Table 2-27. Summary of Cancer Outcomes in Humans[a]

Reference and study population[b]	Serum perfluoroalkyl level	Outcome evaluated	Result[c]
Wielsøe et al. 2017 General population (n=77 cases and 84 controls)	1.30 n and 1.01 ng/mL (median serum PFDA in cases and controls, respectively)	Breast cancer	OR 1.17 (0.97–1.40, p=0.094), continuous **OR 2.36 (1.04–5.36, p=0.041)*, 3rd tertile**
PFUnA			
Hardell et al. 2014 General population (n=201 cases of prostate cancer and 186 controls)	0.308 and 0.285 ng/mL (mean PFUnA in cases and controls)	Prostate cancer	OR 1.2 (0.8–1.9) **OR 2.6 (1.1–5.9)*, among subjects with a heredity risk and serum PFUnA above the median**
Wielsøe et al. 2017 General population (n=77 cases and 84 controls)	2.23 and 2.02 ng/mL (median serum PFUnA in cases and controls, respectively)	Breast cancer	OR 1.06 (0.97–1.15, p=0.207), continuous **OR 2.00 (0.88–4.53, p=0.019)*, 3rd tertile**
PFHpA			
Wielsøe et al. 2017 General population (n=77 cases and 84 controls)	0.11 and 0.08 ng/mL (median serum PFHpA in cases and controls, respectively)	Breast cancer	OR 6.98 (0.61–80.0, p=0.119), continuous OR 1.52 (0.54–4.24, p=0.425), 3rd tertile
PFDoDA			
Wielsøe et al. 2017 General population (n=77 cases and 84 controls)	0.40 and 0.21 ng/mL (median serum PFDoDA in cases and controls, respectively)	Breast cancer	OR 1.03 (1.01–1.06, p=0.447), continuous OR 0.93 (0.45–1.91, p=0.839), 3rd tertile

Table 2-27. Summary of Cancer Outcomes in Humans[a]

Reference and study population[b]	Serum perfluoroalkyl level	Outcome evaluated	Result[c]
FOSA			
Bonefeld-Jorgensen et al. 2014 General population (n=250 breast cancer cases and 115 matched controls)	3.5 ng/mL (mean FOSA)	Breast cancer	**RR 1.89 (1.01–3.54)*, among women with serum FOSA >5.75 ng/mL**

[a]See the *Supporting Document for Epidemiological Studies for Perfluoroalkyls,* Table 15 for more detailed descriptions of studies.
[b]Participants in occupational exposure may have also lived near the site and received residential exposure; community exposure studies involved subjects living near PFOA facilities with known exposure to high levels of PFOA.
[c]Asterisk indicates association with perfluoroalkyl; unless otherwise specified, values in parenthesis are 95% confidence intervals.

AOR = adjusted odds ratio; CI = confidence interval; FOSA = perfluorooctane sulfonamide; HR = hazard ratio; IRR = incidence rate ratio; NIOSH = National Institute for Occupational Safety and Health; NR = not reported; NS = not significant; OR = odds ratio; PFDA = perfluorodecanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; PFUnA = perfluoroundecanoic acid; RR = relative risk; RRE_pC = risk ratio episodes of care; SEER = Surveillance Epidemiology and End Results; SIR = standardized incidence ratio; SMR = standardized mortality ratio

1 year and allowed to recover for an additional year. A discussion of the relevance of the rodent carcinogenicity data to humans is included in Section 2.20.6.

EPA (2016e, 2016f) has concluded that there is suggestive evidence of the carcinogenic potential of PFOA and PFOS in humans. IARC (2017) concluded that PFOA is possibly carcinogenic to humans (Group 2B).

PFOA

Epidemiological Studies. Several studies have examined the possible association between occupational exposure to PFOA and increased cancer risk in workers at two U.S. facilities—3M facility in Cottage Grove, Minnesota (Gilliland and Mandel 1993; Lundin et al. 2009; Raleigh et al. 2014) and DuPont Washington Works facility in West Virginia (Leonard 2006; Leonard et al. 2008; Steenland and Woskie 2012; Steenland et al. 2015). In addition, the potential carcinogenicity of PFOA has been assessed in the community near the Washington Works facility (Barry et al. 2013; Innes et al. 2014; Vieira et al. 2013) and in the general population (Bonefeld-Jorgensen 2011, 2014; Eriksen et al. 2009; Hardell et al. 2014).

Occupational exposure studies have not found increases in the risk of all cancer deaths (Gilliland and Mandel 1993; Leonard 2006; Leonard et al. 2008; Lundin et al. 2009; Raleigh et al. 2014; Steenland and Woskie 2012). The occupational exposure studies have consistently found no increases in the risk of pancreatic, liver, or respiratory tract cancers or deaths from these cancers (Leonard 2006; Leonard et al. 2008; Lundin et al. 2009; Raleigh et al. 2014; Steenland and Woskie 2012); a general population case-control study also found no associations between serum PFOA and pancreas or liver cancer (Eriksen et al. 2009). Additionally, two case-control studies did not find associations between serum PFOA levels and risk of breast cancer (Bonefeld-Jorgensen et al. 2011, 2014); a third case-control study found an association between serum PFOA and breast cancer (Wielsøe et al. 2017). Steenland et al. (2015) found an inverse association between estimated cumulative PFOA exposure and bladder cancer in workers; other studies have not found associations (Eriksen et al. 2009; Gilliland and Mandel 1993; Leonard 2006; Leonard et al. 2008; Raleigh et al. 2014; Steenland and Woskie 2012).

Some associations between PFOA and cancer effects have been observed, including prostate, kidney, and testicular cancers. Ten years of employment in the Chemical Division of the 3M Cottage Grove facility was associated with a 3.3-fold increase in the relative risk of prostate cancer mortality, as compared to no employment in PFOA production areas (Gilliland and Mandel 1993; data also reported in Gilliland 1992);

no increase in prostate cancer risk was observed when all workers in the Chemical Division were analyzed. The investigators noted that the prostate cancer findings are based on a small number of cases and could have resulted from chance or unrecognized confounding from exposure to other factors. An update of this study conducted by Lundin et al. (2009) did not find an increase in prostate cancer deaths in workers with definite PFOA exposure. When the cohort was divided into the three exposure categories and duration of definite exposure, increased risks for prostate cancer were found in the high-exposure category and in workers with definite exposure for at least 5 years, as compared with workers in the low-exposure category and with the shortest cumulative exposure duration, respectively. Interpretation of the Gilliland and Mandel (1993) and Lundin et al. (2009) studies is limited by the qualitative assessment of potential exposure and the fact that workers in the low exposure categories were likely research-and-development professionals rather than production workers (Raleigh et al. 2014). In the most recent evaluation of the Cottage Grove facility, which involved extensive exposure assessment, Raleigh et al. (2014) did not find increases in prostate cancer deaths when compared to the general population or to workers at another facility and did not find an increase in the incidence of prostate cancer when the workers were categorized by cumulative exposure levels. Studies of the Washington Works facility workers did not find increases in prostate cancer deaths (Leonard et al. 2008; Steenland and Woskie 2012) or incidence (Steenland et al. 2015). A case-control general population study by Hardell et al. (2014) did find an increase in prostate risk only among subjects with a heredity risk (first-degree relative with prostate cancer) and serum PFOA levels above the median. In a study of community members, Ducatman et al. (2015b) did not find an association between prostate-specific antigen (PSA) levels and serum PFOA levels in men 20–49 or 50–69 years of age.

In the earliest cancer assessment of workers at the Washington Works facility (Leonard 2006; Leonard et al. 2008), an increase in the number of deaths from kidney cancer relative to workers at other regional DuPont facilities was observed; however, the CI included unity. In a follow-up study that used serum PFOA levels collected in current workers to assess job title exposure (Steenland and Woskie 2012), an increase in kidney cancer deaths was observed in workers with the highest exposures when analyzed with no lag, a 10-year lag, or a 20-year lag. Steenland and Woskie (2012) also found an increase in deaths from mesothelioma; the investigators noted that this was likely due to asbestos exposure. Steenland and Woskie (2012) noted that tetrafluoroethylene, a rodent kidney carcinogen, is used in the manufacture of a variety of fluoropolymers and noted that the tetrafluoroethylene is well controlled due to its volatile and explosive properties. It is noted that in a multisite study of tetrafluoroethylene workers, which included workers at the Washington Works facility (Consonni et al. 2013), an increased risk of renal cancer (SMR 1.44, 95% CI 0.69–2.65) was found, although the CI included unity. Consonni et al. (2013) noted that

88% of the workers were also exposed to PFOA. When PFOA exposure was used as an exposure variable, the findings were the similar as when tetrafluoroethylene was used as the exposure variable, and thus, it was difficult for the investigators to evaluate separate associations for each compound. It is noted that increases in kidney deaths were not observed in the Cottage Grove facility (Raleigh et al. 2014), which did not use tetrafluoroethylene (Chang et al. 2014).

Three studies have examined the community living near the Washington Works facilities; some of these studies also included workers at the facility. Barry et al. (2013) reported an increased risk of testicular cancer that was associated with estimated cumulative PFOA exposure. Vieira et al. (2013) also reported an increase in testicular cancer, but the CIs of the adjusted odds ratio (AOR) included unity. When the participants were grouped by water district, an increased risk of testicular cancer (AOR 5.1, 95% CI 1.6–15.6) was observed in the Little Hocking water district, which had the highest PFOA levels in the water. The Vieira et al. (2013) study also found increased risks of kidney cancer among participants with high or very high exposure to PFOA; Barry et al. (2013) also concluded that there was an association between estimated cumulative PFOA exposure and kidney cancer, although the CIs for the hazard ratio included unity. The third study of the Washington Works community found an inverse association between serum PFOA and risk of colorectal cancer (Innes et al. 2014).

In their review of the available epidemiological data, IARC (2017) concluded that the evidence for testicular cancer was "considered credible and unlikely to be explained by bias and confounding, however, the estimate was based on small numbers." Similarly, IARC (2017) concluded that the evidence for kidney cancer was also credible but noted that chance, bias, and confounding could not be ruled out with reasonable confidence. They considered that there was limited evidence in humans for the carcinogenicity of PFOA.

Laboratory Animal Exposure Studies. Two studies have examined the carcinogenic potential of PFOA in rats. In the first study of male and female Sprague-Dawley rats exposed to PFOA in the diet for 2 years (3M 1983; Butenhoff et al. 2012c), significant increases in the incidence of fibroadenoma of the mammary gland in females and Leydig cell adenoma were found in males exposed to 15 mg/kg/day. A high incidence of pituitary adenoma occurred among all groups, including controls. The incidence of hepatocellular carcinoma was not significantly increased. The investigators noted that the incidence of fibroadenoma in the mammary gland in the 15 mg/kg/day group was similar to the incidence found in untreated aging rats and that the incidence of Leydig cell adenoma was similar to the spontaneous incidence of this tumor in aged rats. The mammary gland pathology slides from this study (3M 1983;

Butenhoff et al. 2012c) study were re-examined in 2005 by a Pathology Working Group (PWG) using current diagnostic criteria (Hardisty et al. 2010). The incidences of fibroadenoma found by the PWG were 36, 44, and 46% in the 0, 1, and 15 mg/kg/day groups, respectively; there were no statistically significant differences between the groups (Hardisty et al. 2010). Additionally, there were no significant differences in the incidence of adenocarcinoma, total benign neoplasms, or total malignant neoplasms between the groups. In the second study of male Sprague-Dawley rats exposed to PFOA in the diet for 2 years (Biegel et al. 2001), an increase in the incidence of hepatocellular adenomas was found, but there were no hepatocellular carcinomas in the treated group. PFOA also increased the incidence of Leydig cell adenomas. In addition, PFOA increased the incidence of pancreatic acinar cell adenomas; a pancreatic carcinoma was observed in one treated rat. Hepatic peroxisome proliferation was increased significantly at all interim evaluation time points (1, 3, 6, 9, 12, 15, 18, and 21 months), but there was no increase in cell proliferation. In Leydig cells, neither peroxisome proliferation nor cell proliferation were increased.

PFOA was a positive modulator of hepatocarcinogenesis in male Wistar rats in a biphasic (initiation with diethylnitrosamine followed by oral treatment with PFOA) or triphasic (initiation with diethylnitrosamine [DEN] followed by dosing with 2-acetylaminofluorene and then PFOA) promotion protocol (Abdellatif et al. 1991, 2004). PFOA induced a marked increase in acylCoA oxidase activity and only a slight increase in catalase activity (Abdellatif et al. 2004). Since PFOA did not significantly increase 8-hydroxy-deoxyguanosine (a marker of oxidative DNA damage *in vivo*) in isolated liver DNA, it appeared that PFOA did not require extensive DNA damage for its promoting activity (Abdellatif et al. 2004). PFOA was also found to act as a promoter in male Wistar rats in an initiation-selection-promotion protocol (Nilsson et al. 1991).

IARC (2017) concluded that there was limited evidence in experimental animals for the carcinogenicity of PFOA.

PFOS

Epidemiological Studies. Four studies have evaluated the carcinogenic potential in workers at a Decatur, Alabama perfluorooctanesulphonyl fluoride (PFOSF) based fluorochemical production facility. In the earliest study, no increase in all cancer deaths was found, as compared to the Alabama general population (Alexander et al. 2003). An increased risk of bladder cancer was observed in workers with high potential exposure and in workers with a high potential exposure for ≥1 year; the mortality ratio was based on three

cases in the high exposure group. In a reanalysis of workers at this facility conducted by Alexander and Olsen (2007), 11 cases of bladder cancer were identified from worker surveys (n=6) and death certificates (n=5). Only two of the six self-reported bladder cancer diagnosis were confirmed via medical records; the other four subjects declined to give consent for medical verification. When compared to incidence data from the National Institute for Occupational Safety and Health (NIOSH) Surveillance Epidemiology and End Results (SEER) referent data, the standardized incidence ratios for the high potential exposure group were elevated, but the CIs included unity. When compared with workers with <1 year of high exposure, workers with 5–<10 and ≥10 years of high exposure had relative risks of 1.92 (95% CI 0.30–12.06) or 1.52 (95% CI 0.21–10.99). Although the study did not adjust for smoking, the investigators noted that 83% of the living bladder cancer cases (five of the six subjects) reported cigarette use, as compared to 56% reported in the noncases. An additional limitation of the study is inclusion of four cases of bladder cancer that were not verified by medical records. The results of this study do not appear to confirm the findings of increased bladder cancer in the mortality study (Alexander et al. 2003). In a subsequent study of this facility, treatment for bladder cancer was not reported among current workers (Olsen et al. 2004a). The study did find increases in the number of episodes of care for malignant neoplasm of the prostate or malignant neoplasms of the colon, as compared to long-term workers in another division, but the CIs included unity. No increases in the risk ratio episodes of care were found for liver, rectum, or respiratory tract (Olsen et al. 2004a). A fourth study of this facility (Grice et al. 2007) examined possible associations between colon cancer, melanoma, and prostate cancer and PFOS exposure. The risks of these cancers were not associated with any of the PFOS-exposure categories for analyses that included all self-reported or only validated cancers.

General population case-control studies have evaluated several cancer types. Innes et al. (2014) reported an inverse association between PFOS and colorectal cancer. A small-scale study of 31 cases by Bonefeld-Jorgensen et al. (2011) found a slight increase in breast cancer risk, a finding not replicated in another larger study of a different population (Bonefeld-Jorgensen et al. 2014). A third case-control study found associations between serum PFOS and breast cancer in subjects with serum PFOS levels in the second tertile and higher (Wielsøe et al. 2017). Eriksen et al. (2009) and Hardell et al. (2014) did not find increases in the risk of prostate cancer associated with serum PFOS. However, an increased risk of prostate cancer was found among subjects with a first-degree relative with prostate cancer and PFOS levels above the median level (Hardell et al. 2014). Eriksen et al. (2009) also found no associations between serum PFOS and the risk of bladder cancer, pancreatic cancer, or liver cancer. Ducatman et al. (2015b) did not find an association between serum PFOS levels and PSA levels in men participating in the C8 studies.

Laboratory Animal Studies. In a 2-year PFOS dietary exposure study bioassay in male and female Sprague-Dawley rats (Butenhoff et al. 2012b; unpublished study by Thomford 2002b), a significant positive trend of hepatocellular adenoma was observed in males; the incidence was significantly higher than controls at 1.04 mg/kg/day. No hepatocellular adenomas were seen in a group of rats exposed to 1.17 mg/kg/day for 1 year and allowed to recover for the second year. High-dose males from the recovery group showed a significant increase in thyroid follicular cell adenoma relative to controls. No significant increase in this type of tumor was observed in rats exposed for 2 years. In females, there was a significant positive trend for incidences of hepatocellular adenoma, which was associated with a significant increase in the 1.04 mg/kg/day group. In females, there were also significant negative trends for mammary adenoma and fibroadenoma carcinoma combined.

PFHxS

Epidemiological Studies. Three case-control studies have examined the possible association between serum PFHxS and cancer. Bonefeld-Jorgensen et al. (2014) found in inverse association between PFHxS levels and breast cancer risk. In contrast, Wielsøe et al. (2017) found a positive association between serum PFHxS levels and breast cancer risk. No association between PFHxS and prostate cancer was observed (Hardell et al. 2014), with the exception of increased risk in men with a first-degree relative with prostate cancer and above-median serum PFHxS levels. No associations between serum PFHxS and PSA levels were observed in a cross-sectional study of men 20–49 or 50–69 years of age participating in the C8 Health Studies (Ducatman et al. 2015b).

PFNA

Epidemiological Studies. The carcinogenic potential of PFNA has been examined in three case-control studies. No consistent associations between serum PFNA levels and breast cancer (Bonefeld-Jorgensen et al. 2014; Wielsøe et al. 2017) or prostate cancer (Hardell et al. 2014) were found. Serum PSA levels were not associated with serum PFNA levels in men participating in the C8 Health Study (Ducatman et al. 2015b).

PFDA

Epidemiological Studies. Hardell et al. (2014) examined the possible association between the serum PFDA level and risk of prostate cancer and only found an association in men with a heredity risk factor and PFDA levels above the median. In a case-control study of breast cancer, Wielsøe et al. (2017) found an association among women with serum PFDA levels in the third quartile.

PFUnA

Epidemiological Studies. An increased risk of prostate cancer was found in men with first-degree relatives with prostate cancer and serum PFUnA levels above the median (Hardell et al. 2014). An increased breast cancer risk was found in women with serum PFUnA levels in the third quartile (Wielsøe et al. 2017).

PFHpA

Epidemiological Studies. One study evaluated possible associations between serum PFHpA and cancer risk and found no association for breast cancer (Wielsøe et al. 2017).

PFDoDA

Epidemiological Studies. In the only cancer study for PFDoDA, Wielsøe et al. (2017) did not find an increased risk of breast cancer in women associated with serum PFDoDA levels.

FOSA

Epidemiological Studies. Bonefeld-Jorgensen et al. (2014) reported an increased risk of breast cancer among women with serum FOSA levels >5.75 ng/mL.

2.20 MECHANISM OF TOXICITY

The primary effects observed in rodents exposed to perfluoroalkyls are liver toxicity, developmental toxicity, and immune toxicity. The cellular mechanisms by which hepatic effects are induced have been extensively studied, while more limited data are available on mechanisms for other effects. The available

data indicate that perfluoroalkyls produce a number of adverse effects through activation of the PPARα, a member of the nuclear receptor superfamily that mediates a broad range of biological responses (Issemann and Green 1990). However, some adverse effects of perfluoroalkyls occur through PPARα-independent mechanisms, which may include activation of other nuclear receptors, increased oxidative stress, dysregulation of mitochondrial function, and inhibition of gap junction intercellular communication (GJIC). In the sections below, cellular mechanisms of action that are mediated by PPARα and independent of PPARα are discussed, followed by discussions of mechanisms specific to the hepatic, developmental, immunotoxic, and hormone effects of perfluoroalkyls.

2.20.1 Cellular Mechanisms of Toxicity

PPARα-Dependent Mechanisms

Activation of the PPARα receptor in rodents initiates a characteristic sequence of morphological and biochemical events, principally, but not exclusively, in the liver. These events include marked hepatocellular hypertrophy due to an increase in number and size of peroxisomes, a large increase in peroxisomal fatty acid β oxidation, increased cytochrome 450-mediated ω hydroxylation of lauric acid, and alterations in lipid metabolism. Although there is uncertainty regarding the exact and possibly, multiple mechanisms for liver effects of perfluoroalkyls, peroxisome proliferation mediated by PPARα is a contributing mechanism. Proliferation of peroxisomes in laboratory animals exposed to perfluoroalkyls is discussed in Section 2.9 (Hepatic); as discussed in that section, hepatic peroxisome proliferation has been shown in rats exposed to PFOA and in mice exposed to PFDA.

Many, but not all, of the adverse effects induced by perfluoroalkyls in rodents are mediated through activation of the PPARα. Ligands, including perfluoroalkyls, bind to and activate PPARα, causing a conformational change in the receptor that leads to dissociation of co-repressors and enables heterodimerization with the retinoid X receptor (Corton et al. 2014). The activated receptor complex binds to a DNA direct repeat motif (the peroxisome proliferator response element or PPRE) located in the promoters of peroxisome proliferator responsive genes. The binding of the receptor complex leads to recruitment of co-activators, which acetylate histones and remodel chromatin, enabling RNA polymerase to transcribe the target gene(s). PPARα regulates lipid homeostasis by modulating the expression of genes involved in fatty acid uptake, activation, and oxidation. Activation of nuclear receptors including PPARα is a complex, dynamic process that depends on levels of expression of the receptors in different

tissues, competition among receptors for endogenous and exogenous ligands and for binding sites on chromatin, and availability and abundance of co-activators and/or co-repressors (Corton et al. 2014).

PPARα Receptor Activation. Many perfluoroalkyls, including PFOA, PFOS, PFUnA, PFHpA, and PFDoDA have been shown to activate PPARα in mammalian cells *in vitro* (Bjork and Wallace 2009; Bjork et al. 2011; Shipley et al. 2004; Takacs and Abbott 2007; Vanden Heuvel et al. 2006; Wolf et al. 2008b, 2012). Cell systems used in these studies include COS-1 cells expressing mouse, rat, or human PPARα, and cultured rat, mouse, and human hepatocytes. In these studies, perfluoroalkyl sulfonate compounds were less potent than perfluoroalkyl carboxylate compounds in activating PPARα-induced gene expression, and the potency of stimulation within each class increased with carbon chain length (Bjork and Wallace 2009; Wolf et al. 2008b, 2012). In comparison with naturally occurring long-chain fatty acids such as linoleic and α linoleic acids, PFOA and PFOS are relatively weak ligands for PPARα (Vanden Heuvel et al. 2006)

PPARα-Dependent Gene Expression Changes. Perfluoroalkyls have been shown to induce changes in the expression of genes under the regulation of PPARα. The expression of PPARα target genes in the liver involved in fatty acid metabolism, cell cycle control, peroxisome biogenesis, and proteasome structure and organization were upregulated, while inflammatory response genes in the liver were downregulated in wild-type mice exposed orally to PFOA or the PPARα agonist WY-14,643 (Rosen et al. 2008a). Furthermore, PFOA and PFDA have been shown to downregulate, via PPARα activation, genes involved in bile transport in the livers of wild-type mice exposed by intraperitoneal administration (Cheng and Klaassen 2008a). Both compounds decreased expression of organic anion transporting polypeptides [*OATP1a1*, *1a4,* and *1b2*], and PFDA also downregulated sodium-taurocholate cotransporting polypeptide [*Nctp*], via activation of PPARα. Many of these expression changes may play roles in the hepatic effects of perfluoroalkyls.

Gene expression changes induced by perfluoroalkyls have been extensively studied in experiments aimed at determining the extent to which the adverse effects of these compounds are dependent on activation of PPARα or interaction with other nuclear receptors (Foreman et al. 2009; Rosen et al. 2008a, 2008b, 2010, 2017). These studies, comparing gene expression changes in wild-type and PPARα-null mice exposed to perfluoroalkyls, demonstrate the following:

- A majority of the gene expression changes induced in rodents by perfluoroalkyls tested to date, especially PFOA and PFNA, are dependent on activation of PPARα.

- Perfluoroalkyls also induce gene expression changes that are independent of PPARα.
- The extent to which gene expression changes induced by perfluoroalkyls are dependent on activation of PPARα varies by compound.

Species Differences in PPARα Activation. Species differences in response to PPARα activators have been reviewed by Corton et al. (2014). Studies of PPARα activation by structurally diverse ligands in various species have shown that rats and mice are the most sensitive species to PPARα agonists, whereas guinea pigs, hamsters, nonhuman primates, and humans are less responsive (Corton et al. 2014). However, the differences do not appear to result from differences in the PPARα gene itself: PPARα cDNA from humans is indistinguishable from the rodent PPARα. Species differences in response to exogenous PPARα activators may stem from any or all of the following: (1) differences in the expression of PPARα in a given tissue; (2) differences in the gene product structure; and (3) differences in the ligand-mediated transactivation of PPARα. Experiments quantifying mRNA and/or protein levels of PPARα show ~10-fold higher expression of PPARα in the livers of mice and rats compared with humans and guinea pigs, but available data are limited and require further study to validate these differences (Corton et al. 2014). In humans, variants of PPARα that may affect its transactivation potential have been identified. For example, humans produce higher levels of a truncated PPARα (that lacks a ligand binding domain) compared with mice and rats (Corton et al. 2014). The truncated form appears to inhibit the activity of the full-length receptor, possibly via sequestering critical co-activators. Other, non-truncated variants of PPARα have been identified in humans, but the sensitivity of these variants to PPARα activators does not differ markedly from that of the wild-type receptor.

Species and compound-related differences in PPARα transactivation by perfluoroalkyls have been demonstrated *in vitro* (Shipley et al. 2004; Takacs and Abbott 2007; Vanden Heuvel et al. 2006; Wolf et al. 2008b, 2012). In a comparison of human and mouse PPARα transactivation by different perfluoroalkyls in transfected COS-1 cells, Wolf et al. (2008b, 2012; see Table 2-28) found that some perfluoroalkyls exhibited marked species differences in transactivation potency (for example, PFUnA, PFDA, PFDoDA), while other compounds showed similar transactivation potency for both human and mouse PPARα (for example, PFNA, PFOA, perfluoropentanoic acid [PFPeA]).

Table 2-28. Transactivation of Human and Mouse PPARα in Transfected Cos-1 Cells Exposed to Perfluoroalkyls (In Order of Decreasing C_{20max} in the Mouse)

		Human		Mouse		C_{20max} (μM)[a]	
Perfluoroalkyl	Carbon number	NOEC (μM)	LOEC (μM)	NOEC (μM)	LOEC (μM)	Human	Mouse
PFNA	9	1	5	1	5	11	5
PFOA[b]	8	5, 0.5	10,1	0.5, 1	1, 3	7	6
PFUnA	11	50	75	5	10	86	8
PFHpA	7	<0.5	0.5	3	5	15	11
PFDA	10	100	>100[c]	<5	5	–	20
PFDoDA	12	75	90	3	5	NA	33
PFPeA	5	0.5	1	1	5	52	45
PFHxA	6	5	10	10	20	86	45
PFBA	4	30	40	30	40	75	51

In addition to differences in transactivation of PPARα, Corton et al. (2014) noted that there are species differences in the transcripts controlled by PPARα. While PPARα activation leads to hypolipidemic changes in both humans and laboratory rodents, the gene sets responsible for these changes may differ. In a comparison between human and mouse hepatocytes exposed to the prototypical PPARα ligand WY-14,643, some genes (ACOX1, ECH1, PEX11A, and ACAA1) were induced in both species, while some (*Ehhadh*, *Pxmp4*, *Acot4*, and *Peci*) were induced only in mouse hepatocytes (Corton et al. 2014). Importantly, PPARα activators induce large increases in the expression of fatty acyl-CoA oxidase (ACO, which is believed to play a role in oxidative stress-induced liver cancer) in rodent hepatocytes, but relatively weak increases in human hepatocytes (Corton et al. 2014). Other hypothesized explanations for the species difference in response to exogenous PPARα ligands include variations in the structure of the

PPRE that alter the response of the human genes compared with rodents; differences between humans and rodents in the functions of genes under the regulation of PPARα; and differences in the ability of ligand-bound human and mouse PPARα receptor complex to recruit or interact with co-activators (Corton et al. 2014).

PPARα-Independent or Associative Mechanisms

Experiments using PPARα-null mice have demonstrated that perfluoroalkyls exert some adverse effects, including developmental and hepatic effects, through mechanisms other than activation of PPARα. These may include activation of other nuclear receptors, increased oxidative stress, dysregulation of mitochondrial function, and inhibition of GJIC. While some of these effects have been seen after exposure to PPARα activators (Corton et al. 2014), these mechanisms may also occur independent of PPARα activation.

Activation of Other Nuclear Receptors. Examination of gene expression changes, as well as studies using other knock-out mice, have shown that some of the PPARα-independent effects induced by perfluoroalkyls may be mediated by activation of other nuclear receptors, especially PPARγ, CAR, and ERα. In a series of experiments, Rosen et al. (2008b, 2010, 2017) compared the gene expression changes induced by perfluoroalkyls in wild-type and PPARα -null mice with gene expression changes induced by known agonists of PPARγ, CAR, and ERα. Using these data, the study authors estimated the percentage of gene expression changes that were independent of activation of PPARα, and identified other nuclear receptors potentially involved in the changes induced by the perfluoroalkyls. The results, summarized in Table 2-29, show that between 10 and 24% of gene expression changes induced by perfluoroalkyls are independent of PPARα. All four compounds tested (PFOA, PFOS, PFNA, and PFHxS) were shown to alter the expression of PPARγ- and CAR-regulated genes in PPARα-null mice, and PFNA and PFHxS also altered the expression of ERα-regulated genes in the knock-out mice. In contrast, none of the compounds altered the expression of genes commonly affected by an agonist of LXR in either wild-type or null mice.

Table 2-29. Gene Expression Changes Induced by Perfluoroalkyls

	Dose (mg/kg/day for 7 days)	% PPARα-independent gene changes	Gene expression changes similar to those induced by prototypical agonist							
			PPARγ		CAR		ERα		LXR	
			WT	PPARα-null	WT	PPARα-null	WT	PPARα-null	WT	PPARα-null
PFOA	3	~14	+	+	+	+	+	–	–	–

+ = significant ($p<0.0001$) similarity to gene expression changes induced by prototypical receptor agonist as assessed by running Fisher test; +/– = equivocal evidence; CAR = constitutive androstane receptor; ER = estrogen receptor; LXR = liver X receptor; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; PPAR = peroxisome proliferator activated receptor; WT = wild-type

Sources: Rosen et al. 2017, 2008b, 2013; Wolf et al. 2008b

Gene expression changes typical of CAR and PXR activators (phenobarbital and pregnenolone 16 α-carbonitrile [PCN]) were also observed in rat liver after oral exposure to PFOA and PFOS (Ren et al. 2009). In addition, PFDA was shown to activate CAR-dependent genes in a study comparing wild-type and CAR-null mice exposed by intraperitoneal injection (Cheng and Klaassen 2008b).

These data suggest that perfluoroalkyls may induce gene expression changes through activation of other nuclear receptors including PPARγ, CAR, and ERα. Support for these findings are available from *in vitro* studies demonstrating binding and/or transactivation of PPARγ, CAR, and ERα by perfluoroalkyls. Both PFOA and PFOS activated PPARγ in cultured human, mouse, and rat hepatocytes, albeit with much lower potency than the known agonist rosiglitazone; neither LXRβ nor RXRα was activated in this system (Vanden Heuvel et al. 2006). Zhang et al. (2014) observed binding of PFOA and PFOS to human PPARγ in transfected *Escherichia coli*. However, in experiments conducted by Takacs and Abbott (2007), neither PFOA nor PFOS activated the mouse or human PPARγ.

Oxidative Stress. Perfluoroalkyls increase oxidative stress in the liver, kidney, and brain. Increases in oxidative stress may be mediated in part via PPARα activation, but may also result from activation of the Nrf2 receptor (Xu et al. 2016).

Oxidative stress may contribute to oxidative DNA damage, tumor promotion, perturbation of lipid homeostasis, and stimulation of inflammation, among other changes; thus, increases in oxidative stress can have diverse physiological effects. Evidence that perfluoroalkyls increase oxidative stress is available from *in vivo* and *in vitro* studies. For example, oxidative DNA damage (measured as 8-OH-dG levels) was significantly increased in the liver, but not the kidneys, of male rats exposed to PFOA via feed for 2 weeks (Takagi et al. 1991). In HepG2 cells cultured with PFOA or PFOS, significant increases in reactive oxygen species (ROS) (measured as 2'7'-dichlorofluorescein diacetate fluorescence) were observed, but there was no evidence of DNA damage measured with the comet assay (Eriksen et al. 2010). In this system, PFNA, PFBS, and PFHxA did not induce ROS production, but a significant increase in DNA damage was seen in cells exposed to PFNA (Eriksen et al. 2010).

In male, but not female, KM mouse pups administered a single subcutaneous injection of PFOS at 1, 2, 3, 4, or 5 weeks of age, brain total antioxidant capacity (T-AOC) was lower than controls at most time points, and significantly decreased after treatment on PND 21 (Liu et al. 2009). In the liver, T-AOC was decreased in male pups treated on PNDs 7 and 14, and in females treated on PND 21. Significant decreases in superoxide dismutase (SOD) activity were noted in the brain of males treated on PNDs 7 and 21, and in the liver of females treated on PND 14.

Increases in oxidative stress can lead to NFκB activation (Corton et al. 2014). NFκB activation plays a role in tumorigenesis, and NFκB transcription factors coordinate immune responses. Few studies have examined NFκB activation after exposure to perfluoroalkyls. An increase in NFκB mRNA level was seen in the hippocampus of neonatal rats exposed to PFOS *in utero* (Zeng et al. 2011). In addition, NFκB nuclear translocation was accelerated, and NFκB was activated, in breast cancer cells exposed to PFOA (Zhang et al. 2014). The activation of NFκB was associated with increased invasiveness of the breast cancer cells, as coexposure to an inhibitor of NFκB reduced the invasiveness induced by PFOA.

Gap Junction Intercellular Communication (GJIC) Inhibition. Perfluoroalkyls also have been shown to inhibit GJIC both *in vivo* and *in vitro* in rats (Corton et al. 2014). GJIC plays an important role in maintenance of tissue homeostasis, intercellular transmission of regulatory signals, and metabolic cooperation. Disruption of GJIC is thought to be involved in neurological, reproductive, and endocrine

abnormalities, as well as in carcinogenesis (Corton et al. 2014; EPA 2016h). There are limited data examining the effects of perfluoroalkyls on GJIC. The available studies showed that both PFOA and PFOS inhibited GJIC in the livers of rats exposed via diet for 1 week or 3 or 21 days, respectively (Hu et al. 2002; Upham et al. 1998, 2009). *In vitro* studies in WB-344 rat liver epithelial cells also showed inhibition of GJIC after exposure to PFOS (Hu et al. 2002) and to perfluorinated fatty acids with 7–10 carbons (Upham et al. 1998, 2009). In this system, PFOA activated extracellular receptor kinase, which may play a role in the inhibition of GJIC. In addition, inhibition of phosphatidylcholine-specific phospholipase C partially mitigated the GJIC inhibition, suggesting that PFOA-induced activation of this enzyme may also be involved in GJIC inhibition (Upham et al. 1998, 2009).

PFOS was also shown to inhibit GJIC in dolphin kidney epithelial cells and rat Sertoli cells *in vitro* (Hu et al. 2002; Wan et al. 2014a). In Sertoli cells, GJIC plays an important role in maintenance of the blood:testes barrier and in intercellular communication during spermatogenesis (EPA 2016i).

Impaired Mitochondrial Function. Mitochondrial function, including cellular respiration as well as mitochondrial membrane potential, has been shown to be perturbed by perfluoroalkyls. Available data suggest that PFOA and PFOS are relatively weak mitochondrial toxicants (EPA 2016h, 2016i). Mitochondrial proliferation was observed in rats exposed orally to PFOA for 28 days and in mice exposed to PFOA during gestation and lactation (Quist et al. 2015a, 2015b; Waters et al. 2009). In isolated rat liver mitochondria, higher concentrations of either PFOA or PFOS were noted to slightly increase resting respiration rate and decrease membrane potential, possibly due to these compounds' effects on membrane fluidity (Starkov and Wallace 2002). Testing of other perfluoroalkyls for effects on mitochondrial respiration rate and oxidative phosphorylation showed a wide range of inhibitory activities, with PFOS demonstrating the highest potency (3-fold higher than PFOA and 20–30-fold higher than PFBS and PFHxA) (Wallace et al. 2013).

2.20.2 Hepatic Toxicity Mechanisms

Hepatic effects of perfluoroalkyls in rodents likely result from a combination of PPARα-dependent and independent changes; see Table 2-30. For example, increased liver weight has been observed in both wild-type and PPARα-null mice orally exposed to PFOA or APFO (Nakagawa et al. 2012; Rosen et al. 2008a), PFOS (Qazi et al. 2009b; Rosen et al. 2010), PFNA (Das et al. 2017; Rosen et al. 2017), or PFHxS (Das et al. 2017; Rosen et al. 2017), but not in null mice exposed to PFBA by intraperitoneal injection (Foreman et al. 2009). Similarly, both wild-type and PPARα-null mice exposed to APFO

exhibited increased hepatocyte vacuolation and proliferation, while exposure to WY-14,643 did not induce such changes in the null mice (Wolf et al. 2008b). Das et al. (2017) showed that PFOA, PFNA, and PFHxS also increased hepatocyte cell size, percent lipid, and hepatic triglyceride levels, and decreased hepatic DNA content, in both wild-type and PPARα-null mice, while WY-14,643 did not, indicating that these effects were not dependent on PPARα activation. Similarly, Nakagawa et al. (2012) showed that at a lower APFO dose (1.0 mg/kg/day for 6 weeks), increases in hepatic triglyceride levels were observed in wild-type, PPARα-null, and humanized PPAR (hPPAR) mouse strains; however, at a higher dose (5 mg/kg/day), hepatic triglyceride levels were still increased in PPARα-null and hPPAR mice, but decreased in wild-type mice.

Table 2-30. Hepatic Effects of Perfluoroalkyls in Wild-Type and PPARα-Null Mice Exposed Orally

		↑ Relative liver weight		↑ % Lipid by cell area		↑ Hepatic triglycerides		↑ Hepatocyte cell size		↓ Hepatic DNA content	
	Dose (mg/kg/day)	WT	PPARα-null	WT	PPARα-null	WT	PPARα-null	WT	PPARα-null	WT	PPARα-null
PFOA	3	+++	+++	+++	-	+++	-	+++	+++	+	+
PFOS	10	++	++	ND							
PFNA	1	++	+	ND							
	3	+++	++								
	10	+++	+++	+++	+++	+++	+++	+++	++	+	+
PFHxS	3	+	+	ND							
	10	+++	+++	+++	+++	+++	–	+++	+++	+	+
WY-14,643[a]	50	+++	–	+++	–	–	–	+++	–	+	–

[a]WY-14,643 is a PPARα agonist.

+ = statistically significant change from control (the number of plus signs indicates degree of change from controls); – = not statistically significantly different from control; DNA = deoxyribonucleic acid; ND = no data; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; PPAR = peroxisome proliferator activated receptor; WT = wild type

Sources: Das et al. 2017; Rosen et al. 2008a, 2010, 2017

Lipid homeostasis is maintained through a balance between fatty acid synthesis or accumulation and fatty acid oxidation. Available data indicate that perfluoroalkyls affect both sides of this balance, but a growing body of evidence indicates that fatty acid accumulation induced by perfluoroalkyls tips the balance in favor of hepatic steatosis (Das et al. 2017). As discussed above, perfluoroalkyls alter lipid homeostasis via PPARα activation, which upregulates genes involved in fatty acid oxidation and reduces lipid levels. However, as noted above, Das et al. (2017) indicate that perfluoroalkyls also perturb lipid homeostasis via PPARα-independent mechanisms. In addition to the effects noted in Table 2-30, increased incidences of hepatic steatosis were seen in PPARα-null mice exposed to perfluoroalkyls (Das

et al. 2017; Minata et al. 2010; Nakagawa et al. 2012), but not in those exposed to the PPARα agonist WY-14,643 (Das et al. 2017). Additionally, microvesicular steatosis was observed in hPPAR mice (Nakagawa et al. 2012). The findings are consistent with earlier studies showing triglyceride accumulation in rodent livers after exposure to perfluoroalkyls (Kudo and Kawashima 1997, 2003; Kudo et al. 1999); hepatic steatosis and glucose intolerance in adult rats exposed to PFOS during the prenatal and postnatal periods (Lv et al. 2013); and inhibited hepatic secretion of VLDL, resulting in steatosis, in APOE3-Leiden mice (a rodent model with lipoprotein metabolism similar to humans) exposed to PFOS or PFHxS (Bijland et al. 2011).

Das et al. (2017) investigated whether the steatosis induced by PFOA, PFNA, and PFHxS was mediated by increased fatty acid or triglyceride synthesis or by inhibition of mitochondrial fatty acid transport or β-oxidation. Microarray analysis of mouse liver after exposure to these compounds showed upregulation of genes involved in fatty acid and triglyceride synthesis in both wild-type and PPARα-null mice. In contrast, *in vitro* experiments demonstrated that these perfluoroalkyls did not affect mitochondrial fatty acid oxidation in isolated rat liver mitochondria, and neither PFOA nor PFOS altered fatty acid oxidation in HepG2/C3A human liver cells. The authors suggested that perfluoroalkyls induce hepatic steatosis by perturbing lipid homeostasis in favor of the accumulation of fatty acids and triglycerides in the liver.

Data are also available to suggest that proinflammatory cytokines may also contribute to the hepatotoxicity of perfluoroalkyls. Studies in rodents have shown that *in vivo* exposure to PFOA (Qazi e al. 2013; Yang et al. 2014) or PFNA (Fang et al. 2012b, 2012c) have resulted in increases in IL-6, IL-1β, tumor necrosis factor-α (TNFα), C-reactive protein, and COX-2 at higher perfluoroalkyl doses (Fang et al. 2012b, 2012c; Yang et al. 2014) and decreases in TNFα, interferon-γ (IFN-γ), IL-4, and IL-6 levels at lower doses (Fang et al. 2012b; Qazi et al. 2013). Exposure to PFNA also resulted in increased expression of TNFα, IL-1β, and IL-6 mRNA (Fang et al. 2012b). Nakagawa et al. (2012) found increases in TNFα-mRNA in wild-type (2.9-fold), PPARα-null (1.9-fold), and humanized PPARα (1.9-fold) mouse strains exposed to 5 mg/kg/day doses of PFOA. Fang et al. (2012c) suggested that PFNA exposure stimulated liver Kupffer cells to release large amounts of TNFα and IL-1β and that the release of these cytokines activated the NFκB p65 pathway causing suppression of PPARα promoter activity and resulting in increases in liver triglyceride levels and steatosis.

2.20.3 Developmental Toxicity Mechanisms

Developmental effects observed in laboratory rodents exposed to perfluoroalkyls include prenatal loss, reduced neonate weight and viability, neurodevelopment toxicity, and delays in mammary gland differentiation, eye opening, vaginal opening, and first estrus (see Section 2.17 Developmental). During development, PPARα, PPARβ, and PPARγ mRNA and protein are expressed in the embryo of rodents and humans (Abbott 2009; Abbott et al. 2010). In humans, the fetal expression levels are equivalent to levels in adult tissues (Abbott et al. 2010). PPARα activation also appears to be involved in some, but not all, of the developmental effects of perfluoroalkyls in mice, and the role of PPARα in mediating developmental toxicity differs among the various compounds. For example, a gestational exposure study of PFOA resulted in decreases in postnatal survival in wild-type mice, but not in PPARα-null mice, while the occurrence of full-litter resorptions was similar between the two genotypes (Abbott 2009; Abbott et al. 2007). In contrast, gestational exposure to PFOS resulted in decreased pup survival in both wild-type and PPARα-null mice (Abbot et al. 2009). The developmental effects of PFNA, including reduced pup survival and body weight and delayed eye opening, were seen only in wild-type, and not in PPARα-null mice; however, maternal pregnancy rate was affected only in the null mice (Wolf et al. 2010). No alterations in postnatal survival or growth were observed in wild-type mice exposed to PFBA *in utero* (Das et al. (2008). The investigators suggested that the contrast of these findings to that of PFOA may be due to the shorter half-life of PFBA (daily administration did not result in reaching steady-state) and that PFBA is a less potent agonist of PPARα than PFOA.

Abbott et al. (2012) showed that PFOA altered expression of genes that are involved in homeostatic control of lipids and glucose, and postulated that decreased neonatal survival and body weights may be, in part, due to metabolic disruption. It has been suggested that PFOS interacts with pulmonary surfactants, and that this effect is responsible for neonatal mortality seen in rats. Grasty et al. (2003, 2005) showed that neonatal mortality in PFOS-exposed rats was highest when exposure occurred during the gestational period of lung maturation (GDs 17–20), and that the morphometry of the lungs in exposed neonates was consistent with immaturity. However, treatment of neonates with rescue agents that hasten lung maturation did not prevent neonatal mortality induced by PFOS, and examination of the pulmonary surfactant profile in exposed animals showed no difference from controls, leading Grasty et al. (2005) to conclude that neonatal mortality in neonatal rats exposed to PFOS was not due to immaturity. Other hypotheses pertaining to the mechanisms of developmental toxicity of perfluoroalkyls were not located. However, other molecular- and cellular-level effects of perfluoroalkyls, including increased oxidative

stress, dysregulation of mitochondrial function, and receptor-mediated events, may be involved in the observed developmental effects of these compounds.

2.20.4 Immunotoxicity Mechanisms

NTP (2016b) conducted a systematic review of the human, animal, and *in vitro* data examining immunotoxic effects of PFOA and PFOS. The conclusion of the systematic review was that both PFOA and PFOS are "presumed to be immune hazards to humans." Evidence was considered strong that both compounds were associated with suppression of the antibody response, while there was weaker evidence for PFOA-induced impairment of infectious disease resistance, increased hypersensitivity-related outcomes, and increased autoimmune disease incidence, and for PFOS-induced suppression of natural killer cell activity. A recent study comparing the T-cell dependent antibody response (TDAR) in female wild-type and PPARα knock-out mice after exposure to PFOA with or without antigen exposure showed that PFOA suppressed TDAR in both wild-type and knock-out mice, indicating that the mechanism for antibody response suppression is independent of PPARα activation (DeWitt et al. 2016). These investigators observed no treatment-related changes in splenic lymphocyte subpopulations in exposed mice of either genotype, suggesting that PFOA suppressed TDAR via impairment of B-cell/plasma cell function rather than by altering lymphocyte numbers. DeWitt et al. (2012) and Corsini et al. (2014) reviewed mechanistic data for perfluoroalkyl-induced suppression of antibody response, and postulated that perfluoroalkyls may modulate cell-signaling responses critical to antibody production, including c-Jun, NF-κB, and IL-6.

2.20.5 Endocrine Mechanisms

Perfluoroalkyls have been shown to induce alterations in thyroid hormone levels in rats, and associations between serum perfluoroalkyl concentrations and thyroid hormone levels have been reported in human epidemiological studies (see Section 2.13). Few data examining mechanisms of thyroid hormone disruption are available, but suggest that effects of perfluoroalkyls on thyroid function may be mediated by binding to the thyroid hormone receptor, and/or by altering expression of genes involved in thyroid function or thyroid hormone regulation. Several perfluoroalkyls were shown to bind to the human thyroid hormone receptor in cultured GH2 cancer cells and in molecular docking experiments (Ren et al. 2015). In the *in vitro* tests, all 16 of the tested compounds exhibited lower affinity for the receptor than T3 (Ren et al. 2015). Among the tested compounds, PFOS exhibited the strongest agonist activity (Ren et al. 2015). Alterations in the mRNA or protein levels of thyroid-regulating genes have been observed after oral exposure of male Sprague-Dawley rats to PFOS. PFOS exposure for 5 or 90 days resulted in

decreased hepatic levels of mRNA type 1 deiodinase (DIO1, which bioactivates T3 by deiodination of T4) (Martin et al. 2007; Yu et al. 2009a); after 5 days of exposure, hepatic mRNA for type 3 deiodinase (DIO3, which inactivates T3) was increased relative to controls (Martin et al. 2007). After 90 days, hepatic levels of uridine diphosphoglucuronosyl transferase 1A1 (UGT1A1, which plays a role in T4 turnover) mRNA and thyroid levels of DOI1 protein were increased, while there were no changes in thyroid levels of the sodium iodide symporter, thyrotropin (THS) receptor, or activity of thyroid peroxidase (Yu et al. 2009a).

Limited data from *in vitro* studies suggest the possibility that perfluoroalkyls may interact with the estrogen and androgen receptors. PFOA, PFOS, PFHxS, PFNA, and PFDA were all shown to be antagonists of the androgen receptor, while PFOA, PFOS, and PFHxS induced transactivation of the estrogen receptor (Kjeldsen and Bonefeld-Jorgensen 2013). Recently, analysis of gene expression data from the livers of wild-type and PPARα-null mice exposed to PFOA, PFOS, PFHxS, and PFNA by gavage for 7 days indicated similarities to gene expression changes induced by known ERα agonists (Rosen et al. 2017), providing indirect evidence for perfluoroalkyl changes in the liver mediated via ER activation. However, at oral doses up to 1 mg/kg, PFOA failed to induce treatment-related alterations in uterine weight, ER-dependent gene expression, or morphology of reproductive organs in uterotrophic assays using immature CD-1 mice (Dixon et al. 2012; Yao et al. 2014), suggesting that PFOA is either inactive *in vivo* or of very low estrogenic potency.

2.20.6 Cancer Mechanisms

PFOA induced hepatocellular adenomas, Leydig cell adenomas, and pancreatic acinar cell adenomas in rats (Biegel et al. 2001). Liver tumors induced by PFOA are believed to be mediated largely through PPARα activation, and considered to be of limited or no relevance to humans (EPA 2016h), based on species differences in response to PPARα (see details above under PPARα activation). An expert panel convened by EPA's Science Advisory Board in 2006 to review issues related to the toxicity of PFOA agreed that the weight of evidence supports the hypothesis that induction of liver tumors in rats by PFOA is mediated by a PPARα agonism mode of action (EPA 2006); this conclusion is also reflected in the EPA Health Effects Support Document for PFOA (EPA 2016h). A recent review by a panel of experts from academia, government, industry, and consulting groups updated the Klaunig et al. (2003) assessment of PPARα agonism as a liver cancer mode of action, and drew the same conclusion: while the PPARα mode of action for liver tumors is biologically plausible, species differences in response to PPARα activation indicate that liver tumors are unlikely to be induced by PPARα induction in humans (Corton et al. 2014).

Studies conducted in rainbow trout, an animal model that is similar to humans in terms of insensitivity to peroxisome proliferators, suggest that some perfluoroalkyls may induce liver cancer by alternate mechanisms (Benninghoff et al. 2011, 2012). The investigators (Benninghoff et al. 2011) found that PFOA, PFNA, PFDA, and PFUnA were potent inducers of vitellogenin, an estrogen-responsive biomarker protein at fairly high doses. Neither PFOA nor PFDA exposure resulted in vitellogenin expression at serum levels corresponding to general population serum levels of 2–7 ng/L. *In vitro*, PFOA, PFOS, PFHpA, PFNA, PFUnA, and PFDA also had weak to very weak affinities for estrogen receptors (ERα) for several species including humans, mice, and rats (Benninghoff et al. 2011). *In vivo* studies demonstrated that PFOA, PFOS, PFNA, and PFDA enhanced liver carcinogenesis in AFB_1 initiated fish via a mechanism that likely involves interactions with hepatic estrogen receptors (Benninghoff et al. 2012).

Although Leydig cell tumors are commonly induced by peroxisome proliferating agents such as perfluoroalkyls, the mode of action by which these tumors are induced, and thus their relevance to humans, is much less clear (Corton et al. 2014; EPA 2016h; Klaunig et al. 2003). One mode of action proposed for the induction of Leydig cell tumors involves PFOA-induced inhibition of testosterone biosynthesis, leading to increased production of gonadotropin releasing hormone and circulating LH, which promotes Leydig cell proliferation. Activation of PPARα may be involved in the decreased serum testosterone levels; PPARα-null mice did not exhibit the reduction in testosterone concentration seen in wild-type mice exposed to PFOA (Li et al. 2011). Evidence of decreased serum testosterone and increased serum estradiol was seen in studies of male rats exposed orally to PFOA for 14 days (Biegel et al. 1995; Cook et al. 1992; Liu et al. 1996). Reduced testosterone levels may occur through the conversion of testosterone to estradiol via the enzyme aromatase. Hepatic aromatase activity was shown to be markedly increased in male rats exposed to APFO by gavage for 14 days, and aromatase activity was positively correlated with serum estradiol levels in these animals (Liu et al. 1996). The relevance of Leydig cell tumors induced by PFOA to human risk assessment is uncertain. For example, an intermediate-duration study in Cynomolgus monkeys exposed to PFOA did not find treatment-related alterations in serum estradiol, estrone, estriol, or testosterone (Butenhoff et al. 2002). Studies of humans occupationally exposed to PFOA have not consistently reported alterations in estradiol or testosterone levels (Klaunig et al. 2012). In addition, humans are less sensitive than rats to LH stimulation, and the average number of LH receptors per Leydig cell is 13-fold higher in rats than humans (Klaunig et al. 2012). In summary, the induction of Leydig cell tumors by PFOA may be mediated by effects on aromatase activity or testosterone biosynthesis, both of which may be related to PPARα activation (EPA

2016h). While the relevance of the PPARα mode of action to humans is uncertain, the data supporting this mode of action for Leydig cell tumors is not sufficient to rule out human relevance (EPA 2016h).

The mechanism of PFOA-induced pancreatic acinar cell tumors in rodents has not been elucidated, and relevant data are limited. A proposed mode of action involves stimulation of PPARα leading to reduced bile flow and/or changes in bile acid composition with subsequent increase in cholecystokinin (CCK), which stimulates pancreatic cell proliferation and tumor formation (EPA 2016h). Effects on bile acid composition induced by PFOA may be mediated by effects on bile acid transporters. PFOA exposure has been shown to decrease expression of OATPs and increase expression of MRP3 and MRP4 (Cheng and Klassen 2008a; Maher et al. 2008). In a study using wild-type and PPARα-null mice, increased biliary excretion of PFOA was seen in wild-type mice compared with null mice, and biliary excretion of bile acids was highest in the null mice (Minata et al. 2010). These observations suggest the possibility that increased excretion of PFOA could diminish the excretion of bile acids that require the same transporters. However, given the limitations in available data, information is insufficient to fully characterize the mode of action for PFOA-induced pancreatic tumors (EPA 2016e).

Mechanisms of carcinogenicity of PFOA are unknown. Liver and Leydig cell tumors produced by PFOS may be associated with PPARα activation or may involve other mechanisms. PFOS activates PPARβ/δ, γ, and CAR and PXR (Ren et al. 2009).

2.21 GENOTOXICITY

The genotoxicity of perfluoroalkyls has not been extensively studied, with the most information available for PFOA and PFOS. To supplement the information reported in the published literature, results of unpublished studies taken from publicly available reviews have been included in the following discussions. No studies of genotoxicity in humans exposed to perfluoroalkyls were located.

PFOA

The genotoxicity of PFOA has been examined in bacterial and mammalian *in vitro* systems and in mammalian *in vivo* assays. In general, results show that PFOA can produce DNA damage, but is not mutagenic at noncytotoxic concentrations.

Results of *in vitro* studies in bacteria show that PFOA induces DNA damage but is not mutagenic. DNA damage was observed in *Paramecium caudatum* following exposure to 100 μM for 12 and 24 hours (Kawamoto et al. 2010). Intracellular ROS was significantly increased but DNA damage was not reversed by the application of glutathione, a ROS inhibitor, indicating that intracellular ROS may not be the cause of PFOA-induced DNA damage. PFOA was not mutagenic in *Salmonella typhimurium* TA1535/pSK1002 (*hisG46, rfa, uvrB*) with or without metabolic activation using the *umu* test (Oda et al. 2007) or in *S. typhimurium* TA98, TA100, TA102, and TA104 strains with or without metabolic activation using an Ames assay (Fernández Freire et al. 2008). Butenhoff et al. (2014) and Kennedy et al. (2004) summarized the results of various unpublished mutagenicity studies with PFOA showing negative results in reverse mutation assays using *S. typhimurium* (strains TA98, TA100, TA1535, TA1537, and TA1538), *Saccharomyces cerevisiae*, and *Escherichia coli* (WP2uvrA strain) with or without metabolic activation.

In vitro genotoxicity assays in mammalian cells show that PFOA induced DNA damage, although conflicting results have been reported for mutagenicity and increased micronuclei formation. Incubation of human hepatoma HepG2 cells with 50–400 μM PFOA caused DNA strand breaks and 100–400 μM increased the incidence of micronuclei, in a dose-related manner in both cases (Yao and Zhong 2005). These effects were accompanied by a significant increase in ROS, which the investigators suggested caused the DNA damage. Bjork and Wallace (2009) measured mRNA expression for DNA damage inducible *Ddit3* to assess DNA damage in primary rat and human hepatocyte cultures and in HepG2/C3a hepatoma cells. Significant increases in mRNA transcription for *Ddit3* were found in primary rat hepatocytes at 100 μM PFOA and in primary human hepatocytes and HepG2/C3a hepatoma cells at 200 μM PFOA. Although both studies provide evidence of DNA damage, the tested concentrations were very high as compared to what could be expected to occur in the environment. A significant increase in mutation frequencies was observed in hamster-human hybrid cells exposed to 200 μM PFOA for 1–16 days; a 79% decrease in cell viability was also observed at this concentration (Zhao et al. 2011). Concurrent treatment with a ROS inhibitor significantly decreased mutations, indicating that ROS may play an important role in mediating the genotoxic effects of PFOA. In contrast, Butenhoff et al. (2014) and Kennedy et al. (2004) summarized the results of various unpublished mutagenicity studies with PFOA. In mammalian cells, PFOA was negative for forward mutations using Chinese hamster ovary cells, for chromosomal aberrations in Chinese hamster ovary cells and human lymphocytes, and for cell transformation in C3H 10T1/2 cells.

Results of *in vivo* exposure of laboratory animals show that PFOA induced DNA damage, but not micronuclei formation. Administration of a single intraperitoneal injection of 100 mg/kg PFOA to male Fischer-344 rats resulted in a significant increase in the levels of 8-hydroxydeoxyguanosine (a marker of oxidative DNA damage) in liver DNA, but not in kidney DNA (Takagi et al. 1991). Oral administration of approximately 20 mg/kg/day PFOA in the diet for 2 weeks to male Fischer-344 rats induced hepatomegaly and increased the levels of 8-hydroxydeoxyguanosine in liver DNA but not in kidney DNA (Takagi et al. 1991). Unpublished studies summarized by Butenhoff et al. (2014) and Kennedy et al. (2004) did not find increased micronuclei formation in mice orally exposed to PFOA.

PFOS

The genotoxicity of PFOS has been examined in bacterial and mammalian *in vitro* systems and in mammalian *in vivo* assays. However, compared to PFOA, less information is available. Results do not provide evidence for genotoxicity of PFOS, except for one *in vitro* study showing cell transformation and one report of increased micronuclei formation following *in vivo* exposure.

Results of *in vitro* studies in bacteria and mammalian cells show that PFOS did not induce DNA damage, mutagenicity or chromosome damage. In bacterial cell assays, as reviewed by OECD (2002), PFOS did not induce reverse mutations in *S. typhimurium* or *E. coli* with or without metabolic activation. A study published after this review also found that PFOS was not mutagenic in *S. typhimurium* TA1535/pSK1002 (*hisG46, rfa, uvrB*) with or without metabolic activation using the *umu* test (Oda et al. 2007).

In vitro genotoxicity assays of PFOS in mammalian cells were negative for DNA damage, mutagenicity, micronuclei formation, and chromosome damage, although one *in vitro* study reported cell transformation. PFOS did not result in DNA damage in Syrian hamster embryo cells at concentrations up to 50 µg/mL but did induce cell transformation at noncytotoxic concentrations (0.2 and 2 µg/mL) following 5 and 24 hours of exposure (Jacquet et al. 2012). Similarly, PFOS did not induce DNA damage or increased micronuclei formation in human hepatoma HepG2 cells following a 24-hour exposure to PFOS concentrations as high as 600 µM; cytotoxicity was observed at ≥300 µM (Florentin et al. 2011). Another study of with HepG2 cells did not find evidence of DNA damage at concentrations of 100 and 400 µM PFOS (Eriksen et al. 2010). As summarized by OECD (2002), PFOS did not induce chromosomal aberrations in human lymphocytes with or without metabolic activation and did not induce unscheduled DNA synthesis in primary cultures of rat hepatocytes.

Conflicting results have been reported on micronuclei formation following *in vivo* exposure to PFOS. Micronuclei frequency was increased and the ratio of polychromatic erythrocytes to normochromatic erythrocytes was decreased in bone marrow of rats following oral exposure to 0.6–2.5 mg/kg PFOS for 30 days (Celik et al. 2013; Eke and Celik 2016). As summarized by OECD (2002), PFOS did not induce micronuclei in the bone marrow of CD-1 mice in an *in vivo* assay.

Other Perfluoroalkyls

Little information is available on the genotoxicity of other perfluoroalkyl compounds, with available studies focused on DNA damage. No DNA damage was found in HepG2 cells incubated with 100 or 400 μM PFHxS or PFBS for 24 hours, although a "modest" increase in DNA damage was observed at 400 μM PFNA, a cytotoxic concentration (Eriksen et al. 2010). Oral administration of approximately 10 mg/kg/day PFDA in the diet for 2 weeks to male Fischer-344 rats induced hepatomegaly and also increased the levels of 8-hydroxydeoxyguanosine in liver DNA but not in kidney DNA (Takagi et al. 1991). In contrast, no DNA damage in liver or kidney was observed following administration of a single intraperitoneal injection of 100 mg/kg PFBA to male Fischer-344 rats (Takagi et al. 1991).

CHAPTER 3. TOXICOKINETICS, SUSCEPTIBLE POPULATIONS, BIOMARKERS, CHEMICAL INTERACTIONS

3.1 TOXICOKINETICS

Toxicokinetic data on perfluoroalkyls examined in this profile are available from studies in humans and animals. Most studies in animals administered perfluoroalkyls by the oral route. These data are briefly summarized below.

- Absorption
  - Perfluoroalkyls are absorbed following oral, inhalation, and dermal exposure.
  - Quantitative estimates of the fractional absorption of orally administered perfluoroalkyls in animals range from >50% for PFHxS to >95% for PFOA, PFBA, PFNA, PFDA, PFUnA, and PFDoDA.
  - No quantitative estimates of the fractional absorption of perfluoroalkyls following inhalation or dermal exposure were identified.
- Distribution
  - Perfluoroalkyls are widely distributed in the body, with the highest concentrations in the liver, kidneys, and blood.
  - In the blood, perfluoroalkyls bind to albumin and other proteins.
  - Perfluoroalkyls can be transferred to the fetus during pregnancy and to nursing infants.
- Metabolism
  - Results of available oral and *in vitro* studies suggest that perfluoroalkyls are not metabolized and do not undergo chemical reactions in the body.
  - Although no studies examining metabolism of perfluoroalkyls following inhalation or dermal exposure were identified, metabolism by these exposure routes is not expected.
- Excretion
  - Studies of elimination rates (i.e., half-lives) of perfluoroalkyls show that elimination $t_{1/2}$ values are similar following intravenous, intraperitoneal, and oral exposures. Findings suggest that the route of absorption has no substantial effect on rates of elimination of absorbed perfluoroalkyls.
  - Perfluoroalkyls are primarily eliminated in the urine, with smaller amounts eliminated in feces and breast milk.

- Perfluoroalkyls undergo biliary excretion, but substantial reabsorption occurs; therefore, biliary excretion is not a major elimination pathway.
- Rates of elimination of perfluoroalkyls vary substantially across chemical species and animal species, and show sex differences and age-dependencies within certain species.
- In general, perfluoroalkyl sulfonates are eliminated more slowly than perfluoroalkyl carboxylates; elimination rate decreases with increasing chain length, and increases with increased branching.
- In humans, estimates for elimination $t_{1/2}$ range from hours (PFBA: 72–81 hours) to several years (PFOA: 2.1–8.5 years; PFOS: 3.1–7.4 years; PFHxS: 4.7–15.5 years).
- Evidence for sex differences in elimination of perfluoroalkyls in humans is not as strong as in rats. Menstruation may contribute to faster elimination of PFOS in younger women (≤50 years) when compared to men and older women.

3.1.1 Absorption

Inhalation Exposure. Studies of the absorption of perfluoroalkyls in humans following inhalation exposure were not located; elevated serum concentrations of perfluoroalkyls in workers in fluorochemical production industry have been reported (see Table 5-22), indicating that perfluoroalkyls are absorbed following inhalation exposure. Occupational exposures in these workers are likely to have included inhalation of aerosols of perfluoroalkyls complexed with airborne dusts. Higher serum levels in workers compared to the general population (see Table 5-20) probably reflect a predominant contribution from inhaled perfluoroalkyls.

Studies conducted in rodents provide direct evidence for absorption of inhaled perfluoroalkyls. PFOA was detected in plasma of rats within 30 minutes of initiating nose-only exposures to aerosols (mass median aerodynamic diameter [MMAD]=1.9–2.1 μm) of 1–25 mg ammonium PFOA/m^3. Plasma concentrations increased during the 6-hour exposure, with the highest concentrations observed at 9 hours (3 hours after cessation of exposure) in male rats and at 7 hours (1 hour after cessation of exposure) in females (Hinderliter et al. 2006a). Assuming an elimination $t_{1/2}$ of absorbed PFOA of approximately 160 hours in male rats, a peak plasma concentration at 9 hours would correspond to an absorption $t_{1/2}$ of approximately 1.3 hours (see discussion below, Equations 3-1 and 3-2). The earlier time of highest plasma concentration observed in female rats appears to be associated with faster elimination of absorbed PFOA in female rats, compared to male rats (see Section 3.1.4).

Nose-only exposure of male rats to dusts of ammonium perfluorononanoate induced significant increases in absolute and relative liver weight, assessed 5 and 12 days after exposure, providing indirect evidence of absorption of this compound through the respiratory airways (Kinney et al. 1989).

Oral Exposure. Studies of absorption of perfluoroalkyls through the gastrointestinal tract in humans are not available. A study of the general population of Europe and North America estimated that the greatest portion of the chronic exposure to PFOS and PFOA results from the intake of contaminated food, including drinking water (Trudel et al. 2008). Direct evidence of oral absorption of perfluoroalkyls was provided in studies that found associations between environmental levels (e.g., drinking water) and perfluoroalkyl concentrations in human serum (Emmett et al. 2006a; Hoffman et al. 2011; Hölzer et al. 2008; Seals et al. 2011; Wilhelm et al. 2008) and by reductions in serum levels after exposures from water were eliminated or reduced (Bartell et al. 2010; Emmett et al. 2009).

Animal data provide quantitative estimates of the fractional absorption of orally administered PFOA, PFOS, PFBA, PFHxA, PFHxS, PFHpA, PFNA, PFDA, PFUnA, and PFDoDA, with estimates ranging from >50% for PFHxS to >95% for PFOA, PFBA, PFNA, PFDA, PFUnA, and PFDoDA. Greater than 95% of an oral dose of ammonium [^{14}C]PFOA was absorbed in rats that received single gavage doses ranging from 0.1 to 25 mg/kg (Kemper 2003). In male and female mice, comparison of the 24-hour area under the curve (AUC) for oral and intravenous administration showed that 90–100% of the oral dose was absorbed for PFOA (females), PFNA (males and female), PFDA (males and females), PFUnA (males and females), and PFDoDA (males and female); however, absorption of PFOA in males was 80%, compared to 100% in females (Fujii et al. 2015a, 2015b). Gannon et al. (2011) estimated an absorption fraction of 99% based on 168-hour urinary excretion of ^{14}C in male and female rats and mice following single oral doses of 2 or 100 mg/kg ^{14}C-PFHxA. Based on comparison of the AUC for oral and intravenous administration, the estimated oral absorption fractions were 50% in female rats administered a single 10 mg/kg dose of potassium [$^{18}O_{3-}$]PFHxS (Sundström et al. 2012) and 79 and 55% in male and female rats administered a single dose of 4 mg/kg sodium [$^{18}O_{3-}$]PFHxS (Kim et al. 2016b). Sundström et al. (2012) stated that this estimate may not be reliable due to the short (24 hours) observation period. Based on 72-hour urinary excretion of ^{14}C, the estimated fractional absorption of a single dose (50 mg/kg) of ^{14}C-PFHxA was approximately 74% in male rats, 90% in female rats, and 80% in male and female mice (Iwai et al. 2011). A comparison of ^{14}C disposition in rats, mice, hamsters, and rabbits following an oral dose of 10 mg ammonium [^{14}C]PFOA/kg showed that similar fractions of the dose were absorbed (Hundley et al. 2006). The estimated absorbed fractions (i.e., ^{14}C in tissues, urine, and exhaled air measured 120–168 hours after the dose) in males were 89% in rats, 82% in mice, 92% in hamsters, and

88% in rabbits. Corresponding values for females were 76% in rats, 61%, in mice, 75% in hamsters, and 88% in rabbits. These estimates exclude ^{14}C excreted in feces, which may have been absorbed and secreted in bile before excretion (see Section 3.1.4). Fasting appears to increase absorption of PFOA. Plasma PFOA concentrations in rats, 24 hours following a gavage dose of 10 mg ammonium PFOA/kg, were 2–3 times higher when administered to fasted rats, compared to fed rats (Hinderliter et al. 2006b). The estimated absorption fractions of ingested ammonium [^{14}C]PFOA or potassium [^{14}C]PFOS (administered as a 4.2 mg/kg oral dose) were >93 and >95% in rats, respectively (Johnson and Ober 1979, 1999a). Based on combined urinary excretion and retention in the carcass (excluding the gastrointestinal tract and its contents), the estimated oral absorption fraction of [^{14}C]PFOS (administered as a single 4.2 mg/kg dose of potassium [^{14}C]PFOS) in male rats was >95% (Chang et al. 2012). The estimated absorption fraction of PFBA (administered as 30 mg/kg oral dose of PFBA) was >95% in rats (Chang et al. 2008a). Cumulative excretion of PFBA 24 hours after an oral dose (administered as 10, 30, or 100 mg/kg ammonium PFBA) was approximately 35% in urine and 4–11% in feces in male mice; and 65–69% in urine, and 5–7% in feces in female mice (Chang et al. 2008a).

Studies examining the rate of absorption of PFOA, PFHxA, PFBA, and PFBS show rapid absorption from the gastrointestinal tract, with values for absorption $t_{1/2}$ of <2 hours. For PFOA, the highest observed concentrations of ^{14}C in plasma occurred in male rats at approximately 10 hours (range 7.5–15 hours) following single oral doses ranging from 0.1 to 25 mg ammonium PFOA/kg (Kemper 2003). The elimination $t_{1/2}$ of ^{14}C in plasma estimated in these same animals was approximately 170 hours (range 138–202 hours), corresponding to an elimination rate constant (k_e) of 0.0044 hour^{-1} (range 0.004–0.005 hour^{-1}). The corresponding absorption $t_{1/2}$ of approximately 1.5 hours (k_a=0.45 hour^{-1}) can be calculated from these observations (Equations 3-1 and 3-2):

$$t_{\max} = \ln\frac{k_a}{k_e} \cdot \frac{1}{(k_a - k_e)} \qquad \text{Eq. (3-1)}$$

$$t_{1/2} = \frac{\ln(2)}{k_e} \qquad \text{Eq. (3-2)}$$

Where t_{max} = time of maximum concentration of ^{14}C; k_e = elimination rate constant; and k_a = absorption constant. The absorption rate of PFOA appears to be greater in female rats compared to male rats. The time to peak concentrations of ^{14}C in plasma occurred at approximately 1.1 hour (range 0.6–1.5 hours) in female rats and 10 hours (range 7–15 hours) in male rats following single oral doses ranging from 0.1 to 25 mg ammonium PFOA/kg (Kemper 2003). The elimination $t_{1/2}$ of ^{14}C in plasma estimated in these same animals varied with dose and ranged from 3.2 hours at the lowest dose (k_e=0.23 hour^{-1}) to 16.2 hours at the highest dose (k_e=0.059 hour^{-1}). The estimated absorption $t_{1/2}$ from the observations

made at all doses (0.1, 1, 5, and 25 mg/kg), based on Equations 3-1 and 3-2, was approximately 0.25 hours (range 0.12–0.38 hours). The absorption $t_{1/2}$ of PFBA in male and female rats following administration of a single oral dose (30 mg/kg ammonium PFBA) was 0.23 hours (3.04 $hour^{-1}$) in males and 0.17 hours (4.15 $hour^{-1}$) in females (Chang et al. 2008a). In male and female mice administered 10–30 mg/kg ammonium PFBA, the absorption $t_{1/2}$ was <1 hour, although the absorption rate may be dose-dependent in males, with higher absorption $t_{1/2}$ at doses >30 mg/kg (Chang et al. 2008a). Estimated t_{max} values following administration of single doses (2 or 100 mg/kg) of ^{14}C-PFHxA to rats and mice ranged from 0.3 to 0.8 hours (Gannon et al. 2011). Similar results for were reported by Olsen et al. (2009) based on estimated compartmental pharmacokinetic parameters for PFBS in serum of male and female rats following a single intravenous or gavage dose of 30 mg potassium PFBS. Plasma concentration-time profiles were fit to a two-compartment elimination model. The absorption $t_{1/2}$ can be approximated from these data using Equation 3-1, with the elimination rate constant represented by the fast-phase elimination rate constant estimated for either the oral or intravenous dose. Using the oral or intravenous parameters yielded similar values for the absorption $t_{1/2}$ (0.12–0.16 hours). The estimated t_{max} values following the gavage dose were 0.42 hours in males and 0.33 hours in females. The fast-phase elimination rate constants following the gavage dose were 0.892 $hours^{-1}$ ($t_{1/2}$=0.79 hours) in males and 1.308 $hours^{-1}$ ($t_{1/2}$=0.53 hours) in females. The corresponding values for absorption $t_{1/2}$ were 0.14 hours (k_a=5.0 $hours^{-1}$) in males and 0.12 hours (k_a=5.8 $hours^{-1}$) in females. Use of the fast-phase elimination rate constants estimated following intravenous administration (male: 1.143 $hours^{-1}$; female: 1.956 $hours^{-1}$) yielded values for the absorption $t_{1/2}$ of 0.16 hours in males (k_a=4.30 $hours^{-1}$) and females (k_a=4.45 $hours^{-1}$).

Mechanisms of oral absorption of perfluoroalkyls have not been elucidated.

Dermal Exposure. Dermal exposures of rats to ammonium PFOA have been shown to produce systemic (e.g., liver, immunotoxicity) toxicity in animals (see Chapter 2). Estimates of the amount or rates of dermal absorption in humans or animals have not been reported. PFOA was detected in serum of mice following dermal application of PFOA dissolved in acetone (Franko et al. 2012). The investigators noted PFOA ingestion may have occurred during grooming and may have contributed to the body burden. Dermal absorption of PFOS was assessed following application of single doses of potassium PFOS (doses up to 0.30 mg/kg) and the diethanolamine salt of PFOS (doses up to 20 µg/kg) to clipped, intact skin of rabbits (Johnson 1995a, 1995b). Analysis of the liver 28 days after application showed no increase in content of total organic fluoride compared to controls, indicating that dermal absorption was not detectable at low dose levels using this methodology. Dermal penetration of PFOA has been studied in preparations of isolated rat, mouse, and human epidermis (Fasano et al. 2005; Franko et al. 2012). These

studies indicate that the rat and mouse skin may be more permeable to PFOA than human skin. Approximately 24% of a dermal dose of PFOA (0.5 mg in 1% acetone) was absorbed across isolated full thickness human skin in 24 hours and 45% of the dose was retained in skin (Franko et al. 2012); it is noted that the acetone, as well as the glycerol used to pretreat the skin may have enhanced PFOA absorption. Permeability was sensitive to pH and was higher when the skin was buffered at pH 2.5 ($5.5x10^{-2}$ cm/hour) compared to pH 5.5 ($4.4x10^{-5}$ cm/hour), well above the pKa for the terminal carboxylic acid of PFOA (Franko et al. 2012). This suggests that permeability of the unionized acid is greater than that of the dissociated anion. Lower permeability of ionized PFOA is also suggested by relatively low permeability of the ammonium salt of PFOA in isolated preparations of rat and human skin. Following application of the ammonium salt of PFOA to isolated human or rat epidermis (150 μL/cm^2 of a 20% aqueous solution of ammonium PFOA; approximately 30 mg ammonium PFOA/cm^2), approximately 0.048% of the dose was absorbed across human epidermis and 1.44% was absorbed across rat epidermis in 40 hours. The estimated dermal penetration coefficients were $9.49x10^{-7}$ cm/hour in the isolated human epidermis and $3.25x10^{-5}$ cm/hour in the isolated rat epidermis.

The available data suggest that absorption of PFOA and PFOS through the skin is limited and is of minimal concern as an exposure route. No dermal absorption data were located for other perfluoroalkyls.

3.1.2 Distribution

Available information on the distribution of perfluoroalkyls is obtained from oral exposure studies in laboratory animals and occupational exposure studies in which exposure is predominantly by inhalation. Studies specifically examining the distribution of perfluoroalkyls by inhalation or dermal exposure were not identified. As discussed in Section 3.1.3 (Metabolism), perfluoroalkyls do not undergo metabolism. Therefore, distribution is expected to be the same regardless of the route of administration.

Distribution in Blood. In a study of 60 healthy Chinese participants from the general population, whole blood:plasma ratios for PFOS, PFOA, PFHxA, and PFHxS were 0.65, 0.83, 3.0, and 0.57 (Jin et al. 2016). These results indicate that PFHxA, but not PFOA, PFOS, or PFHxS, enters cellular components of blood. In a study of perfluoroalkyl workers, serum:plasma ratios for PFHxS, PFOS, and PFOA were 1:1, and this ratio was independent of the concentrations measured (Ehresman et al. 2007). The ratio of whole blood:plasma (or serum) was approximately one-half, which corresponded to volume displacement by red blood cells, suggesting that these perfluoroalkyls do not enter cellular components of blood. In studies conducted in animals, most of the PFOA in blood is in the plasma fraction. In rats, 24 or 48 hours

following an oral dose of 11.4 mg ammonium [^{14}C]PFOA/kg, the red blood cell:plasma PFOA concentration ratio ranged from 0.2 to 0.3, suggesting that there was no selective retention of PFOA by red blood cells (Johnson and Ober 1999a). Blood:plasma (or serum) ratios of approximately 0.5 have also been observed in rats following intravenous injection of PFOA (Kudo et al. 2007).

Perfluoroalkyls in plasma bind to serum albumin. The dissociation constant for binding of PFOA to serum albumin is approximately 0.4 mM (0.38 mM, ±0.04 standard deviation [SD] for human serum albumin; 0.36 mM, ±0.08 SD for rat serum albumin) and involves 6–9 binding sites (Han et al. 2003). Given a dissociation constant (K_D) of 0.4 mM and an albumin concentration of approximately 0.6 mM, >90% of PFOA in serum would be expected to be bound to albumin when the serum concentration of PFOA is <1 mM (<440 mg/L). This is consistent with observations of the bound fraction of perfluoroalkyls in plasma of rats that received a gavage dose of 25 mg PFOA/kg (Han et al. 2003, 2005; Ylinen and Auriola 1990), and in human, rat, and monkey plasma incubated *in vitro* with perfluoroalkyls (e.g., PFHxA, PFOA, PFOS, PFNA, PFDA) (Kerstner-Wood et al. 2003; Ohmori et al. 2003). Comparison of dissociation constants for binding of PFOA and PFOS to human serum albumin indicates that PFOS (K_D: $8x10^{-8}$) has a higher binding affinity than PFOA (K_D: $1x10^{-4}$) for albumin, consistent with the longer $t_{1/2}$ of PFOS versus PFOA in humans (Beesoon and Martin 2015; see Section 3.1.4 for additional information). PFOS has also been shown to bind to human hemoglobin *in vitro* (Wang et al. 2016). PFBS was found to bind only to albumin, whereas PFOS, PFOA, and PFHxS were found to have the potential to bind to other human serum binding proteins, including plasma gamma-globulin, alpha-globulin, alpha-2-macroglobulin, transferrin, and beta-lipoproteins (Kerstner-Wood et al. 2003).

Distribution to Extravascular Tissues. Absorbed perfluoroalkyls distribute from plasma to soft tissues, with the highest extravascular concentrations achieved in liver. An analysis of samples from human cadavers attempted to quantify PFOA, PFOS, FOSA, and PFHxA concentrations in serum and liver (Olsen et al. 2003c). The route of exposure was unknown. Mean serum PFOS concentration was 17.7 ng/mL (95% CI 13.0–22.5, range of <6.9 [limit of quantification] to 57 ng/mL, n=24) and was not different in males (18.2 ng/mL, n=13) and females (17.2 ng/mL, n=11). The mean liver concentration was 18.8 ng/g (95% CI 14.1–23.5; range <7.3–53.8 ng/g, n=30). The mean liver:serum concentration ratio was 1.3 (95% CI 0.9–1.7, n=23) and was not different in males (1.3, n=13) and females (1.3, n=10). Most liver and serum concentrations for PFOA, FOSA, and PFHxA were below the limit of quantification; these limits were <17.9–<35.9 ng/mL for PFOA, <7.5–<19.6 ng/g for FOSA, and <3.4–<18.5 ng/mL for PFHxA.

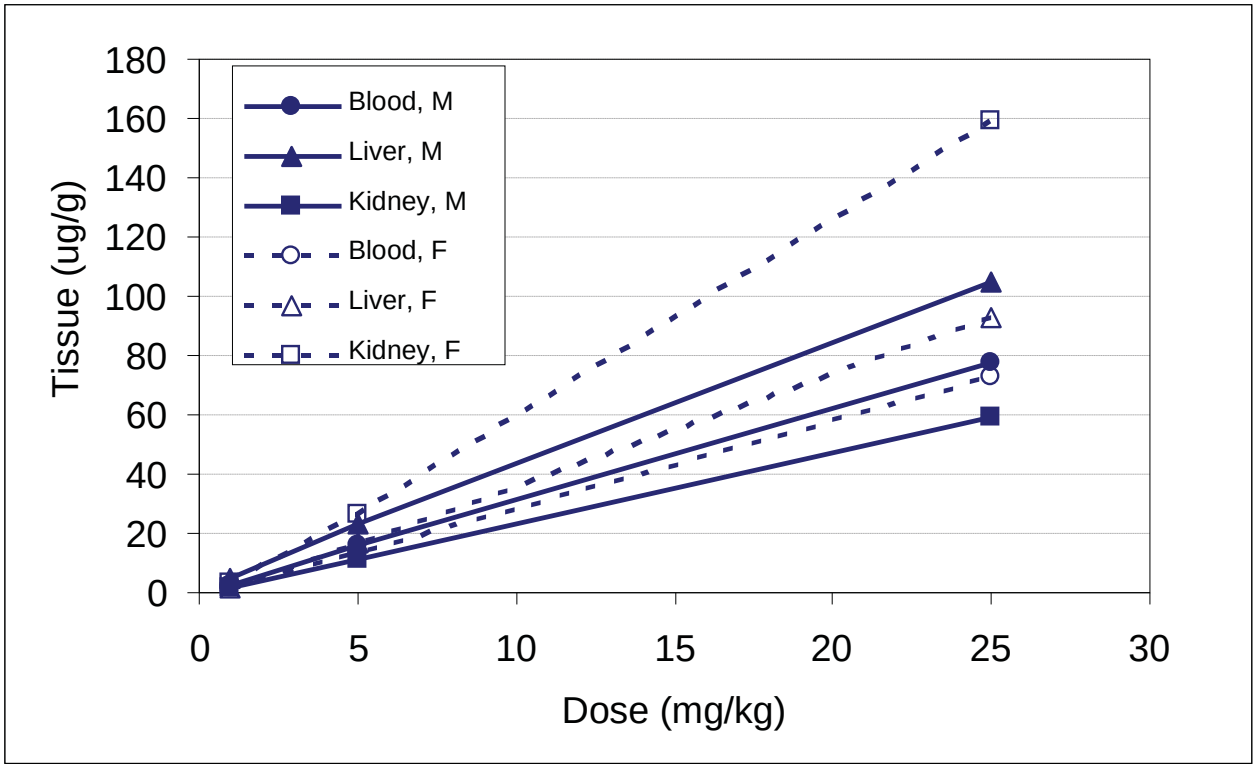
Studies conducted in nonhuman primates and rodents have provided additional information on the distribution of absorbed perfluoroalkyls to extravascular tissues. Distribution, as assessed from tissue perfluoroalkyl concentrations and tissue:serum ratios, exhibits profound species and sex differences as well as dose-dependencies (e.g., tissue levels that change disproportionately with dose). These differences have been attributed, in part, to species and sex differences in elimination kinetics of absorbed perfluoroalkyls and dose-dependence of elimination kinetics (see Section 3.1.4). In general, a consistent finding across species is that the liver receives a relatively high fraction of the absorbed dose and may also experience relatively high tissue concentrations compared with other tissues, with blood (i.e., plasma) and kidney also showing relatively high concentrations. The most extensive investigations of tissue distribution have been conducted in rodents.

Bogdanska et al. (2011) examined distribution of ^{35}S following dietary exposure to adult male C57/BL6 mice to low (environmentally relevant; 0.031 mg/kg/day) and high (experimentally relevant; 23 mg/kg/day) doses of [^{35}S]PFOS for 1–5 days. For both low and high doses after 1, 3, and 5 days of exposure, ^{35}S was distributed to the following tissues: blood, liver, lung, kidney, skin, whole bone, pancreas, spleen, thymus, heart, testes, epididymal fat, fat pads, brain, and muscle; ^{35}S was also detected in tissues throughout the gastrointestinal tract. Similar tissue:blood ratios were observed in both dose groups. In low-dose animals after 5 days of treatment, the highest tissue concentrations (excluding the gastrointestinal tract) were liver (tissue:blood=5.8), followed by lung (tissue:blood=1.4), whole bone, including marrow (tissue:blood=1.1), blood, and kidney (tissue:blood=0.94). In high-dose animals, the highest tissue concentrations were liver (tissue:blood=3.6), followed by lung (tissue:blood=1.6), blood, kidney (tissue:blood=0.81), and whole bone, including marrow (tissue:blood=0.72). A similar pattern of distribution was observed following intravenous administration of [^{14}C]potassium PFOS (4.2 mg/kg) to male rats (Johnson and Ober 1980). For both dose groups, the tissue:blood ratios for all other tissues were <1. In male and female CD-1 mice administered a single oral dose (4.2 mg/kg) of [^{14}C]PFOS, the highest concentrations of ^{14}C was observed in the liver, followed by serum, and then kidney, with similar tissue levels observed in males and females (Chang et al. 2012). In male and female rats fed diets containing 0, 2, 20, 50, or 100 mg/kg [^{13}C]sodium PFOS (equivalent to 0, 0.14, 1.33, 3.21, and 6.34 and 0, 0.15, 1.43, 3.73, and 7.58 mg/kg/day in males and females, respectively) for 28 days, PFOS levels were highest in liver, followed by spleen, heart, and serum. Liver:serum ratios for the 2, 20, 50, and 100 mg/kg/day diets were approximately 52, 42, 41, and 35, respectively, in males and 30, 47, 20, and 23, respectively, in females (Curran et al. 2008). Except for rats fed diets containing 20 mg/kg, the liver:serum ratio in males was higher than in females. No additional data were reported to determine if PFOS distribution differed between male and female rats.

Kemper (2003) determined the distribution of ^{14}C in male and female rats at the approximate time of maximum plasma concentration in both sexes, following single gavage doses of [^{14}C]PFOA (as ammonium PFOA, 0.1–25 mg/kg). This design allows a more direct comparison of patterns of tissue distribution in male and female rats at similar plasma concentrations, even though the elimination kinetics in the female rat are substantially faster than in male rats (see Section 3.1.4). The highest concentrations of ^{14}C were observed in blood, liver, and kidney (Figure 3-1). Liver, blood, and kidney accounted for approximately 22, 22, and 2% of the administered dose of 1 mg/kg in male rats; and 6, 7, and, 3% in female rats (the sex difference reflected more rapid excretory elimination in females). Although blood, liver, and kidney concentrations appeared to increase proportionately with increasing dose in male rats, in female rats, a disproportionately higher concentration in kidney was observed following the 25 mg/kg dose (Figure 3-1). Concentrations in other tissues ranged from 0.1 to 0.25 of that in liver or kidney; concentrations in bone and fat were <0.1 of that in liver or kidney. Profound sex differences and dose-dependencies in tissue concentrations of PFOA were also observed in rats that received oral doses of PFOA for 28 days at doses of 3, 10, or 30 mg PFOA/kg/day (Ylinen et al. 1990; Figure 3-2). Mean serum, kidney, or liver concentrations did not increase proportionally with dose in either sex. Kidney concentrations exhibited a disproportionate increase as the dose increased from 3 to 10 mg/kg/day, with little further increase at the 30 mg/kg/day dose. Sex differences in tissue distribution of PFOA in rats are not explained by sex differences in bioavailability since the differences persist in animals that received parenteral doses of PFOA (Johnson and Ober 1999b; Vanden Heuvel et al. 1991b, 1991c). The differences have been attributed to more rapid elimination of PFOA in female rats, compared to male rats (see Section 3.1.4).

A comparison of PFOA disposition in rats, mice, hamsters, and rabbits showed pronounced species and sex differences (Hundley et al. 2006; Table 3-1). In this study, rats, mice, hamsters, or rabbits received an oral dose of 10 mg ammonium [^{14}C]PFOA/kg and ^{14}C in tissues was measured at 120 or 168 hours (rabbits) hours post-dosing. In male rats, the highest concentrations of ^{14}C occurred in blood, liver and kidney, and all tissues combined accounted for approximately 60% of the dose. However, in female rats, concentrations of ^{14}C in all tissues were below limits of quantification. In mice, liver concentrations were similar in males and females, and liver showed the highest concentrations; ^{14}C levels in all tissues combined were lower in females compared to males. The opposite pattern was evident in hamsters and rabbits, with males having lower tissue levels than females, although, in common with rats and mice,

Figure 3-1. Tissue Concentrations of ^{14}C in Male and Female Rats Following a Single Gavage Dose of [^{14}C]PFOA at 1, 5, or 25 mg/kg*



*Tissue levels are measured at time of maximum concentration in each tissue.

[a]The rabbits were sacrificed 168 hours after dosing; all other animals were sacrificed 120 hours after dosing.
[b]The µg equivalent calculations were based on the specific activity of ^{14}C-labeled APFO, which was 1.1×10^6 DPM/mg. The µg equivalent per g wet weight could not accurately be determined below 0.1 µg/g.
[c]Represents the µg equivalents for the entire organ.

APFO = ammonium perfluorooctanoate

Source: Hundley et al. 2006

blood, liver and kidney had the highest concentrations. Male rats that received a single oral dose of 5 mg FOSA/kg had liver FOSA concentrations that were 3–5 times higher than serum concentrations 1 day post-dosing (Seacat and Luebker 2000).

Sex differences in elimination that give rise to sex differences in tissue levels following oral exposure to perfluoroalkyls in rats are not evident in studies conducted with nonhuman primates. Rhesus monkeys that received 3 or 10 mg ammonium PFOA/kg/day for 90 days had liver concentrations of 48 µg/g (one male) or 50 µg/g (one female) at the low dose and 45 µg/g (one male) and 72 µg/g (one female) at the higher dose, with corresponding serum concentrations of 3 and 7 µg/mL, and 9 and 10 µg/mL, respectively (Griffith and Long 1980). Although limited to only one animal per sex, these results suggest

that liver levels did not increase proportionately with increasing dose. A similar observation was made in a study of male Cynomolgus monkeys (Butenhoff et al. 2004c). In male monkeys that received daily oral doses of 3 or 10 mg ammonium PFOA kg/day for 27 weeks, liver PFOA concentrations ranged from 11 to 18 μg/g at the low dose and from 6 to 22 μg/g at the higher dose. Mean serum concentrations measured after 6 weeks of exposure (which may have represented steady-state concentrations) were 77,000 ng/mL in the low-dose group and 86,000 ng/mL in the higher dose group. In this same study, an analysis of serum PFOA kinetics following an intravenous dose of PFOA revealed similar elimination kinetics in males and females (Butenhoff et al. 2004c; see Section 3.1.4). In Cynomolgus monkeys that received daily oral doses of PFOS (0, 0.03, 0.15, or 0.75 mg PFOS/kg/day) for 26 weeks, liver concentrations of PFOS and serum concentration were similar in males and females (liver:serum ratios ranged from 1 to 2) and increased in approximate proportion to the administered dose (Seacat et al. 2002).

Bogdanska et al. (2014) examined distribution of ^{35}S in 20 tissues following dietary exposure of adult male C57/BL6 mice to PFBS (16 mg/kg/day) for 1–5 days. ^{35}S was detected in all tissues and concentrations reached plateau levels after 3 days of exposure. After 5 days, tissue:blood ratios (excluding stomach and small intestine) were >1 for liver (tissue:blood=1.6), kidney (tissue:blood=1.3), whole bone (tissue:blood=1.1), and cartilage (tissue:blood=1.1). At all-time points, approximately 90% of the ingested ^{35}S was recovered in combined blood, liver, bone, skin, and muscle.

Iwabuchi et al. (2017) compared tissue distribution following single doses or 3-month dosing of PFOS (100 μg/kg), PFOA (100 μg/kg), PFHxA (100 μg/kg), and PFNA (50 μg/kg). Following administration of single doses, the tissue:serum (and/or whole blood) ratio was >1 for the liver for PFOS, PFOA, and PFNA, with tissue:serum ratios <1 for kidney, spleen, heart, and brain. For PFNA, the only tissue with a tissue:serum ratio >1 was kidney. After 3 months of exposure, tissue:serum ratios >1 were observed for the liver for PFOA and PFNA, and the liver and kidney for PFOS. For PFHxA, all tissue:serum ratios were <1. Similar to the single dose study, the lowest serum:tissue ratio for all compounds was observed for brain.

Subcellular Distribution. The subcellular distribution of perfluoroalkyls has been examined in rats (Han et al. 2004, 2005; Kudo et al. 2007; Vanden Heuvel et al. 1992b). Two hours following an oral dose of 25 mg ammonium [^{14}C]PFOA/kg, sex differences were noted in the subcellular distribution of ^{14}C in liver; females had approximately 50% of total ^{14}C in the cytosolic fraction compared to 26% in males (Han et al. 2005). The distributions to other cell fractions were: nuclear/cell debris fraction, 30% females, 40% males; lysosomes, 12% females, 14% males; mitochondria, 8% females, 16% males; and

ribosomes, <3% males and females. In kidney, 80 and 70% of the ^{14}C was associated with the cytosolic fraction in males and females, respectively, 16–22% in the nuclear/cell debris fraction, and the remainder in lysosome/mitochondria/ribosome fractions. In liver, approximately 55% of cytosolic ^{14}C was bound to proteins (>6,000 Da) in both males and females, whereas in kidney, 42% of the cytosolic fraction was bound to protein in males and 17% in females. The subcellular distribution of PFOA is dose-dependent. In rats, 2 hours following an intravenous dose of 0.041 mg [^{14}C]PFOA/kg, approximately 5% ^{14}C in the liver was associated with the cytosolic fraction, whereas approximately 45% was in the cytosolic fraction following a dose of 16.6 mg/kg (Kudo et al. 2007). A small component of tissue-associated PFOA and PFDA appeared to be bound covalently to protein. Following an intraperitoneal dose of 9.4 μmol/kg [^{14}C]PFDA or [^{14}C]PFOA (4.2 mg/kg), approximately 0.1–0.5% of liver ^{14}C was bound covalently (i.e., was not removed by repeated extraction with a methanol/ether and ethyl acetate; Vanden Heuvel et al. 1992b). Covalent binding was detected when cytosolic or microsomal fractions of rat liver were incubated *in vitro* with [^{14}C]PFDA (Vanden Heuvel et al. 1992b).

PFOA binds to rat kidney and urine α2u-globulin; dissociation constants were estimated to be approximately 1.5 and >2 mM (for a single binding site) for the proteins isolated from rat kidney and urine, respectively. These values suggest relatively low affinity for the protein, compared to other ligands that are known to induce hyaline droplet nephropathy (10^{-4}–10^{-7} M; Han et al. 2004).

Maternal-fetal Transfer. Perfluoroalkyls can be transferred to the fetus during pregnancy (Cariou et al. 2015; Chen et al. 2017a; Fei et al. 2007; Fisher et al. 2016; Fromme et al. 2010; Glynn et al. 2012; Gützkow et al. 2012; Hanssen et al. 2010, 2013; Inoue et al. 2004; Kato et al. 2014; Kim et al. 2011, Lee et al. 2013; Lien et al. 2013; Liu et al. 2011; Manzano-Salgado et al. 2015; Midasch et al. 2007; Monroy et al. 2008; Needham et al. 2011; Ode et al. 2013; Porpora et al. 2013; Yang et al. 2016a, 2016b). Studies that measured perfluoroalkyls in maternal and fetal cord blood of matched mother-infant pairs found relatively strong correlations (r>0.8) between maternal and fetal serum (or plasma); however, fetal/maternal serum ratios vary depending on the structure of the perfluoroalkyl (Table 3-2). With some exceptions, longer fluoroalkyl chain length and a terminal sulfonate group are associated with lower fetal/maternal ratios (Glynn et al. 2012; Gützkow et al. 2012; Hanssen et al. 2013; Kim et al. 2011; Liu et al. 2011; Needham et al. 2011). PFOS was detected in amniotic fluid obtained from amniocentesis (Jensen et al. 2012). The median concentration in amniotic fluid samples from 300 pregnancies (from the Danish amniotic fluid pregnancy-screening biobank) was 1.1 ng/mL.

[a]Ratio of cord:maternal perfluoroalkyl level.

FOSA = perfluorooctane sulfonamide; ND = no data (detected but below limit of quantification); NR = not reported; PFBS = perfluorobutane sulfonic acid; PFDA = perfluorodecanoic acid; PFDoDA = perfluorododecanoic acid; PFHxS = perfluorohexane sulfonic acid; PFHpA = Perfluoroheptanoic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; PFTrDA = perfluorotridecanoic acid; PFUnA = perfluoroundecanoic acid

Studies in rats and mice provide further support for maternal-fetal transfer of perfluoroalkyls. Following gavage administration of 0.1–10 mg/kg/day PFOS to rats during gestation, PFOS was distributed to fetal serum, liver, and brain, with fetal concentrations increasing with maternal dose (Chang et al. 2009; Lau et al. 2003; Luebker et al. 2005a, 2005b; Thibodeaux et al. 2003). Levels in fetal serum and liver generally were similar and higher than in brain. Studies did not report on concentrations of PFOS in other fetal tissues. Paired fetal-maternal levels of PFOS were examined in rats following exposure (gavage) to potassium PFOS at doses of 0.1, 0.4, 1.6, or 3.2 mg/kg/day on GDs 0–20 (Luebker et al. 2005b). On GD 21, fetal:maternal serum ratios were 2.1, 1.7, 1.6, and 1.1 at doses of 0.1, 0.4, 1.6, and 3.2 mg/kg/day, respectively; these results suggest that fetal:maternal serum ratios varied inversely with dose. Fetal:maternal liver ratios (0.37–0.44) were similar across the dose range. In mice administered a single

gavage dose of 12.5 mg/kg [^{35}S]PFOS on GD 16, fetal organ:maternal blood ratios of ^{35}S on GD 18 were 2.8 for kidneys, 2.6 for liver, 2.3 for blood, 2.1 for lungs, and 1.2 for brain (Borg et al. 2010).

Maternal-fetal transfer of PFOA has also been studied in rats and mice (Das et al. 2008; Hinderliter et al. 2005). In rats, PFOA concentrations in amniotic fluid, placenta, and fetus (measured on days 10, 15, or 21 of gestation) increased with increasing maternal oral dose (3, 10, or 30 mg/kg/day, administered daily beginning on GD 4) (Hinderliter et al. 2005). Fetal plasma concentrations of PFOA measured on GD 21 were approximately 40% of maternal plasma concentration. Following gavage administration of 0.01, 1, or 5 mg/kg ammonium PFOA on GD 17 in mice, PFOA was detected in amniotic fluid and pup serum, with dose-dependent increases (Fenton et al. 2009). On PND 1, pup serum PFOA concentrations were approximately 1.7–2.0-fold greater than levels in maternal serum.

Following administration of ammonium PFBA (35, 175, or 350 mg/kg) to pregnant mice on GDs 0–17, fetal serum and liver levels of PFBA were determined on PND 1 (Das et al. 2008). The fetal:maternal serum ratio of PFBA was approximately 0.15 and did not vary with maternal dose. Fetal liver:serum ratios were 0.44, 0.75, and 0.78 at maternal doses of 35, 175, and 350 mg/kg, respectively. PFHxS was detected in fetal blood and in the liver of neonates following exposure of dams to potassium PFHxS (0.3, 1, 3, and 10 mg/kg) throughout gestation (Butenhoff et al. 2009a); concentrations in serum and liver increased with dose.

Maternal-infant Transfer. Perfluoroalkyls can be transferred to nursing infants (Barbarossa et al. 2013; Cariou et al. 2015; Fromme et al. 2010; Kärrman et al. 2007; Kim et al. 2011; Kuklenyik et al. 2004; Liu et al. 2011; Tao et al. 2008a, 2008b). Studies that measured perfluoroalkyls in maternal serum (or plasma) and breast milk in matched mother-infant pairs found highly variable correlations (Table 3-3). Relatively high correlations have been reported for PFOA (Kärrman et al. 2007; Liu et al. 2011). Transfer to breast milk appears to be a significant route of elimination of perfluoroalkyls during breastfeeding. Comparisons of serum concentrations of women who did or did not breastfeed their infants showed that breastfeeding significantly decreases maternal serum concentrations of PFOA, PFOS, PFHxS, and PFNA (Bjermo et al. 2013; Brantsaeter et al. 2013; Mondal et al. 2012, 2014; von Ehrenstein et al. 2009). The decrease was estimated to be 2–3% decrease per month of breastfeeding (Brantsaeter et al. 2013; Mondal et al. 2012, 2014). Concentrations of perfluoroalkyls in breast milk also decrease with breastfeeding duration (Tao et al. 2008b; Thomsen et al. 2010). Numerous perfluoroalkyls (including PFOS, PFOA, PFBS, PFHxS, PFNA, PFDA, PFDoDA, PFUnA, and FOSA) have been detected in breast milk samples in women in China, Korea, Japan, Malaysia, Cambodia, India, Korea, Vietnam, Indonesia,

Norway, Philippines, Sweden, and the United States (Forns et al. 2015; Fujii et al. 2012; Kang et al. 2016; Kärrman et al. 2007; Kim et al. 2011; Liu et al. 2010, 2011; Mondal et al. 2014; So et al. 2006b; Tao et al. 2008a). The mean concentrations for perfluoroalkyls in breast milk collected from 45 women in Massachusetts were 0.131 ng/mL (range of <0.032.0–617 ng/mL) for PFOS, 0.043.8 ng/mL (<0.0301–0.161 ng/mL) for PFOA, and 0.0145 ng/mL (<0.0120–0.0638 ng/mL) for PFHxS (Tao et al. 2008b). PFHpA, PFDA, PFUnA, PFDoDA, and PFBS were also detected in the breast milk; however, ≤4 samples had levels that exceeded the limit of quantitation. Serum concentrations in breastfed infants can be higher than maternal levels. Although cord:maternal serum ratios of PFOA, PFOS, and PFNA at birth are typically lower than 1 (see Table 3-2), infant serum levels increase several-fold during the first 6 months after birth (Fromme et al. 2010; Mondal et al. 2014; Post et al. 2012; Verner 2016a, 2016b). This increase is likely because breast milk concentrations of perfluoroalkyls and fluid intake per infant body weight are highest during this time period. Fromme et al. (2010) also showed increases in serum levels of PFNA in infants fed formula made with contaminated drinking water. Mogensen et al. (2015b) reported that following weaning, significant (<0.0001) decreases were observed in infant serum concentrations of PFOS, PFOA, and PFHxS.

[a]Milk to serum ratio.

FOSA = perfluorooctane sulfonamide; ND = no data (detected but below limit of quantification); NS = not significantly correlated; PFDA = perfluorodecanoic acid; PFDoDA = perfluorododecanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; PFTrDA = perfluorotridecanoic acid; PFUnA = perfluoroundecanoic acid

Studies conducted in rats and mice provide further support for maternal-infant transfer of perfluoroalkyls through breast milk (Fenton et al. 2009; Hinderliter et al. 2005; Lau et al. 2003; Luebker et al. 2005a; Yu et al. 2009b). PFOA concentrations in breast milk of nursing rats increased with increasing maternal oral dose (3, 10, or 30 mg/kg/day, administered daily beginning on GD 4) (Hinderliter et al. 2005). Milk concentrations of PFOA measured on postpartum days 3, 7, 14, or 21 in rats were approximately 0.1 of maternal plasma concentration. In dams exposed to 0.1, 1, or 5 mg/kg PFOA by gavage on GD 17, a dose-dependent increase in PFOA concentrations in breast milk was observed on PND 2, with breast milk:serum ratios of approximately 0.15, 0.38, and 0.25 at 0.1, 1, and 5 mg/kg doses, respectively; milk/serum concentration ratios for PFOA ranged from 0.15 to 0.56 (Fenton et al. 2009). Following lactational exposure of control rat pups to PFOS in breast milk of dams treated with dietary PFOS (3.2 mg/kg diet; approximately equivalent to 0.33 mg/kg/day), pup serum and liver concentrations increased throughout the 35-day lactation period (Yu et al. 2009b). At PND 35, the pup liver:serum PFOS ratios were 2.55 and 2.43 in male and female pups, respectively. Results of a cross-foster study show that pups are exposed to PFOS through breast milk (Luebker et al. 2005a). Postnatal toxicity observed in cross-fostered pups that nursed from exposed dams provides additional evidence of maternal-infant transfer of PFOS in rats and mice (see Section 2.17).

Mechanisms of Distribution. Perfluoroalkyls in plasma bind to serum albumin and various other plasma proteins including gamma-globulin, alpha-globulin, alpha-2-macroglobulin, transferrin, and beta-lipoproteins (Bischel et al. 2011; Butenhoff et al. 2012d; Chen and Guo 2009; Han et al. 2003, 2005; Kerstner-Wood et al. 2003; Luo et al. 2012; Ohmori et al. 2003; Salvalaglio et al. 2010; Vanden Heuvel et al. 1992b; Wu et al. 2009; Ylinen and Auriola 1990; Zhang et al. 2009). The dissociation constant for albumin-bound PFOA in serum is approximately 0.4 mM (0.38 mM, ±0.04 SD for human serum albumin; 0.36 nM, ±0.08 SD for rat serum albumin) and involves 6–9 biding sites (Han et al. 2003). Noncovalent binding appears to be at the same sites as fatty acids (Chen and Guo 2009). Interactions between PFOS and human serum albumin include interaction of PFOS polar sulfonyl groups with albumin hydrophilic sites and interaction of perfluorinated groups with albumin hydrophobic sites (Luo et al. 2012).

Absorbed perfluoroalkyls distribute from plasma to soft tissues, with the highest extravascular concentrations achieved in liver. Mechanisms by which perfluoroalkyls enter the liver have not been elucidated and may involve interactions with organic anion transporters that function in the distribution of fatty acids or other organic anions (Andersen et al. 2008). PFOA appears to be a substrate for organic anion transporters in the luminal and basolateral membranes of renal tubular epithelial cells, which facilitates entry of PFOA into renal tubular cells (Kudo et al. 2002; Nakagawa et al. 2008; Vanden Heuvel et al. 1992b; Weaver et al. 2010). The subcellular distribution of PFOA is sex- and dose-dependent in rats (Han et al. 2005; Kudo et al. 2007) and the association with the membrane fraction of liver cells decreases with increasing dose (Kudo et al. 2007), consistent with limited capacity of membrane proteins that bind PFOA (e.g., membrane transport proteins). Intracellular PFOA binds to proteins; protein complexes formed have not been fully characterized. PFOA exhibits a low affinity for binding to rat kidney and urine alpha-2μ-globulin (dissociation constants 1.5 and >2 mM, respectively) (Han et al. 2004).

3.1.3 Metabolism

Results of available intraperitoneal and *in vitro* studies suggest that the perfluoroalkyls discussed in this profile are not metabolized and do not undergo chemical reactions in the body. The absence of significant metabolism is attributed to the high stability and low reactivity of carbon-fluorine bonds in perfluoroalkyls. Studies conducted in male and female rats did not detect fluorine metabolites in the urine, plasma, or liver following a single injection of 4–150 mg/kg PFOA or 5–50 mg/kg PFDA (Goecke et al. 1992; Vanden Heuvel et al. 1991b, 1991c; Ylinen and Auriola 1990). Following a single intraperitoneal dose of approximately 4 mg/kg of ^{14}C-PFOA, only parent compound was excreted in the

urine and bile (Vanden Heuvel et al. 1991c). PFOA was not metabolized when incubated with microsomal fractions of human or rat intestine, kidney, or liver homogenates (Kemper and Nabb 2005). Although no studies examining metabolism of other perfluoroalkyls, including PFOS, following inhalation, oral, or dermal exposure were identified, metabolism by these exposure routes is not anticipated.

3.1.4 Excretion

As noted in Section 3.1.3 (Metabolism), there is presently no evidence that perfluoroalkyls undergo metabolism. The absence of significant metabolism is attributed to the high stability and low reactivity of carbon-fluorine bonds in perfluoroalkyls. Therefore, route-specific differences in excretion patterns are not expected. Selected studies in which elimination half-lives rates (i.e., $t_{1/2}$) of perfluoroalkyls have been determined (see summaries in Table 3-5) show that, in general, elimination $t_{1/2}$ values are similar following intravenous, intraperitoneal, and oral exposures. Findings suggest that the route of absorption has no substantial effect of rates of elimination of absorbed perfluoroalkyls (Butenhoff et al. 2004c; Chang et al. 2008a; Kemper 2003; Kudo et al. 2002; Ohmori et al. 2003; Vanden Heuvel et al. 1991b; Ylinen et al. 1990). As discussed in this section, perfluoroalkyls are primarily eliminated in the urine, with smaller amounts eliminated in the feces, breast milk (see Section 3.1.2; Distribution, Maternal-fetal Transfer), and menstrual fluid. Perfluoroalkyls undergo biliary excretion, but substantial reabsorption occurs; therefore, biliary excretion does not represent a major elimination pathway. Perfluoroalkyls do not appear to be eliminated in sweat, as induction of perspiration by exercise or sauna does not alter clearance of PFOA, PFOA, PFHxA, or PFNA (Genuis et al. 2013). The elimination of perfluoroalkyls in menstrual fluid appears to contribute to sex differences in serum elimination rates (Wong et al. 2014, 2015; Zhang et al. 2013). Only free (unbound) perfluoroalkyls are available for redistribution, excretion, and renal reabsorption; the interaction of perfluoroalkyls with proteins plays a critical role in bioaccumulation, and the tissue environment highly favors protein bonding.

In humans, absorbed perfluoroalkyls are excreted in urine. Estimates of renal clearance of PFOA and PFOS from serum in humans ranged from 0.8 to 3.3 mL/day for PFOA (serum concentration range: 5–16 ng/mL) and 0.1–1.5 mL/day for PFOS (serum concentration range 9–49 ng/mL). These clearance values were <0.001% of glomerular filtration rate (Harada et al. 2005a). Assuming that 99% of the serum PFOA and PFOS was bound to albumin (see Section 3.1.2), <0.1% of filtered perfluoroalkyls were excreted in urine, suggesting extensive reabsorption of filtered PFOA and PFOS in the renal tubule. Renal clearance was not different in males and females. Mean renal clearances for PFOA were

2.12 mL/day (±0.80 SD, n=5) in males and 1.15 (±0.33 SD, n=5) in five females (mean age 22 and 23 years, respectively). Mean renal clearances for PFOS were 0.66 mL/day (±0.48 SD, n=5) in males and 0.91 (±0.56 SD, n=5) for females. Fujii et al. (2015a) reported renal clearances (mL/day/kg; mean±SD) for several perfluoroalkyls in humans (three males and five females), including PFOA (0.044±0.01), PFNA (0.038±0.01), PFDA (0.015±0.01), PFUnA (0.005±0.00), and PFDoDA (0.005±0.00). Zhang et al. (2013) reported renal clearances for several perfluoroalkyls (mL/day/kg) and found that clearance of PFOS was similar in younger females (≤50 years, 0.050 mL/day/kg, 95% CI 0.037–0.064) and a combined group of males and older females (grouped together since there were no significant differences in serum concentrations) (0.037 mL/day/kg, 95% CI 0.026–0.049). However, there appeared to be differences in renal clearance for PFOA; clearance rates were 0.30 mL/day/kg (95% CI 0.11–0.49) in young females and 0.77 mL/day/kg (95% CI 0.47–1.1) in the combined older women and all males group. Urinary excretion of perfluoroalkyls may show sex and age differences (Zhang et al. 2015b). Urinary excretion of PFOA as a fraction of estimated intake in male adults (n=29) was 31% (p=0.002) higher than in nonpregnant female adults (n=25). In addition, urinary excretion of PFOS was inversely correlated with age (r=0.334; p=0.015).

Absorbed PFOA and PFOS are also secreted into bile in humans, but the biliary pathway is not a major excretory pathway because PFOA and PFOS are reabsorbed after biliary secretion. Estimates of total body clearance, serum-to-urine clearance, and serum-to-bile clearance of PFOA and PFOS in humans are presented in Table 3-4 (Harada et al. 2007). Biliary clearances of PFOA and PFOS were 1.06 and 2.98 mL/kg body weight/day, respectively, and greatly exceeded total body clearance (0.150 and 0.106 mL/kg/day) and urinary clearance (0.030 and 0.015 mL/kg/day). Based on these estimates, approximately 89% of the PFOA secreted into bile and 97% of secreted PFOS was estimated to have been reabsorbed from the gastrointestinal tract. Fujii et al. (2015a) also reported that biliary clearances of several perfluoroalkyls (PFOA, PFNA, PFDA, PFUnA, PFDoDA) were much higher than total body clearance in humans, further supporting that perfluoroalkyls excreted in bile undergo extensive reabsorption.

Table 3-4. Excretory Clearance of PFOA and PFOS in Humans

Parameter	Units	PFOA	PFOS
Serum $t_{1/2}$[a]	day	1,387	1,971
Total clearance[b]	mL/kg/day	0.150	0.106
Urinary clearance[c]	mL/kg/day	0.030	0.150

Table 3-4. Excretory Clearance of PFOA and PFOS in Humans

Parameter	Units	PFOA	PFOS

PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid

Source: Harada et al. (2007)

Studies conducted in nonhuman primates and rodents provide further evidence that urine is the major route of excretion of perfluoroalkyls, accounting for >93% of absorbed PFOA and PFOS (Benskin et al. 2009; Butenhoff et al. 2004c; Chang et al. 2008a, 2012; Chengelis et al. 2009a; Hanhijarvi et al. 1982, 1987; Hundley et al. 2006; Johnson and Ober 1979, 1980, 1999a, 1999b; Kemper 2003; Kudo et al. 2001; Olsen et al. 2009; Sundström et al. 2012; Vanden Heuvel et al. 1991b, 1991c). Studies conducted in rats have shown that PFDA, PFNA, PFOA, and PFHxA are secreted in bile and undergo extensive reabsorption from the gastrointestinal tract (Kudo et al. 2001; Vanden Heuvel et al. 1991b, 1991c). PFOS, PFHxS, and PFBS are excreted in feces following intravenous dosing of rats, suggesting that these perfluoroalkyls may also be secreted into bile (Chang et al. 2012; Johnson et al. 1984; Olsen et al. 2009; Sundström et al. 2012). The percentage of the dose excreted in the feces appears to vary with compound, 8–13% for PFOS, <0.5% for PFHxS, and 0.13–0.36% for PFBS. Renal clearances of PFOA from plasma in rats were approximately 0.032 mL/minute/kg body weight in male rats and 0.73 mL/minute/kg in female rats; plasma concentrations of PFOA during these measurements ranged from approximately 0.8 to 80 µg/mL (Kudo et al. 2002). In the latter study, approximately >95% of plasma PFOA was bound to high molecular weight protein and the glomerular filtration rate was approximately 10 mL/minute/kg; therefore, urinary excretion of PFOA was approximately 6% of the rate of glomerular filtration of PFOA in males and 146% in females. These estimates indicate that net renal tubular reabsorption of filtered PFOA occurred in male rats, whereas net renal tubular secretion of PFOA occurred in female rats (i.e., clearance of free PFOA in plasma > glomerular filtration rate). The pronounced sex difference in renal clearance of PFOA has been attributed to modulation of renal excretory transport of PFOA by testosterone and estradiol (Kudo et al. 2002; Vanden Heuvel et al. 1992a; see Section 3.1.5).

Rates of elimination of perfluoroalkyls vary substantially across chemical species and animal species, and show sex differences and age-dependencies within certain species. Table 3-5 summarizes estimates of the elimination $t_{1/2}$ for perfluoroalkyls in humans and experimental animals. In compiling the estimates presented in Table 3-5, preference was given to the terminal $t_{1/2}$ when multiple $t_{1/2}$ values were reported. The significance of the terminal $t_{1/2}$ is that it determines the time required for complete elimination of the perfluoroalkyl as well as the exposure duration required to achieve a steady state. Most of the $t_{1/2}$ values in Table 3-5 were estimated from analyses of data on declining serum concentrations of perfluoroalkyls after a single dose or following cessation of a period of repeated dosing. Estimates of the terminal $t_{1/2}$ based on serum concentrations can vary with the length of the observation period following the last dose and with the modeling approach used to estimate the $t_{1/2}$. Longer observation times are required to estimate the slowest phases of elimination. As a result, estimates of $t_{1/2}$ based on observation periods of 1–2 days can be much shorter than estimates for the same perfluoroalkyl based on observation periods of several weeks. Direct comparisons of $t_{1/2}$ values should be made with consideration of whether or not the observation periods were comparable. Differences in estimation methodology can also contribute to differences in $t_{1/2}$ values. Values reported in Table 3-5 are based on fitting data to single or multi-compartment models, or noncompartmental modeling of the data. While the terminal $t_{1/2}$ provides a metric for comparing times required for complete elimination and steady state, it does not always provide a measure of how rapidly the perfluoroalkyl is cleared from the body. A more useful metric for this is the systemic clearance (Cl_S), typically estimated from the absorbed dose (AD) and the area under the serum concentration curve (AUC_S):

$$Cl_S = \frac{AD}{AUC_S} \qquad \text{Eq. (3-3)}$$

Equation 3-3 will provide an accurate estimate of systemic clearance following an oral dose if the oral dose is completely absorbed. Accurate estimation of AUC_S also depends on fitness of the underlying model used to predict serum concentrations. Estimates of systemic clearance based on pharmacokinetics analyses of serum data from animal studies are presented in Table 3-6.

Table 3-5. Summary Elimination Half-Lives for Perfluoroalkyls Estimated in Humans and Experimental Animals

Species, age, and sex	Route	Dose	Exposure duration[a]	Elimination half-life[b]	Reference
PFOA—Human

[a]Exposure durations of 1 day indicate that a single dose was administered.
[b]Reported half-lives are arithmetic means for the terminal elimination phase if multiple elimination phases were observed.

CI = confidence interval; CL = confidence limit; F = female; GM = geometric mean; IP = intraperitoneal; IV = intravenous; M = male; NA = not applicable; PFBA = perfluorobutanoic acid; PFDA = perfluorodecanoic acid; PFHpA = perfluoroheptanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; FOSA = perfluorooctane sulfonamide; SD = standard deviation; SE = standard error

[a]As reported in units of mL/day/kg or converted from mL/hour (x24), mL/hour (x24/body weight) or mL/minute (x60x24).

CI = confidence interval; F = female; IV = intravenous; M = male; PFBA = perfluorobutanoic acid; PFBS = perfluorobutane sulfonic acid; PFDA = perfluorodecanoic acid; PFHpA = perfluoroheptanoic acid; PFHxA = perfluorohexanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; SD = standard deviation; SE = standard error

Elimination of Perfluoroalkyls in Humans. Elimination $t_{1/2}$ values for PFOA, PFOS, PFHxS, PFBA, and PFBS have been estimated in humans (Bartell et al. 2010; Costa et al. 2009; Chang et al. 2008a; Glynn et al. 2012; Harada et al. 2005a; Li et al. 2018; Olsen et al. 2007a, 2009; Seals et al. 2011; Spliethoff et al. 2008; Yeung et al. 2013; Wong et al. 2014, 2015; Worley et al. 2017a; Zhang et al. 2013). Estimates in humans are based on measurements of the decline in serum perfluoroalkyl concentrations following cessation or an abrupt decrease in exposure, or on measurements of renal plasma clearance

from serum in a general population sample from Japan (Harada et al. 2005a). The latter clearance estimates were converted to $t_{1/2}$ values, for display in Table 3-5 as follows (Equations 3-4 and 3-5):

$$k_e = \frac{Cl}{V} \qquad \text{Eq. (3-4)}$$

$$t_{1/2} = \frac{\ln(2)}{k_e} \qquad \text{Eq. (3-5)}$$

where k_e is the elimination rate constant (e.g., day^{-1}), Cl is the renal plasma clearance (e.g., mL plasma/day/kg), and V is the plasma volume (L/kg), which is assumed to be 4.3% of body weight (ICRP 1981). In general, these studies show that longer chain length is associated with slower elimination rates. For example, the elimination $t_{1/2}$ for PFBA was estimated to be 70–80 hours (Chang et al. 2008a), whereas the $t_{1/2}$ values for PFHxS, PFOS, and PFOA range from 2 to 35 years (Bartell et al. 2010; Harada et al. 2005a; Li et al. 2018; Olsen et al. 2007a; Seals et al. 2011; Worley et al. 2017a; Zhang et al. 2013). Longer $t_{1/2}$ values for PFOA have been reported with longer monitoring follow-up times, which allow the detection of slower elimination phases of multiphasic elimination kinetics (Seals et al. 2011). Perfluoroalkyl sulfonates are eliminated more slowly in humans than corresponding carboxylates of the same chain length (Zhang et al. 2013). Analytical methods typically used to measure serum perfluoroalkyls do not discriminate between linear and branched isomers and, as a result, these studies estimate elimination rates for the isomer mixture. A study that compared elimination rates of isomers of PFOA found that linear isomers tend to be eliminated more slowly than branched isomers (Zhang et al. 2013), consistent with results of studies conducted in rats (Benskin et al. 2009; De Silva et al. 2009).

An analysis of serum PFOS data from NHANES indicated that $t_{1/2}$ in females may be shorter (4.3 years) compared to males (4.7 years; Wong et al. 2014, 2015). The NHANES data are cross-sectional and, therefore, the estimates of $t_{1/2}$ required fitting the data to age patterns of PFOS intake. An improved fit to the data for females was achieved when estimated losses of PFOS in menstrual fluids were considered, suggesting that menstrual loss of PFOS may account for some, but not all, of the sex difference in the elimination rate (Verner and Longnecker 2015; Wong et al. 2015). Li et al. (2018) also found apparent sex differences in PFOS elimination in male and female residents in Sweden exposed to contaminated drinking water. The estimated $t_{1/2}$ for PFOS were 4.6 years in males and 3.1 years in females. Zhang et al. (2013) estimated serum $t_{1/2}$ for various age and sex strata in a population of 86 individuals. Serum $t_{1/2}$ for PFOS was lower for PFOS in younger females (≤50 years, $t_{1/2}$ = 6.2 years±0.3 SE, n=66) compared to males and older females ($t_{1/2}$ =27 years±3.1 SE, n=20). Zhang et al. (2013) attributed the difference in serum $t_{1/2}$ to clearance in menstrual fluids. However, the estimated serum $t_{1/2}$ of 27 years is much higher than values calculated from other studies; Zhang et al. (2013) noted that the serum $t_{1/2}$ should be

considered as an upper limit estimate. Estimated $t_{1/2}$ for PFOA was not different in younger females (2.1±0.3 SE, n=20) compared to males and older females (2.6±0.4 SE, n=66). Declines in serum PFOA concentrations were observed in populations following initiation of activated carbon filtration of public water supplies that had been contaminated with PFOA (Bartell et al. 2010). The estimated mean serum $t_{1/2}$ for a group of 200 adults followed for 1 year after filtration was initiated was 2.3 years (95% CI 2.1–2.4). Elimination rates were not different in males and females. Serum PFOA concentration ranged from 16 to 1,200 ng/mL. A larger follow-up study measured serum PFOA concentrations in two populations of former residents (n=1,672) of the same water districts (Seals et al. 2011). In one population (n=643), the serum $t_{1/2}$ increased with increasing elapsed time since leaving the water district. The $t_{1/2}$ values were 2.9 years (95% CI 2.3–3.8) for elapsed time of <4 years and 10.1 years for elapsed time of >4 years. In a second population with an elapsed time since residence of <9 years, the $t_{1/2}$ was 8.5 years (95% CI 7.1–10.1). Elimination rates (based on the annual percent decrease in serum concentrations) were faster in males (27%) compared to females (18%) for the first 4 years post-exposure; however, no difference was evident between sexes when elapsed time from exposure was >4 years.

Bartell (2012) and Russell et al. (2015) point out that most studies examining PFOA elimination half-lives fail to account for ongoing background exposure, which could result in an overestimation of elimination half-lives. Bartell (2012) estimated that the bias from background exposure could resulted in 1–26% overestimation of calculated PFOA half-lives and that greater overestimations can occur for half-lives based on longer follow-up times. Russell et al. (2015) estimated that the bias was greatest in populations with serum PFOA levels closest to background levels. In a re-analysis of the Olsen et al. (2007) occupational exposure data, Russell et al. (2015) estimated that overestimation was approximately 1.2% in workers with initial serum concentrations >500 ng/mL (100 times higher than NHANES general population data) and 13% for workers with lower initial serum PFOA levels. Restricting the elimination half-life calculation to workers with initial serum PFOA levels of >500 ng/mL would result in a half-life of 3.0 years (Russell et al. 2015), compared to 3.8 years calculated for the whole cohort (Olsen et al. 2007).

Analysis of kinetics of serum PFOS concentrations in retired U.S. fluorochemical production workers (24 males, 2 females) yielded a mean serum elimination $t_{1/2}$ estimate of 5.4 years (95% CI 3.9–6.9; geometric mean: 4.8 years, 95% CI 4.0–5.8) in subjects whose serum PFOS concentrations ranged from 37 to 3,490 ng/mL (Olsen et al. 2007a). Estimates for the two females in the same study were 4.9 and 6.8 years. Estimates based on renal clearance of PFOS from serum in subjects from the general population of Japan ranged from 2.9 to 7.4 years; these subjects had serum PFOS concentrations that

ranged from 4 to 49 ng/mL (Harada et al. 2005a). Estimates in males (7.4, 2.9 years) were similar to females (4.5, 4.6 years). This same study measured serum PFHxS concentrations in retired U.S. fluorochemical production workers (24 males, 2 females) and yielded a mean estimate of 8.5 years (95% CI 6.4–10.6; geometric mean: 7.3 years, 95% CI 5.8–9.2) for the serum elimination $t_{1/2}$ in subjects whose serum PFHxS concentrations ranged from 10 to 1,295 ng/mL (Olsen et al. 2007a). Estimates for the two females in the same study were 12.2 and 13.3 years.

The elimination rate of PFBA was estimated in fluorochemical workers who may have been exposed to various PFBA precursors (Chang et al. 2008a). In three male workers, the estimated mean $t_{1/2}$ based on serum PFBA kinetics was 81 hours (±41 SD). In a larger study of nine workers (seven males, two females), the mean $t_{1/2}$ was 72 hours (±38 SD). Estimates for the two female subjects were 56 and 118 hours. The combined mean value for the 12 estimates was 75 hours (±38 SD). Olsen et al. (2009) estimated serum $t_{1/2}$ of PFBS in six fluorochemical workers. The mean $t_{1/2}$ was 27.4 days (±11.1 SD). The group included a single female whose $t_{1/2}$ was 45.7 days. Based on these observations, PFBA (chain length 3) and PFBS (chain length 4) are eliminated substantially faster in humans than perfluoroalkyls having longer carbon chain lengths, such as PFHxS (chain length 6), PFOA (chain length 7), and PFOS (chain length 8).

Temporal trends in perfluoroalkyl serum concentrations have also been used to estimate population halving times (Glynn et al. 2012; Olsen et al. 2012; Spleithoff et al. 2008; Yeung et al. 2013). Population halving times are influenced by temporal trends in intakes and may therefore not accurately reflect clearance. Population halving times for PFOS ranged from 4 to 5 years (Olsen et al. 2012; Spleithoff et al. 2008; Yeung et al. 2013). Glynn et al. (2012) monitored serum perfluoroalkyls in a population of pregnant women (n=413) in Sweden over the period 1996–2010. Halving times were 22 years (95% CI 16–38) for PFOA and 8.2 years (95% CI 6.3–12) for PFOS.

Elimination of Perfluoroalkyls in Nonhuman Primates. Elimination $t_{1/2}$ values and systemic clearances for PFOA, PFOS, PFHxA, PFHxS, PFBA, and PFBS have been estimated in Cynomolgus monkeys (Buttenoff et al. 2004c; Chang et al. 2012; Chengelis et al. 2009a; Olsen et al. 2009; Seacat et al. 2002; Sundström et al. 2012). Estimated terminal $t_{1/2}$ values were 20–30 days for PFOA, 100–170 days for PFOS, 90–140 days for PFHxS, 40 hours for PFBA and 8–95 hours for PFBS. Elimination of perfluoroalkyls in monkeys is multiphasic and, as a result, estimates of the terminal $t_{1/2}$ can vary with the duration of the observation period and assumptions made in modeling elimination kinetics (Chang et al. 2012; Chengelis et al. 2009a; Olsen et al. 2009; Sundström et al. 2012). For example, the $t_{1/2}$ values for

PFBS were 8 and 15 hours in female and male monkeys, respectively, when monkeys were monitored for 48 hours following a single intravenous dose (Chengelis et al. 2009a), whereas the $t_{1/2}$ values were 95 and 83 hours in male and female monkeys, respectively, when the monitoring period was extended to 14 days and a three-compartment model was used to estimate the terminal $t_{1/2}$ (Olsen et al. 2009). Studies in monkeys confirm general trends observed in humans that perfluoroalkyl sulfonates are more slowly eliminated than perfluoroalkyl carboxylates and that elimination of longer-chain perfluoroalkyls occurs more slowly than short-chain perfluoroalkyls. Systemic clearances were lower for PFOS, PFHxS, and PFBS compared to the corresponding carboxylates, PFOA, PFHxA, and PFBA (Table 3-6). Systemic clearances were similar in male and female monkeys (Table 3-6).

Elimination of Perfluoroalkyls in Rats. Elimination $t_{1/2}$ values and systemic clearances for PFOA, PFOS, FOSA, PFDA, PFNA, PFHpA, PFHxA, PFHxS, PFBA, and PFBS have been estimated in rats (Benskin et al. 2009; Chang et al. 2008b, 2012; Chengelis et al. 2009a; De Silva et al. 2009; Johnson and Ober 1979; Kemper 2003; Kim et al. 2016b; Kudo et al. 2002; Ohmori et al. 2003; Olsen et al. 2009; Seacat and Luebker 2000; Sundström et al. 2012; Vanden Heuvel et al. 1991b, 1991c; Ylinen et al. 1990). Consistent with observations made in humans and Cynomolgus monkeys, perfluoroalkyl sulfonates are more slowly eliminated than perfluoroalkyl carboxylates and short-chain perfluoroalkyls (e.g., PFBA, PFBS) are eliminated faster in rats than long-chain perfluoroalkyls (e.g., PFOA, PFOS, PFHxA, PFHxS); Tables 3-5 and 3-6. Linear PFOA isomers tend to be eliminated more slowly than branched isomers (Benskin et al. 2009; De Silva et al. 2009).

Elimination of perfluoroalkyls exhibits pronounced sex differences in rats, with faster elimination in females than in males (Benskin et al. 2009; Chang et al. 2008b; Chengelis et al. 2009a; Kemper 2003; Kim et al. 2016b; Kudo et al. 2002; Ohmori et al. 2003; Sundström et al. 2012; Tatim-Gibbs et al. 2011; Vanden Heuvel et al. 1991c; Ylinen et al. 1990). Estimates of systemic clearance for PFOA in male rats ranged from 20 to 50 mL/day/kg, whereas estimates for female rats ranged from 600 to 2,200 mL/day/kg (Kemper 2003; Kudo et al. 2002; Ohmori et al. 2003). Systemic clearances of PFOA, PFOS, PFNA, PFHxA, PFHxS, PFBA, and PFBS are also higher in female rats compared to male rats (Table 3-6). Pronounced sex difference in elimination rates in rats (faster elimination in females) was observed in rats following 30-minute nose-only exposures to aerosols (MMAD=1.9–2.1 μm) of 1–25 mg ammonium PFOA/m^3 (Hinderliter et al. 2006a). Plasma PFOA concentrations were not detectable 12 hours after exposure of female rats, and were approximately 90% of peak plasma concentrations 24 hours after the exposure in male rats. The slower elimination of PFOA in male rats resulted in steady-state plasma concentrations within 3 weeks of repeated exposures (6 hours/day, 5 days/week) in male rats, whereas in

female rats, daily periodic oscillations of plasma concentrations from peak to below detection occurred on each day of exposure. Steady-state plasma concentrations in male rats were approximately 10 times that of daily peak concentrations in female rats.

Pronounced dose dependence appears in the $t_{1/2}$ estimates for PFOA in female rats. With increasing dose, plasma elimination kinetics in female rats converts from monophasic to biphasic. Following an oral dose of PFOA of 0.1, 1, 5, or 25 mg/kg, the terminal $t_{1/2}$ values in female rats were 3.2, 3.5, 4.6, or 16.2 hours, respectively; no apparent dose dependence was observed in male rats over the same dose range (Kemper 2003). Dose-dependent elimination of PFOA has been attributed to a capacity-limited renal tubular secretion of PFOA in female rats (see discussion below on *Mechanisms of Excretion*). The divergence in elimination kinetics between male and female rats appears to be age-dependent, with faster elimination becoming evident in female rats after 30 days of age, consistent with the timing of sexual maturation and involvement of sex hormones in the modulation of the renal excretion of PFOA in rats (Hinderliter et al. 2006b).

Elimination of Perfluoroalkyls in Mice. Elimination $t_{1/2}$ values and systemic clearances for PFOS, PFHxS, and PFBA have been estimated in mice (Chang et al. 2008a, 2012; Sundström et al. 2012). Consistent with studies conducted in rats and monkeys, PFBA is eliminated more rapidly in mice than PFOS and PFHxS. Systemic clearances ranged from 5 to 6 mL/day/kg for PFOS (Chang et al. 2012), from 3 to 5 mL/day/kg for PFHxS (Sundström et al. 2012), and from 300 to 1,300 mL/day/kg for PFBA (Chang et al. 2008a). Sex differences in elimination in mice were observed for PFBA, but not PFOS or PFHxS. Systemic clearances of PFBA in female mice were approximately 2 times that of males (Chang et al. 2008a). Systemic clearance of PFBA in male and female mice appeared to be dependent on dose. Systemic clearance following a single oral dose of 100 mg PFBA/kg was approximately 2 times higher than the systemic clearance following a dose of 10 or 30 mg PFBA/kg. Possible explanations for the apparent dependence of clearance on dose are dose-dependent bioavailability or that the one-compartment model used to estimate elimination rates and serum AUC did not adequately fit the serum kinetics observed at the higher dose (Chang et al. 2008a). The latter could occur if renal tubular reabsorption of PFBA or plasma protein binding of PFBA is saturable in mice. Systemic clearance rates for PFOA were similar in male mice (13.1 mL/kg/day) and in female mice (9.0 mL/kg/day) (Fuji et al. 2015a, 2015b).

Elimination of Perfluoroalkyls in Other Species. Sex differences in elimination of PFOA have also been observed in hamsters; unlike the rat, male hamsters excreted absorbed PFOA more rapidly than female hamsters. Following a single gavage dose of 10 mg/kg as ammonium [^{14}C]PFOA, cumulative excretion

of ^{14}C in urine at 24 hours post-dosing was 96.4% of the dose in female rats and 8.7% in male rats; 24.6% and 84.5% in female and male hamsters, respectively; 4.1% in male and female mice; and 90.5 and 80.2% in female and male rabbits, respectively (Hundley et al. 2006).

Mechanisms of Excretion. Urinary excretion of perfluoroalkyls involves glomerular filtration and renal tubular secretion and reabsorption (for PFOA, see Harada et al. 2005a; Kudo et al. 2002; Ohmori et al. 2003). Glomerular filtration of PFOA is limited by extensive binding of PFOA to albumin and other high molecular weight proteins in plasma (Han et al. 2003, 2005; Ohmori et al. 2003; Kerstner-Wood et al. 2003; Vanden Heuvel et al. 1992a, 1992b; Ylinen and Auriola 1990). Elimination of PFOA and other perfluoroalkyls shows pronounced sex differences in rats, with slower elimination in males for PFOA, PFOS, PFNA, PFHxA, PFHxS, PFBA, and PFBS (Chang et al. 2008a, 2012; Chengelis et al. 2009a; Kemper 2003; Kudo et al. 2002; Ohmori et al. 2003; Sundström et al. 2012). The sex difference in PFOA elimination in rats is dependent on testosterone (Hinderliter et al. 2006b; Kudo et al. 2002; Vanden Heuvel et al. 1992a). The significantly slower elimination of PFOA in adult male rats compared to female rats has been attributed to sex hormone modulation of organic anion transporters in kidney. At similar doses administered to male and female rats, PFOA undergoes net tubular reabsorption in male rats (i.e., urinary excretion rate < rate of glomerular filtration of PFOA) and net tubular secretion in female rats (i.e., urinary excretion rate > rate of glomerular filtration of PFOA) (Harada et al. 2005a; Kudo et al. 2002; Ohmori et al. 2003). In rats, several transporters have been shown to have affinity for C7–C9 perfluoroalkyl carboxylates. The transporters, OAT1 and OAT3, located on the basolateral membrane of the renal proximal tubule, appear to participate in secretion of C7–C9 perfluoroalkyl carboxylates into the tubular fluid (Nakagawa et al. 2008; Weaver et al. 2010). The transporters, OATP1a1 (rat), OAT4 (human), and URAT1 (human), located on the apical membrane, appear to mediate reabsorption of C8–C10 perfluoroalkyl carboxylates from the tubular fluid (Katakura et al. 2007; Nakagawa et al. 2009; Weaver et al. 2010; Yang et al. 2009, 2010). In rats and mice, expression of OAT1, OAT3, and OATP1a1 is controlled by male sex hormones and shows higher activities in males (Buist and Klaassen 2004; Gotoh et al. 2002; Kobayashi et al. 2002; Li et al. 2002; Lu et al. 1996; Lubojevic et al. 2004). The slower elimination of PFOA (and other long-chain perfluoroalkyl carboxylates) in male rats has been attributed to OATP1a1 (Weaver et al. 2010; Yang et al. 2009). Higher activity of OATP1a1 in male rats results in higher reabsorptive transport and lower rates of urinary excretion. However, saturation of this transporter could result in an increase in urinary elimination of perfluoroalkyls due to decreased tubular reabsorption. This is consistent with the apparent plateau in plasma concentration with increasing dose observed in cancer patients treated with PFOA (Convertino et al. 2018). Affinities of OATP1a1 (rat), OAT4 (human), and URAT1 (human) are highest for C7–C10 perfluoroalkyl carboxylates (Weaver et al.

2010; Yang et al. 2009, 2010). Affinity of rat OATP1a1 is strongly correlated with total clearance in rats (r^2=0.98; Yang et al. 2009).

Although sex differences for elimination of perfluoroalkyls have been detected in laboratory animals, human monitoring studies have not consistently detected sex differences in elimination $t_{1/2}$ of perfluoroalkyls; this may reflect limitations in the studies, including numbers and age of subjects (Bartell et al. 2010; Seals et al. 2011; Wong et al. 2014, 2015; Zhang et al. 2013). Menstruation may contribute to faster elimination of PFOS in women (Wong et al. 2014, 2015; Zhang et al. 2013). The effect of menstruation or other variables related to menstruation appear to contribute to faster elimination in younger (≤50 years) women compared to men and older women (Zhang et al. 2013). Two studies have found evidence for elimination of PFOS being affected by menstruation (Wong et al. 2014, 2015; Zhang et al. 2013). The estimated $t_{1/2}$ for PFOA was not different in younger females compared to males and older females. Mechanisms by which menstruation could affect PFOS clearance are not understood. Bulk elimination of blood would be expected to affect serum clearance of both PFOS and PFOA; therefore, other mechanisms must contribute that discriminate between perfluoroalkyl species. A better metric than serum $t_{1/2}$ for evaluating sex differences in elimination for this would be systemic or renal clearance of the perfluoroalkyl. Harada et al. (2005a) measured renal clearance in a small sample of young adults (five males and five females, age 22–23 years) and found that renal clearance was not different in males and females. Zhang et al. (2013) estimated renal clearance of PFOA and PFOS in a population of younger females (≤50 years, n=20), older females (>50 years), younger males (≤50 years), and older males (>50 years) and did not find significant sex or age differences. Studies that measured systemic clearance in monkeys also have not found significant sex differences in systemic clearance of PFOA (Buttenoff et al. 2004c) or PFOS (Chang et al. 2012).

Studies conducted in rats have shown that PFDA, PFNA, PFOA, PFOS, and PFHxA are secreted in bile and undergo extensive reabsorption from the gastrointestinal tract (Johnson et al. 1984; Kudo et al. 2001; Vanden Heuvel et al. 1991b, 1991c). Biliary secretion rates of PFOA are similar in male and female rats when renal excretion is blocked by ligation of the kidneys (Vanden Heuvel et al. 1991a, 1991b). This lack of sex influence on biliary secretion (compared to the sex influence on renal clearance) may reflect a relative sex insensitivity of OAT2 (or other organic anion transporter) expression in liver, compared to kidney; the latter is approximately 7–8 times higher in adult female rats compared to male rats (Kudo et al. 2002).

3.1.5 Physiologically Based Pharmacokinetic (PBPK)/Pharmacodynamic (PD) Models

PBPK models use mathematical descriptions of the uptake and disposition of chemical substances to quantitatively describe the relationships among critical biological processes (Krishnan et al. 1994). PBPK models are also called biologically based tissue dosimetry models. PBPK models are increasingly used in risk assessments, primarily to predict the concentration of potentially toxic moieties of a chemical that will be delivered to any given target tissue following various combinations of route, dose level, and test species (Clewell and Andersen 1985). Physiologically based pharmacodynamic (PBPD) models use mathematical descriptions of the dose-response function to quantitatively describe the relationship between target tissue dose and toxic endpoints.

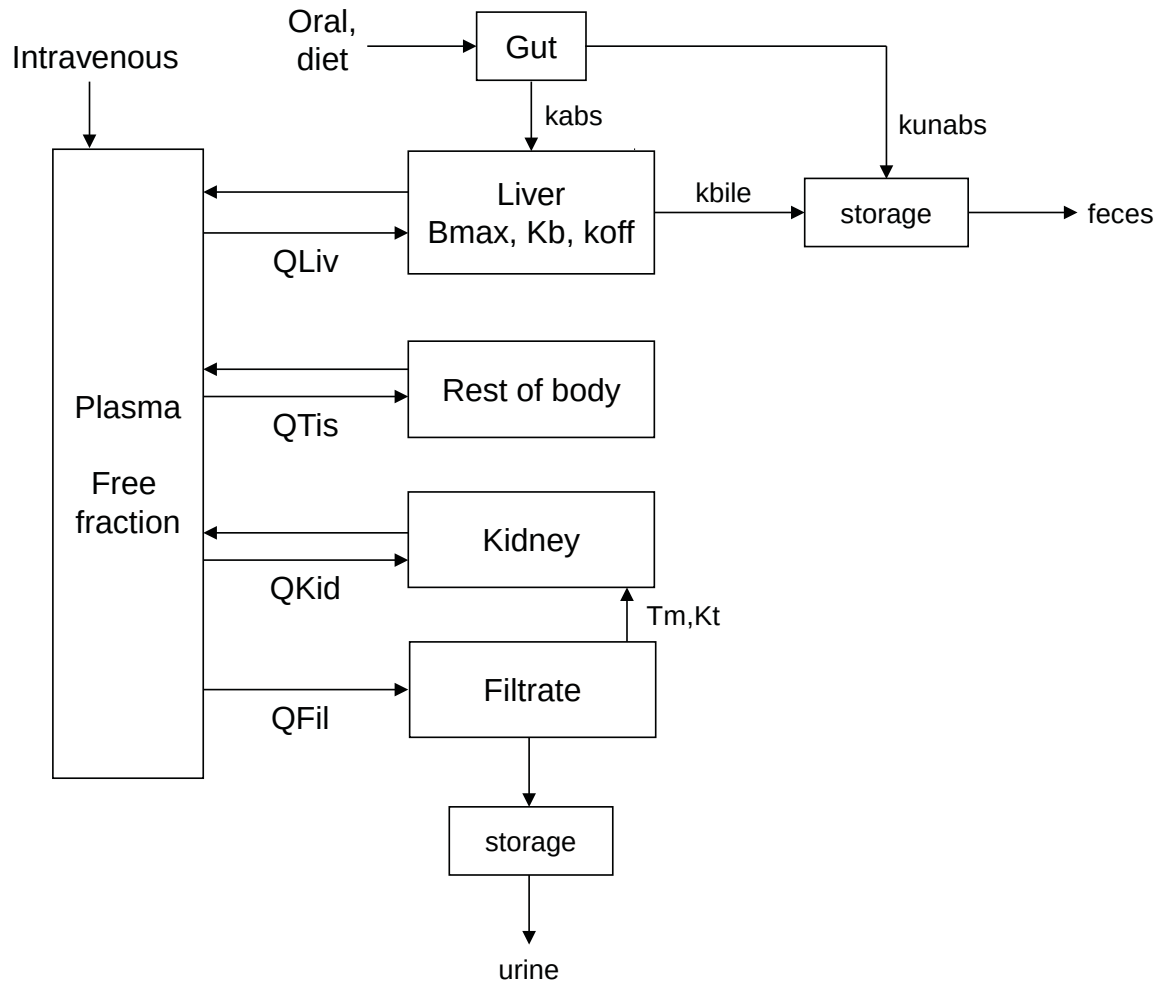
Several PBPK models of PFOA and PFOS have been reported. These include a human model for PFOA and PFOS (Fàbrega et al. 2014, 2016; Loccisano et al. 2011; Worley et al. 2017b), models for PFOA and PFOS in monkeys (Loccisano et al. 2011), models for PFOA and PFOS in rats (Harris and Barton 2008; Loccisano et al. 2012a, 2012b; Tan et al. 2008; Worley and Fisher 2015a. 2015b), and a model for PFOA in mice (Rodriguez et al. 2009). Models of PFOA and PFOS kinetics during gestation and lactation in rats and mice also have been reported (Loccisano et al. 2012a, 2012b; Rodriguez et al. 2009). Various empirical and compartmental models have also been reported (Hoffman et al. 2011; Lorber and Egeghy 2011; Lou et al. 2009; Thompson et al. 2010; Verner et al. 2016; Wambaugh et al. 2013; Wu et al. 2009). Tardiff et al. (2009) utilized a human pharmacokinetic model to estimate an average daily oral dose corresponding to a Reference Dose for PFOA plasma concentration in humans. Cheng and Ng (2017) developed a permeability-limited PBPK model for PFOA in male rats that could be used for *in vitro* to *in vivo* extrapolation. Kim et al. (2018) developed a PBPK model for PFHxS in rats and humans. PBPK models were not identified for other perfluoroalkyls examined in this profile. Given the toxicokinetic differences between compounds, the PFOA, PFOS, and PFHxS PBPK models may not be appropriate for other compounds.

3.1.5.1 Loccisano et al. (2012a, 2012b) Rat Models

Loccisano et al. (2012a) developed a model for simulating the kinetics of PFOA and PFOS in male and female rats. The model was based, in part, on a multi-compartmental model developed by Tan et al. (2008; Andersen et al. 2006). The female rat model (Loccisano et al. 2012a) was subsequently extended to include gestation and lactation (Loccisano et al. 2012b). The general structures of the models are depicted in Figures 3-3, 3-4, and 3-5. Complete lists of parameters and parameter values and the bases

for parameter values and evaluations of model predictions in comparison to observations are described in Loccisano et al. (2012a, 2012b).

Figure 3-3. Structure of PBPK Model of PFOA and PFOS in the Rat



Bmax = liver binding capacity; kabs = first-order absorption rate constant; Kb = liver binding affinity constant; kbile = biliary excretion rate constant; Koff = liver binding dissociation constant; Kt = affinity constant; kunabs = rate of unabsorbed dose to appear in feces; PBPK = physiologically based pharmacokinetic; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; QFil = clearance from plasma to glomerular filtrate; QKid = blood flow in and out of kidney; QLiv = blood flow in and out of liver; QTis = blood flow in and out of tissues; Tm = transporter maximum

The basic (i.e., adult nonpregnant rat) model includes compartments representing plasma (including a bound and free fraction), kidney and renal glomerular filtrate, liver, and a lumped compartment representing all other tissues. Two storage compartments are included in the model: one receives perfluoroalkyl from the gastrointestinal tract (unabsorbed) and liver (bile) and the other receives perfluoroalkyl from the glomerular filtrate. The storage compartments were included in the model to simulate time delays between elimination from plasma and appearance of perfluoroalkyl in feces or urine. Absorption from the gastrointestinal tract is simulated as the balance between first-order absorption and fecal excretion of unabsorbed chemical. Absorbed PFOA and PFOS are assumed to be delivered to the liver where saturable binding of PFOS (but not PFOA) to liver proteins occurs. Saturable binding of PFOS in liver was included to simulate the relatively long retention times of PFOS in liver that have been observed in rats. Exchanges between PFOA or PFOS in liver (free fraction), kidney, and other tissues with the free pool in plasma are assumed to be flow-limited (governed by blood flow) with equilibrium determined by the tissue:blood partition coefficient. PFOA and PFOS in plasma are simulated as instantaneous distributions into free and bound fractions. Extensive binding of PFOA and PFOS to plasma proteins has been demonstrated in various animal species including rats (see Section 3.1.2). For PFOA, the free fraction is assigned a constant of 4.5% in females and 0.6% in males. These values were optimized to fit observed kinetics of PFOA in plasma and urine of rats following intravenous and oral exposures (Loccisano et al. 2012a). Adequate fit to observed PFOS plasma kinetics following single doses of PFOS required introducing a time-dependence in binding of PFOS to protein (Loccisano et al. 2012a; Tan et al. 2008). The free fraction for PFOS in plasma decreases from an initial value (after dosing) of 2.2% to a minimum of 0.1% with a $t_{1/2}$ for the change of approximately 14 hours in a 0.25-kg rat ($k=0.035$ hours^{-1}/kg$^{-0.25}$). The relatively short $t_{1/2}$ for the change limits the effects of the time-dependent plasma kinetics over the first 1–2 days of dosing (including peak concentrations) and has no effect on longer-term kinetics or steady state. Although the time-dependence of the free fraction in plasma was needed to simulate short-term plasma PFOS kinetics in rats, the physiological mechanism for a dependence of plasma binding on the time following dosing (i.e., not on concentration of PFOS in plasma or some other dose surrogate) has not been established. Elimination of absorbed chemical occurs by biliary excretion and urinary excretion. Transfer from liver to feces (representing excretion following biliary transfer) is represented as a first-order process acting on the free fraction in liver. Excretion in urine is simulated as the balance between transfer from the free fraction to the glomerular filtrate and renal tubular reabsorption, which removes PFOA and PFOS from the glomerular filtrate and returns it to kidney tissue. Renal tubular reabsorption is simulated as a capacity-limited process with parameters T_m (µg/hour/kg body weight), representing the maximum rate of transport, and K_T (µg/L), representing affinity for the transporter (the concentration in the glomerular filtrate at which reabsorptive transport rate

is half of maximum). This representation of renal tubular reabsorption is used to simulate observed sex differences in elimination of PFOA from plasma, which have been attributed to higher reabsorptive capacity in male rats (see Section 3.1.4). Values for the maximum and affinity parameters for PFOA result in higher reabsorptive clearances from the glomerular filtrate (T_m/K_T=4.1) in male rats compared to female rats (T_m/K_T=0.045), and correspondingly lower urinary clearance of PFOA from plasma in male rats. Reabsorption parameters for PFOS are the same in both sexes and result in reabsorptive clearances that are approximately twice that of PFOA in female rats (T_m/K_T=7.2).

The basic rat model was extended to simulate gestation with inclusion of additional compartments representing adipose and mammary tissue in the dam, placenta, and fetus (Figure 3-4); Loccisano et al. 2012b). Transfer of PFOA and PFOS to the fetus is simulated as a flow-limited transfer to the placenta, with first-order exchange between the placenta and the free fraction in fetal plasma. The free fraction in fetal plasma is simulated as a constant fraction for PFOA and PFOS (i.e., no dependence on time as in the adult). Within the fetus, PFOA in the free fraction of plasma exchanges with a single lumped compartment representing the fetal body, which exchanges with PFOA in amniotic fluid. The fetal PFOS model subdivides fetal tissue into brain, liver, and a lumped compartment for other tissues, all of which undergo flow-limited exchanges with the free fraction of PFOS in fetal plasma. Binding of PFOA and PFOS in fetal liver is assumed to be negligible. Differences in the structure of the fetal models for PFOA and PFOS reflect the differences in the availability of data for estimating parameter values for the various compartments (e.g., perfluoroalkyl concentrations in amniotic fluid, liver).

The lactation model extends the dam portion of the gestational model to include milk and pup (Figure 3-5; Loccisano et al. 2012b). Transfer of PFOA to milk occurs through the mammary gland with flow-limited exchange between plasma and mammary tissue and diffusion into milk from mammary tissue. The model also includes transfer from the pup to the dam, which occurs during maternal stimulation of the neonatal pup to induce elimination and during pup grooming. Data on PFOS in mammary tissue of rodents were not available to establish parameters for a mammary tissue compartment; therefore, the mammary tissue compartment was left out of the PFOS model, and transfer of PFOS to milk is simulated as diffusion directly from plasma. The pup model includes compartments representing the free fraction in plasma, liver, kidney, glomerular filtrate, and a lumped compartment representing all other pup tissues. This structure is essentially identical to the nonpregnant rat model (Loccisano et al. 2012a) with a few differences. Absorption from the gastrointestinal tract is assumed to be complete in pups, and binding in pup liver is assumed to be negligible in pups. There are no storage compartments for biliary or glomerular filtrate perfluoroalkyl in the pup model. Sex differences in renal

tubular reabsorption of PFOA are assumed to develop in response to sexual maturation and, therefore, are not present during lactation (i.e., parameter values are allometrically scaled to pup body weight from the male rat values). Reabsorptive transport parameters for PFOS are allometrically scaled from the lactating dam. The liver/plasma partition coefficient for PFOS in the pups was set lower than that in the dam, based on observations in rats. All other parameters for PFOA and PFOS in the pup were the same or allometrically scaled from values for the dam.

Optimization of parameter values and evaluations of the rat models are described in Loccisano et al. (2012a, 2012b). Data sets utilized in developing and evaluating the nonpregnant rat models included single-dose intravenous and gavage studies and short-term feeding studies (Johnson and Ober 1979; Kemper 2003; Kudo et al. 2007; Perkins et al. 2004). Data used in development and evaluation of the gestation and lactation models included data from gestational and/or lactational exposure studies in rats (Chang et al. 2009; Hinderliter et al. 2005; Kuklenyik et al. 2004; Luebker et al. 2002, 2005a, 2005b; Thibodeaux et al. 2003).

Applications for Dosimetry Extrapolation and Risk Assessment. The wealth of data on pharmacokinetics of PFOA and PFOS in rats allowed an extensive evaluation of the rat models for predicting plasma urinary and liver PFOA and PFOS following single intravenous or single and repeated oral dosing. Inclusion of renal tubular reabsorption parameters in the model provided accurate simulations of sex differences in elimination rates of PFOA from plasma and excretion in urine, and differences in rates of elimination of PFOA and PFOS. The gestation model successfully predicted fetal plasma and liver PFOA and PFOS at the end (or near the end) of pregnancy. Consistent with observations, the model predicts higher fetal plasma concentrations and lower fetal liver concentrations of PFOS compared to maternal, and lower internal exposure (plasma concentrations) to PFOA in the fetus compared to maternal (fetal liver data were not available for PFOA). The lactation model successfully predicted PFOA and PFOS in pup plasma following dosing of the dam. Predicted plasma concentrations of PFOA in nursing pups were approximately 10–50% lower than maternal concentrations, whereas maternal and pup concentrations of PFOS were similar. The model could be used to estimate liver doses and corresponding plasma profiles resulting from single or repeated dosing of adult male or female rats, and maternal-fetal and maternal-pup transfer of PFOA and PFOS. The rat model was evaluated with data from a 14-week oral dosing study and has not been tested for longer exposures. Harris and Barton (2008) developed a PBPK model for PFOS in the rat and found that time adjustments that increased renal clearance and decreased the liver-plasma partition coefficient as a function of time and dose improved predictions of plasma and liver PFOS in adult rats exposed for a period of 105 weeks. Although the

Harris and Barton (2008) model is very different from the Loccisano et al. (2012a) model, these results suggest the possibility that clearance of PFOS may be age- and/or dose-dependent in rats. This may reflect age- or dose-related changes in kidney function, including tubular reabsorption or secretion of PFOS.

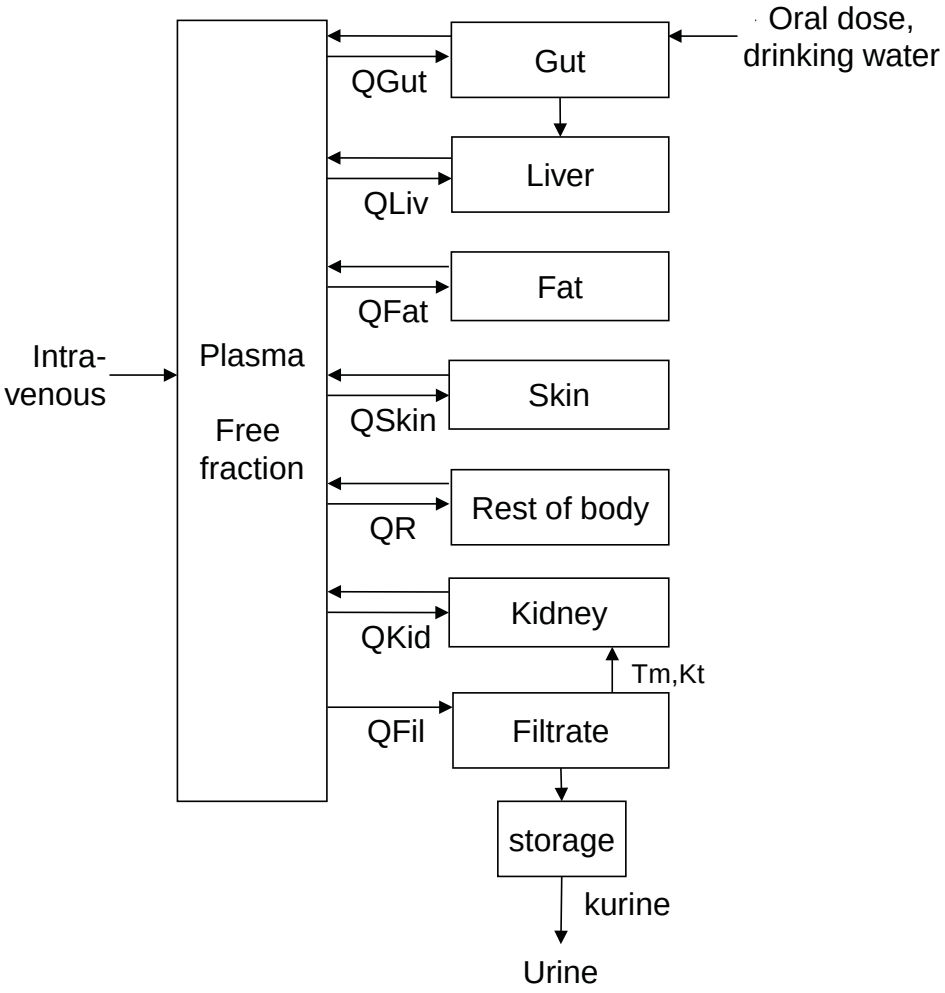
3.1.5.2 Loccisano et al. (2011, 2013) Monkey and Human Models

Loccisano et al. (2011) developed a model for simulating the kinetics of PFOA and PFOS in monkeys and humans. The human model described in Loccisano et al. (2011) was subsequently extended to include simulations of pregnancy and lactation (Loccisano et al. 2013). The monkey model was based, in part, on a multi-compartmental model developed by Tan et al. (2008; Andersen et al. 2006) for simulating the kinetics of plasma and urinary PFOA in monkeys. The structures of the monkey and human models are identical (Figure 3-6) and are very similar to the structure of the rat model (Loccisano et al. 2012a), with inclusion of compartments representing fat and skin, and absence of a storage compartment for biliary transfer. Complete lists of parameters and parameter values and the bases for parameter values and evaluations of model predictions in comparison to observations are reported in Loccisano et al. (2011).

Parameters in the monkey and human models differ in several ways from the rat model. The free fraction in plasma is represented as a constant for both PFOA and PFOS; time-dependency for PFOS in the rat model is absent in the monkey and human models. The parameters for renal tubular reabsorption of PFOA and PFOS are the same for males and females. This is consistent with the absence of evidence for a sex difference in elimination kinetics in monkeys (Butenhoff et al. 2002, 2004a; Seacat et al. 2002).

Values for the affinity constant (K_T) and maximum (T_m) for tubular reabsorption were optimized to plasma concentration kinetics in monkeys. The value for K_T in monkeys was used in the human model. The value for T_m for PFOA in humans was set to yield a plasma elimination $t_{1/2}$ of 2.3 or 3.8 years. The latter two values were derived from estimates of the serum $t_{1/2}$ in populations exposed to PFOA in drinking water (2.3 years; Bartell et al. 2010) or in retired fluorochemical workers (3.8 years; Olsen et al. 2007a). The value for T_m for PFOS in humans was set to yield a plasma elimination $t_{1/2}$ of 5.4 years, based on observations in retired fluorochemical workers (Olsen et al. 2007a). Binding of PFOA and PFOS in the liver was assumed to be negligible in monkeys and humans. Tissue-plasma partition coefficients used in both models were derived from observations in rodents and were the same in the monkey and human models.

Figure 3-6. Structure of PBPK Model for PFOA and PFOS in Monkeys and Humans



Kt = half-saturation constant; kurine = urinary elimination rate; PBPK = physiologically based pharmacokinetic; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; QFat = blood flow in and out of fat; Qfil = clearance from plasma to glomerular filtrate; QGut = blood flow in and out of gut; QKid = blood flow in and out of kidney; QLiv = blood flow in and out of liver; QR = blood flow in and out of rest of body; QSkin = blood flow in and out of skin; Tm = transport maximum

Optimization of parameter values and evaluation of the monkey and human models are described in Loccisano et al. (2011). Data sets utilized in developing and evaluating the monkey model included single-dose intravenous and oral studies and repeated-dose oral studies conducted in Cynomolgus monkeys (Butenhoff et al. 2004c; Noker and Gorman 2003; Seacat et al. 2002). Data used in evaluating the human model consisted of serum measurements in people who experienced environmental exposures (Emmett et al. 2006a; Hölzer et al. 2008; Steenland et al. 2009b), adult Red Cross donors (Olsen et al. 2003b, 2008), and retired fluorochemical workers (Olsen et al. 2007a). In general, PFOA and PFOS intakes and exposure durations were not known with certainty in these populations and, as a result, these data do not yield confident evaluations of the ability of the human model to predict intake-plasma level relationships. Follow-up monitoring after a cessation or decrease in exposure can provide data that allow evaluation of the ability of the model to accurately simulate elimination kinetics. Predicted declines in serum PFOA concentrations encompassed observed group mean declines when the T_m for renal tubular reabsorption was set to yield an elimination $t_{1/2}$ of 2.3 or 3.8 years. Group mean declines in serum PFOS were predicted reasonably well for some populations, but not all populations, when the T_m for renal tubular reabsorption was optimized to yield an elimination $t_{1/2}$ of 5.4 years.

The human pregnancy model includes additional compartments representing the free fractions in plasma, amniotic fluid, and a lumped compartment for fetal tissue (Loccisano et al. 2013). The same conceptual approach was used in the rat pregnancy model (Loccisano et al. 2012b, Figure 3-4). Rate constants for placental transfer were initially those from the rat model, adjusted to yield predicated maternal/fetal plasma ratios that agreed with observed maternal/fetal ratios in cord blood (Apelberg et al. 2007b; Fei et al. 2007; Midasch et al. 2007; Washino et al. 2009). Transfers from amniotic fluid to fetus were the same as those used in the rat model, as there were no data on which to base estimates for humans. The lactation model included additional compartments for mammary milk and a lumped compartment representing the infant. Transfer of PFOA to milk is simulated as flow-limited exchange between plasma and milk, governed by mammary tissue blood flow and a milk/plasma partition coefficient. This structure obviated the need to simulate mammary tissue kinetics, for which there were no data in humans. The milk/plasma partition coefficient was calibrated to yield predictions of observed milk/plasma ratios (Fromme et al. 2010; Kärrman et al. 2007). Transfer from maternal milk to infants is the product of the milk concentration and milk production rate (assumed to be equal to sucking rate). The pregnancy model was evaluated by comparing predicted maternal/fetal plasma ratios for PFOA and PFOS with observations from various human monitoring studies (Fei et al. 2007; Fromme et al. 2010; Hanssen et al. 2010; Inoue et al. 2004; Kim et al. 2011; Midasch et al. 2007; Monroy et al. 2008; Tittlemier et al. 2004). The lactation model was evaluated by comparing predicted maternal plasma/milk ratios for PFOA and PFOS

with observations from various human monitoring studies (Fromme et al. 2009; Kärrman et al. 2007; Liu et al. 2011). In general, most model predictions were within plus or minus 2-fold of observations.

Applications for Dosimetry Extrapolation and Risk Assessment. The model predicts plasma concentrations and tissue levels of PFOA and PFOS following intravenous or oral dosing. A skin compartment is included in the model, which may serve for simulating absorption and distribution following deposition onto the skin surface; however, the dermal absorption model was not evaluated in Loccisano et al. (2011). The human model was calibrated to predict $t_{1/2}$ values estimated for human populations (e.g., 2.3 or 3.8 years for PFOA, 5.4 years for PFOS). As a result, comparisons made between observed and predicted serum concentrations evaluate whether or not the populations actually exhibit the $t_{1/2}$ to which the model was calibrated, and not the validity of the model to predict the internal distribution of PFOA or PFOS. It is not currently possible to assess with confidence whether the human model can accurately predict doses to liver or any other tissues. Fábrega et al. (2014) applied the human adult model to estimate plasma concentrations and tissue levels of PFOA and PFOS in human autopsy samples. Exposure inputs to the model were intakes of PFOA and PFOS estimated from public water supply concentrations in the local area where the subjects had resided (Catalonia, Spain) and concentrations in local market basket foods (Domingo et al. 2012a, 2012b). The human model predicted levels of PFOA in plasma and liver that were approximately 10- and 5-fold higher, respectively, than observed. Predicted plasma levels of PFOS were approximately 2-fold higher than observed, and predicted levels of PFOS in kidney were approximately 25% of observed. Fábrega et al. (2014) explored alternative values for tissue/plasma partition coefficients, determined from human autopsy issues (Maestri et al. 2006). The adjusted partition coefficients improved predictions of observed tissue PFOA and PFOS levels. Although the model could be applied to predicting plasma concentrations of PFOA and PFOS or intakes associated with specific plasma concentrations (e.g., oral MRLs), it is not clear what advantages the model offers over simpler empirical or compartmental models similarly calibrated to predict the serum $t_{1/2}$. The monkey model has been more thoroughly evaluated for predicting plasma and urinary kinetics of PFOA and PFOS. This was possible because of the availability of more extensive experimental data on plasma and urine PFOA and PFOS following intravenous and oral (single and repeated) dosing in male and female monkeys. Nevertheless, data on internal distribution were not available to allow evaluation of how well the monkey model predicts doses to the liver or other tissues. Predictions of plasma PFOA and PFOS concentrations from the monkey (and human) model were highly sensitive to values assigned to the maximum rate for tubular reabsorption (T_m) and other parameters that govern urinary elimination of PFOA and PFOS (e.g., free fraction in plasma and glomerular filtration rate; Loccisano et al. 2011). Optimization of the monkey models relied heavily on adjusting these same parameters and, for the human

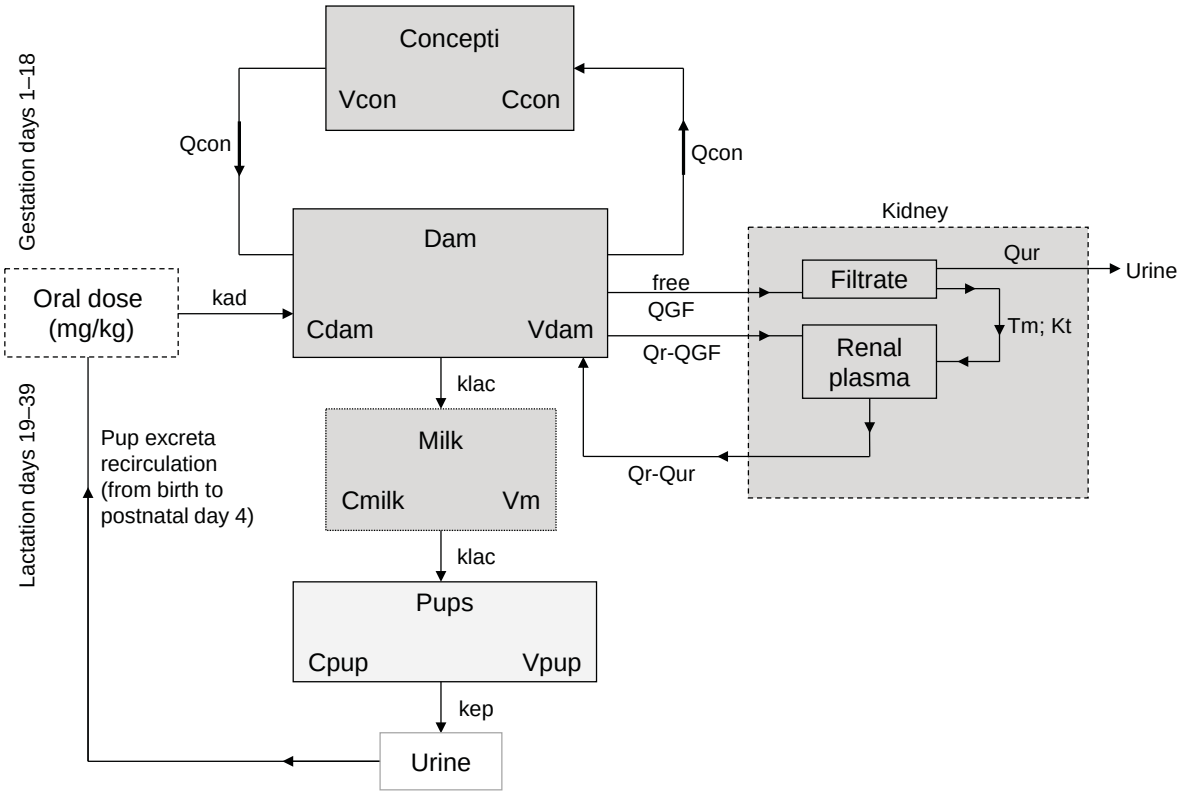
model, the target plasma elimination $t_{1/2}$ was achieved solely by adjusting T_m. Thus, despite the complexity of the models, their potential to accurately predict plasma elimination kinetics and, therefore, steady-state plasma concentrations and associated oral intakes, depends largely on how well they predict plasma clearance. If plasma clearance and the free-fraction in plasma can be reliably predicted empirically for the animal species of interest, then far simpler compartmental models can be used for dosimetry extrapolation of steady-state free plasma concentrations.

3.1.5.3 Rodriguez et al. (2009) Mouse Model

Rodriguez et al. (2009) developed a model for simulating the maternal-fetal and maternal-pup kinetics of PFOA in mice. The general structure of the model is depicted in Figure 3-7. Complete lists of parameters and parameter values and the bases for parameter values and evaluations of model predictions in comparison to observations are reported in Rodriguez et al. (2009). The maternal, fetal, and pup systems are simulated as single well-mixed compartments. Absorption from the gastrointestinal tract is simulated as first-order with complete absorption of the ingested dose. Elimination of absorbed PFOA from the maternal system is simulated as the balance between glomerular filtration and renal tubular reabsorption. The latter is represented as a saturable process with parameters T_m and K_T. Transfer to the fetus is flow-limited and governed by a fetus/maternal partition coefficient and placental blood flow. Transfer from the maternal system to the pup by lactation is simulated as first-order governed by a lactation transfer rate constant. Elimination of PFOA from the pup is first-order to urine. Data sets utilized in developing and evaluating the mouse model included oral gestational dosing studies.

Applications for Dosimetry Extrapolation and Risk Assessment. The model predicted observed concentrations of PFOA in maternal, fetal, and pup serum following oral gestational exposures to mice (Abbott et al. 2007; Lau et al. 2006; White et al. 2007). Residuals for predictions are presented, which provide a quantitative measure of how well the model predicted observations (Rodriguez et al. 2009). Similar to the rat, the mouse model predicts higher internal exposure (serum PFOA concentrations) in the maternal system compared to the fetus. It also predicts accelerated loss of PFOA from the maternal system during lactation. The model simulates the maternal, fetal, and pup systems as single compartments. Although this serves for simulating plasma concentrations (the main objective of the modeling effort), it does not allow for simulation of tissue levels of PFOA in the maternal system, fetus, or pup.

Figure 3-7. Renal Resorption Pharmacokinetic Model of Gestation and Lactation used in the Analysis of CD-1 Mice



Ccon = concentration in concepti; Cdam = concentration in dam; Cmilk = concentration in milk; Cpup = concentration in pup; kad = first-order absorption rate; kep = urinary excretion rate; klac = transfer rate via milk; Kt = half-saturation constant; Qcon = blood flow to and from placenta; QGF = glomerular filtrate; Qr = renal plasma flow; Qur = urine flow; Tm = transport maximum; Vcon = volume in concepti; Vdam = volume in dam; Vmilk = volume in milk; Vpup = volume in pup

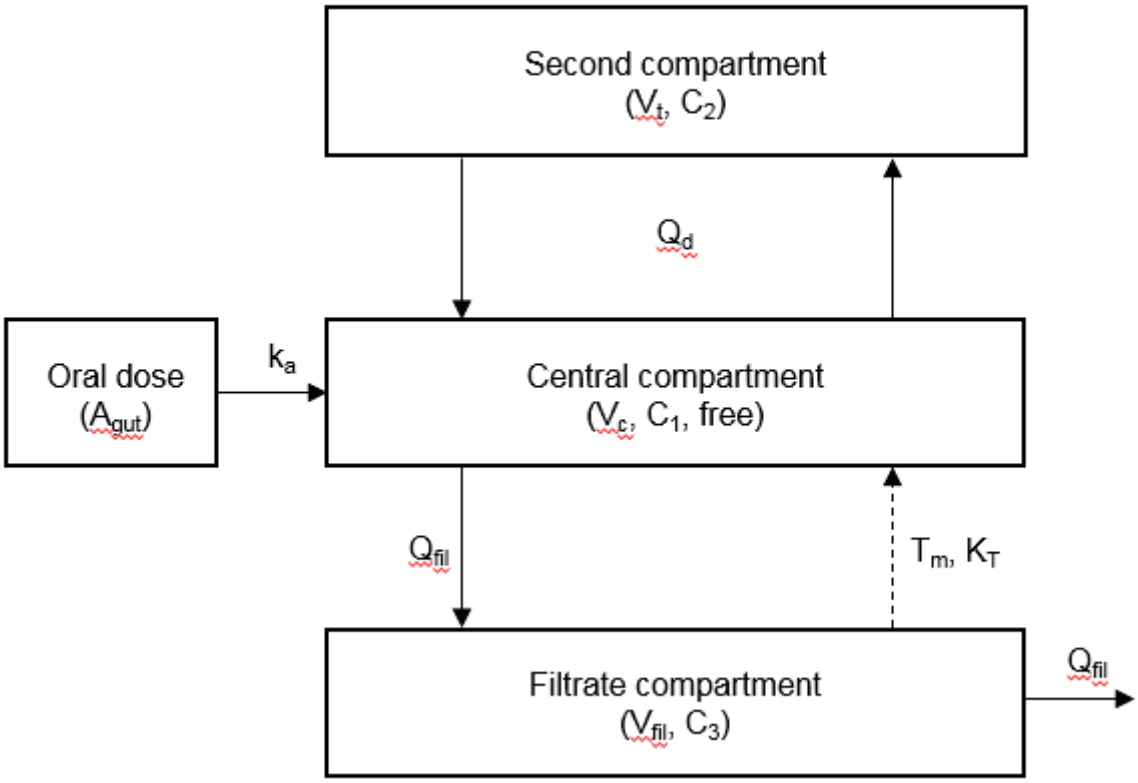
3.1.5.4. Wambaugh et al. 2013 (Andersen et al. 2006) Model

The Wambaugh et al. (2013) model is a three-compartment model based on the three-compartmental monkey model of Andersen et al. (2006). The structure of the two models are identical (Figure 3-8). Parameter values for the Wambaugh et al. (2013) model are presented in Table 3-7. The model includes a central compartment, a secondary distribution compartment, and a renal glomerular filtrate compartment. The central compartment (C1), which includes plasma, receives PFOA or PFOS from oral dosing (first-order k_a, $hour^{-1}$) and exchanges perfluoroalkyl with the secondary compartment (C2, which lumps all other tissues and distribution volumes into a single compartment) and with the glomerular filtrate (C3). A fraction of the perfluoroalkyl in C1 is free (Free) and available for exchange with C2 and C3. Exchanges between C1 and C2 are first order (k_{12}, k_{21}, $hour^{-1}$) with k_{21} assigned a value equal to the $R_{V2/V1}$, where $R_{V2/V1}$ is the ratio of the volumes of the two compartments (V_2/V_1). Transfer of perfluoroalkyl into the glomerular filtrate is first order and governed by the glomerular filtration rate (Q_{filc}, L/hour). Transfer for perfluoroalkyl from the glomerular filtrate to C1 (representing renal tubular reabsorption) is capacity limited (T_{maxc}, μmol/hr; K_T, μM). Perfluoroalkyl that is not reabsorbed is excreted.

Parameter values for the various species and strains were estimated from experimental pharmacokinetic data for each species and strain using Bayesian Markov Chain Monte Carlo (MCMC) analysis. Studies that provided data used to estimate parameter values are listed in Wambaugh et al. (2013). The parameter values shown in Table 3-7 are the mean values and posterior distributions (95% credible interval) from the MCMC analyses.

Applications for Dosimetry Extrapolation and Risk Assessment. Wambaugh et al. (2013) applied the model to predicting internal doses (mean and maximum serum concentrations and plasma AUC) for Benchmark Dose Software (BMDS) modeling and for comparing internal dosimetry from *in vivo* toxicity studies to estimates of potency (AC_{50}, maximum Efficacy) from *in vitro* studies. EPA applied the Wambaugh et al. (2013) model to deriving chronic oral reference doses (RfDs) for PFOA and PFOS (EPA 2016e, 2016f). The model was used to predict internal doses (time-integrated plasma PFOA or PFOS concentrations) achieved in toxicity studies conducted in various laboratory animal models (CD-1 mouse, C57Bl/6 mouse, Sprague-Dawley rat, Cynomolgus monkey). Plasma concentrations were then extrapolated to equivalent steady-state concentrations in humans using a model of first-order elimination of PFOA and PFOS from plasma. The same approach was used to derive MRLs for PFOA and PFOS (see Appendix A).

Figure 3-8. Andersen et al. (2006) Pharmacokinetic Model with Oral Absorption



A_{gut} is the amount of chemical in the gut; k_a is the first-order rate constant for absorption from the gut; Q_{fil} is the flow through the filtrate compartment; C_1, C_2, and C_3 are the chemical concentrations in the central, second, and filtrate compartments, respectively; V_c, V_t, and V_{fil} are the volumes of distribution of the central, second, and filtrate compartments; free is the free fraction of compound in the central compartment; Q_d is the flow between the central and second compartments; the saturable resorption process from the filtrate back into the central compartment is modeled with Michaelis-Menten kinetics, with a maximum rate $T_{maximum}$ and a half-maximum concentration K_T.

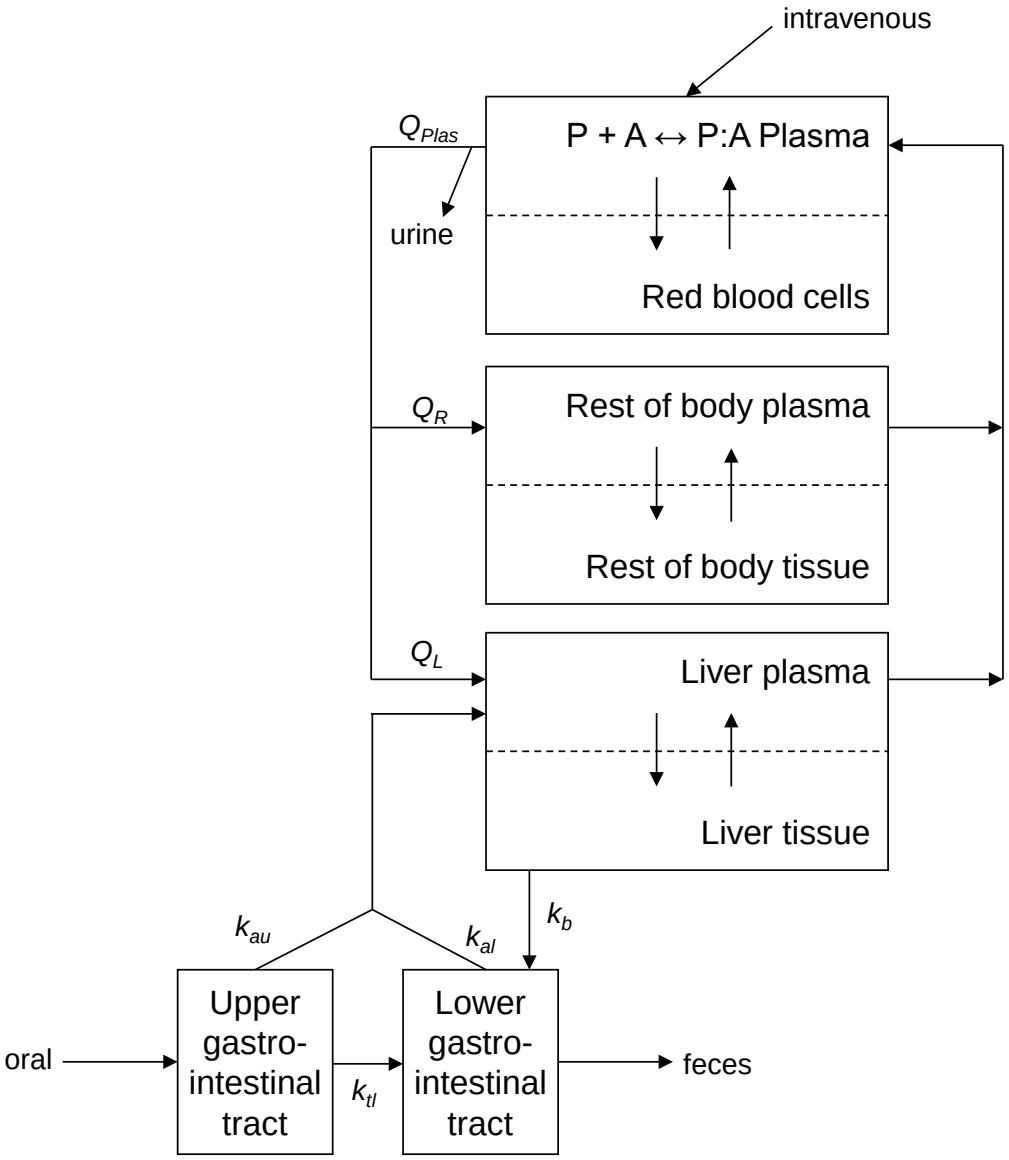
3.1.5.5 Harris and Barton (2008) Rat Model

Harris and Barton (2008) developed a model for simulating PFOS kinetics in adult rats. The general structure of the model is depicted in Figure 3-9. Complete lists of parameters and parameter values and the bases for parameter values and evaluations of model predictions in comparison to observations are reported in Harris and Barton (2008). The model includes systemic compartments representing blood (including a bound and free fraction of plasma and red blood cells), liver, and a lumped compartment representing all other tissues. The gastrointestinal tract is simulated as separate compartments representing the upper and lower tracts. Absorption occurs from both the upper and lower tracts, with distinct first-order rate constants assigned to each. Biliary PFOS is transferred from liver to the lower tract. Absorbed PFOS is delivered to the liver where it enters plasma to be distributed to other tissues. Exchanges between PFOS in plasma and all tissues are assumed to be diffusion-limited, with the free pool in plasma participating in the exchange with red blood cells, and the total plasma pool exchanging with liver and all other tissues. Binding of PFOA to plasma albumin is assumed to be saturable, with a dissociation constant 10^{-7} M and a maximum capacity 4.1x 10^{-4} M. This is implemented by assigning bound PFOA to a subcompartment of plasma in which PFOA enters (binds) or exits (unbinds) at rates governed by binding *on* and *off* rates, respectively, that yield a dissociation constant of 10^{-7} M. Elimination of absorbed chemical occurs by biliary excretion and urinary excretion. Transfer from liver to the lower gastrointestinal tract (representing excretion following biliary transfer) is represented as a first-order process acting on the total amount of PFOS in liver. PFOA is transferred to urine from the free fraction of plasma at a rate governed by a urinary clearance parameter, which is assigned a value of 28% of renal plasma flow.

In evaluating performance of the model for simulating PFOS concentrations in a chronic rat feeding study, Harris and Barton (2008) found that the model predicted plasma and liver concentrations measured at 4 and 16 weeks, but over-predicted both at 104 weeks. Performance of the model was improved by having renal clearance increase and the liver/plasma partition coefficient decrease as a function of time (i.e., study duration). These results suggest the possibility that clearance of PFOS may be dependent on age and/or a metric of dose (e.g., cumulative internal dose). This may reflect age- or dose-related changes in kidney function, including tubular reabsorption or secretion of PFOS.

Figure 3-9. Conceptual Representation of a Physiologically Based Pharmacokinetic Model for PFOS Exposure in Rats



k_{al} = rate of absorption from the lower gastrointestinal tract; k_{au} = rate of absorption from the upper gastrointestinal tract; k_b = maximum rate of biliary elimination; k_{tl} = rate of transfer from upper-lower gastrointestinal tract; P:A = PFOS-bound albumin in plasma; PFOS = perfluorooctane sulfonic acid Q_L = plasma flow rate to the liver; Q_{Plas} = plasma flow rate by the heart; Q_R = plasma flow rate to the rest of body

Applications for Dosimetry Extrapolation and Risk Assessment. The model simulates kinetics of PFOS following oral or intravenous dosing in adult rats and includes several features that are different from other PBPK models of perfluoroalkyls. The Harris and Barton (2008) model includes a red cell compartment that allows predictions of whole-blood concentrations. The utility of this feature remains to be determined, since PFOS does not appreciably concentrate in red blood cells and PFOS (and other perfluoroalkyls) is typically monitored in the central compartment with measurements of plasma or serum concentrations. The model assumes that the total concentration of PFOS (not just the free concentration) in plasma is available for distribution to liver and other tissues, whereas other models assume that only the free pool in plasma exchanges with tissues. The practical consequence of this difference may not be significant in terms of the toxicokinetics of PFOS if the tissue/plasma partition coefficients in the various models were estimated based on the relevant perfluoroalkyl pool in plasma. However, without basing distribution kinetics on the free concentration, it is not possible for concentration-dependent free fraction to be modeled. The model assumes time-dependence in the liver uptake and urinary excretion of PFOS, which were needed to improve predictions of plasma and liver concentrations of PFOS during chronic exposures. Other rat models (Loccisano et al. 2012a) have not been similarly evaluated. A mechanistic understanding of the time-dependent changes in PFOS kinetics will be important for applications of these models for dosimetry extrapolation across exposure durations.

3.1.5.6 Worley and Fisher (2015a, 2015b) Rat Model

Worley and Fisher (2015a, 2015b) expanded the Loccisano et al. (2012a) adult rat model to include simulation of renal proximal tubule apical (tubule-lumen) and basolateral (tubule-plasma) PFOA transport. This configuration allowed the use of data from *in vitro* studies of kinetics of specific transporters thought to be involved in proximal tubular transport of PFOA in the parametrization of the model. The kidney compartment was expanded to include compartments representing the proximal tubule lumen (glomerular filtrate) and proximal tubule cells. In the model, transfer of PFOA to the tubule lumen is governed by the glomerular filtration rate, represented by a clearance parameter (L/hour/kg kidney). PFOA in the tubule lumen can undergo first-order transfer to urine or saturable transport into the tubule cell (Km, Vmax). PFOA in the tubule exchanges with PFOA in plasma by three mechanisms: saturable transport from plasma into the cell (Km, Vmax), first-order transport from the cell to plasma (kefflux), or bidirectional diffusion between the cell and plasma (kdif). Parameter values (Km, Vmax) for apical and basolateral transport of PFOA were derived from *in vitro* estimates for OATP1a1 (apical) and OAT1 and OAT3 (basolateral) (Nakagawa et al. 2008; Weaver et al. 2010; Yamada et al. 2007). These estimates were scaled to kidney proximal tubule cell mass (Hsu et al. 2014) and the mass-scaled estimates

of Vmax were adjusted with relative activity factors, which were calibrated to *in vivo* observations of plasma PFOA elimination kinetics in rats (Kemper 2003). Values for kefflux (proximal tubule cell to kidney plasma) and kdif (diffusion between kidney plasma and the tubule cell) were also calibrated with *in vivo* data (Kemper 2003; Kudo et al. 2007).

Calibration of the relative activity factor for apical and basolateral membrane transport of PFOA to serum observations made in male and female rats resulted in lower values for activity of both transporters in females compared to males. This resulted in the model predicting lower rates of reabsorptive transfer of filtered PFOA to plasma, and higher renal and systemic (plasma) clearance in females compared to males. Because proximal tubule transporters were assumed to be saturable, the model predicts an increase in clearance with increasing PFOA dose, with larger increases in clearance at lower doses in females compared to males. The model simulated the observed dose-dependent increase in serum clearance (decreasing serum $t_{1/2}$) and higher serum clearance of PFOA (lower $t_{1/2}$) in female rats compared to males (Kemper 2003).

3.1.5.7 Worley et al. (2017b) Human Model

Worley et al. (2017b) scaled and calibrated the Worley and Fisher (2015a, 2015b) rat model to simulate PFOA kinetics in humans exposed to PFOA in drinking water. Physiological parameters were allometrically scaled to the human. Tissue-plasma partition coefficients were derived from human autopsy data (kidney, liver) or studies of distribution of PFOA in rats (Fabrega et al. 2014; Kudo et al. 2007; Perez et al. 2013). Parameter values (Km, Vmax) for apical and basolateral transport of PFOA were derived from *in vitro* estimates for OAT4 (apical) and OAT1 and OAT3 (basolateral) (Nakagawa et al. 2008; Weaver et al. 2010; Yang et al. 2010; Yamada et al. 2007). These estimates were scaled to kidney proximal tubule cell mass (Hsu et al. 2014) and the mass-scaled estimates of Vmax were adjusted with relative activity factors. Parameters that control apical and basolateral transfers of PFOA in the proximal tubule and absorption in the gastrointestinal tract were calibrated against data on serum PFOA concentrations measured in people who drank water from a municipal water supply (Worley et al. 2017b). Model parameter values were adjusted to achieve agreement with geometric mean serum PFOA concentrations measured at two times separated by 6 years. The model was evaluated by comparing predicted and observed serum PFOA concentrations in populations exposed to PFOA in drinking water (Bartell et al. 2010; Emmett et al. 2006b; Steenland et al. 2009a, 2009b). A sensitivity analysis of the model identified that following biokinetic parameters that had standardized sensitivity coefficients >0.1: parameters controlling proximal tubule transport and urinary excretion, plasma-liver partition coefficient,

biliary excretion and protein binding. These parameters, along with drinking water consumption, were assigned probability distributions to conduct a Monte Carlo analysis of predicted serum PFOA predictions associated with exposures to PFOA in drinking water. The probabilistic model simulated interindividual variability in serum PFOA concentrations observed in exposed populations (Bartell et al. 2010; Emmett et al. 2006b; Steenland et al. 2009a, 2009b). These results suggest that that biokinetic variability, as well as exposure variability, may contribute to variability in serum PFOA concentrations observed in populations.

3.1.5.8 Fàbrega et al. (2014, 2016) Human Model

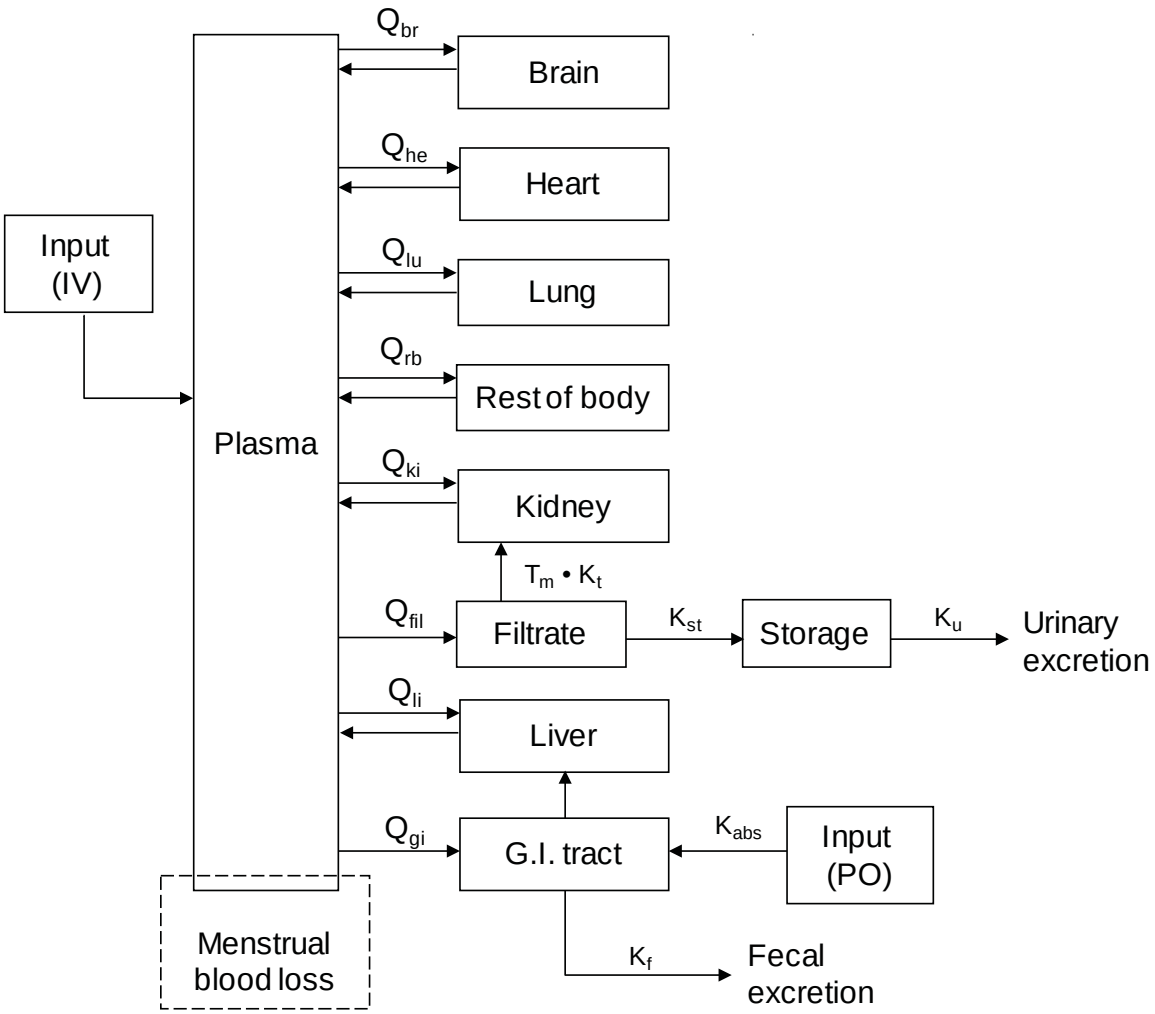
Fàbrega et al. (2014, 2016) modified the Loccisano et al. (2011, 2013) human models for PFOA and PFOS with inclusion of brain and lung compartments and removal of the skin compartment. Tissue-plasma partition coefficients were re-estimated using data from human cadavers (Maestri et al. 2006) in place of estimates based on rat data (Loccisano et al. 2011). The major differences in the partition coefficients for PFOA were lower values for liver in humans (1.03) compared to rats (2.20), higher values for fat in humans (0.47) compared to rats (0.04), and inclusion of partition coefficients for brain (0.17) and lung (1.27). For PFOS, the major differences in the partition coefficients were lower values for liver in humans (2.67) compared to rats (3.72) and higher values for fat in humans (0.33) compared to rats (0.14). Values for parameters that control urinary excretion (Tm and Km for reabsorptive transport from glomerular filtrate to kidney tissue) were recalibrated based on plasma concentration data (Ericson et al. 2007). Fàbrega et al. (2014) compared predictions to observed concentrations of PFOA and PFOS in cadaver samples (from Tarragona County, Spain) for constant intakes of 0.11 μg/day for PFOA or 0.13μg/day for PFOS. Better agreement with observations was achieved with partition coefficients based on cadaver data. Fàbrega et al. (2016) performed a quantitative uncertainty analysis of predictions of tissue PFOA and PFOS concentrations by assigning lognormal probability distributions to renal transport parameters, the unbound fraction in plasma, and intake. Probability distributions for PFOA and PFOS intakes were based on data from Domingo et al. (2012a, 2012b). Distributions for biokinetic parameters were established to achieve a coefficient of variation of 0.3 (Allen et al. 1996; Brochot et al. 2007; Sweeney et al. 2001). Observations of tissue PFOA and PFOS were within uncertainty bounds on predictions.

3.1.5.9 Kim et al. (2018) Rat and Human Model

Kim et al. (2018) developed a model for simulating the kinetics of PFHxS in rats and humans. The structures of the rat and human models are identical (Figure 3-10). Complete lists of parameters and parameter values and the bases for parameter values and evaluations of model predictions in comparison to observations are reported in Kim et al. (2018). The model includes compartments representing plasma (including a bound and free fraction), brain, gastrointestinal tract, heart, lung, kidney and renal glomerular filtrate, liver, and a lumped compartment representing all other tissues. A storage compartment receives PFHxS from the glomerular filtrate and is included in the model to simulate the time delay between elimination from plasma and appearance of PFHxS urine. Absorption from the gastrointestinal tract is simulated as the balance between first-order absorption and fecal excretion of unabsorbed PFHxS. Absorbed PFHxS is assumed to be delivered to the liver. Exchanges between PFHxS in tissues with the free pool in plasma are assumed to be flow-limited (governed by blood flow) with equilibrium determined by the tissue:plasma partition coefficient. Partition coefficients were estimated from the tissue:plasma concentration ratios measured in female and male rats 14 days after a single intravenous dose of PFHxS (0.5–10 mg/kg). Values for each sex were significantly different for brain, lung, liver, spleen, gastrointestinal tract, adipose, and skeletal muscle; in each case, male>female. The highest partition coefficient was in male liver (approximately 0.13), with the value for female being approximately half of the male value. PFHxS in plasma is simulated as instantaneous distributions into free and bound fractions. The free fraction was estimated from ultrafiltration studies of rat and human plasma. The free fraction was assigned a constant of 0.069% in female and 0.076% in male rats.

Elimination of absorbed PFHxS in the rat model occurs by fecal and urinary excretion. Fecal excretion of absorbed PFHxS is represented as flow-limited transfer from plasma to the gastrointestinal tract and first order transfer from the gastrointestinal tract to feces. Excretion in urine is simulated as the balance between transfer from the free fraction of plasma to the glomerular filtrate and renal tubular reabsorption, which removes PFHxS from the glomerular filtrate and returns it to kidney tissue. Renal tubular reabsorption is simulated as a capacity-limited process with parameters T_m (µg/hour), representing the maximum rate of transport, and K_T (µg/L), representing affinity for the transporter (the concentration in the glomerular filtrate at which reabsorptive transport rate is half of maximum). This representation of renal tubular reabsorption is used to simulate observed sex differences in elimination of PFHxS from

Figure 3-10. Structure of the PBPK Model for PFHxS in Rats and Humans*



*PFHxS can be resorbed into the kidney with transporter maximum (T_m) and transporter affinity constant (K_t). Ks indicates a rate constant; K_{st}, the rate constant to the storage compartment; K_u, the urinary elimination rate constant; K_f, the transfer rate constant from the G.I. tract to fecal elimination; and K_{abs}, the oral absorption rate constant. Q_s refers to the blood flows between plasma and tissues, except for Q_{fil}, which is a clearance from the plasma to the filtrate compartment. Menstrual blood loss (dotted square) is only applicable to female humans.

G.I. = gastrointestinal; IV = intravenous; PBPK = physiologically based pharmacokinetic; PFHxS = perfluorohexane sulfonic acid; PO = *per os*

plasma, which have been attributed to higher reabsorptive capacity in male rats (see Section 3.1.4). Values for the maximum and affinity parameters for PFHxS result in higher reabsorptive clearances from the glomerular filtrate (T_m/K_T=5.2) in male rats compared to female rats (T_m/K_T=0.057), and correspondingly lower urinary clearance of PFHxS from plasma in male rats. Values for T_m and K_t in humans were assumed to be the same as those in rats. Tissue volumes and blood flows were assigned values based on various sources (Davies and Morris 1993; Igari et al. 1983). Glomerular filtrate volume and flow were assigned values from Loccisano et al. (2012a).

The rat model was calibrated and evaluated against data on plasma and tissue levels of PFHxS measured following a single intravenous (0.5–10 mg/kg) or gavage dose (1 or 4 mg/kg) of PFHxS (Kim et al. 2018). Temporal profiles of plasma PFHxS and cumulative urinary excretion following intravenous or oral dosing were within ±1 SD of observations. Predicted cumulative urinary excretion of PFHxS reproduced the observed sex differences in urinary excretion with slower excretion and higher plasma levels in males compared to females. Terminal levels of PFHxS in heart, kidney, liver, and lung predicted for 14 days following oral dosing were within the range of observed values.

The human model was developed from the rat model with the following attributes:

- Human tissue volumes and blood flows were assigned values based on various sources (Davies and Morris 1993; Igari et al. 1983).
- Glomerular filtrate volume and flow were assigned values from Loccisano et al. (2011).
- Values for the free fraction in human plasma were 0.023% in females and 0.025% in males, based on results from ultrafiltration studies.
- Sex-specific values for renal tubular reabsorption parameters, T_m and K_t, were assumed to be the same in rats and humans.
- First order rate constants were scaled by 0.25 power of body weight ($BW^{0.25}$).
- Loss of PFHxS in menstrual blood was included in the human female model. This is represented as a direct loss of loss of 42.5 mL blood (25 mL plasma) per month (Verner and Longnecker 2015).

Kim et al. (2018) does not report an evaluation of the human model.

Applications for Dosimetry Extrapolation and Risk Assessment. The rat and human models were applied interspecies dosimetry extrapolation of a rat NOAEL for PFHxS (1 mg/kg/day). The rationale for the rat NOAEL is described in Kim et al. (2018). The dosimetry extrapolation was applied to the rat

model to predict a steady-state plasma concentration of PFHxS corresponding to a chronic oral dose of 1 mg/kg/day (value not reported). The equivalent human dose was predicted from the human PBPK model as the daily dose required to achieve the same steady state concentration in the human.

3.1.6 Animal-to-Human Extrapolations

Interspecies differences in the toxicokinetics of perfluoroalkyls and possible differences in the mechanisms of toxicity have been found. The elimination rate for PFOA in female rats is approximately 45 times faster than in male rat, 150 times faster than in Cynomolgus monkeys, and approximately 5,000–9,000 times faster than in humans (Bartell et al. 2010; Butenhoff et al. 2004c; Kemper 2003; Olsen et al. 2007a). Elimination of PFOS in male rats is approximately 3 times faster than in Cynomolgus monkeys and approximately 40 times faster than in humans (Chang et al. 2012; De Silva et al. 2009; Olsen et al. 2007a; Seacat et al. 2002). These large differences in elimination rates imply that similar external PFOA or PFOS dosages (i.e., mg/kg/day) in rats, monkeys, or humans would be expected to result in substantially different steady-state internal doses (i.e., body burdens, serum concentrations) of these compounds in each species. In addition, exposure durations required to achieve steady state would be expected to be much longer in humans than in monkeys or rats. Assuming a terminal elimination $t_{1/2}$ of 1,400 days for PFOA in humans (Olsen et al. 2007a), a constant rate of intake for 17 years would be required to achieve 95% of steady state. Steady state (i.e., 95%) would be achieved in approximately 110 days in monkeys ($t_{1/2}$=25 days, Butenhoff et al. 2004c), 30 days in male rats ($t_{1/2}$=7 days; Kemper 2003), and 1 day in female rats ($t_{1/2}$=0.2 days; Kemper 2003). Using an internal dose metric such as serum perfluoroalkyl concentration and PBPK models that can account for these differences in elimination rates can decrease the uncertainty in extrapolating from animals to humans.

The mode of action for most health outcomes associated with perfluoroalkyl exposure has not been fully characterized in humans or laboratory animals. Some perfluoroalkyl-induced effects observed in rats and mice appear to be mediated through the PPARα-dependent and -independent mechanisms (see Section 2.20 for additional information). Interpretation of the relevance of the effects observed in laboratory animals is complicated since it is generally agreed that humans and nonhuman primates are refractory, or at least less responsive than rodents, to PPARα-mediated effects (Corton et al. 2014; Klaunig et al. 2003; Maloney and Waxman 1999). While studies in mice have identified specific effects that require PPARα activation, for example, postnatal viability (Abbott et al. 2007) and some immunological effects (Yang et al. 2002b), other effects such as hepatomegaly and antigen-specific antibody response (DeWitt et al. 2016) were reported to be PPARα-independent (Yang et al.

2002b). Therefore, further studies are needed to expand the knowledge regarding PPARα-dependent and -independent effects that would allow selection of an appropriate animal model for perfluoroalkyls toxicity. In the absence of data to the contrary, ATSDR assumes that the health effects observed in laboratory animals are relevant to humans. The exception is some of the hepatic effects observed in rodents; increases in liver weight and hepatocellular hypertrophy observed in rats and mice were considered adaptive and not relevant to humans (see Section 2.9 for details).

3.2 CHILDREN AND OTHER POPULATIONS THAT ARE UNUSUALLY SUSCEPTIBLE

This section discusses potential health effects from exposures during the period from conception to maturity at 18 years of age in humans. Potential effects on offspring resulting from exposures of parental germ cells are considered, as well as any indirect effects on the fetus and neonate resulting from maternal exposure during gestation and lactation. Children may be more or less susceptible than adults to health effects from exposure to hazardous substances and the relationship may change with developmental age.

This section also discusses unusually susceptible populations. A susceptible population may exhibit different or enhanced responses to certain chemicals than most persons exposed to the same level of these chemicals in the environment. Factors involved with increased susceptibility may include genetic makeup, age, health and nutritional status, and exposure to other toxic substances (e.g., cigarette smoke). These parameters can reduce detoxification or excretion or compromise organ function.

Populations at greater exposure risk to unusually high exposure levels to perfluoroalkyls are discussed in Section 5.7, Populations with Potentially High Exposures.

The possible association between serum perfluoroalkyl levels in children and health effects has been examined in participants of the C8 Health Project and in the general population. The studies examined a number of health effects including alterations in serum lipid levels, adverse renal outcomes, neurodevelopmental alterations, and reproductive development. Immunotoxicity has been examined in children in several general population studies. Additionally, a large number of studies have examined the possible association of elevated serum perfluoroalkyl levels and adverse birth outcomes.

Similar to adults, associations between serum PFOA and PFOS and serum cholesterol levels were observed in a study of over 12,000 children (Frisbee et al. 2010); an increased risk of high cholesterol was also observed in children with higher serum PFOA and PFOS levels. A smaller study of children (n=43)

living in the Mid-Ohio Valley did not find associations between serum PFOA levels and hematology parameters, total cholesterol and liver enzymes, indices of kidney function, or serum TSH levels (Emmett et al. 2006b). Another study of highly-exposed residents did not find any associations between serum PFOA levels in children aged 6–12 years and IQ, reading and math skills, language, memory, learning, or attention (Stein et al. 2013). Similarly, no association between serum PFOA, PFOS, or PFNA levels in children 5–18 years old and the likelihood of ADHD diagnosis was observed in a study of highly-exposed residents, although the study did find an increased risk associated with higher PFHxS levels (Stein and Savitz 2011). A general population study that utilized the NHANES data found an association between serum PFOA, PFOS, and PFHxS levels and the risk of ADHD diagnosis (as reported by the parent) (Hoffman et al. 2010). Another smaller-scale study found associations between serum PFOS, PFNA, PFDA, PFHxS, and FOSA and impulsivity; no association with PFOA was found (Gump et al. 2011). A study of children 8–18 years of age participating in the C8 studies found reduced odds of reaching puberty at higher serum PFOA levels (Lopez-Espinosa et al. 2011); however, the biological significance of the short delay (4–5 months) is not known.

Several studies have evaluated immunotoxicity in children and adolescents. These studies have found impaired antibody responses associated with serum PFOA, PFOS, PFHxS, and PFDA (Grandjean et al. 2012, 2017; Granum et al. 2013; Mogensen et al. 2015a; Stein et al. 2016a). An increased asthma diagnosis was also associated with serum PFOA levels (Dong et al. 2013; Humblet et al. 2014; Zhu et al. 2016). Marginal evidence of an association with asthma diagnosis was also found for PFOS, PFHxS, PFNA, PFDA, PFBS, and PFDoDA (Dong et al. 2013; Zhu et al. 2016), although some studies found no associations for these compounds (Humblet et al. 2014; Smit et al. 2015; Stein et al. 2016a).

Hines et al. (2009) showed that *in utero* exposure (GDs 1–17) to low levels of PFOA (0.01–0.3 mg/kg/day) resulted in increases in body weight gain in 10–40-week-old mice; by 18 months of age, the body weights in these mice were similar to controls. Increases in serum insulin and leptin levels were also observed in the mice exposed to 0.01 and 0.1 mg/kg/day. The study also compared body weight and body composition of *in utero* exposed mice (exposed on GDs 1–17) and adult exposed mice (exposed for 17 days starting at 8 weeks of age) and found that *in utero* exposure to 1 mg/kg/day resulted in significantly higher body weight, brown fat weight, and white fat weight; this was not observed in mice exposed to 5 mg/kg/day. The results of the study suggest that gestational exposure to low doses of PFOA may result in increased susceptibility to PFOA toxicity.

A number of studies of highly exposed residents and the general population have examined the potential associations between serum perfluoroalkyl levels and alterations in birth weight. Decreases in birth weight have been found to be associated with higher PFOA (Fei et al. 2007; Lee et al. 2013; Maisonet et al. 2012; Savitz et al. 2012b) or PFOS levels (Maisonet et al. 2012), but not with lower levels of perfluoroalkyls (Fei et al. 2007; Hamm et al. 2010; Inoue et al. 2004; Kim et al. 2011; Monroy et al. 2008; Washino et al. 2009; Whitworth et al. 2012b). The decreases in birth weight were small (<20 g or 0.7 ounces per 1 ng/mL). Additionally, no increases in the risk of low birth weight infants were found in highly exposed populations (Darrow et al. 2013; Nolan et al. 2009; Savitz et al. 2012b; Stein et al. 2009). No apparent alterations in the risk of birth defects were found in C8 Health Studies (Darrow et al. 2013; Savitz et al. 2012b; Stein et al. 2009) or in another study of these communities (Nolan et al. 2009).

The developmental toxicity of PFOA and PFOS has been investigated in a number of rat and mouse studies. The observed effects include PFOA- and PFOS-induced increases in prenatal losses and decreases in pup survival, decreases in pup body weight, and neurodevelopmental toxicity (Abbott et al. 2007; Albrecht et al. 2013; Case et al. 2001; Chen et al. 2012b; Era et al. 2009; Fuentes et al. 2006, 2007a, 2007b; Grasty et al. 2003; Hu et al. 2010; Johansson et al. 2008; Lau et al. 2003, 2006; Luebker et al. 2005a, 2005b; Onishchenko et al. 2011; Thibodeaux et al. 2003; White et al. 2007, 2009, 2011; Wolf et al. 2007; Xia et al. 2011; Yahia et al. 2008, 2010). Additionally, delays in mammary gland development were observed in mice exposed to PFOA (Macon et al. 2011; White et al. 2007, 2009, 2011). A limited number of developmental endpoints have been examined in rats and mice exposed to PFDA, PFHxS, or PFBA (Butenhoff et al. 2009a; Das et al. 2008; Harris and Birnbaum 1989; Johansson et al. 2008; Viberg et al. 2013). A more in-depth discussion of the developmental toxicity of perfluoroalkyls in animals is included in Section 2.17.

PFOA and PFOS, as well as other perfluoroalkyls, are valid biomarkers of exposure to these compounds in children, as they are in adults. No relevant studies were located regarding interactions of perfluoroalkyls with other chemicals in children or adults.

No studies examining increased susceptibility to the toxicity of perfluoroalkyls were identified. The available epidemiological data identify several potential targets of toxicity of perfluoroalkyls, and individuals with pre-existing conditions may be unusually susceptible. For example, it appears that exposure to PFOA or PFOS can result in increases in serum lipid levels, particularly cholesterol levels. Thus, an increase in serum cholesterol may result in a greater health impact in individuals with high levels of cholesterol or with other existing cardiovascular risk factors. Associations have been found between

PFOA and PFOS levels and an increased risk of hypertension/pre-eclampsia in pregnant women. The liver has been shown to be a sensitive target in a number of animal species and there is some indication that it is also a target in humans. Therefore, individuals with compromised liver function may represent a susceptible population. Likewise, individuals with a compromised immune system may have an increased risk of perfluoroalkyl-induced immunotoxicity.

3.3 BIOMARKERS OF EXPOSURE AND EFFECT

Biomarkers are broadly defined as indicators signaling events in biologic systems or samples. They have been classified as biomarkers of exposure, biomarkers of effect, and biomarkers of susceptibility (NAS/NRC 1989).

A biomarker of exposure is a xenobiotic substance or its metabolite(s) or the product of an interaction between a xenobiotic agent and some target molecule(s) or cell(s) that is measured within a compartment of an organism (NAS/NRC 1989). The preferred biomarkers of exposure are generally the substance itself, substance-specific metabolites in readily obtainable body fluid(s), or excreta. Biomarkers of exposure to perfluoroalkyls are discussed in Section 3.3.1. The National Report on Human Exposure to Environmental Chemicals provides an ongoing assessment of the exposure of a generalizable sample of the U.S. population to environmental chemicals using biomonitoring (see http://www.cdc.gov/exposurereport/). If available, biomonitoring data for perfluoroalkyls from this report are discussed in Section 5.6, General Population Exposure.

Biomarkers of effect are defined as any measurable biochemical, physiologic, or other alteration within an organism that (depending on magnitude) can be recognized as an established or potential health impairment or disease (NAS/NRC 1989). This definition encompasses biochemical or cellular signals of tissue dysfunction (e.g., increased liver enzyme activity or pathologic changes in female genital epithelial cells), as well as physiologic signs of dysfunction such as increased blood pressure or decreased lung capacity. Note that these markers are not often substance specific. They also may not be directly adverse, but can indicate potential health impairment (e.g., DNA adducts). Biomarkers of effect caused by perfluoroalkyls are discussed in Section 3.3.2.

A biomarker of susceptibility is an indicator of an inherent or acquired limitation of an organism's ability to respond to the challenge of exposure to a specific xenobiotic substance. It can be an intrinsic genetic or other characteristic or a preexisting disease that results in an increase in absorbed dose, a decrease in the

biologically effective dose, or a target tissue response. If biomarkers of susceptibility exist, they are discussed in Section 3.2, Children and Other Populations that are Unusually Susceptible.

3.3.1 Biomarkers of Exposure

Measurement of serum or whole-blood perfluoroalkyl concentrations is the standard accepted biomarker of perfluoroalkyl exposure in humans. Perfluoroalkyls have been detected in the serum of workers, residents living near perfluoroalkyl facilities, and the general population. As part of NHANES, CDC has been measuring serum levels of perfluoroalkyls in the U.S. general population since 1999. Of the 12 perfluoroalkyls examined in this toxicological profile, blood concentrations of 7 compounds (PFOA, PFOS, PFDA, PFHxS, PFNA, and PFUnA) were detected in enough subjects to allow for estimation of the geometric mean. As compared to the general population, serum PFOA and PFOS levels are much higher in individuals with occupational exposure to these compounds (Olsen et al. 2003a; Sakr et al. 2007a) and PFOA levels are much higher in individuals living near a PFOA manufacturing facility (Emmett et al. 2006a; Steenland et al. 2009a), suggesting that serum levels are a good biomarker of exposure. Due to the long half-life of some perfluoroalkyls, particularly PFOA and PFOS, elevated serum levels may not be indicative of recent exposure. Although elevated serum levels are likely to be indicative of exposure to the parent compound, their presence in blood can also indicate exposure to other perfluoroalkyls. For example, PFOS can be derived from metabolism of FOSA (Olsen et al. 2005; Seacat and Luebker 2000). PFOA can be derived from metabolism of 8-2 fluorotelomer alcohol (Fasano et al. 2006; Henderson and Smith 2007; Kudo et al. 2005; Nabb et al. 2007). Exposure of mice to 8–2 telomer alcohol also generated PFNA as a metabolite (Kudo et al. 2005). Most epidemiological studies measured serum perfluoroalkyl levels as a biomarker of exposure. In general, these studies provided a one-time serum perfluoroalkyl level, but lacked information on actual environmental exposure concentrations or doses, route of exposure, and exposure duration. The differences in elimination half-lives between perfluoroalkyls also confounds the interpretation of one-time measurements; the relative concentration of the perfluoroalkyls measured in serum may not be reflective of the actual mixture to which the individual was exposed.

Two studies have also evaluated the use of perfluoroalkyl levels in hair as a biomarker of exposure. In rats administered PFOA, PFOS, or PFNA in the drinking water for 90 days, significant correlations between hair perfluoroalkyl levels and serum and tissue (liver, heart, lung, kidney) levels were found, suggesting that hair perfluoroalkyl levels may be a reliable biomarker of exposure (Gao et al. 2015). A study in humans (Alves et al. 2015) has also found detectable levels of PFBA, PFHxA, PFOA, PFBS, and

PFHxS in hair samples, but PFHpA, PFNA, and PFOS were not detected in hair samples. The study did not evaluate the potential relationship between serum perfluoroalkyl levels and hair levels, which does not allow for an assessment of whether hair is a viable biomarker of exposure.

Urinary perfluoroalkyl levels have also been evaluated as a biomarker of exposure (Worley et al. 2017a). A study of highly exposed residents measured urinary PFOA, PFOS, PFNA, and PFHxS levels. With the exception of PFOA, the proportion of values below the detection limit was too high to calculate mean or median values. The study found a strong linear correlation between serum PFOA levels and urinary PFOA levels in men and a nonsignificant weak correlation between serum and urinary PFOA levels in women.

3.3.2 Biomarkers of Effect

There are no specific biomarkers of effect caused by perfluoroalkyls.

3.4 INTERACTIONS WITH OTHER CHEMICALS

There are limited data on the interactions of perfluoroalkyls with other chemicals. Particularly absent are studies examining toxicological and toxicokinetic interactions of a perfluoroalkyl with other perfluoroalkyls. Olestra decreased the absorption of PFOA from the gastrointestinal tract of mice (Jandacek et al. 2010). No additional information was located regarding interactions among chemicals of this class or between perfluoroalkyls and other chemicals. Both PFOA and PFOS (and many other diverse chemicals) can activate the PPARα, as well as other PPARs to a lesser extent (Takacs and Abbott 2007; Vanden Heuvel et al. 2006). Therefore, it is not unreasonable to speculate that interactions at the receptor level might occur; however, there are no experimental data to support or rule out this presumption. PPARα-independent mechanism are also involved in the toxicity of perfluoroalkyls and interactions between compounds are also likely to influence these mechanisms.

CHAPTER 4. CHEMICAL AND PHYSICAL INFORMATION

4.1 CHEMICAL IDENTITY

Information regarding the chemical identity of perfluoroalkyls is located in Table 4-1. This information includes synonyms, chemical formulas and structures, and identification numbers. The perfluoroalkyls discussed in this profile exist as linear and branched isomers depending upon the method of production (see Chapter 5) and the reported values for the physical-chemical properties are typically reflective of the mixtures rather than a single specific isomer.

4.2 PHYSICAL AND CHEMICAL PROPERTIES

Information regarding the physical and chemical properties of perfluoroalkyls is located in Table 4-2.

Perfluoroalkyls are very stable, owing to the strength of the carbon-fluorine bonds, the presence of the three electron pairs surrounding each fluorine atom, and the shielding of the carbon atoms by the fluorine atoms (3M 1999; Kissa 2001; Schultz et al. 2003). Perfluoroalkyl carboxylates and sulfonates are resistant to direct photolysis and reaction with acids, bases, oxidants, and reductants (3M 2000; EPA 2008a; OECD 2002, 2006a, 2007; Schultz et al. 2003).

APFO was shown to decompose starting at 196°C (Krusic and Roe 2004) and PFOA was shown to decompose rapidly in the presence of crushed borosilicate glass at 307°C (Krusic et al. 2005). 1-H perfluoroheptane and perfluoroheptene are noted degradation products.

Perfluoroalkyl carboxylates and sulfonates consist of a perfluorocarbon tail that is both hydrophobic and oleophobic and a charged end that is hydrophilic (3M 1999; de Vos et al. 2008; Kissa 2001; Schultz et al. 2003). This combination of hydrophobic and oleophobic characteristics makes these substances very useful as surfactants. The ability of these substances to repel oil, fat, and water has resulted in their use in surface protectants (Kissa 2001). Their ability to reduce the surface tension of aqueous systems to <20 mN/m has resulted in their use as wetting agents (Kissa 2001). Neutral or uncharged perfluoroalkyls or very long chain constituents are expected to form separate layers when mixed with hydrocarbons and water. Conversely, charged species, salts, and ionized species at relevant pH (i.e., PFOS, PFOA, PFHpA, PFNA) and short-chain species (i.e., PFBA, PFBS) have relatively good solubility in water and alcohol.

Table 4-1. Chemical Identity of Perfluoroalkyls

Characteristic	Information		
Chemical name	Perfluorooctanoic acid	Ammonium perfluorooctanoate	Perfluorobutanoic acid
Synonym(s)	PFOA; pentadecafluoro-1-octanoic acid; pentadecafluoro-n-octanoic acid; pentadecafluorooctanoic acid; perfluorocaprylic acid; perfluorooctanoic acid; perfluoroheptanecarboxylic acid; octanoic acid, 2,2,3,3,4,4,5,5,6,6,7,7,8,8, 8-pentadecafluoro-	APFO; ammonium pentadecafluorooctanoate; octanoic acid, 2,2,3,3,4,4,5,5,6,6,7,7,8,8,8-pentadecafluoro-ammonium salt (1:1)	PFBA; heptafluoro-1-butanoic acid; heptafluorobutanoic acid; heptafluorobutyric acid; perfluorobutyric acid; perfluoropropanecarboxylic acid; 2,2,3,3,4,4,4-heptafluorobutanoic acid

APFO= ammonium perfluorooctanoate; FOSA = perfluorooctane sulfonamide; PFBA = perfluorobutanoic acid; PFBS = perfluorobutane sulfonic acid; PFDA = perfluorodecanoic acid; PFDoDA = perfluorododecanoic acid; PFHpA = perfluoroheptanoic acid; PFHxA = perfluorohexanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; PFUnA = perfluoroundecanoic acid

The formation of an emulsified layer between the octanol and water interface makes the accurate measurement of properties such as log K_{ow} very difficult using conventional experimental techniques like the shake flask method or the slow stir technique (EPA 2005a, 3M 1999, 2008c). Xiang et al. (2018) used reverse-phase high-performance liquid chromatography (HPLC) to study the partitioning between the stationary column and mobile phase as a means of simulating the octanol-water partitioning process. As discussed in this study, acidic ionizable compounds are difficult to measure with this method since the pH of the mobile phase should be 2 log units lower than the pK_a of the chemical; however, extremely low pHs damage the stationary column. Therefore, a mobile phase over a range of pHs (1.09–5.00) was used to estimate the log D (sum of the ionized and unionized species in octanol/sum of the ionized and unionized species in water) over this pH range for 11 perfluoroalkylcarboxylic acids, including PFOA, and then the log D was converted to the neutral species log K_{ow}. The estimated log K_{ow} values of the perfluoroalkylcarboxylic acids (C4–C14) were in the range of 1.05 (PFBA) to 7.19 (perfluorotetra-decanoic acid).

Both the potential to form separate layers when mixed with hydrocarbons and water and the propensity for charged or ionized perfluoroalkyls to concentrate at interfaces make the measurement of the n-octanol water partition coefficient impractical (3M 1999; EPA 2005a).

The pKa range (Table 4-2) indicates that perfluoroalkyls will exist in anion form when in contact with water at environmental and physiologically relevant pHs. An estimated pKa of 6.24 indicates that FOSA will exist as both the anion and the neutral species (SPARC 2008). Perfluoroalkyl salts, such as APFO, will form the corresponding anions when dissolved in water. Prevedouros et al. (2006) reported a Krafft point of 22°C and critical micelle concentration of $3.7x10^3$ mg/L for the perfluorooctanoate anion (PFO). At temperatures above the Krafft point, the solubility of PFO is expected to increase abruptly due to the formation of micelles.

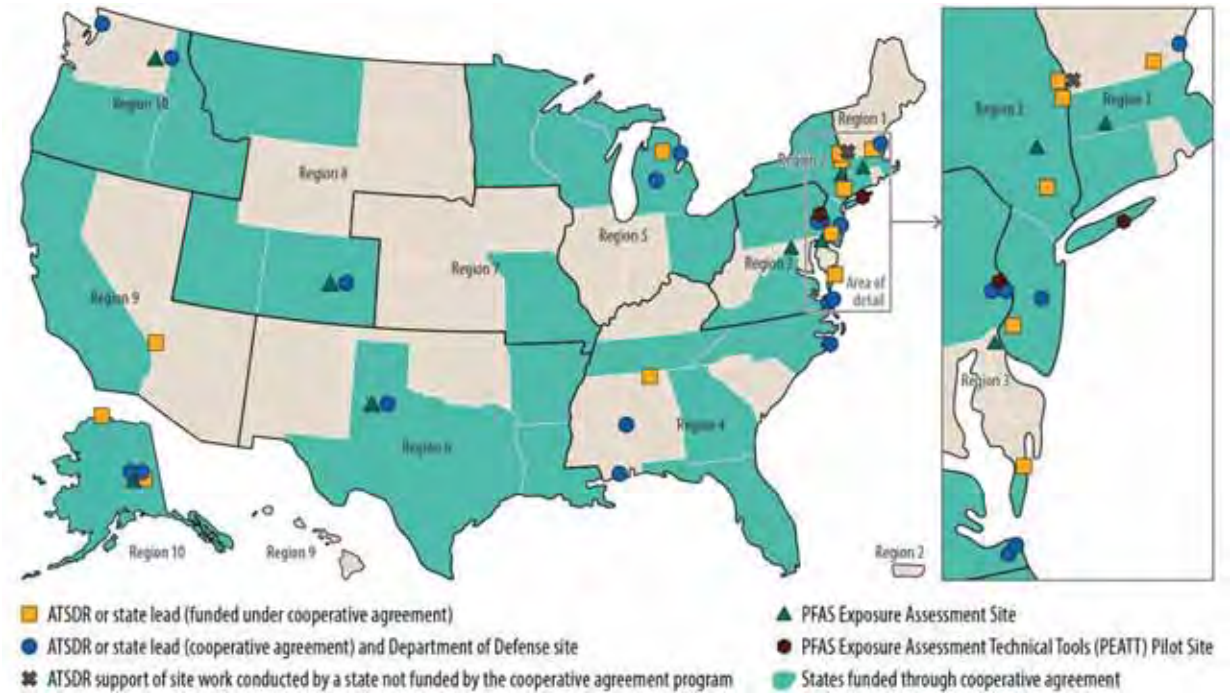
Vapor pressures at 25°C were extrapolated for PFOA, PFNA, PFDA, PFUnA, and PFDoDA using Antoine coefficients. Experimental vapor pressures were as follows: 0.962–724 mm Hg (59.25–190.80°C) for PFOA; 8.40–750 mm Hg (99.63–203.12°C) for PFNA; 23.5–750 mm Hg (129.56–218.88°C) for PFDA; 4.62–750 mm Hg (112.04–237.65°C) for PFUnA; and 6.42–750 mm Hg (127.58–247.36°C) for PFDoDA (Kaiser et al. 2005).

CHAPTER 5. POTENTIAL FOR HUMAN EXPOSURE

5.1 OVERVIEW

Perfluoroalkyls have been identified in at least 4 of the 1,854 hazardous waste sites that have been proposed for inclusion on the EPA National Priorities List (NPL) (ATSDR 2017). However, the number of sites in which substance perfluoroalkyls have been evaluated is not known. Figure 5-1 illustrates perfluorinated compound (PFAS) sites with ATSDR, state health department, EPA, or Department of Defense involvement.

Figure 5-1. Perfluorinated Compound (PFAS) Sites with ATSDR, State Health Department, U.S. Environmental Protection Agency, or Department of Defense Involvement



Source: ATSDR 2018

- The general population is exposed to the perfluoroalkyls through food and water ingestion, dust ingestion, inhalation exposure, and hand-to-mouth transfer of materials containing these substances.
- PFOA, PFOS, and their precursor substances are no longer produced or used in the United States or most other industrialized nations; however, these substances are persistent in the environment and exposure near highly contaminated sites may continue to occur.
- Serum levels of PFOA and PFOS in the general population of the United States have declined dramatically since 2000.

Perfluoroalkyls have been released to air, water, and soil in and around fluorochemical facilities located within the United States (3M 2007b, 2008a, 2008b; Barton et al. 2007; Davis et al. 2007; DuPont 2008; EPA 2008a; Post et al. 2013). Since the early 2000s, eight companies in the fluorochemical industry have been working in concert with the EPA to phase out the production and use of long-chain perfluoroalkyls and their precursors (3M 2008a; DuPont 2008; EPA 2007a, 2008a, 2016a). Perfluorocarboxylic acids containing seven or more perfluorinated carbon groups and perfluoroalkyl sulfonic acids containing six or more perfluorinated carbon units are considered long-chain substances. Perfluorinated carboxylic acids and sulfonic acids containing less than seven and six perfluorinated carbons, respectively, are considered short-chain substances. PFOA, PFOA precursors, and higher homologues have been phased out by the eight corporations in the perfluorotelomer/fluorotelomer industry (Arkema, Asahi, BASF [successor to Ciba], Clariant, Daikin, 3M/Dyneon, DuPont, and Solvay Solexis) as part of the EPA's PFOA Stewardship Program (DuPont 2008; EPA 2008a, 2016a). Industrial releases of these compounds in the United States have declined or have been totally eliminated based on company reports submitted to EPA (EPA 2008a, 2016a). It is noted that PFOA and PFOS may still be produced domestically, imported, and used by companies not participating in the PFOA Stewardship Program. PFOA and PFOS may also be present in imported articles. Although the United States and most industrialized nations have stopped producing PFOA and PFOS, China remains a major producer and user of both substances, and its production has increased as production in the rest of the world has declined (HAES 2017; Li et al. 2015; Lim et al. 2011).

Perfluoroalkyl carboxylic acids and sulfonic acids are expected to dissociate in the environment based on their low pKa values (Kissa 2001; SPARC 2008), and anions will not volatilize from water or soil surfaces (Prevedouros et al. 2006). The unique surfactant properties of these substances may prevent total dissociation of perfluoroalkyls in water (EPA 2005a; Kissa 2001; Prevedouros et al. 2006); therefore, some volatilization of perfluoroalkyls may occur since the neutral forms of these substances are considered to be volatile (Barton et al. 2007; EPA 2005a; Kim and Kannan 2007). Perfluoroalkyls have been detected in air both in the vapor phase and as adsorbed to particulates (Kim and Kannan 2007). Perfluoroalkyls are very stable compounds and are resistant to biodegradation, direct photolysis, atmospheric photooxidation, and hydrolysis (3M 2000; EPA 2008a; OECD 2002, 2007; Schultz et al. 2003). Perfluoroalkyls released to the atmosphere are expected to adsorb to particles and settle to the ground through wet or dry deposition (Barton et al. 2007; Hurley et al. 2004; Prevedouros et al. 2006). The chemical stability of perfluoroalkyls and the low volatility of these substances in ionic form indicate that perfluoroalkyls will be persistent in water and soil (3M 2000; Prevedouros et al. 2006). Soil

adsorption coefficient data as well as monitoring studies suggest that perfluoroalkyls such as PFOA are mobile in soil and can leach into groundwater (Davis et al. 2007; Prevedouros et al. 2006).

Perfluoroalkyls have been detected in environmental media and biota of the Arctic region and in other remote locations such as open ocean waters (Barber et al. 2007; Brown et al. 2018; Prevedouros et al. 2006; Wei et al. 2007a; Yamashita et al. 2005, 2008). Proposed source pathways include long-range atmospheric transport of precursor compounds followed by photooxidation to form perfluoroalkyls, direct long-range transport of perfluoroalkyls via oceanic currents, and transport of perfluoroalkyls in the form of marine aerosols (Armitage et al. 2006; Barber et al. 2007; Brown et al. 2018; Prevedouros et al. 2006; Wania 2007). Direct transport of perfluoroalkyls in the atmosphere has also been proposed as a source pathway since these substances have been detected in the vapor phase in outdoor air samples (CEMN 2008; Prevedouros et al. 2006). The actual source of perfluoroalkyls in remote locations is likely to be a combination of these pathways.

The highest concentrations of PFOA and PFOS were in apex predators, such as polar bears, which indicates that these substances biomagnify in food webs (de Vos et al. 2008; Houde et al. 2006b; Kannan et al. 2005; Kelly et al. 2007; Smithwick et al. 2005a, 2005b, 2006). The bioaccumulation potential of perfluoroalkyls is reported to increase with increasing chain length (de Vos et al. 2008; Furdui et al. 2007; Martin et al. 2004b). In living organisms, perfluoroalkyls bind to protein albumin in blood, liver, and eggs and do not accumulate in fat tissue (de Vos et al. 2008; Kissa 2001).

The levels of PFOA and PFOS in serum samples of U.S. residents have decreased appreciably since the phase out of these substances in the United States. The geometric mean serum levels of PFOS have declined over 84% from NHANES survey years 1999–2000 (30.4 ng/mL) to 2013–2014 (4.72 ng/mL) and the geometric mean serum levels of PFOA have declined 70% over the same temporal period, decreasing from 5.2 ng/mL in years 1999–2000 to 1.56 ng/mL for 2015–2016 (CDC 2018).

Mean concentrations of PFHpA, PFNA, PFDA, PFUnA, PFDoDA, PFBS, PFBA, and FOSA are generally <1 ng/mL (Calafat et al. 2006b, 2007a, 2007b; CDC 2015; De Silva and Mabury 2006; Kuklenyik et al. 2004; Olsen et al. 2003a, 2003b, 2004c, 2005, 2007a). Major PFOS exposure pathways proposed for the general population include food and water ingestion, dust ingestion, and hand-to-mouth transfer from mill- or home-treated carpets (Trudel et al. 2008). For PFOA, the major exposure pathways are proposed to be oral exposure resulting from general food and water ingestion, inhalation from impregnated clothes, and dust ingestion. While migration of residual PFOA in paper packaging and

wrapping into food is also a potential route of exposure (Trudel et al. 2008), polyfluoroalkyl phosphoric acids in food packaging can also be metabolized in the body to PFOA (D'eon and Mabury 2007; D'eon et al. 2009). Polyfluoroalkyl phosphoric acids are fluorinated surfactant substances used to greaseproof food-containing paper products. Biotransformation of the 8:2 polyfluoroalkyl phosphoric acid and the 8:2 fluorotelomer alcohol into PFOA has been demonstrated (D'eon et al. 2009). Based on these proposed exposure pathways, Trudel et al. (2008) estimated that adult uptake doses for high-exposure scenarios were approximately 30 and 47 ng/kg body weight/day for PFOS and PFOA, respectively. The estimated dosage for children under the age of 12 under a high-exposure scenario were estimated to be 101–219 and 65.2–128 ng/kg body weight/day for PFOS and PFOA, respectively (Trudel et al. 2008). It is noted that the Trudel et al. (2008) study used older monitoring data and thus, may not be an accurate reflection of current intakes. Estimated daily doses for the general population were also estimated by Vestergren et al. (2008) to range from 3.9 to 520 ng/kg body weight/day for PFOS and from 0.3 to 150 ng/kg body weight/day for PFOA. Infants and toddlers had the highest estimated dosages due to greater hand-to-mouth contact with treated carpeting, mouthing activities of clothes, and greater dust ingestion. While conversion of precursor compounds to PFOA and PFOS was generally considered as a minor contribution to the total exposure, under certain scenarios, it was estimated that up to 80% of the intake could be attributable to exposure to precursor substances followed by subsequent metabolism to PFOS or PFOA (Vestergren et al. 2008).

Perfluoroalkyls have been detected in human breast milk and umbilical cord blood. The reported maximum concentrations of PFOS and PFOA measured in human breast milk samples were 0.360–0.685 and 0.210–0.609 ng/mL, respectively (Kärrman et al. 2007; Llorca et al. 2010; So et al. 2006b; Völkel et al. 2008). Maximum concentrations of other perfluoroalkyls were <0.18 ng/mL (Kärrman et al. 2007). PFOS and PFOA have been detected in most umbilical cord blood samples with reported concentrations of 4.9–11.0 and 1.6–3.7 ng/mL, respectively (Apelberg et al. 2007a, 2007b; Fei et al. 2007; Inoue et al. 2004; Midasch et al. 2007). Other perfluoroalkyls have been detected less frequently, with maximum concentrations of <2.6 ng/mL.

Individuals who perform jobs that require frequent contact with perfluoroalkyl-containing products, such as individuals who install and treat carpets or firefighters, are expected to have occupational exposure to these substances. Individuals who work at fluorochemical facilities generally have had higher perfluoroalkyl serum levels than the general population based on exposures in the work environment (3M 2007b, 2008b, 2008c; Barton et al. 2006; Davis et al. 2007). Studies of individuals living near fluorochemical facilities indicate that drinking water is the major exposure pathway (Emmett et al. 2006a;

Hölzer et al. 2008; Wilhelm et al. 2009). 3M conducted an exposure assessment to estimate the cumulative exposure to PFOA due to activities at the Decatur, Alabama facility. On-site exposure to groundskeepers, maintenance workers, construction workers, and on-site trespassers were considered. Off-site exposures to anglers, boaters, and residential individuals were also estimated. Various plausible exposure scenarios were considered, and the highest PFOA exposure doses by receptor and pathway occurred for local residents from groundwater followed by residents consuming drinking water from the West Morgan/East Lawrence (WM/EL) public drinking water supply (3M 2008c).

5.2 PRODUCTION, IMPORT/EXPORT, USE, AND DISPOSAL

5.2.1 Production

Perfluoroalkyls have been manufactured industrially by electrochemical fluorination (ECF), fluorotelomer iodide oxidation, fluorotelomer olefin oxidation, and fluorotelomer iodide carboxylation (Prevedouros et al. 2006; Schultz et al. 2003). During the ECF process, an organic acyl or sulfonyl fluoride backbone structure is dissolved in a solution of aqueous hydrogen fluoride (Savu 1994b; Siegemund et al. 2005). A direct electrical current is then passed through the solution, which replaces all of the hydrogens on the molecule with fluorines. Perfluoroacyl fluorides produced by ECF are hydrolyzed to form the perfluorocarboxylic acid, which is then separated via distillation. This method was used extensively by 3M in the production of perfluoroalkylsulfonates such as PFOS (3M 1999; Hekster et al. 2003; Schultz et al. 2003).

$$R_hCOF + HF \longrightarrow R_fCOF + H_2 + \text{byproducts}$$

$$R_fCOF + H_2O \longrightarrow R_fCOOH + HF$$

Perfluoroalkanesulfonyl fluorides produced by ECF are hydrolyzed under alkaline conditions to form the corresponding salt (Savu 1994b; Siegemund et al. 2005). Acidification followed by distillation yields the anhydrous perfluoroalkanesulfonic acid.

$$R_hSO_2F + HF \longrightarrow R_fSO_2F + H_2$$

$$R_fSO_2F + KOH \longrightarrow R_fSO_3K + HF$$

$$R_fSO_3K + H_2SO_4 \longrightarrow R_fSO_3H + KHSO_4$$

Perfluorosulfonamide compounds, such as FOSA, can be formed by reacting the perfluoroalkanesulfonyl fluoride with a primary or secondary amine (3M 1999; Hekster et al. 2003; Siegemund et al. 2005).

The fluorotelomer iodide oxidation process was developed by DuPont and has served as the basis for their fluoropolymer production chemistry (Buck et al. 2011; Hekster et al. 2003; Savu 1994a; Siegemund et al. 2005). It begins with the preparation of pentafluoroiodoethane from tetrafluoroethene. Tetrafluoroethene is then added to this product at a molar ratio that gives a product of desired chain length. Finally, the product is oxidized to form the carboxylic acid. The process produces linear perfluorocarboxylic acids of even carbon numbers as illustrated below.

$$5C_2F_4 + IF_5 + 2I_2 \xrightarrow{\text{catalyst}} 5C_2F_5I$$

$$C_2F_5I + nC_2F_4 \longrightarrow C_2F_5(C_2F_4)_nI$$

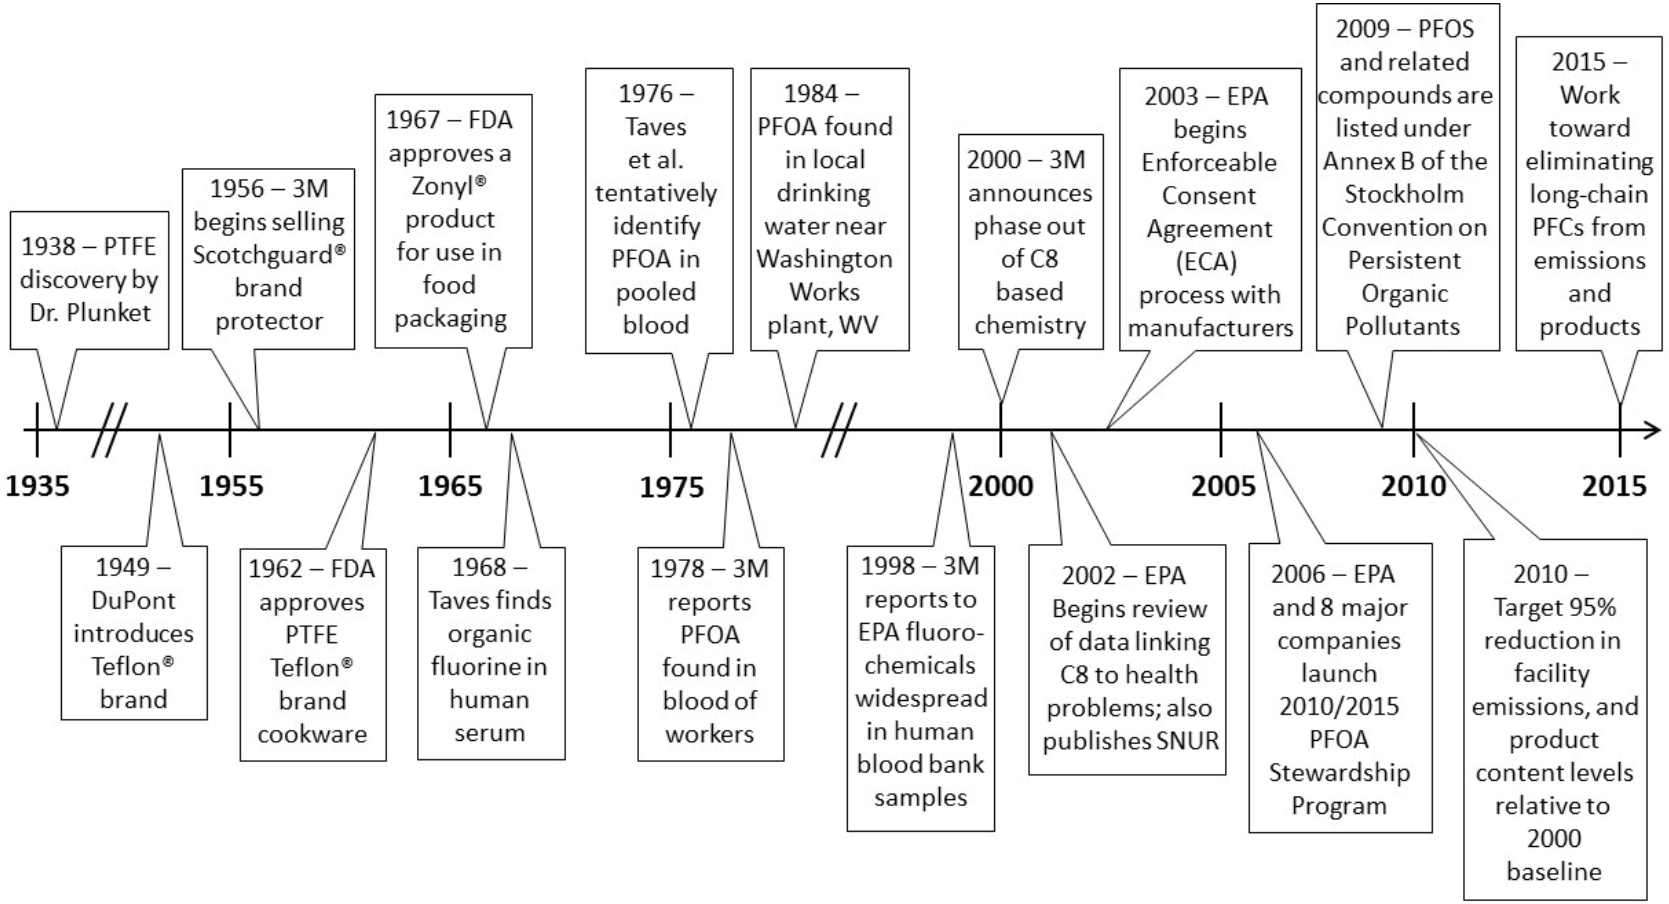
$$C_2F_5(C_2F_4)_nI \xrightarrow{SO_3} C_2F_5(C_2F_4)_{n-1}CF_2COOH$$

Fluorotelomer alcohols are created similarly, but the perfluoroalkyl iodide (telomer A) is reacted with ethylene to create $F(CF_2)_nCH_2CH_2I$ (telomer B), which is converted to the alcohol. The ECF process resulted in a mixture of linear and branched isomers, whereas the telomerization processes yielded predominantly linear products. It has been reported that the 3M ECF process resulted in approximately 70% linear and 30% branched isomers for PFOS and 78% linear and 22% branched isomers for PFOA (Benskin et al. 2009).

No information is available in the TRI database on facilities that manufacture, process, or otherwise use perfluoroalkyls because this class of substances is not required to be reported under Section 313 of the Emergency Planning and Community Right-to-Know Act (Title III of the Superfund Amendments and Reauthorization Act of 1986) (EPA 2005a, 2016g). The Chemical Data Reporting (CDR) rule, under the Toxic Substances Control Act (TSCA), requires manufacturers (including importers) to provide EPA with information on the production and use of chemicals in commerce in large quantities. Information on perfluoroalkyls can be found at (https://www.epa.gov/chemical-data-reporting/basic-information-chemical-data-reporting#what).

Perfluoroalkyls have been manufactured for their direct use in commercial products as well as for their use in industrial process streams. Two important chemicals that have resulted from manufacturing involving perfluoroalkyls, namely PFOS and PFOA, are of worldwide interest given their detection in multiple media in the environment. However, these substances and related long-chain perfluoroalkyls have been essentially phased out as a joint effort by EPA and industry (Lindstrom et al. 2011). The timeline for history of perfluorinated compound production, use, and phase out is presented in Figure 5-2.

Figure 5-2. Timeline of Important Events in the History of Polyfluorinated Compounds



EPA = U.S. Environmental Protection Agency; PFC = perfluorinated compound; PFOA = perfluorooctanoic acid; PTFE = polytetrafluoroethylene; SNUR = significant new use rule; WV = West Virginia

Given their unique properties, certain narrow exceptions exist for specific applications. Additionally, many of the substances that were used in the production of stain resistant or anti-sticking products that could break down into PFOA and PFOS have also been replaced.

The 3M Company was the principal worldwide manufacturer of PFOS and related chemicals. As a result of its phase-out decision in May 2000, 3M no longer manufactures perfluorooctanyl compounds (PFOA and PFOS). The company ceased manufacturing and using the vast majority of these compounds within approximately 2 years of the phase-out announcement, and ceased all manufacturing and the last significant use of this chemistry by the end of 2008 (3M 2008a; EPA 2007a). In 2000, EPA finalized the SNUR for 88 perfluoroalkyl sulfonate compounds, which requires manufacturers to notify EPA 90 days prior to commencing manufacture or import of these substances for a significant new use to allow time for evaluation (EPA 2002, 2007a, 2008a). The purpose of this rule was to limit future manufacturing and importation of these substances. According to EPA, the rule allowed for the continuation of a few limited, highly technical uses for which no alternatives are available, and which are characterized by very low volume, low exposure, and low releases. The SNUR was amended in 2007 to include 183 additional perfluoroalkyl sulfonate compounds (EPA 2007a, 2008a).

Included on the current list are PFOS, PFHxS, and FOSA. EPA believed that the perfluoroalkyl sulfonate compounds listed under the SNUR were no longer manufactured in the United States; however, during the comment period of the 2007 amendment, EPA learned of the ongoing use of tetraethylammonium perfluorooctanesulfonate as a fume/mist suppressant in metal finishing and plating baths (EPA 2007a). EPA has since excluded this from the list of significant uses. This rule has been amended again by the EPA to designate the processing, use, or importation of long-chain perfluoroalkyls as a significant new use if there are no current ongoing uses, or for uses that were scheduled to end December 31, 2015 (EPA 2015). As part of this amendment, EPA proposed to amend a SNUR for perfluoroalkyl sulfonate chemical substances that would make the exemption inapplicable for persons who import perfluoroalkyl sulfonate chemical substances as part of carpets or any articles that contain long-chain perfluoroalkyls.

In 2006, the eight major companies of the perfluoropolymer/fluorotelomer industry agreed to participate in EPA's PFOA Stewardship Program (EPA 2008a). All public documents and reports from the PFOA Stewardship Program may be reviewed at the EPA docket (EPA-HQ-OPPT-2006-0621). This program included voluntary commitments from these companies to reduce facility emissions and product content of PFOA and related chemicals on a global basis by 95% no later than 2010, and to work toward elimination of these substances in products by 2015. Progress reports have been submitted annually

beginning in 2007 and are available from the EPA PFOA Stewardship Program website. Data from these reports that list the content and percent reduction of PFOA, PFOA precursors, and higher PFOA homologues in products are listed in Table 5-1. Nonconfidential emission reports from 2014 and 2015 obtained from the EPA docket indicate that the companies have met the goals of the program. According to its 2015 emission report to EPA, Solvay Specialty Polymers (formerly Solvay Solexis) ceased using PFOA and related higher homologs in 2010 and ceased importation of products containing PFOA residuals in December 2015 (Jones 2016). DuPont does not use PFOA any longer in the emulsion polymerization of polytetrafluoroethylene (PTFE), replacing it with a processing aid consisting of the ammonium salt of 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)-propanoate, also known as GenX or hexafluoropropylene oxide dimer acid (HFPO-DA) (Wang et al. 2013b). (In 2013, DuPont separated its performance chemicals, titanium technologies, fluoroproducts division, and chemical solutions into a separate company named Chemours). Similarly, 3M and other manufacturers are using various poly- and perfluoroether acid salts in fluoropolymer manufacturing and have reformulated surface treatment products to employ short-chain substances that are not as bioaccumulative as the long-chain perfluoroalkyls. Wang et al. (2013b) provide a comprehensive review of the newer substances that manufacturers are using as replacements for legacy perfluoroalkyls in fluoropolymer manufacturing, metal plating, firefighting foams, and other miscellaneous uses such as food packaging materials. Although expected to be less, bioaccumulative modeling studies have suggested that short-chain homologues and other replacements are likely to be persistent and mobile in the environment (Gomis et al. 2015)

[a]Percent reduction in product content of these compounds from baseline year levels. The baseline year is the year nearest to the year 2000 for which company data are available.

PFOA precursors include: octane, 1,1,1,2,2,3,3,4,4,5,5,6,6,7,7, 8,8-heptadecafluoro-8-iodo- (CAS 507-63-1); 1-decanol, 3,3,4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-heptadecafluoro-(CAS 678-39-7); 1-decene, 3,3,4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-heptadecafluoro- (CAS 21652-58-4); 2-propenoic acid, 3,3,4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-heptadecafluorodecyl ester (CAS 27905-45-9); 2-propenoic acid, 2-methy 1-, 3,3,4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-heptadecafluorodecyl ester (CAS 1996-88-9); 2-decenoic acid, 3,4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-hexadecafluoro- (CAS 70887-84-2); and decanoic acid, 3,3,4,4,5,5,6,6,7, 7,8,8,9,9,10,10,10-heptadecafluoro- (CAS 27854-31-5).

Higher homologues include: dodecane, 1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8,9,9,10,10,11,11,12,12-pentacosafluoro-12-iodo (CAS 307-60-8); decane, 1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8,9,9,10,10-heneicosafluoro-10-iodo- (CAS 423-62-1); nonanoic acid, heptadecafluoro- (CAS 375-95-1); decanoic acid, nonadecafluoro- (CAS 335-76-2); 1-Decanol, 3,3,4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-heptadecafluoro- (CAS 678-39-7); decane, 1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8-heptadecafluoro-10-iodo- (CAS 2043-53-0); dodecane, 1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8,9,9,10,10-heneicosafluoro-12-iodo- (CAS 2043-54-1); 2-propenoic acid, 3,3,4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-heptadecafluorodecyl ester (CAS 4980-53-4); and 2-propenoic acid, 2-methyl-, 3,3,4,4,5,5,6,6,7,7,8,8,9,9,10,10,11,11,12,12,12-heneicosafluorododecyl ester (CAS 17741-60-5).

CAS = Chemical Abstracts Service; PFOA = perfluorooctanoic acid

China is one of the few remaining producers and consumers of PFOA and its salts, with a total of 480 metric tons produced from 2004 to 2012 (Li et al. 2015). China also continues to be a producer of PFOS. Growth in production volumes in China have coincided with decreases in production in the west. For example, China produced approximately 30 metric tons of PFOS in 2001; however, as 3M ceased production, China's production of PFOS increased to 91, 165, and 247 metric tons in 2004, 2005, and 2006, respectively (Lim et al. 2011). PFOA production in China was approximately 30 metric tons in 2004, but increased to approximately 90 metric tons in 2012 (Li et al. 2015). According to a report from the Hubei Academy of Environmental Sciences (HAES), China is planning to gradually phase out the production of some PFOS uses before 2019 and conduct a best available technology (BAT)/best environmental practice (BEP) analysis with the ultimate goal of completely phasing out the production and use of PFOS and potential precursors (HAES 2017).

Historical U.S. production volume data for PFOA, PFBA, and PFOS reported by manufacturers under the EPA Inventory Update Rule (IUR) are provided in Table 5-2. Production volume ranges for the ammonium salt of PFOA, APFO, are also listed. During the reporting year 2002, manufacturers reported that the production volumes were within the range of 10,000–500,000 pounds (6–227 metric tons) for PFOS and PFOA and within the range of 500,000–1,000,000 pounds (227–454 metric tons) for APFO (EPA 2008b). PFBA was reported as having a production volume within the range of 10,000–500,000 pounds (6–227 metric tons) during 1986; however, PFBA production volumes were not reported for subsequent years (EPA 2008b). None of the other perfluoroalkyls were listed in EPA's IUR database. Current U.S. production volume data for perfluoroalkyls are limited. The IUR database has been superseded by the Chemical Data Reporting (CDR) database. Data for 2012 indicated that PFOA was not imported into the United States, but any use or production volume data were reported as confidential business information. No data were located in the CDR for the other substances listed in Table 5-2. Nonconfidential emission reports from 2015 obtained from the EPA docket indicate that there is no current production of PFOA or PFOS in the United States.

Table 5-2. U.S. Production Volume Ranges for Perfluoroalkyls (1986–2002) Reported under the EPA Inventory Update Rule

Perfluoro-alkyl	Reporting year production volume range (pounds)				
	1986	1990	1994	1998	2002
PFOA	10,000–500,000	Not reported	10,000–500,000	10,000–500,000	10,000–500,000

5.2.2 Import/Export

The SNURs cited in Section 5.2.1 severely limits the production, import, or export of the long-chain perfluoroalkyls. There were no reported imports of chemicals listed in Table 4-1 in 2012 from the CDR database. Production volumes and import volumes of the 8:2 fluorotelomer alcohol were listed as confidential business information by DuPont. Shaw Industries Group reported that they imported 37,478 pounds of 6:2 fluorotelomer alcohol into the United States in 2012, but DuPont declared both production volume and import volumes as confidential business information (EPA 2016d).

5.2.3 Use

Applications of perfluoroalkyls have made use of their unique surfactant properties (Schultz et al. 2003). The alkyl tails of perfluoroalkyls make these substances both hydrophobic (water-repelling) and oleophobic (oil-repelling) (3M 1999; Kissa 2001; Schultz et al. 2003). Because of these properties, perfluoroalkyls have been used extensively in surface coating and protectant formulations (Kissa 2001). Major applications have included protectants for paper and cardboard packaging products, carpets, leather products, and textiles that enhance water, grease, and soil repellency (Hekster et al. 2003; Schultz et al. 2003). These compounds have been widely used in industrial surfactants, emulsifiers, wetting agents, additives, and coatings as well (3M 1999; Schultz et al. 2003). Perfluoroalkyls have been used in fire-fighting foams since they are effective in extinguishing hydrocarbon fueled fires (Schultz et al. 2003). Perfluoroalkyls have also been used as processing aids in the manufacture of fluoropolymers such as nonstick coatings on cookware, membranes for clothing that are both waterproof and breathable, personal care products (such as dental floss, cosmetics, sunscreens), electrical wire casing, fire and chemical resistant tubing, and plumbing thread seal tape (DuPont 2008; EPA 2008a).

5.2.4 Disposal

Information concerning disposal of individual perfluoroalkyl products may be found on Material Safety Data Sheets (MSDS) or Safety Data Sheets (SDS) from the manufacturers of the chemicals. Two methods are generally recommended for the disposal of fluoropolymer dispersions. The first method involves precipitation, decanting, or filtering to separate solids from liquid waste. The dry solids are then disposed of in an approved industrial solid waste landfill or incinerated, while the liquid waste is discharged to a waste water treatment facility (Plastics Europe 2012). The second method involves incineration at temperatures >800°C using a scrubber to remove hydrogen fluoride (Plastics Europe 2012). According to perfluorochemical facility assessment reports, historical disposal of perfluoroalkyl containing waste has been through on- and off-site landfills, through sludge incorporation (subsurface injection), and through incineration (3M 2007b, 2008a; ATSDR 2005). Pilot scale studies in which carpet samples were incinerated using a rotary kiln incinerator indicated that most perfluoroalkyls were effectively destroyed in combustors (Lemieux et al. 2007). Similar conclusions were reached by Yamada et al. (2005) when studying the incineration of textiles and paper treated with fluorotelomer-based acrylic polymers. Incineration at conventional temperatures is a proven technology for treating wastes containing perfluoroalkyls.

5.3 RELEASES TO THE ENVIRONMENT

There is no information listed in EPA's Toxic Release Inventory (TRI) on releases of perfluoroalkyls to the environment from facilities manufacturing, processing, or otherwise using perfluoroalkyls because these releases are not required to be reported within this program (EPA 2005b, 2016g).

Perfluoroalkyls are man-made compounds that are not naturally occurring in the environment. Perfluoroalkyls such as PFOS and PFOA have been widely used in the manufacturing of many consumer products (Hekster et al. 2003; Schultz et al. 2003). These substances are still detected in both environmental and biological media around the world as well as in serum samples collected from the general population (Calafat et al. 2006b, 2007a, 2007b; CDC 2018, 2019; De Silva and Mabury 2006; Kuklenyik et al. 2004; Olsen et al. 2003b, 2003c, 2004b, 2004c, 2005, 2007a; Prevedouros et al. 2006).

In 2006, the eight major companies of the perfluoropolymer/perfluorotelomer industry agreed to participate in EPA's PFOA Stewardship Program (EPA 2008a). This included voluntary commitments from these companies to reduce facility emissions and product content of PFOA and related chemicals on a global basis by 95% no later than 2010, and to work toward elimination of these substances by 2015 (EPA 2008a). Data from 2007 and 2013 progress reports regarding releases of PFOA, PFOA precursors, and higher PFOA homologues to all media as well as percent reduction in releases are listed in Table 5-3.

Table 5-3. Reported Emissions of PFOA, PFOA Homologues, or PFOA Precursors in Products from the 2006 and 2013 U.S. Operations of Fluoropolymer/Fluorotelomer Companies

		Releases to all media from fluoro-telomer and telomer manufacturing		
Company	Chemicals	kg	kg of release/100 kg of product produced	Percent reduction in emissions[a]
		2006 Data (EPA 2008a)		
Arkema, Inc.	PFOA and higher homologues	>1,000–10,000	For fluorotelomer production: >0.1–1	22%
	Precursors	Not applicable	Not applicable	Not applicable
Asahi Glass Company	PFOA, PFOA salts, and higher homologues	4,922	For fluorotelomer production: <1	6%

[a]Percent reduction in product content of these compounds from baseline year levels. The baseline year is the year nearest to the year 2000 for which company data are available.
[b]Total for emissions and product content

PFOA = perfluorooctanoic acid

While the United States and most industrialized countries around the world have ceased production of PFOS and PFOA, China is still a major producer of both substances (Li et al. 2015; Lim et al. 2011). Over the period from 2004 to 2012, it was estimated that 250 metric tons of PFOA were released to the environment from production in China (Li et al. 2015). Fluoropolymer manufacturing and processing was considered the dominant source of environmental releases, accounting for >80% of the total, while PFOA releases related to end use consumer products accounted for 6% of the total. Brazil produced 379 metric tons of N-EtFOSA for use in the pesticide, Sulfuramid, from 2004 and 2015, which contribute to PFOS releases to the environment (Wang et al. 2017).

Prevedouros et al. (2006) estimated the total global historical emissions of perfluoroalkyl carboxylates into the environment from both direct and indirect sources from the time period of 1951–2004. These data are provided in Table 5-4. Based on these estimations, direct emissions (3,200–6,900 metric tons) have far exceeded indirect emissions (30–350 metric tons). The largest direct emissions identified are

from industrial processes such as the manufacture of perfluoroalkyl carboxylates (470–900 metric tons), fluoropolymer manufacture (2,400–5,400 metric tons), and fluoropolymer processing (210–320 metric tons). Direct release of perfluoroalkyl carboxylates from use of aqueous firefighting foams and consumer and industrial products were estimated to be 50–100 and 40–200 metric tons, respectively. The largest indirect emissions identified were from perfluoroalkyl carboxylate residual impurities in perfluorooctyl-sulfonyl fluoride products (20–130 metric tons) and fluorotelomer-based precursor degradation (6–130 metric tons). Wang et al. (2014) expanded upon the work of Prevedouros et al. (2006) by considering additional emission sources of these substances and estimating emissions from 2003 to 2015 and projecting future emissions. These authors estimated emissions of 820–7,180 metric tons for 2003–2015 and projected between 20 and 6,420 metric tons for years 2016–2030. The estimates by Prevedouros et al. (2006) and Wang et al. (2014) contain a great degree of uncertainty as demonstrated by the wide range of values presented in the data. Wang et al. (2014) stated that uncertainty analysis using Monte Carlo methods is not possible because there is insufficient information available with respect to the range or distribution of the emissions. Instead, they introduced a scoring system to provide a qualitative description of the accuracy of the estimates that ranged from 0–1 (low uncertainty) to 2–3 (high uncertainty where estimates were based on crude assumptions or extrapolations).

Table 5-4. Global Historical PFCA Production and Emissions Estimates from 1951 to 2004[a]

Environmental input source	Historical time period (years)	Estimated total global historical PFCA emissions (tonnes)
Direct PFCA sources		
PFCA manufacture		
PFO/APFO	1951–2004	400–700
PFN/APFN	1975–2004	70–200
Total manufactured		470–900
Industrial and consumer uses		
Fluoropolymer manufacture (APFO)	1951–2004	2,000–4,000
Fluoropolymer dispersion processing (APFO)	1951–2004	200–300
Fluoropolymer manufacture (APFN)	1975–2004	400–1,400
Fluoropolymer processing (APFN)	1975–2004	10–20
Aqueous firefighting foams (AFFF)	1965–1974	50–100
Consumer and industrial products	1960–2000	40–200

Table 5-4. Global Historical PFCA Production and Emissions Estimates from 1951 to 2004[a]

Environmental input source	Historical time period (years)	Estimated total global historical PFCA emissions (tonnes)
Total direct		3,200–6,900
Indirect PFCA sources		
POSF-based products		
PFCA residual impurities[b]	1960–2002	20–130
POSF-based precursor degradation	1960–2002	1–30
POSF-based AFFF	1970–2002	3–30
Fluorotelomer-based products		
PFCA residual impurities[b]	1974–2004	0.3–30
Fluorotelomer-based precursor degradation	1974–2004	6–130
Fluorotelomer-based AFFF	1975–2004	<1
Total indirect		30–350
Total source emissions (direct and indirect)		3,200–7,300

[a]Low and high estimated values as well as the period of use/production for each source are based upon publicly available information cited in the text.
[b]Some authors classify residual impurities as a direct emission source rather than indirect emission source (Buck et al. 2011).

AFFF = aqueous firefighting foams; APFN = ammonium perfluorononanoate; APFO = ammonium perfluoro-octanoate; PFCA = perfluorinated carboxylic acid; PFN = perfluorononanoate; PFO = perfluorooctanoate; POSF = perfluorooctanesulfonyl fluoride

Source: Prevedouros et al. 2006

Wang et al. (2017) estimated the global emissions in 1958–2015 as 1,228–4,930 tonnes of PFOS and 1,230–8,738 tonnes of PFOS precursors, with most emissions occurring from 1958 to 2002. It was estimated that PFOS emissions from 2016 to 2030 will be 8–153 tonnes.

5.3.1 Air

There is no information listed in the TRI on releases of perfluoroalkyls to the atmosphere from facilities manufacturing, processing, or otherwise using perfluoroalkyls because these releases are not required to be reported (EPA 2005b, 2016g).

According to 3M, low levels of PFOA were released to air during manufacturing processes at the Decatur, Alabama facility until use of this substance ceased in 2004 (3M 2008b). This company states that there are currently no process-related air emissions of PFOA at this facility (3M 2008b). PFOA concentrations as high as 75,000–900,000 pg/m^3 were measured at the fence line of the DuPont Washington Works

facility near Parkersburg, West Virginia in 2004 (Barton et al. 2006; Davis et al. 2007; Prevedouros et al. 2006). High volume air samples collected at several monitoring stations near the Washington Works facility during nine events between August and October of 2005 contained PFOA at reported concentrations ranging from 10 to 75,900 pg/m^3 (EPA 2007b). The mean and median of these reported concentrations are 5,500 and 240 pg/m^3, respectively.

The presence of perfluoroalkyls in indoor air and dust indicates that perfluoroalkyl-containing consumer products such as treated carpets and textiles may be sources of release to air (Barber et al. 2007; Jahnke et al. 2007b; Kubwabo et al. 2005; Moriwaki et al. 2003; Prevedouros et al. 2006; Shoeib et al. 2004; Strynar and Lindstrom 2008). Perfluoroalkyls have also been identified on both indoor and outdoor window films (Gewurtz et al. 2009). Disposal of perfluoroalkyl-containing consumer products is also expected to be a source of release to air (Prevedouros et al. 2006). Harada et al. (2005a, 2006) proposed that automobiles may be a source of PFOA in urban air based on elevated levels measured near heavy traffic areas and the widespread use of this substance in automobile materials.

Perfluoroalkyl carboxylic acids and perfluoroalkyl sulfonic acids are formed by the atmospheric photooxidation of precursor compounds such as fluorotelomer alcohols and perfluoroalkyl sulfonamides (D'eon et al. 2006; Ellis et al. 2004; Martin et al. 2006; Wallington et al. 2006; Wania 2007). Perfluoroalkyl carboxylic acids including PFOA, PFNA, PFHpA, and PFBA were observed as products during a laboratory study involving the photooxidation of 4:2, 6:2, and 8:2 fluorotelomer alcohols (Ellis et al. 2003, 2004). D'eon et al. (2006) observed both perfluoroalkyl carboxylic acids and perfluorobutane sulfonate among products of the photooxidation of N-methyl perfluorobutane sulfonamidoethanol.

5.3.2 Water

There is no information listed in the TRI on releases of perfluoroalkyls to water from facilities manufacturing, processing, or otherwise using perfluoroalkyls because these releases are not required to be reported (EPA 2005b, 2016g).

There are a number of sources of perfluoroalkyl release to surface water and groundwater, including release from manufacturing sites, industrial use, use and disposal of perfluoroalkyl-containing consumer products, fire/crash training areas, waste water treatment facilities, and from the use of contaminated biosolids (3M 2008b; Clara et al. 2009; Davis et al. 2007; Eggen et al. 2010; EPA 2009a; Kelly and

Solem 2009; Moody and Field 1999; Moody et al. 2003; Sinclair and Kannan 2006; Prevedouros et al. 2006).

Waste water discharge was identified as a release pathway for APFO from the DuPont Washington Works facility in West Virginia (Davis et al. 2007). The average monthly concentrations of APFO measured in surface water from three outlets at the facility during 2007 and early 2008 ranged from 3.65 to 377 µg/L (EPA 2008d). Reported concentrations of APFO and PFOA measured in surface water from four separate outlets at this facility during the same period were 3–64 and 2.3–61 µg/L, respectively. During perfluorochemical operations at the 3M Cottage Grove facility in Minnesota, waste water treatment plant effluent containing perfluoroalkyls was discharged to the Mississippi River. Discharge into Bakers Creek from the waste water treatment plant at the 3M Decatur facility was a principal source of PFOA release from this facility (3M 2008b).

Elevated levels of perfluoroalkyls, such as PFOA, PFOS, and PFHxS, measured in groundwater near fire-training areas are attributed to the use of these substances in aqueous firefighting foams (Moody and Field 1999; Moody et al. 2003). The concentrations of these three perfluoroalkyls in groundwater near a military fire-training site in Michigan were 8–105, 4.0–110, and 9–120 µg/L, respectively (Moody et al. 2003). A study of landfill leachates showed that perfluoroalkyls were primarily distributed to the water phase of leachates, which could eventually contaminate ground water (Eggen et al. 2010). Lang et al. (2017) estimated that between 563 and 638 kg of perfluoroalkyl substances were released from landfill leachate in the United States in 2013.

Waste water treatment plants have been shown to be significant contributors to perfluoroalkyls contamination of surface and ground water (Clara et al. 2009; EPA 2009a; Kelly and Solem 2009; Loganathan et al. 2007; Sinclair and Kannan 2006; Yu et al. 2009c). Influent, effluent, and sludge samples from 28 public and private waste water treatment plants in Minnesota were analyzed for 13 perfluoroalkyls; detectable concentrations of perfluoroalkyls were found in several facilities, primarily urban treatment plants (Kelly and Solem 2009). Elevated levels of PFOS at one facility (1.51 µg/L in effluent) were attributed to a chrome plating facility using a surfactant containing fluorosulfonate to control hexavalent chromium emissions. Another study of chromium electroplating facilities in Chicago, Illinois and Cleveland, Ohio also found them to be significant sources of PFOS and other perfluoroalkyls in the environment (EPA 2009a). It was determined that perfluoroalkyls were being discharged from all 11 facilities at quantifiable levels and that PFOS was detected in waste water from 10 out of 11 facilities at levels of 0.0314–39 µg/L. PFOA and PFOS were detected in effluents of six waste water treatment

plants located in New York at levels of 0.058–1.05 and 0.003–0.068 µg/L, respectively (Sinclair and Kannan 2006). PFOS and PFOA were detected in effluents of two waste water treatment plants located in Singapore at levels of 0.0053–0.5609 and 0.0112–1.057 µg/L, respectively (Yu et al. 2009c). PFOA, PFOS, and several other perfluoroalkyls were detected in effluent samples of 21 waste water treatment plants and 9 industrial point sources; PFOA and PFOS were reportedly identified in the effluents of all of the facilities monitored at an average level of 0.060 µg/L for both substances (Clara et al. 2009).

Studies comparing perfluoroalkyl levels in influent and effluent from municipal waste water treatment facilities have found higher levels of some perfluoroalkyls, such as PFNA, PFOA, PFOS, and FOSA, in the effluent, as compared to the influent (Loganathan et al. 2007; Schultz et al. 2006b). For others, such as PFHxS and PFDA, waste water treatment resulted in lower concentrations or no change in the concentrations. Increases in perfluoroalkyl concentrations are likely due to the breakdown of perfluoroalkyl precursors such as polyfluoroalkyl phosphoric acids or fluorotelomer alcohols (D'eon et al. 2009; Gauthier and Mabury 2005; Wang et al. 2005a, 2005b).

A study of eight waste water treatment plants that discharge effluent to the San Francisco Bay found increases in PFBA and PFHxA levels between 2009 and 2014 and declines in longer-chain legacy substances (Houtz et al. 2016). Average concentrations of PFBA were 7.4±4.7 ng/L in 2009 and 16±5.8 ng/L in 2014 and the average concentration of PFHxA rose from 17±4.0 ng/L in 2009 to 25±5.1 ng/L in 2014. The average PFOA concentration decreased from 32±30 ng/L in 2009 to 21±13 ng/L in 2014 and the average PFOS concentration decreased from 24±32 ng/L in 2009 to 13±4.4 ng/L in 2014.

Land application of biosolids (treated sewage sludge) can also result in the release of perfluoroalkyls to surface and groundwater (Clark and Smith 2011; Lindstrom et al. 2011; Sepulvado et al. 2011). There appears to be some differences in the distribution of PFOA and PFOS in waste water effluent and biosolids, with higher levels of PFOA in waste water and higher PFOS levels in biosolids (Guo et al. 2010).

5.3.3 Soil

There is no information listed in the TRI on releases of perfluoroalkyls to soil from facilities manufacturing, processing, or otherwise using perfluoroalkyls because these releases are not required to be reported (EPA 2005b, 2016g).

Perfluoroalkyls can be inadvertently released to soils through the use of biosolids applied as fertilizer to help maintain productive agricultural soils and stimulate plant growth. PFOA and PFOS were detected in both biosolids and biosolid-amended soils (Sepulvado et al. 2011). Six samples of biosolids obtained from the Metropolitan Water Reclamation District of Greater Chicago had levels of PFOS and PFOA of 80–219 and 8–68 ng/g, respectively (Sepulvado et al. 2011). The mean sum (±SD) of all perfluoroalkyls in the biosolids was 433±121 ng/g, with PFOS being most prominent. Perfluoroalkyls can also be released into soil due to atmospheric transport and wet/dry deposition (Rankin et al. 2016; Strynar et al. 2012).

Liu et al. (2007) measured PFOA as a product of the biodegradation of 8:2 fluorotelomer alcohol in soil. This result, along with similar findings in activated sludge tests, indicates that biodegradation of fluorotelomer alcohols may result in the formation of perfluoroalkyl carboxylic acids in soil (Liu et al. 2007; Rankin et al. 2014; Wang et al. 2005a, 2005b).

5.4 ENVIRONMENTAL FATE

5.4.1 Transport and Partitioning

Air. Barton et al. (2007) investigated the atmospheric partitioning of PFOA during rain events near an industrial facility and concluded that this substance will be primarily adsorbed to particles in the air since PFOA was not detected in the vapor phase (detection limit of 0.2 ng/m^3). Concentrations of PFOA in raindrops and as particulates were 11.3–1,660 ng/L and 0.09–12.40 ng/m^3, respectively. The authors proposed that PFOA or APFO released into air from industrial facilities will be scavenged by atmospheric particles (including aqueous aerosols and raindrops) and dissociate to form the perfluorooctanoate anion. Although Barton et al. (2007) did not detect PFOA in the vapor phase during rain events, low concentrations (<0.12–3.16 pg/m^3) of vapor-phase perfluoroalkyls measured by Kim and Kannan (2007) in urban air provide evidence of a partitioning equilibrium. Wet and dry deposition are expected to be the principal removal mechanisms for perfluoroalkyl carboxylic acids and sulfonic acids in particulate form from the atmosphere. Residence times with respect to these processes are expected to be days to weeks (Barton et al. 2007; Hurley et al. 2004; Kim and Kannan 2007).

Long-range atmospheric transport of precursor compounds such as fluorotelomer alcohols and perfluoroalkyl sulfonamides followed by the atmospheric photooxidation of these substances to form perfluoroalkyl carboxylic acids and perfluoroalkyl sulfonic acids resulted in PFOA and PFOS

contamination in remote locations with no direct point sources for these compounds (Barber et al. 2007; D'eon et al. 2006; Dinglasan-Panlilio and Mabury 2006; Ellis et al. 2004; Martin et al. 2006; Simcik 2005; Small 2009; Wallington et al. 2006; Wania 2007). Fluorotelomer alcohols and perfluoroalkyl sulfonamides are volatile and possess long enough atmospheric residence times for long-range transport to occur (Barber et al. 2007; Yarwood et al. 2007). The presence of fluorotelomer alcohols and perfluoroalkyl sulfonamides in urban and Arctic air offers evidence of long-range atmospheric transport (Loewen et al. 2005; Shoeib et al. 2006; Stock et al. 2004). Photooxidation studies have demonstrated the conversion of these substances to perfluoroalkyl carboxylic acids and sulfonates. According to Young et al. (2007), the presence of perfluorodecanoic acid and perfluoroundecanoic acid in an Arctic ice cap indicates atmospheric oxidation of precursors as a source. Yeung et al. (2017) collected samples of snow and water from the Central Arctic region in 2012 and observed that perfluorinated alkyl substances were only detectable in ocean waters above a depth of 150 m. Atmospheric deposition from precursors was estimated to account for approximately 34–59% of the PFOA input to the ocean. Gawor et al. (2014) studied the distribution of fluorotelomer alcohols, fluorinated sulfonamides, and fluorinated sulfonamidoethanols in polar, remote, and urban regions of the world during four sampling campaigns covering the years 2005–2011. They observed higher levels of fluorotelomer alcohols as compared to the fluorinated sulfonamides and sulfonamidoethanols, with the 8:2 fluorotelomer alcohol being the predominant species in most samples.

Water. The pKa range of perfluoroalkyls indicates that these substances will exist primarily as the dissociated conjugate base (anion) when in contact with water at environmental pH (pH 5–9). Volatilization will not be an important environmental fate process when the substances exist as anions; however, under acidic conditions, undissociated perfluoroalkyls may volatilize into the atmosphere (Martin et al. 2006). Perfluoroalkyls may be transported to remote areas by direct oceanic advection of these substances (Armitage et al. 2006; Barber et al. 2007; Simcik 2005; Wania 2007; Yamashita et al. 2005, 2008). Perfluoroalkyls may also be transported over long distances in the form of marine aerosols (Barber et al. 2007; CEMN 2008; Prevedouros et al. 2006). This transport mechanism may be especially relevant since surfactants have been shown to accumulate in upper sea layers and at water surfaces (Prevedouros et al. 2006).

Perfluoroalkyls have been measured in invertebrates, fish, amphibians, reptiles, birds, bird eggs, and mammals located around the world (Brown et al. 2018; Dai et al. 2006; Giesy and Kannan 2001; Houde et al. 2005, 2006a, 2006b; Keller et al. 2005; Kannan et al. 2001a, 2001b, 2002a, 2002b, 2002c, 2002d, 2005, 2006; Sinclair et al. 2006; So et al. 2006a; Wang et al. 2008). The highest concentrations of PFOA

and PFOS in animals are measured in apex predators, such as polar bears, which indicates that these substances biomagnify in food webs (de Vos et al. 2008; Houde et al. 2006b; Kannan et al. 2005; Kelly et al. 2007). Loi et al. (2011) also provided evidence of the biomagnification potential of several perfluoroalkyl substances in tropical food webs. Evidence for biomagnification of chlorinated polyfluoroalkyl ether sulfonic acids, which have been used in the plating industry, has recently been reported (Liu et al. 2017; Shi et al. 2015). Table 5-5 shows levels of PFOA and PFOS measured in Arctic organisms. The bioaccumulation potential of perfluoroalkyls increases with increasing chain length from 4 to 8 carbon units and then declines with further increases in chain length (Conder et al. 2008; de Vos et al. 2008; Furdui et al. 2007; Martin et al. 2004b). In living organisms, perfluoroalkyls bind to protein albumin in blood, liver, and eggs and do not accumulate in fat tissue, which may explain why bioconcentration factors (BCFs) are lower than expected in aquatic organisms (de Vos et al. 2008; Kissa 2001). The Arctic Monitoring and Assessment Programme December 2017 report contains a large summary of environmental monitoring data for perfluoroalkyl substances in the Arctic (AMAP 2017). Temporal trends indicated declining residues of PFOA in the liver of ringed seals at several Arctic monitoring sites; however, PFNA and PFDA showed increasing levels at some locations and declining levels at others (AMPA 2017). Declining levels of PFOA and PFOS were observed for polar bears in Canadian Arctic and Greenland; however, total perfluoroalkyl levels remained relatively constant as precursor substances appear to continue to be transported and degraded in the Arctic food web. Moreover, newer perfluorinated substances such as perfluoroethylcyclohexane sulfonate (used in hydraulic fluids) and perfluorobutane sulfonamide (a PFBS precursor) have been detected in some environmental media.

Table 5-5. Biological Monitoring of PFOA and PFOS in the Arctic

[a]Reported as mean values
[b]Minimum detection limits for study analytes ranged from 0.03 to 2.3 ng/g. To calculate means, concentrations less than the MDL were replaced with a random value that was less than half the MDL.

MDL = minimum detection limit; ND = not detected; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid

Sediment and Soil. K_{oc} values of 17–230 measured for PFOA in soils of various organic carbon content indicate that PFOA will be mobile in soil and will not adsorb to suspended solids and sediment in the water column (Davis et al. 2007; Prevedouros et al. 2006); rather, it tends to remain in solution and migrate with groundwater (Davis et al. 2007). This is supported by the presence of PFOA in groundwater at the Decatur, Cottage Grove, and Washington Works fluorochemical industrial facilities (3M 2007b, 2008b; Davis et al. 2007). Other sources of perfluoroalkyls in soil include air emissions followed by atmospheric deposition to soils and subsequent leaching (Davis et al. 2007). Low volatility, high water solubility (9,500 mg/L at 25°C), and low sorption to solids indicate that the perfluorooctanoate anion will accumulate in surface waters, especially oceans (Armitage et al. 2006; Kauck and Diesslin 1951; Prevedouros et al. 2006; Wania 2007). McGuire et al. (2014) reported field-based K_{oc} values for several perfluoroalkyl substances (see Table 4-2).

Perfluoroalkyls can be taken up by plants in contaminated soils. Laboratory studies have suggested that short-chain perfluoroalkyls such as PFBA are more concentrated in edible portions of plants when compared to longer carbon chain substances such as PFOA or PFOS (Blaine et al. 2013, 2014a, 2014b; MDH 2014). Yoo et al. (2011) studied the accumulation of perfluoroalkyl carboxylic acids, perfluorosulfonic acids, and fluorotelomer alcohols in grass samples collected near Decatur, Alabama and calculated the grass-soil accumulation factor (GSAF), which is the concentration of perfluoroalkyl in grass divided by the concentration of perfluoroalkyl in soil. The shortest chain compounds had the largest GSAFs, and accumulation factors decreased rapidly with chain length. The mean (±SD) GSAF values

were 3.4±2.6, 0.90±0.66, 0.25±0.23, 0.12±0.08, 0.10±0.08, 0.11±0.09, and 0.10±0.09 for PFHxA, PFHpA, PFOA, PFNA, PFDA, PFUnA, and PFDoDA, respectively. The GSAF for PFOS was 0.07±0.04. Increasing salinity and temperature was shown to increase uptake and transport from the roots into the shoots by the wheat plants grown in hydroponic systems spiked with perfluorocarboxylic acids (Zhao et al. 2016). Transport into the shoots also increased with decreasing carbon chain length. Concentrations in the shoots of the wheat plants increased in the following order: PFBA > PFHpA > PFOA > PFDoDA. Stahl et al. (2009) demonstrated that both PFOA and PFOS were taken up from soil by five cultivated plants (spring wheat, oats, potatoes, maize, and perennial ryegrass) and the amount of uptake was generally linearly dependent upon the concentration of PFOA or PFOS spiked to the soil. Lysimeter studies suggested that PFOA and short-chain perfluoroalkyls such as PFBA pass through the soil and get taken up by plants more quickly as compared to PFOS (Stahl et al. 2013).

Krippner et al. (2014) analyzed the uptake of perfluoroalkyl substances with chain length of C4–C10 over a pH range of 5–7. They observed that short-chain perfluoroalkyls partition predominantly and at higher concentrations to the shoot. Longer-chain substances such as PFOA, PFNA, and PFDA, as well as PFHxS and PFOS, accumulated at higher concentrations in the roots of maize plants. Maize grown in soil pots containing perfluoroalkyls only accumulated compounds with a chain length ≤C8 in the kernels (Krippner et al. 2015).

Other Media. Data are not available regarding the transport and partitioning of perfluoroalkyls in other media.

5.4.2 Transformation and Degradation

Perfluoroalkyls are considered to be environmentally persistent chemicals (EPA 2008a; OECD 2002, 2007; Schultz et al. 2003). The carbon atoms of the perfluoroalkyl chain are protected from attack by the shielding effect of the fluorine atoms; furthermore, environmental degradation processes generally do not possess the energy needed to break apart the strong fluorine-carbon bonds (3M 2000; Hekster et al. 2003; Schultz et al. 2003). Perfluoroalkyls are resistant to biodegradation, direct photolysis, atmospheric photooxidation, and hydrolysis (OECD 2002, 2007; Prevedouros et al. 2006).

Air. Although transport and partitioning information indicates that air will not be a sink for perfluoroalkyls in the environment, low concentrations of perfluoroalkyl carboxylic acids, sulfonic acids, and sulfonamides have been measured in air both in the vapor phase and as bound to particulates (Barton

et al. 2007; Kim and Kannan 2007). Available information indicates that photodegradation will not compete with wet deposition as an atmospheric removal process for perfluoroalkyls (Barton et al. 2007; Hurley et al. 2004; Prevedouros et al. 2006). However, photooxidation may be an important degradation mechanism for perfluoroalkyl sulfonamides (D'eon et al. 2006; Martin et al. 2006).

PFOA does not absorb UV light at environmentally relevant wavelengths (>290 nm); Hori et al. (2004a) reported a weak absorption band for PFOA that ranged from 220 to 270 nm. Based on the measured absorption wavelength of PFOA, perfluoroalkyl carboxylic acids are not expected to undergo direct photolysis. Following irradiation of the potassium salt of PFOS with light of wavelength 290–800 nm for 67–167 hours, it was concluded that there was no evidence of direct photolysis of PFOS under any of the test conditions (OECD 2002). Based on these test results for PFOS, perfluoroalkyl sulfonic acids are not expected to undergo direct photolysis in the atmosphere.

A measured photooxidation rate constant is not available for PFOA. Hurley et al. (2004) measured the reaction of short-chain (C1–C4) perfluoroalkyl carboxylic acids with photochemically generated hydroxyl radicals. The proposed mechanism begins with abstraction of the carboxyl hydrogen, which is followed by the removal of the carboxyl group and generation of a perfluoroalkyl radical. Finally, the perfluoroalkyl chain is broken down one carbon atom at a time through an unzipping sequence. The same rate constant, 1.69×10^{-13} cm^3/molecule-second, was measured for the photooxidation of the C2, C3, and C4 molecules, indicating that the chain length may have little effect on the reactivity of perfluoroalkyls with hydroxyl radical. According to the authors, this rate constant corresponds to a half-life of 130 days. Based on the data for the short-chain structures, the authors concluded that atmospheric photooxidation of perfluoroalkyl carboxylic acids is not expected to compete with wet and dry deposition, which is predicted to occur on a time scale of the order of 10 days.

Atmospheric photooxidation data are not available for perfluoroalkyl sulfonic acids. Atmospheric photooxidation studies involving n-methyl perfluorobutane sulfonamidoethanol (Me-FBSE) and n-ethyl perfluorobutanesulfonamide (Et-FBSA) indicate possible mechanisms for the reaction of these substances with atmospheric hydroxyl radicals (D'eon et al. 2006; Martin et al. 2006). Products observed from the photooxidation of these compounds indicate the following pathways: removal of an alkyl from the amide (cleavage of the N-C bond); removal of the amido group (cleavage of the S-N bond); and removal of the sulfonamido group (cleavage of the S-C bond) (D'eon et al. 2006; Martin et al. 2006). The last two pathways indicate that FOSA may be photooxidized through removal of the amido or sulfonamido group. The third pathway, cleavage of the S-C bond, also indicates a photooxidation mechanism for

perfluoroalkyl sulfonic acids. Martin et al. (2006) proposes an unzipping sequence for the perfluoroalkyl chain following removal of the sulfonyl group.

Measured rate constants for the reaction of Me-FBSE and Et-FBSA with atmospheric hydroxyl radicals are $5.8x10^{-12}$ and $3.74x10^{-13}$ cm^3/molecule-second, respectively (D'eon et al. 2006; Martin et al. 2006). Atmospheric half-lives calculated using these rate constants were 2 days for Me-FBSE and 20–50 days for Et-FBSA.

Water. PFOS and PFOA are expected to be stable to hydrolysis in the environment based on half-lives of 41 and 92 years, respectively, calculated from experimental hydrolysis data that were measured at pH 5, 7, and 9 (OECD 2002, 2006b). Based on the data for PFOS and PFOA, hydrolysis is not expected to be an important degradation process for perfluorinated carboxylates and sulfonates in the environment. Hydrolysis data were not located for perfluoroalkyl sulfonamides.

Available information indicates that perfluoroalkyls are resistant to aerobic biodegradation. PFOA and PFNA were not biodegraded using an Organisation for Economic Co-operation and Development (OECD) guideline (301F) manometric respirometry screening test for ready biodegradability; 0% of the theoretical oxygen demand was reached after 28 days (Stasinakis et al. 2008). Meesters and Schröder (2004) reported that PFOA and PFOS were not degraded from an initial concentration of 5 mg/L in aerobic sewage sludge in a laboratory scale reactor.

Substances such as fluorotelomer alcohols and perfluoroalkyl sulfonamides are degraded to other substances such as PFOA and PFOS in water and can be considered a source of these substances in the environment (Liu et al. 2007).

Sediment and Soil. Data are not available regarding the transformation and degradation of perfluoroalkyls in sediment and soil. Based on the chemical stability of these substances and their resistance to biodegradation in screening tests, environmental degradation processes are not expected to be important removal mechanisms for perfluoroalkyls in sediment and soil (3M 2000; EPA 2008a; Hekster et al. 2003; OECD 2002, 2007; Prevedouros et al. 2006; Schultz et al. 2003).

Substances such as fluorotelomer alcohols and perfluoroalkyl sulfonamides are degraded to other substances such as PFOA and PFOS in soil and sediment and can be considered a source of these substances in the environment (Liu et al. 2007; Washington and Jenkins 2015; Washington et al. 2015).

Other Media. Data are not available regarding the transformation and degradation of perfluoroalkyls in other media.

5.5 LEVELS IN THE ENVIRONMENT

Reliable evaluation of the potential for human exposure to perfluoroalkyls depends, in part, on the reliability of supporting analytical data from environmental samples and biological specimens. Concentrations of perfluoroalkyls in unpolluted atmospheres and in pristine surface waters are often so low as to be near the limits of current analytical methods. In reviewing data on perfluoroalkyls levels monitored or estimated in the environment, it should also be noted that the amount of chemical identified analytically is not necessarily equivalent to the amount that is bioavailable.

Table 5-6 shows the limits of detection typically achieved by analytical analysis in environmental media. An overview summary of the range of concentrations detected in environmental media is presented in Table 5-7.

Detections of perfluoroalkyls in air, water, and soil at NPL sites are summarized in Table 5-8.

Table 5-6. Lowest Limit of Detection Based on Standards[a]

Media	Detection limit	Reference
Air	0.1 pg/m^3	Harada et al. 2006
Drinking water	0.5–6.5 ng/L	EPA 2009c (Method 537)
Surface water and groundwater	0.2 ng/L	Nakayama et al. 2007
Soil	0.11–0.75 µg/kg (median reporting limits)	Anderson et al. 2016
Sediment	0.21–1.2 µg/kg (median reporting limits)	Anderson et al. 2016
Whole blood Serum	0.1–2 ng/mL 0.082–0.2 ng/mL	Kärrman et al. 2005 CDC 2015

[a]Detection limits based on using appropriate preparation and analytics. These limits may not be possible in all situations.

[a]Concentrations found in ATSDR site documents from 1981 to 2017 for 1,854 NPL sites (ATSDR 2017). Maximum concentrations were abstracted for types of environmental media for which exposure is likely. Pathways do not necessarily involve exposure or levels of concern.

5.5.1 Air

Perfluoroalkyl levels have been measured in outdoor air at locations in the United States, Europe, Japan, and over the Atlantic Ocean (Barber et al. 2007; Barton et al. 2006; Harada et al. 2005a, 2006; Kim and Kannan 2007). Concentrations reported in these studies are provided in Table 5-9.

Mean PFOA levels ranged from 1.54 to 15.2 pg/m^3 in air samples collected in the urban locations in Albany, New York; Fukuchiyama, Japan; and Morioka, Japan and in the rural locations in Kjeller, Norway and Mace Head, Ireland. Higher mean concentrations (101–552 pg/m^3) were measured at the urban locations in Oyamazaki, Japan and Manchester, United Kingdom, and semirural locations in Hazelrigg, United Kingdom. Maximum reported concentrations at Oyamazaki and Hazelrigg were 919 and 828 pg/m^3, respectively. The authors attributed the elevated concentrations at the Hazelrigg location to emissions from a fluoropolymer production plant located 20 km upwind of this semirural community.

Elevated levels of PFOA were observed in air samples collected along the fence line of the DuPont Washington Works fluoropolymer manufacturing facility, which is located near Parkersburg, West Virginia, in the Ohio River valley (Barton et al. 2006).

[a]Mean values were reported for separate sampling sessions.
[b]The second concentration reported was measured during an earlier sampling session (n=2).
[c]A maximum PFOA concentration of 828 pg/m^3 was measured in air at Hazelrigg, United Kingdom.
[d]Average and range of concentrations in 6 out of 28 samples that contained PFOA.

"—" indicates no available data; FOSA = perfluorooctane sulfonamide; ND = not detected; PFBS = perfluorobutane sulfonic acid; PFDA = perfluorodecanoic acid; PFDoDA = perfluorododecanoic acid; PFHpA = perfluoroheptanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; PFUnA = perfluoroundecanoic acid

The reported concentrations in these samples ranged from 75,000 to 900,000 pg/m^3. The highest concentrations were measured at locations downwind of the facility. High volume air samples collected at several monitoring stations near the Washington Works facility contained PFOA at reported concentrations ranging from 10 to 75,900 pg/m^3 (EPA 2007b). The mean and median of these reported concentrations are 5,500 and 240 pg/m^3, respectively.

PFOS was detected above quantitation limits in most of the studies, but concentrations were generally below 5 pg/m^3. A concentration of 46 pg/m^3 was reported in samples from Manchester, United Kingdom. Reported concentrations of other perfluoroalkyls (PFHpA, PFNA, PFDA, PFUnA, PFDoDA, PFBS, PFHxS, and FOSA) were generally <1 pg/m^3 in these studies. PFHpA was detected at slightly higher concentrations (8.2 and 14.4 pg/m^3) at Manchester and Hazelrigg, United Kingdom, respectively.

Jahnke et al. (2007a) collected eight marine air samples during a cruise between Germany and South Africa (53°N to 33°S). Perfluoroalkyl concentrations steadily declined as the sampling moved further from Europe and toward less industrialized regions. Only PFOS was detected in the two samples collected over the Atlantic Ocean east of southern Africa.

Measurements of perfluoroalkyls in snow samples collected from Canadian Arctic ice caps suggest that volatile precursors, such as fluorinated telomer alcohols, may oxidize in the atmosphere at these locations (Young et al. 2007). Reported concentrations in these snow samples were 2.6–86 pg/L for PFOS, 12–147 pg/L for PFOA, 5.0–246 pg/L for PFNA, <8–22 pg/L for PFDA, and <6–27 pg/L for PFUnA.

The concentration of PFOS measured in rainwater collected during a rain event in Winnipeg, Manitoba was 0.59 ng/L (Loewen et al. 2005). PFOA, PFNA, PFDA, PFUnA, and PFDoDA were not detected in the rainwater. Reported method detection limits for these compounds were 7.2, 3.7, 1.7, 1.2, and 1.1 ng/L, respectively.

Studies of perfluoroalkyl concentrations in indoor environments are available. The reported mean concentrations of perfluoroalkyls measured in four indoor air samples collected from Tromso, Norway (Barber et al. 2007) are presented in Table 5-10.

Table 5-10. Concentrations of Perfluoroalkyl in Indoor Air[a]

PFOA	4.4
PFHpA	0.8
PFNA	2.7
PFDA	3.4
PFUnA	<1.3
PFDoDA	1.2
PFOS	<47.4
PFBS	<0.5
PFHxS	<4.1
FOSA	2.8

[a]Samples (n=4) collected in Tromso, Norway in May–June 2005.

FOSA = perfluorooctane sulfonamide; PFBS = perfluorobutane sulfonic acid; PFDA = perfluorodecanoic acid; PFDoDA = perfluorododecanoic acid; PFHpA = perfluoroheptanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; PFUnA = perfluoroundecanoic acid

Source: Barber et al. 2007

Several studies have measured perfluoroalkyl levels in indoor dust samples (Table 5-11). Kubwabo et al. (2005) measured the concentrations of selected perfluoroalkyls in dust samples from 67 Canadian homes. PFOA, PFOS, and PFHxS were each detected in 37, 33, and 15% of these samples, respectively (detection limits of 2.29, 4.56, and 4.56 ng/g, respectively). FOSA was only detected above 0.99 ng/g in 10% of the samples and PFBS was not detected in any of the samples. Moriwaki et al. (2003) measured PFOS and PFOA concentrations in vacuum cleaner dust samples collected from 16 Japanese homes. PFOS and PFOA were detected in every sample with reported concentrations of 11–140 and 69–380 ng/g, respectively, in 15 of the 16 samples. One of the samples contained 2,500 ng/g PFOS and 3,700 ng/g PFOA. The geometric means of PFOA and PFOS in pooled indoor air sample meta data analysis were

reported as 37.34 and 38.91 ng/g, respectively (Mitro et al. 2016). Precursor substances present in dust can be biotransformed to perfluoroalkyl substances and may be a further source of human exposure. Fluorotelomer alcohols were detected in hotel dust in China at levels ranging from 24.8 to 678 ng/g (Yao et al. 2018). Makey et al. (2017) reported precursor substances such as dipolyfluoroalkyl phosphates (diPAPs), fluorotelomer alcohols, perfluorooctyl sulfonamides, and sulfonamidoethanols in airborne and dust samples.

[a]Method detection limits (MDL) and percent below MDL are as follows: PFOA (2.29 ng/g, 37%), PFOS (4.56 ng/g, 33%), PFBS (1.38 ng/g, 100%), PFHxS (4.56, 15%), and FOSA (0.99 ng/g, 90%).
[b]LOQ and percent above LOQ are as follows: PFHpA (12.5 ng/g, 74.1%), PFOA (10.2 ng/g, 96.4%), PFNA (11.3 ng/g, 42.9%), PFDA (9.40 ng/g, 30.4%), PFUnA (10.7 ng/g, 36.6%), PFDoDA (11.0 ng/g, 18.7%), PFOS (8.93 ng/g, 94.6%), PFHxS (12.9 ng/g, 77.7%), PFBS (12.5 ng/g, 33.0%). Values below the LOQ were assigned a value of LOQ/1.412 when calculating the median and mean.
[c]Reported values are the 50th percentile and (maximum) values; all minimum values were <LOQ.
[d]Reported values are the median and range.

"—" indicates no available data; FOSA = perfluorooctane sulfonamide; LOQ = limit of quantification; ND = not detected; PFBS = perfluorobutane sulfonic acid; PFDA = perfluorodecanoic acid; PFDoDA = perfluorododecanoic acid; PFHpA = perfluoroheptanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; PFUnA = perfluorundecanoic acid

Strynar and Lindstrom (2008) measured perfluoroalkyl levels in 112 indoor dust samples collected from homes and daycare centers in North Carolina and Ohio. These authors detected PFHpA, PFOA, PFNA, PFDA, PFUnA, PFDoDA, PFOS, PFHxS, and PFBS. PFOS and PFOA were detected in 94.6 and 96.4% of the samples, respectively. Maximum detections in the samples were as high as 12,100 ng/g for PFOS and 35,700 ng/g for PFHxS. Household dust samples collected from the United Kingdom, Australia, Germany, and the United States showed the presence of perfluoroalkyls (Kato et al. 2009a). PFOS, PFBS, and PFHxS were detected in 74.4, 92.3, and 79.5% of the samples, respectively, whereas PFOA, PFNA, and PFDA were detected in 64.1, 25.6, and 38.5% of the samples, respectively. Björklund et al. (2009) measured PFOA and PFOS in dust samples collected in houses, apartments, daycare centers, offices, and cars in Sweden. PFOA and PFOS were detected in 100 and 79% of the apartment samples and in 100 and 60% of the car samples. The authors concluded that while dietary intake was the major PFOA/PFOS exposure pathway for adults and toddlers in the general population, dust ingestion could become an important pathway under a worst-case scenario (e.g., high dust ingestion and maximum dust levels).

Perfluoroalkyls in indoor and outdoor environments in urban, suburban, and rural locations near Toronto, Ontario, Canada were assessed using window films for passive sampling. The sum of perfluoroalkyls concentrations on outdoor window films ranged from 0.04 to 0.75 pg/cm^2 in winter and from 0.04 to

0.92 pg/cm^2 in summer, with higher values found in urban and suburban locations than in rural locations. Indoors, concentrations on window film ranged from less than the detection limit (which ranged from 0.033 to 0.06 pg/cm^2) to 2.1 pg/cm^2 in winter and from 0.08 to 4.3 pg/cm^2 in summer, although there were no distinct trends between urban and rural for indoor concentrations (Gewurtz et al. 2009).

5.5.2 Water

PFOS and PFOA have been widely detected in surface water samples collected from various rivers, lakes, and streams in the United States (Boulanger et al. 2004; DRBC 2013; Kannan et al. 2005; Kim and Kannan 2007; Nakayama et al. 2007; Simcik and Dorweiler 2005; Sinclair et al. 2004, 2006). Levels of these substances in surface water appear to be declining since the phase out of these two substances. Zhang et al. (2016) measured surface water levels of perfluoroalkyls in 2014 at 37 sites across the northeastern United States. Detectable levels of PFOA and PFNA were found at all sites, and PFHxS, PFOS, and PFDA were detectable at >90% of the sites. The respective maximum concentrations of PFOA, PFOS, PFHxS, and PFNA were 56 ng/L measured in the Passaic River, New Jersey, 27.5 ng/L measured in the Woonasquatucket River, Rhode Island, 43 ng/L measured at Mill Cove, Rhode Island, and 14 ng/L measured at Mill Cove, Rhode Island (Zhang et al. 2016).

Less data are available regarding the concentrations of other perfluoroalkyls in surface water. PFHpA and PFHxS were commonly detected in the few studies that analyzed surface water for these compounds (DRBC 2013; Kim and Kannan 2007; Nakayama et al. 2007; Simcik and Dorweiler 2005). Concentrations of PFOA and PFOS measured in surface water are presented in Table 5-12 and other perfluoroalkyls are summarized in Table 5-13. Maximum concentrations of PFOS, PFOA, PFHpA, PFNA, PFDA, PFUnA, PFDoDA, PFBS, and PFHxS measured in surface water collected from the Cape Fear Basin, North Carolina were 287, 132, 329, 194, 120, 52.1, 4.46, 9.41, and 35.1 ng/L, respectively (Nakayama et al. 2007). Much higher concentrations of PFOS (198–1,090 ng/L) have been measured in Onondaga Lake in Syracuse, New York (Sinclair et al. 2006). Onondaga Lake is a Superfund site that has become contaminated through industrial activity along its banks.

[b]Detection limit = 0.05 ng/L.

"—" indicates no available data; ND = not detected; FOSA = perfluorooctane sulfonamide; PFBS = perfluorobutane sulfonic acid; PFDA = perfluorodecanoic acid; PFDoDA = perfluorododecanoic acid; PFHpA = perfluoroheptanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFUnA = perfluoroundecanoic acid

Higher levels of perfluoroalkyls are expected in surface water and groundwater surrounding perfluorochemical industrial facilities. Paustenbach et al. (2007) estimated PFOA concentrations in environmental media for communities located near the DuPont Washington Works chemical manufacturing facility. From this analysis, the authors concluded that much of the PFOA detected in groundwater near the facility was attributed to deposition to soil surfaces following atmospheric emissions from the plant followed by subsequent leaching into groundwater. DuPont entered into an agreement with the EPA to collect monitoring data for PFOA in the Ohio River around the DuPont Washington Works facility. In its final phase III assessment, it was reported that levels of PFOA downstream from the facility in 2011 were about an order of magnitude lower than when monitoring began in 2002, while levels upstream essentially remained unchanged (URS 2012). The maximum concentration measured in 2011 was 200 ng/L and was obtained from a monitoring location adjacent to the site.

PFOA, PFOS, PFBA, PFHxS, and PFBS have been detected in the municipal drinking water of communities located near the 3M Cottage Grove fluorochemical facility (ATSDR 2008). Xiao et al. (2015) summarized soil and groundwater monitoring data of select perfluoroalkyls near this facility. Groundwater samples for PFBA, PFHxA, PFOA, PFHxS, and PFOS in wells surrounding the site obtained from 2009 to 2013 showed little or no change in concentration over this time period, even though 3M had stopped producing perfluoroalkyls at this facility in 2002. Levels in groundwater were shown to decrease exponentially with distance from the source. A measured PFOA concentration of approximately 20,000 ng/L was observed from a well near the historical unlined disposal site of this

facility, but levels decreased to <100 ng/L measured at a distance of 1.4 km away. Some other examples are provided in Table 5-14.

[a]Analyte was reported as APFO.

"—" indicates no available data; APFO = ammonium perfluorooctanoate; ND = not detected; PFBA = perfluorobutanoic acid; PFBS = perfluorobutane sulfonic acid; PFHxS = perfluorohexane sulfonic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid

Groundwater sampling of PFOA and PFOS was conducted at 401 military installations (DoD 2018). The PFOS/PFOA levels exceeded EPA's lifetime health advisories of 70 ppt at 22% of the installations (9/64 Army, 40/127 Navy/U.S. Marine Corp, 39/203 Air Force, and 2/7 Defense Logistics Agency

installations). The PFOS/PFOA levels exceeded the EPA lifetime health advisories in 1,621 of the 2,668 groundwater wells sampled (61%).

Yamashita et al. (2005) measured PFOA, PFOS, PFNA, and PFHxS concentrations in ocean water collected from locations in the Atlantic Ocean, Pacific Ocean, and areas near China, Korea, and Japan. These concentrations are listed in Table 5-15. Wei et al. (2007a) measured perfluoroalkyl concentrations in surface seawaters from the western Pacific Ocean, Indian Ocean, and near-Antarctic region. PFOS and PFOA were detected in 60 and 40% of the samples, respectively, with maximum concentrations of 71.7 and 441.6 pg/L, respectively. Concentrations of other perfluoroalkyls (PFHxS, PFBS, PFDoDA, PFDA, PFNA, PFHpA) were generally below detection in most samples, with the exceptions being in samples collected near Shanghai, the Philippines, and Indonesia. Maximum concentrations of these perfluoroalkyls ranged from 3.1 to 70.2 pg/L near Shanghai. PFOA, PFOS, and other perfluoroalkyl species were monitored in waste water effluents and 20 rivers located in Japan (Murakami et al. 2008). Perfluoroalkyls were ubiquitous in the river water samples, with concentrations of PFOA as large as 0.054–0.192 μg/L in seven of the river samples with low waste water effluent sources.

Source: Yamashita et al. 2005

The presence of PFOA and PFOS in surface water in the United States indicates that drinking water taken from these sources may contain detectable levels of these substances. The most vulnerable drinking water systems are those in close proximity to sites that are contaminated with perfluoroalkyls. PFOA was detected in 12 out of 13 samples collected from four municipal drinking water treatment plants that draw water from the Tennessee River and are located downstream from the 3M Decatur Facility in Alabama. Reported concentrations ranged from 0.025 to 0.16 μg/L (3M 2008c). PFOA was not detected in any samples collected from a fifth plant located upstream of the 3M Decatur facility (3M 2008c). Sampling conducted in October 2015 continued to show a presence of perfluoroalkyls in water samples collected at nine sites along the Tennessee River near Decatur, with maximum PFOS, PFBS, and PFOA levels reported as 0.220, 0.160, and 0.120 μg/L, respectively (Newton et al. 2017). Waterways adjacent to areas where aqueous film forming foams (AFFFs) used to fight fires have been shown to have high levels of perfluoroalkyls. For example, a PFOS concentration of 2,210 μg/L was detected in the Etobicoke Creek, Canada following the use of AFFF at the Toronto Pearson Airport (D'agostino and Mabury 2017). The vertical distribution of 15 perfluoroalkyl substances was studied in concrete samples obtained from a location in which AFFFs were used in firefighter training (Baduel et al. 2015). At the surface of the concrete pad, PFOS was observed to be the dominant substance measured; however, shorter-chain compounds were observed to a depth of 12 cm from the surface, suggesting vertical transport of the shorter-chain compounds and the potential for movement into groundwater.

Hu et al. (2016) presented geospatial monitoring data for six perfluoroalkyls (PFBS, PFHxS, PFHpA, PFOA, PFOS, and PFNA) in U.S. drinking water from information contained in the EPA third Unregulated Contaminant Monitoring Rule (UCMR 3) program. Frequency of detection and concentrations in drinking water was correlated with proximity to industrial facilities using perfluoroalkyls, military fire training areas, and the number of waste water treatment plants. Note that UCMR 3 required all large water systems (4,120 PWSs, serving >10,000 people) and a representative sample of 800 small water systems (serving ≤10,000 people) to monitor for PFOA and PFOS from 2013 through 2015.

It was reported that 66 public drinking water systems that serve 6 million U.S. residents had at least one sample that exceeded the current EPA health advisory level of 0.07 μg/L for PFOA and PFOS (Hu et al. 2016). The dataset used by Hu et al. (2016) has since been updated by the EPA (EPA 2017). The most recent report dated January 2017 showed that PFOS, PFOA, PFNA, PFHxS, PFHpA, and PFBS were detected above their respective minimal reporting level in 95, 117, 14, 55, 86, and 8 out of 4,920 public water systems (EPA 2017). PFOA and PFOS were identified above the health advisory level of

0.07 µg/L in 13 and 46 out of the 4,920 public water supplies, respectively (EPA 2017). It is possible that combined concentrations of PFOA and PFOS may exceed the advisory level while individual concentrations may still be below 0.07 µg/L.

Based on a memorandum of understanding with the EPA, DuPont began collecting water monitoring data of both public and private wells near the Washington Works chemical plant. The quarterly reports and monitoring data affiliated with these reports may be obtained from the regulations.gov portal (http://www.regulations.gov). In samples of water collected at 17 public water facilities from 2002 to 2009 in West Virginia and Ohio, PFOA levels ranged from below the detection limit (0.0023 µg/L) to nearly 100 µg/L in a few test wells in Little Hocking, Ohio (EPA 2010). In the final phase III summary report, PFOA concentrations were reported to range from below the detection limit to 0.79 µg/L in 34 wells located approximately 3 miles upstream and 82 miles downstream from the facility (URS 2012).

Rumsby et al. (2009) reviewed the presence of PFOS and PFOA in drinking waters worldwide and discussed treatment methods for removing these substances from public water supplies. Conventional waste water treatment does not always efficiently remove perfluoroalkyls, and effluent may contain higher levels of some perfluoroalkyls than influent due to degradation of precursor substances during the treatment process (Schultz et al. 2006a, 2006b). While granulated activated carbon and reverse osmosis followed by nanofiltration have been shown to be effective methods of removing perfluoroalkyls, conventional methods such as chlorination, ozonolysis, and slow sand filtration may not be as effective. As a consequence, public drinking water systems impacted by effluent from waste water treatment plants often contain higher levels of perfluoroalkyls than systems that are not impacted by waste water treatment plant effluent. Quinones and Snyder (2009) analyzed raw and finished water at seven different public water systems in the United States for the presence of perfluoroalkyls. Water systems that were heavily impacted by waste water treatment plant effluents had greater frequency and higher levels of perfluoroalkyls when compared to water systems that were not highly impacted by waste water treatment plants. For example, no perfluoroalkyls were detected in either influent or finished water from a public water system in Aurora, Colorado with no impact from waste water treatment plant effluent; however, PFHxA, PFOA, PFNA, PFDA PFUnA, PFHxS, and PFOS were detected in all samples of a Los Angeles, California public water system that was highly impacted by waste water effluent. Perfluoroalkyls were commonly detected in the influent and effluent of 10 waste water treatment plants across the United States (Schultz et al. 2006a). PFBS was detected in 100% of both influent and effluent samples of the 10 plants, while other perfluoroalkyls like PFOA, PFOS, PFNA, PFHxA, PFHpA, and PFHxS were detected in 80% of the influent and effluent samples at the 10 plants. In a national study of

10 perfluoroalkyls in raw and treated drinking water of France, Boiteux et al. (2012) observed that several perfluoroalkyl carboxylic acids had greater concentrations in treated water than the raw water. In eight drinking water treatment plants, PFBA, PFHxA, and PFHpA were not detected in raw water, but were detected in treated water, indicating that these substances were released from saturated activated carbon used to treat raw waters or were formed by the degradation of precursor substances. Perfluoroalkyl sulfonates appeared to be removed more efficiently than the carboxylates. PFHxS, PFBS, and PFOS were detected less frequently in treated water as compared to raw water influent. These three compounds comprised 53% of the total concentration of perfluoroalkyls in the raw water samples, but only 37% of the total concentration of the perfluoroalkyls in the treated water. The summed concentration of 10 perfluoroalkyls was analyzed in the raw water and treated water of two drinking water treatment plants downstream from a fluoropolymer manufacturing facility located in France (Dauchy et al. 2012). The total concentration of perfluoroalkyls in the raw water at four sampling locations of the first plant ranged from 0.140 to 0.287 μg/L, while the summed concentration in the treated water was 0.179 μg/L. The total concentration of the 10 perfluoroalkyls in raw water at the second plant was 0.132 μg/L, while the total concentration in the treated water was 0.130 μg/L. Levels of PFHxA were greater in the treated water than the raw water at three of the four raw water sampling points, and levels of PFNA were greater in treated water than raw water at all sampling points of the first plant, but were slightly lower in the treated water of the second drinking water plant even though both systems used simple chlorination to treat the water.

PFOA was detected in 65% of the public drinking water systems tested in New Jersey in 2006 at concentrations ranging from 0.005 to 0.039 μg/L (Post et al. 2009). In a follow-up study conducted in 2009, PFOA was detected in 57% of raw water samples from 29 additional public drinking water systems in New Jersey at a maximum concentration of 0.100 μg/L (Post et al. 2013). Nine other perfluoroalkyls were also tested for, with PFOS and PFNA being the most frequently detected compounds (30% detection frequency each) after PFOA. PFOA and PFOS were detected in tap water from 21 cities located in China at concentrations of <0.0001–0.0459 and <0.0001–0.0148 μg/L, respectively (Jin et al. 2009). Mak et al. (2009) published a study comparing detections of perfluoroalkyls including PFOA and PFOS in tap water collected in China, Japan, India, Canada, and the United States. PFOA and PFOS were the predominant species measured, accounting for 40–50% of the total perfluoroalkyls present in water, with the exception of certain location of India where PFOS or PFOA may not have been present or were present at low levels.

Gellrich et al. (2013) analyzed 119 samples of mineral water, 26 samples of tap water, 18 spring water samples, and 14 raw water samples from Germany for the presence of perfluoroalkyls. Perfluoroalkyls were detected in 58% of all of the samples tested, with the greatest summed total concentration observed in tap water at 0.0427 μg/L. The maximum concentration of individual perfluoroalkyls occurring in bottled water, spring water, untreated water, and tap water were observed for PFBS (0.0133 μg/L), PFOA (0.0074 μg/L), PFBS (0.010 μg/L), and PFHxS (0.0121 μg/L), respectively. Perfluoroalkyls were widely detected in drinking water samples collected in 2008 at 40 different locations of Catalonia, Spain (Ericson et al. 2009). Median concentrations ranged from 0.00002 μg/L (FOSA) to 0.00098 μg/L (PFOA). The most frequently detected compounds were PFOS and PFHxS, which were detected in 35 and 31 samples, respectively. PFOS, PFOA, and PFHxS were detected in all samples collected in a study of drinking water contamination of perfluoroalkyls in Rio de Janeiro, Brazil (Quinete et al. 2009). Concentration ranges were 0.00058–0.00670 μg/L (PFOS), 0.00035–0.00282 μg/L (PFOA), and 0.00015–0.001 μg/L (PFHxS) respectively.

Perfluoropolyethers (PFPEs) such as perfluoroether carboxylic and sulfonic acids containing one or more ether oxygens in the carbon backbone are expected to be less persistent than the legacy substances. However, hexafluoropropylene oxide trimer and dimer acid (HFPO-TA and HFPO-DA) were detected in downstream water samples near a fluoropolymer facility in China at levels of 5.2–68.5 μg/L (Pan et al. 2017). Pan et al. (2018) also provided data of HFPO-DA and HFPO-TA in surface waters in China, United Kingdom, United States, Sweden, Germany, Netherlands, and South Korea. The substances were frequently detected in surface waters in all countries with median levels of 0.00095 μg/L (HFPO-DA) and 0.00021 μg/L (HFPO-TA). Gebbink et al. (2017) also reported that the GenX (HFPO-DA) was detected in all sampling sites downstream from a fluoropolymer facility in the Netherlands and at three out of four drinking water facilities located near the facility. Short-chain perfluoroalkyl compounds and legacy perfluoroalkyls were analyzed for in 97 drinking water samples from Canada and other nations in 2015–2016 (Kabore et al. 2018). PFOA and PFOS levels did not exceed 0.005 μg/L in any of the 97 samples; however, high detection frequencies ranging from 64 to 92% were observed in tap water for some short-chain perfluoroalkyls.

5.5.3 Sediment and Soil

Concentrations of perfluoroalkyls in soils are expected to be greater in the vicinity of fluorochemical plants that produced or used these substances as processing aids in the manufacture of fluoropolymers than in the environment at large. Levels of some perfluoroalkyls measured in soil and sediment

surrounding perfluorochemical industrial facilities are listed in Table 5-16. PFOA was detected in most soil and sediment samples collected on- and off-site at the 3M Decatur facility in Alabama in monitoring studies conducted between October 2004 and December 2006. Maximum soil concentrations were as high as 14,750 ng/g on-site and 7.85 ng/g off-site, and maximum sediment concentrations were as high as 347 ng/g on-site and 2,385 ng/g off-site (3M 2008c). The highest levels of PFOA were measured in soil from on-site fields formerly amended with PFOA-containing sludge. In its final project report for this location, six on-site soil samples were analyzed in December 2012 for the presence of PFOA, PFOS, PFBS, and PFHxS. Average levels were 3.86–3,890 ng/g (PFOS), 3.56–270 ng/g (PFHxS), 0.423–64.8 ng/g (PFBS), and 17.0–1,410 ng/g (PFOA) (3M 2012).

[a]Analyte was reported as APFO.

"—" indicates no available data; APFO = ammonium perfluorooctanoate; ND = not detected; PFBA = perfluorobutanoic acid; PFBS = perfluorobutane sulfonic acid; PFHxS = perfluorohexane sulfonic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid

PFOA, PFOS, and PFHxS were detected in 90–100% of soil samples collected from a former tar neutralization area, a former sludge disposal area, a former solids burn pit area, a former waste water treatment plant area, and a former fire training area at the 3M Cottage Grove facility in Minnesota (3M 2007b). PFBS was detected in 60–73% of these samples. Maximum concentrations for these substances were 21,800, 104,000, 3,470, and 139 ng/g, respectively. Levels of PFBA were only reported for soil in the fire training area; it was detected in 9 out of 11 samples from this location at 0.306–11.5 ng/g. The percent detection of these compounds in sediment from the East and West Cove sites was similar to that in soil. Maximum concentrations of PFOA and PFOS were 1,845 and 65,450 ng/g, respectively. These perfluoroalkyls were also analyzed in Mississippi River sediment near the Cottage Grove Facility. Levels of these compounds were much greater along the facility shoreline compared to levels in transect samples collected at points crossing the river. Maximum shoreline concentrations for PFOA, PFBA, PFOS, PFHxS, and PFBS were 341, 124, 79.0, 11.5, and 29.4 ng/g, respectively. PFHxS, PFBS, and PFBA were not detected in any of the transect samples, and PFOA was found in only 18%. Although the maximum concentration of PFOS was 3.16 ng/g, it was still detected in 82% of the transect samples.

PFOA and PFOS were detected in all surface soils (top 10 cm) samples collected at 28 sites in September and October of 2012 along U.S. Highway 10 running from Cottage Grove, Minnesota (where the former 3M perfluoroalkyl manufacturing facility was located) to Big Lake, Minnesota (Xiao et al. 2015). Measured levels of PFOS and PFOA ranged from 0.2 to 28.2 and from 5.5 to 125.7 ng/g, respectively. Subsurface soils up to a depth of 65 cm were collected at four sites as well. Levels of PFOA and PFOS generally increased with increasing depth at each of the locations, suggesting a downward movement of the contaminants and the potential to contaminate groundwater.

The use of aqueous firefighting foams at fire training areas of military installations has resulted in widespread contamination of perfluoroalkyls in the soil and groundwater at these facilities. Monitoring data obtained from 40 sites at 10 U.S. military installations in the continental United States and Alaska were collected for several perfluoroalkyls (Anderson et al. 2016). These data are summarized in Table 5-17.

[a]Water concentrations are ppb (µg/L); soil and sediment levels are ppb (µg/kg).

DF = detection frequency as a percentage; FOSA = perfluorooctane sulfonamide; PFBA = perfluorobutanoic acid; PFBS = perfluorobutane sulfonic acid; PFDoDA = perfluorododecanoic acid; PFDA = perfluoro-n-decanoic acid; PFHpA = perfluoroheptanoic acid; PFHxA = perfluorohexanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOS = perfluorooctane sulfonic acid; PFUnA = perfluoroundecanoic acid

Source: Anderson et al. (2016)

Perfluoroalkyls have been detected in soils that were amended with biosolids (Sepulvado et al. 2011). Several perfluoroalkyls were detected in biosolid-amended soils, with PFOS being the predominant compound with levels ranging from 5.5 to 483 ng/g, depending upon the loading rate.

5.5.4 Other Media

In a study conducted by the Food and Drug Administration (FDA) of 91 food samples collected during the 2017 Total Diet Study, PFOS was detected in 10 meat/seafood samples; the levels ranged from 0.134 ng/g in a boiled frankfurter to 0.865 ng/g in baked tilapia (FDA 2019). PFBA was detected in one sample of raw/frozen pineapple (0.068 ng/g). PFOA, PFHxS, PFNA, PFDA, PFBS, and PFHxA levels were below the lower limit of quantitation. It is important to note that FDA states that the sample size is limited and cannot be used to draw definitive conclusions. Levels of PFOS, PFOA, PFBS, PFHxS, PFHxA, PFHpA, PFDA, PFNA, and PFDoDA were analyzed in 31 food items collected from 5 grocery stores located in Texas in 2009 (Schecter et al. 2010). PFOA was the most frequently detected item (detected in 17 of 31 of the food samples), with levels ranging from 0.07 ng/g in potatoes to 1.80 ng/g in olive oil. PFOS, PFHxA, PFHpA, PFNA, PFDA, and PFDoDA were not detected in any samples. PFBS and PFHxS were detected in cod at 0.12 and 0.07 ng/g, respectively. The data for PFOA are summarized in Table 5-18. Several studies have evaluated the levels of perfluoroalkyls in fish from lakes and rivers in the United States; these data are summarized in Table 5-19.

Table 5-18. Detections of PFOA in 31 U.S. Food Items

[a]Perfluoroalkyl levels measured in muscle.

Grayed cells indicate that study did not evaluate compound; FOSA = perfluorooctane sulfonamide; LOQ = limit of quantification; NE = not evaluated; PFBS = perfluorobutane sulfonic acid; PFDoDA = perfluorododecanoic acid; PFDA = perfluorodecanoic acid; PFHpA = perfluoroheptanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOS = perfluorooctane sulfonic acid; PFUnA = perfluoroundecanoic acid

Concentrations of perfluoroalkyls have been reported in foods sampled in Canada, the United Kingdom, and Germany (Food Standards Agency 2006; Fromme et al. 2007b; Tittlemier et al. 2007). Perfluoroalkyls were detected in only 9 out of 54 food composites collected during Canadian Total Diet studies from 1992 to 2004 (Tittlemier et al. 2007). PFOS was detected in beef steak, ground beef, luncheon meats, marine fish, freshwater fish, and microwave popcorn at concentrations ranging from 0.98 to 2.7 ng/g, wet weight. PFOA was detected in roast beef, pizza, and microwave popcorn at 0.74–3.6 ng/g, wet weight. PFHpA was detected in pizza and microwave popcorn at 1.5–2.0 ng/g, wet weight. PFNA was detected only in beef steak at 4.5 ng/g, wet weight. PFDA, PFUnA, and PFDoDA were analyzed for but not detected in any of the food composites. During the U.K. Food Standards Agency Total Diet Study, PFOS was detected in eggs, sugars and preserves, potatoes, and canned vegetables at 1, 1, 10, and 2 μg/kg, respectively (Food Standards Agency 2006). PFOA was detected only in potatoes at 1 μg/kg. Neither substance was detected in the bread, miscellaneous cereals, carcass meats, offal, meat products, poultry, fish, oils and fats, green vegetables, other vegetables, fresh fruit, fruit products, beverages, milk, dairy products, or nuts categories. Fromme et al. (2007b) detected PFOS, PFOA, and PFHxS in 33, 45, and 3%, respectively, of 214 daily duplicate food portions for 31 adults in the city of Munich, Germany. Concentrations were 0.025–1.03 ng/g fresh weight for PFOS, 0.025–118.29 ng/g fresh weight for PFOA, and 0.05–3.03 ng/g fresh weight for PFHxS. Reported 90th percentile values were 0.11 and 0.21 ng/g fresh weight for PFOS and PFOA, respectively (Fromme et al. 2007b).

The temporal trend of perfluoroalkyl residues in eggs, milk, and farmed rainbow trout from Sweden were studied from 1999 to 2010 (Johansson et al. 2014). Over this period, the mean annual decreases in levels of PFOS were 18 and 31% in rainbow trout and eggs, respectively. The mean annual decreases of PFOA and PFHxS were 12 and 11%, respectively, in eggs. The detection frequency of PFOA and PFHxS was too low in milk samples to assess changes in levels over the time period, and decreases in the levels of PFOS were found to be not statistically significant over the temporal period. The mean annual decrease in levels of PFHxS in rainbow trout was 4.3% annually.

Elevated levels of PFOS were measured in water and fish samples obtained from 2009 and 2012 at six sampling locations along the Welland River and Lake Niapenco in Ontario, Canada (Gewurtz et al. 2014). These locations were downstream from the Hamilton International airport where PFOS containing AFFF was used until the mid-1990s at a firefighting training facility at the airport. PFOS concentrations were generally highest in benthic feeding fish collected at the sampling locations nearest to the airport. The maximum level of PFOS was observed in common carp collected at a site near the airport at a concentration of 2,300 ng/g. Maximum levels of PFOS in smallmouth bass, largemouth bass, and

channel catfish were 640, 450, and 430 ng/g, respectively. Freshwater fish and seafood obtained from China had detectable levels of nine perfluoroalkyls, with PFOS being detected in 62% of the samples at a concentration range of <0.10–26.2 ng/g and PFOA detected in 70% of the samples at levels of <0.10–1.99 ng/g (Zhang et al. 2011).

PFOA was detected in the packaging paper of two microwave popcorn bags at 0.3–4.7 ng/cm^2 uncooked and 0.5–4.3 ng/cm^2 cooked (Sinclair et al. 2007). The mean mass of PFOA in the gas phase of popcorn vapors following popping was 16–17 ng/cm^2. PFHpA, PFNA, PFDA, PFUnA, and PFDoDA were detected in one of the bags at 0.4–3.2 ng/cm^2 uncooked and 0.5–4.3 ng/cm^2 cooked; however, these perfluoroalkyls were not detected (<0.2 ng/cm^2) in the second bag. Begley et al. (2005) measured PFOA concentrations of 6–290 µg/kg in microwave popcorn bags. These authors also tested a hamburger wrapper, sandwich wrapper, French fry box, and soak-proof paper plates and did not find PFOA above the detection limit in these products. The concentration of PFOA measured in undiluted perfluoro paper coating formulations ranged from 88,000 to 160,000 µg/kg (Begley et al. 2005).

A study of perfluorinated and polyfluorinated substances in food packaging from U.S. fast food restaurants found perfluoroalkyl carboxylates (such as PFOA and PFHxA), perfluoroalkyl sulfonates (such as PFBS), fluorotelomer sulfonates, and unknown polyfluorinated compounds (Schaider et al. 2017). PFOA was detected in 6 of the 20 samples collected in 2014–2015. Fluorotelomer alcohols that can degrade or metabolize to perfluoroalkyl carboxylic acids such as PFOA continue to be detected in food packaging materials. Yuan et al. (2016) analyzed 69 food contact materials (paper tableware, paper cups, cupcake cups, paper boxes, paper bags, and microwave popcorn bags) produced in China and 25 materials (paper tableware, microwave popcorn bags, and paper cups) produced in the United States. The median concentration of total fluorotelomer alcohols in food contact materials produced in China (sum of 6:2, 8:2, 10:2, 12:2, 14:2, 16:2, and 18:2 fluorotelomer alcohol) ranged from 2 to 18,200 ng/g, with the highest levels observed in microwave popcorn bags. The detection frequencies of 6:2, 8:2, 10:2, 12:2, 14:2, 16:2, and 18:2 fluorotelomer alcohol in all food contact materials were reported as 38, 65, 77, 70, 58, 35, and 30%, respectively. The only fluorotelomer detected in paper tableware produced in the United States was 6:2 fluorotelomer alcohol, with a detection frequency of 11%; however, all fluorotelomer alcohols, with the exception of 18:2 fluorotelomer alcohol, were detected in microwave popcorn bags from the United States, although the levels were much lower than those produced in China. Table 5-20 shows the median concentration of the fluorotelomer alcohols in microwave popcorn bags produced in the United States versus those produced in China. In contrast to the products produced in China, the predominant fluorotelomer alcohol currently detected in food contact materials produced in the

United States appears to be 6:2 fluorotelomer alcohol. The authors concluded that the results of the PFOA Stewardship Program had effectively reduced the usage of long-chain fluorotelomer alcohols in the United States; however, they were still widely present in products produced in China.

Table 5-20. Fluorotelomer Alcohols Detected in Microwaveable Popcorn Bags Produced in China and the United States

Fluorotelomer alcohol	Median concentration of FTOH in microwave popcorn bag produced in China (ng/g)	Median concentration of FTOH in microwave popcorn bag produced in the United States (ng/g)
6:2 FTOH	80	485
8:2 FTOH	4,810	1.36
10:2 FTOH	6,700	0.73
12:2 FTOH	5,650	0.55
14:2 FTOH	384	0.12
16:2 FTOH	61	<MQL
18:2 FTOH	7.5	Not detected

FTOH = fluorotelomer alcohol; MQL = method quantitation limit

Source: Yuan et al. 2016

Washburn et al. (2005) measured the concentration of the perfluorooctanoate anion in fluorotelomer-treated consumer articles as well as the fluorotelomer formulations used for the treatments. PFOA was detected in mill-treated carpeting (0.2–0.6 mg/kg), carpet-care solution-treated carpeting (0.2–2 mg/kg), treated apparel (<0.02–1.4 mg/kg), treated home textiles (<0.02–1.4 mg/kg), industrial floor waxes and wax removers (0.0005–0.06 mg/kg), latex paint (0.02–0.08 mg/kg), and home and office cleaners (0.005–0.05 mg/kg). The concentrations of PFOA measured in the formulations used for these applications were 30–80, 1–50, <1–40, <1–40, 5–120, 50–150, and 50–150 mg/L, respectively. PFOA was not detected in treated upholstery (<0.034 mg/kg), treated technical textiles (<0.034 mg/kg), treated nonwoven medical garments (<0.034 mg/kg), or stone, tile, and wood sealants (<0.1 mg/kg).

Liu et al. (2014) measured levels of perfluoroalkyls in 35 consumer products that are typically used indoors, such as treated home textiles, food contact paper, carpet care products, and floor waxes. All products were obtained from retail stores in the United States between March 2007 and September 2011. The general trend was that these products contained decreasing quantities of perfluorocarboxylic acids, including PFOA, over the temporal period studied; however, there was an increase in use of PFBS, presumably as a replacement of PFOS in consumer products. Levels of perfluoroalkyls were analyzed in 115 random samples of consumer products obtained in Germany in 2010, including textiles, carpets,

cleaning and impregnating agents, leathers, food contact materials, baking and sandwich paper, and ski waxes (Kotthoff et al. 2015). Cleaning agents and some baking and sandwich papers had nondetectable or negligible amounts of perfluoroalkyls; however, PFOA and PFOS were frequently detected in outdoor textiles, ski wax, leather products, gloves, awning cloths, nanosprays, impregnation sprays, and food contact materials. Cleaning agents, nanosprays, and impregnation sprays tended to have the highest level of fluorotelomer alcohols. EPA (2009b) analyzed 116 articles of commerce obtained from retail outlets in the United States from March 2007 and May 2008 for the presence of perfluorocarboxylic acids ranging in carbon number from C5 (perfluoropentanoic acid) to C12 (perfluorododecanoic acid). Total C5–C12 perfluorocarboxylic acid levels ranged from below the detection limit (1.5 ng/g) to 47,100 ng/g, with levels of PFOA ranging from below the detection limit to 6,750 ng/g.

PTFE is a fluoropolymer used in applications such as nonstick cookware coatings and plumbing sealant tape. In the past, PFOA had been used as a processing aid in the emulsion polymerization of PTFE (DuPont 2008). PFOA was largely removed from the fluoropolymer material during the baking and curing step of nonstick cookware coatings in a high temperature oven; however, residual PFOA could be found in the final coatings (DuPont 2008). Begley et al. (2005) measured PFOA concentrations of 4–75 μg/kg in PTFE cookware, 3 μg/kg in PTFE-based dental floss, 4 μg/kg in PTFE-based dental tape, and 1,800 μg/kg in PTFE film/sealant tape. PFOA was not detected in tubing made of a fluoro-ethylene-propene copolymer (Begley et al. 2005).

Studies have been conducted that investigated the release of PFOA from PTFE cookware when heated. Sinclair et al. (2007) reported PFOA release concentrations ranging from 19 to 287 pg/cm^2 measured using four new nonstick frying pans. These concentrations were measured at normal cooking temperatures within the range of 180–229°C. PFOA was detected in water (7 and 75 ng) boiled for 10 minutes in two out of five non-stick pans (Sinclair et al. 2007). PFOA was not found above the detection limit (0.1 ng/cm^2) during 40 extraction tests on PTFE cookware using an ethanol/water mixture (Washburn et al. 2005). Likewise, Powley et al. (2005) conducted extraction texts on commercial fluoropolymer-treated cookware using water and water/ethanol mixtures at 100 and 125°C. Under simulated cooking conditions, PFOA was not identified above the detection limit of 100 pg/cm^2. Begley et al. (2005) reported that additional PFOA was not generated in the PTFE coating of three empty pans heated to 320°C (DuPont 2008). According to DuPont, the non-stick coating on a pan may begin to deteriorate if the pan is accidentally heated above 348°C, which is well above the maximum recommended cooking temperature of 260°C (DuPont 2008). Although it is possible for an unattended

empty pan to reach these high temperatures, overheating non-stick cookware is expected to be prevented in most cases because food oils begin to generate smoke around 190°C (Begley et al. 2005).

A comprehensive study that examined 116 articles of commerce (AOC) found perfluorocarboxylic acids, including PFOA, in many commercially available substances, such as carpet care products and waxes (EPA 2009b). Levels of PFOA ranged from nondetectable to 6,750 ng/g, and levels of total perfluorocarboxylic acids (the sum of C5–C12 acids) ranged from nondetectable to 47,100 ng/g. Perfluoroalkyls, including PFOA, have been detected at low levels in personal care products such as cosmetics and sunscreens (Fujii et al. 2013).

5.6 GENERAL POPULATION EXPOSURE

Levels of perfluoroalkyls have been measured in indoor air, outdoor air, dust, food, surface water, and various consumer products. Possible exposure pathways have been proposed; however, the relative importance of these pathways, including their association with the accumulation of perfluoroalkyls in blood, remains unclear (Apelberg et al. 2007b; Begley et al. 2005; Calafat et al. 2006b; Trudel et al. 2008; Washburn et al. 2005). For populations that have elevated levels of perfluoroalkyls in water supplies, the primary route of exposure is expected to be ingestion of contaminated drinking water.

Trudel et al. (2008) provides a thorough analysis of general population exposure to PFOS and PFOA based on the available information and proposes the following possible exposure pathways: food and water consumption, ingestion of house dust, hand-to-mouth transfer from treated carpets, migration into food from PFOA-containing paper or cardboard, inhalation of indoor and ambient air, and inhalation of impregnation spray aerosols. Other pathways proposed to be less significant included oral exposure from hand-to-mouth contact with clothes and upholstery, migration into food prepared with PTFE-coated cookware, dermal exposure from wearing treated clothes, deposition of spray droplets on skin while using impregnation sprays, skin contact with treated carpet and upholstery, and deposition of dust onto skin (Trudel et al. 2008). The strong correlation between PFOA and PFOS concentrations in human serum samples indicates that common exposure pathways for these two substances are possible (Calafat et al. 2007a).

In order to estimate human uptake and the major pathways for human exposure to PFOS and PFOA, reported levels of these compounds in various environmental media, including food and consumer products, were analyzed with respect to product use patterns, personal activity patterns, and personal

intake rates (Trudel et al. 2008). For PFOS, the major exposure pathways in a high-exposure scenario were proposed to be food and water ingestion, dust ingestion, and hand-to-mouth transfer from mill-treated carpets. Relative contributions of these pathways to the total uptake of PFOS in adults were estimated to be approximately 80, 15, and 5%, respectively (Trudel et al. 2008). For PFOA, the major exposure pathways in a high-exposure scenario were proposed to be oral exposure resulting from migration from paper packaging and wrapping into food, general food and water ingestion, inhalation from impregnated clothes, and dust ingestion. Relative contributions of these pathways to the total uptake of PFOA in adults were estimated to be approximately 60, 15, 15, and 10%, respectively (Trudel et al. 2008). Major exposure pathways for the intermediate and low exposure scenarios were proposed to be through food and drinking water (PFOA and PFOS) and ingestion of house dust (PFOA only). Based on these proposed exposure pathways, adult uptake doses estimated for low, medium, and high exposure scenarios were approximately 7, 15, and 30 ng/kg body weight/day, respectively, for PFOS and approximately 0.4, 2.5, and 41–47 ng/kg body weight/day, respectively, for PFOA (Trudel et al. 2008). The estimated uptake values were similar for men and women. Trudel et al. (2008) used older monitoring data and the estimated intakes may not be reflective of current exposure since there has been a downward trend in PFOA and PFOS exposure.

Fromme et al. (2009) assessed human exposure to perfluoroalkyls for adults in the general population of western countries. Based on measurements of indoor and outdoor air, house dust, drinking water, and dietary PFOS and PFOA levels, the investigators estimated average daily exposure levels of 1.6 ng/kg body weight/day for PFOS and 2.9 ng/kg body weight/day for PFOA. Upper daily exposure levels were determined to be 8.8 ng/kg body weight/day for PFOS and 12.6 ng/kg body weight/day for PFOA. The investigators concluded that the oral route, especially diet, was the primary route of exposure to perfluoroalkyls (Fromme et al. 2007a, 2007b, 2009).

As a group of compounds, perfluoroalkyls appear to be ubiquitous in human blood based on the widespread detection of these substances in human serum samples (Byrne et al. 2017; Calafat et al. 2006b, 2007a, 2007b; De Silva and Mabury 2006; Kuklenyik et al. 2004; Olsen et al. 2003b, 2003c, 2004b, 2004c, 2005, 2007a). Tables 5-21 and 5-22 list concentrations of perfluoroalkyls measured in serum samples collected from a representative sample of the general population in the United States. Most studies have reported that PFOA and PFOS levels have been detected in over 90% of subjects (Calafat et al. 2006b, 2007a, 2007b; Olsen et al. 2003b, 2007b, 2004c, 2005, 2008). PFHxS, PFNA, and PFDA are also typically detected in over 90% of the subjects (Calafat et al. 2006b, 2007a, 2017a, 2007b; Kuklenyik et al. 2004; Olsen et al. 2017a, 2017b).

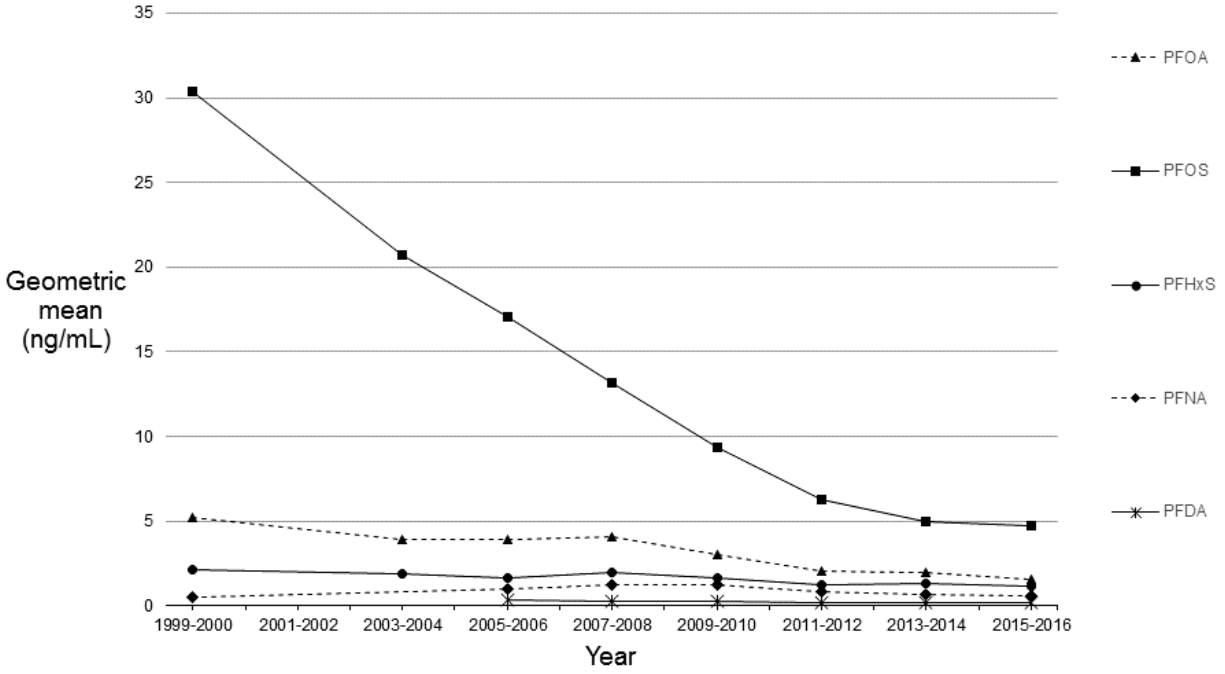
Grayed cells indicate that study did not evaluate compound; "—" indicates no available data;
FOSA = perfluorooctane sulfonamide; LLOQ = lower limit of quantification; LOD = limit of detection; NA = not applicable; NR = not reported; PFBS = perfluorobutane sulfonic acid; PFDA = perfluorodecanoic acid; PFDoDA = perfluorododecanoic acid; PFHpA = perfluoroheptanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFUnA = perfluoroundecanoic acid

As illustrated in Figure 5-3, there has been a clear trend in decreasing serum levels of both PFOS and PFOA in the general population of the United States since 2000 as these substances were phased out; from 1999–2000 to 2015–2015 (CDC 2018, 2019), the geometric mean serum PFOS and PFOA levels in the general population have declined approximately 84 and 70%, respectively. Serum concentrations for PFHxS and PFDA (Figure 5-3) have also been declining over time, whereas serum PFNA concentrations increased from 1999–2000 to 2009–2010 and then started to decrease (Figure 5-3).

Figure 5-3. Geometric Mean Concentrations of PFOA, PFOS, PFHxS, PFNA, and PFDA in U.S. Residents from 1999 to 2016



NHANES = National Health and Nutrition Examination Survey; PFDA = perfluorodecanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid

Source: CDC 2018

Serial studies of American Red Cross blood donors also allow for temporal evaluations of serum perfluoroalkyl levels. Olsen et al. (2008) reported a nearly 60% decline in PFOS blood levels when comparing data from 2001 to 2006; from 2006 to 2015, the serum PFOS levels dropped another 70% (Olsen et al. 2017b). From 2000 to 2015, the PFOS levels dropped 88%. Serum PFOA levels among the blood donors decreased 76% from 2000 to 2015 (Olsen et al. 2003b, 2017b). Geometric mean serum PFHxS levels went from 1.9 ng/mL in 2000 to 0.87 ng/mL in 2015, a 54% decrease (Olsen et al. 2003b, 2017a, 2017b). From 2006 to 2015, both serum PFNA and PFDA levels decreased by 56% (Olsen et al. 2017a, 2017b).

Several studies have evaluated sex- and age-related differences in serum perfluoroalkyl levels in the general population. In an analysis of NHANES data from 1999 to 2008, Kato et al. (2011) found that males had significantly higher levels of PFOA, PFOS, and PFNA than females and that PFOS levels increased with age, especially in females. Fu et al. (2014b) analyzed the effects of sex and age on levels of perfluoroalkyls in a study of 133 (79 male, 54 female) participants. In general, higher levels of PFOA,

PFOS, PFNA, and PFDA were observed in male subjects; however, differences were only statistically significant for PFOA and PFDA. Sex differences in other perfluoroalkyls were not observed. For both male and female subjects, increasing levels of PFOA, PFNA, and PFOS were positively correlated with increasing age. Age- and sex-specific differences have been incorporated into a regression model developed by Jain (2015), which uses measured serum PFOA and PFOS levels to predict total serum perfluoroalkyl levels.

A small number of studies have measured serum perfluoroalkyl levels in U.S. children (Tables 5-23 and 5-24). NHANES has included adolescents (ages 12–19 years) in the 1999–2000 through 2013–2014 surveys (Calafat et al. 2007a, 2007b; CDC 2018). Analysis of NHANES data from younger children were conducted for the 2001–2002 survey (ages 6–11 years) (Kato et al. 2009b) and 2013–2014 survey (ages 3–5 and 6–11 years) (CDC 2018). Pinney et al. (2014) measured serum PFOA, PFOS, PFHxS, PFNA, and PFDA levels in girls (ages 6–8 years) living in Cincinnati, Ohio and San Francisco, California; and Olsen et al. (2004b) measured PFOA, PFOS, PFHxS, and FOSA in the serum of children ages 2–12 years from various locations in the United States who were diagnosed with group A streptococcal infections. Serum levels of several perfluoroalkyls were examined in children exposed to the World Trade Center (WTC) disaster (n=123) and a sociodemographically-matched comparison group (n=185) (Trasande et al. 2017). Children exposed during the WTC disaster were identified from the WTC Health Registry (WTCHR). All participants were ≤8 years of age on September 11, 2001. Blood serum levels of PFOA, PFOS, PFHxS, PFNA, PFDA, and PFUnA were collected during 2014–2016. For all perfluoroalkyls, serum levels in WTCHR children were significantly ($p<0.01$) higher than in matched controls, with percentage increases above control as follows: PFOA 29%; PFOS 34%; PFHxS 26%; PFNA 24%; PFDA 27%; and 200% PFUnA.

Geometric mean serum perfluoroalkyl levels in adolescents (ages 12–19 years) included in NHANES are similar to geometric mean concentrations reported for adults (Calafat et al. 2007a, 2007b; CDC 2018). For example, geometric mean concentrations of PFOA and PFOS measured during the 1999–2000 and 2003–2004 NHANES surveys were 3.9–5.5 and 19.3–29.1 ng/mL, respectively, in adolescent serum and 3.9–5.2 and 20.7–30.4 ng/mL, respectively, in serum of the total population. The most recent NHANES survey (2013–2014) also included serum levels for children aged 3–5 and 6–11 years; the geometric mean concentrations in the younger children were similar to those in adolescents and the total population.

Olsen et al. (2004b) also found that the geometric mean serum PFOA, PFOS, PFHxS, and PFNA levels in older children (12–19 years of age) were similar to those measured in adults (Olsen et al. 2003b).

However, estimated 95th percentile values of PFHxS measured in children were noted to be higher than values estimated for adults. Olsen et al. (2004b) reported bias-corrected 95th percentile estimates of 65 ng/mL for PFHxS in the serum of children ages 2–12 years. This value is higher than bias-corrected 95th percentile estimates of 9.5 and 8.3 ng/mL based on PFHxS measurements in the serum of adult blood donors (Olsen et al. 2003b) and elderly individuals (Olsen et al. 2004c), respectively (see Table 5-22). The difference is less extreme in the NHANES data, with PFHxS 95th percentile values of 12.9–13.1 ng/mL reported for children compared to values of 8.3–8.7 ng/mL reported for the total population. Reasons for the observed differences of PFHxS levels in childhood serum samples compared to adult samples have not been determined. Olsen et al. (2004b) stated that different exposure and activity patterns between children and adults should be considered. For example, children may have a higher exposure than adults to PFHxS, a substance that has been used in carpet treatment applications, since they are lower to the ground and have increased contact with carpeted floors (Calafat et al. 2007a; Olsen et al. 2004b).

When estimating PFOS and PFOA uptake doses for children, Trudel et al. (2008) assumed the same exposure pathways for children as were proposed for adults, but considered exposure from hand-to-mouth transfer from treated carpets to be much larger in children. This pathway was estimated to contribute 40–60% of the total uptake of both PFOS and PFOA in infants (0–1 years), toddlers (1–4 years), and children (5–11 years) in the high-exposure scenario. Exposure via human breast milk was included in the food consumption pathway for infants. Exposure via mouthing of clothes, carpet, and upholstery was also considered for children <12 years old; however, this was considered to be a minor pathway of exposure. PFOS uptake doses estimated for the low-, medium-, and high-exposure scenarios were 18.1–219 ng/kg body weight/day for infants, 14.8–201 ng/kg body weight/day for toddlers, and 9.7–101 ng/kg body weight/day for children. PFOA uptake doses estimated for the low-, medium-, and high-exposure scenarios were 2.2–121 ng/kg body weight/day for infants, 1.2–128 ng/kg body weight/day for toddlers, and 0.8–65.2 ng/kg body weight/day for children. In contrast to the estimates for children under age 12, relative exposure pathways and uptake doses estimated for teenagers (12–20 years old) were approximately the same as for adults.

Perfluoroalkyls have been measured human breast milk and umbilical cord blood; reported concentrations are listed in Tables 5-25 and 5-26. Measurements of perfluoroalkyls in amniotic fluid, meconium, neonatal blood, or other tissues have not been located.

Tao et al. (2008b) measured perfluoroalkyl concentrations in 45 human breast milk samples collected from Massachusetts. PFOS, PFOA, PFHxS, and PFNA were each detected in 96, 89, 51, and 64% of the samples, respectively, with median concentrations of 106, 36.1, 12.1, and 6.97 pg/mL, respectively. PFHpA, PFDA, PFUnA, PFDoDA, and PFBS were each detected in <1% of the samples. Perfluoroalkyls have also been measured in the human breast milk of individuals from Sweden, China, and Germany/ Hungary (Kärrman et al. 2007; So et al. 2006b; Völkel et al. 2008). PFOS was detected in all samples, while detection of PFOA ranged from 8 to 100% in these studies. The reported maximum concentrations of PFOS and PFOA measured in human breast milk samples collected during these studies were 0.360–0.639 and 0.210–0.490 ng/mL, respectively (Kärrman et al. 2007; So et al. 2006b; Völkel et al. 2008). Other perfluoroalkyls detected in human breast milk included PFHpA, PFNA, PFDA, PFUnA, PFBS,

PFHxS, and FOSA. Maximum concentrations of these compounds were reported to be <0.18 ng/mL (Kärrman et al. 2007).

The presence of perfluoroalkyls in umbilical cord blood indicates that these substances can cross the placental barrier resulting in the exposure of babies *in utero* (Apelberg et al. 2007a, 2007b; Fei et al. 2007; Inoue et al. 2004; Midasch et al. 2007). In most studies, PFOS and PFOA have been detected in most umbilical cord blood samples with reported maximum (or 95th percentile) concentrations of 5.3–34.8 and 1.68–7.1 ng/mL, respectively (Apelberg et al. 2007a, 2007b; Fei et al. 2007; Inoue et al. 2004; Midasch et al. 2007; Morello-Frosch et al. 2016). Inoue et al. (2004) did not detect PFOA in 15 cord blood samples from Japan; however, this compound was only detected in the maternal serum of three mothers. Apelberg et al. (2007a) also reported concentrations of other perfluoroalkyls measured in 299 cord serum samples collected during the Baltimore THREE Study. Of these compounds, PFDA, PFUnA, and FOSA were detected most frequently (24, 34, and 26%, respectively). Maximum concentrations in these samples ranged from 1.1 to 1.9 ng/mL. PFHpA, PFDoDA, and PFBS were each detected in <6% of the samples, with maximum concentrations ranging from 0.2 to 2.6 ng/mL. Manzano-Salgado et al. (2015) studied the potential transfer of perfluoroalkyls from mothers to their children during pregnancy. Maternal blood and cord serum were collected from 66 mother-child pairs and analyzed for the presence of perfluoroalkyls. A positive correlation was found between maternal plasma and maternal serum with cord serum levels, and the authors concluded that either maternal plasma or maternal serum could be used as a method to estimate fetal exposure to perfluoroalkyls. Median concentrations of PFOS and PFOA were 6.18 and 2.85 ng/mL, respectively, in maternal plasma and 6.99 and 2.97 ng/mL, respectively, in maternal serum. PFOS and PFOA levels in cord serum were 1.86 and 1.90 ng/mL, respectively. A biomonitoring survey of 1,533 pregnant females in Denmark from 2008 to 2013 showed decreasing levels of most perfluoroalkyls in the females' blood during this time period (Bjerregaard-Olesen et al. 2016). The results of this study showed that serum levels of PFHxS, PFOS, PFOA, PFNA, and PFDA decreased at a rate of 7.0, 9.3, 9.1, 6.2, and 6.3 per year, respectively. Morello-Frosch et al. (2016) measured the levels of perfluoroalkyls in 77 maternal and 65 paired umbilical cord blood samples from pregnant females and newborn children in San Francisco, California. Perfluoroalkyls, including PFOA and PFOS, were widely detected; however, concentrations in cord blood or serum were typically equal to or lower than maternal blood levels.

5.7 POPULATIONS WITH POTENTIALLY HIGH EXPOSURES

Potentially high exposures to perfluoroalkyls can occur in the following population categories: perfluoroalkyl production and manufacturing workers, communities located near fluorochemical facilities, and individuals with prolonged use of perfluoroalkyl-containing products. Workers at perfluoroalkyl production and manufacturing facilities and community members living near these facilities may have higher exposure to perfluoroalkyls than the general population based on elevated concentrations of these substances measured in air, soil, sediment, surface water, groundwater, and vegetation surrounding these facilities (3M 2007b, 2008b, 2008c; Barton et al. 2006; Davis et al. 2007; Olsen 2015). Additionally, children may be at risk for higher potential exposure due to hand-to-mouth transfer of chemicals from dust and the ingestion of dirt (Shoeib et al. 2004; Trudel et al. 2008). Levels of perfluoroalkyls measured in the blood of production and manufacturing workers at several facilities are listed in Table 5-27. The serum PFOA, PFOS, and PFHxS levels in workers were frequently 100–1,000 times higher than in the general population. 3M estimated PFOA doses for various on-site exposure scenarios based on monitoring information collected at the Decatur Facility in Alabama (3M 2008c). Occupational exposure scenarios included groundskeeper/maintenance worker and construction/utility worker exposed to on-site soils, surface water, and sediment. According to 3M, estimated on-site exposure to PFOA ranged from $3.2x10^{-6}$ to 2.4 ng/kg/day, with the highest estimated exposure corresponding to construction/utility workers engaged in projects involving contact with soil from an on-site field. Chang et al. (2008a) measured concentrations of PFBA in the serum of 127 former employees and 50 current employees of the 3M Cottage Grove Facility in Minnesota. PFBA serum concentrations were below the detection limit in 73.2% of the former employees and 68.0% of the current employees. Only 4% of the serum samples contained PFBA above 2 ng/mL, with maximum concentrations of 6.2 ng/mL for the former employees and 2.2 ng/mL for the current employees.

[a]Data include results from three retirees from the 3M plant in Cottage Grove, Minnesota.

Gray cells indicate that chemical was not evaluated; PFHxS = perfluorohexane sulfonic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid

Individuals who performed jobs that require frequent and/or prolonged contact with perfluoroalkyl containing products, such as firefighters, waste handlers, individuals who install and treat carpets, or individuals with prolonged use of ski wax may also have higher occupational exposure to perfluoroalkyls. Some firefighting foams contain perfluoroalkyls, and firefighters who use these products have been shown to have greater exposures as compared to the general population. Dobraca et al. (2015) compared perfluoroalkyl serum levels of a group of firefighters in California to an adult population from the NHANES survey. Levels of PFOA and PFOS were only slightly higher in the firefighter group (geometric means 3.75 and 12.50 ng/mL, respectively) when compared to adult males in the 2009–2010 NHANES general population survey (3.61 and 12.13 ng/mL, respectively); however, PFDA serum concentrations of firefighters were up to 3 times greater than the NHANES comparison group for the 25th–95th percentiles (50th percentile in firefighters; 0.72 ng/mL compared to 0.30 ng/mL) and the geometric mean (0.90 ng/mL compared to 0.30 ng/mL). In a small-scale study of 37 firefighters participating in the C8 Health Project, significantly (adjusted for age, water district, household income, and smoking) higher levels of PFOA and PFHxS were found in the firefighters compared to 5,373 male participants with other jobs (Jin et al. 2011). Geometric mean PFOA and PFHxS levels were 37.59 and 4.77 ng/mL, respectively, in the firefighters and 31.59 and 3.62 ng/mL, respectively, in the other

participants. No significant differences in PFOS or PFNA levels were found between the groups. A biomonitoring study of 149 firefighters in Australia showed that 100% of serum samples collected had detectable levels of PFOA, PFOS, PFHxS, and PFNA (Rotander et al. 2015). Serum levels of PFHxS were found to be approximately 10–15 times higher than levels found in the general population of Australia and Canada, while PFOS levels in the firefighters were approximately 6–10 times greater than the general population of these nations.

Elevated serum levels of PFOA, PFNA, PFHxA, PFHpA, PFDA, and PFUnA have been found in professional ski waxes containing fluorotelomers; the perfluoroalkyls were likely formed via fluorotelomer metabolism (Olsen 2015). Christensen et al. (2016) conducted a biomonitoring study of perfluoroalkyls on male fishermen from Wisconsin ≥50 years old with a history of sport fish consumption. Increasing age and lower BMI were generally associated with higher levels of the perfluoroalkyls; however, there were only weak correlations observed between amounts of fish consumption and perfluoroalkyl levels, with the exception of PFDA. Levels of PFOA, PFNA, and PFHxS in the blood of the male anglers were similar to the levels for a subset of the NHANES 2011–2012 survey (non-Hispanic white males ≥50 years old); however, levels of PFOS and PFDA were approximately 2 times greater in the anglers as compared to the NHANES survey subgroup. The median and 95th percentile concentrations of PFOS in the anglers were 19.00 and 54.00 ng/mL, respectively, as compared to 10.33 and 25.83 ng/mL, respectively, in the NHANES study group. The median and 95th percentile concentrations of PFDA in the anglers were 0.52 and 1.90 ng/mL, respectively, as compared to 0.23 and 0.53 ng/mL in the NHANES study group. Family members of occupationally exposed workers have been shown to have higher exposure to perfluoroalkyls via dust transfer as compared to family members of nonoccupationally exposed workers (Fu et al. 2015).

PFOA, PFOS, PFBA, PFBS, PFNA, and PFHxS have been detected in the municipal drinking water and private wells of some communities located near fluorochemical facilities (3M 2008c; ATSDR 2008; Emmett et al. 2006a; Hoffman et al. 2011; Hölzer et al. 2008; Post et al. 2013; Steenland et al. 2009a; Wilhelm et al. 2009). Emmett et al. (2006a) compared PFOA serum levels to various types of exposure for individuals living in the Little Hocking community (near DuPont's Washington Works facility) and concluded that residential water source was the primary determinant of serum PFOA at this location. These authors reported that the mean human serum PFOA level was 105 times higher than the residential drinking water level. Median serum PFOA levels were 371 ng/mL in residents for whom this was the only residential water source and 71 ng/mL in those who used bottled, cistern, or spring water. Increased serum PFOA was associated with increasing number of drinks of tap water daily and also with increasing

use of water for making soups and stews and in-home canning of fruits and vegetables. Use of a carbon water filter reduced PFOA levels by about 25%. In a follow-up study, 231 study participants in the Little Hocking Water District were evaluated 15 months later with 88% using bottled water exclusively; 8% had made other changes to their ingestion of residential water including use of activated carbon water filters. PFOA levels had decreased an average of 26% from the initial levels (Emmett et al. 2009). Similarly, Bartell et al. (2010) found that serum levels of PFOA declined significantly following the implementation of GAC filtration of the public water supply. The average decrease in serum PFOA levels for Lubeck, West Virginia residents primarily consuming public water at home (n=130) was 26% 1 year after treatment began. Similar trends were reported for residents of Little Hocking, Ohio. The average decrease in PFOA serum levels for residents primarily consuming public water (n=39) was about 11% 6 months after treatment began.

Median PFOA serum levels for residents currently residing in six water districts located in the mid-Ohio Valley near the Washington Works facility ranged from 12.1 to 224.1 ng/mL, while the median concentration ranged from 10.5 to 33.7 ng/mL for residents who previously worked or resided in these districts (Steenland et al. 2009a). Former employees at the chemical plant had much higher levels (median=75 ng/mL) than people who had not worked at the plant (median=24 ng/mL), but lower levels than those who continued to be employed at the plant during the monitoring period (median=148 ng/mL). Another study of this community reported a median serum PFOA concentration of 24.3 ng/mL for 45,276 non-occupationally exposed individuals in 2005–2006 (Shin et al. 2011a). This was about 8 times greater than the median concentration (3.20 ng/mL) of 2,120 residents of the general population taken from the NHANES data for 2005–2006 (CDC 2018).

A study of residents consuming drinking water from the Ohio River and the Ohio River Aquifer reported elevated median PFOA levels of 13.8 ng/mL in blood samples collected in 1991–1993 from 139 residents (Herrick et al. 2017). In samples collected in 2011–2013 (n=133), the serum PFOA levels dropped to 4.3 ng/mL. The serum PFOS levels in samples collected in 1994–1996 (median of 32.2 ng/mL, n=189) were similar to levels in the general population (Herrick et al. 2017); similar to the decline observed in the general population, median serum PFOS levels were 6.3 ng/mL in 2011–2013.

The Minnesota Department of Health conducted a biomonitoring study of 196 residents living in Washington county, east of the Minneapolis-St. Paul metropolitan area; private and municipal drinking water wells were shown to be contaminated with perfluoroalkyls (MDH 2009). In 2008–2009, geometric mean serum PFOA, PFOS, and PFHxS levels were 15.4, 35.9, and 8.4 ng/mL, respectively; these values

were higher than levels reported in NHANES (Landsteiner et al. 2014; MDH 2009). The investigators noted that the geometric mean serum concentrations of these three substances were greater in residents obtaining drinking water from municipal water supplies as compared to residents with private wells (Landsteiner et al. 2014). Monitoring efforts also conducted in Washington County, Minnesota near the 3M Cottage Grove Facility revealed widespread contamination of PFBA in the groundwater in 2006 (ATSDR 2008). PFBA was detected in 28% of the community members' serum samples; the 75th percentile serum concentration for PFBA was 0.135 ng/mL and the maximum concentration was 8.5 ng/mL (MDH 2000).

ATSDR performed an exposure investigation for residents of Decatur, Alabama following an accidental release of perfluoroalkyls into the Decatur waste water treatment plant (ATSDR 2013). A group of 155 residents had their blood tested for levels of eight perfluoroalkyls. Serum levels for PFNA, PFDA, and FOSA were lower or similar to levels of the general population when compared to the NHANES results. Elevated serum PFOA, PFOS, and PFHxS levels were observed; geometric mean values were 16.3, 39.8, and 6.4 ng/mL, respectively. Residents who used the West Morgan/East Lawrence public water supply had significantly higher geometric mean serum levels of PFOA (17.59 ng/mL) and PFHxS (6.68 ng/mL) as compared to the geometric mean for a similar demographic group from the NHANES survey. Serum perfluoroalkyl levels in the residents were shown to be much lower than levels found in occupationally exposed individuals who regularly worked with these substances (ATSDR 2013).

Additional blood serum levels of PFOA and PFOS for residents in selected areas of Ohio, West Virginia, New Jersey, and Minnesota whose residential source of drinking water may have been contaminated are available from the EPA docket on PFOA and related perfluoroalkyls (EPA-HQ-OPPT-2003-0012) (Bilott 2004, 2005a, 2005b, 2007).

The Emmett et al. (2006a) and Steenland et al. (2009a) studies of the community near the Washington Works facility and the 3M (2008c) study of the Decatur Facility in Alabama found age-related differences in serum PFOA levels. In a comparison of serum PFOA levels in various age groups of residents serviced by the Little Hocking Water Association district, Emmett et al. (2006a) found that 2–5-year-old children had a higher serum PFOA (median 600 ng/mL) compared with residents in all other age groups (median 321 ng/mL) except for the group aged >60 years, whose levels were similar to those in young children. Several factors may have contributed to the observed high levels in children: infants and young children proportionally drink more water per kg of body weight than adults; children (and also the elderly) tend to spend more time at home with exclusive use of residential water than other age groups; and trans-

placental and breast milk exposures could also contribute to levels in children. In the Steenland et al. (2009a) study, PFOA serum levels tended to be highest for children aged 0–9 years and persons >50 years old. The serum levels of the 69,030 residents participating in this study categorized by age are provided in Table 5-28. 3M (2008c) estimated doses for various off-site exposure scenarios based on monitoring information collected at the Decatur Facility. Exposure scenarios include local children and adult residents exposed to PFOA in off-site soils, groundwater, municipal water, fish from the Tennessee River, and surface water and sediments in the Tennessee River. According to 3M, estimated off-site exposure of local residents to PFOA ranged from 0.011 to 260 ng/kg/day, with the highest estimated exposure corresponding to children whose source of drinking water was groundwater adjacent to the southern side of the facility.

Table 5-28. Blood Serum Levels for 69,030 Current and Former Residents of Six Water Districts in the Mid-Ohio Valley (2005–2006)

Age (years)	Number (percentage of total)	Median perfluorooctanoic acid (PFOA) level (ng/mL)
0–9	4,915 (7.1)	32.8
10–19	9,658 (14.0)	26.6
20–29	10,073 (14.6)	21.0
30–39	10,547 (15.3)	22.7
40–49	12,113 (17.6)	28.0
50–59	10,515 (15.2)	33.6
60–69	6,881 (10)	42.9
≥70	4,328 (6.3)	40.1

CHAPTER 6. ADEQUACY OF THE DATABASE

Section 104(i)(5) of CERCLA, as amended, directs the Administrator of ATSDR (in consultation with the Administrator of EPA and agencies and programs of the Public Health Service) to assess whether adequate information on the health effects of perfluoroalkyls is available. Where adequate information is not available, ATSDR, in conjunction with NTP, is required to assure the initiation of a program of research designed to determine the adverse health effects (and techniques for developing methods to determine such health effects) of perfluoroalkyls.

Data needs are defined as substance-specific informational needs that, if met, would reduce the uncertainties of human health risk assessment. This definition should not be interpreted to mean that all data needs discussed in this section must be filled. In the future, the identified data needs will be evaluated and prioritized, and a substance-specific research agenda will be proposed.

6.1 Existing Information on Health Effects

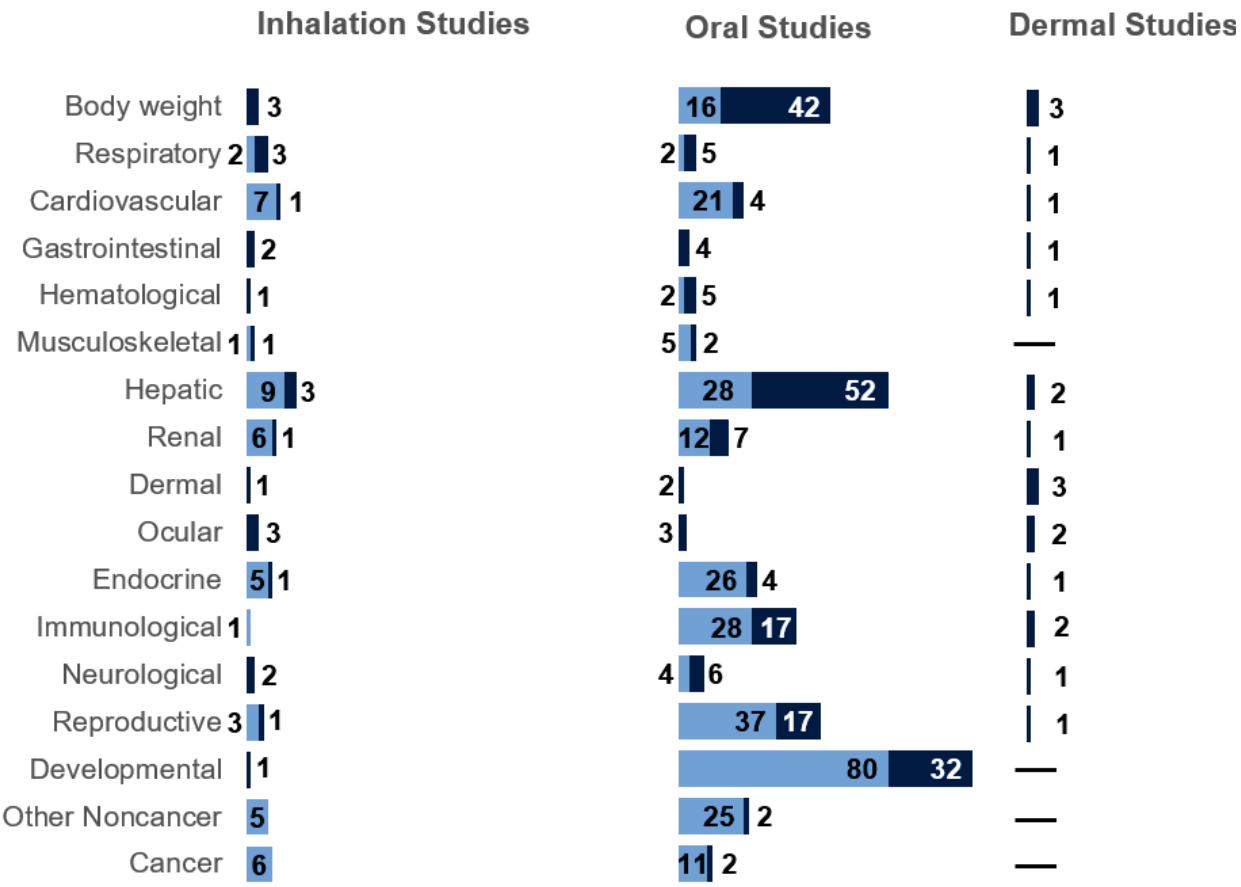
Studies evaluating the health effects of inhalation, oral, and dermal exposure of humans and animals to PFOA, PFOS, and other perfluoroalkyls that are discussed in Chapter 2 are summarized in Figures 6-1, 6-2, and 6-3, respectively. The purpose of these figures is to illustrate the information concerning the health effects of perfluoroalkyls. The number of human and animal studies examining each endpoint is indicated regardless of whether an effect was found and the quality of the study or studies.

As illustrated in Figures 6-1, 6-2, and 6-3, most of the data on the toxicity of PFOA, PFOS, and other perfluoroalkyls come from epidemiological studies in humans; oral exposure is the assumed route of exposure for the epidemiological studies. The epidemiology database consists of health evaluations of subjects exposed in occupational settings (primarily PFOA and PFOS), highly exposed residents living near a PFOA facility, and studies of the general population. The most commonly examined endpoints in the epidemiological studies were developmental, hepatic, reproductive, and immunological effects.

Figure 6-1. Summary of Existing Health Effects Studies on PFOA by Route and Endpoint*

Potential body weight, hepatic, and developmental effects were the most studied endpoints

The majority of the studies examined oral exposure in **humans** (versus **animals**)

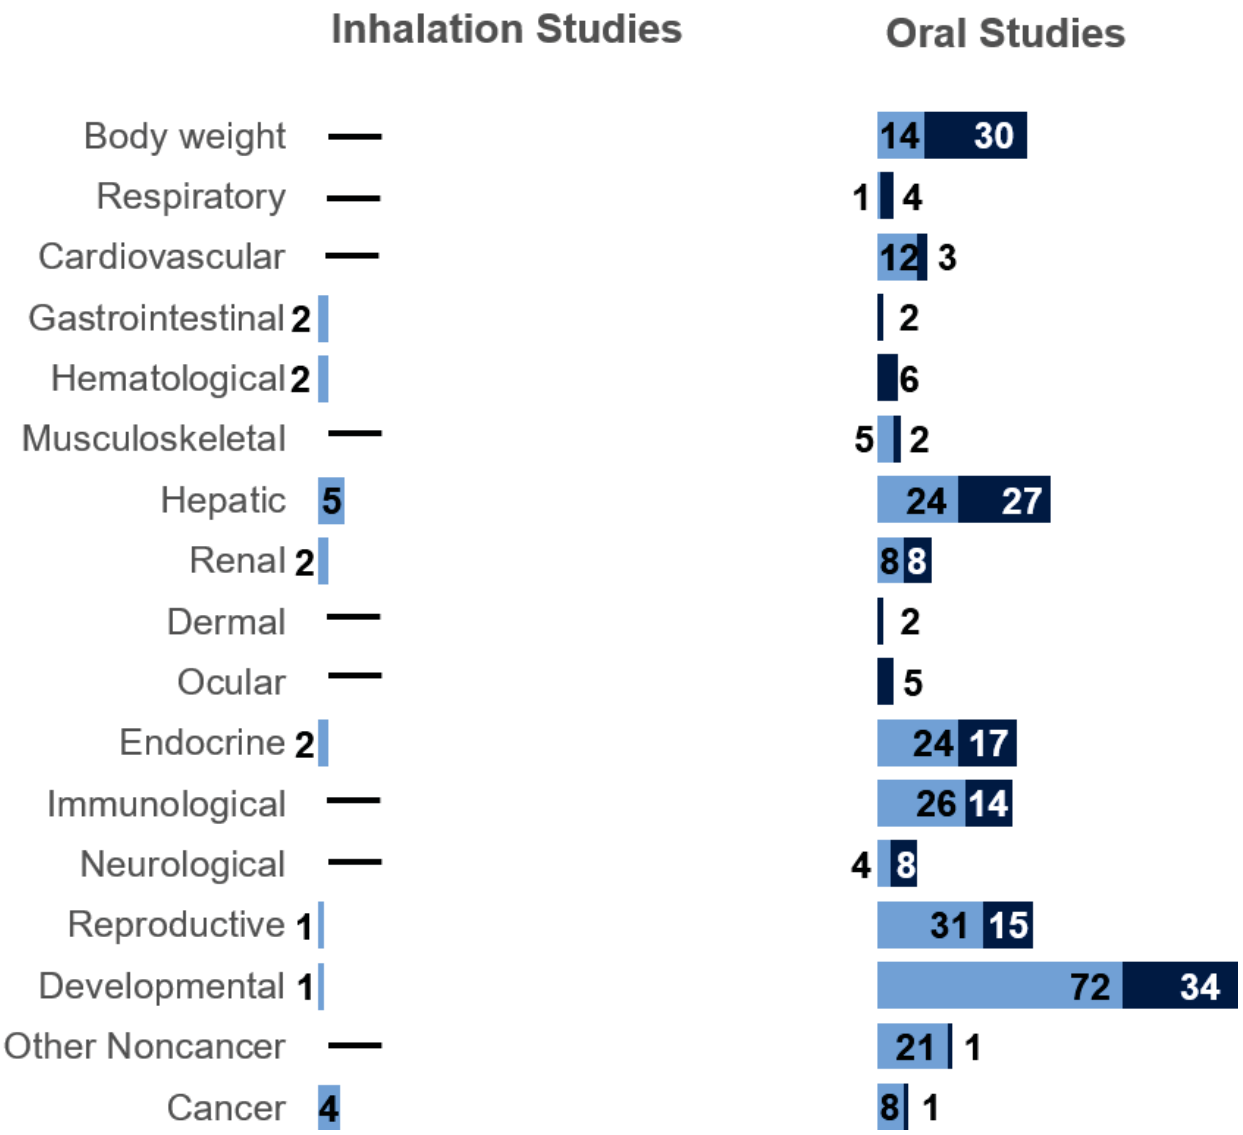


*Oral exposure was the presumed route of exposure for human studies involving environmental exposure. Human and animal studies may have examined more than one endpoint. A "—" indicates that no studies are available.

Figure 6-2. Summary of Existing Health Effects Studies on PFOS by Route and Endpoint*

Potential developmental, hepatic, and reproductive effects were the most studied endpoints

The studies examined oral exposure in **humans** (versus **animals**)

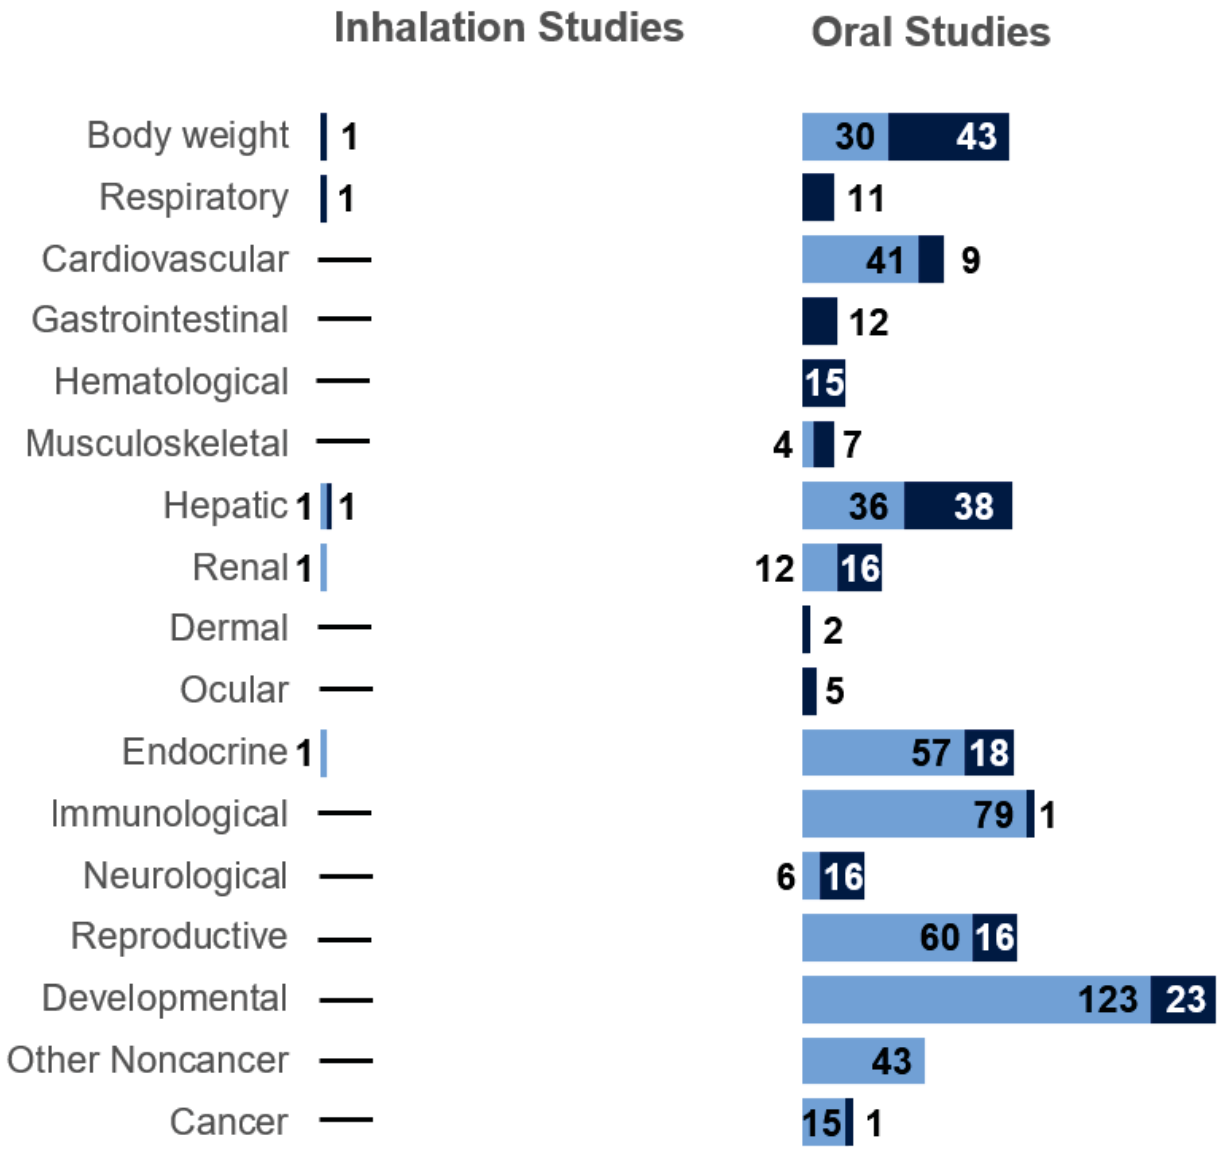


*Oral exposure was the presumed route of exposure for human studies involving environmental exposure. Human and animal studies may have examined more than one endpoint. A "—" indicates that no studies are available.

Figure 6-3. Summary of Existing Health Effects Studies on Other Perfluoroalkyls by Route and Endpoint*

Potential hepatic, immunological, and developmental effects were the most studied endpoints

The majority of the studies examined oral exposure in **humans** (versus **animals**)



*Oral exposure is the presumed route of exposure for human studies involving environmental exposure. Most human studies examined multiple perfluoroalkyls. Human and animal studies may have examined more than one endpoint. A "—" indicates that no studies are available. Includes data for PFBA, PFHxA, PFHpA, PFNA, PFDA, PFUnA, PFBS, PFHxS, PFDoDA, and FOSA.

Most of the information regarding the effects of perfluoroalkyls in animals has been derived from oral studies; considerably less information is available from inhalation and dermal exposure studies. PFOA and PFOS have been the most extensively studied members of this class of chemicals, and oral administration has been the preferred route of exposure in animal studies. Information regarding other perfluoroalkyls covered in this profile is limited to acute-duration oral studies with PFHxS, PFNA, PFDA, PFBA, PFDoDA, PFHxA, and FOSA; intermediate-duration oral studies with PFHxS, PFNA, PFDA, PFUnA, PFBS, PFBA, PFDoDA, and PFHxA; and a chronic-duration oral study with PFHxA. An acute-duration-inhalation study with PFNA is also available. The most commonly examined endpoints were hepatic, body weight, developmental, reproductive, and immunological effects.

6.2 Identification of Data Needs

Missing information in Figures 6-1, 6-2, and 6-3 should not be interpreted as a "data need." A data need, as defined in ATSDR's *Decision Guide for Identifying Substance-Specific Data Needs Related to Toxicological Profiles* (ATSDR 1989), is substance-specific information necessary to conduct comprehensive public health assessments. Generally, ATSDR defines a data gap more broadly as any substance-specific information missing from the scientific literature.

Acute-Duration MRLs. The available acute inhalation database for PFOA was considered inadequate for derivation of an MRL due to lack of measured serum PFOA levels in the available animal studies and the lack of PBPK model parameters that could be used to predict serum levels. The inhalation database for PFNA was not considered adequate due to the limited endpoints examined and the short exposure duration of the only available study. No inhalation data were available for PFOS or the other perfluoroalkyls. A number of studies have evaluated the acute toxicity of PFOA and PFOS following oral exposure and have identified several sensitive targets of toxicity. Smaller numbers of studies evaluated potential sensitive targets of acute toxicity for PFNA and PFDA. However, toxicokinetic differences between humans and laboratory animals, particularly the relative short half-life in rodents compared to humans, preclude derivation of an acute MRL for these compounds. For other perfluoroalkyls (PFHxS, PFBA, PFDoDA, FOSA), the available studies were not considered adequate for identification of critical targets; did not examine sensitive targets that were identified for other perfluoroalkyls, such as developmental and immunological endpoints; or involved a single exposure. No acute oral data were identified for PFUnA, PFHpA, or PFBS. Research is needed to develop a PBPK model that would allow for extrapolation from rodents to humans. Additionally, toxicity studies are needed for most perfluoroalkyls to identify critical targets of toxicity and/or establish dose-response relationships. These

studies should examine developmental and reproductive endpoints that have been established as the most sensitive targets of toxicity for PFOA and PFOS.

Intermediate-Duration MRLs. No intermediate-duration inhalation studies were identified for perfluoroalkyls. Oral studies suggest that developmental and immune effects are the most sensitive targets of toxicity; similar effects are likely to occur following inhalation exposure because perfluoroalkyls are not metabolized. Inhalation studies are needed to establish dose-response relationships and to establish whether the respiratory tract is a sensitive target of toxicity. The intermediate-duration oral databases were considered adequate for derivation of MRLs for PFOA and PFOS. The MRL for PFOA is based on altered bone development measured in mature mice exposed *in utero*. The principal study only tested one PFOA dose level and only examined long bones; additional studies utilizing several dose levels, examining other types of bone, and testing a second species would provide support for the MRL. A modifying factor was used for PFOS due to the lack of PBPK modeling parameters; additional studies are needed that would allow for predicting steady-state serum PFOS levels for immunotoxicity studies in laboratory animals. An important decision made in the derivation of intermediate oral MRLs was to use the time-weighted average serum concentrations (C_{TWA}) of PFOA or PFOS as the basis for extrapolations of the dose-response PODs from animal studies to human equivalent doses (HEDs). However, the available data on the toxicity of PFOA and PFOS do not provide convincing evidence that toxicity outcomes are more likely to be determined by C_{TWA} rather than C_{max}. Since the PBPK model used for dosimetry modeling of the animal studies predicted that C_{TWA} is lower than C_{max} in the principal studies for the MRLs, selection of C_{TWA} as the internal dose metric results in lower values for MRLs. Therefore, use of C_{TWA}, rather than C_{max} is a health-protective decision that might be more adequately evaluated with additional studies that evaluate associations between C_{max}, C_{TWA}, and toxicity outcome responses.

Intermediate-duration MRLs were also derived for PFHxS and PFNA; however, these were based on marginal databases and additional dose-response studies are needed to support the basis of the MRL. The databases were not considered adequate for PFUnA, PFBS, PFBA, or PFDoDA due to the lack of studies examining potential sensitive targets (developmental and/or immune effects). No intermediate-duration oral studies are available for PFDA, PFHpA, or FOSA. Intermediate-duration oral studies are needed for these seven perfluoroalkyls to provide information on sensitive targets and establish dose-response relationships. These studies should include measurement of serum perfluoroalkyl levels, which would allow for estimating HEDs.

An additional uncertainty in the MRLs was the confidence in the elimination half-lives for perfluoroalkyls used in the empirical model for calculating HEDs. Estimated half-lives for PFOA and PFOS vary and contributors to this variability have not been completely characterized. The empirical model used to calculate HEDs is linear; therefore, the change in the HED is approximately proportional to the change in the half-life. A halving of the half-life would result in a doubling of the HED. Studies that can improve confidence in the half-life estimates would increase confidence in MRLs.

Chronic-Duration MRLs. The lack of chronic-duration inhalation studies for perfluoroalkyls precluded derivation of chronic MRLs. Chronic toxicity studies examining a wide range of endpoints are needed to identify the most sensitive target and establish concentration-response relationships. A small number of chronic duration oral studies have been identified in laboratory animals. Four studies examined the chronic toxicity of PFOA, PFOS, or PFHxA. These studies were not considered suitable for derivation of MRLs because they did not evaluate immunotoxicity which was a sensitive target following shorter term exposures. Studies examining this potentially sensitive endpoint are needed to identify the most sensitive target following chronic exposure.

Health Effects. Over 600 studies have evaluated the toxicity of perfluoroalkyls; epidemiological studies account for over 400 of the toxicity studies. Evidence from epidemiological studies suggest associations between perfluoroalkyl exposure and several health outcomes including liver damage, increases in serum lipids, thyroid disease, immune effects, reproductive toxicity, and developmental toxicity. The primary health effects observed in laboratory animals are liver, developmental, and immune toxicity. Although a large number of studies evaluating health effects are available, there is a need for additional studies to address data gaps. Future laboratory animal studies should include measurement of serum perfluoroalkyl levels, as this would provide valuable information for comparing effects observed in laboratory animals to effects observed in humans.

Hepatic Effects. Evidence from acute, intermediate, and/or chronic oral studies in rats, mice, and monkeys indicates that the liver is a sensitive target of PFOA, PFOS, PFHxS, PFNA, PFDA, PFUnA, PFBA, PFBS, PFDoDA, and PFHpA toxicity. The effects observed in rodents differ from those observed in humans. In humans, exposure to PFOA, PFOS, PFNA, and PFDA appear to result in increases in serum lipid levels, particularly total cholesterol levels. However, animal studies have found decreases in serum lipid levels associated with exposure to most perfluoroalkyls. It is not known if the species differences are due to different mechanisms of toxicity or differences in

exposure levels (serum levels observed in animal studies are orders of magnitude higher than those in human studies).

Immune Effects: Epidemiological data suggest an association between PFOA, PFOS, PFHxS, and PFDA and decreased antibody response to vaccines. This is supported by acute- and intermediate-duration studies of PFOA and PFOS in laboratory animals. There is also evidence of immunotoxicity following a single injection of PFNA; some of the immune effects persisted 4 weeks post-exposure. Shorter-term studies are needed for other perfluoroalkyls. In addition, chronic-duration studies evaluating immune endpoints, particularly immunosuppression, for all perfluoroalkyls would allow for identification of the critical targets of toxicity.

Reproductive Effects. Decreases in mammary gland development have been demonstrated in several PFOA mouse studies. The effect levels observed in these studies are very low, although there is some indication that at lower doses, the changes in mammary gland development do not affect lactation. Additional studies are needed to evaluate the adversity of these alterations. This endpoint has not been evaluated for other perfluoroalkyls and studies are needed to determine whether it is also a sensitive effect for these compounds.

Developmental Effects. Based on the results of laboratory animal studies, developmental endpoints are targets of PFOA, PFOS, PFHxS, PFNA, PFDA, PFUnA, and PFBA toxicity following acute- and/or intermediate-duration oral exposure. Studies are needed to evaluate potential developmental effects for PFHxS following intermediate-duration oral exposure. Additionally, cross-fostering studies would provide information that could be used to evaluate the health impact of lactational exposure to perfluoroalkyls. Epidemiological studies in children suggest altered responses to vaccination; two animal studies have evaluated immune effects following perinatal exposure to PFOA and PFOS, but data are lacking for other perfluoroalkyls.

Potential Interactions between Perfluoroalkyls. A common limitation of the epidemiological data is co-exposure to multiple perfluoroalkyls. There are limited data on possible interactions between perfluoroalkyls and possible effects on toxicity and toxicokinetics. Animal studies examining the possible interactions between perfluoroalkyls would be useful for interpreting the epidemiological study results; this is especially important since humans are typically exposed to multiple perfluoroalkyls and many of them are likely to have similar mechanisms of action.

Mechanisms of Toxicity. Many of the effects observed in rodents, particularly liver and developmental effects, involve the activation of PPARα; humans and nonhuman primates are less responsive to PPARα agonists than rats and mice. However, the results of studies in PPARα-null mice suggest that PPARα-independent mechanisms also play a role in the liver, immunological, and developmental toxicity. Additional studies are needed on the mechanisms of toxicity to assess whether the effects observed in laboratory animals are relevant to humans. Mechanistic studies would also provide support for the critical effects used to derive the MRLs for PFOA, PFOS, PFHxS, and PFNA.

Epidemiology and Human Dosimetry Studies. As previously mentioned, information is available regarding the effects of exposure to perfluoroalkyls in humans derived from health evaluations of subjects exposed in occupational settings, residents living near a PFOA manufacturing facility with high levels of PFOA in the drinking water, and the general population. Although many studies found statistically significant associations between serum perfluoroalkyl levels and the occurrence of an adverse health effect, the findings were not consistent across studies. Interpretation of the human data is limited by the reliance of cross-sectional studies, which do not establish causality, and the lack of exposure data. Studies on serum lipids suggest that the dose-response curve is steeper at lower concentrations and flattens out at higher serum perfluoroalkyl concentrations (Steenland et al. 2010a); additional studies that could be used to establish dose-response relationships would be valuable. Mechanistic studies examining the association between perfluoroalkyl exposure and serum lipid levels would also provide valuable insight. Clarification of the significance and dose-response relationships for other observed effects is also needed. Longitudinal studies examining a wide range of endpoints would be useful for identifying critical targets of toxicity in humans exposed to perfluoroalkyls. The available human studies have identified some potential targets of toxicity; however, cause-and-effect relationships have not been established for any of the effects, and the effects have not been consistently found in all studies. Mechanistic studies would be useful for establishing causality. When possible, health assessments should include subjects of different race/ethnicity and age to determine potential race/ethnicity- and age-based susceptibilities. Another limitation of the epidemiological studies is co-exposure to other perfluoroalkyls; studies that statistically controlled for co-exposure to other pollutants would decrease this uncertainty. As noted previously, there is a need for studies evaluating potential interactions between perfluoroalkyls.

Biomarkers of Exposure and Effect. Data are available regarding levels of perfluoroalkyls in serum from the general population, highly exposed residents, and perfluoroalkyl workers. Information is needed regarding the toxicokinetics (see also below) of perfluoroalkyls in humans to be able to relate levels of

these compounds in serum to exposure to specific perfluoroalkyls; data on matched serum and urine samples would be valuable. Also needed is further information on the relationship between serum and liver concentrations of perfluoroalkyls in humans.

Absorption, Distribution, Metabolism, and Excretion. Several epidemiological studies have examined the kinetics of serum perfluoroalkyl concentrations following a change in environmental or occupational exposure, from which estimates of terminal elimination half-lives in adults are available for PFOA, PFOS, PFHxS, PFBA, and PFBS. Other studies provide data on the renal clearances of PFOA and PFOS, binding of PFOA, PFOS, and PFHxS to human plasma protein, tissue levels (primarily blood, maternal and fetal cord serum, and breast milk). Data on other aspects of the toxicokinetics of perfluoroalkyls in humans are not available and could serve to improve predictions of internal dosimetry associated with exposures to perfluoroalkyls (bioavailability, kinetics of tissue distribution and elimination, binding in tissues, external-internal dose relationships, all aspects of toxicokinetics in children and aging populations).

Toxicokinetics of perfluoroalkyls have been studied much more extensively in rodents (rats and mice) and less extensively in Cynomolgus monkeys; however, a number of data gaps have been identified:

- Absorption studies; oral absorption data are available for PFOA, PFOS, and PFBA, but are more limited for other perfluoroalkyls and for other exposure routes. Studies elucidating the mechanisms of pulmonary and gastrointestinal absorption are also needed.

- Studies have shown that elimination kinetics, and therefore, internal dose-external dose relationships, are dependent on structure, including the terminal acid group (carboxylate or sulfonate), carbon chain length, and carbon chain branching. These structural features affect plasma and tissue protein binding, renal and biliary clearances, tissue levels, maternal-fetal transfer, and lactational transfer of perfluoroalkyls. Studies examining differences between perfluoroalkyls would be useful for extrapolating health effects and toxicokinetic data across compounds.

- Toxicokinetic studies have found sex- and dose-dependent subcellular distribution of PFOA in rats. Further studies on the mechanisms for dose-dependency, characterization of subcellular binding proteins, and mechanistic linkages between subcellular distribution and toxicity of perfluoroalkyls are needed.

- The distribution and elimination of PFOA and PFOS are greatly influenced by binding interactions with albumin and other high molecular weight plasma proteins; available data suggest that binding to plasma proteins, as well as the volume of distribution, may be sex- and species-specific. Interactions with albumin have been partially characterized to the extent that binding capacity and affinity constants have been estimated, but the rates of association and dissociation have not been reported.

- Liver uptake and renal clearance of PFOS also appeared to be time-dependent in a PBPK model used to predict plasma and liver in concentrations of PFOS in a chronic rat study (Harris and Barton et al. 2008). Mechanisms underlying these time dependencies have not been elucidated.

Comparative Toxicokinetics. Toxicokinetic studies conducted in various rodent species (mice, rats, hamsters, rabbits) and in Cynomolgus monkeys have revealed profound species and sex differences as well as dose dependencies in the tissue distribution and elimination kinetics of PFOA and PFOS. Studies conducted in rats have revealed contributing mechanisms for sex differences in elimination of PFOA; slower elimination of PFOA in male rats compared to female rats has been attributed to sex hormone-modulated renal tubular transport of PFOA that results in markedly lower renal clearance of PFOA in the sexually mature male rat (see Section 3.5.1, Excretion). Sex differences in elimination of PFOA have also been observed in hamsters; unlike the rat, male hamsters excreted absorbed PFOA more rapidly than female hamsters. Sex differences in elimination of PFOA have not been observed in other rodent species, in Cynomolgus monkeys, or in limited observations made in humans. Sex differences in elimination rates of perfluoroalkyls in humans have not been demonstrated in population studies of serum elimination kinetics or renal clearance. Although the few studies that estimated elimination half-lives or renal clearances in male and female humans have not found significant sex differences, these outcomes may reflect the relatively low serum concentrations in these subjects compared with studies that were conducted in nonhuman primates and rodents (i.e., sex differences in elimination may vary with dose and/or plasma concentration). Additionally, the failure to account for the influence of reduced estrogen levels (in postmenopausal women) and reduced testosterone levels (in older males) in occupational and/or site-related epidemiological studies may also account for the lack of findings of sex-related differences.

Children's Susceptibility. Data needs relating to both prenatal and childhood exposures, and developmental effects expressed either prenatally or during childhood, are discussed in the Health Effects subsection above. It is not known whether children are more or less susceptible than adults to the effects of exposure to perfluoroalkyls because there are no studies that specifically addressed this question. Several studies have examined the possible associations between perfluoroalkyl exposure and health outcomes in children living in an area with high PFOA contamination and in the general population. Although some studies have found statistically significant associations, they are not adequate for establishing causality. Follow-up studies of the C8 population could allow for a longitudinal assessment of health effects in children and would be useful in determining whether the observed effects are due to perfluoroalkyl exposure. Toxicokinetics information in children is needed. Half-life studies have been conducted in adults; there is the need to understand if these are applicable to children. There are no

studies that have examined whether young animals are more or less susceptible than adults to perfluoroalkyls toxicity. Additional information on this issue would be useful.

Physical and Chemical Properties. Perfluoroalkyls have unique and complex physical and chemical properties (Kissa 2001; Schultz et al. 2003). Sources are available that provide helpful insights into the structural aspects and surfactant nature of these substances; however, many of the properties are still not well understood (CEMN 2008; Kissa 2001; Schultz et al. 2003). In general, specific properties such as physical state, melting point, boiling point, density, solubility, vapor pressure, micelle formation, and acid dissociation in water have not been determined or are not well described for these compounds. Measurements of these endpoints are needed. Information regarding the potential association of these species in water would be useful. Where determination of a particular endpoint is not possible, a thorough description of the physical and chemical properties as they relate to that endpoint would be helpful. Perfluoroalkyls discussed in this profile exist as a mixture of linear and branched isomers. Isomer-specific data would also be useful for the various physical-chemical properties. Wang et al. (2013b) identified several of the fluorinated compounds that are currently being used by major manufacturers as alternatives to PFOA and PFOS. These compounds are being used as processing aids in the emulsion polymerization of PTFE and other polymers as well as surface treatment uses, metal plating uses, firefighting foams, and other miscellaneous uses such as food contact materials. A data need exists to determine the physical and chemical properties of these replacement substances.

The production, use, import, and export of perfluoroalkyls have changed dramatically since 2000. Most nations no longer produce or use PFOS or PFOA (China is a notable exception). Major fluoropolymer manufacturers in the United States have altered their chemical processes to use alternative fluorinated substances in their production processes. Information regarding the production, import, and export volumes of these substances is needed.

Recommended methods for the disposal of perfluoroalkyls have not been located. In the past, perfluoroalkyl-containing waste has been disposed of in on- and off-site landfills, through sludge incorporation, and through incineration (3M 2007b, 2008b; ATSDR 2005). New disposal methods that avoid release of these substances into the open environment and prevent contamination of nearby soil, sediment, and groundwater should be developed. The eventual breakdown of fluorotelomer-based polymers with the eventual release of substances such as PFOA is not well understood. Early researchers have concluded that the half-life for this process is >1,000 years; however, more recent data suggest much shorter time scale of 1–2 decades (Rankin et al. 2014; Washington and Jenkins 2015; Washington et al.

2009, 2014, 2015). Additional studies on the potential release of perfluoroalkyls from the eventual degradation of fluoropolymers in landfills would be useful.

Environmental Fate. Perfluoroalkyls are very stable compounds and are resistant to biodegradation, direct photolysis, atmospheric photooxidation, and hydrolysis (3M 2000; EPA 2008a; OECD 2002, 2007; Schultz et al. 2003). The chemical stability of perfluoroalkyls and the low volatility of these substances in ionic form indicate that perfluoroalkyls will be persistent in water and soil (3M 2000; Prevedouros et al. 2006). K_{oc} values ranging from 17 to 230 indicate that PFOA will be mobile in soil and can leach into groundwater (Davis et al. 2007; Prevedouros et al. 2006). Environmental fate and potential pathways of PFOA exposure at and near the DuPont Washington Works site have been discussed (Small 2009). Wang et al. (2013b) identified several of the fluorinated compounds that are currently being used by major manufacturers as alternatives to PFOA and PFOS. Environmental fate and toxicity research of newer replacement substances is ongoing (De Silva et al. 2016; Gomis et al. 2018; Kabore et al. 2018).

Bioavailability from Environmental Media. Perfluoroalkyls are widely detected in humans and animals, indicating that several of these substances are bioavailable. The bioaccumulation potential of perfluoroalkyls is reported to increase with increasing chain length (de Vos et al. 2008; Furdui et al. 2007; Martin et al. 2004b). In living organisms, perfluoroalkyls bind to protein albumin in blood, liver, and eggs and do not accumulate in fat tissue (de Vos et al. 2008; Kissa 2001). The mechanism of perfluoroalkyl uptake in animals is not fully understood; additional studies would be helpful (de Vos et al. 2008). Perfluoroalkyls discussed in this profile exist as a mixture of linear and branched isomers. Data regarding the bioavailability of branched versus linear substances would be useful. A data need exists to determine the bioavailability of the replacement substances identified in Wang et al. (2013b) used in place of PFOA and PFOS.

Food Chain Bioaccumulation. High levels of certain perfluoroalkyls in animals have been measured in apex predators, such as polar bears, which indicates that some perfluoroalkyls possess the ability to bioaccumulate (de Vos et al. 2008; Houde et al. 2006a; Kannan et al. 2005; Smithwick et al. 2005a, 2005b, 2006). Perfluoroalkyl sulfonates with carbon chain length lower than 8 tend to bioaccumulate less than PFOS. Ongoing monitoring of perfluoroalkyl levels in animals may help to determine whether efforts to phase out these substances will have had an effect on their biomagnification. A data need exists to determine the bioaccumulation potential of the new replacement substances used in place of PFOA and PFOS.

Exposure Levels in Environmental Media. Reliable monitoring data for the levels of perfluoroalkyls in contaminated media at hazardous waste sites are needed so that the information obtained on levels of perfluoroalkyls in the environment can be used in combination with the known body burden of perfluoroalkyls to assess the potential risk of adverse health effects in populations living in the vicinity of hazardous waste sites.

Concentrations of perfluoroalkyls have been measured in surface water from several locations across the United States (Boulanger et al. 2004; Kannan et al. 2005; Kim and Kannan 2007; Nakayama et al. 2007; Simcik and Dorweiler 2005; Sinclair et al. 2004, 2006). Continued monitoring for perfluoroalkyls in surface water would be useful. Data are available regarding levels of perfluoroalkyls in outdoor air, indoor air, indoor dust, food, food packaging, and consumer products (3M 2001; Barber et al. 2007; Begley et al. 2005; Food Standards Agency 2006; Fromme et al. 2007b; Harada et al. 2005b, 2006; Jogsten et al. 2009; Kim and Kannan 2007; Kubwabo et al. 2005; Moriwaki et al. 2003; Tittlemier et al. 2007; Washburn et al. 2005). Comprehensive studies monitoring for perfluoroalkyls in these matrices within the United States are needed. Elevated concentrations of perfluoroalkyls have been measured in air, water, soil, and sediment near fluorochemical industrial facilities (3M 2007b, 2008b, 2008c; Barton et al. 2006; Davis et al. 2007; Hansen et al. 2002). Additional research is needed to evaluate how soil physical and chemical properties influence the bioavailability of perfluoroalkyls. Continued monitoring for perfluoroalkyls in these matrices are needed to assess exposure of individuals working at these locations and individuals who live near these facilities. A data need also exists to perform environmental monitoring of the replacement substances identified in Wang et al. (2013b) used in place of PFOA and PFOS, particularly near manufacturing locations.

Exposure Levels in Humans. Trudel et al. (2008) provided a thorough assessment of the exposure of the general population to PFOS and PFOA. 3M (2008b) provided an assessment of exposure of individuals to PFOA on-site at a fluoropolymer facility. Uptake values and exposure pathways determined in these studies should be examined further. Conclusions made in these assessments are expected to be adjusted as future monitoring data are made available. Large-scale monitoring of perfluoroalkyls in human serum in the United States is ongoing (Calafat et al. 2006a). Future results of human monitoring studies would be useful for assessing human exposure to these substances over time. The results of these studies can be examined for correlations between human perfluoroalkyl levels and the phasing out of perfluoroalkyls by companies of the fluorochemical industry. Levels of perfluoroalkyls in human urine have been reported (Jurado-Sanchez et al. 2014). Higher exposure levels for individuals who reside in areas where substances such as PFOA contaminated both public and private water supplies

have been documented (Emmett et al. 2006a, 2009). Continued biomonitoring of legacy compounds such as PFOA and PFOS as well as other perfluoroalkyls is needed.

This information is necessary for assessing the need to conduct health studies on these populations.

Exposures of Children. Trudel et al. (2008) provided a thorough assessment of the exposure of children to PFOS and PFOA. These conclusions should be reexamined with respect to future biomonitoring data when they become available. Data are available regarding the levels of perfluoroalkyls in young children (Kato et al. 2009b; Olsen et al. 2004b; Toms et al. 2009). NHANES monitoring data for 2013–2014 for children of ages 3–11 years have recently been released (CDC 2018; Ye et al. 2018a). Data provided from these efforts will be useful in assessing the exposure of young children to perfluoroalkyls.

Concentrations of perfluoroalkyls have been measured in human breast milk and cord blood (Apelberg et al. 2007a, 2007b; Fei et al. 2007; Inoue et al. 2004; Kärrman et al. 2007; Midasch et al. 2007; So et al. 2006b; Völkel et al. 2008). Additional monitoring for perfluoroalkyls in these media would be useful. Continued biomonitoring of legacy compounds such as PFOA and PFOS as well as replacement substances is needed.

6.3 Ongoing Studies

A number of federal agencies are sponsoring ongoing studies; a list of these studies are available at https://www.atsdr.cdc.gov/pfas/PFAS-health-effects.html.

CHAPTER 7. REGULATIONS AND GUIDELINES

Pertinent international and national regulations, advisories, and guidelines regarding perfluoroalkyls in air, water, and other media are summarized in Table 7-1. This table is not an exhaustive list, and current regulations should be verified by the appropriate regulatory agency. A list of some select state drinking water regulations/guidelines or health-based values are summarized in Table 7-2.

ATSDR develops MRLs, which are substance-specific guidelines intended to serve as screening levels by ATSDR health assessors and other responders to identify contaminants and potential health effects that may be of concern at hazardous waste sites. See Section 1.3 and Appendix A for detailed information on the MRLs for perfluoroalkyls.

Table 7-1. Regulations and Guidelines Applicable to Perfluoroalkyls

Table 7-2. Select State Drinking Water Guidelines for Perfluoroalkyls[a]

	Value (ppb or µg/L)						
Value type	PFOA	PFOS	PFBS	PFBA	PFNA	PFHxS	Reference
North Carolina							
Interim maximum allowable concentration in groundwater	2	ND	ND	ND	ND	ND	NC DEQ 2013, NCDENR 2012
Vermont							
Drinking water health advisory	0.02[b]	0.02[b]	ND	ND	0.02[b]	0.02[b]	Vermont DOH 2018

[a]Current as of September 2018.
[b]Value applies to the sum of PFOA, PFOS, PFHxS, PFHpA, and PFNA concentrations.
[c]MECDC notes that according to the EPA lifetime health advisory for PFOA and PFOS, when both PFOS and PFOA are present in drinking water, the combined levels are not to exceed 0.07 ppb.
[d]Value applies to the sum of PFOA and PFOS groundwater concentrations (Michigan DEQ 2018b).
[e]Health risk limits are rule values and health-based values are guidance values. Guidance is developed in-between rulemaking and may update an older rule. As a result, both rules and guidance values may be available for a contaminant (dual guidance) and the two values may be different (MDH 2014).

DEQ = Department of Environmental Quality; DOH = Department of Health; DPH = Department of Public Health; DWQI = Drinking Water Quality Institute; MassDEP = Massachusetts Department of Environmental Protection; MECDC = Maine Center for Disease Control and Prevention; MDH = Minnesota Department of Health; NCDENR = North Carolina Department of Environment and Natural Resources; ND = no data; NDEP = Nevada Division of Environmental Protection; PFBA = perfluorobutanoic acid; PFBS = perfluorobutane sulfonic acid; PFHpA = perfluoroheptanoic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid

APPENDIX A. ATSDR MINIMAL RISK LEVEL WORKSHEETS

MRLs are derived when reliable and sufficient data exist to identify the target organ(s) of effect or the most sensitive health effect(s) for a specific duration for a given route of exposure. An MRL is an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified route and duration of exposure. MRLs are based on noncancer health effects only; cancer effects are not considered. These substance-specific estimates, which are intended to serve as screening levels, are used by ATSDR health assessors to identify contaminants and potential health effects that may be of concern at hazardous waste sites. It is important to note that MRLs are not intended to define clean-up or action levels.

ATSDR uses the POD/uncertainty factor approach to derive MRLs. Potential PODs are NOAELs, LOAELs, or the BMDL. They are below levels that might cause adverse health effects in the people most sensitive to such chemical-induced effects. MRLs are derived for acute (1–14 days), intermediate (15–364 days), and chronic (≥365 days) durations and for the oral and inhalation routes of exposure. Currently, MRLs for the dermal route of exposure are not derived because ATSDR has not yet identified a method suitable for this route of exposure. MRLs are generally based on the most sensitive substance-induced endpoint considered to be of relevance to humans. Serious health effects (such as irreparable damage to the liver or kidneys, or birth defects) are not used as a basis for establishing MRLs. Exposure to a level above the MRL does not mean that adverse health effects will occur.

MRLs are intended only to serve as a screening tool to help public health professionals decide where to look more closely. They may also be viewed as a mechanism to identify those hazardous waste sites that are not expected to cause adverse health effects. Most MRLs contain a degree of uncertainty because of the lack of precise toxicological information on the people who might be most sensitive (e.g., infants, elderly, nutritionally or immunologically compromised) to the effects of hazardous substances. ATSDR uses a conservative (i.e., protective) approach to address this uncertainty consistent with the public health principle of prevention. Although human data are preferred, MRLs often must be based on animal studies because relevant human studies are lacking. In the absence of evidence to the contrary, ATSDR assumes that humans are more sensitive to the effects of hazardous substance than animals and that certain persons may be particularly sensitive. Thus, the resulting MRL may be as much as 100-fold below levels that have been shown to be nontoxic in laboratory animals. ATSDR utilizes uncertainty factors to account for uncertainties associated with extrapolating from: (1) a LOAEL to a NOAEL; (2) extrapolating from animals to humans; and (3) to account for human variability (Chou et al. 1998; Pohl and Abadin 1995).

Default values of 10 are used for each of these categories of uncertainty factors; a value of 1 can be used if complete certainty exists for a particular uncertainty factor category. A partial uncertainty factor of 3 can be used when chemical-specific data decreases the uncertainty. On a case-by-case basis, ATSDR also utilizes modifying factors to account for MRL-specific database deficiencies.

Proposed MRLs undergo a rigorous review process: Health Effects/MRL Workgroup reviews within the Division of Toxicology and Human Health Sciences, expert panel peer reviews, and agency-wide MRL Workgroup reviews, with participation from other federal agencies and comments from the public. They are subject to change as new information becomes available concomitant with updating the toxicological profiles. Thus, MRLs in the most recent toxicological profiles supersede previously published MRLs. For additional information regarding MRLs, please contact the Division of Toxicology and Human Health Sciences, Agency for Toxic Substances and Disease Registry, 1600 Clifton Road NE, Mailstop S102-1, Atlanta, Georgia 30329-4027.

TABLE OF CONTENTS

INTRODUCTION

Overview of Epidemiological Studies

A large number of epidemiological studies have evaluated a wide range of potential health outcomes resulting from exposure to perfluoroalkyls, particularly PFOA and PFOS. The epidemiological studies fall into three broad categories: occupational exposure primarily to airborne PFOA and PFOS, exposure to PFOA-contaminated drinking water by residents living near a PFOA production facility, and general population exposure to background levels of perfluoroalkyls. Most of the occupational exposure studies were conducted in workers at four facilities in Minnesota, Alabama, West Virginia, and the Netherlands. Studies of the highly-exposed residents primarily come from several large-scale studies (C8 Health Project, C8 Health Study) of Mid-Ohio Valley residents living near the Washington Works facility in West Virginia who were exposed to high levels of PFOA in the drinking water. General population studies primarily utilized data collected in NHANES in the United States and several large-scale health studies conducted in Europe.

Most of the epidemiological studies lack environmental monitoring data and there is a potential for multiple sources of exposure (inhalation and oral). However, the majority of the epidemiological studies used serum perfluoroalkyl levels as a biomarker of exposure. One limitation of the C8 Health Studies is that they used blood samples collected in 2005–2006. However, the facility started using PFOA in the 1950s and peak usage was in the 1990s and by 2003, there was an 87% decline in PFOA emissions, as compared to 1999 levels (Emmett et al. 2006a). Therefore, serum PFOA levels measured in 2005–2006 likely do not represent earlier higher exposures, which may have contributed to observed health outcomes. As an alternative to using older serum PFOA levels, several C8 Health Studies estimated serum levels based on data on the release of PFOA from the facility and pharmacokinetic modeling. Of the three categories of subjects examined in the epidemiological studies, workers have the highest potential exposure to perfluoroalkyls, followed by the highly-exposed residents in the Mid-Ohio Valley (referred to as community exposure), and then the general population. In one study of workers at the Washington Works facility in West Virginia, the average serum PFOA level in 2001–2004 was 1,000 ng/mL (Sakr et al. 2007a); the mean PFOA level in community residents (without occupational exposure) near this facility was 423 ng/mL in 2004–2005 (Emmett et al. 2006a). By comparison, the geometric mean concentration of PFOA in the U.S. population was 3.92 ng/mL in 2005–2006 (CDC 2013).

Identification of Adverse Health Effects Based on Epidemiological Studies. Although a large number of epidemiological studies have examined the potential of perfluoroalkyls to induce adverse health effects, most of the studies were cross-sectional in design and do not establish causality. Epidemiological studies have found statistically significant associations between serum perfluoroalkyl levels and several health effects, although the results were not consistent across studies. Many of the studies reported dose-related trends, but these trends were not as apparent when comparing across studies; some effects were observed in populations with background PFOA levels but not in populations with high serum PFOA levels. Given the inconsistencies, ATSDR evaluated whether the preponderance of the data supported an association between perfluoroalkyl exposure and a particular health effect, taking into consideration the consistency of the findings across studies, the quality of the studies, dose-response, and plausibility. It should be noted that although the data may provide strong evidence for an association, it does not imply that the observed effect is biologically relevant because the magnitude of the change is within the normal limits or not indicative of an adverse health outcome. Plausibility depends primarily on experimental toxicology studies that establish a biological mechanism for the observed effects.

Using this approach, the available epidemiological data identify several potential health hazards of PFOA, PFOS, PFHxS, PFNA, and PFDA in humans as listed below.

PFOA

- Pregnancy-induced hypertension/pre-eclampsia
- Increases in serum hepatic enzymes, particularly alanine aminotransferase, and decreases in serum bilirubin levels
- Increases in serum lipids, particularly total cholesterol and LDL cholesterol
- Decreased antibody response to vaccines
- Small (<20 g or 0.7 ounces per 1 ng/mL increase in blood perfluoroalkyl level) decreases in birth weight

PFOS

- Pregnancy-induced hypertension/pre-eclampsia
- Liver damage, as evidenced by increases in serum enzymes and decreases in serum bilirubin levels
- Increases in serum lipids, particularly total cholesterol and LDL cholesterol
- Decreased antibody response to vaccines
- Small (<20 g or 0.7 ounces per 1 ng/mL increase in blood perfluoroalkyl level) decreases in birth weight

PFHxS

- Liver damage, as evidenced by increases in serum enzymes and decreases in serum bilirubin levels
- Decreased antibody response to vaccines

PFNA

- Increases in serum lipids, particularly total cholesterol and LDL cholesterol
- Decreased antibody response to vaccines (based on limited evidence)

PFDA

- Increases in serum lipids, particularly total cholesterol and LDL cholesterol
- Decreased antibody response to vaccines

Limitations of Epidemiological Data. There are sufficient epidemiological data to identify possible sensitive targets for many of the perfluoroalkyls; however, there are two major limitations to establishing dose-response relationships for these effects and using the epidemiological studies to derive MRLs: accurate identification of environmental exposure levels producing increased risk for adverse effects (exposure estimates and routes of exposure) and likely co-exposure to mixtures of perfluoroalkyls. Other limitations include the cross-sectional design of the majority of epidemiological studies and the potential that reverse causality contributes to the observed associations.

Uncertainty in Exposure Estimates. In general, epidemiological studies provide a one-time serum perfluoroalkyl concentration, but lack information on actual environmental exposure concentration or doses, routes of exposure, and exposure duration. Although serum perfluoroalkyl levels provide reliable information on recent exposure (weeks to years, depending on the elimination $t_{1/2}$ for the perfluoroalkyl), they likely do not reflect historical exposure levels or exposure levels at the onset of the effect. This is especially true for occupational exposure cohorts where past exposure levels were higher before industrial hygiene improved and in the C8 community studies since peak PFOA levels in drinking water occurred at least 10 years prior to the onset of the studies. Additionally, data from NHANES suggest that some

perfluoroalkyl (PFOA, PFOS, PFHxS, and PFDA) levels are declining in the general population; for example, the geometric mean serum levels of PFOA and PFOS declined from 5.2 and 30.4 ng/mL, respectively, in 1999–2000 to 1.56 and 4.72 ng/mL in 2015–2016. In contrast, levels of PFNA have increased during that time frame; the geometric mean went from 0.5 ng/mL in 1999–2000 to 1.26 ng/mL in 2009–2010 and then decreased to 0.675 ng/mL in 2015–2016. Most studies do not provide adequate information to determine whether perfluoroalkyl levels reflect a steady state and relatively constant exposure, since most designs only include a single measurement. An added uncertainty occurs in studies that used maternal serum levels as the biomarker of exposure for effects in children or for effects on fertility.

It is assumed that workers were primarily exposed via inhalation; however, oral exposure may have also contributed to the total perfluoroalkyl body burden, particularly since workers frequently lived in communities with elevated levels of PFOA in the drinking water. It has been determined that drinking water was the primary source of perfluoroalkyls in residents living near a PFOA facility (Emmett et al. 2006a); however, it is likely that airborne PFOA contributed to overall body burden. Drinking water is the likely primary route of exposure for the general population.

Uncertainty due to Co-Exposure to Other Perfluoroalkyls. Based on NHANES data, the U.S. general population is exposed to a variety of perfluoroalkyls. A number of studies reported a high degree of correlation between different perfluoroalkyls; however, most studies did not control for exposure to other perfluoroalkyls. Given that many of the perfluoroalkyls have similar targets of toxicity and possible mechanisms of action, it is likely that several perfluoroalkyls contributed to the observed effects. The potential interactions between different perfluoroalkyls have not been fully elucidated.

In summary, the epidemiological databases for several perfluoroalkyls provide valuable information on hazard identification; however, uncertainties regarding doses associated with adverse effects and possible interactions between compounds preclude use of these data to derive MRLs.

Overview of Laboratory Animal Studies

Laboratory animal studies are available for 11 perfluoroalkyls (no data were located for PFHpA); however, more than 70% of the studies examined PFOA and/or PFOS. The laboratory animal studies primarily involved oral exposure and examined a wide range of potential health outcomes. The primary health effects observed in laboratory animals were liver toxicity, developmental toxicity, and immune toxicity. Other effects typically observed at higher doses included weight loss, histological alterations in reproductive tissues, and histological alterations in the thyroid gland. The sensitive targets of toxicity identified in the laboratory animals are similar to those observed in epidemiological studies.

Limitations of Laboratory Animal Studies for Derivation of MRLs. Use of controlled animal studies eliminates the uncertainties regarding effective doses and co-exposure to other perfluoroalkyls. However, there are uncertainties associated with derivation of MRLs based on animal studies, in part, because of large interspecies differences in the toxicokinetics of perfluoroalkyls for which mechanisms are not completely understood. Available information on the toxicokinetics of perfluoroalkyls in humans, nonhuman primates, and various rodent species indicate that elimination rates (and very likely elimination mechanisms and hormonal regulation of these mechanisms) vary substantially across chemical species (i.e., carbon chain length) and animal species (i.e., slower in humans compared to nonhuman primates and rodents), and show pronounced sex differences within certain species (e.g., faster elimination in female rats). As a result, there is some uncertainty associated with extrapolation of external dose-response relationships from animals to humans. Several PBPK models of PFOA and PFOS have been reported that simulate the substantial differences in pharmacokinetics of these compounds between humans and nonhuman primates or between humans and rats. These include human models for PFOA and PFOS (see

Section 3.1.5). An additional uncertainty in the animal data is the relevance of effects associated with activation of PPARα. Many of the effects observed in rodents, particularly liver and developmental effects, involve the activation of PPARα; humans and nonhuman primates are less responsive to PPARα agonists than rats and mice. However, studies in PPARα-null mice suggest that PPARα-independent mechanisms also play a role in the liver, immunological, and developmental toxicity.

MRL Approach

The following approach was used for derivation of MRLs:

- Identify sensitive endpoints from epidemiological studies
- Identify laboratory animal studies that have evaluated dose-response relationships for toxicity targets identified in epidemiological studies
- Estimate a POD using animal serum perfluoroalkyl levels for sensitive endpoints
- Calculate HEDs using the assumption that a serum concentration resulting in an effect in a laboratory animal would also result in an effect in humans. An empirical pharmacokinetic model was used to estimate a human dose associated with this serum concentration for PFOA and PFOS. Measured serum concentrations in laboratory animal studies were used to calculate the HEDs for PFHxS and PFNA.
- Apply appropriate uncertainty factors informed by comparison of the POD to serum perfluoroalkyl levels reported in epidemiological studies

Rationale for Internal Dose Metric Used in Dosimetry Extrapolation. The time-weighted average serum concentration (C_{TWA}) was selected as the internal dose metric for dose-response modeling and dosimetry extrapolation. The C_{TWA} was used rather than the maximum concentration (C_{max}) for the following reasons:

- C_{TWA} provides a better representation of the history of exposure in the principal studies selected for the MRLs for PFOA (Koskela et al. 2016) and PFOS (Luebker et al. 2005a). The relatively slow elimination of PFOA and PFOS predicted in mice and rats results in a build-up of serum concentrations during the exposure duration. As a result, the C_{max} is predicted to occur soon after the last dose in these studies (based on the Wambaugh et al. 2013 model).

- The assumption that must be accepted to justify using the C_{max} is that only the last dose of PFOA or PFOS, which results in the C_{max}, determines the toxicity outcome, and the earlier exposure history contributes only by building up the levels to the C_{max}.

- The available data on the toxicity of PFOA and PFOS do not provide convincing evidence that toxicity outcomes are more likely to be determined by C_{max} rather than the exposure history, represented by C_{TWA}.

- Given that C_{max} is predicted to exceed C_{TWA} in the principal studies (based on the Wambaugh et al. 2013 model), the resulting HED that achieves a steady-state serum concentration equal to the C_{max} would be larger than the corresponding HED based on C_{TWA}. In the absence of strong evidence for C_{max} being a more appropriate dose metric than C_{TWA}, use of C_{TWA} for dosimetry extrapolation is an appropriate health-protective assumption in the derivation of the MRL.

Predicting Mean Serum PFOA and PFOS Concentrations in Laboratory Animals. TWA serum concentrations corresponding to external doses (mg/kg/day) and exposure durations (days) were predicted with a pharmacokinetic (PK) model for the animal species, strain, and sex used in the studies (Wambaugh et al. 2013). The Wambaugh et al. (2013) model was selected over other available

pharmacokinetic models for the following reasons: (1) it provided a single model structure (parameters) for simulating kinetics of PFOA and PFOS; (2) Wambaugh et al. (2013) derived parameter values for sex-specific species and strains used in the candidate principal studies for the oral MRLs (female and male CD1 mouse, C57BL/6 mouse, Sprague-Dawley rat, cynomolgus monkey); and (3) models were calibrated using Bayesian parameter estimation based on multiple PFOA (n=6) and PFOS (n=2) pharmacokinetics studies for specific species, strains, and sexes; and were then evaluated by comparing predicted and observed serum concentrations from toxicology studies performed on the same species, strains, and sex. Predicted and observed terminal serum concentrations for PFOA and PFOS agreed within a factor of 2, showed strong linear correlation, and distributed symmetrically along the line of identity, suggesting minimal bias in predictions across species, strains, and sexes.

The TWA serum concentration was calculated as follows (Equation A-1):

$$C_{TWA} = \frac{C_{AUC}}{ED} \qquad \text{Eq. (A-1)}$$

where C_{TWA} is the predicted TWA serum concentration (mg/L), C_{AUC} is the predicted area under the curve (AUC) of the serum concentration-time profile for the exposure (mg hour/L), and *ED* is the exposure duration (hour). Gavage studies were simulated as a single dose (e.g., gavage) given once every 24 hours. Daily drinking water exposures were simulated as a 12-hour period of dosing followed by 12 hours with no dosing. This assumes that the animals consumed water during a 12-hour active period and received the total daily dose during this 12-hour period. The dosing interval was 0.1 hour.

The Wambaugh et al. (2013) model was originally implemented in R (v2.10.0) and was migrated to MATLAB (vR2016) for calculations of MRLs. Wambaugh et al. (2013) reported mean and confidence limits for parameter values estimated from a Bayesian Markov Chain Monte Carlo (MCMC) analysis. The posterior means were used as point estimates for parameters in the MATLAB version. Function of the point estimate implementation in MATLAB was verified by comparing predictions of C_{AUC} obtained from the MATLAB version with predictions from the MCMC analysis reported in EPA (2016e, 2016f). This comparison for PFOA included a total of 18 predictions of C_{AUC} for female CD-1 mice (Lau et al. 2006; Wolf et al. 2007), female C57Bl6 mice (DeWitt et al. 2008), and male Sprague-Dawley rats (Butenhoff et al. 2004b). The r^2 for MATLAB vs R predictions of C_{AUC} was 0.99 and the average relative percent difference (MATLAB-R) was 2.8% (range: -6.6–13.5). The comparison for PFOS included a total of 28 predictions of C_{AUC} for female CD-1 mice (Lau et al. 2003), female Sprague-Dawley rats (Butenhoff et al. 2009b; Lau et al. 2003; Luebker et al. 2005a, 2005b), and male and female Cynomolgus monkeys (Seacat et al. 2002). The r^2 for MATLAB vs R predictions of C_{AUC} was 1.00 and the average relative percent difference (MATLAB-R) was 4.6% (range: -11–20).

Estimating TWA Serum PFHxS and PFNA Concentrations in Laboratory Animals. Because a PK model for predicting the TWA serum concentrations was not identified for PFHxS and PFNA, a TWA serum concentration was estimated from measured serum concentrations. ATSDR estimated the TWA values from the areas under the curve calculated using the trapezoid rule. Since most studies did not report pre-exposure levels, serum concentrations in the control group were used as the baseline concentration.

Estimating HEDs for Perfluoroalkyls. The serum concentration PODs identified from the laboratory animal data were converted to an equivalent dose in humans, which is defined as the continuous ingestion dose (mg/kg/day) that would result in steady-state serum concentrations of perfluoroalkyl equal to the serum concentration (µg/mL) selected as the POD. Although human PBPK models for PFOA and PFOS have been reported, the simpler empirical model was selected for deriving

HEDs for the following reasons. Human PBPK models have not been validated with observations made in humans for which individual exposures were known with sufficient certainty to evaluate confidence in predicting dose-serum concentration relationships. Calibration and validation of human PBPK models have relied on comparing predicted and observed declines in serum concentrations following declines or cessation of exposure (Fàbrega et al. 2014, 2016; Loccisano et al. 2011; Worley et al. 2017b). This approach validates the ability of the models to predict serum concentration half-lives, which can be estimated directly from the observation data and represented in the empirical model. However, it does not validate the ability of the models to predict serum concentration in association with known exposures. Worley et al. (2017b) reported good agreement between the distribution of observed and predicted serum concentrations of PFOA within a study population, when assumptions about variability in exposure and biokinetics were incorporated into the simulations.

The relationship between perfluoroalkyl external dosage (mg/kg/day) and steady-state serum concentration (C_{ss}, mg/L) in humans was estimated assuming a single-compartment first-order model in which elimination kinetics are adequately represented by observed serum elimination $t_{1/2}$ values for the specific perfluoroalkyl, an assumed apparent volume of distribution (V_d, L/kg) and gastrointestinal absorption fraction. In the first-order single-compartment model, continuous exposure will result in a steady-state body burden *(BB_{SS}*, mg/kg) for PFOA or PFOS, which will be distributed in a single volume of distribution to yield a steady-state serum concentration (Equation A-2):

$$C_{SS} = \frac{BB_{SS}}{V_d} \quad \text{Eq. (A-2)}$$

At steady state, the rate of first-order elimination rate (a constant fraction of the body burden, k_e per day) will equal the absorbed dosage (D_{ss}, mg/kg/day) adjusted for gastrointestinal absorption (AF) (Equation A-3):

$$D_{SS} \cdot AF = BB_{SS} \cdot k_e \quad \text{Eq. (A-3)}$$

Rearrangement of Equation A-3 allows calculation of the steady-state body burden corresponding to a given external dosage (Equation A-4):

$$BB_{SS} = \frac{D_{SS} \cdot AF}{k_e} \quad \text{Eq. (A-4)}$$

The relationship between the elimination rate constant *(k_e*, day^{-1}) and the elimination half-life ($t_{1/2}$, day), is given in Equation A-5:

$$k_e = \frac{\ln(2)}{t_{1/2}} \quad \text{Eq. (A-5)}$$

Combining Equations A-2 and A-3 yields an expression relating the external steady-state dosage and steady-state serum concentration (Equation A-6):

$$D_{SS} = \frac{C_{SS} \cdot k_e \cdot V_d}{AF} \quad \text{Eq. (A-6)}$$

The above estimates of C_{SS}/D_{SS} are sensitive to the input parameters, $t_{1/2}$, AF, and V_d. The empirical model used to calculate HEDs is linear; therefore, the change in the HED is approximately proportional to the change in the half-life. A halving of the half-life would result in a doubling of the HED.

PFOA and PFOS. Several studies have estimated PFOA and PFOS half-lives ($t_{1/2}$) in workers (Costa et al. 2009; Olsen et al. 2007a) or highly exposed residents (Bartell et al. 2010). Estimates of the half-lives based on Olsen et al. (2007a) were derived from longitudinal measurements of serum concentrations of PFOA and PFOS in a group of fluorochemical production workers (24 males, 2 females); the estimated half-lives were 3.8 years (95% confidence limit [CL] 3.1–4.4) and 5.4 years (95% CL 3.9–6.9), respectively. Costa et al. (2009) reported a half-life for PFOA of 5.1 years (SD 1.7) for a group of workers (n=16) following their cessation of PFOA production work. A longitudinal study by Bartell et al. (2010) followed serum PFOA concentrations in 200 subjects recruited from the Lubeck Public Service District and Little Hocking Water Association and followed for a period of 6–12 months after mitigation of exposures from drinking water. The estimated half-life for PFOA was 2.3 years (95% CL 2.1–2.4). A fourth study estimated half-lives in a cross-sectional study of residents served by the Lubeck Public Service District and Little Hocking Water Association (Seals et al. 2011). The estimated half-lives ranged from 2.9 to 10.1 years (1,059–3,687 days) for PFOA. Results from the longitudinal studies are shown in Table A-1. For the MRL calculations, the PFOA half-life estimated by Olsen et al. (2007a) was selected over the half-life estimated by Bartell et al. (2010) because the Olsen et al. (2007a) study had a longer follow-up time (>5 years compared to 6–12 months) and estimates of the terminal half-life appear to increase with longer follow-ups because slower kinetics make a larger contribution to the terminal half-life (Seals et al. 2011). This may reflect a larger contribution of slower kinetics or ongoing exposure to the terminal half-life observable with longer follow-ups (Worley et al. 2017a) or other factors such as differences in the age-distribution of the populations studied. The decision to use the longer half-life from Olsen et al. (2007a) is also health protective in that a longer half-life would result in higher predicted serum concentrations for a given intake and, therefore, lower HEDs for a given serum concentration POD. Estimates of the half-life for PFOA and PFOS are most applicable to serum concentrations within the above ranges and would be less certain if applied to serum concentrations substantially below or above these ranges. Serum concentrations during the 5-year observation period in the Olsen et al. (2007a) study are provided in Table A-2.

Table A-1. Half-Life PFOA and PFOS Levels in Humans

PFOA $t_{1/2}$ (days)	PFOS $t_{1/2}$ (days)	Exposure type	Number	Source
1,378	1,976	Occupational	26	Olsen et al. (2007a)
1,862	NA	Occupational	16	Costa et al. (2009)
840	NA	Environmental	200	Bartell et al. (2010)

NA = not available; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid

Table A-2. Serum PFOA and PFOS Concentrations Measured in Fluorochemical Production Workers

	PFOA (ppb)	PFOS (ppb)
Initial	408 (72, 5,100)	626 (145, 3,490)
Final	148 (17, 2,435)	295 (37, 1,740)

PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid

Source: Olsen et al. 2007a

Estimates of volume of distribution (V_d) are based on non-compartmental modeling of serum concentration kinetics in monkeys and are assumed to be applicable to humans at the above serum concentrations (Table A-3).

Table A-3. Apparent Volume of Distribution for PFOA and PFOS

PFOA V_d (L/kg)	PFOS V_d (L/kg)	Source
0.18 (male) 0.20 (female)	NA NA	Butenhoff et al. (2004c)
NA NA	0.20 (male) 0.27 (female)	Chang et al. (2012)
0.3	0.3	Harada et al. (2005a)

NA = not applicable; PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid

Numerous studies conducted in various animal models provide evidence for approximately complete absorption of oral doses of PFOA and PFOS (i.e., AF≈1, see Section 3.1.1).

PFHxS. For PFHxS, the estimate of the elimination t½ was derived from longitudinal measurements of serum concentrations of PFHxS in a group of retired fluorochemical production workers (24 males and 2 females) observed for a 5-year period; the estimated half-life was 8.5 years (3,109 days) (Olsen et al. 2007a). The range of initial serum concentrations was 16–1,295 ng/mL (mean of 290 ng/mL), and the final concentrations ranged from 10 to 791 ng/mL (mean of 182 ng/mL). Estimates of the t½ for PFHxS are most applicable to serum concentrations within the above ranges and would be less certain if applied to serum concentrations substantially below or above these ranges.

Estimates of volume of distribution (V_d) are based on non-compartmental modeling of serum concentration kinetics in monkeys and are assumed to be applicable to humans at the above serum concentrations. Sundström et al. (2012) estimated the apparent Vd for PFHxS at 0.287 L/kg for male Cynomolgus monkeys and at 0.213 L/kg for female Cynomolgus monkeys.

Few studies have been conducted in animals that provide estimates for a gastrointestinal absorption factor of oral doses of PFHxS. Sundström et al. (2012), based on comparison of the AUC for oral and intravenous administration, estimated an oral absorption fraction for PFHxS (administered as a single 10 mg/kg dose) of 50% in female rats. However, as the authors point out, this estimate may not be reliable due to the short (24 hours) observation period (Sundström et al. 2012) and that "female C_{max} values did not differ significantly between the oral and IV doses, and T_{max} after oral dosing was estimated to be at approximately 30 min." These latter observations suggest approximately complete bioavailability. The AUC for male rats following oral exposure was not available, and the AUC after

intravenous administration was done in only one male rat (Sundström et al. 2012). A study conducted by Kim et al. (2016) in rats estimated an approximately 100% oral bioavailability based on the C_{max} value and AUC comparison between oral and intravenous doses. Therefore, an absorption fraction (AF) of 1 was used for PFHxS.

PFNA. For PFNA, the elimination half-life estimates were derived by paired blood and urine samples (n=86) from Chinese adults in a study that measured the concentrations of a number of perfluoroalkyls, including PFNA (Zhang et al. 2013). The participants were first divided into four groups; young females (age ≤50 years, n=20), older females (>50 years, n=19), young males (≤50 years, n=32), and older males (>50 years, n=15). The group of young females had significantly lower levels of perfluoroalkyls than the other groups; therefore, the three other groups were combined. The lower perfluoroalkyl levels were likely due to the elimination via menstrual bleeding, pregnancy, and lactation. The estimated arithmetic mean elimination half-lives for the young female group and the combined male and older female group for PFNA were 2.5 and 4.3 years (913 and 1,570 days), respectively.

Toxicokinetics parameters for perfluorocarboxylic acids, among them PFOA and PFNA analogs, were investigated in rats by Ohmori et al. (2003). The authors estimated that the V_d values in steady state were not much different between the perfluorocarboxylic acids and between the sexes. Based on this, the estimated volume of distribution for PFNA in humans will be assumed to be the same for PFOA, 0.2 L/kg.

There are no studies on absorption of PFNA in humans. In rodents, oral absorption occurs rapidly as indicated by its presence in the serum of rodents soon after oral administration (Tatum-Gibbs et al. 2011). Therefore, based on animal studies of PFNA and other perfluorocarboxylic acid analogs, as well as sufficient findings of PFNA and other perfluorocarboxylic acids in human blood, it can be assumed that PFNA is well absorbed after oral exposure; therefore, an AF of 1 was used.

Model Input Parameters. The first-order one-compartment model input parameters ($t_{1/2}$, V_d, and AF) are provided in Table A-4.

Table A-4. First Order One-Compartment Model Parameters

Parameter	PFOA	PFOS	PFHxS	PFNA
Serum elimination half-life[a]; $t_{1/2}$ (day)	1,400[a]	2,000[a]	3,100[a]	900[b]
Serum elimination rate constant[c], k_e (day^{-1})	4.95×10^{-4}	3.47×10^{-4}	2.23×10^{-4}	7.59×10^{-4}
Gastrointestinal absorption fraction[d], AF	1	1	1	1
Apparent volume of distribution, V_d (L/kg)	0.2[e]	0.2[e]	0.287[f]	0.2[e]

[a]Estimates from Olsen et al. (2007a).
[b]Estimates from Zhang et al. (2013) for young females.
[c]Calculated using Equation 5.
[d]Based on studies in rodents and nonhuman primates.
[e]Estimates based on studies in nonhuman primates (Butenhoff et al. 2004c; Chang et al. 2012; Harada et al. 2005a).
[f]Estimates based on studies in nonhuman male primates (Sundström et al. 2012).

PFOA = perfluorooctanoic acid; PFOS = perfluorooctane sulfonic acid; PFHxS = perfluorohexane sulfonic acid; PFNA = perfluorononanoic acid

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorooctanoic acid (PFOA)
CAS Numbers: 335-67-1
Date: March 2020
Profile Status: Final
Route: Inhalation
Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration inhalation MRL for PFOA.

Rationale for Not Deriving an MRL: Derivation of an inhalation MRL was precluded because inhalation-specific PBPK/pharmacokinetic model parameters are not available for PFOA and none of the studies reported serum PFOA concentrations.

Four studies have examined the acute toxicity of airborne PFOA in laboratory animals (Griffith and Long 1980; Kennedy et al. 1986; Staples et al. 1984). The observed effects included excessive salivation and eye and nose irritation in rats exposed to 18,600 mg/m^3 for 1 hour (Griffith and Long 1980), weight loss and pulmonary edema in rats exposed to 380 mg/m^3 for 4 hours (Kennedy et al. 1986), weight loss in rats exposed nose-only to 84 mg/m^3 6 hours/day, 5 days/week for 2 weeks (Kennedy et al. 1986), and decreases in maternal weight gain at 10 mg/m^3 and maternal deaths and decreases in neonatal body weight at 25 mg/m^3 in rats exposed 6 hours/day on GDs 6–15 (Staples et al. 1984). The 2-week study also reported increases in liver weight and hepatocellular hypertrophy in rats exposed to 7.6 mg/m^3.

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorooctanoic acid (PFOA)
CAS Numbers: 335-67-1
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration oral MRL for PFOA.

Rationale for Not Deriving an MRL: An acute-duration oral MRL cannot be derived for PFOA because the modeling approach used for estimating HEDs cannot be used to estimate acute human exposure where the exposure duration of 14 days is 1% of the elimination half-life in humans.

Acute-duration oral studies are available in rats and mice and provide information on body weight, hepatic, immunological, reproductive, and developmental effects. The liver effects consisted of increases in liver weight, hepatocellular hypertrophy, and/or decreases in serum cholesterol and triglycerides in rats and mice exposed to ≥1 mg/kg/day (Cook et al. 1992; Elcombe et al. 2010; Haughom and Spydevold 1992; Ikeda et al. 1985; Kawashima et al. 1995; Kennedy 1987; Liu et al. 1996; Pastoor et al. 1987; Iwai and Yamashita 2006; Permadi et al. 1992, 1993; Vetvicka and Vetvickova 2013; White et al. 2009; Wolf et al. 2007; Xie et al. 2003; Yang et al. 2000, 2001, 2002b). Consistent with the Hall et al. (2012) criteria (see Section 2.9 for a discussion of the criteria), the liver weight increases and hypertrophy observed in rats and mice were not considered relevant to human risk assessment. Although there is uncertainty regarding the exact, and possibly multiple, mechanism(s) for these liver effects, peroxisome proliferation is a likely contributor, a mechanism that cannot be reliably extrapolated to humans (Hall et al. 2012). Therefore, increases in liver weight and hepatocellular hypertrophy, and alterations in serum lipid levels observed in rats and mice, in the absence of other degenerative lesions, were not considered appropriate endpoints for deriving MRLs.

The immunological effects consisted of impaired responses to T-dependent antigens, such as sRBCs, altered antibody response, and decreases in spleen and thymus weights at 11.5 mg/kg/day and higher (DeWitt et al. 2009; Vetvicka and Vetvickova 2013; Yang et al. 2001, 2002a). Information on the potential reproductive toxicity of PFOA is limited to three studies that reported increases in serum estradiol levels in rats exposed to ≥2 mg/kg/day for 14 days (Biegel et al. 1995; Cook et al. 1992; Liu et al. 1996). A number of studies have evaluated the developmental toxicity of PFOA. In the only acute-duration developmental toxicity study in rats, no alterations in fetal body weight or malformations were observed at 100 mg/kg/day (Staples et al. 1984). Mice appear to be more sensitive to PFOA's developmental toxicity; observed effects include decreases in litter weight (Hu et al. 2010), decreases in pup body weight (White et al. 2007, 2009; Wolf et al. 2007), alterations in spontaneous activity (Johansson et al. 2008), increases in resorbed embryos (Chen et al. 2017b), and delays in mammary gland development (White et al. 2007, 2009; Wolf et al. 2007). The lowest LOAEL for developmental effects in mice was 0.5 mg/kg/day for decreased litter weight. A list of the NOAEL and LOAEL values for the immunological, reproductive, and developmental effects is presented in Table A-5.

Table A-5. Summary of the Adverse Effects Observed in Laboratory Animals Following Acute-Duration Oral Exposure

Species and exposure duration	NOAEL (mg/kg/day)	LOAEL[a] (mg/kg/day)	Effect	Reference
Immunological				
Mouse 10 days		11.5	Decreased spleen and thymus weights	Yang et al. 2001
Mouse 10 days	7.5	15	Altered response to sRBC	DeWitt et al. 2009
Mouse 7 days		20	Altered response to sRBC, decreased antibody formation	Vetvicka and Vetvickova 2013
Mouse 7 days		24	Decreased response to horse red blood cells	Yang et al. 2002a
Reproductive				
Rat 14 days	0.2	2	2-Fold increase in serum estradiol levels	Liu et al. 1996
Mouse GDs 1–7		2.5	Decrease in the number of corpora lutea	Chen et al. 2017b
Rat 14 days	1	10	63% increase in serum estradiol levels	Cook et al. 1992
Rat 14 days		25	184% increase in serum estradiol levels	Biegel et al. 1995
Developmental				
Mouse GDs 6–17		0.5	Decreased litter weight on PND 2	Hu et al. 2010
Mouse PND 10		0.58	Decreased spontaneous behavior and altered response to cholinergic stimulant	Johansson et al. 2008
Mouse GDs 8–17 or 12–17		5	Altered mammary gland development, decreased pup body weight on PND 20	White et al. 2007
Mouse GDs 8–17		5	Delayed mammary gland development, decreased pup body weight on PND 20	White et al. 2007
Mouse Various GDs		5	Delayed mammary gland development; decreased pup body weight at weaning	White et al. 2009 Wolf et al. 2007

[a]LOAELs are for less serious effects.

GD = gestation day; LOAEL = lowest-observed-adverse-effect level; NOAEL = no-observed-adverse-effect level; PND = postnatal day; sRBC = sheep red blood cell

The lowest LOAEL values were identified for developmental effects; Hu et al. (2010) identified a LOAEL of 0.5 mg/kg/day for decreases in litter weight on PND 2 and Johansson et al. (2008) identified a LOAEL of 0.58 mg/kg for decreases in spontaneous behavior (locomotion and total activity) and decreased response to a cholinergic stimulant in adult mice exposed to PFOA on PND 10. Neither study identified NOAEL values.

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:**	Perfluorooctanoic acid (PFOA)
CAS Numbers:	335-67-1
Date:	March 2020
Profile Status:	Final
Route:	Oral
Duration:	Intermediate
***MRL*:**	$3x10^{-6}$ mg/kg/day
Critical Effect:	Skeletal alterations in adult offspring
Reference:	Koskela et al. 2016
Point of Departure:	0.000821 mg/kg/day
Uncertainty Factor:	300
LSE Graph Key:	63
Species:	Mouse

MRL Summary: An intermediate-duration oral MRL of $3x10^{-6}$ mg/kg/day was derived for PFOA based on skeletal alterations at 13 and 17 months of age in the offspring of mice fed a diet containing PFOA on GD 1 through GD 21 (Koskela et al. 2016). The MRL is based on a HED LOAEL of 0.000821 mg/kg/day and a total uncertainty factor of 300 (10 for use of a LOAEL, 3 for extrapolation from animals to humans with dosimetric adjustments, and 10 for human variability).

Selection of the Critical Effect: Intermediate-duration oral studies of PFOA in animals indicate that the liver, immune system, reproductive system, and the developing organism are the primary targets of toxicity because adverse outcomes were observed at lower doses than other effects and have been consistently observed across studies. A summary of the lower LOAEL values (and associated NOAEL values) for these tissues/systems is presented in Table A-6; given the large number of studies, this table is limited to studies that identified LOAEL values of ≤4 mg/kg/day. Although these studies identified the lowest LOAEL values, not all were considered suitable as the basis of an intermediate-duration oral MRL.

Exposure to low levels of PFOA results in increases in liver weight, hepatocellular hypertrophy, and decreases in serum lipids in rats, mice, and monkeys exposed to PFOA for intermediate durations. The increases in liver weight, hepatocellular hypertrophy, and alterations in serum lipid levels observed in the rodents are likely adaptive responses to peroxisome proliferation and are not considered relevant for human risk assessment (Hall et al. 2012). Consistent with the Hall et al. (2012) criteria, the increases in liver weight and hepatocellular hypertrophy, in the absence of other degenerative alterations, were not considered adverse. Although there is uncertainty regarding the exact, and possibly multiple, mechanism(s) for these liver effects, peroxisome proliferation is a likely contributor, a mechanism that cannot be reliably extrapolated to humans (Hall et al. 2012). Therefore, increases in liver weight, hepatocellular hypertrophy, and alterations in serum lipid levels, in the absence of other degenerative lesions, were not considered appropriate endpoints for deriving MRLs.

A small number of animal studies have reported degenerative lesions, lesions to specialty cells, bile duct lesions, or inflammation; these endpoints were considered relevant for human risk assessment (Butenhoff et al. 2004b; Cui et al. 2009; Loveless et al. 2008). The lowest LOAEL for adverse liver effects was 0.96 mg/kg/day for increased liver weight, hepatocellular hypertrophy, and focal necrosis in mice exposed for 28 days (Loveless et al. 2008). *In utero* exposure has also resulted in liver effects in offspring (Filgo et al. 2015a; Quist et al. 2015a); the lowest maternal LOAEL identified in these studies was

0.01 mg/kg/day (Quist et al. 2015a). Because the Quist et al. (2015a) study did not provide incidence data for the reported inflammation, this study was not considered suitable for derivation of an MRL. Hepatic effects consisting of increases in absolute liver weight at ≥3 mg/kg/day and increases in serum triglyceride levels at 30/20 mg/kg/day have also been observed in monkeys administered capsules containing PFOA (Butenhoff et al. 2002); no histological alterations were observed in surviving animals, but hepatocellular degeneration and necrosis was noted in a monkey sacrificed early due to morbidity. The small number of animals examined and early deaths at several dose levels precludes using this study as the basis of an MRL.

Two studies examining the immunotoxicity of PFOA following intermediate-duration oral exposure found decreases in antigen-specific antibody responses in mice exposed for 15 days (DeWitt et al. 2008, 2016); the lowest LOAEL was 1.88 mg/kg/day (DeWitt et al. 2016). Reproductive and developmental toxicity studies have identified very low LOAELs of ≥0.0024 mg/kg/day for delays in mammary gland development in dams and offspring (Macon et al. 2011; Tucker et al. 2015; White et al. 2011). However, the mammary gland effect did not result in an adverse effect on lactational support at maternal doses as high as 1 mg/kg/day, based on normal growth and survival in F2 pups (White et al. 2011). Given that milk production was adequate to support growth, the biological significance of the delayed development of the mammary gland observed at very low doses is uncertain and was not considered a suitable basis for the MRL. Other developmental effects include increases in locomotor activity (Cheng et al. 2013; Goulding et al. 2017; Onishchenko et al. 2011; Sobolewski et al. 2014) at ≥0.1 mg/kg/day, reduced ossification of proximal phalanges and early preputial separation and delayed vaginal opening at ≥1 mg/kg/day (Lau et al. 2006; Yang et al. 2009), altered long bone morphology and decreased bone mineral density in 13- and 17-month-old mice following *in utero* exposure to 0.3 mg/kg/day (Koskela et al. 2016), decreases in pup survival at ≥0.6 mg/kg/day (Abbott et al. 2007; Albrecht et al. 2013), decreases in the number of successful births at ≥3 mg/kg/day (Ngo et al. 2014), and reduced neonatal weight gain and delayed eye opening at ≥3 mg/kg/day (Wolf et al. 2007).

Table A-6. Summary of the Adverse Effects Observed in Laboratory Animals Following Intermediate-Duration Oral Exposure

Species and exposure duration	NOAEL (mg/kg/day)	LOAEL[a] (mg/kg/day)	Effect	Reference
Hepatic				
Mouse GDs 1–17		0.01	Hepatocellular hypertrophy and periportal inflammation in offspring	Quist et al. 2015a, 2015b
Mouse 28 days	0.29	0.96	Moderate to severe hepatocellular hypertrophy and focal necrosis	Loveless et al. 2008
Mouse GDs 1–17 (examined at 18 months of age)	0.3	1	Increased severity of chronic inflammation in liver	Filgo et al. 2015a, 2015b
Rat 70–90 days	1	3	Increased liver weight, hepatocellular hypertrophy and necrosis	Butenhoff et al. 2004b
Monkey 26 weeks		3	Increased absolute liver weight	Butenhoff et al. 2002

Table A-6. Summary of the Adverse Effects Observed in Laboratory Animals Following Intermediate-Duration Oral Exposure

Mouse GDs 1–17		3	Reduced pups per litter on PND 20	Albrecht et al. 2013
Mouse GDs 1–17		3	Reduced weight gain, delayed eye opening	Wolf et al. 2007

[a]Unless otherwise noted, LOAELs are for less serious effects.

GD = gestation day; LOAEL = lowest-observed-adverse-effect level; NOAEL = no-observed-adverse-effect level; PND = postnatal day; SLOAEL = serious LOAEL; sRBC = sheep red blood cell

Selection of the Principal Study: As outlined in the MRL approach section, serum PFOA levels were predicted for the administered doses for most of the studies listed in Table A-6. Mean serum PFOA levels could not be predicted for four studies because pharmacokinetic model parameters were not available for Wistar rats (Cheng et al. 2013), male CD-1 mice (Loveless et al. 2008), or 129S1/SvlmJ wild-type mice (Abbott et al. 2007; Albrecht et al. 2013). A summary of the predicted serum PFOA levels is presented in Table A-7.

SV/129 Mouse GDs 1–17	3	Not calculated[b]	Reduced pups per litter on PND 20 at 3 mg/kg/day	Albrecht et al. 2013
CD-1 Mouse GDs 1–17	3 5	84.8 102	Reduced weight gain, delayed eye opening at 3 mg/kg/day	Wolf et al. 2007

[a]Reported serum PFOA concentrations at weaning for the dams that did not have pups which survived to weaning were 4.4, 10.4, 17.4, 26.3, 76.6, 72.4, and 68.2 µg/mL in the 0.1, 0.3, 0.5, 1, 5, 10, and 20 mg/kg/day group, respectively.
[b]Reported serum PFOA concentration was 17 µg/mL for dams treated with 1.6 mg/kg/day.

GD = gestation day; PFOA = perfluorooctanoic acid; PND = postnatal day; sRBC = sheep red blood cell; TWA = time-weighted average

Selection of the Point of Departure for the MRL: The NOAEL/LOAEL and the benchmark dose (BMD) approaches were utilized to identify potential PODs for derivation of the intermediate-duration oral MRL for PFOA. The only datasets with predicted TWA serum PFOA levels amenable to BMD modeling were from the DeWitt et al. (2008, 2016) immunotoxicity studies and Lau et al. (2006) developmental toxicity study. The Sobolewski et al. (2014), Onishchenko et al. (2011), Koskela et al. (2016), Ngo et al. (2014), and Wolf et al. (2007) studies were not considered for BMD modeling because only one or two PFOA doses were tested. No adequate BMD models adequately fit the data from the Lau et al. (2006) study. Adequate fit was found for the DeWitt et al. (2008, 2016) studies; the BMD modeling results are presented at the end of this section.

HEDs were calculated for each potential PODs (NOAEL, LOAEL, or BMD value) identified in laboratory animal studies using the first order single-compartment model previously discussed and the assumption that humans would have similar effects as the laboratory animal at a given serum concentration. The HEDs for each POD are presented in Table A-8. The potential POD_{HED} values were divided by an uncertainty factor to calculate candidate MRLs; these values are also presented in Table A-8. The candidate MRLs range from $7.4x10^{-7}$ mg/kg/day for neurodevelopmental effects in mice

(Sobolewski et al. 2014) to $4.5x10^{-4}$ mg/kg/day for liver effects in male rats (Butenhoff et al. 2004b). The lowest LOAEL (expressed as predicted serum concentration) was identified in the Sobolewski et al. (2014) study, which found neurodevelopmental effects in mouse offspring at predicted serum PFOA concentration of 2.23 µg/mL. However, this study was not considered suitable as the basis of the MRL because the subroute and vehicle used for the controls (peanut oil with anisole administered via gavage) were different from the PFOA group (PFOA dissolved in water and added to diet). Rather, the Onishchenko et al. (2011) and Koskela et al. (2016) studies, which identified the second lowest LOAEL (serum PFOA concentration) of 8.29 µg/mL were considered. In the Onishchenko et al. (2011) study, circadian activity was assessed using a TrafficCage in which all animals in the group were placed in a single cage and activity was measured. Thus, activity was only measured on a group basis and it is possible that one animal could skew the results. Thus, this study was not considered a suitable basis for an MRL.

Table A-8. Summary of Potential Points of Departures (PODs) and Human Equivalent Doses (HEDs) for Intermediate-Duration Oral MRL for PFOA

Endpoint (reference)	Predicted serum concentrations (µg/mL) NOAEL or BMDL	LOAEL	POD_{HED}[a] (mg/kg/day)	Total UF	Candidate MRLs (mg/kg/day)

Endpoint (reference)	Predicted serum concentrations (µg/mL) NOAEL or BMDL	LOAEL	POD_{HED}[a] (mg/kg/day)	Total UF	Candidate MRLs (mg/kg/day)
Reduced response to sRBC in female mice (DeWitt et al. 2008)	33.49 ($BMDL_{1SD}$)		0.00332	30[c]	$1.1x10^{-4}$
Increased liver weight, hepatocellular hypertrophy, and necrosis in male rats (Butenhoff et al. 2004b)	136	222	0.0135	30[c]	$4.5x10^{-4}$

[a]HED calculated using Equation A-6 where C_{ss} is the serum concentration associated with the NOAEL or BMDL or the LOAEL if there was no NOAEL or BMDL, K_e=4.95x10^{-4}; V_d=0.2, and AF=1.
[b]UF of 10 for extrapolation from a LOAEL, 3 for extrapolation from animals to humans with dosimetric adjustments, and UF of 10 for human variability.
[c]UF of 3 for extrapolation from animals to humans with dosimetric adjustments, and 10 for human variability.

BMDL = lower confidence limit on the BMD; HED = human equivalent dose; LOAEL = lowest-observed-adverse-effect level; MRL = Minimal Risk Level; NOAEL = no-observed-adverse-effect level; POD = point of departure; sRBC = sheep red blood cell; UF = uncertainty factor

Summary of the Principal Study:

Koskela A, Finnila MA, Korkalainen M, et al. 2016. Effects of developmental exposure to perfluorooctanoic acid (PFOA) on long bone morphology and bone cell differentiation. Toxicol Appl Pharmacol 301:14-21.

Pregnant C57BL/6/Bk1 mice were exposed to PFOA (96% pure) in food at dose levels of 0 mg/kg/day (n=10) or 0.3 mg/kg/day (n=6) from GD 1 throughout pregnancy (presumed GD 21). PFOA was dissolved in ethanol and applied to palatable food in volumes adjusted according to individual body weights to provide 0.3 mg/kg/day, followed by evaporation of ethanol; controls received food with ethanol applied and then evaporated. It is noted that litter mates of these offspring were examined for neurobehavioral effects in a study conducted by Onishchenko et al. (2011). Groups of five female offspring were sacrificed at either 13 or 17 months of age. The following parameters were used to assess toxicity: body weight and morphometric/biochemical properties in bone (femurs and tibias) of offspring.

As reported in Onishchenko et al. (2011), no differences in dams weight gain, litter size or sex ratio, or pup body weight or brain weight at birth were observed; significant increases in pup liver weight was observed in the PFOA group. Offspring body weight was significantly higher in comparison with controls at 13 and 17 months of age (9.9 and 7.8%, respectively). In 17-month-old offspring, there was a 6.8% increase in periosteal area of the femoral cortical bone and increases in the peri- and endosteal perimeters (3.2 and 5.2%, respectively) and the marrow area (10.0%); an increase in medullary area was also observed. There were no differences in femoral cortical bone area or femoral mineral density. In the tibia, the total area inside the periosteal envelope and the periosteal perimeter were increased (4.9 and 3.5%, respectively). Although the investigators noted in the text that tibial medullary areas were "essentially the same between groups," data in Figure 2 of the paper show a significant increase at 17 months. Significant decreases in tibial mineral density were observed at 13 and 17 months. There

were no significant differences in the tibial medullary area or the endosteal perimeter. There was a trend for increasing maximum force (Fmax); however, the effect was not statistically significant. There were no significant effects on any other measured biochemical parameter in the femur or tibia (stiffness, maximum energy, absorption). Concentrations of PFOA in the femurs and tibias of treated animals were significantly higher (4–5 times) than controls at 13 and 17 months. Koskela et al. (2016) suggested that the PFOA-induced increase in body weight gain may have indirectly affected bone homeostasis, but noted that *in vitro* data provide evidence of a direct effect on osteoblasts and osteoclasts.

Strengths and Weaknesses: The Koskela et al. (2016) study has a number of strengths including examination of several measures of bone status tested at different ages, measurement of bone PFOA levels, and tests to evaluate potential mechanisms of action. To evaluate whether developmental exposure resulted in bone damage in mature animals, the study evaluated bone morphology (periosteal, cortical, and medullary areas and bone mineral density) and bone biomechanical properties (stiffness, maximum force, and maximum energy); all tests were conducted on femur and tibia bone. Measurement at two ages (13 and 17 months) allowed for an evaluation of whether the effect of PFOA on bone changed as the animals aged. The companion *in vitro* study of osteoclasts and osteoblasts provided mechanistic support for the *in vivo* findings. Additionally, the *in vitro* study evaluated four PFOA concentrations and found concentration-related differences.

There are several study limitations that affect the interpretation of the study results; these include the small number of animals tested, use of only one PFOA dose level, inadequate reporting of dietary PFOA levels, and lack of measured serum PFOA levels. Tests of potential alterations in bone mineral density and bone biomechanical properties were only evaluated in 5–6 female offspring per group; however, support for the finding comes from the consistency of the findings at 13 and 17 months of age. The use of only one PFOA dose level does not allow for the establishment of dose-response relationships. This study limitation is mitigated by the extensive intermediate-duration oral exposure database, which allows for an overall assessment of dose-response. The dams were exposed to PFOA dissolved in alcohol and sprayed onto the food pellets. The study did not measure the amount of residual alcohol or the actual amount of PFOA on the food pellets. Koskela et al. (2016) measured PFOA levels in the tibias and femurs but did not measure serum PFOA levels. ATSDR estimated the TWA serum PFOA concentrations using the Wambaugh et al. (2013) model. The lack of measured serum PFOA levels did not allow for validation of whether the model accurately predicted serum levels; the model was validated using data from other intermediate-duration PFOA studies in rats and mice.

Calculation of Internal Dosimetric: TWA serum PFOA concentrations corresponding to external doses and exposure durations were predicted from a pharmacokinetic model (Wambaugh et al. 2013) using animal species-, strain-, and sex-specific parameters (see MRL approach section for details).

Human Equivalent Dose: HEDs were calculated based on the assumption that humans would have similar effects as the laboratory animal at a given serum concentration. HEDs that would result in steady-state serum concentrations of PFOA equal to the serum concentration selected as the POD were calculated using the first-order single-compartment model (see MRL approach section for details).

Uncertainty Factor: The $LOAEL_{HED}$ is divided by a total uncertainty factor of 300:

- 10 for the use of a LOAEL
- 3 for extrapolation from animals to humans with dosimetric adjustment
- 10 for human variability

$MRL = LOAEL_{HED} \div UFs$
$0.000821 \text{ mg/kg/day} \div (10 \times 3 \times 10) = 3 \times 10^{-6} \text{ mg/kg/day}$

Other Additional Studies or Pertinent Information that Lend Support to this MRL: *In vitro* studies conducted by Kosela et al. (2016) found that at lower concentrations (0.1–10 μM), PFOA stimulated osteoblast differentiation, as evidenced by increased osteocalcin mRNA expression and increased calcium secretion. At higher PFOA levels (>100 μM), osteocalcin expression and calcium secretion were decreased. Lower concentrations of PFOA (0.1–1.0 μM) also increased the number of osteoclasts and increased resorption activity; as with osteoblasts, decreased activity was observed at >100 μM PFOA concentrations.

Epidemiological studies have not evaluated the potential association between serum PFOA levels and impaired development of bone. A small number of studies in adults have examined potential associations with osteoarthritis risk. Innes et al. (2011) reported an elevated risk of physician diagnosed osteoarthritis among adults under 55 years of age with serum PFOA concentrations >13.6 ng/mL; the OR (95% CI) was 1.22 (1.02–1.45) among participants with serum PFOA in the second quartile (13.6–28.0 ng/mL). In a study of NHANES participants, Khalil et al. (2016) found an elevated risk of osteoarthritis among women, OR of 1.84 (1.17–2.90); the mean serum PFOA concentration was 3.7 ng/mL. This study also found in inverse association between serum PFOA and femur neck mineral density in women, but not in men. A second study of NHANES participants also found an elevated risk of osteoarthritis in women with serum PFOA levels of >5.89 ng/mL, OR of 1.98 (1.24–3.19) (Uhl et al. 2013). When segregated by age, an association was found in younger women (20–49 years of age), OR of 4.95 (1.27–19.4), but not among older women (50–84 years of age), OR of 1.33 (0.82–1.16) (Uhl et al. 2013). No association between estimated cumulative exposure to PFOA and the risk of osteoarthritis was observed in an occupational study in which 80% of the cohort was male (Steenland et al. 2015). A discussion of the other findings from epidemiological studies is presented in the MRL introduction section.

Benchmark Dose Modeling: BMD modeling was conducted for the DeWitt et al. (2008) and DeWitt et al. (2016) immunotoxicity studies. Using predicted TWA serum PFOA levels as the internal dosimetric, the IgM response data (summarized in Tables A-9 and A-10) were fit to all available continuous models in EPA's Benchmark Dose Software (BMDS, version 2.6.0). The following procedure for fitting continuous data was used: the simplest model (linear) was first applied to the data while assuming constant variance; if the data were consistent with the assumption of constant variance ($p \geq 0.1$), then the fit of the linear model to the means was evaluated and the polynomial, power, and Hill models were fit to the data while assuming constant variance. Adequate model fit was judged by three criteria: goodness-of-fit p-value ($p > 0.1$), visual inspection of the dose-response curve, and scaled residual at the data point (except the control) closest to the predefined benchmark dose response (BMR). Among all of the models providing adequate fit to the data, the lowest BMDL (the lower limit of a one-sided 95% CI on the BMD) was selected as a reasonably conservative POD when differences between the BMDLs estimated from these models are >2–3-fold; otherwise, the BMDL from the model with the lowest Akaike's information criterion (AIC) was chosen. If the test for constant variance was negative, the linear model was run again while applying the power model integrated into the BMDS to account for nonhomogenous variance. If the nonhomogenous variance model provided an adequate fit ($p \geq 0.1$) to the variance data, then the fit of the linear model to the means was evaluated and the polynomial, power, and Hill models were fit to the data and evaluated while the variance model was applied. Model fit and POD selection proceeded as described earlier. For both datasets, a BMR of 1 SD change from the control was used.

Table A-9. T-Cell Independent IgM Antibody Response in C57BL/6N Female Mice Immunized with Sheep Red Blood Cells

The results of the BMD analysis of the DeWitt et al. (2008) and DeWitt et al. (2016) datasets are presented in Tables A-11 and A-12. For the DeWitt et al. (2008) data, the Hill model with constant variance provided the best fit to the IgM response data, as judged by the model with the lowest AIC since the range of BMDL values were sufficiently close; the fit of this model is presented in Figure A-1. For the DeWitt et al. (2016) IgM response data, constant variance models provided adequate fit; since the estimated BMDL values were not sufficiently close, the model with the lowest BMDL (Exponential 4) was selected; the fit of this model is presented in Figure A-2.

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorooctanoic acid (PFOA)
CAS Numbers: 335-67-1
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Chronic

MRL Summary: ATSDR did not identify an adequate study with an exposure duration of ≥365 days. Although adequate data are available for intermediate-duration exposure, ATSDR does not extrapolate across exposure duration.

Rationale for Not Deriving an MRL: The chronic oral animal database for PFOA is limited to dietary exposure studies in male and female rats (3M 1983; Butenhoff et al. 2012c) or male rats (Biegel et al. 2001). The lowest LOAEL identified in the Butenhoff et al. (2012c; 3M 1983) study was 1.5 mg/kg/day for inflammation of salivary gland in male rats exposed to PFOA in the diet for 2 years. At 15 mg/kg/day, hepatocellular necrosis was observed after 1 year of exposure and vascular mineralization was observed in the testes. In the Biegel et al. (2001) study, exposure to 13.6 mg/kg/day PFOA in the diet for 2 years resulted in decreases in body weight gain, increases in Leydig cell hyperplasia, and pancreatic acinar cell hyperplasia in male rats.

The chronic-duration database for PFOA was not considered adequate for MRL derivation due to uncertainty in the selection of the critical effect. The Butenhoff et al. (2012c) study identified the salivary gland as the most sensitive target, but these alterations were only observed in males and may have been due to an antemortem viral infection. Intermediate-duration oral studies have suggested that the immune system is a sensitive target of toxicity in mice; however, potential alterations in immune function have not been investigated in chronic-duration studies; the Butenhoff et al. (2012c) study did conduct histological examinations of immune tissues.

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorooctane sulfonic acid (PFOS)
CAS Numbers: 1763-23-1
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration oral MRL for PFOS.

Rationale for Not Deriving an MRL: An acute-duration oral MRL for PFOS cannot be derived because the modeling approach used for estimating HEDs cannot be used to estimate acute human exposure where the exposure duration of 14 days is <1% of the PFOS elimination half-life in humans.

A number of studies have examined the toxicity of PFOS in laboratory animals following acute-duration exposure. The available data suggest that the liver, developing organism, and immune system are sensitive targets. The liver effects consisted of decreases in serum lipids, increases in liver weight, and hepatocellular hypertrophy (Elcombe et al. 2012a, 2012b; Era et al. 2009; Fuentes et al. 2006; Haughom and Spydevold 1992; Vetvicka and Vetvickova 2013; Wan et al. 2011); using the Hall et al. (2012) criteria (see Section 2.9 for a discussion of the criteria) for assessing the adversity of liver alterations for peroxisome proliferators, these effects were not considered relevant for human risk assessment. Although there is uncertainty regarding the exact, and possibly multiple, mechanism(s) for these liver effects, peroxisome proliferation is a likely contributor, a mechanism that cannot be reliably extrapolated to humans (Hall et al. 2012). Therefore, increases in liver weight, hepatocellular hypertrophy, and alterations in serum lipid levels observed in rats and mice, in the absence of other degenerative lesions, were not considered appropriate endpoints for deriving MRLs. A decrease in serum HDL cholesterol levels was also observed in male and female monkeys receiving three doses of 13.3 or 14 mg/kg/day (TWA dose in males and females, respectively) over 315 days (Chang et al. 2017).

Immunological effects included altered responses to sRBC and decreased IgM antibody formation in response to antigen exposure in mice (Vetvicka and Vetvickova 2013; Zheng et al. 2009). Developmental effects consisted of decreases in neonatal survival (Abbott et al. 2009; Grasty et al. 2003), increases in post-implantation losses (Lee et al. 2015a), decreases in fetal body weight (Case et al. 2001; Era et al. 2009; Fuentes et al. 2007b; Lee et al. 2015a), increases in malformations (Era et al. 2009), and alterations in motor activity (Hallgren et al. 2015; Johansson et al. 2008). The lowest LOAEL identified was 0.5 mg/kg/day for increased post-implantation losses in mice (Lee et al. 2015a). A summary of the adverse effect levels for the immunological and developmental effects are presented in Table A-13.

Table A-13. Summary of the Adverse Effects Observed in Laboratory Animals Following Acute-Duration Oral Exposure to PFOS

Species and exposure duration	NOAEL (mg/kg/day)	LOAEL[a] (mg/kg/day)	Effect	Reference
Immunological				
Mouse 7 days		5	Impaired response to T-cell mitogens; suppressed response to sRBC	Zheng et al. 2009
Mouse 7 days		20	Inhibition of T lymphocyte proliferation in response to sRBC; decreased phagocytosis by peripheral blood cells and NK cell activity; decreased IgM antibody formation in response to OVA	Vetvicka and Vetvickova 2013
Developmental				
Mouse GDs 11–16		0.5	Increased post-implantation losses	Lee et al. 2015a
Mouse Once		0.75	Decreased motor activity	Johansson et al. 2008
Rabbit GDs 6–20	1	2.5	Decreased fetal body weight	Case et al. 2001
Mouse GDs 15–18		4.5	Decreased number of live pups per litter on PND 15	Abbott et al. 2009
Mouse GDs 12–18		6	Reduced pup body weight on PNDs 4 and 8	Fuentes et al. 2007b
Mouse Once		11.3	Altered spontaneous behavior in pups	Hallgren et al. 2015
Rat GDs 19–20		25 (SLOAEL)	Decreased neonatal survival	Grasty et al. 2003
Rat GDs 2–5, 6–9, 10–13, 14–17, or 17–20		25 (SLOAEL)	Decreased neonatal survival	Grasty et al. 2003
Mouse GDs 11–15		50	Cleft palate and reduced fetal body weight	Era et al. 2009

[a]Unless otherwise noted, the LOAEL is for a less serious effect.

GD = gestation day; LOAEL = lowest-observed-adverse-effect level; NK = natural killer; NOAEL = no-observed-adverse-effect level; perfluorooctane sulfonic acid; PND = postnatal day; SLOAEL = LOAEL for a serious effect; sRBC = sheep red blood cell

Critical Effect:	Delayed eye opening and decreased pup body weight
Reference:	Luebker et al. 2005a
Point of Departure:	0.000515 mg/kg/day
Uncertainty Factor:	30
Modifying Factor:	10
LSE Graph Key:	35
Species:	Rat

MRL Summary: An intermediate-duration oral MRL of $2x10^{-6}$ mg/kg/day was derived for PFOS based on delayed eye opening and transient decrease in F2 body weight during lactation in the offspring of rats administered PFOS via gavage in a 2-generation study (Luebker et al. 2005a). The MRL is based on a HED NOAEL of 0.000515 mg/kg/day and a total uncertainty factor of 30 (3 for extrapolation from animals to humans with dosimetric adjustments and 10 for human variability) and a modifying factor of 10 for concern that immunotoxicity may be a more sensitive endpoint than developmental toxicity.

Selection of the Critical Effect: Intermediate-duration studies in monkeys, rats, and mice have identified several sensitive targets of PFOS toxicity including the liver, nervous system, immune system, and the developing organism; adverse outcomes occurred in these tissues at lower doses than other effects. The lowest LOAEL and NOAEL values for these outcomes are presented in Table A-14; given the large number of intermediate-duration studies, this table was limited to studies which identified LOAEL values of ≤3 mg/kg/day. The liver effects observed in monkeys, rats, and mice included increases in liver weight, decreases in serum lipids, hepatocellular degeneration, and focal necrosis (Cui et al. 2009; Curran et al. 2008; Elcombe et al. 2012a; Lefebvre et al. 2008; Seacat et al. 2002, 2003; Thibodeaux et al. 2003; Wan et al. 2011; Yahia et al. 2008). In the absence of degenerative changes such as necrosis, the liver hypertrophy observed in rodent studies was not considered relevant to human risk assessment (Hall et al. 2012). Although there is uncertainty regarding the exact, and possibly multiple, mechanism(s) for these liver effects, peroxisome proliferation is a likely contributor, a mechanism that cannot be reliably extrapolated to humans (Hall et al. 2012). Therefore, increases in liver weight, hepatocellular hypertrophy, and alterations in serum lipid levels observed in rats and mice, in the absence of other degenerative lesions, were not considered appropriate endpoints for deriving MRLs.

Several studies have examined potential neurological endpoints and found overt signs of neurotoxicity (cachexia, lethargy, and tonic convulsions in response to stimuli) in rats exposed to 5 or 8.5 mg/kg/day (Cui et al. 2009; Kawamoto et al. 2011) and impaired spatial learning and memory in mice exposed to 2.15 mg/kg/day (Long et al. 2013). Four studies have evaluated the immune response of PFOS exposed mice following exposure to an antigen (sRBC) or a virus (Dong et al. 2009, 2011; Guruge et al. 2009; Peden-Adams et al. 2008). Although the studies have consistently reported adverse effects, there is considerable overlap in LOAEL values. Peden-Adams et al. (2008) identified the lowest LOAEL of 0.00166 mg/kg/day with a NOAEL of 0.000166 mg/kg/day for a suppressed response to sRBC in mice administered PFOS for 28 days. Longer duration studies (Dong et al. 2009, 2011) have identified NOAEL values (0.0083 and 0.0167 mg/kg/day) in mice exposed to PFOS for 60 days that are higher than

the LOAELs identified in the Peden-Adams et al. (2008) study. It is noted that the studies used different mouse strains (B6C3F1 in the Peden-Adams study and C57BL/6N in the Dong studies), which may account for this difference. A variety of developmental effects have been observed in rats and mice; these include increases in postnatal mortality (Chen et al. 2012b; Lau et al. 2003; Luebker et al. 2005a, 2005b; Xia et al. 2011; Yahia et al. 2008), neurodevelopmental alterations (locomotor activity and impaired learning) (Butenhoff et al. 2009b; Onishchenko et al. 2011; Wang et al. 2015c), developmental delays (Lau et al. 2003; Luebker et al. 2005a), and malformations and anomalies (sternal defects and cleft palate) (Era et al. 2009; Thibodeaux et al. 2003; Yahia et al. 2008). The Wang et al. (2015c) study showed that decreases in spatial learning were observed in rats exposed *in utero* and in rat pups exposed postnatally (PND 7). Other effects that occur at similar doses include decreases in body weight (Lefebvre et al. 2008; Luebker et al. 2005a, 2005b; Seacat et al. 2002) and alterations in thyroid hormone levels (decreases in T3 and T4 levels and increases in TSH levels) (Curran et al. 2008; Luebker et al. 2005b; Thibodeaux et al. 2003).

The most sensitive targets of PFOS toxicity in laboratory animals are similar to those identified in longer term epidemiological studies. These effects include liver damage and increases in serum lipids, decreased antibody response to vaccines, and small decreases in birth weight; epidemiological studies have not consistently found neurological effects to be associated with serum PFOS levels.

Table A-14. Summary of the Adverse Effects Observed in Laboratory Animals Following Intermediate-Duration Oral Exposure to PFOS

Species and exposure duration	NOAEL (mg/kg/day)	LOAEL[a] (mg/kg/day)	Effect	Reference
Hepatic				
Monkey 26 weeks	0.15	0.75	Increased liver weight, decreased serum cholesterol, hepatocellular hypertrophy, lipid vacuolation	Seacat et al. 2002
Neurological				
Mouse 3 months	0.43	2.15	Impaired spatial learning and memory	Long et al. 2013
Immunological				
Mouse 28 days	0.00016	0.00166	Suppressed response to sRBC	Peden-Adams et al. 2008
Mouse 21 days	0.005	0.025	Decreased resistance to influenza virus	Guruge et al. 2009
Mouse 60 days	0.0083	0.083	Impaired response to sRBC	Dong et al. 2009
Mouse 60 days	0.0167	0.083	Impaired response to sRBC	Dong et al. 2011
Developmental				
Mouse GDs 1–21		0.3	Decreased locomotion, muscle strength, motor coordination in adult offspring	Onishchenko et al. 2011
Rat 84 days	0.1	0.4	Delayed eye opening	Luebker et al. 2005a
Rat 67 days		0.4	Decreased pup weight	Luebker et al. 2005b

Table A-14. Summary of the Adverse Effects Observed in Laboratory Animals Following Intermediate-Duration Oral Exposure to PFOS

Species and exposure duration	NOAEL (mg/kg/day)	LOAEL[a] (mg/kg/day)	Effect	Reference
Rat GD 1–PND 1		0.8	Decreased spatial learning	Wang et al. 2015c
Rat GD 0–PND 20	0.3	1	Increased locomotor activity and concurrent failure to habituate to test environment in male pups on PND 17	Butenhoff et al. 2009b
Mouse GDs 1–17		1	Delayed eye opening	Lau et al. 2003
Mouse GDs 0–17		1	Increased sternal defects	Yahia et al. 2008
Rat GDs 1–21	0.1	2	Increased postnatal mortality and severe lung histopathology	Chen et al. 2012b
Rat GDs 2–21	0.6	2	Increased neonatal mortality	Xia et al. 2011

[a]LOAELs for less serious health effects.

GD = gestation day; LOAEL = lowest-observed-adverse-effect level; NK = natural killer; NOAEL = no-observed-adverse-effect level; PFOS = perfluorooctane sulfonic acid; PND = postnatal day; sRBC = sheep red blood cell

Selection of the Principal Study: Using the Wambaugh et al. (2013) pharmacokinetic model, TWA serum concentrations corresponding to external doses (mg/kg/day) and exposure durations (days) were predicted for the studies listed in Table A-14. Pharmacokinetic model parameters were not available for C57BL/6N mice, B6C3F1 mice, or Wistar rats, which precluded predicting TWA serum concentrations for the Long et al. (2013), Dong et al. (2009, 2011), Guruge et al. (2009), Peden-Adams et al. (2008), Wang et al. (2015c), Onishchenko et al. (2011), and Yahia et al. (2008) studies. The predicted serum PFOS levels for each administered dose is presented in Table A-15.

Table A-15. Summary of the Predicted TWA Serum PFOS levels in Laboratory Animals Following Intermediate-Duration Oral Exposure

Species and exposure duration	Dose (mg/kg/day)	Predicted TWA serum PFOS (µg/mL)	Effect	Reference
Hepatic				
Cynomolgus Monkey 26 weeks	0.03 (males)	7.81	Increased liver weight, decreased serum cholesterol, hepatocellular hypertrophy, mild bile stasis, lipid vacuolation at 0.75 mg/kg/day	Seacat et al. 2002

[a]See Table A-17 for measured serum PFOS concentrations.
[b]Reported serum PFOS concentrations of 25.7 and 64.3 µg/mL in dams on PND 7 and 35, respectively.

GD = gestation day; LD = lactation day; PFOS = perfluorooctane sulfonic acid; PND = postnatal day; sRBC = sheep red blood cell; TWA = time-weighted average

Selection of the Point of Departure for the MRL: None of the studies with predicted serum PFOS levels had datasets that were amenable for BMD modeling; thus, the NOAEL/LOAEL approach was used to identify PODs for derivation of the intermediate-duration MRL for PFOS. A summary of the PODs is presented in Table A-16. HEDs were calculated for each potential POD (NOAEL or LOAEL) identified in laboratory animal studies using the first-order single-compartment model previously discussed and the assumption that humans would have similar effects as the laboratory animal at a given serum concentration. The HEDs for each POD are presented in Table A-16. The potential POD_{HED} values were divided by a total uncertainty factor to calculate candidate MRLs; these values are also presented in Table A-16. The lowest administered doses associated with adverse effects were found in the immunotoxicity studies conducted by Dong et al. (2009, 2011), Guruge et al. (2009), and Peden-Adams et al. (2008). These data could not be considered as PODs because TWA serum PFOS values could not be predicted due to the lack of pharmacokinetic model parameters for the two mouse strains tested. Although there is considerable overlap between the LOAEL for IgM response to sRBC (0.00166 mg/kg/day) identified in the Peden-Adams et al. (2008) 28-day study and the NOAELs for IgM

response to sRBC (0.0083 and 0.0167 mg/kg/day) identified in the Dong et al. (2009, 2011) 60-day studies, the data do suggest that immunotoxicity could occur at <0.3 mg/kg/day (the lowest LOAEL identified in developmental toxicity studies).

Table A-16. Summary of Potential Points of Departures Human Equivalent Doses (POD_{HED}) for Intermediate-Duration Oral MRL for PFOS

Endpoint (reference)	Predicted serum concentrations (µg/mL) NOAEL	LOAEL	POD_{HED}[a] (mg/kg/day)	Total UF	Candidate MRLs (mg/kg/day)
Increased rat pup mortality and lung histopathology (Chen et al. 2012b)	2.01	40.1	0.000139	300[b]	$4.6x10^{-7}$
Decreased rat pup weight at birth and on PND 4 (Luebker et al. 2005b)		24.1	0.00167	3,000[c]	$5.6x10^{-7}$
Delayed eye opening in mouse pups (Lau et al. 2003)		31.9	0.00221	3,000[c]	$7.4x10^{-7}$
Neurodevelopmental effects in male rat pups (Butenhoff et al. 2009b)	11.3	37.5	0.000780	300[b]	$2.6x10^{-6}$
Delayed eye opening and decreased F2 rat pup body weight (Luebker et al. 2005a)	7.43	29.7	0.000515	300[b]	$1.7x10^{-6}$
Increased neonatal mortality in rat pups (Xia et al. 2011)	11.5	38.3	0.000797	300[b]	$2.7x10^{-6}$
Hepatic effects in monkeys (Seacat et al. 2002)	37.8	150	0.00262	300[b]	$8.7x10^{-6}$

[a]HED calculated using Equation A-6 where C_{ss} is the serum concentration associated with the NOAEL or BMDL or the LOAEL if there was no NOAEL or BMDL, $K_e=3.74x10^{-4}$; $V_d=0.2$, and AF=1.
[b]UFs of 3 for extrapolation from animals to humans with dosimetric adjustments and 10 for human variability and modifying factor (MF) of 10 for concern that immunotoxicity may be a more sensitive endpoint than developmental toxicity.
[c]UF of 10 for extrapolation from a LOAEL, 3 for extrapolation from animals to humans with dosimetric adjustments, and UF of 10 for human variability and MF of 10 for concern that immunotoxicity may be a more sensitive endpoint than developmental toxicity.

BMDL = lower limit on the benchmark dose; LOAEL = lowest-observed-adverse-effect level; MRL = Minimal Risk Level; NOAEL = no-observed-adverse-effect level; PFOS = perfluorooctane sulfonic acid; PND = postnatal day; UF = uncertainty factor

The serum PFOS concentrations predicted to occur at the lowest LOAEL values were 24.1, 29.7, and 31.9 µg/mL identified in the Luebker et al. (2005b), Luebker et al. (2005a), and Lau et al. (2003) studies; decreases in pup body weight and delays in eye opening were observed at these levels. Luebker et al. (2005a) was the only study that identified a NOAEL for these effects. The predicted serum concentration for this NOAEL dose was selected as the basis for the MRL.

Summary of the Principal Study:

Luebker DJ, Case MT, York RG, et al. 2005a. Two-generation reproduction and cross-foster studies of perfluorooctanesulfonate (PFOS) in rats. Toxicol 215:126-148.

Groups of Sprague-Dawley rats (P generation) (35/sex/dose level) were administered PFOS (86.9% pure) by gavage in deionized water with 2% Tween-80 at doses of 0, 0.1, 0.4, 1.6, or 3.2 mg/kg/day for 6 weeks before mating and until sacrifice (after mating for males, GD 10 for some females, and PND 21 for the remaining females). Body weight and feed consumption were evaluated during the dosing period. Prior to mating, 15 females per dose group were evaluated for estrous cycling. Ten females/dose group were sacrificed on GD 10 and the remaining females were allowed to give birth (F1 generation). Parental rats sacrificed on GD 10 were examined for number of corpora lutea, implantations, and viable and non-viable fetuses. Body weight of F1 was evaluated during lactation; also, F1 rats were assessed for developmental landmarks during lactation. On PND 22, the F1 rats were started on the same diet as the parental rats. At approximately PND 90, F1 were mated to produce the F2 generation. F1 males and females were killed as the P generation. F1 females and males were evaluated for vaginal patency and preputial separation, respectively. At age 24 days, F1 rats were administered three neurobehavioral tests (learning, memory retention, and avoidance memory). At the age of 70 days, F1 were administered three different neurobehavioral tests (neuromuscular coordination, swimming ability, learning, and memory). PFOS was analyzed in liver and blood from parental females and in liver from F1on PND 21; and in liver and serum from parental males after mating and after 42–56 days of dosing.

There were no deaths in parental males or females and no clinical signs in parental males. High-dose parental males had significantly reduced terminal body weight (11% reduction). Absolute and relative food consumption was reduced during treatment in males by less than 10%. Parental females at 0.4 mg/kg/day and higher had localized areas of partial alopecia. Body weight of parental females in the 3.2 mg/kg/day group was significantly lower during cohabitation and gestation (11% reduced). Absolute and relative food consumption were significantly reduced in 3.2 mg/kg/day parental females during premating and gestation (>15%) and in 1.6 mg/kg/day parental females during lactation. Administration of PFOS did not affect any mating or fertility parameter. Estrous cycling was not affected. Examination of parental females sacrificed on GD 10 showed no significant effect on numbers of corpora lutea or implantations or viable and non-viable fetuses. Significant delivery observations for 3.2 mg/kg/day parental females included reduced number of implantations per delivered litter, decreased gestational length, increased number of dams with all pups dying on PNDs 1–4 (also at 1.6 mg/kg/day). Observation of F1 pups during PNDs 1–21 showed significantly reduced weight and decreased viability (≥1.6 mg/kg/day). Examination of dead F1 pups did not reveal a cause of death; no labored breathing was noted in pups at birth. Developmental delays were noted at 1.6 mg/kg/day (pinna unfolding, surface righting, and air righting), and 0.4 mg/kg/day (eye opening). The investigators noted that the delay in eye opening was not considered an adverse outcome but did not provide a rationale for this conclusion. Follow-up observations of 0.1 and 0.4 mg/kg/day offspring showed no alterations in body weight or food consumption, including F1 females during gestation and lactation. Sexual maturation was not affected in F1 males or females; no effects were noted in the neurobehavioral tests. Reproductive performance of F1 were not affected. Viability of F2 pups during PNDs 1–21 was not affected. F2 pup weight was significantly reduced at 0.4 mg/kg/day on PND 7 (13%) and PND 14 (9.6%). The investigators noted that the decrease in pup weight was not considered toxicologically relevant and may have been due to minimally larger live litter sizes, as compared to the control group, and that there were no differences on PND 21. ATSDR notes that there were no significant differences in pup body weight between the control group and the 0.4 mg/kg/day group on PND 4 prior to culling and after culling, and considers the delay in eye opening to be toxicologically relevant. Serum and liver PFOS increased with dose.

Strengths and Weaknesses: The Luebker et al. (2005a) study is a well-designed 2-generation study evaluating a number of reproductive and developmental endpoints in adequate number of animals. The study was designed to evaluate four PFOS dose levels administered prior to mating and during mating, gestation, and lactation across two generations. The test included a number of parameters to assess reproductive performance (mating, estrous cycling, and fertility), reproductive outcomes (gestation length, number of implantation sites, stillbirths), and neonatal toxicity (survival and body weight). The experiment also included a cross-foster study, which allowed for the evaluation of whether neonatal effects were due to maternal care/maternal toxicity or to a direct effect on the pups. An additional strength of the study is that it evaluated several endpoints (e.g., lung morphology and lung glycogen stores) that could elucidate the mechanisms of action for fetal deaths. Luebker et al. (2005a) measured serum and liver PFOS levels, which allowed for validation of the Wambaugh et al. (2013) model's predicted serum TWA PFOS level. Although the study was designed to evaluate four PFOS dose levels, high mortality in the F1 offspring at the two highest dose levels resulted in a discontinuation of these dose levels, which limits the amount of data that can be used to establish dose-response relationships.

Calculations of Internal Dosimetric: TWA serum PFOS concentrations corresponding to external doses and exposure durations were predicted from a pharmacokinetic model (Wambaugh et al. 2013) using animal species-, strain-, and sex-specific parameters (see MRL approach section for details).

Human Equivalent Dose: HEDs were calculated based on the assumption that humans would have similar effects as the laboratory animal at a given serum concentration. HEDs that would result in steady-state serum concentrations of PFOS equal to the serum concentration selected as the POD were calculated using the first order single-compartment model (see MRL approach section for details).

Uncertainty Factor and Modifying Factor: The $NOAEL_{HED}$ is divided by a total uncertainty factor (UF) of 30 and modifying factor (MF) of 10:

- 3 UF for extrapolation from animals to humans with dosimetric adjustment
- 10 UF for human variability
- 10 MF for concern that immunotoxicity may be a more sensitive endpoint of PFOS toxicity than developmental toxicity

$MRL = NOAEL_{HED} \div (UFs \times MF)$
$0.000515 \text{ mg/kg/day} \div ((3 \times 10) \times 10) = 2x10^{-6} \text{ mg/kg/day}$

Although pharmacokinetic model parameters were not available for the strain/sex of the animals tested in the immunotoxicity studies, most of the studies did provide measured serum PFOS levels. The serum PFOS levels at the NOAEL and LOAEL doses are presented in Table A-17. The measured serum PFOS levels associated with altered immune responses are approximately 1–10 times lower than the serum concentration predicted to occur at the NOAEL dose. These data suggest that immunotoxicity may be a more sensitive effect than developmental toxicity.

Table A-17. Measured Serum PFOS Levels at the NOAEL and LOAEL Doses for Immunological Effects

Effect, species and exposure duration		Dose (mg/kg/day)	Measured mean serum PFOS (µg/mL)	Reference
Impaired response to sRBC in mice exposed for 60 days	NOAEL	0.0083	0.674	Dong et al. 2009
	LOAEL	0.083	7.132	

Table A-17. Measured Serum PFOS Levels at the NOAEL and LOAEL Doses for Immunological Effects

Effect, species and exposure duration		Dose (mg/kg/day)	Measured mean serum PFOS (µg/mL)	Reference
Impaired response to sRBC in mice exposed for 60 days	NOAEL	0.0167	2.36	Dong et al. 2011
	LOAEL	0.083	10.75	
Decreased resistance to influenza virus in mice exposed for 21 days	NOAEL	0.005	0.189	Guruge et al. 2009
	LOAEL	0.025	0.670	
Suppressed response to sRBC in mice exposed for 28 days	NOAEL	0.00016	0.0178	Peden-Adams et al. 2008
	LOAEL	0.00166	0.0915	

PFOS = perfluorooctane sulfonic acid; sRBC = sheep red blood cell

A candidate MRL was calculated using the NOAEL of 0.0167 mg/kg/day identified in the Dong et al. (2011). This study was selected over the other immunotoxicity studies because it identified the highest NOAEL for immunotoxicity and it had the longest exposure duration; the Peden-Adams et al. (2008) was not selected because the LOAEL of 0.00166 mg/kg/day is not supported by the other three studies. A TWA concentration was estimated using a similar approach described for PFHxS and PFNA in the MRL approach section. The estimated TWA concentration was 1.2 µg/mL for the 0.0167 mg/kg/day; this estimated TWA concentration was used to calculate a HED of 0.000083 mg/kg/day. A candidate MRL of $3x10^{-6}$ was calculated using an uncertainty factor of 30 (3 for extrapolation from animals to humans using dosimetric adjustments and 10 for human variability). This MRL is similar to the MRL calculated from the Luebker et al. (2005a) study and lends support to using the additional modifying factor of 10 to account for the lack of pharmacokinetic modeling parameters for the mouse strains tested for immunotoxicity.

Other Additional Studies or Pertinent Information that Lend Support to this MRL: A discussion of the findings from epidemiological studies is presented in the MRL introduction section.

Agency Contacts (Chemical Managers): Melanie Buser

APPENDIX A

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorooctane sulfonic acid (PFOS)
CAS Numbers: 1763-23-1
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Chronic

MRL Summary: ATSDR did not identify an adequate study with an exposure duration of ≥365 days. Although adequate data are available for intermediate-duration exposure, ATSDR does not extrapolate across exposure duration.

Rationale for Not Deriving an MRL: Immune function was not examined following chronic-duration oral exposure in laboratory animal studies; the only chronic-duration oral study (Butenhoff et al. 2012b; Thomford 2002b), did not find histological alterations in immune tissues (lymph nodes, spleen, and thymus) in rats at doses as high as 1.04 mg/kg/day. Impaired immune function was the most sensitive endpoint in intermediate-duration mouse studies. Given the concern that immunotoxicity may occur at lower doses than liver toxicity, a chronic-duration oral MRL for PFOS is not recommended at this time.

One study has evaluated the chronic toxicity of PFOS in laboratory animals. Histological alterations in the liver were the primary effects observed in rats exposed to PFOS in the diet for 2 years (Butenhoff et al. 2012b; Thomford 2002b). Centrilobular hepatocellular hypertrophy was observed in rats exposed to ≥0.1 mg/kg/day. At 1.04 mg/kg/day, increases in the incidence of single cell necrosis and cystic degeneration were observed in the liver. Decreases in body weight were observed at 1.04 mg/kg/day in female rats. Thus, the 1.04 mg/kg/day dose was identified as the lowest LOAEL for this study. Epidemiological data (Dalsager et al. 2016; Dong et al. 2013; Fei et al. 2010; Grandjean et al. 2012, 2016; Granum et al. 2013; Kielsen et al. 2016; Mogensen et al. 2015a; Stein et al. 2016a; Zhu et al. 2016) suggest that the immune system is a sensitive target of PFOS toxicity following long-term exposures, which is supported by intermediate-duration PFOS laboratory animal studies (Dong et al. 2009, 2011; Guruge et al. 2009; Peden-Adams et al. 2008).

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorohexane sulfonic acid (PFHxS)
CAS Numbers: 355-46-4
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration oral MRL for PFHxS.

Rationale for Not Deriving an MRL: The acute oral database for PFHxS was not considered adequate for derivation of an MRL due to the short duration of the only available study and the lack of pharmacokinetic model parameters for calculating an HED.

In the only available study of PFHxS in laboratory animals, Viberg et al. (2013) reported altered spontaneous behavior and habituation in adult mice administered a single gavage dose of 9.2 mg/kg/day PFHxS on PND 10; no alterations were observed at 6.1 mg/kg/day. This single exposure study was not considered adequate as the basis of an acute-duration MRL for PFHxS due to the uncertainty of whether an MRL based on this study would be protective for repeated exposures or for other potential sensitive endpoints, such as immunotoxicity.

For perfluoroalkyls, ATSDR has used the approach of predicting TWA serum perfluoroalkyl levels in laboratory animals and calculating HEDs for these serum concentrations. For PFOA and PFOS, the Wambaugh et al. (2013) pharmacokinetic model was utilized for predicting the TWA serum perfluoroalkyl concentrations. However, strain-, sex-, and compound-specific model parameters are not available for other perfluoroalkyls, thus precluding deriving MRLs for other perfluoroalkyls. Other approaches such as “read across” (i.e., using data for a particular endpoint from one chemical to predict the same endpoint for another chemical that has similar chemical structure or mechanisms of action) or equivalency factors were considered for the other perfluoroalkyls; however, there are limited data available that would allow for comparison of the toxicity and toxicokinetic properties of different perfluoroalkyls. Peters and Gonzalez (2011) noted that the toxic equivalency factor approach would not be suitable for perfluoroalkyls because the current data suggest that the toxicity of these compounds appear to be mediated by multiple receptors, including PPARα, CAR, and PXR, and that there may be species differences in the response mediated by different receptors. Additionally, available data suggest that there are qualitative differences in the toxicities of various perfluoroalkyls.

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:**	Perfluorohexane sulfonic acid (PFHxS)
CAS Numbers:	355-46-4
Date:	March 2020
Profile Status:	Final
Route:	Oral
Duration:	Intermediate
MRL:	$2x10^{-5}$ mg/kg/day
Critical Effect:	Thyroid follicular epithelial hypertrophy/hyperplasia
Reference:	Butenhoff et al. 2009a
Point of Departure:	0.0047 mg/kg/day
Uncertainty Factor:	30
Modifying Factor:	10
LSE Graph Key:	33
Species:	Rat

MRL Summary: An intermediate-duration oral MRL of $2x10^{-5}$ mg/kg/day was derived for PFHxS based on thyroid follicular epithelial hypertrophy/hyperplasia in adult male rats administered via gavage PFHxS for a minimum of 42 days (Butenhoff et al. 2009a). The MRL is based on a HED NOAEL of 0.0047 mg/kg/day and a total uncertainty factor of 30 (3 for extrapolation from animals to humans with dosimetric adjustments and 10 for human variability) and a modifying factor of 10 for database limitations.

Selection of the Critical Effect: Four intermediate-duration studies in laboratory animals have been identified for PFHxS. In a developmental toxicity study, increased incidences of thyroid follicular cells hypertrophy/hyperplasia were observed in F0 male rats administered ≥3 mg/kg/day (Butenhoff et al. 2009a). Increased liver weight and centrilobular hepatocellular hypertrophy were also observed in the males at ≥3 mg/kg/day. Consistent with the Hall et al. (2012), the liver effects were not considered a relevant endpoint for humans. Although there is uncertainty regarding the exact, and possibly multiple, mechanism(s) for these liver effects, peroxisome proliferation is a likely contributor, a mechanism that cannot be reliably extrapolated to humans (Hall et al. 2012). Therefore, increases in liver weight and hepatic lipid levels and alterations in serum lipid levels observed in rats and mice, in the absence of other degenerative lesions, were not considered appropriate endpoints for deriving MRLs.

No reproductive or developmental effects were reported in the Butenhoff et al. (2009a) study. A second developmental toxicity study reported decreases in serum thyroxine levels in rat dams and pups administered 5 mg/kg/day PFHxS on GDs 7–22 (Ramhøj et al. 2018); no alterations in pup birth weight or weight gain were observed. In a 1-generation reproductive/developmental toxicity study, decreases in the number of pups per litter were observed in the offspring of mice administered 1 mg/kg/day (Chang et al. 2018). At 3 mg/kg/day, single cell necrosis and microvascular fatty changes were observed at 3 mg/kg/day. Liver effects (decreases in serum lipids, increases in hepatic triglyceride levels, and increases in liver weight) were also observed in mice exposed to 6 mg/kg/day PFHxS in the diet for 4–6 weeks (Bijland et al. 2011) and mice administered 0.3 mg/kg/day (Chang et al. 2018). Using the Hall et al. (2012) criteria (see Section 2.9 for a discussion of the criteria), the liver effects were not considered relevant for human risk assessment. Thus, the lowest LOAEL identified in intermediate-duration studies was 3 mg/kg/day for thyroid effects.

There is some uncertainty regarding the selection of thyroid alterations as the critical effect. Butenhoff et al. (2009a) suggested that the histological alterations in the thyroid may be secondary to the liver effects

(hepatocellular hypertrophy). The alteration may be due to binding competition between PFHxS and thyroid hormones and possible induction of thyroid hormone metabolism by the liver. Ramhøj et al. (2018) reported decreases in serum T4 levels but did not evaluate possible thyroid gland histological alterations. The Chang et al. (2018) 1-generation reproduction study did not find alterations in serum TSH levels in mice.

A limited number of epidemiological studies have examined potential thyroid effects. Two epidemiological studies have examined thyroid disease associated with PFHxS exposure (Chan et al. 2011; Wen et al. 2013); one study found increased risk of subclinical hypothyroidism and subclinical hyperthyroidism among women (Wen et al. 2013) and the second study did not find an increased risk of hypothyroxinemia (Chan et al. 2011). The small number of studies precludes evaluating the possible association between PFHxS exposure and thyroid disease in humans. A meta-analysis of epidemiological data (Kim et al. 2018) found an inverse correlation between serum PFHxS levels and total T4 levels in the general population; there was no correlation among pregnant women. No associations were found for free T4, total T3, or TSH.

Species-related differences in thyroid parameters between rats and humans also add to the uncertainty. Some differences include higher rate of T4 production in rats than in humans, and very low levels of thyroxine binding globulin compared to high levels in humans, and sex-related differences in serum TSH levels (higher levels in males compared to females) in rats, but not in humans (Choksi et al. 2003). It is not known if these species differences would influence the relative toxicity of PFHxS.

Selection of the Principal Study: Since the liver effects were not considered relevant to humans, the lowest LOAEL identified for PFHxS was 1 mg/kg/day for decreases in the number of pups per litter identified in the Chang et al. (2018) study. The investigators noted that the toxicological significance of this alteration was uncertain because there was no clear dose-response and no alterations in the number of implantation sites, number of viable pups, or pup to implant ratios. Thus, the Butenhoff et al. (2009a) study, which reported thyroid effects in male rats at LOAEL of 3 mg/kg/day, with a NOAEL of 1 mg/kg/day, was selected as the principal study.

Summary of the Principal Study:

Butenhoff JL, Chang SC, Ehresman DJ, et al. 2009a. Evaluation of potential reproductive and developmental toxicity of potassium perfluorohexanesulfonate in Sprague Dawley rats. Reprod Toxicol 27:331-341. (Results from this study are also reported in Hoberman and York 2003.)

The reproductive/developmental effects of PFHxS were studied in Sprague-Dawley rats (15/sex/group). Doses of 0, 0.3, 1, 3, or 10 mg/kg/day PFHxS were administered by gavage in an aqueous vehicle. Male rats were dosed beginning 14 days before cohabitation and continued until 1 day before sacrifice (a minimum of 42 days). Females were dosed beginning 14 days before cohabitation and continued until 1 day before sacrifice on PND 21 or GD 25 (rats that did not deliver a litter). Endpoints evaluated included: body weight, food consumption, estrous cycling, functional observational battery (FOB; tests of autonomic function, reactivity and sensitivity, excitability, gait and sensorimotor coordination, grip strength, and clinical signs), hematology and clinical chemistry, gross necropsy, organ weights, histopathology, and sperm evaluations. At parturition, litters were evaluated for size and viability; weight of the pups was also recorded. Pups were sacrificed on PND 22.

The following are findings for male F0 rats. Treatment with PFHxS did not affect survival and did not induce clinical signs that could be attributed to the chemical. Terminal body weight in the 10 mg/kg/day groups was approximately 6% lower than controls. Food consumption was not affected. Necropsy did not reveal any treatment-related changes. Histopathological effects were restricted to the liver and

thyroid of males treated with 3 and 10 mg/kg/day. Liver effects consisted of minimal to moderate hypertrophy of centrilobular hepatocytes. The affected hepatocytes were enlarged with an increased amount of dense eosinophilic granular cytoplasm. In the thyroid, the changes consisted of hypertrophy and/or hyperplasia of follicular cells. These effects could have been associated with the liver effects.

Significant organ weight changes consisted of increased absolute and relative liver weight at 3 and 10 mg/kg/day and decreased heart/brain weight at 10 mg/kg/day. Significant hematology changes consisted of decreased hemoglobin at 1 mg/kg/day, decreased red cell count and hematocrit at 3 mg/kg/day, and increased prothrombin time at 0.3 mg/kg/day. Increases in albumin, BUN, alkaline phosphatase, calcium, and albumin/globulin ratio were seen at 10 mg/kg/day. The investigators noted that the alterations in prothrombin time were slight and did not follow a specific trend and the values were within the normal range. There were no significant effects on the FOB or on motor activity and no significant effects on sperm parameters. There were no significant effects in any parameter monitored in F0 females or in pups. Treatment with PFHxS had no significant effect on the gross or microscopic morphology of the spleen, thymus, or lymph nodes. There were no significant effects on sex organ weights or gross or microscopic lesions in the reproductive organs of males and females. Fertility was not affected by treatment with PFHxS and there were no significant effects on sperm parameters. Estrous cycling was not affected by dosing with PFHxS. Treatment with PFHxS did not significantly affect any of the developmental parameters evaluated including gestation length, number of dams delivering litters, averages for implantation sites per delivered litter, number of dams with stillborn pups, number of dams with no live pups, dams with all pups dying, number of pups surviving per litter, sex ratios, litter size, or pup weight. Also, necropsy of the pups showed no treatment-related effects, and pup liver weight was not affected. Treatment with PFHxS had no significant effect on the FOB or motor activity. The battery tested autonomic functions, reactivity and sensitivity to stimuli, excitability, gait and sensorimotor coordination, limb grip strength, and abnormal clinical signs.

Strengths and Weaknesses: The Butenhoff et al. (2009a) study is a well-designed study evaluating male and female reproductive endpoints and developmental endpoints. An adequate number of animals were exposed to three PFHxS dose levels. An additional strength of the study is the inclusion of parameters that evaluated potential neurobehavioral effects, hematological and clinical chemistry parameters, and histopathological examination of the liver and thyroid. Measurement of serum PFHxS levels allowed for estimation of a TWA serum concentration that could be used to calculate a HED. One weakness of the study is that thyroid hormone levels were not measured; these data could have been useful in evaluating the observed histological alterations in the thyroid gland.

Selection of the Point of Departure for the MRL: The HED of the NOAEL of 1 mg/kg/day identified in the Butenhoff et al. (2009a) developmental toxicity study was selected as the POD for the MRL. A TWA serum PFHxS concentration of 73.22 µg/mL was estimated for the adult males exposed to 1 mg/kg/day (Butenhoff et al. 2009a).

Human Equivalent Dose: The HED was calculated based on the assumption that humans would have similar effects as the laboratory animal at a given serum concentration. HEDs that would result in steady-state serum concentrations of PFHxS equal to the estimated TWA serum concentration selected as the POD were calculated using the first-order single-compartment model (see MRL approach section for details). The HED was calculated using Equation A-6 where C_{ss} is 73.22 µg/mL, K_e=2.23x10^{-4}; V_d=0.287, and AF=1. The $NOAEL_{HED}$ is 0.0047 mg/kg/day

Uncertainty Factor and Modifying Factor: The $NOAEL_{HED}$ is divided by a total uncertainty factor (UF) of 30 and a modifying factor (MF) of 10:

- 3 UF for extrapolation from animals to humans with dosimetric adjustment
- 10 UF for human variability

- 10 MF for database limitations to account for small number of studies examining the toxicity of PFHxS following intermediate-duration exposure and the limited scope of these studies in particular studies examining immunotoxicity, a sensitive endpoint for other perfluoroalkyls.

  MRL = $NOAEL_{HED}$ ÷ (UFs x MF)
  0.0047 mg/kg/day ÷ ((10 x 3) x 10) = $2x10^{-5}$ mg/kg/day

Other Additional Studies or Pertinent Information that Lend Support to this MRL: A discussion of the findings from epidemiological studies is presented in the MRL introduction section. An empirical steady state model was used to estimate the HED from a POD based on a 42-day exposure of adult rats. The resulting HED is lower than the daily 42-day human dose that would be expected to achieve the POD serum concentration.

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorohexane sulfonic acid (PFHxS)
CAS Numbers: 355-46-4
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Chronic

MRL Summary: No chronic duration studies were identified for PFHxS. Although adequate data are available for intermediate-duration exposure, ATSDR does not extrapolate across exposure duration.

Rationale for Not Deriving an MRL: No chronic-duration oral studies in laboratory animals were identified for PFHxS.

Agency Contacts (Chemical Managers): Melanie Buser

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorononanoic acid (PFNA)
CAS Numbers: 375-95-1
Date: March 2020
Profile Status: Final
Route: Inhalation
Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration inhalation MRL for PFNA.

Rationale for Not Deriving an MRL: The only available inhalation exposure study for PFNA (Kinney et al. 1989) was not considered suitable for derivation of an inhalation MRL due to its lack of histopathological examination and short exposure duration.

In the only available inhalation exposure study for PFNA, Kinney et al. (1989) noted labored breathing in rats during and after a 4-hour nose-only exposure to 590 mg/m^3 exposure; the study also reported an increase in relative liver weight 5 days after exposure to $\geq$67 mg/m^3.

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorononanoic acid (PFNA)
CAS Numbers: 375-95-1
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration oral MRL for PFNA.

Rationale for Not Deriving an MRL: An acute-duration oral MRL cannot be derived for PFNA because the study identifying the lowest dose for a non-hepatic effect (Fang et al. 2009) did not measure serum PFNA levels, which are needed for estimating an HED.

A number of studies examined the toxicity of PFNA in rats and mice exposed for acute durations. These studies reported immune, liver, and body weight effects. Immune effects included increases in thymus weight in rats at 1 mg/kg/day (Fang et al. 2009), decreases in thymus and spleen weights in rats at 3 mg/kg/day (Fang et al. 2009, 2010), and an alteration in splenic lymphocyte phenotypes in mice at 1 mg/kg/day (Fang et al. 2008). In the only study examining immune function, no alterations in splenic lymphocyte response to ConA were observed at doses as high as 5 mg/kg/day in mice (Fang et al. 2008). Liver effects included increases in hepatic lipid levels at ≥0.2 mg/kg/day (Wang et al. 2015a), increases in liver weights at ≥0.2 mg/kg/day (Wang et al. 2015a; Kennedy 1987), serum lipid levels at ≥1 mg/kg/day (Fang et al. 2012a, 2012b), hepatocellular vacuolation at 5 mg/kg/day (Fang et al. 2012b), and increases in serum aminotransferases at 5 mg/kg/day (Wang et al. 2015a). Although there is uncertainty regarding the exact, and possibly multiple, mechanism(s) for these liver effects, peroxisome proliferation is a likely contributor, a mechanism that cannot be reliably extrapolated to humans (Hall et al. 2012). Therefore, increases in liver weight and hepatic lipid levels and alterations in serum lipid levels observed in rats and mice, in the absence of other degenerative lesions, were not considered appropriate endpoints for deriving MRLs.

Decreases in body weight were observed in rats and mice administered 5 mg/kg/day (Hadrup et al. 2016; Wang et al. 2015a).

Agency Contacts (Chemical Managers): Melanie Buser

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorononanoic acid (PFNA)
CAS Numbers: 375-95-1
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Intermediate
MRL: $3x10^{-6}$ mg/kg/day
Critical Effect: Decreased body weight and developmental delays
Reference: Das et al. 2015
Point of Departure: 0.001 mg/kg/day
Uncertainty Factor: 30
Modifying Factor: 10
LSE Graph Key: 39
Species: Mouse

MRL Summary: An intermediate-duration oral MRL of $3x10^{-6}$ mg/kg/day was derived for PFNA based on decreased body weight gain and developmental delays in the offspring of mice administered via gavage PFNA on GDs 1–17 (Das et al. 2015). The MRL is based on a HED NOAEL of 0.001 mg/kg/day and a total uncertainty factor of 30 (3 for extrapolation from animals to humans with dosimetric adjustments and 10 for human variability), and a modifying factor of 10 for database limitations.

Selection of the Critical Effect: The intermediate-duration database consists of three developmental toxicity studies in rats and mice and a 90-day study in mice. The lowest LOAEL for developmental toxicity was 1.1 mg/kg/day in mice administered PFNA on GDs 1–18; at this dose, decreases in litter size and pup survival were observed (Wolf et al. 2010). At higher doses (2–5 mg/kg/day), decreases in pup body weight, delays in postnatal development (Das et al. 2015; Rogers et al. 2014; Wolf et al. 2010), increases in pup systolic blood pressure (Rogers et al. 2014), and reduced nephron endowment (Rogers et al. 2014) were observed. A study of PPARα knockout mice did not find alterations pup body weight or postnatal development at 2 mg/kg/day (Wolf et al. 2010). In the 90-day study, decreased sperm motility, viability, and number; degenerative changes in seminiferous tubules; and decreased litter size (males mated to unexposed females) were observed at 0.5 mg/kg/day; no changes were observed at 0.2 mg/kg/day (Singh and Singh 2018). A summary of the observed effects is presented in Table A-18.

Table A-18. Summary of the Adverse Effects Observed in Laboratory Animals Following Intermediate-Duration Oral Exposure to PFNA

Species and exposure duration	Dose (mg/kg/day)	Effect	Reference
Parkes mouse 90 days	0.2	No effects reported	Singh and Singh 2018
	0.5	Decreased sperm motility, viability, and number; degenerative changes in seminiferous tubules; decreased litter size	

Table A-18. Summary of the Adverse Effects Observed in Laboratory Animals Following Intermediate-Duration Oral Exposure to PFNA

Species and exposure duration	Dose (mg/kg/day)	Effect	Reference
129S1/svlm mouse GDs 1–18 (offspring followed until PND 21)	0.83	No effects reported	Wolf et al. 2010
	1.1	Decreased litter size and pup survival	
	1.5	No effects reported	
	2.0	Decreased number of live pups per litter and decreased pup body weight gain	
CD-1 mouse GDs 1–17 (offspring followed until PND 287)	1	No effects reported	Das et al. 2015
	3	Decreased body weight gain and delayed eye opening, preputial separation, and vaginal opening	
	5	Decreased postnatal survival, 80% mortality between PND 2 and 10	
	10	Full litter resorption	
Sprague-Dawley rat GDs 1–20 offspring followed through PND 434)	5	Decreased birth weight, increased blood pressure at 10 weeks of age; reduced nephron endowment	Rogers et al. 2014

GD = gestation day; PFNA = perfluorononanoic acid; PND = postnatal day

Selection of the Principal Study: The lowest LOAEL was 0.5 mg/kg/day identified in the Singh and Singh (2018) reproductive toxicity study. However, this study could not be used to derive an MRL for PFNA because the investigators did not measure serum PFNA levels. Developmental toxicity, including decreases in pup survival, developmental delays, and decreases in birth weight have been observed in three studies. A comparison of the estimated TWA serum PFNA levels (Table A-19) for the Wolf et al. (2010) and Das et al. (2015) studies (measured serum levels were not available from the Rogers et al. 2014 study) showed that the lowest LOAEL for developmental effects was 10.9 µg/mL (Das et al. 2015); this study reported a NOAEL of 6.8 µg/mL. Thus, the Das et al. (2015) study was selected as the principal study for the MRL.

Table A-19. Summary of Estimated TWA Serum PFNA levels in Laboratory Animals Following Intermediate-Duration Oral Exposure

Species and exposure duration	Dose (mg/kg/day)	Estimated TWA serum PFNA (µg/mL)	Effect	Reference
Parkes mouse 90 days	0.2	Not calculated	No effects reported	Singh and Singh 2018
	0.5		Decreased sperm motility, viability, and number; degenerative changes in seminiferous tubules; decreased litter size	

Table A-19. Summary of Estimated TWA Serum PFNA levels in Laboratory Animals Following Intermediate-Duration Oral Exposure

Species and exposure duration	Dose (mg/kg/day)	Estimated TWA serum PFNA (µg/mL)	Effect	Reference
129S1/svlm mouse GDs 1–18 (offspring followed until PND 21)	0.83	4.47	No effects reported	Wolf et al. 2010
	1.1	11.6	Decreased litter size and pup survival	
	1.5	10.5	No effects reported	
	2.0	17.6	Decreased number of live pups per litter and decreased pup body weight gain

	3	10.9	Decreased body weight gain and delayed eye opening, preputial separation, and vaginal opening	
	5	39.7	Decreased postnatal survival, 80% mortality between PND 2 and 10	
	10	NA	Full litter resorption	
Sprague-Dawley rat GDs 1–20 (offspring followed through PND 434)	5	Not calculated	Decreased birth weight, increased blood pressure at 10 weeks of age; reduced nephron endowment	Rogers et al. 2014

GD = gestation day; PFNA perfluorononanoic acid; PND = postnatal day

Summary of the Principal Study:

Das KP, Grey BE, Rosen MB, et al. 2015. Developmental toxicity of perfluorononanoic acid in mice. Reprod Toxicol 51:133-144.

Groups of 8–10 timed-pregnant female CD-1 mice were administered via gavage 0, 1, 3, 5, or 10 mg/kg/day PNFA at a dosing volume of 10 ml/kg body weight in deionized water on GDs 1–17. On GD 17, selected mice from each group were sacrificed for maternal and fetal examination, while the remaining mice were allowed to give birth. Pups were observed for postnatal survival up to PND 24 as well as growth and development up to PND 287. The following parameters were used to assess toxicity: clinical observations, maternal body weight, pup body weight (pre- and postnatal), organ weights (liver, gravid uterus weight), number of implantation sites, percent of live fetuses, percent of prenatal loss per litter, and morphological changes (eye opening, vaginal opening, preputial separation).

Maternal weight loss beginning on GD 8 was observed at 10 mg/kg/day; on GD 13, the 10 mg/kg/day group weighed approximately 30% less than controls. The 10 mg/kg/day group was terminated on GD 13. Significant increases in full litter resorptions occurred at 10 mg/kg/day (7/7 compared to 2/8 in controls). There were no adverse effects on pregnancy outcome following *in utero* exposure to 5 mg/kg. Statistically significant dose-related increases in absolute and relative liver weights were observed in dams in the 1, 3, and 5 mg/kg/day groups examined on GD 17, as well as in dams examined on post-weaning day 28. There were no effects on the number of implants, number of live fetuses, or fetal body weight. Relative and absolute fetal liver weight were significantly increased; however, the increase did not appear to be dose-related. Visceral and skeletal examination of fetuses revealed no treatment-related

effects. Increases in postnatal deaths were observed in the 5 mg/kg/day offspring between PND 2 and 10; postnatal survival was approximately 20% on PND 10. Weight gain was significantly reduced in pups from the 3 and 5 mg/kg dose groups from PND 1 to 24. The changes in males were dose-related and persisted from PND 25 to 287. Weight reduction in females was less substantial in comparison with males and returned to control levels by 7 weeks of age. Relative pup liver weights were significantly increased at all doses up to PND 24 and at 3 and 5 mg/kg/day on PND 42. No significant effects on liver weight were detectable by PND 70. Postnatal development (eye opening, preputial separation, and vaginal opening) was significantly delayed (by 2–7 days) at 3 and 5 mg/kg/day.

The serum PFNA levels (means±standard error of the mean) in the pregnant dams (measured at term) were 0.015±0.003, 13.67±1.45, 21.85±3.17, and 79.48±22.69 μg/mL in the 0. 1, 3, and 5 mg/kg/day groups (serum concentrations were provided to ATSDR by C. Lau).

Strengths and Weaknesses: Das et al. (2015) is a well-designed developmental toxicity study in mice. One strength of the study is that it included evaluation of potential anomalies in fetuses, as well as monitoring postnatal growth and development through PND 70. An additional strength of the study is the inclusion of serum and liver PFNA measurements, which allow for cross-species evaluations. Inclusion of measurement of the expression of genes related to PPARα, CAR, and PXR provides valuable mechanisms-of-action data. Although the study tested four PFNA dose levels, increases in maternal morbidity at 10 mg/kg/day and pup lethality at 5 mg/kg/day limited the data available to establish dose-response relationships.

Selection of the Point of Departure for the MRL: The HED of the NOAEL of 1 mg/kg/day identified in the Das et al. (2015) developmental toxicity study was selected as the POD for the MRL. A TWA serum PFNA concentration was estimated for dams using the serum concentration in the control group (0.015 μg/mL) as the baseline concentrations and the terminal concentration for the 1 mg/kg/day group (13.67 μg/mL) resulting in an estimated TWA serum concentration of 6.8 μg/mL.

Human Equivalent Dose: The HED was calculated based on the assumption that humans would have similar effects as the laboratory animal at a given serum concentration. HEDs that would result in steady-state serum concentrations of PFNA equal to the estimated TWA serum concentration selected as the POD were calculated using the first-order single-compartment model (see MRL approach section for details). The HED was calculated using Equation A-6 where C_{ss} is 6.8 μg/mL, K_e=7.59x10^{-4}; V_d=0.2, and AF=1. The K_e was calculated using the 2.5-year elimination half-life in young women; this value was selected over the 4.3-year value for the combined group of males and older females because the MRL is based on a developmental toxicity study. The $NOAEL_{HED}$ is 0.001 mg/kg/day.

Uncertainty Factor and Modifying Factor: The $NOAEL_{HED}$ is divided by a total uncertainty factor (UF) of 30 and modifying factor (MF) of 10:

- 3 UF for extrapolation from animals to humans with dosimetric adjustment
- 10 UF for human variability
- 10 MF for database limitations to account for small number of studies examining the toxicity of PFNA following intermediate-duration exposure and the limited scope of these studies. The available data suggest that reproductive toxicity may be a more sensitive endpoint than developmental toxicity; however, this endpoint could not be used to derive the MRL because the Singh and Singh (2018) study did not measure serum PFNA levels. Additionally, intermediate-duration studies for other perfluoroalkyls suggest that immune function is a sensitive target of toxicity; however, this potential endpoint has not been examined in intermediate-duration PFNA studies.

$$MRL = NOAEL_{HED} \div (UFs \times MF)$$

0.001 mg/kg/day ÷ ((10 x 3) x 10) = $3x10^{-6}$ mg/kg/day

Other Additional Studies or Pertinent Information that Lend Support to this MRL: A discussion of the findings from epidemiological studies is presented in the MRL introduction section.

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorodecanoic acid (PFDA)
CAS Numbers: 335-76-2
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration oral MRL for PFDA.

Rationale for Not Deriving an MRL: The available acute oral database for PFDA was not considered adequate for derivation of an MRL because the study identifying the lowest adverse effect level did not measure serum PFDA levels, which are needed to estimate HEDs.

Several laboratory animal studies have examined the acute oral toxicity of PFDA; most were limited in scope. The lowest LOAEL was 1 mg/kg/day for decreases in fetal weight in mice administered PFDA on GDs 6–15 (Harris and Birnbaum 1989). At 12.8 mg/kg/day, decreases in the number of live fetuses per litter were observed; maternal weight loss was also observed at this dose level (Harris and Birnbaum 1989). Another developmental toxicity study did not report alterations in performance on neurobehavioral tests in 2–4-month-old mice administered 10.8 mg/kg/day PFDA on PND 10 (Johansson et al. 2008). Other effects observed in acute exposure studies include decreases in maternal weight gain at 6.4 mg/kg/day (Harris and Birnbaum 1989), weight loss at ≥9.5 mg/kg/day in rats (Kawashima et al. 1995) and mice (Harris and Birnbaum 1989; Permadi et al. 1992, 1993), increases in T3 and T4 levels in mice at 80 mg/kg/day (Harris et al. 1989), decreases in spleen weight in mice at 80 mg/kg/day (Harris et al. 1989), and atrophy and lymphoid depletion in thymus and spleen in mice at 160 mg/kg/day (Harris et al. 1989). Liver effects included increases in liver weight at ≥2.4 mg/kg/day (Brewster and Birnbaum 1989; Harris et al. 1989; Kawashima et al. 1995; Permadi et al. 1992, 1993), increases in hepatic lipid levels at ≥9.5 mg/kg/day (Brewster and Birnbaum 1989; Kawashima et al. 1995), and hepatocellular hypertrophy at ≥20 mg/kg/day (Harris et al. 1989). Although there is uncertainty regarding the exact, and possibly multiple, mechanism(s) for these liver effects, peroxisome proliferation is a likely contributor, a mechanism that cannot be reliably extrapolated to humans (Hall et al. 2012). Therefore, increases in liver weight and hepatic lipid levels and alterations in serum lipid levels observed in rats and mice, in the absence of other degenerative lesions, were not considered appropriate endpoints for deriving MRLs.

To derive MRLs for perfluoroalkyls, ATSDR used the approach of predicting TWA serum perfluoroalkyl levels in laboratory animals or measured serum perfluoroalkyl levels and calculating HEDs for these serum concentrations. For PFOA and PFOS, the Wambaugh et al. (2013) pharmacokinetic model was utilized for predicting the TWA serum perfluoroalkyl concentrations. However, strain-, sex-, and compound-specific model parameters are not available for other perfluoroalkyls. The Harris and Birnbaum (1989) study, which identified the lowest adverse effect level, did not measure maternal serum PFDA levels. Thus, HEDs could not be calculated using animal serum PFDA levels. Other approaches such as “read across” or equivalency factors were considered; however, there are limited data available that would allow for comparison of the toxicity and toxicokinetic properties of different perfluoroalkyls. Peters and Gonzalez (2011) noted that the toxic equivalency factor approach would not be suitable for perfluoroalkyls because the current data suggest that the toxicity of these compounds appear to be mediated by multiple receptors, including PPARα, CAR, and PXR, and that there may be species differences in the response mediated by different receptors. Additionally, available data suggest that there are qualitative differences in the toxicities of various perfluoroalkyls.

***Chemical Name*:** Perfluorodecanoic acid (PFDA)
CAS Numbers: 335-76-2
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Intermediate

MRL Summary: There are insufficient data for derivation of an intermediate-duration oral MRL for PFDA.

Rationale for Not Deriving an MRL: Two studies conducted by Frawley et al. (2018) evaluated the intermediate-duration toxicity of PFDA. In a 28-day study in rats, increases in mean corpuscular hemoglobin and mean corpuscular hemoglobin concentration and decreases in phagocytosis by fixed tissue macrophages in the liver were observed in female rats administered 0.25 mg/kg/day PFDA. At 0.5 mg/kg/day, single cell necrosis was observed. In the second study, decreases in splenic T-cells and macrophages were observed in mice administered 1.25 mg/kg PFDA once a week for 4 weeks.

The Frawley et al. (2018) study was not considered for the principal study since it did not measure serum PFDA levels.

***Chemical Name*:** Perfluoroundecanoic acid (PFUnA)
CAS Numbers: 2058-94-8
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Intermediate

MRL Summary: There are insufficient data for derivation of an intermediate-duration oral MRL for PFUnA.

Rationale for Not Deriving an MRL: Intermediate-duration oral database was considered inadequate for derivation of an MRL for PFUnA because the only available study did not measure serum PFUnA levels, which are needed to calculated HEDs (see MRL approach in Appendix A introduction).

One study was identified that examined the oral toxicity of PFUnA in laboratory animals. In this study, decreases in body weight, hematological alterations, increases in liver weight, and centrilobular hypertrophy were observed in rat dams administered 1.0 mg/kg/day for 41–46 days (Takahashi et al. 2014). The study also found decreases in pup body weight on PNDs 0 and 4 at 1.0 mg/kg/day.

APPENDIX A

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorobutane sulfonic acid (PFBS)
CAS Numbers: 375-73-5
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Intermediate

MRL Summary: There are insufficient data for derivation of an intermediate-duration oral MRL for PFBS.

Rationale for Not Deriving an MRL: Several studies have evaluated the toxicity of PFBS following intermediate-duration oral exposure and have identified several targets of toxicity. However, none of these studies included measurement of serum PFBS levels that are needed to calculate a HED and MRL derivation.

Limited data available on the toxicity of PFBS in laboratory animals have identified the liver, kidneys, stomach, and hematological systems and the developing organism as targets of toxicity. Decreases in hemoglobin and hematocrit levels were observed in male rats administered 200 mg/kg/day PFBS for 90 days (Lieder et al. 2009a); decreases in erythrocyte levels were observed at 600 mg/kg/day. Administration of 600 mg/kg/day for 90 days also resulted in tubular and ductal papillary epithelial hyperplasia in the kidneys and necrosis and hyperplasia/hyperkeratosis in the forestomach (Lieder et al. 2009a). Effects in the liver consisted of decreases in plasma triglyceride levels in mice exposed to 30 mg/kg/day for 4–6 weeks (Bijland et al. 2011), increases in absolute and relative liver weight in male rats administered 300 mg/kg/day for at least 70 days (Lieder et al. 2009b) or 900 mg/kg/day for 28 days (3M 2001), and hepatocellular hypertrophy in rats administered 1,000 mg/kg/day in a 2-generation study (Lieder et al. 2009b). In general, no biologically relevant alterations in performance on FOB tests or motor activity tests were observed in rats administered 900 mg/kg/day PFBS for 28 days (3M 2001) or 600 mg/kg/day for 90 days (Lieder et al. 2009a).

Decreases in fetal body weight were observed in two studies involving administration of PFBS to rats on GDs 6–20 (York 2002, 2003a); one study reported a LOAEL of 1,000 mg/kg/day (York 2002) and the other a LOAEL of 2,000 mg/kg/day with a NOAEL of 1,000 mg/kg/day (York 2003a). In a developmental toxicity mouse study, decreases in pup body weight, developmental delays (eye opening and vaginal opening), impaired development of the reproductive system (delay in first estrous, decreases in ovarian follicles, decreases in uterine endometrial and myometrial thickness), and decreases in total T4 and T3 and increases in TSH were observed in the offspring of mice administered 200 mg/kg/day PFBS (Feng et al. 2017). Decreases in maternal total T4, free T4, and total T3 and increases in TSH were observed at 200 mg/kg/day.

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorobutanoic acid (PFBA)
CAS Numbers: 375-22-4
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration oral MRL for PFBA.

Rationale for Not Deriving an MRL: Laboratory animal studies for other perfluoroalkyls have identified immunotoxicity and developmental toxicity as sensitive endpoints following acute-duration oral exposure; these potential targets have not been investigated for PFBA. Thus, the database was considered inadequate for identifying a critical endpoint and evaluating dose-response relationships.

Three studies have examined the acute toxicity of PFBA in laboratory animals for a limited number of potential endpoints. Ikeda et al. (1985) reported that administration of approximately 20 mg/kg/day PFBA in the diet to male rats for 2 weeks did not significantly affect relative liver weight, but increased catalase activity in liver homogenates by 42% and induced peroxisome proliferation, as assessed by electron microscopy. In a similar study, dietary administration of approximately 78 mg/kg/day PFBA to male mice for 10 days induced a 63% increase in absolute liver weight (Permadi et al. 1992). The increase in liver weight was accompanied by changes in enzymes involved in drug metabolism and/or in deactivation of reactive oxygen species; however, PFBA did not have a significant effect on parameters of peroxisomal fatty acid β-oxidation (Permadi et al. 1993). In a more comprehensive study, no significant effect on a wide range of endpoints including body and organ weights, hematology and clinical chemistry, and histopathology were observed in rats administered 184 mg/kg/day for 5 days (3M 2007a).

Agency Contacts (Chemical Managers): Melanie Buser

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorobutanoic acid (PFBA)
CAS Numbers: 375-22-4
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Intermediate

MRL Summary: There are insufficient data for derivation of an intermediate-duration oral MRL for PFBA.

Rationale for Not Deriving an MRL: The available intermediate-duration database was not considered adequate for derivation of an MRL. Although the available studies have examined potentially sensitive endpoints and developmental toxicity and both studies measured serum PFBA levels, the database is missing a reliable estimate of elimination half-life in humans. Chang et al. (2008b) reported serum half-lives in small groups of subjects (<10 subjects); only 2 of the subjects were females. Because developmental toxicity is one of the more sensitive endpoints, data from females is needed in order to estimate the HED.

The intermediate-duration oral database for PFBA consists of a developmental study in mice (Das et al. 2008) and 28- and 90-day gavage studies in rats (Butenhoff et al. 2012a; van Otterdijk 2007a, 2007b). In the developmental study, PFBA administered to pregnant mice on GDs 1–17 did not affect newborn weight gain or viability (Das et al. 2008). The most sensitive response was a delay in eye opening in the pups at maternal doses of PFBA of 35 mg/kg/day. In the 28- and 90-day studies, hyperplasia/hypertrophy of the follicular epithelium of the thyroid and hepatocellular hypertrophy were observed at ≥30 mg/kg/day (Butenhoff et al. 2012a; van Otterdijk 2007a, 2007b). In addition, the 90-day study reported hematological alterations in male rats dosed with 30 mg/kg/day PFBA. The NOAEL for these effects was 6 mg/kg/day.

Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration oral MRL for PFDoDA.

Rationale for Not Deriving an MRL: The database was considered inadequate for derivation of an MRL.

Two studies have examined the acute-oral toxicity of PFDoDA. Shi et al. (2007) reported decreases in body weight and decreases in serum testosterone and estradiol levels in rats following a 14-day gavage administration of 5 mg/kg/day (Shi et al. 2007). The study also reported an increase in serum cholesterol levels at 10 mg/kg/day. In the second study, Zhang et al. (2008) found increases in liver weight and hepatic triglyceride and cholesterol levels in rats administered via gavage ≥5 mg/kg/day for 14 days; these liver effects were not considered relevant to humans. Given the limited number of endpoints examined in Shi et al. (2007) this study, including the lack of histopathological examination, this study was not considered suitable for the derivation of an MRL.

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorododecanoic acid (PFDoDA)
CAS Numbers: 307-55-1
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Intermediate

MRL Summary: There are insufficient data for derivation of an intermediate-duration oral MRL for PFDoDA.

Rationale for Not Deriving an MRL: Three intermediate-duration studies examined the oral toxicity of PFDoDA. Decreases in serum estradiol and increases in serum cholesterol were observed in pubertal females exposed to 3 mg/kg/day PFDoDA on PNDs 24–72 (Shi et al. 2009b). In a second study by this group, decreases in serum testosterone levels were observed in male rats administered 0.2 mg/kg/day PFDoDA for 110 days (Shi et al. 2009a). In a one-generation reproductive/developmental toxicity study, increases in maternal deaths were observed in rats administered 2.5 mg/kg/day PFDoDA prior to mating and throughout gestation, and lactation days 1–5 (Kato et al. 2015). Other effects observed in the male and female parental animals administered 2.5 mg/kg/day included decreases in body weight, decreases in mean corpuscular volume and reticulocytes, single cell hepatocellular necrosis (females only), pancreatic interstitial edema (females only), atrophy of the thymic cortex (females only), atrophy of the adrenal cortex (males only), decrease forelimb grip strength (males only), hemorrhage at the implantation site, and continuous diestrus in unmated females (Kato et al. 2015). The study also reported decreases in pup body weight in the only litter with live pups.

The Shi et al. (2009a) study identified the lowest LOAEL of 0.5 mg/kg/day. However, this study was not considered suitable for MRL derivation because it examined a limited number of endpoints (body weight and reproductive toxicity in males). The Kato et al. (2015) study examined a wide range of endpoints, but effects were only observed at a lethal dose.

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorododecanoic acid (PFDoDA)
CAS Numbers: 307-55-1
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Chronic

MRL Summary: There are insufficient data for derivation of a chronic-duration oral MRL for PFDoDA.

Rationale for Not Deriving an MRL: No chronic-duration oral studies in laboratory animals were identified for PFDoDA.

Agency Contacts (Chemical Managers): Melanie Buser

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorooctanesulfonamide (FOSA)
CAS Numbers: 754-91-6
Date: March 2020
Profile Status: Final
Route: Inhalation
Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration inhalation MRL for FOSA.

Rationale for Not Deriving an MRL: No inhalation studies in laboratory animals were identified for FOSA.

Agency Contacts (Chemical Managers): Melanie Buser

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorooctanesulfonamide (FOSA)
CAS Numbers: 754-91-6
Date: March 2020
Profile Status: Final
Route: Inhalation
Duration: Intermediate

MRL Summary: There are insufficient data for derivation of an intermediate-duration inhalation MRL for FOSA.

Rationale for Not Deriving an MRL: No inhalation studies in laboratory animals were identified for FOSA.

Agency Contacts (Chemical Managers): Melanie Buser

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorooctanesulfonamide (FOSA)
CAS Numbers: 754-91-6
Date: March 2020
Profile Status: Final
Route: Inhalation
Duration: Chronic

MRL Summary: There are insufficient data for derivation of a chronic-duration inhalation MRL for FOSA.

Rationale for Not Deriving an MRL: No inhalation studies in laboratory animals were identified for FOSA.

Agency Contacts (Chemical Managers): Melanie Buser

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorooctanesulfonamide (FOSA)
CAS Numbers: 754-91-6
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration oral MRL for FOSA.

Rationale for Not Deriving an MRL: The acute-duration database for FOSA was not considered adequate for identifying critical targets of toxicity because the Seacat and Luebker (2000) study only examined a limited number of potential endpoints and the potential developmental and immunological effects (sensitive targets for other perfluoroalkyls) were not examined.

One laboratory animal study evaluated the acute oral toxicity of FOSA. Seacat and Luebker (2000) did not find alterations in body weight or liver weight in rats administered a single dose of 5 mg/kg/day FOSA.

Agency Contacts (Chemical Managers): Melanie Buser

***Chemical Name*:** Perfluorohexanoic acid (PFHxA)
CAS Numbers: 307-24-4
Date: March 2020
Profile Status: Final
Route: Inhalation
Duration: Chronic

MRL Summary: There are insufficient data for derivation of a chronic-duration inhalation MRL for PFHxA.

Rationale for Not Deriving an MRL: No chronic-duration inhalation studies in laboratory animals were identified for PFHxA.

Agency Contacts (Chemical Managers): Melanie Buser

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorohexanoic acid (PFHxA)
CAS Numbers: 307-24-4
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Acute

MRL Summary: There are insufficient data for derivation of an acute-duration oral MRL for PFHxA.

Rationale for Not Deriving an MRL: The acute database for PFHxA was not considered adequate for derivation of an MRL because serum PFHxA levels at the lowest LOAEL were below the detection limit and an elimination half-life has not been estimated for humans; both of these toxicokinetic parameters are needed to estimate HEDs.

Two developmental toxicity studies conducted by Iwai and Hoberman (2014) examined the acute toxicity of PFHxA following gavage administration. Increases in stillborn pups and decreases in pup body weight were observed at 175 mg/kg/day; no effects were observed at 35 mg/kg/day. In the second study, decreases in birth weight and delayed eye opening was observed at 350 mg/kg/day; the NOAEL was 100 mg/kg/day. These studies were not considered adequate for derivation of an MRL because the measured serum PFHxA levels at 35 and 175 mg/kg/day groups were below the limit of detection. Additionally, the elimination half-life has not been estimated in humans.

Agency Contacts (Chemical Managers): Melanie Buser

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorohexanoic acid (PFHxA)
CAS Numbers: 307-24-4
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Intermediate

MRL Summary: There are insufficient data for derivation of an intermediate-duration oral MRL for PFHxA.

Rationale for Not Deriving an MRL: Five studies have evaluated the intermediate-duration toxicity of PFHxA in rats. A summary of the adverse effects observed in these studies is presented in Table A-20. These studies identify several targets of toxicity including the respiratory tract, erythrocytes, thyroid, thymus, and developing organism; the lowest LOAEL is 100 mg/kg/day for nasal lesions and decrease in body weight gain in males. None of the available studies evaluated immune function, which has been identified as a sensitive target in intermediate oral studies for other perfluoroalkyls.

The data are considered inadequate for MRL derivation because an elimination half-life has not been estimated in humans. Thus, a HED cannot be calculated and an MRL cannot be derived.

Table A-20. Summary of the Adverse Effects Observed in Laboratory Animals Following Intermediate-Duration Oral Exposure to PFHxA

Species and exposure duration	Dose (mg/kg/day)	Effect	Reference
Rat 92–93 days (GW) 30 M, 30 F	20	No effects observed	Loveless et al. 2009
	100	Degeneration/atrophy of nasal olfactory epithelium	
	500	Respiratory metaplasia, decreased RBC, hemoglobin, and hematocrit; increased reticulocytes; thyroid follicular epithelial hypertrophy	
Rat 110–120 days (premating, gestation, lactation) (GW) 20 M, 20 F	20	No effect observed	Loveless et al. 2009
	100	Decreased weight gain in males	
	500	Decreased maternal weight gain, decreased pup body weight during lactation period	
Rat 90 days (GW) 10 M, 10 F	10	No effects observed	Chengelis et al. 2009b
	50	No effects observed	
	200	Slight decrease in RBC, hemoglobin, and hematocrit and increase in reticulocytes	

Table A-20. Summary of the Adverse Effects Observed in Laboratory Animals Following Intermediate-Duration Oral Exposure to PFHxA

Species and exposure duration	Dose (mg/kg/day)	Effect	Reference
Rat 32–44 days (GW) 10–15 M, 10–15 F	50	No effects observed	Kirkpatrick 2005
	150	Decreased hemoglobin levels (males only)	
	315 (TWA dose)	Decreased hemoglobin levels (males only), increased reticulocyte levels (males only), thymic atrophy (females only)	
Rat GDs 1–20 (GW) 22 F	20	No effect observed	Loveless et al. 2009
	100	No effect observed	
	500	Decreased maternal weight gain; decreased fetal body weight	

F = female(s); GD = gestation day; (GW) = gavage in water; M = male(s); RBC = red blood cell; TWA = time-weighted average

Agency Contacts (Chemical Managers): Melanie Buser

MINIMAL RISK LEVEL (MRL) WORKSHEET

***Chemical Name*:** Perfluorohexanoic acid (PFHxA)
CAS Numbers: 307-24-4
Date: March 2020
Profile Status: Final
Route: Oral
Duration: Chronic

MRL Summary: There are insufficient data for derivation of a chronic-duration oral MRL for PFHxA.

Rationale for Not Deriving an MRL: The chronic duration oral database for PFHxA is not considered adequate for derivation of a chronic MRL because the only study available did not measure serum PFHxA levels and elimination half-life data are not available for humans. These toxicokinetic data are needed to derive HEDs.

One study has evaluated the chronic oral toxicity of PFHxA in laboratory animals (Klaunig et al. 2015). Exposure to female rats to 200 mg/kg/day resulted in hematological alterations (decreases in red blood cells and hemoglobin levels and increases in reticulocyte counts), renal effects (tubular degeneration, necrosis, increased urine volume and reduced specific gravity), and liver effects (necrosis); no adverse alterations were observed at 30 mg/kg/day or at 100 mg/kg/day in males. This study was not considered suitable for derivation of an MRL because serum PFHxA levels were not measured. Additionally, an elimination half-life has not been estimated in humans.

APPENDIX B. LITERATURE SEARCH FRAMEWORK FOR PERFLUOROALKYLS

The objective of the toxicological profile is to evaluate the potential for human exposure and the potential health hazards associated with inhalation, oral, or dermal/ocular exposure to perfluoroalkyls.

B.1 LITERATURE SEARCH AND SCREEN

A literature search and screen was conducted to identify studies examining health effects, toxicokinetics, mechanisms of action, susceptible populations, biomarkers, chemical interactions, physical and chemical properties, production, use, environmental fate, environmental releases, and environmental and biological monitoring data for perfluoroalkyls. ATSDR primarily focused on peer-reviewed articles without publication date or language restrictions. Non-peer-reviewed studies that were considered relevant to the assessment of the health effects of perfluoroalkyls have undergone peer review by at least three ATSDR-selected experts who have been screened for conflict of interest. The inclusion criteria used to identify relevant studies examining the health effects of perfluoroalkyls are presented in Table B-1.

Table B-1. Inclusion Criteria for the Literature Search and Screen

- Health Effects
  - Species
    - Human
    - Laboratory mammals
  - Route of exposure
    - Inhalation
    - Oral
    - Dermal (or ocular)
    - Parenteral (these studies will be considered supporting data)
  - Health outcome
    - Death
    - Systemic effects
    - Body weight effects
    - Respiratory effects
    - Cardiovascular effects
    - Gastrointestinal effects
    - Hematological effects
    - Musculoskeletal effects
    - Hepatic effects
    - Renal effects
    - Dermal effects
    - Ocular effects
    - Endocrine effects
    - Immunological effects
    - Neurological effects
    - Reproductive effects
    - Developmental effects

Table B-1. Inclusion Criteria for the Literature Search and Screen

Other noncancer effects
Cancer
Toxicokinetics
Absorption
Distribution
Metabolism
Excretion
PBPK models
Biomarkers
Biomarkers of exposure
Biomarkers of effect
Interactions with other chemicals
Potential for human exposure
Releases to the environment
Air
Water
Soil
Environmental fate
Transport and partitioning
Transformation and degradation
Environmental monitoring

Water
Sediment and soil
Other media
Biomonitoring
General populations
Occupation populations

B.1.1 Literature Search

The current literature search was intended to update the draft toxicological profile for perfluoroalkyls released for public comment in 2015. The following main databases were searched in March 2008, September/October 2013, May 2016, and September 2018:

- PubMed
- National Library of Medicine's TOXLINE
- Scientific and Technical Information Network's TOXCENTER

The search strategy used the chemical names, Chemical Abstracts Service (CAS) numbers, synonyms, and Medical Subject Headings (MeSH) terms for perfluoroalkyls. The query strings used for the literature search are presented in Table B-2.

The search was augmented by searching the Toxic Substances Control Act Test Submissions (TSCATS), NTP website, and National Institute of Health Research Portfolio Online Reporting Tools Expenditures and Results (NIH RePORTER) databases using the queries presented in Table B-3. Additional databases were searched in the creation of various tables and figures, such as the TRI Explorer, the Substance priority list (SPL) resource page, and other items as needed. Regulations applicable to perfluoroalkyls were identified by searching international and U.S. agency websites and documents.

Review articles were identified and used for the purpose of providing background information and identifying additional references. ATSDR also identified reports from the grey literature, which included unpublished research reports, technical reports from government agencies, conference proceedings and abstracts, and theses and dissertations.

[a]Several versions of the TSCATS database were searched, as needed, by CASRN including TSCATS1 via Toxline (no date limit), TSCATS2 via https://yosemite.epa.gov/oppts/epatscat8.nsf/ReportSearch?OpenForm (date restricted by EPA receipt date), and TSCATS via CDAT (date restricted by 'Mail Received Date Range'), as well as google for recent TSCA submissions.

The September 2018 results were:

- Number of records identified from PubMed, TOXLINE, and TOXCENTER (after duplicate removal): 941
- Number of records identified from other strategies: 153
- Total number of records to undergo literature screening: 1,094

B.1.2 Literature Screening

A two-step process was used to screen the literature search to identify relevant studies on perfluoroalkyls:

- Title and abstract screen
- Full text screen

Title and Abstract Screen. Within the reference library, titles and abstracts were screened manually for relevance. Studies that were considered relevant (see Table B-1 for inclusion criteria) were moved to the second step of the literature screening process. Studies were excluded when the title and abstract clearly indicated that the study was not relevant to the toxicological profile.

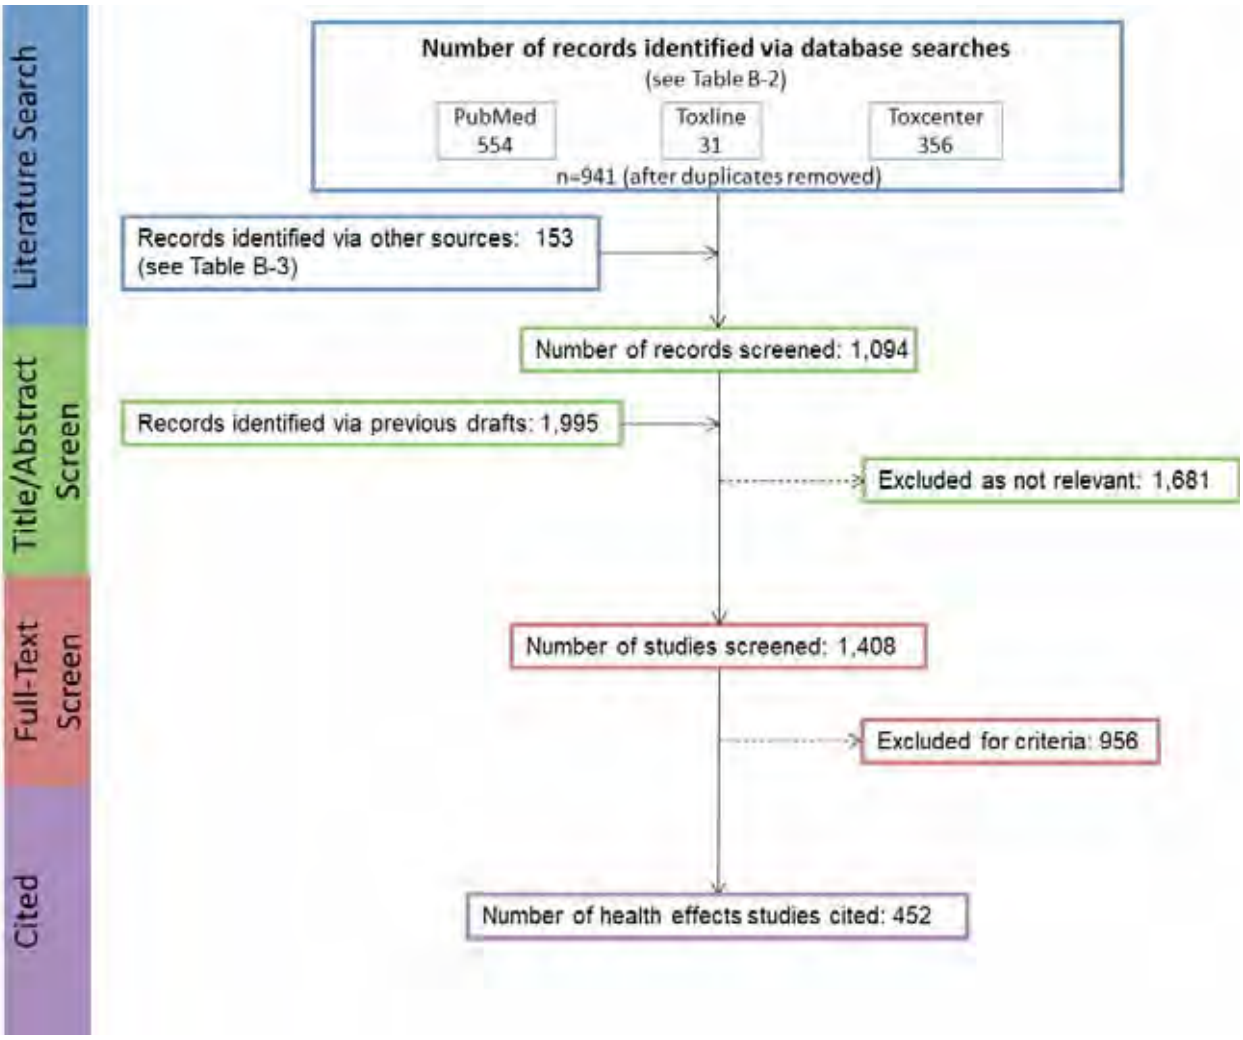
- Number of titles and abstracts screened: 1,094
- Number of studies considered relevant and moved to the next step: 1,408

Full Text Screen. The second step in the literature screening process was a full text review of individual studies considered relevant in the title and abstract screen step. Each study was reviewed to determine whether it was relevant for inclusion in the toxicological profile.

- Number of studies undergoing full text review: 1,408
- Total number of health effects studies cited in the profile: 452

A summary of the results of the literature search and screening is presented in Figure B-1.

Figure B-1. September 2018 Literature Search Results and Screen for Perfluoroalkyls



APPENDIX C. USER'S GUIDE

Chapter 1. Relevance to Public Health

This chapter provides an overview of U.S. exposures, a summary of health effects based on evaluations of existing toxicologic, epidemiologic, and toxicokinetic information, and an overview of the minimal risk levels. This is designed to present interpretive, weight-of-evidence discussions for human health endpoints by addressing the following questions:

1. What effects are known to occur in humans?

2. What effects observed in animals are likely to be of concern to humans?

3. What exposure conditions are likely to be of concern to humans, especially around hazardous waste sites?

Minimal Risk Levels (MRLs)

Where sufficient toxicologic information is available, ATSDR derives MRLs for inhalation and oral routes of entry at each duration of exposure (acute, intermediate, and chronic). These MRLs are not meant to support regulatory action, but to acquaint health professionals with exposure levels at which adverse health effects are not expected to occur in humans.

MRLs should help physicians and public health officials determine the safety of a community living near a hazardous substance emission, given the concentration of a contaminant in air or the estimated daily dose in water. MRLs are based largely on toxicological studies in animals and on reports of human occupational exposure.

MRL users should be familiar with the toxicologic information on which the number is based. Section 1.2, Summary of Health Effects, contains basic information known about the substance. Other sections, such as Section 3.2 Children and Other Populations that are Unusually Susceptible and Section 3.4 Interactions with Other Substances, provide important supplemental information.

MRL users should also understand the MRL derivation methodology. MRLs are derived using a modified version of the risk assessment methodology that the Environmental Protection Agency (EPA) provides (Barnes and Dourson 1988) to determine reference doses (RfDs) for lifetime exposure.

To derive an MRL, ATSDR generally selects the most sensitive endpoint which, in its best judgement, represents the most sensitive human health effect for a given exposure route and duration. ATSDR cannot make this judgement or derive an MRL unless information (quantitative or qualitative) is available for all potential systemic, neurological, and developmental effects. If this information and reliable quantitative data on the chosen endpoint are available, ATSDR derives an MRL using the most sensitive species (when information from multiple species is available) with the highest no-observed-adverse-effect level (NOAEL) that does not exceed any adverse effect levels. When a NOAEL is not available, a lowest-observed-adverse-effect level (LOAEL) can be used to derive an MRL, and an uncertainty factor of 10 must be employed. Additional uncertainty factors of 10 must be used both for human variability to protect sensitive subpopulations (people who are most susceptible to the health effects caused by the substance) and for interspecies variability (extrapolation from animals to humans). In deriving an MRL, these individual uncertainty factors are multiplied together. The product is then divided into the inhalation concentration or oral dosage selected from the study. Uncertainty factors used in developing a

substance-specific MRL are provided in the footnotes of the levels of significant exposure (LSE) tables that are provided in Chapter 2. Detailed discussions of the MRLs are presented in Appendix A.

Chapter 2. Health Effects

Tables and Figures for Levels of Significant Exposure (LSE)

Tables and figures are used to summarize health effects and illustrate graphically levels of exposure associated with those effects. These levels cover health effects observed at increasing dose concentrations and durations, differences in response by species and MRLs to humans for noncancer endpoints. The LSE tables and figures can be used for a quick review of the health effects and to locate data for a specific exposure scenario. The LSE tables and figures should always be used in conjunction with the text. All entries in these tables and figures represent studies that provide reliable, quantitative estimates of NOAELs, LOAELs, or Cancer Effect Levels (CELs).

The legends presented below demonstrate the application of these tables and figures. Representative examples of LSE tables and figures follow. The numbers in the left column of the legends correspond to the numbers in the example table and figure.

TABLE LEGEND

See Sample LSE Table (page C-5)

(1) Route of exposure. One of the first considerations when reviewing the toxicity of a substance using these tables and figures should be the relevant and appropriate route of exposure. Typically, when sufficient data exist, three LSE tables and two LSE figures are presented in the document. The three LSE tables present data on the three principal routes of exposure (i.e., inhalation, oral, and dermal). LSE figures are limited to the inhalation and oral routes. Not all substances will have data on each route of exposure and will not, therefore, have all five of the tables and figures. Profiles with more than one chemical may have more LSE tables and figures.

(2) Exposure period. Three exposure periods—acute (<15 days), intermediate (15–364 days), and chronic (≥365 days)—are presented within each relevant route of exposure. In this example, two oral studies of chronic-duration exposure are reported. For quick reference to health effects occurring from a known length of exposure, locate the applicable exposure period within the LSE table and figure.

(3) Figure key. Each key number in the LSE table links study information to one or more data points using the same key number in the corresponding LSE figure. In this example, the study represented by key number 51 identified NOAELs and less serious LOAELs (also see the three "51R" data points in sample LSE Figure 2-X).

(4) Species (strain) No./group. The test species (and strain), whether animal or human, are identified in this column. The column also contains information on the number of subjects and sex per group. Chapter 1, Relevance to Public Health, covers the relevance of animal data to human toxicity and Section 3.1, Toxicokinetics, contains any available information on comparative toxicokinetics. Although NOAELs and LOAELs are species specific, the levels are extrapolated to equivalent human doses to derive an MRL.

(5) Exposure parameters/doses. The duration of the study and exposure regimens are provided in these columns. This permits comparison of NOAELs and LOAELs from different studies. In this case (key number 51), rats were orally exposed to “Chemical X” via feed for 2 years. For a

more complete review of the dosing regimen, refer to the appropriate sections of the text or the original reference paper (i.e., Aida et al. 1992).

(6) Parameters monitored. This column lists the parameters used to assess health effects. Parameters monitored could include serum (blood) chemistry (BC), behavioral (BH), biochemical changes (BI), body weight (BW), clinical signs (CS), developmental toxicity (DX), enzyme activity (EA), food intake (FI), fetal toxicity (FX), gross necropsy (GN), hematology (HE), histopathology (HP), lethality (LE), maternal toxicity (MX), organ function (OF), ophthalmology (OP), organ weight (OW), teratogenicity (TG), urinalysis (UR), and water intake (WI).

(7) Endpoint. This column lists the endpoint examined. The major categories of health endpoints included in LSE tables and figures are death, body weight, respiratory, cardiovascular, gastrointestinal, hematological, musculoskeletal, hepatic, renal, dermal, ocular, endocrine, immunological, neurological, reproductive, developmental, other noncancer, and cancer. "Other noncancer" refers to any effect (e.g., alterations in blood glucose levels) not covered in these systems. In the example of key number 51, three endpoints (body weight, hematological, and hepatic) were investigated.

(8) NOAEL. A NOAEL is the highest exposure level at which no adverse effects were seen in the organ system studied. The body weight effect reported in key number 51 is a NOAEL at 25.5 mg/kg/day. NOAELs are not reported for cancer and death; with the exception of these two endpoints, this field is left blank if no NOAEL was identified in the study.

(9) LOAEL. A LOAEL is the lowest dose used in the study that caused an adverse health effect. LOAELs have been classified into "Less Serious" and "Serious" effects. These distinctions help readers identify the levels of exposure at which adverse health effects first appear and the gradation of effects with increasing dose. A brief description of the specific endpoint used to quantify the adverse effect accompanies the LOAEL. Key number 51 reports a less serious LOAEL of 6.1 mg/kg/day for the hepatic system, which was used to derive a chronic exposure, oral MRL of 0.008 mg/kg/day (see footnote "c"). MRLs are not derived from serious LOAELs. A cancer effect level (CEL) is the lowest exposure level associated with the onset of carcinogenesis in experimental or epidemiologic studies. CELs are always considered serious effects. The LSE tables and figures do not contain NOAELs for cancer, but the text may report doses not causing measurable cancer increases. If no LOAEL/CEL values were identified in the study, this field is left blank.

(10) Reference. The complete reference citation is provided in Chapter 8 of the profile.

(11) Footnotes. Explanations of abbreviations or reference notes for data in the LSE tables are found in the footnotes. For example, footnote "c" indicates that the LOAEL of 6.1 mg/kg/day in key number 51 was used to derive an oral MRL of 0.008 mg/kg/day.

FIGURE LEGEND

See Sample LSE Figure (page C-6)

LSE figures graphically illustrate the data presented in the corresponding LSE tables. Figures help the reader quickly compare health effects according to exposure concentrations for particular exposure periods.

(13) Exposure period. The same exposure periods appear as in the LSE table. In this example, health effects observed within the chronic exposure period are illustrated.

(14) Endpoint. These are the categories of health effects for which reliable quantitative data exist. The same health effect endpoints appear in the LSE table.

(15) Levels of exposure. Concentrations or doses for each health effect in the LSE tables are graphically displayed in the LSE figures. Exposure concentration or dose is measured on the log scale "y" axis. Inhalation exposure is reported in mg/m^3 or ppm and oral exposure is reported in mg/kg/day.

(16) LOAEL. In this example, the half-shaded circle that is designated 51R identifies a LOAEL critical endpoint in the rat upon which a chronic oral exposure MRL is based. The key number 51 corresponds to the entry in the LSE table. The dashed descending arrow indicates the extrapolation from the exposure level of 6.1 mg/kg/day (see entry 51 in the sample LSE table) to the MRL of 0.008 mg/kg/day (see footnote "c" in the sample LSE table).

(17) CEL. Key number 59R is one of studies for which CELs were derived. The diamond symbol refers to a CEL for the test species (rat). The number 59 corresponds to the entry in the LSE table.

(18) Key to LSE figure. The key provides the abbreviations and symbols used in the figure.

APPENDIX B

Table 2-X. Levels of Significant Exposure to [Chemical X] – Oral (1)

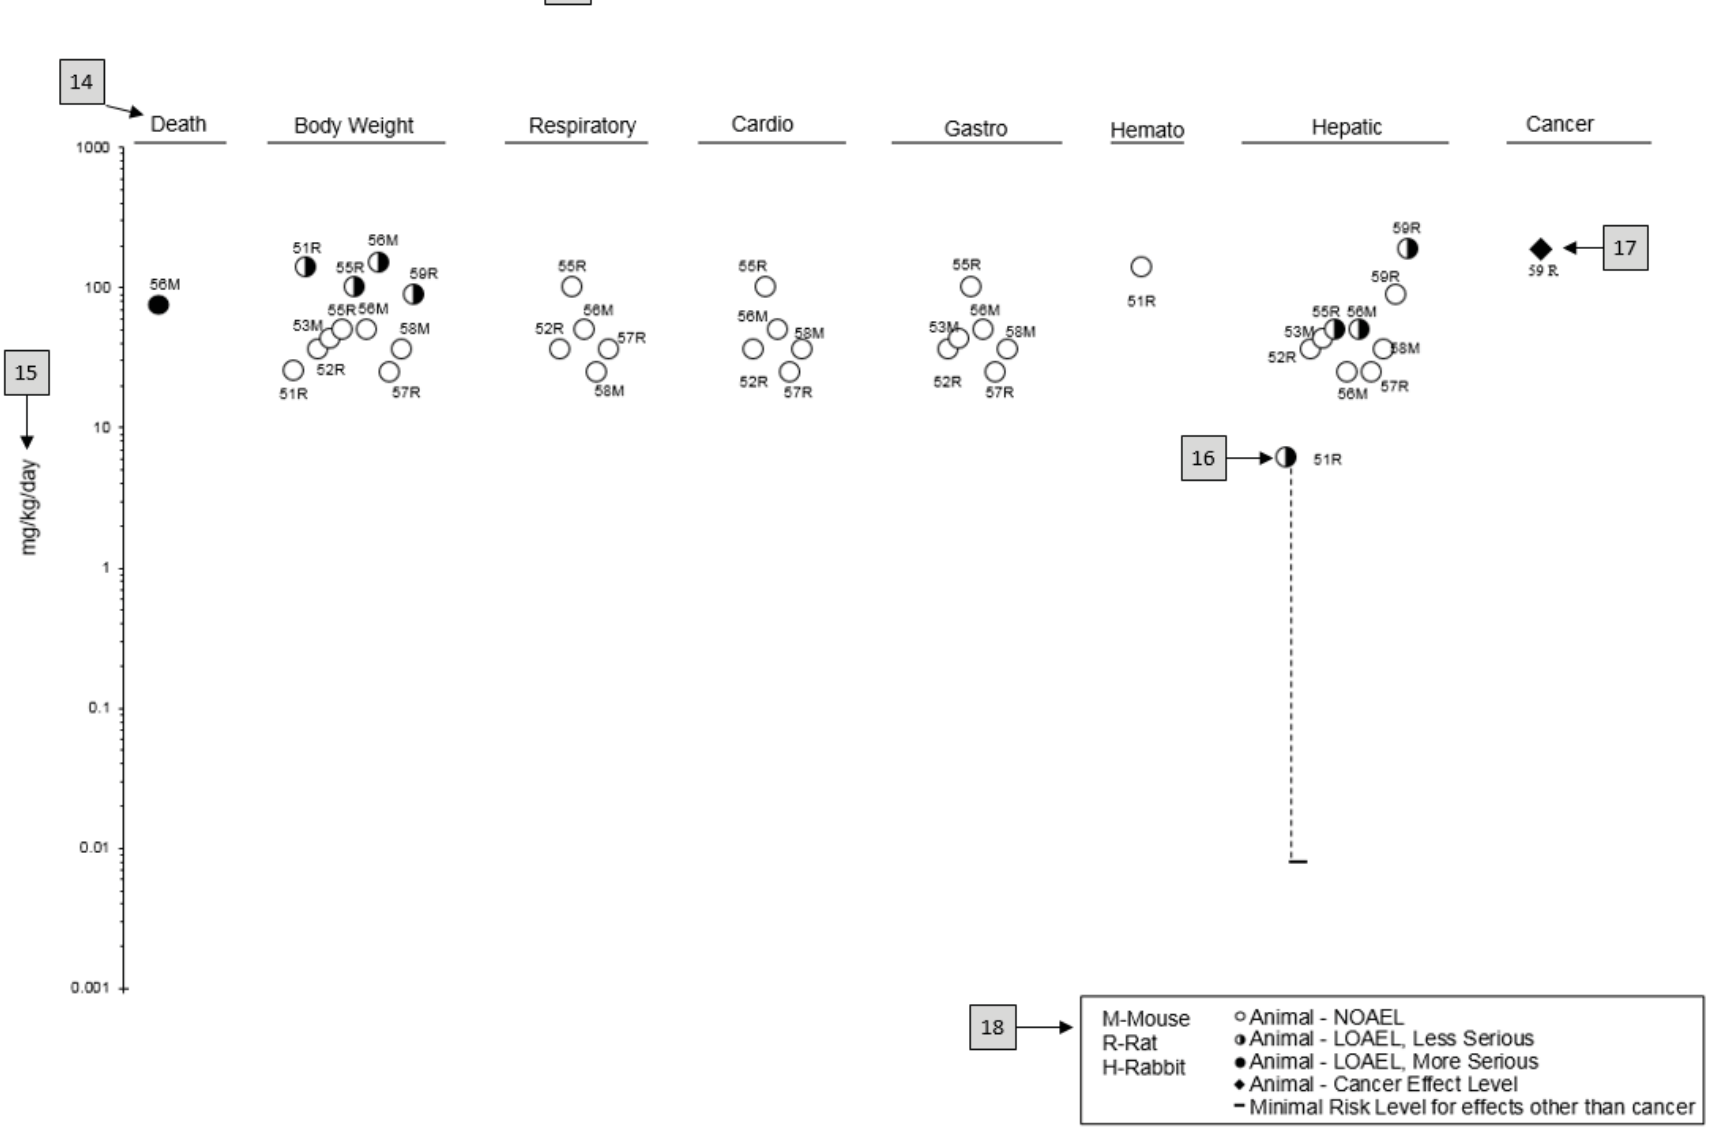
Figure key[a] (3)	Species (strain) No./group (4)	Exposure parameters (5)	Doses (mg/kg/day) (5)	Parameters monitored (6)	Endpoint (7)	NOAEL (mg/kg/day) (8)	Less serious LOAEL (mg/kg/day) (9)	Serious LOAEL (mg/kg/day) (9)	Effect
CHRONIC EXPOSURE (2)									
51	Rat (Wistar) 40 M, 40 F	2 years (F)	M: 0, 6.1, 25.5, 138.0 F: 0, 8.0, 31.7, 168.4	CS, WI, BW, OW, HE, BC, HP	Bd wt	25.5	138.0		Decreased body weight gain in males (23–25%) and females (31–39%)
					Hemato	138.0			
					Hepatic		6.1[c]		Increases in absolute and relative weights at ≥6.1/8.0 mg/kg/day after 12 months of exposure; fatty generation at ≥6.1 mg/kg/day in males and at ≥31.7 mg/kg/day in females, and granulomas in females at 31.7 and 168.4 mg/kg/day after 12, 18, or 24 months of exposure and in males at ≥6.1 mg/kg/day only after 24 months of exposure
Aida et al. 1992 (10)									
52	Rat (F344) 78 M	104 weeks (W)	0, 3.9, 20.6, 36.3	CS, BW, FI, BC, OW, HP	Hepatic	36.3			
					Renal	20.6	36.3		Increased incidence of renal tubular cell hyperplasia
					Endocr	36.3			
George et al. 2002									
59	Rat (Wistar) 58M, 58F	Lifetime (W)	M: 0, 90 F: 0, 190	BW, HP	Cancer		190 F		Increased incidence of hepatic neoplastic nodules in females only; no additional description of the tumors was provided
Tumasonis et al. 1985									

[a]The number corresponds to entries in Figure 2-x.

(11) [b]Used to derive an acute-duration oral minimal risk level (MRL) of 0.1 mg/kg/day based on the $BMDL_{05}$ of 10 mg/kg/day and an uncertainty factor of 100 (10 for extrapolation from animals to humans and 10 for human variability).

[c]Used to derive a chronic-duration oral MRL of 0.008 mg/kg/day based on the $BMDL_{10}$ of 0.78 mg/kg/day and an uncertainty factor of 100 (10 for extrapolation from animals to humans and 10 for human variability).

Figure 2-X. Levels of Significant Exposure to [Chemical X] - Oral



APPENDIX D. QUICK REFERENCE FOR HEALTH CARE PROVIDERS

Toxicological Profiles are a unique compilation of toxicological information on a given hazardous substance. Each profile reflects a comprehensive and extensive evaluation, summary, and interpretation of available toxicologic and epidemiologic information on a substance. Health care providers treating patients potentially exposed to hazardous substances may find the following information helpful for fast answers to often-asked questions.

Primary Chapters/Sections of Interest

Chapter 1: Relevance to Public Health: The Relevance to Public Health Section provides an overview of exposure and health effects and evaluates, interprets, and assesses the significance of toxicity data to human health. A table listing minimal risk levels (MRLs) is also included in this chapter.

Chapter 2: Health Effects: Specific health effects identified in both human and animal studies are reported by type of health effect (e.g., death, hepatic, renal, immune, reproductive), route of exposure (e.g., inhalation, oral, dermal), and length of exposure (e.g., acute, intermediate, and chronic).
NOTE: Not all health effects reported in this section are necessarily observed in the clinical setting.

Section 3.2 Children and Other Populations that are Unusually Susceptible
Section 3.3 Biomarkers of Exposure and Effect

ATSDR Information Center

Phone: 1-800-CDC-INFO (800-232-4636) or 1-888-232-6348 (TTY)
Internet: http://www.atsdr.cdc.gov

The following additional materials are available online:

Case Studies in Environmental Medicine are self-instructional publications designed to increase primary health care providers' knowledge of a hazardous substance in the environment and to aid in the evaluation of potentially exposed patients (see https://www.atsdr.cdc.gov/csem/csem.html).

Managing Hazardous Materials Incidents is a three-volume set of recommendations for on-scene (prehospital) and hospital medical management of patients exposed during a hazardous materials incident (see https://www.atsdr.cdc.gov/MHMI/index.asp). Volumes I and II are planning guides to assist first responders and hospital emergency department personnel in planning for incidents that involve hazardous materials. Volume III—*Medical Management Guidelines for Acute Chemical Exposures*—is a guide for health care professionals treating patients exposed to hazardous materials.

Fact Sheets (ToxFAQs™) provide answers to frequently asked questions about toxic substances (see https://www.atsdr.cdc.gov/toxfaqs/Index.asp).

Other Agencies and Organizations

The National Center for Environmental Health (NCEH) focuses on preventing or controlling disease, injury, and disability related to the interactions between people and their environment outside the workplace. Contact: NCEH, Mailstop F-29, 4770 Buford Highway, NE, Atlanta, GA 30341-3724 • Phone: 770-488-7000 • FAX: 770-488-7015 • Web Page: https://www.cdc.gov/nceh/.

The National Institute for Occupational Safety and Health (NIOSH) conducts research on occupational diseases and injuries, responds to requests for assistance by investigating problems of health and safety in the workplace, recommends standards to the Occupational Safety and Health Administration (OSHA) and the Mine Safety and Health Administration (MSHA), and trains professionals in occupational safety and health. Contact: NIOSH, 395 E Street, S.W., Suite 9200, Patriots Plaza Building, Washington, DC 20201 • Phone: 202-245-0625 or 1-800-CDC-INFO (800-232-4636) • Web Page: https://www.cdc.gov/niosh/.

The National Institute of Environmental Health Sciences (NIEHS) is the principal federal agency for biomedical research on the effects of chemical, physical, and biologic environmental agents on human health and well-being. Contact: NIEHS, PO Box 12233, 104 T.W. Alexander Drive, Research Triangle Park, NC 27709 • Phone: 919-541-3212 • Web Page: https://www.niehs.nih.gov/.

Clinical Resources (Publicly Available Information)

The Association of Occupational and Environmental Clinics (AOEC) has developed a network of clinics in the United States to provide expertise in occupational and environmental issues. Contact: AOEC, 1010 Vermont Avenue, NW, #513, Washington, DC 20005 • Phone: 202-347-4976 • FAX: 202-347-4950 • e-mail: AOEC@AOEC.ORG • Web Page: http://www.aoec.org/.

The American College of Occupational and Environmental Medicine (ACOEM) is an association of physicians and other health care providers specializing in the field of occupational and environmental medicine. Contact: ACOEM, 25 Northwest Point Boulevard, Suite 700, Elk Grove Village, IL 60007-1030 • Phone: 847-818-1800 • FAX: 847-818-9266 • Web Page: http://www.acoem.org/.

The American College of Medical Toxicology (ACMT) is a nonprofit association of physicians with recognized expertise in medical toxicology. Contact: ACMT, 10645 North Tatum Boulevard, Suite 200-111, Phoenix AZ 85028 • Phone: 844-226-8333 • FAX: 844-226-8333 • Web Page: http://www.acmt.net.

The Pediatric Environmental Health Specialty Units (PEHSUs) is an interconnected system of specialists who respond to questions from public health professionals, clinicians, policy makers, and the public about the impact of environmental factors on the health of children and reproductive-aged adults. Contact information for regional centers can be found at http://pehsu.net/findhelp.html.

The American Association of Poison Control Centers (AAPCC) provide support on the prevention and treatment of poison exposures. Contact: AAPCC, 515 King Street, Suite 510, Alexandria VA 22314 • Phone: 701-894-1858 • Poison Help Line: 1-800-222-1222 • Web Page: http://www.aapcc.org/.

APPENDIX E. GLOSSARY

Absorption—The process by which a substance crosses biological membranes and enters systemic circulation. Absorption can also refer to the taking up of liquids by solids, or of gases by solids or liquids.

Acute Exposure—Exposure to a chemical for a duration of ≤14 days, as specified in the Toxicological Profiles.

Adsorption—The adhesion in an extremely thin layer of molecules (as of gases, solutes, or liquids) to the surfaces of solid bodies or liquids with which they are in contact.

Adsorption Coefficient (K_{oc})—The ratio of the amount of a chemical adsorbed per unit weight of organic carbon in the soil or sediment to the concentration of the chemical in solution at equilibrium.

Adsorption Ratio (Kd)—The amount of a chemical adsorbed by sediment or soil (i.e., the solid phase) divided by the amount of chemical in the solution phase, which is in equilibrium with the solid phase, at a fixed solid/solution ratio. It is generally expressed in micrograms of chemical sorbed per gram of soil or sediment.

Benchmark Dose (BMD) or Benchmark Concentration (BMC)—is the dose/concentration corresponding to a specific response level estimate using a statistical dose-response model applied to either experimental toxicology or epidemiology data. For example, a BMD_{10} would be the dose corresponding to a 10% benchmark response (BMR). The BMD is determined by modeling the dose-response curve in the region of the dose-response relationship where biologically observable data are feasible. The BMDL or BMCL is the 95% lower confidence limit on the BMD or BMC.

Bioconcentration Factor (BCF)—The quotient of the concentration of a chemical in aquatic organisms at a specific time or during a discrete time period of exposure divided by the concentration in the surrounding water at the same time or during the same period.

Biomarkers—Indicators signaling events in biologic systems or samples, typically classified as markers of exposure, effect, and susceptibility.

Cancer Effect Level (CEL)—The lowest dose of a chemical in a study, or group of studies, that produces significant increases in the incidence of cancer (or tumors) between the exposed population and its appropriate control.

Carcinogen—A chemical capable of inducing cancer.

Case-Control Study—A type of epidemiological study that examines the relationship between a particular outcome (disease or condition) and a variety of potential causative agents (such as toxic chemicals). In a case-control study, a group of people with a specified and well-defined outcome is identified and compared to a similar group of people without the outcome.

Case Report—A report that describes a single individual with a particular disease or exposure. These reports may suggest some potential topics for scientific research, but are not actual research studies.

Case Series—Reports that describe the experience of a small number of individuals with the same disease or exposure. These reports may suggest potential topics for scientific research, but are not actual research studies.

Ceiling Value—A concentration that must not be exceeded.

Chronic Exposure—Exposure to a chemical for ≥365 days, as specified in the Toxicological Profiles.

Clastogen—A substance that causes breaks in chromosomes resulting in addition, deletion, or rearrangement of parts of the chromosome.

Cohort Study—A type of epidemiological study of a specific group or groups of people who have had a common insult (e.g., exposure to an agent suspected of causing disease or a common disease) and are followed forward from exposure to outcome, and who are disease-free at start of follow-up. Often, at least one exposed group is compared to one unexposed group, while in other cohorts, exposure is a continuous variable and analyses are directed towards analyzing an exposure-response coefficient.

Cross-sectional Study—A type of epidemiological study of a group or groups of people that examines the relationship between exposure and outcome to a chemical or to chemicals at a specific point in time.

Data Needs—Substance-specific informational needs that, if met, would reduce the uncertainties of human health risk assessment.

Developmental Toxicity—The occurrence of adverse effects on the developing organism that may result from exposure to a chemical prior to conception (either parent), during prenatal development, or postnatally to the time of sexual maturation. Adverse developmental effects may be detected at any point in the life span of the organism.

Dose-Response Relationship—The quantitative relationship between the amount of exposure to a toxicant and the incidence of the response or amount of the response.

Embryotoxicity and Fetotoxicity—Any toxic effect on the conceptus as a result of prenatal exposure to a chemical; the distinguishing feature between the two terms is the stage of development during which the effect occurs. Effects include malformations and variations, altered growth, and *in utero* death.

Epidemiology—The investigation of factors that determine the frequency and distribution of disease or other health-related conditions within a defined human population during a specified period.

Excretion—The process by which metabolic waste products are removed from the body.

Genotoxicity—A specific adverse effect on the genome of living cells that, upon the duplication of affected cells, can be expressed as a mutagenic, clastogenic, or carcinogenic event because of specific alteration of the molecular structure of the genome.

Half-life—A measure of rate for the time required to eliminate one-half of a quantity of a chemical from the body or environmental media.

Health Advisory—An estimate of acceptable drinking water levels for a chemical substance derived by EPA and based on health effects information. A health advisory is not a legally enforceable federal standard, but serves as technical guidance to assist federal, state, and local officials.

Immediately Dangerous to Life or Health (IDLH)—A condition that poses a threat of life or health, or conditions that pose an immediate threat of severe exposure to contaminants that are likely to have adverse cumulative or delayed effects on health.

Immunotoxicity—Adverse effect on the functioning of the immune system that may result from exposure to chemical substances.

Incidence—The ratio of new cases of individuals in a population who develop a specified condition to the total number of individuals in that population who could have developed that condition in a specified time period.

Intermediate Exposure—Exposure to a chemical for a duration of 15–364 days, as specified in the Toxicological Profiles.

***In Vitro*—**Isolated from the living organism and artificially maintained, as in a test tube.

***In Vivo*—**Occurring within the living organism.

Lethal Concentration$_{(LO)}$ (LC_{LO})—The lowest concentration of a chemical in air that has been reported to have caused death in humans or animals.

Lethal Concentration$_{(50)}$ (LC_{50})—A calculated concentration of a chemical in air to which exposure for a specific length of time is expected to cause death in 50% of a defined experimental animal population.

Lethal Dose$_{(LO)}$ (LD_{Lo})—The lowest dose of a chemical introduced by a route other than inhalation that has been reported to have caused death in humans or animals.

Lethal Dose$_{(50)}$ (LD_{50})—The dose of a chemical that has been calculated to cause death in 50% of a defined experimental animal population.

Lethal Time$_{(50)}$ (LT_{50})—A calculated period of time within which a specific concentration of a chemical is expected to cause death in 50% of a defined experimental animal population.

Lowest-Observed-Adverse-Effect Level (LOAEL)—The lowest exposure level of chemical in a study, or group of studies, that produces statistically or biologically significant increases in frequency or severity of adverse effects between the exposed population and its appropriate control.

Lymphoreticular Effects—Represent morphological effects involving lymphatic tissues such as the lymph nodes, spleen, and thymus.

Malformations—Permanent structural changes that may adversely affect survival, development, or function.

Metabolism—Process in which chemical substances are biotransformed in the body that could result in less toxic and/or readily excreted compounds or produce a biologically active intermediate.

Minimal Risk Level (MRL)—An estimate of daily human exposure to a hazardous substance that is likely to be without an appreciable risk of adverse noncancer health effects over a specified route and duration of exposure.

Modifying Factor (MF)—A value (greater than zero) that is applied to the derivation of a Minimal Risk Level (MRL) to reflect additional concerns about the database that are not covered by the uncertainty factors. The default value for a MF is 1.

Morbidity—The state of being diseased; the morbidity rate is the incidence or prevalence of a disease in a specific population.

Mortality—Death; the mortality rate is a measure of the number of deaths in a population during a specified interval of time.

Mutagen—A substance that causes mutations, which are changes in the DNA sequence of a cell's DNA. Mutations can lead to birth defects, miscarriages, or cancer.

Necropsy—The gross examination of the organs and tissues of a dead body to determine the cause of death or pathological conditions.

Neurotoxicity—The occurrence of adverse effects on the nervous system following exposure to a hazardous substance.

No-Observed-Adverse-Effect Level (NOAEL)—The dose of a chemical at which there were no statistically or biologically significant increases in frequency or severity of adverse effects seen between the exposed population and its appropriate control. Although effects may be produced at this dose, they are not considered to be adverse.

Octanol-Water Partition Coefficient (K_{ow})—The equilibrium ratio of the concentrations of a chemical in *n*-octanol and water, in dilute solution.

Odds Ratio (OR)—A means of measuring the association between an exposure (such as toxic substances and a disease or condition) that represents the best estimate of relative risk (risk as a ratio of the incidence among subjects exposed to a particular risk factor divided by the incidence among subjects who were not exposed to the risk factor). An odds ratio that is greater than 1 is considered to indicate greater risk of disease in the exposed group compared to the unexposed group.

Permissible Exposure Limit (PEL)—An Occupational Safety and Health Administration (OSHA) regulatory limit on the amount or concentration of a substance not to be exceeded in workplace air averaged over any 8-hour work shift of a 40-hour workweek.

Pesticide—General classification of chemicals specifically developed and produced for use in the control of agricultural and public health pests (insects or other organisms harmful to cultivated plants or animals).

Pharmacokinetics—The dynamic behavior of a material in the body, used to predict the fate (disposition) of an exogenous substance in an organism. Utilizing computational techniques, it provides the means of studying the absorption, distribution, metabolism, and excretion of chemicals by the body.

Pharmacokinetic Model—A set of equations that can be used to describe the time course of a parent chemical or metabolite in an animal system. There are two types of pharmacokinetic models: data-based and physiologically-based. A data-based model divides the animal system into a series of compartments, which, in general, do not represent real, identifiable anatomic regions of the body, whereas the physiologically-based model compartments represent real anatomic regions of the body.

Physiologically Based Pharmacodynamic (PBPD) Model—A type of physiologically based dose-response model that quantitatively describes the relationship between target tissue dose and toxic endpoints. These models advance the importance of physiologically based models in that they clearly describe the biological effect (response) produced by the system following exposure to an exogenous substance.

Physiologically Based Pharmacokinetic (PBPK) Model—A type of physiologically based dose-response model that is comprised of a series of compartments representing organs or tissue groups with realistic weights and blood flows. These models require a variety of physiological information, including tissue volumes, blood flow rates to tissues, cardiac output, alveolar ventilation rates, and possibly membrane permeabilities. The models also utilize biochemical information, such as blood:air partition coefficients, and metabolic parameters. PBPK models are also called biologically based tissue dosimetry models.

Prevalence—The number of cases of a disease or condition in a population at one point in time.

Prospective Study—A type of cohort study in which a group is followed over time and the pertinent observations are made on events occurring after the start of the study.

Recommended Exposure Limit (REL)—A National Institute for Occupational Safety and Health (NIOSH) time-weighted average (TWA) concentration for up to a 10-hour workday during a 40-hour workweek.

Reference Concentration (RfC)—An estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious noncancer health effects during a lifetime. The inhalation RfC is expressed in units of mg/m^3 or ppm.

Reference Dose (RfD)—An estimate (with uncertainty spanning perhaps an order of magnitude) of the daily oral exposure of the human population to a potential hazard that is likely to be without risk of deleterious noncancer health effects during a lifetime. The oral RfD is expressed in units of mg/kg/day.

Reportable Quantity (RQ)—The quantity of a hazardous substance that is considered reportable under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA). RQs are (1) ≥1 pound or (2) for selected substances, an amount established by regulation either under CERCLA or under Section 311 of the Clean Water Act. Quantities are measured over a 24-hour period.

Reproductive Toxicity—The occurrence of adverse effects on the reproductive system that may result from exposure to a hazardous substance. The toxicity may be directed to the reproductive organs and/or the related endocrine system. The manifestation of such toxicity may be noted as alterations in sexual behavior, fertility, pregnancy outcomes, or modifications in other functions that are dependent on the integrity of this system.

Retrospective Study—A type of cohort study based on a group of persons known to have been exposed at some time in the past. Data are collected from routinely recorded events, up to the time the study is undertaken. Retrospective studies are limited to causal factors that can be ascertained from existing records and/or examining survivors of the cohort.

Reverse Causation—Describes an association where the outcome results in a change in the biomarker of exposure.

Risk—The possibility or chance that some adverse effect will result from a given exposure to a hazardous substance.

Risk Factor—An aspect of personal behavior or lifestyle, an environmental exposure, existing health condition, or an inborn or inherited characteristic that is associated with an increased occurrence of disease or other health-related event or condition.

Risk Ratio/Relative Risk—The ratio of the risk among persons with specific risk factors compared to the risk among persons without risk factors. A risk ratio that is greater than 1 indicates greater risk of disease in the exposed group compared to the unexposed group.

Short-Term Exposure Limit (STEL)—A STEL is a 15-minute TWA exposure that should not be exceeded at any time during a workday.

Standardized Mortality Ratio (SMR)—A ratio of the observed number of deaths and the expected number of deaths in a specific standard population.

Target Organ Toxicity—This term covers a broad range of adverse effects on target organs or physiological systems (e.g., renal, cardiovascular) extending from those arising through a single limited exposure to those assumed over a lifetime of exposure to a chemical.

Teratogen—A chemical that causes structural defects that affect the development of an organism.

Threshold Limit Value (TLV)—An American Conference of Governmental Industrial Hygienists (ACGIH) concentration of a substance to which it is believed that nearly all workers may be repeatedly exposed, day after day, for a working lifetime without adverse effect. The TLV may be expressed as a Time-Weighted Average (TLV-TWA), as a Short-Term Exposure Limit (TLV-STEL), or as a ceiling limit (TLV-C).

Time-Weighted Average (TWA)—An average exposure within a given time period.

Toxicokinetic—The absorption, distribution, metabolism, and elimination of toxic compounds in the living organism.

Toxics Release Inventory (TRI)—The TRI is an EPA program that tracks toxic chemical releases and pollution prevention activities reported by industrial and federal facilities.

Uncertainty Factor (UF)—A factor used in operationally deriving the Minimal Risk Level (MRL), Reference Dose (RfD), or Reference Concentration (RfC) from experimental data. UFs are intended to account for (1) the variation in sensitivity among the members of the human population, (2) the uncertainty in extrapolating animal data to the case of human, (3) the uncertainty in extrapolating from data obtained in a study that is of less than lifetime exposure, and (4) the uncertainty in using lowest-observed-adverse-effect level (LOAEL) data rather than no-observed-adverse-effect level (NOAEL) data. A default for each individual UF is 10; if complete certainty in data exists, a value of 1 can be used; however, a reduced UF of 3 may be used on a case-by-case basis (3 being the approximate logarithmic average of 10 and 1).

Xenobiotic—Any substance that is foreign to the biological system.

APPENDIX F. ACRONYMS, ABBREVIATIONS, AND SYMBOLS

AAPCC	American Association of Poison Control Centers
ACGIH	American Conference of Governmental Industrial Hygienists
ACOEM	American College of Occupational and Environmental Medicine
ACMT	American College of Medical Toxicology
ADI	acceptable daily intake
ADME	absorption, distribution, metabolism, and excretion
AEGL	Acute Exposure Guideline Level
AIC	Akaike's information criterion
AIHA	American Industrial Hygiene Association
ALT	alanine aminotransferase
AOEC	Association of Occupational and Environmental Clinics
AP	alkaline phosphatase
APFO	ammonium perfluorooctanoate
AST	aspartate aminotransferase
atm	atmosphere
ATSDR	Agency for Toxic Substances and Disease Registry
AWQC	Ambient Water Quality Criteria
BCF	bioconcentration factor
BMD/C	benchmark dose or benchmark concentration
BMD_X	dose that produces a X% change in response rate of an adverse effect
$BMDL_X$	95% lower confidence limit on the BMD_X
BMDS	Benchmark Dose Software
BMR	benchmark response
BUN	blood urea nitrogen
C	centigrade
CAA	Clean Air Act
CAS	Chemical Abstract Services
CDC	Centers for Disease Control and Prevention
CEL	cancer effect level
CERCLA	Comprehensive Environmental Response, Compensation, and Liability Act
CFR	Code of Federal Regulations
Ci	curie
CI	confidence interval
cm	centimeter
CPSC	Consumer Products Safety Commission
CWA	Clean Water Act
DNA	deoxyribonucleic acid
DOD	Department of Defense
DOE	Department of Energy
DWEL	drinking water exposure level
EAFUS	Everything Added to Food in the United States
ECG/EKG	electrocardiogram
EEG	electroencephalogram
EPA	Environmental Protection Agency
ERPG	emergency response planning guidelines
F	Fahrenheit
F1	first-filial generation
FDA	Food and Drug Administration
FIFRA	Federal Insecticide, Fungicide, and Rodenticide Act

FR	Federal Register
FSH	follicle stimulating hormone
g	gram
GC	gas chromatography
gd	gestational day
GGT	γ-glutamyl transferase
GRAS	generally recognized as safe
HEC	human equivalent concentration
HED	human equivalent dose
HHS	Department of Health and Human Services
HPLC	high-performance liquid chromatography
HSDB	Hazardous Substance Data Bank
IARC	International Agency for Research on Cancer
IDLH	immediately dangerous to life and health
IRIS	Integrated Risk Information System
Kd	adsorption ratio
kg	kilogram
kkg	kilokilogram; 1 kilokilogram is equivalent to 1,000 kilograms and 1 metric ton
K_{oc}	organic carbon partition coefficient
K_{ow}	octanol-water partition coefficient
L	liter
LC	liquid chromatography
LC_{50}	lethal concentration, 50% kill
LC_{Lo}	lethal concentration, low
LD_{50}	lethal dose, 50% kill
LD_{Lo}	lethal dose, low
LDH	lactic dehydrogenase
LH	luteinizing hormone
LOAEL	lowest-observed-adverse-effect level
LSE	Level of Significant Exposure
LT_{50}	lethal time, 50% kill
m	meter
mCi	millicurie
MCL	maximum contaminant level
MCLG	maximum contaminant level goal
MF	modifying factor
mg	milligram
mL	milliliter
mm	millimeter
mmHg	millimeters of mercury
mmol	millimole
MRL	Minimal Risk Level
MS	mass spectrometry
MSHA	Mine Safety and Health Administration
Mt	metric ton
NAAQS	National Ambient Air Quality Standard
NAS	National Academy of Science
NCEH	National Center for Environmental Health
ND	not detected
ng	nanogram
NHANES	National Health and Nutrition Examination Survey

NIEHS	National Institute of Environmental Health Sciences
NIOSH	National Institute for Occupational Safety and Health
NLM	National Library of Medicine
nm	nanometer
nmol	nanomole
NOAEL	no-observed-adverse-effect level
NPL	National Priorities List
NR	not reported
NRC	National Research Council
NS	not specified

TABLE OF CONTENTS

SUMMARY

This document presents final notification level (NL) recommendations by the Office of Environmental Health Hazard Assessment (OEHHA) for perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS) in drinking water. This supersedes the underlying scientific analysis (OEHHA, 2018) that supported the interim NLs that were adopted in 2018 (SWRCB, 2018a,b).

Based on the current evaluation of recent human and animal toxicity data, and applying OEHHA's risk assessment methodology and the US Environmental Protection Agency's (US EPA) human clearance factors (US EPA, 2016a,b) to account for the chemical half-life differences between rodents and humans, OEHHA developed PFOA and PFOS reference levels (RLs) for cancer effects. These levels represent concentrations of the chemicals in drinking water that would not pose more than a one in one million cancer risk over a lifetime:

- 0.1 ng/L (nanogram/liter) or parts per trillion (ppt) for PFOA, based on pancreatic and liver tumors in male rats (NTP, 2018c);
- 0.4 ng/L (or ppt) for PFOS, based on liver tumors in male rats (Butenhoff et al. 2012a) and the structural and biological similarity of PFOS to PFOA.

OEHHA also developed RLs for noncancer effects as follows:

- 2 ng/L (or ppt) for PFOA, based on liver toxicity in female mice (Li et al., 2017);
- 7 ng/L (or ppt) for PFOS, based on immunotoxicity in male mice (Dong et al., 2009).

The cancer RLs cited above are lower than the levels of PFOA and PFOS that can be reliably detected in drinking water using currently available technologies. In light of this, OEHHA recommends that the State Water Resources Control Board (SWRCB) set the NLs at the lowest levels at which PFOA and PFOS can be reliably detected in drinking water using available and appropriate technologies.

INTRODUCTION

At SWRCB's request, OEHHA has developed recommendations for drinking water NLs for PFOA and PFOS. Health and Safety Code Section 116455 defines an NL as the level of a drinking water contaminant that SWRCB has determined, based on available scientific information, does not pose a significant health risk but, when exceeded, warrants notification to a water system's governing body and other specified entities. NLs are nonregulatory, health-based advisory levels that SWRCB establishes as a precautionary measure for contaminants for which regulatory standards have not been set but that may be considered candidates for the establishment of maximum contaminant levels.

As a first step, OEHHA in June 2018 presented recommended interim NLs for PFOA and PFOS to SWRCB. OEHHA performed an expedited review of health-based values developed by several federal and state government agencies (US EPA, 2016a; US EPA, 2016b; New Jersey DWQI, 2017; ATSDR, 2018; New Jersey DWQI, 2018) and found the process used by New Jersey to be sufficient for establishing the interim NLs for PFOA and PFOS. Thus, OEHHA recommended that SWRCB adopt the following interim NLs based on New Jersey's evaluation:

- 14 ng/L (or ppt) for PFOA, based on liver toxicity in mice (Loveless et al., 2006) and carcinogenicity in rats (Butenhoff et al., 2012b);
- 13 ng/L (or ppt) for PFOS, based on immunotoxicity in mice (Dong et al., 2009).

In July 2018, SWRCB adopted these interim NLs for PFOA and PFOS, based on OEHHA's recommendations.

OEHHA has now completed a focused review, primarily evaluating studies that have been published since the above-cited reviews. This review evaluated human and animal toxicity studies published since 2016 and focused on hepatotoxicity, immunotoxicity, thyroid toxicity, reproductive toxicity, and cancer. These endpoints are known hazards of PFOA and PFOS exposure, and were readily observed in recent studies.

OEHHA recommends that SWRCB set the final NLs at the lowest levels at which PFOA and PFOS can be reliably detected in drinking water using currently available and appropriate technologies. OEHHA has developed RLs of 0.1 ppt for PFOA and 0.4 ppt for PFOS based on cancer endpoints, which are below levels that can be reliably detected with current technologies. RLs for noncancer endpoints are 2 ppt for PFOA based on liver toxicity and 7 ppt for PFOS based on immunotoxicity.

While OEHHA reviewed human epidemiology studies focusing on liver toxicity, immunotoxicity, and thyroid toxicity, an epidemiological analysis is not presented in this document because there were no studies that could be used for point of departure (POD) determination and dose-response assessment. Nonetheless, the epidemiology data suggest that there are associations between PFOA and/or PFOS and suppressed antibody response and increased liver enzymes. These epidemiological data are supportive of the animal toxicology data used to derive the RLs for noncancer effects. Use of data on immunotoxicity for noncancer RLs is further supported by the National Toxicology Program's (NTP) immunotoxicity review of PFOA and PFOS, which concluded that these chemicals are presumed to be an immune hazard to humans (NTP, 2016). The epidemiology data on thyroid hormone levels are inconsistent and, at times, contradictory.

TOXICOLOGICAL REVIEW

Liver Toxicity – PFOA

In vivo studies

PFOA exposure has consistently induced liver toxicity in experimental animals, and as with PFOS, a thorough examination of the literature was previously conducted by other agencies (US EPA, 2016a; New Jersey DWQI, 2017; ATSDR, 2018). In general, increases in absolute and/or relative liver weight, increased liver histopathology, increased biomarkers of liver damage, and changes in liver lipid content were observed.

OEHHA's review of recent animal studies that were not included in the above-cited reviews by other agencies is summarized in Table 1. Notable studies are described in greater detail below.

Table 1. Summary of recent animal toxicity studies of PFOA reporting liver effects

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Male Balb/c mice (n not specified)	0, 1, or 5 mg/kg-day orally for 7 days	↑ absolute liver weight; hepatocyte cytoplasmic vacuolization; ↑ serum ALT; changes in serum and liver lipid levels	LOAEL: 1 mg/kg-day for ↑ serum ALT levels	Hui et al. (2017)
Male Balb/c mice (n=20/dose)	0 or 1.25 mg/kg-day for 28 days	↑ relative liver weight; altered glucose metabolism	NA[a]	Zheng et al. (2017)
Male Balb/c mice (n=5/dose)	0, 0.5, or 2.5 mg/kg-day via oral infusion for 28 days	↑ absolute and relative liver weight; changes in lipid metabolism; altered glucose metabolism	NOAEL: 0.5 mg/kg-day for increased liver weight	Yu et al. (2016)
Male Balb/c mice (n not specified)	0, 0.08, 0.31, 1.25, 5, or 20 mg/kg-day via gavage for 28 days	hepatocyte swelling; lipid deposits	Not provided[b]	Yan et al. (2017)
C57BL/6 mice (n=4/dose, sex not specified)	0 or 20 mg/kg-day i.p. for 1 or 3 days	↑ relative liver weight	NA[a]	Abe et al. (2017)

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Male Sprague Dawley rats (n=5/dose)	Single dose of 0 or 150 mg/kg intragastrically	↑ relative liver weight	NA[a]	Cavallini et al. (2017)
Male Kunming mice (n not specified)	Single oral dose of 0 or 5 mg/kg	↑ hepatic cytoplasmic vesicles; ↑ inflammatory cells around the hepatic portal area; changes in hepatic cholesterol level	NA[a]	Wu et al. (2017)
Male and female Balb/c mice (n=30/sex/ group)	0, 0.05, 0.5, or 2.5 mg/kg-day via oral gavage for 28 days	↑ absolute liver weight; hepatocellular hypertrophy and apoptosis; lipid accumulation in cytoplasm of hepatocytes; mitochondrial morphology changes; changes in mitochondrial membrane potential; oxidative DNA damage (ROS generation)	LOAEL: 0.05 mg/kg-day for hepatic mito-chondrial membrane potential changes, apoptosis, oxidative DNA damage	Li et al. (2017)
Male Kunming mice (n=8/dose)	0, 1, or 5 mg/kg-day intragastrically for 21 days	↑ absolute and relative liver weight; ↑ serum ALT and AST; elevated blood insulin; ↓serum triglycerides and H-LDL; elevated triglycerides in liver; ↑ L-LDL in serum; ↑ hepatic vacuoles	NOAEL: 1 mg/kg-day for ↑ liver enzymes and triglyceride levels	Wu et al. (2018)
Pregnant Kunming mice (n=8/dose)	0 or 5 mg/kg-day intragastrically throughout gestation	↑ ALT, AST, triglycerides, and cholesterol in pup serum on PND 21 (although the changes were not statistically significant)	NA[a]	Qin et al. (2018)

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Male and female Sprague Dawley rats (n=10/sex/ dose)	0, 0.625, 1.25, 2.5, 5 or 10 mg/kg-day via oral gavage for males and females for 28 days	Hepatocyte hypertrophy, hepatocyte cytoplasmic alteration, ↑ absolute and relative liver weight, changes in cholesterol and triglyceride levels, ↑ serum ALT and ALP **Males**: ↑ serum AST and bilirubin	LOAEL: 0.625 mg/kg-day for hepatocyte cytoplasmic alteration and ↑ liver weight in males	NTP (2018b)
Female Sprague Dawley rats (n=10/dose)	0, 300, or 1,000 ppm (0, 27.7, or 92.7 mg/kg-day, calculated by OEHHA) in feed for 16 weeks	↑ absolute and relative liver weight, hepatocyte cytoplasmic alteration, hepatocyte hypertrophy, ↑ serum ALT and ALP	NOAEL: 300 ppm (27.7 mg/kg-day) for all liver endpoints	NTP (2018c)
Male Sprague Dawley rats (n=10/dose)	0, 150, or 300 ppm (0, 14.7, or 29.5 mg/kg-day) in feed for 16 weeks	↑ relative liver weight, liver necrosis, liver pigment, hepatocyte hypertrophy, hepatocyte cytoplasmic alteration, hepatocyte single cell death, ↑ serum ALT and ALP, ↑ bile salts	LOAEL: 150 ppm (14.7 mg/kg-day) for all liver endpoints	NTP (2018c)
Male Sprague Dawley rats (n=10/dose)	0, 20, 40, or 80 ppm (0, 1.8, 3.7, or 7.5 mg/kg-day) in feed for 16 weeks	↑ absolute and relative liver weight, liver necrosis, liver pigment, hepatocyte cytoplasmic alteration, hepatocyte hypertrophy, hepatocyte single cell death, ↑ serum ALT and ALP	LOAEL: 20 ppm (1.8 mg/kg-day) for ↑ liver weight, ↑ ALT and ALP, and hepatocyte necrosis, cytoplasmic alteration, and single cell death	NTP (2018c)

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Female Sprague Dawley rats (n=50/dose)	0, 300, or 1,000 ppm (0, 18, or 63 mg/kg-day) in feed for 107 weeks	Liver necrosis, liver pigment, bile duct hyperplasia, hepatocyte cytoplasmic alteration, hepatocyte hypertrophy, hepatocyte single cell death, hepatocyte ↑ mitoses	LOAEL: 300 ppm (18 mg/kg-day) for hepatocyte cytoplasmic alteration and hepatocyte hypertrophy	NTP (2018c)
Male Sprague Dawley rats (n=50/dose)	0, 20, 40, or 80 ppm (0, 1, 2.2, or 4.5 mg/kg-day) in feed for 107 weeks	Liver cystic degeneration, liver eosinophilic and mixed cell focus, liver focal inflammation, liver necrosis, liver pigment, hepatocyte hypertrophy, hepatocyte cytoplasmic alteration, hepatocyte single cell death	LOAEL: 20 ppm (1 mg/kg-day) for liver necrosis, hepatocyte hypertrophy, and hepatocyte cytoplasmic alteration	NTP (2018c)

[a] LOAEL/NOAEL not applicable for single dose studies.
[b] Histology data are presented in the supplementary materials, but specific doses for which hepatocyte swelling and lipid deposits become significant are not provided.
ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; GD, gestation day; i.p., intraperitoneal; LOAEL, lowest-observed-adverse-effect level; NOAEL, no-observed-adverse-effect level; PND, postnatal day

Recently, the NTP released toxicity data from subacute (28 days) and chronic (16 or 107 weeks) bioassays for PFOA conducted in male and female rats. Animals were given PFOA in feed (concentrations are provided in Table 1). For the chronic studies, an additional cohort of animals was exposed to PFOA during gestation and lactation (perinatal exposure; 150 or 300 parts per million [ppm] for males and females). The toxicity data obtained from this additional cohort were examined to provide supportive evidence of toxicity (when compared with non-perinatally exposed animals), but were not evaluated specifically for NL development. Although the initial chronic study in male rats with concentrations of 0, 150, or 300 ppm (0, 14.7, or 29.5 milligrams per kilogram of bodyweight per day [mg/kg-day]) in feed was ended at 21 weeks due to overt toxicity, it appears a subset of animals receiving these doses were examined at 16 weeks, and the study was repeated with lower doses. Liver toxicity was observed in all of the studies, regardless of sex or duration. Common liver effects include increased weight, increased alanine aminotransferase (ALT) and alkaline phosphatase (ALP), necrosis, liver pigment, hepatocyte cytoplasmic alteration and hypertrophy, and hepatocyte single

cell death (NTP, 2018b,c). Liver toxicity lowest-observed-adverse-effect levels (LOAELs) of 0.625 mg/kg-day and 1 mg/kg-day for the 28-day and 107-week studies in male rats, respectively, were identified. This corresponds to plasma concentrations of 50.7 and 81.4 milligrams per liter (mg/L) respectively. Plasma/serum concentration is the most appropriate dose metric for extrapolating toxicity data from rodent studies to humans because of the large difference in the chemical's half-life between rodents (1-3 weeks) and humans (2-3 years). This accounts for the accumulation of PFOA in humans due to the chemical's long half-life. Plasma concentration in the chronic male rat study was determined at 16 weeks, but because the serum half-life of PFOA is estimated to be 4-6 days in male rats (New Jersey, 2017; Lau et al., 2006), it is anticipated that by 16 weeks, a steady-state concentration would have been reached. Thus, the plasma concentration would remain relatively stable over the 107-week period of continuous dosing.

Male Kunming mice administered 0, 1, or 5 mg/kg-day PFOA intragastrically for 21 days displayed increased absolute and relative liver weight, increased serum ALT and aspartate aminotransferase (AST), elevated hepatic triglycerides, decreased serum triglycerides, increased hepatic vacuoles, changes in serum cholesterol levels, and increased blood insulin (Wu et al., 2018). OEHHA identified a no-observed-adverse-effect level (NOAEL) of 1 mg/kg-day based on these effects.

Li et al. (2017) administered 0, 0.05, 0.5 or 2.5 mg/kg-day PFOA via oral gavage to male and female Balb/c mice for 28 days. The authors reported decreased body weight, increased absolute liver weight, hepatocellular hypertrophy and apoptosis, lipid accumulation in hepatocyte cytoplasm, changes to mitochondrial morphology and membrane potential, and oxidative DNA damage (increased 8-hydroxydeoxyguanosine formation) in the liver. Toxicity endpoint data and PFOA serum concentrations were quantified using GetData graph digitizer software (version 2.26), and are presented in Table 2. Female mice were more sensitive to apoptosis than male mice. The administered dose of 0.05 mg/kg-day corresponds to a serum concentration of approximately 1 microgram per milliliter (µg/ml) (for both sexes), which was measured at the end of the exposure period. OEHHA identified a LOAEL of 0.05 mg/kg-day (serum concentration of 1 µg/ml) for changes in mitochondrial membrane potential, increases in biomarkers of apoptosis (caspase-9 and p53), and increased oxidative DNA damage (Li et al., 2017).

Table 2. Dose metrics and endpoints in female mice from Li et al. (2017)

Administered dose (mg/kg-day)	Reported serum concentration (mg/L)	Cells with mitochondrial membrane potential changes (%)	Caspase-9 levels (iU/g)	p53 levels (iU/g)	8-OHdG (ng/g)
0	0	1.2 ± 0.5	71.3 ± 4.2	28.9 ± 3.5	22.9 ± 7.3
0.05	0.97	12.3 ± 1.2**	130.2 ± 9.0**	46.8 ± 5.1**	68.6 ± 6.2**
0.5	2.7	17.6 ± 1.1**	157.9 ± 3.5**	58.3 ± 4.5**	87.9 ± 9.3**
2.5	9.5	39.3 ± 14.6**	220.9 ± 1.1**	69.0 ± 3.2**	96.8 ± 2.6**

8-OHdG, 8-hydroxydeoxyguanosine; iU/g, international units/gram
**p<0.01, statistical analysis by OEHHA

Reduced body weight and increased absolute and/or relative liver weight were also reported in several other studies using Balb/c mice and Sprague Dawley rats with higher doses (ranging from 0 to 10 mg/kg-day) for 7-28 days (Du et al., 2018; Hui et al., 2017; Zheng et al., 2017; Yu et al., 2016; NTP, 2018b). Sprague Dawley rats also displayed hepatocyte hypertrophy and cytoplasmic alteration, changes in cholesterol and triglyceride levels, and increased serum ALT, AST, ALP, and bilirubin levels following oral exposure to PFOA for 28 days (NTP, 2018b).

Hepatotoxicity was also observed in frogs (Tang et al., 2018).

In vitro studies

Human liver HL-7702 cells treated with 0, 1, 2.5, or 7.5 micromoles/L (μM) PFOA had elevated levels of apoptosis and oxidative DNA damage (Li et al., 2017). Increased apoptosis was also observed in the mouse liver AML12 cell line (Wu et al., 2017). PFOA increased apoptosis, decreased mitochondrial membrane integrity, and increased anti-inflammatory interleukin 10 (IL-10) levels in rat and/or human organotypic multi-culture hepatocellular models (Orbach et al., 2018). Impaired proteolysis and autophagosome accumulation were observed in HepG2 cells treated with 0, 50, 100, or 200 μM PFOA (Yan et al., 2017). Liu et al. (2017) reported increased oxidative stress in primary rat hepatocytes treated with ≥6.25 μM PFOA.

Mechanistic studies

Mechanisms of hepatotoxicity have been previously reviewed (US EPA, 2016a; New Jersey DWQI, 2017). It has been established that PFOA can induce toxicity via activation of the nuclear receptor peroxisome proliferator-activated receptor alpha

(PPARα). However, PPARα activation does not explain all of the observed toxicity, and studies in PPARα knockout mice clearly demonstrate PPARα-independent toxicity (reviewed by US EPA, 2016a; New Jersey DWQI, 2017). Furthermore, there is evidence that PFOA activates other nuclear receptors, including constitutive androstane receptor (CAR), pregnane X receptor (PXR), and estrogen receptor alpha (ERα) (New Jersey DWQI, 2017). Recently, it was demonstrated that PFOA indirectly activates CAR, differently from the prototypical CAR activator phenobarbital (Abe et al., 2017).

Additional recent studies examining mechanisms of hepatotoxicity are briefly summarized here.

In mouse liver and human hepatocytes, PFOA administration decreased hepatocellular hepatocyte nuclear factor 4 alpha (HNF4α), which has an important role in hepatocyte differentiation (Beggs et al., 2016). Additionally, PFOA increased levels of the anti-inflammatory cytokine iterleukin-10 (IL-10) in human and rat organotypic cell culture models (Orbach et al., 2018).

Several studies have examined hepatic transcriptomic/proteomic changes in mice (Hui et al., 2017; Li et al., 2017; Abe et al., 2017; Zheng et al., 2017), and in mammalian liver cells (Beggs et al., 2016; Song et al., 2016; Zhang et al., 2016a; Liu et al., 2017; Yan et al., 2017) following PFOA administration. In general, PFOA exposure altered the levels of mRNA transcripts and/or proteins involved with apoptosis, lipid metabolism, cell proliferation, autophagy and vesicular trafficking, and the Krebs cycle. These data suggest that PFOA induces significant gene expression changes in the liver, and are supportive of the observed hepatotoxicity in animals.

Critical Study Selection

Li et al. (2017) generated a LOAEL of 0.05 mg/kg-day (administered dose) for changes in mitochondrial membrane potential, increases in biomarkers of apoptosis, and increased oxidative DNA damage in the liver of female mice. This LOAEL corresponds to a serum concentration of 0.97 mg/L, which is lower than the POD of 4.35 mg/L based on increased relative liver weight in male mice (Loveless et al., 2006) that formed the basis for the interim NL. Therefore, the Li et al. (2017) study is more appropriate than the Loveless et al. (2006) study as a critical study for POD derivation.

Liver Toxicity – PFOS

In vivo studies

PFOS exposure has consistently induced liver toxicity in experimental animals, and a thorough examination of the literature was previously conducted by other agencies (US EPA, 2016b; New Jersey DWQI, 2018). In general, increases in absolute and/or relative liver weight, increased liver histopathology, increased biomarkers of liver damage, and changes in liver lipid content were observed.

Several animal studies published after 2016 reported various hepatotoxic endpoints following oral exposure to PFOS. These studies are summarized in Table 3.

Table 3. Summary of recent animal toxicity studies of PFOS reporting liver effects

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Pregnant mice (strain not specified) (n=3-5/ dose)	0, 1, 10, or 20 mg/kg-day orally from GD1 to GD14	fetal liver enlargement	Doses that caused effect were not specified	Mehri et al. (2016)
Male and female Cynomolgus monkeys (n=6/sex/ dose)	0 or 14 mg/kg orally on three separate occasions over 422 days; maximum PFOS serum concentrations of 165 µg/mL for females and 160.8 µg/mL for males on day 365	no toxicologically significant effects reported	NOAEL: 165 µg/mL serum PFOS	Chang et al. (2017)
Male and female Sprague Dawley rats (n=12/sex/ dose)	0 or 100 ppm in diet; equivalent to 6 mg/kg-day for males and 6.6 mg/kg-day for females	**Both sexes:** ↑ absolute and relative liver weight; hepatocellular hypertrophy **Males:** ↓ serum cholesterol and triglyceride levels; cytoplasmic vacuolization; ↑ lipid content **Females:** ↓ free fatty acids and triglycerides	NA[a]	Bagley et al. (2017)

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Male Sprague Dawley rats (n=6/dose)	0, 1, or 10 mg/kg-day orally for 4 weeks (males only)	hepatocellular hypertrophy; cytoplasmic vacuolization; ↑ serum ALT and AST; ↑ oxidative stress and apoptosis	LOAEL: 1 mg/kg-day for ↑ liver enzymes, oxidative stress, and apoptosis	Han et al. (2018a)
Male Sprague Dawley rats (n=6/dose)	0, 1, or 10 mg/kg-day orally for 4 weeks (males only)	↑ absolute liver weight; hepatocyte degeneration; cytoplasmic vacuolization; ↑ serum ALT and AST	NOAEL: 1 mg/kg-day for increased liver enzymes	Han et al. (2018b)
Male Sprague Dawley rats (n=7/dose)	0, 1, or 10 mg/kg-day orally for 4 weeks (males only)	↑ absolute and relative liver weight; hepatocellular hypertrophy; cytoplasmic vacuolization; ↑ serum ALT and AST; inflammatory cellular infiltration; ↑ apoptosis	LOAEL: 1 mg/kg-day for increased liver enzymes	Wan et al. (2016)
Male C57BL/6 mice (n=10/dose)	0, 2.5, 5, or 10 mg/kg-day via oral gavage for 30 days	↑ absolute liver weight; ↑ serum ALT and AST; hepatocyte vacuolization and necrosis; ↑ oxidative stress and apoptosis	LOAEL: 2.5 mg/kg-day for ↑ liver enzymes, oxidative stress, and apoptosis	Xing et al. (2016)
Male wild-type or ERβ knock-out mice (n=8/dose/ group)	0 or 5 mg/kg-day via oral gavage for 28 days	Hepatocyte degeneration and vacuolization; ↓ hepatic cholesterol and bile acids	NA[a]	Xu et al. (2017)

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Male C57BL/6 mice (n=5-6/dose)	0, 0.003, 0.006, or 0.012% (0, 30, 60 or 120 mg/kg-day) in diet for 21 or 23 days	↑ relative liver weight; ↑ ALT, bile acids and triglycerides; hepatocyte vacuolization and necrosis; altered lipid metabolism	LOAEL: 30 mg/kg-day for increased liver weight and triglycerides	Zhang et al. (2016b)
Male and female Sprague Dawley rats (n=10/sex/ dose)	0, 0.312, 0.625, 1.25, 2.5, or 5 mg/kg-day via oral gavage for males and females for 28 days	Hepatocyte hypertrophy, ↑ absolute/relative liver weight, ↓ cholesterol and triglycerides, ↑ ALT, ALP, bile salt/acid, albumin, and direct bilirubin; **Males**: ↑ AST, ↓ globulin, hepatocyte cytoplasmic vacuolization; **Females**: hepatocyte cytoplasmic alteration, ↑ total bilirubin	LOAEL: 0.312 mg/kg-day for ↑ relative liver weight in males and females	NTP (2018a)

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; ERβ, estrogen receptor beta; GD, gestation day; LOAEL, lowest-observed-adverse-effect level; NOAEL, no-observed-adverse-effect level

Briefly, several recent studies in Sprague Dawley rats reported various hepatotoxic endpoints following 3-4 weeks of oral exposure to PFOS, including increased absolute and/or relative liver weight (Han et al. 2018b; Bagley et al., 2017; Wan et al. 2016; NTP, 2018a), increased serum ALT and AST (Han et al., 2018a; Wan et al., 2016; NTP, 2018a), altered cholesterol and triglyceride levels (Bagley et al., 2017; NTP, 2018a), hepatocellular hypertrophy (Han et al., 2018a; Bagley et al., 2017; Wan et al., 2016; NTP, 2018a), cytoplasmic vacuolization (Han et al., 2018a; Han et al., 2018b; Wan et al., 2016; NTP, 2018a), and hepatocyte degeneration/necrosis (Han et al., 2018b; Bagley et al., 2017). Additionally, increased levels of oxidative stress markers (Han et al., 2018a), apoptosis (Han et al., 2018a; Wan et al., 2016), and hepatic cell proliferation

(Han et al., 2018b) were observed. OEHHA identified a LOAEL of 0.312 mg/kg-day, based on increased relative liver weight in rats (NTP, 2018a).

Similar endpoints (decreased body weight, increased liver weight, increased ALT, AST, and bile acids, hepatocyte vacuolization and necrosis, and increased oxidative stress) were observed in mice given PFOS orally (doses from 2.5-120 mg/kg-day) for 3-4 weeks (Xing et al., 2016; Xu et al., 2017; Zhang et al., 2016b). OEHHA identified a LOAEL of 2.5 mg/kg-day for increases in liver enzymes, markers of oxidative stress, and apoptosis in C57BL/6 mice (Xing et al., 2016).

Choline supplementation reduced PFOS-induced hepatic oxidative stress and changes in lipid metabolism in male C57BL/6 mice (Zhang et al., 2016b), but had no impact on steatosis in Sprague Dawley rats (Bagley et al., 2017). Additionally, ERβ (estrogen receptor beta) knockout mice did not show the hepatotoxic effects (hydropic degeneration and vacuolization of hepatocytes, decreased hepatic cholesterol and bile acid levels) that were present in wild-type mice (Xu et al., 2017). Furthermore, hepatocyte vacuolization, fatty degeneration, lipid accumulation, and ultrastructural changes in the liver were observed in zebrafish exposed to PFOS (Cheng et al., 2016; Cui et al., 2017).

In vitro studies

Cytotoxicity, oxidative stress, mitochondrial dysfunction, impaired proteolysis, autophagosome formation, and lysosomal membrane permeabilization were observed in HepG2 cells exposed to up to 200 µM PFOS (Wan et al., 2016; Yao et al., 2016; Yan et al., 2017). Primary hepatocytes from Sprague Dawley rats (that were depleted of glutathione prior to PFOS exposure) showed increased oxidative stress, decreased mitochondrial membrane potential, lysosomal membrane damage, and proteolysis following exposure to PFOS (Khansari et al., 2017).

Mechanistic studies

Mechanisms of hepatotoxicity have been previously reviewed (US EPA, 2016b; New Jersey DWQI, 2018). It has been established that PFOS can induce hepatotoxicity via activation of the nuclear receptor PPARα. However, PPARα activation does not explain all of the observed hepatotoxicity. It has been suggested that PFOS may interact with other nuclear receptors, including CAR, PXR, PPARβ/δ, PPARγ, HNF4α, and ERα (New Jersey DWQI, 2018). Recently, it was shown that PFOS-induced liver toxicity also appears to act via ERβ, as ERβ knockout mice did not display the adverse effects (hepatocyte vacuolization, hydropic degeneration, changes in levels of cholesterol and bile acids) observed in wild-type mice (Xu et al., 2017). PFOS also increased expression of ERβ in HepG2 cells (Xu et al., 2017). Beggs et al. (2016) demonstrated that PFOS decreased HNF4α levels in mouse liver and human hepatocytes.

Additional recent studies examining mechanisms of hepatotoxicity are briefly summarized below.

PFOS induced autophagosome formation and lysosome membrane permeabilization in HepG2 cells (Yao et al., 2016). Spinster-1, a sphingolipid transporter involved in cell death, was implicated in toxicity, as knocking out this protein attenuated lysosome membrane permeabilization. PFOS also inhibited activation of protein kinase B in HepG2 cells, which could lead to changes in cell proliferation and apoptosis (Qiu et al., 2016b).

Several studies have examined hepatic transcriptomic/proteomic changes in rats (Dong et al., 2016; Wan et al., 2016; Han et al., 2018a; Han et al., 2018b), mice (Lai et al., 2017; Xu et al., 2017), zebrafish (Cheng et al., 2016; Fai Tse et al., 2016; Cui et al., 2017), mammalian liver cells (Han et al., 2018b; Wan et al., 2016; Beggs et al., 2016; Song et al., 2016), and chicken eggs (Jacobsen et al., 2018) following PFOS administration. In general, PFOS exposure altered the levels of mRNA transcripts and/or proteins involved with apoptosis, lipid metabolism, cell proliferation, necrosis, and carcinogenesis. The transcriptomic/proteomic evidence is indicative of hepatotoxicity and supports the animal toxicity data.

Critical Study Selection

The NOAELs/LOAELs (based on administered dose) determined from these recent PFOS studies showing liver toxicity are orders of magnitude higher than the NOAEL of 0.008 mg/kg-day (administered dose) for immunotoxicity from Dong et al. (2009) (discussed below in the PFOS immunotoxicity section), which was the basis for OEHHA's interim NL recommendation. Therefore, these studies are not considered for POD derivation in support of a final recommendation on the PFOS NL.

Immunotoxicity - PFOA

In a systematic review, NTP (2016) determined that PFOA is "presumed to be an immune hazard to humans" through suppression of antibody response as shown in animal and human studies. Assessments by US EPA (2016a), New Jersey Drinking Water Quality Institute (DWQI) (2017) and the US Agency for Toxic Substances and Disease Registry (ATSDR) (2018) have also described immune toxicity effects in humans and animals. Effects on spleen and thymus have been observed as well as the inability for the immune system to respond to a challenge.

In vivo studies

Since the publication of the above cited assessments, several recent studies reported similar effects on the immune system. These studies are summarized in Table 4.

Table 4. Summary of recent animal toxicity studies of PFOA reporting immune toxicity

Sex/Species	Exposure	Endpoints	NOAEL/LOAEL	Reference
Female C57BL/6N PPARα KO and WT mice (n=6/dose/ group)	0, 7.5 or 30 mg/kg-day in drinking water for 15 days	↓ relative spleen and relative thymus weights in WT mice; ↓SRBC-specific IgM antibody responses in KO and WT mice.	LOAEL: 7.5 mg/kg-day for ↓ relative thymus weight in WT mice	Dewitt et al. (2016)
Female C57BL/6N WT mice (n=8/dose)	0, 0.94, 1,88, 3.75, or 7.5 mg/kg-day in drinking water for 15 days	↓ dinitrophenyl-ficoll (DNP)-specific IgM antibody response; ↓ relative spleen and thymus weight (high dose)	NOAEL: 0.94 mg/kg-day for ↓ antibody response	Dewitt et al. (2016)
Female C57BL/6N WT mice (n=4/dose/ group)	0, 3.75 or 7.5 mg/kg-day in drinking water for 10, 13 or 15 days	Changes in splenic lymphocyte subpopulations	LOAEL: 3.75 mg/kg-day for changes in splenic lymphocyte subpopulations	Dewitt et al. (2016)
Male ICR mice (n=5/dose)	Treated mice were sensitized with OVA to induce active systemic anaphylaxis on day 0 and 7. OVA + 100 or 150 mg/kg 3 times on days 9 and 13 orally. Control mice had 150 mg/kg PFOA only or OVA only.	↓ rectal temperature; ↑ serum histamine, TNF-α, IgG1 and IgE levels	LOAEL: 100 mg/kg for ↑ TNF-α and IgE levels in sensitized mice	Lee et al. (2017)

Sex/Species	Exposure	Endpoints	NOAEL/LOAEL	Reference
C57BL/6 mice (sex not specified) (n=4/group)	0 or 2 mg/kg via oral gavage for 25 days. Mice infected with *Citrobacter* at day 7.	↓weight gain; ↓ in pathogen clearance at late stage infection; induction of IL-22 from ILC3 and Th17 cells; ↓ mucin	NA[a]	Suo et al. (2017)
Male Sprague Dawley rats (n=10/dose)	0, 150, or 300 ppm (0, 14.7, or 29.5 mg/kg-day) in feed for 16 weeks	↓ absolute and relative spleen weight; lymphoid follicle atrophy	LOAEL: 14.7 mg/kg-day for ↓ absolute and relative spleen weight	NTP (2018c)
Female Sprague Dawley rats (n=10/dose)	0, 300, or 1,000 ppm (0, 27.7, or 92.7 mg/kg-day) in feed for 16 weeks	Pigment in spleen	LOAEL: 27.6 mg/kg-day for pigment in spleen	NTP (2018c)

[a] LOAEL/NOAEL not applicable for single dose studies.
GD, gestation day; IgE, immunoglobulin E; IgM, immunoglobulin M; IL-22, interleukin 22; KO, knockout; LOAEL, lowest-observed-adverse-effect level; NOAEL, no-observed-adverse-effect level; OVA, ovalbumin; PND, postnatal day; PPARα, peroxisome proliferator-activated receptor alpha; SRBC, sheep red blood cells; TNF-α, tumor necrosis factor alpha; WT, wild-type

In vitro studies

Lee et al. (2016) investigated the effect of PFOA on mast cells and its association with allergic inflammation. Increased histamine and β-hexoaminidase release was observed in IgE-stimulated mast cells. The increased histamine release was the result of increased intracellular calcium induced by PFOA. Cytokine gene and protein expression were also increased. A decrease in IL-10 was also observed in PFOA-treated multicellular organotypic culture models of human or rat cells (Orbach et al., 2018).

Mechanistic studies

The database of studies on the mechanism for immune toxicity is limited. US EPA (2016a) and New Jersey DWQI (2017) suggested that the effects of PFOA on the immune system may have a mode of action that is both PPARα-dependent and independent.

Lee et al. (2016) found that the mechanism for cytokine induction observed in PFOA-treated mast cells was the result of activation of nuclear factor kappa B (NF-κB), a nuclear factor that helps regulate immune response in cells.

Critical Study Selection

The NOAELs/LOAELs (based on administered dose) determined from these recent immunotoxicity studies are substantially higher than the LOAEL of 0.05 mg/kg-day for liver toxicity from the Li et al. (2017) study, which is selected as a critical study for development of a noncancer RL. Therefore, these studies are not considered for POD derivation in support of a final recommendation on the PFOA NL.

Immunotoxicity – PFOS

A systematic review by NTP (2016) determined that PFOS is presumed to be an immune hazard to humans. The database of studies investigating the immune toxicity of PFOS is limited and has been reviewed in recent assessments by US EPA (2016a), New Jersey DWQI (2018) and ATSDR (2018). Effects on immune organs as well as immune suppression have been observed.

In vivo studies

OEHHA conducted a literature search to find additional studies published after the above-cited reviews and these recent studies are summarized in Table 5.

Table 5. Summary of recent animal toxicity studies of PFOS reporting immune toxicity

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Male and female Sprague Dawley rats (n=10/sex/dose)	0, 0.312, 0.625, 1.25, 2.5 or 5 mg/kg-day for 28 days via oral gavage	**Males**: ↓white blood cells, ↓neutrophils, ↓ eosinophils, ↓ relative thymus weight **Females**: ↓ relative thymus weight at 1.25 mg/kg-day (not statistically significant at higher doses)	NOAEL: 2.5 mg/kg-day for all endpoints in males	NTP (2018a)

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Male ICR mice (n=5/dose)	Treated mice were sensitized with OVA to induce active systemic anaphylaxis on day 0 and 7. OVA + 50, 100 or 150 mg/kg, 3 times on days 9, 11 and 13 orally. Control mice had 150 mg/kg PFOS only or OVA only.	↓ rectal temperature; ↑ histamine, TNF-α, IgG and IgE levels in sensitized mice	LOAEL: 50 mg/kg for ↑TNF-α and IgE levels	Lee et al. (2018)
Male Sprague Dawley rats (n=6/dose)	0, 1, or 10 mg/kg-day orally for 4 weeks	↑ serum TNF-α and IL-6 levels	LOAEL: 1 mg/kg-day for ↑ serum TNF-α and IL-6 levels	Han et al. (2018b)

IgE, immunoglobulin E; IgG, immunoglobulin G; IL-6, interleukin 6; LOAEL, lowest-observed-adverse-effect level; NOAEL, no-observed-adverse-effect level; OVA, ovalbumin; TNF-α, tumor necrosis factor alpha

There are no new studies that are more sensitive than the Dong et al. (2009) study for derivation of the noncancer RL for PFOS. In this study, 10 adult male C57BL/6 mice per dose group were administered 0, 0.008, 0.083, 0.417, 0.833, or 2.08 mg/kg-day PFOS via oral gavage for 60 days. Significant toxicity endpoints include: decreased body, spleen, thymus, and kidney weights; increased liver weight; decreased splenic and thymic cellularity, and T cell CD4/CD8 subpopulations; altered natural killer cell activity; decreased splenic lymphocyte proliferation; and decreased sheep red blood cell (SRBC)-specific IgM plaque forming cell response. Serum concentrations were reported for each dose. A NOAEL of 0.008 mg/kg-day (serum concentration of 0.674 mg/L) was identified for decreased plaque-forming cell response.

In vitro studies

Han et al. (2018b) compared changes in tumor necrosis factor alpha (TNF-α) and interleukin 6 (IL-6) levels between Kupffer cells and hepatocytes treated with PFOS. Exposure to 100 µM PFOS for 48 hours caused a transient but significant increase in TNF-α in Kupffer cells while levels remained unchanged in hepatocytes. Interleukin 7 (IL-7) was significantly elevated in Kupffer cells for the entire 48-hour exposure duration

while levels remained unchanged in hepatocytes. Blockage of TNF-α and IL-6 inhibited gadolinium chloride-induced hepatocyte proliferation. The authors suggest that cytokine expression in Kupffer cells is involved in hepatocyte proliferation through a NF-kB/TNF-α/IL-6 dependent pathway. In a study in primary human decidual stromal cells, PFOS inhibited cortisone induced reduction of the inflammatory cytokines, IL-6 and interleukin 1 beta (IL-1β) (Yang et al., 2016).

Mechanistic studies

In the risk assessment by New Jersey DWQI (2018), the authors summarized that the immunotoxicity of PFOS may be PPARα mediated, or it may be due to lipid imbalance or be a stress response, but the specific mechanism remains unclear.

Han et al. (2018b) found that hepatocyte proliferation observed in PFOS treated mice was influenced by PFOS-induced cytokine expression in Kupffer cells, and occurred through the NF-kB/TNF-α/IL-6 pathway. Blocking TNF-α and IL-6 inhibited hepatocyte proliferation.

Critical Study Selection

The recent immunotoxicity studies of PFOS are much less sensitive than the Dong et al. (2009) study, which was the basis for OEHHA's interim NL recommendation. Thus, these recent immunotoxicity studies are not considered as critical studies for POD derivation.

Thyroid Toxicity – PFOA

Thyroid effects have been reported in animals environmentally exposed to perfluoroalkyl and polyfluoroalkyl substances (PFAS). Levels of the thyroid hormone, T3 (triiodothyronine), were negatively associated with PFAS in polar bears and hooded seals (Bourgeon et al., 2017; Grønnestad et al., 2018).

Several recent mechanistic studies showed that PFOA, PFOS, and other medium-chain PFAS bind to the thyroxine transport protein transthyretin (Ren et al., 2016; Zhang et al., 2016b; Xin et al., 2018). Xin et al. (2018) also showed that PFOS can bind to thyroid hormone receptors.

NTP recently released subacute (28 days) and chronic (16 or 107 weeks) bioassays for PFOA conducted in male and female rats. Animals were given PFOA in feed (concentrations are provided in Table 6). For the chronic studies, an additional cohort of animals was exposed to PFOA during gestation and lactation (perinatal exposure). Although the initial chronic study in male rats with concentrations of 0, 150, or 300 ppm (0, 14.7, or 29.5 mg/kg-day) in feed was ended at 21 weeks due to overt toxicity, it appears a subset of animals receiving these doses were examined at 16 weeks, and

the study was repeated with lower doses. Results are summarized in Table 6. Thyroid follicular cell hypertrophy was observed in male and female rats in the 28-day studies, and in female rats in the 107-week study. Thyroid toxicity was not observed in female rats in the 16-week study and male rats in the 107-week study (NTP, 2018c). It should be noted, however, that male rats exposed perinatally in the 107-week study had higher incidences of thyroid follicular cell hypertrophy, although statistical significance was not reached (p=0.087, Fisher's exact test, done by NTP). OEHHA identified a LOAEL of 0.625 mg/kg-day (corresponding to a plasma concentrations of 50.7 and 0.49 mg/L in males and females, respectively) for changes in thyroid hormone levels in male and female rats for the 28-day studies, and a NOAEL of 14.7 mg/kg-day (plasma concentration of 193 mg/L) for thyroid follicular cell hypertrophy and changes in thyroid weight in male rats in the chronic studies.

Table 6. Thyroid toxicity from the NTP (2018b,c) subacute and chronic studies of PFOA in Sprague Dawley rats

Sex	Exposure	Endpoints	NOAEL/ LOAEL
Male (n=10/dose)	0, 0.625, 1.25, 2.5, 5, or 10 mg/kg-day via oral gavage for 28 days	Thyroid follicular cell hypertrophy (trend), increased relative thyroid weight, decreased TSH, T3, fT4 and tT4	LOAEL: 0.625 mg/kg-day for changes in thyroid hormones
Female (n=10/dose)	0, 0.625, 1.25, 2.5, 5, or 10 mg/kg-day via oral gavage for 28 days	Thyroid follicular cell hypertrophy, increased TSH, decreased fT4 and tT4	LOAEL: 0.625 mg/kg-day for increased TSH
Male (n=10/dose)	0, 150, or 300 ppm (0, 14.7, or 29.5 mg/kg-day) in feed for 16 weeks	Decreased relative and increased absolute thyroid weight, thyroid follicular cell hypertrophy	NOAEL: 14.7 mg/kg-day for all thyroid endpoints
Male (n=10/dose)	0, 20, 40, or 80 ppm (0, 1.8, 3.7, or 7.5 mg/kg-day) in feed for 16 weeks	Decreased absolute thyroid weight (not significant at the highest dose)	NOAEL: 1.8 mg/kg-day for decreased thyroid weight
Female (n=50/dose)	0, 300, or 1,000 ppm (0, 18, or 63 mg/kg-day) in feed for 107 weeks	Thyroid follicular cell hypertrophy	NOAEL: 18 mg/kg-day for thyroid follicular cell hypertrophy

LOAEL, lowest-observed-adverse-effect level; NOAEL, no-observed-adverse-effect level; TSH, thyroid stimulating hormone; T3, triiodothyronine; fT4, free thyroxine; tT4, total thyroxine

PFOA was associated with hyperthyroidism in a case control study of 72 cats (Bost et al., 2016).

Critical Study Selection

Thyroid toxicity observed in the NTP (2018b,c) subacute and chronic studies of PFOA is not considered for POD derivation because this endpoint is much less sensitive than the hepatotoxicity endpoints reported by Li et al. (2017).

Thyroid Toxicity – PFOS

NTP (2018a) conducted subacute studies in male and female rats with PFOS. Animals were given 0, 0.312, 0.625, 1.25, 2.5, or 5 mg/kg-day PFOS via oral gavage for 28 days. Decreases in T3, fT4 (free thyroxine), and tT4 (total thyroxine) were observed in both sexes, while decreased absolute thyroid weight was reported in males only (NTP, 2018). A LOAEL of 0.312 mg/kg-day (corresponding to plasma concentrations of 23.7 and 30.5 mg/L for males and females, respectively) was identified based on decreases in fT4 and tT4 in both sexes.

A recent study in male and female cynomolgus monkeys given 14 mg/kg PFOS via oral gavage on three separate occasions over an observation period of 422 days showed a slight reduction in serum tT4 in both sexes (Chang et al., 2017b). There were no significant changes in TSH or fT4. The authors did not consider the reduction in tT4 to be toxicologically relevant because a sufficient reservoir of inactive (bound to protein) T4 remained available to maintain thyroid hormone homeostasis.

Critical Study Selection

Thyroid toxicity observed in the subacute NTP (2018a) studies is not considered for POD derivation because this endpoint is much less sensitive than the immunotoxicity reported by Dong et al. (2009).

Reproductive Toxicity – PFOA

In vivo studies

Reproductive effects of PFOA in animals were described in recent assessments by US EPA (2016a), New Jersey DWQI (New Jersey DWQI, 2017) and ATSDR (2018). Additionally, in 2017, PFOA was listed under Proposition 65 as a chemical known to the state of California to cause reproductive toxicity. Subchronic studies in mice showed reproductive toxicity effects such as decreased litter size, increased litter resorptions, and increased fetal death. Male mice exposed to PFOA had decreased testis weight, decreased sperm count and testicular damage. A two-generational study in rats showed no reproductive toxicity.

Studies of PFOA exposure reporting reproductive toxicity effects published after 2016 are summarized in Table 7.

Table 7. Summary of recent animal toxicity studies of PFOA reporting reproductive toxicity

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Male Kunning mice (n=6/dose)	0, 2.5, 5, or 10 mg/kg-day for 14 days orally	↓ absolute testis weight (high dose); ↓ sperm count (all doses); morphological changes in seminiferous tubules; ↓ SOD levels, CAT activity in testes (all doses); ↓ MDA and H_2O_2 levels in the testis (mid and high dose)	LOAEL: 2.5 mg/kg-day for ↓ sperm count	Liu et al. (2015)
Male BALB/C mice (n=11/dose)	0, 1.25, 5, or 20 mg/kg-day via oral gavage for 28 days	↓ triglyceride and cholesterol in epididymis (mid and high dose); ↓ in relative epididymis weight (low and high dose); changes in expression of genes and proteins related to triglyceride, cholesterol and fatty acid metabolism in the epididymis; changes in fatty acid composition in epididymis; ↑ MDA levels in epididymis (low and mid dose) ↓ GSH-Px levels in epididymis (mid and high dose)	LOAEL: 1.25 mg/kg-day for ↓ in relative epididymis weight	Lu et al. (2016)

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Pregnant Kunming mice (n=10/dose), male offspring evaluated for effects on PND 21 and 70	0,1 ,2.5, or 5 mg/kg-day via oral gavage from GD 1-17	**Pups**: ↓ number of surviving mice at weaning (high dose); ↑ absolute testis weight (high dose) on PND 21, ↓ absolute testis weight (low dose) on PND 70; ↑ testosterone (low dose) on PND 70, ↓ testosterone in testis (all doses) on PND 21 and (mid and high dose) on PND 70; ↓ Leydig cells (mid and high dose, PND 21 and 70); vacuolization of Sertoli cells and ↓ spermatozoa at high dose	LOAEL: 1 mg/kg-day for ↑ testoster-one, ↓ in absolute testis weight	Song et al. (2018)
Pregnant Kunning mice (n=12/dose)	0, 2.5, 5, or 10 mg/kg-day via oral gavage from GD 1 to GD 7 or 13	**Dams:** ↑ number of resorbed embryos on GD 13 (high dose); ↑ serum estradiol on GD 7 (high dose); ↓ serum progesterone on GD 13 (mid and high dose); ↓ number of corpora lutea on GD 7 (low and mid dose); ↓ number of corpora lutea on GD 13 (mid and high dose); ↓ ratio of corpora lutea to ovarian areas on GD 7 and 13; ↑ CAT and SOD activity, H_2O_2, and MDA levels in ovary; ↑ apoptosis protein markers (p53 and Bax) in ovary	LOAEL: 2.5 mg/kg-day for oxidative stress, apoptosis markers and ↓ in number of corpora lutea	Chen et al. (2017b)

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Male BALB/c mice (n=15/dose)	0, 1.25, 5 or 20 mg/kg-day via oral gavage for 28 days	↑ CBG protein levels in testes (low and mid dose); ↓ CBG protein levels in testis (high dose); ↑ CBG (all doses) and corticosterone levels (mid and high dose) ↓ adrenocorticotropic hormone serum levels (ACTH) (high dose)	LOAEL: 1.25 mg/kg-day for ↑ CBG levels in testis and serum	Sun et al. (2018)
Pregnant C57BL/6J mice (n=6/dose for dams, 9/dose for pups)	Dietary exposure to 0, 0.003, 0.01, 0.03, 0.1, 0.3, 1, or 3 mg/kg-day (targeted concentration). Exposure started 2 weeks before mating and continued during mating (1 week), gestation (3 weeks), and lactation (3 weeks). Pups organs evaluated at 26 weeks (males) or 28 weeks (females).	**Dams**: ↓ litter size at two highest doses **Pups (both sexes)**: ↓ body weight at PND 4; hepatocellular anisokary-osis and karyomegaly **Male pups**: ↑ absolute and relative liver weight; ↑ eosinophilic liver foci; lipid accumulation in liver **Female pups**: ↓ triglycerides and cholesterol	**Dams:** NOAEL: 0.3 mg/kg-day for ↓ litter size **Pups:** NOAEL: 0.003 mg/kg-day for ↓ body weight in females on PND 4	van Esterik et al. (2016)
Male and female Sprague Dawley rats (n=10/sex/ dose)	0, 0.625, 1.25, 2.5, 5, or 10 mg/kg-day for 28 days via oral gavage	**Males**: ↑ relative testis weight, ↓ absolute epididymis weight, ↓ cauda epididymis weight, ↓ cauda epididymis sperm count	NOAEL: 2.5 mg/kg-day for ↑ relative testis weight and ↓ cauda epididymis weight	NTP (2018b)

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Male Sprague Dawley rats (n=10/dose)	0, 150, or 300 ppm (0, 14.7, or 29.5 mg/kg-day) in feed for 16 weeks	↓ absolute testis weight	NOAEL: 14.7 mg/kg-day for ↓ absolute testis weight	NTP (2018c)
Female Sprague Dawley rats (n=10/dose)	0, 300, or 1,000 ppm (0, 27.7, or 92.7 mg/kg-day) in feed for 16 weeks	Ovarian cysts	NOAEL: 27.7 mg/kg-day for ovarian cysts	NTP (2018c)
Female Sprague Dawley rats (n=50/dose)	0, 300, or 1,000 ppm (0, 18, or 63 mg/kg-day) in feed for 107 weeks	Squamous metaplasia in the endometrium	LOAEL: 18 mg/kg-day for endometrial squamous metaplasia	NTP (2018c)

ACTH, adrenocorticotropic hormone; CAT, catalase; CBG, corticosteroid binding globulin; GD, gestation day; GSH-Px, glutathione peroxidase; H_2O_2, hydrogen peroxide; LOAEL, lowest-observed-adverse-effect level; MDA, malondialdehyde; NOAEL, no-observed-adverse-effect level; PND, postnatal day; SOD, superoxide dismutase

As seen in studies cited in previous risk assessments by other agencies, a number of studies in mice reported reproductive toxicity following exposure to PFOA for 1-4 weeks. In male mice, studies reported decreased testis and epididymis weights and sperm count (Lu et al., 2016; Liu et al., 2015; Song et al., 2018). In females, studies reported decreases in litter size, changes in estrous cycle and changes in hormone levels (van Esterik et al, 2016; Chen et al; 2017b). A study by NTP (2018b) was the only study found in rats. Decreased absolute cauda epididymis weight and sperm count and increased relative testis weight were observed after a 28-day gavage study. In a 16-week oral gavage study, decreased absolute testis weight was observed in male rats (NTP, 2018c).

van Esterik et al. (2016) administered 0, 0.003, 0.01, 0.03, 0.1, 0.3, 1, or 3 mg/kg-day PFOA in the diet to 6 pregnant C57BL/6J mice per dose group. Exposure started 2 weeks before mating and continued through mating (1 week), gestation (3 weeks), and lactation (3 weeks). Toxicity in the F_1 generation was monitored in 6-9 pups from 2-3 litters in each dose group. Decreased litter sizes were reported at the two highest doses. Additionally, several developmental disorders were reported in pups, including the following: increased liver weight, increased eosinophilic liver foci and lipid

accumulation in liver in males; decreased femur length and femur weight, decreased quadriceps femoris muscle weight, decreased adipocyte cell size, and decreased serum triglycerides and cholesterol in females; and decreased body weight at postnatal day (PND) 4, decreased tibia length, and hepatocellular anisokaryosis and karyomegaly in pups of both sexes. OEHHA determined a NOAEL of 0.003 mg/kg-day based on decreased body weight in female pups on PND 4 ($p<0.001$; student's T-test determined by OEHHA).

In vitro studies

A number of in vitro studies investigated the effects of PFOA treatment on Leydig cells. Mouse Leydig tumor cell lines showed an increase in gene and protein expression of cortisol binding protein (CBG) (Sun et al., 2018). Decreased mitochondrial membrane potential and increases in reactive oxygen species (ROS) were observed at PFOA concentrations of 50 µM and greater in mouse Leydig tumor cells (Zhao et al., 2017).

PFOA did not induce cell death or ROS production in male human embryonic stem cells; however, cells showed a decrease in spermatid production (Steves et al., 2018). Cytotoxicity was observed at concentrations greater than 250 µM PFOA in the human cell lines HEK293T, MCF-7, LNCaP, and H295R while no cytotoxicity was observed in MDA-kb2 cells at concentrations up to 500 µM (Behr et al., 2018). In the same study, a concentration of 100 µM PFOA co-incubated with estradiol (E2) increased ERβ activity in HEK293T cells. An increase in the production of estrone was measured in H295R cells treated with 100 µM PFOA.

Mechanistic studies

An earlier assessment by New Jersey DWQI (2017) reviewed possible mechanisms for reproductive toxicity, specifically in male mice. Possible modes of action described were PPARα activation and disruption of the blood-testis barrier leading to oxidative stress and estrogenic effects of PFOA. A recent study by Zhao et al. (2017) showed impairment of mitochondrial function and increase in ROS in mouse Leydig tumor cells.

Mice treated with 5 mg/kg-day PFOA for 28 days showed alterations in gene and protein expression related to endocytosis and the blood-testis barrier that are supportive of studies showing toxicity in the male testis (Lu et al., 2017).

A possible mechanism for male reproductive toxicity involves changes in cholesterol and fatty acid metabolism. Lu et al. (2016) showed PFOA activated Akt/AMPK signaling, a pathway that regulates lipid metabolism.

Critical Study Selection

van Esterik et al. (2016) generated a NOAEL of 0.003 mg/kg-day based on decreased body weight in female pups on PND 4. This NOAEL is two orders of magnitude lower than the NOAEL of 0.3 mg/kg-day from Loveless et al. (2006), which is associated with increased relative liver weight in male mice and was the basis for the interim NL. Although the van Esterik et al. (2016) study may provide a lower POD than the Loveless et al. (2006) study, the most appropriate dose metric, serum levels of PFOA, is not available for RL derivation.

Reproductive Toxicity – PFOS

In vivo studies

Reproductive effects of PFOS were described in recent assessments by US EPA (2016b), New Jersey DWQI (2018) and ATSDR (2018). Additionally, in 2017, PFOS was listed under Proposition 65 as a chemical known to the state of California to cause reproductive toxicity. More recent studies identified effects such as decreases in testis and/or epididymis weights, decreases in sperm count, increases in apoptosis and apoptosis markers in the ovary or testis, decreases in litter size, changes in hormone levels, and changes in estrous cycle. These studies are summarized in Table 8.

Table 8. Summary of recent animal toxicity studies of PFOS reporting reproductive toxicity

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Female ICR mice (n=136/dose)	0 or 0.1 mg/kg-day in drinking water for 4 months[a]	Prolongation of estrous cycle; ↓ estrous cycles per month; increase in atretic follicles; ↓ number of corpora luteum; changes in hormone levels at each estrous cycle	NA	Feng et al. (2015)

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Pregnant Sprague Dawley rats (n=4/dose)	0, 5, or 20 mg/kg-day via oral gavage from GD 11-19	**Dams**: ↓ body weight, serum cholesterol levels **Pups**: ↓ body weight, body length, absolute testis weight, anogenital distance of male pups, testosterone in testis, Leydig cell number, testosterone biosynthetic enzyme levels, HDL levels in liver and testis; apoptosis in fetal Leydig cells	NOAEL: 5 mg/kg-day for all pup endpoints	Zhao et al. (2014)
Male ICR mice (n=20/dose)	0, 0.25, 2.5, 25, or 50 mg/kg-day via oral gavage for 28 days	↓sperm count, ↑ Sertoli cell vacuolization and derangement of cells layers; damage in blood-testis barrier between Sertoli cells	NOAEL: 0.25 mg/kg-day for all endpoints	Qiu et al. (2013)
Female ICR mice (n=20/dose)	0 or 10 mg/kg-day orally for 30 days	Prolongation of duration of diestrus; ↓ number of corpora lutea; ↓ serum levels of P4, LH and GnRH on day 7, ↓ serum levels of GnRH, E2, T4 and T3 on day 14; ↑ serum levels of CORT on day 14	NA	Wang et al. (2018)
Male C57 mice (n=12/dose)	0, 0.5 or 10 mg/kg-day via oral gavage for 5 weeks	↓ body weight, absolute and relative testis weight, sperm count, serum testosterone levels; vacuolization in spermatogonia, spermatocytes and Leydig cells; ↑ apoptotic cells in testes, apoptosis related proteins, ↑ ERα and ERβ protein expression	LOAEL: 0.5 mg/kg-day for ↑ ERβ protein expression	Qu et al. (2016)

Sex/Species	Exposure	Endpoints	NOAEL/ LOAEL	Reference
Male ICR mice (n=10/dose)	0, 0.5, 5 or 10 mg/kg-day via oral gavage for 4 weeks	↓ sperm count	NOAEL: 0.5 mg/kg-day for ↓ sperm count	Qiu et al. (2016a)
Male and female Sprague Dawley Rats (n=10/sex/ dose)	0, 0.312, 0.625, 1.25, 2.5, or 5 mg/kg-day for 28 days via oral gavage	**Females**: ↑ testosterone	NOAEL: 0.625 mg/kg-day for ↑ testosterone	NTP (2018a)

[a] Animals were exposed up to 6 months. Due to a significant decrease in body weight of PFOS exposed animals at 6 months, only animals treated for 4 months were used for subsequent endpoints. It is unclear how many animals were exposed to PFOS for 4 months or 6 months.
CORT, corticosterone; ERα,β, estrogen receptor α,β; E2, estradiol; GnRH, gonadotrophin-releasing hormone; HDL, high density lipoprotein; LH, luteinizing hormone; LOAEL, lowest-observed-adverse-effect level; NOAEL, no-observed-adverse-effect level; P4, progesterone; T3, triiodothyronine; T4, thyroxine

In vitro studies

Studies in Sertoli cells isolated from mice, rats and humans reported effects such as perturbation of tight junction proteins resulting in inhibition of the tight junction permeability barrier (Li et al., 2016; Qiu et al., 2016a; Chen et al., 2017a; Gao et al., 2017). Decreases in mitochondrial membrane potential and increases in ROS generation were observed at PFOS concentrations of 50 µM and greater in mouse Leydig tumor cells (Zhao et al., 2017).

Cytotoxicity was observed at concentrations greater than 250 µM in human HEK293T, MCF-7, LNCaP, H295R and MDA-kb2 cell lines (Behr et al., 2018). In the same study, concentrations greater than 50 µM PFOS co-incubated with E2 increased ERβ activity in HEK293T cells. In MDA-kb2 cells, PFOS co-incubated with dihydrotestosterone (DHT) increased androgen receptor (AR) activity. An increase in production of estrone and progesterone was measured in H295R cells treated with 100 µM PFOS. In porcine ovarian theca and granulosa cells, PFOS at 1.2 µM caused a decrease in basal secretion of progesterone, androstenedione and estradiol (Chaparro-Ortega et al., 2018).

Mechanistic studies

An earlier assessment by US EPA (2016b) reviewed possible mechanisms for reproductive toxicity. Male reproductive toxicity may be caused by disruptions in gap junction intercellular communication by PFOS, compromising the blood-testis barrier in Sertoli cells. Recent in vitro studies assessed effects of PFOS on the blood-testis barrier and showed that PFOS perturbs tight junction proteins and function, and causes

microfilament disruption resulting in Sertoli cell injury (Gao et al., 2017; Li et al., 2016; Qiu et al., 2016a; Chen et al., 2017a).

Gene and protein expression were analyzed in the testes of rats exposed to PFOS for 28 days (Lopez-Doval et al., 2016). These investigators showed that PFOS inhibits the expression of follicle stimulating hormone receptor and AR, while inducing the expression of gonadotropin-releasing hormone receptor and luteinizing hormone receptor.

PFOS has been suggested to interact with estrogen receptors. Qu et al. (2016) found that PFOS altered expression of ERα and ERβ in mouse testis after exposure to at least 0.5 mg/kg-day for 5 weeks. ERα-induced anteroventral periventricular nucleus (AVPV)-kisspeptin neuron activation was suppressed by PFOS, causing alterations in the estrous cycle in female ICR mice (Wang et al., 2018).

Critical Study Selection

The NOAELs/LOAELs (based on administered dose) determined from these recent studies reporting reproductive effects are orders of magnitude larger than the NOAEL of 0.008 mg/kg-day (administered dose) for immunotoxicity from Dong et al. (2009), which was the basis for OEHHA's interim NL recommendation. Therefore, these studies are not considered for POD derivation in support of a final recommendation on the PFOS NL.

Cancer – PFOA

Cancer bioassays in laboratory animals conducted prior to 2016 have been thoroughly described previously (US EPA, 2016; New Jersey, 2018; IARC, 2017). These studies are briefly described below, and significant cancer incidences are reported in Table 9.

Table 9. Significant tumor incidences following exposure to PFOA

Sex/Species	Exposure	Tumor type	Dose (mg/kg-day)	Incidence	Reference
Male Sprague Dawley rats (n=50/dose)	Oral in diet for 106 weeks	Leydig Cell Adenoma	0, 1.3, or 14.2	0/33, 2/36, 7/44*	Butenhoff et al. (2012b), data from Sibinsky (1987)
Male Sprague Dawley rats (n=76-79/ dose)	Oral in diet for 104 weeks	Hepatocellular adenoma or carcinoma	0[a] or 13.6	3/79, 10/76*	Biegel et al. (2001)

Sex/Species	Exposure	Tumor type	Dose (mg/kg-day)	Incidence	Reference
Male Sprague Dawley rats (n=76-79/ dose)	Oral in diet for 104 weeks	Pancreatic acinar cell adenoma or carcinoma	0[a] or 13.6	1/79, 8/76*	Biegel et al. (2001)
Male Sprague Dawley rats (n=76-79/ dose)	Oral in diet for 104 weeks	Leydig cell adenoma	0[a] or 13.6	2/78, 8/76*	Biegel et al. (2001)
Pregnant CD-1 mice (n=6-14 dams/dose or 21-37 female pups/dose)	Oral in drinking water from GD 1 to GD 17, pups followed for 18 months	Hepatocellular adenoma	0, 0.01, 0.1, 0.3, 1, or 5	0/29, 1/29, 1/37, 4/26*, 0/31, 1/21	Filgo et al. (2015)

[a] Pair-fed control, fed same amount of food as treated group
*p<0.05, pairwise comparison with Fisher's exact test, statistical analysis by OEHHA
GD, gestation day

Sibinsky (1987), as reported by Butenhoff et al. (2012), administered 0, 30, or 300 ppm PFOA to rats (0, 1.3, or 14.2 mg/kg-day for males; 0, 1.6 or 16.1 mg/kg-day for females) in the diet for 105-106 weeks. In male animals, a significant increase in Leydig cell adenomas and preneoplastic pancreatic acinar cell hyperplasia was observed in the high dose group. In females, a significant increase in preneoplastic ovarian tubular hyperplasia was observed (later reclassified as gonadal stromal hyperplasia in a pathology review by Mann and Frame, 2004). An increase in mammary gland fibroadenoma was initially reported, but a follow-up examination of the pathology revealed no significant increase over controls (Hardisty et al., 2010).

Biegel et al. (2001) administered 0 or 300 ppm (0 or 13.6 mg/kg-day) to male rats in the diet for 24 months. A significant increase in several tumor types was reported, including hepatocellular adenomas or carcinomas, pancreatic acinar cell adenomas or carcinomas, and Leydig cell adenomas. Additionally, preneoplastic pancreatic acinar cell hyperplasia and Leydig cell hyperplasia were increased.

Filgo et al. (2015) exposed three different strains of pregnant mice (CD-1, 129/SV wild-type, and 129-SV PPARα knock-out) to doses of PFOA in drinking water ranging from 0 to 5 mg/kg-day from gestation day (GD) 1 to GD 17. Offspring were observed for 18

months. A significant increase in hepatocellular adenomas, and a significant trend for hepatic hemangiosarcomas, were observed in the CD-1 F_1 generation. Liver tumors were not significantly increased in wild-type or knock-out 129/SV mice. It should be noted that the liver was the only organ evaluated in these studies.

Recently, NTP (2018c) released carcinogenicity data from chronic bioassays of PFOA in male and female rats (see Liver Toxicity section for study details). Significant increases in hepatocellular adenomas/carcinomas and pancreatic acinar cell adenomas/carcinomas were observed in male rats, shown in Table 10. Female rats had an increase in uterine adenomas/carcinomas, shown in Table 11. Animals that died before the first observed tumor incidence were not included in the dose-response analysis. Furthermore, carcinogenicity data from animals exposed perinatally were not considered for derivation of the RL because the tumor incidences in these animals were comparable to animals that were not exposed perinatally, suggesting that exposure during gestation and lactation had minimal impact on tumor development later in life.

Table 10. Hepatocellular and pancreatic tumor incidences in male rats exposed to PFOA in the diet for 107 weeks (NTP, 2018c)

Conc. (ppm)	Dose (mg/kg-day)	Plasma conc. (mg/L)	Human Equivalent Dose (mg/kg-day)	Hepatocellular adenoma or carcinoma	Pancreatic acinar cell adenoma or carcinoma
0	0	BD[a]	0	0/36[b]	3/43

Plasma concentrations in the chronic male rat study were determined at 16 weeks, but because the serum half-life of PFOA is estimated to be 4-6 days in male rats, it is

anticipated that by 16 weeks, a steady-state concentration would have been reached. Therefore, the plasma concentration would remain relatively stable over the 107-week period of continuous dosing. Plasma concentrations are converted to human equivalent doses (HEDs) using the human clearance factor of 1.4×10^{-4} L/kg-day for PFOA, determined by US EPA (2016a). The formula is shown below:

Serum concentration (mg/L) × clearance factor (L/kg-day) = HED (mg/kg-day)

The resulting HEDs are presented in Table 10. Hepatic adenomas/carcinomas and pancreatic acinar cell adenomas/carcinomas are critically evaluated for RL development.

Cancer – PFOS

Summaries of the sole report of carcinogenicity bioassays (Butenhoff et al., 2012a) for PFOS have been previously published (US EPA, 2016b; New Jersey DWQI, 2018). The study design and significant results are briefly described below.

Butenhoff et al. (2012a) published a report of carcinogenicity studies from 2002 by 3M, a former PFOS manufacturer (Thomford, 2002). In these studies, male and female Sprague Dawley rats were administered 0, 0.5, 2, 5, or 20 ppm PFOS (0, 0.024, 0.098, 0.242, or 0.984 mg/kg-day for males; 0, 0.029, 0.120, 0.299, or 1.251 mg/kg-day for females) in the diet for two years. An additional group was administered 20 ppm for one year, and then control diet for the next year (data not shown). An increase in hepatocellular adenoma incidence was observed in both male and female animals at the highest dose. Combined hepatocellular adenoma/carcinoma incidence was also increased in female rats. Positive trends for hepatocellular adenomas were reported in both sexes. Tumor incidence data are summarized in Tables 12 and 13. It should be noted that the relatively low effective number of female rats was not due to high levels of premature mortality (mortality in treated groups was comparable to controls), but due to the fact that the first incidence of hepatocellular adenoma/carcinoma appeared quite late in the bioassay (day 653).

Table 12. Hepatocellular tumor incidences in male rats exposed to PFOS in the diet for 2 years (Butenhoff et al., 2012a)

Conc. (ppm)	Dose (mg/kg-day)	Serum conc. (mg/L)[a]	Human equivalent dose (mg/kg-day)	Hepatocellular adenoma
0	0	0.014	1.2×10^{-6}	0/41[b]
0.5	0.024	2.64	2.1×10^{-4}	3/42
2.5	0.098	12.1	9.8×10^{-4}	3/47
5	0.242	32.3	2.6×10^{-3}	1/44
20	0.984	121	9.8×10^{-3}	7/43*

[a] Calculated by OEHHA

[b] Incidence/effective number of animals. Animals that died before the first tumor incidence were not considered in the dose-response assessment.

*p<0.05, reported by study authors

Table 13. Hepatocellular tumor incidences in female rats exposed to PFOS in the diet for 2 years (Butenhoff et al., 2012a)

Conc. (ppm)	Dose (mg/kg-day)	Serum conc. (mg/L)[a]	Human equivalent dose (mg/kg-day)	Hepatocellular adenoma or carcinoma
0	0	0.841	6.8×10^{-5}	0/28[b]
0.5	0.029	5.49	4.5×10^{-4}	1/29
2.5	0.120	23.0	1.9×10^{-3}	1/16
5	0.299	66.4	5.4×10^{-3}	1/31
20	1.251	215	1.7×10^{-2}	6/32*

[b] Incidence/effective number of animals. Animals that died before the first tumor incidence were not considered in the dose-response assessment.

*p<0.05, reported by study authors

Because the biological half-life of PFOS differs greatly between rats (9-10 weeks) and humans (4-5 years), administered dose is not the appropriate dose metric for toxicity assessment. Serum PFOS concentration is a more suitable dose metric for extrapolating toxicity in rodents to toxicity in humans. Serum concentrations at various time points were measured, and the results are reported in Table 14.

Table 14. Mean serum PFOS concentrations (in mg/L) in rats from Butenhoff et al. (2012)

Week	Sex	0 ppm	0.5 ppm	2.5 ppm	5 ppm	20 ppm
4	Male	0	0.907	4.33	7.57	41.8
4	Female	0.026	1.61	6.62	12.6	54
14	Male	0	4.04	17.1	43.9	148

Week	Sex	0 ppm	0.5 ppm	2.5 ppm	5 ppm	20 ppm
14	Female	2.67	6.96	27.3	64.4	223
53	Male	0.025	-	-	-	146
53	Female	0.395	-	-	-	220
103	Male	-	-	-	-	-
103	Female	-	-	20.2	-	-
105	Male	0.012	1.31	7.6	22.5	69.3
105	Female	0.084	4.35	-	75	233

A dash (-) indicates that data were not collected at that time point

In males, the maximum serum concentration was reached at 14 weeks. At 105 weeks, serum concentrations in all dose groups were typically 2- to 3-fold less than at 14 weeks, indicating that PFOS is more rapidly eliminated at later time points. The authors attributed this increased urinary elimination of PFOS to chronic progressive nephritis. In females, serum concentrations measured at 105 weeks were typically comparable to the values measured at 14 weeks. Because serum concentrations in males declined after 14 weeks, the PFOS serum concentration values at terminal sacrifice would underestimate the serum concentrations at earlier time points. Therefore, OEHHA calculated the area under the curve (AUC) for each dose group using a simple linear interpolation. The time-weighted average serum concentration at each dose is determined by dividing the AUC by the duration of the study (103 or 105 weeks). These time-weighted average serum concentrations are presented in Tables 12 and 13.

Serum concentrations in rats are converted to HEDs using the human clearance factor of 8.1×10^{-5} L/kg-day for PFOS, determined by US EPA (US EPA, 2016). These values are presented in Tables 12 and 13, and the conversion formula is shown below:

Serum concentration (mg/L) × clearance factor (L/kg-day) = HED (mg/kg-day)

There is sufficient evidence to consider and critically evaluate the liver tumors in male and female rats for RL development. First, the two chronic bioassays reported in Butenhoff et al. (2012) are of sufficient quality (appropriate length, suitable number of animals per dose, adequate reporting, etc.) to warrant consideration as critical studies. Second, recent studies of PFOA by NTP (2018c) provide additional support for considering carcinogenicity as a critical endpoint for PFOS. In their assessment, NTP (2018c) showed that chronic exposure to PFOA led to a significant increase in hepatocellular adenomas and/or carcinomas in male rats (data presented in Table 10), which is similar to the carcinogenic effects of PFOS reported by Butenhoff et al. (2012). The similarity in molecular structure between PFOS and PFOA suggests that these two chemicals may have comparable biological activities, and in fact, the noncancer toxicology profiles of these two chemicals are similar. The International Agency for Research on Cancer (IARC, 2017) designated PFOA possibly carcinogenic to humans (Group 2B). PFOS also produced a positive trend for pancreatic carcinomas in male

rats (data not shown), which is a critical tumor type in PFOA-exposed male rats in the NTP (2018c) bioassay (Table 10). It should be noted that the highest administered dose in the Butenhoff et al. (2012) PFOS bioassay (0.984 mg/kg-day) was essentially the same as the lowest administered dose in the NTP (2018c) PFOA bioassay (1.0 mg/kg-day). This suggests that the Butenhoff et al. (2012) studies are less sensitive than the NTP (2018c) studies, and that the modest, but significant, tumor incidences observed (when compared against the NTP (2018c) PFOA data) are the result of overall lower administered doses. Third, although there is minimal evidence to indicate PFOS is genotoxic or mutagenic (US EPA, 2016b; New Jersey DWQI, 2018), increases in hepatic oxidative stress (Xing et al., 2016; Han et al., 2018a), hepatocellular hypertrophy (Han et al., 2018a; Bagley et al., 2017; Wan et al., 2016; NTP, 2018a), and cell proliferation (Han et al., 2018b) in rodents have been observed in recent short-term studies of PFOS. Additional data regarding the modes of action of PFOS are needed to clarify whether or not these effects are precursors of liver tumors, but at present, there is not enough evidence to rule out the possibility.

DOSE-RESPONSE ASSESSMENT AND REFERENCE LEVEL CALCULATIONS

Noncancer – PFOA

From Table 1, the lowest LOAEL is 0.05 mg/kg-day, which corresponds to a serum concentration of 0.97 mg/L, for hepatic mitochondrial membrane potential changes and increased apoptosis and oxidative DNA damage (Li et al., 2017). These endpoints were also frequently observed in in vitro studies. OEHHA selected the data from this study as the basis of a POD for calculating an RL for noncancer effects. For the purpose of comparison, the recommended interim NL was based on increased relative liver weight in a mouse study, from which a NOAEL of 0.3 mg/kg-day (based on administered dose) was determined (Loveless et al., 2006).

A NOAEL of 0.003 mg/kg-day was identified from the van Esterik et al. (2016) study, based on reduced female pup body weight on PND 4 in animals exposed to PFOA during gestation and lactation. However, serum concentrations were not reported in this study, and due to the complexity of the dosing scheme (PFOA was administered to dams during pregnancy and lactation), kinetic modeling was not conducted to predict serum concentrations. Therefore, this study is not considered for derivation of a noncancer RL. However, OEHHA acknowledges the potential for developmental toxicity at PFOA levels below the selected POD, and an additional uncertainty factor is added to account for this (discussed below).

The most sensitive endpoints from the Li et al. (2017) study (increased oxidative DNA damage, changes in mitochondrial membrane potential, and increased biomarkers of apoptosis in the liver of female mice) were analyzed with benchmark dose (BMD) software (BMDS version 2.6, US EPA). BMD modeling of the endpoints in Table 2 did

not generate any models with an acceptable goodness-of-fit. Therefore, the LOAEL of 0.97 mg/L is selected as the POD for noncancer effects.

Pharmacokinetic (PK) modeling

Administered dose in rodent studies of PFOA is not the optimal dose metric for toxicity evaluation because of the great difference in the chemical's half-life between humans (2-3 years) and rodents (1-3 weeks). The preferred dose metric is PFOA serum concentration. OEHHA evaluated available PK models to predict PFOA serum concentrations from administered doses. However, after critical evaluation, OEHHA found several shortcomings with the available models that lowered overall confidence in these models' ability to adequately predict serum concentrations. Therefore, OEHHA is using reported serum concentrations for RL derivation.

Acceptable Daily Dose Calculation

To calculate the acceptable daily dose (ADD), which is an estimated maximum daily dose of a chemical that can be consumed by humans for an entire lifetime without toxic effects, the POD is divided by the total uncertainty factor (UF). Because the dose metric for the POD is serum concentration, the ADD is first expressed as a target human serum concentration rather than the typical mg/kg-day dose.

A total uncertainty factor (UF) of 300 is applied in calculating the ADD for PFOA: 3 for interspecies extrapolation, 10 for intraspecies variability, 3 for LOAEL to NOAEL extrapolation, and 3 for the potential for developmental toxicity at the point of departure. When developing a health-protective RL of a chemical in drinking water, the adverse effect or an upstream physiological change that leads to an adverse effect occuring at the lowest dose is selected as the critical effect. Because the critical endpoints here are upstream physiological changes that can lead to adverse effects in a known target organ of PFOA toxicity, the liver, OEHHA is applying a LOAEL to NOAEL UF of 3 rather than 10. OEHHA also is applying a subchronic to chronic extrapolation UF of 1, consistent with the New Jersey DWQI (2017) assessment for PFOA, in which the critical endpoint was increased liver weight from a 14-day study, and a subchronic to chronic UF of 1 was used. New Jersey DWQI's rationale was that, based on evaluation of multiple studies, early manifestations of liver toxicity do not appear to increase in magnitude with chronic exposures. This rationale would also apply to the upstream endpoints used as the basis of the POD from the Li et al. (2017) critical study. For animal studies, OEHHA typically uses a UF of 10 for interspecies extrapolation ($\sqrt{10}$ for pharmacokinetics and $\sqrt{10}$ for pharmacodynamics) and a UF of 30 for intraspecies variability (10 for pharmacokinetics and $\sqrt{10}$ for pharmacodynamics). Since PFOA is not known to be metabolized in animals or humans, and because PFOA serum concentration is the dose metric used in the dose-response analysis, the pharmacokinetic components of the interspecies and intraspecies uncertainty factors

are reduced. An intraspecies pharmacokinetics UF of √10 (rather than 10) is kept to account for potential PK differences in infants and children. Thus,

ADD = POD ÷ UF = 0.97 mg/L ÷ 300 = 0.0032 mg/L (target human serum concentration).

A NOAEL (based on administered dose) of 0.003 mg/kg-day was determined by OEHHA from the van Esterik et al. (2016) study, based on decreased female pup body weight in the F_1 generation of dams administered PFOA throughout gestation and lactation. By comparison, the administered dose LOAEL from the Li et al. (2017) study is 0.05 mg/kg-day. Although it is unknown what the serum concentrations are in the van Esterik et al. (2016) study, it is possible that developmental toxicity occurred at a lower concentration than the hepatotoxicity in the Li et al. (2017) study. Therefore, an additional uncertainty factor of 3 is included to account for this possibility.

The ADD, expressed as a target human serum concentration of 3.2 µg/L, is slightly higher than average PFOA serum levels nationally and in California. Biomonitoring data from California[1] reported a geometric mean of 1.49 µg/L PFOA in the serum of 337 people in 2013 (the 95th percentile was 4.57 ng/mL). This is comparable to the geometric mean of 1.94 µg/L PFOA in the serum of the general US population, as determined from the National Health and Nutrition Examination Survey (NHANES) data (ATSDR, 2018).

As noted above, in order to account for PFOA's long half-life in humans relative to rodents, the ADD is expressed as a target serum concentration. To calculate a noncancer RL, the target serum concentration must be converted to an HED expressed as a dose in mg/kg-day. This is done by multiplying the ADD by a daily clearance factor, which reflects the clearance of PFOA from the body, of 1.4×10^{-4} L/kg-day for PFOA (US EPA, 2016a), as shown below.

ADD = 3.2 µg/L × 1.4×10^{-4} L/kg-day = 4.5×10^{-4} µg/kg-day or 0.45 ng/kg-day

The relative source contribution (RSC) is the proportion of exposures to a chemical attributed to tap water (including inhalation and dermal exposures, e.g., during showering), as part of total exposure from all sources (including food and air pollution). The RSC values typically range from 20 to 80 percent (expressed as 0.20 to 0.80), and are determined based on available exposure data. The default RSC of 0.2 is selected because there is not enough data to determine specific exposure patterns for PFOA. In addition to drinking water, there are several other sources of PFOA that may contribute to exposure in the general population, including air, soil, food, and consumer and industrial products. PFOA released to air may adsorb to airborne particles and travel long distances (US EPA, 2016a). Additionally, the use of PFOA in many consumer

[1] From Biomonitoring California, Results for Perfluorochemicals (PFCs) (last accessed February 1, 2019)

products and its environmental persistence has led to the presence of PFOA in indoor air and dust. In fact, US EPA (2016a) reports that the most common exposure routes of PFOA are diet and indoor dust. Thus, an RSC of 0.2 is appropriate, and consistent with RSCs used by other agencies, including US EPA and the State of New Jersey.

Oral ingestion is the primary route of exposure for PFOA in drinking water. PFOA is not very volatile in its ionized form (its predominant form in water) (Johansson et al., 2017), so inhalation of PFOA directly from drinking water is not anticipated to be a major route of exposure. Dermal absorption is also not anticipated to be a significant route of exposure from typical household uses of tap water. Ionized PFOA penetrates skin poorly compared to the neutral form, and PFOA should remain ionized in the stratum corneum due to its buffering capacity (Franko et al., 2012).

PFOA can permeate mouse and human skin in vitro, and be absorbed following dermal application in mice in vivo (Franko et al., 2012). However, a time-course of >5 hours is needed for PFOA to penetrate full-thickness human skin, and this exposure scenario is unlikely to occur from typical household uses of tap water. Additionally, solid PFOA and 1% PFOA in acetone were determined to be non-corrosive in an in vitro epidermal cell viability assay following three minutes of exposure. It should be noted, however, that solid PFOA was corrosive following one hour of exposure, whereas 1% PFOA in acetone was not.

Because oral ingestion is considered to be the only significant route of drinking water exposure, a lifetime average drinking water intake rate of 0.053 L/kg-day (OEHHA, 2012) is used to determine the noncancer RL, which is calculated using the following formula:

RL = ADD × RSC ÷ DWI, where

ADD = acceptable daily dose of 0.45 ng/kg-day,
RSC = relative source contribution of 0.2, and
DWI = daily water intake rate of 0.053 L/kg-day

RL = (0.45 ng/kg-day × 0.2) ÷ 0.053 L/kg-day = 2 ng/L or 2 ppt

Thus, the reference drinking water level for the noncancer effects of PFOA is 2 ng/L or 2 ppt based on a recent hepatotoxicity study in mice (Li et al., 2017).

Noncancer – PFOS

OEHHA did not identify any new studies to replace the Dong et al. (2009) study as the critical toxicity study for the noncancer effects of PFOS. Decreased plaque forming cell response was the most sensitive endpoint, and a NOAEL of 0.008 mg/kg-day was identified. The data are summarized in Table 15.

Table 15. Plaque forming cell response in male mice exposed to PFOS (Dong et al., 2009)

Dose (mg/kg-day)	Serum Concentration (mg/L)	Human Equivalent Dose (mg/kg-day)	Plaque Forming Response[a] (PFC/10^6 spleen cells)
0	0.048 ± 0.014[b]	3.9×10^{-6}	597 ± 64[b]
0.008	0.674 ± 0.166	5.5×10^{-5}	538 ± 52
0.083	7.132 ± 1.039	5.8×10^{-4}	416 ± 43*
0.417	21.638 ± 4.410	1.8×10^{-3}	309 ± 27*
0.833	65.426 ± 11.726	5.3×10^{-3}	253 ± 21*
2.08	120.670 ± 21.759	9.8×10^{-3}	137 ± 16*

[a] Data taken from New Jersey DWQI (2018). Authors state they received numerical data via personal communication with GH Dong.
[b] Mean ± SEM (n = 10/dose)
* p<0.05, reported by study authors

Using the equations shown above for PFOA, serum concentrations are converted to HEDs using the human clearance factor of 8.1×10^{-5} L/kg-day for PFOS, determined by US EPA (US EPA, 2016b). The formula is shown below:

Serum concentration (mg/L) × clearance factor (L/kg-day) = HED (mg/kg-day)

The resulting HEDs are presented in Table 15.

BMD modeling was performed using both serum concentrations and HEDs as the dose metric. However, an adequate model fit was not attained in either case. Therefore, the NOAEL of 0.008 mg/kg-day (corresponding to a serum concentration of 0.674 mg/L, Table 15) is selected as the POD.

A total UF of 30 is applied in calculating the ADD for PFOS: 3 for interspecies extrapolation and 10 for intraspecies variability. For animal studies, OEHHA typically uses a UF of 10 for interspecies extrapolation (√10 for pharmacokinetics and √10 for pharmacodynamics) and a UF of 30 for intraspecies variability (10 for pharmacokinetics and √10 for pharmacodynamics). However, because PFOS is not known to be metabolized in animals or humans, and because PFOS serum concentration is the dose metric used in the dose-response analysis, the pharmacokinetic components of the interspecies and intraspecies uncertainty factors are reduced. A subchronic to chronic UF of 3 is typically applied when the study duration is 8-12% of the animal's lifetime (OEHHA, 2008), in order to account for the potential exacerbation of toxicity following chronic exposure. However, New Jersey DWQI (2018) argues that the subchronic to chronic uncertainty factor is not necessary because the maximum decrease in plaque forming cell response remained relatively constant (~70-85%) across studies with different exposure durations (ranging from 7 to 60 days), thus increased exposure

duration does not lead to increased toxicity. OEHHA agrees and is applying a subchronic to chronic UF of 1 rather than 3.

To determine the ADD, expressed as a target human serum concentration, the POD is divided by the total UF, as shown below.

ADD = 0.674 mg/L ÷ 30 = 0.022 mg/L or 22 µg/L (target human serum concentration)

The target serum concentration of 22 µg/L is higher than average PFOS serum levels nationally and in California. Biomonitoring data from California[2] report a geometric mean of 5.21 µg/L PFOS in the serum of 337 people in 2013 (the 95th percentile was 17.6 ng/mL). This is comparable to the geometric mean of 4.99 µg/L PFOS in serum of the general US population, as determined from NHANES data (ATSDR, 2018).

The ADD is converted to an HED by multiplying the target human serum concentration by a daily clearance factor of 8.1×10^{-5} L/kg-day (US EPA, 2016b), as shown below.

ADD = 22 µg/L × 8.1×10^{-5} L/kg-day = 1.8×10^{-3} µg/kg-day or 1.8 ng/kg-day

The default RSC of 0.2 is selected because there is not enough specific data to determine specific exposure patterns to PFOS. In addition to drinking water, there are several other sources of PFOS that may contribute to exposure in the general population, including air, soil, food, and consumer and industrial products. PFOS released to air may adsorb to airborne particles and travel long distances (US EPA, 2016b). Additionally, the use of PFOS in many consumer products and its environmental persistence has led to the presence of PFOS in indoor air and dust. As with PFOA, US EPA (2016b) reports that the most common exposure routes of PFOS are diet and indoor dust. Thus, an RSC of 0.2 is appropriate, and consistent with RSCs used by other agencies, including US EPA and the State of New Jersey.

Oral ingestion is the primary route of exposure for PFOS in drinking water. Volatilization of the predominant anionic form in water (pKA <1.0) is not expected to occur (HSDB, 2018).

Dermal absorption is also not anticipated to be a significant route of exposure from typical household uses of tap water, based on its physicochemical similarities to PFOA. However, no specific studies could be identified that addressed absorption of PFOS following dermal exposure. ATSDR (2018) reports the results of an unpublished single-dose dermal absorption study in rabbits, where potassium PFOS or its diethanolamine salt (at doses up to 20 µg/kg) was applied to clipped, intact skin (Johnson et al., 1995a,b, as reported by ATSDR, 2018). Compared to controls, no increase in organic fluoride in the liver was detected, suggesting that PFOS was not absorbed.

[2] From Biomonitoring California, Results for Perfluorochemicals (PFCs) (last accessed February 1, 2019)

Because oral ingestion is considered to be the only significant route of drinking water exposure, a lifetime average drinking rate of 0.053 L/kg-day (OEHHA, 2012) is used to determine the noncancer RL, which is calculated using the following formula:

RL = ADD × RSC ÷ DWI, where

ADD = acceptable daily dose of 1.8 ng/kg-day,
RSC = relative source contribution of 0.2, and
DWI = daily water intake of 0.053 L/kg-day

RL = (1.8 ng/kg-day × 0.2) ÷ 0.053 L/kg-day = 7 ng/L or 7 ppt

Thus, the reference drinking water level for the noncancer effects of PFOS is 7 ng/L or 7 ppt based on immunotoxicity in mice.

Cancer – PFOA

Hepatocellular adenoma/carcinoma and pancreatic acinar cell adenoma/carcinoma in male rats were evaluated for RL derivation. For individual tumor sites, OEHHA uses the linear multistage cancer model from US EPA's BMD software (BMDS version 2.6, US EPA) to determine the dose associated with a benchmark response (BMR) of 5% increased risk of developing a tumor and the lower 95% confidence limit of that dose, the $BMDL_{05}$. For carcinogens that induce tumors at multiple sites and/or in different cell types at the same site in a particular species and sex, BMDS can be used to derive maximum likelihood estimates (MLEs) for the parameters of the multisite carcinogenicity model by summing the MLEs for the individual multistage models from the different sites and/or cell types. This multisite model is then used to provide a basis for estimating the cancer potency of a chemical that causes tumors at multiple sites. Using the HEDs as the dose metric, multisite benchmark dose modeling was performed to determine the cancer slope factor (CSF) for the hepatic and pancreatic tumors in male rats.

A multisite $BMDL_{05}$ of 0.000648 mg/kg-day was determined from the animal bioassay data (Table 10). To estimate from animal data an HED that would result in an equal lifetime risk of cancer, OEHHA uses body weight (BW) scaling to the ¾ power (OEHHA, 2009). This adjustment accounts for interspecies differences in pharmacokinetics and pharmacodynamics. Because pharmacokinetic differences have already been accounted for by using serum concentration as the dose metric instead of administered dose, the $BMDL_{05}$ only needs modification for pharmacodynamic differences ($BW^{1/8}$ adjustment). The equation is provided below.

$$BMDL_{05(human)} = BMDL_{05(animal)} \times (BW_{animal}/BW_{human})^{1/8}$$

where BW_{animal} is 0.509 kg, the time-weighted average body weight of control male rats from the NTP (2018c) 2-year bioassay, and BW_{human} is the default value of 70 kg. Thus,

the $BMDL_{05(human)}$ is 3.5×10^{-4} mg/kg-day. The human CSF is determined using the following equation:

$$CSF = BMR \div BMDL_{05} = 0.05 \div 3.5 \times 10^{-4} \text{ mg/kg-day} = 143 \text{ (mg/kg-day)}^{-1}$$

As described in the noncancer reference level derivation, oral ingestion is the primary route of exposure to PFOA in drinking water, and inhalation and dermal exposures are considered negligible.

When determining cancer risk, OEHHA typically applies age sensitivity factors (ASFs, unitless) to account for the increased susceptibility of infants and children to carcinogens (OEHHA, 2009). A weighting factor of 10 is applied for exposures that occur from the 3rd trimester to <2 years of age, and a factor of 3 is applied for exposures that occur from 2 through 15 years of age. These factors are typically applied unless chemical-specific data exist to better guide the risk assessment.

NTP (2018c) administered 300 ppm PFOA from GD 6 through PND 21 to a concurrent cohort of animals. There were no significant differences in tumor incidences between animals with and without perinatal exposure in the 20, 40 and 80 ppm dose groups (Table 16). This suggests that early-life exposures to PFOA do not substantially increase the likelihood of tumor formation later in life. Therefore, OEHHA is not applying ASFs for derivation of the cancer RL.

Table 16. Comparison of tumors in perinatally and non-perinatally exposed male rats (NTP, 2018c)

Tumor type	Exposure	0 ppm	20 ppm	40 ppm	80 ppm
Hepatocellular adenoma or carcinoma	No perinatal exposure	0/36[b]	0/42	7/35	11/37
Hepatocellular adenoma or carcinoma	300 ppm perinatal exposure	0/35	1/38	5/38	12/39
Pancreatic acinar cell adenoma or carcinoma	No perinatal exposure	3/43	29/49	26/41	32/40
Pancreatic acinar cell adenoma or carcinoma	300 ppm perinatal exposure	7/41	20/44	30/44	30/43

Perinatal exposure – GD 6 through PND 21

[b] Incidence/effective number of animals

Because oral ingestion is considered to be the only significant route of drinking water exposure to the compound, a lifetime average drinking rate of 0.053 L/kg-day (OEHHA, 2012) is used to determine the RL. The RL for carcinogenic effects can be calculated using the following equation:

RL = R ÷ (CSF × DWI), where

R = default risk level of one in one million, or 10^{-6}
CSF = cancer slope factor in $(mg/kg\text{-}day)^{-1}$
DWI = daily water intake rate of 0.053 L/kg-day

Using the total lifetime drinking water exposure estimate of 0.053 L/kg-day, a RL for a one in one million cancer risk from PFOA in tap water is:

$RL = 10^{-6} \div (143\ (mg/kg\text{-}day)^{-1} \times 0.053\ L/kg\text{-}day) = 1.3 \times 10^{-7}$ mg/L

RL = 0.1 ng/L or 0.1 ppt (rounded)

The cancer RL of 0.1 ppt should protect against the noncancer effects of PFOA since it is lower than the 2 ppt level for noncancer effects.

Cancer – PFOS

Hepatocellular adenomas in male rats, and hepatocellular adenomas/carcinomas in female rats were evaluated for RL derivation. As noted above, PFOS is being evaluated as a carcinogen because of the positive animal carcinogenicity bioassay data from Butenhoff et al. (2012), and because of the similarities in chemical structure and biologic activity between PFOS and PFOA. Calculation of the PFOS RL for cancer uses the same methods as used above for PFOA. Using the HEDs as the dose metric, BMD modeling produces a $BMDL_{05}$ of 0.0020 mg/kg-day for male rats and a $BMDL_{05}$ of 0.0027 mg/kg-day for female rats.

Applying the $BW^{1/8}$ adjustment for pharmacodynamics differences between animals, where the time-weighted average male body weight is 0.690 kg (from Thomford 2002), the time-weighted average female body weight is 0.414 kg (from Thomford 2002), and the body weight of humans is the default of 70 kg, the human $BMDL_{05}$ is 0.0011 mg/kg-day for males and 0.0014 mg/kg-day for females. These BMDLs result in human CSFs of 45.5 $(mg/kg\text{-}day)^{-1}$ for males and 35.7 $(mg/kg\text{-}day)^{-1}$ for females. The higher CSF from male animals is used to derive the RL for PFOS. As described in the noncancer RL derivation, oral ingestion is the primary route of exposure to PFOS in drinking water, and inhalation and dermal exposures are considered negligible.

When determining cancer risk, OEHHA typically applies ASFs to account for the increased susceptibility of infants and children to carcinogens (OEHHA, 2009). A weighting factor of 10 is applied for exposures that occur from the 3rd trimester to <2

years of age, and a factor of 3 is applied for exposures that occur from 2 through 15 years of age. These factors are typically applied unless chemical-specific data exist to better guide the risk assessment.

However, ASFs are not included when deriving the cancer RL for PFOA because the NTP (2018c) study provided evidence that early life exposure did not increase tumor incidences later in life (Table 16). Because it is anticipated that PFOS behaves in a similar manner as PFOA, OEHHA is excluding ASFs in the RL derivation for cancer.

Since oral ingestion is considered to be the only significant route of drinking water exposure to the compound, a lifetime average drinking rate of 0.053 L/kg-day (OEHHA, 2012) is used to calculate the RL for carcinogenic effects:

$$RL = 10^{-6} \div (45.5\ (mg/kg\text{-}day)^{-1} \times 0.053\ L/kg\text{-}day) = 4.2 \times 10^{-7}\ mg/L$$

RL = 0.4 ng/L or 0.4 ppt (rounded)

The cancer RL of 0.4 ppt should protect against the noncancer effects of PFOS since it is lower than the 7 ppt level for noncancer effects.

RECOMMENDED NOTIFICATION LEVELS

The cancer RLs for PFOA and PFOS should protect against both cancer and noncancer effects of these chemicals. However, these levels are below concentrations of PFOA and PFOS that can be reliably detected in drinking water, which limits the utility of setting the NLs at these levels.

OEHHA recommends that SWRCB establish the NLs at the lowest levels that can be reliably detected in drinking water using currently available and appropriate technologies.

Executive Summary

The U.S. Environmental Protection Agency (EPA) is issuing final subchronic and chronic oral toxicity values (i.e., reference doses, or RfDs) for 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)propanoic acid (Chemical Abstracts Service Registry Number (CASRN) 13252-13-6)—or hexafluoropropylene oxide (HFPO) dimer acid—and ammonium 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)propanoate (CASRN 62037-80-3)—or HFPO dimer acid ammonium salt. These chemicals are also known as "GenX chemicals" because they are the two major chemicals associated with GenX processing aid technology. The toxicity assessment for GenX chemicals is a scientific and technical report that provides an assessment of all available toxicity and carcinogenicity data and includes toxicity values associated with potential noncancer health effects following oral exposure (in this case, oral RfDs). This toxicity assessment evaluates human health hazards. It is not a risk assessment as it does not include an exposure assessment nor an overall risk characterization. Further, the toxicity assessment does not address the legal, political, social, economic, or technical considerations involved in risk management. The GenX chemicals toxicity assessment can be used by EPA, states, tribes, and local communities, along with specific exposure and other relevant information, to determine, under the appropriate regulations and statutes, if, and when, it is necessary to take action to address potential risk associated with human exposures to GenX chemicals.

These GenX chemicals are organic fluorinated ether chemicals that are part of a larger group of chemicals referred to as "per- and polyfluoroalkyl substances" or PFAS. In 2006, EPA initiated a stewardship program with the goal of eliminating chemical emissions of perfluorooctanoic acid (PFOA) and related chemicals by 2015. GenX chemicals are replacements for PFOA. Specifically, GenX is a trade name for a processing aid technology that enables the creation of fluoropolymers without the use of PFOA. Information on specific products containing these chemicals is not available, however, GenX chemicals may be used in the manufacture of the same or similar commercial fluoropolymer end products that formerly used PFOA. Fluoropolymers are used in many applications, including the manufacture of nonstick coatings for cookware, water repellent garments, and other specialty agrochemical and pharmaceutical applications.

For HFPO dimer acid and its ammonium salt, acute, short-term, subchronic, chronic, and reproductive and developmental oral animal toxicity studies are available in rats and mice. Limited information identifying health effects in animals from inhalation of or dermal exposures to GenX chemicals is available. Repeated-dose toxicity data are available for oral exposure, but not for the other exposure routes (inhalation and dermal exposures). Thus, this assessment applies only to the oral route of exposure. These studies report liver toxicity (increased relative liver weight, hepatocellular hypertrophy, apoptosis, and single-cell/focal necrosis), kidney toxicity (increased relative kidney weight), immune effects (antibody suppression), hematological effects (decreased red blood cell count, hemoglobin, and hematocrit), reproductive/developmental effects (increased early deliveries, placental lesions, changes in maternal gestational weight gain, and delays in genital development in offspring), and cancer (liver and pancreatic tumors). Overall, the available toxicity studies demonstrate that the liver is particularly sensitive to HFPO dimer acid- and HFPO dimer acid ammonium salt-induced toxicity. Consistent with the *Guidelines for Carcinogen Risk Assessment* (EPA, 2005a), EPA

concluded that there is *Suggestive Evidence of Carcinogenic Potential* of oral exposure to GenX chemicals in humans, based on the female hepatocellular adenomas and hepatocellular carcinomas and male combined pancreatic acinar adenomas and carcinomas observed in the chronic 2-year study in rats.

EPA followed the general guidelines for risk assessment set forth by the National Research Council (1983) and EPA's *Framework for Human Health Risk Assessment to Inform Decision Making* (EPA, 2014a) in determining the point of departure (POD) for the derivation of the RfDs for these chemicals. Consistent with the recommendations presented in EPA's *A Review of the Reference Dose and Reference Concentration Processes* (EPA, 2002), EPA applied uncertainty factors (UFs) to address intraspecies variability, interspecies variability, and extrapolation from a subchronic to a chronic exposure duration.

The critical study chosen for determining the subchronic and chronic RfDs for HFPO dimer acid and/or its ammonium salt was the oral reproductive/developmental toxicity study in mice with a no-observed-adverse-effect level (NOAEL) of 0.1 milligram per kilogram per day (mg/kg/day) based on liver effects (a constellation of lesions, including cytoplasmic alteration, hepatocellular single-cell and focal necrosis, and hepatocellular apoptosis) in females (DuPont-18405-1037, 2010; NTP, 2019). EPA determined that the constellation of liver lesions observed in the rodent are relevant to human health and not a result of PPARα-induced cell proliferation unique to rodents. Using EPA's *Benchmark Dose Technical Guidance Document* (EPA, 2012), EPA conducted benchmark dose modeling to empirically model the dose-response relationship in the range of observed data. Additionally, EPA's *Recommended Use of Body Weight$^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose* (EPA, 2011b) was used to allometrically scale a toxicologically equivalent dose of orally administered agents from adult laboratory animals to adult humans. Allometric scaling addresses some aspects of cross-species extrapolation of toxicokinetic and toxicodynamic processes (i.e., interspecies UFs). The resulting POD human equivalent dose is 0.01 mg/kg/day. UFs applied include a 10 for intraspecies variability, 3 for interspecies differences, and 10 for database deficiencies, including immune effects and additional developmental studies, to yield a subchronic RfD of 0.00003 mg/kg/day or 0.03 µg/kg/day. In addition to those above, a UF of 10 was also applied for extrapolation from a subchronic to a chronic duration in the derivation of the chronic RfD of 0.000003 mg/kg/day or 0.003 µg/kg/day.

1.0 Introduction and Background

1.1 History of Assessment of GenX Chemicals

In 2008, DuPont de Nemours, Inc. (hereinafter DuPont) submitted premanufacture notices (PMNs) to the U.S. Environmental Protection Agency (EPA) under the Toxic Substances Control Act (TSCA) (Title 15 of the United States Code § 2601 *et seq*.) for two chemicals—2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)propanoic acid (Chemical Abstracts Service Registry Number (CASRN) 13252-13-6)—or hexafluoropropylene oxide (HFPO) dimer acid—and ammonium 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)propanoate (CASRN 62037-80-3)—or HFPO dimer acid ammonium salt—which are part of the GenX processing aid technology they developed.

Note: In July 2015, DuPont announced it had separated its Performance Chemicals segment through the creation of The Chemours Company. As a result, the GenX processing technology and associated chemicals are now products of The Chemours Company (Chemours, 2018). Because the submitted studies were conducted prior to the 2015 separation, however, the studies are referenced with DuPont identifiers.

Upon receipt, EPA assigned these PMNs case numbers P-08-0508 and P-08-0509, and they were reviewed by the New Chemicals Program in the Office of Pollution Prevention and Toxics (OPPT) and posted in the Federal Register (73 FR 46263, August 8, 2008) for public comment (EPA, 2008). A PMN assessment was completed and included a hazard assessment based on EPA review of test data submitted to the agency with the PMNs (including two 28-day oral (gavage) toxicity studies in mice (DuPont-24459, 2008) and rats (DuPont-24447, 2008)), as well as publicly available literature and TSCA confidential business information on other per- and polyfluoroalkyl substances (PFAS). Submitted test data on HFPO dimer acid and/or its ammonium salt were available for numerous endpoints such as acute toxicity, metabolism and toxicokinetics, genotoxicity, and systemic toxicity in mice and rats with dosing durations of up to 28 days.

EPA OPPT evaluated the methods and data submitted and deemed the studies acceptable to the agency. The studies submitted in 2008 with the PMNs formed the primary basis of EPA's hazard assessment at that time. The 28-day toxicity study in mice, from which EPA OPPT derived the point of departure (POD) of 0.1 milligrams per kilogram per day (mg/kg/day), was conducted according to Organization for Economic Cooperation and Development (OECD) Test Guideline (TG) 407 (OECD, 2008a) and followed Good Laboratory Practices (GLP) (DuPont-24459, 2008; OECD, 2008a). The submitted studies were also used, in concert with information on other PFAS chemicals, to inform the decision to require further testing, as described in the Consent Order that concluded the PMN review (EPA, 2009).

The Consent Order included, among other things, additional testing pertaining to human health. The tests were identified in the Consent Order according to OECD TG numbers and/or EPA health effects TGs for pesticides and toxic substances numbers. Following are the studies included in the Consent Order relevant to human health and this assessment:

- Repeated dose metabolism and pharmacokinetics studies (OPPTS 870.7485) in mice and rats (Dupont-18405-1017, 2011)

- Modified Oral (Gavage) Reproduction/Developmental Toxicity Study in Mice (OECD TG 421) (Dupont-18405-1037, 2010; OECD, 2016a)
- 90 Day Oral (Gavage) Toxicity Study (OECD, 1998) (species not specified): Both mice (DuPont-18405-1307, 2010) and rats (Dupont-17751-1026, 2009) were submitted
- Combined Chronic Toxicity/Oncogenicity Study in Rats (OECD, 2009) (Dupont-18405-1238, 2013)

The OECD TGs are accepted internationally as standard methods for safety testing and:

> …are covered by the Mutual Acceptance of Data, implying that data generated in the testing of chemicals in an OECD member country, or a partner country having adhered to the Decision, in accordance with OECD Test Guidelines and Principles of GLP, be accepted in other OECD countries and partner countries having adhered to the Decision, for the purposes of assessment and other uses relating to the protection of human health and the environment (OECD, 2018a).

Specifically, for the required oral reproductive/developmental toxicity test, EPA OPPT included requirements for specific modifications to the test to increase the robustness of the study for this class of chemicals (DuPont-18405-1037, 2010; OECD, 2016a). These modifications are stated in the Consent Order (EPA, 2009) and were followed by the testing laboratory as outlined in the study report (DuPont-18405-1037, 2010). For the required combined chronic toxicity/oncogenicity study, EPA reviewed and concurred with protocols submitted to the agency prior to the study being conducted (DuPont-18405-1238, 2013). In addition, the submitter consulted with EPA on study findings to determine the need for additional data (e.g., further toxicokinetic testing based on results of the first tier OPPTS 870.7485 study). Finally, while not specifically required under the Consent Order, DuPont conducted and submitted results for additional OECD TG studies for Agency review (e.g., the prenatal and developmental toxicity study in rats (OECD, 2001b) (DuPont-18405-841, 2010).

1.2 Uses of GenX Chemicals under TSCA

GenX is a trade name for a processing aid technology developed by DuPont to make high-performance fluoropolymers without the use of perfluorooctanoic acid (PFOA) (Chemours, 2018). Transition to GenX processing aid technology began in 2009 as part of the company's commitment under the 2010/2015 PFOA Stewardship Program to work toward the elimination of these chemicals from emissions and products by 2015. Although production of most long-chain PFAS has been phased out in the United States and has been generally replaced by production of shorter chain PFAS, EPA is aware of ongoing use of long-chain PFAS by companies that did not participate in the PFOA Stewardship Program and ongoing use of the chemicals available in existing stocks or being newly introduced via imports.

Fluoropolymers are used in many applications because of their unique physical properties such as resistance to high and low temperatures, resistance to chemical and environmental degradation, and nonstick characteristics. Fluoropolymers also have dielectric and fire-resistant properties that have a wide range of electrical and electronic applications, including architecture, fabrics, automotive uses, cabling materials, food processing, electronics, pharmaceutical and biotech manufacturing, and semiconductor manufacturing (Gardiner, 2014).

One of the two PMNs EPA received in 2008, P-08-0508, was for HFPO dimer acid, a chemical used as an intermediate to make the polymerization aid HFPO dimer acid ammonium salt. The PMN for HFPO dimer acid ammonium salt was received by EPA under PMN P-08-0509 and is used as a replacement for PFOA in the manufacture of fluoropolymers. The GenX resin manufacturing process includes the thermal transformation of the HFPO dimer acid ammonium salt processing aid into a hydrophobic hydride. HFPO is used in the manufacture of HFPO dimer acid, HFPO dimer acid ammonium salt, other HFPO dimer acid derivatives, fluoropolymers (including polyethers), and other specialty agrochemical and pharmaceutical applications. Information on specific products containing GenX chemicals is not available, however, GenX chemicals may be used in the manufacture of the same or similar commercial fluoropolymer end products that formerly used PFOA. GenX chemicals may also be generated as a byproduct of fluoromonomer production. When in water, both HFPO dimer acid and HFPO dimer acid ammonium salt dissociate to form the HFPO dimer acid anion ($HFPO^-$) as a common analyte. HFPO is manufactured from hexafluoropropene. HFPO dimer acid can react with additional HFPO to form the HFPO trimer acid and longer polymer fluorides. Other PFAS chemicals might be part of the GenX processing aid technology, but HFPO dimer acid and its ammonium salt are the major chemicals associated with this technology.

1.3 Occurrence

GenX chemicals were identified in North Carolina's Cape Fear River and its tributaries in the summer of 2012 (Strynar et al., 2015). Following this discovery, between June and December 2013, Sun et al. (2016) sampled source water at three drinking water treatment plants (DWTPs) (identified as DWTPs A, B, and C) treating surface water from the Cape Fear River watershed. The mean concentration of HFPO dimer acid in the finished drinking water treated by DWTP C was 0.631 microgram per liter (µg/L) (Sun et al., 2016). In a separate experiment to look at removal efficiency of DWTP C, water samples were taken during August 2014 from the raw water intake and after each treatment process step used by DWTP C (i.e., coagulation/ flocculation/sedimentation, raw and settled water ozonation, biological activated carbon filtration, and disinfection by medium-pressure ultraviolet lamps and free chlorine). GenX chemicals were found at concentrations of 0.4–0.5 µg/L at all steps of the treatment process, indicating that the concentrations of HFPO dimer acid were only slightly decreased by the conventional and advanced water treatment processes used at this DWTP.

The publication of these data prompted the North Carolina Department of Environmental Quality to sample sites for GenX chemicals along the Cape Fear River and in private wells close to the Chemours facility. In certain samples of surface water, groundwater, and finished drinking water, GenX chemicals were detected above 0.140 µg/L, which is North Carolina's drinking water health goal for GenX chemicals (NCDEQ, 2018c). Chemours has indicated that GenX chemicals have been discharged into the Cape Fear River for several decades as a byproduct of other manufacturing processes (NCDEQ, 2017). Petre et al. (2021) quantified the mass transfer of PFAS from contaminated groundwater to five tributaries of the Cape Fear River, including GenX chemicals. HFPO dimer acid and another fluoroether accounted for 61% of the total quantified PFAS. The study authors calculated that 32 kg/year of PFAS discharges from the groundwater to the five tributaries and the movement of these fluoroethers from the groundwater through the subsurface and into the streams occurred in less than the past 50 years. These data indicate that

the discharge of contaminated groundwater has led to long-term contamination of surface water and could lead to subsequent impacts on downstream drinking water (Petre et al, 2021).

Community concern over the detection of GenX chemicals in the Cape Fear Watershed led to the initiation of the GenX exposure study in Wilmington, North Carolina[1]. Blood samples from 344 Wilmington residents were collected between November 2017 and May 2018 and repeated blood samples from 44 of the participants were collected 6 months after the first sample collection. The blood sampling coincided with source control of GenX chemicals, and it is unknown whether study participants were drinking tap water at the time of collection. GenX chemicals were not detected above the analytical reporting limit of 2 ng/mL in any of the blood samples collected (Kotlarz et al., 2020).

GenX chemicals and other PFAS were also analyzed in 2682 urine samples from 2013–2014 National Health and Nutrition Examination Survey (NHANES) participants ≥ 6 years of age (Calafat et al., 2019). GenX chemicals were one of the few tested PFAS to be detected in the urine and was detected in approximately 1.2% of the population. The limit of detection was 0.1 µg/L. Importantly, this study demonstrated that the urine does not appear to be a good biomarker for PFAS. For example, PFOA and PFOS were detected in serum samples for > 98% of this study population, yet PFOA and PFOS were only detected in paired urine samples for < 0.1% of the same population.

In a report submitted by The Chemours Company to EPA, 24 human plasma samples were analyzed for HFPO dimer acid and were found at concentrations ranging from 1.0 ng/mL – 51.2 ng/mL. In seven of the samples, HFPO dimer acid was not detected above the analytical reporting limit of less than 1.0 ng/mL. No additional information about the study participants was provided in the report (DuPont- C30031_516655, 2017). GenX chemicals have been identified in other media, including rainwater and air emissions. North Carolina Department of Environmental Quality estimates for the Chemours Fayetteville Works plant (in the North Carolina Cape Fear watershed) indicate that Chemours' annual emissions of GenX chemicals could have exceeded 2,700 pounds per year during the reporting period (2017–2018) (NCDEQ, 2018a). Additional details on air emissions of GenX chemicals at the Fayetteville Works plant can be found at https://files.nc.gov/ncdeq/GenX/2018_April6_Letter_to_Chemours_DAQ_FINAL_signed.pdf. Rainwater samples were collected between February 28 and March 2, 2018 up to 7 miles from the North Carolina plant (NCDEQ, 2018b). The highest concentration of GenX chemicals in a rainwater sample (0.810 µg/L) was detected 5 miles from the Fayetteville Works facility center. The three samples collected 7 miles from the plant ranged from 0.045 to 0.060 µg/L (NCDEQ, 2018b). GenX chemicals also have been detected in three on-site production wells and one on-site drinking water well at the Chemours Washington Works facility in Parkersburg, WV. EPA subsequently requested that Chemours test for GenX chemicals in both raw and finished water at four public drinking water systems and 10 private drinking water wells. Chemours agreed to the testing and completed sampling during February 2018. The results from these samples are available at https://www.epa.gov/sites/production/files/2018-04/documents/hfpo_chemours_wash_works_sampling_2018.pdf and range before treatment from less than 0.010–0.081 µg/L in the public drinking water systems and less than 0.010–0.052

[1] https://genxstudy.ncsu.edu/

µg/L in the private drinking water wells (EPA, 2018a). All samples were below the limit of detection (0.010 µg/L) after treatment (EPA, 2018a).

Additionally, between the summer of 2016 and March 2018, GenX chemicals were identified in surface water and some soil samples collected upstream and downwind of a fluoropolymer production facility in Parkersburg, WV (Galloway et al., 2020). The highest concentrations of HFPO dimer acid in surface water samples (37–227 ng/L) were found in the direction of prevailing winds, directly across the Ohio River to the north and upstream to the northeast of the plant on the East Fork of the Little Hocking River. HFPO dimer acid was found in surface water samples up to 24 kilometers north of the facility, close to Beverly, OH. HFPO dimer acid was also detected in soil samples from Drag Strip Road, Veto Lake, and the Little Hocking Water Association at concentrations ranging from 3.09 nanograms per gram (ng/g) to 8.14 ng/g. These data reveal the downwind atmospheric transport of HFPO dimer acid.

Low concentrations of HFPO dimer acid (0.003–0.004 µg/L) were detected in the Delaware River, as reported in the recent publication by Pan et al. (2018).

The Kentucky Department of Environmental Protection (2019) reported detecting HFPO dimer acid in 11 samples from DWTPs at concentrations ranging from more than 1.32 ng/L to 29.7 ng/L. The study analyzed DWTPs using both surface water and ground water as sources and found the most frequent and highest detections of HPFO dimer acid at plants that use the Ohio River and ground water from the Ohio River alluvial aquifer as sources. For HFPO dimer acid, 10 detections were from surface water DWTPs and one detection was from a ground water DWTP. The ground water DWTP reported the highest concentration of HFPO dimer acid of all detections.

Globally, GenX chemical occurrence has been reported in Germany (Heydebreck et al., 2015; Pan et al., 2018), China (Heydebreck et al., 2015; Pan et al., 2017, 2018; Song et al., 2018), the Netherlands (Heydebreck et al., 2015; Gebbink et al., 2017; Pan et al., 2018), the United Kingdom (Pan et al., 2018), South Korea (Pan et al., 2018), and Sweden (Pan et al., 2018). HFPO dimer acid was also detected with a mean concentration of 30 pg/L in Artic surface water samples, suggesting long range transport (Joerss et al., 2020).

1.4 Other Assessments of GenX Chemicals

1.4.1 North Carolina Assessment

The North Carolina Department of Health and Human Services (NC DHHS) released a health assessment and provisional drinking water health goal for GenX chemicals in July 2017, which was finalized in October 2018 (NCDEQ, 2018c). North Carolina defines “health goal” as a nonregulatory, non-enforceable level of contamination below which no adverse health effects would be expected over a lifetime of exposure. The provisional health goal for exposure to GenX chemicals in drinking water is 0.140 µg/L, which is intended to protect the most sensitive population, namely bottle-fed infants. The state selected bottle-fed infants as the most sensitive population because they drink the largest volume of water per body weight (BW).

North Carolina’s provisional health goal is based on a reference dose (RfD) derived from a NOAEL of 0.1 mg/kg/day for liver effects (single-cell necrosis) in mice (DuPont-24459, 2008; DuPont-18405-1037, 2010). The total UF applied was 1,000, including individual factors to

account for interspecies variability (10), intraspecies variability (10), and extrapolation from a subchronic to a chronic exposure duration (10). This RfD of 0.0001 mg/kg/day was used to derive a drinking water equivalent level (DWEL), which considers exposure. The DWEL was calculated using BW and drinking water intake for bottle-fed infants and a relative source contribution of 20% to account for potential exposure to GenX chemicals from other media and routes, including air, soil, dust, and food (NCDEQ, 2018c). Additional details are available at NC DHHS.

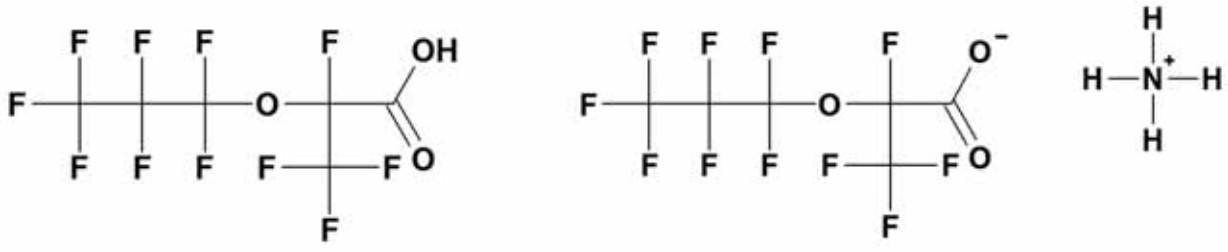
1.4.2 Report by the Netherlands National Institute for Public Health and the Environment

The National Institute for Public Health and the Environment (RIVM) in the Netherlands evaluated the data for GenX chemicals to set a safe limit for air. RIVM's assessment focused on the precursor 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)propanoic acid (FRD-903) (a synonym for HFPO dimer acid), the processing agent ammonium 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)propanoate (FRD-902) (a synonym for HFPO dimer acid ammonium salt), and the transformation product heptafluoropropyl 1,2,2,2-tetrafluoroethyl ether (E1). Overall, RIVM concluded that there is no health risk expected for people living near plants from emissions of FRD-902 and FRD-903 at a limit of 73 nanograms per cubic meter (insufficient data are available to determine the toxicity of E1) (Beekman et al., 2016). RIVM used the oral carcinogenicity study in rats as the critical study (DuPont-18405-1238, 2013) and concluded that the study NOAEL was 0.1 mg/kg/day, based on increased albumin and the albumin-to-globulin (A/G) ratio observed at 12 months in males dosed with 1 mg/kg/day, an effect that indicates the potential for immunotoxicity. Using route-to-route extrapolation, RIVM converted this NOAEL to an air concentration to be used as the POD. UFs to account for intraspecies differences (10) and interspecies differences (1.8), and an additional factor to account for uncertainty in the human elimination of GenX chemicals (66) were applied to the POD to determine the chronic inhalation limit.

2.0 Nature of the Stressor

2.1 Chemical/Physical Properties

HFPO dimer acid and its ammonium salt are fluorinated organic compounds (Figure 1).



HFPO dimer acid
CASRN 13252-13-6

HFPO dimer acid ammonium salt
CASRN 62037-80-3

Figure 1. Structure of HFPO Dimer Acid and HFPO Dimer Acid Ammonium Salt

HFPO dimer acid is a liquid whereas its ammonium salt is a solid at room temperature. Both are highly soluble in water. Except in very acidic solvents (pH less than 3), the acid will dissolve and be present as the acid anion with a -1 charge. The associated cation ion will be a hydronium ion (H_3O^+) in water if other hydrogen ion acceptors are absent. Both compounds can volatilize from water to air, where they will dissolve in aerosolized water droplets or bind to suspended particulate matter. In soils, they will migrate with the aqueous phase or bind to the soil particle surfaces with areas of positive charge. The organic portions of HFPO dimer acid and its ammonium salt are stable to environmental degradation. Table 1 presents the chemical and physical properties of HFPO dimer acid and its ammonium salt.

Table 1. Chemical and Physical Properties of HFPO Dimer Acid and HFPO Dimer Acid Ammonium Salt

Property	HFPO dimer acid	HFPO dimer acid ammonium salt	Source
CASRN	13252-13-6	62037-80-3	Chemical Abstracts Service.
CAS Index Name	Propanoic acid, 2,3,3,3-tetrafluoro-2-(1,1,2,2,3,3,3-heptafluoropropoxy)	Propanoic acid, 2,3,3,3-tetrafluoro-2-(1,1,2,2,3,3,3-heptafluoropropoxy)-ammonium salt (1:1)	Chemical Abstracts Service.
IUPAC Name	2,3,3,3-tetrafluoro-2-(1,1,2,2,3,3,3-heptafluoropropoxy)propanoic acid	azanium;2,3,3,3-tetrafluoro-2-(1,1,2,2,3,3,3-heptafluoropropoxy)propanoate	PubChem.

Chemical Formula	$C_6HF_{11}O_3$	$C_6H_4F_{11}NO_3$	
Molecular Weight	330.06 g/mol	347.08 g/mol	

Property	HFPO dimer acid	HFPO dimer acid ammonium salt	Source
Color/Physical State	Clear, colorless liquid (20 ˚C, 101.3 kPa)	Solid	DuPont-24637, 2008; DuPont-24698, 2008.
Boiling Point	129 ˚C	108 ˚C (as 86% salt solution in water) No measurement available for salt form	DuPont-24637, 2008; DuPont-24698, 2008.
Melting Point	< –40.0 ˚C	-21.0 ˚C (as 86% salt solution in water) No measurement available for salt form	DuPont-24637, 2008; DuPont-24698, 2008.
Vapor Pressure	306 Pa (2.7 mm Hg) (20 ˚C)	No measurement available	DuPont-24128, 2008; DuPont-24129, 2008.
Henry's Law Constant	< 2.5 x 10^{-4} atm-m^3/mol	No measurement available	Calculated from measured vapor pressure and highest measured solubility. Water solubility is reported to be "infinite" (DuPont-24128, 2008; DuPont-24129, 2008), so the actual K_h is expected to be much lower. These values should not be used to estimate partitioning between water and air.
Pk_a	2.84 (20 ˚C)	3.82	DuPont-26349, 2008.
Pk_b	8.1	8.1	DuPont-24198, 2008 (HFPO dimer acid ammonium salt).
K_{oc}		Soil–12 L/Kg (log 1.10) Sludge–12.6 L/Kg (log = 1.08)	DuPont-17568-1675, 2008.
K_{ow}	Not applicable[a]	Not applicable[a]	
Solubility in Water @ 20 ˚C	>751 g/L	>739 g/L	Highest tested values. Actual solubility not determined but described as "infinite" (DuPont-24128, 2008; DuPont-24129, 2008).

Property	HFPO dimer acid	HFPO dimer acid ammonium salt	Source
Half-life ($T_{1/2}$) in Water (25 ˚C)	Stable	Stable	Measured hydrolysis values for salt. No degradation in 5 days at 50 ˚C and pH 4, 7, and 9 (DuPont-24199, 2008).
Half-life ($T_{1/2}$) in Air	Stable	Stable	Ultraviolet-visible and visible spectrophotometry spectra for acid showed little absorption above 240 nm (DuPont-26349, 2008). EPA concurs with DuPont's assessment that the salt is assumed to be similar. Measured OH· reaction rate for E1 reaction product indicates T½ > 37 years.
Biodegradation	Biodegradation was not observed in ready biodegradation and inherent biodegradation tests	Biodegradation was not observed in ready biodegradation and inherent biodegradation tests	DuPont-A080558, 2009; DuPont-1388231-R2009NC031(a)-02, 2010; DuPont-1388231-R2009NC031(s)-02, 2010.
Bioconcentration (Fish BCF)	< 30 (log < 1)	< 30 (log < 1)	Measured BCF[b] < 30 at 0.02 mg/L and < 3 at 0.2 mg/L in Medaka 28 days (DuPont-A080560, 2009).
Bioaccumulation (Field BAF)	< 10	< 10	Pan et al., 2017.[c]

Notes: ºC = degrees Celsius; atm-m^3/mol = atmosphere cubic meters per mole; BAF = bioaccumulation factor; BCF = bioconcentration factor; g/L = grams per liter; g/mol = grams per mole; International Union of Pure and Applied Chemistry (IUPAC); K_{OC} = soil-water partition coefficient for organic compounds; K_{OW} = octanol-water partition coefficient; kPa = kilopascals; L/kg = liters per kilogram; mg/L = milligrams per liter; mm Hg = millimeters of mercury; nm = nanometer; Pk_a = acid dissociation constant; Pk_b = base dissociation constant; $T_{1/2}$ = half-life.

[a] Surfactants are surface acting agents that lower the interfacial tension between two liquids. Their amphiphilic nature (i.e., they contain both a hydrophilic part and a hydrophobic part) causes them to accumulate at interfaces such as the water-air interface, the water-food interface, and glass walls, which hampers the determination of their aqueous concentration. These surfactant properties present difficulties in applying existing methods for the experimental determination of log K_{ow} and produce unreliable results.

[b] The concentration of the propionate ion was not quantified in the BCF study, so the values are limits based on the limit of quantification for the analytical technique employed in the study.

[c] Pan et al. (2017) quantified the propionate ion and found that the concentrations were low in the tissues expected to most likely accumulate perfluorinated compounds (e.g., muscle, blood, and so forth). The tissue values indicate a BAF less than 10. Lipid tissue concentrations are not the basis for this BAF as is common for "traditional" organic compounds.

2.2 Environmental Fate

HFPO dimer acid and its ammonium salt are stable to photolysis, hydrolysis, and biodegradation. The degradation data suggest that the substances will be persistent (i.e., have a half-life ($T_{1/2}$) longer than 6 months) in air, water, soil, and sediments. Based on measured physical-chemical and sorption data, they are expected to run off into surface water and to rapidly leach to ground water from soil and landfills. As seen with PFOA and chemicals with similar properties, HFPO dimer acid and its ammonium salt might undergo long-range atmospheric transport in the vapor phase and associated with particulates. They are not expected to be removed during conventional wastewater treatment or conventional drinking water treatment.

When released to the freshwater environment, HFPO dimer acid will dissociate to the HFPO carboxylate anion and H_3O^+. The ammonium salt will dissolve to the HFPO carboxylate anion and the ammonium cation ($NH4^+$). It is expected that other salts of the HFPO dimer acid (e.g., potassium and sodium salts) will behave similarly. Both have high solubilities in water and are expected to remain in water with low sorption to sediment or soil. Given the vapor pressure, the acid can partition to air as well as to water. The salt can also be transported in air, although the mechanism of vapor phase transport is not understood (DuPont CCAS, 2009). In the vapor phase, the acid and salt are expected to be stable to direct photolysis and will undergo hydroxyl radical catalyzed indirect photolysis very slowly.

2.2.1 Water

Measured data for HFPO dimer acid and/or ammonium salt show that they are highly soluble in water (Table 1). The measured base dissociation constants (pK_b) indicate that the chemicals will exist primarily as the propionate ion at most environmental pH levels.

The chemicals are stable to hydrolysis. A hydrolysis study on the ammonium salt found no degradation at pH 4, 7, and 9 at 50 degrees Celsius (ºC) in 5 days, indicating a hydrolysis $T_{1/2}$ of more than 1 year at 20 ºC (DuPont-24199, 2008). Calculated Henry's Law constants (Table 1) suggest that partitioning from water to air might occur. Experimental data on the transfer of the acid and salt from water to air indicate that partitioning from surface water to the vapor phase might occur and some transfer from surface water to air is expected (DuPont CCAS, 2009). Water-air transport of these chemicals, however, is not well understood. Their surfactant properties, equilibrium between chemical forms as a function of pH, and interaction with dissolved cations make it difficult to accurately predict how the chemicals will behave in the aquatic environment.

2.2.2 Air

The acid was described as having "a significant vapor pressure" (DuPont CCAS, 2009). As observed with PFOA and other perfluorochemicals, these chemicals could be transported in the vapor phase or could associate with particulate material and be transported with the solids when released or partitioned into air.

When released to air or volatilized from water, the chemicals are stable and short- and long-range transport has occurred (D'Ambro et al., 2021; Galloway et al., 2020). For example, D'Ambro et al. (2021) demonstrated that just 2.5% of the total GenX concentrations (defined as the HFPO dimer acid and HFPO dimer acid fluoride) emitted from a fluoropolymer manufacturing facility in North Carolina were deposited within 150 kilometers of the facility. Removal from air is expected to occur through scavenging by water droplets and attachment to particulates followed by precipitation and settling. No studies of long-range transport or air removal rates are available.

2.2.3 Sediments and Soils

Organic carbon normalized sorption coefficients were measured by high-performance liquid chromatography (HPLC) (following OECD, 2001a). The sorption of the HFPO dimer acid ammonium salt to soil and sludge were 12.0 liters per kilogram (L/kg) (log = 1.10) and 12.6 L/kg (log = 1.08), respectively (DuPont-17568-1675, 2008; OECD, 2001a). Their high water solubility and low sorption potential indicate that the chemicals will tend to remain largely in water with little partitioning to soil or sediment. If applied or deposited to soil, they will run off or leach to ground water and, as indicated by the vapor pressure, could volatilize to air.

2.2.4 Biodegradation

GenX chemicals are resistant to biodegradation; no degradation was observed in standardized internationally recognized test methods for biodegradability. The aerobic aquatic biodegradation $T_{1/2}$ is on the order of years based on no measured inherent biodegradation of the acid or ammonium salt in OECD 302C, modified Ministry of International Trade and Industry studies (DuPont-1388231-R2009NC031(a)-02, 2010; DuPont-1388231-R2009NC031(s)-02, 2010; OECD, 2008b).[2] The HFPO dimer acid ammonium salt showed no inhibition of activated sludge respiration (OECD TG 209) (OECD, 2010a) at up to 1,000 milligrams per liter (mg/L) (DuPont-25938 RV1, 2008).

2.2.5 Incineration

A preliminary study submitted to EPA by DuPont/Chemours indicates that thermal degradation occurs (DuPont-PMN Attachment 119, 2008) and the potential for significant removal during incineration exists. Thermal degradation was reported to be rapid for HFPO dimer acid and/or its ammonium salt. The acid $T_{1/2}$ was reported to be about 2,500 seconds (about 42 minutes) at 150 ºC and about 1,900 seconds (about 32 minutes) at 200 ºC. The salt $T_{1/2}$ was 500 seconds (8.3 minutes) at 150 ºC and 200 seconds (3.3 minutes) at 200 ºC (DuPont-PMN Attachment 119, 2008).

2.2.6 Bioaccumulation

Measured steady-state fish BCFs in medaka (*Oryzias latipes*) exposed to the acid at 0.2 mg/L and 0.02 mg/L in a flow-through system for 28 days were less than 3 and less than 30, respectively (DuPont-A080560, 2009). These BCF results were observed—BCFs of less than 3

[2] HFPO dimer acid aerobic aquatic biodegradation $T_{1/2}$ = 0% by biochemical oxygen demand (BOD) and 1.5% by high-performance liquid chromatography-tandem mass spectrometry (HPLC/MS/MS); HFPO dimer acid ammonium salt aerobic aquatic biodegradation $T_{1/2}$ = < 1% by BOD and 0% by HPLC/MS/MS in 28 days (DuPont-1388231-R2009NC031(a)-02, 2010; DuPont-1388231-R2009NC031(s)-02, 2010).

and less than 30 when exposures were 0.2 mg/L and 0.02 mg/L of the acid, respectively—under the same conditions in common carp (*Cyprinus carpio*) (Hoke et al., 2016). A field-derived BAF was determined from a water body impacted by industrial perfluoroether releases. The log BAFs for specific tissues in the carp were 0.86 for blood, 0.50 for liver, and 0.61 for muscle. The tissue values indicate a BAF of less than 10 (Pan et al., 2017).

In a 4-day trout hepatocyte bioaccumulation screening test (non-TG) with the HFPO dimer acid ammonium salt, no metabolism was observed, suggesting that *in vivo* metabolism does not significantly affect potential bioaccumulation (DuPont-23459, 2007).

2.3 Toxicokinetics

In rats and mice, HFPO dimer acid and its ammonium salt are both absorbed from the gastrointestinal tract at levels that are proportional to dose following acute oral exposures. Transfer from plasma/serum to the liver, but not adipose tissue, was demonstrated in the few studies that conducted tissue analysis. The potential for maternal transfer to the fetus (Conley et al., 2019; Blake et al., 2020) during development and to the neonate during lactation (DuPont-18405-1037, 2010) was noted. Urine is the primary pathway for excretion. Based on data from studies of acute, single-dose, gavage, and intravenous exposures, $T_{1/2}$s in the beta (elimination) phase are longer in male rats and mice than in females. The male rats' $T_{1/2}$s in the beta (elimination) phase are relatively comparable to those for the male and female monkeys, whereas the female rats' $T_{1/2}$s are shorter.

HFPO dimer acid is a strong acid (acid dissociation constant (pK_a) = 2.84) and will be predominantly ionized in aqueous solutions with pH values higher than 4 and in both plasma and serum (DuPont-26349, 2008). Once in solution, the cation that counterbalances the HFPO dimer anion will vary with the salt used or the mineral ion composition of the solvent, plasma, serum, intercellular, and intracellular fluids. Based on the physical and chemical properties of HFPO dimer acid and its ammonium salt, once these chemicals enter physiologic compartments with pH values higher than 4 (e.g., most ambient water, serum, or blood), they will either dissociate (acid) or dissolve (ammonium salt) to yield the carboxylate anion. Thus, what is being measured in the studies outlined in this section is the HFPO dimer acid anion concentration regardless of whether animals are dosed with HFPO dimer acid or its ammonium salt.

2.3.1 Absorption

Oral. Sprague Dawley (Crl:CD(SD)) rats (five of each sex (5/sex)) were administered (via gavage) a single oral dose of 30 milligrams per kilogram (mg/kg) HFPO dimer acid ammonium salt in aqueous solution (purity 84%) in a study conducted according to EPA TG OPPTS 870.7485. Two animals of each sex served as controls. Urine and feces were collected at 0–6 hours, 6–12 hours, 12–24 hours, and every 24 hours until 168 hours post-dose. The 0–12-hour urine collections accounted for a mean of 95% to 97% of the dose, supporting a conclusion that these GenX chemicals are rapidly absorbed from the GI tract by male and female rats (DuPont-18405-1017 RV1, 2011).

In a similar guideline study with Crl/CD-1(ICR) mice (5/sex) (OPPTS 870.7485), the animals were administered a single oral dose of 3 mg/kg HFPO dimer acid ammonium salt (purity 84%) by gavage in aqueous solution (DuPont-18647-1017 RV1, 2011). Two animals of each sex served as controls. Urine and feces were collected at 0–6 hours, 6–12 hours, 12–24 hours, and

every 24 hours until 168 hours post-dose. In the 0–12-hour urine collections, 31% (mean) of the substance was found for the males and 39% (mean) for the females. By 168 hours post-dosing, the total accumulated urine values accounted for 90% and 92% of the total dose for male and female mice, respectively, indicating that both rats and mice extensively absorb the HFPO dimer acid anion. This study additionally shows mice either incompletely absorb HFPO dimer acid anions or eliminate it in urine at a slower rate than was seen in the rats (DuPont-18647-1017 RV1, 2011).

A 28-day gavage study by Rushing et al. (2017) indicates a potentially more complex toxicokinetic profile for HFPO dimer acid when dosing occurs over multiple days. Groups of six male and six female C57BL/6 mice were given doses of 1, 10, or 100 mg/kg/day of HFPO dimer acid daily for 28 days. Serum concentrations were measured at intervals of 1, 5, 14, and 28 days, and urine concentrations were measured on days 1, 2, 3, 5, 10, and 14. At each time point, serum levels reflected the magnitude of the dose, but not the exposure duration. The peak serum concentration occurred at day 5 for all but the high-dose males, where it occurred at day 14. Serum measurements for the 1- and 10-mg/kg/day doses were lower on days 14 and 28 than on day 5. The differences in serum concentration between days 5, 14, and 28 are not explained by the study authors, but could possibly indicate changes in absorption, tissue storage, or elimination after repeated dosing. The males exposed to 10 and 100 mg/kg/day had higher serum and urine concentrations than the females, as described in section 2.3.5 (Excretion). Based on the higher serum and urine concentrations, there appeared to be greater absorption in males than in females.

In a repeated-dose study following OECD TG 408 (OECD, 1998) guidelines, HFPO dimer acid ammonium salt (purity 84%) was administered to Crl:CD1(ICR) mice for 95 (males) or 96 (females) consecutive days via gavage at doses of 0, 0.1, 0.5, and 5 mg/kg/day (DuPont-18405-1307, 2010). Ten animals per sex per group (animals/sex/group) were included for toxicity evaluation, and an additional 15/sex/group were included for quantitation of the test substance plasma concentration 2 hours after dosing on day 0 (the first day of dosing) (5/sex/dose), providing a measure of post-dosing absorption (Table 2). Overall, plasma concentrations increased with increasing dose, indicating that absorption was not saturated, and displayed broad standard deviations indicative of considerable inter-animal variability in the absorption. The doses evaluated differ from those used by Rushing et al. (2017), limiting comparisons of the postexposure serum and plasma data. The sex difference seen by Rushing et al. (2017) (i.e., where male uptake to serum for the 1 and 10 mg/kg/day doses at the end of day 1 was greater than female uptake) is not as apparent at 2 hours post-dosing in this dataset.

Table 2. Plasma Concentration in Crl:CD1(ICR) Mice at 2 Hours after the First Gavage Exposure to HFPO Dimer Acid Ammonium Salt

Dose mg/kg/day	Males		Females	
	µg/mL	SD	µg/mL	SD

[a] Detection limit of the method was 0.005 µg/mL in plasma.

Inhalation. There are no studies investigating HFPO dimer acid or its ammonium salt's uptake following inhalation exposures of aerosols. In a study conducted by Dupont (17751-723, 2009), one group of 5 male and 5 female Crl:CD(SD) rats were exposed to 5,200 milligrams per cubic meter (mg/m^3) and two groups of male and female Crl:CD(SD) rats (3/sex/group) were exposed to aerosols containing 0, 13, and 100 mg/m^3 of HFPO dimer acid ammonium salt (84% purity) for a single 4 hour period. One male and one female rat exposed to air only were used as the control. The rats in the 0, 13, and 100 mg/m^3 groups had a 2-day recovery period. The rats in the 5,200 mg/m^3 group recovered for 14-days. There were no measurements of the chemical in serum or plasma, however, to support an estimate of absorption by way of the respiratory tract.

Dermal. Absorption of HFPO dimer acid ammonium salt through the skin was determined *in vitro* with rat and human skin specimens (DuPont-25292, 2008). HFPO dimer acid ammonium salt (86% purity) was diluted with water to a concentration of 124 milligrams per milliliter (mg/mL). Serial receptor fluid samples were collected at 0.5, 1, 2, 3, 4, 5, 6, 7, 8, 12, and 24 hours and analyzed for cumulative HFPO anion concentration.

Steady-state penetration rates were 70.3 ± 5.3 and 6.2 ± 5.3 micrograms per square centimeter per hour for rat and human skin, respectively, which yielded dermal permeability coefficients of 5.71E-4 ± 4.3E-5 centimeters per hour (cm/hr) for rats and 5.02E-5 ± 4.3E-5 cm/hr for humans. These dermal kinetic parameters demonstrate dermal absorption occurs, but at a relatively slower rate than chemicals that are well absorbed dermally.

2.3.2 Distribution

Crl:CD(SD) rats (3/sex/dose) were administered a single oral dose of 10 or 30 mg/kg by gavage in aqueous solution of either HFPO dimer acid ammonium salt (purity 84.5%) or HFPO dimer acid (purity 98%) (DuPont-24281, 2008; DuPont-24286, 2008). Plasma samples were collected at 0, 0.25, 0.5, 1, 2, 4, 8, 12, 24, 48, 72, 96, 120, 144, and 168 hours, as described in section 2.3.6 (Clearance and Half-life Data). Liver and fat samples were presumed to be collected for analysis after the 168-hour plasma sample collection. In male rats dosed with HFPO dimer acid ammonium salt, the mean concentration in plasma at 168 hours post-dose was 0.036 ± 0.011 micrograms per milliliter (µg/mL) (36 ± 11 nanograms per milliliter (ng/mL)) for the low dose (10 mg/kg) and 0.057 ± 0.036 µg/mL (57 ± 36 ng/mL) for the high dose (30 mg/kg). In male rats dosed with HFPO dimer acid, the mean concentration in plasma at 168 hours post-dose was 0.041 ± 0.01 µg/mL (41 ± 10 ng/mL) for the low dose (10 mg/kg) and 0.128 ± 0.023 µg/mL (128 ± 23 ng/mL) for the high dose (30 mg/kg). In female rats, plasma concentrations of HFPO dimer acid anion were not above the limit of quantification (LOQ) in any sample at 168 hours post-dosing. In males dosed with HFPO dimer acid ammonium salt, the mean concentration of HFPO dimer acid anion in the liver 168 hours post-dose was 73 ± 25 ng/g for the low dose (10 mg/kg)

and 38 ± 15 ng/g for the high dose (30 mg/kg). In males dosed with HFPO dimer acid, the mean concentration of HFPO dimer acid anion in the liver 168 hours post-dose was 24 ± 6 ng/g for the low dose (10 mg/kg) and 89 ± 4 ng/g for the high dose (30 mg/kg). The mean liver tissue-to-plasma concentration ratio was higher in males for the ammonium salt (2.19) than for the acid (0.64) at the low dose (10 mg/kg). At the high 30 mg/kg dose, the liver tissue-plasma concentration ratio values in male rats were similar: 0.78 for the ammonium salt and 0.71 for the acid. Females at both doses, however, had a lower accumulation of HFPO dimer acid and its ammonium salt in the liver than in the male did. Overall, 10 out of 12 female rats dosed with HFPO dimer acid or its ammonium salt had undetectable concentrations of HFPO dimer acid anion in the liver (LOQ = 20 ng/g). Two females dosed with HFPO dimer acid ammonium salt at the low dose (10 mg/kg) had liver HFPO dimer acid anion concentrations above the LOQ, containing 20.6 and 54.1 ng/g of HFPO dimer acid anion. Females dosed with HFPO dimer acid did not have liver anion concentrations above the LOQ (20 ng/g). HFPO dimer acid anion concentrations in the fat tissue samples were below the LOQ of 20 ng/g in all the rats given HFPO dimer acid or HFPO dimer acid ammonium salt (DuPont-24281, 2008; DuPont-24286, 2008).

Crl:CD1(ICR) mice (3/sex/dose) were administered a single oral dose of 10 or 30 mg/kg by gavage in aqueous solution of HFPO dimer acid ammonium salt (purity 86%) (DuPont-25300, 2008). Unlike the rat studies, HFPO dimer acid was not evaluated in the mice. Plasma samples were collected at 0, 0.25, 0.5, 1, 2, 4, 8, 12, 24, 48, 72, 96, 120, 144, and 168 hours, as described in section 2.3.6 (Clearance and Half-Life Data). Liver and fat samples were presumed to be collected for analysis after the 168 hour plasma sample collection. In males, the mean concentration of HFPO dimer acid anion in the liver was 384 ± 472 ng/g for the low dose (10 mg/kg) and 457 ± 337 ng/g for the high dose (30 mg/kg). The mean concentration in fat tissue was 31.6 ng/g in males for the high dose (30 mg/kg) and less than the LOQ (20 ng/g) for the low dose (10 mg/kg) and for both doses in females.

In male mice, the mean concentration in plasma at 168 hours post-dose was 0.759 ± 0.946 μg/mL (759 ± 946 ng/mL) for the low dose (10 mg/kg) and 0.83 ± 0.618 μg/mL (830 ± 618 ng/mL) for the high dose (30 mg/kg). In females, only one of three mice in each dose group had a plasma concentration above the LOQ at 168 hours post-dose, which was 0.0232 μg/mL (23.2 ng/mL) for the high dose (30 mg/kg) and 29.2 ng/g for the low dose (10 mg/kg). Based on the plasma and liver concentrations reported in the study, a liver-to-plasma ratio was calculated for males, but not for females because the females did not have liver concentrations above the LOQ. At the low dose (10 mg/kg), the average male liver-to-plasma ratio was 0.52, and at the high dose (30 mg/kg), it was 0.58.

Because the perfluorinated portion of the HFPO dimer acid ether is similar to that of the perfluorinated alkane acids (e.g., PFOA), HFPO dimer acid and its ammonium salt are anticipated to be transported in serum either freely dissolved or bound to serum protein (Gomis et al., 2018). Additionally, studies have demonstrated that the major serum protein interaction site for some PFAS, including PFOA and perfluorohexanoic acid (PFHxA), is albumin (D'eon et al., 2010; Han et al., 2003). Considering these points and that albumin is the major transport protein in the blood, it is likely that GenX chemicals are also distributed via serum albumin (Peters, 1995). Indeed, Allendorf et al. (2019) demonstrate that bovine serum albumin binds

HFPO dimer acid, and that the albumin/water partition coefficient is in the same range as other PFAS (e.g., perfluorobutanoic acid (PFBA) and perfluorohexane sulfonic acid (PFHxS)).

A study by Sheng et al. (2018) reported that the HFPO dimer acid anion also binds to fatty acid-binding protein (FABP). FABPs are intracellular lipid carrier proteins for long-chain fatty acids, phospholipids, and a variety of chemicals that induce peroxisome proliferation (Erol et al., 2003). They constitute 2%–5% of the cytosolic protein in the liver. FABPs can be synthesized in the gastrointestinal tract and act as a systemic carrier of long-chain fatty acids in plasma and serum (Storch and McDermott, 2009). Thus, FABPs likely play a role in the systemic distribution of HFPO dimer acid in both its neutral and ionized forms.

2.3.3 Distribution during Gestation and Lactation

HFPO dimer acid ammonium salt can be transferred (distributed) from a pregnant animal to the fetus, as demonstrated in multiple studies. In an OECD TG 421 (OECD, 2016a) reproduction/developmental toxicity study (DuPont-18405-1037, 2010), pregnant Crl:CD1(ICR) mice (25/sex/group) were administered, by gavage, 0, 0.1, 0.5, or 5 mg/kg/day HFPO dimer acid ammonium salt from premating day 14 to lactation day (LD) 20/21. Blood was collected from the dams 2 hours after dosing on LD/postnatal day (PND) 21 (scheduled termination) and pooled. The litters were normalized on PND4 to 8 pups per litter (4/sex). Blood was collected and pooled from the pups not randomly selected on PND4. The HFPO dimer acid anion was present in the pooled plasma of PND4 pups at concentrations approximately two to four times lower than the concentrations in the dams on LD21. These results indicate that there is transfer of HFPO dimer acid anion from maternal serum. The PND/LD21 plasma levels in both male and female pups, however, were forty- to sixtyfold lower than the maternal LD21 plasma concentrations, indicating that the majority of fetal transfer occurred during gestation (DuPont-18405-1037, 2010).

Blake et al. (2020) demonstrated that HFPO dimer acid can be transferred from the pregnant dam to the embryo during gestation. Pregnant CD-1 mouse dams were dosed from embryonic day (E) 1.5 to E11.5 or E17.5 with either deionized water (vehicle control), 1 or 5 mg/kg/day of PFOA, or 2 or 10 mg/kg/day of HFPO dimer acid. At E11.5 and E17.5, serum and a portion of the hepatic left lateral lobe were collected from pregnant dams after the final dose. Amniotic fluid was collected by needle aspiration from litters euthanized on E11.5 and whole embryos were collected on E11.5 and E17.5 to determine the concentration of HFPO dimer acid. HFPO dimer acid was detected in both the amniotic fluid and the whole embryo at 2 and 10 mg/kg/day and at both time points, demonstrating transfer of HFPO dimer acid from the pregnant dam to the fetus during gestation (Table 3).

Table 3. Concentrations of HFPO Dimer Acid in CD1 Pregnant Mice and Their Embryos at Embryonic Day 11.5 or 17.5[a]

Measurement [b]	Embryonic day	HFPO dimer acid	
		2 mg/kg/day	10 mg/kg/day
Maternal Serum (µg/mL)	11.5	33.5 ± 15.7	118.1 ± 10.4
	17.5 [c]	22.9 ± 17.1	58.5 ± 34.5

Measurement [b]	Embryonic day	HFPO dimer acid	
		2 mg/kg/day	10 mg/kg/day
Amniotic Fluid (µg/mL)	11.5	3.6 ± 2.2	9.3 ± 2.0
	17.5	NQ	NQ
Maternal Liver (µg/g)	11.5	5.45 ± 3.43	19.9 ± 4.2
	17.5	4.56 ± 2.80	14.2 ± 7.6
Whole Embryo (µg/g)	11.5	0.91 ± 0.22	3.21 ± 0.51
	17.5	3.23 ± 1.28	7.69 ± 2.92

Source: Blake et al., 2020.
Notes: µg/mL = micrograms per milliliter; µg/g = micrograms per gram embryo weight; SD = standard deviation; NQ = not quantified due to limited volume.
[a] For each reported measurement in this table, N = 6–8 per group.
[b] Limit of detection was 0.010 µg/mL; note all vehicle control samples were below the limit of detection.
[c] HFPO dimer acid was detected in the serum of vehicle control mice in the E17.5 group (0.211 ± 0.55 µg/mL).

HFPO dimer acid concentrations increased with increasing dose in all samples. The concentration of HFPO dimer acid in the whole embryo increased from E11.5 to E17.5 in both dose groups, indicating bioaccumulation in the embryo over the gestational period. Conversely, the concentration of HFPO dimer acid in the maternal serum decreases from E11.5 to E17.5 in both dose groups. The authors note that the decrease in maternal serum HFPO dimer acid could be the result of increased transfer to embryos over time or to dilution effect from blood volume expansion over the course of gestation.

In the DuPont-18405-1037 (2010) study, generally, the standard deviations were large in all dose groups, especially as compared to PND21. The male pups tended to have slightly higher plasma concentrations of HFPO dimer acid anion than the female pups at PND40. For example, at the 0.1 mg/kg/day-dose group, the concentration of HFPO dimer acid anion was 1.352 and 0.946 µg/mL (1,352 and 946 ng/mL) in male and female pups, respectively. Similarly, at the 0.5 mg/kg/day-dose group, the concentration of HFPO dimer acid anion was 6.282 and 4.074 µg/mL (6,282 and 4,074 ng/mL) in male and female pups, respectively, and it was 51.34 µg/mL (51,340 ng/mL) in male pups and 43.34 µg/mL (43,340 ng/mL) in female pups at 5 mg/kg/day (DuPont-18405-1037, 2010).

Transfer of HFPO dimer acid anion to the fetus was also demonstrated in groups of five Crl:CD(SD) rats exposed to doses of 0, 5, 10, 100, or 1,000 mg/kg/day from gestation day (GD)6 to GD20 (Dupont-18405-849 RV1, 2011). On GD20, blood was collected from individual dams 2 hours after dosing and trunk blood was collected from the fetuses and pooled by litter for analysis. The plasma concentration in the blood samples from the dams was three times higher than the plasma concentration in the pooled blood of their fetuses. The detection of HFPO dimer acid anion in the pooled fetus plasma demonstrates gestational transfer from dam to fetus.

Similarly, Conley et al. (2019) demonstrated transfer of HFPO dimer acid anion to the fetus by measuring serum concentrations of pregnant Crl:CD(SD) rats exposed to 0, 1, 3, 10, 30, 62.5, 125, 250, and 500 mg/kg/day HFPO dimer acid ammonium salt from GD14 through GD18.

Serum was collected from the dams in all dose groups and plasma was collected from the fetuses in the 0, 1, 3, 10 and 30 mg/kg/day groups. On GD18, trunk blood was collected from individual dams 2 hours after dosing and blood was collected from the fetuses' jugular vein and pooled per litter for analysis. HFPO dimer acid anion was detected in the pooled fetal plasma at all doses and the concentration increased with increasing maternal dose (Table 4). The study authors noted that, while the increases in maternal serum and fetal plasma were linear in the lower dose range (0–30 mg/kg/day), the maternal slope was significantly greater than the fetal slope. The maternal serum concentration of HFPO dimer acid anion increased 0.46 µg/mL (460 ng/mL) per 1 mg/kg increase in maternal dose while the fetal plasma concentration increased 0.12 µg/mL (120 ng/mL) per 1 mg/kg increase in maternal dose. Additionally, the study authors modeled uptake over the full maternal dose range (1–500 mg/kg) (Table 4) using exponential one-phase association and determined that a plateau was reached at 112 ± 15 µg/mL (112,000 ± 15,000 ng/mL), indicative of uptake saturation (Conley et al., 2019).

Table 4. Maternal Serum and Fetal Plasma Concentrations on GD18 in Crl:CD(SD) Rats Exposed to HFPO Dimer Acid Ammonium Salt from GD14-18

Oral dose mg/kg/day	Pregnant dam serum		Fetal plasma	
	µg/mL	SE	µg/mL	SE
0	0.027	0.008	0.018	0.01
1	0.68	0.08	0.13	0.06
3	1.2	0.3	0.49	0.04
10	4.6	1.1	1.9	0.2
30	13.9	3.1	3.5	0.4
62.5	30.7	2.9	N/A	N/A
125	46.0	10.3	N/A	N/A
250	81.8	21.6	N/A	N/A
500	100.7	26.4	N/A	N/A

Notes: µg/mL = micrograms per milliliter; N/A = not applicable because no sample collected at that dose; SE = standard error.

Conley et al. (2021) also demonstrated transfer of HFPO dimer acid anion to the fetus and pup by measuring serum concentrations of pregnant Crl:CD(SD) rats exposed to 0, 1, 3, 10, 30, 62.5, or 125 mg/kg/day HFPO dimer acid ammonium salt from GD16 through GD20 or to 0, 10, 30, 62.5, 125, or 250 mg/kg/day from GD8 through PND2. Serum was collected from the dams and fetuses in all dose groups on GD20 in the GD16-20 experiment and from the dams on PND2 in the neonatal experiment. In the GD16–20 experiment, trunk blood and liver samples were collected from both dams and fetuses 2 to 4 hours after the final oral dose on GD20. Fetal serum was pooled per litter for analysis. On PND2 in the neonatal experiment, trunk blood and liver samples were collected from the dams 2 to 5.5 hours after the final oral dose and liver samples were collected from the pups. Maternal serum and liver HFPO dimer acid anion concentrations

increased as a function of dose during both experiments (Table 5). The study authors noted that there was no statistically significant difference in serum or liver concentration within a given dose group between the two experiments indicating that bioaccumulation did not occur after longer exposure. HFPO dimer acid anion was detected in the pooled fetal serum at all doses and the concentration generally increased with increasing maternal dose. Regression analyses showed that fetal and maternal serum concentrations increased log-linearly as a function of maternal oral dose, and maternal serum concentrations were approximately 2- to 3-fold greater than fetal serum concentrations. Liver concentrations of HFPO dimer acid anion in dams, fetuses, and pups also increased log-linearly. The fetal and maternal liver concentrations on GD20 were nearly identical for the 30–125 mg/kg/day dose levels. On PND2, male pup liver concentrations were significantly greater than female pup liver concentrations, which was most prominent at the 125 mg/kg/day dose level. PND2 liver concentrations for both sexes were approximately 10-fold lower than concentrations observed in GD20 fetal livers.

Table 5. Maternal and Offspring HFPO Dimer Acid Anion Concentrations in Serum and Liver Samples Collected on GD20 or PND2 from Crl:CD(SD) Rats Orally Exposed to HFPO Dimer Acid Ammonium Salt from GD16-20 or GD8-PND2

Oral dose mg/kg/day	Maternal serum GD20 (µg/mL)	Fetal serum GD20 (µg/mL)	Maternal serum PND2 (µg/mL)	Maternal liver GD20 (µg/g)	Fetal liver GD20 (µg/g)	Maternal liver PND 2 (µg/g)	Female pup liver PND 2 (µg/g)	Male pup liver PND 2 (µg/g)
0	0.016 ± 0.014	0.014 ± 0.008	<LOQ	0.29 ± 0.12	0.07 ± 0.04	0.14 ± 0.05	0.07 ± 0.021	<LOQ

Source: Conley et al., 2021, Table S11.
Notes: Values reported as mean ± standard error of the mean (SEM); sample size n = 2–6 except where noted; LOQ = limit of quantitation (0.005 µg/mL for serum, 0.1 µg/g for liver); µg/mL = micrograms per milliliter; µg/g = micrograms per gram; N/A = not applicable because no sample collected at that dose.

In the studies of rats dosed during pregnancy in which plasma concentrations in both the dams and fetuses were measured at GD20 (Dupont-18405-849 RV1, 2011) or GD18 (Conley et al., 2019), the HFPO dimer acid anion plasma concentration ratio for dams to fetuses is approximately two to four. In the study of mice dosed during pregnancy (Dupont 18405-1037, 2010), plasma concentrations were measured in dams on LD21 and in pups on PND4, PND21, and PND40. If the plasma concentrations in dams on LD21 are assumed to be representative of those on LD4, the comparison to pup plasma concentrations on PND4 indicate a dam-to-pup plasma concentration ratio of two to four. Together these data indicate the efficiency of transfer in rats and mice is of a similar magnitude.

2.3.4 Metabolism

In two *in vitro* studies, hepatocytes (1 x 10^6 cells/mL for clearance incubations and 5 x 10^6 cells/mL for biotransformation incubations) prepared from male and female Crl:CD(SD) rats were incubated with 2 micromolar (μM) (clearance) or 200 μM (biotransformation) solutions of HFPO dimer acid ammonium salt for a total of 120 minutes (DuPont-23460, 2007). Samples were analyzed for HFPO dimer acid ammonium salt and potential metabolites at 5, 15, 30, 45, 60, 90, and 120 minutes. Heat-inactivated hepatocytes were used as negative controls and 4-nonylphenol in live hepatocytes were used as a positive control. There was no difference in the concentration of HFPO dimer acid between the viable and heat-inactivated hepatocytes, indicating that HFPO dimer acid ammonium salt is not metabolized by rat hepatocytes. Additionally, no metabolites were detected in the biotransformation incubation samples (DuPont-23460, 2007). Similar *in vitro* studies were conducted in rat hepatocytes in Gannon et al. (2016). Hepatocytes (1 x 10^6 cells/mL for clearance incubations and 5 x 10^6 cells/mL for biotransformation incubations) prepared from male and female Crl:CD(SD)rats were incubated with 5 μM (clearance) or 50 μM (biotransformation) solutions of HFPO dimer acid ammonium salt for a total of 120 minutes. Heat-inactivated hepatocytes were used as negative controls and samples were collected at 0, 30, 45, 60, 90, and 120 minutes. Gannon et al. (2016) concluded that the test substance was not metabolized by rat hepatocytes because there was no difference in clearance rate between live and heat-inactivated hepatocytes and no metabolites were identified.

In the single oral (gavage) study of rats described in section 2.3.1 (Absorption), the total accumulated amount of HFPO dimer acid ammonium salt at 168 hours post-dosing in the collected urine accounted for 103% $\pm$ 2.73% and 99.8% $\pm$ 6.41% of the administered dose for male and female rats, respectively, and there was no detection of metabolites (DuPont-18405-1017 RV1, 2011).

Similarly, in the single oral (gavage) study of mice described in section 2.3.1 (Absorption), the total accumulated amount of HFPO dimer acid ammonium salt accounted for 89.5% ± 6.91% and 91.5% ± 6.04% of the total dose for male and female mice, respectively, and there was no detection of metabolites in the urine (DuPont-18647-1017 RV1, 2011).

2.3.5 Excretion

Urine. Studies in rats, mice, and monkeys indicate that urine is the primary excretory pathway for GenX chemicals. In the DuPont-18405-1017 RV1 (2011) study, Crl:CD(SD)rats (5/sex) administered a single oral (gavage) dose of 30 mg/kg HFPO dimer acid ammonium salt excreted 95% to 97% of the dose in urine within 12 hours. The pooled urine collections accounted for virtually all the substance administered with no evidence of metabolic alteration. Study authors calculated the elimination $T_{1/2}$ in the urine for male and female rats to be 3 hours and 8 hours, respectively. In a companion study, Crl/CD1(ICR) mice (5/sex) were administered a single oral (gavage) dose of 3 mg/kg HFPO dimer acid ammonium salt (purity 84%) (DuPont-18647-1017 RV1, 2011). Urinary elimination in mice appeared to be less efficient than in the rats given that only 31% (mean) and 39% (mean) of the dose material was found in the 12-hour pooled urine for the male and female mice, respectively. At 168 hours post-dosing, the mean values for the pooled urine samples accounted for 90% and 92% of the total dose for the male and female mice, respectively (DuPont-18647-1017 RV1, 2011). Study authors calculated the elimination $T_{1/2}$ in the urine for male and female mice to be 21 hours and 18 hours, respectively. Based on the amounts in urine and the clearance from blood (see section 2.3.6), mice appear to have less of an

ability than rats to clear the HFPO dimer acid anion by transferring it to urine in the early postexposure period. The differences in the results of these studies might have been influenced by the different doses given to the rats (30 mg/kg) and the mice (3 mg/kg) (DuPont-18647-1017 RV1, 2011; DuPont-18405-1017 RV1, 2011).

The dynamic relationship across dose and exposure duration observed in serum measurements from the Rushing et al. (2017) study is also reflected in their data on urinary excretion. Urine concentrations were monitored on exposure days 1, 2, 3, 5, 10, and 14. For the 1- and 10-mg/kg/day doses, urinary concentration peaked on day 3 and, thereafter, declined monotonically. Males had higher urine concentrations than females at each time point, consistent with their higher serum concentrations. For the 100-mg/kg/day-dose group, the concentrations in urine peaked at day 2 and again at day 14 in males while in females they appeared to peak at 5 days followed by a decline at 10 and 14 days.

Feces. Fecal elimination of HFPO dimer acid appears to be minor in rats and mice in the available single-dose studies (DuPont-18405-1017 RV1, 2011; DuPont-18647-1017 RV1, 2011). Specifically, feces + cage wash (dried fecal matter) from male and female rats had 2% and 6% of recovered compound, respectively, while feces + cage wash from male and female mice had 12% and 8% of recovered compound, respectively. The data for combined fecal matter and cage wash suggest that mice might lose slightly more HFPO dimer acid through fecal matter than rats. Low fecal excretion could reflect low levels of hepatic loss via biliary excretion.

2.3.6 Clearance and Half-Life Data

Clearance time. In multiple study reports, the study authors did not calculate pharmacokinetic parameters such as $T_{½}$ or area under the curve and instead defined the metric “clearance time” as the time when 98.4% of the anion from the HFPO dimer acid ammonium salt was cleared from the plasma.

A total of 12 Crl:CD(SD) rats, 3/sex/dose, received a single oral dose of 10 or 30 mg/kg/day HFPO dimer acid ammonium salt (84.5% purity) by gavage (Dupont-24281, 2008). Plasma samples were collected from animals serially at 0, 0.25, 0.5, 1, 2, 4, 8, 12, 24, 48, 72, 96, 120, 144, and 168 hours. In males, plasma levels peaked within the first 1–2 hours after dosing for the low dose, and within the first 30 minutes to 1 hour for the high dose. By days 4 to 5, plasma concentrations were less than 1% of the peak level, although still above the LOQ (0.02 µg/mL (20 ng/mL)). In females, the plasma levels peaked at 1 hour for the low dose and had usually declined to the LOQ (0.02 µg/mL (20 ng/mL)) by 24 hours. At the 30-mg/kg dose, the plasma levels of female rats peaked at 30 minutes to 1-hour post-dosing and declined to the LOQ (0.02 µg/mL (20 ng/mL)) by 24 or 48 hours. In male rats, the authors identified 12 hours as the clearance time at the low dose and 22 hours at the high dose (Table 6). In female rats, the clearance values were 4 hours and 8 hours for the low dose and high dose, respectively.

Table 6. Clearance Times in Plasma for Male and Female Rats and Mice Following a Single Oral Dose[a]

Chemical	Male rat	Male mouse	Female rat	Female mouse
10 mg/kg				
HFPO dimer acid ammonium salt	12 hr	143 hr	4 hr	57 hr
HFPO dimer acid	28 hr	ND	8 hr	no data
30 mg/kg				
HFPO dimer acid ammonium salt	22 hr	139 hr	8 hr	62 hr
HFPO dimer acid	22 hr	ND	4 hr	no data

Sources: Dupont-24281, 2008; Dupont-24286, 2008; Dupont-25300, 2008.
Notes: hr = hour
[a] "Clearance time" is defined as the time when 98.4% of the HFPO dimer acid ammonium salt was cleared from the plasma.

The same protocol was followed using HFPO dimer acid (98% purity) (Dupont-24286, 2008). At the low dose, plasma concentrations peaked within 1 hour in both male and female rats, while at the high dose, the peak plasma concentrations occurred in males at 1 or 2 hours and in females at 15 minutes. The clearance times in males were 28 hours and 22 hours for the low dose and high dose, respectively. The clearance times in females were 8 hours and 4 hours for the low dose and high dose, respectively (Table 6).

The protocol outlined in this section was also followed for mice with a total of 12 Crl:CD(ICR) mice, 3/sex/dose, receiving a single oral dose of 10 or 30 mg/kg/day HFPO dimer acid ammonium salt (86% purity) by gavage (Dupont-25300, 2008). Plasma samples were collected from animals serially at 0, 0.25, 0.5, 1, 2, 4, 8, 12, 24, 48, 72, 96, 120, 144, and 168 hours post-dosing. Peak plasma HFPO dimer acid anion concentrations were reached within 8 hours for the males and 4 hours for the females at the 10-mg/kg dose. At the 30-mg/kg dose, the peak HFPO dimer acid anion concentrations were reached within 2 hours for both males and females. The mean clearance time was slower in the males (143 hours and 139 hours at the low dose and high dose, respectively) than in the females (57 hours and 62 hours at the low dose and high dose, respectively) (Table 6).

In the oral toxicokinetic studies, the clearance times were shorter in rats than in mice and were shortest in female rats compared to male rats for both anions from HFPO dimer acid and its ammonium salt. In rats at the 10-mg/kg dose, HFPO dimer acid took longer to clear than its ammonium salt in both male and female rats. At the 30-mg/kg dose, however, both HFPO dimer acid and its ammonium salt had the same clearance times in male rats, but the HFPO dimer acid ammonium salt took longer to clear in female rats.

In a cross-species pharmacokinetic study, Crl:CD(SD) rats (3/sex) were administered a single intravenous bolus of 10 or 50 mg/kg of HFPO dimer acid ammonium salt and Cynomolgus monkeys (3/sex) were administered a single intravenous bolus of the HFPO dimer acid ammonium salt (10 mg/kg) (DuPont-17751-1579 RV1, 2009). Plasma samples were collected at intervals over the first 24 hours post-dosing and once per day for the subsequent 7 days in the

rats and 21 days in the monkeys. In the rats, the plasma concentrations were consistently higher for the males than for females by approximately one to two orders of magnitude, consistent with the indication that female rats have more rapid elimination. The clearance times for male rats were 22 hours and 17 hours in the 10- and 50-mg/kg dose groups, respectively. The clearance times for female rats were 3 hours and 4 hours in the 10- and 50-mg/kg dose groups, respectively. Notably, the calculated clearance time in the male rats was longer for the 10-mg/kg dose group (22 hours) than the clearance time calculated in Dupont-24281 (2008) for male rats in the 10-mg/kg dose group (12 hours). Female rats had similar clearance times. Additionally, the standard deviations on each serum mean were broad for the rats in the 50-mg/kg dose group, indicative of wide differences between the three males and three females evaluated at that dose. In the monkeys, the standard deviations on each serum mean were broad, especially for the female monkeys over the first 2 hours, which is indicative of wide differences between the three males and three females evaluated. The plasma levels were generally higher in females over the first 2 hours, were nearly identical at 4 hours, and were slightly higher in the males from 4 to 336 hours. The levels of the anion from HFPO dimer acid ammonium salt were very low at 168 hours in male (0.004 µg/mL (4 ng/mL)) and female (0.001 µg/mL (1 ng/mL)) monkeys. For 408 hours and beyond, concentrations were below the LOQ of 0.001 µg/mL (1 ng/mL). The clearance times calculated for the male and female monkeys were 11 hours and 10 hours, respectively.

Half-lives. In Gannon et al. (2016), the goodness of fit was calculated for the plasma concentrations after oral and intravenous dosing (DuPont studies outlined above) using one- and two-compartment models, and the two-compartment model had a better fit. Pharmacokinetic parameters identified by Gannon et al. (2016) are presented for the intravenous studies in Table 7 and for the oral studies in Table 8. The alpha phase $T_{1/2}$ represents the plasma concentration in the early post-injection period and is considered to reflect the plasma distribution phase (Klaassen, 1996). The beta phase $T_{1/2}$ represents the period during which the chemical in the plasma has established an equilibrium with the levels in the body tissues and represents the elimination phase. The two-compartment model is a refinement of the prior pharmacokinetic analysis in which the clearance time was calculated. The two-compartment model better fits the data and separates distribution and elimination phases; therefore, generally for comparisons across the datasets, the $T_{1/2}$s are preferred.

Table 7. $T_{1/2}$ Estimates from Intravenous Injection in Sprague Dawley Rats and Cynomolgus Monkeys

$T_{1/2}$	Intravenous Exposures (in hours)			
	Male rat	Male monkey	Female rat	Female monkey
Alpha (Plasma Distribution) Phase	3.6	2.3	0.4	1.9
Beta (Plasma Elimination) Phase	89.1	64.1	22.6	79.6

Source: Gannon et al., 2016.

In the intravenous injection studies, the $T_{1/2}$ of the alpha phase of distribution is similar (about 2 hours) for male and female monkeys, but the $T_{1/2}$ of the beta (elimination) phase is longer in female monkeys. The $T_{1/2}$ of the beta (elimination) phase in female monkeys is longer than it is in the female rats, which could be a result of female monkeys having higher tissue stores than

female rats or clearance of HFPO dimer acid anion from their tissues might be slower. There are no studies, however, to distinguish these explanations such as a study of tissue concentrations over time. In rats, both the alpha and beta phases are shorter in females than in males; the beta phase $T_{1/2}$ is about four times longer in males, suggesting higher levels in tissues of males or slower clearance of HFPO dimer acid anion from their tissues (Gannon et al., 2016).

Gannon et al. (2016) also used the data from the single oral dose studies in rats and mice to derive estimates of alpha and beta phase $T_{1/2}$s to represent the distribution and elimination phases. The oral exposure data are not ideal for this calculation because the chemical is not directly injected into the blood. However, because intestinal uptake of HFPO dimer acid anion from the ammonium salt is believed to be rapid and there appears to be no metabolism, the estimates are reasonable for a two-compartment model.

In rats, following oral exposure, the alpha (distribution) $T_{1/2}$ phase is shorter in females than in males and the beta (elimination) phase $T_{1/2}$ is comparable for both sexes (Table 8). In mice, the $T_{1/2}$ estimates for the alpha phase are similar for both sexes and the $T_{1/2}$ estimates for the beta phase are shorter for females than for males (Table 8). The $T_{1/2}$ estimated for the beta phase in female rats is shorter from the intravenous data (22.6 hours) than from the oral gavage data (67.4 hours), while the other estimates of $T_{1/2}$ from the intravenous and oral gavage data for males and females are similar.

Table 8. $T_{1/2}$ Estimates from Single Oral Dose in Sprague Dawley Rats and Crl/CD1(ICR) Mice

$T_{1/2}$	Oral Exposures (in hours)			
	Male rat	Female rat	Male mouse	Female mouse
Alpha (Plasma Distribution) Phase	2.8	0.2	5.8	4.6
Beta (Plasma Elimination) Phase	72.2	67.4	36.9	24.2

Source: Gannon et al., 2016.

The time it takes to achieve a balance between gastrointestinal uptake and excretion (i.e., steady state) following daily gavage exposures to the HFPO dimer acid anion is dependent on the $T_{1/2}$s of the alpha and beta phases. When the data are well described by a multicompartmental model, the steady state is a function of the multiple $T_{1/2}$s for the intercompartmental distribution (alpha phase) and elimination (beta phase); however, at later times, the elimination $T_{1/2}$ is expected to dominate the time to steady state and to be reached approximately within four $T_{1/2}$s, or 6.15 days, for male mice (Ito, 2011). This was calculated by multiplying the oral gavage beta phase $T_{1/2}$ (36.9 hours) for male mice by 4 and dividing that product by 24 hours. The data from Rushing et al. (2017) for male mice clearly demonstrate a lack of serum steady state for male mice after receiving doses of 1, 10, and 100 mg/kg/day for 28 days because the serum concentrations do not remain constant after the expected 6 days. In fact, HFPO dimer acid concentrations continue to change between 5 and 14 days and 14 and 28 days. These continual changes in plasma concentration after 6 days indicate dynamics over multiple days that are not represented by typical multicompartment models and, therefore, are not appropriate for modeling the complexity of the pharmacokinetics of HFPO dimer acid and its ammonium salt.

Repeated-dose study. In a repeated-dose study with Crl:CD1(ICR) mice dosed with 0, 0.1, 0.5, or 5 mg/kg/day for at least 90 days, plasma measurements were determined 2 hours post-dosing on days 0, 28, and 95 (Dupont 18405-1307, 2010). Plasma concentrations increased less than twofold between the 2 hour and the 28-day measurements for both the males and females in all dose groups (Table 9). Unfortunately, the study provides no measurements between the 2-hour and 28-day time points to allow for a determination regarding steady state. As mentioned above, however, the Rushing et al. (2017) study in mice provides measurements in serum at 1, 5, 14, and 28 days following daily gavage dosing of C57BL/6 mice that clearly establish the lack of steady-state conditions, which supports development of a more complex model to represent these data.

Table 9. Mean Plasma Concentrations with Standard Deviations of Dosing Crl:CD1(ICR) Mice with HFPO Dimer Acid Ammonium Salt for at Least 90 Days

Dose mg/kg/day	Day 0			Day 28			Day 95		
	µg/mL	SD	COV	µg/mL	SD	COV	µg/mL	SD	COV
Males

Source: Dupont 18405-1307, 2010.
Notes: COV = coefficient of variation (SD / mean); µg/mL = micrograms per milliliter; N/A = not applicable; ND = not detected; SD = standard deviation.
[a] Limit of detection = 0.005 µg/mL

Plasma concentrations remained relatively constant between 28 days and 95 days for male and female mice administered the 0.1-mg/kg/day dose in the Dupont 18405-1307 (2010) study (Table 9). At the 0.5-mg/kg/day dose, plasma concentrations were relatively constant from day 28 to 95 days for the males, but the females' plasma concentrations increased from 4.198 to 5.438 µg/mL (4,198 ng/mL to 5,438 ng/mL) (a 30% increase). This indicates that the HFPO dimer acid anion does not appear to accumulate at 0.1 mg/kg/day; however, it might have accumulation potential at 0.5 mg/kg/day. Interestingly, this increase in female plasma concentrations from 28 days to 95 days is equal to the coefficient of variation (COV) in the 28-day measurement, thus the difference between days 28 and 95 could be the result of inter-animal

differences in response to the same dose. Also interesting is that, at the 5-mg/kg/day dose, female plasma levels returned to approximately the same levels at 28 and 95 days (46.58 and 45.58 µg/mL (46,580 and 45,580 ng/mL), respectively) (Table 9). In the males, the plasma levels at 28 days increased from 52.24 to 67.98 µg/mL (52,240 ng/mL to 67,980 ng/mL) at 95 days (a 30% increase), again equaling the COV in the 28-day measurement. Thus, the difference between days 28 and 95 could be the result of variability in these measurements as a result of inter-animal differences and might not necessarily reflect accumulation of HFPO dimer acid anion.

3.0 Problem Formulation

3.1 Conceptual Model

The conceptual model provides useful, publicly available information to characterize and communicate the potential health hazards related to oral exposure to HFPO dimer acid and its ammonium salt. Figure 2 depicts in a conceptual diagram the sources of these GenX chemicals, the routes of exposure to biological receptors of concern (e.g., human activities related to ingested tap water such as drinking, food preparation, and consumption), the potential assessment endpoints (e.g., effects such as liver toxicity), and populations at risk of exposure to HFPO dimer acid and its ammonium salt. As outlined in the legend for Figure 2, the green boxes indicate where there are limited data available for these GenX chemicals. This includes quantitative data for oral exposure to HFPO dimer acid and its ammonium salt, as well as the limited data available for some of the potential sources of exposure to these chemicals. The quantitative data for oral exposure to HFPO dimer acid and its ammonium salt includes animal toxicity and toxicokinetic studies; no epidemiological studies on health effects in humans are available. The white boxes indicate that no data are publicly available to allow for determining if GenX chemicals are found in certain sources and that no human toxicity data exist.

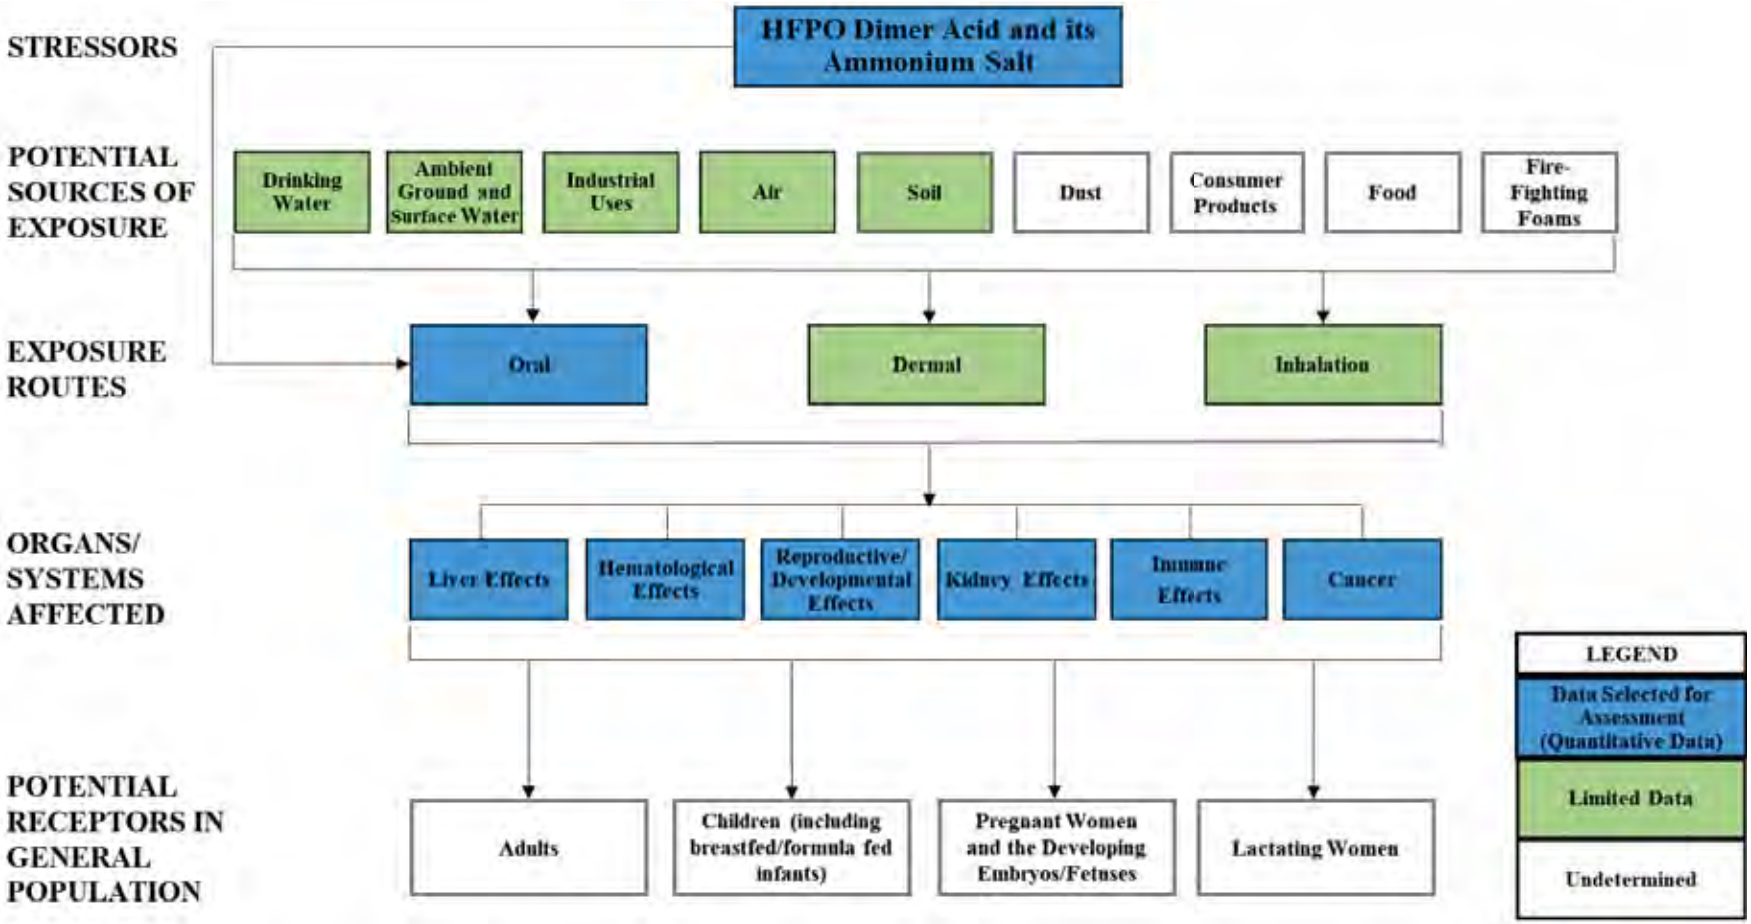

Figure 2. Conceptual Model for HFPO Dimer Acid and Its Ammonium Salt

3.2 Overall Scientific Objectives

This document provides the health effects basis for the development of oral RfDs for subchronic and chronic durations for GenX chemicals, including the science-based decisions providing the basis for estimating the POD. This section discusses the factors EPA considers in the process of developing a POD (depicted in Figure 2).

Stressors: This assessment addresses only HFPO dimer acid and its ammonium salt. It does not address any other chemicals used in the GenX processing technology or any other precursors, metabolites, or degradate of HFPO dimer acid and its ammonium salt. Uses of GenX chemicals include as intermediates and as polymerization aids in the production of fluoropolymers. These chemicals are two of several replacements for PFOA and its ammonium salt and could have many applications in consumer products (e.g., stain- and water-repellant textiles) and industrial processes (e.g., pharmaceutical and semiconductor manufacturing). Information on specific products containing GenX chemicals is not available, however, GenX chemicals may be used in the manufacture of the same or similar commercial fluoropolymer end products that formerly used PFOA. GenX chemicals may also be generated as a byproduct of fluoromonomer production. Publicly available data, although limited, indicate that sources of exposure to GenX chemicals include both ground and surface waters used for drinking. Many other potentially important sources of exposure to GenX chemicals exist given their use as a replacement for PFOA, including foods; indoor dust in a home or work environment; indoor and outdoor air; soil; biosolids; and consumer products within the home, workplace, children's schools, and daycare centers. Very little quantitative information on these sources of exposure, however, is available.

Routes of Exposure: Nonoccupational exposure to GenX chemicals in water can occur through oral exposure (i.e., drinking water, cooking with water, and incidental ingestion from showering) and is expected to occur by dermal exposure (i.e., contact of exposed parts of the body with water containing GenX chemicals during bathing or showering, and dishwashing) and inhalation exposure (e.g., volatilization of the GenX chemicals from the water during bathing or showering, or while using a humidifier or vaporizer). There is limited information identifying health effects from inhalation or dermal exposures to GenX chemicals in animals. Specifically, two acute dermal toxicity tests (one in rats and one in rabbits), one dermal irritation study in rabbits, and one acute inhalation toxicity test in rats (see section 4.1) have been conducted. Repeated-dose toxicity data are available for oral exposure, but not for inhalation and dermal exposures. Since the only quantitative data available for HFPO dimer acid and its ammonium salt are for oral exposure, this assessment applies only to that route.

Receptors: The receptors are those in the general population who could be exposed to GenX chemicals in tap water through ingestion (i.e., adults, the elderly, women of childbearing age, pregnant women, fetuses, infants, and children). In the conceptual model in Figure 2, the box for adults includes sensitive life stages (e.g., women of childbearing age and the elderly). In this toxicity assessment, the first two steps (Step 1. Hazard Identification and Step 2. Dose Response) of the four-step risk assessment process developed by the National Academy of Sciences are addressed. This toxicity assessment summarizes potential health effects associated with exposure to GenX chemicals and identifies levels at which those health effects might occur. Potential exposure to receptors is not determined. Toxicity values from this assessment can be combined with specific exposure information (Step 3. Exposure Assessment) to help characterize the

potential public health risks associated with exposure to these chemicals (Step 4. Risk Characterization) to the receptors outlined here.

Endpoints: No human epidemiological studies for GenX chemicals are available. Oral exposure studies of acute, subchronic, and chronic duration are available in rodent species, including rats and mice. The recommended definitions of study duration were applied as outlined in *A Review of the Reference Dose and Reference Concentration Processes* (EPA, 2002). Using this approach, the employed study durations are as follows:

- **Acute:** Exposure by the oral, dermal, or inhalation route for 24 hours or less.
- **Short-term:** Repeated exposure by the oral, dermal, or inhalation route for more than 24 hours, up to 30 days.
- **Subchronic**: Repeated exposure by the oral, dermal, or inhalation route for more than 30 days, up to approximately 10% of the life span in humans (more than 30 days up to approximately 90 days in typically used laboratory animal species).
- **Chronic:** Repeated exposure by the oral, dermal, or inhalation route for more than approximately 10% of the life span in humans (more than approximately 90 days to 2 years in typically used laboratory animal species).

Adverse effects observed following exposure to HFPO dimer acid and/or its ammonium salt include liver toxicity (e.g., hypertrophy, single-cell necrosis, focal necrosis and apoptosis), hematological effects (e.g., decreased red blood cell (RBC) count, hemoglobin, and hematocrit), kidney toxicity (e.g., increased kidney weight, necrosis, and hyperplasia), reproductive and developmental effects (e.g., placental lesions, changes in maternal gestational weight gain (GWG), and BW changes), immune effects (e.g., T cell-dependent antibody response (TDAR) suppression and lymphocyte increases), and *Suggestive Evidence of Carcinogenic Potential* of oral exposure to GenX chemicals in humans (e.g., liver and pancreatic acinar cell tumors).

In most of the available animal studies, hepatocellular hypertrophy and necrosis of the liver appear to be the most sensitive effects observed. The increases in relative liver weight, hepatocellular hypertrophy, and peroxisome activity (e.g., peroxisomal beta-oxidation induction) can be associated with activation of cellular peroxisome proliferator-activated receptor alpha (PPARα) receptors, making it difficult to determine if this change is a reflection of PPARα activation or an indication of GenX chemical toxicity. This is important because the PPARα response could be more relevant to rodents than humans. EPA evaluated liver effects resulting from exposure to GenX chemicals in the context of the Hall criteria (Hall et al., 2012), through which changes in liver weight or hepatocellular hypertrophy can be considered adverse when they are accompanied by histologic or clinical pathology indicative of liver toxicity such as necrosis, inflammation, and/or fibrosis. In this assessment, EPA listed hepatocellular hypertrophy or changes in serum liver enzymes as adverse only when they were accompanied by histologic pathology indicative of liver toxicity such as necrosis, inflammation, and/or fibrosis. The observance of liver necrosis indicates that cytotoxicity also could be a mode of action (MOA) for liver damage.

No physiologically based pharmacokinetic (PBPK) models are available that address the relationship between external exposure and internal dose for GenX chemicals; however, allometric scaling methodology is available to calculate a toxicologically equivalent dose of orally administered agents from adult laboratory animals to adult humans (EPA, 2011b). The use

of allometric scaling addresses some aspects of the cross-species extrapolation of toxicokinetic and toxicodynamic processes.

The toxicity values for this assessment include a chronic oral RfD (chronic RfD) and a subchronic oral RfD (subchronic RfD) for HFPO dimer acid and its ammonium salt. An RfD is an estimate of the concentration or dose of a substance (with uncertainty spanning perhaps an order of magnitude) to which a human population (including sensitive subgroups) can be exposed that is likely to be without an appreciable risk of deleterious effects during a lifetime. In addition to chronic RfDs, other durations of exposure can be considered, including subchronic exposures. RfDs are derived for noncarcinogenic toxicological endpoints of concern.

3.3 Methods

3.3.1 Literature Search Strategy and Results

EPA assembled and evaluated available information on toxicokinetics; acute, short-term, subchronic, and chronic toxicity; developmental and reproductive toxicity; neurotoxicity; immunotoxicity; genotoxicity; and cancer in animals. Most of the available data for HFPO dimer acid and its ammonium salt were submitted with PMNs to EPA by DuPont/Chemours, the manufacturer of GenX chemicals, under TSCA, as required pursuant to a consent order (EPA, 2009) or as required under TSCA reporting requirements (15 U.S.C. § 2607.8(e)). Submitted test data on HFPO dimer acid and its ammonium salt were available for numerous endpoints such as acute toxicity, metabolism and toxicokinetics, genotoxicity, and systemic toxicity in mice and rats with dosing durations of up to 2 years. Most of these submitted studies were conducted according to OECD TGs and/or EPA health effects TGs for pesticides and toxic substances, which:

> …are generally intended to meet testing requirements for human health impacts of chemical substances under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and TSCA (EPA, 2021b).

All available studies were considered for inclusion. Most of the studies considered for dose-response analysis in this assessment adhered to the principles of GLP, and full study reports were submitted for Agency review. As noted by OECD,[3] the OECD TGs are accepted internationally as standard methods for safety testing and:

> …are covered by the Mutual Acceptance of Data, implying that data generated in the testing of chemicals in an OECD member country, or a partner country having adhered to the Decision, in accordance with OECD Test Guidelines and Principles of GLP, be accepted in other OECD countries and partner countries having adhered to the Decision, for the purposes of assessment and other uses relating to the protection of human health and the environment.

To identify public literature available for HFPO dimer acid and its ammonium salt, literature searches were conducted of four databases (PubMed, Toxline, Web of Science (WOS), and Toxic Substances Control Act Test Submissions (TSCATS)) using CASRN, synonyms, and additional relevant search strings (see Table A-2 in appendix A for a full list). Because the results of this core search were so limited, additional databases were searched for

[3] http://www.oecd.org/chemicalsafety/testing/oecdguidelinesforthetestingofchemicals.htm.

physicochemical property information, health effects, toxicokinetics, and mechanistic information. A list of the additional databases searched is provided in Table A-3 and Table A-4 in appendix A. The initial searches of these databases specific to HFPO dimer acid were conducted in July 2017 and specific to the HFPO dimer acid ammonium salt in January and February 2018. They returned 27 studies for HFPO dimer acid and its ammonium salt, after accounting for duplicates. Additional updates to the literature search were completed in February 2019, October 2019, and March 3, 2020 using the same search strategy as described in appendix A. These searches returned an additional 48 studies.

The submitted studies from DuPont/Chemours and the literature identified by the search of publicly available sources are available through EPA's Health & Environmental Research Online website at https://hero.epa.gov/hero/index.cfm/project/page/project_id/2627.

3.3.2 Study Screening and Evaluation

In accordance with EPA's Office of Research and Development (ORD) systematic review practices, relevancy screenings were conducted on all the studies submitted from DuPont/Chemours and the publicly available, peer-reviewed literature resulting from the literature searches mentioned above (EPA, 2020). These studies were subjected to title and abstract screening to determine relevancy according to the PECO criteria statement/inclusion and exclusion criteria outlined in Table A-6 in appendix A. The title and abstract of each study were independently screened by two screeners using Distiller SR[4]. The studies that met the PECO criteria were tagged as having relevant human data, animal data in a mammalian model, or a PBPK model. A study was included as relevant if it was unclear from the title and abstract whether it met the inclusion or exclusion criteria. Studies that did not meet the inclusion criteria but provide supporting information were categorized as supplemental, relative to the type of supporting information they provided. These supplemental categories are outlined in Table A-7 in appendix A. When two screeners did not agree if a study should be included, excluded, or tagged as supplemental, a third reviewer made the final decision. The title and abstract screening resulted in 12 studies tagged as relevant (i.e., containing dose-response information). The relevancy of these studies was confirmed by a full-text review.

The twelve studies providing dose-response information were then evaluated for study quality using an approach consistent with the draft ORD Handbook for developing IRIS assessments (DuPont-24447, 2008; DuPont-24459, 2008; DuPont-17751-1026, 2009; DuPont-18405-1307, 2010; DuPont-18405-1037, 2010; DuPont-18405-841, 2010; DuPont-18405-1238, 2013; Rushing et al., 2017, Conley et al., 2019, 2021; Thompson et al., 2019; Blake et al., 2020; EPA, 2020). Study quality was determined by two independent reviewers who assessed risk of bias and sensitivity for the following domains: reporting quality, risk of bias (selection or performance bias, confounding/variable control, and reporting or attrition bias), and study sensitivity (exposure methods sensitivity, and outcome measures and results display) using EPA's version of HAWC[5]. A third reviewer made the final decision on the quality ratings based on the primary ratings. The results of the study quality evaluation are provided in Figure 3 and an interactive version of the heatmap can be found here:

[4] Distiller SR is a fee-based, multi-user, web-based platform that manages, tracks, and streamlines the screening of literature reviews.
[5] HAWC is a free and open-source web-based software application that enables multiple users to synthesize multiple data sources into an overall human health assessment of chemicals.

https://hawcprd.epa.gov/summary/visual/assessment/100500273/GenX-SQE-Heatmap/. All twelve studies were rated as medium or high-quality studies and were summarized in section 4 and considered for dose response in section 7.

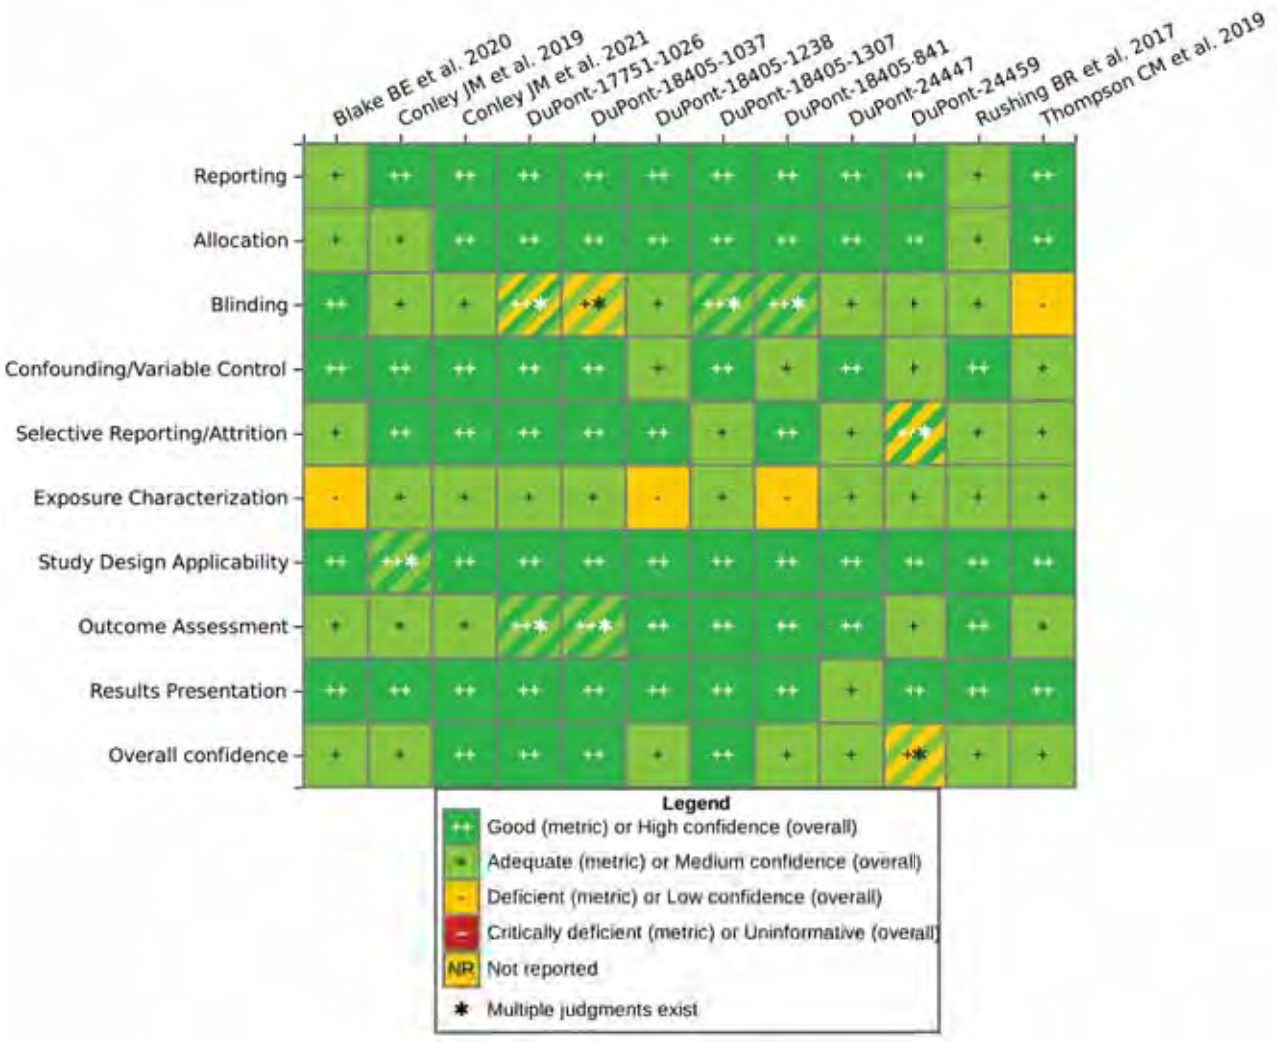

Figure 3. Evaluation Results for Animal Studies Assessing Effects of GenX Chemicals Exposure (Click to see interactive data graphic for rating rationales)

Additionally, all studies tagged as supplemental that provided toxicokinetic or mechanistic information were summarized and incorporated into the assessment in sections 2.3 and 4.6, respectively. Study summaries were also provided for all acute toxicity studies in section 4.1. Finally, two mechanistic studies were included in this assessment that were published after the final literature search (Gaballah et al., 2020; Cannon et al., 2020).

3.4 Approach to Deriving Reference Values

Development of the hazard identification and dose-response assessment for HFPO dimer acid and its ammonium salt has followed the general guidelines for risk assessment published by the National Research Council (1983) and EPA's *Framework for Human Health Risk Assessment to Inform Decision Making* (EPA, 2014a). Additional EPA guidelines and other Agency reports used in developing this assessment include the following:

- *Guidelines for Developmental Toxicity Risk Assessment* (EPA, 1991)
- *Guidelines for Reproductive Toxicity Risk Assessment* (EPA, 1996)
- *Guidelines for Neurotoxicity Risk Assessment* (EPA, 1998)
- *A Review of the Reference Dose and Reference Concentration Processes* (EPA, 2002)
- *Guidelines for Carcinogen Risk Assessment* (EPA, 2005a)
- *Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens* (EPA, 2005b)
- *A Framework for Assessing Health Risks of Environmental Exposures to Children* (EPA, 2006a)
- *Exposure Factors Handbook* (EPA, 2011a)
- *Recommended Use of Body Weight$^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose* (EPA, 2011b)
- *Benchmark Dose Technical Guidance Document* (EPA, 2012)
- *Child-Specific Exposure Scenarios Examples* (EPA, 2014b)
- *Guidance for Applying Quantitative Data to Develop Data-Derived Extrapolation Factors for Interspecies and Intraspecies Extrapolation* (EPA, 2014c)

EPA's *A Review of the Reference Dose and Reference Concentration Processes* describes a multistep approach to dose-response assessment, including analysis in the range of observation followed by extrapolation to lower levels (EPA, 2002). EPA conducted a dose-response assessment to define a POD and extrapolated from the POD to an RfD. For HFPO dimer acid and its ammonium salt, EPA used benchmark dose (BMD) modeling to refine the critical effect POD in deriving the RfD.

The steps for deriving an RfD are summarized below.

Step 1: Evaluate the data to identify and characterize endpoints related to exposure to GenX chemicals. This step involves determining the relevant studies and adverse effects to be considered for BMD modeling. Once the appropriate data are collected, evaluated for study quality, and characterized for adverse outcomes, the risk assessor selects endpoints judged to be relevant and the most sensitive (typically defined by the NOAEL value). Considerations that might influence selection of endpoints include data with dose response, percent change from controls, adversity of effect, and consistency across studies.

Step 2: Conduct BMD Modeling. Using EPA's *Benchmark Dose Technical Guidance Document* (EPA, 2012), a benchmark response (BMR) is selected and BMD modeling is applied to the endpoints selected as most relevant. The BMR is a predetermined change in the response rate of an adverse effect. It serves as the basis for obtaining the benchmark dose lower limit (BMDL), which is the 95% lower bound of the BMD. A family of BMD models are fit to the

dose-response data that describe the dataset of the identified adverse effect. From the family of models, either a best fitting model with the corresponding BMD and BMDL is derived or, if no adequate models are found, the NOAEL or lowest-observed-adverse-effect level (LOAEL) identified in step 1 is used as the POD.

Step 3: Convert the POD to a human equivalent dose (HED) or point of departure human equivalent dose (POD_{HED}). The POD (either a BMDL, NOAEL, or LOAEL) is then converted to an HED following the method described in EPA's *Recommended Use of Body Weight$^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose* (EPA, 2011b).

Step 4: Provide rationale for selecting UFs. UFs are selected in accordance with EPA guidelines considering variations in sensitivity among humans, differences between animals and humans, the duration of exposure in the critical study compared to the lifetime of the species studied, and the completeness of the toxicology database.

Step 5: Calculate the chronic and subchronic RfDs. The RfDs are calculated by dividing POD_{HED} by the selected UF.

$$RfD = \frac{POD_{HED}}{\text{Total UF}}$$

where:

- POD_{HED} = calculated from the BMDL or NOAEL/LOAEL using a $BW^{3/4}$ allometric scaling approach consistent with EPA guidance (EPA, 2011b).
- UF = Total UF established in accordance with EPA guidelines considering variations in sensitivity among humans, differences between animals and humans, duration of exposure in the critical study compared to the lifetime of the species studied, and completeness of the toxicology database.

3.5 Measures of Effect

The available dataset regarding the toxicity of these GenX chemicals includes *in vivo* and *in vitro* studies. The *in vivo* studies were considered in the dose-response assessment for HFPO dimer acid and its ammonium salt. The available data indicate that the liver, kidney, RBCs, immunological responses, and reproductive and developmental effects (BW and fetal development) are adversely impacted by exposure to GenX chemicals. Tumors were also observed following oral exposure to GenX chemicals (DuPont-18405-1238, 2013). In this analysis, all reported changes in relative organ weights were presented as relative to BW (data relative to brain weight were not included). The endpoints presented in this assessment represent potentially adverse effects that were statistically significantly different ($p < 0.05$ or 0.01) from control unless otherwise noted. Additionally, statistically significant changes from the control are presented as the percent change from control, unless otherwise noted.

The animal studies demonstrated dose-related effects on the liver in rodent species (rats and mice) following exposure to HFPO dimer acid and/or its ammonium salt for durations of 28 days to 104 weeks. The studies and endpoints reviewed as possible critical studies and effects for determination of the POD were evaluated for experimental design, data quality, and dose response identified through the range of experimental NOAELs/LOAELs. A route-to-route

extrapolation of oral toxicity data from which to derive an inhalation reference concentration was not conducted because of data limitations. For example, no toxicokinetic data are available characterizing the uptake of GenX chemicals through the lung for systemic distribution, and only one acute inhalation toxicity study is available (DuPont-17751-723, 2009). This study identifies the portal of entry effects, albeit at a high dose.

4.0 Study Summaries

4.1 Acute Toxicity Studies

There are over 10 studies available detailing the acute toxicity and irritation effects of HFPO dimer acid and its ammonium salt. This section summarizes the available acute oral, dermal, and inhalation toxicity studies as well as dermal and eye irritation studies for HFPO dimer acid and its ammonium salt. Appendix B provides additional details on each of the studies.

Oral Toxicity. Several studies have evaluated oral toxicity in rats and mice from single doses of the HFPO dimer acid ammonium salt at doses ranging from 1.5 mg/kg to 17,000 mg/kg (DuPont-22932, 2007; DuPont-24126, 2007; DuPont-25438 RV1, 2008; DuPont-2-63, 1963; DuPont-770-95, 1996). Also, male and female rats were evaluated with doses of 175–5,000 mg/kg HFPO dimer acid (DuPont-25875, 2008). The rats and mice in these studies received a single dose of the compound and were observed for clinical effects of toxicity for 14 days.

Four studies were conducted according to OECD TG 425 (OPPTS 870.1100) (OECD, 2008c) using the Up-and-Down Procedure (DuPont-22932, 2007; DuPont-25438 RV1, 2008; DuPont-25875, 2008; DuPont-24126, 2007). Two studies that estimated approximate lethal doses (ALDs) did not have identified TGs (DuPont-2-63, 1963; DuPont-770-95, 1996). For HFPO dimer acid, the oral median lethal doses (LD_{50}s) were 1,730 mg/kg and 1,750 mg/kg in male rats and female rats, respectively (DuPont-25875, 2008). For the HFPO dimer acid ammonium salt, the LD_{50} was 3,129 mg/kg for female rats (DuPont-22932, 2007); 1,030 mg/kg for female mice (DuPont-24126, 2007); and 1,750 mg/kg for male rats (DuPont-25438 RV1, 2008). The estimated ALD for male rats for the ammonium salt ranged from 5,000 mg/kg to 7,500 mg/kg (DuPont-2-63, 1963; DuPont-770-95, 1996).

The more common clinical signs observed across studies included wet fur, fur/skin stain or discoloration, altered posture, and lethargy; changes in BW were also seen (DuPont-770-95, 1996; DuPont-22932, 2007; DuPont-24126, 2007; Dupont-25438 RV1, 2008; DuPont-25875, 2008). Effects in mice were observed after exposure to HFPO dimer acid ammonium salt (86% purity) doses at 550 mg/kg and higher. Effects in rats were observed after exposure to either HFPO dimer acid (98% purity) or its ammonium salt (82.6% to 99% purity) at doses of 175 mg/kg and higher (DuPont-22932, 2007; DuPont-25875, 2008).

Gross evidence of organ or tissue damage included discoloration of lungs, stomach, skin, lymph nodes, liver, and/or esophagus (DuPont-22932, 2007; DuPont-25438 RV1, 2008; DuPont-25875, 2008). Enlarged livers and enlarged hepatocytes were observed in young male rats following single doses of 2,250, 3,400, or 5,000 mg/kg for HFPO dimer acid ammonium salt (DuPont-2-63, 1963).

Dermal Toxicity. Two studies reported acute dermal toxicity of HFPO dimer acid ammonium salt in rats or rabbits following acute dermal exposure (DuPont-24113, 2007; DuPont-839-95, 1996). In an OECD TG 402 (OPPTS 870.1200) (OECD, 2017) study, 5,000 mg/kg HFPO dimer acid ammonium salt (86% purity) was applied to shaved, intact skin of male and female rats under a semi-occlusive dressing for 24 hours. The dermal LD_{50} was more than 5,000 mg/kg (both sexes). Erythema was observed only in females, whereas hyperkeratosis and ulceration were observed in rats of both sexes. All dermal effects cleared by 13 days posttreatment (DuPont-24113, 2007). In another study (in which no guideline is cited), HFPO dimer acid ammonium salt (99% purity) was applied to shaved, intact skin of New Zealand white rabbits for 24 hours. The ALD was determined to be more than 5,000 mg/kg. In this study, erythema persisted for 13 days post application and was accompanied by scaling and sloughing of skin. One of the rabbits also exhibited necrosis for 2–6 days post application (DuPont-839-95, 1996).

Inhalation Toxicity. One study (conducted using the GLP Compliance Statement in compliance with Title 40 of the Code of Federal Regulations (CFR) part 792) evaluated acute inhalation toxicity of HFPO dimer acid ammonium salt (84% purity) in male and female rats following a single 4-hour nose-only exposure to aerosol concentrations of 0, 13, 100, and 5,200 mg/m^3. The median lethal concentration (LC_{50}) was more than 5,200 mg/m^3. Red discharge from the nose, eyes, and mouth was observed in rats at doses of 100 and 5,200 mg/m^3 for up to 2 days postexposure. No gross lesions were observed. Microscopic evaluation of respiratory tract tissue (lung, larynx/pharynx, trachea, and nose) from rats exposed to concentrations of 0, 13, and 100 mg/m^3 detected no substance-related effects (DuPont-17751-723, 2009).

Dermal Irritation. In an OECD TG 404 (OPPTS 870.2500) (OECD, 2002) dermal irritation study, very slight-to-well-defined erythema was observed in three male New Zealand white rabbits following a single application of a 0.5-mL aliquot of HFPO dimer acid ammonium salt (86% purity) in an area of shaved skin for a period of 4 hours on the day of application. Erythema cleared by 24 hours postexposure (DuPont-24030, 2007).

Eye Irritation. New Zealand white rabbits were administered a single application of a 0.1 mL aliquot of HFPO dimer acid ammonium salt (86% purity) to the lower conjunctival sac in an eye irritation study conducted according to OECD TG 405 (OPPTS 870.2400) (OECD, 2020a). At 28 hours after instillation of the compound, necrosis, corneal opacity, iritis, conjunctival chemosis (swelling), discharge, and corneal injury were observed (DuPont-24114, 2007).

4.2 Short-Term Toxicity Studies

Seven-Day Toxicity Studies. Hepatic effects were observed in 6-week-old mice and rats of both sexes in four 7-day studies (in which no TG is cited) evaluating repeated-dose oral toxicity of HFPO dimer acid and its ammonium salt (DuPont-24010, 2008; DuPont-25281, 2008; DuPont-24116, 2008; DuPont-24009, 2008). Water was used as the vehicle control in all studies. Two 7-day studies evaluated the toxicity of HFPO dimer acid ammonium salt (86.6% purity) and HFPO dimer acid (99% purity) at doses of 30 mg/kg/day in male mice and rats, respectively. In both studies, a twofold increase in liver weight relative to control, cell necrosis of hepatocytes, and hepatocellular hypertrophy were observed in all exposed animals (DuPont-24010, 2008; DuPont-25281, 2008). A third 7-day study evaluating toxicity of HFPO dimer acid (99% purity) also detected increased liver weight in male rats (at 30, 100, and 300 mg/kg/day) and in female rats (at 300 mg/kg/day). Hepatocellular hypertrophy was present in both sexes at all doses (DuPont-

24116, 2008). Hypertrophy and increased liver weight were observed in another similar 7-day gavage study evaluating effects of HFPO dimer acid ammonium salt (86.6% purity). Males appeared to be more sensitive to hepatic effects because increases in liver weight were observed at 30, 300, and 1,000 mg/kg/day, whereas increased liver weight was observed in females only at 1,000 mg/kg/day. These effects were accompanied by increases in β-oxidation and increases in cytochrome P450 enzyme activity, biomarkers for activation of PPARα nuclear receptors. Mild-to-minimal hepatocellular hypertrophy was observed in both sexes at 1,000 mg/kg/day (DuPont-24009, 2008).

Twenty-Eight-Day Toxicity Studies. Two 28-day studies evaluating systemic toxicity in rats and mice are available for HFPO dimer acid ammonium salt.

DuPont-24447 (2008)
In a study with 7-week-old Crl:CD(SD) rats (10/sex/group) conducted according to OECD TG 407 (OECD, 2008a), HFPO dimer acid ammonium salt (purity 88%) was administered on 28 consecutive days via gavage (vehicle was deionized water) (OECD, 2008a; DuPont-24447, 2008). Male rats received doses of 0, 0.3, 3, or 30 mg/kg/day while females received 0, 3, 30, or 300 mg/kg/day. In this study, there were no mortalities and clinical signs were confined to high-dose females (e.g., urogenital staining).

Hematological evaluation revealed statistically significantly decreased RBC count, hemoglobin, and hematocrit at greater than or equal to 3 mg/kg/day in males. The maximum decreases compared to control at 4 weeks were observed at the highest dose (30 mg/kg/day) and were 6%, 7%, and 8% for RBC count, hemoglobin, and hematocrit, respectively. Increases in absolute reticulocyte counts were also observed in males at all dose levels, but this increase was only statistically significant from control at the highest dose (27%) at 4 weeks. No statistically significant hematological effects were observed in the females (DuPont-24447, 2008).

Alterations in serum clinical chemistry parameters were seen in both sexes, but most of the significant effects were observed in the male rats. Decreases in total globulin and increases in the A/G ratio were observed in males and females. In males, total serum albumin increased (15% at 30 mg/kg/day) while total globulin decreased 13% and 22% compared to control at 3 mg/kg/day and 30 mg/kg/day, respectively. This resulted in an increase in the A/G ratio to 16% and 41% in the 3 mg/kg/day and 30 mg/kg/day males, respectively, most likely the result of underproduction of globulin. Females exhibited a 9% decrease in total globulin and a 20% increase in the A/G ratio compared to control at 300 mg/kg/day. Males also showed statistically significant decreases in serum cholesterol at all doses, with the largest decrease compared to control (28%) in the 30-mg/kg/day group. Triglyceride levels were decreased at all doses but were significantly decreased (22%) only at 3 mg/kg/day. Males also exhibited increases in blood urea nitrogen (BUN) (24%) and glucose (15%) at 30 mg/kg/day when compared to controls (DuPont-24447, 2008).

In males, relative kidney weight was significantly increased (15% compared to control) only at the highest dose tested. Minimal mineralization of the kidneys was also observed in 1/10 male rats in the high-dose group. There were no statistically significant changes in kidney weight in the females; however, there was minimal basophilic staining of cells in the tubules for 3/10 female mice in the 300-mg/kg/day group, while none were observed in the control group. Dose response could not be determined for basophilic tubules because no rats were examined in the 3-

mg/kg/day-dose group and only one rat was examined in the 30-mg/kg/day-dose group. No statistical analyses were completed on these microscopic observations.

Relative liver weights were statistically increased in a dose-response manner in males, 19% and 56% compared to control at 3 mg/kg/day and 30 mg/kg/day, respectively. These increases were accompanied by decreases compared to control in sorbitol dehydrogenase (SDH) at 0.3 mg/kg/day (-36%) and 30 mg/kg/day (-21%) in males. In females, the only statistically significant change in liver weight was a 12% increase compared to control at the highest dose (300 mg/kg/day). Microscopically, 4/10 and 7/10 male rats exhibited hepatocellular hypertrophy at 3-mg/kg/day and 30-mg/kg/day doses, respectively. In female rats, hepatocellular hypertrophy was observed in 4/10 rats in the high-dose group. Hepatocellular necrosis (3/10) and single-cell necrosis (1/10) were observed in males at 30 mg/kg/day. No statistical analyses were completed on these histological observations. The authors note that hepatic peroxisomal β-oxidation activity was induced in both sexes at the middle and high doses. Specifically, β-oxidation activity was determined using [14C] palmitoyl-coenzyme A (CoA) as the substrate and total cytochrome P450 content as markers of peroxisome proliferation. In the males, β-oxidation activity was significantly increased compared to control at dosages of 0.3 mg/kg/day, 3 mg/kg/day, and 30 mg/kg/day by 42%, 274%, and 772%, respectively, and total cytochrome P450 content was significantly increased by 23% at 30 mg/kg/day (DuPont-24447, 2008). In female rats dosed with 30 mg/kg/day and 300 mg/kg/day, β-oxidation activity was significantly increased compared to control by 49% and 198%, respectively, while total cytochrome P450 content remained unaltered (DuPont-24447, 2008). EPA identified the NOAEL to be 0.3 mg/kg/day and the LOAEL to be 3 mg/kg/day based on hematological (decreased hemoglobin, RBC count, and hematocrit) and immune (decreased globulin levels) findings in males (DuPont-24447, 2008). These findings were also accompanied by liver effects, including an increase in relative liver weight and hepatocellular hypertrophy; however, necrosis was observed only at the high dose (30 mg/kg/day).

DuPont-24459 (2008)

In another repeated-dose study conducted according to OECD TG 407 (OECD, 2008a), 7-week-old Crl:CD-1 mice (10/sex/group) were administered 0, 0.1, 3, or 30 mg/kg/day HFPO dimer acid ammonium salt (purity 88%) for 28 consecutive days via gavage (vehicle was deionized water) (DuPont-24459, 2008). Increases in mean BW gain were observed at 30 mg/kg/day in both males and females. In males, increases in mean cumulative BWs were reported as statistically different from the control group in the 30-mg/kg/day group during study weeks 1, 2, 3, and 4. In females, mean cumulative BW gains were significantly increased in the 30-mg/kg/day group during study weeks 2, 3, and 4.

Similar to the findings observed in the 28-day toxicity study in Crl:CD(SD) rats (DuPont-24447, 2008), decreases of 5.0% in hemoglobin and hematocrit were reported at greater than or equal to 3 mg/kg/day, and RBC count was significantly decreased by 7.6% in the Crl:CD-1 male mice at 30 mg/kg/day. In both males and females, the A/G ratio was statistically increased compared to control at greater than or equal to 3 mg/kg/day. Albumin alone was significantly increased by 31.3% compared to controls in males at 30 mg/kg/day, and globulin alone was decreased in females at greater than or equal to 3 mg/kg/day by 15.8% and 21.1% at 3 mg/kg/day and 30 mg/kg/day, respectively. Finally, in males, the serum liver enzymes aspartate aminotransferase (AST) (478%), alanine aminotransferase (ALT) (1,254%), alkaline

phosphatase (ALP) (1,222%), and SDH (1,800%) were significantly increased from control at the 30-mg/kg/day dose. Note that the hematology measures in female mice were inexplicably underpowered. Though a sample size of 9-10 mice per dose group was expected, only 2, 6, 3, and 5 female mice had hematology measurements in the 0, 0.1, 3 and 30 mg/kg/day dose groups, respectively.

In male mice, no statistically significant effect was observed on kidney weight. Female kidney weight findings were equivocal with the mean relative kidney weight showing statistically significant increases compared to control only at the low dose (8%) and high dose (17%). Minimal increases in basophilic tubular cells and tubular dilatation were observed in females at 30 mg/kg/day (3 of 10 animals for both effects) (DuPont-24459, 2008).

Macroscopic and microscopic tissue pathology evaluations were conducted for all dose groups. The inspection of male adrenal cortex at the highest dose found minimal hypertrophy in 8 of 10 tissue samples examined, while females showed mild or minimal adrenal cortex congestion at only the highest dose (DuPont-24459, 2008). No statistical analyses were completed on these microscopic observations.

Liver effects were also reported in both males and females in this study. In males, relative liver weights were significantly increased compared to control at 3 mg/kg/day and 30 mg/kg/day by 78% and 163%, respectively. In females, relative liver weights were increased at 3 mg/kg/day and 30 mg/kg/day by 32% and 103%, respectively, compared to controls. Absolute liver weights also increased at these doses in both sexes and to similar extents. Increases in liver weight correlated with microscopic liver findings (including single-cell necrosis, increased mitosis, and hepatocellular hypertrophy). Single-cell necrosis was observed in 40% (4/10) and 100% (10/10) of the male mice at 3 mg/kg/day and 30 mg/kg/day, respectively, while no liver necrosis was observed in the control mice. As noted above, serum liver enzymes were significantly increased from control at the 30 mg/kg/day dose: AST (478%), ALT (1,254%), ALP (1,222%), and SDH (1,800%). Single-cell necrosis was also detected in 40% (4/10) of female mice at 30 mg/kg/day compared to zero in the control. This was associated with an increase in serum SDH (186%) at 30 mg/kg/day. Hepatic peroxisomal β-oxidation activity was induced in both sexes. Specifically, β-oxidation activity was determined using [14C] palmitoyl-CoA as the substrate and total cytochrome P450 content as markers of peroxisome proliferation. In the male mice, β-oxidation activity significantly increased compared to control at doses of 0.1 mg/kg/day, 3 mg/kg/day, and 30 mg/kg/day HFPO dimer acid ammonium salt by 57%, 744%, and 648%, respectively, yet total cytochrome P450 content significantly decreased at 3 mg/kg/day and 30 mg/kg/day by 26% and 53%, respectively (DuPont-24459, 2008). β-oxidation activity significantly increased relative to control in female mice at 3 mg/kg/day and 30 mg/kg/day by 495% and 823%, respectively, with no alterations in total cytochrome P450 content. EPA identified the NOAEL for this study as 0.1 mg/kg/day and the LOAEL as 3 mg/kg/day based on increase in single-cell necrosis in males, which was accompanied by increased relative liver weight and hepatocellular hypertrophy, hematological, and immune effects.

4.3 Subchronic Toxicity Studies

DuPont-17751-1026 (2009)

In a repeated-dose study with rats, HFPO dimer acid ammonium salt (purity 84%) was administered to 8-week-old Crl:CD(SD) rats (10–20/sex/dose) on 90 consecutive days via oral

gavage (vehicle was deionized water) in accordance with OECD TG 408 (DuPont-17751-1026, 2009; OECD, 1998). Male rats were administered the test substance at doses of 0, 0.1, 10, or 100 mg/kg/day while females received 0, 10, 100, or 1,000 mg/kg/day. In this study, three high-dose females died before dosing was complete (two deaths considered as treatment-related; one death of undetermined cause).

Hematological evaluations revealed decreased hemoglobin, erythrocyte counts, and hematocrit in males administered greater than or equal to 10 mg/kg/day. The decreases in all three parameters for males were significantly different from control at 10 and 100 mg/kg/day and decreased in a dose-dependent manner at 90 days (study week 13). The maximum decreases from control in males were observed at the highest dose and were 11%, 13%, and 12% for RBC count, hemoglobin, and hematocrit, respectively. Likewise, female rats exhibited significant and dose-dependent decreases in RBC count (28%), hemoglobin (21%), and hematocrit (18%), but only at the 1,000 mg/kg/day dose. In males, absolute (52%) and percent (67%) reticulocytes and platelet count (17%) were significantly increased from control at the highest dose and exhibited a dose response. Additionally, both the absolute and percent of basophils (a type of white blood cell) were significantly decreased relative to control at 10 mg/kg/day (25%) and 100 mg/kg/day (50%) in males. Finally, female rats saw significant increases from control in mean corpuscular volume (15%), mean corpuscular hemoglobin (11%), mean corpuscular hemoglobin concentration (4%), platelet count (30%), and absolute (212%) and percent (392%) reticulocytes and a decrease relative to control in the percent of basophils (33%) at the high dose (1,000 mg/kg/day) (DuPont-17751-1026, 2009).

There were alterations in the clinical chemistry values in both sexes. Males exhibited a dose-dependent increase in total albumin and the A/G ratio and a decrease in total globulin compared to control. These changes were statistically significant at 10 mg/kg/day and 100 mg/kg/day. The maximum increases compared to control observed at the highest dose in total albumin, total globulin, and A/G ratio were 12%, 15%, and 35%, respectively. As in the 28-day study, females exhibited a dose-dependent decrease in globulin (33%) and an increase in A/G ratio (58%) that was significantly different from control for both effects at the highest dose only. Males and females also showed dose-dependent decreases in serum cholesterol that were statistically significantly different from control at 100 mg/kg/day (31%) in males and at both 100 mg/kg/day (20%) and 1,000 mg/kg/day (31%) in females. BUN was significantly increased relative to control in males at 100 mg/kg/day (38%). The trend for BUN was dose-related and positive in both sexes. ALP levels were significantly increased from control in a dose-dependent manner at 10 mg/kg/day (48%) and 100 mg/kg/day (106%) in the males and at 1,000 mg/kg/day (66%) in the females. Serum phosphorus levels increased dose-dependently in males and females and were significantly different from control at 10 mg/kg/day (10%) and 100 mg/kg/day (11%) in males and at 1,000 mg/kg/day (18%) in females. Total bilirubin was significantly decreased from control in a dose-dependent manner at the mid-dose (25%) and high dose (50%) only in females. Total protein and γ-glutamyl transferase decreased 10% and 69%, respectively, at the high dose in females. Finally, a slight but significant and dose-dependent decrease compared to controls in urine pH (8%) and a large increase in total urine volume (252%) were observed in female rats at 1,000 mg/kg/day (DuPont-17751-1026, 2009).

Kidney weight relative to BW was significantly and dose-dependently increased from control at 10 mg/kg/day (13%) and 100 mg/kg/day (16%) in male rats. Likewise, kidney weight relative to

BW was significantly increased at all dose levels in females and reached a maximum increase of 23% from control; however, microscopic damage of the kidney (tubular and papillary necrosis) was observed in only one of the rats at the highest dose. Additionally, one of the females that died prior to study termination exhibited tubular and papillary necrosis of the kidney. Transitional cell hyperplasia and mild acute inflammation were observed in the kidney of 1/10 male rats at the 100-mg/kg/day dose. Statistical analyses were not completed for the microscopic renal findings.

Liver weight relative to BW was significantly and dose-dependently increased from control at 10 mg/kg/day (31%) and 100 mg/kg/day (67%) in male rats. Females exhibited an 85% increase from control in liver weight at the high dose (1,000 mg/kg/day). Hepatocellular hypertrophy was observed in 3/10 and 10/10 males at the 10-mg/kg/day dose and 100-mg/kg/day dose, respectively, and in 10/10 females at the 1,000-mg/kg/day dose. Statistical analyses were not conducted for hepatocellular hypertrophy. Furthermore, it is not documented in the data tables whether other histological effects such as liver necrosis were detected in the 90-day study, although the pathology report states that the hypertrophy was not associated with microscopic changes indicative of liver injury such as necrosis (DuPont-17751-1026, 2009). EPA has determined the study NOAEL to be 0.1 mg/kg/day and the LOAEL to be 10 mg/kg/day based on blood effects (i.e., decreased RBC count, hemoglobin, and hematocrit) in males.

DuPont-18405-1307 (2010)

DuPont-18405-1307 (2010) was submitted to EPA under a TSCA Consent Order (see section 1.1 for more detail). Subsequently, in comments submitted to regulations.gov (Docket EPA-HQ-OW-2018-0614) by ToxStrategies LLC (2019a,b) a reevaluation of the study results for DuPont-18405-1307 (2010) and DuPont-18405-1037 (2010) was submitted. The reevaluation of DuPont-18405-1037 (2010) was published as Thompson et al. (2019) (discussed in section 4.5); however, the results of the reevaluation of DuPont-18405-1307 (2010) were not included in this publication. In response to these comments and the publication, EPA requested an independent review of DuPont-18405-1307 (2010) by the National Toxicology Program (NTP, 2019) Pathology Working Group (PWG) (appendix D). The results of the DuPont-18405-1307 (2010) and the NTP PWG review are described next.

In a repeated-dose, subchronic study with 7-week-old Crl:CD1(ICR) mice, the HFPO dimer acid ammonium salt (purity 84%) was administered to 10/sex/group for 95 days (males) or 96 days (females) via gavage (vehicle was deionized water) at doses of 0, 0.1, 0.5, and 5 mg/kg/day in accordance with OECD TG 408 (DuPont-18405-1307, 2010; OECD, 1998). A statistically significant increase in male BW and overall BW gain was observed at the high dose only. Mean daily food consumption was statistically increased in males between days 0 and 91 in a dose-related manner. The study authors reported that there were no treatment-related deaths. Two female mice (one at 0.5 mg/kg/day on day 6 and one at 5 mg/kg/day on day 20) died during the study. The authors reported that these animals displayed signs indicative of injury from gavage misdosing. The mice that died prematurely were included in the study results presented in the report.

A small decrease compared to control in mean corpuscular hemoglobin concentration (3%) in males and increased bilirubin (14%) in females was reported at 5 mg/kg/day. Clinical chemistry changes were more evident among male mice than female mice. Specifically, AST, ALT, and

ALP were statistically increased from control 106%, 420%, and 1,134%, respectively, at the 5-mg/kg/day dose in males. Comparatively, female mice saw significant increases relative to control in ALT (42%) and ALP (143%). SDH levels significantly increase compared to control in both males (308%) and females (32%) at 5 mg/kg/day. Albumin levels were increased relative to control in the 5-mg/kg/day-dose group in both males (14%) and females (4%), but total serum protein was significantly increased (14%) only in males at this dose (DuPont-18405-1307, 2010).

Macroscopic and microscopic tissue pathology evaluations were conducted for all dose groups. Male mice exhibited kidney tubular epithelial hypertrophy (9/10 treated mice compared to 0 in control) while females exhibited dilated kidney tubules (4/10 in treated compared to 2/10 in control) in the 5-mg/kg/day-dose group. Both effects were classified as minimal by the study authors. Female mice exhibited a decrease in relative spleen weight (10%, 21%, and 18% at 0.1 mg/kg/day, 0.5 mg/kg/day, and 5 mg/kg/day, respectively). No effects on the spleen were observed in male mice in any dose group. The study authors reported that changes in female spleen weight did not occur in a dose-related manner and were not associated with changes in absolute spleen weights or histological abnormalities in the spleen (DuPont-18405-1307, 2010).

Increased relative liver weights compared to control in both male mice (130%) and female mice (69%) were accompanied by minimal-to-mild hepatocellular hypertrophy at 5 mg/kg/day in all dosed mice. Minimal hepatocellular hypertrophy was also observed at the 0.5-mg/kg/day dose as well in males (8/10 mice). No hepatocellular hypertrophy was observed in the control group. Large and discolored livers were observed at doses greater than or equal to 0.5 mg/kg/day in males, but only in the 5-mg/kg/day-dose group in females. Key treatment-related findings considered as adverse at 5 mg/kg/day included increased enzymes indicative of liver injury (i.e., AST, ALT, ALP, and SDH) and increased total bile acids that co-occurred with histopathological findings in the liver. Histopathological findings in male mice included an increase in the incidence of single-cell necrosis (10/10 treated mice versus 0 in control), Kupffer cell pigments (10/10 treated mice versus 0 in control), and mitotic figures (9/10 treated mice versus 0 in control). Females also exhibited histopathological liver findings, but to a lesser degree. For example, 3/10 female mice exhibited focal necrosis and only 1/10 mice presented single-cell necrosis at 5 mg/kg/day (DuPont-18405-1307, 2010).

EPA concluded that the NOAEL in this study is 0.5 mg/kg/day and the LOAEL is 5 mg/kg/day based on the histological findings for the liver (i.e., necrosis and mitotic figures) accompanied by the clinical chemistry changes (i.e., AST, ALT, ALP, and SDH).

Reanalysis of DuPont 18405-1307 (2010) by National Toxicology Program Pathology Working Group (NTP, 2019)

The National Institute of Environmental Health Sciences (NIEHS), NTP in Research Triangle Park, NC convened a pathology working group (PWG) to provide an independent review of slides from the 90-day mouse study (DuPont-18405-1307, 2010) and the reproductive/developmental study (DuPont-18405-1037, 2010). All pathology slides provided by DuPont/Chemours were reviewed by the NTP PWG, including those of animals that died on study. The data and slides were reviewed per NTP standards (Sills et al., 2019).

As part of this PWG, one pathologist reviewed slides from the two studies and classified liver effects according to the International Harmonization of Nomenclature and Diagnostic Criteria (INHAND) Organ Working Group’s diagnostic criteria which describes how pathologists can

distinguish between apoptosis and single-cell necrosis in standard hematoxylin and eosin- (H&E) stained tissue sections (Elmore et al., 2016). The PWG coordinator then confirmed the classifications and selected example slides representative of the observed liver effects for review by the full, eight-member PWG. The selected slides included three examples each of normal liver, hepatocellular apoptosis, hepatocellular single-cell necrosis, and hepatocellular cytoplasmic alteration; two examples each of focal necrosis, pigment, increased mitoses, mixed-cell infiltrates, and cytoplasmic vacuolation; and one example of oval cell hyperplasia. The PWG's description of cytoplasmic alteration indicates that this endpoint includes hepatocellular hypertrophy occurrence along with eosinophilic change to the hepatocytes. There was a majority consensus for all reviewed lesions. The PWG consensus opinion for each slide, including any additional diagnoses made by the PWG panel, was recorded and presented in the final PWG report (appendix D of this revised assessment).

The PWG's classification of liver lesions included, but was not limited to, the following: apoptosis, single-cell necrosis, cytoplasmic alteration, and focal necrosis. Single-cell necrosis was observed in the high-dose group for male and female mice (DuPont-18405-1307, 2010). The PWG agreed that the observed single-cell necrosis was often accompanied with inflammation. Findings of apoptosis were also observed in the high-dose groups in both sexes.

Additionally, the PWG offered general observations about the histopathology reported in the original study. The NTP pathologists identified hepatocellular hypertrophy, including morphological changes such as eosinophilic stippling. The pathologists agreed that hypertrophy was present, but often less severe than reported in the original study. In addition, the pathologists recommended adding the diagnosis of cytoplasmic alteration to account for the eosinophilic, granular appearance of the cytoplasm of the hepatocytes. The pathologists recommended using this term to account for hypertrophy and eosinophilic changes as they are considered part of the same process. Cytoplasmic alteration was noted in the mid- and high-dose groups in males.

The PWG majority consensus opinion for each slide was recorded in review worksheets in a final report to EPA (see appendix D). Overall, the PWG review confirmed the results of the original study. Specifically, the PWG confirmed that single-cell necrosis was observed and is a treatment-related, adverse effect. The PWG concluded that the dose response and constellation of lesions (i.e., cytoplasmic alteration, apoptosis, single-cell necrosis, and focal necrosis) rather than one lesion individually, represents adversity within these studies (appendix D). EPA interpreted the NTP PWG's definition that the constellation of liver lesions is adverse applies to the dose group level instead of the individual animal level since the histopathological evaluation represents a snapshot in time of a biological process within one portion of the liver that can vary across animals. Table 10 presents a comparison of the incidence data for the 90-day mouse study (DuPont-18405-1307, 2010) and the NTP (2019) PWG reevaluation. Because the PWG analysis reflects more recent histopathological criteria for the grading of liver lesions, the incidence data as reported by NTP (see appendix D) were considered the more appropriate measure of response in the liver from the 90-day mouse study (DuPont-18405-1307, 2010). The NTP PWG reported that 10 out of 10 male mice exhibited cytoplasmic alteration, compared to 0 in control at the 0.5-mg/kg/day dose in this study. Although NTP classified cytoplasmic alteration as part of the constellation of liver lesions considered adverse, no other liver lesions indicative of liver damage (i.e., single-cell or focal necrosis or apoptosis) were observed at the 0.5-mg/kg/day dose level in males. Consistent with the Hall criteria, EPA did not consider the cytoplasmic alteration findings

alone as an adverse effect in the 0.5 mg/kg/day dose group but considered the constellation of liver lesions observed across the male mice in the high-dose group as adverse. Additionally, the female mice in this study did not exhibit a dose response for the constellation of liver lesions. Based on EPA's interpretation of the NTP PWG results, EPA derived the study NOAEL for DuPont-18405-1307 (2010) of 0.5 mg/kg/day and the LOAEL is 5 mg/kg/day based on the histological findings for the liver (i.e., cytoplasmic alteration, apoptosis, single cell necrosis, and focal necrosis) in male and female mice.

Table 10. Comparison of Results from 90-Day Mouse Study (DuPont-18405-1307, 2010) and NTP PWG Reevaluation (NTP, 2019)

Notes:
[a] Slides for animal number 251 were not provided for analysis.
[b] EPA did not include animals that died due to gavage misdosing in the presentation of incidence data from the NTP PWG.

4.4 Chronic Toxicity and Carcinogenicity Studies

DuPont-18405-1238 (2013)

In a combined chronic toxicity/carcinogenicity study in 7-week-old Crl:CD(SD) rats, HFPO dimer acid ammonium salt (purity 84%) was administered by oral gavage (vehicle was deionized water) for up to 104 weeks (80/sex/group, of which 10/sex/group were designated for a 12-month interim necropsy in accordance with OECD TG 453) (DuPont-18405-1238, 2013; OECD, 2009, 2018b; Caverly Rae et al., 2015). Dose levels administered were 0, 0.1, 1, and 50 mg/kg/day for males and 0, 1, 50, and 500 mg/kg/day for females. Numerous animals in all dose groups (both male and female) were found dead or euthanized *in extremis* over the course of the study. Across all dosing groups in both male and female rats, 25.4% of the test animals survived to their planned terminal necropsy while 74.6% of the animals experienced unscheduled death/ moribundity prior to the scheduled study termination at 104 weeks. The authors state that mean survival in males and females was unaffected by treatment; however, all females were sacrificed before study termination at 101 weeks because of decreased survival across all groups, including the control. There were no statistically significant differences in survival across the female

dosing groups and female survival was comparable across all dosing groups. Among the animals that experienced unscheduled death/moribundity on study due to effects determined to be unrelated to treatment, DuPont stated the males most commonly died from pituitary tumors and undetermined causes while the females most commonly died from pituitary tumors and mammary tumors.

The females in the high-dose group were observed to have papillary necrosis and inflammation of the kidneys deemed by the authors to be related to treatment. BW and BW gain were unaffected in males but reduced compared to control (13% and 20%, respectively) in high-dose females at 52 weeks. The incidence of alopecia and hypotrichosis (abnormal patterns of hair growth) was statistically significantly increased in females at 500 mg/kg/day.

Statistically significant hematological effects were observed in this study, primarily in female rats. Blood samples were taken at 3, 6, and 12 months. At 3 months, RBC count, hemoglobin, and hematocrit were significantly decreased at the highest dose in males and females, although these decreases did not occur in a dose-dependent manner. Similarly, at 6 months, hemoglobin and hematocrit were significantly decreased at the highest dose in males, yet these decreases did not occur in a dose-dependent manner. There were no significant differences in any of these parameters in male rats at the 12-month time point. At 6 and 12 months, female rats exhibited a significant decrease in RBC count, hemoglobin, and hematocrit at 500 mg/kg/day and in a dose-dependent manner. The RBC count was also significantly decreased at 50 mg/kg/day in females at the 12-month time point; however, hemoglobin and hematocrit were not. The largest decreases compared to control in RBC count, hemoglobin, and hematocrit in female rats were 28%, 24%, and 20%, respectively, which were observed at 12 months. Additionally, the percent change from control of these effects increased over time (i.e., 3 months < 6 months < 12 months). At 12 months, serum albumin levels increased in males at 1 mg/kg/day and 50 mg/kg/day by 8% and 16% from control, respectively, which led to a concomitant increase in the A/G ratio by 16% and 28%, respectively.

Statistically significant changes from control were observed in the kidneys of females, but only at the highest dose (500 mg/kg/day). For example, there were increased incidences of tubular dilatation (increased by 34% compared to control), edema of the renal papilla (increased by 56% compared to control), transitional cell hyperplasia (increased by 39% compared to control), tubular and pelvic mineralization (increased by 15% and 24% compared to control, respectively), renal papillary necrosis (increased by 23% compared to control), and chronic progressive nephropathy (increased by 36% compared to control), all statistically significant from control. These microscopic indications of kidney damage were also associated with a 15% increase in relative kidney weight compared to control in females administered 500 mg/kg/day of HFPO dimer acid ammonium salt.

Liver enzyme levels also were affected by exposure to HFPO dimer acid ammonium salt at 12 months in the chronic study. In males, statistically significant increases in ALP (180%), ALT (228%), and SDH (141%) were observed at 50 mg/kg/day. These enzyme changes were correlated with microscopic findings in the liver, including focal necrosis. Relative liver weights were increased in high-dose males (16% compared to controls) and females (69% compared to controls) at the 12-month sacrifice. The change in liver weight in females corresponded to centrilobular hypertrophy in the high-dose females at the interim sacrifice. Females exposed to 500 mg/kg/day of HFPO dimer acid ammonium salt for 2 years also had significantly increased

relative liver weights (43% compared to control) at terminal sacrifice. There was no difference in organ weights in males at any dose at terminal sacrifice despite the changes observed at 12 months. Male and female rats exposed to 50 mg/kg/day and 500 mg/kg/day, respectively, had statistically significantly increased centrilobular hepatocellular hypertrophy compared to control rats (7/70 in treated males compared to 0/70 in control; 65/70 in treated females compared to 0/70 in control) and centrilobular hepatocellular necrosis (5/70 in treated males compared to 1/70 in control; 7/70 in treated females compared to 1/70 in control). Male rats also saw a decrease in incidence from control of 16% and 10% in focal and periportal vacuolization, respectively, at 50 mg/kg/day, and female rats had a 4% decrease from control in centrilobular vacuolation at 500 mg/kg/day. Finally, in females, panlobular hepatocellular hypertrophy (increase in incidence compared to control of 4%), individual cell hepatocellular necrosis (increase in incidence compared to control of 4%), and angiectasis (i.e., dilation of a blood or lymphatic vessel) (increase in incidence compared to control of 6%) were reported at the high dose.

Nonneoplastic effects also were observed in the stomach and tongue of females exposed to the high dose. Specifically, there were increased incidences of hyperplasia of the limiting ridge of the nonglandular stomach (increased by 13% compared to control; incidence was 9/70 for treated females and 0/70 in control) and of the squamous cell in the tongue (increased 16% from control; incidence was 13/70 in treated females and 2/70 in control). The tongue also exhibited an increased incidence of inflammation (increased 14% from control; incidence was 13/70 in treated and 3/70 in control). EPA concluded that the NOAEL for chronic toxicity in this study was 1 mg/kg/day and the LOAEL was 50 mg/kg/day for the liver effects in males.

Statistically significant increases in the incidence of liver tumors in females at 500 mg/kg/day and pancreatic acinar cell tumors in males at 50 mg/kg/day were reported. An increase in testicular interstitial (Leydig) cell tumors was noted at the high dose but was not statistically significant. Because of the observed early deaths in both control and treated male rats, EPA recommended that the submitter (a) reexamine their test data, (b) identify the animals that died without Leydig cell tumor within the first year, (c) exclude the animals identified in the previous step (i.e., those that died within the first year and had no tumors) from consideration for cancer data analysis, (d) recalculate tumor incidences, and (e) perform statistical analyses. Because the initial results indicated that the increased incidences of liver tumors in female rats (500 mg/kg/d) and combined pancreatic acinar tumors in male rats (50 mg/kg/d) were significantly increased from control despite the inclusion of early deaths, EPA decided to limit the reanalysis to testicular hyperplasia and tumors in male rats only. Additional discussion of tumor findings for the liver, pancreas, and testes is presented below.

Females. There were increases in the incidence of liver tumors at the high dose only (500 mg/kg/day), where degenerative and necrotic changes were also observed. The tumor incidences were 0/70 (0%), 0/70 (0%), 0/70 (0%), and 11/70 (15.7%) for hepatocellular adenomas and 0/70 (0%), 0/70 (0%), 0/70 (0%), and 4/70 (5.7%) for hepatocellular carcinomas at the doses of 0, 1, 50, and 500 mg/kg/day, respectively. The increased incidences of hepatocellular adenomas were statistically significant by the Cochran-Armitage trend test, the Peto test, and the pairwise Fisher Exact test and the increased incidences of hepatocellular carcinomas were statistically significant by the Cochran-Armitage trend test and the Peto test. The incidences of adenomas and carcinomas observed at 500 mg/kg/day also exceeded the test laboratory historical control ranges of 0%–5% and 0%–1.7%, respectively.

Males: A statistically significant increase was reported in the incidence of pancreatic acinar cell adenomas/carcinomas combined (but not adenomas or carcinomas alone) at 50 mg/kg/day. Incidences of pancreatic acinar cell adenomas were 0/70 (0%), 1/70 (1.4%), 0/70 (0%), and 3/70 (4.3%) at 0 mg/kg/day, 0.1 mg/kg/day, 1 mg/kg/day, and 50 mg/kg/day, respectively. The increased incidence at the high dose was not statistically significant and was within the test laboratory historical control range (0%–5%). The incidence of pancreatic acinar cell carcinomas was 0/70 (0%) in all groups other than the high-dose group, in which 2/70 (2.9%) were observed. The incidence of carcinomas at 50 mg/kg/day was not statistically significant but was slightly higher than the upper end of the laboratory's historical control range (0%–1.7%). When these two types of tumor were combined, the incidences of adenoma/carcinoma were 0/70 (0%), 1/70 (1.4%), 0/70 (0%), and 5/70 (7.1%) at 0 mg/kg/day, 0.1 mg/kg/day, 1 mg/kg/day, and 50 mg/kg/day, respectively, with the increased incidence at the high dose significant by the Cochran-Armitage trend test and the Peto test. For reference, the incidences of pancreatic acinar cell hyperplasia were 16/70 (22.9%), 18/70 (25.7%), 7/70 (10%), and 21/70 (30%) at 0 mg/kg/day, 0.1 mg/kg/day, 1 mg/kg/day, and 50 mg/kg/day, respectively, indicating a lack of dose-response relationship for this finding. Furthermore, the increased incidence of hyperplasia at the high dose was not statistically significant (compared to control).

In the testes, the incidences of interstitial cell adenomas were 4/70 (5.7%), 4/70 (5.7%), 1/70 (1.4%), and 8/70 (11.4%) at 0 mg/kg/day, 0.1 mg/kg/day, 1 mg/kg/day, and 50 mg/kg/day, respectively at 2 years. An interstitial cell adenoma was also present in 1/10 high-dose males at the interim sacrifice (12 months). The increased adenoma incidence at 50 mg/kg/day (11.4%) was not statistically significant but was slightly higher than the upper end of the testing laboratory's historical control range (0%–8.3%). For reference, the incidences of interstitial cell hyperplasia were 7/70 (10%), 7/70 (10%), 3/70 (4.3%), and 15/70 (21.4%) at 0 mg/kg/day, 0.1 mg/kg/day, 1 mg/kg/day, and 50 mg/kg/day, respectively. The increased incidence of hyperplasia at the high dose was not statistically significant (compared to control), although the incidence of hyperplasia at 50 mg/kg/day exceeded the historical control range (0%–8.3%). The observed incidences in the control and low-dose groups (both 10%) were also slightly above the upper end of historical controls. DuPont's reanalysis of these findings in the testes indicated that the number of male rats that died before 1 year was 4, 9, 8, and 3 in the 0 mg/kg/day (control), 0.1 mg/kg/day, 1 mg/kg/day, and 50 mg/kg/day groups, respectively. The causes of death were generally dosing injury or undetermined causes, and there were no testicular lesions or tumors in the testicular tissues of these animals. Excluding these early deaths, the incidences of testicular interstitial cell hyperplasia were 7/66 (10.6%), 7/61 (11.5%), 3/62 (4.8%), and 15/67 (22.4%) in the 0 mg/kg/day (control), 0.1 mg/kg/day, 1 mg/kg/day, and 50 mg/kg/day groups, respectively. The corresponding incidences of testicular interstitial cell adenomas were 4/66 (6.0%), 4/61 (6.6%), 1/62 (1.6%), and 8/67 (11.9%). Thus, there were no statistically significant differences for either hyperplasia or adenoma, consistent with results from the original report in which all early deaths were included. Although the incidence of testicular interstitial cell adenomas was not statistically significant compared to controls, the authors of the study conclude that "a relationship to treatment for these findings in the 50 mg/kg/day group cannot be ruled out" while also suggesting that Leydig cell tumor induction in rodents might have low relevance to humans (Caverly Rae et al., 2015).

Based upon EPA's review of the study, the increased incidence of liver tumors in females at 500 mg/kg/day and combined pancreatic acinar adenomas and carcinomas in males at

50 mg/kg/day are treatment related. The increased incidence of testicular interstitial cell adenoma was not statistically significant, and EPA accepted the results of the reanalysis that excluded the early deaths. EPA concluded that the NOAEL is 1 mg/kg/day and the LOAEL is 50 mg/kg/day based on the reported liver effects (i.e., centrilobular necrosis in both sexes; increased ALP, ALT, and SDH in males; and increased centrilobular hepatocellular hypertrophy and cystic focal degeneration in males).

4.5 Reproductive and Developmental Toxicity Studies

DuPont-18405-1037 (2010)

DuPont-18405-1037 (2010) was submitted to EPA under a TSCA Consent Order (see section 1.1 for more detail). Subsequently, Thompson et al. (2019), a contractor to Chemours (previously DuPont), performed a reevaluation of the study results for DuPont-18405-1037 (2010). In response to this publication, EPA requested an independent review of DuPont-18405-1037 (2010) by the NTP PWG (appendix D). The results of the original DuPont study, and these two reanalyses are described next.

In a combined oral gavage reproductive/developmental toxicity study in mice with HFPO dimer acid ammonium salt, the test compound (purity 84%) was administered by oral gavage (vehicle was deionized water) to Crl:CD1(ICR) mice (25/sex/group) at doses of 0, 0.1, 0.5, or 5 mg/kg/day, according to a modified OECD TG 421 (DuPont-18405-1037, 2010; OECD, 2016a). The male mice were approximately 6 weeks old and the female mice were approximately 10 weeks old. Parental (F_0) males were dosed 70 days prior to mating and throughout mating through 1 day prior to scheduled termination, for a total of 84 to 85 total doses. Parental F_0 females were dosed for 2 weeks prior to pairing and were dosed through LD20 for a total of 53 to 65 doses (exceptions include females with no evidence of mating or those that failed to deliver yet were administered a total of 37 to 50 doses). F_1 animals (offspring) were dosed daily beginning on PND21 through PND40.

In this study, increases in BWs and food consumption were observed at 5 mg/kg/day in F_0 animals. In F_0 males, increased mean BW gains were reported in the 5-mg/kg/day group during study days 0–49; differences from the control group achieved significance during study days 0–7, 14–21, and 21–28. Significantly higher mean BW gains were observed in this high-dose male group when the overall premating period (study days 0–69) and treatment period (study days 0–84) were evaluated. Mean BW gains were statistically significantly increased in females during both the premating period and throughout gestation at 0.5 and 5 mg/kg/day. Specifically, during the pre-mating period, BW gain increased by 100% and 70% in the 0.5- and 5-mg/kg/day-dose groups, respectively. Mean maternal GWG, calculated from individual differences, also significantly increased over the gestational period (0–18 days) by 18% and 22% in the 0.5- and 5-mg/kg/day-dose groups, respectively. At the high dose, mean BW gains were increased (5.1%–14.0%) compared to controls throughout lactation; the differences were significant on LD1, LD4, and LD21. BWs were unaffected at 0.1 and 0.5 mg/kg/day during lactation. Overall, final BW was significantly increased from control by 9% and 14% in males and females, respectively, administered 5 mg/kg/day.

The authors reported no treatment-related deaths in the F_0 mice. However, three males (one in each of the dose groups) and six females (one in the control, three in the low-dose group, and one each in the mid- and high-dose group) did not survive until scheduled sacrifice. The cause of

death was undetermined in all cases except the male in the mid-dose group, which appeared to have ulcerative dermatitis. Due to the lack of dose response, the study authors concluded that these deaths were not related to treatment. The study authors did not include the mice with premature deaths in the study results (e.g., histopathological incidence counts).

An increase in relative kidney weight compared to control by 6.5% was observed only in F_0 females at the 5-mg/kg/day dose. Mild increases in tubular cell hypertrophy were observed in the kidneys of males at greater than or equal to 0.5 mg/kg/day–6/24 mice or 25% and 18/24 mice or 75% of male mice at 0.5 mg/kg/day and 5 mg/kg/day, respectively, compared to 1/25 mice or 4% in the control. Chronic progressive nephropathy was also noted in males at 0.5 mg/kg/day (4/24 mice or 17%) and 5 mg/kg/day (5/24 mice or 21%). This effect was not associated with any evidence of tubular cell degeneration.

Liver effects also were reported in both males and females in this study. In males, mean absolute liver weights were increased 26% and 142% at 0.5 mg/kg/day and 5 mg/kg/day, respectively, as compared to control values. Mean relative liver weights were increased by 26% and 121%, respectively, at the 0.5-mg/kg/day and 5-mg/kg/day doses. In females, mean absolute liver weights were increased by 26% and 101% at 0.5 mg/kg/day and 5 mg/kg/day, respectively, as compared to control values. Mean relative (% BW) liver weights were increased by 17% and 80%, respectively. Microscopic findings observed in the liver of F_0 males and females administered 0.5–5 mg/kg/day included increases in hepatocellular hypertrophy, single-cell necrosis, mitotic figures, and lipofuscin pigment. F_0 females exhibited an increase in the incidence of gross white areas in the liver at 5 mg/kg/day, which correlated with microscopic focal and single-cell necrosis. At doses greater than or equal to 0.5 mg/kg/day, minimal-to-moderate hepatocellular hypertrophy was observed in both sexes, along with the corresponding increases in relative liver weight outlined above. Specifically, male mice exhibited a 50% and 100% increase in the incidence of hepatocellular hypertrophy compared to control at 0.5 mg/kg/day and 5 mg/kg/day, respectively, and similar increases in incidence was also observed in female mice (58% and 100% at 0.5 mg/kg/day and 5 mg/kg/day, respectively, compared to control). At greater than or equal to 0.5 mg/kg/day, single-cell necrosis of hepatocytes was observed in males. Specifically, single-cell necrosis was observed in 5/24 mice at 0.5 mg/kg/day and 24/24 mice at 5 mg/kg/day compared to 1/25 mice in the control. Female mice exhibited an increase compared to control in both focal/multifocal necrosis and single-cell necrosis at 5mg/kg/day. Specifically, 5/24 mice had focal/multifocal necrosis compared to 1/24 in the control and 21/24 mice had single-cell necrosis compared to 1/24 mice in the control. Finally, the incidence of mitotic figures increased in males and females administered 5 mg/kg/day by 75% and 21% compared to control, respectively, while the incidence of lipofuscin pigment increased by 88% and 21% compared to control, respectively.

No treatment-related effects were identified for reproductive parameters (mating, fertility, and copulation indices; mean days between pairing and coitus), although male epididymal weight relative to final BW was statistically decreased at 5 mg/kg/day in both the left and right testes (12% decrease relative to control). No treatment-related effects were observed for mean gestation length, mean numbers of implantation sites, mean numbers of pups born, live litter size, percentage of males at birth, postnatal survival, or general condition of pups. At 5 mg/kg/day, however, F_1 male and female pups exhibited lower mean BWs at PND4, PND7, PND14, PND21, and PND28. F_1 male pups continued to exhibit lower mean BWs at PND35 and PND40.

Although values for the attainment of balanopreputial separation and vaginal patency (markers of pubertal onset) were within the range of historical control values, the pups showed statistically significant delays in these endpoints at 5 mg/kg/day (a finding that might be related to the observed effects on BW during the preweaning period). Additionally, the day for attainment of vaginal patency did not exhibit a dose response. The NOAEL (F_0) is 0.1 mg/kg/day, and the LOAEL is 0.5 mg/kg/day based on liver effects (single-cell necrosis in males). The NOAEL (F_1) is 0.5 mg/kg/day based on decreased pup BW and delays in attainment of balanopreputial separation and vaginal patency at the high dose.

Reanalysis of DuPont 18405-1037 (2010) published by Thompson et al. (2019)

In a publication presenting alternative approaches to deriving toxicity values and subsequent drinking water concentrations for GenX chemicals, Thompson et al. (2019) present a reevaluation of slides of liver sections in the reproductive/developmental toxicity study in mice (DuPont-18405-1037, 2010). Thompson et al. (2019) presents the reevaluation of the liver sections from the reproductive/developmental toxicity study in mice in the supplemental file, Table S3.

Thompson et al. (2019) reevaluated these slides using more current diagnostic criteria (Elmore et al., 2016) than those used in the original study (DuPont-18405-1037, 2010) to distinguish between apoptosis and single-cell necrosis in standard H&E-stained tissue sections. Cell death was classified as apoptosis and necrosis based on the proposed nomenclature from the Terminology Recommendations from the INHAND Apoptosis/Necrosis Working Group described by Elmore et al. (2016). The INHAND Nomenclature for Non-neoplastic Findings of the Rodent Liver was also consulted for final diagnostic nomenclature (Thoolen et al., 2010). The samples were specifically evaluated for the presence and type of individual hepatocyte necrosis. The veterinary pathologist who reviewed the slides concluded that apoptosis was the primary adverse effect of note at 5 mg/kg/day. Thompson et al. (2019) also reported increased mitosis at doses with apparent increased apoptosis; the study authors concluded that it is well established that peroxisome proliferator-activated receptor (PPAR) activators can increase mitosis and apoptosis *in vivo*. Therefore, the authors conclude that this effect is likely a part of PPARα signaling pathways that are specific to rodents. EPA identified the NOAEL for this study as 0.5 mg/kg/day and the LOAEL as 5 mg/kg/day based on increased apoptosis in male mice.

Reanalysis of DuPont 18405-1037 (2010) by National Toxicology Program Pathology Working Group (2019)

As described in section 4.3, slides from the 90-day mouse study (DuPont-18405-1307, 2010) and the reproductive/developmental study (DuPont-18405-1037, 2010) were reevaluated by an NTP PWG (see appendix D). The same protocol was used by the PWG in their analysis of each of these studies (see section 4.3 for protocol details). The NTP PWG consensus opinion for each slide was recorded on a review worksheet. Worksheets for the slides were provided as appendices A and B in the final PWG report to EPA (see the full report provided in appendix D of this assessment). Similar to the Thompson et al. (2019) publication, the NTP used the terminology of the INHAND document containing standardized terminology of the liver (Thoolen et al., 2010) except where it would be superseded by the terminology published by the INHAND committee with reference to cell death/necrosis/apoptosis (Elmore et al., 2016). For the reproductive/developmental study (DuPont-18405-1037, 2010), the PWG confirmed single-cell necrosis and focal necrosis in the mid- and high-dose groups of both sexes. Single-cell

necrosis alone and single-cell and focal necrosis combined exhibited a dose-response relationship in both sexes. The PWG agreed that the observed single-cell necrosis was often accompanied with inflammation in this study. Findings of apoptosis were observed but were limited to the highest dose groups in both sexes. Additionally, cytoplasmic alteration (which includes hepatocellular hypertrophy occurrence along with eosinophilic change to the hepatocytes) was noted in the mid- and high-dose groups in both males and females.

The PWG review confirmed the results of the original DuPont study and did not agree with the conclusion of the reanalysis published by Thompson et al. (2019). Specifically, the PWG concluded that the dose response and constellation of lesions (i.e., cytoplasmic alteration, apoptosis, single-cell necrosis, and focal necrosis) rather than one lesion by itself, represents adversity within the confines of the study. Table 11 presents a comparison the incidence data for the reproductive/developmental toxicity study (DuPont-18405-1037, 2010), Thompson et al. (2019), and the NTP PWG reevaluation (NTP, 2019) of DuPont-18405-1037 (2010). The incidence data as reported by NTP (see appendix D) were considered the more appropriate measure of response in the liver from the reproductive/developmental study (DuPont-18405-1037, 2010) because the PWG analysis reflects the more recent scientific histopathological criteria developed for the grading of liver lesions and the PWG results were the consensus of eight pathologists. The NTP PWG confirmed that the study NOAEL for DuPont-18405-1037 (2010) is 0.1 mg/kg/day and the LOAEL is 0.5 mg/kg/day based on the constellation of liver effects (i.e., cytoplasmic alteration, apoptosis, single-cell necrosis, and focal necrosis) in male and female mice.

Table 11. Comparison of Study Results from DuPont-18405-1037 (2010), Thompson et al. (2019), and NTP PWG Reevaluation of DuPont-18405-1037 (NTP, 2019)

Notes: N/A = not applicable
[a] Thompson et al. (2019) stated that "Emphasis was placed on evaluating the samples for the presence and type of individual hepatocyte necrosis. The two terms recommended for hepatocyte death were apoptosis and necrosis based on the proposed nomenclature from the Terminology Recommendations from the INHAND Apoptosis/Necrosis Working Group."
[b] EPA did not include animals that died due to gavage misdoing in the presentation of incidence data from the NTP PWG.

DuPont-18405-841 (2010)

In a prenatal and developmental toxicity study in 12-week-old female Crl:CD(SD) rats, HFPO dimer acid ammonium salt (purity 84%) was administered via oral gavage (vehicle was deionized water) once daily from GD6 through GD20 at doses of 0, 10, 100, and 1,000 mg/kg/day (22 females/group), according to OECD TG 414 (DuPont-18405-841, 2010; OECD, 2001b). The parental males and females were not dosed prior to or during mating and dosing for the dams was not initiated until GD6. Lack of dosing for males and females prior to and during mating and failure to dose the dams during the GD0 to GD6 period are limitations when evaluating this study to fully reflect the ability of the HFPO dimer acid ammonium salt to cause reproductive/developmental toxicity.

The dams' BW decreased at all doses, but significantly decreased (-22% compared to control) at 1,000 mg/kg/day. This decrease in BW also resulted in a decrease (-25%) in maternal GWG compared to control at 1,000 mg/kg/day. Moreover, gravid uterine weight was significantly decreased by 10% and 25% compared to control at 100 mg/kg/day and 1,000 mg/kg/day, respectively. Food consumption in the dams was significantly decreased by 9% over the dosing period (GD6–GD21) at the highest dose. Early delivery on GD21 was observed in 18% and 41% of the dams at 100 mg/kg/day and 1,000 mg/kg/day, respectively. Importantly, the authors noted that, in the available historical controls data for early deliveries in this rat strain (17 datasets), no females showed early deliveries (i.e., before GD21).

Statistically significant increases relative to control in absolute liver weight (12% and 34%) were observed at 100 mg/kg/day and 1,000 mg/kg/day, respectively. Changes in liver weight relative to BW were not documented. This increase in liver weight was associated with hepatocellular hypertrophy at the high dose (19/22 rats, or 86%) and focal necrosis was observed in 9% and 23% of the dams dosed with 100 mg/kg/day and 1,000 mg/kg/day, respectively. Additionally, absolute kidney weight increased dose-dependently in the dams and was significantly increased compared to control (10%) at the highest dose. Changes in kidney weight relative to BW were not documented, and there were no notable microscopic changes in the kidney tissue of the dams. Of note is that a 1,000-mg/kg/day dam that died on GD20 had moderate multifocal/focal necrosis of the liver and disseminated intravascular coagulation in the kidney glomerular capillaries.

The pups experienced a 9% and 28% decrease compared to control in fetal weight at doses of 100 mg/kg/day and 1,000 mg/kg/day, respectively. The percentage of male (47%) and female (53%) pups born were significantly altered from control (55% male; 45% female) at 1,000 mg/kg/day. Additionally, a 14th rudimentary rib developed in 9% of the control fetuses, 10% of fetuses in the 10-mg/kg/day-dose group, 12% of fetuses in the 100-mg/kg/day-dose group, and 27% of the fetuses in the 1,000-mg/kg/day-dose group. Statistical analyses were not completed for the development of the 14th rudimentary rib in individual pups, but a statistically significant increase in the number of litters developing a 14th rudimentary rib was observed for those receiving the high dose.

The NOAEL for this prenatal and developmental toxicity study is 10 mg/kg/day based on an increase in early deliveries, decreases in gravid uterine weight, and decreased fetal weights for both sexes, all occurring at the LOAEL of 100 mg/kg/day.

Conley et al. (2019)

Conley et al. (2019) reported on two experiments evaluating the effects of oral gestational exposures to HFPO dimer acid ammonium salt. In the first experiment, pregnant Crl:CD(SD) rats were dosed from GD14 to GD18 with either water (control), or 1, 3, 10, 30, 62.5, 125, 250, or 500 mg/kg/day of HFPO dimer acid ammonium salt. HFPO dimer acid purity was 100% as determined by the supplier via perchloric acid titration. Dams were dosed during GD14 to GD18 because this window is identified as the critical period for masculinization of the male reproductive tract. The study authors stated that the experiment was completed in three separate "blocks" of animals (15 animals/block). There was a total of nine control animals (three control animals/block), three animals each for the 62.5-, 125-, 250-, and 500-mg/kg/day doses (first block) and six animals each for the 1-, 3-, 10-, or 30-mg/kg/day doses (second and third blocks). Across all three blocks, GWG, reproductive output (number of fetuses and absorptions), maternal sera, and maternal liver weight were measured. In the first two blocks, fetal testis gene expression and testosterone production, fetal BW, fetal and maternal liver gene expression, and maternal serum thyroid hormone and lipid concentrations were also evaluated. In the third block, fetal plasma was collected for determining HFPO dimer acid ammonium salt concentrations (see section 2.3.3 for detail).

A variety of effects were observed in the dams at doses greater than or equal to 30 mg/kg/day. Serum total triiodothyronine (T3) levels were decreased at doses greater than or equal to 30 mg/kg/day and total thyroxine (T4) levels decreased at doses greater than or equal to 125

mg/kg/day. Liver weight was increased on GD18 at doses greater than or equal to 62.5 mg/kg/day. Decreases in serum low-density lipoprotein (LDL) were observed at doses greater than or equal to 125 mg/kg/day and in serum high-density lipoprotein (HDL) and total cholesterol at doses greater than or equal to 250 mg/kg/day. Additionally, serum triglycerides were decreased at the highest dose tested. GWG was also decreased at doses greater than or equal to 250 mg/kg/day.

No significant effects from control were observed on the number of fetuses or resorptions.

In a second pilot experiment evaluating postnatal development, five Crl:CD(SD) dams were dosed from GD14 through GD18 with either water (control; *n*=2 pregnant dams) or 125 mg/kg/day of HFPO dimer acid ammonium salt (*n*=3 pregnant dams) (Conley et al., 2019). The single dose of 125 mg/kg/day was selected because it was the highest dose evaluated that did not cause a significant decrease in GWG during the study described above. Pup delivery began on GD22 and the following schedule was followed for postnatal monitoring:

- PND2: Pups were weighed and sexed and anogenital distance (AGD) was measured.
- PND13: Pups were weighed, sexed, and evaluated for retention of female-like nipples/areolae.
- PND27: Dams were euthanized, and uterine implantation sites scored. Pups were weaned to 2/sex/treatment group.
- PND31–PND37: F_1 female offspring were examined daily for vaginal opening (a marker of pubertal onset).
- PND41–PND45: F_1 male offspring were evaluated daily for balanopreputial separation (a marker of pubertal onset).
- PND128: F_1 females were weighed, euthanized, and examined for reproductive tract malformations. Tissue weights were recorded for the uterus, paired ovaries, liver, paired kidneys, and visceral adipose tissues.
- PND146: F_1 males were weighed, euthanized, and examined for reproductive track abnormalities. Tissue weights were collected for glans penis, ventral prostate, paired seminal vesicles, paired testes, paired epididymis, levator ani-bulbocavernosus, paired bulbourethral (Cowper's) glands, paired kidneys, and visceral and epididymal adipose tissues. Total sperm counts were measured in epididymal sections.

Viable pup number was not affected by treatment. The only significant effect in the treated F_1 generation was a decrease in right epididymis weight on a litter mean basis compared to control. However, multiple significant effects were observed on an individual pup basis. For example, F_1 female BW was significantly decreased compared to control on PND2, PND27, and at the time of vaginal opening (PND31–PND37). Additionally, AGD and liver weight were significantly decreased in F_1 female offspring on an individual pup basis. For F_1 males, paired testes, paired epididymides, right testis, right corpus/caput, right epididymis, left testis, and epididymal adipose tissue were significantly decreased compared to control on an individual pup basis.

Conley et al. (2019) conducted gene expression analyses to determine if HFPO dimer acid ammonium salt activates PPAR signaling pathways. Maternal and fetal livers and fetal testes were collected on GD18 for gene expression analyses. Gene expression was assessed using reverse transcriptase real-time polymerase chain reaction (PCR) of complementary

deoxyribonucleic acid (DNA). Maternal and fetal livers were assessed for 84 target genes relevant to PPARα, PPAR beta/delta (PPAR-β/δ), and -γ signaling pathways in the rat.

Maternal and fetal livers shared upregulation of 16 genes and most of these shared genes were associated with fatty acid metabolism. Enoyl-CoA, hydratase/3-hydroxyacyl-CoA dehydrogenase *(Ehhadh*) was the most highly upregulated gene in both the maternal (fifty-five-fold at 500 mg/kg/day) and fetal (321-fold at 500 mg/kg/day) livers. Other shared upregulated genes were associated with adipogenesis (e.g., *Ech1*), PPAR transcription factors (e.g., *Rxrg*), and PPAR ligand transporters (e.g., *Slc27a5*). Generally, the fetal liver tended to display a greater sensitivity to HFPO dimer acid ammonium salt exposure with respect to the number of genes upregulated and the magnitude of upregulation. For example, the fetal liver exhibited upregulation of 12 genes that were not affected in the maternal liver (e.g., *Pck1, Aqp7, Gk* (gluconeogenesis) and *Angptl4* (lipid transport)). Additionally, all but one of the upregulated genes shared by maternal and fetal livers (i.e., *Ech1*) was upregulated to a greater extent in the fetal liver. In maternal livers, the genes most sensitive to HFPO dimer acid ammonium salt exposure were *Ech1* and *Rxrg* and, in the fetal livers, *Cpt1b* (mitochondrial fatty acid metabolism), *Acox1* (fatty acid metabolism) and *Angptl4* were the most sensitive. These genes were significantly increased at 1 mg/kg/day of HFPO dimer acid ammonium salt.

Overall, Conley et al. (2019) concluded that HFPO dimer acid ammonium salt activated PPAR signaling pathways in maternal and fetal livers, but the effects observed in this study are not exclusive to PPARα or even general PPAR signaling.

Conley et al. (2019) also measured fetal testis testosterone production and gene expression to understand if HFPO dimer acid ammonium salt exposure produces effects similar to those of some phthalate ester metabolites. Fetal testes were collected from male pups on GD18, with a single testis from the first three male pups used for the *ex vivo* testosterone production assay and the remaining testes for gene expression analysis. Unlike some phthalate ester metabolites, there was no effect of HFPO dimer acid ammonium salt exposure on fetal testis testosterone production or on the expression of genes that are typically changed in the fetal testis by exposure to phthalates (e.g., steroidogenic enzymes).

HFPO dimer acid ammonium salt was also assessed for *in vitro* agonism and antagonism of transcriptional activation for estrogen (100 picomolar (pM) to 10 μM), androgen (100 pM to 100 μM), and glucocorticoid (100 pM to 100 μM) receptors (Conley et al., 2019). HFPO dimer acid ammonium salt displayed no agonism of any of the receptors. At 100 μM, the study authors classified HFPO dimer acid ammonium salt antagonism as slight for the glucocorticoid receptor (28% reduction in luciferase expression) and as moderate for the androgen receptor (AR) (42% reduction in luciferase expression). The study authors noted that the 100 μM dose was approaching the cytotoxic dose of 300 μM.

EPA concluded that the study NOAEL is 62.5 mg/kg/day and the LOAEL is 125 mg/kg/day based on the indications of reduced BW in F_1 females and tissue weights in F_1 animals, decreased maternal GWG, and decreased maternal serum total T4 levels. Although maternal serum total T3 levels were significantly decreased compared to control at 30 mg/kg/day, EPA selected the LOAEL at 125 mg/kg/day because the deiodination of free T4 results in the formation of T3 (Forhead and Fowden, 2014), and T4 is the thyroid hormone that preferentially crosses the placenta of humans and rodents during early gestation (Calvo et al., 2002).

Blake et al. (2020)

Blake et al. (2020) evaluated the effects of gestational PFOA and HFPO dimer acid exposure on maternal and embryonic endpoints in mice. Pregnant CD-1 dams were dosed from E1.5 to E11.5 or E17.5 with either deionized water (vehicle control), 1 or 5 mg/kg/day PFOA, or 2 or 10 mg/kg/day HFPO dimer acid. PFOA results, as they compare to HFPO dimer acid, are presented in section 2.3.3. These time points were selected because the placenta had not fully matured at E11.5 and this time point overlaps with critical periods of placental development, including vascularization with the uterine wall and chorioallantoic branching of vessels. The E17.5 time point was selected to capture treatment-related effects on embryo weight and because the placenta is fully mature at E17.5.

Blake et al. (2020) evaluated albumin, ALP, ALT, AST, BUN, total cholesterol, creatine, glucose, HDL, LDL, SDH, total bile acid, total protein, triglycerides, and urinary creatine in maternal serum at E11.5 and E17.5. Total cholesterol and HDL were significantly increased 66% and 56%, respectively, compared to vehicle control in the 2 mg/kg/day HFPO dimer acid-dose group at E11.5, but these effects did not reach statistical significance at E17.5. Additionally, serum triglyceride levels were significantly decreased at 2 mg/kg/day (-43%) and 10 mg/kg/day (-61%) of HFPO dimer acid at E11.5 and remained significantly decreased in the 10-mg/kg/day (-74%) dose group at E17.5. Finally, serum ALP was significantly increased (53%) compared to vehicle control at E17.5 in the 10-mg/kg/day HFPO dimer acid-dose group.

Absolute and relative maternal liver weights significantly increased compared to vehicle control at both time points and in both HFPO dimer acid dose groups. Specifically, absolute liver weight increased by 41% and 91% and relative liver weights increased 37% and 73% compared to vehicle control at 2 and 10 mg/kg/day, respectively, at E11.5. At E17.5, absolute liver weight increased by 30% and 70% and relative liver weights increased 31% and 69% compared to vehicle control at 2 and 10 mg/kg/day, respectively. A variety of hepatocellular lesions were observed to increase as compared to vehicle control, including cytoplasmic alteration, mitotic figures, cell death (included both apoptosis and single-cell necrosis), and vacuolation. At E11.5, all dosed livers presented with cytoplasmic alteration, which increased in severity at the 10 mg/kg/day HFPO dimer acid dose. Mitotic figures and cell death increased in both dose groups and vacuolation rated as minimal was observed in 100% of the 10 mg/kg/day-dose group livers. At E17.5, all dosed livers presented with more severe cytoplasmic alteration than at E11.5, and this cytoplasmic alteration was most severe in the 10-mg/kg/day HFPO dimer acid-dose group. Mitotic figures were no longer increased at E17.5 and increased cell death was only observed in the 10-mg/kg/day-dose group. Vacuolation rated as minimal and mild was observed in the 10-mg/kg/day-dose group. Additionally, a portion of E17.5 livers from all dose groups were processed for transmission electron microscopy (TEM). As compared to vehicle control, the livers from the 2- and 10-mg/kg/day HFPO dimer acid-dose groups exhibited “abnormal ultrastructure with enlarged hepatocytes containing more abundant cytoplasmic organelles consistent with mitochondria and peroxisomes and vacuolation” (Blake et al., 2020). Additionally, the livers in the 10-mg/kg/day HFPO dimer acid-dose group presented “vacuolation often with remnant membrane material as myelin figures, abundant rough endoplasmic reticulum with few ribosomes present, and unevenly dispersed glycogen appearing as clustered clumps” (Blake et al., 2020).

Absolute and relative kidney weights were unchanged at E11.5. Absolute (19%) and relative (16%) kidney weight was increased compared to vehicle control in the 10-mg/kg/day HFPO dimer acid-dose group at E17.5. No histopathologic changes in kidneys were noted in any dose groups.

GWG was significantly increased (30%) relative to vehicle control at E11.5 in the 10-mg/kg/day HFPO dimer acid-dose group. When controlling for litter size, GWG was significantly greater in the 10-mg/kg/day HFPO dimer acid-dose group than in vehicle control at both E11.5 (7.1%) and E17.5 (19.1%). Finally, GWG was significantly increased compared to vehicle control at 2 mg/kg/day and 10 mg/kg/day at E17.5 using effect estimates from mixed effect models adjusting for repeated measures of relative GWG, litter size, and embryonic day.

Implantation sites, viable embryos, nonviable embryos, and resorptions were not significantly different than vehicle control in any dose group. Placental weight was significantly increased by ~15.5 milligrams (mg) and the embryo:placental weight ratio significantly decreased by 15% in the 10-mg/kg/day HFPO dimer acid-dose group relative to vehicle control at E17.5. Additionally, placentas from litters (an average of seven individual placentas per litter) per treatment group and sacrifice time point were evaluated for histopathology. There were no significant histopathological changes at E11.5 between vehicle control and the HFPO dimer acid dose groups, with nearly all the placentas evaluated within normal limits. However, 58% and 83% of placentas evaluated at E17.5 were classified as abnormal in the 2 and 10 mg/kg/day HFPO dimer acid dose groups, respectively, compared to 2% in the vehicle control group. The number of abnormal placentas in the 10 mg/kg/day HFPO dimer acid dose group was significantly different than vehicle control. The most frequent lesion detected was labyrinth atrophy, which was observed in 0/41 (0%), 15/31 (48%), and 16/35 (46%) placentas in 0-, 2-, and 10-mg/kg/day-dose groups, respectively. Labyrinth congestion and early fibrin clots increased with increasing HFPO dimer acid dose. Specifically, labyrinth congestion was observed in 0/41 (0%), 1/31 (3%), and 8/35 (23%) placentas in 0-, 2-, and 10-mg/kg/day-dose groups, respectively, and early fibrin clot was observed in 0/41 (0%), 1/31 (3%), and 4/35 (11%) placentas in 0-, 2-, and 10-mg/kg/day-dose groups, respectively. Placental lesions were evaluated against the proportion of placentas within a litter within normal limits to account for litter effects, and the proportion of abnormal placentas was significantly higher at the 2- and 10-mg/kg/day HFPO dimer acid-dose groups relative to vehicle control. Finally, placental thyroid hormones (reverse triiodothyronine (rT3), T3, and T4) were quantified at E17.5 from 2-3 pooled placental tissues of same-sex embryos. Each pooled sample was considered as one biological replicate and three replicates were used for each sex and treatment group. There was no significant effect of sex or treatment on rT3, T3, T3:T4 ratio, or rT3:T4 ratio. A significant increase (60%) in T4 relative to vehicle control was reported for the 10-mg/kg/day HFPO dimer acid-dose group.

The authors noted that, in some HFPO dimer acid-exposed dams, gross anomalies were apparent, including excess abdominal fluid, edematous tissues, and clotted placentas.

EPA concluded that there is no NOAEL for this study because the study LOAEL is 2 mg/kg/day, which is the lowest dose tested. The LOAEL is based on increased incidence of placental lesions within a litter and increased GWG using effect estimates from mixed-effect models adjusting for repeated measures of relative GWG, litter size, and embryonic day in maternal mice.

Conley et al. (2021)

In a follow-up to their 2019 study, Conley et al. (2021) reported on two experiments evaluating the effects of oral gestational exposures to HFPO dimer acid ammonium salt. In one experiment, pregnant Crl:CD(SD) rats were dosed once daily by gavage from GD16 to GD20 with either water (control) or 1, 3, 10, 30, 62.5, or 125 mg/kg/day of HFPO dimer acid ammonium salt. HFPO dimer acid purity was 100% as determined by the supplier via perchloric acid titration. The study authors stated that the experiment was completed in two separate "blocks" of animals (15 animals/block). There were three control animals/block (total of six control animals) and two animals/treatment group/block (total of four treated animals/group). In both blocks, dams and fetuses were euthanized on GD20 and maternal and fetal sera were collected for determining HFPO dimer acid concentrations (see section 2.3.3 for detail). Maternal serum was also analyzed for thyroid hormone concentrations (total T3 and total T4) and clinical chemistry parameters (ALT, AST, triglycerides, cholesterol, albumin, and glucose (non-fasting)). Maternal weight gain, reproductive output (number of fetuses and resorptions), and maternal liver weight were measured. Maternal liver samples were collected for determining HFPO dimer acid concentrations and gene expression analyses. In the first block, two male and two female fetuses were randomly selected from each litter for measurements of body and liver weight and HFPO dimer acid concentration in liver samples. The individual body weights of the remaining fetuses were recorded irrespective of sex. Because there was no indication of an effect of sex on fetal body weight in the first block, body weights in the second block were recorded for three randomly selected fetuses per litter (irrespective of sex); out of those fetuses, one was randomly selected per litter to determine liver weight and HFPO dimer acid concentration in the liver and for gene expression analyses.

There were no significant differences observed for fetal body weight or liver weight (broken out by sex or combined), maternal body weight gain, or maternal terminal body weight in any dose groups compared with controls. Maternal liver weight was increased at 62.5 and 125 mg/kg/day. Maternal serum T3 and T4 levels were decreased at doses ≥62.5 mg/kg/day. Albumin was decreased at 3, 62.5, and 125 mg/kg/day. Triglycerides were decreased at doses ≥10 mg/kg/day and cholesterol was decreased at doses ≥30 mg/kg/day. There were no significant effects on the numbers of viable fetuses or resorptions in any dose groups compared with controls.

In another experiment reported in Conley et al. (2021), pregnant Crl:CD(SD) rats (five per group) were dosed once daily by gavage from GD8 to PND2 with either water (control) or 10, 30, 62.5, 125, or 250 mg/kg/day of HFPO dimer acid ammonium salt. Dams gave birth naturally and were checked for parturition beginning on GD22. Once delivery was complete, pups were counted and the litter weight was recorded. All pups were returned to the nest except for two randomly selected pups per litter that were sacrificed. Trunk blood was collected, and serum was analyzed for HFPO dimer acid concentration and clinical chemistry parameters. Livers were collected for histopathological examination and gene expression analyses. The carcasses of three deceased newborn pups (one each from 30, 125, and 250 mg/kg/day dose groups) were sent for histopathological examination. On PND2, dams received their final dose in the morning and were weighed and euthanized 2–5.5 hours later. Maternal trunk blood was collected, and serum was analyzed for thyroid hormone concentrations (total T3 and total T4), clinical chemistry parameters (ALT, AST, triglycerides, cholesterol, albumin, and glucose (non-fasting)), and HFPO dimer acid concentration. Maternal liver weight was recorded, and liver samples were collected for gene expression analyses and HFPO dimer acid determination. Uterine implantation

sites were scored. The pups were sexed and weighed, anogenital distance was measured, trunk blood was collected, liver weight was recorded (one male and one female per litter), and liver samples were analyzed for HFPO dimer acid concentration. PND2 pup serum was analyzed for clinical chemistry parameters (ALT, AST, triglycerides, cholesterol, albumin, and glucose (non-fasting)) and HFPO dimer acid concentration.

All pups were alive at birth with no remarkable gross external malformations. Dams displayed typical nesting behaviors; however, shortly after delivery, pups in the higher dose groups began displaying lethargy, morbidity, or were found dead. Pups continued to die or require euthanasia throughout PND0 and PND1. Pup survival was reduced on PND1 and PND2 at doses ≥62.5 mg/kg/day. Many of the pups that died had visible milk bands indicating they had nursed. Pup survival scores on PND2 were 100 ± 0, 96 ± 2, 97 ± 2, 87 ± 5, 38 ± 13, and 5 ± 5% in the 0, 10, 30, 62.5, 125, 250 mg/kg/day groups, respectively. Pup survival scores were significantly decreased at doses ≥62.5 mg/kg/day Pup body weight gain (birth to PND2) and PND2 body weight in the surviving pups were both reduced at doses ≥30 mg/kg/day. Anogenital distance was not affected in male or female pups, but relative liver weight was increased in all dose groups. No remarkable histopathological lesions were observed in pup livers, but glycogen accumulation scores in the liver were significantly lower in all dose groups compared with control pups. Significant changes were observed in some pup serum clinical chemistry parameters. Glucose was decreased at doses ≥62.5 mg/kg/day in newborn pups and at doses ≥125 mg/kg/day in PND2 pups. Albumin was decreased at 62.5 and 250 mg/kg/day only in newborn pups. Cholesterol was increased at doses ≥125 mg/kg/day in newborn pups and at doses ≥62.5 mg/kg/day in PND2 pups. Triglycerides were increased at doses ≥125 mg/kg/day in newborn pups, and AST was increased at doses ≥30 mg/kg/day in PND2 pups.

Purple discoloration of the entire right hind limb was observed in one pup each from the 30, 125, and 250 mg/kg/day dose groups beginning on PND1 and those pups were examined for histopathology. All three had milk protein in the stomach lumen, vascular thrombi in various vessels, and small dense basophilic cells throughout liver lobes. The two from the higher dose groups also had moderate subcutaneous hemorrhage in the area of the umbilical artery and vein. Subcutaneous edema or vascular congestion of the lower limb was observed in the pups from the 30 and 250 mg/kg/day dose groups.

A variety of significant adverse effects were observed in the dams. Maternal body weight (on GD22 and PND2) and gestational weight gain were reduced at doses ≥125 mg/kg/day. At necropsy on PND2, maternal absolute liver weight was increased at doses ≥30 mg/kg/day, and relative liver weight was increased at all dose levels. There was no significant effect on the number of uterine implants. Maternal serum total T3 and T4 levels were decreased at doses ≥62.5 mg/kg/day (with the exception of T3 at 250 mg/kg/day). Albumin was decreased at 250 mg/kg/day, and triglycerides were increased at 125 and 250 mg/kg/day. Serum AST was increased at all dose levels. The study authors noted that, even though maternal serum and levels of HFPO dimer acid ammonium salt did not increase when dosing was extended from 4 days in the fetal study to 16 days in the postnatal study (see section 2.3.3), maternal liver weight was more affected in the postnatal study and at lower dose levels.

Conley et al. (2021) also conducted gene expression analyses using liver samples from both experiments (GD16–20 and GD8–PND2) to determine if HFPO dimer acid ammonium salt activates PPAR signaling pathways or alters genes related to glucose and glycogen metabolism.

Gene expression was assessed using reverse transcriptase real-time polymerase chain reaction (PCR) of complementary deoxyribonucleic acid (DNA) synthesized from ribonucleic acid (RNA) extracted from sample homogenates. Maternal (GD20), fetal (GD20), and neonatal (PND0) livers were assessed for 84 target genes relevant to PPARα, PPARβ/δ, and PPAR-γ signaling pathways in the rat. Fetal and neonatal livers were also assessed for 84 genes involved in the regulation and enzymatic pathways of glucose and glycogen metabolism.

Expression of five genes related to glucose metabolism were affected in the GD20 fetal livers. Four genes (*Pck1, Pdk4, G6pc, Pdp2*) were significantly upregulated compared with controls and one (*Ugp2*, critical to glycogen synthesis) was significantly downregulated. All genes were significantly different at doses ≥10 mg/kg/day, except for *G6pc* (critical to gluconeogenesis) which was significantly different at doses ≥3 mg/kg/day. *Pck1* (critical to gluconeogenesis) was the most highly upregulated gene (37.5-fold compared with control at the highest dose). No genes were significantly affected at 1 mg/kg/day.

Conley et al. (2021) compared the gene alterations observed in PPAR signaling pathways for fetal livers exposed GD16 to 20 (this study) with those exposed GD14 to 18 (reported in Conley et al., 2019). All 28 genes involved in PPAR signaling that were significantly upregulated on GD18 were also upregulated on GD20, and 16 of these genes had a highly significant interval effect with greater upregulation on GD20 than on GD18. The remaining upregulated genes did not differ significantly between GD18 and GD20. There were no significantly downregulated PPAR signaling genes. Overall, Conley et al. (2021) concluded that greater gene expression effects were observed later in gestation on genes that code for proteins critical to mitochondrial (*Acaa2, Acadm, Cpt1a*) or peroxisomal (*Acox1, Ech1, Ehhadh*) fatty acid β-oxidation or both (*Mlycd*), gluconeogenesis (*Pck1*), glycerol metabolism (*Gk*), fatty acyl-CoA conversion (*Acsl1, Acsl3*), mediation of triglyceride clearance (*Angptl4*), triglyceride biosynthesis (*Dgat1*), fatty acid biosynthesis (*Fads2, Scd1*), and PPAR coactivation (*Rxrg*).

Analysis of maternal livers showed that the 19 PPAR signaling genes that were upregulated on GD18 (Conley et al., 2019) were also upregulated on GD20, and seven of those showed greater upregulation on GD20. The upregulated genes code for proteins critical to mitochondrial and peroxisomal fatty acid β-oxidation, ketogenesis, fatty acid transport, fatty acyl-CoA conversion, triglyceride turnover, carnitine transport, mitochondrial protein import, accumulation of reactive oxygen species, and transcriptional coactivation. Conley et al. (2021) concluded that the data from this study provide evidence for PPARα activation in the maternal, fetal, and neonatal livers following exposure to HFPO dimer acid ammonium salt.

Gene expression analyses of newborn pup livers showed that 13 glucose metabolism genes were upregulated and 15 were downregulated, 11 of which were significantly different from controls in all dose groups. *Pdk4* was upregulated and *Ugp2* was downregulated, similar to fetal livers, but *Pck1* and *G6pc* were unaffected. The most highly affected upregulated genes were *Fbp2* (gluconeogenesis) and *Ldha* (anaerobic glycolysis); the most highly affected downregulated genes included *Aldob* (glycolysis), *Agl* (glycogen degradation), *Ugp2* (glycogen synthesis), and *Gsk3a* (glycogen synthesis). There were 21 upregulated and 8 downregulated PPAR signaling pathway genes, 21 of which were significantly different from controls in all dose groups. Several gene expression changes were unique to PND0 livers including *Fabp2* (downregulated, a lipid sensor and high affinity long-chain fatty acid binding protein), *Slc27a5* (downregulated, activates very long-chain fatty acids and bile acids), *Apoc3* (downregulated, associated with metabolism of

triglyceride-rich lipoproteins), *Ppara* (downregulated, codes for the PPAR alpha nuclear receptor), and *Cd36* (upregulated, has pleiotropic effects associated with angiogenesis, inflammation, and fatty acid metabolism). Overall, Conley et al. (2021) concluded that many genes associated with carbohydrate and lipid metabolism were affected at multiple stages of development by HFPO dimer acid ammonium salt exposure.

Conley et al. (2021) observed multiple significant adverse effects when dams were dosed with HFPO dimer acid ammonium salt from GD8 to PND2. Significant pup mortality was observed at doses ≥62.5 mg/kg/day and growth rates were significantly lower at doses ≥30 mg/kg/day. Newborns displayed hypoglycemia at doses ≥62.5 mg/kg/day, elevated serum lipid levels at doses ≥125 mg/kg/day, and significantly lower glycogen accumulation scores in the PND2 livers of all dose groups. Maternal body weights were decreased at doses ≥125 mg/kg/day, and maternal relative liver weight was increased in all dose groups. Maternal serum total T3 and T4 levels were decreased at doses ≥62.5 mg/kg/day (with the exception of T3 at 250 mg/kg/day). The authors noted that disruption of carbohydrate and lipid metabolism across the maternal-placental-fetal unit (beginning in the 1 mg/kg/day dosing group) were likely key events in the observed adverse effects, including decreases in pup body weight and survival. EPA concluded that the study NOAEL is 10 mg/kg/day and the LOAEL is 30 mg/kg/day based on reduced BW in F_1 pups at PND0 and PND2.

4.6 Other Studies

4.6.1 Immunotoxicity Studies

Rushing et al. (2017)
Male and female C57BL/6 mice (6–12/sex/group) were administered HFPO dimer acid by gavage at doses of 0, 1, 10, or 100 mg/kg/day for 28 days (Rushing et al., 2017). The animals were immunized with sheep RBC antigen on day 24 and, 5 days later, were evaluated for TDARs and splenic lymphocyte subpopulations. Organs were collected 1 day after the final gavage exposure.

T lymphocyte numbers were significantly increased (the average increase of $CD8^+$, $CD4^+/CD8^+$, and $CD4^-/CD8^-$ T cells was 74%) in males at 100 mg/kg/day, yet suppression of TDAR was observed in female mice only at 100 mg/kg/day. TDAR suppression was measured through immunoglobulin M (IgM) antibody production, which decreased by 7.3% in females at the high dose. Liver weight relative to BW significantly increased (40%–160%) in both sexes at 10 mg/kg/day in a dose-dependent manner. Relative spleen weights significantly decreased by 11% in females treated with 100 mg/kg/day, and there were no significant changes in thymus weight.

Peroxisomal fatty acid oxidation was measured using hepatic acyl-CoA oxidase activity as a readout. In male mice, hepatic acyl-CoA oxidase activity increased 122% and 222% at 10 mg/kg/day and 100 mg/kg/day, respectively. Female mice had a 100% increase in acyl-CoA oxidase activity at the highest dose tested. The NOAEL for immune effects that include TDAR suppression in females and increased T cells in males is 10 mg/kg/day.

4.6.2 Mechanistic Studies

The studies in this section provide mechanistic insight into the effects of HFPO dimer acid and/or its ammonium salt. Available studies address biological mechanisms applicable to liver

effects, serum lipids and lipoproteins, thyroid hormones, and developmental effects. Of note, many of the studies outlined here report using dimethyl sulfoxide (DMSO) to prepare HFPO dimer acid or its ammonium salt. This is important because a 2020 publication (Gaballah et al., 2020) demonstrates that HFPO dimer acid is unstable in DMSO but is stable in deionized water. Where reported, EPA has listed the vehicle that the study authors used to dissolve these chemicals and the vehicle control.

Wang et al. (2017)

In one study investigating changes in gene expression, male ICR mice (*n*=12/group) were administered either (control) or 1 mg/kg/day HFPO dimer acid ammonium salt prepared in 0.5% Tween-20 via oral gavage for 28 days (Wang et al., 2017). Although the authors state that HFPO dimer acid was tested and its chemical structure is presented, the CASRN is listed as 62037-80-3, which is the HFPO dimer acid ammonium salt. Nevertheless, whether the chemical evaluated was the acid or the ammonium salt does not impact the form dissolved in serum or plasma. In both cases, the HFPO dimer anion is present in solution.

At the end of 28 days, blood samples were collected and analyzed. After sacrifice the liver was recovered for measurement of organ weight and histological examination. High-throughput ribonucleic acid (RNA)-sequencing was conducted to gain mechanistic insights into the observed liver effects. Liver tissue samples from three controls and three treated animals were frozen for RNA isolation, library preparation, and sequencing.

Statistically significant treatment-related findings reported include increased absolute liver weight (31%) and relative liver weight (28%), ALP (51%), LDL cholesterol (50%), decreased total bilirubin (-37%), and decreased direct bilirubin (-45%) when compared to control. Qualitative hepatic histopathological findings documented abnormalities from the treated animals, including lipid droplet accumulation, hepatocellular hypertrophy, mild steatosis, and karyolysis.

High-throughput RNA-sequencing of liver tissues resulted in the identification of 146 transcripts (101 upregulated and 45 downregulated) with altered differential gene expression due to treatment with the HFPO dimer. Pathway analyses (using the National Center for Biotechnology Information, Ensemble, gene ontology, and Kyoto Encyclopedia of Genes and Genomes databases) revealed four enriched pathways from these altered hepatic transcripts: the PPAR signaling pathway, arachidonic acid (an essential polyunsaturated fatty acid) metabolism, retinol metabolism, and fatty acid degradation. All four of these pathways are associated with lipid metabolism. Gene ontology analyses of the 146 altered transcripts identified several other enriched processes, cellular components, and molecular functions related to immune system function, lipid metabolism, membrane parameters, and others that were altered by HFPO dimer acid treatment.

Behr et al. (2018)

H295R, MDA-kb2, HEK293T, LNCaP, and MCF-7 cell lines were cultured and incubated with various individual PFAS in a variety of experiments to investigate effects on cytotoxicity, estrogen and AR activity, and steroidogenesis (Behr et al., 2018). The study authors do not report how the HFPO dimer acid ammonium salt was prepared but report 99% purity.

The MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay was employed to assess cell viability in HEK293T, H295R, MCF-7, and LNCaP cell lines following exposure to various concentrations of each PFAS. HEK293T and LNCaP cells were exposed for 24 hours, H295R cells for 48 hours, and MCF-7 cells for 6 days. The WST-1 assay was used to determine viability of MDA-kb2 cells following 24 hours of exposure to each PFAS. Although the study authors do not report how the HFPO dimer acid ammonium salt was prepared, 0.1% DMSO was used as the vehicle control in this assy. HFPO dimer acid ammonium salt (referred to as "PMOH" (ammonium perfluoro(2-methyl-3-oxahexanoate)) in this study) was not cytotoxic in HEK293T, MDA-kb2, H295R, or LNCaP cell lines up to concentrations of 500 μM and caused cytotoxicity in the MCF-7 cell line at 500 μM.

HEK293T cells were assayed for agonistic and antagonistic estrogen receptor (ER) alpha and beta (ERα and ERβ) transactivation. None of the tested PFAS were found to affect either ERα or ERβ at the highest tested concentrations (500 μM for HFPO dimer acid ammonium salt). Estrogen co-exposure with 500 μM HFPO dimer acid ammonium salt was found to co-stimulate ERβ activity. Additionally, HFPO dimer acid ammonium salt was found to enhance estrogen-mediated ERβ activation.

The agonistic and antagonistic AR reporter gene assay was performed in MDA-kb2 cells. HFPO dimer acid ammonium salt was found to be negative for AR transactivation and inhibition up to concentrations of 100 μM. HFPO dimer acid ammonium salt enhanced dihydrotestosterone-stimulated AR activity in a dose-responsive fashion at concentrations above 50 μM.

A steroidogenesis assay was performed in which H295R cells were exposed for 48 hours and enzyme-linked immunosorbent assay (ELISA) kits were used to quantify estradiol (E2), estrone, testosterone, and progesterone levels. HFPO dimer acid ammonium salt significantly decreased testosterone at 100 μM.

An E-screen assay was used to evaluate proliferation of MCF-7 cells following 6 days of exposure to various PFAS. HFPO dimer acid ammonium salt did not significantly affect cell proliferation compared to estrogen. Exposure to high concentrations of HFPO dimer acid ammonium salt (100 μM) in combination with estrogen slightly diminished cell proliferation, but the effect was not statistically significant.

MCF-7 and LNCaP cells were cultured with HFPO dimer acid ammonium salt for 24 hours, and H295R cells were cultured for 48 hours prior to RNA extraction followed by quantitative reverse transcription PCR. HFPO dimer acid ammonium salt did not stimulate estrogenic responsive gene expression of *TFF1, GREB1, PGR, ESR1, ESR2,* or *CTSD* in MCF-7 cells, or *AR, PSA, NKX3-1, TMPRSS2,* or *CDKN1A* in LNCaP cells at concentrations up to 100 μM. Additionally, HFPO dimer acid ammonium salt did not affect expression of *CYP19A1, CYP17A1, CYP21A2, CYP11A1, STAR,* or *HSD3B* at concentrations up to 100 μM.

Sheng et al. (2018)

Sheng et al. (2018) used *in vitro* experiments to investigate perfluoroalkyl cytotoxicity and binding to proteins for HFPO dimer acid ammonium salt (referred to as "HFPO-DA" in this study), HFPO dimer acid trimer, HFPO dimer acid tetramer, PFOA, and perfluorooctane sulfonate (PFOS) in a human liver HL-7702 cell line. The study authors assessed cell viability to determine the cytotoxicity of the various perfluoroalkyl substances and used flow cytometry to

investigate effects on cell proliferation. The authors noted, however, that no effects of HFPO dimer acid ammonium salt on cytotoxicity and cell proliferation could be determined through these assays because of the chemical's low boiling point and high volatility. The study authors do not report how the HFPO dimer acid ammonium salt was prepared.

Data quantifying the HFPO dimer acid anion's ability to bind to human liver fatty acid-binding protein (hL-FABP) was also generated. Binding affinity was explored because other PFAS compounds have exhibited effective binding to hL-FABP and such binding might explain how PFAS can enter into hepatocytes, a potential target cell for HFPO dimer acid and/or its ammonium salt (Luebker et al., 2002; Sheng et al., 2016; Zhang et al., 2013). Binding affinity was measured in a fluorescence competitive binding assay and found that HFPO dimer acid anion exhibited a weaker binding affinity than PFOA or PFOS. However, the study found that the HFPO dimer acid anion fit well in the hL-FABP binding pocket with a docking energy in between PFOS and PFOA. This indicates direct interaction between the HFPO dimer acid anion and hL-FABP. Additionally, the HFPO dimer acid anion bound differently to hL-FABP than PFOA and PFOS (Sheng et al., 2018). These results were replicated using a predictive model of binding affinity to hL-FABP (Cheng and Ng, 2018).

Li et al. (2019)

Li et al. (2019) investigated the binding affinity of HFPO dimer acid (referred to as "HFPO-DA" in the paper), HFPO trimer acid (HFPO-TA), and PFOA to human and mouse PPAR gamma (PPARγ) ligand binding domains. PPARγ is a second member of the PPAR family of nuclear receptors. It functions as a regulator of cell proliferation and differentiation in addition to impacting lipid metabolism. The study authors report that HFPO dimer acid was dissolved in DMSO to make stock solutions and was reported as 97% pure. Binding affinity was measured in a fluorescence competitive binding assay. The study authors observed a higher affinity for the human PPARγ ligand binding domain for HFPO-TA and PFOA, while HFPO dimer acid bound with greater affinity for the mouse PPARγ ligand binding domain. Among the three PFAS tested, a binding potency order of HFPO-TA> PFOA>HFPO dimer acid was identified for both human and mouse ligand binding. Li et al. (2019) also assessed the activity of HFPO dimer acid, HFPO-TA, and PFOA using HEK293 cells transfected with a luciferin-tagged PPARγ vector. After exposure to HFPO dimer acid, HFPO-TA, and PFOA, the luciferase activity of the cells was quantified as an indicator of the PFAS's ability to impact PPARγ transcription. The authors conclude that HFPO dimer acid, HFPO-TA, and PFOA acted as transcriptional agonists, resulting in enhanced PPARγ transcriptional activity in a dose-dependent manner.

Because PPARγ activation is involved in the modulation of adipogenesis (Tontonoz et al., 1994), Li et al. (2019) also exposed cultured human (HPA-s) and mouse (3T3-L1) preadipocytes to the three compounds for ten days during a period of cellular differentiation into adipocytes. To quantify adipogenic activity, an Oil Red O staining assay was performed to quantify lipid accumulation using the dosed human and mouse adipocytes. HFPO dimer acid significantly increased lipid accumulation at 6 μM and 25 μM for the human HPA-s cells and mouse 3T3-L1 cells, respectively. HFPO dimer acid showed comparable or weaker adipogenesis activity than PFOA and HFPO-TA. Relative PPARγ messenger RNA (mRNA) levels were statistically significantly increased in human HPA-s cells exposed to 25 μM HFPO dimer acid and at 50 μM HFPO dimer acid in mouse 3T3-L1 cells.

Sun et al. (2019)

Three dimensional (3D) spheroids were used to evaluate the cytotoxicity of PFOA, HFPO dimer acid (referred to as "HFPO-DA" in this study) and PFO4DA (3,5,7,9-tetraoxadecanoic perfluoro acid) (Sun et al., 2019). HFPO dimer acid was diluted with serum-free DMEM/F-12 (Dulbecco's Modified Eagle Medium: Nutrient Mixture F-12) medium and was reported as 95% pure. 3D spheroids were exposed to 100 μM of each of these three substances for 28 days. No changes in adenosine triphosphate (ATP) content or albumin secretion were observed. Lactic dehydrogenase and reactive oxygen species levels were significantly increased (compared with controls) after PFOA, HFPO dimer acid, or PFO4DA exposure. A 1.5- to twofold increase in *Scd1* expression (compared with control) was observed in PFOA, HFPO dimer acid, and PFO4DA exposure groups. PFOA exposure, but not HFPO dimer acid exposure, significantly increased PPARα expression compared to the control. For the apoptosis-related genes, PFOA exposure significantly increased expression of *caspase3*, *p53*, and *p21* compared to control, whereas HFPO dimer acid exposure produced no changes. For the oxidative stress genes, only PFOA significantly increased *Nqo1* expression, and PFOA, HFPO-dimer acid, and PFO4DA all significantly induced expression of *Gsta2* and *Ho-1*.

Xin et al. (2019)

Estrogenic effects of PFOA and HFPO dimer acid (referred to as "HFPO-DA" in this study) were evaluated in a series of *in vitro* assays (Xin et al., 2019). All tests were also performed on additional HFPO homologs (HFPO-TA and hexafluoropropylene oxide tetramer acid (HFPO-TeA)). HFPO dimer acid was prepared in DMSO at a concentration of 20 millimolar (mM) and was reported as 97% pure.

HFPO dimer acid binding affinity to the human ERα and ERβ ligand binding domains were compared to that of PFOA using a fluorescence polarization-based competitive fluorescence binding assay. HFPO dimer acid did not bind either ERα or ERβ (not detected; no IC_{50} (concentration at which 50% inhibition is observed) could be derived). PFOA displaced estrogen in a concentration-dependent manner, with IC_{50} values of 469.5 μM for ERα and 384.4 μM for ERβ.

The cytotoxic effects of HFPO dimer acid at concentrations ranging from 0.8 to 1,600 μM were determined in MVLN cells using the WST-1 assay. HFPO dimer acid produced no cytotoxicity, whereas PFOA inhibited cell viability at concentrations above 800 μM. MVLN cells were also exposed to PFOA or HFPO dimer acid at concentrations ranging from 1.6 to 800 μM, with or without E2 for 12 or 24 hours, and estrogenic/anti-estrogenic activity was assessed. Exposure to HFPO dimer acid did not result in any effects on ERs. PFOA exposure resulted in concentration-dependent antagonism of ERs and PFOA was also found to compete with E2 to activate ERs.

ELISA kits were used to measure E2, testosterone, and vitellogenin (VTG) in wildtype zebrafish larvae exposed to 0.4 or 1.6 μM PFOA or HFPO dimer acid for 168 hours post-fertilization. HFPO dimer acid and PFOA significantly increased E2, testosterone, and VTG compared to controls in all dose groups, except for VTG levels at 0.4 μM HFPO dimer acid.

Molecular docking and molecular dynamics simulations were performed using AutoDock 4.2 to compare binding interactions of HFPO dimer acid and PFOA with ERα and ERβ. The simulations illustrated that both HFPO dimer acid and PFOA fit into the binding cavity of ERα

and ERβ. The calculated energies from the simulations indicated that the order of the binding affinity for these compounds is HFPO-TeA > HFPO-TA > PFOA > HFPO dimer acid.

Behr et al. (2020)

The cytotoxicity, human nuclear receptor activation, and gene expression changes induced by HFPO dimer acid ammonium salt (referred to as "PMOH" (ammonium perfluoro(2-methyl-3-oxahexanoate)) in this study) was investigated *in vitro* using HEK293T and HepG2 cells. Seven other PFAS (PFOA, PFOS, PFHxA, perfluorobutanesulfonic acid (PFBS), PFBA, PFHxS, and 3H-perfluoro-3-((3-methoxypropoxy) propanoic acid (PMPP) were also analyzed in this study (Behr et al., 2020). The study authors do not report how the HFPO dimer acid ammonium salt was prepared.

The cytotoxicity of HFPO dimer acid ammonium salt was assessed in HepG2 cells. The cells were exposed to 50–500 μM of HFPO dimer acid ammonium salt for 24 hours, and cellular viability was determined using the MTT assay. Cell viability was not significantly decreased at any concentration.

Luciferase-based reporter gene assays were used to determine the ability of HFPO dimer acid ammonium salt to activate various human nuclear receptors that function in the regulation of lipid or xenobiotic metabolism. HEK293T cells were transfected with expression plasmids for hCAR, hFXR, hLXRα, hPPARα, hPPARδ, hPPARγ, hPXR, hRARα, or hRXRα. The cells were co-transfected with a luciferase reporter plasmid and the *Renilla*-luciferase construct pcDNA3-Rluc for normalization. Positive controls were included. Receptor activity was measured after 24 hours of exposure to 25, 50, or 100 μM of each chemical. Values were normalized to *Renilla reniformis* luciferase activities and compared to untreated cells. HFPO dimer acid ammonium salt significantly induced PPARα activation (sevenfold) at 25 μM and higher. HFPO dimer acid ammonium salt also significantly induced activation of PPARγ (2.4-fold) at 100 μM. The other human nuclear receptors were not significantly affected. Reporter gene assays for PPARα were repeated for PFOA and PMOH using concentrations up to 250 μM. Concentration-response curves were calculated and EC_{10} values were determined relative to a positive control (GW7647). HFPO dimer acid ammonium salt activated PPARα to a level of 10% at 5 μM, and a comparable activation was induced by PFOA at 50 μM.

HepG2 cells were exposed to concentrations up to 250 μM HFPO dimer acid ammonium salt for 24 hours, and the RNA was extracted for analysis of PPARα-dependent target gene expression. Untreated cells served as control. At 250 μM, PMOH significantly induced expression of *CPT1A* (1.7-fold), *HMGCS2* (2.8-fold), and *PLIN2* (1.4-fold). Compared to PFOA, the effects of PMOH were not as substantial. PFOA produced similar effects on the target genes as PPARα agonists GW7647 and WY14,643.

Although HFPO dimer acid ammonium salt was a more potent PPARα agonist than PFOA under the conditions of this study, it produced weaker effects on PPARα-dependent target gene expression.

Wen et al. (2020)

The epigenetic toxicities of HFPO dimer acid (referred to as "GenX" in this study) and PFOA were explored and compared *in vitro* using a liver hepatocellular carcinoma cell line (Wen et al., 2020). HepG2 cells were exposed to concentration gradients of the ammonium salt form of

PFOA (20–600 μM) or HFPO dimer acid (20–1,000 μM) for 48 hours. The test chemicals were first dissolved in DMSO (< 0.4% volume/volume), and vehicle controls were included. HFPO dimer acid was reported as 97% pure.

The MTT and neutral red assays were used to assess cell metabolism rates and viability. Following HFPO dimer acid exposure, cell metabolic activity was only slightly increased at all concentrations compared to control. Cell viability was increased from 20 to 200 μM, and then decreased linearly from 200 to 1,000 μM.

Following PFOA exposure, cell metabolic activity increased in a concentration-dependent fashion from 0 to 100 μM, peaked at 100 μM, and decreased in a concentration-dependent fashion from 100 to 400 μM. Cell viability decreased with increasing PFOA concentration (decreased by 87% at 600 μM).

Gene expression analysis was performed for 22 genes related to cell cycle, proliferation, apoptosis, and lipid metabolism. HepG2 cells were cultured in flasks and treated with 100–600 μM HFPO dimer acid for 48 hours, and the RNA was extracted for gene expression analysis. Overall, HFPO dimer acid did not have a strong impact on the genes examined; expression of most lipid metabolism and transport-related genes was either decreased or not significantly affected by HFPO dimer acid. In contrast, expression of lipid synthesis-related genes was mostly elevated, and expression of lipid transport genes was mostly decreased by PFOA.

Global methylation assays were performed using genomic DNA from HepG2 cells extracted immediately after the treatment period. Expression profiles of 10–11 translocation methylcytosine dioxygenases (*TET*s) and DNA methyltransferases (*DNMT*s) were also evaluated. In HFPO dimer acid-treated cells, global methylation (5mc) levels significantly decreased from 100 to 400 μM, and then increased from 600 to 800 μM. GenX caused decreased expression of *DNMT*s but had no clear effect on *TET*s. PFOA caused a significant, concentration-dependent decrease in global methylation (5-mC) levels from 20 to 400 μM, and significant concentration-dependent changes in *TET*s (*TET1* decreased whereas *TET2* and *TET3* increased with increasing PFOA concentration), but no significant trends in the expression of *DNMT*s.

Cannon et al. (2020)

The effects of HFPO dimer acid ammonium salt (referred to as “GenX” in this paper) on expression and activity of three ATP binding cassette (ABC) transporters at the blood-brain barrier were studied using rat brain capillaries exposed *ex vivo* to low nanomolar (nM) concentrations (Cannon et al., 2020). Rats were also exposed to 97% pure HFPO dimer acid ammonium salt *in vivo* followed by *ex vivo* measurement of transport activity. ATPase levels were measured *in vitro*, and protein levels were measured with Western blotting. The cytotoxicity of HFPO dimer acid ammonium salt was assessed using two human cell lines. HFPO dimer acid ammonium salt was prepared in fresh DMSO (0.1% volume/volume) prior to each experiment.

The brains from 4–6 male or female Hsd:Sprague Dawley rats (age 12–15 weeks) were harvested and capillaries were isolated from cortical gray matter. Capillaries were exposed to varying concentrations of HFPO dimer acid ammonium salt (0.01–1,000 nM) for 3 hours and P-glycoprotein (P-gp), breast cancer resistance protein (BCRP), and multidrug resistance-

associated protein 2 (MRP2) transporter activities were measured with a confocal microscopy-based method. Hourly changes in transport activities were also measured during a 4-hour exposure to 100 nM HFPO dimer acid ammonium salt. In addition, reversibility assays were performed using 100 nM HFPO dimer acid ammonium salt exposure for 1 hour for P-gp and 2 hours for BCRP. After transport activities were measured, HFPO dimer acid ammonium salt was removed from the assay media and transport activities were measured at 0.5, 1, 2, and 3 hours after removal. In the main assays, P-gp transport activity was significantly lower in male capillaries exposed to 0.1–100 nM HFPO dimer acid ammonium salt and in female capillaries exposed to 1.0–100 nM HFPO dimer acid ammonium salt compared with controls. P-gp transport activity was significantly decreased beginning at 15 or 30 minutes of treatment with 100 nM and persisted to the 4-hour mark. BCRP transport activity was significantly lower in male capillaries exposed to 1.0–1,000 nM HFPO dimer acid ammonium salt and in female capillaries exposed to 0.1–1,000 nM, and a significant decrease in activity during a 4-hour exposure to 100 nM was observed beginning at the 1-hour time point for both sexes. MRP2 transport activity was not significantly affected by HFPO dimer acid ammonium salt. In the reversibility assays, P-gp transport activity in capillaries from both sexes was restored to control levels within 1 hour of HFPO dimer acid ammonium salt removal, but BCRP transport activity remained lowered for 2 hours after removal for both sexes.

A reconstituted transport assay system containing vesicle membranes and transport proteins was used to determine the effects of HFPO dimer acid ammonium salt on transport-associated ATPase activity *in vitro*. Purified P-gp and BRCP transport proteins were exposed to 0.001–1.0 μM HFPO dimer acid ammonium salt for 20 minutes and the enzymatic hydrolysis of ATP to inorganic phosphate was measured. The substrate was stimulated with paclitaxel for P-gp and sulfasalazine for BCRP. HFPO dimer acid ammonium salt did not alter ATPase activity associated with P-gp or BCRP transport either when the substrate was stimulated or when no substrate was added, indicating that HFPO dimer acid ammonium salt was not a substrate for either transporter using this particular *in vitro* reconstituted transport assay system.

Isolated brain capillaries pooled from male or female rats (n=6 rats/sex) were exposed to 100 nM HFPO dimer acid ammonium salt for 4 hours, and P-gp and BCRP protein levels were measured by Western blotting. No significant differences in P-gp or BCRP protein levels were identified for treated capillaries compared with control (vehicle-treated) capillaries for either sex.

Isolated brain capillaries from male or female rats (n=6 rats/sex) were also treated with HFPO dimer acid ammonium salt (1.0 or 100 nM) for 4 hours with or without the PPARγ inhibitor GW9662. HFPO dimer acid ammonium salt decreased P-gp transport activity at both concentrations for both sexes compared with controls. The addition of GW9662 blocked the reduction in activity in male capillaries at both concentrations, but only at 1.0 nM HFPO dimer acid ammonium salt in female capillaries. BCRP transport activity was lowered by treatment at both concentrations in both sexes, and co-treatment with GW9662 had no effect on the reduced BCRP transport activities for either sex.

Male and female Hsd:Sprague Dawley rats (5/sex/group) were administered a single oral gavage dose of 0, 10, 100, or 1,000 ng/kg (30 picomole (pmol)/kg, 300 pmol/kg, or 3 nanomole/kg) of HFPO dimer acid ammonium salt and sacrificed 5 hours later. Brains from each dose group were pooled, and capillaries were isolated for measurement of P-gp and BCRP transport activities. All

dose levels produced significant decreases in P-gp and BCRP transport activities in both sexes compared with controls.

Cell survival following HFPO dimer acid ammonium salt exposure was determined using the human ovarian cell line NCI/ADR-RES (with high P-gp expression) and human mammary epithelial cell line MX-MCF-7 (with high BCRP expression). The cells were first exposed to HFPO dimer acid ammonium salt alone at increasing concentrations of 10^{-9}–10^{-4} M for 72 hours, and the remaining cells were counted. No significant differences in survival were observed. Next, to determine if HFPO dimer acid ammonium salt affected the toxicity of known cytotoxic substrates for P-gp or BCRP, each cell line was exposed to 100 nM HFPO dimer acid ammonium salt for 72 hours in the presence of Adriamycin (for NCI/ADR-RES cells) or mitoxantrone (for MX-MCF-7 cells). Co-treatment of 100 nM HFPO dimer acid ammonium salt and 10 μM Adriamycin significantly reduced NCI/ADR-RES cell survival from 85% to 45%, and co-treatment of 100 nM HFPO dimer acid ammonium salt and 100 μM mitoxantrone significantly reduced MX-MCF-7 cell survival from 63% to 37%.

The results of these assays show that both *ex vivo* and *in vivo* exposure to low nM levels of HFPO dimer acid ammonium salt can inhibit P-gp and BCRP transport in rat brain capillaries. The effect of HFPO dimer acid ammonium salt on P-gp transport was shown to involve PPARγ.

4.6.3 Genotoxicity Studies

HFPO dimer acid ammonium salt was not observed to induce genetic mutations both with and without metabolic activation of the test substance by rat liver S9 fraction in two species of prokaryotes: *Escherichia coli* (strain WP2uvrA) and *Salmonella typhimurium* (strains TA98, TA100, TA1535, and TA 1537) (DuPont-19713 RV1, 2008; DuPont-22734 RV1, 2008). An *in vitro* gene mutation test of the HFPO dimer acid ammonium salt in mouse lymphoma cells (strain L5178Y/TK+/-) was negative in the presence and absence of rat liver S9 fraction (DuPont-26129, 2008). HFPO dimer acid ammonium salt was observed to induce chromosomal aberrations in Chinese hamster ovary cells *in vitro* in the presence and absence of S9 activation (DuPont-19714 RV1, 2008; DuPont-22620 RV1, 2009). In *in vivo* mammalian studies, exposure to HFPO dimer acid ammonium salt by the oral route did not induce chromosomal mutations in the form of structural aberrations, numerical aberrations, or micronuclei nor DNA effects in the form of unscheduled DNA synthesis (DuPont-23219, 2007; DuPont-23220, 2007). A table summarizing the findings of the available genotoxicity studies is provided in appendix C.

5.0 Summary of Hazard

The available studies indicate adverse effects including liver, developmental, hematological, and immune effects occur following exposures in the range of 0.5–1,000 mg/kg/day GenX chemicals. Table 12 presents the available studies and their NOAELs and LOAELs. Discussion of the weight of evidence for hazard is presented following the table.

Table 12. Summary of Study NOAELs/LOAELs

Study	Overall study quality	Doses (mg/kg/day)	NOAEL or LOAEL (mg/kg/day)	Effects at the LOAEL
28 Day Oral (Gavage) Toxicity Study in Rats (OECD, 2008a) DuPont-24447 (2008)	Medium	Males: 0, 0.3, 3, and 30 Females: 0, 3, 30, and 300	NOAEL = 0.3 LOAEL = 3	Hematological effects (↓ RBC count, hemoglobin, and hematocrit in males) Immune effects (↓ globulin, and ↑ A/G ratio in males)
28 Day Oral (Gavage) Toxicity Study in Mice (OECD, 2008a) DuPont-24459 (2008)	Medium/Low	Males and Females: 0, 0.1, 3, and 30	NOAEL = 0.1 LOAEL = 3	Liver effects (single-cell necrosis in males, ↑ relative liver weight in in males, and ↑ hepatocellular hypertrophy in males) Hematological effects (↓ hemoglobin and hematocrit in males) Immune effects (↓ globulin in females, and ↑ A/G ratio in both sexes)
28 Day Oral (Gavage) Immunotoxicity Study in Mice Rushing et al. (2017)	Medium	Males and Females: 0, 1, 10, and 100 Note: HFPO dimer acid	NOAEL = 10 LOAEL = 100	Immune effects (TDAR suppression in females, and ↑ lymphocytes in males)
90 Day Oral (Gavage) Toxicity Study in Rats (OECD, 1998) DuPont-17751-1026 (2009)	High	Males: 0, 0.1, 10, and 100 Females: 0, 10, 100, and 1,000	NOAEL = 0.1 LOAEL = 10	Hematological effects (↓ RBC count, hemoglobin, and hematocrit in males)

Study	Overall study quality	Doses (mg/kg/day)	NOAEL or LOAEL (mg/kg/day)	Effects at the LOAEL
90 Day Oral (Gavage) Toxicity Study in Mice (OECD, 1998) DuPont-18405-1307 (2010); Reevaluation by NTP PWG Pathology (NTP, 2019)	High	Males and Females: 0, 0.1, 0.5, and 5	NOAEL = 0.5 LOAEL = 5	Liver effects (↑AST, ALT, and ALP in males; ↑ relative liver weight in males and females; and ↑ in constellation of liver lesions: cytoplasmic alteration, single-cell necrosis, focal necrosis, and hepatocellular apoptosis in males and females)
Combined Chronic Toxicity/ Oncogenicity Study in Rats (OECD, 2009) DuPont-18405-1238 (2013)	Medium	Males: 0, 0.1, 1, and 50 Females: 0, 1, 50, and 500	NOAEL = 1 LOAEL = 50	Liver effects (centrilobular necrosis in both sexes; ↑ ALP, ALT, and SDH in males; and ↑ centrilobular hepatocellular hypertrophy and cystic focal degeneration in males)
Oral (Gavage) Reproduction/ Developmental Toxicity Study in Mice (OECD, 2016a; modified according to the Consent Order) DuPont-18405-1037 (2010); Reevaluation by NTP PWG Pathology (NTP, 2019)	High	Males and Females: 0, 0.1, 0.5, and 5	NOAEL (F_0) = 0.1 LOAEL (F_0) = 0.5 NOAEL (F_1) = 0.5 LOAEL (F_1) = 5	Liver effects ((single-cell necrosis, focal necrosis, and cytoplasmic alteration), and ↑ relative liver weight in males and females); reproductive/developmental effects (↑ maternal GWG from GD0 through GD18) Developmental effects (↓ pup weights, and delays in the attainment of balanopreputial separation and vaginal patency)

Study	Overall study quality	Doses (mg/kg/day)	NOAEL or LOAEL (mg/kg/day)	Effects at the LOAEL
Prenatal and Developmental Toxicity Study in Rats (OECD, 2001b) DuPont-18405-841 (2010)	Medium	Females: 0, 10, 100, and 1,000	NOAEL (F_0 and F_1) = 10 LOAEL (F_0 and F_1) = 100	Developmental effects (↑ early deliveries, ↓ fetal weights in both sexes, ↓ gravid uterine weight, and focal liver necrosis)
Reproductive and Developmental Toxicity in Rats Conley et al. (2019)	Medium	Females: 0, 1, 3, 10, 30, 62.5, 125, 250, and 500	NOAEL (F_0 and F_1) = 62.5 LOAEL (F_0 and F_1) = 125	Reproduction/developmental effects (↓ maternal GWG, , and indications of reduced body (females) and reproductive and non-reproductive organ weights in F_1 animals) Thyroid effects (↓maternal serum total T3 and T4 levels)
Reproductive and Developmental Toxicity in Mice Blake et al. (2020)	Medium	Females: 0, 2, and 10	NOAEL = NA LOAEL = 2	Reproductive/developmental effects (↑ mean abnormal placental lesions (including labyrinth atrophy, labyrinth congestion, labyrinth necrosis, early fibrin clot, and placental nodule), and ↑ maternal GWG)
Reproductive and Developmental Toxicity in Rats Conley et al. (2021)	High	Females: 0, 10, 30, 62.5, 125, or 250	NOAEL (F_0) = 30 LOAEL (F_0) = 62.5 NOAEL (F_1) = 10 LOAEL (F_1) = 30	Thyroid effects (↓maternal serum total T3 and T4 levels) Reproductive/developmental effects (↓ BW in F1 pups at PND0 and PND2)

5.1 Hepatic

The liver is a target organ for toxicity from oral exposure to HFPO dimer acid and its ammonium salt. Liver effects are observed in both male and female mice and rats at varying durations of exposures and doses of GenX chemicals. Liver effects are also the endpoints that are observed at the lowest doses for these chemicals. Hepatocellular hypertrophy and an increased liver-to-BW ratio are common findings in rodents but are considered nonadverse and less relevant to humans when there is evidence that PPARα activation is the only MOA. The increased relative liver weight and hepatocellular hypertrophy were only considered adverse when accompanied by effects such as necrosis, fibrosis, inflammation, and significantly increased serum levels for enzymes indicative of liver tissue damage (Hall et al., 2012).

Significant increases in liver weight relative to BW were observed in male and female Crl:CD(SD) rats and several strains of male and female mice treated with 0.5 mg/kg/day–1,000 mg/kg/day of HFPO dimer acid ammonium salt for 28–90 days (DuPont-17751-1026, 2009; DuPont-18405-1037, 2010; DuPont-18405-1307, 2010; DuPont-24447, 2008; DuPont-24459, 2008; Rushing et al., 2017; Wang et al., 2017). These increases were observed in doses as low as 0.5 mg/kg/day in male Crl:CD-1 mice (26% increase) over 84–85 days (DuPont-18405-1037, 2010), and the greatest increases were observed when male (163%) and female (102.7%) Crl:CD-1 mice were administered 30 mg/kg/day for 28 days. Likewise, male Crl:CD(SD) rats exhibited increased relative liver weights of 19%–61% compared to control when administered 3 mg/kg/day–100 mg/kg/day for 28–90 days, while female rats' relative liver weights compared to control did not increase until much higher doses (12% at 300 mg/kg/day for 28 days and 85% at 1,000 mg/kg/day for 90 days) were administered. Comparatively, the one available chronic study in rats indicates that liver weight may increase and return to control levels after a time. For example, relative liver weights in male rats increased only 15% when administered 50 mg/kg/day for 1 year and did not exhibit a significant increase from control at 2 years. Likewise, female rat relative liver weights increased 67% and 42% after administration of 500 mg/kg/day for 1 and 2 years, respectively (DuPont-18405-1238, 2013).

Indications of liver damage were also reflected through increases in serum liver enzymes of Crl:CD-1 mice, particularly males, and Crl:CD(SD) rats administered HFPO dimer acid ammonium salt. For example, significant increases in ALT (420%–1,254%), AST (106%–478%), ALP (1,134%–1,221%), and SDH (1,134%–1,221%) were observed in male mice administered the ammonium salt at 5–30 mg/kg/day for 28–90 days. Female mice saw smaller increases in ALP (140%–143%) and SDH (32%–186%) compared to male mice administered the same dose. Overall, rats exhibited far fewer and smaller increases in serum liver enzyme levels following subchronic exposure than the mouse, with increases in AST (106%) and ALP (52%) at 100 mg/kg/day in male rats and AST (66%) in female rats at 1,000 mg/kg/day. In the chronic study, however, ALT (228%), ALP (180%), and SDH (140%) significantly increased in male rats only when administered 50 mg/kg/day for 1 year (DuPont-18405-1238, 2013).

Liver damage was confirmed microscopically in male and female mice and rats in several less-than-chronic studies (15–90 days) and one chronic study (DuPont-17751-1026, 2009; DuPont-18405-841, 2010; DuPont-18405-1037, 2010; DuPont-18405-1238, 2013; DuPont-18405-1307, 2010; DuPont-24447, 2008; DuPont-24459, 2008; Wang et al., 2017; Thompson et al., 2019; NTP, 2019). The most prevalent liver effects following both subchronic and chronic exposure to

HFPO dimer acid and/or its ammonium salt were hepatocellular hypertrophy (also referenced here as cytoplasmic alteration per NTP PWG's review) and single-cell and/or focal necrosis.

In both sexes of mice exposed either short term (28 days) or subchronically (30–90 days), hepatocellular hypertrophy was observed at 0.5 mg/kg/day, while male and female rats showed this effect at 3 mg/kg/day and 30 mg/kg/day, respectively. Interestingly, in the chronic study, male rats did not show any significant increases in hepatocellular hypertrophy when administered 0.1–50 mg/kg/day of HFPO dimer acid ammonium salt for 1 year, and only 10% of the rats exhibited minimal hypertrophy with 50 mg/kg/day administered for 2 years (DuPont-18405-1238, 2013). Conversely, female rats had significant hepatocellular hypertrophy at 500 mg/kg/day after 1 year (100%) and 2 years (93%).

Single-cell and focal necrosis were detected in all the available studies. The reanalysis of the liver pathology slides from DuPont 18405-1037 (2010) by Thompson et al. (2019) did not report necrosis in mice. This interpretation conflicts with the results from the original pathology conducted in DuPont 18405-1037 (2010) and the 2019 NTP PWG reanalysis (NTP, 2019) of DuPont 18405-1037 (2010). The incidence data as reported by NTP (see appendix D) were considered the appropriate measure of response in the liver from the reproductive/developmental study (DuPont-18405-1037, 2010) because the PWG analysis reflects more recent histopathological criteria for the grading of liver lesions and the PWG results were the consensus of eight pathologists.

In the subchronic toxicity studies in mice, males and females presented with single-cell and focal necrosis in doses as low as 0.5 mg/kg/day, which significantly increased at 5 mg/kg/day. Specifically, the incidence rates for single-cell and focal necrosis at 5 mg/kg/day were 100% and 83% in males and females, respectively, in DuPont 18405-1037 (2010) and 90% and 44% in males and females, respectively, in DuPont 18405-1307 (2010) (NTP, 2019). Apoptosis was observed in the 5 mg/kg/day-dose groups in these studies as well, but not in the 0.5 mg/kg/day-dose group (NTP, 2019). As noted in section 4.0 and appendix D in this assessment, the NTP PWG agreed that the dose response and constellation of liver lesions (i.e., hepatocellular hypertrophy, single-cell and focal necrosis and apoptosis) observed in DuPont 18405-1037 (2010) and DuPont 18405-1307 (2010) should be considered as adverse (NTP, 2019). Male and female rats exhibited hepatocellular necrosis at much higher doses in the available short-term study, with males exhibiting what was classified as general necrosis (30%) at 30 mg/kg/day and females presenting focal liver necrosis at 100 mg/kg/day (9%) and 1,000 mg/kg/day (23%). Interestingly, no liver necrosis was reported for either sex in the subchronic rat study (DuPont-17751-1026, 2009). It is possible that apoptosis could have been present in the other DuPont studies, but these studies might not have separated apoptotic lesions from other liver lesions reported (i.e., single-cell necrosis) since they were conducted prior to the histopathological guidance on separating apoptosis from single-cell necrosis (i.e., Elmore et al., 2016) and were not reanalyzed by the 2019 NTP PWG.

These findings suggest that mice are more sensitive to liver necrosis than rats in short-term and subchronic exposure scenarios. In the 2-year chronic rat study, centrilobular necrosis increased at 50 mg/kg/day and 500 mg/kg/day for males (7%) and females (4%), respectively, while single-cell necrosis was observed only in females (4%) at 500 mg/kg/day. Taken together, the male rat liver necrosis data appear to be inconsistent. Specifically, 30% of male rats have necrotic liver cells after 28 days of dosing with 30 mg/kg/day of HFPO dimer acid ammonium salt, yet no

necrosis is reported in male rats after 90 days of dosing with 0.1–100 mg/kg/day. However, necrosis returns in 50% of male rats after 1 year of dosing with 50 mg/kg/day to then be reduced to 7–13% incidence after 2 years of dosing.

Similarly, these data suggest that the pregnant rodent might be more susceptible than nonpregnant rodents to liver effects following exposures to GenX chemicals. Liver effects were reported in the pregnant dams in the available reproductive/developmental studies dosing during gestation (DuPont-18405-841, 2010; Conley et al., 2019; DuPont 18405-1037, 2010; Blake et al., 2020). All the studies reported increases in liver weight ranging from 12% to 34% in rats and 26% to 101% in mice over the gestational period. Conley et al. (2019) did not conduct liver histopathology, but both DuPont-18405-841 (2010) and Blake et al. (2020) reported hepatocellular hypertrophy and increased cell death as compared to control with increasing HFPO dimer acid ammonium salt concentration. Specifically, focal necrosis was observed in 2/22 (9%) and 5/22 (23%) pregnant rats after 15 days (GD6–GD20) of 10 mg/kg/day or 100 mg/kg/day of HFPO dimer acid ammonium salt, respectively, compared to 0 in the control group. Comparatively, nonpregnant female rats dosed from 28 to 90 days did not exhibit necrosis when treated with doses up to 1,000 mg/kg/day of HFPO dimer acid ammonium salt. Necrosis was observed in female rats only after 2 years of dosing with 500 mg/kg/day of HFPO dimer acid ammonium salt. Increased cell death (including both apoptosis and single-cell necrosis) or focal necrosis was observed in pregnant mice after 11 and 17 days (GD1.5–GD11.5 or 17.5) of 2 mg/kg/day or 10 mg/kg/day of HFPO dimer acid ammonium salt. Similarly, and as noted above, female mice dosed 14 days prior to mating and throughout gestation/lactation exhibited cytoplasmic alteration, apoptosis, single-cell necrosis, and focal necrosis after 53–64 days of dosing (NTP, 2019 reanalysis of DuPont 18405-1037, 2010). The incidence of single-cell and focal necrosis in the F_0 females was 6/24 (25%) and 20/24 (83%) in the 0.5- and 5-mg/kg/day-dose groups, respectively (NTP, 2019).

5.2 Hematological

The hematologic system could be a target of HFPO dimer acid ammonium salt toxicity as effects have been observed across studies of varying durations of oral exposure to the chemical. The primary effects observed are decreases in RBC number, hemoglobin, and percentage of RBCs in the blood, indicating that oral exposure to HFPO dimer acid ammonium salt might promote anemic conditions. In male mice and rats, the percent change in these effects from the controls was relatively small. For example, male Crl:CD-1 mice and Crl:CD(SD) rats treated with 3 mg/kg/day–100 mg/kg/day of HFPO dimer acid ammonium salt for 28–180 days had maximum decreases of 12%, 11%, and 12% in hemoglobin, erythrocyte count, and hematocrit, respectively (DuPont-17751-1026, 2009; DuPont-18405-1238, 2013; DuPont-18405-1307, 2010; DuPont-24447, 2008; DuPont-24459, 2008). Interestingly, in the available chronic study, no hematological effects were observed at the 12-month time point in male rats (DuPont-18405-1238, 2013). Female Crl:CD-1 mice and Crl:CD(SD) rats presented hematological effects at greater than 90 days and typically at higher doses than males, with one exception. Hemoglobin significantly decreased by 4% when female Crl:CD(SD) rats were administered 1 mg/kg/day of HFPO dimer acid ammonium salt for 90 days (DuPont-18405-1238, 2013). Otherwise, hematological effects occurred at doses greater than or equal to 50 mg/kg/day and the maximum decreases from control were 24%, 28%, and 20% for hemoglobin, erythrocyte count, and hematocrit, respectively (DuPont-18405-1238, 2013; DuPont-24447, 2008).

5.3 Renal

The kidney could also be a target organ for toxicity from oral exposure to HFPO dimer acid and/or ammonium salt; however, kidney effects typically presented at higher doses than the liver effects.

Significant increases in kidney weight relative to BW were observed in several less-than-chronic studies in Crl:CD-1 mice and Crl:CD(SD) rats treated with 0.1 mg/kg/day–1,000 mg/kg/day (DuPont-17751-1026, 2009; DuPont-18405-1037, 2010; DuPont-24459, 2008; DuPont-24447, 2008). The maximum increase in kidney weight for male rodents was an increase of 16% compared to control in male rats treated with 100 mg/kg/day of HFPO dimer acid ammonium salt over 90 days. Likewise, the maximum kidney weight relative to BW increase in female rodents was 23% in female rats administered 1,000 mg/kg/day over 90 days (DuPont-17751-1026, 2009). Interestingly, increases in relative kidney weights were not observed in the same type of male rat when administered HFPO dimer acid ammonium salt for 1 or 2 years (DuPont-18405-1238, 2013). Relative kidney weight did increase in female Crl:CD(SD) rats by 25% and 14% when administered 500 mg/kg/day of HFPO dimer acid ammonium salt for 1 and 2 years, respectively (DuPont-18405-1238, 2013).

These increases in kidney weight were often associated with increases in BUN, which can be used as an indicator of renal damage. In several studies, urea nitrogen levels were significantly increased (16%–38%) in male mice and rats administered doses greater than or equal to 30 mg/kg/day of HFPO dimer acid ammonium salt for 28–180 days (DuPont-17751-1026, 2009; DuPont-18405-1238, 2013; DuPont-24447, 2008; DuPont-24459, 2008). Female rats exhibited an increase in urea nitrogen levels (35%) only when administered 500 mg/kg/day of HFPO dimer acid ammonium salt for 1 year (DuPont-18405-1238, 2013). Kidney damage was equivocal microscopically in the less-than-chronic studies (28–90 days), and typically presented as increases in basophilic tubular cells and tubular epithelial hypertrophy or dilation without tubular degeneration and/or necrosis (DuPont-17751-1026, 2009; DuPont-18405-1037, 2010; DuPont-24459, 2008; DuPont-24447, 2008).

In the chronic study, the increases in BUN and relative kidney weight noted above for female rats were associated with multiple microscopic observations of kidney damage when female rats were treated with HFPO dimer acid ammonium salt for 2 years. For example, at 50 mg/kg/day–500 mg/kg/day, female rats exhibited transitional cell hyperplasia, tubular dilation, pelvic and tubular mineralization, and papillary edema, which ultimately resulted in papillary necrosis at 500 mg/kg/day (DuPont-18405-1238, 2013).

To summarize, significant and dose-dependent increases in relative kidney weight occurred in rats at lower doses (e.g., 10 mg/kg/day) in a subchronic study (DuPont-18405-1307, 2010). Kidney hypertrophy, however, was not associated with microscopic damage of the kidney such as necrosis in this study. Additionally, there are instances in which kidney hypertrophy occurred at low doses in female mice (e.g., 0.1 mg/kg/day (DuPont-24459, 2008) or 5 mg/kg/day (DuPont-18405-1037, 2010)), but there was not a dose response in these datasets, and microscopic damage to the kidney tissues was not reported. Of the available studies, kidney hypertrophy was associated with significant microscopic damage only in female rats treated with 500 mg/kg/day of HFPO dimer acid ammonium salt for 2 years (DuPont-18405-1238, 2013). Thus, the observed kidney effects are potentially of concern. The biological significance,

however, of the observed hypertrophy and increases in BUN without microscopic evidence of kidney damage is not clear.

5.4 Reproductive/Developmental

Evidence in animals suggests HFPO dimer acid and/or ammonium salt could target the reproductive system and the developing fetus.

In a reproduction/developmental toxicity mouse study, there were no effects on mating, fertility, or copulation indices; mean days between pairing and coitus; mean gestation length; mean numbers of implantation sites; mean numbers of pups born; live litter size; percentage of males at birth; postnatal survival; or the general condition of pups (DuPont-18405-1037, 2010). Similarly, implantation sites, viable embryos, nonviable embryos, and resorptions were not significantly different than control when pregnant mice were dosed with 2 or 10 mg/kg/day of HFPO dimer acid from E1.5 to E17.5 (Blake et al., 2020). In the rat developmental toxicity study, however, early delivery on GD21 was observed in 18% and 41% of the dams at 100 mg/kg/day and 1,000 mg/kg/day, respectively, and the percentage of male (47%) and female (53%) pups born was significantly altered from control at 1,000 mg/kg/day (DuPont-18405-841, 2010). Conley et al. (2019) reported no significant effects from control on the number of fetuses or resorptions in pregnant rats dosed with 1–500 mg/kg/day HFPO dimer acid from GD14 through GD18. Conley et al. (2021) also reported no significant effects on the numbers of viable fetuses or resorptions in pregnant rats dosed with 1–125 mg/kg/day HFPO dimer acid from GD16 through GD20. However, pup survival was significantly reduced on PND1 and PND2 at doses ≥62.5 mg/kg/day in pups born to dams dosed from GD8 to PND2. Specifically, pup survival percentages on PND2 were 100 ± 0, 96 ± 2, 97 ± 2, 87 ± 5, 38 ± 13, and 5 ± 5% in the 0–250 mg/kg/day groups, respectively.

Changes in maternal GWG were a consistently observed effect. In pregnant rats dosed during gestation and through PND2, maternal GWG significantly decreased 25%–70% compared to control at doses greater than or equal to 125 mg/kg/day of HFPO dimer acid ammonium salt (DuPont-18405-841, 2010; Conley et al., 2019, 2021). Conversely, pregnant mice dosed during gestation saw increases in maternal GWG ranging from 7% to 22% at doses as low as 0.5 mg/kg/day (DuPont-18405-1037, 2010; Blake et al, 2020). It is unclear why this response is different for mice and rats, but in Blake et al. (2020), the study authors hypothesize that it could be the result of differences in the exposure window or interspecies toxicokinetic differences in elimination rates. Specifically, the available rat studies dosed from GD6 through GD20 (DuPont-18405-841, 2010), GD14–GD18 (Conley et al., 2019), GD16-GD20 (Conley et al., 2021), or GD8-PND2 (Conley et al., 2021), while the mice were dosed earlier in gestation (GD1.5–GD17.5) in Blake et al. (2020) and 14 days prior to mating through LD21 in DuPont-18405-1037. Additionally, the elimination $T_{1/2}$ in urine (see section 2.3.5) for female mice (18 hours) is much longer than for female rats (8 hours) and there are also differences in the alpha and beta phase $T_{1/2}$ for female rats and mice (see Table 8).

Blake et al. (2020) presented data indicating that the placenta might be a target of GenX chemical exposure. Placental lesions were detected in 58% and 83% of mouse placentas evaluated after dosing with 2 and 10 mg/kg/day of HFPO dimer acid from E1.5 to E17.5, respectively, compared to 2% in the control group (Blake et al., 2020). The most frequent lesion detected was labyrinth atrophy, which was observed in 0/41 (0%), 15/31 (48%), and 16/35 (46%)

placentas in 0-, 2-, and 10-mg/kg/day-dose groups, respectively. Labyrinth congestion and early fibrin clots increased with increasing HFPO dimer acid doses. These placental lesions are indicative of a placental insufficiency phenotype (Blake et al., 2020). Additionally, placental weights increased in the 10-mg/kg/day-dose group and large placentas are associated with adverse health outcomes in neonates and adult offspring (Hutcheon et al., 2012; Risnes et al., 2009). It is unclear how these effects might impact reproductive and developmental outcomes.

In some of the available developmental studies, there was also a decrease in rodent pup weight that ranged from 9% to 24% when the pups were exposed to 5 mg/kg/day–1,000 mg/kg/day in utero (DuPont-18405-841, 2010; DuPont-18405-1037, 2010; Conley et al., 2019, 2021). The mouse pups showed delays in attaining balanopreputial separation and vaginal patency at 5 mg/kg/day of 2.6 days and 3.4 days, respectively, which could be related to the observed effects on BW during the preweaning period (DuPont-18405-1037, 2010). Additionally, the attainment of vaginal patency did not exhibit a dose-response relationship. The decrease in pup weight was associated with a decrease in gravid uterine weight by 10% and 25% at 100 mg/kg/day and 1,000 mg/kg/day, respectively, in the rat prenatal developmental toxicity study (DuPont-18405-841, 2010). Moreover, in a rat prenatal developmental study, a 14th rudimentary rib developed in 9% of the control fetuses, 10% of fetuses in the 10-mg/kg/day dose, 12% of fetuses in the 100-mg/kg/day dose, and 27% of the fetuses in the 1,000-mg/kg/day dose (DuPont-18405-841, 2010). Statistical analyses were not completed on the development of the 14th rudimentary rib in individual fetuses, but a statistically significant increase in the number of litters developing a 14th rudimentary rib was observed at the high dose. Conley et al. (2019) reported significant effects for the F_1 generation in their postnatal pilot study where F_0 pregnant rats were dosed with 125 mg/kg/day of HFPO dimer acid ammonium salt from GD14 through GD18. F_1 male pups had a decrease in right epididymis weight on a litter mean basis compared to control. Multiple significant effects were observed on an individual pup basis, including AGD and liver weight decreases in female F_1 offspring and paired testes, paired epididymides, right testis, right corpus/caput, right epididymis, left testis, and epididymal adipose tissue decreases in F_1 male mice. Similarly, F_1 male mice in the 5 mg/kg/day-dose group exhibited a decrease of 12% in the relative epididymis weight in a reproduction/developmental toxicity mouse study (DuPont-18405-1037, 2010).

Changes in thyroid hormones, which are important for neurodevelopment, were reported in Conley et al. (2019), Conley et al. (2021) and Blake et al. (2020). In pregnant rats (*n*=3) dosed with 0–500 mg/kg/day of HFPO dimer acid ammonium salt from GD14 through GD18 (Conley et al., 2019), maternal serum total T3 levels were decreased at greater than or equal to 30 mg/kg/day and total T4 levels at greater than or equal to 125 mg/kg/day. The decreases in maternal serum total T4 levels compared to control were -50%, -63%, and -76% in the 125-, 250-, and 500-mg/kg/day-dose groups, respectively. The decreases in maternal serum total T3 levels compared to control were -27%, -39%, and -48% in the 30-, 62.5-, and 125-mg/kg/day-dose groups, respectively. Maternal total T3 levels in the 250 and 500 mg/kg/day-dose groups were below the detection limit. Similar findings were reported in Conley et al. (2021) for pregnant rats (*n*=4-5) dosed with 0–250 mg/kg/day of HFPO dimer acid ammonium salt from GD16 through GD20 and GD8 through PND2. Notably, significant decreases in maternal total T4 (-35% for GD16-GD20 and -51% for GD8-PND2) were also observed in the 62.5 mg/kg/day dose groups in Conley et al. (2021). In Blake et al. (2020), placental thyroid hormones (rT3, T3, and T4) were quantified at GD17.5 from 2–3 pooled placental tissues of same-sex embryos. A

significant increase (60%) in T4 relative to control was reported for the 10-mg/kg/day HFPO dimer acid-dose group.

5.5 Immune System

In the one available study specifically addressing immunotoxicity, suppression of TDARs was measured through IgM antibody production in mice (Rushing et al., 2017). IgM antibody production was decreased by 7.3% in female C57BL/6 mice treated with 100 mg/kg/day of HFPO dimer acid. In male mice treated with the same dose of HFPO dimer acid, significant increases in the number of T lymphocytes were observed, but no suppression of TDARs.

In two studies of less-than-chronic duration (28–90 days), decreases in spleen weight relative to BW were observed in female mice and rats (DuPont-18405-1307, 2010; Rushing et al., 2017). For example, in C57BL/6 mice, relative spleen weights significantly decreased by 11% in females treated with 100 mg/kg/day of HFPO dimer acid for 28 days (Rushing et al., 2017).

Changes in early markers of potential immunotoxic effects were observed in multiple studies examining the oral toxicity of HFPO dimer acid and/or ammonium salt. The most prevalent indications were statistically significant decreases from control in serum globulin levels (6%–22%), which resulted in an increase in the serum A/G ratio (7%–58%) from the controls when both sexes of Crl:CD-1 mice and Crl:CD(SD) rats were treated with 1 mg/kg/day–500 mg/kg/day of HFPO dimer acid ammonium salt for 12 months or less (DuPont-17751-1026, 2009; DuPont-18405-1238, 2013; DuPont-18405-1307, 2010; DuPont-24447, 2008; DuPont-24459, 2008). Alterations in the serum levels of globulin can be associated with decreases in antibody production (FDA, 2002). To determine the biological significance of the apparent decrease in globulin production, however, immune function tests (such as TDAR) need to be conducted. Finally, female Crl:CD-1 mice exhibited a 21% and 18% decrease in spleen weight relative to BW when administered 0.5 mg/kg/day and 5 mg/kg/day of HFPO dimer acid ammonium salt for 90 days, respectively (DuPont-18405-1307, 2010). For HFPO dimer acid and/or ammonium salt, there were also two local lymph node assays (LLNAs) conducted in mice that showed equivocal results (DuPont-19897, 2006; DuPont-22616 RV1, 2007).

In summation, the results of the Rushing et al. (2017) TDAR assay in combination with the supportive findings of decreased globulin levels and spleen weight provide evidence that GenX chemicals can induce immune suppression in female mice.

5.6 Cancer

The single cancer bioassay for HFPO dimer acid ammonium salt showed increased incidence of liver tumors (females) and combined pancreatic acinar adenomas and carcinomas (males) in rats at the high doses only. Additionally, a statistically insignificant increase in the incidence of testicular interstitial cell adenoma was noted at the high dose. Although that result was not statistically significant compared to controls, the authors of the study conclude that “a relationship to treatment for these findings in the 50 mg/kg/day group cannot be ruled out,” while also suggesting that Leydig cell tumor induction in rodents might have low relevance to humans (Caverly Rae et al., 2015). Given these uncertainties and the large number of early deaths in the study (see section 4.4), the existing evidence from this single chronic study is considered inadequate to justify a quantitative assessment. Further, the available data for HFPO dimer acid ammonium salt suggest that mice might be more sensitive to exposure to GenX chemicals than

rats. The available study (DuPont-18405-1238, 2013) only evaluated rats; there are no studies measuring cancer endpoints in mice. Given the evidence that the liver is the target organ for toxicity and primary organ for tumor development, the lack of data evaluating cancer in mice is a database deficiency. Thus, under EPA's *Guidelines for Carcinogen Risk Assessment* (EPA, 2005a), there is *Suggestive Evidence of Carcinogenic Potential* of oral exposure to GenX chemicals in humans, based on the female hepatocellular adenomas and hepatocellular carcinomas and male combined pancreatic acinar adenomas and carcinomas. No data are available to evaluate cancer risk via dermal or inhalation exposure.

6.0 Mode of Action

The available data indicate that multiple MOAs could be involved in the liver effects observed after GenX chemical exposure. The available studies provide support for a role for PPARα, cytotoxicity, mitochondrial dysfunction, and PPARγ. The potential MOA(s) for the observed reproductive and developmental effects (e.g., changes in GWG and placental lesions) are unknown. Additionally, no data support identification of a potential carcinogenic MOA for tumors in the pancreas and testes as being related to any of the proposed MOAs for the tumor development in either organ.

For some PFAS (e.g., PFOA), PPARα activation has been proposed as a potential MOA for some of the effects in the liver (i.e., liver tumors) (Klaunig et al., 2003, 2012; Maloney and Waxman, 1999). PPARα is primarily expressed in the liver, but also is present in the kidney, intestines, heart, and brown adipose tissue (Hall et al., 2012). Klaunig et al. (2003) describes the causal key events of the PPARα MOA for liver tumors as activation of PPARα, perturbation of cell proliferation and apoptosis, and selective clonal expansion. There are multiple effects associated with the PPARα MOA such as hepatocellular hypertrophy, peroxisome proliferation, expression of peroxisomal genes, Kupffer cell-mediated events, and increased liver weight. However, these associative effects might not be specific to the PPARα MOA (e.g., hepatocellular hypertrophy) or might not be causal to the development of liver tumors (e.g., peroxisome proliferation) (Klaunig et al., 2003). According to Klaunig et al. (2003), demonstration of PPARα agonism combined with microscopic evidence for peroxisome proliferation or increases in liver weight and one or more of the specific *in vivo* markers of peroxisome proliferation (e.g., induction of acyl-CoA oxidase or cytochrome P450 4A) are sufficient to establish a PPARα MOA.

For HFPO dimer acid and/or ammonium salt, there are data that demonstrate peroxisome proliferation in the liver. Activation of PPARα was measured in multiple 28-day studies in rodents (DuPont-24447, 2008; DuPont-24459, 2008; Rushing et al., 2017; Wang et al., 2017). Using acyl-CoA oxidase activity as a measure, Rushing et al. (2017) showed increased activity compared to control in male C57BL/6 mice administered 10 mg/kg/day and 100 mg/kg/day of HFPO dimer acid (122% and 222%, respectively) and a 100% increase compared to control in C57BL/6 female mice at 100 mg/kg/day. Notably, there were no significant increases in acyl-CoA oxidase activity at 1 mg/kg/day, indicating that it might be a high dose effect.

The DuPont studies used β-oxidation activity and total cytochrome P450 content as markers of peroxisome proliferation in the livers of rats and mice (DuPont-24447, 2008; DuPont-24459, 2008). In Crl:CD-1 male mice, β-oxidation activity significantly increased compared to control at

doses of 0.1 mg/kg/day, 3 mg/kg/day, and 30 mg/kg/day of HFPO dimer acid ammonium salt by 57%, 744%, and 648%, respectively, and total cytochrome P450 content significantly decreased at 3 mg/kg/day and 30 mg/kg/day by 26% and 53%, respectively (DuPont-24459, 2008). β-oxidation activity significantly increased compared to control in female Crl:CD-1 mice at 3 mg/kg/day and 30 mg/kg/day by 495% and 823%, respectively, with no alterations in total cytochrome P450 content (DuPont-24459, 2008). In male Crl:CD(SD) rats, β-oxidation activity was significantly increased relative to control at dosages of 0.3 mg/kg/day, 3 mg/kg/day, and 30 mg/kg/day by 42%, 274%, and 772%, respectively, and total cytochrome P450 content was significantly increased by 23% at 30 mg/kg/day (DuPont-24447, 2008). In female rats dosed with 30 mg/kg/day and 300 mg/kg/day, β-oxidation activity was significantly increased compared to control to 49% and 198%, respectively, while total cytochrome P450 content remained unaltered (DuPont-24447, 2008).

Induction of genes associated with peroxisome proliferation in the liver was also demonstrated (Wang et al., 2017; Conley et al., 2019). Wang et al. (2017) demonstrates significant increases in hepatic mRNA levels of many PPAR targets (e.g., CD36 antigen, acyl-CoA oxidase 1, and cytochrome P450 family members) after administration of 1 mg/kg/day of HFPO dimer acid ammonium salt for 28 days. Relatedly, Conley et al. (2019) found upregulation of gene expression associated with PPARα signaling in maternal and fetal livers following *in vivo* exposure during GD14–GD18.

Additionally, significant increases in liver weight relative to BW were observed in male and female Crl:CD(SD) rats and several strains of male and female mice treated with 0.5 mg/kg/day–1,000 mg/kg/day of HFPO dimer acid ammonium salt for 28–90 days (DuPont-17751-1026, 2009; DuPont-18405-1037, 2010; DuPont-18405-1307, 2010; DuPont-24447, 2008; DuPont-24459, 2008; Rushing et al., 2017; Wang et al., 2017; NTP, 2019). Increases in liver weight were also reported in the pregnant dams in the available reproductive/developmental studies dosing during gestation (Blake et al., 2020; Conley et al., 2019; DuPont-18405-841, 2010; DuPont 18405-1037, 2010). Additionally, hepatocellular hypertrophy was observed at 0.5 mg/kg/day in both sexes of mice, while male and female rats showed these effects at 3 mg/kg/day and 30 mg/kg/day, respectively, in subchronic studies. Interestingly, in the chronic study, male rats showed only a 10% incidence of hepatocellular hypertrophy with dosing at 50 mg/kg/day for 2 years (DuPont-18405-1238, 2013). Conversely, female rats had significant hepatocellular hypertrophy at 500 mg/kg/day after 1 year (100%) and 2 years (93%).

There is evidence of perturbations to cell proliferation and apoptosis in the liver following short-term and subchronic exposure to HFPO dimer acid ammonium salt, particularly in the high-dose groups. In the 28-day mouse study, increased mitosis was observed in male (9/10) and female (5/10) mice in the high-dose groups only (30 mg/kg/day) and apoptosis was not reported (DuPont-24459, 2008). In the 90-day mouse study, increases in mitotic figures and apoptosis were reported in 7/10 and 10/10 male mice in the high-dose (5 mg/kg/day) group, respectively (NTP, 2019). No mitotic figures were detected in female mice, but an increase in apoptosis was observed in 3/9 mice (NTP, 2019). In the reproductive/developmental mouse study, mitotic figures were observed in 17/24 males and 2/24 females in the 5-mg/kg/day-dose group, but in no other dose groups (NTP, 2019). Similarly, apoptosis was reported in 21/24 males and 10/24 females in the 5-mg/kg/day high-dose group (NTP, 2019). Notably, decreases in the rates of apoptosis are typically observed with PPARα agonists, with Klaunig et al. (2003) describing

decreased rates of apoptosis as a "hallmark of liver growth seen in the early stages of treatment with PPARα agonists." Interestingly, increases in mitoses/mitotic figures and apoptosis are consistently restricted to the high-dose group in all available mouse studies; however, necrosis is observed in both the mid- and high-dose groups. These data suggest that PPARα's role in the observed liver effects may be dose dependent. In the 28-day rat study, mitosis/mitotic figures, hyperplasia, and apoptosis were not reported (DuPont-24447, 2008). In the 90-day rat study, mitosis/mitotic figures, hyperplasia, and apoptosis were not reported (DuPont-17751-1026, 2009). In the chronic rat study, mitotic figures and apoptosis were not reported, and hyperplasia was no different than control in the male and female rats in any dose group (DuPont-18405-1238, 2013). It is possible that the rat studies might not have separated apoptotic lesions from other liver lesions reported (i.e., single-cell necrosis) since these studies were conducted prior to the guidelines outlined in Elmore et al. (2016) and were not reanalyzed by the NTP PWG.

Although there is evidence for a PPARα MOA in the liver, particularly in the high-dose groups in the available studies, data indicate that liver toxicity extends beyond a single PPARα-based MOA. For example, liver necrosis was consistently observed in rodent toxicity studies with HFPO dimer acid ammonium salt and was reaffirmed by the NTP PWG's review of the 90-day subchronic study in mice and the reproductive and developmental toxicity study in mice (appendix D), which suggests that cytotoxicity is also a possible MOA. Felter et al. (2018) identified the following key events for establishing a cytotoxicity MOA:

1.) The chemical is not DNA reactive.
2.) Clear evidence of cytotoxicity by histopathology such as the presence of necrosis and/or increased apoptosis.
3.) Evidence of toxicity by increased serum enzymes that are relevant to humans.
4.) Presence of increased cell proliferation as evidenced by increased labeling index and/or increased number of hepatocytes.
5.) Demonstration of a parallel dose response for cytotoxicity and formation of tumors.
6.) Reversibility (ideally).

The available data for HFPO dimer acid support cytotoxicity as a potential MOA. For example, HFPO dimer acid does not appear to be DNA reactive *in vivo* (see section 4.6.3 and appendix C). It did not induce chromosomal mutations in the form of structural aberrations, numerical aberrations, or micronuclei or DNA effects in the form of unscheduled DNA synthesis (DuPont-23219, 2007; DuPont-23220, 2007). Secondly, clear evidence of cytotoxicity in the form of increased liver necrosis and apoptosis was confirmed microscopically in male and female mice and rats in several less-than-chronic studies (15–90 day) and one 2-year chronic study (DuPont-17751-1026, 2009; DuPont-18405-841, 2010; DuPont-18405-1037, 2010; DuPont-18405-1238, 2013; DuPont-18405-1307, 2010; DuPont-24447, 2008; DuPont-24459, 2008; Wang et al., 2017; NTP, 2019). There is also evidence of increased serum liver enzymes. Hall et al. (2012) identifies significant increases in ALT/AST, ALP, and bilirubin/bile acids as potentially clinically relevant. Additionally, other enzymes such as SDH might reflect alterations in liver function (Hall et al., 2012). For HFPO dimer acid, significant increases in ALT (420%–1,254%), AST (106%–478%), ALP (1,134%–1,221%), and SDH (1,134%–1,221%) were observed in male mice administered the ammonium salt at 5–30 mg/kg/day for 28–90 days. Female mice had smaller increases in ALP (140%–143%) and SDH (32%–186%) as compared to male mice administered the same dose over the same duration. Overall, rats exhibited far fewer and smaller increases in serum liver enzyme levels following subchronic exposure compared to the mouse,

with increases in AST (106%) and ALP (52%) at 100 mg/kg/day in male rats and AST (66%) in female rats at 1,000 mg/kg/day. In the chronic study, however, ALT (228%), ALP (180%), and SDH (140%) significantly increased in male rats only when administered 50 mg/kg/day for 1 year. Typically, an increase in bilirubin, when accompanied with increased bile acids, is a reliable index of liver toxicity (Hall et al., 2012). For HFPO dimer acid, however, a decrease in serum bilirubin is a consistent effect observed across multiple studies, especially in female rodents (DuPont-17751-1026, 2009; DuPont-18405-1238, 2013; DuPont-18405-1307, 2010; Wang et al., 2017).

Data gaps exist for the other key events related to a cytotoxic MOA. Studies investigating if exposure to HFPO dimer acid result in increased labeling index and/or increased number of hepatocytes are unavailable. A 2-year chronic study in rats reported centrilobular and single cell necrosis in females in the 500-mg/kg/day high-dose group only (DuPont-18405-1238, 2013). Additionally, treatment-related liver tumors were also observed in the 500-mg/kg/day dose group (0/70 in control versus 11/70 in 500 mg/kg/day), which suggests a parallel response for cytotoxicity and formation of tumors. However, these effects were observed only in the high-dose group and dose selection in this study resulted in a large gap between the mid-dose (50 mg/kg/day) and high-dose (500 mg/kg/day). Therefore, the potential for a parallel dose response is unclear. Additionally, while liver necrosis exhibits a dose response in the 84/85 day modified reproductive developmental study (DuPont-18405-1037, 2010; NTP, 2019), there are no chronic studies in the mouse to determine if liver tumors form. The available data indicate that the mouse is the more sensitive to the liver effects resulting from HFPO dimer acid exposure.

Additionally, Blake et al. (2020) reports an increase in subcellular organelles consistent with peroxisomes and mitochondria in pregnant dam livers exposed to 2 or 10 mg/kg/day of HFPO dimer acid from E1.5 to E11.5 or E17.5 using TEM. This increase in mitochondria is not typical of PPARα activation and suggests an alternate MOA such as mitochondrial alteration could also be operative for the liver effects resulting from exposure to HFPO dimer acid and/or ammonium salt. Further supporting this alternate MOA, a number of genes upregulated in maternal and fetal livers exposed to 1–500 mg/kg/day of HFPO dimer acid ammonium salt from GD14 to GD18 are specific to mitochondrial beta oxidation (*Cpt1a*, *Cpt1b*, *Cpt2*, *Acaa2*, *Acadl*, *Acadm*), mitochondrial ketogenesis (*Hmgcs2*), and mitochondrial electron transfer (*Etfdh*) (Conley et al., 2019).

Finally, a study of HFPO dimer acid in HEK293 embryonal kidney cells found activation of genes associated with the PPARγ signaling pathway (Li et al., 2019). Further supporting a role for the PPARγ signaling pathway, Conley et al. (2019) reports upregulation of genes in maternal and fetal livers exposed to 1–500 mg/kg/day of HFPO dimer acid ammonium salt from GD14 to GD18, which are associated with PPARγ signaling, including *Pck1*, *Aqp7*, and *Gk.* Additionally, Rosen et al. (2017) concluded that 11%–24% of the PFAS-induced increase in transcriptional activity is PPARα independent, depending on the PFAS. This study identified 67 genes that were similarly upregulated in wild type (129S1/Sv1mJ) and PPARα-null (129S4/SvJae-*Ppara*^{tm1Gonz}/J) mouse livers exposed to either 3 or 10 mg/kg/day of PFHxS, 1 or 3 mg/kg/day of perfluorononanoic acid, 3 mg/kg/day of PFOA, or 10 mg/kg/day PFOS for 7 days, indicative of PPARα independence. The authors note that genes typically associated with the activation of PPARα such as *Acox1* were similarly upregulated in wild type and PPARα-null mice livers, suggesting that these genes might not be specific indicators of PPARα activation. Interestingly,

Conley et al. (2019) found that five of the 67 genes identified as PPARα independent in the Rosen et al. (2017) study are also significantly upregulated in the liver of pregnant rats and their fetuses exposed to HFPO dimer acid at doses greater than or equal to 1 mg/kg/day (i.e., *Ehhadh*, *Slc22a5*, *Ech1*, *Cpt2*, and *Acox1*). *Slc22a5* and *Cpt2* are associated with mitochondrial fatty acid oxidation.

Taken together, the available data indicate that a PPARα MOA is plausible in the liver in response to GenX chemical exposure, especially at doses greater than 0.5 mg/kg/day; however, there are not yet enough data to conclude that PPARα activation is the sole mechanism underlying the liver effects associated with exposure to GenX chemicals. For example, there are no studies investigating GenX chemical exposure in PPARα-null mice. It is worth noting that exposure to PFOA has been demonstrated to induce liver effects in PPARα-null mice, including hepatocellular hypertrophy (Minata et al., 2010). Additionally, available studies indicate that other MOAs (e.g., PPARγ, mitochondrial dysfunction, and cytotoxicity) are also plausible. The data are not adequate to conclude that any of the MOAs described here are the sole toxicologic MOA for HFPO dimer acid and/or ammonium salt in the liver and especially in other organ systems. For example, the potential MOA(s) for the observed reproductive and developmental effects (e.g., changes in GWG, placental lesions, reduced pup body weight, and reduced pup survival) are unknown, though Conley et al. (2021) provides mechanistic evidence that dysregulation of carbohydrate and lipid metabolism in the mother and developing offspring may be contributing to some of these effects. Of note, glycogen accumulation scores in pup livers were significantly lower compared to control in pups exposed to doses as low as 10 mg/kg/day of HFPO dimer acid ammonium salt from GD8-PND2. Additionally, no data support identification of a potential carcinogenic MOA for tumors in the pancreas or testes as being related to PPARα or any of the proposed alternative MOAs for the tumor development in either organ.

7.0 Dose-Response Assessment

7.1 Identification of Studies and Effects for Dose-Response Analysis

Several studies were evaluated further for identification of specific endpoints to carry forward for dose-response (BMD) modeling. EPA evaluated studies based on identification of adverse effects, duration of exposure, use of a control and two or more doses, and provision of NOAEL and/or LOAEL values. Data from available studies indicate that the liver is the most sensitive target of toxicity from exposure to GenX chemicals. Liver effects were observed in both male and female mice and rats at varying durations of exposures and doses. These effects occurred at the lowest doses and shortest durations of exposure to GenX chemicals.

Because liver effects such as increases in liver weight and hepatocellular hypertrophy (also referenced here as cytoplasmic alteration per NTP PWG's review) can be associated with activation of cellular PPARα receptors, EPA evaluated observed liver effects resulting from HFPO dimer acid ammonium salt exposure against the Hall criteria (Hall et al., 2012). These criteria indicate that increased liver weight and hepatocellular hypertrophy must be accompanied by histologic or clinical pathology indicative of liver toxicity to be considered adverse. Histologic or clinical pathology indicative of liver toxicity can include changes in liver enzyme concentrations in the serum, necrosis, inflammation, and degeneration. With these criteria in mind, EPA concluded that some of the observed liver effects such as single-cell and focal

necrosis, increased apoptosis, and increases in serum liver enzymes indicate toxicity of relevance to humans as opposed to PPARα-induced cell proliferation unique to rodents.

For the GenX chemicals database, many studies identified the mouse as the most sensitive species and the liver as a target organ for toxicity. Liver effects at low doses (e.g., less than or equal to 5 mg/kg/day) were identified in the 28 day oral (gavage) toxicity study in mice (DuPont-24459, 2008), the 90 day oral (gavage) toxicity study in mice (DuPont-18405-1307, 2010), and the oral (gavage) reproduction/developmental toxicity study in mice (DuPont-18405-1037, 2010). In these studies, increases in relative liver weight were accompanied by increases in hepatocellular hypertrophy, single-cell/focal necrosis and apoptosis.

EPA requested that NIEHS, NTP convene a PWG to provide independent, expert review of the liver tissues from the oral (gavage) reproduction/ developmental toxicity study in mice (DuPont-18405-1037, 2010) and the 90 day oral (gavage) toxicity study in mice (DuPont-18405-1307, 2010). Given the availability of longer duration studies demonstrating effects at low doses, the 28-day study in mice was not included in this review. The NTP PWG classified cell death according to the INHAND Organ Working Group's diagnostic criteria that describes how pathologists can distinguish between apoptosis and single-cell necrosis in standard H&E-stained tissue sections (Elmore et al., 2016). These criteria were unavailable at the time the DuPont studies were conducted and submitted to EPA.

The liver effects noted in the 28 day oral (gavage) toxicity study in mice (DuPont-24459, 2008) were not considered as a potential POD in support of the derivation of the RfD. The 28 day study did not use a dose range optimized for the identification of low-dose effects compared to the 90 day and reproduction/developmental toxicity studies (0, 0.1, 3, and 30 mg/kg/day-dose groups in the 28 day study versus 0, 0.1, 0.5 and 5 mg/kg/day in the 90 day and reproduction/developmental studies). For example, in DuPont-18405-1037 (2010), the LOAEL (i.e., the lowest dose at which an adverse effect is observed) of 0.5 mg/kg/day falls between the low and mid-doses of the dosing design used in DuPont-24459 (2008). Additionally, as described above, this short-term study was not reviewed by the NTP PWG because there were two longer duration studies in the most sensitive species.

The liver effects noted in the 90 day and reproduction/developmental toxicity studies (DuPont-18405-1307, 2010 and DuPont-18405-1037, 2010) were considered for determination of PODs in support of the derivation of RfDs. The NTP PWG concluded, that the dose response and constellation of lesions (i.e., cytoplasmic alteration (including hepatocellular hypertrophy), single-cell necrosis, focal necrosis, and apoptosis), rather than each lesion individually, represent adversity in these studies (appendix D). EPA interpreted the NTP PWG's definition that the constellation of liver lesions is adverse to apply to the dose group level, as opposed to individual animal level, given that the histopathology assessment represents a snapshot in time of a biological process within one portion of the liver that can vary across animals. Therefore, if multiple liver lesion types and progression of adverse liver effects (e.g., necrosis or apoptosis) were observed within a dose group, all animals in that dose group were included in the dose-response modeling. The constellation of liver lesions in the reproduction/developmental toxicity study in mice (DuPont-18405-1037, 2010) was selected for BMD modeling based on the incidence data as reported by the NTP PWG. Multiple liver lesions, including cytoplasmic alteration, single-cell, and focal necrosis, exhibited a dose response in both male and female mice in this study. These effects were observed at doses as low as 0.5 mg/kg/day. A constellation

of liver lesions observed in the 90-day toxicity study in mice (DuPont-18405-1307, 2010) were observed at higher doses (5 mg/kg/day) than in the reproduction/developmental toxicity study in mice (DuPont-18405-1037, 2010). The NTP PWG reported that 10 out of 10 male mice exhibited cytoplasmic alteration, compared to 0 in control at the 0.5-mg/kg/day dose in the 90-day toxicity study in mice (DuPont-18405-1307, 2010). Although NTP classified cytoplasmic alteration as part of the constellation of liver lesions considered adverse, no other liver lesions indicative of liver damage (i.e., single-cell or focal necrosis or apoptosis) were observed at the 0.5-mg/kg/day dose group in males. Consistent with the Hall criteria, EPA did not consider the cytoplasmic alteration findings alone as an adverse effect in the 0.5 mg/kg/day dose group but considered the constellation of liver lesions observed across the male mice in the high-dose group as adverse. Additionally, the female mice in this study did not exhibit a dose response for the constellation of liver lesions. For these reasons, the constellation of liver lesions observed in the 90-day toxicity study in mice were not selected for BMD modeling.

Additionally, the chronic rat 2-year cancer bioassay (DuPont-18405-1238, 2013) was not selected for the derivation of candidate RfDs for several reasons. Across all dosing groups in both male and female rats, just 25.4% of the test animals survived to their planned terminal necropsy with most of the animals experiencing unscheduled death/moribundity prior to the scheduled study termination at 104 weeks. Effects observed at low doses in this study include changes in serum albumin levels and the A/G ratio in male rats. For males, an increase in A/G ratio at 1 mg/kg/day at the 3-month time point and increases in both albumin and A/G ratio at the 12-month time point were observed, but these changes were not seen at 6 months. These changes, while indicative of an immune system effect, were deemed of unclear biological significance especially given these temporal inconsistencies. For these reasons, the changes in albumin and A/G ratio observed in DuPont-18405-1238 (2013) were not considered for determination of PODs in support of the derivation of the RfD. Liver effects were also observed in this study but did not occur at comparable doses to the oral reproductive/developmental toxicity study in mice. Also, the available chronic study evaluated only rats, and the data indicate that mice appear to be more sensitive. For example, mice presented with single-cell necrosis in doses as low as 0.5 mg/kg/day, with a large increase in response at 5 mg/kg/day in the oral reproductive/developmental toxicity study in mice (DuPont-18405-1037, 2010; NTP, 2019). Female mice also had a large increase in incidence compared to control at 5 mg/kg/day for both focal/multifocal and single-cell necrosis (DuPont-18405-1037, 2010; NTP, 2019). Conversely, the study authors did not report subchronic hepatocellular necrosis in the 90-day study of male and female rats. (DuPont-17751-1026, 2009). Hepatocellular necrosis is observed in the 2-year chronic rat study, but at higher doses (50 mg/kg/day for male rats and 500 mg/kg/day for female rats) as compared to the developmental/reproductive mouse study (0.5 mg/kg/day for male and female mice) (DuPont-18405-1238, 2013; NTP, 2019 reread of DuPont-18405-1037, 2010). While a chronic study is typically the preferred duration for development of lifetime RfD, in this case, the oral reproductive/developmental toxicity study indicates that adverse effects in the liver are observed in the parental mice at lower doses than those reported in the chronic study in rats. For these reasons, the adverse liver effects observed in DuPont-18405-1238 (2013) were not selected for determination of PODs in support of the derivation of the RfD.

Adverse health outcomes resulting from exposure from HFPO dimer acid or its ammonium salt are not limited to the liver. Studies in both rats and mice indicate that exposure to GenX chemicals during pregnancy and gestation results in adverse effects at low doses. Specifically,

Blake et al. (2020) determined that 58% and 83% of placentas evaluated at E17.5 were classified as abnormal in the 2- and 10-mg/kg/day HFPO dimer acid dose groups, respectively, with the number of abnormal placentas in the 10-mg/kg/day HFPO dimer acid dose group reaching statistical significance. Different placental lesions were recorded in the study, including labyrinth atrophy, labyrinth congestion, labyrinth necrosis, early fibrin clot, and the presence of placental nodules. Placental lesions were also evaluated against the proportion of placentas within a litter that were within normal limits to account for litter effects. The proportion of abnormal placentas was significantly higher at the 2- and 10-mg/kg/day dose groups relative to vehicle control. The placental lesions observed in Blake et al. (2020) exhibited a dose response; however, only two dose groups were used in this study, and the study LOAEL (2 mg/kg/day) is much higher than the LOAELs observed for liver effects (0.5 mg/kg/day). It is possible that the placental lesions occur at lower doses, especially given that 58% of placentas were classified as abnormal at the lowest dose tested, but these data are lacking. While the placental lesions observed are considered adverse, additional research is needed to understand if they would be seen at lower doses. Additionally, further research should evaluate the impact of GenX chemicals-induced placental lesions on development after gestation, including latent health outcomes. Blake et al. (2020) reported that these lesions did not impact some measured reproductive and developmental outcomes such as implantation sites, viable embryos, nonviable embryos, and resorptions. Because, however, a full two-generation reproductive toxicity study is not available for mice, the impact of placental lesions on development after gestation, including latent health outcomes, is unclear.

An increase in maternal GWG ranging from 13 to 22% was reported by DuPont-18405-1037 (2010) at doses as low as 0.5 mg/kg/day. Similarly, an increase in maternal GWG in mice at E17.5 at doses greater than or equal to 2 mg/kg/day (i.e., the lowest tested dose) was also reported by Blake et al. (2020) using a mixed-effect modeling approach that adjusts for repeated measures of relative maternal GWG, litter size, and embryonic day. Furthermore, Conley et al. (2019) evaluated maternal GWG in rats and observed a *decrease* in GWG following exposure to dosing greater or less than 250 mg/kg/day of HFPO dimer acid. A decrease in maternal GWG in rats was also reported in DuPont-18405-841 (2010), which suggests that the shift in maternal GWG might be species specific. Given the lack of mechanistic clarity for the maternal GWG endpoints in two similar species, the endpoint was not considered for determination of PODs in support of the RfD derivation. According to Blake et al. (2020), the inconsistency in maternal GWG response between rats (Conley et al., 2019; DuPont-18405-841, 2010) and mice (Blake et al., 2020; DuPont-18405-1037, 2010) might be due to differing statistical methods, interspecies elimination rates, and/or developmental exposure windows. All other reproductive and developmental effects reported as a result of gestational exposure to GenX chemicals (see Table 12 for a summary) were observed at higher doses than the placental lesions and changes in GWG and were not selected for determination of PODs in support of the RfD derivation.

Immune and hematological effects were also observed at low doses; however, these endpoints are not as consistently observed as the liver effects. Additionally, there is some uncertainty regarding the biological significance of both the hematological and immune endpoints. For example, the observed changes in albumin and A/G ratio at dosing of 3 mg/kg/day (DuPont-24447, 2008; DuPont-24459, 2008) are considered early markers of potential immunotoxic effects. Evaluation of additional immune function assays, histopathology, and immune endpoints such as antibody levels, however, are not available. Currently little or no data exist on the

potential for GenX chemicals to impact aspects of immune function beyond the immunosuppression (e.g., allergic responses and autoimmunity). Furthermore, while considered adverse, the hematological effects were inconsistently observed, especially as study duration increased. For example, the hematological effects observed in the 28-day mouse study at 3 mg/kg/day were not observed in the 90-day subchronic study in mice, except for a 3% decrease in hemoglobin concentration at 5 mg/kg/day. No hematological changes were observed at the 0.1- or 0.5-mg/kg/day dose in the subchronic mouse study (DuPont-18405-1307, 2010). Likewise, the hematological effects observed in the subchronic rat study at low doses are not observed in the chronic rat study (DuPont-17751-1026, 2009; DuPont-18405-1238, 2013). Specifically, decreases in hemoglobin, hematocrit, and RBC count that are observed at 10 mg/kg/day in the subchronic study are not observed after 12 months of dosing, which adds additional uncertainty to the significance of these effects (DuPont-18405-1238, 2013). For these reasons, hematological and immune endpoints from these studies were not considered further for determination of PODs in support of the derivation of the RfD.

7.2 Methods of Analysis

7.2.1 BMD Modeling

There are no biologically based dose-response (BBDR) models available for HFPO dimer acid and its ammonium salt. Thus, using the most current version of its Benchmark Dose Software at the time data were modeled, EPA evaluated a range of dose-response models thought to be consistent with underlying biological processes to determine how best to empirically model the dose-response relationship in the range of observed data (appendix E).

Consistent with EPA's *Benchmark Dose Technical Guidance* (EPA, 2012), the BMD and the BMDL were estimated using a BMR of 10% extra risk for dichotomous data, in the absence of information regarding the level of change considered biologically important, and to facilitate a consistent basis of comparison across endpoints, studies, and assessments. Using the pathology analysis from the NTP PWG, candidate PODs were estimated from all three doses (plus control) for DuPont-18405-1037 (2010) (Table 13).

Further details, including the BMD modeling output and graphical results for the selected models, are provided in appendix E of this assessment.

7.2.2 Dosimetric Adjustment of the Experimental Animal-Based POD to POD_{HED}

EPA guidance was followed to calculate a candidate POD_{HED} from the animal-based POD using a $BW^{3/4}$ allometric scaling approach (EPA, 2011b), which is derived from the relationship between body surface area and basal metabolic rate in adults. With infants and children, surface area and basal metabolic rates are very different than for adults with a slower metabolic rate. While this $BW^{3/4}$ allometric scaling is not appropriate for infants and children because of the limited toxicokinetic data available, the critical effect of liver single-cell necrosis observed in adult mice is not a developmental endpoint nor is it specific to early life stages. However, the exposure for the parental females in DuPont-18405-1037 (2010) took place during pregnancy. EPA indicates that:

> …exposure and internal dosimetry of pregnant, nursing, and growing animals may vary compared to adult animals, so use of the administered dose for toxicity studies involving

these periods is associated with relatively greater uncertainty, absent life stage-specific information (EPA, 2011b).

In this case, however, $BW^{3/4}$ allometric scaling relied on life stage-specific BW data from the pregnant or lactating dams as appropriate. The HFPO dimer acid ammonium salt POD_{HED}s from the experimental animal studies (DuPont-18405-1037, 2010) were adjusted via the dosimetric adjustment factor (DAF) equation below:

$$DAF = (BW_a^{1/4}/BW_h^{1/4}),$$

where:

- BW_a = animal BW
- BW_h = human BW

For the chronic reproductive/developmental toxicity study (DuPont-18405-1037, 2010), a BW_a value of 0.0372 kg was identified as the mean BW of the F_0 male mouse controls on study day 84 (the final day of animal dosing). The mean BW_a for the F_0 females in this study was 0.0349 kg taken from the controls upon sacrifice on LD21.

A BW_h of 80 kg for humans was selected based on National Health and Nutrition Examination Survey (NHANES) sampling data (EPA, 2011a). For adults more than 21 years of age, EPA updated the default BW assumption from 70 kg to 80 kg based on NHANES data from 1999 to 2006 as reported in Table 8.1 of EPA's *Exposure Factors Handbook* (EPA, 2011a). The updated BW represents the mean weight for adults ages 21 and older. The resulting DAF for the allometric scaling of doses from male mice to humans is 0.15 for DuPont-18405-1037 (2010). For the female mice, the DAF is 0.14 for DuPont-18405-1037 (2010). Applying the DAF to the identified PODs identified for liver effects in adult mice yields a POD_{HED} as follows:

$$POD_{HED} = \text{POD animal dose (mg/kg/day)} \times DAF$$

Table 13. Summary of Determination of POD_{HED}

Endpoint and reference	Species/ Sex	Model	BMR	BMD_{10} (mg/kg/day)	POD (mg/kg/day)	POD Type	DAF	POD_{HED}[a] (mg/kg/day)
HEPATIC								
Constellation of liver lesions in parental males (DuPont-18405-1037, 2010)[b]	Crl:CD1(ICR) mice F_0 parental male	Benchmark dose (ver. 3.1.2) Probit	10%	0.19	0.14	$BMDL_{10}$	0.15	0.02
Constellation of liver lesions in parental females (DuPont-18405-1037, 2010)[b]	Crl:CD1(ICR) mice F_0 parental female	Benchmark dose (ver. 3.1.2) Probit	10%	0.12	0.09	$BMDL_{10}$	0.14	0.01

Notes: N/A = not applicable.

[b]Calculations for DuPont 18405-1037 (2010) rely on pathology conclusions of the NTP PWG (Appendix D)

7.3 Derivation of Candidate RfD Values

To calculate the candidate RfD values, EPA applied UFs to the POD_{HED}s from the oral reproduction/developmental toxicity study in mice as described in this section. UFs were applied according to guidance in EPA's *Review of the Reference Dose and Reference Concentration Processes* (EPA, 2002).

An interspecies uncertainty factor (UF_A) of 3 ($10^{1/2}$ = 3.16, rounded to 3) was applied to account for uncertainty in extrapolating from laboratory animals to humans. The UF_A is generally presumed to include both toxicokinetic (i.e., absorption, distribution, metabolism, and elimination) and toxicodynamic (i.e., MOA) aspects. A POD_{HED} was derived from the BMDL using EPA's *Recommended Use of Body Weight$^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose* (EPA, 2011b). This guidance describes approaches for deriving POD_{HED}s from data from laboratory animals, with the preferred approach being PBPK modeling. For HFPO dimer acid and ammonium salt, no PBPK models have been developed or published. Other approaches described by the guidance include the use of chemical-specific data to inform the derivation of human equivalent oral exposures. In the absence of either PBPK models or chemical-specific information, a BW scaling to the ¾ power approach is applied to extrapolate toxicologically equivalent doses of orally administered agents from adult laboratory animals to adult humans. Although this scaling addresses most aspects of cross-species extrapolation of toxicokinetic processes, there is some residual uncertainty for toxicokinetics and uncertainty around toxicodynamic processes (EPA, 2011b). Thus, in the absence of chemical-specific data to quantify this uncertainty, a UF of 3 was applied.

An intraspecies uncertainty factor (UF_H) of 10 is applied to account for variability in the responses within the human populations because of both intrinsic (toxicokinetic, toxicodynamic, genetic, life stage, and health status) and extrinsic (lifestyle) factors that can influence the response to dose. No information to support a UF_H other than 10 was available to characterize interindividual and age-related variability in the toxicokinetics or toxicodynamics.

A LOAEL-to-NOAEL extrapolation uncertainty factor (UF_L) of 1 is applied because a BMDL is used as the basis for the POD_{HED} derivation. When the POD type is a BMDL, the current approach is to address this factor as one of the considerations in selecting a BMR for BMD modeling. In this case, the BMR of a 10% change for the modeled liver endpoints was selected under the assumption that it represents a minimal, but biologically significant, change for these effects.

A UF for extrapolation from a subchronic to a chronic exposure duration (UF_S) of 10 was applied for the derivation of the chronic RfD, but not of the subchronic RfD. The reproduction/ developmental study (DuPont-18405-1037, 2010) considered for dose-response analysis is shorter than the duration of a chronic study. Chronic studies typically employ repeated dosing for longer than 90 days or for more than 10% of the human life span (EPA, 2002). In DuPont-18405-1037 (2010), F_0 females that delivered were dosed daily starting 14 days prior to pairing and were dosed through LD20 for a total of 53 to 64 days of exposure, depending on delivery date. By contrast, F_0 males in this study were dosed 70 days prior to mating and throughout mating through 1 day prior to scheduled termination, for a total of 84 to 85 days of exposure.

Because a 2-year chronic mouse study is unavailable and since female mice were dosed well below the 90-day exposure window typically employed in a subchronic study, the impact of a longer dosing duration on both the incidence and severity of liver effects in mice is unknown. This is important because duration of exposure appears to play a role in the progression and severity of liver effects resulting from GenX chemical exposure, as evidenced in female rats. Specifically, necrosis in female rats was not reported in the 28- or 90-day rat studies or the interim 1-year time point in the 2-year chronic rat study, which dosed the rats from 3 to 1,000 mg/kg/day. However, at the completion of the 2-year chronic rat study, centrilobular and single-cell necrosis are reported in the 500-mg/kg/day-dose group. Moreover, treatment-related liver tumors were observed in the 500-mg/kg/day rat dose group (0/70 in control versus 11/70 in the 500-mg/kg/day group). These data demonstrate progression of liver effects over the 2-year dosing period. Additionally, Blake et al. (2020) did not find clear evidence of changes in maternal liver serum enzymes (i.e., ALP, ALT or AST) or increases in liver necrosis as compared to control after 10-16 days of dosing at 2 mg/kg/day. Similarly, DuPont-24459 (2008) did not report single cell necrosis in female mice treated with 0.1 or 3 mg/kg/day after 28 days of dosing, though 4/10 mice displayed single cell necrosis in the 30 mg/kg/day dose group. However, DuPont-18405-1037 (2010) found liver necrosis in mice after 53-85 days of dosing at 0.5 mg/kg/day, indicating progression of liver effects as the duration of dosing increases. Because the mouse presents with liver necrosis at much lower doses and shorter durations (0.5 mg/kg/day at 53–85 days) than the rat and because the mode of action for these liver effects is uncertain (see section 6), it is critical to have a 2-year chronic study in the mouse to understand the progression of these liver effects. Specifically, a longer duration study would likely result in an increased frequency and/or magnitude of response and could also reveal additional adverse effects at lower doses than currently observed in the existing less-than-chronic mouse studies (DuPont-24459, 2008; DuPont-18405-1307, 2010; DuPont-18405-1037, 2010). For these reasons, EPA applied a UF of 10 to account for duration of exposure for the chronic RfD. For the subchronic RfD, a UF was not applied to account for duration as the study is of subchronic duration.

A database uncertainty factor (UF_D) of 10 was applied to account for database deficiencies. The database uncertainty factor is applied to account for a potentially lower reference value as a result of an incomplete characterization of a chemical's toxicity (EPA, 2002). The GenX chemicals database contains a number of toxicological studies including acute studies in both mice and rats, subchronic studies in mice and rats, a chronic study in rats, a one generation reproductive and developmental study in mice and gestational reproductive and developmental toxicity studies in mice and rats, as well as a single immunotoxicity study; however, when evaluating the available endpoints and studies to ensure comprehensive characterization of the potential toxicity, there are important deficiencies that need to be considered, particularly for understanding developmental toxicity. If data from the available toxicology studies raise suspicions of developmental toxicity and signal the need for developmental data on specific organ systems (e.g., detailed nervous system, immune system, carcinogenesis, or endocrine system), then the database factor should take into account whether or not these data are available and used in the assessment (EPA, 2002). For GenX chemicals, there are reproductive or developmental effects of concern in mice occurring at similar dose levels to the liver effects (changes in maternal GWG and placental lesions indicative of placental insufficiency) or ongoing research related to these and other endpoints or effects that have not been studied yet

(skeletal ossification, mammary gland development, altered metabolism in offspring, changes in thyroid hormones in the mouse).

For example, increases in maternal gestational weight gain and placental lesions were observed in mice at doses similar to the observed liver effects. In DuPont-18405-1037 (2010) mean maternal GWG, calculated from individual differences, significantly increased over the gestational period (0–18 days) by 18% and 22% in the 0.5- and 5-mg/kg/day-dose groups, respectively. The NOAEL for this effect would be 0.1 mg/kg/day which is the same as the liver effects. Additionally, Blake et al., 2020 found that maternal GWG was significantly increased compared to vehicle control at 2 mg/kg/day and 10 mg/kg/day at gestational day 17.5 using effect estimates from mixed effect models adjusting for repeated measures of relative GWG, litter size, and embryonic day. This is a consistent effect observed in two studies conducted by two different groups. Conley et al. (2019, 2021) also evaluated GWG in rats and observed a decrease following exposure to dosing greater than 125 mg/kg/day of HFPO dimer acid. A decrease in GWG in rats was also reported in DuPont-18405-841 (2010), which suggests that the shift in GWG might be species specific. Blake et al. (2020) also suggested that differing statistical methods, interspecies elimination rates, and exposure windows could explain these disparate results. In humans, altered GWG has been shown to adversely impact both mothers and infants. Effects including pregnancy-induced hypertension, gestational diabetes, postpartum weight retention, difficulty breast feeding, increased risk of stillbirth and infant mortality, and preterm birth have been associated with increased GWG (Rasmussen and Yaktine, 2009).

Secondly, Blake et al. (2020) reports a statistically significant increase (58%) in placental lesions over control at 2 mg/kg/day, the lowest dose used in this study. The placenta is critical to the transfer of nutrients, oxygen, and waste between mother and baby. Because of its role in maintaining pregnancy and programming latent health outcomes it is a relevant endpoint to evaluate maternal and embryo health. Placental insufficiency, as evidenced by effects such as those observed by Blake can result in reduced transfer of vital oxygen and nutrients. Additionally, deficiencies in placental development or function can result in hypertensive disorders of pregnancy which increases the risk of post-pregnancy hypertension, heart disease, and stroke in affected women, as well as increased risk for adverse cardiometabolic outcomes in adult offspring (Pinheiro et al., 2016). EPA notes that it is unclear how the placental lesions might impact reproductive and developmental outcomes. For example, implantation sites, viable embryos, nonviable embryos, and resorptions were not significantly different than control in Blake et al. (2020). Because, however, a full two-generation reproductive toxicity study is not available for mice, the impact of placental lesions on development after gestation or latent effects resulting from a placental insufficiency phenotype are unclear. Notably, Blake et al. (2020) also reported placental lesions for PFOA and, studies in humans have shown associations between PFOA exposure and health outcomes resulting from placental insufficiency such as pregnancy-induced hypertension or preeclampsia (EPA, 2016a).

As mentioned above, other database deficiencies include the absence of a full two-generation reproductive and developmental toxicity study to understand if latent effects occur as a result of exposure to GenX chemicals during development (e.g., adverse cardiometabolic outcomes in adult offspring associated with placental insufficiency). Additionally, Conley et al. (2021) reported that survival of pups born to dams dosed from GD8-PND2 was significantly reduced on PND1 and PND2 at doses ≥62.5 mg/kg/day. Pup body weight gain (birth to PND2) and PND2

body weight in the surviving pups were both reduced at doses ≥30 mg/kg/day. These effects were attributed to the hypoglycemia and elevated serum lipid levels newborns displayed, consistent with impaired fetal glycogen storage. Metabolic disturbance during fetal development is likely to lead to long-term negative metabolic outcomes in the offspring. These effects are among the most sensitive effects observed in the rat resulting from exposure to GenX chemicals and highlight the importance of having a full two-generation reproductive and developmental toxicity study.

Additionally, the evaluation of particular developmental endpoints during early organogenesis (i.e., GD0 to GD6) such as delayed skeletal ossification and mammary gland development in the mouse that have been observed following exposure to other PFAS like PFOA (EPA, 2016a,b) are lacking. For PFOA, the LOAEL for mammary gland developmental effects was 0.01 mg/kg/day, with no study NOAEL. There are no published studies looking at mammary gland development for GenX chemicals at this time. Similarly, studies that evaluate skeletal ossification in the more sensitive species, mice, do not exist for GenX chemicals. The LOAEL for reduced skeletal ossification was 1 mg/kg/day for PFOA (no study NOAEL) and studies looking at lower dose ranges were not available. These studies are especially important considering that Blake et al. (2020) demonstrated accumulation of HFPO dimer acid in whole mouse embryos from E1.5 to E11.5 to E1.5 to E17.5. The lack of studies evaluating these endpoints at or below doses included in the critical study identifies this as a significant gap in the understanding of the developmental toxicity of GenX chemicals.

In addition to the gaps in the database concerning reproductive and developmental toxicity, other database gaps are noted for GenX chemicals with respect to potential immune, hematological and neurological effects, which are outlined below. Additionally, there are no human toxicity data from epidemiological studies in the general population or worker cohorts evaluating the health effects of exposure to these GenX chemicals.

The immunotoxicity of GenX chemicals has not yet been fully elucidated. PFAS chemicals, including PFOS and PFOA, interact with the immune system in studies of both humans and animals (NTP, 2016; EPA, 2016a,b). The GenX chemical immunotoxicity database is less robust than PFOA and PFOS, but does include two LLNAs (DuPont-19897, 2006; DuPont-22616 RV1, 2007) and a 28-day immunotoxicity study (Rushing et al., 2017). Rushing et al. (2017) identified suppression of TDAR by a reduction in antigen-specific IgM antibody production in females and increased T cell numbers in males at the high dose only (100 mg/kg/day). The LLNA is typically used to identify potential skin-sensitizing chemicals through their ability to induce allergic immune response (OECD, 2010b). The LLNAs were conducted with HFPO dimer acid ammonium salt preparations of varied purity and yielded equivocal results (one positive (DuPont-19897, 2006) and one negative (DuPont-22616 RV1, 2007). Evaluations of additional immune function assays, histopathology, and immune endpoints such as antibody levels are not available. The combined GenX chemicals immunotoxicity dataset was found to be incomplete as it did not include sufficient measures of immunopathology, humoral immunity, cell-mediated immunity, nonspecific immunity, or host resistance, but the available studies are suggestive of a potential immune hazard. Data on the potential for these GenX chemicals to impact aspects of immune function beyond immunosuppression are lacking. Additional studies, therefore, would be useful to support a more conclusive determination of immunotoxic potential.

Finally, additional research is needed to help determine if the inconsistent hematological effects observed in many of the studies are adverse and to investigate potential neural effects of GenX chemical exposure. As mentioned above, the hematological effects observed in the 28-day mouse study at 3 mg/kg/day were not observed in the 90-day subchronic study in mice, except for a 3% decrease in hemoglobin concentration at 5 mg/kg/day. No hematological changes were observed at the 0.1- or 0.5-mg/kg/day dose in the subchronic mouse study (DuPont-18405-1307, 2010). Likewise, the hematological effects observed in the subchronic rat study at low doses are not observed in the chronic rat study (DuPont-17751-1026, 2009; DuPont-18405-1238, 2013). Cannon et al. (2020) demonstrated that HFPO dimer acid can modify the activity of transporters at the blood-brain barrier. Specifically, HFPO dimer acid inhibited P-gp and BCRP transport in rat brain capillaries. The potential neural effects that might result from inhibition of transport activity are unknown and require additional investigation.

Furthermore, Conley et al. (2019), Conley et al. (2021) and Blake et al. (2020) observed alterations in thyroid hormones in the pregnant dam after gestational exposure to GenX chemicals. Specifically, Conley et al. (2019, 2021) demonstrated significant decreases in maternal serum total T3 and T4 levels in the pregnant rat (e.g., a 51% decrease in total T4 in pregnant dams dosed with 62.5 mg/kg/day from GD8-PND2) while Blake et al. (2020) reported a significant increase in mouse placental total T4 levels relative to control. In the Blake et al (2020) study, there was a trend towards a significant effect of higher T4 in placentas exposed to 2 mg/kg/day GenX (38% increase) though not statistically significant. Maternal serum thyroid hormones could not be measured due to volume constraints in the study. The potential neurodevelopmental effects that might result from the disruption of these thyroid hormones are unknown and require additional investigation at lower doses.

Given the residual concerns for potentially more sensitive effects outlined above, a database uncertainty factor is considered necessary to account for the possibility that the currently available database for GenX chemicals may result in an under-protective point of departure. Specifically, a value of 10 was selected for the UF_D to account for the uncertainty surrounding reproductive or developmental effects of concern occurring at similar dose levels to the liver effects (maternal GWG, placental lesions indicative of placental insufficiency, changes in thyroid hormones) or effects that observed to occur with exposure to other PFAS (e.g., PFOA) but have not been studied or do not have published studies currently for GenX chemicals (skeletal ossification, changes in thyroid hormones, mammary gland development, and altered metabolism in the mouse).

The UFs described above were applied to the POD_{HED}s from section 7.2.2 to derive a candidate RfDs applicable to both subchronic and chronic exposures. Table 14 summarizes the results of this quantification for the subchronic scenario. The subchronic candidate RfDs range from 0.00003 mg/kg/day to 0.00007 mg/kg/day. Likewise, Table 15 summarizes the results of this quantification for the chronic scenario. The chronic candidate RfDs range from 0.000003 mg/kg/day to 0.000007 mg/kg/day. Each POD_{HED} is impacted by the doses used in the subject study, the endpoints monitored, and the animal species/gender studied. Thus, the array of outcomes, combined with knowledge of the individual study characteristics, helps to inform selection of a subchronic and chronic RfDs that will be protective for humans.

Table 14. Candidate Subchronic RfD Values

Endpoint and reference	POD_{HED}[a] (mg/kg/day)	POD Type	UF_L	UF_S	UF_A	UF_H	UF_D	UF_{TOT}	Candidate RfD value (mg/kg/day)
HEPATIC									
Liver constellation of lesions in parental male mice (DuPont-18405-1037, 2010)	0.02	$BMDL_{10}$	1	1	3	10	10	300	7×10^{-5}
Liver constellation of lesions in parental female mice (DuPont-18405-1037, 2010)	0.01	$BMDL_{10}$	1	1	3	10	10	300	3×10^{-5}

Note:
[a] Calculated using $BW^{3/4}$ scaling (EPA, 2011b).

Table 15. Candidate Chronic RfD Values

Endpoint and reference	POD_{HED}[a] (mg/kg/day)	POD Type	UF_L	UF_S	UF_A	UF_H	UF_D	UF_{TOT}	Candidate RfD value (mg/kg/day)
HEPATIC									
Liver constellation of lesions in parental male mice (DuPont-18405-1037, 2010)	0.02	$BMDL_{10}$	1	10	3	10	10	3000	7×10^{-6}
Liver constellation of lesions in parental female mice (DuPont-18405-1037, 2010)	0.01	$BMDL_{10}$	1	10	3	10	10	3000	3×10^{-6}

Note:
[a] Calculated using $BW^{3/4}$ scaling (EPA, 2011b).

7.4 Selection of Overall RfD

The oral reproductive/developmental toxicity mouse study (DuPont-18405-1037, 2010) and its pathologic demonstration of liver effects in females (constellation of lesions including cytoplasmic alteration, hepatocellular single-cell and focal necrosis, and hepatocellular apoptosis) were selected as the critical study and effect, respectively, for deriving the subchronic and chronic RfDs for HFPO dimer acid and its ammonium salt. The RfD based on this grouping of effects occurred at the lowest dose and therefore provides the most health-protective RfD among the modeled endpoints based on the available data. The selection of the constellation of lesions is supported by the NTP PWG conclusion that the dose response and constellation of lesions (i.e., cytoplasmic alteration, apoptosis, single-cell necrosis, and focal necrosis) rather than one lesion by itself, represents adversity within the confines of the study. Because there is a negligible difference between the molecular weight of the HFPO dimer acid ammonium salt (347.08 grams per mol (g/mol)) and the free HFPO dimer acid (330.06 g/mol), the subchronic and chronic RfDs presented here are applicable for both chemicals.

Several of the other studies provide support for the selection of the DuPont-18405-1037 (2010) study as the critical analysis and the constellation of liver lesions as the critical effect (DuPont-24447, 2008; DuPont-24459, 2008; DuPont-18405-841, 2010; DuPont-18405-1307, 2010; DuPont-18405-1238, 2013) on which to base the subchronic and chronic RfDs. The liver is the primary target organ for toxicity from oral exposure to HFPO dimer acid and its ammonium salt. Liver effects are observed in both male and female mice and rats at varying durations of exposures and doses of GenX chemicals. Specifically, changes in liver enzyme levels, histopathological lesions, and tumors are observed in both male and female mice and rats at varying durations of exposures (15 days to 2 years) and doses of these GenX chemicals (0.5–1,000 mg/kg/day).

7.4.1 Subchronic RfD

This section provides the calculation for the subchronic RfD. The values and rationale describing the input parameters for the RfD calculation can be found in sections 7.2 and 7.3, and appendix E.

$$\text{Subchronic RfD} = \frac{POD_{HED}}{Total\ UF}$$

$$= \frac{0.01 \frac{mg}{kg}/day}{300}$$

$$= \mathbf{3 \times 10^{-5}\ mg/kg/day\ or\ 0.03\ \mu g/kg/day}$$

where:

- POD_{HED} = 0.01 mg/kg/day, the HED based on the $BMDL_{10}$ for liver effects (constellation of liver lesions as defined by the NTP PWG) in parental female mice exposed to HFPO dimer acid ammonium salt by gavage for 53–64 days (DuPont-18405-1037, 2010).
- Total UF = 300, including 10 for UF_H, 3 for UF_A, and 10 for UF_D.

7.4.2 Chronic RfD

This section provides the calculation for the chronic RfD. The values and rationale describing the input parameters for the RfD calculation can be found in sections 7.2 and 7.3, and appendix E.

$$\text{Chronic RfD} = \frac{POD_{HED}}{Total\ UF}$$

$$= \frac{0.01\frac{mg}{kg}/day}{3000}$$

$$= \mathbf{3 \times 10^{-6}\ mg/kg/day\ or\ 0.003\ \mu g/kg/day}$$

where:

- POD_{HED} = 0.01 mg/kg/day, the HED based on the $BMDL_{10}$ for liver effects (constellation of liver lesions as defined by the NTP PWG) in parental female mice exposed to HFPO dimer acid ammonium salt by gavage for 53–64 days (DuPont-18405-1037, 2010).
- Total UF = 3000, including 10 for UF_H, 3 for UF_A, 10 for UF_S, and 10 for UF_D.

8.0 Effects Characterization

8.1 Uncertainty and Variability

The uncertainty and variability in an RfD are a function of both intrinsic and extrinsic factors. EPA has identified multiple short-term subchronic and chronic studies that provide dose-response information and were considered during the quantitative assessment of risk. The range of external dose NOAELs among these studies is 0.1 mg/kg/day–10 mg/kg/day. The LOAELs range from 0.5 mg/kg/day to 100 mg/kg/day.

The intrinsic uncertainties in the assessment reflect the fact that the NOAELs and LOAELs are derived using central tendency estimates for variables such as BW, food and drinking water intakes, and dose. The central tendency estimates are derived from small numbers of relatively genetically similar animals representing one or more strains of rats or mice living in controlled environments. The animals lack the heterogeneous genetic complexity, behavioral diversity, and complex habitats experienced by humans. These differences, to some extent, have been minimized using the modeled outcomes and use of allometric scaling to help inform the application of the UF.

While EPA has routinely used BW to allometrically scale toxicity data from animal test species to HEDs during the development of human health risk assessments, the applied methodology is not without limitation (EPA, 2011b). Allometric scaling using BW scaled to the ¾ power primarily addresses uncertainty associated with toxicokinetics, although the exact amount of uncertainty addressed by this method for any specific chemical is often not quantifiable. In following the recommended method to apply $BW^{3/4}$ scaling, it remains possible that the toxicokinetic uncertainty associated with GenX chemicals might be more or less than what is accounted for using this scaling methodology.

For all selected candidate studies, $BW^{3/4}$ scaling was found to be appropriate because GenX chemicals are not metabolized and have relatively short clearance times, especially compared to other longer chain PFAS chemicals such as PFOA (DuPont-18405-1017 RV1, 2011; EPA, 2011b; Gannon et al., 2016). The $BW^{3/4}$ scaling methodology is not appropriate, however, when using children's BWs. This limitation exists due to the absence of quantitative information describing the toxicokinetic and toxicodynamic differences between test animals and early life-stage humans (EPA, 2011b). Because the liver effects observed following exposure to GenX chemicals were in adult animals, the allometric scaling methodology was scaled to the average adult human BW.

Variability in the study outcomes is extrinsically a function of study design and the endpoints monitored. Studies of systemic toxicity monitor an array of endpoints that are not evaluated in studies of reproductive, developmental, neurological, and immunological toxicity. The reverse is true for the other types of toxicity studies compared to standard short-term and long-term systemic studies. Studies of systemic toxicity do not often examine neurological or immunological endpoints. Increases in liver weight were seen in many of the studies with dose-response information, and the histological evaluation of the liver supported a determination that the increase in liver weight when it is accompanied by necrosis can be considered as adverse rather than adaptive, according to the Hall et al. (2012) criteria. Increases in relative liver weight with confirmed liver necrosis were observed in DuPont-24447 (2008), DuPont-24459 (2008), DuPont-18405-1037 (2010), DuPont-18405-1307 (2010), and DuPont-18405-1238 (2013).

The subchronic and chronic RfDs are based on the POD_{HED} derived from the parental females from the oral reproductive/developmental toxicity study in mice with application of UFs to account for variability in the human population, database uncertainties, and possible differences in the ways in which humans and rodents respond to HFPO dimer acid and/or its ammonium salt that reaches their tissues (DuPont-18405-1037, 2010). Uncertainty associated with relying on a less-than-chronic study to derive a chronic RfD is addressed with a UF applied only for the chronic RfD calculation. The selected RfDs are based on the adverse liver effects observed in the parental female animals. Selection of this endpoint is expected to provide protection to both the sensitive life stages and the general population. The RfDs are supported by the outcomes from other studies based on different endpoints, including hematological, immune, and developmental effects (DuPont-24459, 2008; DuPont-17751-1026, 2009; DuPont-18405-1037, 2010). These supporting data from the HFPO dimer acid and its ammonium salt database increase confidence in the RfD.

8.2 Composition of Test Substance

Most of the available data for HFPO dimer acid and its ammonium salt with PMNs were submitted to EPA by DuPont, the manufacturer of GenX chemicals, under TSCA, as required pursuant to a consent order for these chemicals (EPA, 2009) or as required under TSCA reporting requirements (e.g., section 8(e) 15 U.S.C. § 2607.8(e)). In these submissions, DuPont provided information on the purity of the test substance used in each of the studies. Purity ranged from 84% to 88% across the toxicity studies considered in this assessment. DuPont provided a certificate of these analyses and noted that they were conducted under EPA GLP standards (40 CFR part 792). The major impurity identified is water (12.7%–13.3%). Trace amounts of PFOA were also identified in the test substance (3.4–150 parts per million). DuPont noted that test results were adjusted for purity based on the reported test article formulations. Based on the

information provided, administered doses of PFOA present as a contaminant in the formulations used by DuPont are low. For example, in the critical study chosen for the derivation of the RfDs, the dose of administered PFOA is 0.000075 mg/kg/day at the GenX chemicals NOAEL (0.1 mg/kg/day) (DuPont-18405-1037, 2010). For PFOA, NOAELs ranging from 0.01 mg/kg/day to 30 mg/kg/day have been identified for effects including developmental, liver, and immune endpoints (EPA, 2016a). Despite trace amounts of PFOA that might be present as an impurity, EPA recognizes the potential for this impurity to contribute to the observed toxicity at very high doses of GenX chemicals. At present, however, discerning the contribution of this low level of PFOA to observed toxicity is not possible. Thus, EPA concluded that the presence of PFOA at these low levels is not the primary driver of toxicity observed in the studies. Of note is that the same test substance (Lot H-28548) was used in the 90-day mouse and rat studies, the chronic rat study, and the oral reproductive and developmental toxicity and prenatal developmental toxicity studies (DuPont-17751-1026, 2009; DuPont-18405-841, 2010; DuPont-18405-1307, 2010; DuPont-18405-1238, 2013). Additionally, the same test substance (Lot H-28397) was used in both the mouse and the rat 28-day studies (DuPont-24447, 2008; DuPont-24459, 2008). Despite differences in test substance purity, adverse effects were observed consistently across the DuPont studies. Many of the peer-reviewed studies did not report purity in their methods or formulations of HFPO dimer acid and ammonium salt (Behr et al., 2020; Blake et al., 2020; Rushing et al., 2017; Sheng et al., 2018; Wang et al., 2017).

Given the database for GenX chemicals, the quality of these studies—including adequacy of reporting of methods and results—and the weight of evidence for effects on the liver, hematological and immune systems, and reproductive and developmental endpoints, EPA concluded that the DuPont studies demonstrated adverse effects as a result of exposure to the HFPO dimer acid ammonium salt formulations and were appropriate for derivation of toxicity values for these chemicals.

8.3 Use of Data-Derived Extrapolation Factors

For HFPO dimer acid and/or ammonium salt, there are limited human half-life data (see section 8.4) and no BBDR or PBPK models available to evaluate toxicokinetic and toxicodynamic differences between humans and animals. Additionally, only a few repeat-dose studies are available on rats and mice that evaluate toxicokinetics. These studies indicate that there is little-to-no metabolism and that clearance is relatively rapid compared to other longer chain PFAS. MOA (both *in vivo* and *in vitro*) data are also inadequate. EPA considered the 2014 *Guidance for Applying Quantitative Data to Develop Data-Derived Extrapolation Factors for Interspecies and Intraspecies Extrapolation* in determining UF_A and UF_H (EPA, 2014c). Using the decision process described in Figure 2, EPA concluded that data are not adequate to support derivation of data-derived extrapolation factors. Specifically, given the lack of available models and data to address external dose and clearance in humans, default approaches to the application of UF_A and UF_H were employed, including BW scaling for oral exposure (EPA, 2011b). These approaches are described further in section 7.3.

8.4 Use of Data-Derived Dosimetric Adjustment Factor

EPA guidance recommends a hierarchical approach to deriving human equivalent oral exposures from animal studies, with the preferred approach being physiologically based toxicokinetic modeling. There are no such toxicokinetic models available for GenX chemicals. The next

preferred approach is to use chemical-specific information to derive a data-informed dosimetric adjustment factor (DAF). For GenX chemicals there are limited human data (outlined below) and a few repeat-dose studies available on rats and mice that evaluate toxicokinetics (see section 2.3.6).

In the one available human half-life study, twenty-five workers from a Chemours facility in the Netherlands volunteered blood samples before an off-work weekend and twenty-two workers provided a second sample at the start of the next shift (72-96 hours between sample collections) (Clark, 2021). Samples were sent to two independent laboratories. HFPO dimer acid concentrations ranged from below the level of detection (less than 0.5 µg/L) to 25 µg/L (Arbo Unie, 2020). Samples containing measurable amounts of HFPO dimer acid at both time points were used to calculate an average approximate half-life of 81 ± 55 hours, assuming an exponential rate of decay (Clark, 2021). The range was 42 to 333 hours with a median of 66 hours. Serum from eighteen of the twenty-two workers contained HFPO dimer acid at detectable levels (i.e., at or above the limit of detection) at both time points.

A letter summarizing the data and briefly outlining the methods used to calculate the human half-life was provided to TSCA in 2021 by Chemours (similar information can also be found on ECHA). However, EPA has not received the full study report and these data have not been peer reviewed. The dataset used by Chemours to calculate the half-life is limited to only 18 individuals. Chemours also provided EPA with an unpublished report containing the raw data (Arbo Unie, 2020); however, this report did not stratify the data based on sex or provide any additional details on the test subjects (including sex). Sex-stratification of the human worker data is potentially important because the critical effect in mice is more severe in females (DuPont-18405-1037, 2010). Because the information provided are insufficient, EPA did not use the human half-life data to estimate a data-informed DAF. Instead, EPA employed the default procedure of body weight scaling to the ¾ power (i.e., $BW^{3/4}$) to derive human equivalent oral exposures from animal studies in concordance with EPA guidance (EPA, 2011b; outlined in section 7.2.2).

Although the Chemours human half-life data are insufficient for use in the allometric scaling of animal to human dose for toxicity and risk assessment purposes, EPA conducted an exploratory analysis to determine the magnitude of the impact on the resulting POD_{HED} if this information was used to calculate a POD_{HED} in place of the default $BW^{3/4}$ DAF (which, as outlined above, is the agency's standard approach where acceptable data are not available) (Table 16).

Table 16. Comparison of POD_{HED} using different allometric scaling methods

Endpoint and reference	POD_{HED} (mg/kg/day) calculated using…	
	$BW^{3/4}$ DAF	Data Derived Human DAF
Liver constellation of lesions in parental males (DuPont-18405-1037, 2010)	0.02	0.06
Liver constellation of lesions in parental females (DuPont-18405-1037, 2010)	0.01	0.03

The method used to calculate the data-derived DAF is outlined in Section 6.1.1.2 of the Human Health Toxicity Values for Perfluorobutane Sulfonic Acid (CASRN 375-73-5) and Related Compound Potassium Perfluorobutane Sulfonate (CASRN 29420-49-3) (EPA, 2021a). Briefly, the ratio of elimination half-life in animals from which the POD is obtained ($t_{1/2A}$) to that in humans ($t_{1/2H}$) can be used to calculate the DAF, and the human equivalent dose (HED) can be calculated as follows:

$$POD_{HED} = POD \times \frac{t_{1/2A}}{t_{1/2H}}$$

For the comparison exercise in Table 16, the $t_{1/2A}$ used for GenX chemicals were the male and female mouse data from the beta elimination phase outlined in Table 8 and the $t_{1/2H}$ was the 81 hours calculated from the data outlined above (Arbo Unie, 2020; Clark, 2021). Although the Chemours human half-life data were found to be insufficient for this purpose (Chemours, 2021) describes the dataset as "limited"), this comparison demonstrates that the POD_{HED} calculated using either the $BW^{3/4}$ DAF or the Data Derived Human DAF are similar. This comparison exercise illustrates a degree of consistency between the $BW^{3/4}$ approach and the use of the only available human half-life dataset for deriving human equivalent oral doses for GenX chemicals.

8.5 Limited Data on Carcinogenicity

One study is available on evaluating carcinogenicity of HFPO dimer acid and its ammonium salt in rats (DuPont-18405-1238, 2013). In this study, liver and pancreatic tumors were noted at the highest doses tested. Although the incidence of testicular interstitial cell adenomas was not statistically significant compared to controls, the authors of the study conclude that "a relationship to treatment for these findings in the 50 mg/kg/day group cannot be ruled out" while also suggesting that Leydig cell tumor induction in rodents might have low relevance to humans (Caverly Rae et al., 2015).The available data for HFPO dimer acid ammonium salt suggest that mice might be more sensitive than rats to exposure to these GenX chemicals. Given the evidence that the liver is the target organ for toxicity and the primary organ for tumor development, additional research is needed using chronic duration exposures in mice. This uncertainty was not considered in the application of the UF_D because a noncancer toxicity value was developed for this assessment.

8.6 Internal Dosimetry Data for GenX Chemicals

EPA recognizes that there are similarities in the health effects observed across various PFAS. Specifically, GenX chemicals are linked to adverse effects on the liver, kidney, immune system, development, and cancer and these health effects have also been associated with PFOA exposure (EPA, 2016a,b). There are data available that demonstrate that the toxicokinetic profile for GenX chemicals is different than PFOA in that GenX chemicals are more rapidly excreted than PFOA and appear not to bioaccumulate like PFOA. These data lead one to question whether administering the same dose of these chemicals could result in a much lower internal dose for GenX chemicals than PFOA or PFOS and thus differences in potency between the two chemicals.

There are currently two studies evaluating the internal dose of the HFPO dimer acid and comparing it to the internal dose of either PFOA (Blake et al., 2020) or PFOS (Conley et al.,

2021). Specifically, Blake et al. (2020) evaluated internal dose of both chemicals in pregnant mice and their embryos. Concentrations of PFOA and HFPO dimer acid were measured in the maternal serum, maternal liver, amniotic fluid, and whole embryo dosed with 0, 1, or 5 mg/kg/day of PFOA or 2 or 10 mg/kg/day of HFPO dimer acid from E1.5 to E11.5 or E17.5. Although concentrations in the maternal serum were relatively similar, the total concentration of HFPO dimer acid is an order of magnitude less than PFOA in the maternal liver. Additionally, PFOA appears to accumulate in the liver from E11.5 to E17.5 in mice exposed to 1 mg/kg/day PFOA (48.3 ± 12.5 ug/mL to 181.1 ± 46.0 ug/mL); however, the concentration of HFPO dimer acid at 2 mg/kg/day is similar at both time points (5.45 ± 3.43 ug/mL to 4.56 ± 2.80 ug/mL). These differences are noteworthy because PFOA and HFPO dimer acid affected the maternal liver similarly in this study (e.g., increased liver weight and increased incidence of liver lesions) despite the concentration of HFPO dimer acid being an order of magnitude lower than PFOA and displaying no apparent accumulation between E11.5 and E17.5. The concentrations of PFOA and HFPO dimer acid are similar in the amniotic fluid and whole embryo in the 1- and 2-mg/kg/day-dose groups, respectively. These data suggest that a lower internal dose of HFPO dimer acid elicits the same effects on the liver as a higher internal dose of PFOA in the pregnant mouse. Additional research is needed to further elicit whether internal dosimetry is in fact different between these chemicals and to determine if these results are specific to the pregnant mouse.

Conley et al. (2021) compared the maternal serum levels of HFPO dimer acid and PFOS with respect to neonatal mortality. Conley et al. (2021) concluded that based on maternal serum concentrations, HFPO dimer acid (EC_{50} = 35.4 ug/mL) was ~2-fold more potent than PFOS (EC_{50} = 74.5 ug/mL). However, given that the molecular weight of PFOS (500 g/mol) is 34% greater than HFPO-DA (330 g/mol), the potency of PFOS (EC_{50} =148.9 uM) and HFPO dimer acid (EC_{50} = 107.1 uM) are very similar when correcting for molecular weight differences.

8.7 Effects on Bilirubin

A decrease in serum bilirubin is a consistent effect observed across multiple studies, especially in female rodents (DuPont-17751-1026, 2009; DuPont-18405-1307, 2010; DuPont-18405-1238, 2013; Wang et al., 2017). This finding was surprising given that increased rather than decreased levels of serum bilirubin are typically indicative of liver damage, and multiple studies outlined above have confirmed microscopic liver damage (DuPont-18405-841, 2010; DuPont-18405-1037, 2010; DuPont-18405-1307, 2010; DuPont-18405-1238, 2013; Tietze, 2012). In female mice and rats, however, serum bilirubin levels were significantly decreased by 14%–50% relative to controls when the females were administered 5 mg/kg/day–1,000 mg/kg/day of HFPO dimer acid ammonium salt for 3–12 months (DuPont-17751-1026, 2009; DuPont-18405-1307, 2010; DuPont-18405-1238, 2013). Additionally, male ICR mice treated with 1 mg/kg/day of HFPO dimer acid ammonium salt exhibited a significant 37% and 45% decrease in total and direct bilirubin, respectively, when compared to controls (Wang et al., 2017); this finding was not replicated in the other 28-day studies (DuPont-24447, 2008; DuPont-24459, 2008). The biological or mechanistic significance of this effect is unknown, yet its consistency across multiple studies is noteworthy.

8.8 Susceptible Populations and Life Stages

Data for the elucidation of differential susceptibility dependent on life stage (e.g., developing embryo/fetus, women of reproductive age, or pregnant women) are not available. Children are

frequently more vulnerable to pollutants than the average adult because of the differences in their behaviors and biology. These differences can result in greater exposure and/or unique windows of developmental susceptibility during the prenatal and postnatal periods for both the pregnant mother and the developing fetus. No human toxicity or epidemiological studies are available in the literature that address early developmental or reproductive life stages. Peer-reviewed literature and DuPont submitted data examining reproductive and developmental endpoints in both mice and rats (Blake et al., 2020; Conley et al., 2019, 2021; DuPont-18405-841, 2010; DuPont-18405-1037, 2010) and summaries of these studies can be found in section 5.4 (Reproductive/Developmental). HFPO dimer acid ammonium salt can be transferred from a pregnant animal to the fetus during gestation and lactation (Blake et al., 2020; Conley et al., 2019, 2021; DuPont-18405-1037, 2010; Dupont-18405-849 RV1, 2011). When present, developmental and reproductive effects were found at doses similar to and higher than those associated with the selected critical effect: liver effects in females (constellation of lesions as defined by the NTP PWG to include cytoplasmic alteration, hepatocellular single-cell and focal necrosis, and hepatocellular apoptosis). The UF_H of 10 accounts for variability in the responses within human populations because of both intrinsic (including life stage) and extrinsic (lifestyle) factors that can influence the response to dose. No information to characterize interindividual and age-related variability in the toxicokinetics or toxicodynamics is available. Thus, the RfDs provided in sections 7.4.1 and 7.4.2 (Subchronic RfD and Chronic RfD) are applicable to all life stages. When reviewing data pertinent to the hazard potential of GenX chemicals, EPA adhered to the requirements of its 2013 reaffirmation of the Policy on Evaluating Health Risks to Children (EPA, 2013).

There is some sex-specific variation in the toxicokinetics of these two GenX chemicals in rodents. Toxicokinetic data from DuPont calculate clearance times from the urine and plasma, which is defined by DuPont as the time when 98.4% of the anion from the HFPO dimer acid ammonium salt was cleared from the urine or plasma. These data show the HFPO dimer acid and its ammonium salt clearance time in the plasma to be considerably faster for female rodents than for male rodents (see the summary in section 2.3.6 (Clearance and Half-Life Data). For example, Dupont-25300 (2008) identified 143 hours as the clearance time for HFPO dimer acid ammonium salt in male mice at 10 mg/kg and 139 hours for 30 mg/kg. In female mice, the clearance values were 57 and 62 hours for the low dose and the high dose, respectively. However, this difference was not as pronounced in mice in the $T_{1/2}$ estimates. Specifically, the alpha (distribution) phase $T_{1/2}$s were 5.8 and 4.6 hours for male and female mice, respectively, and the beta (elimination) phase $T_{1/2}$s were 36.9 hours and 24.2 hours for male and female mice, respectively. It is unknown if or how these observed sex-specific toxicokinetic differences in rodents contribute to the toxic response.

The available data suggest that the pregnant rodent might be more susceptible to liver effects following exposure to GenX chemicals during gestation. Liver effects were reported in the pregnant dams in the available reproductive/developmental studies dosed during gestation (Blake et al., 2020; Conley et al., 2019; DuPont-18405-841, 2010; DuPont 18405-1037, 2010). All the studies reported increases in liver weight ranging from 12% to 34% in rats and 26% to 101% in mice over the gestational period. Conley et al. (2019) did not conduct liver histopathology, but both DuPont-18405-841 (2010) and Blake et al. (2020) reported hepatocellular hypertrophy and increased cell death as compared to controls with increasing HFPO dimer acid ammonium salt concentration. Specifically, focal necrosis was observed in 2/22 (9%) and 5/22 (23%) pregnant

rats after just 15 days (GD6–GD20) of 10 mg/kg/day or 100 mg/kg/day of HFPO dimer acid ammonium salt, respectively, compared to 0 in the control group. Comparatively, nonpregnant female rats dosed from 28 to 90 days did not exhibit necrosis when treated with doses up to 1,000 mg/kg/day of HFPO dimer acid ammonium salt. Necrosis was observed in nonpregnant female rats only after 2 years of dosing with 500 mg/kg/day of HFPO dimer acid ammonium salt. Increased cell death (including both apoptosis and single-cell or focal necrosis) was observed in pregnant mice after 11 and 17 days (GD1.5–GD11.5 or GD17.5) of 2 mg/kg/day or 10 mg/kg/day of HFPO dimer acid ammonium salt. Similarly, and as noted above, female mice dosed 14 days prior to mating and throughout gestation and lactation exhibited cytoplasmic alteration, apoptosis, single-cell necrosis, and focal necrosis after 53–64 days of dosing (NTP, 2019 reread of DuPont 18405-1037, 2010). The incidence of single-cell and focal necrosis in the F_0 females was 6/24 (25%) and 20/24 (83%) in the 0.5- and 5-mg/kg/day-dose groups, respectively (NTP, 2019). A chronic study in mice is not available to compare to the gestational exposures in female pregnant mice, and comparisons to the 90-day subchronic study in mice is potentially limited by sample size (n = 9) in the 0.1 and 0.5 mg/kg/day-dose groups.

Susceptible populations include groups who have relatively high exposure to GenX chemicals. While data are currently unavailable, there is the potential for highly exposed populations. For example, formula fed infants, who have high daily water ingestion relative to body weight, have the potential for relatively high exposure to GenX chemicals when GenX chemicals are present in tap water and this tap water is used to reconstitute formula. As a second example, workers and their families who work at and/or live near facilities that use the GenX processing aid technology have the potential for greater exposure levels and duration of exposure. Finally, communities living in close proximity to facilities using the GenX processing aid technology have the potential for increased exposure as evidenced by the detection of GenX chemicals in drinking water, surface water, soil and rainwater samples collected close to the facility (see section 1.3).

Appendix A: Literature Search Strategy

This appendix presents the details of the literature search strategy U.S. Environmental Protection Agency (EPA) used to identify primary, peer-reviewed literature pertaining to hexafluoropropylene oxide (HFPO) dimer acid (Chemical Abstracts Service Registry Number (CASRN) 13252-13-6) and its ammonium salt (CASRN 62037-80-3). The literature searches were conducted using the databases listed in Table A-1.

The initial literature searches for these GenX chemicals were conducted in July 2017 (acid) and January/February 2018 (ammonium salt). Subsequent literature searches were conducted from 2018 to March 2020. The searches were conducted using CASRN, synonyms, and additional relevant search strings (see Table A-2). Because the results of this core search were so limited, additional databases were identified and searched for physiochemical property information, health effects, toxicokinetics, and mechanistic information (see Table A-3 and Table A-4). Combined, these initial literature searches returned 27 studies for HFPO dimer acid and HFPO dimer acid ammonium salt after duplicates across the two chemicals were deleted. The literature searches conducted after publication of the public comment draft in November 2018 resulted in 48 additional studies for HFPO dimer acid and HFPO dimer acid ammonium salt after duplicates were deleted.

As previously stated, the available data for GenX chemicals come primarily from studies submitted under the Toxic Substances Control Act (TSCA). Those studies were combined with the results of the search of the publicly available peer-reviewed literature for evaluation for relevance to the assessment. The submitted studies and literature identified by the search of publicly available sources are available through EPA's Health & Environmental Research Online (HERO) website at https://hero.epa.gov/hero/index.cfm/project/page/project_id/2627. Potential relevance was based primarily on a title and abstract screen. Table A-5 presents the inclusion/exclusion criteria applied to conducting the literature searches. An additional 48 studies from peer-reviewed literature were identified during the updated literature searches conducted in February 2019, October 2019, and March 3, 2020. These studies were subjected to title and abstract screening to determine relevancy according to the inclusion/exclusion criteria outlined in Table A-6. Relevancy was confirmed by review of the full text of studies included in the title abstract screen. Studies that did not meet the inclusion criteria but provide supporting information were categorized as supplemental, relative to the type of supporting information they provided. These supplemental categories are outlined in Table A-7.

Table A-1. Summary of Core Database Search Results

Search date	PubMed	WOS	Toxline	TSCATS via Toxline/NLM	Other sources	Combined dataset after duplicate removal
HFPO dimer acid (CASRN 13252-13-6)						
7/24/17	3	12	0	0	3	16
7/17–2/19	6	11	0	0	0	11

Table A-5. Inclusion-Exclusion Criteria for HFPO Dimer Acid and HFPO Dimer Acid Ammonium Salt Studies

PECO Parameter	Inclusion criteria	Exclusion criteria
Population	• Humans • Standard mammalian animal models, including rat, mouse, rabbit, guinea pig, hamster, monkey, dog • Alternative animal models in standard laboratory conditions (e.g., *Xenopus*, zebrafish, minipig) • Human or animal cells, tissues, or organs (not whole animals); bacteria; nonmammalian eukaryotes; other nonmammalian laboratory species	• Ecological species
Exposure	• Exposure is to HFPO dimer acid and/or its ammonium salt • Exposure via oral, inhalation, dermal, intraperitoneal, or intravenous injection routes • Exposure is measured in air, dust, drinking water, diet, gavage, or injection vehicle, or via a biomarker of exposure (PFAS levels in whole blood, serum, plasma, or breast milk) • Exposure is via cells in culture or subcellular matrices	• Study population is not exposed to HFPO dimer acid and/or its ammonium salt • Exposure is to a mixture only without evaluating HFPO dimer acid and/or its ammonium salt individually
Outcome	• Studies that include a measure of one or more health effect endpoints, including effects on reproduction, development, developmental neurotoxicity, liver, thyroid, immune system, nervous system, genotoxicity, and cancer • *In vivo* and/or *in vitro* studies related to toxicity mechanisms or physiological effects/adverse outcomes, and studies useful for elucidating toxic modes of action • Qualitative or quantitative description of absorption, distribution, metabolism, elimination, and toxicokinetic and/or toxicodynamic models (e.g., PBPK, PBTK, PBTK/TD) • Studies addressing risks to infants, children, pregnant women, occupational workers, the elderly, and any other susceptible or differentially exposed populations	

PECO Parameter	Inclusion criteria	Exclusion criteria
Other	• Structure and physiochemical properties • Reviews and regulatory documents	Not on topic, including:[a] • Abstract only, inadequately reported abstract, or no abstract and not considered further because study was not potentially relevant • Bioremediation, biodegradation, or chemical or physical treatment of HFPO dimer acid and/or its ammonium salt, including evaluation of wastewater treatment technologies and methods for remediation or contaminated water and soil • Ecosystem effects, studies in ecological species that are not relevant to health effects in humans • Studies of environmental fate and transport of HFPO dimer acid and/or its ammonium salt compounds in environmental media • Analytical methods for detecting/measuring HFPO dimer acid and/or its ammonium salt compounds in environmental media and use in sample preparations and assays • Studies describing the manufacture and use of HFPO dimer acid and/or its ammonium salt compounds • Not chemical-specific (studies that do not involve testing of HFPO dimer acid and/or its ammonium salt compounds) • Studies that describe measures of exposure to HFPO dimer acid and/or its ammonium salt compounds without data on associated health effects

Notes: PBPK = physiologically based pharmacokinetic; PBTK = physiologically based toxicokinetic; PBTK/TD = physiologically based toxicokinetic and toxicodynamic; PFAS = pre- and polyfluoroalkyl substances.

[a] Although these criteria were used for the peer-reviewed literature, the current document describes environmental fate data submitted by DuPont (now the Chemours Company). A subsequent targeted search for bioconcentration and bioaccumulation data was also conducted. In addition, a summary of occurrence data is also provided in the current document to give context to the toxicity values.

Table A-6. Inclusion-Exclusion Criteria for HFPO Dimer Acid and HFPO Dimer Acid Ammonium Salt Studies after the Public Comment Draft

PECO Parameter	Inclusion criteria	Exclusion criteria
Population	• Humans • Standard mammalian animal models, including rat, mouse, rabbit, guinea pig, hamster, monkey, dog	• Ecological species (*supplemental tag —non-PECO model*) • Alternative animal models in standard laboratory conditions (e.g., *Xenopus*, zebrafish, minipig) (*supplemental tag—non-PECO model*) • Human or animal cells, tissues, or organs (not whole animals); bacteria; nonmammalian eukaryotes; other nonmammalian laboratory species (*supplemental tag—mechanistic*)
Exposure	• Exposure is to HFPO dimer acid and/or its ammonium salt • Must include 2 or more levels of exposure to HFPO dimer acid and/or its ammonium salt (if not stated, include at title/abstract screening) • **Humans**: Exposure is measured in air, dust, drinking water, diet, or gavage or injection vehicle, or via a biomarker of exposure (PFAS levels in whole blood, serum, plasma, or breast milk) • Any exposure length is acceptable • **Animals**: Exposure via oral route only • Any exposure length for an animal study is acceptable for reproductive or developmental exposures • Exposure duration for all other animal study designs require an exposure duration of 28 days or more (if not stated, include at title/abstract screening)	• Study population is not exposed to HFPO dimer acid and/or its ammonium salt • There is only 1 exposure group (*supplemental tag—single-dose group in study*) • Exposure is to a mixture only without evaluating HFPO dimer acid and/or its ammonium salt individually (*supplemental tag—mixture study*) • Exposure via inhalation, dermal, intraperitoneal, or intravenous injection routes (*supplemental tag—non-oral route of administration*) • Exposure is via cells in culture or subcellular matrices (*supplemental tag—mechanistic*) • Acute exposures (< 28 days) in animal studies (*supplemental tag—acute/short-term duration exposures*)
Comparator	• A concurrent control group exposed to vehicle-only treatment or an untreated control • A comparison or referent population exposed to HFPO dimer acid and/or its ammonium salt at lower levels (or no exposure/exposure below detection limits) or for shorter periods of time • Biological monitoring (e.g., whole blood, serum, plasma, or breast milk) that can be used to establish a range of exposure	• Case reports and case series (*supplemental tag—case report or case series*)

PECO Parameter	Inclusion criteria	Exclusion criteria
Outcome	• Studies that include a measure of one or more health effect endpoints, including effects on reproduction, development, developmental neurotoxicity, liver, thyroid, immune system, nervous system, genotoxicity, and cancer • Qualitative or quantitative description of absorption, distribution, metabolism, elimination, and toxicokinetic and/or toxicodynamic models (e.g., PBPK, PBTK, PBTK/TD)	• *In vivo* and/or *in vitro* studies related to toxicity mechanisms, physiological effects/adverse outcomes, and studies useful for elucidating toxic modes of action (*supplemental tag—mechanistic*) • Studies addressing risks to infants, children, pregnant women, occupational workers, the elderly, and any other susceptible or differentially exposed populations (*supplemental tag—susceptible population*)
Other Exclusion Criteria		• Not on topic, including: • Structure and physiochemical properties (*supplemental tag—structure and physiochemical properties*) • Reviews and regulatory documents (*supplemental tag—other assessments or records with no original data*) • Abstract only, inadequately reported abstract, or no abstract and not considered further because study was not potentially relevant (*supplemental tag—conference abstract*) • Ecosystem effects, studies in ecological species that are not relevant to health effects in humans (*supplemental tag—non-PECO model*) • Bioaccumulation of the target chemical in fish (*supplemental tag—bioaccumulation data in fish*) • Studies of environmental fate and transport of HFPO dimer acid and/or its ammonium salt compounds in environmental media or food (*supplemental tag—environmental fate or occurrence*) • Studies that describe measures of exposure to HFPO dimer acid and/or its ammonium salt compounds without data on associated health effects (*supplemental tag—exposure characteristics*) • Bioremediation, biodegradation, or chemical or physical treatment of HFPO dimer acid and/or its ammonium salt, including evaluation of wastewater treatment technologies and methods for remediation or contaminated water and soil • Analytical methods for detecting/measuring HFPO dimer acid and/or its ammonium salt compounds in environmental media and use in sample preparations and assays • Studies describing the manufacture and use of HFPO dimer acid and/or its ammonium salt compounds • Not chemical specific (studies that do not involve testing of HFPO dimer acid and/or its ammonium salt compounds)

Notes: **PBPK = physiologically based pharmacokinetic; PBTK = physiologically based toxicokinetic; PBTK/TD = physiologically based toxicokinetic and toxicodynamic; PFAS = per- and polyfluoroalkyl substances.**

Table A-7. Supplemental Tags for the GenX Chemicals Literature Search

Category	Evidence
Mechanistic studies	Studies reporting measurements related to a health outcome that inform the biological or chemical events associated with phenotypic effects, in both mammalian and non-mammalian model systems, including *in vitro*, *in vivo* (by various routes of exposure), *ex vivo*, and *in silico* studies. When possible, mechanistic studies will be sub-tagged as pertinent to cancer, non-cancer, or unclear/unknown.
Non-mammalian model systems	Studies in non-mammalian model systems (e.g., fish, birds, *C. elegans*).
ADME and toxicokinetic	Studies designed to capture information regarding absorption, distribution, metabolism, and excretion, including toxicokinetic studies. Such information might be helpful in updating or revising the parameters used in existing PBPK models.
Acute/short-term duration exposures	Animal studies of less than 28 days.
Single-dose group	Studies that used only a single-dose group were tagged as supplemental due to the GenX chemicals database having several multi-dose group studies.
Exposure characteristics	Studies that include data unrelated to toxicological endpoints, but which provide information on exposure sources or measurement properties of the environmental agent (e.g., demonstrate a biomarker of exposure).
Susceptible populations	Studies that identify potentially susceptible subgroups (e.g., studies that focus on a specific demographic, life stage, or genotype).
Mixture studies	Studies not considered PECO-relevant because they do not contain an exposure or treatment group assessing only the chemical of interest.
Non-oral routes of exposure	Studies not addressing routes of exposure that fall outside the PECO scope, and include inhalation and dermal exposure routes
Case studies or case series	Case reports and case series will be tracked as potentially relevant supplemental information.
Records with no original data	Records that do not contain original data such as other agency assessments, informative scientific literature reviews, editorials, or commentaries.
Conference abstracts	Records that contain insufficient documentation to support study evaluation and data extraction.

Category	
Bioaccumulation in fish	BAFs were mentioned in the public comment draft assessment.

Notes: ADME = absorption, distribution, metabolism, and excretion; BAFs = bioaccumulation factors; PBPK = physiologically based pharmacokinetic; and PECO = population, exposure, comparator, and outcome.

Appendix B: Acute and 7-Day Study Summaries

This appendix summarizes studies evaluating acute exposure to hexafluoropropylene oxide (HFPO) dimer acid or HFPO dimer acid ammonium salt by the oral, dermal, and inhalation routes of exposure and investigating dermal and eye irritation.

Oral Toxicity. In a study of the HFPO dimer acid ammonium salt (no Test Guideline (TG) cited), a single dose of 1.5, 12, 130, 1,000, 2,250, 3,400, 5,000, 7,500, 11,000, 12,963, or 17,000 milligrams per kilogram (mg/kg) of HFPO dimer acid ammonium salt was administered by stomach tube to young male rats. The approximate lethal dose (ALD) was determined to be 7,500 mg/kg. Discomfort, gasping, and tonic convulsions were observed before death at lethal doses (7,500 mg/kg and higher). Discomfort, increased water intake, inactivity, polyuria, and initial weight loss were observed in rats at the three highest sublethal doses (2,250 mg/kg, 3,400 mg/kg, and 5,000 mg/kg). Slightly enlarged livers with enlarged hepatocytes and pronounced cell membranes were also observed in rats at the three highest sublethal doses. Slight-to-moderate degenerative changes in the pancreas were also observed in doses at 2,250 mg/kg and higher. No effects were observed at doses of less than or equal to 1,000 mg/kg (DuPont-2-63, 1963).

In another study evaluating toxicity of HFPO dimer acid ammonium salt by the oral route of exposure (no TG identified), a single dose of 670, 2,300, 3,400, 5,000, 7,500, or 11,000 mg/kg of HFPO dimer acid ammonium salt (purity > 99%) was administered to 7-week-old male rats (1/dose group). Rats were evaluated for clinical signs of toxicity over a 14-day observation period. No clinical signs of toxicity were observed in the rat dosed at 670 mg/kg. Rats dosed at 2,300 and 3,400 mg/kg exhibited weight loss (17% and 14%, respectively); ruffled fur; and a wet, yellow-stained perineum at 1 day postexposure. The rats dosed at 2,300 and 3,400 mg/kg no longer exhibited these effects at 2 days and 4 days postexposure, respectively. Rats dosed with greater than or equal to 5,000 mg/kg died by 1 day after dosing. The rat dosed with 11,000 mg/kg exhibited lethargy, low carriage, and low posture before its death. The ALD was determined to be 5,000 mg/kg (DuPont-770-95, 1996).

A single dose of HFPO dimer acid ammonium salt (82.6% purity) was administered by oral gavage to 10- to 11-week-old female rats at a dose of 175, 550, 1750, or 5,000 mg/kg (1–3 rats/group) in a study conducted according to Organization of Economic Cooperation and Development (OECD) TG 425 (Up-and-Down Procedure) (OECD, 2008c). Rats were then evaluated for clinical signs of toxicity over a 14-day observation period. All rats exhibited clinical signs of toxicity such as hair loss, lethargy, high posture, stained fur/skin, clear ocular discharge, prostrate posture, partially closed eyes, or salivation. With the exception of hair loss, clinical signs disappeared by 2 days postexposure. All three rats dosed at 5,000 mg/kg died within 2 days after dosing. Grossly observable evidence of organ or tissue damage in these rats included discoloration of lungs (rat #1651), discoloration of lungs and mandibular lymph nodes (rat #1746), and discoloration of lungs and liver (rat #1975). No visible lesions were observed in females dosed at 175 mg/kg, 550 mg/kg, or 1,750 mg/kg. With the exception of rats dosed at 5,000 mg/kg, increases in body weight (BW) were observed in all rats over the course of the study. The oral median lethal dose (LD_{50}) was estimated to be 3,129 mg/kg for female rats (DuPont-22932, 2007).

Oral toxicity of HFPO dimer acid ammonium salt was also evaluated in male rats in a study conducted according to OECD TG 425 (OECD, 2008c). A single dose of HFPO dimer acid ammonium salt (86% purity) was administered by oral gavage to 9- to 11-week-old male rats at a dose of 175, 550, 1,750, or 5,000 mg/kg (three rats). Rats were then evaluated for clinical signs of toxicity over a 14-day observation period. All rats exhibited clinical signs of toxicity such as lethargy, wet fur, stained fur/skin, decreased muscle tone, low posture, or lung noise. One rat dosed at 1,750 mg/kg and all three rats dosed at 5,000 mg/kg died either the day dosed or by the day after dosing. Grossly observable evidence of organ or tissue damage in rats dosed at 5,000 mg/kg included expanded lungs and discolored stomach, discoloration and cloudiness of eyes, and stained skin. With the exception of rats dosed at 5,000 mg/kg, increases in BW were observed in all rats over the course of the study. The oral LD_{50} was determined to be 1,750 mg/kg for male rats (DuPont-25438 RV1, 2008).

Another study evaluated oral toxicity of HFPO dimer acid in both male and female rats in a study conducted according to OECD TG 425 (OECD, 2008c). A single dose of HFPO dimer acid (98% purity) was administered to 9- to 11-week-old rats. Males were dosed at 175, 550, 1,750, or 5,000 mg/kg (2–6 rats/group). Female rats were also dosed at 175, 550, 1,750, or 5,000 mg/kg (1–4 rats/group). Clinical signs were not observed in rats dosed at 175 mg/kg or in one male rat dosed at 550 mg/kg. The rest of the rats in this study exhibited clinical signs of toxicity. Clinical signs of toxicity in male rats observed up to 5 days after dosing included lung noise, absent feces, lethargy, not eating, stained fur/skin, wet fur, labored breathing, decreased muscle tone, prostrate posture, tremors, clear oral discharge, diarrhea, ataxia, and/or high posture. Clinical signs in female rats were observed for up to 3 days after dosing and included wet fur, stained fur/skin, ataxia, labored breathing, cold to touch, clear ocular or oral discharge, lethargy, lung noise, absent feces, not eating, and/or rubbing face on the bottom of the cage (DuPont-25875, 2008).

All rats dosed at 5,000 mg/kg died by the day after dosing. Among rats dosed at 1,750 mg/kg, two males and three females died by the day after dosing. One male rat dosed at 550 mg/kg (rat #274) was sacrificed in extremis on the fourth day after dosing following a 23% reduction in BW. Gross findings were detected in three male rats dosed at 5,000 mg/kg, in four rats dosed at 1,750 mg/kg, and in one rat dosed at 550 mg/kg. Small testes and epididymis were observed in rat #274. A discolored, glandular stomach was observed in two of the male rats dosed at 1,750 mg/kg. Gross findings for male rats dosed at 5,000 mg/kg included a glandular stomach; a glandular, discolored stomach (rats #640, #796, and #821); and discolored skin (rat #796). Gross findings for female rats dosed at 1,750 mg/kg included a glandular, discolored stomach (rats #478, #527, and #626); discolored lymph nodes (rat #527); and discolored skin (#527). The female rat dosed at 5,000 mg/kg exhibited wet skin; a discolored esophagus with foamy fluid; and a thick, discolored stomach. Increases in BW were observed in animals that survived until the end of the study. The oral LD_{50} was estimated to be 1,730 mg/kg for male rats and 1,750 mg/kg for female rats (DuPont-25875, 2008).

Another study conducted according to OECD TG 425 (OECD, 2008c) evaluated toxicity of HFPO dimer acid by the oral route of exposure in female mice. A single dose of HFPO dimer acid ammonium salt (86% purity) was administered to 8- to 9-week-old female mice at a dose of 175, 550, or 1,750 mg/kg (1–3 mice). No clinical signs of toxicity were observed in mice dosed at 175 mg/kg or in two mice dosed at 550 mg/kg. One mouse dosed at 550 mg/kg, however,

exhibited wet fur on the day of dosing. All three mice dosed at 1,750 mg/kg died on the day of dosing. Discoloration of lungs and an ovarian cyst were observed in a mouse dosed at 550 mg/kg. Skin stain was also observed in two mice dosed at 1,750 mg/kg. These observations were considered by study authors to be nonspecific and not indicative of test substance related. With the exception of mice dosed at 1,750 mg/kg, increases in BW were observed in all mice over the course of the study. The oral LD_{50} was estimated to be 1,030 mg/kg for female mice (DuPont-24126, 2007).

Dermal Toxicity. In a study evaluating toxicity through dermal absorption (no TG identified), 5,000 mg/kg of HFPO dimer acid ammonium salt (purity > 99%) was applied directly onto the shaved, intact skin of two young adult male New Zealand white rabbits for a period of 24 hours. One rabbit exhibited necrosis from days 2–6 post-application in a small area of treated skin. The necrotic area sloughed off by day 7, and alopecia was then observed in this area until the study was completed. Moderate erythema was observed in both rabbits at 1 day post-application and was still observed up to 3 days post-application. Erythema persisted until 13 days post-application, with the degree of severity decreasing over time. Both rabbits exhibited scaling and sloughing of skin 6–13 days after application. Increases in BW were observed for both rabbits at the conclusion (day 14) of the study. The ALD was determined to be higher than 5,000 mg/kg (DuPont-839-95, 1996).

The dermal toxicity of HFPO dimer acid ammonium salt (86% purity) was also evaluated in rats in a study conducted according to OECD TG 402 (OPPTS 870.1200) (OECD, 2017). A single dose of 5,000 mg/kg (five males and five females) was applied directly onto the shaved, intact skin for 24 hours. Rats were then observed daily for 14 days posttreatment. All female rats exhibited mild erythema on the test site 1 day post-application. Erythema was no longer detectable by the second day after application. Erythema was not observed in male rats. Hyperkeratosis was observed in four male and four female rats. Ulceration was observed in one male and two female rats. All dermal effects cleared up by 13 days posttreatment. Increases in BW were observed for male and female rats by the conclusion (day 14) of the study. The LD_{50} of the compound was determined to be higher than 5,000 mg/kg (DuPont-24113, 2007).

Inhalation Toxicity. The toxicity of HFPO dimer acid ammonium salt by the inhalation route of exposure was evaluated in 8-week-old male and female rats (no TG identified) (DuPont-17751-723, 2009). One group of five male and five female rats were exposed to an aerosol atmosphere containing 5,200 milligrams per cubic meter (mg/m^3) of HFPO dimer acid ammonium salt (84% purity) to determine the inhalation median lethal concentration (LC_{50}). Two other groups of three male and three female rats were exposed to HFPO dimer acid ammonium salt at concentrations of 0, 13, and 100 mg/m^3 in air to evaluate respiratory tract pathology. All rats were exposed nose-only for a single 4-hour period. Rats exposed to 0, 13, and 100 mg/m^3 of HFPO dimer acid ammonium salt in air were evaluated for clinical signs of toxicity for 2 days following exposure and rats exposed to 5,200 mg/m^3 were evaluated for a period of 14 days following exposure. Respiratory tract tissues (lung, larynx/pharynx, trachea, and nose) of the 0-, 13-, and 100-mg/m^3 exposure groups were also evaluated microscopically. According to study authors, no clinical signs of toxicity were observed for any animals at any exposure in this study. However, following the 100 mg/m^3 exposure, all rats displayed a red nasal discharge immediately after exposure. Rats exposed to 5,200 mg/m^3 exhibited red discharge from eyes, nose, and mouth as well as red stains on skin/fur immediately after exposure. Red discharge and staining were absent

within 1 or 2 days after exposure. Rats in the 5,200-mg/m^3 exposure group lost 2.5% to 6.8% of their original BW for 1 or 2 days after exposure but exhibited normal weight gain for the remainder of the experiment. The LC_{50} was determined to be greater than 5,200 mg/m^3 (DuPont-17751-723, 2009).

Dermal Irritation. The dermal irritation of HFPO dimer acid ammonium salt (86% purity) was evaluated in three male New Zealand white rabbits in a study conducted according to OECD TG 404 (OPPTS 870.2500) (OECD, 2002). A 0.5-mL aliquot of the compound was applied to an area of shaved skin for a period of 4 hours. Very slight erythema was observed in one rabbit following removal of the compound. At 60 minutes post-application, very slight erythema was observed in one rabbit and well-defined erythema was observed in the other two rabbits. Erythema had cleared by 24 hours postexposure (DuPont-24030, 2007).

Eye Irritation. In an OECD TG 405 (OPPTS 870.2400) (OECD, 2020a) study evaluating eye irritation of HFPO dimer acid ammonium salt (86% purity), a 0.1-mL aliquot of compound was administered to one eye of a young adult male New Zealand white rabbit. Necrosis, characterized by brown and white discoloration of the conjunctival membrane of the treated eye, was observed at 1, 24, and 28 hours after application. Corneal opacity, iritis, conjunctival chemosis, and discharge were also observed. Fluorescein stain examination of the treated eye indicated corneal injury (DuPont-24114, 2007).

Seven-Day Toxicity Studies. Four 7-day studies are available for HFPO dimer acid or ammonium salt in rats or mice. The toxicity of HFPO dimer acid ammonium salt (86.6% purity) by the oral route of exposure was evaluated in 6-week-old male and female rats (DuPont-24009, 2008). Five rats of each sex were exposed to 0, 30, 300, or 1,000 mg/kg HFPO by oral gavage for 7 days. No clinical signs of toxicity were observed in either sex at any dose level tested. A significant decrease in BW was observed on test day 7 in males exposed to 1,000 mg/kg versus control. Significant decreases in red blood cells (RBCs), hemoglobin, and hematocrit were observed in male rats at 300 milligrams per kilogram per day (mg/kg/day) and in both male and female rats at 1,000 mg/kg/day. A significant increase in red cell distribution width, reticulocytes, and neutrophils was also observed in female rats exposed to 1,000 mg/kg/day. Decreases in serum lipids and globulins were observed in males at all dosage groups as well as in females at 300 and 1,000 mg/kg/day. Increased alanine aminotransferase, urea nitrogen, and glucose as well as decreased sorbitol dehydrogenase, creatinine, and calcium were observed at doses of 300 and/or 1,000 mg/kg/day. Increases in liver weight were observed in males at all doses and in females at 1,000 mg/kg/day and corresponded with increases in B-oxidation and/or increases in P450 enzyme activity. Mild-to-minimal hepatocellular hypertrophy was also observed in both sexes at 1,000 mg/kg/day. Decreases in heart weight were observed in males at 1,000 mg/kg and increases in kidney weight were observed in females at 1,000 mg/kg/day: No microscopic changes were observed in these organs.

In another study evaluating toxicity of HFPO dimer acid (99% purity) by the oral route of exposure, 6-week-old male and female rats (5/sex) were exposed to 0, 30, 100, and 300 mg/kg of HFPO dimer acid by gavage over a period of 7 days (DuPont-24116, 2008). No clinical signs of toxicity were observed. Significant decrease in RBC count and a significant increase in red cell distribution width were observed in females at 300 mg/kg/day. Significant decreases in hemoglobin and hematocrit were observed in male rats at 300 mg/kg/day. A significant increase in mean corpuscular cell volume was observed in males at 30 mg/kg/day. Decreases in serum

lipids were detected in all dosed male groups versus control. Increased alkaline phosphatase and urea nitrogen and decreased bilirubin, creatinine, total protein, globulin, and calcium were observed at 30 and/or 300 mg/kg/day. Increased liver weight was observed in males at all doses and in females at 300 mg/kg/day. Microscopic examination of livers detected hepatocellular hypertrophy in all treated males and females. Lesions observed in males and females were mild and minimal, respectively. A statistically significant increase in β-oxidation was detected in females exposed to 300 mg/kg/day versus control.

A 7-day study was conducted in 6-week-old male mice to evaluate toxicity of HFPO dimer acid ammonium salt (86.6% purity) by the oral route of exposure (DuPont-24010, 2008). Doses of 0 or 30 mg/kg/day were administered over a period of 7 days. By test day 7, BWs were significantly higher in exposed males versus controls. A twofold increase in liver weight relative to control was detected in exposed males. No grossly observable lesions in the liver were observed. Microscopic changes in the liver observed at 30 mg/kg/day included minimal single-cell necrosis of hepatocytes, moderate hepatocellular hypertrophy, and moderate increases in mitotic figures. Minimal vacuolation of hepatocytes was also observed in one treated mouse.

Another 7-day gavage study was conducted in 6-week-old male mice to evaluate toxicity of HFPO dimer acid (99% purity) by the oral route of exposure (DuPont-25281, 2008). Doses of 0 or 30 mg/kg/day were administered over a period of 7 days. By test day 7, BWs were significantly higher in exposed males versus controls. A twofold increase in liver weight was detected in exposed males versus control. Microscopic changes to the liver of exposed animals included minimal single-cell necrosis of hepatocytes, moderate hepatocellular hypertrophy, and moderate increases in mitotic figures. Minimal vacuolization was also observed in 2/5 treated mice.

Appendix C: Genotoxicity Study Summary

Table C-1 provides a summary of the available genotoxicity data for hexafluoropropylene oxide (HFPO) dimer acid and/or its ammonium salt.

Table C-1. Genotoxicity Study Summary

Study	Assay	Strain/Species	Dosing	Activation	Results
DuPont-19713 RV1 (2008)	*In vitro* Bacterial Reverse Mutation Test (OECD TG 471) (OECD, 2020b)	*Salmonella typhimurium* (strains TA98, TA100, TA1535, and TA1537) and *Escherichia coli* (strain WP2*uvr*A)	HFPO dimer acid ammonium salt (85% purity) 33.3, 66.7, 100, 333, 667, 1,000, 3,333, and 5,000 µg/plate for preliminary toxicity test 333, 667, 1,000, 3,333, and 5,000 µg/plate for toxicity-mutation test Negative control (sterile water) and positive control (benzo[a]pyrene, 2-nitrofluorine, 2-aminoanthracene, sodium azide, acridine mutagen Institute of Cancer Research (ICR)-191, or 4-nistroquinoline-N-oxide) also included in study	With S9	Negative.
				Without S9	Negative.
DuPont-22620 RV1 (2009)	*In vitro* Mammalian Chromosome Aberration Test (OECD TG 473) (OECD, 1997a)	Chinese hamster ovary cells (CHO-K_1 line)	HFPO dimer acid ammonium salt (83% purity) 49, 98, 244, 489, 977, 1954, and 3391 µg/mL for preliminary toxicity test* 977, 1954, and 3391 µg/mL for the 4-hour nonactivated and activated test conditions* 489, 977, and 1954 µg/mL for the 20-hour nonactivated test condition* Negative control (sterile water) and positive control (mitomycin C or cyclophosphamide) also included in study * Doses have been corrected to account for 83% HFPO dimer acid ammonium salt purity.	With S9	Positive at 3,391 µg/mL* in 4-hour activated test conditions.
				Without S9	Negative.

Study	Assay	Strain/Species	Dosing	Activation	Results
DuPont-23219 (2007)	*In vivo* Unscheduled DNA Synthesis Test in Mammalian Cells (OECD TG 486) (OECD, 1997b)	Primary hepatocytes harvested from male rats (5/dose group)	HFPO dimer acid ammonium salt (83% purity) 1, 10, 100, 1,000, and 2,000 mg/kg for preliminary toxicity test 500, 1,000, and 2,000 mg/kg/day for Unscheduled DNA Synthesis Test Negative control (distilled water) and positive control (dimethylnitrosamine) also included in study	Negative–No significant increase in the mean number of net nuclear grain counts in hepatocytes at 2–4 or 12–16 hours after dosing.	
Dupont-26129 (2008)	*In vitro* Mammalian Cell Gene Mutation Test (OECD TG 476) (OECD, 1997c)	L5178Y/TK$^{+/-}$ Mouse lymphoma cells	HFPO dimer acid ammonium salt (87% purity) 0.5, 1.5, 5, 15, 50, 150, 500, 1,500, and 3,500 µg/mL for both non-activated and S9-activated cultures at both 4-hour and 24-hour exposures for preliminary toxicity assay 500, 750, 1,000, 1,500, and 2,000 µg/mL for nonactivated cultures with a 4-hour exposure 150, 250, 500, 600, and 750 µg/mL for S9-activated cultures with a 4-hour exposure 250, 500, 600, 750, and 1,000 µg/mL for nonactivated cultures with a 24-hour exposure Negative control (sterile, distilled water) and positive control (methyl methanesulfonate or 7,12-dimethylbenz(a)anthracene) also included in study	With S9	Negative.
				Without S9	Negative.

Study	Assay	Strain/Species	Dosing	Activation	Results
Dupont-19714 RV1 (2008)	*In vitro* Mammalian Chromosome Aberration Test (OECD TG 473) (OECD, 1997a)	Chinese hamster ovary cells (CHO-K_1 line)	HFPO dimer acid ammonium salt (85% purity) 0.3, 1, 3, 10, 30, 100, 300, 1,000, and 3,471 µg/mL for preliminary toxicity test 100, 500, 1,000, 2500, and 3,471 µg/mL for the chromosome aberration assay for the 4-hour nonactivated, 4-hour S9-activated, and 20-hour nonactivated test conditions Cytogenetic evaluations were conducted at 1,000, 2,500, and 3,471 µg/mL for the 4-hour nonactivated and 4-hour S9-activated test conditions and at 100, 500, and 1,000 µg/mL for the 20-hour nonactivated test condition	With S9	The percentage of cells with structural aberrations in the test substance-treated groups was not increased above that of the vehicle control at any concentration. The percentage of cells with numerical chromosome aberrations at 2,500 and 3,471 µg/mL in the 4-hour S9-activated test conditions was increased in a dose-dependent manner above that of the vehicle control. The change was outside the historical control range and considered biologically relevant.

Study	Assay	Strain/Species	Dosing	Activation	Results
			Negative control (sterile water) and positive control (mitomycin-C or cyclophosphamide) also included in study	Without S9	In the 20-hour nonactivated test condition, substantial toxicity was observed at 3,471 µg/mL and a substantial reduction in mitotic index relative to vehicle control was observed in the mitotic index relative to vehicle control. The percentage of cells with structural aberrations in the test substance-treated groups was not increased above that of the vehicle control at any concentration. An increase in the percentage of cells with numerical chromosome aberrations was observed at 3,471 µg/mL in the 4-hour nonactivated condition relative to vehicle control.
DuPont-22734 RV1 (2008)	*In vitro* Bacterial Reverse Mutation Test (OECD TG 471) (OECD, 2020b)	*Salmonella typhimurium* (strains TA98, TA100, TA1535, and TA1537) and *Escherichia coli* (strain WP2*uvr*A)	HFPO dimer acid ammonium salt (82.6% purity) 32.5, 65.2, 97.7, 325, 652, 977, 3,256, and 4,885 µg/plate for the toxicity-mutation assay* 325, 652, 977, 3256, and 4885 µg/plate for the mutagenicity test* * Doses have been correct to account for 82.6% HFPO dimer acid ammonium salt purity.	With S9	Negative.
				Without S9	Negative.

Study	Assay	Strain/Species	Dosing	Activation	Results
DuPont-23220 (2007)	*In vivo* Micronucleus and Chromosome Aberration Assay (OECD TGs 474 and 475) (OECD, 2014, 2016b)	Primary bone marrow cells harvested from male and female ICR mice (2 males or 5 of each sex/dose for preliminary toxicity study) (5 of each sex/dose for toxicity study) (5 of each sex/dose for Micronucleus and Chromosome Aberration Assay)	HFPO dimer acid ammonium salt (82.6% purity) 1, 10, 98, 975, and 1,950 mg/kg by oral gavage for preliminary toxicity study* 1170, 1365, 1560, and 1,755 mg/kg by oral gavage for toxicity study* 317, 634, and 1,268 mg/kg by oral gavage for Micronucleus and Chromosome Aberration Assay* Positive control (colchicine) and negative control (sterile water) also included in the study * Doses have been corrected to account for 82.6% HFPO dimer acid ammonium salt purity.	Negative–No statistically significant increases in the incidence of micronucleated polychromatic erythrocytes or structural or numerical chromosomal aberrations in bone marrow of male and female ICR mice at doses up to and including the maximum tolerated dose (1,268 mg/kg).	

Notes: DNA = deoxyribonucleic acid; µg/mL = micrograms per milliliter; µg/plate = micrograms per plate; mg/kg = milligrams per kilogram; mg/kg/day = milligrams per kilogram per day; OECD = Organization for Economic Cooperation and Development; TG = test guideline.

Appendix D: NTP PWG Final Report on the Pathology Peer Review of Liver Findings

FINAL REPORT

December 4, 2019

PATHOLOGY PEER REVIEW
OF LIVER FINDINGS

H-28548: SUBCHRONIC TOXICITY 90 DAY GAVAGE STUDY IN MICE
(PROJECT ID: DUPONT-18405-1307)
&
AN ORAL (GAVAGE) REPRODUCTION/DEVELOPMENTAL TOXICITY SCREENING STUDY OF H-28548 IN MICE
(STUDY NUMBER WIL-189225)
(STUDY SPONSOR NUMBER: DUPONT-18405-1037)

Prepared by:

Susan A. Elmore, MS, DVM, DACVP, DABT, FIATP
Amy Brix, DVM, PhD, DACVP

INTRODUCTION

The study report, summary tables and individual animal findings, along with hematoxylin and eosin stained microscope slides used in the Subchronic Toxicity 90 Day Gavage Study In Mice (Project ID: DuPont-18405-1307) and An Oral (Gavage) Reproduction/Developmental Toxicity Screening Study of H-28548 In Mice (Study Number WIL-180225) (Project ID: DuPont-18405-1037) were received by the NTP reviewing pathologist. The slides for review each contained two liver lobes presumed to be the left and median lobes. The data and slides of the liver were reviewed per NTP standards (Sills et al, 2017), and the results are summarized in this report. The experimental design for this study is as follows:

DUPONT-18405-1307 **SUBCHRONIC TOXICITY STUDY**		
DOSAGE (mg/kg/day)	**MICE**

SUMMARY OF ORIGINAL STUDY RESULTS

DUPONT-18405-1307 (Subchronic Toxicity 90 Day Gavage Study)

The following information is excerpted from the Final Report entitled "H-28548: Subchronic Toxicity 90 Day Gavage Study in Mice," dated February 19, 2010:

> In 5 mg/kg/day male and female dose groups, increases were observed in the incidence of single cell necrosis, mitotic figures, and/or pigment. The liver effects at 5 mg/kg/day correlated with clinical chemistry effects and were considered test substance related and adverse. Other test substance-related effects were observed in the livers of 0.5 and 5 mg/kg/day males and 5 mg/kg/day females, including increases in absolute and/or relative liver weight, enlarged and/or discolored livers, and centrilobular hepatocellular hypertrophy. The liver effects observed in 0.5 mg/kg/day males were considered to be non-adverse adaptive responses as they were not correlated with clinical or microscopic pathology evidence of liver toxicity.

DUPONT-18405-1037 (Reproduction/Developmental Toxicity Screening Study)

The following information is excerpted from the Final Report entitled "An Oral (Gavage) Reproduction/Developmental Toxicity Screening Study of H-28548 in Mice," dated December 29, 2010:

> In male and female mice given 5 mg/kg/day, mild to moderate hepatocellular hypertrophy was observed microscopically. The hepatocellular hypertrophy was characterized by cytoplasmic eosinophilic stippling that is consistent with peroxisome proliferation and was associated with correlative increases in liver weights. Other microscopic changes in the liver at 5 mg/kg/day included increases in single cell necrosis, mitotic figures, pigment, and focal necrosis (females only). In male and female mice given 0.5 mg/kg/day, the incidence and severity of hepatocellular hypertrophy, as well as the correlative liver weight changes was reduced. Other lesions at the 0.5 mg/kg/day dose level were limited to minimal single cell necrosis in 5 of 24 males.

SLIDE REVIEW WORK SHEETS (SRWS)

The Slide Review Work Sheets are presented in appendix A (Dupont-18405-1307 Subchronic Toxicity Study) and appendix B (Dupont-18405-1037 Reproduction/ developmental Toxicity Screening Study). These work sheets list, in animal ID number order, the original study pathologist's findings, along with the reviewing pathologist's comments. Entries other than "Agree" under the reviewing pathologist's comments indicate a disagreement with the study pathologist's (SP's) diagnosis. In each instance, space is provided to record remarks made during the Slide Review.

FINDINGS OF THE SLIDE REVIEW

DUPONT-18405-1307 (Subchronic Toxicity 90 Day Gavage Study)

The slides reviewed during this quality assessment were of adequate quality and had no artifacts that interfered with making diagnoses. The liver was reviewed from all animals for all lesions. It was requested by the NTP pathologist that the reviewing pathologist use the terminology of the INHAND document containing standardized terminology of the liver (Thoolen et al, 2010) except where it would be superseded by the terminology published by the INHAND committee with reference to cell death/necrosis/apoptosis (Elmore et al, 2016). The study pathologist diagnosed hepatocellular hypertrophy which included the morphologic change of eosinophilic stippling commonly observed with peroxisome proliferators. The reviewing pathologist agreed that there was hypertrophy of the hepatocytes, but often regarded the severity to be less than recorded by the study pathologist. In addition, the reviewing pathologist recommended adding the diagnosis cytoplasmic alteration to account for the brightly eosinophilic, frequently granular, appearance of the cytoplasm of hepatocytes. After reviewing these lesions with the NTP pathologist, the NTP pathologist recommended using the term cytoplasmic alteration to encompass both hypertrophy and eosinophilic change to the hepatocytes, as she considered them part of the same process. The reviewing pathologist agreed with most occurrences and severities of single cell necrosis. However, the reviewing pathologist also observed apoptosis, and recommended adding the diagnosis of "apoptosis, hepatocellular" when present. Descriptions of individual lesions recorded during this review are listed below. The summary incidences are found in Table 1.

DUPONT-18405-1037 (Reproduction/Developmental Toxicity Screening Study)

The slides reviewed during this quality assessment were of adequate quality and had no artifacts that interfered with making diagnoses. The liver was reviewed from all animals for all lesions. For the most part, the reviewing pathologist agreed with the study pathologist's diagnoses and severities. It was requested by the NTP pathologist that the reviewing pathologist use the terminology of the INHAND document containing standardized terminology of the liver (Thoolen et al, 2010) except where it would be superseded by the terminology published by the INHAND committee with reference to cell death/necrosis/apoptosis (Elmore et al, 2016). The study pathologist diagnosed hepatocellular hypertrophy which included the morphologic change of eosinophilic stippling commonly observed with peroxisome proliferators. The reviewing pathologist agreed that there was hypertrophy of the hepatocytes, but used the terminology "cytoplasmic alteration" at the request of the NTP pathologist, based upon review of the slides from the 18405-1307 subchronic study. The reviewing pathologist agreed with most occurrences and severities of single cell necrosis. However, the reviewing pathologist also observed apoptosis, and recommended adding the diagnosis of "apoptosis, hepatocellular" when present. The reviewing pathologist recorded additional occurrences of mixed cell infiltrates in most groups of animals. Descriptions of individual lesions recorded during this review are listed below. The summary incidences are found in Table 2.

DESCRIPTIONS OF LESIONS

Single cell necrosis (Figures 1 & 2) consisted of individual hepatocytes that had pale, granular, vacuolated or eosinophilic cytoplasm; nuclei were either swollen or pyknotic and karyorrhectic.

The cells frequently appeared fragmented and were often surrounded by degenerative inflammatory cells. Inflammatory cells were not documented separately as they were considered a response to the necrosis. All of the lesions were considered minimal in severity, which was recorded when 1-10 cells were observed in ten 20X fields. Single cell necrosis was not recorded unless at least two affected cells were observed in the entirety of the liver sections examined; if 2 or more necrotic cells were observed, counting of ten 20X fields was done to determine severity. This lesion was observed in both the 18405-1307 subchronic & the 18405-1037 reproduction/developmental studies.

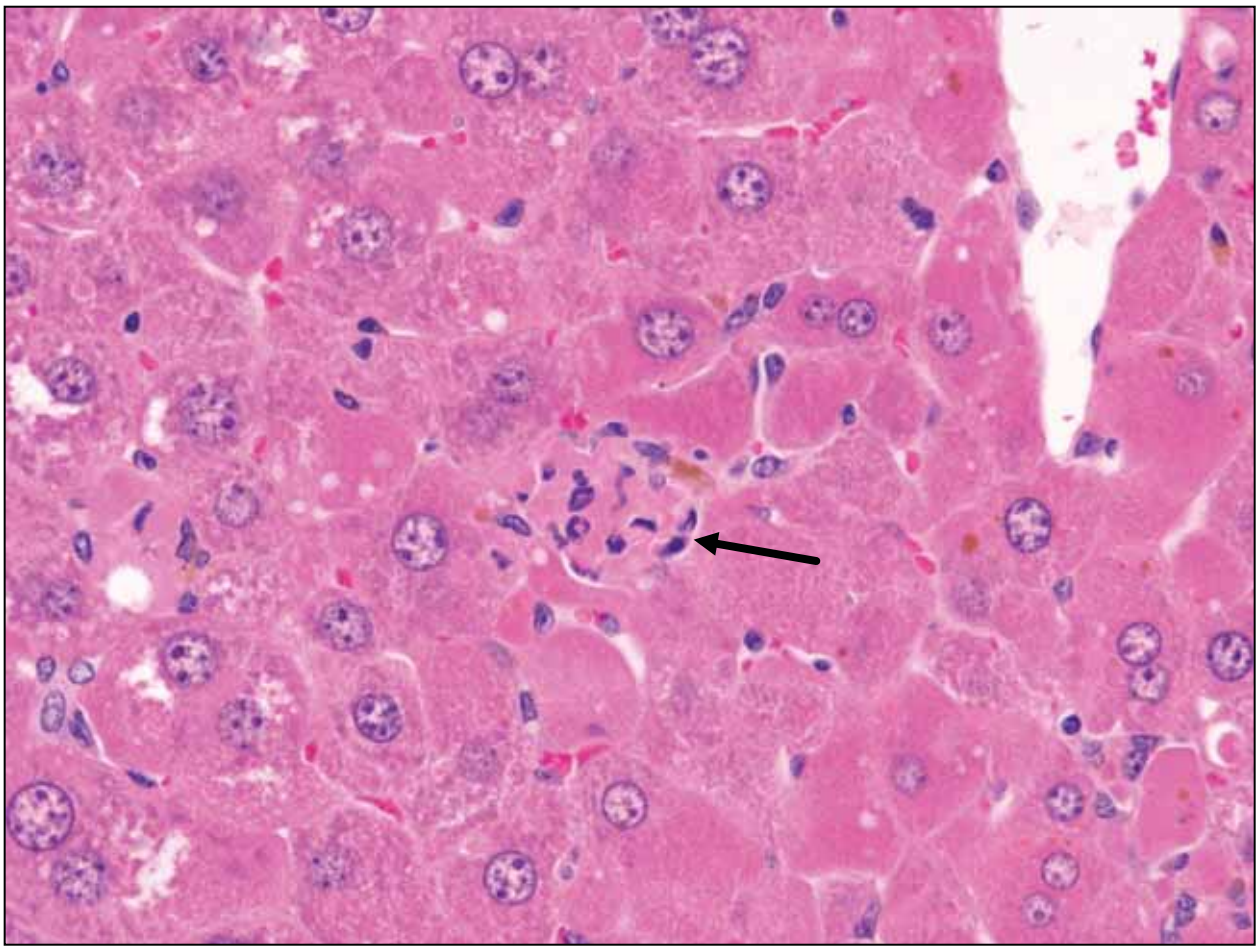

Figure 1. Single cell necrosis in the liver of a Group 4 male mouse (animal 410) from the 18405-1307 subchronic study. The necrotic cell (arrow) is fragmented and surrounded by inflammatory cells.

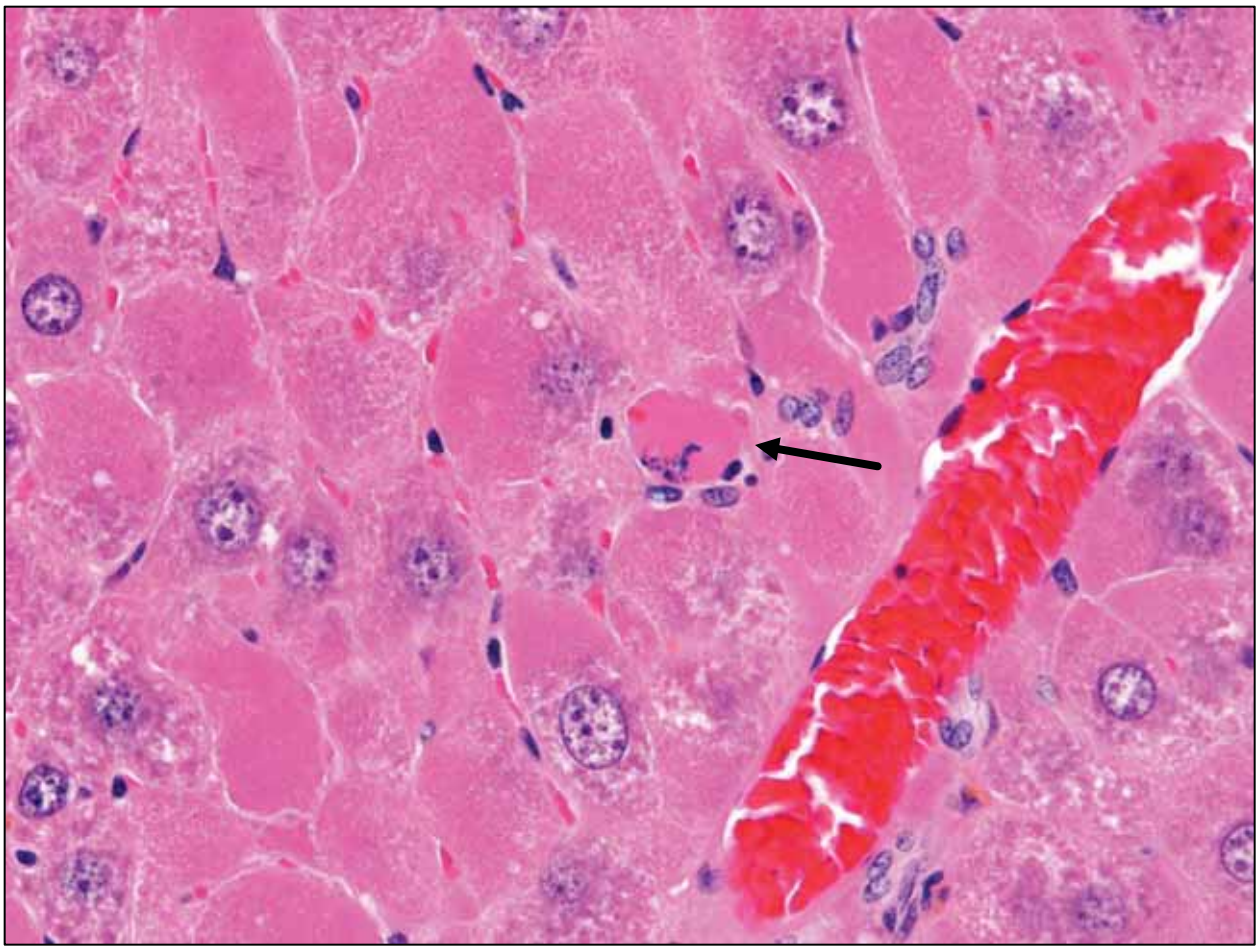

Figure 2. Single cell necrosis in the liver of a Group 4 male mouse (animal 405) from the 18405-1307 subchronic study. The necrotic cell (arrow) is swollen, and has brightly eosinophilic cytoplasm and a karyorrhectic nucleus.

Apoptosis; hepatocellular was recorded when individual hepatocytes were observed that had characteristics, as described in the article by Elmore (Elmore et al, 2016), of apoptosis. Briefly, affected cells were typically shrunken, with hyper-eosinophilic cytoplasm and condensed, pyknotic or karyorrhectic nuclei. The cells were round and often small; occasionally they were phagocytosed by surrounding cells. There was a lack of associated inflammatory cells with apoptotic hepatocytes. Grading was done based upon the Thompson article (Thompson et al, 2018) to be consistent with the reviewing pathologist's grading criteria. All of the lesions were considered minimal to mild in severity, which was recorded when 1-10 cells, or 11-40 cells, respectively, were observed in ten 20X fields. Apoptosis was not recorded unless at least two affected cells were observed in the entirety of the liver sections examined; if 2 or more apoptotic cells were observed, counting of ten 20X fields was done to determine severity. This lesion was observed in both the 18405-1307 subchronic & the 18405-1037 reproduction/developmental studies.

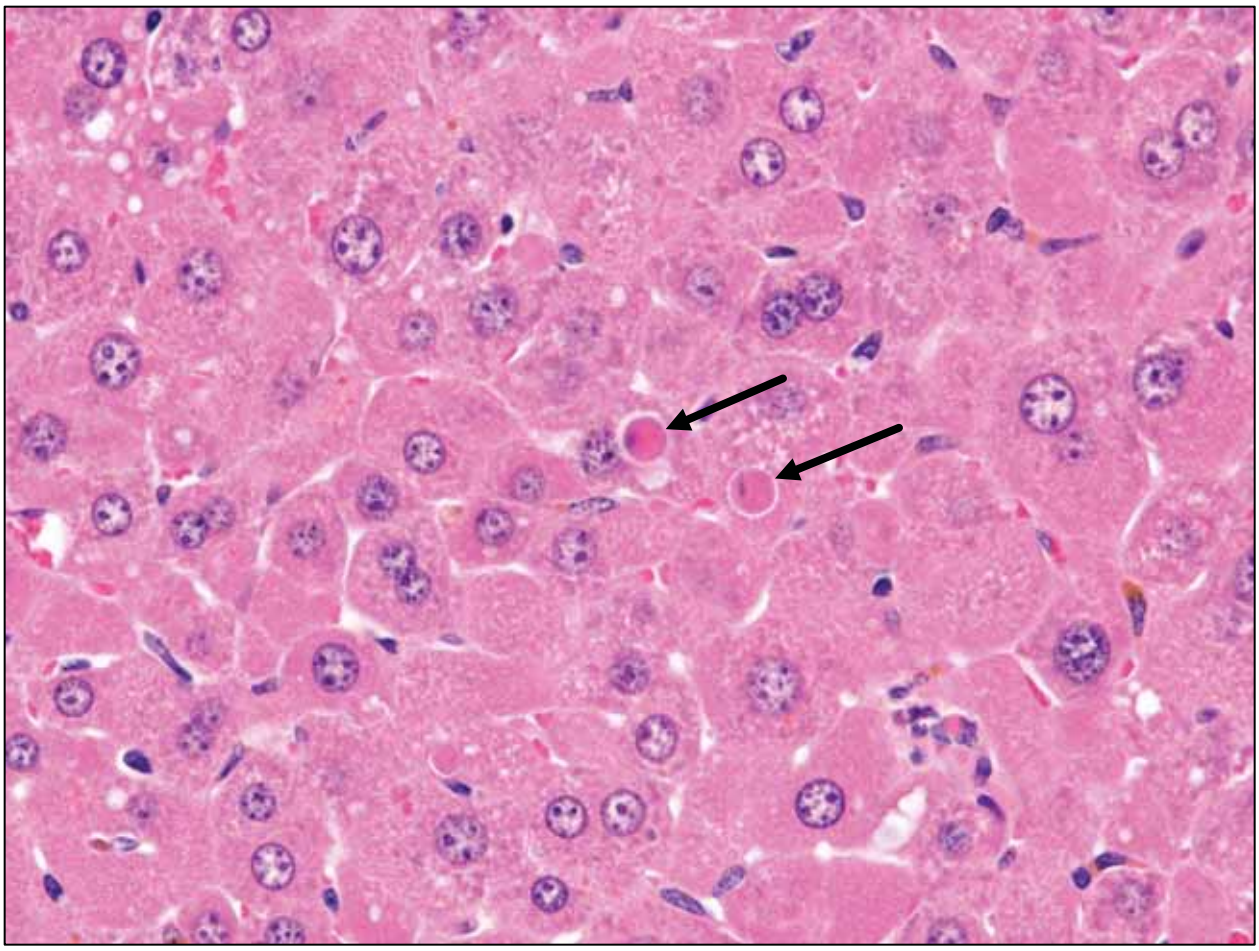

Figure 3. Apoptosis in the liver of a Group 4 male mouse (animal 410) from the 18405-1307 subchronic study. The apoptotic hepatocytes are small, rounded, and brightly eosinophilic (arrows).

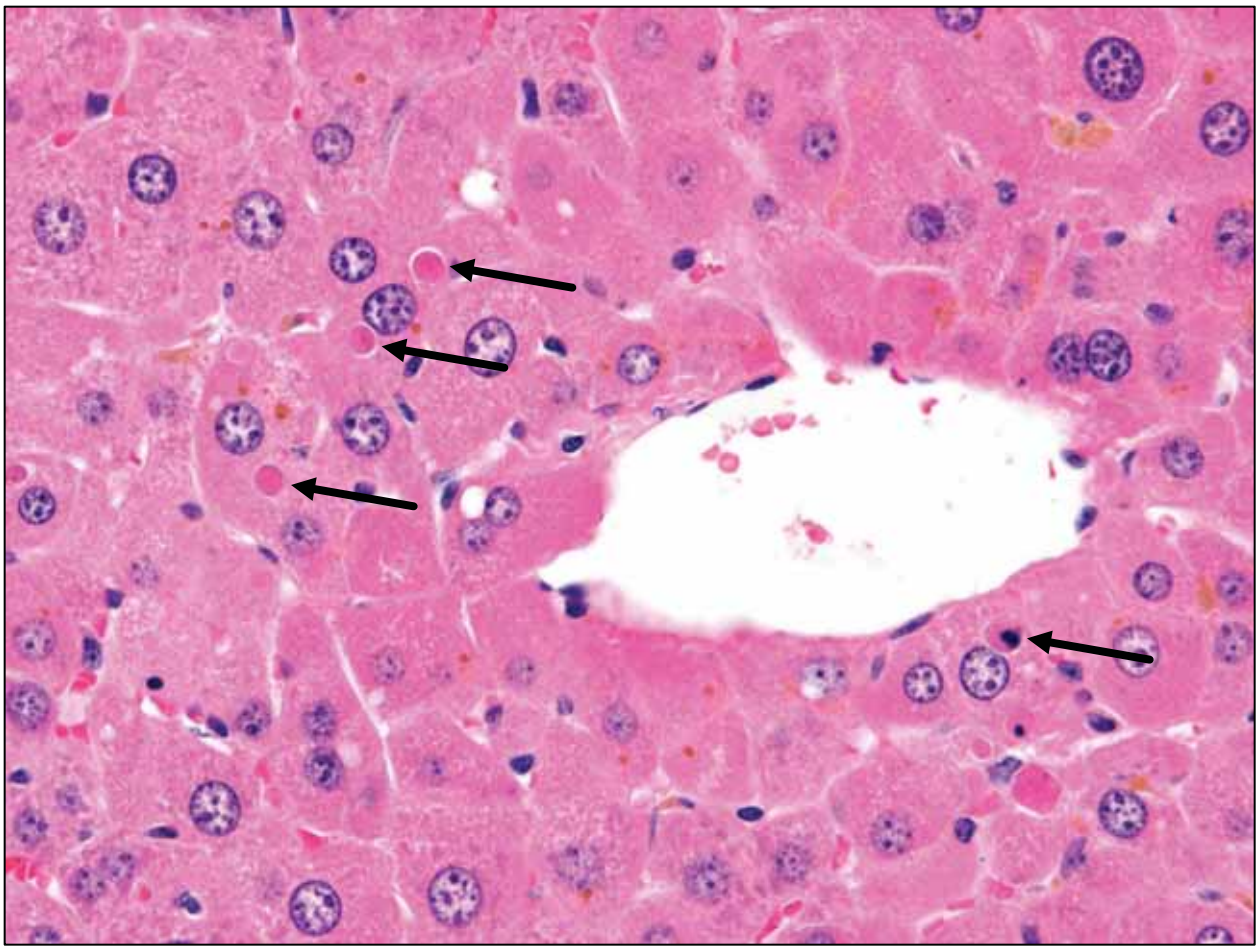

Figure 4. Apoptosis in the liver of a Group 4 male mouse (animal 410) from the 18405-1307 subchronic study. Evidence of apoptosis is provided by small round eosinophilic remnants of hepatocytes (arrows).

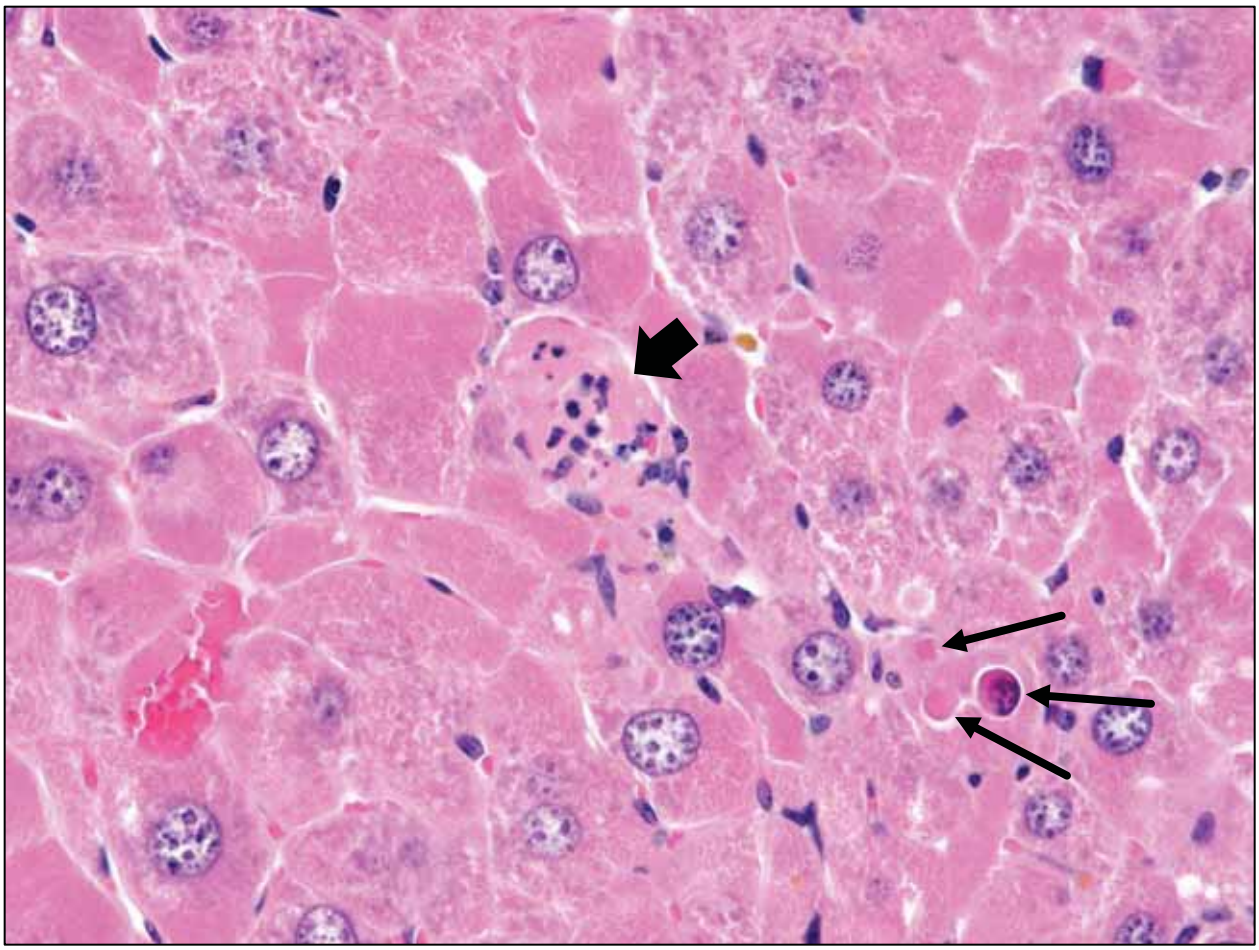

Figure 5. Apoptosis (long arrows) and single cell necrosis (short arrow) in the liver of a Group 4 male mouse (animal 405) from the 18405-1307 subchronic study.

Focal necrosis consisted of a localized area of coagulative necrosis. Generally, there was a loss of cellular detail of the affected hepatocytes; rarely there was a small amount of mineral (dystrophic) associated with the areas of necrosis. Inflammatory cell infiltrates typically ringed the region of necrotic hepatocytes. This lesion was observed in both the 18405-1307 subchronic & the 18405-1037 reproduction/developmental studies.

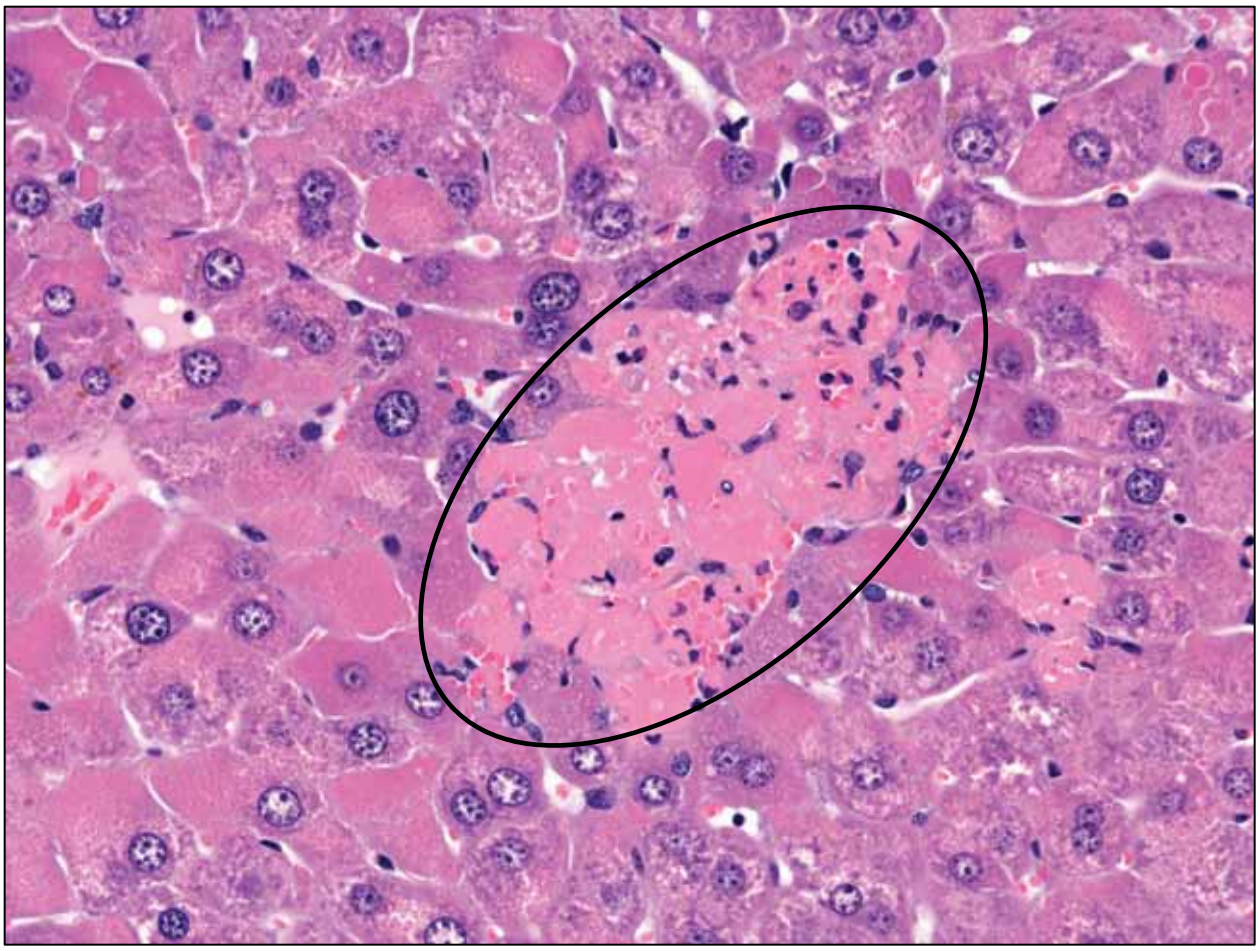

Figure 6. Focal necrosis (outlined) in the liver of a Group 4 male mouse (animal 7744) from the 18405-1037 reproduction/developmental study. There is a small area of contiguous hepatocytes that are necrotic. Many of the cell borders are indistinct.

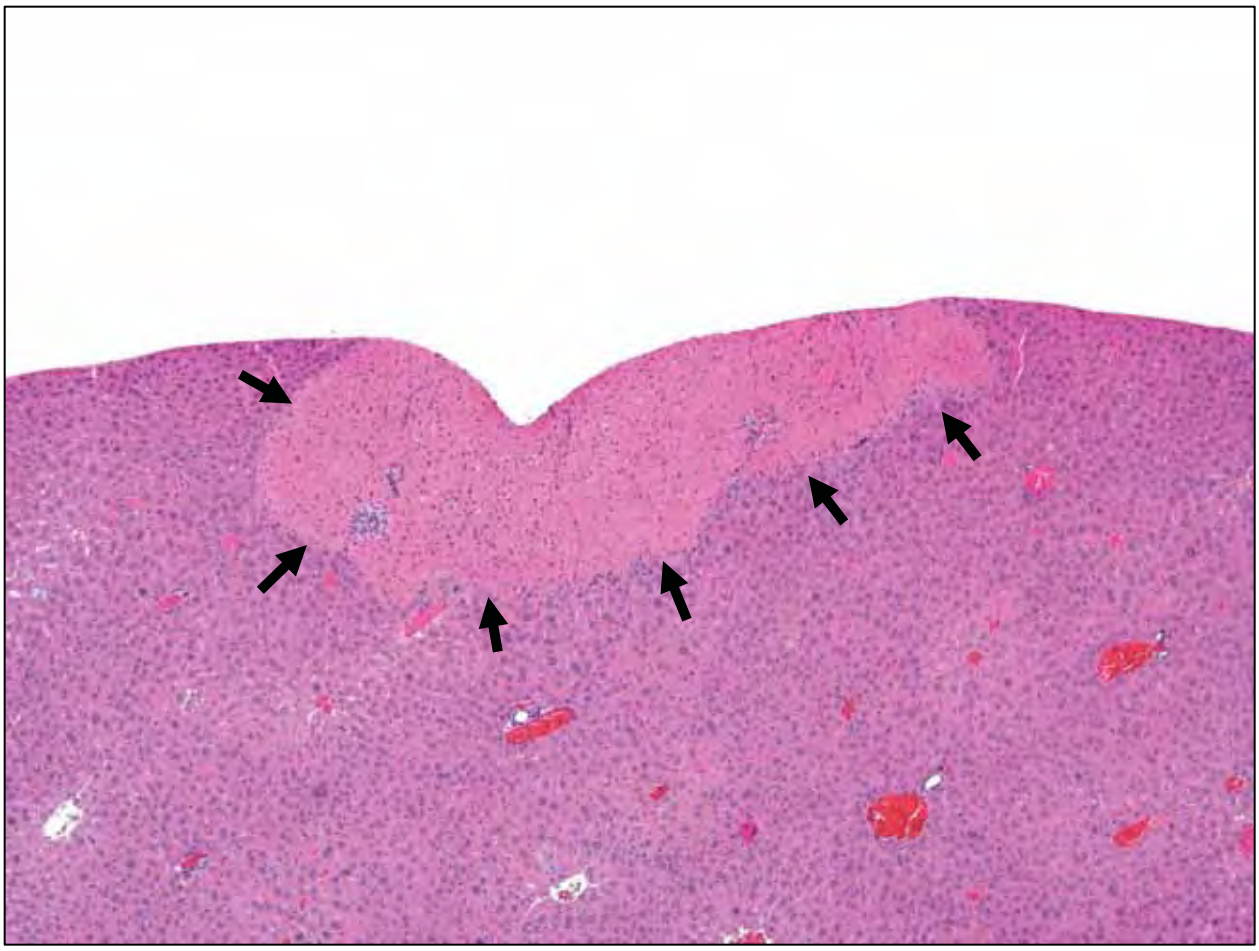

Figure 7. Focal necrosis (area delineated by arrows) in the liver of a Group 4 male mouse (animal 456) from the 18405-1307 subchronic study. This example of focal necrosis is more extensive than that shown in figure 6.

Cytoplasmic alteration was characterized by a bright eosinophilia to the cytoplasm of hepatocytes, usually accompanied by a slight increase in cell, and sometimes nuclear, size. The cytoplasm usually had a granular appearance to it, although with greater severities, the cytoplasm lost its granular appearance, and was just filled with smooth, homogeneous, brightly eosinophilic material. Severity grading was subjectively based on the number of hepatocytes involved and the amount of material within the affected hepatocytes. Minimal (+1) cytoplasmic alteration was recorded when there was an eosinophilic granular appearance to the hepatocytes in the centrilobular region of most hepatic lobules. With mild (+2) cytoplasmic alteration, more of each hepatic lobule was involved, so that many of the hepatic lobules appeared to be completely affected, rather than having alteration limited to the centrilobular area. All the hepatocytes appeared to be affected with moderate (+3) cytoplasmic alteration and those in the centrilobular area usually had lost the granular appearance to the cytoplasm and instead had a more solid, brightly eosinophilic appearance to it. Many of the hepatocytes with moderate cytoplasmic alteration were also larger than normal, and some also had larger than normal nuclei. These latter changes were not recorded separately, but were considered part of the cytoplasmic alteration. Marked (+4) cytoplasmic alteration was a diffuse change, with most of the hepatocytes distended by increased amounts of brightly eosinophilic cytoplasm that lacked granularity or definition,

similar to what was seen with moderate cytoplasmic alteration, but affected the entire hepatic lobule rather than just the centrilobular part. This lesion was observed in both the 18405-1307 subchronic & the 18405-1037 reproduction/developmental studies.

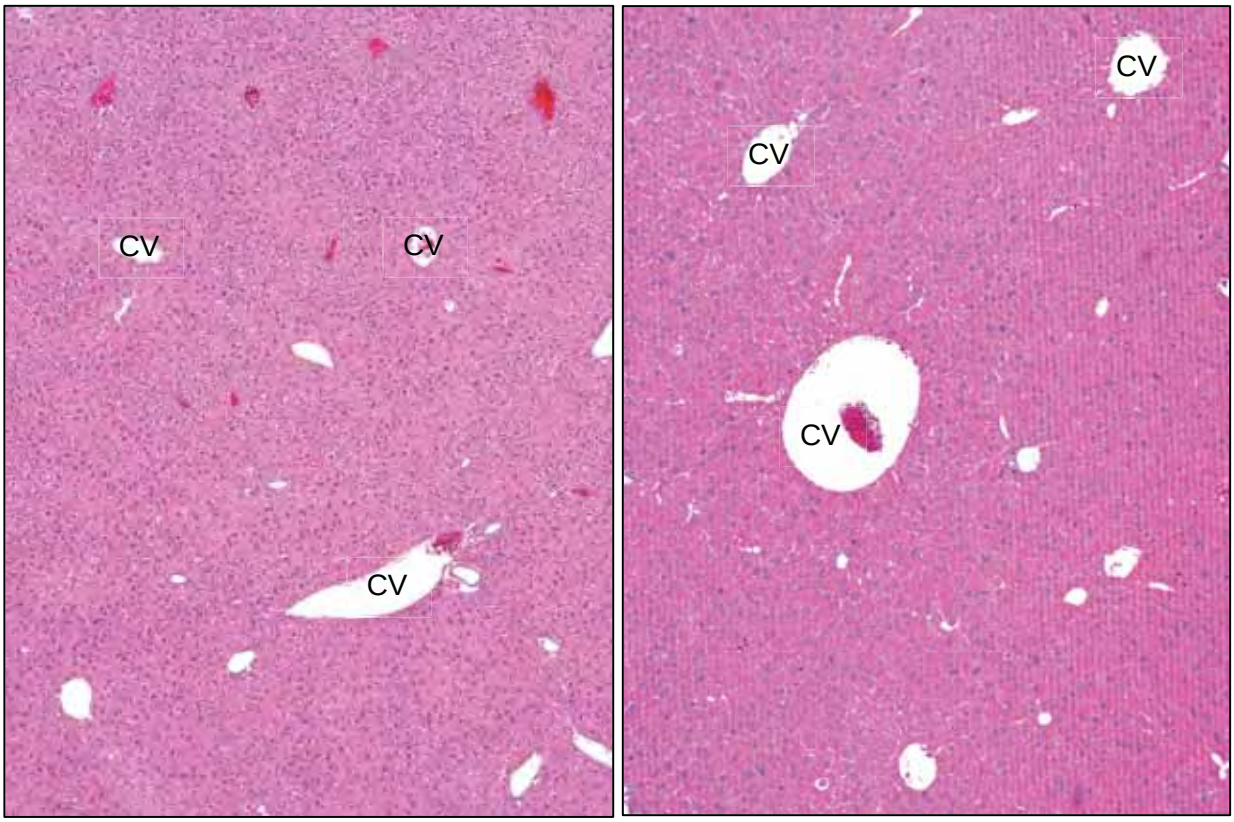

Figure 8. Control liver from a Group 1 mouse (animal 101) on the left; cytoplasmic alteration in the liver of a Group 4 male mouse (animal 401) on the right; from the 18405-1307 subchronic study. At this low magnification, the Group 4 mouse liver appears brightly eosinophilic when compared to the Group 1 (control) liver. The nuclei are also spaced further apart from each other, consistent with hypertrophied cells. CV=central vein.

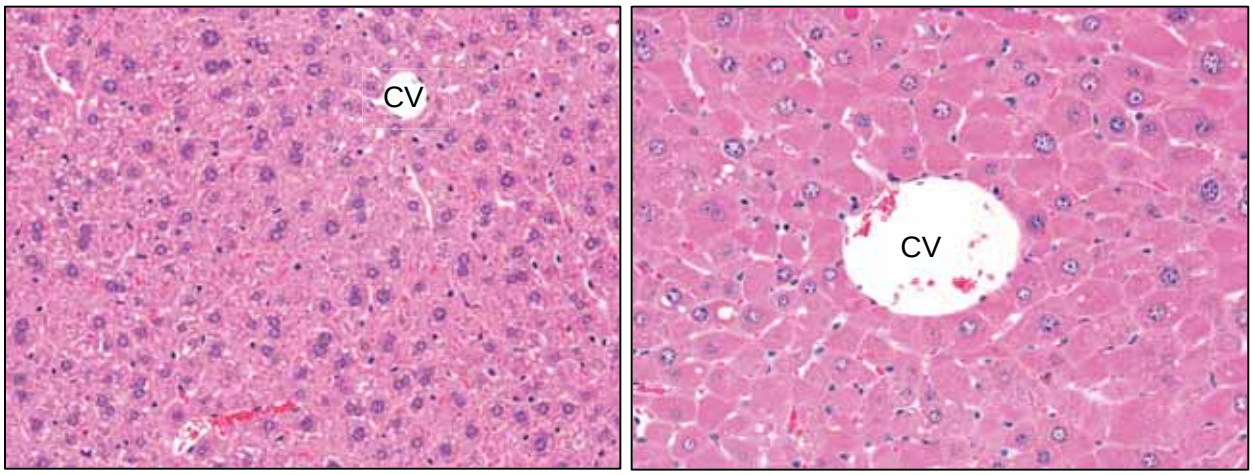

Figure 9. Control liver from a Group 1 mouse (animal 105) on the left; cytoplasmic alteration in the liver of a Group 4 male mouse (animal 401) on the right; from the 18405-1307 subchronic study. This higher magnification photo reveals the eosinophilic granular nature of the cytoplasm in the Group 4 mouse. CV=central vein.

Mixed cell infiltrate was characterized by the presence clusters of inflammatory cells within the hepatic parenchyma. They were often found randomly scattered throughout the liver, and less commonly in the periportal or centrilobular areas. The infiltrates were composed primarily of lymphocytes with fewer macrophages and plasma cells. Neutrophils were a small component of many of the foci, and were a major component of a few of them. Occasionally, a necrotic hepatocyte could be found within the focus of inflammatory cells. Mixed cell infiltrate was used as a diagnostic term as it is the term preferred in INHAND (Thoolen et al, 2010). This lesion was observed in both the 18405-1307 subchronic & the 18405-1037 reproduction/developmental studies. Mixed cell infiltrates are common background lesions in mice, although they may be exacerbated with treatment.

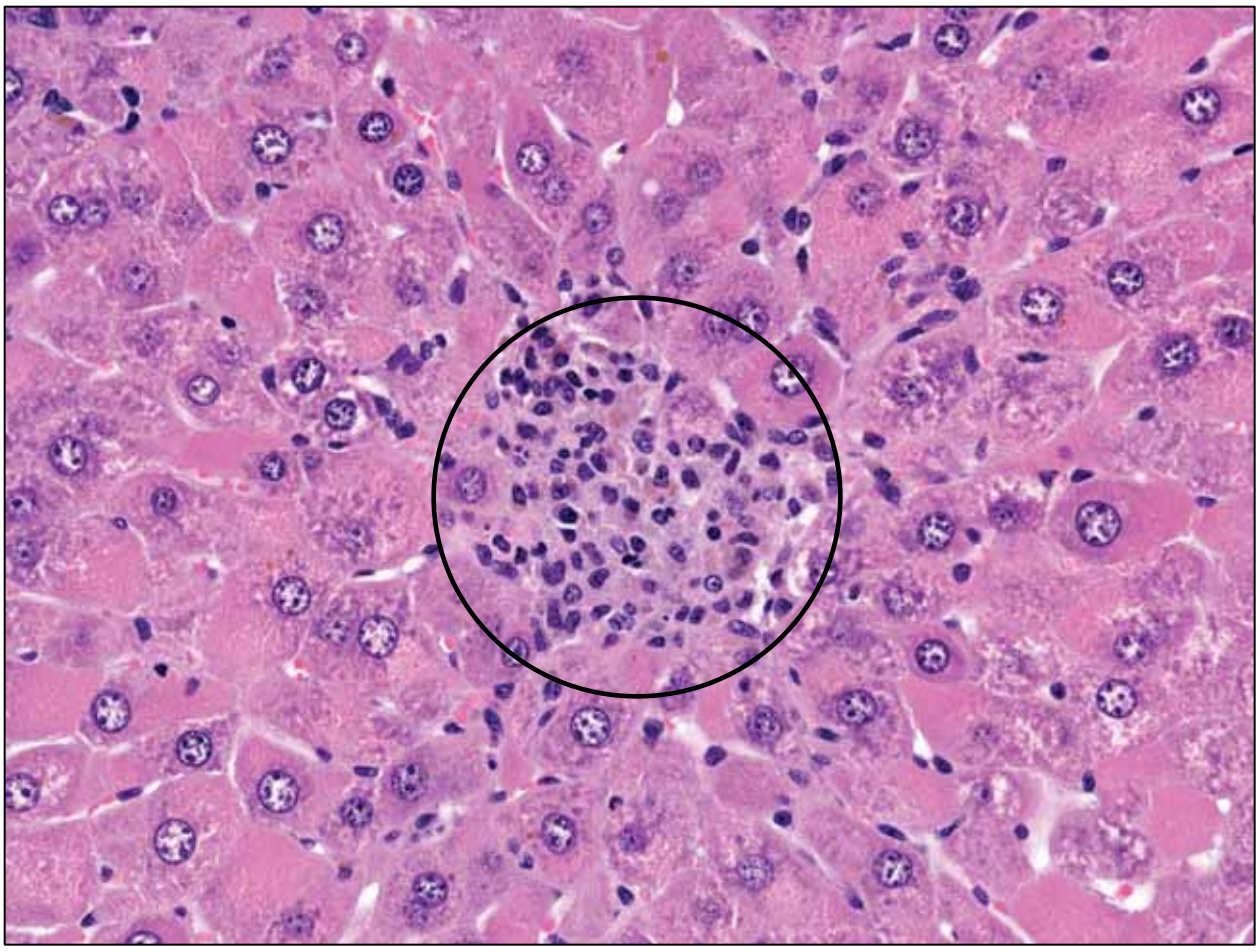

Figure 10. Mixed cell infiltrates (circled) in the liver of a Group 4 male mouse (animal 7744) from the 18405-1037 reproduction/developmental study. Different types of inflammatory cells, including macrophages (some containing pigment consistent with cell breakdown product), lymphocytes, plasma cells, and neutrophils are present in a focal area. Some of these areas also contained an occasional necrotic hepatocyte.

Mitotic figures were considered to be present when there were an increased number of mitotic figures observed in the sections of liver examined. Typically, if 3 or more mitotic figures were observed, ten 20X fields were counted for the number of mitotic figures, and severity scores were based upon how many mitotic figures were counted: Minimal if 1-10 cells were observed in ten 20X fields; mild if 11-40 cells were observed in ten 20X fields. All the occurrences of mitotic figures were considered of minimal or mild severity. This lesion was observed in both the 18405-1307 subchronic & the 18405-1037 reproduction/developmental studies.

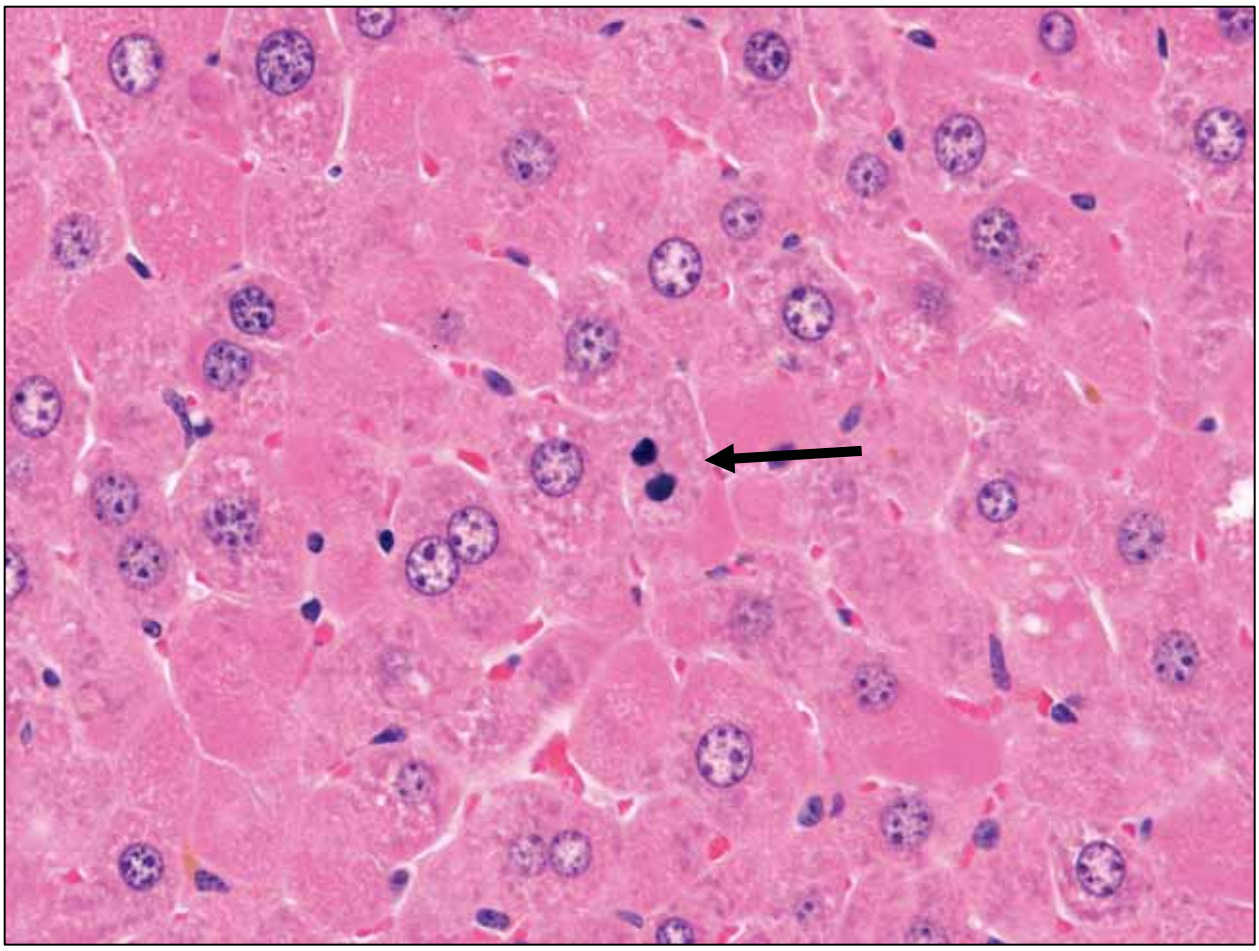

Figure 11. A mitotic figure (arrow) in the liver of a Group 4 male mouse (animal 7744) from the 18405-1037 reproduction/developmental study. Although mitotic figures can be found in the livers of normal mice, there were increased numbers observed in the livers of some animals in this study.

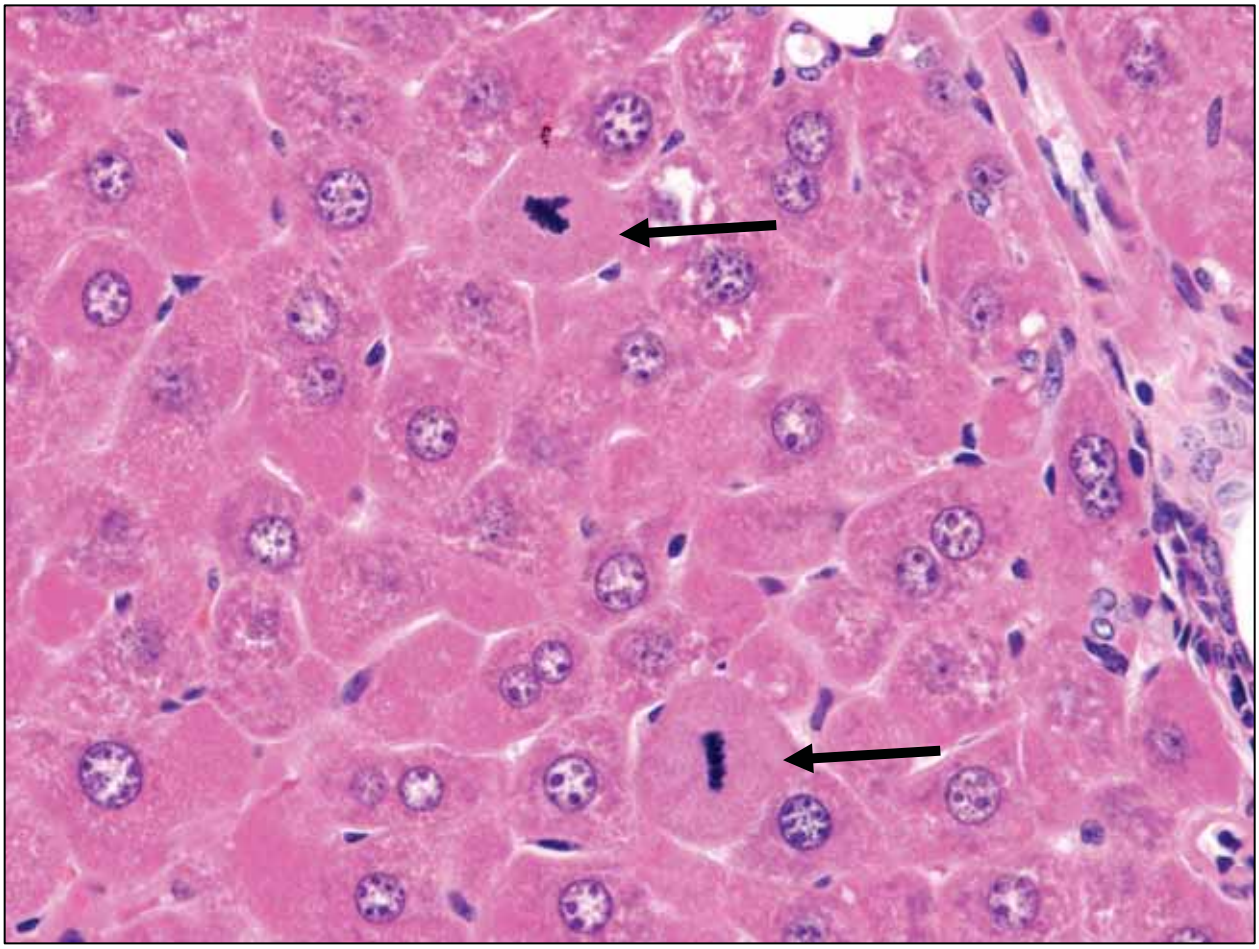

Figure 12. Mitotic figures (arrows) in the liver of a Group 4 male mouse (animal 409) from the 18405-1307 subchronic study. Increased mitotic figures were observed in both the 18405-1307 subchronic and the 18405-1037 reproduction/developmental studies.

Pigment increased; was characterized by golden brown pigment that was found primarily in bile canaliculi, Kupffer cells, but occasionally in hepatocytes as well. All the occurrences were of minimal severity. This lesion was observed in both the 18405-1307 subchronic & the 18405-1037 reproduction/developmental studies.

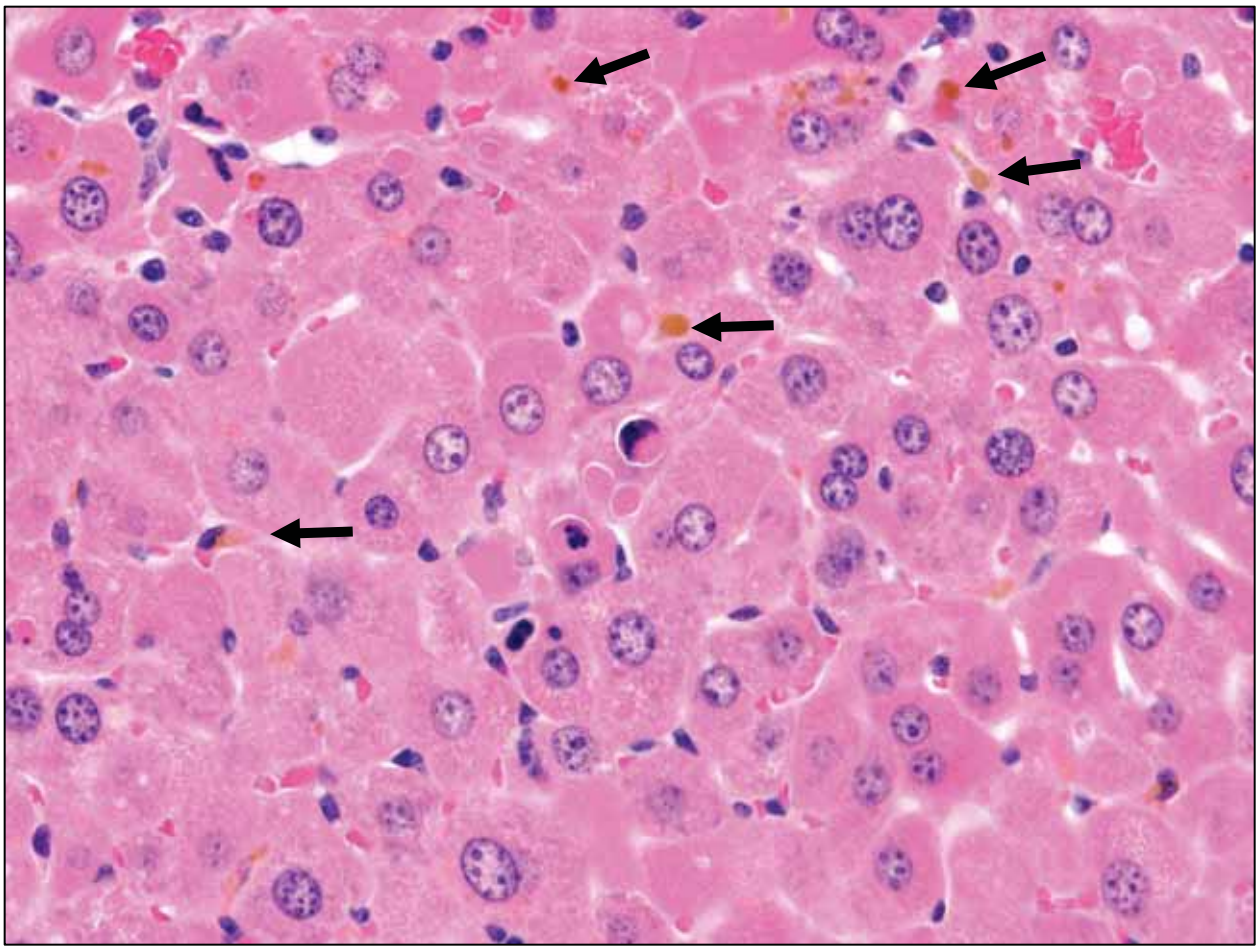

Figure 13. Pigment (arrows) in the liver of a Group 4 male mouse (animal 410) from the 18405-1307 subchronic study. Special stains were not performed to identify the pigment, but the appearance and location were consistent with either inspissated bile in canaliculi (arrows) or byproducts from cell breakdown in Kupffer cells (see figure 14).

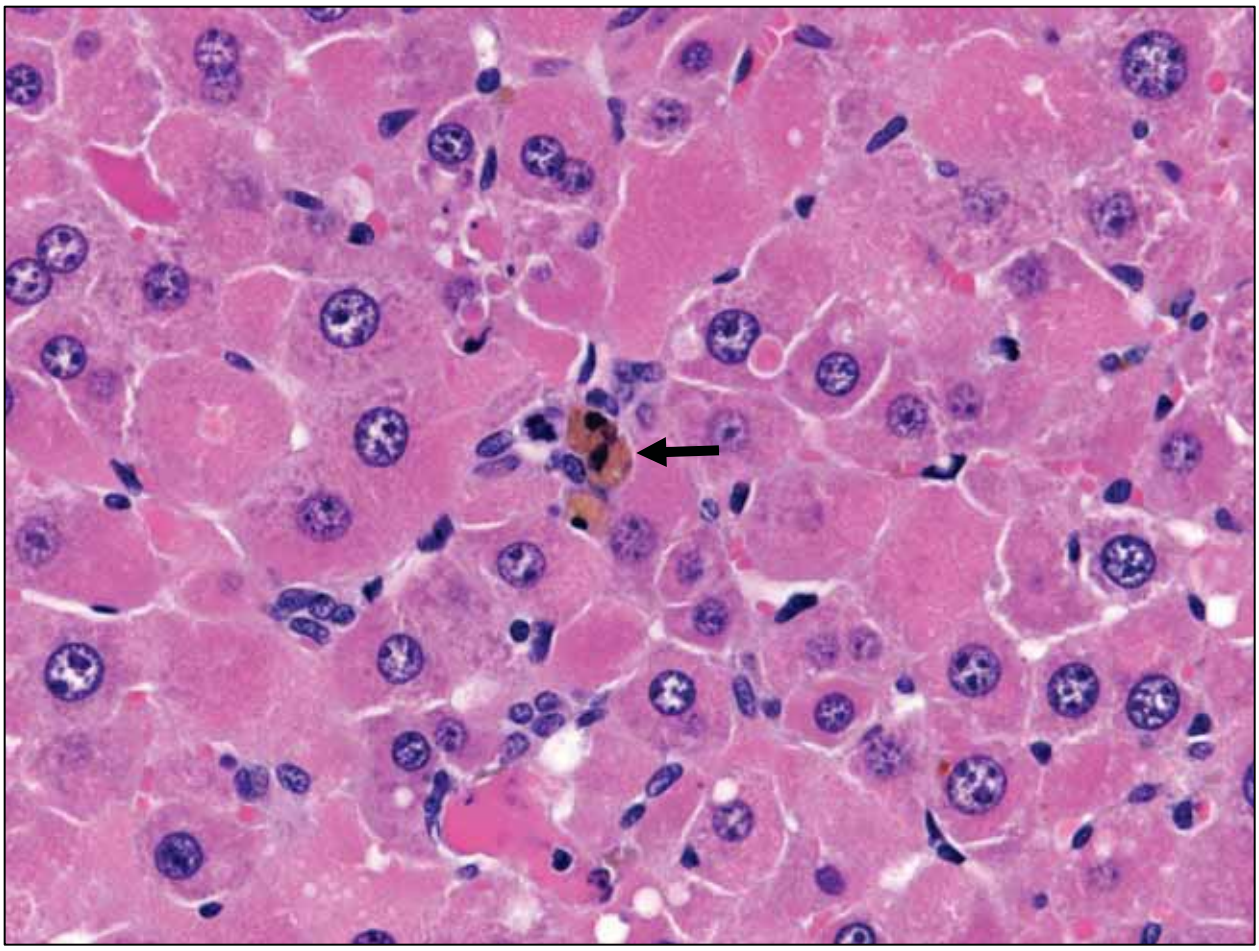

Figure 14. Pigment in the liver of a Group 4 male mouse (animal 410) from the 18405-1307 subchronic study. The pigment was found primarily in bile canaliculi or macrophages (Kupffer cells) but also in hepatocytes on occasion and was consistent with either inspissated bile in canaliculi or byproducts from cell breakdown (e.g. hemosiderin) (arrow).

Extramedullary hematopoiesis was recorded in one animal (a Group 4 male) in the 18405-1307 subchronic, and in 4 animals (a Group 3 male; two Group 4 males; & a Group 4 female) in the 18405-1037 reproduction/developmental study. It consisted of tight clusters of hematopoietic cells in varying degrees of maturity; most of the cells appeared to be myeloid cells.

Cytoplasmic vacuolation was recorded in several male mice in Group 3 and several female mice in Group 4 in the 18405-1037 reproduction/developmental study. It was characterized by very small vacuoles within the cytoplasm of hepatocytes, consistent with microvesicular fatty change. In most of the animals, it primarily involved the centrilobular hepatocytes, although in some animals the change was also present in midzonal hepatocytes.

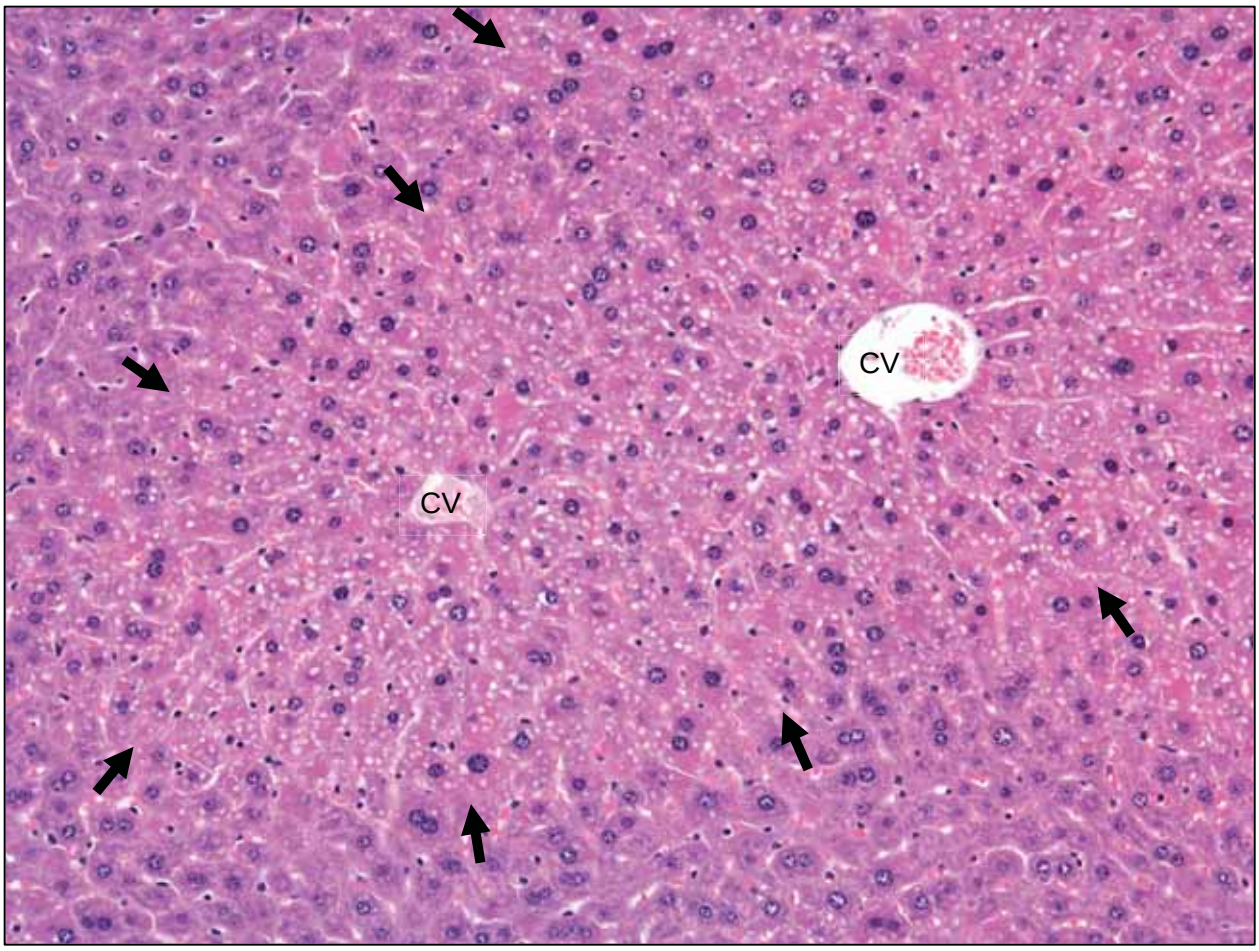

Figure 15. Cytoplasmic vacuolation in the liver of a Group 4 female mouse (animal 5073) from the 18405-1037 reproduction/developmental study. The vacuoles were small and slightly less regular than those observed in macrovesicular fatty change, and found primarily in the centrilobular region (area delineated by arrows), around the central vein. CV=central vein.

Oval cell hyperplasia was recorded in six Group 4 male mice in the 18405-1037 reproduction/developmental study. Only minimal oval cell hyperplasia was recorded, and it was characterized by an increase in oval cells in several periportal regions, with some oval cells present in the surrounding hepatic parenchyma.

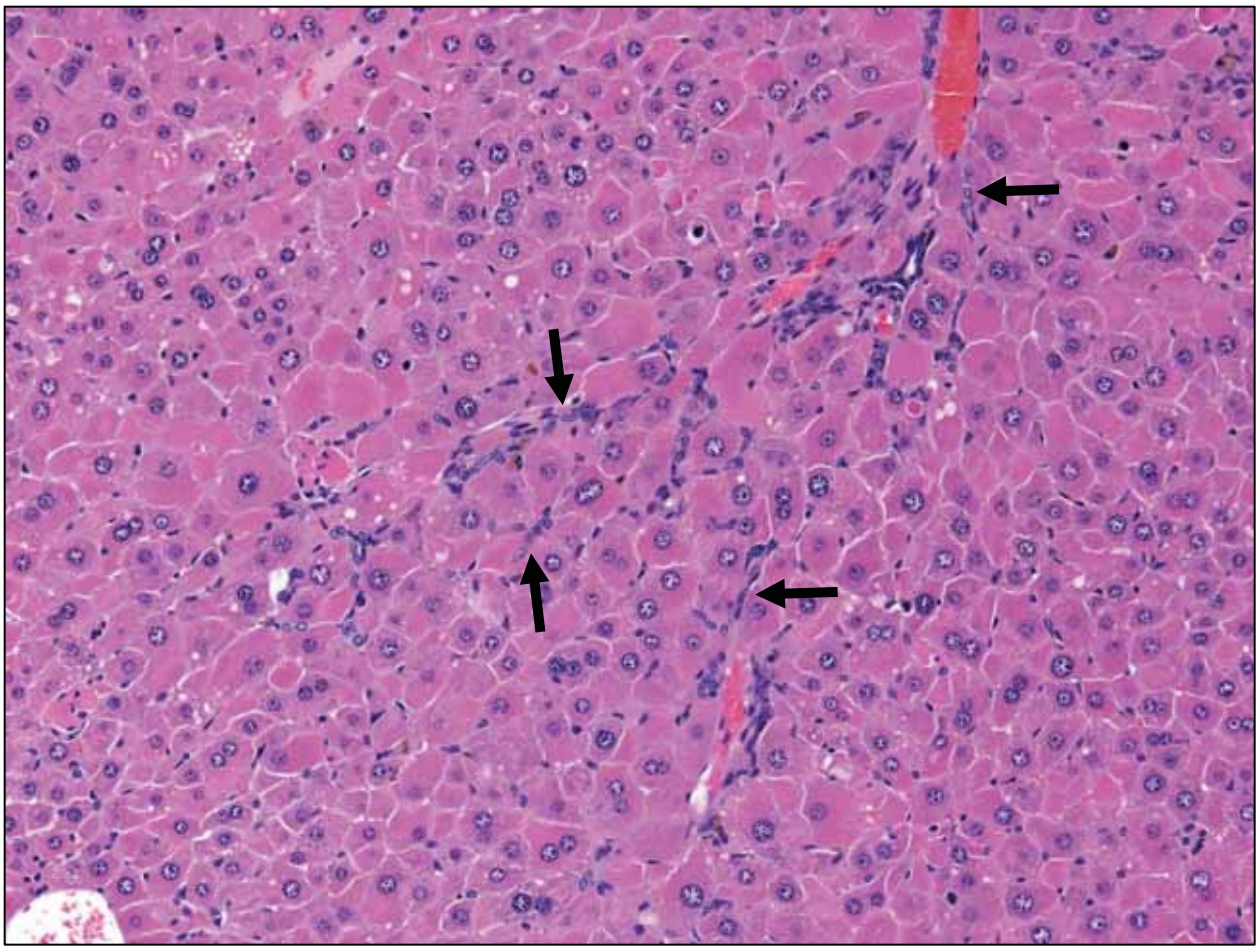

Figure 16. Oval cell hyperplasia in the liver of a Group 4 male mouse (animal 7730) from the 18405-1037 reproduction/developmental study. Oval cells (arrows), small cells with round to oval nuclei, appear to originate in the portal region and branch out from there.

Bile duct hyperplasia was recorded in one Group 4 male mouse in the 18405-1307 subchronic study, and was characterized by increased profiles of bile ducts in the periportal region; only minimal bile duct hyperplasia was recorded.

Table 1. Study 18405-1307 Subchronic Toxicity 90-Day Gavage Study
Summary incidences of lesions observed in the liver during slide review

PATHOLOGY WORKING GROUP

A PWG was convened on October 15, 2019 at the National Institute of Environmental Health Sciences (NIEHS), Research Triangle Park (RTP), NC to histologically evaluate selected tissues from this study. The participants were Drs. Susan A. Elmore, MS, DVM, DACVP, DABT (NTP/NIEHS - PWG Coordinator), Amy Brix, DVM, PhD, DACVP (EPL - Reviewing Pathologist), David Malarkey, DVM, PhD, DACVP (NTP/NIEHS), Arun Pandiri, BVSc&AH, PhD, DACVP, DABT (NTP/NIEHS), Robert Sills, DVM, PhD, DACVP (NTP/NIEHS), Brian Berridge, DVM, PhD, DACVP (NTP/NIEHS), Robert Maronpot, DVM, MS, MPH (Maronpot Consulting, LLC) and Michael Elwell, DVM, PhD (Apex ToxPath, LLC).

The PWG Coordinator selected slides for review by the PWG that included 3 examples each of normal liver, hepatocellular apoptosis, hepatocellular single cell necrosis and hepatocellular cytoplasmic alteration, as well as 2 examples each of focal necrosis, pigment, increased mitoses, mixed cell infiltrates, cytoplasmic vacuolation and 1 example of oval cell hyperplasia. There was a majority consensus for all reviewed lesions. The PWG consensus opinion for each slide, including any additional diagnoses made by the PWG panel, was recorded on the slide review worksheet attached to the end of this report.

After review of all lesions, there was discussion about potential adversity. Adversity is a term indicating “harm” to the test animal within the constraints of a given study design (dose, duration, etc.). Assessment of adversity should represent empirical measurements (i.e. objective data) integrated with well-informed subjective judgements to determine whether or not a response is considered harmful to an organism (Kerlin et al. 2016). After discussion, the PWG members agreed that the dose response and constellation of lesions (i.e. cytoplasmic alteration, apoptosis, single cell necrosis, and focal necrosis) rather than one lesion by itself, represents adversity within the confines of this study.

SUMMARY

This review generally supported the study pathologist's findings. When appropriate, the diagnosis of apoptosis, hepatocellular was added to distinguish cells with morphological characteristics of apoptosis from those with morphologic characteristics of single cell necrosis. The diagnostic term of "cytoplasmic alteration" was used to indicate hepatocyte hypertrophy, frequently coupled with a brightly eosinophilic, often granular appearance of the cytoplasm of hepatocytes. Other changes were recommended based upon using terminology preferred by the NTP. The dose response and constellation of lesions were together considered to be indicators of adversity within the confines of this study.

CONFLICT OF INTEREST STATEMENT

This statement is to certify that the reviewing pathologist, Dr. Brix, an on-site NTP Pathologist employed by Experimental Pathology Laboratories, Inc. (EPL®), participated in the pathology peer review of the liver of the Subchronic Toxicity 90 Day Gavage Study In Mice (Project ID: DuPont-18405-1307) and An Oral (Gavage) Reproduction/Developmental Toxicity Screening Study of H-28548 In Mice (Study Number WIL-180225) (Project ID: DuPont-18405-1037). She has not been involved in any aspect of the study for any organization other than NTP which conducted the study nor the generation and/or evaluation of materials or data which were reviewed prior to the receipt of materials from the study lab. Hence, her participation in the review poses no apparent or actual conflict of interest.

Appendix E: Benchmark Dose Modeling

E.1 Oral Reproduction/Developmental Toxicity Study in Mice (DuPont-18405-1037 2010)

U.S. Environmental Protection Agency (EPA) Center for Public Health and Environmental Assessment conducted dose response modeling of this study using the Benchmark Dose Software (BMDS) 3.1.2. program. This work used data from the reevaluation of the DuPont oral reproductive/ developmental toxicity study slides by the National Toxicology Program (NTP) Pathology Working Group (see section 4.5 for a description) and addresses the constellation of liver lesions the NTP defined as adverse (i.e., cytoplasmic alteration, single-cell and focal necrosis, and apoptosis) in parental male and parental female mice.

E.1.1 Constellation of Lesions (Cytoplasmic Alteration, Apoptosis, Single-Cell Necrosis, and Focal Necrosis) in the Liver, Parental Males

Increased incidence of a constellation of lesions in the liver was observed in the parental males. Dichotomous models were used to fit dose-response data (DuPont-18405-1037, 2010). A benchmark response (BMR) of 10% extra risk was chosen per EPA's *Benchmark Dose Technical Guidance* (EPA, 2012). The doses and response data used for the modeling are listed in Table E-1.

Table E-1. Constellation of Lesions in the Male Liver Selected for Dose-Response Modeling

Dose (mg/kg/day)	Number of mice (males)	Constellation of Liver Lesions
0	25	1
0.1	24	1
0.5	24	13
5	24	24

Note: mg/kg/day = milligrams per kilogram per day.

The benchmark dose (BMD) modeling results for the constellation of lesions are summarized in Table E-2 and Figure E-1. The best fitting model was the Probit model based on adequate *p*-values (greater than 0.1), the benchmark dose lower limits (BMDLs) were sufficiently close (less than threefold difference) among adequately fitted models, and the Probit model had the lowest Akaike information criterion (AIC). The lower bound on the dose level corresponding to the 95% lower confidence limit for a 10% response level ($BMDL_{10}$) from the selected Probit model is 0.14 milligram per kilogram per day (mg/kg/day).

Table E-2. Summary of BMD Modeling Results for Constellation of Lesions in Male Mice

Model[a]	Goodness of fit		Scaled residual for:		BMD_{10Pct} (mg/kg/day)	$BMDL_{10Pct}$ (mg/kg/day)	Basis for model selection
	p-value	AIC	Dose group near BMD	Dose group near BMDL			
Dichotomous Hill	N/A[b]	57.818	0.007	-0.007	0.29	0.11	EPA ORD selected the Weibull model. All models, except Dichotomous Hill, had adequate fit (*p*-values > 0.1), the BMDLs were sufficiently close (<3-fold difference), and the Probit model had the lowest AIC.
Gamma	0.994	55.815	-0.005	0.005	0.26	0.09	
Log-Logistic	0.977	55.816	0.000	-0.020	0.34	0.11	
Multistage Degree 3	0.997	53.820	-0.053	0.047	0.26	0.08	
Multistage Degree 2	0.905	54.026	-0.368	0.248	0.19	0.08	
Multistage Degree 1	0.279	57.026	-1.402	0.452	0.08	0.05	
Weibull	0.937	53.951	-0.290	0.205	0.20	0.08	
Logistic	0.888	54.048	-0.327	0.359	0.22	0.15	
Log-Probit	0.990	55.816	0.001	-0.001	0.24	0.10	
Probit	**0.907**	**52.444**	**-0.635**	**0.093**	**0.19**	**0.14**	

Notes: ORD = Office of Research and Development.
[a] Selected model in bold.
[b] degrees of freedom=0, saturated model (Goodness of fit test cannot be calculated).

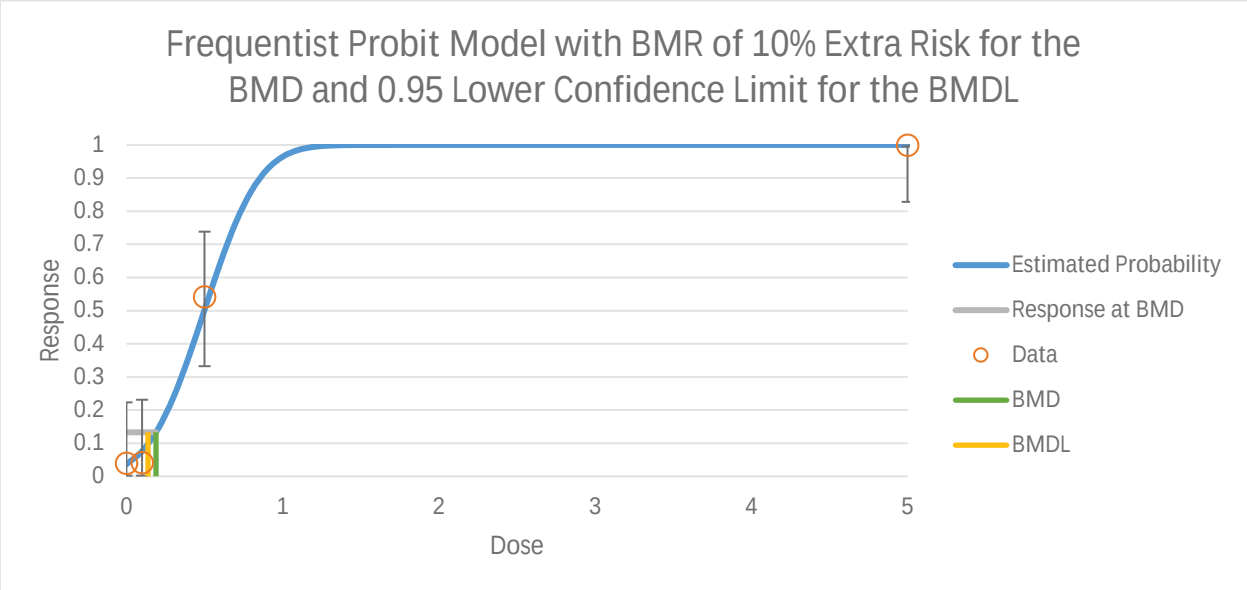

Figure E-1. Plot of Incidence Rate by Dose with Fitted Curve for the Selected Probit Model for Constellation of Lesions in Male Mice (dose shown in mg/kg/day)

E.1.2 Constellation of Lesions (Cytoplasmic Alteration, Apoptosis, Single-Cell Necrosis, and Focal Necrosis) in the Liver, Parental Females

Increased incidence of the constellation of lesions in the liver was observed in the parental females. Dichotomous models were used to fit dose-response data (DuPont-18405-1037, 2010). A BMR of 10% extra risk was chosen per EPA's *Benchmark Dose Technical Guidance* (EPA, 2012). The doses and response data used for the modeling are listed in Table E-3.

Table E-3. Constellation of Lesions in the Female Liver Selected for Dose-Response Modeling

Dose (mg/kg/day)	Number of mice (females)	Constellation of Liver Lesions
0	24	2
0.1	22	3
0.5	24	17
5	24	24

The BMD modeling results for constellation of lesions are summarized in Table E-4 and Figure E-2. The best fitting model was the Probit model based on adequate *p*-values greater than 0.1), the BMDLs were sufficiently close (less than threefold difference) among adequately fitted models, and the Probit model had the lowest AIC. The $BMDL_{10}$ from the selected Probit model is 0.09 mg/kg/day.

Table E-4. Summary of BMD Modeling Results for Constellation of Lesions in Female Mice

Model[a]	Goodness of fit		Scaled residual for:		BMD_{10Pct} (mg/kg/day)	$BMDL_{10Pct}$ (mg/kg/day)	Basis for model selection

TSCA	Toxic Substance Control Act
TWA	Time-weighted average
UF	Uncertainty factor

PREFACE

The U.S. Environmental Protection Agency (EPA) Risk Assessment Forum was established to promote scientific consensus on risk assessment issues and to ensure that this consensus is incorporated into appropriate risk assessment guidance. To accomplish this, the Forum assembles experts throughout EPA in a formal process to study and report on these issues from an Agency-wide perspective. For major risk assessment activities, the Forum has established Technical Panels to conduct scientific reviews and analyses. Members are chosen to ensure that necessary technical expertise is available.

The RfD/RfC Technical Panel (hereafter the Technical Panel) was established by the Risk Assessment Forum in early 1999 in response to a request from the Agency's 10X Task Force[1] to the Science Policy Council and the Forum. In the process of developing a strategy for implementing the Food Quality Protection Act (FQPA) relative to protecting children's health and application of the 10X safety factor, the 10X Task Force produced two draft reports, one on toxicology (U.S. EPA, 1999b) and one on exposure data requirements (U.S. EPA, 1999c) that were used by the Office of Pesticide Programs to develop a policy document for implementation of the FQPA safety factor (U.S. EPA, 2002b).

The draft 10X toxicology report (U.S. EPA, 1999b) raised a number of issues that relate to the derivation of the oral reference dose (RfD) and inhalation reference concentration (RfC). Examples of these issues include the following. (1) Appropriate application of a database uncertainty factor (UF) or modifying factor for studies that are considered necessary but are absent or judged inadequate that may show children to be significantly more sensitive or susceptible than adults. Addressing this issue also implicates aspects of other UFs that relate to children's health, including the factor for inter-individual variability in humans (e.g., response of the aged vs. response of the younger adult or child), and the interspecies UF (e.g., young animals vs. young humans). (2) How to account for degree of concern for potential toxicity to children in the RfD/RfC process. Degree of concern, as used in the 10X toxicology report, refers to the characterization of the database as to the likelihood that the agent under review would have effects in humans within the context of dose, route, duration, and timing of exposure. (3) The

[1]The 10X Task Force was created by the EPA Administrator to explore the adequacy of current testing approaches for pesticides for protecting children's health and to recommend approaches for implementing the additional 10X safety factor mandated by the 1996 Food Quality Protection Act.

use of developmental toxicity data as the basis for reference values[2] of chronic duration (RfDs or RfCs) and the appropriate setting of acute, short-term, and longer-term reference values, including the application of developmental toxicity data for these shorter-duration reference values. (4) The appropriateness and/or rationale for adjusting the no-observed-adverse-effect level (NOAEL) or the benchmark dose from developmental toxicity data with inhalation exposures using a concentration-times-time (C x t) adjustment, as is done for other study types.

The Technical Panel also was asked to consider the need for additional toxicity test protocols related to children's health as recommended by the 10X Task Force, when such protocols should be required, and how the data should be interpreted for risk assessment purposes. These additional protocols include (1) collection of toxicokinetic data, both in adults and at different developmental stages; (2) direct dosing of neonates, especially when early exposure is of concern; (3) perinatal carcinogenesis studies and appropriate triggers for when they should be required; (4) developmental immunotoxicity testing and appropriate triggers; (5) advanced developmental neurotoxicity testing, in particular, cognitive testing that is more similar to that used in humans; and (6) exposure assessments that are more compatible with the dose-response assessment. (See Appendix A for more a detailed discussion of the issues raised by the 10X Task Force.)

The Science Policy Council and the Risk Assessment Forum agreed that these issues should be examined—with input from various program offices within the Agency and from the outside scientific/policy community—on a broader scale than just for pesticides. This charge was expanded by the Forum to include a more in-depth review of a number of issues related to the RfD/RfC process, in part because of several other Forum activities that were underway. These activities included development of *Framework for the Harmonization of Cancer and Noncancer Risk Assessment*, revision of *Benchmark Dose Guidance Document*, and revision of *Guidelines for Carcinogen Risk Assessment*. In addition, the RfD/RfC derivation process (Barnes and Dourson, 1998; U.S. EPA, 1994, 2002c) had not been evaluated in detail for a number of years, and several scientific issues concerning children's health, for example, neurotoxicity and immunotoxicity, have become increasingly important in risk assessment. These various but related activities have prompted the need to re-examine the RfD/RfC process and to coordinate these efforts with other related activities. In particular, it was important that efforts continue to focus on moving toward the goal of harmonization of risk assessment

[2]The term reference value is used generically here to refer to values such as the RfD, RfC, acute reference exposure (ARE), Health Advisory (HA), acute exposure guideline level (AEGL), minimal risk level (MRL), or other similar values.

approaches for all health endpoints. This document represents the review and deliberations of the RfD and RfC processes by the Risk Assessment Forum Technical Panel.

EXECUTIVE SUMMARY

This document summarizes the review and deliberations of the Risk Assessment Forum's RfD/RfC Technical Panel and its recommendations for improvements in oral reference dose/inhalation reference concentration (RfD/RfC) process as well as additional efforts that are needed. It discusses revisions to the framework for the derivation of reference values. The document is a review, not guidance, but it does make recommendations that should be considered in the implementation of changes in the current process and/or development of needed guidance.

The Technical Panel reviewed most of the issues relating to hazard characterization for developing reference values and the need for developing reference values for different durations of exposure as well as the process of deriving reference values, but it did not go into detail on the quantitative aspects of the dose-response process, which is being covered in other Forum activities. The Technical Panel views the RfD/RfC process as one that should be continually evolving as new information becomes available and new scientific and risk assessment approaches are developed. This does not mean that current RfDs or RfCs are invalid, but these new scientific issues should be included in the process of re-evaluating of current reference values.

This document reviews and discusses a number of issues and provides conclusions and recommendations that are intended to improve the RfD/RfC process. The Technical Panel has provided specific recommendations for the development of guidance in some cases and more general conclusions and recommendations in others. In the latter cases, the Technical Panel felt that development of specific recommendations was beyond the scope of its efforts or that policies needed to be further developed before specific guidance could be written to implement the recommendations. The document is divided into five chapters:

Chapter 1 provides an introduction, background, purpose, and scope for the project.

Chapter 2 reviews current approaches to developing acute, short-term, and longer-term reference values as well as the chronic reference values, the RfD and the RfC. This chapter incorporates the presentations and discussions on developing less-than-lifetime values from briefings to the Technical Panel and a colloquium held August 2, 2000, and includes discussions of the proposed Acute Reference Exposure (ARE) methodology for acute inhalation exposures, the Acute Exposure Guideline Level (AEGL) Program, the Office of Pesticide Programs' procedures for setting acute and longer-term duration RfDs, the Office of Water's Health Advisories, and the Agency for Toxic Substances and Disease Registry's Minimal Risk Levels.

On the basis of its review of the various approaches to setting acute, short-term, and longer-term reference values, the Technical Panel concurred with the recommendation of the 10X Task Force that such values should be set, where possible, and that they should be incorporated into the Integrated Risk Information System (IRIS) database. In addition, the Technical Panel recommended that this process be done in a consistent manner using standardized definitions for acute, short-term, longer-term, and chronic durations that are consistent with current practice. These values can then be used by various program offices, where applicable. A framework for deriving these additional values is presented in Chapter 4.

Chapter 3 reviews the current Office of Prevention, Pesticides and Toxic Substances' harmonized health effects testing guidelines for the purpose of determining the data available for setting various duration reference values. The intent of this review is not to suggest that additional testing be conducted for each and every chemical in order to fill in the information gaps identified for those organ systems evaluated. Nor is it suggested that alternative testing protocols that are discussed in this chapter should be conducted for every chemical or become part of current toxicology testing requirements or that these alternative protocols are the only options available. Rather, it is the goal of this document to provide a basis for the development of innovative alternative testing approaches and the use of such data in risk assessment, and to then illustrate some aspects of this concept with a few examples. In reviewing the current testing protocols, target organs/systems that are evaluated were reviewed as was the thoroughness of testing with respect to life stage assessment, endpoint assessment, route, timing and duration of exposure, and latency to response. These issues were all considered important in evaluating potentially susceptible subpopulations, including life stages. The testing guideline protocols were reviewed overall for these issues; in addition, four biological systems were evaluated in depth, two that are fairly thoroughly evaluated (the reproductive and nervous systems) and two that are evaluated to a more limited extent (the immune and cardiovascular systems). In each case, an overview of the tests for the particular system is given, as well as a more specific discussion of gaps in life stage of assessment, gaps in assessment endpoints, and gaps in duration and latency assessment.

The Technical Panel has made a number of recommendations concerning toxicity testing, including development of a strategy for approaches to toxicity testing, with guidance on how and when to use existing and newly recommended guidelines; development of guidelines or guideline study protocols that will provide more systematic information on toxicokinetics and toxicodynamics (i.e., mechanism or mode of action), including at different life stages; development of protocols for acute and short-term studies that provide more comprehensive data

for setting reference values; modification of existing guideline study protocols to provide more comprehensive coverage of life stages for both exposure and outcomes; collection of more information from less-than-lifetime exposure to evaluate latency to effect and reversibility of effect; development of guidelines or guideline study protocols to assess immunotoxicity, carcinogenicity, and cardiovascular toxicity at different life stages; and exploration of the feasibility of setting dermal reference values for direct toxicity at the portal of entry, including sensitization.

A primary goal of this review was to provide the basis for recommendations for the development of a strategy for approaches to toxicity testing and for innovative alternative testing approaches to provide data for risk assessment. The Technical Panel is suggesting that alternative strategies and guidance for testing approaches be developed that incorporate information on toxicokinetics and mode of action early in the process, thus allowing a more targeted testing approach. In addition, alternative protocols are discussed that are aimed at more efficient use of animals and resources in combined studies that would provide more extensive data on life stages, endpoints, and other factors not well characterized in current testing approaches. Recommendations are also made about research areas that should be encouraged to aid in better study design and interpretation of data for risk assessment.

Finally, an example of an alternative testing protocol for acute exposure and evaluation that incorporates the types of endpoints and evaluations optimal for setting acute reference values is discussed. Two sample alternative protocols are presented for chronic exposures and options are discussed for combining studies and evaluations to include a wider array of life stage and endpoint assessments.

Chapter 4 discusses a number of modifications to the existing framework for use in deriving reference values, both for the current chronic reference values (RfD and RfC) as well as for acute, short-term, and longer-term reference values. The approach to reference values discussed here is intended for risk assessments of any type of health effect known or assumed to be produced through a nonlinear and/or threshold mode of action (which may include U-shaped or other nonmonotonic dose-response curves as well as thresholds). Thus, the Technical Panel recommends moving away from the dichotomy between “cancer” and “noncancer.” The term “noncancer” has been removed from the reference value definition, denoting the move toward defining approaches for low-dose estimation or extrapolation based on mode of action. Two case studies that illustrate many of the concepts discussed in this chapter are presented in more detail in Appendix B. The Technical Panel recommends including the acute, short-term, longer-term, and chronic reference values derived on the basis of the recommendations in this report in

IRIS after appropriate internal, external, and consensus review. Standard exposure durations are proposed, as is a definition for the reference value, including a designation for route and duration of exposure.

The Technical Panel is aware that there will be data limitations for an individual chemical that may preclude development of all four reference values, and it is aware that time and resources need to be considered when implementing these recommendations. The IRIS program has begun to implement a pilot program to test whether development of the expanded array of reference values is practical and can be accomplished without unduly delaying the completion of an IRIS file. As a part of the pilot, the IRIS program will need to identify the methods to be used in deriving these additional values.

The Technical Panel recommends that endpoint-specific reference values should not be developed, including the reference dose for developmental toxicity, RfD_{DT}. Rather, a sample reference value should be calculated for each relevant and appropriate endpoint and these should be considered in the derivation of various duration reference values. The reference values should be derived to be protective of all types of effects for a given duration of exposure.

An expanded approach to the evaluation of studies and characterization of the extent of the database as a whole is recommended; in particular, several factors are discussed that should be considered in a weight-of-evidence approach for characterizing hazard for the population as a whole as well as for potentially susceptible subpopulations. Those considerations for assessing level of concern raised by the Toxicology Working Group of the 10X Task Force have been incorporated into this approach.

In the context of this framework, the Technical Panel recommends a somewhat different approach to characterizing the extent of the database for reference values. Instead of specifying particular studies, this approach emphasizes the types of data needed (both in terms of human and animal data) for deriving reference values, and it recommends the use of a narrative description of the extent of the database rather than a single confidence ranking of high, medium, or low. To characterize the database, the Technical Panel has developed a description of a "minimal" database and a "robust" database as a way of describing the range of data that can be used for deriving a reference value, and the Panel urges the use of a great deal of scientific judgement in the process of summarizing the extent of the database, including its strengths and limitations.

The narrative approach is intended to emphasize the types of data available (both human and animal) as well as the data gaps that could improve the derivation of reference values. This approach should encourage the use of a wider range of information in deriving reference values,

taking into consideration the issues of duration, timing, and route of exposure; the types and extent of endpoint assessments (i.e., structure and function); the life stages evaluated; and the potential for latent effects and/or reversibility of effects.

Dosimetric adjustment of values for deriving a human equivalent concentration (HEC) for inhalation exposure is discussed, as is the derivation of a human equivalent dose (HED) for oral or dermal exposure. The Technical Panel recommends that duration adjustment procedures to continuous exposures based on concentration times time (C x t) be used as a default procedure for inhalation developmental toxicity studies as for other health effects from inhalation exposures. In addition, further evaluation of current dosimetric adjustments for deriving HECs should be pursued to confirm or assess the relevance for population subgroups (particularly for children).

Because of the recommendation for deriving several duration reference values, the Technical Panel recommends that the data for the point of departure (POD) be evaluated on the basis of a comparison of all relevant endpoints carried through the derivation of sample reference values, with selection of the limiting value(s) as the final step rather than on the basis of selection of a single "critical study" and "critical effect." To aid in this evaluation, the use of an exposure-response array is recommended as a visual display of all relevant and appropriate endpoints and durations of exposure in order to determine the range of numerical values for each reference value.

The Technical Panel makes a number of recommendations concerning the application of uncertainty factors (UFs) for reference value derivation. In particular, it is imperative that the IRIS documentation contain a justification for the individual factors selected for each chemical or assessment because rigid application of UFs could lead to an illogical set of reference values. Although default factors of 10 are recommended, with 3 used in place of half-power values (i.e., $10^{0.5}$) when occurring singly, the exact value of the UF chosen should depend on the quality of the studies available, the extent of the database, and scientific judgment. Sound scientific judgment should be used in the application of UFs to derive reference values that are applied to the value chosen for the POD derived from the available database (BMDL, NOAEL, or LOAEL).

The Technical Panel recommends that if there is uncertainty in more than four areas of extrapolation, it is unlikely that the database is sufficient to derive a reference value. Even when there is uncertainty in four areas, the database should be carefully evaluated to determine whether the derivation of a reference value is appropriate. In addition, the Technical Panel recommends limiting the total UF applied to a chronic reference value for any particular

chemical to 3000. This maximum of 3000 applies only to the UFs and does not include the various adjustment factors discussed in Chapter 4.

The intraspecies UF is applied to account for variations in susceptibility within the human population (interhuman variability) and the possibility (given a lack of relevant data) that the database available is not representative of the dose/exposure-response relationship in the subgroups of the human population that are most sensitive to the health hazards of the chemical being assessed. Because the RfD/RfC is defined to be applicable to "susceptible subgroups," this UF was established to account for uncertainty in that regard. In general, the Technical Panel reaffirms the importance of this UF, recommending that reduction of the intraspecies UF from a default of 10 be considered only if data are sufficiently representative of the exposure/dose-response data for the most susceptible subpopulation(s). At the other extreme, a 10-fold factor may sometimes be too small because of factors that can influence large differences in susceptibility, such as genetic polymorphisms. The Technical Panel urges the development of data to support the selection of the appropriate size of this factor, but recognizes that often there are insufficient data to support a factor other than the default.

The Technical Panel urges continued research and evaluation of the similarities and differences between the general population and susceptible subpopulations, particularly children and the elderly, in their responses to particular agents. From such evaluations, the protectiveness of the 10-fold default factor should continue to be assessed. The Technical Panel urges the development of data to support the selection of the appropriate size of this factor, but it recognizes that often there are insufficient data to support a factor other than the default. The database UF is intended to account for the potential for deriving an underprotective RfD/RfC as a result of an incomplete characterization of the chemical's toxicity. In addition to the identification of toxicity information that is lacking, review of existing data may also suggest that a lower reference value might result if additional data were available. Consequently, in deciding to apply this factor to account for deficiencies in the available data set, and in identifying its magnitude, the assessor should consider both the data lacking and the data available for particular organ systems as well as life stages. The Panel considers the purpose of the modifying factor (MF) to be sufficiently subsumed in the general database UF, and recommends that use of the MF be discontinued.

Given that there are several UFs that can be used to deal with data deficiencies as part of the current reference value process, and given that these are assumed to overlap to some extent, the Technical Panel agrees with the 10X Task Force Toxicology Working Group that the current interspecies, intraspecies, and database deficiency UFs, if appropriately applied using the

approaches recommended in this review, will be adequate in most cases to cover concerns and uncertainties regarding the potential for pre- and postnatal toxicity and the completeness of the toxicology database. In other words, an additional uncertainty factor is not needed in the RfC/RfD methodology because the currently available factors are considered sufficient to account for uncertainties in the database from which the reference values are derived (and does not exclude the possibility that these UFs may be decreased *or* increased from the default value of 10). The approach to using chemical-specific data for toxicokinetic and toxicodynamic components of the interspecies UF is part of the current RfC methodology. The Technical Panel encourages the Agency to develop its own guidance for chemical-specific adjustment factors (CSAFs) on the basis of some of the available methodologies (e.g., the International Programme on Chemical Safety [IPCS]).

Several other issues discussed by the Technical Panel were considered more appropriate for deliberation by other panels/committees, for example, further consideration of the use of BMD modeling approaches for deriving reference values; harmonization of the approaches for HEC and HED derivation for all types of health effects; further evaluation of approaches such as probabilistic analysis for characterizing variability and uncertainty in toxicity reference values; further evaluation of appropriate adjustment of doses for duration of exposure for acute toxicity data; and further evaluation of duration adjustment for short-term and longer-term reference values analogous to the subchronic-to-chronic duration UF for chronic reference values.

Chapter 5 summarizes the recommendations of the Technical Panel.

1. INTRODUCTION, PURPOSE, AND SCOPE

The RfD/RfC Technical Panel (hereafter the Technical Panel) was established by the U.S. Environmental Protection Agency's (EPA's, or the Agency's) Risk Assessment Forum in early 1999 to review the current oral reference dose (RfD) and inhalation reference concentration (RfC) processes, in particular with respect to how well children and other potentially susceptible subpopulations are protected; to consider new scientific issues that have become more important and of greater concern in risk assessment; and to raise issues that should be explored or developed further for application in the RfD/RfC process. This document summarizes the review and deliberations of the Technical Panel and its recommendations for improvements in the process as well as additional efforts that are needed. It discusses revisions to the framework for the derivation of RfDs and RfCs. The document is a review, not guidance, but it does make recommendations that should be considered in the implementation of changes in the current process and/or development of needed guidance.

Many of the recommendations made in this report are consistent with the Agency's commitment to harmonization of health risk assessment procedures, including the harmonization of approaches for noncancer and cancer endpoints, and to making efficient use of animal testing to achieve this goal. As noted in several places in the document, all such topics have not been discussed and resolved by the Agency. For instance, the differences in scaling factors used for cancer and noncancer derivations from oral exposure data are raised as an issue that has not been resolved; thus, there will likely be a need for revised or further guidance on this issue.

Although mixtures or multiple chemical exposures are not specifically discussed in this review, most of the recommendations are applicable to the approach to risk assessment of mixtures. The Agency's mixtures risk assessment guidelines should be consulted for issues specific to the evaluation of mixtures (U.S. EPA, 1986, 2000a). In addition, the Agency has recently issued the draft *Framework for Cumulative Risk Assessment* (U.S. EPA, 2002a), which deals with the issue of multiple stressors and their overall impacts on exposure-effect relationships. The risk assessment approaches discussed within this framework are likely to be the subject of further guidance as well.

The Technical Panel attempted to review most of the issues relating to hazard characterization for developing reference values, to the need for developing reference values for different durations of exposure, and to the process of deriving reference values. The Technical Panel did not go into detail on the quantitative aspects of the dose-response process, as this is being covered in other Forum activities (e.g., the benchmark dose [BMD] guidance document

and the quantitative dose-response aspects of the cancer guidelines revision process). The Technical Panel approached its review from the point of view that the RfD/RfC process has been and should be a continually evolving process. Thus, as new information becomes available and new scientific and risk assessment approaches are developed, they are incorporated into new RfDs and RfCs as these values are developed or as current RfDs and RfCs are reevaluated. This process of incorporating new science does not invalidate current RfDs or RfCs, because consideration of these new scientific issues is included in the reevaluation of current values; higher or lower values or, in some cases, no change in the current value may result.

This report provides conclusions and recommendations that are intended to improve the RfD/RfC process. The audience for this review is primarily the Integrated Risk Information System (IRIS) program, IRIS chemical managers, and other scientists within the Agency who are involved in developing the RfDs and RfCs, as well as IRIS users and the program offices within EPA that develop RfDs and RfCs or similar values (see Chapter 2), particularly resource managers who may be impacted by the potential for additional workload due to several of the recommendations. The Technical Panel has provided specific recommendations for guidance in some cases and more general conclusions and recommendations in others. In the latter cases, the Technical Panel felt that development of specific recommendations was beyond the scope of its efforts or that policies needed to be further developed before specific guidance could be written to implement the recommendations.

The methodology recommended in the RfD document is considered generally applicable to both cancer and noncancer endpoints where dose-response relationships are thought to be either nonlinear or consistent with a threshold. Although the emphasis in this document is on the calculation of RfDs and RfCs, the same processes and considerations are applicable to the margin of exposure (MOE), as discussed in the draft cancer risk assessment guidelines (U.S. EPA, 1999a).

The Technical Panel discussed a number of issues concerning a revised framework for the RfD/RfC process, with particular emphasis on the extent to which children and other potentially susceptible subpopulations are considered. The next three chapters summarize these issues, and several recommendations are made. Chapter 2 reviews current approaches to developing acute, short-term, and longer-term reference values as well as the chronic reference values, the RfD and the RfC. Chapter 3 reviews the current testing guidelines with respect to life stage assessment and discusses the gaps in life stage assessment, endpoint assessment, and assessment of duration and latency. Alternative testing protocols and strategies as options for combining studies and evaluations are discussed.

Chapter 4 provides constructive commentary on the current framework used in deriving reference values and on the need and possibilities for calculating reference values for different durations and routes of exposure. In addition, an expanded approach to evaluating studies and characterizing the extent of the database as a whole is presented and discussed, including dosimetric adjustment, the application of uncertainty factors (UFs), and derivation of sample reference values for each appropriate and relevant endpoint to aid in selecting the point of departure (POD) for deriving reference values.

The final chapter (Chapter 5) summarizes all of the recommendations of the Technical Panel. Two case studies that illustrate several of the recommended changes are also included as Appendix B.

2. REVIEW OF THE CURRENT USE OF ACUTE, SHORT-TERM, AND LONGER-TERM REFERENCE VALUES

The Technical Panel considered the recommendation of the 10X Task Force that acute, short-term, and longer-term reference values as well as chronic reference values should be set for environmental agents (see Appendix A). It is likely that the endpoints critical for setting acute, short-term, and longer-term reference values may differ from those for setting chronic RfDs and RfCs, although studies that use acute and short-term exposure conditions from which the appropriate data for many types of effects could be derived are not often available. Data on acute and short-term health effects must often be derived from observations after the first exposure in a repeated-exposure testing protocol.

Several acute and short-term values currently are set for various chemical types and media. For example, acute and chronic oral RfDs are set for pesticides, with some intermediate values set for occupational and residential pesticide exposures. Health advisories (HAs) of several durations have been developed for drinking water. In addition, the Office of Solid Waste and Emergency Response, the Office of Prevention, Pesticides, and Toxic Substances (OPPTS), and other program offices and regional offices use values derived through the interagency acute exposure guidelines (AEGL) process for emergency response planning. The National Center for Environmental Assessment (NCEA) is currently developing the acute reference exposure (ARE) methodology for acute inhalation exposures. These developments are reviewed in more detail below.

2.1. REVIEW OF CURRENT LESS-THAN-LIFETIME REFERENCE VALUES

The Technical Panel was briefed by representatives of several Agency offices on the methods currently used to set various less-than-lifetime reference values. Subsequently, on August 2, 2000, a Risk Assessment Forum colloquium was held on this topic (CDM Group, Inc., 2000). Each of the methods was presented and discussed. In addition, a recommendation by the Technical Panel to begin deriving acute, short-term, and longer-term reference values as well as chronic values and to standardize the definitions for each duration was presented and discussed. Each method presented is summarized below.

2.1.1. Acute Reference Exposure (ARE) Methodology

The ARE methodology is being developed at the request of the EPA's Office of Air and Radiation. It is intended for development of reference values for acute inhalation exposures of

24 hours or less. The criteria air pollutants are not included, because they are assessed within the National Ambient Air Quality Standards (NAAQS) setting process.[1] The ARE is defined as an inhalation exposure of 24 hours or less that is not likely to cause noncancer adverse effects. The ARE can be applied to intermittent exposures or to a continuous exposure. AREs are being developed in order to address the acute risk aspects of risk-related provisions of the hazardous air pollutant sections of the 1990 Clean Air Act Amendments. The ARE methodology is described in a 1998 EPA external review draft document (U.S. EPA, 1998a). The method builds on the procedures of the RfC methodology.

The ARE methodology includes three approaches in order to accommodate the varying types of data available for acute exposure. The first two approaches, the no-observed-adverse-effect level (NOAEL) and the benchmark concentration (BMC) are familiar. The third approach, categorical regression (CatReg), is newer. The NOAEL approach is useful for chemicals that have limited available data and for which no or limited dose-response relationships have been established. The BMC approach is suitable for analysis of studies that establish dose-response relationships. The CatReg approach requires multiple studies that report not only dose and response, but also duration; it is most applicable for data-rich chemicals. A feature of the CatReg approach is that effects data are grouped into severity categories (e.g., mild or severe to lethal) to which sophisticated regression procedures are then applied.

Adjustments for deriving ARE values of different durations (e.g., 15 minutes or 8 hours) are made differently for the CatReg approach than for the NOAEL and BMC approaches. For any approach, the preferred adjustment procedure is to use a pharmacokinetic model, if available. When the NOAEL or BMD approach is used, the default procedure is to use the multiple of concentration times time (C x t) (C^n x t = k; ten Berge et al., 1986) to extrapolate from short to long duration and to use the same concentration as obtained for long duration to extrapolate from long to short duration. When more than one duration is available, interpolation is performed. When the CatReg approach is used, the procedure involves reading the values directly from the concentration duration curve that is generated by the CatReg software. These approaches are explained more fully and illustrated in Chapter 4.

A minimal data set has not been defined for the ARE. Also, extrapolation from the oral to the inhalation route of exposure is not addressed in the ARE approach. UFs in the ARE approach include a lowest-observed-adverse-effect level- (LOAEL-) to-NOAEL UF of 10 and a

[1]Criteria air pollutants are those air pollutants for which NAAQS have been established under the Clean Air Act; at present, the six criteria air pollutants are particulate matter, ozone, carbon monoxide, nitrogen oxides, sulfur dioxide, and lead.

default value of 10 for interspecies and for intraspecies extrapolation. No factor is assigned for database inadequacies and study quality.

In 1998, the EPA Science Advisory Board (SAB) reviewed the ARE methodology document and made a number of comments that addressed, among other things, issues about the NOAEL and BMC approaches, the need for addressing protection of children, the dosimetry adjustment and duration extrapolation, and the CatReg approach. The SAB discussed the fact that the CatReg model, as currently set up, forces parallelism of the concentration-duration curves for the various severity categories. In addition, there were concerns about judging severity categories across various target organs and species, and there was discussion about the reliability of the confidence limits around the maximum likelihood estimate and about the appropriateness of the approach used to accommodate group versus individual data. This methodology has since (March 2001) undergone an Agency review by the Risk Assessment Forum. The principal comments from this review concerned reevaluation of whether CatReg should remain as an approach in the ARE methodology and further evaluation of the procedures for cross-species dosimetry adjustment. Revision of the ARE methodology is currently underway. In addition to revising the ARE methodology and CatReg software documents, NCEA-Research Triangle Park will develop a framework for adding AREs to the IRIS database.

2.1.2. Acute Exposure Guidelines (AEGL) Program

The primary purpose of the AEGL program is to develop guideline levels for once-in-a-lifetime short-term exposures to airborne concentrations of acutely toxic chemicals (NRC, 2000). AEGLs are needed for a wide variety of emergency planning, response, and prevention applications. AEGLs represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 minutes to 8 hours. Specific values are set for 10 minutes, 30 minutes, 1 hour, 4 hours, and 8 hours. It is believed that the recommended exposure levels are applicable to the general population, including infants and children and other individuals (e.g., asthmatics) who may be sensitive or susceptible. It is recognized that certain individuals who may be subject to unique or idiosyncratic responses could experience the effects described at concentrations below the corresponding AEGL level.

The AEGL-1, AEGL-2, and AEGL-3 levels are distinguished by varying degrees of severity of toxic effects. With increasing airborne concentrations above each AEGL level there is a progressive increase in the likelihood of occurrence and the severity of effects described for each level.

AEGL-1 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects would not be disabling and would be transient and reversible upon cessation of exposure.

AEGL-2 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape.

AEGL-3 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals could experience life-threatening health effects or death.

Airborne concentrations below AEGL-1 represent exposure levels that could produce mild and progressively increasing odor, taste, and sensory irritation or certain asymptomatic, nonsensory effects.

UFs are used for extrapolations. If there are no appropriate human data, an interspecies UF of 1, 3, or 10 is used. The factors considered when deciding on a specific value include (1) the species tested (type, appropriateness, and range), (2) the toxicological endpoint observed and the likely mechanism of action, (3) the range of response in the species tested, (4) the variability of response among the species tested, and (5) pharmacokinetic differences among the species tested. An intraspecies UF of 1, 3, or 10 is also used. The factors considered when assigning a specific value include (1) the toxicological endpoint observed and the likely mechanism of action, (2) the range of response among humans and subpopulations, and (3) pharmacokinetic differences among individuals. Individual factors of 3 are often used to ensure that the final values are not overly conservative.

Adjustment for duration is conducted using the equation $C^n \times t = k$. If data are available for the endpoint of concern, the value of n is derived from regression analysis. If data are not available for the endpoint of concern, the value of n is usually derived from lethality data by regression analysis and used for the other endpoints. If the study duration is greater than 1 hour, the 10-minute value is usually assigned equal to the 30-minute value. If no data are available to derive a value of n, a value of 3 is used to extrapolate to shorter durations, and a value of 1 is used to extrapolate to longer durations. As mentioned above, this procedure is further explained and illustrated in Chapter 4.

2.1.3. Office of Pesticide Programs (OPP) Procedures for Setting Acute and Intermediate RfDs

OPP developed methodologies for acute dietary as well as occupational and residential risk assessments during the process of re-registration following the 1988 revision to the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). In 1998, a guidance document, *Toxicology Endpoint Selection Process* (U.S. EPA, 1998b), was presented to the FIFRA Scientific Advisory Panel for review and comment. This document, which provided the basis for procedures that are still in place, describes toxicology endpoint selection for less-than-lifetime dietary and occupational/residential risk assessments for pesticides. It includes guidance on evaluating toxicity studies that are relevant for use, selecting appropriate endpoints for hazard identification, the process of hazard identification, the influence of dermal absorption in hazard identification, the criteria for the use of the NOAEL and the LOAEL, and the use of MOEs in risk assessments. Since this guidance was first issued, some changes have evolved, such as the replacement of the acute MOE with the acute RfD and the addition of standard consideration of short- and intermediate-term incidental nondietary ingestion exposures for toddlers.

Toxicology Endpoint Selection Process (U.S. EPA, 1998b) describes the types of studies that are most likely to provide appropriate endpoints for the various exposure durations and risk assessments that will be conducted for each pesticide. OPP can rely on the availability of a wide variety of standard guideline toxicity studies from which to select endpoints because such studies are required by regulation for any pesticide registration (40 CFR Part 158). Additionally, OPP considers other sources of toxicology data, such as studies published in the open literature, as appropriate.

For the establishment of the acute RfD, OPP uses a weight-of-evidence approach in evaluating all the available data. Three guideline studies have been found to be particularly useful by OPP: the acute neurotoxicity study, the prenatal developmental toxicity study, and the developmental neurotoxicity (DNT) study.

Acute effects from subchronic and chronic dietary studies are also used in the establishment of the acute dietary RfD. Careful scrutiny of toxicological data from early in the first week of treatment can sometimes identify effects that can be described as acute. However, for a number of reasons, this option has not often been used. These reasons include the absence of detailed toxicological observations other than morbidity and mortality checks in subchronic and chronic studies before the end of the first week of treatment (i.e., after 7 days of treatment), the nature of the dietary exposure (i.e., each daily exposure results from an extended period of nightly feeding rather than from a discrete acute dose), and the possibility that apparent adverse

effects during the first week of treatment may be related to palatability issues as the animals adjust to treated feed.

OPP does not calculate short- or intermediate-term references doses. However, risk assessments are conducted for incidental nondietary ingestion exposures to toddlers—a very specific population subgroup—that result from the use of a pesticide in and around the home or other nonoccupational sources such as schools, parks, and golf courses. The post-application risk assessment considers or accounts primarily for incidental ingestion of (1) the dry pesticide materials (granules or pellets) used to treat outdoor residential areas, (2) pesticide residues in soil that are ingested by toddlers who play in treated areas (e.g., yards, gardens, playgrounds) as a result of normal mouthing activities, and (3) pesticide residues that are transferred to the skin of toddlers playing in treated areas and are subsequently ingested as a result of hand-to-mouth transfer. These risk assessments consider short-term (1 day to 1 month) and intermediate-term (1–6 months) exposure durations. Risks are expressed as MOEs. The MOE approach is used because these exposures are considered to be nondietary in source and are based on high-end values or (when adequate site- or chemical-specific field data are unavailable) on assumptions.

OPP also conducts short-term, intermediate, and long-term (longer than 6 months) dermal and inhalation risk assessments for occupational and residential exposures. The MOE approach is also used to calculate the risk for these nondietary exposure scenarios. A difficulty that OPP often faces when conducting these risk assessments is that dermal absorption and inhalation toxicity data are often not available for food-use pesticides; in that case, appropriate assumptions are applied, and the available oral toxicity data are converted for use in dermal and inhalation risk assessment.

Toxicology Endpoint Selection Process (U.S. EPA, 1998b) does not address the use of UFs in acute dietary risk assessment. In practice, however, the same 10-fold inter- and intraspecies UFs are used in calculating the acute dietary RfD as are used for the chronic RfD. Other standard UFs may be used when appropriate (e.g., the LOAEL-to-NOAEL threefold factor). Others are not appropriate for an acute risk assessment, for example, the threefold subchronic-to-chronic factor. However, no standard set of “core” studies has been defined for acute dietary risk assessment; therefore, a database UF is not used. If appropriate endpoints and doses cannot be selected for acute dietary risk assessment from the studies in the database, then an acute RfD is not calculated.

2.1.4. Office of Water (OW) Health Advisories (HAs)

The OW HA program was initiated in 1978 to provide guidance on unregulated contaminants found in drinking water. Since then, HAs have also been developed for regulated

contaminants. HAs are derived for contaminants that are known to or are likely to occur in drinking water and that may cause adverse, noncarcinogenic health effects (Orme and Ohanian, 1991). The approach for developing HAs is based on recommendations from the National Academy of Sciences (NAS, 1977). HAs are developed for specific exposure durations (1 day, 10 days, longer-term, and lifetime) that reflect different emergency contamination situations. HAs are not legally enforceable, but they do serve as technical guidance to assist in emergency spills or contamination situations or for determining unreasonable risks to health under sections 1415 and 1416 of the Safe Drinking Water Act. They also are issued at the request of State or local governments or to fill a need for criteria, guidelines, or standards. HAs undergo scientific peer review and can function as a preliminary risk assessment, if necessary.

The following assumptions are used in setting the various HAs. The 1-day HA represents a concentration of the contaminant in drinking water that is considered protective of adverse noncancer health effects in a 10 kg child. The 10 kg child serves as the protected individual for the less-than-lifetime HAs because a child of this size is likely to receive a greater dose on a mg/kg basis. This 1-day HA can serve as a guideline for each day for up to 5 consecutive days of exposure. The 1-day HA is usually derived from experimental studies of 7 days duration or less.

The 10-day HA is considered protective of these effects in a 10 kg child for each day for up to 14 days of continuous exposure and may be based on experimental studies of 30-day duration or less.

The longer-term HA, which is based on subchronic exposure studies covering 10% of an animal's lifetime, is considered protective of an exposure period in humans of up to 7 years (i.e., 10% of an individual's lifetime). The longer-term HA is developed to protect both a 10 kg child and a 70 kg adult.

The lifetime HA is considered protective of lifetime exposures and is usually based on chronic or subchronic or other more relevant experimental data. The Lifetime HA is based on the chronic oral RfD, adjusted for a 70 kg adult drinking 2 L water per day; the value is apportioned by a relative source contribution, for example, 20% of the toxicant represented by intake of water.

HA levels are generally based on available, well-conducted studies that involve humans or animals. Data from drinking water studies are preferred; however, data from dietary or gavage studies can also be used. In the absence of oral data, studies by other routes of exposure, such as inhalation or injection, are considered. Following identification of an appropriate study to develop a HA, the NOAEL or the LOAEL is adjusted for water consumption by the protected

individual. For a child, the assumed water consumption level is 1 L/day; for an adult, 2 L/day is used.

When data are absent for setting a 1-day or a 10-day HA, OW uses scientific judgment on how to handle any given situation on the basis of the overall weight of evidence. In the absence of short-term toxicity studies, a subchronic or chronic study may be used to develop a less-than-lifetime HA. Given the pressure under which HAs need to be calculated, many assessments are based on whatever toxicological data are available and on scientific judgment. Although this may be an overly conservative approach, OW considers the error to be protective of public health.

OW applies the same factors for minimum data as those outlined in the Agency's RfD methodology. For example, in emergency situations, missing data are accounted for by applying another factor of 3 or 10. Or, for instance, where inhalation data might be applied to estimate a HA based on water consumption, a factor may be applied to account for differences in absorption. Judgments based on toxicokinetic and toxicodynamic considerations are reached through intensive consultation.

Calculation of HAs is straightforward and familiar, and in most cases the NOAEL/UF approach is used. For each of the less-than-lifetime HA values, it is assumed that all of an individual's exposure to a contaminant comes from a drinking water source. The calculation of the lifetime HA differs from that of the less-than-lifetime values in that a relative source contribution factor is included. This factor adjusts the exposure to reflect the portion that is likely to be contributed from drinking water. Unless actual exposure data are available, a default factor of 20% is used to reflect the assumed contribution to exposure from drinking water. Also, in cases where there is limited evidence suggesting a carcinogenic potential of a contaminant, an additional "policy" factor of 10 is applied in calculating the lifetime HA.

The methodology for developing HAs was reviewed by the SAB and the FIFRA Scientific Advisory Panel in 1986. Each HA that is developed undergoes external peer review and Agency review before it is released to the public. The availability of the HAs is announced in the *Federal Register* and distributed through the Safe Drinking Water Hotline and the Water Docket and by the Office of Science and Technology in OW. In addition, HAs have been published in a collection of books and are available in English, Japanese, and Italian.

2.1.5. Agency for Toxic Substances and Disease Registry (ATSDR) Minimal Risk Levels (MRLs)

The ATSDR is tasked with establishing MRLs, which are defined as

> " *... an estimate of daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified route and duration of exposure.*"

MRLs are considered by ATSDR to be substance-specific estimates intended to be screening levels in identifying contaminants and potential health effects that may be of concern; they do not define clean-up or action levels. The derivation procedures for MRLs have many similarities and parallels to the derivation of RfDs and RfCs; MRLs are based on careful scientific consideration of noncancer health effects only, not on consideration of cancer effects. A list of various procedural specifics employed in the derivation of MRLs, including specific effects and the level of severity, is codified in a *Federal Register* notice (ATSDR, 1996). The definition of an MRL differs expressly from EPA's definition of an RfD or an RfC in that both route and duration are included. The current routes of concern for MRL derivation are oral and inhalation (but not dermal).

The EPA procedures and methodologies discussed above address the issue of duration through a variety of extrapolation procedures. For MRLs, however, duration is addressed by providing for the designation of MRLs in three different duration categories: acute = $\leq$14 days, intermediate = 15–364 days, and chronic = $\geq$365 days. These duration categories are absolute and apply to all species, regardless of relative life span. Thus, it is possible for a contaminant to have a total of six different MRL values: two routes by three different durations.

The use of UFs is a parallel practice in RfD/RfC and MRL derivation. The UFs used by ATSDR are intraspecies 1, 3, 10; interspecies 1, 3, 10; and LOAEL/NOAEL 3, 10. The modifying factor (MF) can include database considerations, that is, deficiencies in the data or overestimates from bioaccumulative chemicals.

2.2. SUMMARY OF CURRENT METHODS FOR SETTING ACUTE, SHORT-TERM, AND LONGER-TERM REFERENCE VALUES

In summary, several methods are used by various EPA programs for setting acute, short-term, and longer-term reference values. The definitions for each of the durations used for the methods reviewed are included in Table 2-1. Because there are some differences in these

Table 2-1. Duration definitions used for various reference values

Reference value duration	Definition
Acute	
ARE	Inhalation single continuous exposure values for durations ≤ 24 hrs (to be protective of intermittent exposures)
AEGL	10 and 30 min; 1, 4, and 8 hrs
OPP acute RfD	Maximum 1-day dietary exposure
OW 1-day HA	1 day (5 successive daily doses)
ATSDR acute MRL	≤14 days
Standardized definition[a]	24 hrs or less
Short-term	
ARE	NA
AEGL	NA
OPP short-term RfD	1 day–1 month
OW 10-day HA	10 days (7–14 successive daily doses)
ATSDR MRL	NA
Standardized definition[a]	>24 hrs up to 30 days
Longer-term	
ARE	NA
AEGL	NA
OPP intermediate RfD	1–6 months
OW longer-term HA	Approximately 10% of life span in humans (90 days to 1 year in test species)
ATSDR intermediate MRL	15–364 days
Standardized definition[a]	>30 days up to approximately 10% of the life span in humans (>30–90 days in typically used laboratory species)

[a] See Chapter 4 for further discussion of these definitions.

definitions, standardized definitions were discussed at the Risk Assessment Forum Colloquium (CDM Group, 2000), and these are shown in Table 2-1. Definitions for durations are further discussed in Chapter 4.

A comparison of the UFs applied for various reference values is shown in Table 2-2. Although there is some variation in the UFs applied, those for animal-to-human extrapolation (U_A), for within-human variability (U_H), and for LOAEL-to-NOAEL (U_L) are fairly consistent. Less consistent is the way in which database deficiencies (U_D) are taken into consideration, particularly for pesticides where the Food Quality Protection Act (FQPA) safety factor is used to account for deficiencies in the database related to children's health risks.

Duration extrapolation for each of these values was also reviewed. Some type of duration adjustment of the NOAEL or the BMD is done for the ARE and the AEGL methods, and there appears to be consistency in the use of $C^n \times t$ for extrapolating from shorter to longer exposures but in using the same value (i.e., no duration adjustment) when extrapolating from longer to shorter exposures. Duration extrapolation is not done for the OPP RfDs, the OW HAs, or the ATSDR MRLs.

2.3. RECOMMENDATION

On the basis of its review of the various approaches to setting acute, short-term, and longer-term reference values, the Technical Panel concurred with the recommendation of the 10X Task Force that acute, short-term, and longer-term reference values should be set, where possible, and that they be incorporated into the IRIS database. In addition, the Technical Panel recommended that these values be set in a consistent manner, using standardized definitions for acute, short-term, longer-term, and chronic durations that are consistent with current practice. These values can then be used by various program offices, where applicable. A scheme for deriving these additional values is presented in Chapter 4.

Table 2-2. Uncertainty/safety factors for various reference values

Reference value	UF[a]				FQPA[b]
	U_A	U_H	U_L	U_D	
ARE	1, 3, 10	1, 3, 10	1, 3, 10	ND	NA
AEGL	1, 3, 10	1, 3, 10	3[c]	ND[d]	NA
OPP acute and intermediate RfDs	10	10	3, 10	ND[e]	10+
OW HAs	1, 3, 10	1, 3, 10	1, 3, 10	case-specific	NA
ATSDR MRLs	1, 3, 10	1, 3, 10	1, 3, 10	ND[d]	NA

[a] Uncertainty factors: U_A = animal-to-human; U_H = within-human variability; U_L = LOAEL-to-NOAEL; U_D = database deficiency.
[b] Additional safety factor required under FQPA.
[c] Endpoint = lethality, not really a LOAEL-to-NOAEL adjustment in this case.
[d] Database deficiencies considered, and a factor may be included for intermediate RfDs if, for example, there is no reproduction and fertility study.
[e] Overlaps with the FQPA safety factor (see U.S. EPA, 2002b)

ND = not done
NA = not applicable

3. REVIEW OF TESTING GUIDELINES WITH RESPECT TO LIFE STAGE ASSESSMENT

As a first step in determining the data necessary for setting various duration reference values for protecting potentially susceptible subpopulations, the Technical Panel reviewed the current OPPTS Series 870 health effects testing guidelines[2] to determine what information is gathered in these studies. The intent of this review is not to suggest that additional testing be conducted for each and every chemical in order to fill in the information gaps identified for those organ systems evaluated. Nor is it suggested that the alternative testing protocols that are discussed in this chapter should be conducted for every chemical or become part of current toxicology testing requirements or that these alternative protocols are the only options available. Rather, it is the goal of this document to provide a basis for the development of innovative alternative testing approaches and the use of such data in risk assessment and to then illustrate some aspects of this concept with a few examples.

Development of a toxicology testing paradigm that is based not on rigid conformance to a list of required guideline screening studies but rather on the application of knowledge about the chemical is encouraged. Under such a paradigm, both the selection of studies that would be required as well as the design of the tests themselves could be influenced by other substantive and reliable information about the chemical. For example, the incorporation of toxicokinetic and mode-of-action data early in the development of the testing strategy for a chemical would provide particularly valuable direction for development of research protocols.

Other input could include toxicity and dose-response data from other guideline or nonguideline studies, in vitro screening assays, structure-activity relationships, studies that examine age-related sensitivity or susceptibility to chemical exposure, and information on potential or actual exposure to humans. These data could be used to inform a more targeted approach in the design of individual studies or of an overall testing strategy and might in some cases result in a reduction in the number of animals used in testing or support a position that a traditionally required toxicology test should be waived.

The purpose of the review of the current OPPTS guidelines was to understand which target organ systems are evaluated in current testing protocols and how thorough the testing protocols are with respect to life stage assessment; endpoint assessment; route, timing, and

[2]The guidelines are available on the OPPTS web page (http://www.epa.gov/docs/OPPTS_Harmonized/870_Health_Effects_Test _Guidelines/Series/).

duration of exposure; reversibility; and latency to response. These issues were all considered of importance in evaluating potentially susceptible subpopulations, including children. The following sections give an overview of the current testing protocols evaluated in this way and, for certain organ/functional systems, provide a more in-depth analysis as to whether and how current protocols address these issues. The organs/functional systems that were examined in greater detail included the reproductive and the nervous systems, which were selected to represent systems that are thought to be rather well-evaluated. The immune and the cardiovascular systems were selected for review because the current evaluation of these systems is limited. It should be noted that testing guidelines were not originally designed with a focus on evaluations of different life stages or different durations of exposure. Therefore, a number of gaps in life stage assessment, endpoint assessment, timing and duration of exposure, reversibility, and latency to response were noted for each organ system that is reviewed in depth.

The last section provides recommendations for alternative testing approaches that are designed to make more efficient use of animals and resources in combined studies that would provide more extensive data on life stages, endpoints, and other factors not well characterized in current testing approaches.

3.1. EVALUATION OF CURRENT GUIDELINE TESTING PROTOCOLS

The following tables and figures summarize the exposures and endpoints covered in current testing guidelines, what is covered for each organ system/endpoint measured, and the relative depth of evaluation for each system/endpoint. In addition, the life stages covered by exposures and outcomes are illustrated. The discussions that correspond to the figures give an overview of the tests that are currently available and the gaps in assessment of life stages, endpoints, timing and duration of exposure, and latency to response. Together, these analyses provide a clear picture of the testing guidelines currently available, the systems/endpoints measured, the life stages during which exposures and outcomes are measured, the timing and duration of exposures included, and the degree of detail covered for both structural and functional outcomes.

In order to make comparisons among laboratory animal species and humans in terms of life stages covered, the approximate ages that correspond to specific events or life stages (e.g., birth, weaning, puberty, etc.) in different species are shown in Table 3-1, and these events/life stages are indicated in the figures. In a few cases, no data could be found on appropriate ages corresponding to particular life stages. In particular, the ages for mature adults and older adults often were not available, and there is some controversy about what constitutes old age in today’s

Table 3-1. Approximate age at equivalent life stages in several species

Rat		Mouse		Rabbit		Beagle dog		Human	
Life stage	**Age**	**Life stage**	**Age**	**Life stage**	**Age**	**Life stage**	**Age**	**Life stage**	**Age**

[c] Range of weaning ages in parentheses.

GD = gestation day
PND = postnatal day

population. A background paper on aging commissioned as part of this review discusses this issue to some extent (Versar Inc., 2001a). In animal studies, the use of dietary restriction has been shown to affect aging and life span to a significant extent, so the issue of what constitutes an older animal is also somewhat controversial.

3.1.1. Exposures and Endpoints Related to General Toxicity Testing

Table 3-2 provides an overview of the biological systems and other endpoints that are evaluated by routine toxicity test designs. The table includes all of the routine test designs that are available in Agency testing guidelines for evaluating toxicity and most of the test designs that focus on specific biological functions. The acute and subchronic studies are intended to give general information on the potential toxicity of an agent by screening the major organ systems, in particular, the liver, the kidney, and the gastrointestinal tract. This information can be used to determine where to look in more detail at specific organ system structure and function. The chronic studies, which are usually done in combination with a carcinogenicity study, evaluate general toxicity in all major organ systems. Several testing guidelines have been developed with the idea that certain systems should be evaluated frequently in more detail (e.g., the nervous system) or that the general toxicity studies do not provide any indication of a potential for effects (e.g., reproductive and developmental toxicity studies). More detailed information about specific aspects of guideline test designs for certain systems (e.g., life stages covered, exposure periods, outcomes measured, etc.) is included in the figures.

Table 3-2 is shaded and marked to indicate the extent of the evaluation of a particular system/endpoint within a particular test design. XXX indicates that the system/endpoint is a primary focus of the particular test design and that detailed assessment of the dose-response relationship of an exposure is carried out within some defined life stage and exposure period for major elements of the system/endpoint. XX indicates those systems/endpoints for which some histopathology or clinical measure of system function is carried out. X indicates those systems/endpoints that are assessed in some observational or gross manner. “0” indicates that the system/endpoint cannot be included, generally because of the design of the test. Blank cells indicate that the system/endpoint is not presently included but could be if the test design were altered appropriately.

It is obvious from the table that few systems/endpoints are examined in any significant detail. The systems/endpoints under the acute test designs are for the most part observational in nature. The acute inhalation toxicity with histopathology guideline (40 CFR 799.9135) was developed under the Toxic Substances Control Act for characterizing the exposure-response

Table 3-2. Systems/endpoints evaluated by routine toxicity guideline testing protocols[a]

Guideline[b]	Systems															Other endpoints		
	Lung-respira-tory	Cardio-vascular	Hema-tologic	Musculo-skeletal	Skin	Eye	Gastro-intest-inal	Kidney-urinary	Liver	Immuno-logical	Repro-ductive	Neuro-logical	Endocrino-logical	Pharmaco-kinetic-metabolic	Mutagenic	Cancer	Immediate death	Short life span

[a] X indicates that some observational or gross endpoints are included; XX indicates level X plus histopathology or some clinical measure of system function. The prenatal developmental toxicity study includes a more in-depth structural evaluation. XXX indicates the major focus of the evaluation. 0 indicates that this endpoint cannot be included as a major aspect in this protocol. A blank indicates that an aspect is not routinely included but could be.

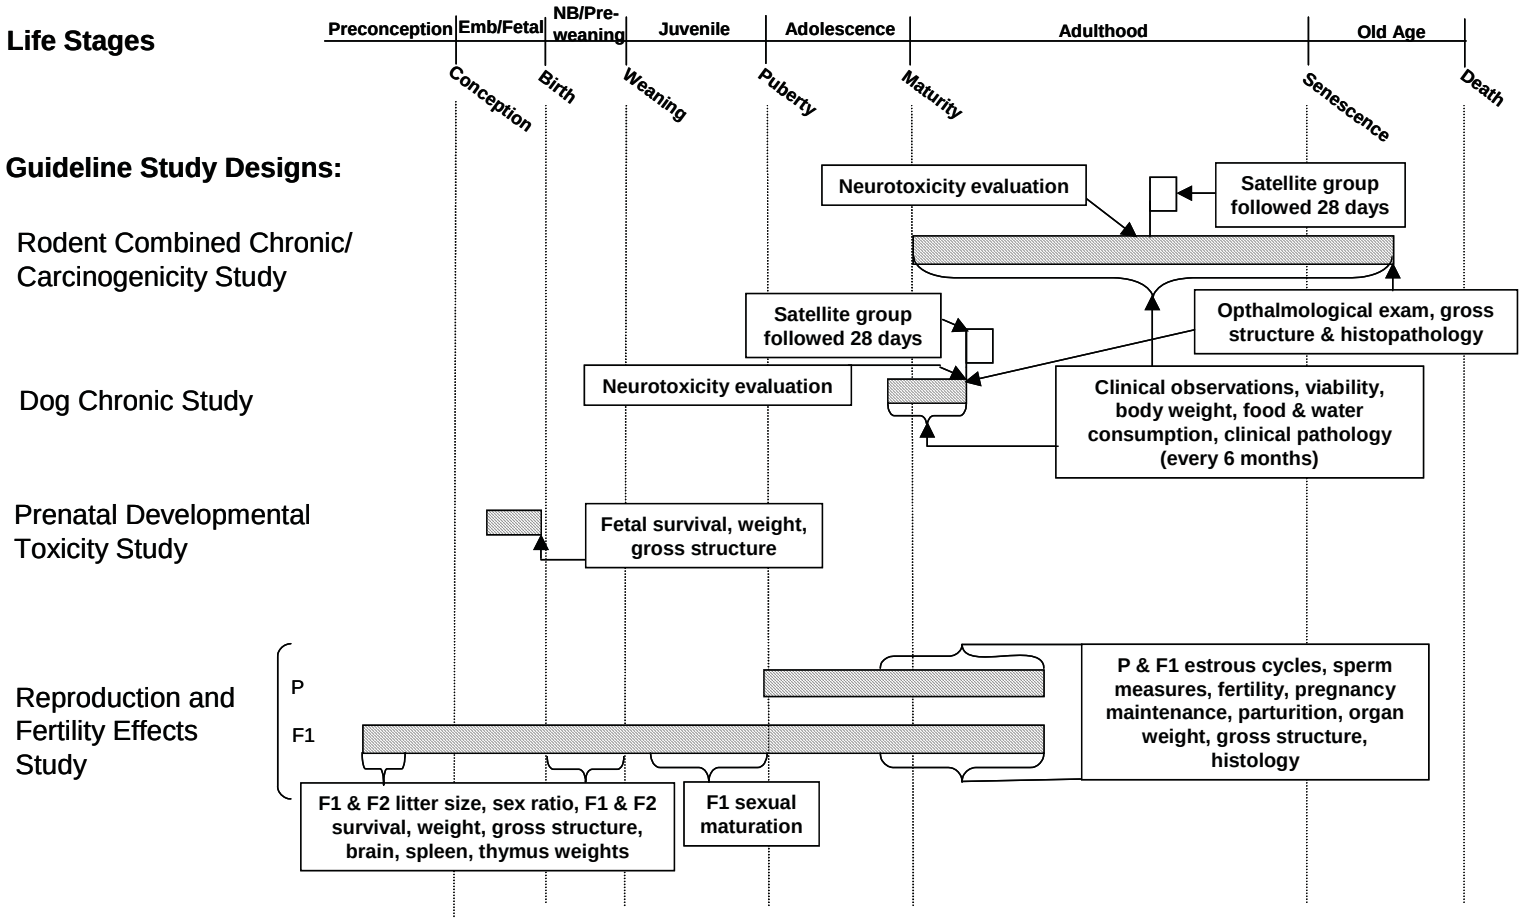
[b] A Series 870 guideline(s) exists for conducting each of the above tests.

relationship for sensitive endpoints following acute inhalation exposure and the toxicologic response following acute high exposures (see further discussion in section 3.1.1.1). Acute toxicity information is useful in establishing reference values for short-duration exposures and for establishing dose-ranges for subchronic and chronic studies. The subchronic and chronic test designs evaluate most endpoints with somewhat greater detail than do the acute test designs. Although the histopathology and/or clinical measures of system function are screening in nature, there is greater confidence that with this level of examination the dose-response relationship will be more clearly defined. Nevertheless, it should be recognized that most systems/endpoints are evaluated at a screening level, and detailed analyses of pathology and function are generally not carried out. Even in those test designs that do incorporate detailed analyses, these analyses are limited in regard to the life stages, exposure periods, and measures that are assessed.

Figure 3-1 shows the study designs that are used for general toxicity testing superimposed on a time line that indicates the life stages during which exposure occurs (hatched bars) and endpoints are measured (indicated in the boxes). The guideline studies shown represent the minimum requirement for derivation of a chronic oral RfD. Similar studies are required for the chronic inhalation RfC, with appropriate endpoints for inhalation exposure and toxicity included. In some cases, only a 90-day subchronic study is available instead of the chronic studies shown. Because the relative length of time between life stages varies among species, the placement of exposures and endpoints on the figures is not necessarily to scale. The following sections discuss the studies that address acute and short-term toxicity as well as chronic toxicity. Similar figures related to specific organ system toxicity testing are shown in subsequent sections.

3.1.1.1. *Acute and Short-Term Toxicity Studies*

3.1.1.1.1. ***Overview of tests.*** The primary purpose of the guideline acute toxicity tests (870.1100 acute oral; 870.1200 acute dermal; and 870.1300 acute inhalation) and other short-term studies (e.g., 14–28-day studies, no OPPTS guidelines available) is to identify hazards (focusing on route-specific lethality) from short-term exposure studies, provide a basis for classification and



Emb = Embryonic NB = Newborn P = Parental F1 and F2 = 1st and 2nd filial generations

Figure 3-1. Exposures and endpoints related to general toxicity evaluations. Endpoints shown are for oral exposures; endpoints specific to inhalation and dermal exposure are included for studies by those routes of exposure.

labeling, and enable the selection of exposure ranges for longer-term studies.[3] Acute guideline studies are conducted in young adult animals, with a 14-day post-exposure observation period. Other than mortality, the endpoints include cage-side observations, body weight at the end of the observation period, gross pathology changes at necropsy, and histopathological examination of organs showing evidence of gross pathology in animals surviving 24 hours or more. Two other available guideline studies cover acute exposures followed by extensive assessment of a specific organ system. The first is the acute inhalation toxicity study with histopathology (40 CFR 799.9135), which was developed for hazardous air pollutants. This study includes assessments of liver, kidney, and broncho alveolar lavage samples for several indicators of cellular damage (e.g., total protein, cell count, percent leukocytes) and a phagocytosis assay to determine macrophage activity. For the respiratory tract histopathology, detailed specifications are provided.

The second expanded study that includes observations following an acute exposure is the acute neurotoxicity study (870.6200), which was developed for the evaluation of neurotoxic chemicals and includes assessments of functional behavior and motor activity at the time of peak effect and again at 14-days post-treatment and histopathology of the central and peripheral nervous systems at 14-days post-treatment. The prenatal developmental toxicity study (870.3700) in two species (typically rats and rabbits) and the DNT study (870.6300) can also provide relevant data for acute risk assessment because maternal observations are often recorded daily and there is a presumption that effects during development may result from a single exposure.

3.1.1.1.2. ***Gaps in life stage of assessment.*** Acute/short-term testing is done only in prenatally exposed animals and in young adults. No direct information is available from any of these studies on acute or short-term exposure in postweaning young animals or aged animals.

---

[3]Alternative test protocols have been adopted by the Organization for Economic Cooperation and Development for acute toxicity testing for oral, dermal, and inhalation exposure, including the fixed-dose procedure, the acute toxic class method, and the up-and-down procedure. All are designed to minimize animal usage and provide minimal hazard and dose-response information for classification, labeling, and dose selection. In the future, EPA plans to put primary reliance on the up-and-down procedure for testing of technical grade pesticides, although the other tests may be acceptable in some circumstances, e.g., testing of pesticidal products. These studies are not designed to provide information for use in less-than-lifetime risk assessments.

3.1.1.1.3. ***Gaps in assessment endpoints.*** Data on only a limited number of toxicological endpoints are available from guideline acute toxicity (lethality) studies except in the case of the acute inhalation toxicity guideline study with histopathology and the acute neurotoxicity study. Consequently, these studies often are not suitable for use in deriving reference values unless additional data, such as those from subchronic studies (e.g., hematological, clinical, histology of more organs), are collected. Some data from animals examined at early times might be available in guideline subchronic or chronic studies. These data could augment the results from guideline acute studies.

3.1.1.1.4. ***Gaps in duration of exposure/latency to response assessment.*** There is no guideline study for short-term toxicity testing, although the prenatal developmental toxicity studies in rats and rabbits and the DNT study include repeated dosing of maternal animals for periods of less than 25 days. Because of the post-exposure observation period in acute guideline studies and in the DNT study, some information on latency to effect and reversibility of effect may be available.

3.1.1.2. ***Subchronic and Chronic Toxicity Studies***

The subchronic exposure studies (870.3100, 870.3150, 870.3200, 870.3250, 870.3465) are used for setting chronic RfDs and RfCs when a chronic study is not available. The guideline studies for chronic exposures (870.4100, 870.4200, 870.4300) (1 year in rodents, although the typical study is a combined chronic and carcinogenicity study with a 2-year exposure) provide an in-depth look at a number of organ systems, and in some cases they evaluate both structure and function (see Figure 3-1). The chronic study in nonrodents, usually dogs, involves a 12-month exposure with similar endpoints assessed as in rodents. The prenatal developmental toxicity study (870.3700) in two species (typically rats and rabbits), the DNT study (870.6300), and the reproduction and fertility effects study (870.3800), typically in rats, are also considered in setting chronic RfDs or RfCs.

3.1.1.2.1. ***Gaps in life stage of assessment.*** The subchronic and chronic studies are conducted in young adult animals, with exposure in the chronic/carcinogenicity study continuing into old age. No information is available from chronic studies in pre- or postnatal animals. Exposures in subchronic study protocols do not include pre- or postnatal development, although the reproduction and fertility effects study does provide data on subchronic exposures in animals that are exposed before birth, through prenatal and postnatal development up to mating of the F1

males and females and through pregnancy (F1 young adult females). No subchronic toxicity evaluations are conducted in aged animals. No chronic studies are conducted in pre- or postnatal animals, although aged animals are exposed and evaluated as part of the chronic study protocol.

3.1.1.2.2. ***Gaps in assessment endpoints.*** The greatest gaps appear to be the lack of routine testing for subchronic neurotoxicity in adults, immunotoxicity testing in adults, and more thorough toxicokinetics in animals at various life stages. Gaps in assessment endpoints during prenatal and postnatal development are discussed in the next section. Assessment endpoints for routine toxicity testing in old age are completely lacking, as is background information on endpoints related to the aging process itself.

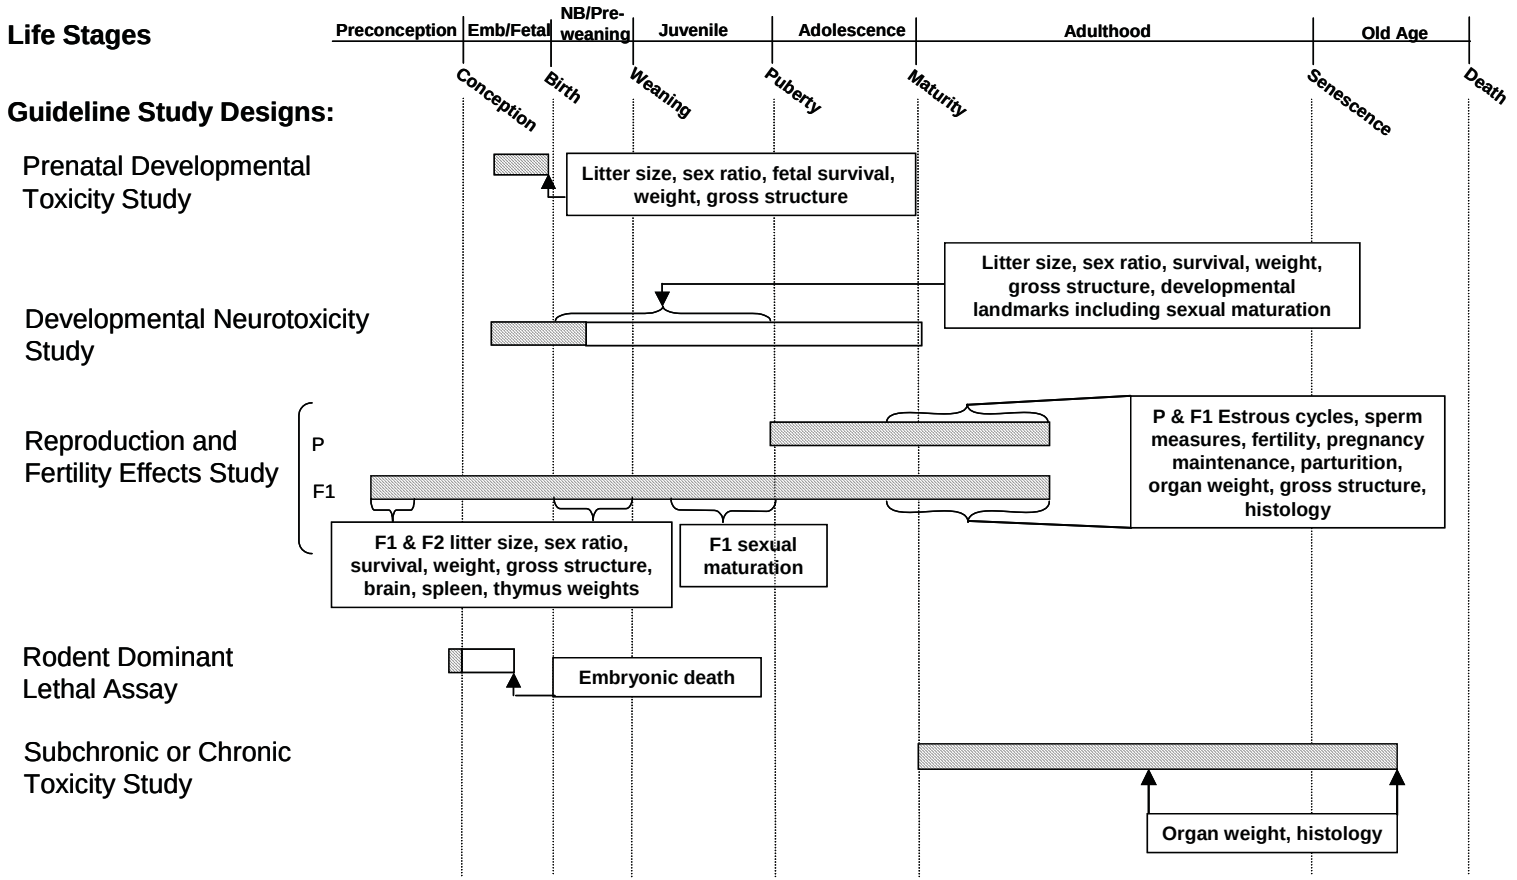
3.1.1.2.3. ***Gaps in duration/latency assessment.*** Chronic studies that include prenatal and postnatal exposure into old age are lacking. The so-called chronic study in dogs is actually a short-term study, as it does not cover at least 10% of the life span. Chronic studies that include a satellite group in which exposure is stopped after 12 months in rodents do assess latency to response for a brief period of time (28 days or more).

3.1.2. Exposures and Endpoints Related to Evaluation of Reproductive Toxicity

3.1.2.1. *Overview of Tests*

The reproductive organs are examined structurally in a number of general guideline screening studies, including the 90-day subchronic study (OPPTS 870.3100, 870.3150, 870.3250, 870.3465), chronic/carcinogenicity studies (OPPTS 870.4100, 870.4200, 870.4300), the prenatal developmental toxicity study (OPPTS 870.3700), and the reproduction and fertility effects study (OPPTS 870.3800), which is a two-generation reproduction study. In addition, extensive assessment of numerous functional aspects of the reproductive system is conducted in the reproduction and fertility effects study. Specific functional effects on the reproductive system of male animals can also be assessed in the rodent dominant lethal assay (OPPTS 870.5450). As illustrated in Figure 3-2, these studies include a variety of both structural and functional assessments of the reproductive system over a wide sampling of life stages.

In guideline subchronic and chronic/carcinogenicity studies, gross structural evaluation and general qualitative histopathology are conducted on reproductive organs and tissues. The animals in these studies are adults, but at the time of organ assessment they may be young (e.g., rats 45 days to 5 months of age from a subchronic study), mature (e.g., rats 5–18 months of age from a reproduction study), or old animals (e.g., rats 18 months to 2 years of age from a chronic study), depending on the protocol.



Emb = Embryonic NB = Newborn P = Parental F1 and F2 = 1st and 2nd filial generations

Figure 3-2. Exposures and endpoints related to reproductive evaluations.

Standard guideline prenatal developmental toxicity studies are designed to evaluate the potential effects of the test substance on the developing fetus. Observations on the reproductive capacity of the maternal animals in this study generally consist only of clinical observations (including any abnormalities of pregnancy maintenance) and gross necropsy data (including uterine). Selected fetuses are examined for gross structural changes to the internal reproductive organs. In studies that employ methods of serial sectioning in the process of soft tissue examination, a limited macroscopic evaluation of the internal structure and integrity of the reproductive organs is performed; however, the fetal tissues are not examined microscopically. Additionally, there are no assessments of organ function in this study design.

In the guideline reproduction and fertility effects study, rats are exposed to the test substance over the duration of two generations, beginning when the first generation animals are young adults of approximately 6–9 weeks of age. Daily exposure continues during all phases of development and reproductive function. Adult animals of both generations are killed as mature adults, generally prior to reaching reproductive senescence (that is, the cessation of normal reproductive function) or an age that would be considered geriatric in that species. Assessments of reproductive capability and function are conducted at least once in each generation. These assessments include direct evaluation of the age of sexual maturation, estrous cyclicity (immediately prior to mating), sperm measures (at termination), mating success, fertility and fecundity, implantation, pregnancy maintenance, gestation duration, parturition, and success of lactation (e.g., maternal nurturing and nesting behavior).

Indirect assessments of some reproductive functions are also evaluated. These observations are based on evidence of normality in a structure, function, or process that is dependent on normal functioning of the component parts, including, for example, hormonal homeostasis, ejaculation, accessory gland function, placental function, milk production, pup nursing behavior or ability, and, to some extent, reproductive senescence (although the adult animals are terminated at the end of each generation, when they are only around 6 months of age; therefore, there are no assessments conducted in older rats). Gross structural assessments of the whole animal are conducted on adult and immature animals throughout the course of the study; gross internal (organ) structural assessments are conducted on offspring that are killed at litter standardization (postnatal day [PND] 4), weaning (PND 21), and termination of each generation (mature adults). Histopathological evaluation of the reproductive organs (gonads and accessory structures) is conducted only in the mature parental adult animals that are killed at the termination of each generation. The guideline specifies a very focused pathological examination of the reproductive organs in this study.

The dominant lethal assay is not conducted for every chemical, but it may be conducted in response to a concern raised by other developmental or reproductive toxicity findings in the database. In this study, sexually mature adult males are treated with the test substance to determine whether there is an effect in the germinal tissue that does not cause dysfunction in the gamete but is lethal to the fertilized egg or developing embryo. Exposed males are mated with untreated females, and uterine contents are evaluated. Evidence of pre- and/or postimplantation loss is generally thought to be indicative of treatment-related chromosomal damage in germinal tissue.

3.1.2.2. *Gaps in Life Stage of Assessment*

Determination of gaps in the assessment of potential effects of any chemical across all life stages requires consideration of both the exposure period and the time of assessment. In the prenatal developmental toxicity study, animals are exposed from implantation through gestation. The reproductive organs are examined for gross structural changes, but no microscopic examination is conducted. There is no follow-up of the animals to determine the functional consequences of prenatal exposure. In the reproduction and fertility effects study, the F1 animals are exposed from preconception throughout prenatal and postnatal development until after mating. The reproductive organs are examined macroscopically at weaning and adulthood. The maturation of the reproductive system is assessed, as is its function. Thus, the study provides a fairly thorough assessment of structure and function following exposure during many critical periods of development. In the parental generation, the animals are exposed as young adults, and the structure and function of the reproductive organs are assessed.

The dominant lethal study, when conducted, assesses a single aspect of the function of the reproductive system for one sex, although a detailed structural assessment is not conducted. In the subchronic and chronic studies, the animals are exposed beginning as young adults, and the structure—but not the function—of the reproductive organs is assessed. Therefore, the major gaps include (1) the lack of functional assessment (particularly the age of onset of reproductive senescence) in older adult animals following adult-only exposures, and (2) the lack of structural and functional assessments in older adult animals following developmental exposures.

The onset of reproductive senescence can be marked by findings such as altered hormonal homeostasis, disruption of estrous cyclicity, diminished sperm measures (number, motility, or morphology), or gonadal atrophy. Studies in rodents have demonstrated the adverse effects of a number of agents (e.g., ionizing radiation, chemotherapeutic agents, polycyclic aromatic hydrocarbons, and agents that form epoxides, such as 1, 3-butadiene and 4-vinylcyclohexene) on reproductive senescence (reviewed by Hoyer and Sipes, 1996).

In humans, premature reproductive senescence has been associated with cigarette smoking (Jick et al., 1977). In addition to potentially diminishing fertility in individuals who are only slightly past prime reproductive age, early reproductive senescence can adversely affect the general health of the aged human. For example, hormonal alterations that are associated with early senescence have been linked to abnormalities of cardiovascular function, osteoporosis, and even a predisposition to early mortality.

3.1.2.3. *Gaps in Assessment Endpoints*

As described above, there are identifiable gaps in the endpoints that are used to assess reproductive toxicity in guideline studies. Currently, there is no assessment of functional endpoints in older animals following adult exposures, and there are no structural or functional endpoints assessed in older animals following developmental exposures, including reproductive senescence. In addition, concerns have recently been raised about the ability to detect rare malformations of the reproductive organs and abnormalities in the maturation of the reproductive system in the two-generation reproductive toxicity study. This concern relates particularly to endocrine-active chemicals. In the current guideline, three pups/sex/litter are examined macroscopically at weaning.

Questions have been raised about whether these weanlings should be retained until day 45 (females) or day 60 (males) to ensure that any later-appearing gross or functional changes are detected. This issue is currently being examined within the endocrine validation/standardization program.

3.1.2.4. *Gaps in Duration/Latency Assessment*

There are no studies that include acute or chronic exposures that can be used to assess the development of the reproductive system. As indicated above, it has been suggested that animals be retained until older ages in the two-generation study in order to assess later-appearing structural or functional changes in reproductive organs. In addition, there is no consideration of latent responses for reproductive toxicity, such as early onset of reproductive senescence, as a result of an exposure earlier in life in any of the studies that can be used to evaluate reproductive toxicity, except for a few endpoints in the DNT study.

3.1.3. Exposures and Endpoints Related to Evaluation of Neurotoxicity

3.1.3.1. *Overview of Tests*

Observation of the animals for signs of overt toxicity and routine gross pathological assessment of the nervous system is required under OPPTS acute, subchronic, and chronic study protocols (870.100–870.400 series). In rat studies, age at initiation of testing is to be 8–12 weeks under acute and subchronic testing protocols. In acute studies, cage-side observation and gross neuropathology are the only endpoints required under 870.100 (oral, dermal, or inhalation exposure). Motor activity, grip strength, and sensory reactivity and neuropathology are measured in the rodent oral study, the dermal 21–28- and 90-day subchronic studies, and the 90-day inhalation study. In rodent subchronic studies, specific assessment for neurotoxicity is performed at or near the end of the study, although observations of the animals, including those for detection of overt neurotoxicity, are made routinely throughout the study. No specific functional tests for neurotoxicity are required for nonrodent subchronic studies, although observation and neuropathology are required.

Chronic toxicity studies (oral, dermal, inhalation) are to be performed in two species (one rodent) over a 12-month period, regardless of the life span of the species. Exposure in rodents is to begin no later than 8 weeks of age. Motor activity, grip strength, and sensory reactivity are to be assessed at or near the end of the study, but no earlier than the 11th month. Clinical observation is performed weekly throughout the study and would presumably detect gross neurological abnormality. In current practice, the chronic study is often combined with the carcinogenicity test, in which dosing extends for 24 months in rats and 18 months in mice (OPPTS 870.4300). Motor activity would be performed at 11–12 months only, as in the chronic study, and not again until near the end of exposure.

The neurotoxicity screening battery (870.6200) is designed to be included in acute, subchronic, or chronic toxicity studies (Figure 3-3). The endpoints examined extend those required in the 870.100 series, although there is no guidance as to when these extended batteries would be required. The functional observation battery includes a ranking system for general reactivity, activity, and gait abnormalities, as well as forelimb and hindlimb grip strength, landing foot splay, sensorimotor reactivity to sensory stimuli, and pain reception. Motor activity and a more detailed neuropathological observation are also required in this battery. For acute studies, assessments are made before initiation of dosing, at the estimated peak of activity within 8 hours of dosing, and at 7 and 14 days post-dosing. For subchronic studies, assessments are performed pre-exposure and at 7, 8, and 13 weeks of exposure. For chronic studies, assessment is at pre-exposure and every 3 months post-exposure. There is no specific guidance regarding

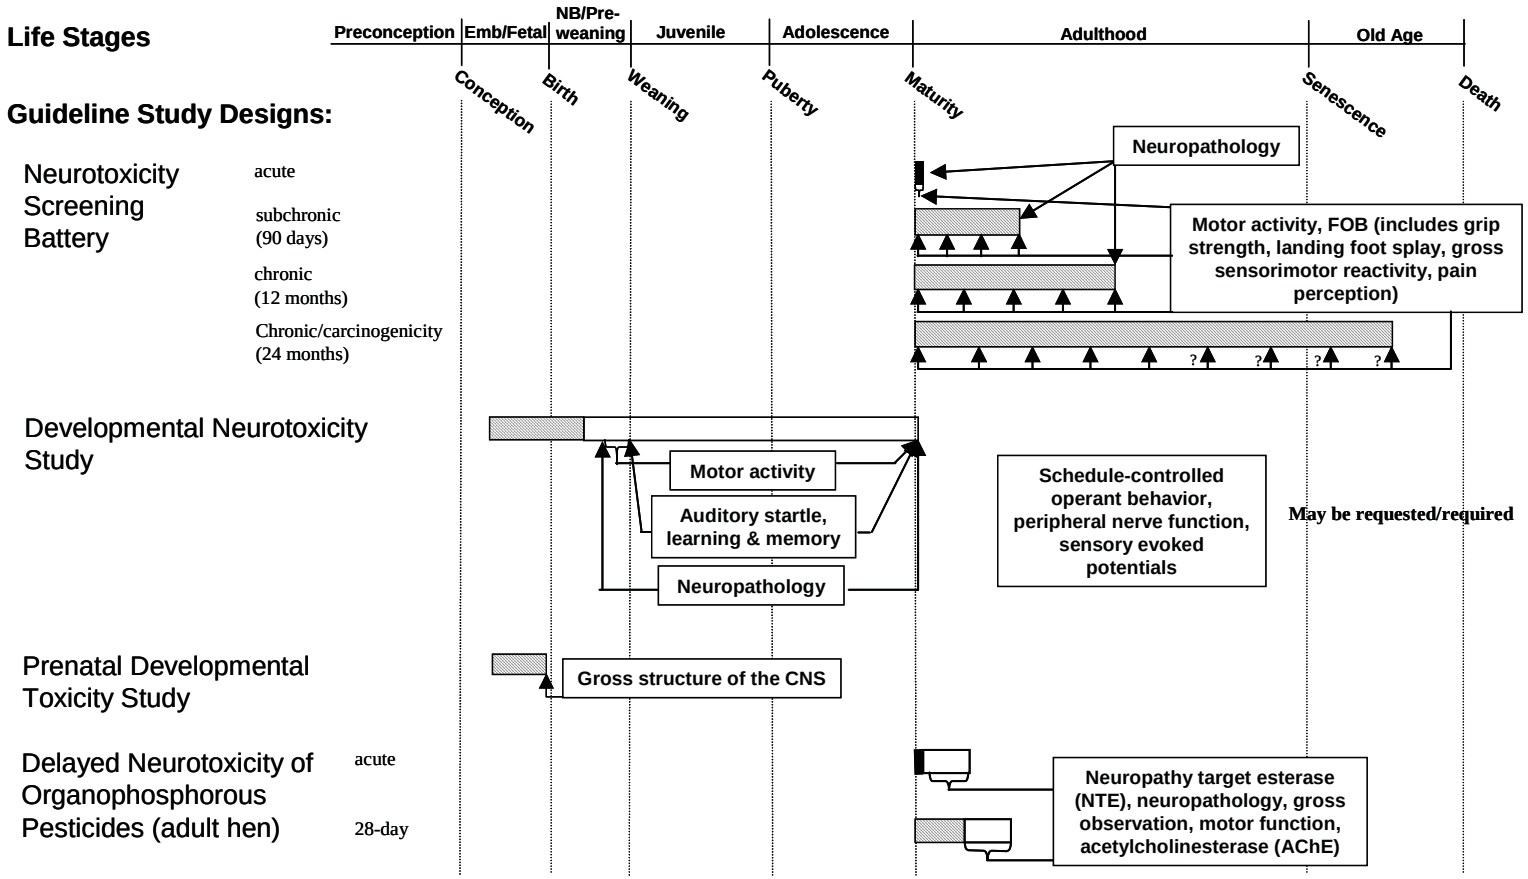


Figure 3-3. Exposures and endpoints for neurotoxicity evaluations.

the assessment schedule for the combined chronic/carcinogenicity study, but presumably the schedule required for the chronic study would be maintained.

The DNT study protocol (870.6300) currently requires dosing of the dams from gestational day (GD) 6 through PND 10, although the requirement may soon be extended to PND 21 (i.e., until weaning). Motor activity is measured at PNDs 13, 17, 21, and 60. Auditory startle is measured around weaning and at PND 60, as is a test of learning and memory, which may be the same test or different tests at the two time points. Cage-side observation of both dams and pups is required, and neuropathology in the pups is required at PND 11 and at the termination of the study (usually PND 60). The prenatal developmental toxicity study (870.3700) requires dosing of the dams on GDs 6–20 in rats and 6–29 in rabbits. Gross structural evaluation of the nervous system is evaluated as part of the fetal examinations conducted in this study.

3.1.3.2. *Gaps in Life Stage of Assessment*

One of the most significant gaps revealed by Figure 3-3 is the lack of exposure or assessment under any protocol during old age. For example, following acute exposure, assessment is for 14 days in juvenile or young adult animals. The chronic exposure protocol extends exposure into adulthood and the combined chronic/carcinogenicity protocol extends exposure up to approximately the aged period in the rat, but neurotoxicology assessments are not performed in aged animals. Thus, none of the protocols assess potential effects of chemicals on aging as a function of exposure during development. This may be important, because studies in animals have shown that developmental exposure to agents that cause neurotoxicity, such as trimethyl tin, can accelerate the onset of cognitive deficits measured later in life. Other studies with methyl mercury have documented early-onset sensory dysfunction in monkeys exposed during development. Furthermore, current testing protocols do not provide information collected at different life stages—that is, comparison of effects of exposure during infancy, adulthood, or old age. This is important, because life stage-dependent differences in pharmacokinetic, and possibly toxicodynamic, parameters could result in quantitatively or qualitatively different effects at different life stages.

Under the DNT protocol, there currently is no requirement to perform kinetic studies to ascertain either in utero or postnatal exposure. There is no mechanism to guarantee exposure postnatally (i.e., direct dosing of pups) because the compound may not be excreted into breast milk or it may be excreted only at very low concentrations. This is of particular importance, because the early postnatal period in the rodent is equivalent to a prenatal life stage in humans.

There is no long-term follow-up assessment to detect delayed neurotoxic effects, a situation that is arguably more worrisome for developmental exposure than for exposure later in life.

3.1.3.3. *Gaps in Assessment Endpoints*

The nervous system is one of the most fully assessed organ systems in the EPA/OPPTS 870 guidelines. Nonetheless, most of the endpoint assessments are designed to be screening procedures rather than sensitive assessments of nervous system function. In addition, the assessments required are different in the neurotoxicity screening battery than in the DNT study. The adult neurotoxicity screening battery does not require assessment of learning and memory or auditory startle. The lack of assessment of cognitive function in the neurotoxicity screening battery constitutes a significant omission that should be addressed.

It may also be pointed out that even in the developmental protocol, the tests that are used to assess learning and memory may be very simple, potentially revealing only relatively gross deficits. In addition, although potentially more sensitive cognitive, sensory, and motor tests are available (Figure 3-3), there is no guidance as to what would trigger a requirement for these assessments. Except for the protocol for delayed neurotoxicity for organophosphorous pesticides in the hen, there is no assessment of neurochemical endpoints. Additionally, the required neuropathological assessments may also be considered screening.

Minimal morphometric analysis, consisting of the thickness of “representative” layers in the neocortex, hippocampus, and cerebellum, is required in the DNT study. No morphometric analyses are required in the adult neurotoxicity testing protocols. Although more sophisticated tests would presumably not be performed on all agents, more sophisticated measures could be triggered by results from screening tests. It also may be advisable to require more sensitive tests in instances of particular concern, for example, adding more extensive morphometric analysis to the DNT protocol.

In summary, although the nervous system is one of the most thoroughly assessed systems in the 870 test guideline studies, it must be kept well in mind when interpreting the results that these are screening tests. Positive findings must be viewed as indicative of relatively overt toxicity, not so-called subtle effects.

3.1.3.4. *Gaps in Duration/Latency Assessment*

One of the principles in the neurotoxicity risk assessment guidelines (U.S. EPA, 1998c) is that neurotoxicity could occur after one or a few exposures, such as in the case of an organophosphate insecticide that produces a delayed neuropathy, or only after a series of repeated exposures, as in the case of acrylamide. For DNT, it is assumed that a single exposure

to a chemical during a critical period of development could result in an adverse effect on the developing nervous system. There are, however, few data that compare the effects of a single exposure to a chemical with the effects of the same chemical given multiple times during development.

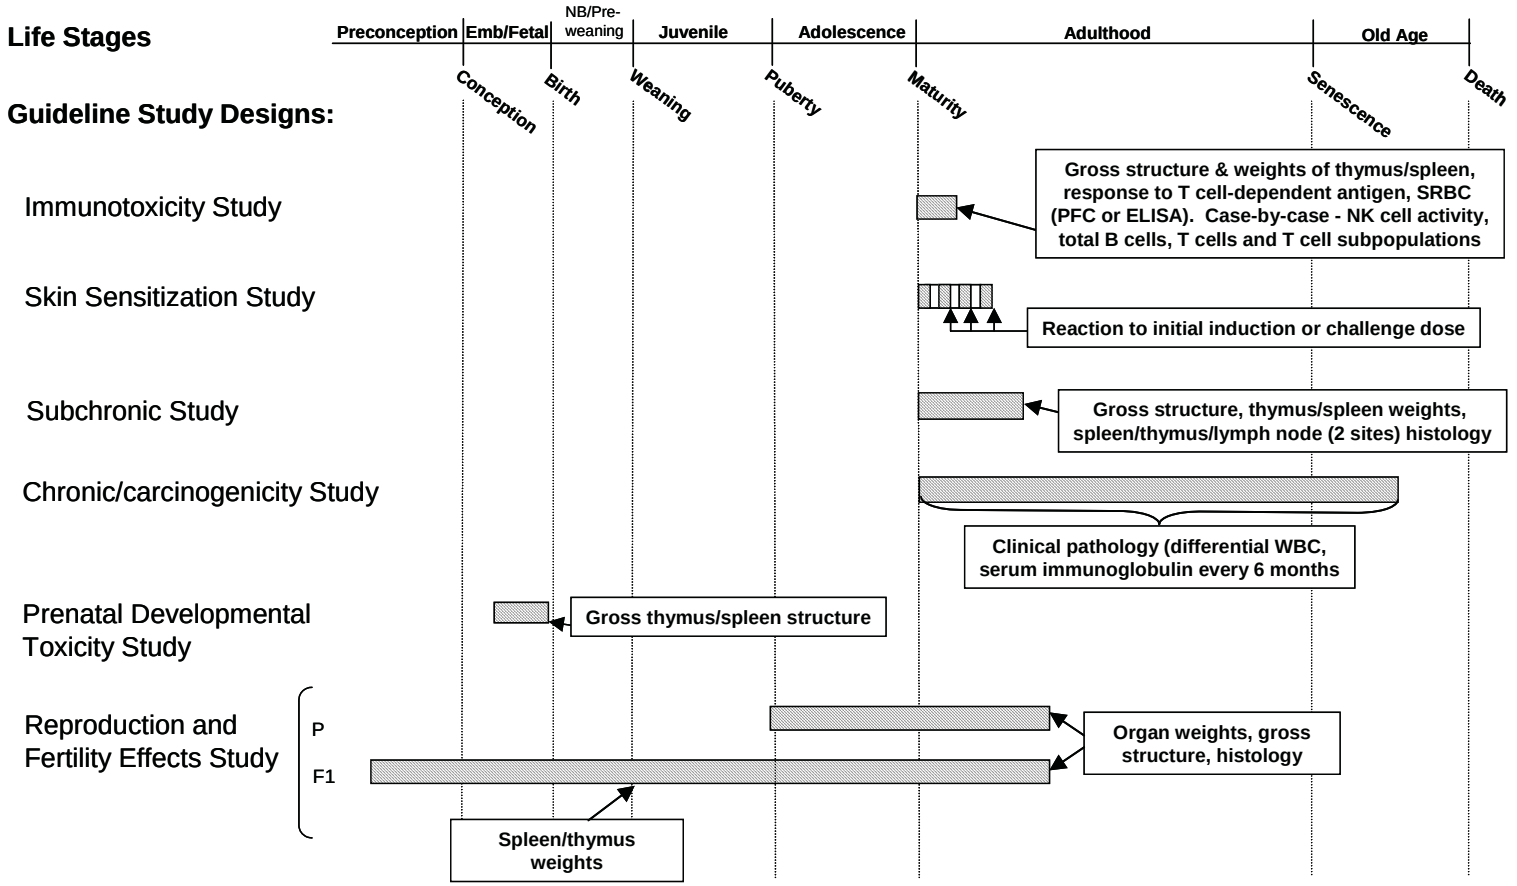
3.1.4. Exposures and Endpoints Related to Evaluation of Immunotoxicity

3.1.4.1. *Overview of Tests*

Examination of the macro- and/or microscopic structural anatomy of immune system organs and tissues is performed in a number of general guideline screening studies, including the acute inhalation toxicity with histopathology guideline (40 CFR 799.9135), the 90-day subchronic study (OPPTS 870.3100, 870.3150, 870.3250, 870.3465), the chronic/carcinogenicity studies (OPPTS 870.4100, 870.4200, 870.4300), the prenatal developmental toxicity study (OPPTS 870.3700), and the two-generation reproduction study (OPPTS 870.3800). In addition, functional assessments of the immune system are evaluated in the skin sensitization study (OPPTS 870.2600) and the immunotoxicity testing guideline (OPPTS 870.7800) (see Figure 3-4).

In the guideline immunotoxicity study, young adult rats (6–8 weeks of age) are exposed to the test substance for 28 days, at which time they are terminated. The spleen and thymus are examined macroscopically, and organ weights are recorded; a histopathological evaluation is not performed. Assessments of immune system function include an evaluation of the response to the T cell-dependent antigen, sheep red blood cells (SRBC). The SRBC antigen response assays can be conducted either by an antibody plaque-forming cell (PFC) assay or an immunoglobulin quantification by enzyme-linked immunosorbent assay (ELISA). In addition, an assessment of natural killer (NK) cell activity and/or enumeration of splenic or peripheral blood total B cells, total T cells, and T cell subpopulations may be required on a case-by-case basis.

The skin sensitization study has been generally conducted in guinea pigs as a Guinea Pig Maximization Test (GPMT) or a Buehler test. In a recent review by the FIFRA Science Advisory Panel (U.S. EPA, 2001a), it was recommended that in the future, skin sensitization methods should preferentially include the local lymph node assay (LLNA), which uses young adult mice. The skin sensitization test involves an initial intradermal (GPMT) and/or epidermal (Buehler, LLNA) exposure of the test animal to a substance, followed by a challenge exposure approximately 1 week later. In the guinea pig tests, sensitization is determined by examining the reaction to the challenge exposure and comparing this reaction with that of the initial induction



Emb = Embryonic NB = Newborn P = Parental F1= 1st filial generation SRBC = Sheep red blood cell

WBC = White blood cells

Figure 3-4. Exposures and endpoints for immunotoxicity evaluations.

exposure. In the LLNA, proliferation of lymphocytes is measured (as a function of in vivo radioisotope incorporation into cellular DNA) in draining lymph nodes proximal to the application site. Hence, although the GPMT and Buehler tests result in a qualitative assessment of hypersensitivity, the LLNA provides a quantitative dose-response evaluation. Histopathological evaluation of the skin is not required with any of these methods, but it may be conducted. No other immune system endpoints or organs are evaluated in this study.

In guideline subchronic and chronic/carcinogenicity studies, an evaluation of macroscopic structure and general qualitative histopathology are conducted on only a few immune system tissues. In studies that include young adult animals (e.g., rats 45 days to 5 months of age from a subchronic study), the spleen, thymus, and lymph nodes from two locations (one near to and the other distant from the site of administration) are examined; the spleen and thymus are weighed. In chronic and carcinogenicity study guidelines, there is no requirement that the thymus be examined and/or weighed. For rodents (e.g., rats or mice 18 months to 2 years of age), it is reasonable to assume that the thymus would have undergone normal age-related atrophy by study termination. However, the thymus might be present at early interim sacrifices of rodents (e.g., at 6 months or 12 months of study) during a long-term study, and it would certainly be present at study termination in a canine chronic study (at which point the dogs are young adults of only approximately 1.5 years of age).

Differential white cell counts in the circulating blood are examined at study termination in the subchronic study and at approximately 6-month intervals in long-term studies. Serum immunoglobulin levels may be measured at the same intervals. Perturbations may indicate increased immune system response to some unspecified initiator, but this information does not address the adequacy of immune system function. In the same manner, histopathological evaluation of other organ systems in the subchronic and chronic/carcinogenicity studies may identify cellular alterations that are nonspecific indicators of an effect on immune response, for example, the presence of increased numbers of macrophages in lung tissue or an increased incidence of inflammatory dermal lesions.

In the reproduction and fertility effects study in rats, a macroscopic evaluation of all organ systems is conducted in a sample of offspring at weaning and in the mature adult parental animals at the termination of each generation. Additionally, the spleen and thymus are weighed for those pups that are necropsied at weaning; these measurements are intended to provide information on the need for further evaluation of the immunotoxic potential of a chemical to the immature animal.

In the prenatal developmental toxicity study, an evaluation of the macroscopic structure of the thymus and spleen is conducted in at least half of the fetuses from each litter.

3.1.4.2. *Gaps in Life Stage of Assessment*

In the available guideline studies, assessments of organs with immune system function are conducted in fetuses following prenatal exposure, in weanling animals following pre- and postnatal exposure, and in young and/or mature adult animals at a variety of time points. With prenatal exposures and evaluation at early life stages, these assessments consist entirely of the evaluation of macroscopic changes, with no microscopic examination. Toxicokinetic data that characterize the exposure in the young (i.e., exposure of the fetus to the chemical or its metabolites via the placenta or of the neonate via breast milk) are not routinely required and are seldom available.

Some detailed structural assessment (histopathology) is conducted in mature or older adult animals. Indirect assessment of immune system function is conducted in adult animals of various ages via the evaluation of peripheral blood cells and chemistry. Direct functional assessments of the immune system are conducted only in young adult animals; generally this age group is selected for assessment because of the anticipated robustness of the immune response.

There is no guideline that examines potential perturbation of immune system function following early pre- and/or postnatal exposure (often referred to as a developmental immunotoxicity study). Comparisons of immune effects following exposure at various life stages (i.e., during in utero or postnatal development, adulthood, or old age), including data that analyze whether these effects are more severe in one age group or whether the effects are persistent, are not required. To achieve even a minimal assessment of immune system structure and function, a broad variety of studies would need to be conducted and assessed; yet there could still be relatively low confidence in the ability of the results of these combined studies to predict the outcome of age-specific insults to the immune system.

3.1.4.3. *Gaps in Assessment Endpoints*

There are identifiable gaps in the endpoints that are used to assess immunotoxicity in guideline studies. For example, for fetuses, immature animals, and old animals (rodents), assessments are composed entirely of the evaluation of macroscopic structural changes, with no histopathological or functional evaluations. In mature adult animals, thorough macroscopic and microscopic structural assessments, as well as routine hematological testing (e.g., blood cell counts), are performed; however, those assessments are generally very limited in young animals, and guideline requirements do not consider species differences. The only assessments of functional integrity of the immune system are provided by the guideline sensitization study and the 28-day immunotoxicity study. These studies are conducted only in young adult animals, and

they include only a few examples of potential immune system response (e.g., hypersensitivity, humoral immunity, or nonspecific cell-mediated immunity). In very young and very old animals, there is no direct assessment of immunological function. No assessment of autoimmune effects is conducted in any of the current guideline protocols.

3.1.4.4. *Gaps in Duration/Latency Assessment*

Latent effects on immune function that result from early lifetime exposure are not assessed; these can include effects in aged animals that result from in utero, neonatal, or young-adult exposure. Exacerbation of effects in relation to aging and response to subsequent immunological challenge are not routinely or systematically assessed to any extent. The two-generation reproduction study offers an opportunity to evaluate immunotoxic response in adulthood that resulted from prenatal or early postnatal exposure. In the chronic toxicity studies in rodents, aged animals are available for evaluation. However, in both cases there is little focus on the evaluation of the immune system. Only indirect evidence of perturbation of the immune system may be observed through macroscopic and microscopic evaluation of various organs; corollary functional assessment is not performed. Response to an immunological challenge is examined only in the hypersensitization study, and even when the results from this study are positive, no further specific assessment of the immune system is pursued.

3.1.5. Exposures and Endpoints Related to Evaluation of Cardiovascular Toxicity

3.1.5.1. *Overview of Tests*

Gross observation of the heart and major vessels augmented by conditional standard pathology is mentioned in most applicable OPPTS Series 870 health effect guidelines (Figure 3-5).

3.1.5.2. *Gaps in Life Stage of Assessment*

The period from birth to maturity is essentially without toxicological monitoring of cardiovascular endpoints for both repeated chronic and single acute-exposure regimes.

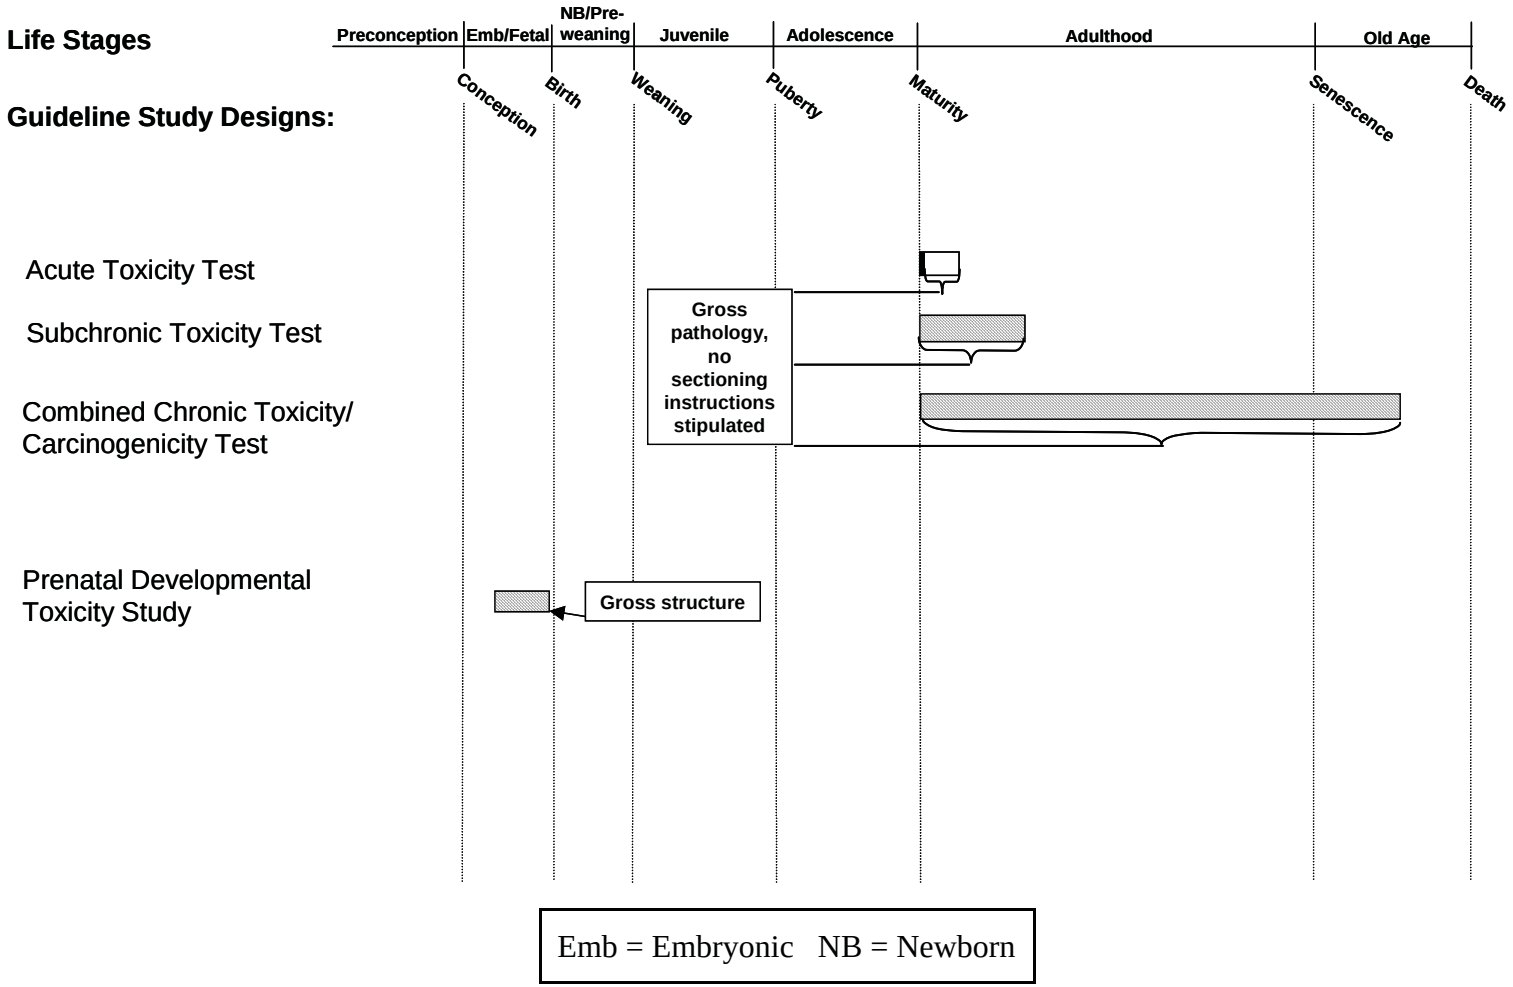

Figure 3-5. Exposures and endpoints related to cardiovascular evaluations.

3.1.5.3. ***Gaps in Assessment Endpoints***

Gross observation only of the heart is provided for in most OPPTS guidelines. Functional clinical or histopathological cardiac examination is not currently part of any testing guideline. Even gross pathology could be improved and brought into line with current cardiovascular evaluation by separating, weighing, and constructing right and left ventricle-to-body weight ratios to give an evaluation of cardiac hypertrophy. Also, guidelines regarding sectioning procedures for the heart, either number or plane, could be provided.

No simple cardiac functional evaluation is currently available, including even systolic or diastolic blood pressures. It should be noted that telemetric in-dwelling echocardiograms (ultrasound examinations of the heart) can be used to detect occlusions and atherosclerosis and to detect alterations in cardiac output. Combination echocardiograms and electrocardiogram analysis can detect cardiac wave forms as well as heart rate variability in high- and low-frequency power ranges (i.e., beat-to-beat changes in heart rate ascribed to varying control by the autonomic nervous system). Heart rate variability may be critical in explaining toxicity, as was shown in recent work associating exposures to fine particulate matter with decreases in heart rate variability in elderly humans (Creason et al., 2001). Both echocardiograms and electrocardiograms can be done on rats down to 100 g, well within the size range of juvenile and adolescent rats.

Chemicals can produce degenerative and/or inflammatory changes in the peripheral blood vessels as a consequence of an excessive pharmacologic effect or by an interaction with a vascular structural or functional macromolecule. As a result of sustained arterial vasoconstriction, peripheral arterial lesions consisting of intimal proliferation and medial degenerative changes could result in gangrene. Also, chemicals can induce or enhance atheroma formation, which is characterized by endothelial damage with increased permeability, monocyte adhesion, and endothelial proliferation.

Selected representative techniques to study the peripheral vascular system consist of flow measurement techniques (Smith et al., 1994), such as electromagnetic flowmetry, pulsed Doppler flowmetry, transit time flowmetry, laser Doppler fluxmetry, and laser scanner methods. These techniques allow investigation of blood flow in vessels as large as the aorta and as small as the capillary, determination of the level of perfusion in tissues, and calculation of the derived hemodynamic variable of resistance.

The two major noninvasive techniques for determining microvascular velocity are the flying spot technique and the dual-slit technique. External ultrasound may be used to examine internal vascular dimensions. A noninvasive assessment of arterial flow in rodents and monkeys can be performed using Doppler spectrum analysis (duplex ultrasound technology) (Leopold et

al., 1997). This test detects arterial compromise in extremities, functional severity, and the hemodynamic significance of vascular lesions. In most cases, the locations in the arteries involved can be designated. Information regarding the extent and effectiveness of collateral circulation can also be gained. This testing is a valuable tool for monitoring early flow compromise secondary to chronic reoccurrence of anastomotic or distal disease.

Several blood/plasma tests for clinical assessment are in active use in cardiovascular research. In general, these are tests that may be used to document a cardiovascular accident (within 48–96 hours). Their utility for risk assessment has yet to be evaluated. Specific enzymes currently being used by the research community for these purposes include LDH-I, creatinine kinase-II, and troponin. Other enzymes useful as prognostic indicators of risk of a cardiovascular accident include angiotensin converting enzyme II, plasma renin activity, endothelin-converting enzyme-1, and catecholamines (epinephrine and norepinephrine).

3.2. CONCLUSIONS AND RECOMMENDATIONS

A review of current testing guidelines was conducted to determine the types of data available for setting reference values. The approach used was to evaluate testing guidelines from the point of view of (1) life stages covered, (2) endpoints assessed generally and for specific organ systems, (3) timing and duration of exposure, and (4) evaluation of reversibility and latency to response.

The relevance of these issues to the health evaluation of children and other potentially susceptible subpopulations should be apparent from the gaps identified in each of the above sections regarding life stage assessment, endpoints assessed, timing and duration of exposures included in guideline studies, reversibility, and latency to response. Although a number of areas of toxicity testing have been discussed, this review should not be considered exhaustive, and other health effects may be as or more important for particular chemicals than those reviewed in detail here.

Issues of particular concern for children’s health that have not been discussed in great detail here are effects related to asthma and other respiratory tract toxicity. For both children and the elderly, renal and liver function can be a major factor in the disposition, metabolism, and excretion of chemicals and, therefore, their toxicity. Thus, the evaluation of toxicity and the interpretation of data in terms of its completeness will always require scientific judgment about whether or not adequate data have been collected on effects of importance at the appropriate life stages and timing and duration of exposure, for example, for a given agent.

Effects seen at the termination of a chronic study may be due to cumulative damage from a continued repeated chemical insult, but they could also be a latent response from an earlier

single or short-term multiple exposure. Thus, latent effects might be revealed in chronic studies, but it would not be clear whether they were the result of acute/short-term exposure or the chronic exposure. Specific information on the latency of a response would follow only from a clearer understanding of the mechanism of the effect and from actual "stop exposure" protocols (e.g., the satellite studies depicted in Figure 3-1) or from shorter-term exposures with follow-up over a much longer period of time. It thus follows that any chemical database that does not have exposure-response studies of lifetime duration or any specific exposure-latency protocols would not cover the possibility of latent effects.

Effects that persist throughout a designated post-exposure period may be considered irreversible; those that do not are reversible. For chronic lifetime exposures, designation of an effect as irreversible or reversible is academic, as exposure is presumed to be lifetime (i.e., there is no post-exposure period). For shorter-term values (e.g., acute, short-term) where an appreciable period of time post-exposure is anticipated, designation of an effect as reversible or irreversible becomes more relevant. Derivation of a reference value based on shorter-term exposure guideline protocols would have to fully consider the aspect of reversibility in interpretation of the data. It is important to understand the difference between an endpoint that is truly reversible and one that is related to or is a precursor of other adverse effects. For example, low birth weight may be "reversible" through catch-up growth postnatally, but it also may be related to developmental delays or other health outcomes that result from prenatal growth reduction/retardation.

3.2.1. Conclusions

From this review, the Technical Panel reached the following major conclusions:

1. There are a number of gaps in life stages covered in current guideline testing protocols, particularly in terms of the exposure periods included. In particular, there is minimal evaluation of aged animals, especially after exposures that include early development.

2. There are a number of gaps in the evaluation of endpoints included for certain systems; for example, the evaluations of the cardiovascular and immune systems in various guideline studies were reviewed as examples of systems that are minimally covered. Other systems, for example, the reproductive and nervous systems, are evaluated in more detail, but even in these systems there are gaps that need to be

considered; notably, functional evaluations are not always included or integrated with structural evaluations of particular systems.

3. Acute and short-term exposure studies are either not available or include only gross effects, so that the data needed to derive acute and short-term reference values are often not available.

4. Latency to response and reversibility are only rarely evaluated directly. These types of effects could have a major impact on hazard characterization, especially in designing acute and short-term test guideline protocols and ultimately on the risk management options that can be used for intervention or prevention.

5. Although not more specifically discussed, it is clear that there is a lack of information on toxicokinetics. The available data are generally limited to studies that are conducted in young adult animals, but there are no guideline protocols for toxicokinetic evaluations during development or in older age related to exposures and outcomes.

6. The underlying assumption that the internal dose of the active form of an agent to the target site is the relevant measure of dose clearly underscores toxicokinetics as an essential tool that must be used in both hazard identification and dose-response evaluations. This should not only continue to be a central and critical area of exploration, it should be an area of direct application to assessment activities to address various issues, including but not limited to (a) design of studies, (b) delivery to the fetus/neonate, (c) dose scaling, (d) toxicokinetic and toxicodynamic considerations, and (e) route extrapolation.

A white paper on pharmacokinetics commissioned by the Technical Panel (Versar Inc., 2001b) is meant to serve as a technical resource for the application of toxicokinetics to these and other issues addressed throughout this document. Another white paper on aging (Versar Inc., 2001a) also addresses issues of changing pharmacokinetics during this life stage.

7. Portal-of-entry effects (i.e., respiratory, gastrointestinal, dermal) are acknowledged as being important in the effects of chemicals, and they may preclude systemic toxicity as being sentinel. Chronic oral RfDs and inhalation RfCs have been developed for a

number of agents, but rarely have dermal RfDs been derived. In some cases, oral RfDs and oral cancer potency factors have been used to assess systemic toxicity from dermal exposures. However, the dermal route of exposure can result in different patterns of distribution, metabolism, and excretion than those that occur from the oral route. Dermal contact with a chemical may also result in direct dermal toxicity, such as allergic contact dermatitis, urticaria reactions, chemical irritation, and skin cancer.

The dose-response relationship for the portal-of-entry effects in skin is likely to be independent of any associated systemic toxicity exhibited by a particular chemical. Therefore, there is a long-term need for the development of dermal RfDs that consider both the systemic toxicity effects and the portal-of-entry effects of individual chemicals. In addition, there is a need for data on the dermal uptake of chemicals from soil, water, and air, including information about specific chemical forms and bioavailability from different soil types that contribute to variations in uptake. Different exposure duration RfDs, such as acute chemical injury to the skin, need to be developed.

3.2.2. Recommendations

On the basis of the review of the guideline toxicity studies, the Technical Panel makes the following recommendations (in no particular order) regarding the development of testing procedures and guidance for their use. In identifying the need for development of specific protocols, the Technical Panel is not recommending that these tests be used for every chemical or in all circumstances, as pointed out at the beginning of the chapter.

- *Develop a strategy for alternative approaches to toxicity testing, with guidance on how and when to use existing and newly recommended guidelines.* Information on all aspects of a chemical should be considered in the strategy for testing, including chemical-physical characteristics, intended use, and toxicokinetic and toxicodynamic (mode of action) data, to allow a more efficient and targeted testing approach. In addition, the strategy should consider life stages in evaluating exposures and outcomes, as well as other sensitive subpopulations.

- *Develop guidelines or guideline study protocols that will provide more systematic information on toxicokinetics and toxicodynamics (i.e., mechanism or mode of action), including at different life stages.* Such studies could provide information that would be relevant to susceptible subpopulations, including life stages (i.e., inform the

selection of the intraspecies UF). Such studies also could provide information on species differences (i.e., inform the selection of the interspecies UF). Finally, such studies can provide information to conduct route-to-route extrapolations and reduce the number of route-specific tests required to derive a reference value.

- *Develop protocols for acute and short-term studies that provide more comprehensive data for setting reference values (see Section 3.3).* The existing protocols for acute studies (except for the acute inhalation protocol with histopathologic evaluation) generally collect data only on what could be called frank effects, which may not be protective of more subtle effects.

- *Modify existing guideline study protocols to provide more comprehensive coverage of life stages for both exposure and outcomes (see Section 3.3).* Existing guideline studies do not include, for example, the evaluation of toxic effects that may occur in old age from prenatal or early postnatal exposure (including carcinogenesis) or premature aging from exposure earlier in life.

- *Collect more information from less-than-lifetime exposure to evaluate latency to effect and to evaluate reversibility of effect.* Existing guideline studies, with the exception of the acute tests and some developmental toxicity studies, expose animals up to the time of testing. Some form of "stop exposure" studies would provide useful information that could increase or decrease the level of concern for an observed toxic event.

- *Develop guidelines or guideline study protocols to assess immunotoxicity, carcinogenicity, and cardiovascular toxicity at different life stages.* Immunotoxicity and cardiovascular toxicity are presently looked at only in a cursory manner. Carcinogenicity is currently evaluated only after chronic exposure to adult animals. There is a need to integrate functional measurements into evaluations of these and other systems.
- *Explore the feasibility of setting dermal reference values for direct toxicity at the portal of entry, including sensitization.* Reference values have been derived for lesions in the gastrointestinal and respiratory tracts from direct exposure. The lack of procedures for dealing with similar effects on the skin is a glaring omission.

3.3. OPTIONS FOR ALTERNATIVE TESTING APPROACHES

The Technical Panel explored alternative testing protocols for acute toxicity testing as well as alternative protocols for subchronic/chronic toxicity testing. These are offered here as alternatives that may be used, depending on the agent being tested or the type of reference values needed.

3.3.1. Alternative Acute Toxicity Testing Protocol

The current EPA test guidelines for acute toxicity focus on the determination of an LD50 in adult test species. A gross necropsy is conducted on the animals, and histologic evaluation of target organs may or may not be conducted. Therefore, very limited information is obtained from the current protocol that would be useful for determining an acute reference value. However, a number of alternative study designs are available that would provide information for consideration in establishing the acute reference value (Gad and Chengelis, 1998).

One basic study design is shown in Figure 3-6. In this protocol, a control group and a minimum of three dose groups with 10 animals/sex/group are used. The animals are dosed once on day 1 and followed for 2 weeks. Clinical signs of toxicity are recorded daily, food consumption and body weights are recorded on days 1–4, 8, and 14. There is an interim sacrifice of 5 animals/sex/group at 3 days after dosing and a final sacrifice of the remaining animals at 2 weeks after dosing. At both sacrifices, hematological and clinical chemistry analyses are conducted, as is a urinalysis. The animals are necropsied, organ weights are recorded, and the organs are examined histologically.

Because the purpose of this study design is to provide hazard and dose-response information rather than determination of an LD50, the dose levels should be chosen accordingly. This study would initially be conducted on adult animals. As information is obtained from other toxicology and/or toxicokinetic studies, it may be necessary to conduct the study with animals at different life stages and to include other endpoints.

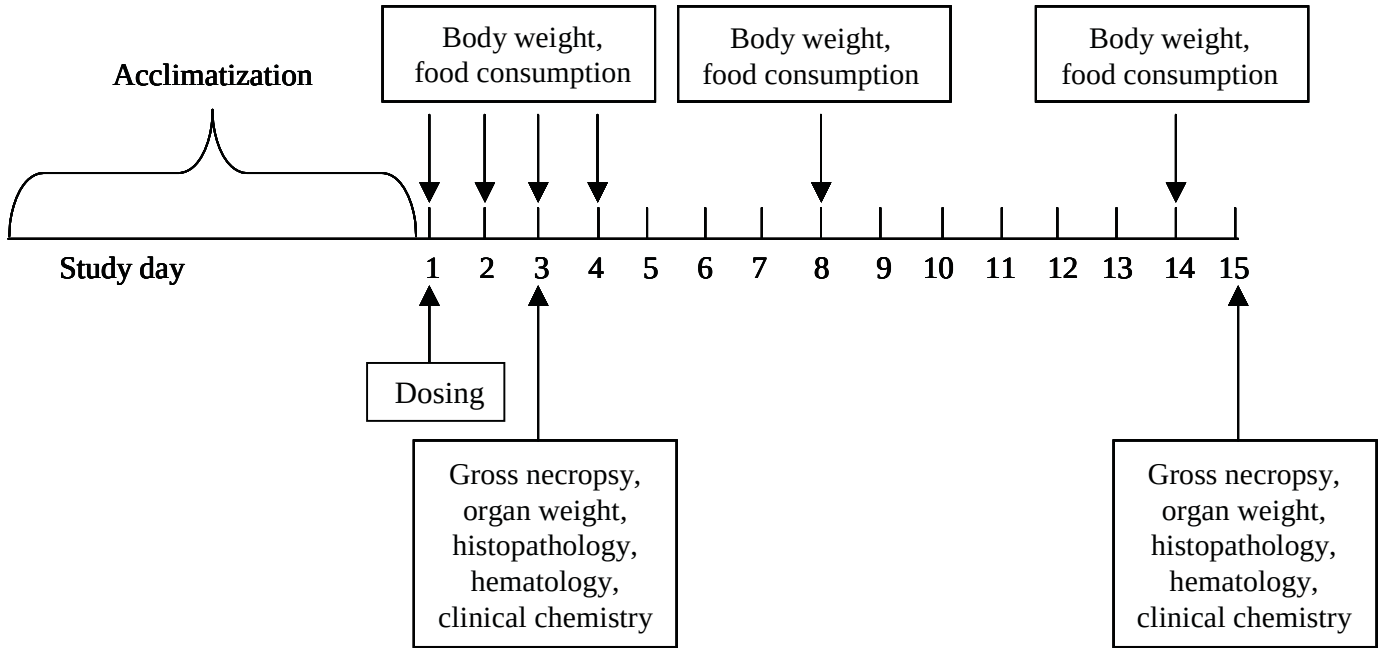

Figure 3-6. Alternative acute toxicity protocol.

3.3.2. Alternative Chronic Toxicity Testing Protocols

As stated, a review of currently available EPA guideline toxicology studies (OPPTS 870 Series) demonstrates that there is no single protocol that addresses continuous exposure through all life stages of any test species. To address this issue, two possible alternative study designs were considered: the "expanded chronic/carcinogenicity study" and the "unified screening study." These are described in some detail below and are illustrated in accompanying figures. The intent of this discussion is to demonstrate the advantages (and disadvantages) of exploring nontraditional testing paradigms; however, such discussion does not constitute a recommendation for implementation. For many chemicals, the existence of adequate (by Agency standards) stand-alone studies would preclude the need for further testing, with or without expanded or combined protocols such as those described below. In any case, any proposal to use alternative study designs in a regulatory setting should be thoroughly discussed by Agency and registrant scientists prior to study initiation.

3.3.2.1. *The Expanded Chronic/Carcinogenicity Study*

An example of a study design that would incorporate lifetime (in utero through old age) exposure is the expanded chronic/carcinogenicity study (shown in Figure 3-7), which could serve as a replacement for a standard guideline chronic/carcinogenicity study in rats. In this expanded study, female rats are assigned to treatment groups, mated, and treated with test substance throughout gestation and lactation. When pups are weaned on PND 21, they are assigned individual animal numbers and maintained within their established treatment group. Prenatal and early postnatal exposure to the test substance in this study is similar to that required for the in utero carcinogenicity study that is used to evaluate food additive chemicals for regulation by the Food and Drug Administration's Center for Food Safety and Nutrition.

The difference here is that the study duration is extended to a period of 3 years (vs. a typical chronic duration of 2 years for rats), with interim sacrifices scheduled at yearly intervals. The total number of animals used in this expanded study is greater than for a standard guideline chronic/carcinogenicity study because of the additional interim sacrifice; for each annual segment, the sacrifice of 25 rats/sex/group is required. To reduce this number, the study could be conducted with fewer animals per segment (e.g., 20/sex/group), or only two sacrifices could be scheduled (e.g., at 1.5 and 3 years). Of course, such actions will either reduce the power of the evaluation for tumor data or will eliminate examination of an important life phase.

Parameters typical of a guideline chronic/carcinogenicity study are examined in this expanded study (e.g., mortality, clinical observations, body weight, food consumption, clinical

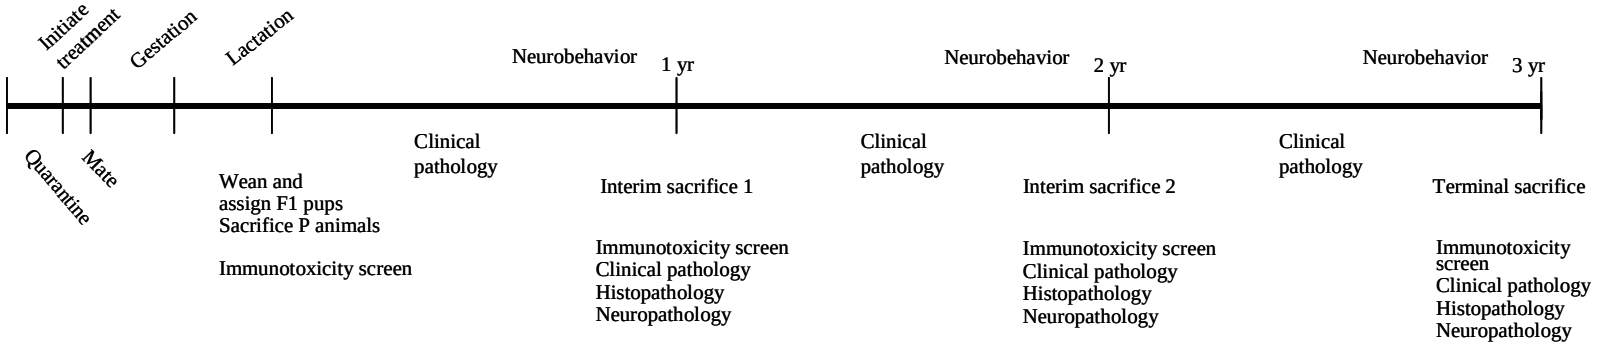

Figure 3-7. Expanded chronic/carcinogenicity study.

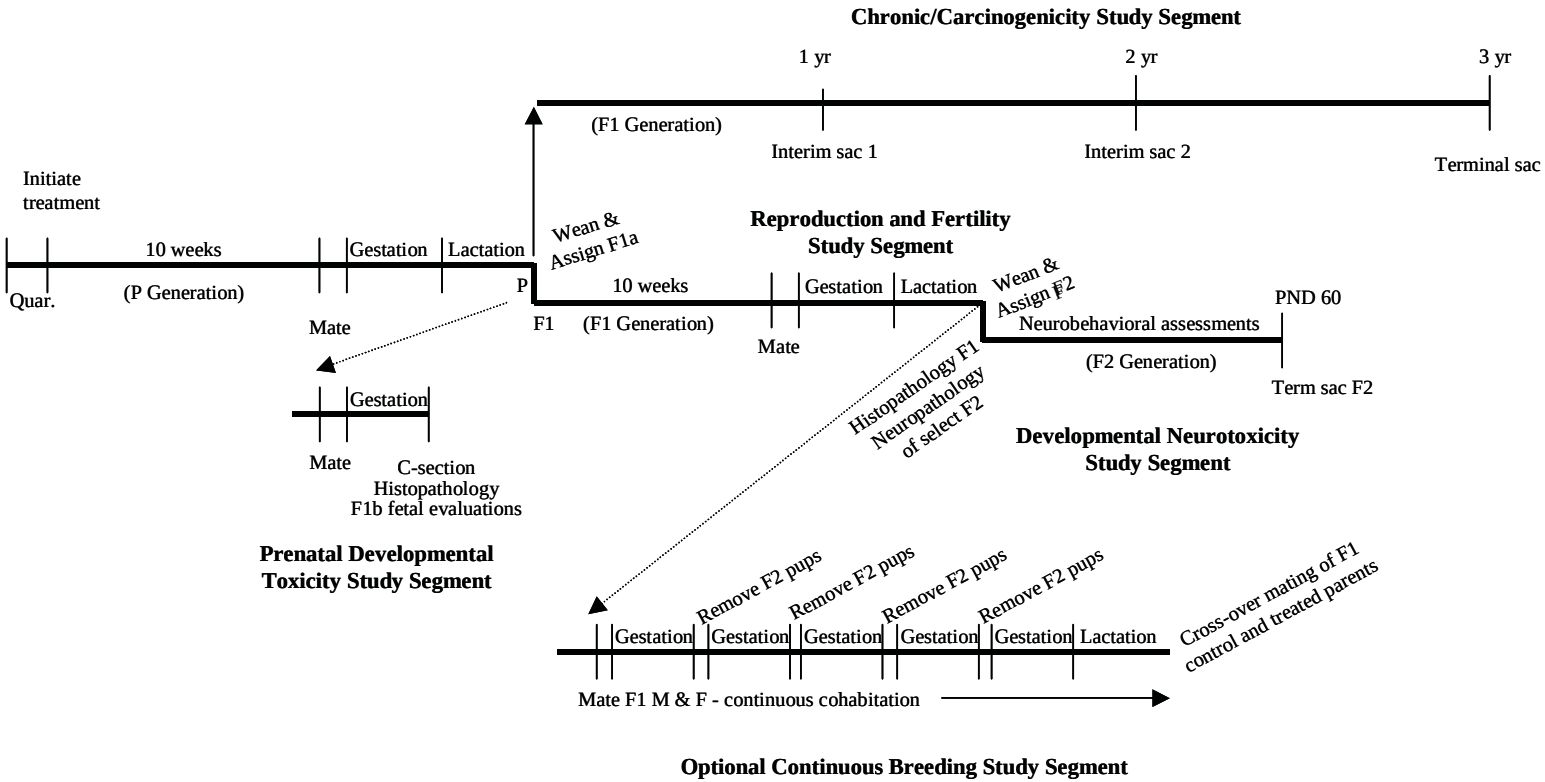
chemistry and hematology, ophthalmology, gross pathology, and histopathology). In addition, neurological and immunological evaluations are performed in the adult animals at multiple intervals into old age, which, along with the fact that the animals are exposed to the chemical during all life stages, contributes to the superiority of this study design.

Although the temporal linear nature of this study protocol makes it less complicated to conduct in the laboratory, this attribute also results in the inability to easily assess some other important endpoints, such as prenatal development, reproduction and endocrine function, and DNT. Additionally, by 3 years of age, when this study would be terminated, survival in laboratory rats may be compromised; therefore, it may be necessary to consider using feed restriction to maximize the number of animals available for in vivo and post mortem assessment of aged animals. In addition, housing from birth in specific-pathogen-free facilities may be necessary to maintain sufficient viable animals for such an extended period of time (see the background white paper on aging, Versar Inc., 2001a).

3.3.2.2. *The Unified Screening Study*

An alternative study design, the unified screening study, is illustrated in Figure 3-8. This study is composed of at least four segments: a two-generation reproduction and fertility study, an expanded chronic/carcinogenicity study, a developmental toxicity study, and a DNT study. Each of these is currently conducted as a separate study. An optional continuous-breeding study segment could be added to the design. When conducted in the rat, the unified screening study assesses all life stages of the animals and provides a means to evaluate prenatal developmental toxicity, DNT, reproduction, and endocrine function, all within animals that are derived from the same gene pool and are evaluated within two generations of the progenitor rodents that are initially placed on study.

The unified screening study begins as a typical two-generation reproduction and fertility study, with 10 weeks of treatment, mating, gestation, and lactation phases conducted according to OPPTS 870.3800. The F1 weanlings are selected for either the second generation of the reproduction and fertility study or the expanded chronic/carcinogenicity study. (As a point of clarification, at any point that animals are selected and/or assigned to a different study segment, it is assumed that the treatment group remains constant for each animal.) The parental (P) animals from the first generation are not immediately terminated; rather, they are transferred to a prenatal developmental study segment. After a short rest, they are mated. The P males can be terminated at any time point; the P females are continued through to caesarian section on approximately GD 20. The resulting F1b fetuses are processed and examined for external, soft tissue, and skeletal



Quar. = Quarantine P = Parental F1 and F2 = 1st and 2nd filial generations

Figure 3-8. Unified screening study. Study lines are not drawn to scale.

abnormalities, as is typical in an OPPTS 870.3700 study. At necropsy, however, the P-generation animals receive an extended postmortem examination, according to the procedures for the two-generation reproduction and fertility study, that includes sperm measures for the males and extensive histopathology of the reproductive and other organ systems for both sexes.

The expanded chronic/carcinogenicity study segment, using F1 animals, would continue as described above concurrently with all other segments of the unified screening study but continuing well past the time that the others have been terminated. The other F1 pups that are selected as second-generation parental animals in the reproduction and fertility study segment are treated for 10 weeks and then undergo the standard reproductive functional assessments, as specified in the OPPTS 870.3800 guideline. Because a number of F2 pups from this generation will continue on into the DNT study segment, some additional observations are required during the lactation segment of the second generation. Specifically, F2 pups are selected and assigned for neurobehavioral assessments on PND 4 (at the time of litter standardization). Preweaning observations include weekly age-appropriate clinical/functional behavioral observations conducted outside of the home cage and motor activity assessments on PNDs 13 and 17. Additional assessments of physical, reflex, and sensory development may also be conducted during this period.

At the time of weaning of the F2 pups on PND 21, those preselected for neurobehavioral assessment continue into the DNT segment and other weanlings are sacrificed for postmortem evaluations that address the considerations of both the reproduction protocol (including organ weight data) and the DNT protocol (requiring in situ perfusion fixation of tissues and neuropathology, including morphometric analysis). The DNT-segment F2 animals are evaluated as per OPPTS 870.6300, which includes multiple assessments of clinical and functional observations, motor activity, auditory startle habituation, and learning and memory. They are maintained until termination (with postmortem evaluations, including neuropathology following perfusion fixation) at approximately PND 60.

Also at the time of weaning of the F2 pups, a decision could be made to either sacrifice the F1 parental animals immediately (with the usual sperm measures and postmortem evaluations) or to maintain them through a continuous-breeding reproduction study segment, sequentially mating the F1 adults for the production of five litters (the pups from these litters are terminated in early lactation). This continuous-breeding study segment, which would extend the reproduction study for about 100 additional days, uses a standardized assessment protocol that has been well characterized in the peer-reviewed literature (Lamb, 1985; Lamb et al., 1985; Morrissey et al., 1989) but does not have a corresponding OPPTS guideline.

As previously stated, in this unified study protocol, the animals are both exposed and assessed during all life stages, and the evaluation of both structural and functional endpoints for multiple organ systems are maximized in the overall design, for example, by the inclusion of immunotoxicity and neurotoxicity endpoints. There is one notable exception to this statement in that reproductive senescence is not standardly examined. Nevertheless, if the two-generation reproduction study segment identifies problems with fertility or cyclicity, this could be pursued more rigorously by the addition of testing during the second or third year of the expanded chronic/carcinogenicity study, for example, evaluating cyclicity in aged female rats and/or evaluating ovarian follicular counts and atrophy at sacrifice.

Another benefit of using the unified screening study design is that it results in the purchase and use of many fewer naive animals for study initiation and it increases the efficient utilization of animals, particularly of the F2 offspring from the reproduction study.

Although there are obvious benefits in using a unified screening study, there are also a number of concerns or potential problems involved with its conduct. Although it is assumed that treatment levels and route of administration will remain constant across all study segments, this approach to dose-setting and route selection may not always be optimal for every phase. Generally, a temporal nonlinear design of this nature is more difficult to manage in the laboratory. The strain of rat generally used in toxicity studies is the Sprague-Dawley, whereas the Fischer 344 rat is often used in the standard chronic/carcinogenicity study. Fischer 344 rats have not typically been used in reproductive and developmental toxicity studies. The use of either strain for the unified study could compromise the use of historical data for comparison, for example, for the chronic/carcinogenicity study if the Sprague-Dawley is used and for the reproductive and developmental toxicity studies if the F344 is used.

As study complexity increases, so does the opportunity for error. In some cases, a serious technical error in one study segment could compromise subsequent study segments and result in an extensive waste of animals and resources. As with the expanded chronic/carcinogenicity study discussed above (section 3.3.2.1.), survival during the chronic/carcinogenicity study segment in this design may need to be enhanced via feed restriction. Also, if the test substance interferes with reproduction or results in increased mortality, the number of offspring that are available for assignment to subsequent study segments (e.g., the selection of F2 animals for the DNT phase) may be critically reduced. An additional but similar problem could arise when selecting F1 animals for the expanded chronic/carcinogenicity study segment at the same time as for the second generation of the reproduction and fertility study segment, because a large number of offspring needs to be available all at one time. Additionally, the offspring that are assigned to the

chronic/carcinogenicity segment should be genetically diverse within each dose group and should originate from as many litters as possible (i.e., not be siblings).

A number of possible solutions that could be used alone or in combination to increase the number of F1 pups available for selection in other study phases include the following:

1. Reducing the number of animals needed for the expanded chronic/carcinogenicity segment by examining fewer animals at each serial sacrifice or by abandoning the final year of evaluation, as described above.

2. Reducing the number of animals assigned to the second generation of the reproduction and fertility study segment; however, this could compromise the number of F1 offspring that would be available for the DNT study segment.

3. Standardizing litters to 10 rather than 8 pups per sex and assuming that no litter has less than 10 pups and that no pups die during lactation. Because some small litters and neonatal pup deaths almost always occur, even in controls, it is wiser to design the study more conservatively in order to avoid discovering that there are not enough F1 pups to assign to the later segment(s).

4. Assigning additional females to the two-generation reproduction and fertility study segment in order to produce extra F1 pups for selection. Although even a modest increase in the number in each group would increase the probability of producing a sufficient number of F1 pups, a larger number of litters would generally be required in order to ensure genetic diversity among the weanlings that are assigned to the chronic/carcinogenicity study segment. This could be accomplished by placing additional P-generation females or breeding pairs on study, perhaps combined with 2:1 mating procedures, or by mating the males with the reproduction and fertility study-segment females first and then with an extra set of females. One adverse consequence of placing additional females on study so that their litters can be used for selection of genetically diverse offspring for the chronic/carcinogenicity study segment is that this method results in a larger number of excess F1 weanling pups that would not be used for evaluations in this protocol. However, these pups could be used for other evaluations, such as immunotoxicity, specialized neurotoxicity tests, or adult onset disease or diseases of aging.

Some of the above options appear to be more advantageous and preferable than others; however, no recommendation is proffered because the list is presented only to illustrate some of the many possibilities that could be used in a customized study design. It should be noted that simply combining the reproduction and fertility study and the DNT study when a two-generation reproduction and fertility study has not already been conducted greatly reduces the total number of animals that would be required to conduct the two studies individually. No additional animals are required over the reproduction and fertility study alone, and there is greater efficiency in the use of the F2 offspring when the DNT study is conducted in that group.

4. FRAMEWORK FOR SETTING ACUTE, SHORT-TERM, LONGER-TERM, AND CHRONIC REFERENCE VALUES

As noted in Chapter 2, the Technical Panel is recommending that EPA begin deriving acute, short-term, and longer-term reference values in addition to chronic reference values. The approach to reference values discussed here is intended for use in risk assessments for health effects known or assumed to be produced through a nonlinear and/or threshold mode of action. Although there has been a dichotomy between cancer and noncancer risk assessment in terms of the underlying assumption about the linearity or nonlinearity of the dose-response curve, there is a move toward harmonization among approaches for all health effects (Butterworth and Bogdanffy, 1999; Bogdanffy et al., 2001). This includes recognition of the possibility that some carcinogenic agents may work through nonlinear mechanisms (U.S. EPA, 1999a), whereas some agents that produce effects other than cancer may work through linear mechanisms (see discussion in U.S. EPA, 1998d). Thus, the decision to use a linear extrapolation approach or a reference value approach should take into consideration the underlying mode of action and presumed dose-response relationship.

The approach described here is the default approach to be used when the assumption is a nonlinear and/or threshold mode of action, except for cases where other methods have been developed (e.g., in support of the NAAQS). This approach can and should be improved upon or replaced when more specific data on toxicokinetics and mode of action are available to allow the development of a chemical-specific or a biologically based dose-response model for prediction of risks to humans and to susceptible individuals within the population. The acute, short-term, longer-term, and chronic reference values derived on the basis of the recommendations in this report should be included in IRIS after appropriate internal, external, and consensus review. These values would then be available for use by program offices, where appropriate.

In this chapter, we discuss the definitions of the exposure durations and the proposed changes in the definition of the corresponding reference values. In addition, several issues are discussed regarding the adequacy of studies and characterization of the extent of the database with regard to sufficiency of data for deriving reference values. The derivation of reference values also is discussed with regard to dosimetric adjustment and application of UFs. A number of recommendations are made with regard to this process. In particular, the Technical Panel recommends incorporating the concept of life stage and expanding the endpoints evaluated as well as consideration of duration and timing of exposure and latency to response in characterizing the extent of the database used for setting reference values. The Technical Panel

strongly encourages the use of a narrative description of the database, including strengths and limitations, rather than a single confidence statement for support of a reference value.

The adjustments required for derivation of the human equivalent dose (HED) for oral and dermal exposure and the human equivalent concentration (HEC) for inhalation exposure are described and discussed. This is followed by recommendations about the evaluation and comparison of data for the POD, based on an analysis of each potentially limiting endpoint carried through the reference value derivation process, followed by selection of the appropriate health-protective reference value.

Finally, the Technical Panel emphasizes that considerable use of scientific judgment is advisable and necessary in practically all phases of the process, especially in the application of UFs. This review and its recommendations build on the principles in the Agency's handbook on risk characterization (U.S. EPA, 2000b), which calls for transparency, clarity, consistency, and reasonableness in the risk assessment process.

4.1. DEFINITIONS OF EXPOSURE DURATIONS FOR USE IN SETTING REFERENCE VALUES

The Technical Panel proposes the following definitions of exposure duration as a first step in the development of consistent approaches for the Agency. These definitions are based on exposure durations for humans; analogous exposure durations for rodents are indicated for the longer-term and chronic durations. The definitions are not intended to be rigid specifications, but simply general descriptions of the relevant exposure time period. Their application is meant to be flexible, so that, for example, if a 4-month animal study is available, it may be used as the basis for both a longer-term and a chronic reference value.

The definitions were developed on the basis of the review of values currently set by various program offices (see Chapter 2), and they have been standardized to be compatible with those definitions currently used by various program offices within the Agency. The definitions for various durations, as follow, were discussed at an EPA Risk Assessment Forum Colloquium (CDM Group Inc, 2000).

Acute: Exposure by the oral, dermal, or inhalation route for 24 hours or less.

Short-term: Repeated exposure[4] by the oral, dermal, or inhalation route for more than 24 hours, up to 30 days.

Longer-term: Repeated exposure by the oral, dermal, or inhalation route for more than 30 days, up to approximately 10% of the life span in humans[5] (more than 30 days up to approximately 90 days in typically used laboratory animal species[6]).

Chronic: Repeated exposure by the oral, dermal, or inhalation route for more than approximately 10% of the life span in humans (more than approximately 90 days to 2 years in typically used laboratory animal species).

The Technical Panel believes there is an advantage in having a central source of consensus reference values of various exposure durations available to risk assessors throughout EPA. EPA Program Offices could use the values for risk assessments in which the known or assumed exposure duration approximated the exposure duration in the appropriate reference value definition. The Panel recognizes that Program Offices may make further adjustments to the reference values depending on circumstances that are unique in their assessments.

The Technical Panel recommends that the principles of sound science be used when the expanded array of reference values are developed. The Panel cautions that the exposure-response relationships for all durations of exposure and issues of latency need to be carefully considered to ensure that there are no obvious conflicts in the series of recommended reference values for any specific chemical. This analysis can become complex in a case where the toxicological endpoint may differ for the different durations of exposure.

The Technical Panel is aware that there will be data limitations for an individual chemical that may preclude development of all four reference values. For example, currently, a chronic RfD or RfC would not ordinarily be considered for inclusion in the IRIS database unless

---

[4]A repeated exposure may be either continuous, periodic, or intermittent. A continuous exposure is a daily exposure for the total duration of interest. A periodic exposure is one occurring at regular intervals, e.g., inhalation exposure 6 hrs/day, 5 days/wk or oral exposure 5 days/wk. An intermittent exposure is one in which there is no effect of one exposure on the effect of the next; this definition implies sufficient time for the chemical and its metabolites to clear the biological system before the subsequent exposure, that is, noncumulative pharmacokinetics. A periodic exposure may or may not be intermittent.

[5]The lifespan value used depends on the situation under consideration. For example, an average of 70 years has been the typical default used for chronic exposures, but the average life span based on U.S. census data is 75.5 years (U.S. EPA, 1997a).

[6]Typically used laboratory animal species refers to rats, mice, and rabbits, for example.

a subchronic or chronic study were available. Similarly, where data of the type needed for deriving acute, short-term, or longer-term reference values are not available, theses values would not ordinarily be considered for inclusion in the IRIS database. In situations where an acute, short-term, or longer-term reference value is needed but appropriate data fitting the definition for duration are not available, then the Program Office may wish to consider several options. One option would be to not develop a reference value for that particular duration of exposure. Another option would be to use the reference value for the next longer duration of exposure as a conservative estimate of a reference value that would be protective for a short-term exposure duration. For example, the Office of Water (see Chapter 2) will use a longer-term health advisory for a child as a conservative estimate for a 10-day exposure in the absence of data to derive a 10-day health advisory. Other program-specific options might also be considered.

The Technical Panel is aware that time and resources need to be considered when implementing its recommendations. The IRIS program has begun to implement a pilot program to test whether development of the expanded array of reference values is practical and can be accomplished without unduly delaying the completion of an IRIS file. As a part of the pilot, the IRIS program will need to identify the methods to be used in deriving these additional values.

4.2. PROPOSED CHANGES IN THE REFERENCE VALUE DEFINITIONS

In the process of considering definitions for different duration reference values, the Technical Panel discussed several issues that have been raised about the current definitions of the chronic RfD and RfC (Box 4-1). The following items describe the issues and the recommended changes.

1. The parenthetical statement in the current RfD and RfC definitions—"with uncertainty spanning perhaps an order of magnitude"—has been variously used by risk assessors and risk managers to mean that the estimate is at the upper end, the lower end, or the middle of the range of an

Box 4-1. Current definitions for the chronic oral RfD and inhalation RfC

RfD: an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime. It can be derived from a NOAEL, LOAEL, or BMD, with UFs generally applied to reflect limitations of the data used. Generally used in EPA's noncancer health assessments.

RfC: an estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime. It can be derived from a NOAEL, LOAEL, or BMD, with UFs generally applied to reflect limitations of the data used. Generally used in EPA's noncancer health assessments.

order of magnitude. This statement has been removed from the proposed revision of the definition for reference value (Box 4-2), and it is recommended that issues of uncertainty/variability be discussed qualitatively as part of the weight of evidence and characterization of the database. Attempts to adapt such a qualitative derivation process to formal quantitative procedures for prediction of accuracy presents major difficulties. A particularly obvious difficulty is that the same definition and phrase were applied to different reference values that may have varied markedly in their underlying data and, thus, their potential for accuracy. For example, the same "order-of-magnitude" range applied equally to a robust reference value with known exposures plus observable and quantifiable dose-response data derived from a segment of the human population and to a marginal reference value based only on animal data with minimal supporting information.

Box 4-2. Proposed revisions in the reference value definitions

Reference Value: an estimate of an exposure, designated by duration[a] and route, to the human population (including susceptible subgroups[b]) that is likely to be without an appreciable risk of adverse health effects over a lifetime. It is derived from a BMDL, a NOAEL, a LOAEL, or another suitable point of departure, with uncertainty/variability factors[c] applied to reflect limitations of the data used.

---

[a] The generalized durations are similar to those given in Section 4.1. for acute (≤24 hours), short-term (up to 30 days), longer-term (up to 10% of average lifespan), and chronic (up to a lifetime), all considered to be continuous exposures throughout the duration specified.

[b] Susceptible subgroups may refer to life stages, e.g., children or the elderly, or to other segments of the population, e.g., asthmatics or the immune-compromised, but they are likely to be somewhat chemical specific and they may not be consistently defined in all cases. See below (Section 4.3.2.3) for further discussion.

[c] See discussion later in this chapter (Section 4.4.5) on application of uncertainty/variability factors.

The Technical Panel notes a lack of support from the external reviewers of this document for any such prediction and recommends that the database characterizations for reference values be approached in a comprehensive way, as discussed in Section 4.3 to ensure that they are authoritative and as complete as possible in order to yield qualitative information about the range that could be predicted around the individual estimates rather than attempting quantitative evaluations of accuracy and ranges.

2. The term “deleterious” is considered ambiguous by some, so it has been replaced with the term “adverse,” because the latter is more commonly understood in the context of data evaluation and selection of endpoints for setting reference values.

3. In the spirit of harmonization of risk assessment approaches for human health effects, it has been recommended that health effects no longer be categorized as “cancer” or “noncancer” for the purposes of hazard characterization and dose-response analysis (U.S. EPA, 1997b, 1998d; Bogdanffy et al., 2001). As indicated earlier, the approach to reference values discussed here is intended for risk assessments for any type of health effect known or assumed to be produced through a nonlinear and/or threshold mode of action (which may include U-shaped or other nonmonotonic dose-response curves as well as thresholds). In light of this recommendation, the term “noncancer” has been removed from the definition, denoting the move toward defining approaches for low-dose estimation or extrapolation based on mode of action. It is recommended that this issue be considered further in the deliberations by the Risk Assessment Forum’s Technical Panel on a framework for harmonization of approaches for human health risk assessment.

To fulfill the need for consistency in the designation of various duration reference values, the Panel recommends that the terminology for reference values be standardized. Rather than continuing to use RfD and RfC only to denote chronic oral and inhalation reference values, respectively, standardized terminology should be developed that denotes both duration and route of exposure. Although Technical Panel members did not come to agreement on the best way to do this (and we welcome alternative suggestions), the terminology shown below is offered as an example of the way in which consistent labels could be developed and used. Either new standard terminology, (e.g., reference value) could be used, or RfD and RfC could continue to be used, but they would always need to be accompanied by the qualifying duration of exposure and, in the case of the RfD, by the route of exposure. Thus, the following alternatives for terminology are offered:

Acute (Oral, Dermal) Reference Value or Dose, Acute (Inhalation) Reference Value or Concentration: RfV_{AO}, RfV_{AD}, RfV_{AI}; RfD_{AO}, RfD_{AD}, RfC_{AI} or RfC_{A}

Short-term (Oral, Dermal) Reference Value or Dose; Short-term (Inhalation) Reference Value or Concentration: RfV_{SO}, RfV_{SD}, RfV_{SI}; RfD_{SO}, RfD_{SD}, RfC_{SI} or RfC_{S}

Longer-term (Oral, Dermal) Reference Value or Dose; Longer-term (Inhalation) Reference Value or Concentration: RfV_{LO}, RfV_{LD}, RfV_{LI}; RfD_{LO}, RfD_{LD}, RfC_{LI} or RfC_{L}

Chronic (Oral, Dermal) Reference Value or Dose; Chronic (Inhalation) Reference Value or Concentration: RfV_{CO}, RfV_{CD}, RfV_{CI}; RfD_{CO}, RfD_{CD}, RfC_{CI} or RfC_{C}

The Panel recommends that endpoint- or life stage-specific reference values such as the RfD_{DT} (reference dose for developmental toxicity), which were originally proposed in *Guidelines for Developmental Toxicity Risk Assessment* (U.S. EPA, 1991), not be derived. Rather, a sample reference value should be calculated for each relevant and appropriate endpoint and these should then be considered in the derivation of various duration reference values. Reference values should be derived to be protective of all types of effects for a given duration of exposure and are intended to protect the population as a whole, including potentially susceptible subgroups. Thus, the RfD_{DT} concept of a critical window of exposure for some health effects is addressed in the adoption of the less-than-chronic reference values. This recommendation does not preclude, however, using specific common endpoints in the assessment of cumulative risk for mixtures or chemicals that have a common mode of action or for risk management purposes.

4.3. CHARACTERIZATION OF THE EXTENT OF THE HEALTH-RELATED DATABASE FOR SETTING REFERENCE VALUES

A necessary first step in hazard characterization is the critical evaluation of all pertinent and relevant human and animal data that are available in the open literature as well as data submitted to the Agency in response to various regulatory standards, data call-ins, or other requirements and agreements.

4.3.1. Review of Studies

Data will be available from a wide variety of sources, including studies conducted according to EPA guidelines, studies conducted by industry using Organization for Economic Cooperation and Development or other protocols, experimental studies conducted by academic researchers, epidemiology studies, case reports or series, and controlled clinical studies in

volunteers.[7] These studies will be of widely differing quality; EPA must evaluate each study to determine whether it is of acceptable quality.

4.3.1.1. *Adequacy of Studies*

The following list of questions could be helpful in the process of evaluating data from animal and human studies.

All types of studies:

- What was the purpose of the study and is there a clearly delineated hypothesis?
- Is there sufficient description of the protocol, statistical analyses, and results to make an evaluation?
- Were the appropriate endpoints assessed in the study?[8] Were the techniques used for the assessment scientifically sound?
- Were appropriate statistical techniques applied for each endpoint? Was the power of the study adequate to detect effects?
- Did the study establish dose-response relationships? Was a BMD lower confidence level (BMDL), LOAEL or NOAEL established?
- Is the shape of the dose-response curve consistent with the known toxicokinetics of the test compound?

---

[7]Currently, OPP is reviewing its policy concerning use of human data from studies in which there is intentional pesticide exposure, and it has asked the National Academy of Sciences for input on the acceptability of such studies and ethical criteria for their use under the Protection of Human Subjects Rule (the "Common Rule") (EPA, 2001c).

[8]A chemical may cause a variety of toxic effects depending on the amount, duration, timing, and pattern of exposure (i.e., continuous, periodic, or intermittent). These effects may range from severe—such as death—to more subtle biochemical, physiological, or pathological changes in one or more organ systems. In addition, the effects will vary depending on their latency following exposure and when the observations are made. Primary attention is given in risk assessment to those effects in the lower exposure range and/or the effects most biologically appropriate for a human health risk assessment.

- Do effects fit with what is known about mode of action?

- Is the dose-response curve for precursor events consistent with the dose-response curve for clinical effects?

- Are the results of the study biologically plausible?

- What uncertainties exist? Do the results of the study indicate the need for follow-up studies to reduce uncertainties?

- Are the study conclusions supported by the data?

Human studies:

- What were the data sources for exposure, health status, and risk factors (e.g., questionnaires, biological measurements, exposure/work history record reviews, or exposure/disease registries) and what were their strengths and limitations?

- What methods were used to control, measure, or reduce various forms of error (e.g., misclassification or interviewer bias, confounding factors and potential effect modifiers) and their potential impact on the findings? What is the validity (accuracy) and reliability (reproducibility) of the methods used to determine exposure and outcome? What were the response rates?

- What major demographic and other personal factors were examined (e.g., age, sex, ethnic group, socioeconomic status, smoking status, and occupational exposure)? What other climate or life stage factors were important for the endpoints and exposures assessed?

- Were the findings examined for biologic plausibility, internal and external consistency of the findings, and the influence of limitations of the design, data sources, and analytic methods?

Animal studies:

- Was the study sufficiently documented (e.g., conducted in accordance with good laboratory practices)?

- Were appropriate analytical techniques used to measure the stability, homogeneity, and actual level of the test substance in the study (in the water, feed, air, etc.)?

- Was an appropriate animal species used?[9] Was an appropriate number of animals used? Were sex and age considered?

- Were the dose levels appropriate? What was the basis for choosing the dose levels?

- Was an appropriate method used to assign the animals to dose groups?

- Was an appropriate route and matrix of exposure employed?[10]

- Was the duration of exposure adequate for the particular study design?

- Were possible alterations in metabolism considered at the higher exposure levels?

---

[9]The laboratory animals used most often are the rat, mouse, rabbit, guinea pig, hamster, dog, or monkey. When reviewing these studies, the risk assessor makes judgments about the ability of the study to predict the potential for toxicity in humans and tries to select data from the species that is most relevant to humans using the most defensible biological rationale. When available, comparative toxicokinetics can be used to support this decision. Absent a clearly most-relevant species, the most sensitive mammalian species is used, that is, the species that shows toxicity at the lowest exposure level.

[10]The most appropriate route of exposure is the route for which an evaluation is to be made. The toxicity of the chemical may differ with route of exposure because of differences in mechanism of action or toxicokinetics (absorption, distribution, metabolism, and excretion). Development of data to establish dosimetry for the purpose of route-to-route extrapolation is encouraged; however, route-to-route extrapolation is inappropriate when based exclusively upon default assumptions regarding exposure and toxicokinetics. Even within the same route of exposure, responses may differ due to alterations in toxicokinetics, for example, dietary or water exposure versus oral gavage.

Professional judgment is required to decide, on the basis of a thorough review of all available data and studies, whether any observed effect is adverse and how the results fit with what is known about the underlying mode of action. These judgments require the input of experts trained in toxicology, statistics, and epidemiology and, often, of specialists in the structure and function of the target organ systems. Both the biological and the statistical significance of the effects are considered when making these judgments. Biological significance is the determination that the observed effect (a biochemical change, a functional impairment, or a pathological lesion) is likely to impair the performance or reduce the ability of an individual to function or to respond to additional challenge from the agent. Biological significance is also attributed to effects that are consistent with steps in a known mode of action. Statistical significance quantifies the likelihood that the observed effect is not due to chance alone. Precedence is given to biological significance, and a statistically significant change that lacks biological significance is not considered an adverse response.

For many discrete or quantal endpoints (e.g., birth defects, tumors, or some discrete pathological changes), this judgment is more straightforward because criteria have been established for deciding what type and incidence of effects are to be considered to be adverse, and an increase above the background rate can be judged using statistical tools. In the case of continuous measures (e.g., body weight, enzyme changes, physiological measures), this tends to be more difficult, because the amount of change to be considered adverse has not been defined by toxicologists or health scientists. Consequently, the endpoint is often decided in the context of the endpoint itself, the study, and the relationship of changes in that endpoint to other effects of the agent.

Decisions about the amount of change to consider adverse must always be made using professional judgment and must be viewed in light of all the data available on the endpoint of concern. All toxicological data on a chemical must be reviewed before deciding whether an effect is biologically significant and adverse. Using a default cutoff value to define adversity for continuous measures may result in an inappropriate interpretation of data and less than optimum evaluation of a chemical's effects.

4.3.2. Issues to be Considered in Characterizing the Database for Risk Assessment

4.3.2.1. *The Weight-of-Evidence Approach*

A weight-of-evidence approach such as that provided in EPA's RfC Methodology (U.S. EPA, 1994) or in EPA's proposed guidelines for carcinogen risk assessment (U.S. EPA, 1999a) should be used in assessing the database for an agent. This approach requires a critical

evaluation of the entire body of available data for consistency and biological plausibility. Potentially relevant studies should be judged for quality and studies of high quality given much more weight than those of lower quality. When both epidemiological and experimental data are available, similarity of effects between humans and animals is given more weight. If the mechanism or mode of action is well characterized, this information is used in the interpretation of observed effects in either human or animal studies. Weight of evidence is not to be interpreted as simply tallying the number of positive and negative studies, nor does it imply an averaging of the doses or exposures identified in individual studies that may be suitable as PODs for risk assessment. The study or studies used for the POD are identified by an informed and expert evaluation of all the available evidence.

4.3.2.2. *Use of Human and Animal Data in Risk Assessment*

Adequate human data are the most relevant for assessing risks to humans. When sufficient human data are available to describe the exposure-response relationship for an adverse outcome(s) that is judged to be the most sensitive effect(s), reference values should be based on human data. Much more data on a wide range of endpoints typically are required to establish confidence that there are no effects of exposure. If sufficient human data are not available to provide the basis for reference values, data from animal studies must be employed. It is advantageous if some human data are available to compare with effects observed in animals, even if the human data are not adequate for quantitative analysis. Availability of data on effects in humans at least allows qualitative comparison with effects observed in animals for determining whether toxicity occurs in the same organ systems and whether the nature of the effects is similar or different. If no human data are available, reliance must be exclusively on animal data. In that case, attention should be paid to whether data are available in more than one species and, if so, whether the same or similar effects occur in different species and possible sources of any observed differences.

One of the major default assumptions in EPA's risk assessment guidelines is that animal data are relevant for humans (e.g., U.S. EPA, 1991, 1996, 1998c). Such defaults are intended to be used in the absence of experimental data that can provide direct information on the relevance of animal data.

Several types of information should be considered when determining the relevance or nonrelevance of effects observed in animal models for humans. This information is used in a variety of ways, from determining the role of metabolism in toxicity (Is the parent chemical or a metabolite responsible for toxicity?), to assessing whether homologous activity would be

expected across species (Do humans share the sensitivity of the animal model, or is the response due to some species-specific idiosyncratic reaction?), to determining whether or not a threshold is likely to exist for the response (Are repair mechanisms capable of maintaining a homeostatic process?). All of this information must be weighed in light of the known heterogeneity of the human population versus the relatively inbred status of laboratory animals used in toxicity testing studies and housed under carefully controlled environmental conditions.

Table 4-1 presents several factors to consider when evaluating the weight of evidence about the likelihood of the occurrence of effects in humans that is based on animal data (in conjunction with human data, if available). The table is not necessarily intended to delineate all factors that may need to be considered, but rather to provide a framework for evaluation and interpretation. It is important to evaluate the database in a holistic manner, determining strengths and weaknesses that are relevant to the overall assessment. Each chemical and database presents a unique set of issues that must be evaluated critically and thoughtfully.

The dose-response nature of the data is an important characteristic of the database or individual study. When data are **dose related**, that is, when the incidence and/or intensity of response changes in an orderly manner as a function of dose, the effect should be considered to be of greater importance than when there is no apparent association between exposure and toxicity. Note, however, that the dose-response relationship need not be monotonic. U-shaped (or inverted U-shaped) dose-response functions are not uncommon in toxicology. For example, a chemical may induce an enzyme at low doses and inhibit it at high doses. Similarly, many solvent-like chemicals (including alcohol) produce increased motor activity at lower doses and depressed activity at high doses.

Similarly, comparative **toxicokinetic/metabolism** data that suggest qualitative and quantitative comparability to that in humans would support the relevancy of animal data. Evidence suggesting a difference in toxicokinetics/metabolism would require additional exploration regarding whether the difference(s) results in a major qualitative or quantitative difference in internal dose in humans.

The **similarity of effects** between species is also an important aspect in characterizing the database. Similar effects in more than one species indicate that the effect provides increased weight of evidence for the risk assessment process, even if such data are not available in humans. In contrast, response data that show inconsistency of effects among studies and/or species that cannot be explained by differences in toxicokinetics/metabolism or timing and/or magnitude of exposure, may suggest that less emphasis be placed on the effect. “Similarity” does not necessarily require identical effects between species. For example, changes in motor activity in

Table 4-1. Factors for evaluation of the weight of evidence regarding the likelihood of effects in humans

Factor	Increased weight	Decreased weight
Dose-response relationship	Orderly change in effect as a function of exposure (need not be monotonic)	No identified relationship between exposure and magnitude of effect
Toxicokinetics/ metabolism	Qualitative and quantitative comparability between humans and animals	Qualitative and quantitative differences between humans and animals
Similarity of effects	Similar effects in more than one animal species or in animals and humans	Inconsistency of effects among studies and/or species that cannot be explained by differences in timing and/or magnitude of exposure or toxicokinetics/metabolism
Mode of action	Demonstration of homologous mode of action in animal model and humans	Evidence suggesting that the mode of action is species specific and irrelevant to humans
Temporal relationship	Consistent temporal relationship between exposure and effect	Lack of temporality between exposure and effect

animals evaluated in the neurotoxicity screening test and cognitive effects in humans would generally be considered similar, because both are indicative of changes in nervous system function.

Mode of action information is also important in understanding whether a particular effect may be important for humans. For example, a transient reduction in anogenital distance in the postnatal animal following perinatal exposure to an anti-androgen has increased weight if the chemical is also known to act as an anti-androgen in humans. Likewise, the interpretation of increased skeletal variants observed following exposure to many chemicals would be enhanced by data indicating that the mechanistic pathways for these agents and the overall biological significance defined were also a possibility in humans. Mode of action data are also important in determining whether various chemicals work by common modes or mechanisms of action, which would then be considered in a cumulative risk assessment.

Another criterion that is important in evaluating data is the **temporal relationship** between exposure and effect. The exposure should precede the effect at an interval that is consistent with what is known about the toxicokinetics and mode of action of the agent. It may be the case, however, that higher doses produce a shorter latency to effect than do lower doses.

4.3.2.3. *Characterization of Effects in Potentially Susceptible Subpopulations*

A dose-response analysis for potentially susceptible subpopulations should be done as part of the overall dose-response analysis for health effects in general. "Susceptible" in this context means a differential (greater) response at the same internal dose in a particular segment of the population due to intrinsic (possibly unknown) factors. "Susceptible subpopulations" is used here to refer both to life stages and to other factors that may predispose individuals to greater response to an exposure. Life stages may include the developing individual before and after birth up to maturity (e.g., embryo, fetus, young child, adolescent), adults, or aging individuals. Other susceptible subpopulations may include people with specific genetic polymorphisms that render them more vulnerable to a specific agent or people with specific diseases or pre-existing conditions (e.g., asthmatics). The term may also refer to gender differences, lifestyle choices, or nutritional state.

It is important to recognize that little basis currently exists for a priori identification of susceptible subpopulations for many chemicals. Without other data to raise suspicions, only the evaluation of effects in various segments of the population such as those mentioned above can identify susceptible subpopulations for a particular chemical and a particular set of exposure conditions. In some situations, differential exposure rather than differential susceptibility per se may be the critical issue (e.g., hand-to-mouth activity in toddlers). Economic differences may also result in differential exposure and susceptibility.

A great deal of attention has been given in recent years to the issue of children as a susceptible subpopulation. Several approaches have been proposed for characterizing the database concerning the potential pre- and postnatal toxicity of a particular chemical and providing some guidance as to the weight of evidence or degree of concern for children's health. However, each approach has been developed for a slightly different purpose and, as such, is generally complementary to, but not the same as, the other approaches.

EPA's developmental toxicity (U.S. EPA, 1991) and reproductive toxicity (U.S. EPA, 1996) risk assessment guidelines describe an approach that characterizes the database as sufficient or insufficient to judge whether a chemical does or does not pose a hazard within the context of dose, route, duration, and timing of exposure. The International Programme on Chemical Safety (IPCS) (IPCS, 1995) proposed an approach based on the quality of information gathered in developmental and reproductive toxicity studies and the types of data that were not available from these studies. EPA's draft 10X toxicology report (U.S. EPA, 1999b) further extended the recommendations for characterizing risks to children's health within the context of the FQPA by discussing issues that would increase or decrease the level of concern.

The present report endorses and extends the recommendations of the 10X Toxicology Working Group's report by incorporating the issues dealing with level of concern into a framework for evaluating the evidence regarding the identification and characterization of susceptible subpopulations (see below). A workshop was held recently to discuss aspects of a framework for children's health risk assessment and to emphasize a broader perspective on the issues that should be considered in hazard characterization, dose-response assessment, exposure assessment, and risk characterization for children as a susceptible subpopulation (ILSI RSI, 2001).

In contrast with the attention paid to children and asthmatics as potentially susceptible subpopulations in recent years, little attention has been focused on risk assessment for other potentially susceptible subgroups. As outlined in Chapter 3, there currently are no requirements in EPA animal study protocols for exposure during old age or for outcome evaluations near the end of the life span following earlier life stage exposures. Similarly, healthy animals that are more genetically homogeneous than humans are used in standard toxicity testing protocols, and information on pre-existing conditions or genetic polymorphisms is largely unavailable from animal studies.

Human studies also usually employ healthy nonelderly individuals, although some studies in more susceptible populations have been conducted, such as studies of the effects of air pollutants in asthmatics. Individuals who have identified risk factors that are not the focus of a study are usually excluded from the study sample. It is important to consider such characteristics of the database if human data are used as the basis for the risk assessment.

As can be seen in Table 4-2, several issues must be considered in assessing the potential for some subpopulations, including different life stages, to have greater susceptibility than others to a chemical. These include the **timing (life stage)-response relationship,** indicating greater susceptibility to exposure at some life stages than at others; whether effects are of a **different type** in identifiable subgroups of the population; and the **dose-response relationship**, that is, whether effects are observed at different levels of exposure in different subpopulations.

Another important consideration is whether effects are observed at the same dose but with a shorter **latency** in different subpopulations. Additionally, differences among groups in terms of the **seriousness** and **reversibility of effects** must be considered. For example, an agent may produce relatively mild and reversible neurological effects in adults but produce permanent behavioral impairment following in utero exposure. It is also important to keep in mind that effects that may initially appear to be reversible may re-appear later or be predictive of later adverse outcomes. This is probably best exemplified by certain outcomes following a

Table 4-2. Factors for evaluating evidence regarding identification and characterization of susceptible subpopulations[a]

Factor	Increased weight	Decreased weight
Timing (life stage) - response relationship	Effects occur at greater magnitude at one or more life stage(s)	No difference in effects at different life stage(s)
Type of effect	Different types of effects in specific subpopulations	Same effect(s) across all potential subpopulations
Dose-response relationship	Effect occurs at lower exposures in one or more subpopulation(s)	No evidence for differential dose-response across different subpopulations
Latency of effect	Latency to observed effect different in specific subpopulations	No difference between subpopulations in latency to effect
Seriousness/ reversibility of effects	Effects different in seriousness or degree of reversibility in specific subpopulations and/or differences in later consequence of an initially reversible effect	No differences between subpopulations in seriousness and/or reversibility of effects, or in later consequences of an initially reversible effect

[a] Subpopulations may be defined by gender, individuals at different life stages (fetus, child, adult, elderly), differences in genetic polymorphisms, and/or pre-existing diseases or conditions that may result in differential sensitivity to adverse effects from exposure to a specific toxic agent.

developmental exposure; for example, an initial depression in birth weight or weight gain or subtle developmental retardation may be indicators of more serious abnormalities later in life.

4.3.3. Characterization of the Extent of the Database

The derivation of an RfD or an RfC is a multifaceted process that involves the coordination of data gathering and evaluation, analysis and judgment in varying proportions, and integration of all the information available. A vital part of the chronic RfD and RfC derivation process that relies heavily on judgment, for example, is the current approach to characterizing the database. For example, the minimum dataset for low-confidence and high-confidence RfDs and RfCs has been specifically defined as follows (U.S. EPA, 1994, 2002c): *minimum dataset for a low confidence chronic RfD or RfC* is a single subchronic study. The *minimum dataset for*

a high confidence chronic RfD or RfC is a chronic study in two species, a single two-generation reproductive toxicity study, and a developmental toxicity study in two species by the appropriate route of exposure.

The Technical Panel is recommending a somewhat different approach. Instead of specifying particular studies, this approach emphasizes the types of data needed (in terms of both human and animal data) for deriving reference values and recommends the use of a narrative description of the extent of the database rather than a single confidence statement. The Technical Panel believes that this approach encourages the use of a wider range of information in deriving reference values that take into consideration the issues of duration and route of exposure, the timing of exposures, the types and extent of endpoint assessment (i.e., structural and function), the susceptible subpopulations evaluated, and the potential for latent effects and/or reversibility of effects. In addition, this approach encourages the identification of data that would be needed or useful for improving the risk assessment for a particular chemical or group of chemicals.

To characterize the database, the Technical Panel has developed a description of a "minimal" database and a "robust" database as a way of describing the range of data that can be used for deriving a reference value (Box 4-3). A great deal of scientific judgment is necessary when evaluating the extent of the database for a particular chemical. Defining the extent of the database requires an overall evaluation and judgment as to where in the minimal–robust continuum the available database should be characterized. The Technical Panel purposely did not define additional categories between minimal and robust (moderate), and the Panel has serious concerns about developing such categories because of the tendency to try to characterize a database with single word descriptors. Instead, we strongly support a narrative description of the extent of the database, with emphasis on the strengths and limitations of the data. It should also be noted that a database that is less than minimal should not be used to derive a reference value.

Rather than presenting separate "minimal" and "robust" database descriptions for each type of reference value that might be derived, the descriptions in Box 4-3 are intended to apply generally across the various reference value types (e.g., acute, short-term, longer-term , or chronic durations for oral, dermal, or inhalation routes of exposure). Additionally, it is expected that the different types of reference values for a particular chemical will be developed within the same assessment. In this manner, the entire database for a chemical may be relied upon in the development of each of the different values (e.g., important and relevant insights may be gleaned

from toxicity studies for exposure durations other than those directly corresponding to the type of reference value being developed).

A minimal database as defined above can be used to set reference values, but the limitations of such a database should be clearly recognized and discussed in the narrative description. For example, a minimal database may provide data on only one duration or route of exposure or it may be specific to only one endpoint or organ system. Thus, the uncertainties related to such a database will be great and should be reflected in the size of the UFs applied for reference value derivation (see further discussion below).

Box 4-3. Description of minimal and robust databases

Minimal Database: no human data available, route-specific toxicity data are limited to dose-response data applicable to the duration in question with assessment of endpoints other than mortality. A study showing only effect levels for mortality or other extremely severe toxicity would not be sufficient to set a reference value.

Robust Database: includes extensive human and/or animal toxicology data that cover route-specific information on many health endpoints, durations of exposure, timing of exposure, life stages and susceptible subpopulations. In the absence of complete human data, mechanistic and other data show the relevance of the animal data for predicting human response. Specifically, the dose-response data for the reference value in question includes endpoint-specific data (e.g., developmental toxicity, neurotoxicity) coupled with toxicokinetic information as needed for route-to-route extrapolation. The toxicity studies include the evaluation of a variety of endpoints (e.g., hematological, clinical, histology of target organs) and endpoints specific to any known hazard characterization. The database for a reference value of less-than-chronic duration has also addressed the issue of reversibility of effects and latency to response, taking into consideration the possibility that less-than-chronic exposure may lead to effects at some period of time after exposure. Biological and chemical characteristics of the exposure and outcomes, as well as known limits on reserve capacities and repair of damage, form the basis for determining the appropriate length of follow-up.

On the other hand, a robust database would address issues of potential toxicity in humans and animals and include data on several durations and routes of exposure as well as a thorough assessment of a variety of health endpoints. It would also include sufficient data on toxicokinetics and mode action to provide extensive information for extrapolation of effects to humans, including potentially susceptible subpopulations. A complete database on a single health endpoint that does not contain information on other endpoints of possible relevancy would not necessarily constitute a robust database, nor would a database that provides complete information on one route and/or duration of exposure be considered robust.

It is clear that a robust database represents a “gold standard” that will rarely, if ever, be available. However, a lack of robustness does not mean that the database is deficient to the extent that a reference value could not be derived or that large UFs would need to be applied. Sound scientific judgement will be required to determine which UFs are appropriate in each case.

A critical assessment of the extent and quality of the database will inform the selection of the endpoints to be used to derive the reference values and the appropriate UFs. A reference value based on a single study would likely have a high degree of uncertainty. As more information from additional toxicology studies, toxicokinetic studies, structure-activity relationships, and human data becomes available, EPA can have greater assurance that the appropriate species, route of exposure, and target organ system(s) are known for each duration reference value needed for a human health risk assessment. As this additional information becomes available, the use of UFs will likely decrease. The ultimate objective is to account for all human health endpoints resulting from exposures over all life stages from before conception to the elderly adult.

The optimum assessment considers subtle effects that impact an individual's quality of life as well as so-called "frank" effects (death and major disease). The evaluation should encompass immediate health outcomes as well delayed responses to an exposure (i.e., latent responses), although most current testing guidelines do not explicitly evaluate latency to response.

4.3.3.1. *Extent of the Database*

The following series of questions regarding the extent of the database can help guide the assessment process:

- Have adequate studies been conducted to establish the target organs/endpoints?
- Have the effects been characterized for both sexes and all life stages?
- Are data pertaining to potentially susceptible subpopulations available?
- Are the responses consistent across species? Are the results of the studies biologically plausible?
- Is the route and matrix of exposure relevant to the specific reference value being derived?
- Is the duration of exposure appropriate for the specific reference value being derived?

- Is the animal species and strain appropriate for extrapolation to humans?

- To what degree may the biological endpoints be extrapolated (qualitatively and quantitatively) to humans?

- Are toxicokinetic data available? Are they available for both sexes, for relevant life stages, for other susceptible subpopulations?

- Is the shape of the dose-response curve consistent with the known toxicokinetics of the test compound?

- Are the metabolism and toxicokinetics in the animal species similar to those of humans?

- Has the dose-response curve been replicated by or is it consistent with data from other laboratories and other test species?

- Have the data for all relevant endpoints been adequately modeled by the BMD or other appropriate quantitative analysis to determine the most sensitive endpoint(s)?

- How well is the toxicity characterized? Do the results of all the studies indicate the possibility of effects on particular systems that have not yet been explored sufficiently or do they indicate that additional studies may reveal effects not yet characterized?

4.4. DERIVATION OF REFERENCE VALUES

After the database has been thoroughly evaluated for quality and extent, as outlined above, several decisions must be made and procedures applied before the final derivation of a reference value. This section summarizes the current procedures and points out assumptions made and areas for improvement and clarification. A variety of factors related to the derivation of reference values is discussed, including the selection of relevant endpoints for the POD for various duration reference values (Section 4.4.1). Adjustment of the study dose/exposure for duration is described in Section 4.4.2, and derivation of a HED or HEC is discussed in Section 4.4.3.

Other issues are discussed briefly in Section 4.4.4, such as varying levels of response at the BMDL, BMCL (lower confidence limit on the BMC), or NOAEL due to varying study designs and test sensitivity and considerations of adversity and severity (i.e., nature of the response) for choosing the benchmark response (BMR) level. The nature and application of uncertainty/variability factors and MFs are discussed and critiqued in Section 4.4.5, and future directions are briefly discussed in Section 4.4.6. Section 4.4.7 summarizes key points from two case studies that are presented in detail in Appendix B.

4.4.1. Sample Reference Values and Selection of Endpoints to Use as the POD for Reference Values

Currently, the "critical effect" is used as the basis for the POD, and various UFs are applied to the dose at the critical effect to derive the RfD or the RfC. The critical effect is defined as "the first adverse effect, or its known precursor, that occurs to the most sensitive species as the dose rate of an agent increases" (U.S. EPA, 2002c). The underlying assumption is that if the RfD or the RfC is derived to prevent the critical effect from occurring, then no other effects of concern will occur; in addition, this approach assumes that the relationship of various health effects for a particular chemical is maintained across species.

The Technical Panel is concerned that presenting only a single critical effect and the critical study from which it was derived in the IRIS summary table that appears at the beginning of each RfD or RfC file may not provide enough information to the reader who is unfamiliar with risk assessment and thus could be misleading. Presenting a single endpoint as a POD for a systemic effect, for example, cannot capture the nature of the dose-response curve for that particular endpoint, nor does it convey the possibility that other more serious endpoints may have a dose-response character markedly different from the less serious endpoint. For example, an agent may have a clear progression of responses with increasing dose that is seen as one type of effect at the lowest exposure level (e.g., proteinuria in the case of cadmium), but at a higher level it produces additional effects (proteinuria PLUS GFR decrements) and at the highest level even more types of effects (proteinuria PLUS GFR decrements PLUS osteomalacia). Each of these effects could have a markedly different dose-response character.

Focusing on a single critical effect also does not reflect the situation in which other types of effects may be found at similar levels of exposure or the variety of health outcomes that may result when an exposure significantly exceeds the RfD or the RfC. Most importantly, in light of the Technical Panel's recommendations for deriving an expanded number of reference values for different durations and routes of exposure, the limitations of focusing only on the critical effect

become apparent because the most sensitive endpoint may be different for different durations or routes of exposure.

Layered upon this complex consideration of dose-response is the further complication that all of the exposure levels producing these effects are or should be adjusted to a human equivalent exposure at the time of their comparison. These adjustments may profoundly affect what is considered the most sensitive organ or system. Effects that occur at the same external inhaled concentration but in different organs in the same exposed animals (e.g., effects in the liver and the nasal cavity) may have quite different HECs, based on the current RfC methodology (U.S. EPA, 1994), because the underlying basis for the adjustment used for systemic effects is markedly different from that used for portal-of-entry effects between animals and humans. This adjustment procedure is discussed further below but is noted here because of its interrelationship with identifying what is to be considered a critical effect.

These aspects all support the case that a more comprehensive approach to setting reference values requires a more extensive and systematic analysis of endpoints than has typically been conducted in the past. In the approach proposed here, the selection of the POD would be similar to the current critical effect approach (e.g., U.S. EPA, 1994) and would include the use of sound scientific judgment in evaluating the strength and validity of studies and the extent of the database, as described in Section 4.3. In this approach, however, the selection of the POD would be based on consideration of all relevant and appropriate endpoints carried through the derivation of sample reference values, with selection of the limiting value(s) protective of all endpoints as the final step (the same approach would be used for deriving a POD for low-dose modeling, as discussed in the proposed cancer risk assessment guidelines [U.S. EPA, 1999a]).

For example, the dose-response curves would be modeled for several adverse endpoints and the corresponding BMDs and BMCs and their lower 95% confidence limits (BMDLs/BMCLs) calculated (U.S. EPA, 2000c) or NOAELs determined if dose-response modeling is not possible. Next, duration adjustment to the continuous exposure scenario would be performed for each endpoint, with further adjustment to the corresponding HECs using the RfC methodology (U.S. EPA, 1994) or adjusted BMDLs or NOAELs for oral or dermal exposures (see Section 4.4.3 for further discussion). These adjusted values would represent the POD for each relevant endpoint. Then, uncertainty/variability factors that take into account a variety of issues, including chemical-specific data, such as known toxicokinetic differences between the laboratory animal species tested and humans, and mode of action information would be applied to the adjusted values for each relevant endpoint. The sample reference values would

then be compared across endpoints and organ systems to determine which are the most relevant for use in deriving the final reference value for each exposure duration that will be protective of the human population (including susceptible subgroups).

The Technical Panel recommends the use of a more visual and graphic exposure-response array to depict the PODs for all relevant endpoints for various routes and durations of exposure, somewhat like those shown in the ATSDR toxicology profiles but with appropriate changes for the purpose of deriving reference values. The exposure-response array of the PODs would facilitate the evaluation and comparison of relevant endpoints and values. (See examples of the proposed approach discussed in Section 4.4.7 and in two case studies in Appendix B.)

4.4.2. Dose Adjustment for Duration of Exposure

Available studies from which reference values are derived seldom if ever match the intent of the reference value regarding species or duration. For example, chronic RfD and RfC values are intended by definition to be for "a continuous exposure to the... human population." Doses or exposures from studies in which animals are exposed for less than a lifetime or in which worker populations are exposed only during working hours require adjustment to continuous exposure in order to be concordant with the intended duration of the reference value (see Rozman and Doull, 2000; Rozman et al., 2001, for further discussion). This section describes various procedures that are currently used by the Agency to adjust a LOAEL, a NOAEL, or a BMDL with regard to duration. The basis for these adjustments is discussed, as is the applicability of these procedures to various routes of exposure.

The Agency has invested considerable time and effort into exploring these aspects for the inhalation route. A major point that will become apparent in this discussion is that methodologies for duration adjustment via the inhalation route are currently in place as part of the existing methodology for the chronic RfC and as proposed for ARE derivations, whereas no comparable documents yet exist for the oral or dermal routes of exposure.

4.4.2.1. *Duration Adjustment Procedures for Inhalation Exposures to Continuous-Exposure Scenarios*

Adjustment of duration to a continuous exposure scenario is regularly applied as a default procedure to studies with repeated exposures but not to single-exposure inhalation toxicity studies in animals and humans (U.S. EPA, 1994). Operationally, this is accomplished by

applying a C^n x t product[11] for both the number of hours in a daily exposure period and the number of days per week that the exposures are performed. In an inhalation study in which animals are exposed to 100 mg/m^3 for 6 hours, 5 days per week, the adjustment to a continuous exposure concentration would consider both hours per day and days per week:

$$100 \text{ mg/m}^3 \times 6/24 \text{ hrs x } 5/7 \text{ days/wk} = 17.9 \text{ mg/m}^3,$$

with 17.9 mg/m^3 being the concentration adjusted for continuous exposure. Study designs that include exposures 7 days/wk, for example, prenatal developmental toxicity studies and DNT studies, do not require the 5/7 days/wk adjustment.

Exposures from human occupational studies are most often reported as 8-hr time-weighted averages (TWAs) and are therefore also discontinuous. Adjustment of these exposures to derive a HEC is explained below in Section 4.4.3.

These adjustment procedures imply that the C × t product and not C is associated with the endpoints observed; this may be restated as implying that the area under the curve (AUC), C × t, rather than the peak concentration, C, is the dosimeter associated with toxicity. Although neither of these dosimeters may be demonstrable experimentally to be the appropriate measure of dose, the Agency uses adjustment to a continuous inhalation exposure based on the C × t relationship as a matter of policy.

When applied to a discontinuous inhalation exposure regimen from an experimental study, adjustment to a continuous exposure will always result in a lower value of C and maintain a measure of total exposure, that is, C × t. Thus, application of this procedure provides an automatic margin of protectiveness for chemicals for which C alone may be appropriate, and it reflects the maximum dose for agents for which total or cumulative dose is the appropriate measure. When considered in this way, this policy can be regarded as being protective of public health. However, assessors are encouraged to look for data on specific chemicals that support the use of C x t or that offer alternative models for adjustment of exposure duration.

4.4.2.2. *Duration Adjustment for Inhalation Developmental Toxicity Studies—A Current Exception*

A notable exception to duration adjustment of inhalation exposures is for inhalation developmental toxicity studies in which this practice historically has not been done. The current

[11]Where $C^n = C^1$, as described in Section 4.4.2.3.

guidelines for developmental toxicity risk assessment (U.S. EPA, 1991) recommend against duration adjustment (i.e., from a discontinuous to a continuous exposure) as a default procedure unless toxicokinetic data are available to indicate an accumulation with continuous exposure. This is contrary to the default approach used for other types of studies in which duration adjustment is done without a requirement for toxicokinetic information. In fact, for other types of studies, toxicokinetic information is often used as the basis for moving away from the default adjustment.

Furthermore, although the effects of some agents that cause developmental toxicity have been shown to be more a function of peak concentration (Nau, 1991), the effects of other agents have been shown to be related to either AUC or C, depending on the timing of exposure and the developmental timing of the organ system affected (Terry et al., 1994). In addition, recent studies have shown that the developmental effects of certain agents that have a short half-life, such as all-trans-retinoic acid (Tzimas et al., 1997) and ethylene oxide (Weller et al.,1999), or a very discrete exposure period, for example, hyperthermia (Kimmel et al., 2002), are a function of AUC.

On the basis of this information and the rationale used for duration adjustment for other health effects (i.e., that exposure adjustment based on $C \times t$ tends to be more health protective), the Technical Panel recommends that duration adjustment procedures to continuous exposures based on $C \times t$ be used as a default procedure for inhalation developmental toxicity studies as it is for other health effects from inhalation exposure. The Technical Panel also urges continued development of data, modeling, and improved procedures for dose-duration adjustments related to developmental toxicity.

4.4.2.3. *Duration Adjustment for Acute Reference Values—Discontinuous Scenarios of 24 Hours or Less*

As discussed above, the magnitude of response to a toxic chemical exposure usually depends on both the concentration and the duration of the exposure, such that the combination of these components, $C \times t$, determines the response and, by logical extension, the internal dose of a chemical at the target tissue. In deriving acute, short-term, or longer-term reference values, there may be a need to specifically adjust or present these values under alternative $C \times t$ combinations. For example, an acute reference value may be required for both a 1-hour duration and an 8-hour duration, but the available data are from a 4-hour exposure. The current guidance on this issue is contained in the draft methodology for development of AREs (U.S. EPA, 1998a). This section presents the adjustment procedures recommended in the draft ARE methodology.

Because of the recognized limitations of the C x t model, a modification has been developed such that $C^n \times T = k$, with n being empirically derived. The consequences of varying the values of the "n" exponent are shown in Figure 4-1. This figure, which was derived from the

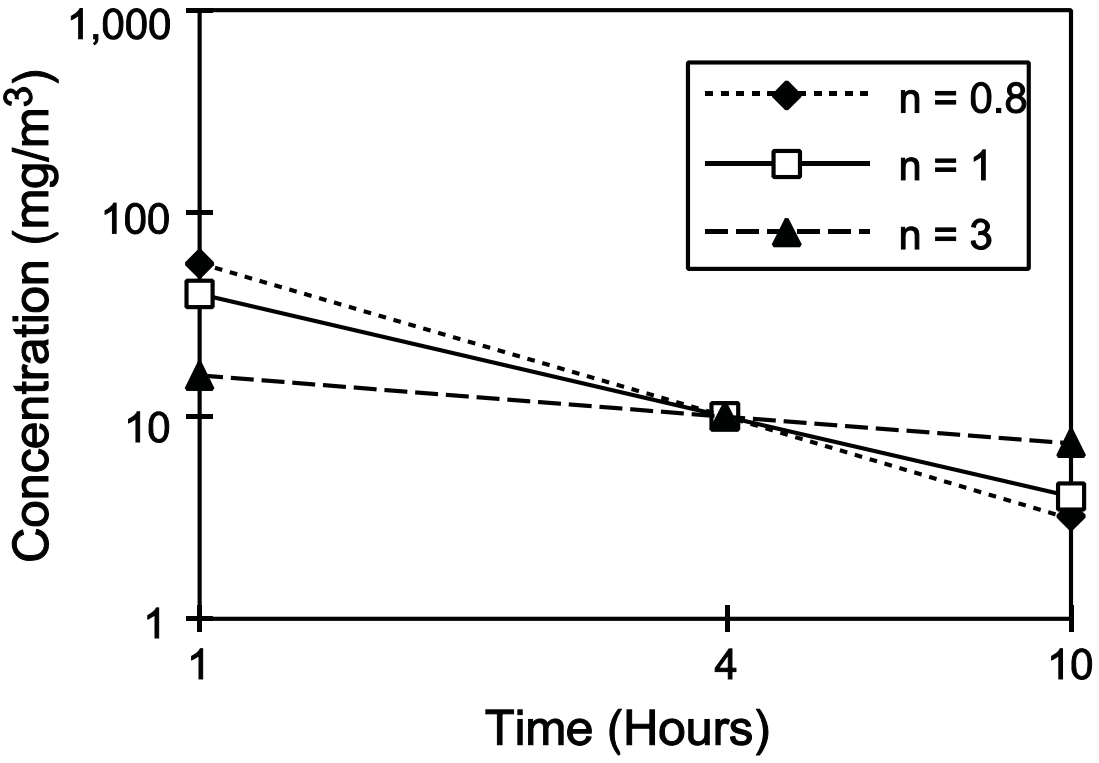


Figure 4-1. Concentration-by-duration plot showing the effect of the exponent in the C^n x T = k on extrapolation across time.

Source: Adapted from ten Berge et al., 1986.

current version of the Agency's ARE methodology, is based on the data of ten Berge et al. (1986). These investigators were able to empirically derive values of "n" that ranged from 0.8 to 3.5 for a number of chemicals on the basis of acute lethality. A value of 1 for the exponent "n" would indicate that the relationship described by Haber's law holds and that the response is related to total dose.

Note that for any degree of downward slope with increasing duration (lines marked with n = 1 or n = 0.8), an extrapolation from a longer to a shorter duration (i.e., from right to left) would result in a higher value for C. Extrapolating from a shorter to a longer duration (i.e., from left to right), however, would have a different consequence in that with any degree of downward slope, C would always be lower for the longer duration. Several possible approaches for extrapolation in this situation could be envisioned. One approach would be to assume a value of 1 for "n," such that $C^n \times T = k$ and lower values of C would always result; this approach is likely to be the actual case, because the value of "n" for most chemicals so far examined has shown an appreciable downward slope (e.g., $0.8 < n < 3.5$ [ten Berge et al., 1986]).

The optimal approach for extrapolating from one dose-duration response situation to another is the use of a physiologically based pharmacokinetic model (PBPK) model. The principle of using PBPK models as the basis for describing the correlations between level and duration of exposure, internal dose, and biological effect has been stated clearly by Andersen et al. (1987). Integration of information using PBPK models requires a chemical database that is rich in toxicity data; therefore, this approach is not applicable to most chemicals for which toxicokinetic data are scarce or nonexistent.

In the absence of such a database to support the development of a PBPK model, the approach recommended by the draft ARE methodology is the use of chemical-specific data on duration dependence from other adequate but longer-duration data, if they exist (e.g., in extrapolating to 28 days using 7-day data, the 90-day repeated-dose data should also be considered). This is considered a conservative approach, because the duration adjustment approach (i.e., averaging to continuous exposure), when applied to multiple exposure studies always results in decreased values for C (i.e., extrapolation would be from shorter to longer durations on the curves in Figure 4-1).

In the absence of chemical-specific data to inform duration adjustment, the response has most often been related to the simple $C \times t$ product. This is also the default in the draft ARE methodology for adjustment to longer durations. For adjustment to shorter durations, the ARE methodology conservatively recommends that there be no change in concentration.

Further investigation would increase confidence in the basic assumptions made for the latter two methods of duration adjustment, including the applicability of the C x t relationship over spans of exposure from months to years and assessing the "conservativeness" of these approaches in relation to public health. Further investigation of C x t relationships relative to life stage is also recognized as a research need.

4.4.3. Derivation of a HEC or a HED

Animal data often form the basis for dose-response assessment. By definition, the IRIS risk values are for humans, thereby making animal-to-human extrapolation requisite. The specific point of this extrapolation is to estimate from animal exposure information the human exposure scenario that would result in the same response. The simplest manner in which this may be done is application of an animal-to-human UF (discussed further below), typically with a value of 10; in application this means that humans are assumed to be more sensitive to effects than are animals by a factor of 10.

Much of the RfC methodology (U.S. EPA, 1994) focused on improving the science underlying the animal-to-human UF, segregating it into toxicokinetic and toxicodynamic components and providing generalized procedures to derive dosimetric adjustment factors (DAF). Application of DAFs to the animal airborne exposure values yields estimates of the concentration that would result in the same concentration to humans, that is, the HEC. Application of a DAF in the calculation of a HEC is considered to address the toxicokinetic aspects of the animal-to-human UF (i.e., to estimate from animal exposure information the human exposure scenario that would result in the same dose to a given target tissue).

Current Agency practice is to accommodate uncertainty about the remaining toxicodynamic component through application of a partial animal-to-human UF ($10^{0.5}$, which is typically rounded to 3). The theoretical basis for deriving DAFs used in calculating HECs, along with recommendations for improvement of this process, is discussed in this section.

Exposures from human occupational studies are most often reported as 8-hr TWAs for exposures during work days (5 days/wk). As with discontinuous exposures of animal studies (e.g., 6 hrs/day, 5 days/wk), exposures from occupational studies are also adjusted to derive continuous HECs relevant to the human population (U.S. EPA, 1994). As described below for animal data, the optimal approach is to use a biologically motivated mathematical, or PBPK, model. An occupational exposure can be extrapolated in the same fashion as intermittent exposure regimens from experimental laboratory animals, using particle deposition or PBPK models with human exertion (work) ventilation rates and exposure durations appropriate to the occupational setting.

In the event that a PBPK model or required physicochemical and physiological parameters are not available, the default approach for human exposure scenarios is to adjust by the default occupational ventilation rate and for the intermittent work week schedule. The ventilation rate adjustment is based on the assumed amount of air used by a worker during the work period, that is, half of the daily ventilatory capacity of an adult male human is assigned (10

m^3 of 20 m^3 total) to the 8-hour occupational exposure (i.e., instead of 1/3 or 8/24 hrs) (ICRP, 1994). By basing this adjustment on a functioning physiological parameter, that is, a fractional ventilatory capacity based on the assumption that activity levels are higher in this setting than in others, such as at rest or asleep, this adjustment may be considered to have a toxicokinetic basis. The 8-hour TWA concentrations are multiplied by this factor, 10/20 m^3, and the product is considered to be an average continuous airborne concentration.

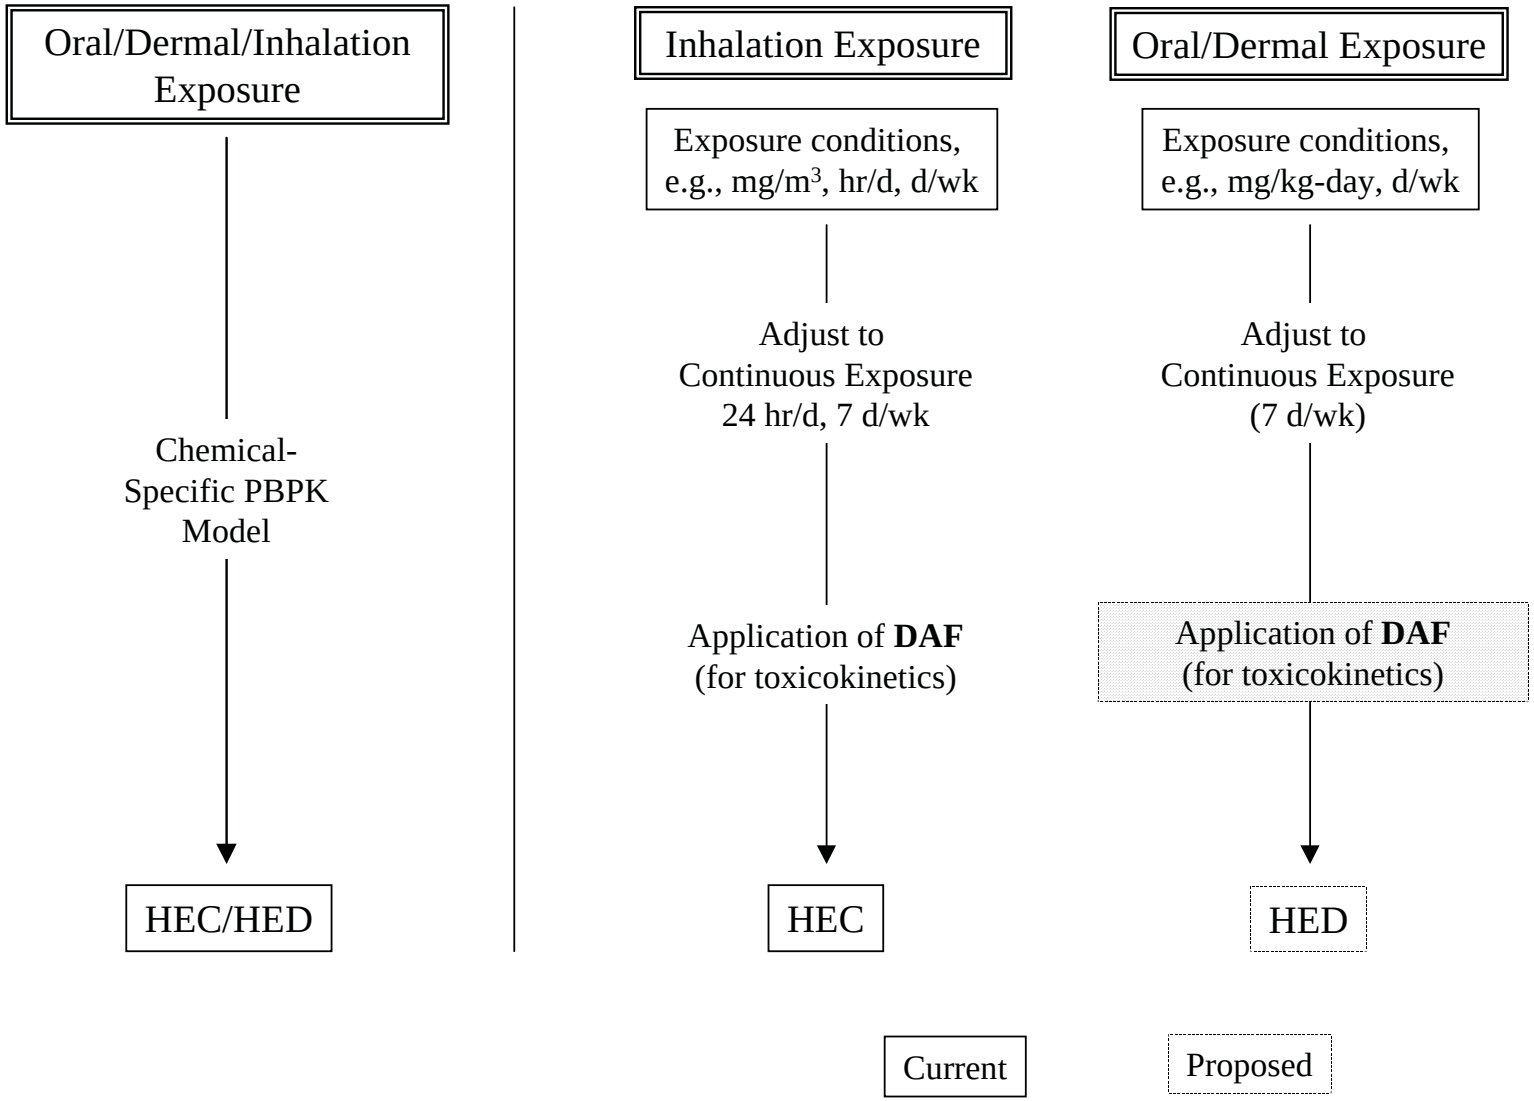
In parallel with the animal studies, an adjustment for days per week (usually 5/7 days/wk) is also made, if applicable. This adjusted airborne concentration is considered to be a HEC. This default calculation, as with those described below for extrapolation from animal data, was developed for the general human population. It may be appropriate to further evaluate this approach or to develop an alternate default approach to ensure adequate consideration of intrahuman variation.

Currently, no procedures parallel to the inhalation RfC methodology exist for deriving either oral or dermal human equivalents from animal data. Default factors (usually of 10) are routinely applied to address the issue of animal-to-human extrapolation. Thus, no parallel to the HEC, that is, a HED, is derived nor are other adjustments applied to the animal oral or dermal dose.

This section recommends that dose adjustments similar to those by which HECs are estimated be explored in deriving HEDs for oral and dermal exposures. This would be accomplished in a manner parallel to the HEC derivation, by instituting and applying a DAF to animal oral or dermal exposures. Specific recommendations are also presented and discussed concerning the basis for deriving DAFs for HED calculation. These recommendations, along with current procedures for estimating human equivalent values, are illustrated in Figure 4-2. This figure also demonstrates how calculation of the HEC through application of a DAF is considered to address the toxicokinetic but not the toxicodynamic component of the animal-to-human extrapolation. Procedures outlined in this figure for deriving a HEC may be applied to any animal inhalation exposure, regardless of whether it is a BMDL, a NOAEL, a LOAEL, or another effect level.

4.4.3.1. *PBPK Models and Derivation of HEDs and HECs: Estimating Internal Dose*

The preferred option for calculating a HED or a HEC is to use a chemical-specific PBPK model parameterized for the species and regions (e.g., respiratory tract) involved in the toxicity, as shown on the left-hand side in Figure 4-2. When sufficiently parameterized, a PBPK model is capable of calculating internal doses to a target organ from any exposure scenario in an animal



DAF = Dosimetric Adjustment Factor

Figure 4-2. Current and proposed generalized procedures for deriving HECs or HEDs from animal exposures.

and then estimating what human exposure would result in this same internal dose, that is, the HED or the HEC. A formal DAF is not calculated in this process; rather, the model itself serves as a DAF in estimating HECs or HEDs. However, constructing a PBPK model is an information-intensive process that requires much chemical-specific data, including route-specific data. Such sophisticated data and models are available usually for only a subset of chemicals that have extensive databases.

It should be noted that even these sophisticated models are often parameterized on the basis of adult members of the species. Many of the parameters critical to PBPK model solutions are sensitive to life stages, such as lung function/development in humans (Pinkerton and Joad, 2000), for which no or few data are available. Thus, these models are available but often cannot specifically address species differences at life stages other than mature adults (and then usually males). The Technical Panel encourages research and data gathering to support the construction of PBPK models, it endorses attempts to produce PBPK models that are sensitive to life stages, and it supports fully attempts to produce template models for suites of related chemicals, as has recently been done by Barton et al. (2000).

4.4.3.2. *Default Procedures and Derivation of HECs from the RfC Methodology: Derivation and Application of DAFs*

The next lower level of complexity in deriving HECs is less data intensive than the PBPK approach. As shown in Figure 4-2, this procedure involves the use of species-specific physiologic and anatomic factors relevant to the form of pollutant (e.g., particle or gas) and categorized with regard to elicitation of response either locally (i.e., within the respiratory tract) or remotely. These factors are all employed in determining the appropriate DAF. For HECs, DAFs are applied to the "duration-adjusted" concentration to which the animals were exposed (e.g., to a weekly average). The generalized DAF procedures may also employ chemical-specific parameters, such as mass transport coefficients, when available. In lieu of such data, however, default procedures that yield generalized adjustments are recommended. Although these generalized procedures were developed from the existing scientific understanding of the relevant processes, they have not been comprehensively evaluated (e.g., using data from humans and animals). They are explained fully in the RfC methodology (U.S. EPA, 1994).

For example, the manner in which a HEC is calculated for a reactive gas that elicits an effect in the extrathoracic region of the respiratory tract (i.e., the nasal tract) of a rat is by creating a surface area/ventilation ratio for both humans and rats and applying it to the external exposure concentration for rats. The current default values used for both the human and the rat

extrathoracic surface area are single estimates from the literature and are apparently estimated from adult specimens. The ventilation measure for humans is set at a default value of 20 m^3, and the ventilation measure for rats is based on an algorithm of body weight (from U.S. EPA, 1988).

A major assumption made in this particular adjustment is that the distribution of a gas in the region of interest is uniform, although it is known to be highly nonuniform (Kimbell et al., 1993, 1997). Data are not available to address this simplified assumption directly. Use of the method, for example on effects in the extrathoracic region, results in a DAF of about 0.2, such that the resultant HECs are about 20% of the animal-duration-adjusted concentration. Although information is not yet available to address this assumption, indications are that resolution with actual data may produce DAFs that are much closer to unity, that is, that are near the animal-adjusted concentration.

In comparison to the procedure for gases that elicit respiratory effects, calculation of a HEC for a category 3 gas (i.e., a gas that is relatively water-insoluble and unreactive in the respiratory tract and for which the site of toxicity is generally remote to the site of absorption in the pulmonary region) is usually accomplished by creating a ratio of the blood:gas partition coefficient for the laboratory animal species to the human value. The ratio is used as the DAF and applied to the experimental exposure concentration. In lieu of data on the values for blood:gas partition coefficients for the chemical or when the data indicate the ratio to be >1, the default assumption is that the ratio of animal coefficient to human coefficient is 1, and therefore the DAF would be 1. However, available data on partition coefficients for a number of compounds indicate that the animal/human ratio is usually >1 (Gargas et al., 1989; Jepson et al., 1994) such that the DAF would also be >1. In the context of substituting data-derived values for UFs, the Technical Panel recommends further investigation into using data-derived values in constructing the animal/human ratios—even when much greater than 1—in place of the default.

The default dosimetric adjustment procedure for particulate substances is an empirical model that estimates regional deposition only, although it is recognized that with the development of the relevant data, clearance and the retained dose may be used as a DAF (U.S. EPA, 1994). The DAF for particles is more specifically termed the regional deposited dose ratio and is derived from a normalizing factor (surface area being the recommended factor for all three regions of the respiratory tract), the ratio of animal-to-human minute volumes (where the human default value is the traditional adult value of 13.8 L vs. the adult value for the relevant animal), and the ratio of animal-to-human regional fractional deposition. Physiological parameters used in estimating the regional deposition include body weight, minute volume, and surface area for the three areas of the respiratory tract. Defaults for the human values are based on adult data

(e.g., 70 kg body weight, 13.8 L minute ventilatory volume, etc); the animal values are also traditionally based on adult data. To evaluate protectiveness of these default calculations for different life stages, it may be appropriate to perform ratio calculations using data for other life stages.

As a general recommendation, the Technical Panel encourages further consideration of the existing animal-to-human extrapolation procedures described in current methodologies (e.g., the chronic RfC methodology [U.S. EPA, 1994]) and the development of procedures for inhalation adjustment to incorporate the most current scientific thought and data to address, as needed, issues of variability due to life stage and other intrinsic factors. This consideration would include examining the extent to which calculating a HEC (or any recommended HED) addresses cross-species toxicokinetics as well as identification and parallel investigation into issues of toxicodynamics.

4.4.3.3. *HECs and Children—A Special Case?*

Children are often characterized as constituting a potentially susceptible subgroup because they could be at greater risk than adults for inhaled toxic agents (including both gases and particulates) for reasons relating to either toxicokinetics or toxicodynamics. It is clear for any of a variety of reasons related to toxicokinetics that an adult and a child breathing the same concentration of an agent such as a reactive gas may receive different doses to the body or to the lungs. A generalized theoretical approach to judging whether children would receive greater doses than would adults when both breathe the same concentration of a reactive gas, for example, would be to compare the amount of gas breathed in (which would be directly proportional to the ventilatory volume) with the overall surface area in the respiratory tract on which the gas may impinge. The current Agency default assumption used in deriving HECs for particles and reactive gases that elicit respiratory effects is that the surface area of the total respiratory tract of an adult male, estimated at 54.3 m^2, is exposed to a total daily air intake of 20 m^3, a volume for an adult male derived from a combination 24-hour activity pattern in ICRP (1994) of sitting awake for 8 hours, exercising lightly for 8 hours, and sleeping for 8 hours.

It has been well established that the human respiratory system passes through several distinct stages of maturation and growth that involve branching morphogenesis and cellular differentiation during the first several years of life and into adolescence (Pinkerton and Joad, 2000). The proportion of surface area to ventilation volume may be markedly different during these developmental stages. The significance of these disproportions with regard to toxicant exposure overall or to the sites of active cellular differentiation have yet to be elucidated.

The Technical Panel recommends that issues involving dose to the young from inhalation exposures be pursued both theoretically and experimentally in order to establish the basis on which children should be considered as a susceptible subpopulation for inhalation exposures. It should also be reiterated that this is an estimate of the toxicokinetic aspect of dose only, and toxicodynamic differences between the lungs of young children and adults are not addressed.

4.4.3.4. *Deriving a HED for Oral and Dermal Exposure—Use of $BW^{3/4}$ as a Cross-Species DAF*

As indicated above, the Agency currently does not provide a procedure for calculating a HED for oral or dermal exposure scenarios that would parallel calculation of the inhalation HEC. Instead, assumptions are made regarding the comparability of ingested or applied dose, based on a mg/kg body-weight basis, and there is no adjustment for portal-of-entry alterations to internal dose or on portal-of-entry versus systemic effects. The Technical Panel recognizes the work of an interagency workgroup to develop and propose dosimetric adjustment procedures for both dermal and oral routes of exposure in order to address those aspects of cross-species dosimetric adjustment that are missing in Figure 4-2. Some of these proposals have already appeared in abstract form (Jarabek, 2000; Hanna and Jarabek, 2000; Hubal et al., 2000; Rigas et al., 2000).

Figure 4-2 demonstrates that dosimetric adjustment procedures for estimating human equivalents from animal values are not consistent for different exposure routes. Other procedures, both from within and external to the Agency, could be explored for the purposes of deriving a DAF and employing it to estimate a HED. For example, in the absence of more sophisticated physiologically based models, the Agency has endorsed scaling of doses for carcinogens between species according to body mass raised to the 3/4 power ($BW^{3/4}$) (U.S. EPA, 1992). This procedure presumes that equal doses in these units (i.e., in $mg/kg^{3/4}/day$) when administered daily over a lifetime, will result in equal lifetime cancer risks across mammalian species. This same relationship (i.e., $BW^{3/4}$) has been affirmed to apply across entire phyla, including plants (Gillooly et al., 2001), for general metabolic rates.

The basis for the less-than-full-power relationship for general metabolic processes (i.e., $< BW^{1}$) is thought to be related to species differences in exchange surfaces and distribution networks that constrain concentration and flux of metabolic reactants (West et al., 1997; Enquist et al., 1998). Thus, when this procedure is applied to animal data, the resulting scaled human dose may be viewed as a valid cross-species relationship not only of cancer potency but also for general metabolic processes and, by extension, for other phenomena involving the fundamental determinants of concentration and flux, the same ones that drive basic toxicokinetics.

This brief analysis of the $BW^{3/4}$ cross-species relationship and toxicokinetic processes and the Agency's endorsement of this procedure for carcinogenic agents makes this process a possible candidate for estimating cross-species toxicokinetic relationships in the absence of adequate toxicokinetic information. That is, $BW^{3/4}$ factors could be applied as DAFs for deriving a HED. This procedure would parallel the one used for deriving the HEC. As with the HEC, however, this process applies only to toxicokinetic aspects of cross-species extrapolation and does not address toxicodynamic differences that may exist between species. As with the HEC, consideration of toxicodynamics is proposed to be through application of a portion of the animal-to-human extrapolation ($10^{0.5}$, which is typically rounded to 3). Table 4-3 shows the general magnitude of the DAFs that would be applied to various species to obtain the HED along with the default UF of 3 to cover toxicodynamic differences.

Table 4-3. DAFs based on $BW^{3/4}$ for various species

Species	Weight (kg)	DAF[a]
Mouse	0.03	7
Rat	0.25	4
Guinea pig	0.5	3
Rabbit	2.5	2
Human	70	1

[a] Derived on the basis of $BW^{3/4}$ relationship. All variables in $BW^{3/4}$ relationship containing time will scale $BW^{-1/4}$, such that animal $BW^{-1/4}$/human $BW^{-1/4}$ = DAF.

The Technical Panel encourages consideration of cross-species extrapolation procedures for oral and dermal reference values, including evaluation of the most current scientific thought and data to address, as needed, issues of variability due to life stage and other intrinsic factors. This consideration would include examination of the extent to which calculation of a HED addresses cross-species toxicokinetics and identification and parallel investigation into issues of toxicodynamics.

4.4.4. Other Issues

The Technical Panel considered several other issues related to the application of a factor (data-derived or default) to the BMDL, the BMCL, the NOAEL, or the LOAEL selected as the POD from data considered adequate for risk assessment. In particular, there was controversy about the application of such a factor on the basis of the level of response at the BMD, the BMC, the NOAEL, or the LOAEL. For example, the use of a quantitative dose-response modeling approach results in the calculation of a BMD or a BMC, which is based on a particular level of response, that is, the BMR. The BMR is usually selected to be at the low end of the observable range of the data, which is dependent on the power of the study to detect changes from control values. The limit of sensitivity for most long-term bioassays is in the range of 10%, as determined from both the typical number of animals used in bioassays (~50/group) and a low spontaneous background rate (e.g., 0.1%) for a given effect (Haseman, 1984; Haseman et al., 1989).

For other types of studies, however, the limit of sensitivity may be lower or higher than 10%. For example, in an analysis of a large number of standard prenatal developmental toxicity studies with an average sample size of 15–20 litters, the limit of sensitivity averaged 5% for the proportion of pups affected per litter, whereas when the quantal endpoint (i.e., the number of litters affected) was analyzed in dams from the same studies, the limit of sensitivity averaged 30% (Allen et al., 1994). For data from some human studies (e.g., high-quality, large epidemiology studies), the limit of sensitivity may be in the range of 1 to 5%.

In the BMD guidance document (U.S. EPA, 2000c), the BMDL or BMCL is recommended for the POD in order to ensure that a majority of the population is below the selected BMR. However, a concern has been raised that a BMD or BMC based on a response rate of $\geq$10% may not be appropriate to use in deriving an exposure to the human population (including sensitive or susceptible subgroups) *that is likely to be without appreciable risk of deleterious or adverse effects* (from current and proposed reference value definitions [Boxes 4-1 and 4-2]) without application of a factor to extrapolate to a lower dose/exposure level considered to reflect a more appropriate level of risk (e.g., <10%).

Similarly, the NOAEL is not necessarily a no-effect level, and it depends on the study design, including sample size, background rate, and response variability, which can be used to determine the limit of detection for a particular study. Thus, a NOAEL may be equivalent to no response or it may actually represent a substantial response rate. Previously, there has been no attempt to apply a factor to the NOAEL on the basis of power calculations, sample size, or response variability for deriving a POD, although professional judgment is recommended in deciding whether the study is acceptable for use in deriving a POD.

Adjustment for the steepness of the dose-response curve has been noted as another critical aspect of the dose-response character that is not currently considered in the choice of a response level using either a BMD/BMC or a NOAEL approach.

The Technical Panel was unable to fully evaluate these issues or to reach agreement about any recommendation for change to the current methodology, and it recommends that they be considered further by the Agency. The Technical Panel also recommends that factors such as the response rates at the BMD or the NOAEL, the power of the study, and the slope of the dose-response curve be included in the description of the database, where possible, as part of risk characterization.

Box 4-4. Variability and Uncertainty

Variability refers to true heterogeneity or diversity. For example, among a population that drinks water from the same source and with the same contaminant concentration, the risks from consuming the water may vary. This may be due to differences in exposure (i.e., different people drinking different amounts of water and having different body weights, different exposure frequencies, and different exposure durations) as well as differences in response (e.g., genetic differences in resistance to a chemical dose). Those inherent differences are referred to as variability. Differences among individuals in a population are referred to as inter-individual variability, while differences for one individual over time is referred to as intra-individual variability.

Uncertainty occurs because of a lack of knowledge. It is not the same as variability. For example, a risk assessor may be very certain that different people drink different amounts of water but may be uncertain about how much variability there is in water intakes within the population. Uncertainty can often be reduced by collecting more and better data, while variability is an inherent property of the population being evaluated. Variability can be better characterized with more data, but it cannot be reduced or eliminated. Efforts to clearly distinguish between variability and uncertainty are important for both risk assessment and risk characterization.

4.4.5. Application of Uncertainty/Variability Factors

Reference values are derived in a way that attempts to account for both the uncertainty and the variability in the data available (see Box 4-4). The existing definition of UF in the IRIS glossary mixes the above concepts. The present definition for UF is as follows.

> **Uncertainty Factor**: One of several, generally 10-fold, factors used in operationally deriving the RfD and RfC from experimental data. UFs are intended to account for (1) the variation in sensitivity among the members of the human population (i.e., interhuman or intraspecies variability); (2) the uncertainty in extrapolating animal data to humans (i.e., interspecies variability); (3) the uncertainty in extrapolating from data obtained in a study with less-than-lifetime exposure to lifetime exposure (i.e., extrapolating from subchronic to chronic exposure); (4) the uncertainty in extrapolating from a LOAEL rather than from a NOAEL; and (5) the uncertainty associated with extrapolation from animal data when the database is incomplete.

Following the logic above, the LOAEL-to-NOAEL extrapolation, the subchronic-to-chronic extrapolation, and the database deficiency factors are UFs. The variation in susceptibility among members of the human population is a variability factor. When a default factor is used for intrahuman variability, however, this factor also contains some degree of uncertainty, because the range of uncertainty is not really known, although it is presumed to be no more than 10-fold. Rather than adding a new definition of variability factor, we propose to modify the wording of the UF definition as follows.

> **Uncertainty/Variability Factor:** One of several, generally 10-fold, default factors used in operationally deriving the RfD and the RfC from experimental data. The factors are intended to account for (1) the variation in sensitivity among the members of the human population (i.e., inter-individual variability); (2) the uncertainty in extrapolating animal data to humans (i.e., interspecies uncertainty); (3) the uncertainty in extrapolating from data obtained in a study with less-than-lifetime exposure to lifetime exposure (i.e., extrapolating from subchronic to chronic exposure); (4) the uncertainty in extrapolating from a LOAEL rather than from a NOAEL; and (5) the uncertainty associated with extrapolation when the database is incomplete.

In setting pesticide tolerances, the FQPA directs EPA to use an additional 10-fold margin of safety to protect infants and children, taking into account the potential for pre- and postnatal toxicity and the completeness of the toxicology and exposure databases. The statute authorizes EPA to replace this additional 10X factor with a factor of a different value (higher or lower, including 1) only if, on the basis of reliable data, the resulting level of exposure would be safe for infants and children. The Agency use of this FQPA safety factor has been discussed in several documents (U.S. EPA, 1999b, c, 2002b).

The Agency has concluded that in many cases, concerns regarding pre- and postnatal toxicity can be addressed by calculating an RfD or an MOE using pre- or postnatal developmental endpoints and applying traditional UFs to account for deficiencies in the toxicity data (U.S. EPA, 2002b). These traditional UFs include extrapolation from the LOAEL when a NOAEL is not available, extrapolation from a subchronic study to a chronic-exposure scenario when no chronic study data are available, and application of a database UF when there are gaps in the data considered essential for setting a reference value, including lack of data on children.

In addition to considering these FQPA-relevant areas of uncertainty, which are addressed in the development of an RfD/RfC, OPP assessments of pesticide risk to children also consider applying part or all of the FQPA factor in certain situations to account for areas of residual

uncertainty that the traditional UFs do not address or for which they are believed to be insufficient. These areas of residual uncertainty include exposure uncertainties and high concern for an observed susceptibility. This risk management approach is consistent with procedures used in the past for managing potential risks, although the FQPA has brought a significant new focus on improving the process of risk assessment relative to children's health risks from environmental exposures.

In considering the robustness of the RfC/RfD methodology and its adequacy for assessing hazards to infants and children, the Technical Panel also recognized the overlap of areas covered by the FQPA factor and those addressed by the traditional UFs. For example, the database UF may be invoked where data are unavailable or are insufficient to explicitly consider the potential sensitivity of the developing organism. The Technical Panel agrees with the 10X Task Force draft Toxicology Working Group report (U.S. EPA, 1999b) that the current interspecies, intraspecies, LOAEL-to-NOAEL, subchronic-to-chronic, and database-deficiency UFs, if appropriately applied using the approaches recommended in this review, will be adequate in most cases to cover concerns and uncertainties regarding the potential for pre- and postnatal toxicity and the completeness of the toxicology database. In other words, an additional UF is not needed in the RfC/RfD methodology because the currently available factors are considered sufficient to account for uncertainties in the database from which the reference values are derived (and it does not exclude the possibility that these UFs may be decreased *or* increased from the default value of 10).

Guidance is needed on the use of developmental toxicity data in all reference values, including the appropriate application of UFs, because of the assumption that a single exposure during development may produce an effect (U.S. EPA, 1991) and the concomitant recognition that multiple exposures may result in effects at lower doses in many cases or cause tolerance in other cases. These issues are chemical specific, and scientific judgement about when and how to apply UFs must include consideration of toxicokinetics/metabolism as well as the mode of action for each agent.

4.4.5.1. *Recommendations for Application of UFs*

The exact value of the UFs chosen should depend on the quality of the studies available, the extent of the database, and scientific judgment. It is imperative that the IRIS documentation contain a justification for the individual UFs selected for a particular agent. The default factors typically used cover a single order of magnitude (i.e., 10^{1}). By convention, in the Agency, a value of 3 is used in place of one-half power (i.e., $10^{0.5}$) when appropriate. The Technical Panel recommends that these half-power values be factored as whole numbers when they occur singly

but as powers or logs when they occur in tandem. A composite UF of 3 and 10 would be expressed as 30 (3×10^1), whereas a composite UF of 3 and 3 would be expressed as 10 ($10^{0.5} \times 10^{0.5} = 10^1$). It should be noted, in addition, that rigid application of log or ½ log units for UFs could lead to an illogical set of reference values; therefore, the Technical Panel emphasizes that application of scientific judgment is critical to the overall process.

It is imperative that the IRIS documentation contain a justification for the individual factors selected for each chemical or assessment and for each duration reference value. Although default factors of 10 are recommended, with 3 used in place of half-power values (i.e., $10^{0.5}$) when occurring singly, the exact value of the UF chosen should depend on the quality of the studies available, the extent of the database, and scientific judgment. Sound scientific judgment should be used in the application of UFs to derive reference values that are applied to the value chosen for the POD derived from the available database (BMDL, NOAEL, or LOAEL).

The Technical Panel recognizes that there is overlap in the individual UFs and believes that the application of five UFs of 10 for the chronic reference value (yielding a total UF of 100,000) is inappropriate. In fact, in cases where maximum uncertainty exists in all five areas, it is unlikely that the database is sufficient to derive a reference value. Uncertainty in four areas may also indicate that the database is insufficient to derive a reference value. In the case of the RfC, the maximum UF would be 3000, whereas the maximum would be 10,000 for the RfD. This is because the derivation of RfCs and RfDs have evolved somewhat differently. The RfC methodology (U.S. EPA, 1994) recommends dividing the interspecies UF in half, one-half ($10^{0.5}$) each for toxicokinetic and toxicodynamic considerations, and it includes a DAF to account for toxicokinetic differences in calculating the HEC, thus reducing the interspecies UF to 3 for toxicodynamic issues. RfDs, however, do not incorporate a DAF for deriving a HED, and the interspecies UF of 10 is typically applied.

The Technical Panel recommends limiting the total UF applied for any particular chemical to no more than 3000 and avoiding the derivation of a reference value that involves application of the full 10-fold UF in four or more areas of extrapolation. This maximum of 3000 applies only to the UFs discussed in the following sections and does not include the various adjustment factors that have been discussed previously (Sections 4.4.2. and 4.4.3.). Similar concerns would need to be considered for the less-than-lifetime reference values, taking into account those UFs that are appropriate for each duration reference value.

4.4.5.2. *Interspecies UF*

The interspecies UF is applied to account for the extrapolation of laboratory animal data to humans, and it generally is presumed to include both toxicokinetic and toxicodynamic aspects. The toxicokinetic aspects of this factor were addressed in the section on deriving HEDs and HECs (Section 4.4.3). This UF is intended also to account for differences in species sensitivity (i.e., toxicodynamics) between the laboratory animal species used for testing and humans. Seldom are there data available to inform toxicodynamic differences. One-half the default 10-fold interspecies UF (i.e., $10^{0.5}$) is assumed to account for such differences, but more specific data should be used when available (see discussion of chemical-specific adjustment factors, Section 4.4.6.1 below), and the flexibility for applying a factor greater than 10 should be recognized. Unless data support the conclusion that the test species is more or equally as susceptible to the pollutant as are humans, and in the absence of any other specific toxicokinetic or toxicodynamic data, a default factor of 3 (in conjunction with HEC derivation) or 10 is applied.

4.4.5.3. *Intraspecies UF*

The intraspecies UF is applied to account for variations in susceptibility within the human population (interhuman variability) and the possibility (given a lack of relevant data) that the database available is not representative of the dose/exposure-response relationship in the subgroups of the human population that are most sensitive to the health hazards of the chemical being assessed. As the reference concentration/dose is defined to be applicable to "susceptible subgroups," this UF was established to account for uncertainty in that regard. In general, the Technical Panel reaffirms the importance of this UF, recommending that reduction of the intraspecies UF from a default of 10 be considered only if data are sufficiently representative of the exposure/dose-response data for the most susceptible subpopulation(s).

Various authors who have evaluated the intraspecies UF using data from animal or human studies (as summarized by Dourson et al. [1996]) have concluded that the 10-fold default factor appears to be protective when starting from a median response—by inference a NOAEL assumed to be from an average group of humans. Renwick and Lazarus (1998) considered data on toxicokinetics and toxicodynamics to support the idea that the 10-fold intraspecies factor can be divided into two factors to account for kinetics and dynamics. When they evaluated the composite 10-fold factor to account for variability in both kinetics and dynamics, they concluded that a 10-fold factor would cover the vast majority (>99%) of the population. These evaluations, however, did not specifically consider children as part of the range of human variability when evaluating the adequacy of the intraspecies UF.

In papers that have evaluated this factor for the general population as well as for specific subpopulations, including children (Renwick and Lazarus,1998; Renwick, 1998) and the elderly (Abdel-Mageed et al., 2001), the 10-fold intraspecies factor appears to be sufficient in most cases, and chemical-specific factors often indicate a requirement for less than a l0-fold factor. Renwick (1998) indicated that the 10-fold factor is more likely to be sufficient if developmental toxicity data are available on the specific agent. Calabrese (2001) reviewed the data available on a number of chemical classes and concluded that the young are often more susceptible than adults but that there is a not-infrequent occurrence of greater susceptibility in adults. The sometimes greater sensitivity among the elderly than among mature adults appears to be related primarily to reduced renal clearance (Abdel-Mageed et al., 2001; Skowronski and Abdel-Rahman, 2001).

The Technical Panel urges continued research and evaluation of the similarities and differences between the general population and susceptible subpopulations—particularly children and the elderly—in their responses to specific agents. From such evaluations, the protectiveness of the 10-fold default factor can continue to be assessed.

The cases on IRIS in which the intraspecies UF has been reduced from the default of 10-fold have been documented by Dourson et al. (1996). These include 2/46 RfCs and 13/346 RfDs (overall frequency 3.6%). In those cases where developmental effects were the most sensitive endpoint (0 RfCs, 6 RfDs), reduction of the intraspecies UF from 10 to 3 was based on data derived either from human data showing which age groups or time periods were most susceptible (e.g., methyl mercury exposure to the developing fetus) or from an animal study with support from strong human or other data (e.g., Aroclor 1016 in utero exposure in monkeys, strontium-induced rachitic bones in young rats). In three cases the intraspecies UF was reduced to 1, based on very specific data about the particular vulnerability of infants and children within certain age ranges to an agent (e.g., nitrate, nitrite, fluorine/soluble fluoride). However, even within these populations it is possible that some variability exists, based on genetics, lifestyle, or other factors.

In cases where the susceptible subpopulation is quite specifically defined (e.g., through knowledge of the chemical’s mode of action) so that the resultant RfC is truly applicable to the susceptible subpopulation (although not necessarily to hypersensitive individuals), reduction of the intraspecies UF is warranted. Thus, the Technical Panel supports and expands the recommendation of the Toxicology Working Group of the 10X Task Force (U.S. EPA, 1999b) that reduction of the intraspecies UF from a default of 10 be considered only if data are sufficient to support the conclusion that the data set on which the POD is based is representative of the exposure/dose-response data for the susceptible subpopulation(s). Given this, whether and how

much the intraspecies UF may be reduced must be linked to how completely the susceptible subpopulation has been identified and their sensitivity described (vs. assumed). At the other extreme, a 10-fold factor may sometimes be too small because of factors that can influence large differences in susceptibility, such as genetic polymorphisms. The Technical Panel urges the development of data to support the selection of the appropriate size of this factor, but recognizes that often there are insufficient data to support a factor other than the default.

4.4.5.4. *LOAEL-to-NOAEL UF*

A UF (default 10) is typically applied to the LOAEL when a NOAEL is not available. The size of the LOAEL-to-NOAEL UF may be altered, depending on the magnitude and nature of the response at the LOAEL. It is important to consider the slope of the dose-response curve in the range of the LOAEL in making the determination to reduce the size of the LOAEL-to-NOAEL UF. Several papers have described the magnitude of the difference between the dose at the LOAEL and at the NOAEL. For example, Lewis et al. (1990) and Faustman et al. (1994) showed that the ratio of the LOAEL-to-NOAEL in many cases was approximately threefold, but in a few cases the difference was as much as 10-fold.

In general, the ratio of the doses at the LOAEL and the NOAEL is likely to vary considerably among studies and may not be informative. This is because the lowest dose in a study is often selected to ensure that no statistically significant response above control is observed and the next higher dose is selected to ensure that some significant response is observed, rather than selecting doses that will give a maximum NOAEL and a minimum LOAEL. Data should be carefully evaluated, taking into consideration the level of response at the LOAEL and the NOAEL and the slope of the dose-response curve before reducing the size of the UF applied to the LOAEL.

4.4.5.5. *Database UF*

The database UF is intended to account for the potential for deriving an underprotective RfD/RfC as a result of an incomplete characterization of the chemical's toxicity. In addition to identifying toxicity information that is lacking, review of existing data may also suggest that a lower reference value might result if additional data were available. Consequently, in deciding to apply this factor to account for deficiencies in the available data set and in identifying its magnitude, the assessor should consider both the data lacking and the data available for particular organ systems as well as life stages.

In many respects, the additional 10-fold factor for infants recommended by the National Research Council (NRC, 1993) and by Schilter et al. (1996) and called for in the 1996 FQPA is
