPARα-independent genes including ones involved in lipid homeostasis (upregulated), amino acid metabolism (downregulated), and xenobiotic metabolism (upregulated).

The transcription profiles of PFOA exposed wild-type and PPARα-null mice were compared to the transcription profile of PB- or TCPOBOP-exposed wild-type and CAR-null mice and dithiol-3-thione-exposed wild-type and Nrf2-null mice to determine if PFOA activated CAR or Nrf2. A similar pattern was observed in the modified gene expression of PFOA-exposed PPARα-null mice and PB- (0.86 Pearson's correlation) or TCPOBOP- (0.84 Pearson's correlation) exposed wild-type mice, but no pattern was observed in gene expression of dithiol-3-thione-exposed mice (≤0.06 Pearson's correlation) and PFOA-exposed PPARα-null mice. These results suggest that some genes altered by PFOA exposure in PPARα-null mice are regulated by CAR but not by Nrf2.

Bjork and Wallace (2009) examined the PPARα-dependent transcriptional activation potential of PFOA in rodent and human hepatic liver cells. Primary rat and human hepatocytes and HEPG2/C3A cells were incubated with 0, 5, 10, 20, 30, 50, 100, and 200 μmol PFOA for 24 hours. Expression of Acox, Cyp4a1 (rat), Cyp4a11 (human), acyl-CoA thioesterase (Cte–rat, Acot1–human), and DNA damage inducible transcript (Ddit3) were determined by quantitative

RT-PCR. These genes are inducible by peroxisome proliferators, except Ddit3, which is induced in the presence of direct or indirect DNA damage. Exposure to ≥ 100 μmol PFOA significantly increased Ddit3 mRNA expression in primary rat hepatocytes. At the highest dose, Ddit3 was significantly increased in human hepatocytes and HepG2/C3A cells. Expression of Acox was significantly induced by 5, 10, 20, and 30 μmol PFOA, and Cte/Acot1 was significantly induced at ≥20 μmol PFOA in rat hepatocytes only. Expression of Cyp4a1/11 was significantly induced in rat hepatocytes at 5–-50 μmol and in human hepatocytes at 20–50 μmol. The authors concluded that induction of peroxisome-related fatty acid oxidation gene expression is not observed in primary human liver cells or in transformed human liver cells *in vitro.*

Nakamura et al. (2009) investigated the differences in PFOA response between mice and humans using a humanized PPARα transgenic mouse line (hPPARα). The study design and whole animal toxicity data are described in section 3.2.2. Male 8-week-old wild-type (mPPARα) mice, PPARα-null mice, and hPPARα mice were gavage-dosed with 0, 0.1, and 0.3 mg/kg PFOA (n = 4–6 per group) for 2 weeks and sacrificed 18–20 hours following the last dose. Livers were collected and analyzed for mRNA (RT-QPCR) and protein levels (western blot analysis) of PPARα and related genes (retinoid X receptor alpha [RXRα], peroxisomal bifunctional protein [PH], peroxisomal thiolase [PT], very long chain acyl-CoA dehydrogenase [VLCAD], medium chain acyl-CoA dehydrogenase [MCAD], and cytochrome P450 4a10 [CYP4A10]). RXRα forms a heterodimer with PPARα to control transcription of genes affecting lipid metabolism. CYP4A10 also plays a role in lipid metabolism. Treatment with peroxisome proliferators caused an increase in both PH and PT. MCAD and VLCAD are mitochondrial fatty acid metabolizing enzymes whose gene expression is mediated by PPARα (Aoyama et al. 1998). The results of mRNA expression impacted by PFOA exposure are shown in Table 3-38.

Treatment with PFOA did not alter mRNA expression or protein expression of PPARα, RXRα, or MCAD in mPPARα mice. At 0.1 mg/kg PFOA, mRNA expression of CYP4A10 was significantly increased ($p<0.05$) in mPPARα mice compared to control mPPARα mice. Treatment with 0.3 mg/kg PFOA resulted in significantly increased ($p<0.05$) mRNA expression of CYP4A10 and mRNA and protein expression of PH, PT, and VLCAD in mPPARα mice when compared to control mPPARα mice.

Notes:
- Not different from respective control.
+ Significantly different from respective control.
* Significantly different from mPPARα mice treated with same concentration.
↓ Decreased expression relative to respective control or mPPARα mice at same concentration.
↑ Increased expression relative to respective control or mPPARα mice at same concentration.

As expected, mRNA and protein expression of PPARα was absent in PPARα-null mice. Treatment with 0.1 and 0.3 mg/kg PFOA did not alter mRNA or protein expression for any genes investigated compared to control PPARα-null mice. VLCAD mRNA expression and PT protein expression in control PPARα-null mice was significantly decreased ($p<0.05$) compared to mPPARα control mice. VLCAD mRNA and protein expression of PFOA treated PPARα-null mice was significantly decreased ($p<0.05$) compared to mPPARα mice treated with the same doses. Following treatment with 0.1 mg/kg PFOA, MCAD mRNA expression was decreased ($p<0.05$) compared to mPPARα mice treated with the same dose. When compared to mPPARα mice treated with the same dose, mRNA and protein expression of PH and PT was significantly decreased ($p<0.05$) in PPARα-null mice, as was CYP4A10 mRNA expression.

Treatment with PFOA did not alter mRNA or protein expression of PPARα, RXRα, PH, PT, or VLCAD in hPPARα mice compared with their respective controls. Expression of CYP4A10 mRNA also was not altered by PFOA treatment. MCAD mRNA and protein expression were significantly increased ($p<0.5$) in hPPARα mice treated with 0.3 mg/kg PFOA compared to hPPARα control mice. Expression of PPARα mRNA and protein levels were significantly higher ($p<0.05$) in all hPPARα mice than in mPPARα mice given the same concentration of PFOA. Treatment of hPPARα mice with 0.1 and 0.3 mg/kg PFOA caused a decrease ($p<0.05$) in mRNA expression of PH, VLCAD, and CYP4A10 compared to mPPARα mice at the same dose. Only hPPARα mice treated with 0.3 mg/kg PFOA had decreased protein expression of PH and VLCAD compared to mPPARα mice given the same treatment. An important finding from this study was the significant downregulation of some genes in PPARα-null and hPPARα mice that are significantly upregulated by PPARα in the control animals. In the animals with the humanized PPARα gene or no PPARα gene, there was a response, but the response was the opposite of what occurred with normal mouse PPARα activation. In the null and humanized mice, the significantly decreased alterations in gene expression occurred at 0.1 mg/kg/day; this dose level had no change in expression for all but one gene in the normal mice and increased expression, rather than decreased expression, at 0.3 mg/kg/day (see Table 3-38).

Treatment with 0.3 mg/kg PFOA caused activation of PPARα in mouse, but not in humanized PPARα mice. The results suggest that the functional activation of human PPARα could be weaker than that of mice as expression of human PPARα in mice was greater than the expression of mouse PPARα. Higher concentrations of PFOA might be needed to cause activation of human PPARα in hPPARα mice.

To further evaluate the developmental effects potentially mediated by PPARα, groups of female wild-type, PPARα-null, and PPARα-humanized mice were given 0 and 3 mg PFOA/kg on GDs 1–17 by oral gavage (Albrecht et al. 2013). The study design and developmental toxicity data are described in section 3.2.5. Females were either sacrificed on GD 18 (n = 5–8 per group) or allowed to give birth and then sacrificed, along with their litters (n = 8–14), on PND 20. Livers from dams, fetuses, and pups were collected for measurement of mRNAs encoding the PPARα target genes Cyp4a10 and Acox1, the CAR target gene (Cyp2b10), and the PXR target gene (Cyp3a11).

On GD 18, maternal liver samples from treated groups showed increased expression of Acox1 in wild-type mice and Cyp4a10 in wild-type and humanized mice. Expression of Cyp2b10 and Cyp3a11 were increased following PFOA administration in all three genotypes. On PND 20, maternal liver samples from treated groups showed increased expression of Acox1 in wild-type mice; expression of Cyp2b10 was unchanged in all groups; and expression of Cyp3a11 was increased following PFOA administration in all three genotypes.

For fetuses on GD 18, liver samples from treated groups showed increased expression of Acox1 and Cyp4a10 in wild-type and humanized mice. Expression of Cyp2b10 was unchanged following maternal PFOA administration in all three genotypes, while expression of Cyp3a11 was increased in humanized fetal liver. On PND 20, pup liver samples from treated dams showed increased expression of Acox1 and Cyp4a10 in wild-type mice; expression of Cyp2b10 was increased in all genotypes; and expression of Cyp3a11 was increased following maternal PFOA administration in wild-type and humanized pups. Thus, expression of PPARα target genes that modulate lipid metabolism was increased in both wild-type and humanized mice coincident with increased liver weight and microscopic lesions; however, the neonatal mortality was observed only in wild-type offspring (Albrecht et al. 2013).

Walters et al. (2009) examined the impact of PFOA on mitochondrial biogenesis and gene transcription in adult male Sprague-Dawley rats orally dosed with 0 or 30 mg/kg PFOA for 28 days. At sacrifice, a portion of the midlobe region of the livers was collected. Liver DNA and RNA were isolated for RT-PCR of genes in the peroxisome proliferator-activated receptor gamma coactivator 1α- (Pgc-1α-) mediated pathway of mitochondrial biogenesis: Pgc-1α, estrogen-related receptor α (Errα), nuclear respiratory factor 1 (Nrf1) and Nrf2, transcription factor A (Tfam), cytochrome c oxidase subunit II and IV (Cox II and Cox IV), NADH dehydrogenase 2 (Nd2), and NADH dehydrogenase iron-sulfur protein 8 (Ndufs8). In mitochondrial biogenesis, Pgc-1α and Errα increase expression of the transcription factors Nrf1 and Nrf2. The Nrf transcription factors promote expression of Tfam, which is required for mitochondrial DNA replication and transcription. Within the mitochondrial membrane, oxidative phosphorylation proteins (Cox II and IV, Nds, and Ndufs8) catalyze the transfer of electrons and/or pump protons from the matrix to the intermembrane space. Western blotting was used to analyze protein expression of Pgc-1α, Tfam, Cox II, and Cox IV.

Mitochondrial DNA in rats treated with PFOA was significantly increased ($p<0.05$) compared to control rats. In PFOA-treated rats, the expression of Pgc-1α, Errα, Nrf1, Nrf2, and Tfam was significantly increased 1.3–2.2-fold ($p<0.05$), and expression of Cox II, Cox IV, Nd2, and Ndufs8 was significantly increased 2–9-fold ($p<0.05$) compared to controls. Protein expression of Pgc-1α was increased, and expression of Cox II and Cox IV were decreased in PFOA-treated rats. Protein expression of Tfam was not affected by treatment with PFOA. The results suggested that PFOA induced mitochondrial biogenesis at the transcriptional level by activation of the Pgc-1α pathway, confirming the potential for effects on mitochondria but not clarifying whether those effects are in some way linked to PPARα activation.

Elcombe et al. (2010) examined the expression of some cytochrome P450 isoforms in the livers of male Sprague-Dawley rats fed diets containing 300 ppm PFOA or 50 ppm Wyeth 14,643 for 1, 7, or 28 days. The isoforms included those involved in activation of PPARα (CYP4A1), CAR (CYP2B1/2), and PXR (CYP3A1). All three isoforms were induced by PFOA exposure. CYP2B1/2 and CYP4A1 were induced after 1 day of exposure to PFOA. CYP3A1 was induced in all PFOA-exposed rats after 7 days of exposure. Treatment with Wyeth 14,643 caused the induction of CYP4A1 only.

PPAR Activation. Takacs and Abbott (2007) evaluated the potential for PFOA to activate PPARs, using a transient transfection cell assay. Cos-1 cells, derived from the kidney cells of the African green monkey, were transfected with mouse or human PPARα, PPARβ/δ, or PPARγ reporter plasmids and exposed to 0.5–100 μmol PFOA or 0.5–100 μmol PFOA and MK-886 (PPARα antagonist) or GW9662 (PPARγ antagonist). An antagonist for PPARβ/δ was not available. The three types, PPARα, β/δ, and γ, are encoded by different genes, expressed in many

tissues, and have specific roles during development as well as in the adult. The results are shown in Table 3-39. PFOA activated PPARα in a dose-dependent manner with a significant increase in activity observed at 10, 20, 30, and 40 µmol for the mouse receptor and 30 and 40 µmol for the human receptor compared to the negative control. The presence of the PPARα antagonist MK-886 prevented the activity increase resulting from PFOA exposure alone in mouse and human PPARα constructs.

Table 3-39. Activation of Mouse and Human PPAR by PFOA

PPARα			PPARβ/δ			PPARγ		
PFOA (µm)	Mouse	Human	PFOA (µm)	Mouse	Human	PFOA (µm)	Mouse	Human

30	+	+	70	+	-	75	-	-
40	+	+	80	+	-	100	-	-

Source: Takacs and Abbott 2007
Notes:
+ Significant increase in activity between treated and control.
- No difference in activity between treated and control.

Activity of mouse PPARβ/δ was significantly increased after exposure to 40–80 µmol PFOA compared to the negative control. Activity of human PPARβ/δ was not increased by PFOA exposure. Activity of mouse and human PPARγ were not increased by exposure to PFOA. PFOA was found to activate mouse and human PPARα and mouse PPAR β/δ under the conditions in this study.

Biomarkers for Peroxisome Proliferation. Pastoor et al. (1987) dosed male Crl:CD (SD) BR rats for 1, 3, and 7 days with 0 or 50 mg PFOA/kg/day. Hepatic DNA content, cytochrome P450 content, UDP-glucuronyltransferase, glutathione S-transferase, benzphetamine N-demethylase activity (marker for smooth ER proliferation), and ethoxyresorufin O-deethylase activity (marker for cytochrome P450 induction via the aryl hydrocarbon receptor) were measured from rats dosed 1 and 3 days. Liver microsomes were prepared from rats dosed for 3 days for CAT and CPT activity assays. CAT served as a marker for peroxisome proliferation and CPT was a marker for mitochondrial proliferation. Incorporation of [^{14}C]acetate into hepatic lipids was used to determine the effect of PFOA on hepatic lipid metabolism. Plasma TC and triacylglycerides was determined from rats dosed for 7 days.

Hepatic DNA content was not increased in treated rats when compared to content in control rats. Cytochrome P450 was significantly increased ($p<0.05$) and ethoxyresorufin O-deethylase activity was significantly decreased ($p<0.05$) after treatment for 1 and 3 days. Benzphetamine N-demethylase activity was significantly increased ($p<0.05$) after treatment with PFOA for 3 days. CAT activity increased 12-fold ($p<0.05$) and CPT increased twofold ($p<0.05$) after a 3-day treatment with 50 mg PFOA/kg. No differences were observed among the groups for the

other enzymes. No differences were observed between rats treated for 7 days and control rats in plasma TC or triacylglycerol. Although a significant increase ($p<0.05$) was observed for [^{14}C]acetate incorporation into triacylglycerols, cholesteryl esters, and polar lipids, there was no difference in the distribution of the incorporated label between control and treated rats. The authors concluded that the lack of increased DNA content, proliferation of smooth ER, and peroxisome proliferation pointed to increased liver weight due to hepatocyte hypertrophy.

Gap Junction Intercellular Communication. Upham et al. (1998, 2009) examined the effects of perfluorinated fatty acids on gap junction intercellular communication (GJIC) in male Fischer 344 rats fed diets containing 0 or 0.02% PFOA (intake 37.9 mg/kg/day) for 1 week and in WB-F344 rat liver epithelial cells. The chain lengths of the perfluorinated fatty acids ranged from 2–10, 16, and 18 carbons. Liver weight in the rats fed diets containing 0.02% PFOA was significantly increased compared to control rat liver weight. No differences were observed in serum AST, ALT, and ALP. PFOA significantly inhibited GJIC in the livers of rats after treatment for 1 week. In WB-F344 cells, GJIC was inhibited by perfluorinated fatty acids with 7–10 carbons within 15 mins of incubation. The inhibition was reversible with full recovery occurring within 30 mins of PFOA removal from media. Extracellular receptor kinase was activated by PFOA within 5 mins of incubation in the cells. Preincubation of cells with the phosphatidylcholine-specific phospholipase C inhibitor D609 partially prevented GJIC inhibition by PFOA. The authors concluded that PFOA, having an 8-carbon chain, inhibited GJIC by activation of extracellular receptor kinase and phosphatidylcholine-specific phospholipase C, but noted that other mechanisms might be involved.

Production of ROS. Takagi et al. (1991) fed male Fischer 344 rats diets containing 0, 10, and 20 mg PFOA/kg for 2 weeks to determine the formation of 8-OH-dG (marker of oxidative DNA damage). Livers and kidneys were removed at necropsy and DNA was isolated from each organ and analyzed. The relative liver and kidney weights were significantly increased ($p<0.05$) in the treated rats compared to the control. A significant increase in 8-OH-dG liver levels was observed at ≥ 10 mg PFOA/kg. There were no significant differences in 8-OH-dG kidney levels between PFOA-treated and control rats. The authors concluded that PFOA could cause organ-specific oxidative DNA damage.

Hu and Hu (2009) exposed human hepatoma cells, HepG2, to PFOA to evaluate cytotoxic effects. Cells also were exposed to a mixture of PFOA and PFOS to determine antagonistic or synergic effects. The cells were exposed to 0, 50, 100, 150, and 200 µmol PFOA or to 0, 50, 150, and 200 µmol each of PFOA and PFOS. A group of cells also were exposed to 0, 50, 100, 150, and 200 µmol PFOS. The cells were cultured for 24, 48, and 72 hours. Cell viability, apoptosis, ROS, mitochondrial membrane potential, antioxidant enzymes, glutathione content, and differential expression of apoptosis gene regulators p53, Bax, Bcl-2, caspace-3, and caspace-9 genes were evaluated.

Exposure to PFOA or PFOS caused a dose-dependent decrease in viability of HepG2 cells. A nonsignificant dose-dependent increase in apoptosis was observed in the cells cultured with PFOA. However, the combination of PFOA and PFOS showed a significant dose-dependent increase ($p<0.05$) in apoptosis. Intracellular ROS were significantly increased ($p<0.05$) in cells cultured with 100, 150, and 200 µmol PFOA or PFOS. HepG2 cells exposed to the mixture of 100 and 200 µmol PFOA and PFOS exhibited a decline in fluorescence intensity in the mitochondrial membrane potential assay, indicating that mitochondrial pathways were involved in the apoptosis observed. Exposure to 100 µmol PFOA significantly decreased ($p<0.05$) glutathione concentration and glutathione peroxidase activity; and 150 µmol PFOA significantly

increased ($p<0.05$) the activities of SOD, catalase, and glutathione reductase, and significantly decreased ($p<0.05$) glutathione peroxidase activity, and glutathione concentration in HepG2 cells. The trend was the same at 200 μmol PFOA, with the exception of GST activity being significantly decreased ($p<0.05$).

Exposure to PFOA did not change p53, Bax, or caspace-3 expression in HepG2 cells. Expression of Bcl-2 was downregulated and caspace-9 was upregulated in a dose-dependent manner in HepG2 cells following exposure to 50–200 μ/Mol PFOA. The authors proposed that PFOA and PFOS induced cell apoptosis by overwhelming the homeostasis of antioxidative systems, increasing ROS, impacting mitochondria, and changing gene expression of apoptosis gene regulators.

Eriksen et al. (2010) examined ability of PFOA to generate ROS and induce oxidative DNA damage in human HepG2 cells. Cell were incubated with 0, 0.4, 4, 40, 200, 400, 1,000, and 2,000 μmol PFOA and 2',7'-dichlorofluorescein diacetate. Hydrogen peroxide, H_2O_2, was used as a positive control. A fluorescence spectrophotometer was used to measure ROS production every 15 mins during the 3-hour incubation period in all cultures. The comet assay was used to measure DNA damage in cells exposed to 0, 100, and 400 μmol PFOA for 24 hours. Cytotoxicity was determined by measuring the level of lactate dehydrogenase activity in the cell medium. Exposure to PFOA caused a dose-independent increase (all doses $p<0.05$) in ROS production in HepG2 cells. Compared to ROS production in negative control cells, PFOA induced a 1.52-fold increase in production. There was no difference in oxidative DNA damage and lactase dehydrogenase activity between PFOA-treated cells and negative control cells. The authors concluded that oxidative stress and DNA damage were probably not relevant to potential adverse effects of PFOA.

Protein Binding. The ability of PFOA to bind to serum proteins for distribution is discussed in section 2.2. PFAS protein binding also can impact cellular function in cases in which the proteins in question are transporters (serum albumin and fatty acid binding protein) or enzymes (lysine decarboxylase) as well as membrane receptors (e.g., members of the PPAR family) and thyroid hormone receptors. The mechanistic studies of the nuclear PPARα membrane receptors are described in section 3.3.4.

Ren et al. (2015) examined the relative binding affinities of 16 PFASs for the human thyroid hormone receptor's α ligand binding domain (TRα-LBD) using a fluorescence competitive binding assay. Solutions of 1 μmol TRα-LBD were prepared in DMSO. Changes in TRα-LBD tryptophan fluorescence after binding to 10-μmol T3 in the absence or presence of the PFAS was used to determine the binding properties of the PFAS. IC_{50} values were calculated by linear extrapolation between two responses located in the vicinity of a 50% inhibition level. All the PFASs had a lower affinity for the receptor than T3. Affinity of PFOA was less than that for PFDA, PFUnA, PFNA, and PFOS.

ToxCast Assay Results. The Toxicity Forecaster (ToxCast) database is a large high-throughput screening compilation of public *in vitro* and *in vivo* assays on over 9,000 chemicals (USEPA 2015). PFOA was tested in 1,084 assays and was active in 40 (USEPA 2015). Assays with less than 50% efficacy reported or overfitting issues are not included in the summary of results that follows.

Three of the acceptable ToxCast active cytotoxicity assays evaluated the impact of PFOA. All three of these assays are based on one cell type. If there was no cytotoxicity reported for a specific cell type, the AC50 (the minimum concentration with 50% cytotoxicity activity) was used for comparison when reporting the ToxCast results. The lowest recorded AC50 (109 μmol) measured the degradation of microtubules in liver cells at 109 μmol and the highest recorded (123 μmol) measured general cytotoxicity in liver cells.

PFOA activated two of the 21 estrogen related assays in ToxCast; both were ESR1-related. Estrogen and its receptors are essential for sexual development and reproductive function, but also play a role in other tissues such as bone. PFOA induced estrogen response element and inhibited ESR1 at concentrations lower than their AC50 values with concentrations of 33.8 μmol and 47.4 μmol, respectively. This implies that PFOA could have some estrogenic potential; however, due to the small fraction of estrogenic assays activated (10%), any activity is likely weak.

PFOA activated PPARs, PXR, CAR, and retinoic acid receptor (RAR) assays within the ToxCast program. From the PPAR assays, PFOA induced the DNA sequences for PPARα, PPARγ, and the peroxisome proliferator hormone response element (PPRE) and antagonized the PPARγ receptor. The only PPAR assay AC50 value that was above the cell-specific AC50 was that for PPARγ antagonism at 5.91 μmol. However, it is possible that cytotoxicity occurs due to PPAR induction, or that PPAR cytotoxicity leads to PPAR induction confounding interpretation of the outcome. PFOA induced DNA sequences for PXR (AC50 9.42 μmol) at a concentration lower than the cell-specific AC50. CAR and RAR alpha antagonism also was observed, but the concentrations of 17.57 μmol and 28.45 μmol, respectively, were not below the cell-specific cytotoxicity value. PPAR, PXR, CAR, and RAR pathways are all nuclear receptors that can form heterodimers with one another to induce translation of various genes. Some of these genes are important for development, reproduction, and waste degradation, and could play a role in PFOA-induced cancer.

The ToxCast program examined Cytochrome P450 (CYP) activation associated with PFOA exposure. Although PFOA is not metabolically active, it was found to activate four CYPs: CYP2C18, CYP2C19, and CYP2C9 in human cells and CYP2C11 in rat cells. All of the CYP assays were activated at concentrations lower than the lowest AC50 (109 μmol) but lacked cell-specific AC50s. The CYP2C class of CYPs is involved in the metabolism of xenobiotics such as the following drugs: the antiseizure medication diazepam, beta blocker propranolol, and selective serotonergic reuptake inhibitor citalopram. Though there is no evidence of metabolism of PFOA by these CYPs, it is possible that it acts as a competitive or allosteric inhibitor for known substrates of the CYPs activated. This coupled with PFOA's high affinity for binding to albumin could significantly alter the PKs of various pharmaceutical bound to serum albumin, thus potentially playing a role in increasing systemic toxicity of some pharmaceuticals by increasing the free serum concentration.

PFOA failed to cause toxicity in the *in vivo* fish model for neurological and developmental toxicity. This is important because PFOA induces developmental toxicity in mice and rats *in vivo*.

3.3.5 Structure-Activity Relationship

Bjork and Wallace (2009) compared the PPARα-dependent transcriptional activation potential of linear perfluorocarboxylic and sulfonic acids in rodent and human hepatic liver cells. The PFAAs tested included perfluorinated carboxylic acids with carbon chain lengths of 2–8 and perfluorinated sulfonic acids with chain lengths of 4–8. Primary rat and human hepatocytes and HEPG2/C3A cells were incubated with 0 and 25 μmol perfluorinated compounds for 24 hours. Expression of Acox, Cyp4a1 (rat), Cyp4a11 (human), Cte/Acot1, and Ddit3 (GADD153) transcripts were determined by quantitative RT-PCR. All the genes are inducible by peroxisome proliferators except Ddit3, which is induced in the presence of direct or indirect DNA damage.

Perfluorinated compounds induced mRNA expression of either Acox or Cte/Acot1 only in rat hepatocytes, and the degree of stimulation of gene expression increased with increasing carbon number. The Cyp4a11 gene was not expressed or stimulated by any of the PFAAs in HepG2/C3A cells. However, this gene expression was stimulated by perfluorinated exposure in both rat and human hepatocytes with the perfluorocarboxylates showing a chain-length-dependent structure activity relationship. The study results suggest that the PPARα-related changes in gene expression induced by perfluorinated compounds in primary rat hepatocytes are directly related to the carbon chain length and appear to be stronger for the carboxylic acids (i.e., PFOA) than the sulfonates (i.e., PFOS). There was no induction in expression of Acox and Cte/Acot 1 in either primary or transformed human liver cells in culture. The authors suggested that the PPARα mediated peroxisome proliferation observed in rodent liver might not be relevant as an indicator to human risk.

Wolf et al. (2008b) tested PFAAs, including PFOA, to determine if mouse and human PPARα activity could be induced in transiently transfected COS-1 cell assays. COS-1 cells were transfected with either a mouse or human PPAR-α receptor-luciferase reporter plasmid and, after 24 hours, were exposed to either negative controls (water or 0.1% DMSO), a positive control (Wyeth 14,643), or PFOA at 0.5–100 μmol. Other concentrations of PFAAs were used but not provided in this report. At the end of 24 hours of exposure, the luciferase activity was measured. The positive and negative controls had the expected results. A lowest observed effect concentration (LOEC) and no observed effect concentration (NOEC) were determined for each PFAA. In the study, the mouse PPARα was more responsive than the human. Also, carboxylates induced higher mouse and human PPARα activity than the sulfonates. In this study, the NOEC for PFOA was 0.5 μmol in the mouse and 5 μmol in humans; the LOEC was 1 μmol (0.43 μg/mL) in the mouse and 10 μmol (4.3 μg/mL) in humans.

A similar study included additional PFAAs (Wolf et al. 2012). Transfected cells were incubated with PFAAs at concentrations of 0.5 to 100 μmol, vehicle (water or 0.1% DMSO as negative control) or with 10 μmol Wyeth 14,643 (positive control) on each plate. Assays were performed with three identical plates per compound per species with nine concentrations per plate and eight wells per concentration. Cell viability was assessed using the Cell Titer Blue cell viability kit and read in a fluorometer. The positive and negative controls had the expected results. All cells transfected with either human and mouse PPARα responded to the PFAAs. Again, the carboxylates were stronger inducers than the sulfonates, and the mouse PPARα was more reactive than the human PPARα. The study also provided the C_{20max} values for each PFAA (the concentration at which the PFAA produced 20% of the maximal response elicited by the most active PFAA). For PFOA, this was 6 μmol in mouse PPARα and 7 μmol in human PPARα. For comparison, PFOS was 94 μmol and 262 μmol, respectively.

3.4 Hazard Characterization

3.4.1 Synthesis and Evaluation of Major Noncancer Effects

Serum Lipids. Because of the structural similarities between linear perfluorinated acids and the short- and medium-chain fatty acids, the potential for these chemicals to cause elevated serum lipids has been an area of considerable interest. High levels of serum lipids (TC and LDL) are risk factors for cardiovascular disease in humans, including IHD, a condition in which blood flow to the heart is decreased through the development of atherosclerotic plaque or clots in the cardiac arteries.

The association between PFOA and serum lipids has been examined in several studies in different populations. Cross-sectional and longitudinal studies in occupational settings (Costa et al. 2009; Olsen et al. 2000, 2003; Olsen and Zobel 2007; Sakr et al. 2007a, 2007b; Steenland et al. 2015) and in the high-exposure community (the C8 Health Project study population) (Fitz-Simon et al. 2013; Frisbee et al. 2010; Steenland et al. 2009; Winquist and Steenland 2014a) generally observed positive associations between serum PFOA and TC in adults and children (aged 1–< 18 yrs); most of these effect estimates were statistically significant. Although exceptions to this pattern are present (i.e., some of the analyses examining incidence of self-reported high cholesterol based on medication use in Winquist and Steenland 2014a and in Steenland et al. 2015), the results are relatively consistent and robust. Similar associations were seen in analyses of LDL, but were not seen with HDL. The range of exposure in occupational studies is large (means varying between 0.4 and > 12 μg/mL), and the mean serum levels in the C8 population studies were around 0.08 μg/mL. Positive associations between serum PFOA and TC (i.e., increasing lipid level with increasing PFOA) were observed in most of the general population studies at mean exposure levels of 0.002–0.007 μg/mL (Eriksen et al. 2013; Fisher et al. 2013; Geiger et al. 2014a; Nelson et al. 2010; Starling et al. 2014). The interpretation of these general population results is limited, however, by the moderately strong correlations (Spearman r > 0.6) and similarity in results seen for PFOS and PFOA. The most recent update of disease incidence in workers in the C8 Health Project study population identified 35 cases of nonhepatitis liver disease (with medical validation) (Steenland et al. 2015); no association was seen with cumulative exposure when analyzed without a lag (HRs by quartile 1.0, 0.58, 1.43, 1.20; trend p = 0.86 for log cumulative exposure), but there was a possible trend in the analysis using a 10-year lag (HRs by quartile 1.0, 1.46, 2.13, and 2.02; trend p = 0.40).

Cholesterol and/or triglycerides were monitored in only a few of the animal studies, which did not all measure concurrent serum PFOA levels. Information on serum lipids from animal studies has received less attention than in the human population because of the fact that decreases in triglycerides, cholesterol, and lipoprotein complexes are an expected consequence of PPARα activation in rodents. The PPARα response in animals tends to lower rather than raise serum cholesterol and associated lipid levels. Peroxisomes are subcellular organelles that increase beta oxidation of long-chain fatty acids using a beta oxidation pathway that is not linked to adenosine triphosphate (ATP) production and release the shortened fatty acids to the cytosol as an endproduct for export in VLDLs or hepatic ATP-production via mitochondrial beta oxidation (Garrett and Grisham 1999). PPARα activation also stimulates metabolic changes that lower hepatic cholesterol. The effects of human PPARα activation are much less pronounced than those in rats and mice.

Nakamura et al. (2009) and Minata et al. (2010) examined the lipid endpoints relative to the mouse strain's PPARα status and PFOA exposure. Nakamura et al. (2009) found that mice with a normal PPARα receptor had significantly increased levels of cholesterol and triglycerides in liver but not plasma at a LOAEL of 0.3 mg/kg/day. However, there were no differences in serum or liver cholesterol or triglycerides between PFOA-treated mice with a humanized PPARα receptor or PPARα-null mice (NOAEL= 0.3 mg/kg/day) and their respective controls. The study by Minata et al. (2010) used higher doses than Nakamura et al. (2009) and found that TC was significantly decreased (LOAEL= 10.8 mg/kg/day; whole blood 47 μg/mL) and total triglycerides significantly increased (LOAEL= 5.4 mg/kg/day; whole blood 21 μg/mL) in wild-type mice. In the PPARα-null mice, the TC was significantly decreased for the 5.4- and 10.8-mg/kg/day doses but significantly increased for a 21.6-mg/kg/day dose while total triglycerides were significantly increased at all doses; these doses corresponded to whole blood PFOA levels of 13, 36, and 71 μg/mL, respectively. Rosen et al. (2007) found that PFOA activated genes for fatty acid catabolism, cholesterol biosynthesis; bile acid biosynthesis; and lipoprotein, steroid, and glucose metabolism in fetal livers. When comparing the response in PPARα wild-type to null mice (Rosen et al. 2008b), 62 of 81 activated genes were the same for both strains and were ones involved with lipid metabolism.

Martin et al. (2007) identified a 45–72% decrease in serum cholesterol after treatment of male Sprague-Dawley rats with 20 mg PFOA/kg/day for up to 5 days (serum PFOA 245 μg/mL after 3 days), and Loveless et al. (2008) reported decreased TC, HDL, and non-HDL in male CD rats after doses of 0.3 and 1 mg/kg/day for 28 days. Triglycerides were decreased in the rats at ≥0.3 mg/kg/day. De Witt et al. (2009) found a dose-dependent decrease in triglyceride levels in female C57BL/6N mice exposed to 0, 7.5, and 15 mg PFOA/kg bw in drinking water for 10 days. In male CD-1 mice, TC, HDL, and triglycerides were decreased at 10 and 30 mg/kg/day (Loveless et al. 2008). In pregnant female ICR mice, triglyceride, TC, and free fatty acids were significantly decreased at 10 mg/kg (Yahia et al. 2010). Elcombe et al. (2010) found a significant decrease in cholesterol in male Sprague-Dawley rats following a 7- or 28-day exposure to 300 ppm PFOA in the diet with a resulting serum level of 252 μg/mL at 28 days. Accordingly, there is not a high degree of concordance between the lipidemic effects of PFOA as noted in human epidemiology studies and those seen in animals.

Filgo et al. (2015) found a trend for increased liver Ito (fat) cell atrophy and lesion severity across the doses in CD-1 and SV-129 mice at 18 months. PFOA exposure occurred only through the dam during gestation and lactation in this study. This observation suggests that liver steatosis could be a concern late in life for animals exposed to PFOA gestationally and during their early postnatal period. However, the 18-month fat accumulation could also be related to normal aging and/or dietary fat intakes across the animal's lifetime (Quist et al. 2015). Tan et al. (2013) found that the fat content of the diet was an important variable in determining the impact of PFOA (5 mg/kg/day) on liver and serum lipids. Intake of an HFD plus PFOA increased liver triglycerides and serum free fatty acids compared to an RFD plus PFOA but had no impact on liver cholesterol concentrations. Serum cholesterol was not monitored.

Hepatic Effects. Both the human and animal studies suggest effects on the liver as indicated by increases in liver enzymes. The results of the occupational studies provide evidence of an association with increases in serum AST, ALT and GGT, with the most consistent results seen for ALT. The associations were not large and could depend on the covariates in the models, such as BMI, use of lipid-lowering medications, and triglycerides (Costa et al. 2009; Olsen et al. 2000, 2003; Olsen and Zobel 2007; Sakr et al. 2007a, 2007b). Two population-based studies of highly

exposed residents in contaminated regions near a fluorochemical industry in West Virginia have evaluated associations with liver enzymes, and the larger of the two studies reported associations of increasing serum ln ALT and ln GGT levels with increasing serum PFOA concentrations (Emmett et al. 2006; Gallo et al. 2012). A cross-sectional analysis of data from NHANES, representative of the U.S. national population, also found associations with ln PFOA concentration with increasing serum ALT and ln GGT levels. Serum bilirubin was inversely associated with serum PFOA in the occupational studies. A U-shaped exposure-response pattern for serum bilirubin was observed among the participants in the C8 Health Project, which might explain the inverse associations reported for occupational cohorts. Overall, an association of serum PFOA concentration with elevations in serum levels of ALT and GGT has been consistently observed in occupational, highly exposed residential communities, and the U.S. general population. The associations are not large in magnitude, but indicate the potential to affect liver function.

The data from animal studies for increases in ALT and AST support the findings in human epidemiology studies; however, the animal studies for both aminotransferases lacked serum PFOA measurements for comparison with the human serum data. Concurrent with the evidence in animals of damage to liver cells, levels of some membrane transport proteins were altered. In mice, the increased expression of MRP3 and MRP4 (Maher et al. 2008) and the decreased expression of OATPs (Cheng and Klaassen 2008) favor excretion of PFOA into the bile. Competition of PFOA with bile acids for transport could alter the excretion of the cholesterol derivatives excreted in bile.

In animal studies, serum levels of ALT and/or AST were significantly increased indicating apoptosis or necrosis of liver cells (Butenhoff et al. 2012; Minata et al. 2010; Son et al. 2008). Increased levels of ALT were observed at a LOAEL of 2.65 mg/kg/day in ICR mice by Son et al. (2008). Yahia et al. (2010) reported significantly increased ALT, GGT, AST, and ALP in PFOA-exposed (10 mg/kg) pregnant ICR mice. Total protein, albumin, and globulin were significantly decreased in the same mice.

No evidence of liver damage has been found in the human epidemiology studies with the exception of the few enzyme changes discussed above. In most PFOA animal studies (e.g., monkeys, rats, and mice), short-term and chronic exposure caused a dose-related increase in liver weight as at least one of the co-occurring effects (Butenhoff et al. 2002, 2004a, 2012; DeWitt et al. 2009; Elcombe et al. 2010; Minata et al. 2010; Pastoor et al. 1987; Perkins et al. 2004; Son et al. 2008; Wolf et al. 2008a). Increased liver weights were observed in mice that are both active and null for PPARα activation (Albrecht et al. 2013; Minata et al. 2010; Wolf et al. 2008a). The histological characteristics of the liver differed in the mice with and without the PPARα receptor, but the liver weight increase was the same. Liver effects were seen in mice with an active PPARα receptor at doses as low as 0.3 mg/kg/day (Nakamura et al. 2009) and 1 mg/kg/day in the null mice (Wolf et al. 2008a).

Histological examination of liver tissues from PFOA-exposed wild-type mice and PPARα-null mice were distinctly different from their respective controls (Minata et al. 2010; Wolf et al. 2008a). In the case of the wild-type PFOA-exposed mice, there was less rough ER than in controls and more lipid-like vacuoles scattered throughout the cytoplasm. The PFOA-exposed PPARα-null mice had proliferation of smooth ER and limited rough ER and Golgi bodies compared to their controls. The PPARα-null control mice had the scattered lipid-like vacuoles seen in the wild-type PFOA exposed mice; however, their lipid-like vacuoles were considerably larger than those seen in the wild-type animals and occupied a considerable volume within the

cytoplasm. The vacuoles in the PPARα-null PFOA-exposed mice were hypothesized to be filled with PFOA as a consequence of its uptake into the cell without dispersion or assimilation.

Similarly, Albrecht et al. (2013) observed centrilobular hepatocellular hypertrophy in mouse dams given 3 mg/kg on GDs 1–17, but the morphological features differed slightly between wild-type, PPARα-humanized, and PPARα-null mice. In wild-type mice, hypertrophy was characterized primarily by centrilobular hepatocytes with increased amounts of densely eosinophilic and coarsely granular cytoplasm consistent with increased peroxisomes. In null mice, hypertrophy was generally less prominent than seen in wild-type mice, and affected hepatocytes had pale eosinophilic, finely granular-to-amorphous cytoplasm. The morphological features of centrilobular hepatocytes in humanized mice were intermediate between those observed in wild-type and null mice. The lesion was graded as mild in wild-type mice, minimal in null mice, and minimal or mild in humanized mice. An additional finding in PFOA-treated null and humanized mice, but not in wild-type mice, was the presence of few clear, discrete vacuoles within the cytoplasm of centrilobular hepatocytes.

Hepatocellular hypertrophy and an increased liver-to-body weight ratio are common findings in rodents when PPARα activation leads to peroxisome proliferation and these effects are considered nonadverse in wild-type strains when they occur. Hepatic necrosis, effects on bile ducts, and other signs of liver damage unrelated to PPARα activation observed in conjunction with the increased liver weight and hepatpcellular hypertrophy are sufficient to justify the liver weight and hypertrophy as adverse (Hall et al. 2012). Low-level necrotic cell damage was observed in the Perkins et al. (2004) rat study and in the Loveless et al. study (2008) in CD rats at 10 mg/kg/day and CD1 mice at 1 mg/kg/day. In the Perkins et al. study (2004), there was a slight increase in coagulative necrosis at 1.94 and 6.5 mg/kg/day when compared to the control and lower doses. Some hepatocellular necrosis also was observed in conjunction with hepatocellular hypertrophy and increased liver weight in F1 male rats from the Butenhoff et al. (2004a) two-generation study at 3 mg/kg/day.

Minata et al. (2010) reported degenerative histological changes in the bile ducts of PPARα-null mice at doses ≥10.6 mg/kg/day and Loveless et al. (2008) observed bile duct hyperplasia in CD1 mice at doses ≥10 mg/kg/day. PPARα-null mice had an increased hepatocyte PCNA labeling index at a dose of 10 mg/kg/day (Wolf et al. 2008a). When considering the studies in animals with and without the active PPARα receptor, it is clear that PFOA has some effects of potential toxicological significance that appear to be independent of PPARα activation.

Kidney and Other Organ Effects. Overall, studies of occupational cohorts (Costa et al. 2009), a highly exposed community (Steenland et al. 2010; Watkins et al. 2013), and the U.S. general population (Shankar et al. 2011) that evaluated uric acid levels or eGFR as measure of kidney function found associations with decreased function. Reverse causality as an explanation cannot be ruled out in studies using serum PFOA as a biomarker of exposure, as a low GFR would diminish the removal of PFOA from serum for excretion by the kidney.

Some studies in animals have shown effects on the kidney, mainly increased organ weight in male rats, but the studies lacked concurrent PFOA serum levels and histological examination of the kidney tissues. In general, kidney effects in rats occurred at doses similar to those resulting in liver effects.

Increases in absolute and relative-to-body kidney weights occurred in rats given 5 mg/kg/day (lowest dose tested) for 28 days (Cui et al. 2009). In a two-generation study, F0 and F1 males

had significantly increased absolute kidney weight at 1 and 3 mg/kg/day, but significantly decreased organ weight at 30 mg/kg/day. Organ weight-to-terminal body weight ratios for the kidney were statistically significantly increased at ≥1 mg/kg/day. Kidney weight-to-brain weight ratios were significantly increased at 1, 3, and 10 mg/kg/day, but decreased at 30 mg/kg/day, following the trends in absolute weights (Butenhoff et al. 2004a). In the high-dose group, absolute and relative kidney weight changes occurred in a pattern typically associated with decrements in body weight. However, in the lower dose groups kidney weight, consistently displayed an increase (absolute and relative to body and brain weights), suggesting an induction of transporters for renal removal of the foreign molecule. The differential expression of transporters in the kidney of rats has been shown to be under hormonal control with males having lower levels of export transporters compared with females (Kudo et al. 2002).

In both the Cui et al. (2009) and Butenhoff et al. (2004a) studies, PFOA was administered by daily gavage. No changes in kidney weight were found with dietary administration with a resulting dose of 14.2 mg/kg/day to male rats for 2 years (Butenhoff et al. 2012).

In general, effects on organs other than the liver tend to occur at doses higher than those that affect the liver. Lung effects, including pulmonary congestion, have been observed in male Sprague-Dawley rats (LOAEL = 5 mg/kg/day) (Cui et al. 2009). Increased thickness and prominence of the adrenal zona glomerulosa and vacuolation in the cells of the adrenal cortex were observed in male rats fed 10 mg/kg/day for approximately 56 days (Butenhoff et al. 2004a).

Thyroid Effects. Three large studies provide support for an association between PFOA exposure and incidence or prevalence of thyroid disease in female adults or children, but not in males (Lopez-Espinosa et al 2012; Melzer et al. 2010; Winquist and Steenland 2014b). In addition, associations between PFOA and TSH were also seen in pregnant females with anti-TPO antibodies (Webster et al. 2014). However, generally null associations were found between PFOA and TSH or thyroid hormones (T4 or T3) in people who have not been diagnosed with thyroid disease.

Effects of PFOA on thyroid hormones in animals are generally not as well characterized as those of PFOS. Butenhoff et al. (2002) evaluated the toxicity of PFOA in male cynomolgus monkeys during 6 months of oral administration and reported that levels of total T3 and FT3 in circulation were reduced significantly in the 30/20 mg/kg/day treatment group. The effect seen as early as 5 weeks after initiation of treatment, 2 weeks after the dose was lowered to 20 mg/kg/day. Recovery of T3 deficits was noted upon cessation of chemical treatment once the serum level of PFOA returned to baseline 90 days later. Serum total T4, FT4, and TSH were not altered throughout the study. The preferential effects of PFOA on serum T3 and a lack of a TSH compensatory response are similar to those observed with PFOS.

Martin et al. (2007) showed that serum total T4 and FT4 were markedly and abruptly depressed (~ 80%) in adult male rats 1 day after oral gavage treatment with PFOA (20 mg/kg); serum T3 was also reduced (25%), although to a lesser extent. These findings were confirmed when both male and female rats were given PFOA (10 mg/kg) daily for 3 weeks and serum thyroid hormones were monitored (Lau, personal communication) (Martin et al. 2007). Serum total T4 and FT4 were profoundly depressed (>85%) and T3 less so (~ 25%) in male rats, but serum TSH levels were not altered significantly. These hormonal changes were noted when serum PFOA level reached about 67 µg/ml. The dose-response relationship of serum total T4 with PFOA exposure has yet to be fully evaluated and the lowest effective dose remains unknown.

None of the thyroid hormones were affected by PFOA in mature female rats, primarily because these animals were able to clear the chemical effectively (with half-life estimate of 2–4 hours compared to that of 6–7 days for male rats). This suggests that the thyroid disrupting effects of PFOA are directly related to endogenous accumulation of the chemical and could be relevant to humans because of the long PFOA human half-life.

Displacement of T4 from binding to TTR has been proposed as a possible mechanism to account for the hypothyroxinemia in rats. However, although PFOA binds to human TTR, its binding affinity is only one-fifteenth of that of the natural ligand T4 (Weiss et al. 2009). Based on a toxicogenomic analysis of rat liver after an acute exposure to PFOA, Martin et al. (2007) suggested a possible role of peroxisome proliferators in the thyroid hormone imbalance, although this hypothesis has yet to be explored in detail.

Hyperglycemia. Several human epidemiology studies have examined PFOA in relation to diabetes (incidence or prevalence) or measures of hyperglycemia These studies do not show a pattern of results that suggest an association between PFOA and diabetes or hyperglycermia in occupational settings (Costa et al. 2009; Olsen et al. 2000, 2003; Sakr et al. 2007a; Steenland et al. 2015), in the high-exposure community population (MacNeil et al. 2009), or in the general population (Lin et al. 2009; Nelson et al. 2010).

Hines et al. (2009) found no differences in glucose tolerance tests at 15–16 weeks and at 17 months of age in PFOA-exposed CD-1 mice, but did observe significantly increased serum leptin and insulin levels at 21 and 31 weeks of age, suggesting that the insulin resistance mechanistic pathway could be affected by PFOA. Conversely, Quist et al. (2015) found no dose-related impact on serum leptin in CD-1 pups from the Hines et al. study (2009) when examined on PND 91 for the mice on an RFD and on an HFD fasted for 4 hours before serum collection. In the animals on a HFD that did not fast before serum collection, there was a trend towards a dose-related decrease in serum leptin. Thus, the fat content of the diet and the timing of serum collection are important variables that can influence study results relative to leptin levels and indicators of insulin resistance.

Nervous System Effects. The data pertaining to neurotoxicity (including neurodevelopmental effects) of PFOA are limited, but do not indicate the presence of associations between PFOA and a variety of outcomes. Fei et al. (2008b) found no association between maternal serum PFOA concentrations and fine motor skills, gross motor skills, and cognitive abilities of children aged 6 and 18 months. Fei and Olsen (2011) found no association between behavioral or coordination problems in children aged 7 years and prenatal PFOA exposure. Epidemiology studies of children derived from the NHANES and C8 populations found a weak statistical association between serum PFOA with parental reports of ADHD (Hoffman et al. 2010; Stein et al. 2013).

One animal study (Johansson et al. 2009) suggests a potential effect on habituation and activity patterns in NMRI mice treated on PND 10 with a single dose of PFOA and evaluated at and 2 and 4 months of age (LOAEL=0.58 mg/kg). The *in vivo* observations were supported by changes in the expression of a variety of neurologically active brain proteins in the treated pups (Johansson et al. 2009). The offspring of C57BL/6/Bkl dams fed 0.3 mg PFOA/kg/day throughout gestation had detectable levels of PFOA in their brains at birth (Onishchenko et al. 2011). Behavioral assessments of the offspring starting at 5 weeks of age revealed gender-related differences in exploratory behavior patterns. In the social group setting, the PFOA-exposed males were more active and PFOA-exposed females were less active than their respective controls. The PFOA-exposed males also had increased activity counts compared to control males

in circadian activity experiments. The results of an *in vitro* study of hippocampal synaptic transmission and neurite growth in the presence of long-chain perfluorinated compounds showed that 50 and 100 μmol PFOA increased spontaneous synaptic current and had an equivocal impact on neurite growth (Liao et al. 2009a, 2009b). These data suggest a need for additional studies of the effects of PFASs, including PFOA, on the brain.

Reproductive and Developmental Effects. There have been numerous human studies examining PFOA exposure and reproductive and/or developmental effects in both humans and animals. A series of studies in the high-exposure C8 Health Project study population have reported associations between PFOA exposure and pregnancy-induced hypertension or preeclampsia (Darrow et al. 2013; Savitz et al. 2012a, 2012b; Stein et al. 2009). Each of these studies provides evidence of an association between PFOA exposure and risk of pregnancy-induced hypertension or preeclampsia, with the most robust findings from the methodologically strongest study (Darrow et al. 2013).

The association between PFOA and birth weight has been examined in numerous human studies. Most studies measured PFOA using maternal blood samples taken in the second or third trimester or in cord blood samples. Studies on the high-exposure C8 community population (Darrow et al. 2013; Nolan et al. 2009; Stein et al. 2009; Savitz et al. 2012a, 2012b) have not observed associations between PFOA and either birth weight among term births or the risk of low birth weight among all (singleton) births. In contrast, several analyses of general populations indicate a negative association between PFOA levels and birth weight (Apelberg et al. 2007; Fei et al. 2007; Maisonet et al. 2012), while others did not attain statistical significance (Chen et al. 2012; Hamm et al. 2010; Monroy et al. 2008; Washino et al. 2009). A meta-analysis of many of these studies found a mean birth weight reduction of 19 g (95% CI: -30, -9) per each 1-unit (ng/mL) increase in maternal or cord serum PFOA levels (Johnson et al. 2014). However, when low GFR was accounted for in PBPK simulations by Verner et al. (2015), the association reported between PFOA and birth weight is less than that found in their meta-analysis of the epidemiology data. The study authors reported that the actual association might be closer to a 7-g reduction (95% CI: -8, -6). Verner et al. (2015) also showed that, in individuals with low GFR, there are increased levels of serum PFOA and lower birth weights. This suggests that a portion of the association between PFOA and birth weight could be confounded by low maternal GFR under conditions such as preeclampsia and pregnancy-induced hypertension. While there is some uncertainty in the interpretation of the observed association between PFOA and low GFR with birth weight, given the available information, the association between PFOA exposure and reduced birth weight observed for the general population is plausible. In humans with low GFR, the impact on body weight is likely due to a combination of the low GFR and the serum PFOA.

Two studies examined development of puberty in females in relation to prenatal exposure to PFOA as measured through maternal or cord blood samples in follow-up of pregnancy cohorts conducted in England (Christensen et al. 2011) and in Denmark (Kristensen et al. 2013). The results of these two studies are conflicting, with no association (or a possible indication of an earlier menarche seen with higher PFOA) in Christensen et al. (2011), and a later menarche seen with higher PFOA in Kristensen et al. (2013). Another study examined PFOA exposure measured concurrently with the assessment of pubertal status (Lopez-Espinosa et al. 2011). An association between later age at menarche and higher PFOA levels was observed, but the interpretation of this finding is complicated by the potential effect of puberty on the exposure biomarker levels (i.e., reverse causality).

Limited data suggest a correlation between higher PFOA levels (>0.02 μg/mL) in females and decreases in fecundity and fertility (Fei et al. 2009; Vélez et al. 2015), but there are no clear effects of PFOA on male fertility endpoints (0.0035–0.005 μg/mL) (Joensen et al. 2009, 2013).

Knox et al. (2011) found that the odds of having experienced menopause were significantly higher in the highest PFOA quintile group relative to the lowest PFOA group. Two studies found delayed puberty in females (Kristensen et al. 2013; Lopez-Espinosa et al. 2011), but reverse causality needs to be considered. However, Christensen et al. (2011) found no association between puberty and PFOA exposure in children of the Avon Longitudinal Study of Parents and Children in the United Kingdom. Removal of PFOA with the start of monthly menstruation and the cessation of this route with menopause or hysterectomy are additional factors that can influence serum PFOA levels that are the result of the developmental milestones rather than a cause (Taylor et al. 2014; Wong et al. 2014). Costa et al. (2009) found no association between serum PFOA concentration and estradiol or testosterone in workers at a PFOA production plant.

Measures of postnatal development and behavior in children were not associated with PFOA levels in the mother (0.001–0.0057 μg/mL) (Andersen et al. 2010, 2013; Fei et al. 2008b; Fei and Olsen 2011; Høyer et al. 2015a, 2015b). Fei et al. (2008b) found no association between maternal PFOA concentration and fine motor skills, gross motor skills, and cognitive skills in offspring at 6 and 18 months of age. Fei and Olsen (2011) also found no association between prenatal PFOA exposure and behavior or coordination problems in children aged 7 years. The age at which children reached developmental milestones did not show any relationship to maternal plasma PFOA concentration. Halldorsson et al. (2012) found that low-dose developmental exposures to PFOA resulted in obesogenic effects in female offspring at 20 years.

Among the animal studies, there was no effect of PFOA on reproductive or fertility parameters in rats (Butenhoff et al. 2004a; York et al. 2010), but effects on male fertility were observed in male mice (Lu et al. 2015). In mouse gavage studies, decreased body weight and decreased neonatal survival were observed at ≥ 1 mg/kg/day, increased full litter resorptions and increased stillbirths were observed at ≥ 5 mg/kg/day, increased time to parturition was observed at ≥10 mg/kg/day, and decreased maternal weight gain was observed at ≥20 mg/kg/day for exposures lasting from GD1–17 (Abbott et al. 2007; Lau et al. 2006; White et al. 2007; Wolf et al. 2007).

Postnatal development also has been studied extensively in rats and mice as discussed below. A separate group of studies in mice focused on mammary gland development in dams and female offspring. Both species showed some indication of potential developmental toxicity. Doses that elicited a response were higher in rats compared with in mice. The species differences in dose response are likely related to half-life differences of hours for the female rat and days-to-weeks for the female mouse.

Reduced postnatal growth leading to developmental delays was observed in both rats and mice. A two-generation diet study in rats resulted in significantly decreased body weight gain prior to weaning and delayed sexual maturity in the first generation males and females at 30 mg/kg/day (Butenhoff et al. 2004a). For treatment beginning on PND 21, delayed vaginal opening was also observed in BALB/c mice at ≥1 mg/kg/day and in C57BL/6 mice at ≥5 mg/kg/day, although body weight was not decreased until doses of ≥10 mg/kg/day in both strains (C. Yang et al. 2009). Cross-fostering studies in mice showed that gestational PFOA exposure maximized decreased postnatal body weight, delayed eye opening, delayed body hair growth, and decreased survival in the offspring (Wolf et al. 2007). Restricted exposure studies

showed that gestational exposure to PFOA over differing gestational time periods led to differing offspring effects (Wolf et al. 2007). The longer the gestational exposure, the greater the body weight deficit in the male and female pups over PND 2–22. In males, the difference in body weight persisted until PND 92. Delayed eye opening and body hair growth were observed at 5 mg/kg/day in offspring exposed GD 7–17 or 10–17, but decreased postnatal survival was observed at the same dose in offspring exposed GD 15–17.

Two developmental studies compared wild-type mice with PPARα-null mice, but results are inconclusive. One study revealed that the litter resorptions were independent of PPARα expression (≥5 mg/kg), while decreased neonatal survival (0.6 mg/kg) and delayed eye opening (1 mg/kg) were dependent upon PPARα expression (Abbott et al. 2007). These results are only partially supported by Albrecht et al. (2013), who used a single dose of 3 mg/kg. They found decreased pup survival only in wild-type mice, but no differences in litter resorptions or eye opening between wild-type and null mice. Albrecht et al. (2013) did not find effects on pup survival in PPARα-humanized mice, suggesting that the mouse PPARα could be involved in the etiology of PFOA-induced neonatal mortality.

Qualitative assessment found delayed mammary gland development of female CD1 mouse pups following maternal doses ≥ 0.01 mg PFOA/kg in Macon et al. (2011) and Tucker et al. (2015). Macon et al. (2011) also found significant differences from controls in quantitative measures of longitudinal and lateral growth and numbers of terminal end buds at 1 mg/kg/day. However, Albrecht et al. (2013) found no significant differences in the average length of mammary gland ducts and the average number of terminal end buds per mammary gland per litter in female pups of PPARα wild-type, PPARα-null, or hPPARα sv/129 mice following a maternal dose of 3 mg/kg, using an approach to scoring that lacked a qualitative component adjustment such as that used by Macon et al. (2011).
