(8) NOAEL. A NOAEL is the highest exposure level at which no harmful effects were seen in the organ system studied. Key number 18 reports a NOAEL of 3 ppm for the respiratory system,

which was used to derive an intermediate exposure, inhalation MRL of 0.005 ppm (see footnote "b").

(9) LOAEL. A LOAEL is the lowest dose used in the study that caused a harmful health effect. LOAELs have been classified into "Less Serious" and "Serious" effects. These distinctions help readers identify the levels of exposure at which adverse health effects first appear and the gradation of effects with increasing dose. A brief description of the specific end point used to quantify the adverse effect accompanies the LOAEL. The respiratory effect reported in key number 18 (hyperplasia) is a Less Serious LOAEL of 10 ppm. MRLs are not derived from Serious LOAELs.

(10) Reference. The complete reference citation is given in Chapter 9 of the profile.

(11) CEL. A CEL is the lowest exposure level associated with the onset of carcinogenesis in experimental or epidemiologic studies. CELs are always considered serious effects. The LSE tables and figures do not contain NOAELs for cancer, but the text may report doses not causing measurable cancer increases.

(12) Footnotes. Explanations of abbreviations or reference notes for data in the LSE tables are found in the footnotes. Footnote "b" indicates that the NOAEL of 3 ppm in key number 18 was used to derive an MRL of 0.005 ppm.

LEGEND

See Sample Figure 3-1 (page B-7)

LSE figures graphically illustrate the data presented in the corresponding LSE tables. Figures help the reader quickly compare health effects according to exposure concentrations for particular exposure periods.

(13) Exposure Period. The same exposure periods appear as in the LSE table. In this example, health effects observed within the acute and intermediate exposure periods are illustrated.

(14) Health Effect. These are the categories of health effects for which reliable quantitative data exists. The same health effects appear in the LSE table.

(15) Levels of Exposure. Concentrations or doses for each health effect in the LSE tables are graphically displayed in the LSE figures. Exposure concentration or dose is measured on the log scale "y" axis. Inhalation exposure is reported in mg/m^3 or ppm and oral exposure is reported in mg/kg/day.

(16) NOAEL. In this example, the open circle designated 18r identifies a NOAEL critical end point in the rat upon which an intermediate inhalation exposure MRL is based. The key number 18 corresponds to the entry in the LSE table. The dashed descending arrow indicates the extrapolation from the exposure level of 3 ppm (see entry 18 in the table) to the MRL of 0.005 ppm (see footnote "b" in the LSE table).

(17) CEL. Key number 38m is one of three studies for which CELs were derived. The diamond symbol refers to a CEL for the test species-mouse. The number 38 corresponds to the entry in the LSE table.

(18) Estimated Upper-Bound Human Cancer Risk Levels. This is the range associated with the upper-bound for lifetime cancer risk of 1 in 10,000 to 1 in 10,000,000. These risk levels are derived from the EPA's Human Health Assessment Group's upper-bound estimates of the slope of the cancer dose response curve at low dose levels (q_1*).

(19) Key to LSE Figure. The Key explains the abbreviations and symbols used in the figure.

PREFACE

This assessment titled *Human Health Toxicity Values for Perfluorobutane Sulfonic Acid and Related Compound Potassium Perfluorobutane Sulfonate* is a toxicity assessment developed by the U.S. EPA's Office of Research and Development (ORD) Center for Public Health and Environmental Assessment (CPHEA).

The perfluorobutane sulfonic acid (PFBS) toxicity assessment is one of the key goals of the Agency's PFAS Action Plan (U.S. EPA, 2019) and provides qualitative and quantitative toxicity information that can be used along with exposure information and other important considerations to assess potential health risks to determine if, and when, it is appropriate to take action to address this chemical. This assessment is available for use across multiple U.S. EPA program and regional offices, other federal agencies, states, tribes, external stakeholders, and other entities as needed.

The PFBS human health toxicity values presented in this assessment were developed based on the best available science. The assessment provides high-quality evaluations and conclusions drawn from publicly available information on the toxicity of PFBS. This assessment is not a regulation; rather, it provides a critical part of the scientific foundation for risk assessment decision making. The PFBS assessment provides toxicity values and information about the adverse effects of the chemical and the evidence on which the value is based, including the strengths and limitations of the data. All users, including risk assessors and risk managers, are advised to review the information, including potential uncertainties, provided in this document to ensure that the assessment is appropriate for the circumstances (e.g., exposure pathways, concentrations, presence of sensitive subpopulations) in question and the risk management decisions that would be supported by the risk assessment.

The PFBS toxicity assessment underwent a rigorous development and review process, as described below.

Overview of major steps in the PFBS assessment development and review process

- Draft assessment development
- Review by U.S. EPA program and regional offices (i.e., Intra-agency review)
- Review by other federal agencies (i.e., interagency review)
- External letter peer review
- Public comment period
- Second external letter peer review
- Intra-agency and interagency review

This assessment was provided for review to scientists in U.S. EPA's program and regional offices prior to external peer review and after external peer review. Comments were submitted by:

Office of the Administrator/Office of Children's Health Protection
Office of the Administrator/Office of Policy
Office of Chemical Safety and Pollution Prevention
Office of Land and Emergency Management
Office of Research and Development
Office of Water
Region 2, New York, NY
Region 3, Boston, MA
Region 4, Atlanta, GA
Region 5, Chicago, IL
Region 8, Denver, CO

This assessment was provided for review to other federal agencies prior to external peer review and after external peer review. Representatives from federal agencies and from the Environmental Council of the States (ECOS) were briefed during the assessment scoping and draft development process on March 9, 2018; May 2, 2018; and August 27, 2018. After public comment, interagency review was conducted by the Office of Management and Budget's PFAS Technical Working Group (TWG), an interagency group composed of career staff chief scientists or their equivalents from across the Executive Branch. Comments on this assessment were submitted by a subset of TWG representatives, namely:

Department of Defense
Department of Health and Human Services
  Agency for Toxic Substances and Disease Registry
  Food and Drug Administration
  National Institute of Environmental Health Sciences/National Toxicology Program
  National Institute of Occupational Safety and Health
Executive Office of the President
  Office of Management and Budget
National Aeronautics and Space Administration

This assessment was peer reviewed by independent, expert scientists external to U.S. EPA before and after the public comment period. The reports of the two external peer reviews and responses to comments on the U.S. EPA's draft Human Health Toxicity Values for PFBS, dated November 2018 and October 2020, are available at https://www.epa.gov/pfas/learn-about-human-health-toxicity-assessment-pfbs. Comments from external peer review were submitted by:

Karen Chou, PhD
Dale Hattis, PhD
Lisa M. Kamendulis, PhD
Angela M. Leung, MD
Angela L. Slitt, PhD
David Alan Warren, MPH, PhD
R. Thomas Zoeller, PhD

This assessment was released for public comment from November 21, 2018 to January 22, 2019. The public comments are available on Regulations.gov in the Docket ID No. EPA-HQ-OW-2018-0614.

VLDL	very low-density lipoprotein

EXECUTIVE SUMMARY

SUMMARY OF OCCURRENCE AND HEALTH EFFECTS

The U.S. Environmental Protection Agency (U.S. EPA) is issuing subchronic and chronic oral toxicity values for perfluorobutane sulfonic acid (PFBS) (Chemical Abstracts Service registry number [CASRN] 375-73-5) and its related salt, potassium perfluorobutane sulfonate (K^+PFBS) (CASRN 29420-49-3). The ionic state of per- and polyfluoroalkyl substances (PFAS) such as PFBS influence physicochemical properties such as water or lipid solubility and bioaccumulative potential, which in turn impact fate and transport in the environment and potential human health and ecological effects in exposed populations. K^+PFBS fully dissociates in aqueous solutions with pH levels ranging from 4–9; thus, the oral toxicity values derived in this document are also applicable to the deprotonated anionic form of PFBS (i.e., $PFBS^-$; CASRN 45187-15-3).

The toxicity assessment for PFBS includes toxicity values associated with potential noncancer health effects following oral exposure (in this case, oral reference doses [RfDs]). This assessment evaluates human health hazards. The toxicity assessment and the values contained within is not a risk assessment because it does not include an exposure assessment nor an overall risk characterization. Further, the toxicity assessment does not address the legal, political, social, economic, or technical considerations involved in risk management. The PFBS toxicity assessment can be used by U.S. EPA, states, tribes, and local communities, along with specific exposure and other relevant information, to determine, under the appropriate regulations and statutes, if, and when, it is necessary to take action to address potential risk associated with human exposures to PFBS.

PFBS and K^+PFBS are both four-carbon, fully fluorinated alkane members of a large and diverse class of linear and branched compounds known as "per- and polyfluoroalkyl substances," or PFAS. In the early 2000s, concerns grew over the environmental persistence, bioaccumulation potential, and long half-lives in humans of longer chain PFAS, in particular, perfluorooctanoic acid (PFOA) and perfluorooctane sulfonic acid (PFOS). As a result, shorter chain PFAS such as PFBS were developed and integrated into various consumer products and industrial applications, because PFBS has the desired properties and characteristics associated with this class of compounds but with faster elimination from the body than PFOA and PFOS. PFBS is associated with aqueous film-forming foam (foams (AFFFs) and used during chrome electroplating as a mist suppressant (See Section 1.2). It has also been found in food contact materials, dust, and source and finished drinking water. Accordingly, oral intake of water and food, inhalation, and dermal contact are plausible modes of PFBS exposure, with the oral route being the primary route of exposure. PFBS has been detected in humans, confirming exposure to this PFAS; however, the magnitude of human exposure likely depends on factors such as occupation (e.g., processing and/or manufacture of PFBS or PFBS-containing products and chrome electroplating) and living conditions (e.g., proximity to locations that make or use PFBS-containing products and nearby well-water use).

Human studies have examined possible associations between PFBS exposure and potential health outcomes such as alteration of menstruation, reproductive hormones or semen parameters, kidney function (uric acid production), lung function (induction of asthma), and lipid

profile. The ability to draw conclusions about associations is limited due to the small number of human studies per outcome. Of the examined health outcomes, only asthma and serum cholesterol levels in humans were found to exhibit a statistically significant positive association with PFBS exposure. No studies have been identified that evaluate the association between PFBS exposure and potential cancer outcomes. While the epidemiology studies were not influential to drawing evidence integration judgments or the derivation of toxicity values, the general findings identify potential areas of future research.

Animal studies of repeated-dose PFBS exposure have been exclusively via the oral route, used the potassium salt of PFBS (K^+PFBS) as the source exposure material, and have examined noncancer effects only. The available rat and mouse studies support identification of thyroid, developmental, and kidney endpoints as potential health effects following repeated exposures in utero and/or during adulthood. Animal studies have also evaluated other health outcomes, such as liver effects, reproductive parameters, lipid/lipoprotein homeostasis, and effects on the spleen and hematology; however, the available evidence does not support a clear association with PFBS exposure and these outcomes.

Noncancer Effects Observed Following Oral Exposure

Oral exposures to PFBS or its K^+ salt in adult and developing rats and mice have been shown to result in thyroid, developmental, and kidney effects. Thyroid effects in exposed adult rats and mice and in developing mice were primarily expressed through significant decreases in circulating levels of hormones such as thyroxine (T_4) and triiodothyronine (T_3). In early developmental life stages in mice (e.g., newborn), decreases in thyroid hormone were accompanied by other effects indicative of delayed maturation or reproductive development (e.g., vaginal patency and eyes opening). Kidney weight and/or histopathological alterations (e.g., renal tubular and ductal epithelial hyperplasia) were observed in rats following short-term and subchronic oral exposures. Many of the kidney effects, however, occurred at higher doses than did the thyroid and developmental effects. The limited number of human studies examining oral PFBS exposure does not inform the potential for effects in thyroid, developing offspring, or the renal system.

Oral Reference Doses for Noncancer Effects

Subchronic[1] and chronic[2] oral RfDs were derived for PFBS. The hazards of potential concern include thyroid, developmental, and kidney effects. From these identified targets of PFBS toxicity, perturbation of thyroid hormone levels (e.g., T_4) was used as the critical effect for deriving a subchronic and chronic RfD. Based on recommendations in the U.S. EPA's *Recommended Use of Body Weight$^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose* (U.S. EPA, 2011b), chemical-specific toxicokinetic data (e.g., serum half-lives) were used to scale a toxicologically equivalent dose of orally administered PFBS from animals to humans. Following the U.S. EPA's *Benchmark Dose Technical Guidance Document* (U.S. EPA, 2012),

[1]Subchronic exposure: Repeated exposure by the oral, dermal, or inhalation route for more than 30 days, up to approximately 10% of the lifespan in humans (more than 30 days up to approximately 90 days in typically used laboratory animal species).

[2]Chronic exposure: Repeated exposure by the oral, dermal, or inhalation route for more than approximately 10% of the lifespan in humans (more than approximately 90 days to 2 years in typically used laboratory animal species). (https://ofmpub.epa.gov/sor_internet/registry/termreg/searchandretrieve/glossariesandkeywordlists/search.do?details=&glossaryName=IRIS%20Glossary#formTop)

benchmark dose (BMD) modeling of thyroid effects in a developmental life stage following exposure to K^+PFBS in utero resulted in a $BMDL_{0.5SD}$ human equivalent dose (HED) of 0.095 milligrams per kilogram per day (mg/kg-day). This HED associated with thyroid effects served as the point of departure (POD) for deriving the subchronic and chronic RfDs.

The subchronic RfD for K^+PFBS was calculated by dividing the POD (HED) for decreased serum total T_4 observed in newborn (Postnatal Day [PND] 1) mice, in the study conducted by Feng et al. (2017), by a composite uncertainty factor (UF_C) of 100 to account for extrapolation from mice to humans (an interspecies uncertainty factor, or UF_A, of 3), for interindividual differences in human susceptibility (intraspecies uncertainty factor, or UF_H, of 10), and for deficiencies in the toxicity database (database uncertainty factor, or UF_D, of 3) (a value of 1 was applied for subchronic-to-chronic UF, or UF_S, and LOAEL-to-NOAEL uncertainty factor, or UF_L) (see Table 10), yielding a subchronic RfD of 0.00095 mg/kg-day rounded to 1×10^{-3} mg/kg-day. Because K^+PFBS is fully dissociated in water at the environmental pH range of 4–9 to the PFBS anion ($PFBS^-$) and the K^+ cation, data for K^+PFBS were used to derive a subchronic RfD for the free acid (PFBS) by adjusting for differences in molecular weight (MW) between K^+PFBS (338.19) and PFBS (300.10), yielding the value of 0.00085 mg/kg-day rounded to 9×10^{-4} mg/kg-day for the subchronic RfD for PFBS (free acid).

The chronic RfD for K^+PFBS associated with thyroid effects was calculated by dividing the POD (HED) for decreased serum total T_4 observed in newborn (PND 1) mice, in the study conducted by Feng et al. (2017), by a UF_C of 300 to account for extrapolation from mice to humans (UF_A of 3), for interindividual differences in human susceptibility (UF_H of 10), and deficiencies in the toxicity database (UF_D of 10) (a value of 1 was applied for UF_S and UF_L) (see Table 12), yielding a chronic RfD of 0.00032 mg/kg-day rounded to 3×10^{-4} mg/kg-day. Like the subchronic RfD for thyroid effect, based on the data for K^+PFBS, a chronic RfD for PFBS (free acid) of 0.00028 mg/kg-day rounded to 3×10^{-4} mg/kg-day was derived.

Confidence in the Oral RfDs

The overall confidence in the subchronic RfD for thyroid effects is medium. The gestational exposure study conducted by Feng et al. (2017) reported administration of K^+PFBS by gavage in pregnant Institute of Cancer Research (ICR) mice (10/dose) from Gestation Days (GDs) 1 to 20. This study was of good quality (i.e., high confidence) with adequate reporting and consideration of appropriate study design, methods, and conduct (click to see risk of bias analysis in HAWC[3]). Confidence in the oral toxicity database for derivation of the subchronic RfD is medium because, although there are multiple short-term studies and a subchronic-duration toxicity study in laboratory animals, a two-generation reproductive toxicity study in rats (Lieder et al., 2009b), and multiple developmental toxicity studies in mice and rats, there are no PFBS studies available that have specifically evaluated health effect domains of emerging concern across the PFAS class such as immunotoxicity and mammary gland development (Dewitt et al., 2012; White et al., 2007). Further, neurodevelopmental effects are of particular concern when perturbations in thyroid hormone occur during a sensitive early life

[3]HAWC: A modular web-based interface to facilitate development of human health assessments of chemicals; see Appendix D for details.

stage, and the absence of a study evaluating neurodevelopmental effects following PFBS exposure is a source of uncertainty in the assessment.

The overall confidence in the chronic RfD for thyroid effects is low. Although the chronic RfD, like the subchronic RfD, was derived using data from the high-confidence principal study conducted by Feng et al. (2017), there is increased concern about the potential for identification of hazards following longer (i.e., chronic) duration PFBS exposures. In addition, because of the lack of studies that specifically evaluated health effect domains of emerging concern across the PFAS class, such as immunotoxicity, mammary gland development, or neurodevelopmental at any exposure duration—but particularly for chronic duration—confidence in the database specifically for a chronic RfD is low.

Effects Other Than Cancer Observed Following Inhalation Exposure

There are no studies available that examined toxicity in humans or experimental animals following inhalation exposure, thereby precluding the derivation of an inhalation reference concentration (RfC).

Evidence for Carcinogenicity

Under the U.S. EPA's *Guidelines for Carcinogen Risk Assessment* (U.S. EPA, 2005), the Agency concluded that there is *"Inadequate Information to Assess Carcinogenic Potential"* for PFBS and K^+PFBS by either oral or inhalation routes of exposure. Therefore, the lack of data on the carcinogenicity of PFBS and the related compound K^+PFBS precludes the derivation of quantitative estimates for either oral (oral slope factor) or inhalation (inhalation unit risk) exposure.

1.0 BACKGROUND

1.1 PHYSICAL AND CHEMICAL PROPERTIES

Perfluorobutane sulfonic acid (PFBS) (Chemical Abstracts Service registry number [CASRN] 375-73-5)[4] and its related salt, potassium perfluorobutane sulfonate (K^+PFBS) (CASRN 29420-49-3), are members of the group of per- and polyfluoroalkyl substances (PFAS), more specifically the short-chain perfluoroalkane sulfonates. For purposes of this assessment, "PFBS" will signify the ion, acid, or any salt of PFBS. Concerns about PFBS and other PFAS stem from the resistance of these compounds to hydrolysis, photolysis, and biodegradation, which leads to their persistence in the environment (Sundström et al., 2012). The chemical formula of PFBS is $C_4HF_9O_3S$ and the chemical formula of K^+PFBS is $C_4F_9KO_3S$. Their respective chemical structures are presented in Figure 1. K^+PFBS differs from PFBS by being associated with a potassium ion. The reported water solubility of each species suggests that in aqueous environments the sulfonate would be the predominant form. The preferential use of K^+PFBS in laboratory studies is related to the optimal dissociation of the salt to the sulfonate (i.e., $PFBS^-$) at pH values ranging from 4 to 9 (see Table 1). Table 1 provides a list of the physicochemical properties for PFBS and K^+PFBS.

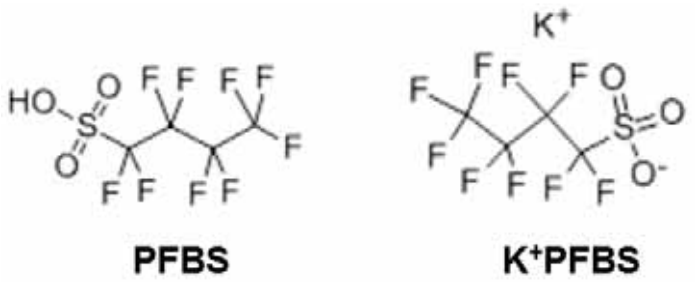

Figure 1. PFBS and K^+PFBS Chemical Structures

[4]The CASRN given is for linear PFBS; the source PFBS used in toxicity studies was assayed at ≥98% linear, suggesting some minor proportion of other chemicals, such as branched PFBS isomers, are present. Thus, observed health effects may apply to the total linear and branched isomers in a given exposure source.

Table 1. Physicochemical Properties of PFBS (CASRN 375-73-5) and Related Compound K^+PFBS (CASRN 29420-49-3)

Property (unit)	Value[a]	
	PFBS (free acid)[b]	K^+PFBS (potassium salt)[c]
Boiling point (°C)	152	447
Density (g/cm^3)	1.83 (predicted)	1.83 (predicted)
Vapor pressure (mm Hg)	0.104 (predicted)	1.12×10^{-8}
pH	ND	ND
Solubility in water (mol/L)	0.0017	0.08
Molecular weight (g/mol)	300.09	338.18
Dissociation constant	NA	Fully dissociated in water over the pH range of 4−9

[a]Values are experimentally determined unless otherwise indicated.

K^+PFBS = potassium perfluorobutane sulfonate; NA = not applicable; ND = no data; PFBS = perfluorobutane sulfonic acid.

1.2 OCCURRENCE

PFBS-based compounds are surfactants used primarily in the manufacture of paints, cleaning agents, and water- and stain-repellent products and coatings. They serve as replacements for perfluorooctane sulfonic acid (PFOS) (3M, 2002b). Various sources report detection or occurrence in environmental media and consumer products, including drinking water, ambient water, dust, carpeting and carpet cleaners, floor wax, and food packaging. To assess potential health risks associated with these occurrences, an exposure assessment, which is beyond the scope of this document, would be necessary to determine the relative source contribution to human PFBS exposure from each reported occurrence and the relevance, if any, to human health.

Oral exposure via drinking water might be expected in areas where contamination has been reported. U.S. EPA Unregulated Contaminant Monitoring Rule data for public drinking water utilities in 2013−2015 showed levels of PFBS above the minimum reporting level (>0.09 micrograms per liter [µg/L]) in water systems serving Alabama, Colorado, Georgia, the Northern Mariana Islands, and Pennsylvania (U.S. EPA, 2017; Hu et al., 2016). These utilities used both ground and surface drinking water sources, with PFBS concentrations ranging from 0.09 to 0.37 µg/L. The estimated combined number of people served by these water systems is more than 340,000 (U.S. EPA, 2018).

Measurements from 37 surface water bodies in the northeastern United States (metropolitan New York area and Rhode Island) collected in 2014 showed an 85% site detection rate (Zhang et al., 2016). PFBS has also been identified in surface waters in Georgia, New

Jersey, North Carolina, and the Upper Mississippi River Basin (Post et al., 2013; Lasier et al., 2011; Nakayama et al., 2010; Nakayama et al., 2007). It has also been detected in wastewater treatment plant effluent, seawater, soil, and biosolids (Houtz et al., 2016; Zhao et al., 2012; Sepulvado et al., 2011).

PFBS contamination, which has been associated with the use of aqueous film-forming foams (AFFFs) (ESTCP, 2017; Anderson et al., 2016), was reported at Superfund sites and areas under assessment for Superfund designation. Contaminated sites include the former Wurtsmith Air Force Base, Ellsworth Air Force Base, and Dover Air Force Base (Aerostar SES LLC, 2017; Anonymous, 2017; ASTSWMO, 2015). At the Wurtsmith site, PFBS was detected at a concentration of 6.4 µg/L in groundwater contaminated by a PFAS plume originating from the fire training area (ASTSWMO, 2015). It is also present in some drinking water samples from nearby residential wells at low nanograms per liter concentrations, which were below the screening value cited by the Michigan Department of Community Health (MDCH, 2015). Other sources of PFAS and/or PFBS contamination include chrome plating operations, PFAS manufacture, and sites that use PFAS in product formulations such as textile and electronics facilities (Wang et al., 2013).

PFBS has also been detected in household dust and consumer products. There was a 92% detection frequency for PFBS among 39 household dust samples (10 from the United States) analyzed with levels ranging from 86 nanograms per gram (ng/g) for the 25th percentile to 782 ng/g for the 75th percentile (Kato et al., 2009). In a separate study, PFBS dust levels were measured in Boston area offices (n = 31), homes (n = 30), and vehicles (n = 13) with detection frequencies being relatively low—10, 3, and 0%, respectively—and ranging in the low parts per billion (Fraser et al., 2013). Consumer products could also be an exposure source. Limited quantitative testing showed the presence of PFBS in carpet and upholstery protectors (45.8 and 89.6 ng/g), carpet shampoo (25.7 and 911 ng/g), textiles (2 ng/g), and floor wax (143 ng/g) purchased in the United States (Liu et al., 2014).

PFBS is not authorized for use in food packaging. However, PFBS was detected in fast food packaging (7/20 samples) in one U.S. study (Schaider et al., 2017) although the magnitude of the detection was not reported.

The European Food Safety Authority reported the presence of PFBS in various food and drink items, including fruits, vegetables, cheese, and bottled water. For average adult consumers, the estimated exposure ranges for PFBS were 0.03−1.89 nanograms per kilogram per day (ng/kg-day) (minimum) to 0.10−3.72 ng/kg-day (maximum) (EFSA, 2012).

PFBS has been reported in serum of humans in the general population. In American Red Cross samples collected in 2015, 8.4% had a quantifiable serum PFBS concentration; the majority of samples were below the lower limit of quantitation (4.2 nanograms per milliliter [ng/mL]) (Olsen et al., 2017). The National Health and Nutrition Examination Survey (NHANES) included PFBS in consecutive biomonitoring cycles, including 2013–2014 where the 95th percentile reported for PFBS was at or below the level of detection (0.1 ng/mL). Considering the relatively rapid rate of elimination of PFBS (days to weeks), compared with longer chain PFAS (years), the lack of biomonitoring detects (e.g., NHANES 2013–2014 cycle) should not be interpreted as a lack of occurrence or exposure potential. Another study with a

lower limit of detection (0.013 ng/g) reported increasing levels of PFBS in serum from primiparous nursing women in Sweden from 1996 to 2010 (Glynn et al., 2012).

1.3 TOXICOKINETICS

1.3.1 Overview

Animal evidence has shown that PFBS, like other PFAS, is well absorbed following oral administration. PFBS distributes to all tissues of the body (Bogdanska et al., 2014), but a study evaluating the volume of distribution (V_d) concluded that distribution is predominantly extracellular (Olsen et al., 2009). Because of its resistance to metabolic degradation, PFBS is primarily eliminated unchanged in urine and feces.

Three sets of investigators have conducted toxicokinetic studies in rats and monkeys (Huang et al., 2019a; Chengelis et al., 2009; Olsen et al., 2009). Olsen et al. (2009) and Xu et al. (2020) have measured the half-life of PFBS in humans. Bogdanska et al. (2014) and Lau et al. (2020) have reported limited toxicokinetic information in mice. One study developed a physiologically based pharmacokinetic (PBPK) model that includes parameterization for PFBS (Fàbrega et al., 2015).

Results of all studies discussed in this section are summarized in Table 2.

Table 2. Summary of the Toxicokinetics of Serum PFBS (Mean ± SE)

Species/Sex	Study Design	Elimination Half-Life (hr)	AUC (µg-hr/mL)	Clearance	V_d (L/kg)	Reference
Mice

	Single i.v. dose (10 mg/kg)	83.2 ± 41.9	35.4 ± 13.3	368 ± 120 (mL/hr)	0.255 ± 0.017	Olsen et al. (2009)
Humans						
Males and female	Occupational (n = 6)	619.2[f]	NA	NA	NA	Olsen et al. (2009)
Males	Occupational (n =5)	552[f]	NA	NA	NA	Olsen et al. (2009)
Female	Occupational (n = 1)	1,096.8	NA	NA	NA	Olsen et al. (2009)
Males and females	Occupational (n = 26)	1,056	NA	NA	NA	Xu et al. (2020)

[a]Olsen et al. (2009) reported $t_{1/2,\alpha}$ and $t_{1/2,\beta}$ in rats, presenting data for $t_{1/2,\beta}$.
[b]Body weights were reported to be 0.200−0.250 kg (with corresponding clearance of approximately 476 mL/hr-kg).
[c]Huang et al. (2019a) reported $t_{1/2,\alpha}$, $t_{1/2,\beta}$, and $t_{1/2}k_{10}$ in male rats (both oral and i.v.) and female rats (i.v. only); only $t_{1/2}k_{10}$ was reported in female rats (oral). Presenting data for $t_{1/2,\beta}$ for male rats (both oral and i.v.) and female rats (i.v.) and $t_{1/2}k_{10}$ for female rats (oral). The volume of distribution (V_d) was calculated as the sum of volume terms of the central compartment and that of the peripheral compartment except for orally exposed female rats. The volume of the peripheral compartment was not reported for orally exposed female rats, representing the volume of the central compartment only.
[d]The data were monitored 48 hours and 31 days postdosing for Chengelis et al. (2009) and Olsen et al. (2009), respectively.
[e]One male monkey had a serum concentration more than 10-fold higher than the others at 48 hours postdosing with an estimated PFBS half-life of 26 hours.
[f]Olsen et al. (2009) reported mean and geometric mean values for males only and all subjects, presenting data for geometric mean values.

AUC = area under the curve; i.v. = intravenous; NA = not available; PFBS = perfluorobutane sulfonic acid; SE = standard error; $t_{1/2}$ = half-life; V_d = volume of distribution.

1.3.2 Absorption

Olsen et al. (2009) conducted intravenous (i.v.) and oral uptake studies in rats (n = 3/sex) that were given a single dose (30 milligrams per kilogram [mg/kg]) of potassium PFBS (K^+PFBS). The serum area under the concentration curve (AUC) after i.v. administration was 294 ± 77 and 65 ± 5 (µg-hour/mL) in male and female rats, respectively, and 163 ± 10 and 85 ± 12 in males and females, respectively, after oral dosing. The large variance in AUC for male rats after i.v. dosing and greater AUC after oral dosing compared to i.v. dosing in females makes it difficult to interpret these results with certainty, but it seems that PFBS is 100% bioavailable in female rats, whereas the nominal bioavailability in male rats is only 55% based on AUC. Peak concentrations (C_{max}) occurred at 0.3−0.4 hours after oral dosing, showing that absorption was fairly rapid. Bioavailability based on C_{max} was 60% in male rats and 85% in female rats, suggesting a similar sex difference as estimated from the AUCs.

The above findings are generally confirmed by Huang et al. (2019a) who found that absorption of PFBS usually occurred within 24 hours, along with the time reaching the maximal plasma concentration (T_{max}) under 2.4 hours in male rats and under 1.4 hours in female rats, following a single dose of gavage administration in Hsd:Sprague-Dawley (S-D) rats (4, 20, 100 mg/kg of K^+PFBS). However, bioavailability calculated based on the AUC after i.v. and oral doses of 4 mg/kg reported by Huang et al. (2019a) was 75% in males and 60% in females. The C_{max} values of 45% and 27% in males and females, respectively, are qualitatively the opposite of the results from Olsen et al. (2009).

Given the range of estimated bioavailability from the results of Olsen et al. (2009) and Huang et al. (2019a), a difference in this parameter between male and female rats cannot be determined. Averaging the AUC-based values for both males and females from the two studies yields an overall average of 73%.

Notably, Huang et al. (2019a) also observed that the dose-adjusted AUC decreased with increasing doses for both males and females. However, this result could be attributed to saturation of renal resorption at higher doses, rather than a reduction in absorption.

Similar observations indicating rapid absorption of PFBS have been reported for CD-1 mice orally exposed to PFBS at 30 or 300 mg/kg, where T_{max} was estimated to occur between 1 and 2 hours after gavage (Lau et al., 2020).

1.3.3 Distribution

PFBS has been shown to distribute to tissues within 24 hours of exposure, with the liver and kidney being the organs with highest distribution. Lau et al. (2020) evaluated the pharmacokinetic properties of PFBS in CD-1 mice at 8 weeks of age. Male and female mice were given a single dose of 0, 30, or 300 mg/kg body weight PFBS via gavage. The liver and kidneys were harvested 24 hours postdosing. PFBS distributed to both organs readily in a dose-dependent manner but did not accumulate in either organ. Lau et al. (2020) reported similar combined V_d values of 0.275 or 0.278 liter per kilogram [L/kg] in male and female mice, respectively (Table 2).

Olsen et al. (2009) estimated volumes of distribution for K^+PFBS as 0.7 and 0.4 L/kg in male and female rats, respectively, and 0.25 L/kg in male and female cynomolgus macaques and

concluded that K^+PFBS is primarily distributed in the extracellular space. Consistent with the observations by Olsen et al. (2009), Huang et al. (2019a) found that the overall V_d for PFBS was generally comparable between male rats (0.167–0.335 L/kg) and female rats (0.165–0.415 L/kg). Chengelis et al. (2009) calculated a V_d of 0.248 L/kg in female cynomolgus macaques, consistent with females from Olsen et al. (2009). The male monkey V_d from Chengelis et al. (2009) was slightly lower (0.209 L/kg) than corresponding females and males from Olsen et al. (2009). These results indicate V_d is generally comparable between male and female monkeys. Huang et al. (2019a) also evaluated tissue concentrations in the liver, kidney, and brain of male and female rats and reported higher PFBS concentrations in the liver than the kidney, with the lowest concentrations occurring in the brain.

Bogdanska et al. (2014) characterized the tissue distribution of ^{35}S-labeled PFBS in male C57BL/6 mice. The animals (3/group) were exposed for either 1, 3, or 5 days to an average of 16 mg of PFBS/kg-day in the diet. Following 1, 3, and 5 days of exposure, the total estimated recovery of PFBS from all tissues evaluated was 10, 5, and 3.4% of the ingested dose, respectively. The declining recovery with time reflects the lack of accumulation in tissues after the first few days, with continued elimination in the urine. The study authors suggested that these low recovery rates most likely reflect rapid excretion of PFBS and/or potentially limited uptake of the compound; however, the results of Lau et al. (2020) and Olsen et al. (2009) suggest that limited tissue distribution is also a factor.

Bogdanska et al. (2014) found that blood levels of PFBS did not change when comparing values observed after 1 and 5 days of exposure. As with PFOS, PFBS was found to distribute to most of the 20 tissues examined at all exposure durations, but the levels of PFBS were significantly lower (fivefold to 40-fold lower) than those of PFOS in tissues after similar exposure to PFOS, especially in liver and lungs (Bogdanska et al., 2014). These differences might be attributed to chain-length-dependent active transport of perfluorinated chemicals (Weaver et al., 2010). Excluding stomach and fat tissue, PFBS tissue levels increased between 1 and 3 days of exposure, but there were no significant changes in tissue levels between 3 and 5 days of exposure in any tissue examined. As with PFOS, whole bone, liver, blood, skin, and muscle accounted for approximately 90% of the recovered PFBS at all time points. The highest tissue concentrations outside of blood, however, were found in the liver, GI tissues, kidney, and cartilage. The significant total PFBS mass found in muscle and skin was due to the large total volume of these tissues rather than the per unit concentration in them. The liver contained the highest tissue concentration of PFBS at all time points, while the brain contained the lowest.

Human studies were not available on lactational transfer of PFBS. Studies are sparse pertaining to the transplacental transfer of PFBS in humans; in a Spanish mother-child paired cohort, PFBS was not found in maternal blood samples or in corresponding cord blood during the first trimester of pregnancy (Manzano-Salgado et al., 2015). However, developmental studies in animals indicate the potential for effects in offspring following gestational exposure, suggesting direct (i.e., fetus) and/or indirect (maternal/pregnant dam) effects of PFBS on offspring (Feng et al., 2017; York, 2003a, 2002).

Volume of distribution is expected to be similar across mammalian species. For PFBS, the average value for male and female monkeys (0.23 L/kg) is in the range estimated for male

and female rats by Huang et al. (2019a) (0.17–0.42 L/kg), although estimates by Olsen et al. (2009) were slightly higher.

1.3.4 Metabolism

There is no evidence of biotransformation of PFBS. It is expected that PFBS, a short-chain (C4) of perfluoroalkyl acids (PFAAs), is metabolically inert because of the chemical stability that also exists in the longer chain PFAA chemicals, including perfluorohexane sulfonic acid (PFHxS) (C6), PFOS (C8), and perfluorooctanoic acid (PFOA) (C8).

1.3.5 Excretion

To facilitate comparison of differing studies for a given species, results for excretion are organized by species.

1.3.5.1 Mice

Lau et al. (2020) dosed male and female CD-1 mice with 0, 30, or 300 mg/kg body weight PFBS via a single gavage dose. Trunk blood was collected at 0.5, 1, 2, 4, 8, 16, 24, and 48 hours after dosing and urine at 24 hours after dosing. Within 24 hours of dosing, more than 95% of the PFBS measured in serum was excreted into urine. Although the rate of PFBS clearance was linear with administered doses, urine accounted for only 30–43% of the original gavage doses. The half-life of PFBS was estimated to be 4.5 hours in the female mice and 5.8 hours in the males. Sex difference in PFBS elimination was also noted in that the elimination rate of absorbed PFBS was about 28% faster in female mice than male mice. Similarly, AUC estimates for the serum, kidney, and liver compartments were higher in males than in females. The findings are generally comparable to previous studies on rats (Huang et al., 2019a; Olsen et al., 2009).

1.3.5.2 Rats

Chengelis et al. (2009) conducted a single-dose pharmacokinetic study in S-D rats, designed to compare the toxicokinetic behavior of PFBS with that of perfluorohexanoic acid (PFHxA), another PFAA. In this study, 12 male and 12 female rats were each administered a bolus dose of PFBS (10 mg/kg) via i.v. injection. Blood samples were collected from three animals per sex at 0.5, 1, 1.5, 2, 4, 8, and 24 hours after dosing. Additionally, to determine urinary excretion, three animals per sex were housed in metabolic cages following dose administration and their urine collected over the following time intervals: 0−6, 6−12, and 12−24 hours postdosing. Chengelis et al. (2009) fit the data to a noncompartmental model to calculate pharmacokinetic parameters. Female rats had an approximately threefold shorter mean elimination half-life of PFBS in serum (0.64 hour) than male rats (2.1 hour). This result could be in part due to the difference in clearance and V_d. The mean apparent clearance of PFBS from the serum was approximately eightfold higher for female rats (0.311 L/hour-kg) than for male rats (0.0394 L/hour-kg), and the mean apparent V_d for PFBS in the serum was approximately 2.4-fold higher for female rats (0.288 L/kg) than for male rats (0.118 L/kg). Approximately 70% of the administered dose of PFBS was recovered in the urine over 24 hours postdosing regardless of sex. Using the urine data, the mean half-life values for male rats and female rats were determined to be 3.1 and 2.4 hours, respectively; the finding of longer urinary half-lives in males is consistent with those observed for serum half-lives.

Olsen et al. (2009) evaluated the elimination of PFBS in S-D rats after i.v. and oral exposure to K^+PFBS. The terminal serum elimination half-lives following i.v. administration of 30 mg/kg K^+PFBS were 4.51 ± 2.22 hours for males and 3.96 ± 0.21 hours for females (mean ± standard deviation [SD]). Although there was no statistically significant difference between the terminal serum half-lives in male and female rats, there was a statistically significant difference in the urinary clearance rates ($p \leq 0.01$), with female rats (469 ± 40 mL/hour) having faster clearance rates than male rats (119 ± 34 mL/hour). Because clearance [CL] is calculated from the ratio of the volume of distribution [V_d] to the half-life [$t_{1/2}$], CL = 0.693 × V_d ÷ $t_{1/2}$, differences in V_d can lead to differences in CL, even when $t_{1/2}$ is similar between comparison groups. For rats receiving an oral dose, terminal serum K^+PFBS elimination half-lives were significantly different ($p \leq 0.05$) for males ($t_{1/2}$ = 4.68 ± 0.43 hour) versus females ($t_{1/2}$ = 7.42 ± 0.79 hour).

Huang et al. (2019a) also evaluated elimination of PFBS following a single i.v. or gavage dose in male or female Hsd:S-D rats (4, 20, 100 mg/kg of K^+PFBS). They reported elimination half-lives ($t_{1/2,\beta}$) following i.v. administration of PFBS in male and female rats of 4.22 and 0.95 hours, respectively. The data for male rats after both oral and i.v. dosing and female rats administered PFBS by i.v. fit a two-compartment model, whereas data in female rats dosed via gavage fit a one-compartment model. Thus, elimination half-lives were only reported for male rats following oral exposure and ranged from 4.89−5.36 hours. Overall plasma elimination half-lives ($t_{1/2}$ k_{10}) reported in female rats after oral administration were between 1.11−1.50 hours, approximately three to fourfold faster than in males that ranged from 4.89−5.36 hours. Similarly, clearance was three to sixfold higher in females than males given the same dose (26.5−75.5 mL/hour-kg in males, 152−259 mL/hour-kg in females).

The serum K^+PFBS elimination half-lives reported by Huang et al. (2019a) are consistent with the findings of Olsen et al. (2009) in male rats but not in female rats. In general, the elimination half-life of serum PFBS observed by Huang et al. (2019a) in female rats was two to fourfold shorter than seen by Olsen et al. (2009). Similarly, Chengelis et al. (2009) calculated half-lives using a one compartment model for each group, whereas Olsen et al. (2009) determined separate α and β phases via a two-compartment model. Thus, the half-life estimates of Olsen et al. (2009) following i.v. administration (4.51−3.96 hours) are higher than those estimated by Chengelis et al. (2009) based on urine data (0.64-2.1 hours).

1.3.5.3 Monkeys

Similar to their study in rats, Chengelis et al. (2009) investigated the toxicokinetic profile of PFBS through a series of experiments in the cynomolgus macaque (*Macaca fascicularis*). Monkeys (three males and three females) were each administered a bolus i.v. dose of 10 mg/kg PFBS. The controlled exposure to PFBS occurred 7 days after the same animals were each administered a bolus dose of PFHxA (10 mg/kg). Blood samples were collected at 0 hours (immediately prior to dosing) and at 1, 2, 4, 8, 24, and 48 hours after dose administration and were analyzed to determine PFBS concentration in serum. Only a single clearance half-life was estimated. The estimated half-life of PFBS in serum ranged from 5.8 to 26.0 hours in this experiment, and the median half-life was 9.55 hours for the six animals.

Olsen et al. (2009) also evaluated the elimination of PFBS (specifically, K^+PFBS) in cynomolgus macaques after i.v. dosing. A significant difference in design from the study of

Chengelis et al. (2009) is that Olsen et al. (2009) followed PFBS elimination for 31 days in monkeys (vs. 48 hours), allowing them to identify both an initial clearance half-life and a terminal-phase half-life. Olsen et al. (2009) did not observe statistically significant sex-related differences in half-life or clearance between male and female monkeys, unlike those observed in rats. In monkeys, the mean terminal serum elimination half-lives, after i.v. administration of 10 mg/kg K^+PFBS, were 95.2 ± 27.1 hours in males and 83.2 ± 41.9 hours in females.

The serum half-life data in Olsen et al. (2009) clearly show a slow elimination phase in monkeys that does not begin until 4−10 days after dosing. Chengelis et al. (2009) followed elimination for only 48 hours, hence could not have observed this terminal clearance phase. The initial elimination half-life ($t_{1/2,\beta}$) estimated by Olsen et al. (2009) in monkeys—13 hours for males, 11 hours for females—is essentially identical to the values estimated by Chengelis et al. (2009)—10 or 15 hours for males (without/with outlier) and 8 hours in females. Hence the two studies appear consistent in identifying an initial elimination half-life, but the difference in design precluded Chengelis and colleagues from identifying the longer (terminal) half-life of PFBS.

1.3.5.4 Humans

In addition to their experimental studies in rats and monkeys, Olsen et al. (2009) evaluated the elimination of human serum K^+PFBS in a group of workers with occupational exposure, with serum concentrations measured up to 180 days after cessation of further K^+PFBS work-related activity. Given that the workers had been occupationally exposed, distribution into the tissues is expected to have been complete before the observations began. The reported mean serum half-life was 23 days in males (n = 5) and 45.7 days in females (n = 1). Among the six subjects (five males, one female), the reported geometric mean serum elimination half-life for K^+PFBS was 25.8 days (95% confidence interval [CI]: 16.6−40.2 days). Because there was only one female subject, these data cannot be used to establish a significant sex difference in elimination. Urine appeared to be a major route of elimination in humans based on observed urine levels of PFBS in the study.

Xu et al. (2020) also measured PFBS elimination in a study population with previous occupational exposure, in this case airport employees who were exposed to firefighting foam that contained PFBS. Eleven male and six female employees provided repeated blood samples during a period of observation with minimal exposure, and the data were analyzed with a linear mixed-effects pharmacokinetic model. The average half-life was 44 days (95% CI: 37−55 days). Although Xu et al. (2020) evaluated age and sex as covariates of their statistical model, they did not report either as being a significant factor for PFBS elimination. The average half-life (44 days) is larger than that reported by Olsen et al. (2009) (25.8 days), but there is significant overlap: the range of Xu et al. (2020) is 21.6−87.2 days while the range of Olsen et al. (2009) is 13.1−45.7 days.

For the sake of comparison, the linear mixed model used by Xu et al. (2020) was also applied to the estimated serum PFBS elimination half-life for the population and each individual worker (five male, one female) who manufactured K^+PFBS, described in Olsen et al. (2009). In brief, a linear mixed effect model is an extension of simple linear models that can be used to estimate toxicokinetic parameters such as the serum elimination rate constant (k_{elim}) and half-life by assuming one-compartment first-order elimination kinetics. The details of the linear

mixed-effect model have been reported previously Li et al. (2018). Because of the limited sample size (only one female worker) and the lack of data on participant age for each worker in the study, age and sex were not included in the linear mixed model for reanalysis of the Olsen et al. (2009) data, whereas both were included in Xu et al. (2020). In general, the estimated half-life using the linear mixed effect model were similar to originally reported values in Olsen et al. (2009). For instance, as compared with the reported average of 25.8 days ranging from 13.1−45.7 days (Olsen et al., 2009), the estimated population elimination half-life for serum PFBS was 25.0 days with individual estimates of 14.6−42.9 days using the linear mixed effect model.

Although the estimated serum half-lives of PFBS in Olsen et al. (2009) overlapped with those of Xu et al. (2020) (mean = 43.8 days, range = 21.9−87.6 days), there is a statistically significant difference between these two studies as suggested by both parametric (one-way analysis of variance [ANOVA]) and nonparametric analyses (Kruskal-Wallis test). Overall, the estimated serum half-life of PFBS by Xu et al. (2020) is about twofold higher than Olsen et al. (2009).

Some of the difference between Xu et al. (2020) and Olsen et al. (2009) may be due to the difference in initial concentration, where the Olsen et al. (2009) subjects had initial concentrations ranging from 100−1,000 ng/mL PFBS, while the highest initial concentrations in Xu et al. (2020) was 1.3 ng/mL. It is possible that the higher serum levels in the Olsen et al. (2009) subjects resulted in saturation of renal resorption, hence more rapid excretion/shorter half-lives. However, to the extent that some ongoing low-level exposure occurred during the period of observation, such exposure would cause a greater bias towards over-estimation of the elimination half-life for the Xu et al. (2020) subjects than those of Olsen et al. (2009). The data of Olsen et al. (2009) might also have a greater signal:noise ratio than the data of Xu et al. (2020). Despite this uncertainty, the fact that the blood concentrations of the Xu et al. (2020) are more representative of environmental exposure, that their sample size was larger, and a significant statistical difference was observed, the two data sets will not be combined and the half-life estimated by Xu et al. (2020) is presumed to better predict human dosimetry at environmental levels.

The possibility that menstrual blood loss could contribute to overall clearance was evaluated, assuming that the concentration of PFBS in menstrual blood is the same as in the general circulation and that the V_d in humans is equal to the average value estimated for monkeys (0.23 L/kg). The results indicate that this avenue of loss is more than two orders of magnitude slower than that indicated by the measured PFBS half-life in humans. Thus, menstrual blood loss is unlikely to contribute significantly to overall PFBS elimination.

1.3.6 Physiologically Based Pharmacokinetic Models

Fàbrega et al. (2015) developed a physiologically based pharmacokinetic model to estimate the concentration of PFAS, including PFBS, in human tissues based on an existing model and experimental data on concentrations of PFAS in human tissues from individuals in Catalonia, Spain. Several uncertainties in the model limit the use for this assessment of PFBS.

There are three chemical-specific parameters that determine the rate of elimination: the free fraction in blood, the maximum rate of resorption in the kidney (T_m), and the saturation

constant for that resorption (K_t). No details beyond a rough description are provided on how these parameter values were identified. The data used for calibration are population samples in adults, who would essentially be at steady state, and only a single average level of exposure and corresponding blood concentration are reported, precluding the possibility of evaluating exposure or concentration dependence. In this situation it is not possible to uniquely identify the three parameters. This lack of identifiability is likely to be an underlying cause of the extreme variability in the individual parameter values (among the 11 PFAS evaluated) reported by Fàbrega et al. (2015).

In addition, the rate constant for elimination from the glomerular filtrate compartment to the urine "storage" compartment (i.e., the bladder) is the total glomerular filtration rate (GFR), which is approximately 10 L/hour in a 70 kg adult. But most of the glomerular flow is resorbed in the nephrons, and human urinary output is less than 2 L/day. Hence, the use of GFR for elimination is not realistic. Finally, note that while the model structure and the equations listed by Fàbrega et al. (2015) appear to be appropriate for most humans, excretion via lactation is not included.

Of considerable concern is the way in which partition coefficients (PCs) were identified. In particular, PCs were obtained by taking tissue concentration data from cadavers and comparing those to average blood concentrations from volunteer subjects, albeit from the same geographical area (county in Spain). The liver:blood PC for PFDA was thereby estimated to be 0.001 while the value for PFNA was 1.65. By contrast, Kim et al. (2019) obtained values of ~0.6–0.7 for PFDA in male and female rats, ~1.2 for PFNA in male rats, and ~0.5 for PFNA in female rats. Thus, there seems to be extreme inconsistency and hence uncertainty in these parameters as estimated by Fàbrega et al. (2015). Generally, human PCs should have values similar to those in rats.

The study authors do not compare model predictions for Tarragona County, Spain, with measured values for county residents (i.e., the data used for model calibration). Also, the study authors state that 20−30 years of simulated time are required to reach steady state. These steady-state estimates are inconsistent with the elimination data from Olsen et al. (2009), in which the half-life in males was 24 days, and in one female subject 46 days. These empirical half-lives are consistent with a time to steady state of less than a year, indicating that the predicted clearance from Fàbrega et al. (2015) may be an order of magnitude or more too low. At the same time, the simulated levels of five PFAS (average levels) were consistently lower than the averages in the validation data, four of these being lower by an order of magnitude or more.

Thus, predictions of the Fàbrega et al. (2015) model are considered highly uncertain, and data other than those used by the study authors will be needed to accurately estimate key pharmacokinetic (PK) parameters for PFBS and these other PFAS, a task that would require significant additional research.

1.3.7 Summary

Collectively, elimination half-lives appear to be similar for mice and rats, with potential sex-specific toxicokinetic differences being reported (i.e., females appearing to have a faster elimination rate). Humans have a longer serum elimination half-life (~weeks) than both rodents

(~hours) and monkeys (~days). Further, although V_d information is not available for humans, observations in male and female mice, rats, and monkeys exposed to comparable doses indicate comparability across species. Results of all studies discussed in this section are summarized in Table 2.

2.0 PROBLEM FORMULATION

2.1 CONCEPTUAL MODEL

A conceptual model was developed to summarize the availability of data to understand potential health hazards related to exposure to PFBS and/or K^+PFBS. The potential sources of these chemicals, the routes of exposure for biological receptors of concern (e.g., various human activities related to ingested drinking water, and food preparation and consumption), the potential organs and systems affected by exposure (e.g., effects such as developmental toxicity), and potential populations at risk due to exposure to PFBS and/or potassium salt are depicted in the conceptual diagram in Figure 2. Arrows indicate linkage between one or more boxes between levels of organization.

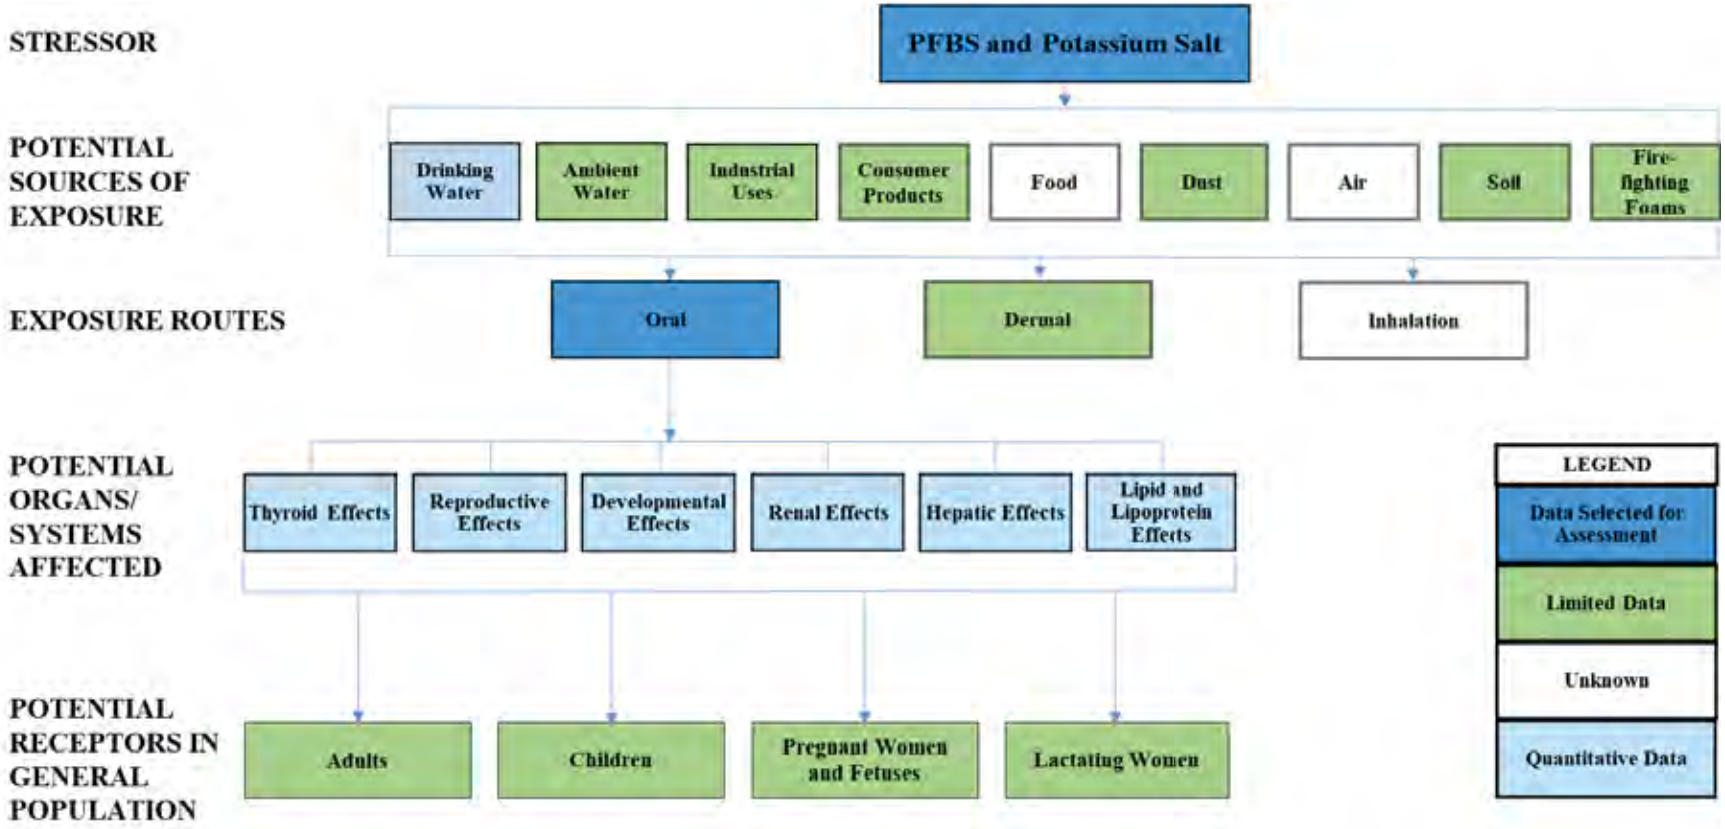

Figure 2. Conceptual Model for PFBS and/or Potassium Salt

2.2 OBJECTIVE

The overall objective of this assessment is to provide the health effects basis for the development of oral reference doses (RfDs) for PFBS (CASRN 375-73-5) and its related compound K^+PFBS (CASRN 29420-49-3), including the science-based decisions providing the basis for identifying potential human health effects and estimating PODs. Based on the needs of the U.S. EPA partner program offices, regions, states, and/or tribes as they pertain to diverse exposure scenarios and human populations, subchronic and chronic RfDs have been derived. The assessment includes studies and information previously provided in the 2014 PPRTV assessment (U.S. EPA, 2014f) and builds upon data from the literature published since that review.

2.3 METHODS

2.3.1 Literature Search

Four online scientific databases (PubMed, Web of Science, TOXLINE, and TSCATS via TOXLINE) were searched by the U.S. EPA's Health and Environmental Research Online (HERO) staff and stored in the HERO database.[5] The literature search focused on chemical name and synonyms with no limitations on publication type, evidence stream (i.e., human, animal, in vitro, and in silico), or health outcomes. Full details of the search strategy for each database are presented in Appendix A. The initial database searches were conducted on July 18, 2017 and updated on February 28, 2018; May 1, 2019; and May 15, 2020. Additional studies [e.g., Lau et al. (2020); Xu et al. (2020)] were identified during subsequent review periods and integrated into the assessment as appropriate. Studies were also identified from other sources relevant to PFBS, including studies submitted to the U.S. EPA by the manufacturer of PFBS (i.e., 3M) as part of the Toxic Substances Control Act (TSCA) premanufacture notices for other PFAS chemicals or as required under TSCA reporting requirements and studies referenced in prior evaluations of PFBS toxicity (MDH, 2020; ATSDR, 2015). In addition, on March 29, 2018, the National Toxicology Program (NTP) published study tables and individual animal data from a 28-day toxicity study of PFBS (http://doi.org/10.22427/NTP-DATA-002-01134-0003-0000-4), with a protocol outlining the NTP study methods available in HERO (https://hero.epa.gov/hero/index.cfm/reference/details/reference_id/4309741) (NTP, 2011). The final *NTP Technical Report on the Toxicity Studies of Perfluoroalkyl Sulfonates Administered by Gavage to Sprague-Dawley Rats* was published in August, 2019 (NTP, 2019).

2.3.2 Screening Process

Two screeners independently conducted a title and abstract screening of the search results using DistillerSR[6] to identify study records that met the Population, Exposure, Comparator, and Outcome (PECO) eligibility criteria (see Appendix B for a more detailed summary):

[5]The U.S. EPA's HERO database provides access to the scientific literature behind U.S. EPA science assessments. The database includes more than 2,500,000 scientific references and data from the peer-reviewed literature used by the U.S. EPA to develop its regulations.

[6]DistillerSR is a web-based systematic review software used to screen studies available at https://www.evidencepartners.com/products/distillersr-systematic-review-software.

- Population: Human and nonhuman mammalian animal species (whole organism) of any life stage and in vitro models of genotoxicity.
- Exposure: Any qualitative or quantitative estimates of exposure of PFBS or K^+PFBS, via oral or inhalation routes of exposure. (Note: Nonoral and noninhalation studies are tracked as potential supplemental material and are presented in Section 4.8.2.)
- Comparator: A comparison or reference population exposed to lower levels or for shorter periods of time for humans. Exposure to vehicle-only or untreated control in animals.
- Outcome: Any examination of cancer or noncancer health outcomes.

In addition to the PECO criteria, the following additional exclusion criteria were applied, although these study types were tracked as supplemental material as described following the exclusion criteria:

- Records that do not contain original data such as other agency assessments, scientific literature reviews, editorials, and commentaries;
- Abstract only (e.g., conference abstracts); and
- Retracted studies.

Records that were not excluded based on title and abstract screening advanced to full-text review using the same PECO eligibility criteria. Studies that have not undergone peer review were included if the information could be made public and sufficient details of study methods and findings were included in the reports. Full-text copies of potentially relevant records identified from title and abstract screening were retrieved, stored in the HERO database, and independently assessed by the screeners using DistillerSR to confirm eligibility. At both title/abstract and full-text review levels, screening conflicts were resolved by discussion between the primary screeners in consultation with a third reviewer to resolve any remaining disagreements. During title/abstract or full-text level screening, studies that were not directly relevant to the PECO, but could provide supplemental information, were categorized (or "tagged") by the type of supplemental information they provided (e.g., review, commentary, or letter with no original data; conference abstract; toxicokinetics; mechanistic information aside from in vitro genotoxicity studies; other routes of exposure; exposure only). Conflict resolution was not required during the screening process to identify supplemental information (i.e., tagging by a single screener was sufficient to identify the study as potential supplemental information).

2.3.3 Study Evaluation

Study evaluation was conducted by one reviewer for epidemiological studies and by two independent reviewers for animal studies using the U.S. EPA's version of Health Assessment Workspace Collaborative (HAWC), a free and open source web-based software application designed to manage and facilitate the process of conducting literature assessments.[7] For pragmatic purposes, only one reviewer was considered necessary for epidemiological studies because it was apparent during literature screening that the animal evidence would be the most informative for deriving toxicity values. The available outcomes in the epidemiological studies were heterogeneous and unrelated to each other, and only a single study was available for each

[7]HAWC: A modular web-based interface to facilitate development of human health assessments of chemicals (https://hawcproject.org/).

outcome. This approach is consistent with recommendations from the National Academies of Science encouraging the U.S. EPA to explore ways to make systematic review more feasible, including a "rapid review in which components of the systematic review process are simplified or omitted (e.g., the need for two independent reviewers)" (NASEM, 2017). Study evaluation was not conducted for studies tagged during screening as supplemental information.

The general approach for evaluating epidemiology and animal toxicology was the same (see Figure 3), but the specifics of applying the approach differed. These evaluations were focused on the methodological approaches and completeness of reporting in the individual studies, rather than on the direction or magnitude of the study results. Evaluation of epidemiology studies was conducted for the following domains: exposure measures, outcome measures, participant selection, confounding, analysis, sensitivity, and selective reporting. For animal studies, the evaluation process focused on assessing aspects of the study design and conduct through three broad types of evaluations: reporting quality, risk of bias, and study sensitivity. A set of domains with accompanying core questions fall under each evaluation type and directed individual reviewers to evaluate specific study characteristics. For each domain evaluated for experimental animal studies (reporting quality, selection or performance bias, confounding/variable control, reporting or attrition bias, exposure methods sensitivity, and outcome measures and results display), basic considerations provided additional guidance on how a reviewer might evaluate and judge a study for that domain. Core and prompting questions used to guide the criteria and judgment for each domain are presented in Appendix C. Key concerns for the review of epidemiology and animal toxicology studies are potential sources of bias (factors that could systematically affect the magnitude or direction of an effect in either direction) and insensitivity (factors that limit the ability of a study to detect a true effect).

For each study in each evaluation domain, reviewers reached a consensus rating regarding the utility of the study for hazard identification, with categories of *good*, *adequate*, *deficient*, *not reported*, or *critically deficient*. These ratings were then combined across domains to reach an overall classification of *high*, *medium*, or *low confidence* or *uninformative* (definitions of these classifications are available in Appendix C). The rationale for the classification, including a brief description of any identified strengths and/or limitations from the domains and their potential impact on the overall confidence determination, is documented and retrievable in HAWC. Uninformative studies were not used in evidence synthesis or dose-response analysis. Studies were evaluated for their suitability for each health outcome investigated and could receive different ratings for each outcome.

For epidemiological studies, exposure-specific criteria were developed prior to evaluation and are described in detail in Appendix C. In brief, standard analytical methods of measurement of PFBS in serum or whole-blood using quantitative techniques such as liquid chromatograph-triple quadrupole mass spectrometry and high-pressure liquid chromatography with tandem mass spectrometry were preferred. In addition, exposure must have been assessed in a relevant time window for development of the outcome.

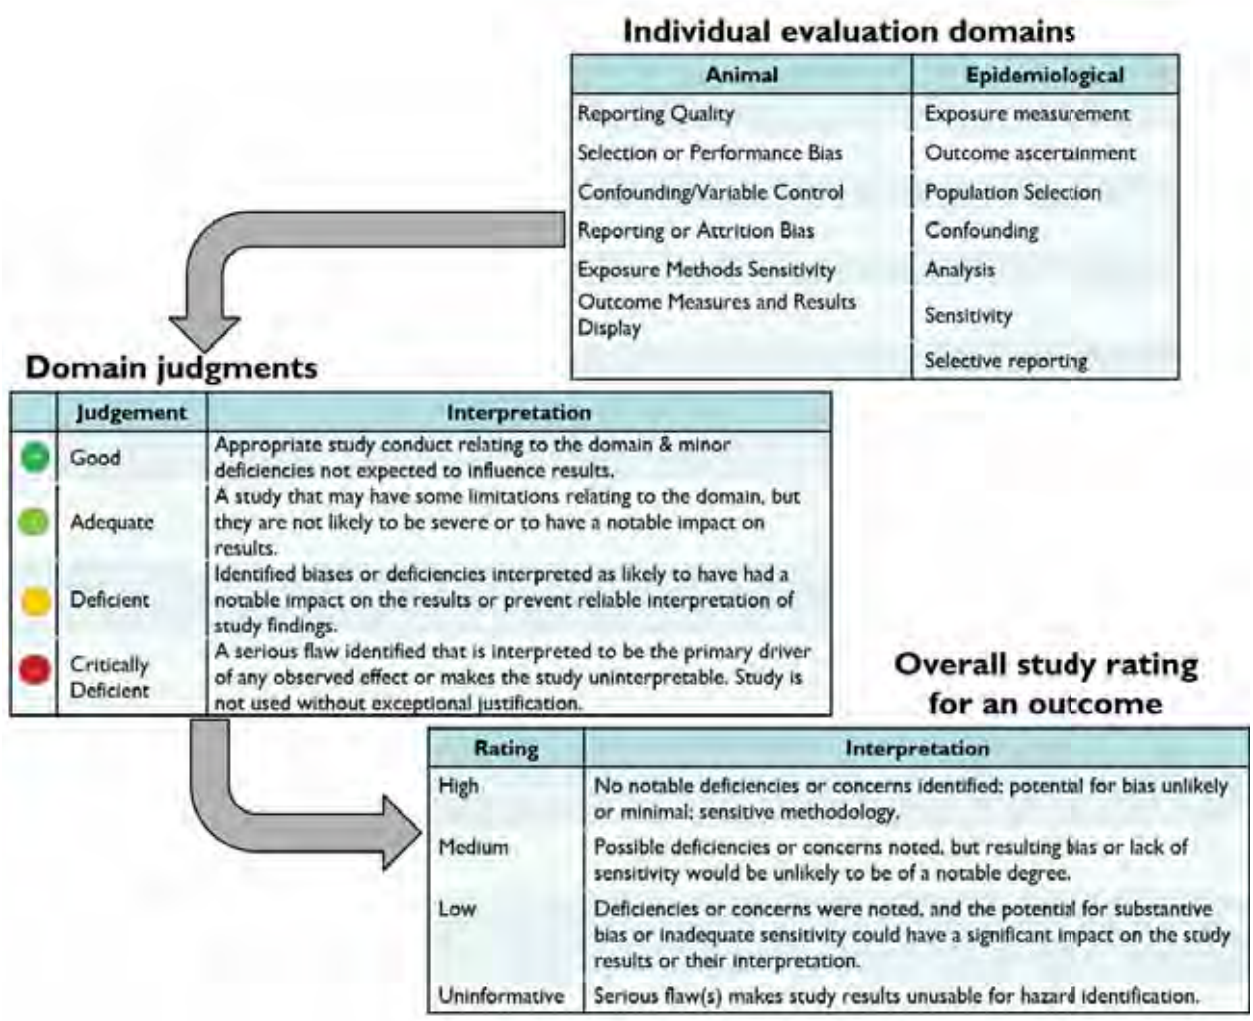

Figure 3. Approach for Evaluating Epidemiological and Animal Toxicology Studies

2.3.4 Data Extraction

Information on study design, methods, results, and data from animal toxicology studies were extracted into the HAWC and are available at https://hawcprd.epa.gov/assessment/100000037/. Visual graphics prepared from HAWC are embedded as hyperlinks and are fully interactive when viewed online by way of a "click to see more" capability. Clicking on content allows access to study evaluation ratings, methodological details, and underlying study data. The action of clicking on content contained in those visual graphics (e.g., data points, endpoint, and study design) will yield the underlying data supporting the visual content.[8] A HAWC user guide can be found in Appendix D. Study methods and findings from epidemiological studies were described in narratives, given the small size and heterogeneity of the evidence base. Data extraction was performed by one member of the evaluation team and checked by one to two other members. Any discrepancies in data extraction

[8]The following browsers are fully supported for accessing HAWC: Google Chrome (preferred), Mozilla Firefox, and Apple Safari. There are errors in functionality when viewed with Internet Explorer.

were resolved by discussion or consultation with a third member of the evaluation team. Digital rulers such as WebPlotDigitizer and Grab It! (https://automeris.io/WebPlotDigitizer/ and https://grab-it.soft112.com/, respectively) were used to extract numerical information from figures. Use of digital rulers was documented during extraction. Dose levels were extracted as reported in the study and converted to mg/kg-day (HED) for endpoints that were considered for use in the dose-response and derivation of toxicity values.

2.3.5 Evidence Synthesis

For the purposes of this assessment, after study evaluation, the informative evidence for each outcome was summarized from the available human studies and, separately, the available animal studies. This synthesis provides a short synopsis of the breadth of data available to inform each outcome and summarizes information on the general study design, doses tested, outcomes evaluated, and results for the endpoints of interest within each study. While the evidence synthesis describes inferences about the methodological rigor and sensitivity of the individual studies (i.e., study confidence) and discusses the pattern and magnitude of the experimental findings within studies, it does not include conclusions drawn across the sets of studies (see "Evidence Integration and Hazard Characterization," next).

2.3.6 Evidence Integration and Hazard Characterization

In this assessment, the evaluation of the available evidence from informative human and animal studies was described in an evidence integration narrative for each outcome, including overall evidence integration judgments as to whether the data provide evidence sufficient to support a hazard. These integrated judgments serve to characterize the extent of the available evidence for each outcome, including information on potential susceptible populations and life stages, as well as important uncertainties in interpreting the data.

The evidence integration for each health effect considered aspects of an association that might suggest causation first introduced by Austin Bradford Hill (Hill, 1965), including the consistency, exposure-response relationship, strength of association, biological plausibility, and coherence of the evidence. This involved weighing the PFBS-specific human and animal evidence relating to each of these considerations within or across studies, including both evidence that supports causation as well as evidence that indicates lack of support. For example, the evaluation of consistency examined the similarity of results across studies (e.g., direction and magnitude). When inconsistencies across studies were identified, the evaluation considered whether results were "conflicting" (i.e., unexplained positive and negative results in similarly exposed human populations or in similar animal models) or "differing" (i.e., mixed results explained by differences between human populations, animal models, exposure conditions, or study methods), based on analyses of potentially important explanatory factors such as confidence in the studies' results (the results of higher confidence studies were emphasized), exposure levels or duration, or differences in populations or species (including potential susceptible groups) across studies (U.S. EPA, 2005). While consistent evidence across studies increases support for a hazard, unexplained inconsistency or conflicting evidence decreases support for a hazard. The evaluations of these considerations were informed by U.S. EPA guidelines, including *Guidelines for Developmental Toxicity Risk Assessment* (U.S. EPA, 1991a) and *Guidelines for Reproductive Toxicity Risk Assessment* (U.S. EPA, 1996a).

The overall evidence integration judgments were developed using a structured framework based on evaluation of the considerations above (see Table 3). Using this framework, the human and animal evidence for each health effect was judged separately as *supports a hazard*, *equivocal*, or *supports no hazard*. Evidence integration judgments of *supports a hazard* span a range of supportive evidence bases that can be further differentiated by the quantity and quality of information available to rule out alternative explanations for the results. *Equivocal* evidence is limited in terms of the quantity, consistency, or confidence level of the available studies and serves to encourage additional research. *Supports no hazard* requires several high-confidence studies across potentially susceptible populations with consistent null results; this judgment was not reached in this assessment. Overall evidence integration judgments were made based on conclusions from both the animal and human data, considering the available information on the human relevance of findings in animals. Thus, for example, evidence in animals that *supports a hazard* alongside *equivocal* human evidence in the absence of information indicating that the responses in animals are unlikely to be relevant to humans would result in an overall judgment of *supports a hazard* for that outcome.

Table 3. Criteria for Overall Evidence Integration Judgments

	Animal	**Human**
Supports a hazard	The evidence for effects is consistent or largely consistent in at least one high- or medium-confidence experiment.[a] Although notable uncertainties across studies might remain, any inconsistent evidence or remaining uncertainties are insufficient to discount the cause for concern from the positive experiments. In the strongest scenarios, the set of experiments provide evidence supporting a causal association across independent laboratories or species. In other scenarios, including evidence for an effect in a single study, the experiment(s) demonstrate additional support for causality such as coherent effects across multiple related endpoints; an unusual magnitude of effect, rarity, age at onset, or severity; a strong dose-response relationship; and/or consistent observations across exposure scenarios (e.g., route, timing, or duration), sexes, or animal strains.	One or more high- or medium-confidence independent studies reporting an association between the exposure and the health outcome. In general, the study results are largely consistent or any inconsistent results are insufficient to discount the cause for concern from the higher confidence study or studies, and there is reasonable confidence that alternative explanations, including chance, bias, and confounding, have been ruled out. In situations in which only a single study is available, the results of multiple studies are heterogeneous, or alternative explanations, including chance, bias and confounding, have not been ruled out, there is additional supporting evidence such as associations with biologically related endpoints in other human studies (coherence), large estimates of risk, or strong evidence of an exposure-response within or across studies.

Table 3. Criteria for Overall Evidence Integration Judgments

	Animal	Human
Equivocal	The evidence is generally inadequate to determine hazard. This includes a lack of relevant studies available or a set of low-confidence experiments. It also includes scenarios with a set of high- or medium-confidence experiments that are not reasonably consistent or not considered informative to the hazard question under evaluation. This category would also include a single high- or medium-confidence experiment with weak evidence of an effect (e.g., changes in one endpoint among several related endpoints, and without additional evidence supporting causality).	The evidence is considered inadequate to describe an association between exposure and the health outcome with confidence. This includes a lack of studies available in humans, only low-confidence studies, or considerable heterogeneity across medium- or high-confidence studies. This also includes scenarios in which there are serious residual uncertainties across studies (these uncertainties typically relate to exposure characterization or outcome ascertainment, including temporality) in a set of largely consistent medium- or high-confidence studies.
Supports no hazard	A set of high-confidence experiments examining the full spectrum of related endpoints within a type of toxicity, with multiple species, and testing a reasonable range of exposure levels and adequate sample size in both sexes, with none showing any indication of effects. The data are compelling in that the experiments have examined the range of scenarios across which health effects in animals could be observed, and an alternative explanation (e.g., inadequately controlled features of the studies' experimental designs) for the observed lack of effects is not available. The experiments were designed to specifically test for effects of interest, including suitable exposure timing and duration, post-exposure latency, and endpoint evaluation procedures, and to address potentially susceptible populations and life stages.	Several high-confidence studies, showing consistently null results (e.g., an OR of 1.0) ruling out alternative explanations including chance, bias, and confounding with reasonable confidence. Each of the studies should have used an optimal outcome and exposure assessment and adequate sample size (specifically for higher exposure groups and for sensitive populations). The set as a whole should include the full range of levels of exposures that human beings are known to encounter, an evaluation of an exposure response gradient, and at-risk populations and life stages and should be mutually consistent in not showing any indication of effect at any level of exposure.

[a]"Experiment" refers to measurements in a single population of exposed animals (e.g., a study that included separate evaluations of rats and of mice, or separate cohorts exposed at different life stages, would be considered as multiple experiments). Conversely, two papers or studies that report on the same cohort of exposed animals (e.g., examining different endpoints) would not be considered separate experiments.

OR = odds ratio.

The primary evidence and rationale supporting these decisions were summarized in a single evidence profile table to transparently convey the aspects of the evidence that were considered to increase or decrease the hazard support for each health effect. For the purposes of this assessment, only the integrated evidence that *supports a hazard* was considered for use in the dose-response analysis and derivation of toxicity values.

2.3.7 Derivation of Values

Development of the dose-response assessment for PFBS and/or the potassium salt has followed the general guidelines for risk assessment put forth by the National Research Council (NRC, 1983) and the U.S. EPA's *Framework for Human Health Risk Assessment to Inform*

Decision Making (U.S. EPA, 2014c). Other U.S. EPA guidelines and reviews considered in the development of this assessment include the following:

- *A Review of the Reference Dose and Reference Concentration Processes* (U.S. EPA, 2002).
- *A Framework for Assessing Health Risks of Environmental Exposures to Children* (U.S. EPA, 2006).
- *Exposure Factors Handbook* (U.S. EPA, 2011a).[9]
- *Recommended Use of Body Weight$^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose* (U.S. EPA, 2011b).
- *Guidance for Applying Quantitative Data to Develop Data-Derived Extrapolation Factors for Interspecies and Intraspecies Extrapolation* (U.S. EPA, 2014d).
- *Benchmark Dose Technical Guidance Document* (U.S. EPA, 2012).
- *Child-Specific Exposure Scenarios Examples* (U.S. EPA, 2014a).

The U.S. EPA's *A Review of the Reference Dose and Reference Concentration Processes* describes a multistep approach to dose–response assessment, including analysis in the range of observation followed by extrapolation to lower levels (U.S. EPA, 2002). As described above, before deriving toxicity values, the U.S. EPA conducted a comprehensive evaluation of available human epidemiological and animal toxicity studies to identify potential health hazards and associated dose-response information through the literature search and screening, study evaluation, evidence synthesis, and evidence integration steps. This evaluation informed the selection of candidate key studies and critical effects for dose-response analysis, from which the U.S. EPA identified a critical effect and point of departure (POD) for subchronic and chronic reference value derivation and extrapolated a selected POD to a corresponding RfD (e.g., subchronic RfD). For dose-response analysis of PFBS and/or the potassium salt, the U.S. EPA used the BMD approach to identify a POD. The steps for deriving an RfD using the BMD approach are summarized below.

- **Step 1: Evaluate the data to identify and characterize endpoints related to exposure to PFBS chemicals.** This step involved determining the relevant studies and adverse effects to be considered for BMD modeling. Once the appropriate data were collected, evaluated for study quality, and characterized for adverse outcomes, endpoints were selected that were judged to be relevant (i.e., for the purposes of this assessment, effects that were sufficient to *support a hazard*) and sensitive as a function of dose (typically defined by the no-observed-adverse-effect level [NOAEL] value). In this assessment, these decisions were directly informed by the evidence integration judgments arrived at for each assessed health outcome. Some of the most important considerations that influenced selection of endpoints for BMD modeling include data showing a dose-response relationship, percent change from controls, adversity of effect, and consistency across studies. For PFBS, thyroid, developmental, and kidney endpoints were considered for toxicity value derivations.

[9]Please note that specific updates to this handbook are available at https://cfpub.epa.gov/ncea/risk/recordisplay.cfm?deid=236252.

- **Step 2: Convert the adjusted daily doses to an HED.** The adjusted daily doses were converted to HEDs by considering U.S. EPA's *Recommended Use of Body Weight$^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose* (U.S. EPA, 2011b).
- **Step 3: Select the benchmark response (BMR) level.** The endpoints selected were modeled using the U.S. EPA's *Benchmark Dose Technical Guidance Document* (U.S. EPA, 2012). The BMR is a predetermined change in the response rate of an adverse effect. It serves as the basis for obtaining the benchmark dose lower confidence limit (BMDL), which is the 95% lower bound of the BMD. BMRs were identified and applied consistent with quantal and continuous data and, when possible, informed by understanding of biological significance.
- **Step 4: BMD model the data.** This step involved fitting a statistical model to the dose-response data that describes the data set of the identified adverse effect. Typically, this involved selecting a family or families of models (e.g., polynomial continuous, Hill continuous, or exponential continuous) for further consideration based on the data and experimental design. In this step, a BMDL was derived by placing confidence limits (one- or two-sided) and a confidence level (typically 95%) on a BMD to obtain the dose that ensures with high confidence that the BMR is not exceeded.
- **Step 5: Determine a POD (HED).** If modeling was feasible, the estimated BMDL (HED)s were used as PODs (i.e., POD [HED]). If dose-response modeling was not feasible, NOAEL (HED)s or lowest-observed-adverse-effect level (LOAEL) (HED)s were identified.
- **Step 6: Provide rationale for selecting uncertainty factors.** Uncertainty factors were selected in accordance with U.S. EPA guidelines considering variations in sensitivity among humans, differences between animals and humans, the duration of exposure in the key study compared to a lifetime of the species studied, and the potential limitations of the toxicology database (U.S. EPA, 2014d, 2011b, 2002, 1994).
- **Step 7: Calculate the subchronic and chronic RfDs.** The RfDs were calculated by dividing a POD (HED) by the selected uncertainty factors.

$$\text{RfD} = \frac{\text{POD (HED)}}{\text{UF}_C}$$

where:

POD (HED) is calculated from the BMDL or NOAEL using a $BW^{3/4}$ allometric scaling approach consistent with U.S. EPA guidance (U.S. EPA, 2011b)

UF_C is established in accordance with U.S. EPA guidelines (U.S. EPA, 2014d, 2011b, 2002, 1994) considering variations in sensitivity among humans, differences between animals and humans, the duration of exposure in the key study compared to a lifetime of the species studied, and the potential limitations of the toxicology database.

- **Step 8: Assignment of Confidence Levels.** In assessments in which an RfD or RfC is derived, characterization of the level of confidence in the principal study(ies), the database associated with that reference value, and the overall confidence in the reference value(s) are provided. Details on characterizing confidence are provided in Chapter 4

(specifically Section 4.3.9.2) of the U.S. EPA's *Methods for Derivation of Inhalation Reference Concentrations and Application of Inhalation Dosimetry* (U.S. EPA, 1994). For example, the ranking of confidence in the database (low, medium, or high) reflects EPA's assessment of the degree to which the reference value (e.g., RfD) might potentially change (in either direction) with the acquisition of new data.

3.0 OVERVIEW OF EVIDENCE IDENTIFICATION FOR SYNTHESIS AND DOSE-RESPONSE ANALYSIS

3.1 LITERATURE SEARCH AND SCREENING RESULTS

The database searches yielded 451 unique records, with 50 records identified from additional sources, such as TSCA submissions, posted NTP study tables, peer-review recommendations, and review of reference lists from other authoritative sources. Of the 501 studies identified, 377 were excluded during title and abstract screening, 124 were reviewed at the full-text level, and 42 were considered relevant to the PECO eligibility criteria (see Figure 4). This included 19 epidemiologic studies (described in 22 publications), 10 in vivo animal studies (described in 15 peer-reviewed and non-peer-reviewed publications), and 5 in vitro genotoxicity studies. The detailed search approach, including the query strings and PECO criteria, is provided in Appendix A and Appendix B, respectively.

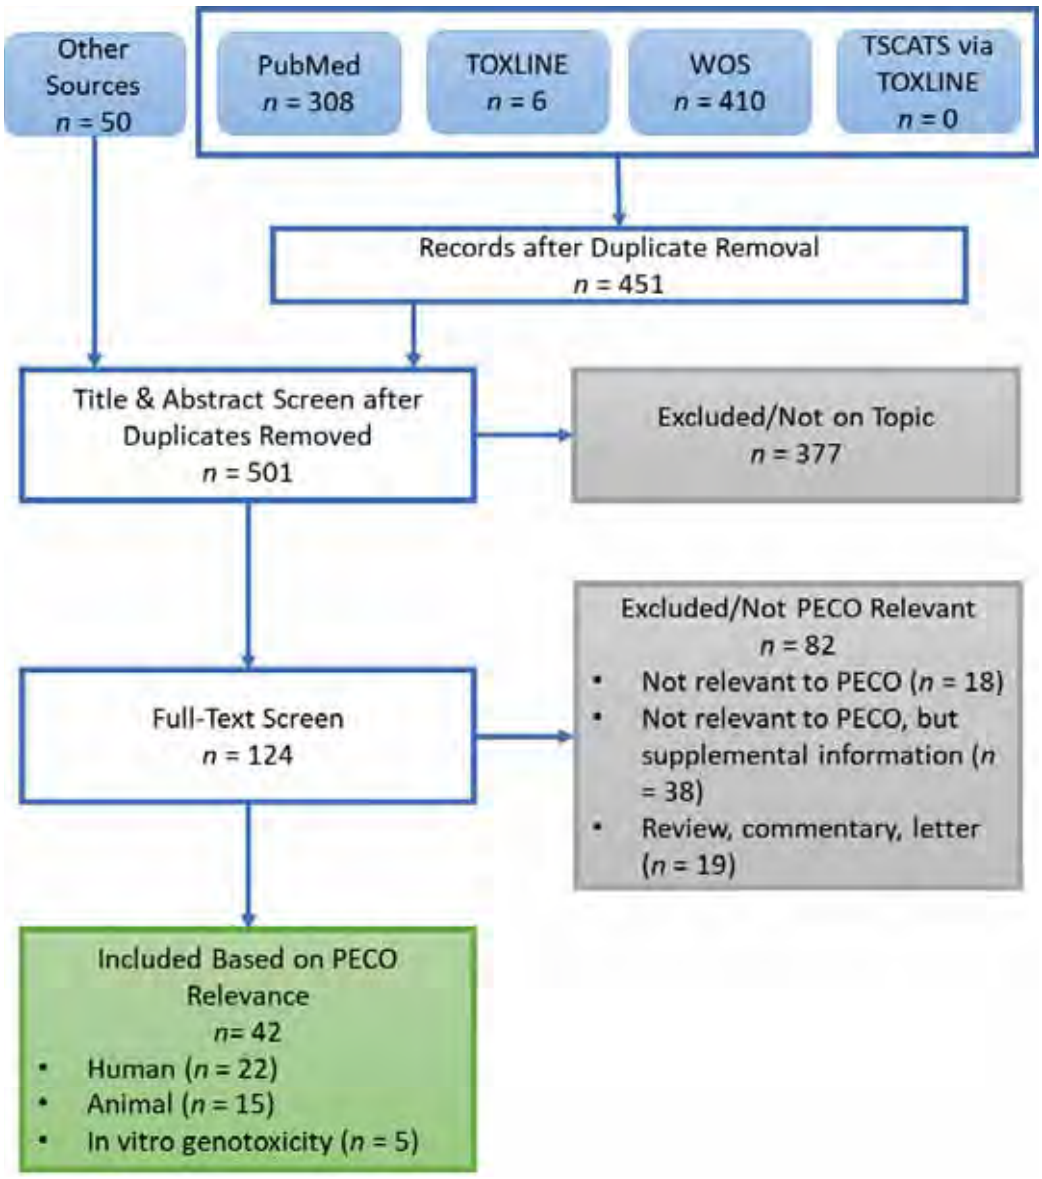

Figure 4. Literature Search and Screening Flow Diagram for PFBS (CASRN 375-73-5)

3.2 STUDY EVALUATION RESULTS

Based on the study evaluations, seven human epidemiology studies were considered uninformative and are not discussed any further in this assessment (see Table 4). All animal studies were considered informative and thus were identified as relevant during literature screening and included in the evidence synthesis and dose-response analysis. Overall, 12 epidemiologic studies (described in 15 publications) and 10 in vivo animal studies (described in 15 peer-reviewed and non-peer-reviewed publications) were included in the evidence synthesis and further evaluated for use in the development of toxicity values for PFBS. As shown in Figures 5 and 6, while the database of studies on PFBS is not large, several high- and medium-confidence oral exposure studies in animals were identified, as were several

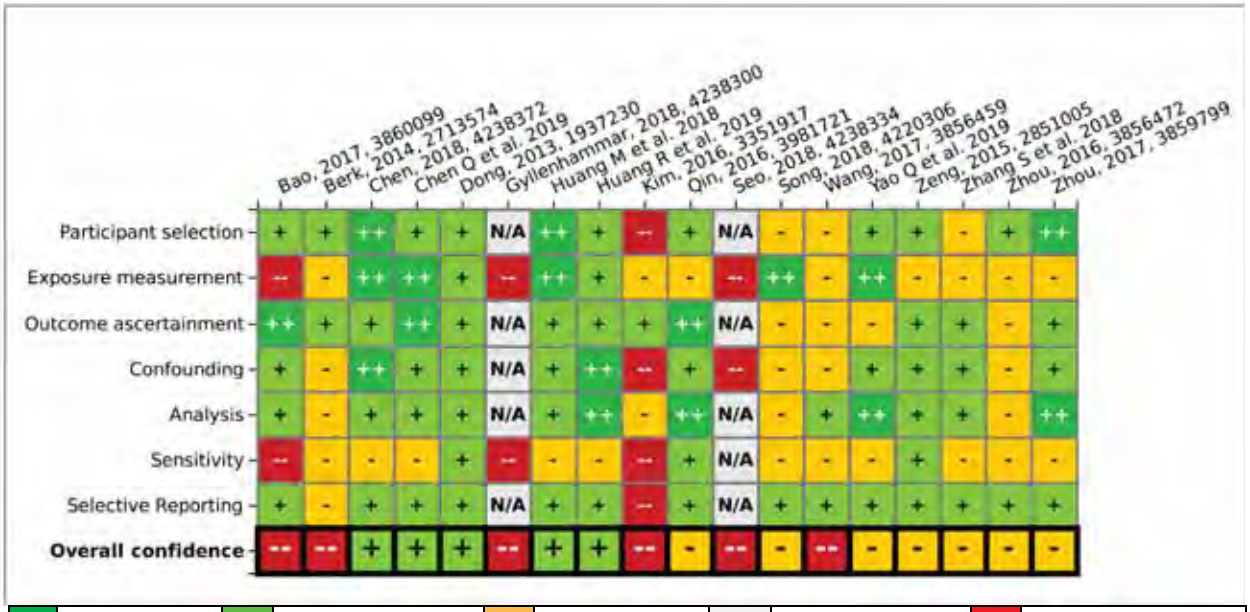
medium-confidence studies in humans. Multiple publications of the same study are not listed as independent studies in HAWC, they are reviewed together in one entry. In addition, Shiue (2016) was not evaluated because the outcome (i.e., sleep disturbances) was considered a nonspecific effect, and thus was not entered into HAWC. No studies were identified evaluating the toxicity of PFBS or K^+PFBS following inhalation exposure or on the carcinogenicity of PFBS or K^+PFBS in humans or animals.

Table 4. Epidemiological Studies Excluded Based on Study Evaluation

Reference	Outcome	Reason for Exclusion
Bao et al. (2017)	Blood pressure	Extremely poor sensitivity (96% of participants below the LOD for PFBS measurement) with no observed association.
Berk et al. (2014)	Depression	Serious concerns with temporality between exposure and outcome, confounding, and analysis.
Gyllenhammar et al. (2018)	Birth size, weight gain	Extremely poor sensitivity (median exposure = 0.01 ng/g, IQR LOD-0.04, 43% below the LOD for PFBS measurement) with no observed association.
Kim et al. (2016)	Congenital hypothyroidism	Excluded from full statistical analysis by study authors because of a high percentage below the LOD (72%) for PFBS measurement.
Seo et al. (2018)	Cholesterol, uric acid, diabetes, BMI, thyroid hormones	No consideration of potential confounding.
Shiue (2016)[a]	Sleep disturbances	Not evaluated because of nonspecific effect.
Wang et al. (2017)	Endometriosis-related infertility	Exposure measured concurrent with outcome for chronic outcome; serious concerns for exposure and outcome misclassification.

[a]Shiue (2016) was not evaluated because the outcome was sleep disturbances, which was considered a nonspecific effect, and thus was not entered in HAWC.

BMI = body mass index; HAWC = Health Assessment Workspace Collaborative; IQR = interquartile range; LOD = limit of detection; PFBS = perfluorobutane sulfonic acid.



++	Good (metric) or high (overall)	+	Adequate (metric) or medium (overall)	–	Deficient (metric) or low (overall)	N/A	Not assessed because of critical deficiency in other domain	- -	Critically deficient (metric) or uninformative (overall)

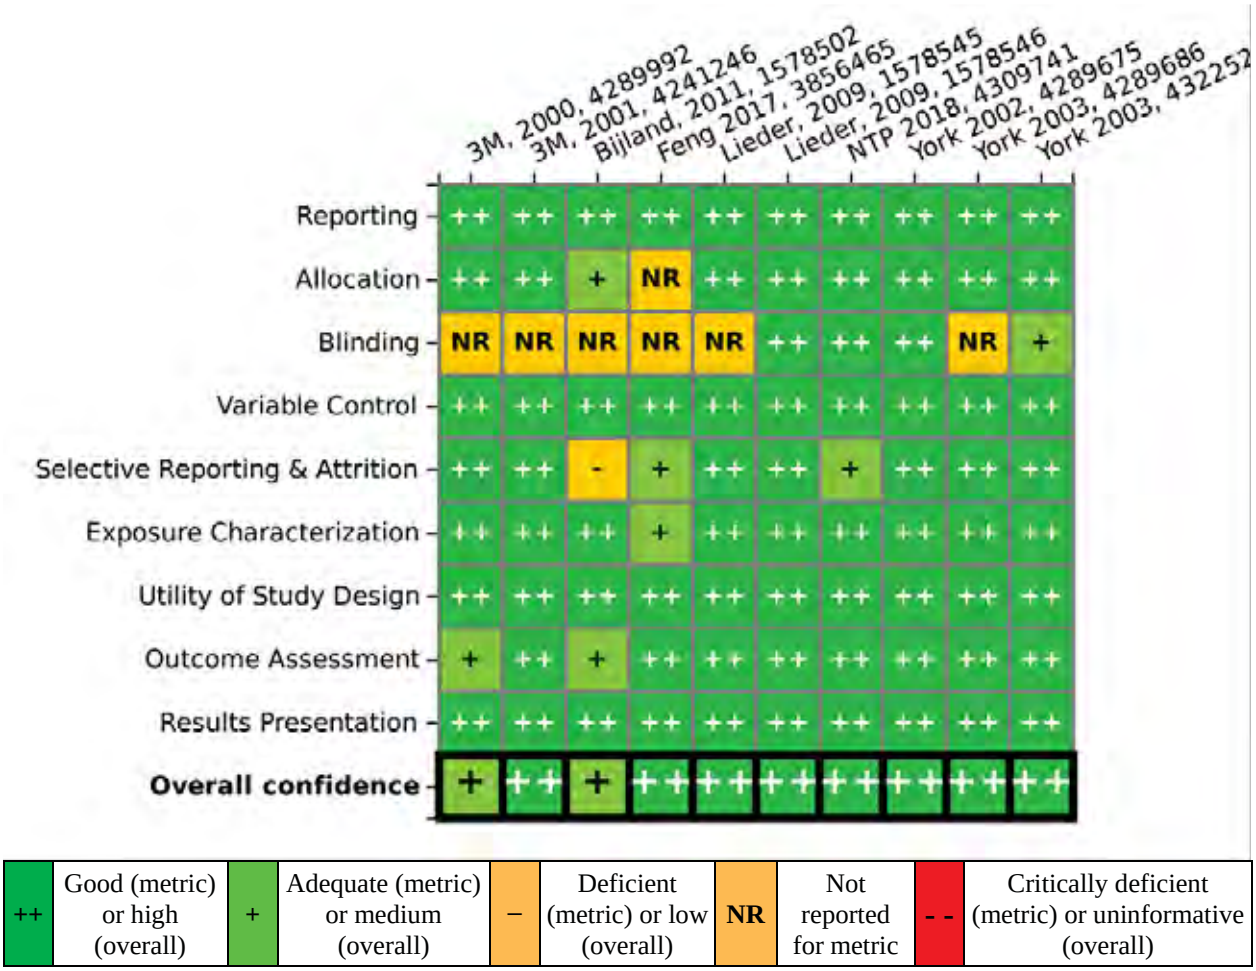

Figure 6. Evaluation Results for Animal Studies Assessing Effects of PFBS Exposure (Click to see interactive data graphic for rating rationales)

4.0 EVIDENCE SYNTHESIS: OVERVIEW OF INCLUDED STUDIES

The database of all repeated-dose oral toxicity studies for PFBS and the related compound K^+PFBS that are potentially relevant for deriving RfD values includes a short-term range-finding study in rats (3M, 2000d), two 28-day studies in rats (NTP, 2019; 3M, 2001), one subchronic study in rats (Lieder et al., 2009a; York, 2003b), one subchronic-duration lipoprotein metabolism study in mice (Bijland et al., 2011; 3M, 2010), three gestational exposure studies in mice and rats (Feng et al., 2017; York, 2003a, 2002), and a two-generation reproductive toxicity study in rats (Lieder et al., 2009b; York, 2003c, d, e). In addition, 19 epidemiological studies (described in 22 publications) were identified that report on the association between PFBS and human health effects. Specific study limitations identified during evaluation (see HAWC) are discussed only for studies interpreted as low confidence or if a limitation affected a specific inference for drawing conclusions.

Human and animal studies have evaluated potential effects on the thyroid, reproductive systems, development, kidneys, liver, and lipid and lipoprotein homeostasis following exposure to PFBS. The evidence base for these outcomes is presented in this section. For each potential health effect, the synthesis describes the database of human and animal studies, as well as an array of the animal results across studies. NOAELs and LOAELs presented in the figures and text are based on statistical significance and/or biological significance (e.g., directionality of effect [statistically significantly decreased cholesterol/triglycerides is of unclear toxicological relevance], abnormal or irregular dose-response relationship [nonmonotonicity], tissue-specific considerations for magnitude of effect [statistically nonsignificant increase of ≥10% in liver weight interpreted as biologically significant]). A summary of the available database is presented in Table 6 of Section 5. For information in this section, evidence to inform organ/system-specific effects of PFBS in animals following developmental exposure is discussed in the individual organ/system-specific sections (e.g., reproductive cycling endpoints after developmental exposure are discussed in the "Reproductive Effects" section). Other effects informing potential developmental effects (e.g., pup BW) are discussed in the "Offspring Growth and Early Development" section.

Evidence integration analyses and overall judgments on the hazard support for each outcome domain provided by the available human and animal studies are discussed in the "Evidence Integration and Hazard Characterization" section. Notably, in that section, the evidence informing organ/system-specific endpoints after developmental exposure was considered potentially informative to both the developmental effects outcome domain and the organ/system-specific outcome domain.

4.1 THYROID EFFECTS

4.1.1 Human Studies

One low-confidence study examined cross-sectional associations between PFBS exposure and thyroid hormones in women with premature ovarian insufficiency (Zhang et al., 2018) and reported no association with free T_3, free T_4, or thyroid-stimulating hormone. However, this study had poor sensitivity and methodological limitations that make interpreting these null results difficult; further, the results in this highly selected population may not be generalizable.

4.1.2 Animal Studies

Two high-confidence studies evaluated the effects of PFBS exposure on the thyroid, specifically thyroid hormone levels, thyroid histopathology, and thyroid weight (NTP, 2019; Feng et al., 2017) (see Figure 7). Dams exposed to K^+PFBS through gestation (GDs 1−20) exhibited a statistically significant decrease in total triiodothyronine (T_3), total thyroxine (T_4), and free T_4 (reduced 17, 21, and 12%, respectively, relative to control at 200 mg/kg-day and reduced 16, 20, and 11%, respectively, relative to control at 500 mg/kg-day) on GD 20 at doses of 200 and 500 mg/kg-day, but not at 50 mg/kg-day (Feng et al., 2017). Decreased total T_3 and total T_4 were also reported at PNDs 1, 30, and 60 in offspring gestationally exposed to K^+PFBS at the same doses (up to 37% reduction in T_3 and 52% reduction in T_4). Increased thyroid-stimulating hormone (TSH) was reported in dams and pubertal (PND 30) offspring (21 and 14% relative to control at 200 mg/kg-day, respectively) exposed gestationally to K^+PFBS. Statistically significant dose-dependent decreases in total T_3, total T_4, and free T_4 were also reported after exposure in male and female rats to K^+PFBS for 28 days at all doses tested (≥62.6 mg/kg-day) (NTP, 2019). The reported reductions in rat total T_3 were up to −57% (male) and −43% (female), in free T_4 up to −86% (male) and −77% (female), and in total T_4 up to −97% (male) and −71% (female). Dose-response graphics for T_4, T_3, and TSH, including effect size and variability, are included in Appendix E, Figures Figure E-1, Figure E-2, and Figure E-3, respectively. Thyroid gland weight, thyroid histopathology, and TSH levels were not changed after 28 days of PFBS exposure in male or female rats at doses up to 1,000 mg/kg-day (NTP, 2019).

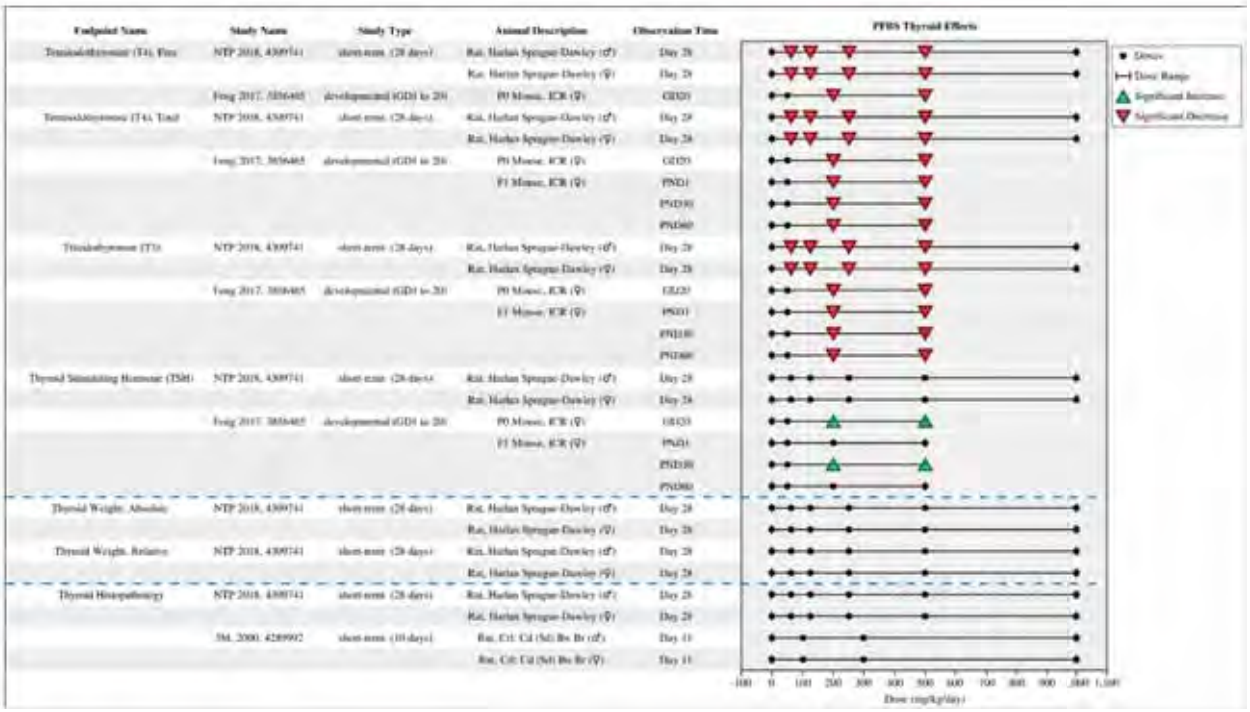

Figure 7. Thyroid Effects from K^+PFBS Exposure
(Click to see interactive data graphic and rationale for study evaluations for effects on the thyroid in HAWC)

4.2 REPRODUCTIVE EFFECTS

4.2.1 Human Studies

Five studies of populations in China and Taiwan examined different reproductive outcomes in women and men (Yao et al., 2019; Song et al., 2018; Zhang et al., 2018; Zhou et al., 2017a; Zhou et al., 2016).

Three low-confidence studies examined reproductive hormones in newborn boys and girls in China (Yao et al., 2019), adolescent boys and girls in Taiwan (Zhou et al., 2016), and adult women in China (Zhang et al., 2018). The study in newborns reported lower testosterone (β: −0.23; 95% CI: −0.46−0.01) and estradiol (β: −0.09; 95% CI: −0.2−0.01) in cord blood in male babies, but these differences were not statistically significant (Yao et al., 2019). The other two studies reported no clear associations between PFBS levels and reproductive hormones in women with premature ovarian insufficiency (Zhang et al., 2018) or in adolescents, either among the entire study population or stratified by sex (Zhou et al., 2016).

One low-confidence cross-sectional study (Song et al., 2018) examined the association between PFBS exposure and semen parameters. There was no indication of decreased semen quality in this study (correlation coefficients of −0.022 for semen concentration and 0.195 [$p < 0.05$] for progressive motility), although issues were noted regarding the ability of this study to detect an effect and important methodological details were missing.

Two studies examined other female reproductive effects: a cross-sectional study of menstrual cycle characteristics in a general population sample of women planning to become pregnant who were enrolled at preconception care clinics in China (Zhou et al., 2017a) and a case-control study in China of premature ovarian insufficiency (Zhang et al., 2018), defined by FSH level and oligo/amenorrhea. For any outcome related to menstruation, there is significant potential for reverse causation because menstruation is a potential mechanism by which PFAS are removed from the body (Wong et al., 2014; Zhang et al., 2013); therefore, both of these studies are considered low confidence. Zhou et al. (2017a) reported adjusted odds ratios (OR) of 1.30 (95% CI: 0.54−3.12) for menorrhagia and 1.48 (95% CI: 0.54−4.03) for hypomenorrhea in preconception women in China for each one unit increase in PFBS, but these results were not statistically significant. The study authors also reported inverse statistically nonsignificant associations for these two outcomes based on exposure quartiles (OR range: 0.61−0.84 for the highest quartiles relative to the referent) with no evidence of an exposure-response relationship, indicating that the associations are not robust. All of the analyses in this study examined continuous outcome measures. Zhang et al. (2018) reported no increase in odds of premature ovarian insufficiency with higher PFBS exposure (OR for tertile 2 vs. tertile 1: 0.84, 95% CI: 0.44–1.60; OR for tertile 3: 0.92, 95% CI: 0.48–1.76).

4.2.2 Animal Studies

Reproductive outcomes were evaluated in a high-confidence study of prenatal exposure to PFBS in mice (Feng et al., 2017), in two high-confidence gestational exposure studies in rats (York, 2003c, 2002), in high-confidence short-term and subchronic studies in rats [NTP (2019) and Lieder et al. (2009a), respectively], and in a high-confidence two-generation reproductive study in rats (Lieder et al., 2009b). Endpoints evaluated in these studies include fertility and

pregnancy outcomes, hormone levels, markers of reproductive development, and reproductive organ weights.

4.2.2.1 Female Fertility and Pregnancy Outcomes

Female fertility parameters were evaluated by both Feng et al. (2017) and Lieder et al. (2009b), who reported generally no effects in exposed parents, but some effects after gestational exposure in the F_1 offspring (click to see interactive graphic for female fertility effects in HAWC). Female fertility (e.g., fertility index and days in cohabitation) and delivery parameters (e.g., length of gestation, % deliveries, stillborn pups, and implantation sites) evaluated in Lieder et al. (2009b) were generally unaffected by K^+PFBS treatment for P_0- and F_1-generation dams at doses up to 1,000 mg/kg-day. The mean number of live born F_1 pups was statistically significantly decreased in the 30-mg/kg-day group, but this change was not dose dependent. The viability index in F_1 pups and the lactation index in F_1 and F_2 pups showed statistically significant changes at various doses but were not dose dependent (Lieder et al., 2009b). Similarly, no effects were observed in delivery and litter parameters (e.g., implantations, litter sizes, live fetuses, corpora lutea, and early resorptions) following prenatal exposure from GDs 6 to 20 (York, 2003c, 2002). Adult (PND 60) F_1 females gestationally exposed to PFBS at doses ≥200 mg/kg-day, however, exhibited fewer primordial, primary, secondary, early antral, antral, and preovulatory follicles, as well as fewer corpora lutea than control animals (Feng et al., 2017). Importantly, no effects on the health (e.g., weight gain) of the exposed dams were observed at any dose (Feng et al., 2017). Lieder et al. (2009b) evaluated ovarian follicles in F_1 females after they were mated and their pups had been weaned (i.e., Lactation Day [LD] 22) and observed no effects compared with controls at 1,000 mg/kg-day; however, no quantitative data were reported. Ovarian parameters were not evaluated in the study by York (2002).

4.2.2.2 Male Fertility

Two studies using S-D rats evaluated several potential responses in the male reproductive system (NTP, 2019; Lieder et al., 2009b). Male fertility parameters and reproductive effects (e.g., sperm parameters) were generally unaffected by K^+PFBS treatment in P_0- and F_1-generation males observed by Lieder et al. (2009b). At the highest dose, there were statistically significant increases in the percentage of abnormal sperm in F_1 animals and decreases in testicular sperm count in P_0-generation males. In addition, the study authors reported that the number of spermatids per gram testis was within the historical control of the testing facility. These effects were not statistically changed at lower doses. Alterations in parameters such as sperm count/number and morphology are considered indicative of adverse responses in the male reproductive system (Foster and Gray, 2013; Mangelsdorf et al., 2003; U.S. EPA, 1996a). A 28-day exposure study reported a decreased trend in testicular spermatid count per mg testis evaluated at the time of necropsy; however, no significant effects on other sperm measures were reported, including caudal epididymal sperm count and sperm motility (NTP, 2019). Note that a complete spermatogenesis cycle in male rats is typically 7 weeks in length, thus study designs of shorter duration could potentially miss effects of chemical exposure on some sperm parameters. Accordingly, the differences in responses observed in the two available studies might have been due to experimental design differences, because Lieder et al. (2009b) exposed P_0 animals for 70 days and F_1 animals during the entire period of gestation plus lactation, whereas NTP (2019) exposed animals for 28 days. Future studies should be conducted

to determine whether long-term and/or gestational exposure to PFBS significantly affects sperm measures in sexually mature and developing animals.

4.2.2.3 Reproductive Hormones (Female and Male)

Reproductive hormones were evaluated in mice (Feng et al., 2017) and, to a limited extent, in rats (NTP, 2019) (see Figure 8). Exposure to K^+PFBS for 28 days resulted in a significant trend for increased testosterone levels in females, but not in males (NTP, 2019). The increase in testosterone was not statistically significant when compared to control at any dose by pairwise analysis. Prenatal exposure to PFBS at and above 200 mg/kg-day resulted in statistically significant reduced serum estradiol levels and increased serum luteinizing hormone levels in pubertal offspring (i.e., PND 30) (Feng et al., 2017). The change in serum estradiol levels, but not luteinizing hormone, continued into adulthood in the K^+PFBS-exposed offspring (i.e., PND 60). Adult PFBS-exposed offspring also exhibited decreased serum progesterone levels at doses of 200 mg/kg-day and greater. PFBS exposure did not alter maternal estradiol-, progesterone-, or gonadotropin-releasing hormone. Reproductive hormone levels in males and females were not evaluated by Lieder et al. (2009b). The changes in follicle and corpora lutea development reported in the same study, however, may be associated with alterations in hormone production/levels because ovarian follicles and corpora lutea produce estrogen and progesterone, respectively (Foster and Gray, 2013; U.S. EPA, 1996b).

The hormonal effects observed in the NTP (2019) and Feng et al. (2017) studies might be associated with adverse reproductive effects reported in these studies. Androgens, luteinizing hormone, estradiol, and progesterone play an important role in normal development and in the functioning of the female reproductive system (Woldemeskel, 2017; Foster and Gray, 2013). Alterations in the levels and production of these reproductive hormones can disrupt endocrine signals at the hypothalamic-pituitary level and lead to delayed reproductive development and changes in functions (Rudmann and Foley, 2018; Woldemeskel, 2017; Foster and Gray, 2013).

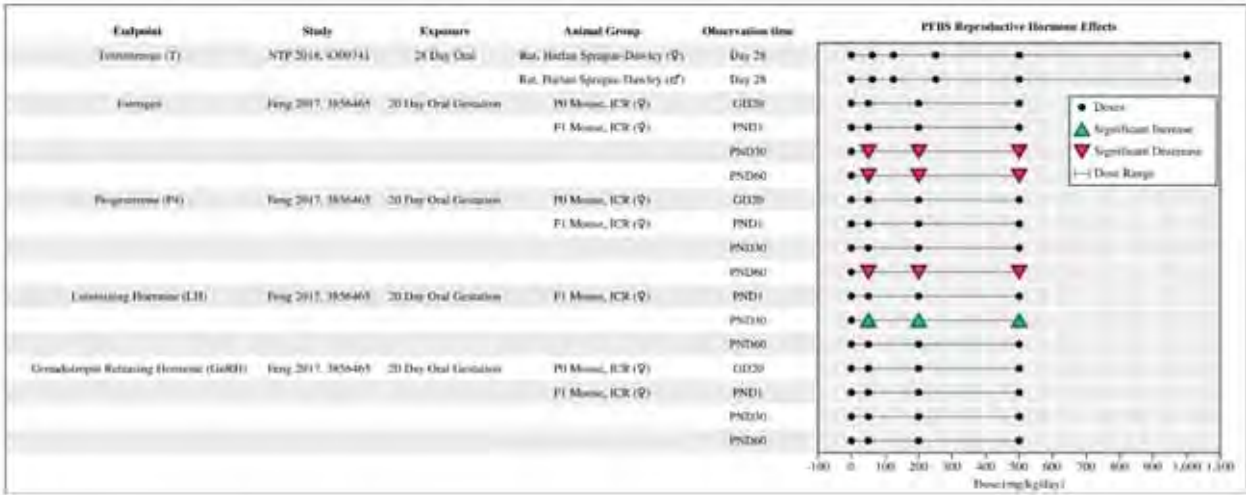

Figure 8. Reproductive Hormone Response to K^+PFBS Exposure
(Click to see interactive data graphic and rationale for study evaluations for reproductive hormone levels in HAWC)

4.2.2.4 Reproductive System Development, Including Markers of Sexual Differentiation and Maturation (Female and Male)

Several measures of female reproductive development were affected by gestational K^+PFBS exposure in mice (see Figure 9, Figure E-5, and Figure E-6). Feng et al. (2017) reported a delayed first estrous in female PFBS-exposed offspring (≥200 mg/kg-day) compared with control (see Figure E-5). Estrous cyclicity was also affected in K^+PFBS-exposed PNDs 40−60 offspring as exhibited by a prolongation of the diestrus stage compared with control. Estrous cycling was generally not statistically significantly altered in P_0- or F_1-generation females treated with K^+PFBS in the two-generation study by Lieder et al. (2009b). An increase in the number of rats with ≥6 consecutive days of diestrus was observed in the F_1 females exposed to 100 mg/kg-day; however, the increase was not present at higher doses (Lieder et al., 2009b). Estrous cyclicity was affected after adult exposure to K^+PFBS for 28 days as shown by a dose-dependent prolongation of diestrus at doses of 250 mg/kg-day and greater with marginal significance at the lowest dose tested (125 mg/kg-day) ($p = 0.063$) (NTP, 2019). Lieder et al. (2009b) reported a delay in the days to preputial separation in F_1 males of the 30- and 1,000-mg/kg-day groups;[10] however, the measure was no longer statistically significant when adjusted for BW. There was similarly no change in the days to vaginal patency in F_1 female rats (Lieder et al., 2009b). Unlike Lieder et al. (2009b), Feng et al. (2017) reported a delay in vaginal patency in F_1 females after gestational exposure of 200 mg/kg-day and greater (see Figure E-6).

[10]A marker of delayed reproductive development (Foster and Gray, 2013; U.S. EPA, 1996a).

Figure 9. Effects on Reproductive Development and Estrous Cycling Following PFBS Exposure (Click to see interactive data graphic)

4.2.2.5 Reproductive Organ Weights and Histopathology (Female and Male)

Studies have not consistently reported changes in reproductive organ weights (click to see interactive graphic for reproductive organ effects in HAWC). Reproductive organ weights, including testes, ovaries, and uterus, were unchanged in the two-generation reproductive study in P_0 and F_1 males and females (Lieder et al., 2009b) and following short-term and subchronic exposure to K^+PFBS (NTP, 2019; Lieder et al., 2009a; 3M, 2001, 2000d). F_1 females gestationally exposed to PFBS, however, exhibited decreased size and weight of the ovaries and uterus (Feng et al., 2017). In addition, the total uterine section diameter and endometrial and myometrial thickness were significantly reduced. There were no significant histopathological alterations in the male or female reproductive organs evaluated following exposure to K^+PFBS for 28 days (NTP, 2019) or in parental or offspring from the two-generation reproductive study (Lieder et al., 2009b).

4.3 OFFSPRING GROWTH AND EARLY DEVELOPMENT

4.3.1 Human Studies

No human studies were available to inform the potential for PFBS exposure to cause effects on the growth or early development of children.

4.3.2 Animal Studies

Evidence to inform organ/system-specific effects of PFBS in animals following developmental exposure are discussed in the individual hazard sections (e.g., reproductive cycling after developmental exposure is discussed in the "Reproductive Effects" section). This section is limited to discussion of other, specific developmental effects commonly evaluated in guideline developmental toxicity studies, including pup BW, developmental markers, and bone measures. Four high- or medium-confidence studies examined potential alterations in offspring growth and early development following PFBS exposure, including two gestational exposure studies in rats (York, 2003a, 2002) and one gestational exposure study in mice (Feng et al., 2017), as well as a two-generation study in rats (Lieder et al., 2009b; York, 2003c). (Click to see interactive graphic for developmental effects in HAWC.)

None of the studies identified significant effects in either rats or mice on measures of fetal morphology (i.e., malformations and variations). BW of female offspring of PFBS-exposed mice at doses greater than 200 mg/kg-day was statistically significantly lower than control at PND 1, and the pups remained underweight through weaning, pubertal, and adult periods, with decreases of approximately 25% observable in pups nearing weaning (Feng et al., 2017). At around PND 16, Feng et al. (2017) also reported an ~1.5-day developmental delay in eye opening in pups gestationally exposed to 200 mg/kg-day PFBS and greater. Importantly, no effects on the health of the exposed dams (e.g., weight gain) were observed at any dose (Feng et al., 2017). Dose-response graphics for eye opening, including effect size and variability, are included in Appendix E, Figure E-4. Fetal BWs (male and female) were also reduced (approximately 10%) compared with controls following gestational exposure from GDs 6 to 20 at the highest tested dose (1,000 mg/kg-day in York (2002) and 2,000 mg/kg-day in York (2003a)]). Parental BWs and organ weights, however, were also affected to a similar degree at those doses (Lieder et al., 2009b; York, 2003c, 2002), limiting the interpretation of the results. No statistically significant changes in F_1- and F_2-generation pup mean pup weight at birth and mean pup weight at weaning were reported by Lieder et al. (2009b) or York (2003c).

Several measures of thyroid hormone development and female reproductive development were affected by gestational PFBS exposure in mice and are described in more detail in the "Thyroid Effects" and "Reproductive Effects" sections, respectively.

4.4 RENAL EFFECTS

4.4.1 Human Studies

One low-confidence study (Qin et al. (2016), with additional details in Bao et al. (2014), selected 225 subjects ages 12−15 years old from a prior cohort study population in seven public schools in northern Taiwan (Tsai et al., 2010) and examined the association between PFBS exposure and uric acid concentrations. There was no association between ln(PFBS) concentration and uric acid concentrations in the total population (β: 0.0064 mg/dL increase in uric acid per 1 ln-µg/L increase in PFBS; 95% CI: −0.22−0.23). U.S. EPA identified that a nonsignificant positive association in boys was offset by a nonsignificant negative association in girls, and there is not enough information to determine whether there is a sex dependence. When PFBS exposure was analyzed for high uric acid (>6 mg/dL), the risk was somewhat elevated in boys (OR: 1.53; 95% CI: 0.92−2.54), but not in girls (OR: 0.99; 95% CI: 0.58−1.73). The potential for reverse causation (i.e., that renal function could influence the levels of PFBS in the blood) tempers any conclusions that might be drawn.

4.4.2 Animal Studies

Renal effects were evaluated in high-confidence short-term and subchronic-duration exposure studies in rats (NTP, 2019; Lieder et al., 2009a; 3M, 2001, 2000d) and in a high-confidence two-generation reproductive study in rats (Lieder et al., 2009b). Endpoints evaluated in these studies include kidney weights, histopathological changes, and serum biomarkers of effect (see Figure E-8 and Figure E-9). Dose-response graphics for histopathological effects, including effect size and variability, are included in Appendix E, Figure E-7.

Absolute and relative kidney weights of males and females were unchanged in S-D rats exposed daily for 90 days to K^+PFBS at doses up to 600 mg/kg-day compared with control rats (Lieder et al., 2009a). This lack of effect on kidney weight was also observed in parental and F_1 male and female rats of the same strain exposed to K^+PFBS at doses up to 1,000 mg/kg-day during a two-generation reproductive study (Lieder et al., 2009b). Although none of the findings reached statistical significance, an approximate 9% increase in absolute kidney weight was observed in female S-D rats exposed to 1,000 mg/kg-day K^+PFBS for 10 days (3M, 2000d); relative-to-body kidney weights were also increased approximately 6−9%. This organ-weight effect was not observed in corresponding males of the study. In a follow-up 28-day study by the same lab, a 9−11% increase in absolute and relative-to-body kidney weight was observed in female S-D rats exposed to 900 mg/kg-day K^+PFBS (3M, 2001), although these changes were not statistically significant. In this study, U.S. EPA also observed that smaller nonsignificant increases in kidney weight occurred in male rats. In another 28-day study, K^+PFBS exposure significantly increased absolute and relative right kidney weights in high-dose (500 mg/kg-day) male S-D rats (NTP, 2019). Only relative kidney weights were altered in female rats, but this effect was significant at all tested K^+PFBS doses (≥62.6 mg/kg-day). Click to see interactive graphic for kidney-weight effects in HAWC.

After 90 days of exposure, Lieder et al. (2009a) observed increased incidences of histopathological alterations of the kidneys of male and female rats of the high-dose group (600 mg/kg-day). Increased incidence of hyperplasia of the epithelium of renal papillary tubules and ducts was observed in rats of both sexes (see Figure E-7Figure E-8). A single incidence of papillary necrosis in both kidneys was observed in one male in the high-dose group. Further, focal papillary edema was observed in 3/10 rats of both sexes of the high-dose groups compared with no evidence of this effect in control rats. Similar histopathological alterations were observed in parental and F_1 male and female rats in the two-generation reproduction study (Lieder et al., 2009b). Compared with control rats, increased incidences of hyperplasia of the renal tubular and ductal papillary epithelium, and focal papillary edema were observed in parental male and female rats at PFBS doses ≥300 mg/kg-day. Hyperplastic foci in the same locations of the kidney were also observed in male and female F_1 rats exposed to ≥300 mg/kg-day PFBS across life stages from gestation to adulthood (Lieder et al., 2009b). Focal papillary edema was observed in male (≥1,000 mg/kg-day) and female (≥300 mg/kg-day) F_1 rats, although this specific alteration did not appear to be dose-dependent in females. Although kidney alterations such as hydronephrosis, mineralization, and tubular degeneration were observed in male or female S-D rats after just 10 days of oral K^+PFBS exposure, these effects were not significant compared to control and/or did not appear to be dose-dependent (3M, 2000d). The same histopathological lesions were noted in the 28-day rat study albeit with lack of statistical significance compared to control (3M, 2001). In another 28-day gavage study in S-D rats, chronic progressive nephropathy (CPN) was observed in all male and female PFBS treatment groups and control rats, with no evidence of dose dependence for this effect (NTP, 2019). Renal papillary necrosis was also observed in these rats but only at the highest exposure dose (1,000 mg/kg-day).

Serum levels of biomarkers indicative of kidney injury and/or function, including blood urea nitrogen (BUN) and creatinine, have been examined across multiple studies of varying exposure durations, and were found to be unchanged in male and female rats treated with K^+PFBS at doses up to 1,000 mg/kg-day (Lieder et al., 2009a; 3M, 2001, 2000d). After 28 days of gavage exposure in S-D rats, however, NTP (2019) observed significantly increased levels of BUN in males (≥250 mg/kg-day). This increased circulating BUN was not observed in female rats at doses up to 1,000 mg/kg-day. Click to see interactive graphic for other kidney effects in HAWC.

4.5 HEPATIC EFFECTS

4.5.1 Human Studies

No human studies were available to inform the potential for PFBS exposure to cause hepatic effects.

4.5.2 Animal Studies

Hepatic effects were evaluated in high-confidence short-term and subchronic studies in rats (NTP, 2019; Lieder et al., 2009a; 3M, 2001, 2000d) and in a high-confidence two-generation reproductive study in rats (Lieder et al., 2009b). Endpoints evaluated in these studies include liver weights, histopathological changes, and serum biomarkers of effect (see Figure E-10).

Ten days of daily gavage exposure to K^+PFBS significantly increased absolute, relative-to-body, and relative-to-brain weights of liver in adult male and female S-D rats exposed to 1,000 mg/kg-day (3M, 2000d). The absolute liver mass of male rats was increased by 36% compared with females (22%). A similar profile of liver-weight alteration in S-D rats was observed following 28 days of exposure wherein absolute and relative liver weights of high-dose (900 mg/kg-day) male rats had increased 25%−30% (3M, 2001). Female rats at the same treatment dose did not experience a similar magnitude increase in absolute or relative liver weights (4−6%). In another 28-day study in S-D rats, K^+PFBS exposure significantly increased absolute and relative liver weights in males (≥125 and ≥62.6 mg/kg-day, respectively) and females (≥250 and ≥125 mg/kg-day, respectively) (NTP, 2019). In contrast, the livers of male and female S-D rats exposed to K^+PFBS at doses up to 600 mg/kg-day for 90 days were not significantly changed compared with respective controls (Lieder et al., 2009a). In a two-generation reproduction study using the same strain of rat, however, increased absolute and relative liver weights were observed in male parental rats exposed to doses of K^+PFBS ≥300 mg/kg-day for approximately 70 days (Lieder et al., 2009b). In the F_1 adult males, only relative liver weight was significantly increased at the high dose (1,000 mg/kg-day), although terminal BW was significantly decreased in this group compared with control.

Histopathological examination of the livers of S-D rats across three separate gavage studies of increasing K^+PFBS exposure duration [10-day, 3M (2000d); 28-day, 3M (2001); 90-day, Lieder et al. (2009a)] did not reveal any significant dose-dependent alterations or lesions. For example, focal/multifocal hepatic inflammation was observed in 3/10 male and 4/10 female rats of the high-dose group (no incidence at the low or mid dose) compared to 6/10 male and female rats in the control groups (Lieder et al., 2009a). The Lieder et al. (2009b) two-generation reproduction gavage study did identify increased incidences of hepatocellular hypertrophy in parental and F_1 adult male rats at ≥300 mg/kg-day; however, this effect was absent in female rats at doses of K^+PFBS up to 1,000 mg/kg-day. NTP (2019) identified a significantly increased incidence of hepatocellular hypertrophy in male (≥125 mg/kg-day) and female (≥500 mg/kg-day) S-D rats after 28 days of K^+PFBS exposure. Further, significantly increased cytoplasmic alteration of hepatocytes was observed in these rats (male and female at ≥500 mg/kg-day). Hepatic necrosis was also observed but was not significant compared with control and only occurred at the high dose (1,000 mg/kg-day) in both sexes (NTP, 2019).

In general, serum biomarkers associated with altered liver function or injury, including alanine aminotransferase (ALT) and aspartate aminotransferase (AST), were not significantly changed in male and female S-D rats across multiple gavage studies of varying exposure durations up to 90 days and at K^+PFBS doses up to 1,000 mg/kg-day (Lieder et al., 2009a; 3M, 2001, 2000d). NTP (2019), however, reported increased serum ALT and AST in male (500 mg/kg-day only) and female (≥250 mg/kg-day for ALT; ≥500 mg/kg-day for AST) rats exposed to K^+PFBS for 28 days. Click to see interactive graphic for liver effects in HAWC.

4.6 EFFECTS ON LIPIDS OR LIPOPROTEINS

4.6.1 Human Studies

One low-confidence study (Zeng et al., 2015) used the controls from the case-control study of asthma described below (Dong et al., 2013a) and examined the association between PFBS exposure and serum lipids. There was a statistically significant increase in total

cholesterol (β: 19.3 mg/dL increase per 1 µg/L increase in PFBS; 95% CI: 0.6−38.0) but when PFBS exposure was analyzed in quartiles, no exposure-response gradient was observed.

In addition, a medium-confidence birth cohort study in China examined associations with childhood adiposity (Chen et al., 2019). PFBS was measured in cord blood samples at birth and several measures of adiposity were collected at age 5 years. There was higher adiposity with higher exposure in girls, with significant exposure-response relationships across tertiles with waist circumference, fat mass, body fat percentage, and waist-to-height ratio. No association with adiposity was observed in boys. It is unlikely that the association in girls can be explained by confounding across the other PFAS measured in this study as the associations were strongest for PFBS, but it is possible that there is other unmeasured confounding.

4.6.2 Animal Studies

Beyond a single medium-confidence mouse study [Bijland et al. (2011); 3M (2010); summarized below], PFBS studies have not particularly focused on perturbations in lipids or lipoproteins as a potential health outcome, because studies have typically focused only on measures of serum cholesterol and triglyceride as part of a broader panel of clinical chemistry measures in high- or medium-confidence rat studies of 10, 28, and 90 days (see Figure E-11) [3M (2000d), 3M (2001), and Lieder et al. (2009a), respectively]. Circulating levels of cholesterol and triglycerides were unchanged in male and female S-D rats following daily gavage exposure to K^+PFBS for 10 days at doses up to 1,000 mg/kg-day (3M, 2000d). In a similarly designed study from the same laboratory, serum cholesterol and triglyceride levels were decreased in male rats but at the high dose only, and this effect was neither statistically significant compared with control nor observed in female rats of the same dose group (3M, 2001). Following exposure for up to 90 days, cholesterol and triglycerides were unchanged in male and female rats at doses up to 600 mg/kg-day (Lieder et al., 2009a). PFBS was included in a multi-PFAS study specifically designed to interrogate the mechanism of effect on lipid and lipoprotein metabolism in a transgenic mouse line (APOE*3-Leiden CETP) that is highly responsive to fat and cholesterol intake, consistent with human populations exposed to a western-type diet (containing 14% beef tallow, 1% corn oil, and 0.25% cholesterol) (Bijland et al., 2011; 3M, 2010). Adult male mice were fed a western-type, high-fat diet for 4 weeks prior to initiation of PFBS exposure and throughout the 4- to 6-week PFBS exposure period (at approximately 30 mg/kg-day). This study included several measures of lipid and lipoprotein synthesis, modification, and transport or clearance, such as circulating plasma levels, in vivo clearance of very low-density lipoprotein (VLDL)-like particles, fecal bile acid and sterol excretion, hepatic lipid levels, lipase activity, VLDL-triglyceride and VLDL-apoB production, and gene expression profiles. After 4 weeks of PFBS exposure, fasting plasma triglycerides, cholesteryl ester transfer protein, and glycerol were significantly decreased compared with mice on the control diet. Further, the half-life of VLDL-like particles and hepatic lipase activity, and hepatic cholesteryl ester and free cholesterol levels were decreased (Bijland et al., 2011; 3M, 2010). Hepatic uptake of VLDL-like particles (represents fatty acid/lipid transport into hepatic tissue) was modestly, but significantly, increased compared with control mice. This increased hepatic lipid uptake in the liver was accompanied by increased expression of genes associated with lipid binding, activation, and metabolism (e.g., β-oxidation).

4.7 OTHER EFFECTS

4.7.1 Human Studies

Two studies in China examined different immune outcomes in children (Chen et al., 2018; Dong et al., 2013a).

One medium-confidence study reported in five publications (Qin et al., 2017; Zhou et al., 2017b; Zhou et al., 2017a; Zhu et al., 2016; Dong et al., 2013b) examined the association between PFBS exposure and asthma, asthma symptoms, pulmonary function, and related immune markers (immunoglobulin E [IgE], absolute eosinophil count [AEC], eosinophilic cationic protein [ECP], T-helper cell-specific cytokines, and 16-kDa club cell secretory protein). The primary finding was a statistically significant (in the fourth quartile) positive association between incident asthma (i.e., diagnosis in the previous year) and PFBS exposure (OR for Q2: 1.3, 95% CI: 0.7−2.3; OR for Q3: 1.2, 95% CI: 0.7−2.2; OR for Q4: 1.9, 95% CI: 1.1−3.4). There were also increases in AEC and ECP with increased exposure (not statistically significant with the exception of AEC in children with asthma). There was no clear association with IgE or T-helper cell-specific cytokines. There was also no clear association with asthma severity or control of asthma symptoms (Dong et al., 2013a), or pulmonary function measured with spirometry among children with asthma (Qin et al., 2017). While reduced pulmonary function could be considered an outcome separate from asthma, the study authors noted no associations in pulmonary function (i.e., in nonasthmatics across the PFAS they studied), so for these purposes, it was considered an indicator of asthma severity.

One medium-confidence study (Chen et al., 2018) examined the association between PFBS exposure and atopic dermatitis and reported a statistically nonsignificant increase in atopic dermatitis with increased exposure (OR: 1.23; 95% CI: 0.74−2.04).

In addition, two studies examined cardiovascular effects (Huang et al., 2019b; Huang et al., 2018), but it is difficult to evaluate consistency across studies given the different outcomes in each.

One medium-confidence study (Huang et al., 2018) using data from NHANES cycles for 1999−2014 reported significantly higher odds of total cardiovascular disease with higher exposure (OR for above vs. below the LOD: 1.19; 95% CI: 1.06−1.32) and elevated, though not statistically significant, odds of individual types of cardiovascular disease (congestive heart failure, coronary heart disease, angina pectoris, heart attack, and stroke). There is potential in this study for confounding across the PFAS, because PFBS was highly correlated with some other PFAS with slightly stronger associations.

A medium-confidence cross-sectional study (Huang et al., 2019b) of hypertensive disorders of pregnancy reported higher odds for all such disorders in pregnancy (in the third tertile) (OR for Tertile 2 vs. Tertile 1: 0.89, 95% CI: 0.39−2.44; OR for Tertile 3: 2.26, 95% CI: 1.02−5.0; *p*-trend 0.03) and pre-eclampsia (OR for Tertile 2 vs. Tertile 1: 2.09, 95% CI: 0.51−8.53; OR for Tertile 3: 3.51, 95% CI: 0.94−13.2; *p*-trend 0.05), with both trends being statistically significant after mutual adjustment of PFAS.

4.7.2 Animal Studies

Other effects were evaluated following exposure to PFBS, including outcomes related to the spleen, hematological system, BW, neurotoxicity, and nonspecific clinical chemistry. These groups of outcomes were not synthesized because of inadequate available information, uncertain biological relevance, and/or inconsistencies across studies and sexes.

4.8 OTHER DATA

Other studies that used PFBS or K^+PFBS are described in this section. These studies are not adequate for determining RfD values and were considered supportive data. These data might include acute-duration exposures, genotoxicity, mechanistic, and other studies (see Table 5).

Table 5. Other Studies

Test	Materials and Methods	Results	Conclusions	References
Genotoxicity				
Mutagenicity test	*Salmonella typhimurium* (strains TA98 and TA100) and *Escherichia coli* (strain pKM101) in the presence or absence of S9. Concentrations of PFBS were between 0−5,000 μg/plate.	Test was negative for TA100 and pKM101 strains and equivocal for TA98 strain.	There is no in vitro evidence of PFBS mutagenicity.	NTP (2005)
Ames	*S. typhimurium* (strains TA98, TA100, TA1535, and TA1537) and *E. coli* (strain WP2uvrA) were tested in the presence or absence of S9 and with or without a preincubation treatment. Concentrations of K^+PFBS were between 0−5,000 μg/plate.	The results of both mutation assays indicate that PFBS did not induce any significant increase in the number of revertant colonies for any of the tester strains in the presence or absence of induced rat liver S9.	There is no in vitro evidence of PFBS mutagenicity.	Pant (2001)
Genotoxicity test	Human hepatoma (HepG2) cells were treated with 0.4 μM to 2 mM PFBS. Intracellular ROS production was measured by use of 2′,7′-dichlorofluorescein diacetate and DNA damage was measured with the comet assay.	The amount of ROS and DNA strand breaks remained unaffected by PFBS treatment.	PFBS did not generate ROS or DNA damage in human liver cells.	Eriksen et al. (2010)
CHO chromosomal aberration	Cultures of CHO cells were treated with K^+PFBS at concentrations ranging from 0 to 5,000 μg/mL with or without exogenous metabolic activation. The in vitro exposure duration was 3 hr.	PFBS did not induce a statistically significant increase in the percentage of cells with aberrations at any of the concentrations tested, either with or without metabolic activation, in either assay when compared to the solvent controls.	Based on the negative results in the in vitro CA assay in CHO cells, PFBS is not considered to be a clastogenic agent.	Xu (2001)
Micronucleus assay	Male and female S-D rats (5/group) were exposed twice daily to K^+PFBS by gavage at doses of 31.3, 62.5, 125, or 250 mg/kg for 28 d.	PFBS did not induce a statistically significant increase in the frequency of micronucleated polychromatic erythrocytes.	PFBS was negative for micronuclei in the blood of male and female rats, indicating a lack of genotoxic potential.	NTP (2012)

Table 5. Other Studies

Test	Materials and Methods	Results	Conclusions	References
Acute duration and other routes of exposure				
Acute	10 rats/group, young adult male rat (strain not specified), administered PFBS by gavage, single dose, 50, 100, 300, 600, or 800 µL/kg and observed for 14 d postexposure.	Mortality: 0, 20, 60, 80, and 100% at 50, 100, 300, 600, and 800 µL/kg PFBS, respectively.	Acute oral PFBS rat LD_{50} in male rats is 236 µL/kg (corresponding to 430 mg/kg).	Bomhard and Löser (1996) Low confidence
Acute dermal	Adult (8 wk of age) male and female S-D rats (5/group) were exposed dermally (10% of body surface area) to 500, 1,000, or 2,000 mg/kg K^+PFBS for 24 hr and then observed for 15 d postexposure for signs of clinical toxicity, mortality, BW changes, or gross pathology (terminus of study).	No treatment-related observations were noted.	PFBS is not acutely toxic via the dermal route of exposure in rats.	3M (2000b)
Dermal irritation	Adult (14-wk of age) female NZW rabbits (3 rabbits total for study) were exposed dermally (6 cm^2 of skin) to 500 mg K^+PFBS for approximately 4 hr and then observed for 9 d postexposure for signs of clinical toxicity, mortality, or BW changes.	Draize scoring was performed on the patch site immediately following the exposure period and 24, 48, and 72 hr postexposure. No signs of dermal irritation were observed. No signs of clinical toxicity or mortality occurred. No treatment-related alterations in BW were noted.	PFBS did not induce erythema, edema, or other possible dermal findings during the scoring periods, indicating a lack of dermal irritant properties in rabbits.	3M (2000a)
Ocular sensitivity	Adult (16-wk of age) female NZW rabbits (3 rabbits total for study) were exposed to approximately 80 mg K^+PFBS via ocular installation in the left eye for 2 sec. Eyes were flushed with 0.9% saline after 24 hr and then observed and scored for up to 21 d postexposure. The rabbits were also followed for clinical signs of toxicity or mortality/moribundity.	Excessive lacrimation of the left eyes noted throughout study postexposure. Based on the laboratory scoring system, PFBS was "moderately" irritating at 24 and 72 hr postexposure.	PFBS is a moderate ocular irritant in rabbits.	3M (2000c)

Table 5. Other Studies

Test	Materials and Methods	Results	Conclusions	References
Contact hypersensitivity	Adult male (10−12 wk old) and female (9 wk old) CRL:(HA)BR Hartley guinea pigs were injected intradermally with sterile water, Freund's adjuvant, or adjuvant containing 125 mg/mL K^+PFBS (induction phase). D 7 after induction, a petrolatum paste containing 0.5 g K^+PFBS was applied to the previous injection site of the guinea pigs for 48 hr (topical induction phase). D 22, a challenge dose of 0.5 g K^+PFBS (petrolatum paste) was applied to the shaved left cranial flank (right flanks were treated with petrolatum paste only) (challenge phase). This challenge procedure was repeated on D 29. Challenge sites were observed and scored following each challenge period (D 24−25 males and females and D 31−32 males only). Guinea pigs were also followed for signs of clinical toxicity, mortality/moribundity, or alterations in BW.	No mortalities, clinical signs of toxicity, or changes in BW associated with PFBS exposure were noted. Dermal scores were zero (no response) in females and did not exceed 1 in males (discreet or patchy edema), which was not considered significant compared with control guinea pigs exposed to Freund's adjuvant alone.	PFBS is not considered an allergen in the guinea pig maximization test.	3M (2002a)

BW = body weight; CA = chromosomal aberration; CHO = Chinese hamster ovary; DNA = deoxyribonucleic acid; K^+PFBS = potassium perfluorobutane sulfonate; LD_{50} = median lethal dose; NZW = New Zealand White; PFBS = perfluorobutane sulfonic acid; ROS = reactive oxygen species; S-D = Sprague-Dawley.

4.8.1 Tests Evaluating Genotoxicity and Mutagenicity

Genotoxic, mutagenic, and clastogenic effects of PFBS have been tested in mammalian and prokaryotic cells in vitro (Eriksen et al., 2010; NTP, 2005; Pant, 2001; Xu, 2001), and in rats in vivo (NTP, 2019). PFBS was negative for mutagenicity in *Escherichia coli* strain pKM101 and *Salmonella typhimurium* strain TA100 (NTP, 2005). Mutagenicity test results were equivocal in *S. typhimurium* strain TA98. Pant (2001) tested PFBS at concentrations up to 5,000 μg/plate in *E. coli* strain WP2uvrA and *S. typhimurium* strains TA98, TA100, TA1535, and TA1537 in the presence or absence of exogenous metabolic activation and found no evidence of mutagenic activity. In mammalian cells in vitro, PFBS did not generate reactive oxygen species (ROS) or oxidative deoxyribonucleic acid damage in HepG2 cells (Eriksen et al., 2010). PFBS also failed to induce chromosomal aberrations in Chinese hamster ovary cells, suggesting a lack of clastogenic activity (Xu, 2001). Adult male and female S-D rats exposed twice daily to oral PFBS at doses up to 250 mg/kg for 28 days did not experience any significant increases in micronucleated polychromatic erythrocytes, indicating a lack of genotoxic activity (see Table 5) (NTP, 2012).

4.8.2 Acute Duration and Other Routes of Exposure

Limited data are available to evaluate acute toxicity and effects from dermal exposure to PFBS (see Table 5). One low-confidence acute oral toxicity study on male rats administered PFBS by gavage reported a median lethal dose (LD_{50}) of 236 μL/kg (corresponding to 430 mg/kg) (Bomhard and Löser, 1996). One acute dermal toxicity study concluded that PFBS is not acutely toxic via the dermal route of exposure in rats, with no treatment-related observation at doses up to 2,000 mg/kg (3M, 2000b). PFBS was not reported to induce erythema, edema, or other possible dermal findings during the scoring periods, indicating a lack of dermal irritant properties in rabbits exposed to 500 mg K^+PFBS for approximately 4 hours (3M, 2000a). PFBS was found to be a moderate ocular irritant in rabbits exposed to 80 mg K^+PFBS via ocular installation (3M, 2000c). PFBS did not induce skin sensitization in the guinea pig maximization test with an intradermal injection of 125 mg/mL and topical induction of 0.5 g K^+PFBS (3M, 2002a).

5.0 EVIDENCE INTEGRATION AND HAZARD CHARACTERIZATION

The epidemiology database of studies of PFBS exposure and health effects consists of 19 epidemiologic studies (described in 22 publications), summarized in the previous section. The experimental animal database of all repeated-dose oral toxicity studies for PFBS and the related compound K^+PFBS includes a short-term range-finding study in rats (3M, 2000d), two 28-day studies in rats (NTP, 2019; 3M, 2001), one subchronic study in rats (Lieder et al., 2009a), one subchronic-duration lipoprotein metabolism study in mice (Bijland et al., 2011; 3M, 2010), three gestational exposure studies in mice and rats (Feng et al., 2017; York, 2003a, 2002), and a two-generation reproductive toxicity study in rats (Lieder et al., 2009b). Health outcomes evaluated across available studies included effects on the thyroid, reproductive organs and tissues, developing offspring, kidneys, liver, and lipids/lipoproteins following oral exposure to PFBS. Table 6 provides an overview of this database of potentially relevant studies and effects. This table includes only the high- and medium-confidence animal studies (a single, low-confidence animal study was not considered informative for drawing conclusions on potential health hazard[s]). The available epidemiology studies are also not included because their ability to inform conclusions about associations was limited because of the small number of studies (typically one) per outcome and poor sensitivity resulting from low exposure levels.

Following the summary of the available database in Table 6, narrative summaries describe the evidence integration judgments and the primary rationales supporting these decisions for each health effect. These narratives are supported by an evidence profile table that succinctly lays out the various factors that were judged to increase or decrease the support for a hazard. While the epidemiology studies were not influential in drawing evidence integration judgments (i.e., they were judged as equivocal for all outcomes) or the derivation of toxicity values (i.e., these studies are not discussed in the next section), the general findings are summarized below to provide context to the animal study findings and identify potential areas of future research.

Table 6. Summary of Noncancer Data for Oral Exposure to PFBS (CASRN 375-73-5) and the Related Compound K^+PFBS (CASRN 29420-49-3)

Exposure Duration[a]	Reference	Study Confidence	Number of Male/Female, Strain, Species, Study Type, Study Duration	Doses Tested (mg/kg-d)	Effects Observed at LOAEL	NOAEL (mg/kg-d)	LOAEL (mg/kg-d)
Short term	3M (2000d)	Medium confidence	5/5, S-D rat, K^+PFBS administered by gavage, 10 d	0, 100, 300, 1,000	Increased absolute and relative liver weight.	300	1,000
Short term	3M (2001)	High confidence	10/10, S-D rat, K^+PFBS administered by gavage, 28 d	0, 100, 300, 900	Increased absolute and relative liver weight (male) and relative kidney weight (female).	300	900
Short term	NTP (2019)	High confidence	10/10, S-D rat, PFBS administered by gavage, twice/d, 28 d	0, 62.6, 125, 250, 500, 1,000[b]	Decreased T_3, free T_4, total T_4 in males and females. Increased relative liver weight in females and increased relative right kidney weight in males.	NDr	62.6
Subchronic	Lieder et al. (2009a); York (2003b)	High confidence	10/10, S-D rat, K^+PFBS administered by gavage, 7 d/wk, 90 d	0, 60, 200, 600	Increased incidence of renal hyperplasia in males and females.	200	600
Subchronic	Bijland et al. (2011); 3M (2010)	Medium confidence	6−8/0, Apoe*3-Leiden CETP mice, K^+PFBS in diet, 4−6 wk	0, 30	Alterations in lipid homeostasis (e.g., decreased hepatic lipase, triglycerides) is of uncertain biological significance.	NDr	NDr
Developmental	Feng et al. (2017)	High confidence	0/10, ICR mice, K^+PFBS administered by gavage, GDs 1−20	0, 50, 200, 500	Decreased T_3, free T_4, and total T_4 in dams and PND 1, 30, and 60 offspring. Increased TSH in maternal and offspring (PND 30 only). Delayed eyes opening, vaginal opening, and first estrous and decreased BW in pups.	50	200
Developmental	York (2003a)	High confidence	0/8, S-D rat, K^+PFBS administered by gavage, GDs 6−20	0, 100, 300, 1,000, 2,000	Decreased maternal feed consumption, BW gain, and gravid uterine weight. Decreased pup BW occurred at doses affecting maternal health, limiting the interpretation of the results; thus, developmental effect levels were not determined. (Limited endpoints evaluated—pilot study.)	P_0: 1,000 F_1: NDr	P_0: 2,000 F_1: NDr

Table 6. Summary of Noncancer Data for Oral Exposure to PFBS (CASRN 375-73-5) and the Related Compound K^+PFBS (CASRN 29420-49-3)

Exposure Duration[a]	Reference	Study Confidence	Number of Male/Female, Strain, Species, Study Type, Study Duration	Doses Tested (mg/kg-d)	Effects Observed at LOAEL	NOAEL (mg/kg-d)	LOAEL (mg/kg-d)
Developmental	York (2002)	High confidence	0/25, S-D rat, K^+PFBS administered by gavage, GDs 6–20	0, 100, 300, 1,000	Decreased maternal feed consumption and BW gain. Decreased pup BW occurred at doses affecting maternal health, limiting the interpretation of the results; thus, developmental effect levels were not determined.	P_0: 300 F_1: NDr	P_0: 1,000 F_1: NDr
Reproductive	Lieder et al. (2009b); York (2003c); York (2003d); York (2003e)	High confidence	30/30, S-D rat, K^+PFBS administered by gavage, two-generation reproductive study	P_0 adults: 0, 30, 100, 300, 1,000 F_1 adults: 0, 30, 100, 300, 1,000	P_0 and F_1 adults: increased incidence of hyperplasia and focal papillary edema in the kidneys of males and females. F_2 pups: no dose-related effects at the highest dose tested (1,000 mg/kg-d).	P_0, F_1: 100 F_2: 1,000	P_0, F_1: 300 F_2: NDr

[a]Duration categories are defined as follows: Acute = exposure for ≤24 hours; short term = repeated exposure for 24 hours to ≤30 days; long term (subchronic) = repeated exposure for >30 days ≤10% lifespan for humans (>30 days up to approximately 90 days in typically used laboratory animal species); chronic = repeated exposure for >10% lifespan for humans (>~90 days to 2 years in typically used laboratory animal species) (U.S. EPA, 2002).
[b]Rats were gavaged twice daily at administered doses of 0, 31.3, 62.6, 125, 250, and 500 mg/kg in NTP (2019).

BW = body weight; GD = gestation day; NDr = not determined; ICR = Institute of Cancer Research; K^+PFBS = potassium perfluorobutane sulfonate; LOAEL = lowest-observed-adverse-effect level; NOAEL = no-observed-adverse-effect level; PFBS = perfluorobutane sulfonic acid; PND = postnatal day; S-D = Sprague-Dawley; T_3 = triiodothyronine; T_4 = thyroxine; TSH = thyroid-stimulating hormone.

5.1 THYROID EFFECTS

PFBS-induced perturbation of the thyroid was consistently observed across two species, sexes, life stages, and exposure durations in two independent, high-confidence studies. These perturbations involved a coherent pattern of hormonal changes. Significant changes in tissue weight or histopathology were not observed.

Similar patterns of decreases in total T_3, total T_4, and free T_4 were observed in PFBS-exposed pregnant mice, nonpregnant adult female and adult male rats from a 28-day study, and gestationally exposed female mouse offspring (NTP, 2019; Feng et al., 2017). These decreases were statistically significant (~20% in dams and ~50% in offspring) and shown to persist at least 60 days after gestational exposure in offspring and exhibited dose dependence in both studies.

Development of numerous organ systems, including neuronal, reproductive, hepatic, and immune systems, is affected by altered thyroid homeostasis because adequate levels of thyroid hormones are necessary for normal growth and development in early life stages (Forhead and Fowden, 2014; Gilbert and Zoeller, 2010; Hulbert, 2000). Thus, the observed effects of PFBS exposure on thyroid hormone economy are biologically consistent with the reported delays and abnormalities in organ/system development discussed below. It is well established that the presence of sufficient thyroid hormones during the gestational and neonatal period is essential for brain development and maturation. Studies specifically evaluating the effect of PFBS on neurodevelopment were not identified, leaving uncertainty as to the potential for adverse developmental effects. Nonetheless, the coherence of these PFBS findings, in addition to the large number of xenobiotic exposure studies demonstrating associations between thyroid hormone economy and decrements in early life stage growth, development, and survival, provides support for thyroid hazard.

Taken together, the evidence in animals for thyroid effects *supports a hazard*. The single available study in humans did not report an association with thyroid hormones, but had severe limitations hindering its interpretation. This low-confidence cross-sectional study was conducted in a highly selected population (i.e., women with premature ovarian insufficiency), had poor sensitivity, and methodological limitations (Zhang et al., 2018). The limited evidence for thyroid effects in human studies is *equivocal*. Although there are some differences in hypothalamic-pituitary-thyroid (HPT) regulation across species (e.g., serum hormone-binding proteins, hormone turnover rates, and timing of in utero thyroid development), rodents are generally considered to be a good model for evaluating the potential for thyroid effects of chemicals in humans (Zoeller et al., 2007). For more details pertaining to HPT dynamics and the similarities and differences associated with thyroid hormone economy between rodents and humans, please refer to *A Literature Review of the Current State of the Science Regarding Species Differences in the Control of, and Response to, Thyroid Hormone Perturbations. Part 1: A Human Health Perspective* (Regulatory Science Associates, 2019). The pattern of decreased thyroid hormones in the absence of a coordinated reflex increase in TSH and commensurate alterations in thyroid tissue weight and/or histology, observed in PFBS studies [e.g., Feng et al. (2017)], is consistent with the human clinical condition referred to as "hypothyroxinemia," which is commonly associated with pregnancy in humans. Hypothyroxinemia has been defined as a low percentile value of FT_4 (ranging from the 2.5th percentile to the 10th percentile of FT_4), with a TSH level within the normal reference range (Hales et al., 2018; Alexander et al., 2017;

Lazarus et al., 2012; Negro et al., 2011). Overall, based on findings in animal models considered to be informative for evaluating the potential for thyroid effects in humans, the available evidence *supports a hazard,* and the thyroid is considered a potential target organ for PFBS toxicity in humans.

5.2 DEVELOPMENTAL EFFECTS

Overt effects on birth parameters and early development have generally not been observed in either rats or mice after PFBS exposure. Specifically, the available studies do not provide evidence of effects on endpoints relating to pregnancy loss, fetal survival, or fetal morphology (Feng et al., 2017; Lieder et al., 2009a; York, 2003a, c, 2002). While one mouse study indicated pronounced decreases in female offspring BW at several ages after gestational exposure (Feng et al., 2017), several other studies either did not observe decreases in offspring BW or only detected these changes when parental BWs were similarly affected (Feng et al., 2017; Lieder et al., 2009a; York, 2003a, c, 2002).

Delays in development have been reported following gestational PFBS exposure in mice, including delayed development of the female reproductive organs (i.e., ovaries, uterus, and vaginal patency), delayed and abnormal estrous cycling (i.e., first estrous and prolongation of diestrus), and delayed eye opening (Feng et al., 2017). Age at vaginal patency and ovarian follicle counts (i.e., in F_1 rat offspring after delivery of the F_2 generation) were unaffected at 1,000 mg/kg-day in a two-generation reproductive toxicity study (Lieder et al., 2009a). This observed lack of effects (i.e., on vaginal patency) is inconsistent with the findings in mice. However, Feng et al. (2017) also noted changes in reproductive hormones that might be relevant to the delays in female sexual development, including a decrease in serum estradiol and increased luteinizing hormone in pubertal offspring (i.e., PND 30 [Note: progesterone was decreased at a later age, PND 60, but not PND 30]). Because the changes reported in mice by Feng et al. (2017) were observed in parallel with effects on thyroid hormone levels (discussed above), it is plausible that these developmental delays and hormonal changes could represent sequalae of reduced thyroid function, although that was not directly tested.

For the most part, developmental effects have been reported in a single study and species (mouse); however, the findings are coherent with one another as well as with the consequences of decreased thyroid hormone levels. Because of the coherence across effects on the thyroid and several interrelated developmental effects in mice (i.e., delays and hormonal changes), the evidence in animals for developmental effects *supports a hazard*. There is no reason to expect that the specific developmental delays observed in mice would not be directly relevant to similar processes in humans. Thus, based on findings in animals that are presumed to be relevant to humans, the available evidence *supports a hazard* and the developing offspring is considered a potential target for PFBS toxicity in humans. Because no studies in humans were available that investigated these endpoints, this represents an area deserving of additional research.

5.3 REPRODUCTIVE EFFECTS

Reproductive outcomes, including male and female fertility, pregnancy outcomes, hormone levels, markers of reproductive development, and reproductive organ weights and histopathology, have been evaluated in a number of high-confidence studies in mice (Feng et al., 2017) and rats (NTP, 2019; Lieder et al., 2009a; Lieder et al., 2009b). In addition, five low-confidence human studies evaluated potential associations between PFBS exposure and

reproductive effects (Yao et al., 2019; Song et al., 2018; Zhang et al., 2018; Zhou et al., 2017a; Zhou et al., 2016).

PFBS exposure has resulted in no significant changes in male mating and fertility parameters, reproductive organ weights, or reproductive hormones. Although there were some slight, statistically significant effects on male reproductive endpoints in two rat studies [specifically, altered sperm parameters such as percentage of abnormal sperm or testicular sperm count (NTP, 2019; Lieder et al., 2009a) and delayed preputial separation at 1,000 mg/kg-day (Lieder et al., 2009a)], these findings were observed only at the highest doses and the levels of change were of questionable biological significance. No significant reproductive effects in men were noted across two human studies (Song et al., 2018; Zhou et al., 2016), although U.S. EPA noted a nonsignificant inverse association with testosterone and estradiol in male infants in one study (Yao et al., 2019).

In general, PFBS exposure in adults has also resulted in no significant alterations in female fertility or pregnancy outcomes in rats or mice (NTP, 2019; Feng et al., 2017; Lieder et al., 2009a; Lieder et al., 2009b) or in two human studies (Yao et al., 2019; Zhang et al., 2018; Zhou et al., 2017a; Zhou et al., 2016), and inconsistent changes in rodent reproductive organ weights were reported across studies regardless of duration and timing of exposure. However, changes in normal estrous cyclicity, specifically prolongation of the diestrus stage, have been reported in both nonpregnant adult rats exposed to PFBS (NTP, 2019) and adult mouse offspring exposed gestationally from GDs 1 to 20 (Feng et al., 2017). PFBS exposures in NTP (2019) began between 8 and 10 weeks of age; although the exposures might overlap with some aspects of reproductive development or changes in function during adolescence, these rats were sexually mature and thus the endpoints are considered in the context of reproductive, rather than developmental, effects. The mouse offspring in the study by Feng et al. (2017) also displayed delayed vaginal patency and histopathological markers of decreased fertility (i.e., decreased follicles and corpora lutea); however, the reproductive function of those offspring was not tested. While adult rat offspring (F_1) in a two-generation toxicity study also exhibited variable changes in estrous cyclicity (Lieder et al., 2009b), including prolonged diestrus at 100 mg/kg-day, this effect was not observed at higher doses, limiting interpretation, and no effects on vaginal patency were observed. Female reproductive hormones can inform the potential for effects on reproductive organ development, estrous cyclicity, and fertility. Changes in serum hormones included increased testosterone after exposure of female rats as adults (NTP, 2019), increased luteinizing hormone and decreased estradiol in pubertal mice after gestational exposure (Feng et al., 2017), and decreased estradiol and progesterone when these gestationally exposed mice were assessed as adults. Overall, the pattern and timing of hormonal changes after PFBS exposure is difficult to interpret and likely incomplete. However, the hormonal alterations after gestational PFBS exposure in mice are most relevant to conclusions about female reproductive health.

Taken together, the evidence indicates that the developing reproductive system, particularly in females, might be a target for PFBS toxicity. However, the potential for reproductive effects in adults was less clear, and significant impacts on mating or fertility parameters were not observed across the available studies. Therefore, the evidence in developing animals is considered most informative to conclusions relating to potential developmental effects (see above) and the evidence for reproductive effects (i.e., in adults) is *equivocal*. In the three studies of potential reproductive effects in humans, no clear associations

were observed, so the evidence in human studies is *equivocal*. Overall, based on *equivocal* human and animal evidence, the available evidence for reproductive effects is *equivocal*.

5.4 RENAL EFFECTS

Renal effects associated with oral exposure to PFBS have been observed in adult or developing rats across high- or medium-confidence gavage studies of various duration (NTP, 2019; Lieder et al., 2009a; Lieder et al., 2009b; 3M, 2001, 2000d).

Statistically significant increases in kidney weights have been observed in male and female rats after short-term exposure in one study (NTP, 2019), with strong dose-dependence for changes in relative weights in female rats at doses as low as 62.6 mg/kg-day. This study was likewise the only study to observe changes in serum markers of renal injury, specifically increased BUN in males at ≥250 mg/kg-day. However, while several other studies noted slight increases in weights, typically at higher PFBS doses (≥500 mg/kg-day), U.S. EPA found that these nonsignificant changes were not consistently observed across the set of available studies and no other studies reported changes in serum markers of renal injury (Lieder et al., 2009a; Lieder et al., 2009b; 3M, 2001, 2000d).

Several kidney histopathology lesions (i.e., CPN, hydronephrosis, tubular degeneration, and tubular dilation) were unaffected by PFBS exposure in rats, although each of these endpoints was not assessed across several studies (NTP, 2019; Lieder et al., 2009a; 3M, 2000d). Mixed results were reported for mineralization and necrosis. Both of these endpoints were noted in females, but not males, after subchronic exposure to 600 mg/kg-day (Lieder et al., 2009a), whereas mineralization was unaffected in male or female rats after short-term exposure (3M, 2000d), and necrosis was unaffected in male or female rats in short-term and two-generation (in both generations) studies (NTP, 2019; Lieder et al., 2009b). Multiple markers of inflammatory changes were consistently noted in the two longest exposure duration studies, which were the only studies to report on these endpoints. Specifically, increases in chronic pyelonephritis, tubular basophilia, and mononuclear cell infiltration were observed in female, but not male, rats following subchronic exposure to 600 mg/kg-day (Lieder et al., 2009a). Similarly, increases in papillary edema and hyperplasia were observed in male and female rats after subchronic exposure to 600 mg/kg-day (Lieder et al., 2009a), and in both generations of rats in the two-generation study at ≥300 mg/kg-day (Lieder et al., 2009b), with female rats being more sensitive than males.

Overall, the evidence in animals suggests an increased sensitivity of female rats (i.e., based on histopathology and organ-weight changes). Due primarily to the consistency and coherence in renal effects observed in the subchronic study by Lieder et al. (2009a) and the reproductive toxicity study by Lieder et al. (2009b) in male and female rats, the evidence in animals *supports a hazard*. There is insufficient evidence in the epidemiology studies of PFBS to inform the human relevance of these findings. Taken together, the renal histopathology evidence in rodents identifies a toxicologically significant spectrum of effects that is presumed to be relevant to similar changes known to occur in humans. Renal effects (i.e., uric acid) were evaluated in one low-confidence human study, and no clear association was observed; therefore, the evidence in human studies is *equivocal*. Overall, based on findings in animals that are presumed to be relevant to humans, the available evidence *supports a hazard* and indicates the kidney as a target organ of PFBS toxicity.

5.5 HEPATIC EFFECTS

Hepatic effects, including organ-weight changes and histopathology associated with oral exposures to PFBS, have been observed in high- or medium-confidence studies in adult or developing rats following short-term- and subchronic-duration exposures (NTP, 2019; Lieder et al., 2009a; 3M, 2001, 2000d) and in a two-generation reproductive study in rats (Lieder et al., 2009b). Increased absolute and/or relative liver weights were consistently observed in male and female rats after short-term and multigenerational exposure (NTP, 2019; Lieder et al., 2009b; 3M, 2001, 2000d). In some studies, the magnitude of the liver-weight changes and the doses at which effects occurred differed across sexes of rat, although the pattern across studies was unclear and did not consistently indicate one sex as more sensitive. Liver histopathology, including necrosis and inflammation, was not consistently observed across PFBS studies. One possible exception is increases in hepatocellular hypertrophy in male rats observed across two studies (NTP, 2019; Lieder et al., 2009b), although female rats were unaffected in the multigenerational study and this lesion was not observed at up to 600 mg/kg-day in the subchronic study by Lieder et al. (2009a). The only study to observe changes in serum markers of liver injury was NTP (2019), at ≥250 mg/kg-day in females and ≥500 mg/kg-day in males. The biological relevance or significance of the observed liver effects is not clear. In particular, the adversity of the variable changes in liver weight and observations of cellular hypertrophy is unclear. Further, the observed lesions either occurred in only one sex of rat, were not dose dependent compared with control, and/or occurred only at the highest PFBS dose tested. Thus, the evidence in animals is *equivocal*. Overall, based on *equivocal* animal evidence and a lack of human studies, the available evidence for hepatic effects is *equivocal*.

5.6 EFFECTS ON LIPIDS OR LIPOPROTEINS

Few studies have examined the effects of PFBS on circulating or hepatic lipid or lipoprotein homeostasis. It is recognized that increased circulating levels of lipids and lipoprotein products and/or increased hepatic lipid load are clinical observations of concern in humans. However, the lack of effect on lipid dynamics in most studies of rats exposed to high oral K^+PFBS doses for up to 90 days and the generally modest effects in transgenic mice, fed a high-fat, western-type diet renders this potential health outcome of unclear toxicological significance at this time. Thus, given the inconsistent, modest effects and the unclear biological relevance of these changes in isolation (i.e., lipids/lipoproteins were decreased, not increased) the evidence in animals is *equivocal*. Effects on serum lipids were evaluated in one low-confidence human study and childhood adiposity was evaluated in one medium-confidence study. Although an association was observed between increased PFBS exposure and increased total cholesterol and higher adiposity, this evidence in humans is *equivocal* due to lack of additional supportive evidence. Overall, based on *equivocal* evidence in both animal and human studies, the available evidence for effects on lipid or lipoprotein homeostasis is *equivocal*.

5.7 IMMUNE EFFECTS

Immune effects were observed in two human studies, including associations with asthma (Dong et al., 2013a) and atopic dermatitis (Chen et al., 2018). Exposure of human peripheral blood leukocytes or human promyelocytic THP-1 cells to PFBS, in culture, decreased cytokine (e.g., TNFα and IL-10) secretion following antigen challenge (Corsini et al., 2012). Because of the lack of additional evidence and some concerns about potential for residual confounding by other PFAS, the evidence in human studies is *equivocal*. Overall, based on *equivocal* evidence

in human studies and a lack of animal studies, the available evidence for immune effects is *equivocal*.

5.8 CARDIOVASCULAR EFFECTS

Cardiovascular effects were observed in two human studies, including associations with cardiovascular disease in adults (Huang et al., 2018) and hypertensive disorders in pregnancy (Huang et al., 2019b). The results are compelling, but as with the evidence for immune effects, there is a lack of additional supportive evidence and some concerns about potential for confounding; thus, the evidence in human studies is *equivocal.* Overall, based on *equivocal* evidence in human studies and a lack of animal studies, the available evidence for cardiovascular effects is *equivocal*.

5.9 EVIDENCE INTEGRATION AND HAZARD CHARACTERIZATION SUMMARY

Based on the evidence integration judgments regarding the potential for PFBS exposure to cause health effects (the narrative above is summarized in Table 7), the animal studies informing the potential effects of PFBS exposure on thyroid function, renal function, and development were concluded to *support a hazard*. Thus, for the purposes of this assessment, the animal data supporting these outcomes were considered for use in dose-response analysis, and other data were considered no further.

Table 7. Summary of Hazard Characterization and Evidence Integration Judgments

Studies and Confidence	Factors That Increase Support for Hazard	Factors That Decrease Support for Hazard	Summary of Findings	Overall Evidence Integration Judgment and Basis
Thyroid effects				
Human studies				*Supports a hazard* (animal evidence *supports a hazard*; human evidence is *equivocal*). The primary basis for this judgment is thyroid hormone decreases in mice and rats at ≥62.6 mg/kg-d.
• Low-confidence case-control study (Zhang et al., 2018)	• No factors noted.	• Single study of low confidence and poor sensitivity.	No association of PFBS with free T_3, free T_4, or thyroid stimulating hormone, but the study had poor sensitivity and other methodological limitations that hinder interpretability.	
Animal studies (all gavage)				
Mouse Studies: • High-confidence gestational (GDs 1−20) exposure study (Feng et al., 2017) Rat Studies: • High-confidence short-term (28-d) toxicity study (NTP, 2019)	• Consistent thyroid hormone decreases (i.e., for total T_3, total T_4, and free T_4) across two high-confidence studies of varied design. The findings were consistent across two species, sexes, life stages, and exposure durations. • Dose-response gradients were observed for those thyroid hormones. • Large magnitudes of effect (e.g., up to ~50% reductions in offspring serum hormones) were reported for those thyroid hormones.	• No factors noted.	Similar patterns of decreases in thyroid hormones (i.e., for total T_3, total T_4, and free T_4) were observed in PFBS-exposed pregnant mice and gestationally exposed female mouse offspring at ≥200 mg/kg-d (Feng et al., 2017) and in adult female and male rats at ≥62.6 mg/kg-d (NTP, 2019). Increased TSH was reported in mouse dams and in pubertal (PND 30) offspring following gestational exposure (Feng et al., 2017), but no changes were noted in rats exposed as adults (NTP, 2019). Thyroid weight and histopathology were not changed after short-term exposure in adult male or female rats (NTP, 2019).	

Table 7. Summary of Hazard Characterization and Evidence Integration Judgments

Studies and Confidence	Factors That Increase Support for Hazard	Factors That Decrease Support for Hazard	Summary of Findings	Overall Evidence Integration Judgment and Basis
Developmental effects				
Human studies				*Supports a hazard* (animal evidence *supports a hazard*; human evidence is *equivocal*). The primary basis for this judgment is a set of persistent developmental delays and alterations in reproductive system maturation in female mice, generally at ≥200 mg/kg-d.
No studies available to evaluate.	--	--	--	
Animal studies (all gavage)				
Mouse Studies: • High-confidence gestational (GDs 1−20) exposure study (Feng et al., 2017) Rat Studies: • Two high-confidence gestational exposure (GDs 6−20) studies: a range-finding study and a follow-up study (York, 2003c, 2002) • High-confidence two-generation study (Lieder et al., 2009b)	• Biologically consistent spectrum of developmental effects in female offspring in a high-confidence mouse study at doses not causing maternal toxicity, including pronounced and persistent effects on BW, delays in developmental milestones and sexual maturation, concordant effects on reproductive organs, and altered serum hormones. • Concerning magnitude of effect (e.g., ~25% change in pup weight) and dose-dependence for several parameters. • Coherence of effects with thyroid hormone insufficiency (see above).	• Developmental effects were limited to changes in one study, sex, and species. • A high-confidence rat study reported some inconsistent evidence, including lack of a delay in vaginal patency and lack of clear effects on estrous cyclicity or ovarian morphology, although the latter endpoint was assessed in much older animals. These potential differences across species are not explainable based on toxicokinetics alone.	In the only mouse study (Feng et al., 2017), developmental effects and altered markers of female reproductive development or function were observed in female offspring after gestational PFBS exposure, including decreased BW, delayed eye opening, delayed vaginal opening, altered estrous cyclicity (including prolonged diestrus), altered reproductive hormones (e.g., decreased estradiol and progesterone), and effects on reproductive organs (e.g., weight and ovarian morphology). Most effects were observed at ≥200 mg/kg-d, with several changes noted at PND 60. Endpoints relating to fertility, pregnancy, survival, and fetal alterations were unchanged in both rats and mice across the four available studies, although this was not tested in mouse offspring (Feng et al., 2017). Developmental BW changes in rat offspring were either unchanged (Lieder et al., 2009b) or observed only at doses causing parental toxicity (York, 2003c, 2002).	

Table 7. Summary of Hazard Characterization and Evidence Integration Judgments				
Studies and Confidence	**Factors That Increase Support for Hazard**	**Factors That Decrease Support for Hazard**	**Summary of Findings**	**Overall Evidence Integration Judgment and Basis**
Continued:	Continued: Note: these effects were also coherent with effects on estrous cyclicity observed after short-term exposure in adult rats (NTP, 2019), but this was categorized as a reproductive effect (see below).	Continued:	Continued: In a rat two-generation study, while some statistically significant findings were noted for markers of female reproductive development or function, they were not dose-dependent or were of questionable biological relevance; thus, no clear changes in F_1 offspring were noted at doses up to 1,000 mg/kg-d regarding vaginal patency or estrous cycling at comparable ages to (Feng et al., 2017), or in ovarian morphology after the F_1 females gave birth to the F_2 pups. Reproductive effects				
Human studies				
Male reproductive effects				
• Low-confidence cohort study (Zhou et al., 2016) • Low-confidence cross-sectional study (Song et al., 2018) • Low-confidence cross-sectional study (Yao et al., 2019)	• No factors noted.	• Lack of clear association in studies of low confidence with poor sensitivity (i.e., due to low exposure levels, range).	No clear association between PFBS exposure and male reproductive hormones (Zhou et al., 2016) or semen parameters (Song et al., 2018) in adults. A study in newborns reported nonsignificant inverse associations between PFBS exposure and testosterone and estradiol (Yao et al., 2019).	

Table 7. Summary of Hazard Characterization and Evidence Integration Judgments

Studies and Confidence	Factors That Increase Support for Hazard	Factors That Decrease Support for Hazard	Summary of Findings	Overall Evidence Integration Judgment and Basis
Female reproductive effects				*Equivocal* (*equivocal* human and animal evidence). Note: As the strongest evidence for female reproductive effects was in offspring that were gestationally exposed, these findings were considered most relevant to developmental, not reproductive, effects.
• Low-confidence cross-sectional study (Zhou et al., 2017a) • Low-confidence cohort study (Zhou et al., 2016) • Low-confidence cross-sectional study (Yao et al., 2019) • Low-confidence case-control study (Zhang et al., 2018)	• No factors noted.	• Lack of clear association in studies of low confidence with poor sensitivity (i.e., due to low exposure levels, range). • Potential for reverse causation for menstrual cycle characteristics and premature ovarian insufficiency.	No clear association between PFBS exposure and female reproductive hormones (Zhou et al., 2016) or menstrual cycle characteristics (Song et al., 2018).	
Animal studies *(all gavage)*				
Male reproductive effects				
Rat Studies: • High-confidence short-term (28-d) toxicity study (NTP, 2019) • High-confidence two-generation study (Lieder et al., 2009b) • High-confidence subchronic study (Lieder et al., 2009a)	• No factors noted.	• A few small, statistically significant changes were not dose-dependent or were of questionable biological relevance. • Lack of effects on male mating and fertility, hormones, or reproductive organs in rats.	Statistically significant effects on sperm health (NTP, 2019; Lieder et al., 2009a) and delayed preputial separation at 1,000 mg/kg-d (Lieder et al., 2009b) were not observed at lower doses, were within the normal range of historical controls for the laboratory, and/or were no longer significantly changed after correcting for other variables (e.g., BW). Other relevant parameters (e.g., organ weights, mating success, and so forth) were unchanged in the three studies.	

Table 7. Summary of Hazard Characterization and Evidence Integration Judgments

Studies and Confidence	Factors That Increase Support for Hazard	Factors That Decrease Support for Hazard	Summary of Findings	Overall Evidence Integration Judgment and Basis
Female reproductive effects				
Mouse Studies: • High-confidence gestational (GDs 1−20) exposure study (Feng et al., 2017) Rat Studies: • High-confidence short-term (28-d) toxicity study (NTP, 2019) • High-confidence subchronic study (Lieder et al., 2009a) • High-confidence two-generation study (Lieder et al., 2009b)	• Effects on markers of female reproductive function (i.e., estrous cyclicity) were observed in high-confidence studies in rats and mice. • Changes in reproductive serum hormones were observed in female rats (i.e., increased testosterone) and mice (e.g., decreased estradiol and progesterone). Although the pattern of change is difficult to interpret and likely incomplete, there were no conflicting data.	• Lack of similar effects on reproductive function (i.e., estrous cyclicity) in a second high-confidence rat study. • Lack of effects on female fertility or pregnancy measures, although this was untested in prenatally exposed female mouse offspring. • Lack of organ-weight changes in three rat studies. Note: The lack of effects on ovarian follicles in rats did not decrease the support for hazard provided by findings in mice, as the age at endpoint assessment was not comparable.	See "Developmental effects" (above) for findings from Feng et al. (2017) and Lieder et al. (2009b). Altered estrous cyclicity (including prolonged diestrus) and increased serum testosterone were observed in female rats after short-term exposure, primarily at ≥250 mg/kg-d (NTP, 2019). Female reproductive organ weights were reduced in gestationally exposed mouse offspring (Feng et al., 2017), but were unchanged after short-term, subchronic, or two-generational exposure (NTP, 2019; Lieder et al., 2009a; Lieder et al., 2009b).	

Table 7. Summary of Hazard Characterization and Evidence Integration Judgments

Studies and Confidence	Factors That Increase Support for Hazard	Factors That Decrease Support for Hazard	Summary of Findings	Overall Evidence Integration Judgment and Basis
Renal effects				
Human studies				*Supports a hazard.* (animal evidence *supports a hazard*; human evidence is *equivocal*). The primary basis for this judgment is kidney histopathology in rats, primarily females, at ≥300 mg/kg-d.
• Low-confidence cross-sectional study (Qin et al., 2016)	• No factors noted.	• Inconsistency across subpopulations in single study. • Single study of low confidence with concern for potential reverse causality.	Overall, there was no clear association for PFBS and uric acid. No association observed between PFBS and uric acid in the total population. Increase in uric acid with increased exposure in boys but decrease for girls (neither was statistically significant).	
Animal studies (all gavage)				
Rat Studies: • One high-confidence subchronic study (Lieder et al., 2009a) • Two high-confidence study (NTP, 2019; 3M, 2001) and one medium-confidence (3M, 2000d) short-term (10−28 d) study • One high-confidence two-generation study (Lieder et al., 2009b)	• Two high-confidence studies with the longest exposure durations reported consistent effects on kidney histopathology in male and female rats (females were more sensitive). • The histopathological effects related to inflammation were largely dose-dependent and of a concerning magnitude, although primarily at high doses (300 or 600 mg/kg-d).	• Inconsistency in kidney-weight changes across studies. • Findings are from a single laboratory and species. Note: The general lack of effects on other pathology endpoints in the shorter term studies was not considered to decrease support for hazard, as this was not interpreted as inconsistent.	Increases in kidney weight in male and female rats were observed in one short-term study at ≥ 62.6 mg/kg-d, but clear changes were not observed in the other short-term, subchronic, or two-generation rat studies. Kidney histopathology for some effects (i.e., CPN, hydronephrosis, tubular degeneration, and tubular dilation) was unchanged in single-study evaluations, and mixed results across studies were reported for mineralization and necrosis (NTP, 2019; Lieder et al., 2009a; Lieder et al., 2009b; 3M, 2000d). Multiple markers potentially related to inflammation and most notably papillary edema and hyperplasia were increased in the two longest duration studies (Lieder et al., 2009a; Lieder et al., 2009b), without contrary evidence.	

Table 7. Summary of Hazard Characterization and Evidence Integration Judgments

Studies and Confidence	Factors That Increase Support for Hazard	Factors That Decrease Support for Hazard	Summary of Findings	Overall Evidence Integration Judgment and Basis
Continued:	Continued:	Continued:	Continued: Other markers of renal injury, including BUN and creatinine, were mostly unaffected across studies (NTP, 2019; Lieder et al., 2009a; Lieder et al., 2009b; 3M, 2001, 2000d), although the NTP study did observe effects on BUN in males at ≥250 mg/kg-d. Animal studies (all gavage)				
Rat Studies: • One high-confidence subchronic study (Lieder et al., 2009a) • Two high-confidence studies (NTP, 2019; 3M, 2001) and one medium-confidence (3M, 2000d) short-term (10−28 d) study • One high-confidence two-generation study (Lieder et al., 2009b)	• Consistent changes in liver weights in rats of both sexes across four studies. Although the pattern (e.g., by sex and dose) and magnitude of changes varied across studies, weights were consistently increased.	• Other than liver-weight changes, there were notable unexplained inconsistencies in the findings across studies. • One high-confidence study was entirely inconsistent.[a]	Absolute or relative liver weights were increased in all studies except the 90-d exposure component of the study by Lieder et al. (2009a), which tested doses up to 600 mg/kg-d. Note: 70 d of exposure in this study did elicit effects. Effects generally occurred at ≥300 mg/kg-d, although one study reported effects at lower doses (NTP, 2019; 3M, 2001), and two others (3M, 2001, 2000d) observed changes at ≥900 mg/kg-d. Serum markers of liver injury were unchanged in three studies (Lieder et al., 2009a; 3M, 2001, 2000d) and increased in one short-term study at ≥250 mg/kg-d (NTP, 2019).

Studies and Confidence	Factors That Increase Support for Hazard	Factors That Decrease Support for Hazard	Summary of Findings	Overall Evidence Integration Judgment and Basis
Animal studies				
Mouse Studies (diet): • Medium-confidence short-term (4−6 wk) study (Bijland et al., 2011); transgenic mice (human-like lipid metabolism) were fed a high-fat diet Rat Studies (all gavage): • One high-confidence subchronic study (Lieder et al., 2009a) • One high-confidence study (3M, 2001) and one medium-confidence (3M, 2000d) short-term (10−28 d) study	• Decreases in serum cholesterol and triglycerides were observed in male rats and mice.	• Inconsistent evidence in other rat studies and across sexes. • Small effect magnitudes and unclear direction (decreases) of changes are of questionable biological relevance and could not be informed by evaluating dose-dependency (i.e., only single-dose or high-dose effects were observed).	Serum lipids, specifically cholesterol and triglyceride levels, were slightly decreased (~20%) at 900 mg/kg-d in males, but not females, in one rat study (3M, 2001), but not in two other rat studies at up to 1,000 mg/kg-d. Serum and hepatic lipids and lipoproteins were also decreased in male mice exposed to ~30 mg/kg-d in diet.

Immune effects				
Human studies				*Equivocal* (*equivocal* human and animal evidence).
Asthma				
• Medium-confidence case-control study (Zhou et al., 2016; Zhu et al., 2016; Dong et al., 2013b)	• Statistically significant association in a medium-confidence study. Note: Increases in eosinophil markers were not interpreted to increase support for hazard, because they were not statistically significant and other markers important to asthma etiology (e.g., IgE) were unchanged.	• Association was observed in a single study with concern regarding the potential for residual confounding (e.g., with other PFAS chemicals).	Statistically significant increase in odds of asthma diagnosis in the previous year (OR: 1.2−1.9) with increased PFBS exposure. Eosinophil markers (i.e., AEC and ECP) were increased with increased PFBS exposure in asthmatics and nonasthmatics; however, these increases did not reach statistical significance. IgE and T-helper cell-specific cytokines were unchanged (Zhu et al., 2016).	
Atopic dermatitis				
• Medium-confidence cohort study (Chen et al., 2018)	• No factors noted.	• Slight associations were not statistically significant in a single study with concern regarding the potential for residual confounding (e.g., with other PFAS chemicals).	Statistically nonsignificant increase in odds of atopic dermatitis (OR: 1.2) with increased PFBS exposure.

Human studies				
• Medium-confidence cross-section study (Huang et al., 2018) • Medium-confidence cross-sectional study (Huang et al., 2019b)	• Statistically significant associations in medium-confidence studies.	• Single study per outcome.	Higher odds of cardiovascular disease (total and individual types of disease) with PFBS exposure (Huang et al., 2018). Higher odds of hypertensive disorders in pregnancy with higher PFBS exposure (Huang et al., 2019b). There is potential for residual confounding that decreases confidence in the evidence.	*Equivocal* (*equivocal* human and animal evidence).
Animal studies				
No studies available to evaluate.	–	–	–	

[a]The lack of liver effects in the subchronic study was not interpreted to significantly reduce support for hazard because the maximum tolerated dose was 600 mg/kg-d, and other studies reported only liver effects at ≥900 mg/kg-d.

AEC = absolute eosinophil count; BUN = blood urea nitrogen; BW = body weight; CPN = chronic progressive nephropathy; ECP = eosinophilic cationic protein; GD = gestation day; IgE = immunoglobulin E; NTP = National Toxicology Program; OR = odds ratio; PFAS = per- and polyfluoroalkyl substances; PFBS = perfluorobutane sulfonic acid; PND = postnatal day; T_3 = triiodothyronine; T_4 = thyroxine; TSH = thyroid stimulating hormone.

6.0 DERIVATION OF VALUES

The hazard and dose-response database for PFBS and the potassium salt is primarily associated with the oral route of exposure. There are a limited number of dermal studies (see Table 5) and no known inhalation studies. There are no known studies evaluating potential cancer effects of PFBS. Therefore, only noncancer reference values are derived in this assessment for the oral route.

6.1 DERIVATION OF ORAL REFERENCE DOSES

The hazards of potential concern for oral PFBS exposure include thyroid, developmental, and kidney effects. Overall, the evidence *supports a hazard* for thyroid, developmental, and kidney effects based on the evidence from animal studies. The limited evidence for thyroid or renal effects in human studies is *equivocal*, and no studies evaluating developmental effects following PFBS exposure in humans were available. Thus, data in humans were not considered further, and the available animal studies that evaluated these effects are considered in the derivation of oral RfDs.

6.1.1 Derivation of the Subchronic Oral Reference Dose

6.1.1.1 Estimation of Points of Departure

Effects in the thyroid were considered when determining potential PODs for deriving a subchronic RfD. Similar patterns of decreases in total T_3, total T_4, and free T_4 were observed in PFBS-exposed pregnant mice, nonpregnant adult female rats, adult male rats, and gestationally exposed female mouse offspring (NTP, 2019; Feng et al., 2017). These decreases were significant (~20% in dams and ~50% in offspring), were shown to persist at least 60 days after gestational exposure in offspring, and they exhibited a clear dose dependence in both studies. Reflex increases in TSH in response to decreased T_4 or T_3 were not observed in male or female rats following 28 days of exposure (NTP, 2019). Such an increase in TSH was observed in pregnant mice (measured at GD 20) and their corresponding female offspring, at PND 30 only, with an irregular dose-response or time course (Feng et al., 2017). This pattern of decreased thyroid hormone without a concomitant increase in TSH is consistent with a human clinical condition referred to as "hypothyroxinemia" (Negro et al., 2011). Importantly, milder forms of thyroid perturbation are up to 10 times more prevalent in human populations than overt gestational hypothyroidism (Korevaar et al., 2016; Stagnaro-Green et al., 2011). Hypothyroxinemia has been associated with impairments in neurodevelopment and/or cognition later in life (Thompson et al., 2018; Min et al., 2016). Because the single available study in humans had severe limitations hindering the interpretation of the relationship between PFBS exposure and thyroid hormone alterations, at this time the available evidence in humans is not able to inform the potential for thyroid effects in humans. This hypothyroxinemia, rather than overt or subclinical hypothyroidism, is further supported by the lack of effect on thyroid weight or tissue architecture in rats after 28 days of PFBS exposure (NTP, 2019).

Developmental effects were considered in determining potential PODs for derivation of a subchronic RfD. Specifically, in Feng et al. (2017), developmental delays or abnormalities in growth (i.e., BW and eye opening), reproductive organs (i.e., ovaries, uterus, and vaginal opening), and reproductive cycling (i.e., first estrous and prolongation of diestrus) were observed

in mouse offspring. These effects were observed in mice from litters in which thyroid hormone deficiency occurred at PND 1 and then sustained through pubertal and adult periods (i.e., PNDs 30 and 60, respectively). These interrelated developmental effects in mice (i.e., delays and hormonal changes) are coherent with effects on the thyroid and presumed to be directly relevant to similar processes in humans; however, studies evaluating these outcomes in humans are not available.

Effects in the kidney were considered in determining potential PODs for deriving a subchronic RfD. Lieder et al. (2009a) reported mild to moderate hyperplasia in the kidneys of male and female rats following subchronic-duration exposure to PFBS, and Lieder et al. (2009b) found the same effects in the P_0- and F_1-generation animals in their reproductive toxicity study. Other studies evaluating effects in the kidney were of shorter duration and thus less suitable as a candidate principal study. Additional histopathological alterations accompanied the hyperplasia observed in the kidney, including papillary edema and inflammatory changes, specifically increases in chronic pyelonephritis, tubular basophilia, and mononuclear cell infiltration (Lieder et al., 2009a; Lieder et al., 2009b). Across the reported kidney histopathological effects following PFBS exposure, female rats were generally more sensitive than males.

Selected data sets from studies with multiple exposure levels for thyroid, developmental, and kidney effects were modeled using the U.S. EPA's Benchmark Dose Software (BMDS) Version 2.7. Consistent with the U.S. EPA's *Benchmark Dose Technical Guidance Document* (U.S. EPA, 2012), the BMD and 95% lower confidence limit on the BMD (BMDL) were estimated using a benchmark response (BMR) to represent a minimal, biologically significant level of change. Based on BMD guidance, in the absence of information regarding the level of change that is considered biologically significant, a BMR of 1 SD from the control mean for continuous data or a BMR of 10% extra risk for dichotomous data is used to estimate the BMD and BMDL, and to facilitate a consistent basis of comparison across endpoints, studies, and assessments. For some types of effects (e.g., frank effects, developmental effects), biological considerations may warrant the use of a BMR of 0.5 SD or lower.

For effects in developing offspring, including thyroid hormone changes, a BMR of 0.5 SD change from the control mean is used for continuous data to account for effects occurring in a sensitive life stage. A 1 SD BMR is also presented as the basis for model comparison as directed in the U.S. EPA *Benchmark Dose Technical Guidance* (U.S. EPA, 2012).

For thyroid hormone effects in offspring, a biological level of concern was considered in the identification of a BMR. Multiple lines of evidence regarding the degree of thyroid hormone disruption and developmental outcomes in offspring were evaluated. During developmental life stages, such as gestational/fetal and postnatal/early newborn, thyroid hormones are critical in many physiological processes associated with somatic growth and maturation and with life functions like thermogenesis, pulmonary gas exchange, and cardiac development (Sferruzzi-Perri et al., 2013; Hillman et al., 2012). Further, thyroid hormones are critically important in early neurodevelopment because they directly influence neurogenesis, synaptogenesis, and myelination (Rovet, 2014; Puig-Domingo and Vila, 2013; Stenzel and Huttner, 2013; Patel et al., 2011). Note that evidence from human epidemiological studies examining the association between thyroid hormone economy in pregnant mothers and neurodevelopment in their offspring is inconsistent. Several human epidemiologic studies have demonstrated key relationships between decreased

levels of thyroid hormones such as FT_4 in a pregnant woman and in utero and early postnatal life neurodevelopmental status. For example, children born euthyroid but who were exposed to thyroid hormone insufficiency in utero (e.g., ≤10th percentile free T_4), present with cognitive impairments (e.g., decreased intelligence quotient [IQ], increased risk of expressive language) and/or concomitant abnormalities in brain imaging (Levie et al., 2018; Korevaar et al., 2016; Henrichs et al., 2010; Lavado-Autric et al., 2003; Mirabella et al., 2000). Maternal hypothyroxinemia was also associated with adverse motor function and teacher-reported problems of behavior in offspring at 5 years of age (Andersen et al., 2018). Other human epidemiologic studies have not reported significant associations between thyroid hormone status during pregnancy and neurodevelopmental outcomes in offspring. For example, there was no statistically significant association between thyroid status and IQ decrements or neuropsychological parameters in children born to mothers screened and diagnosed with subclinical hypothyroidism (Hales et al., 2018; Lazarus et al., 2012) or mothers undergoing treatment for hypothyroxinemia during gestation (Casey et al., 2017). In these studies, the timing of maternal hypothyroxinemia during pregnancy may be a critical consideration for developmental health outcomes in offspring. Studies have observed a relationship between low free T_4 levels in women at 12 weeks gestation, but not 32 weeks gestation, and impaired psychomotor development in their offspring (Kooistra et al., 2006; Pop et al., 2003). In addition, differences in the type of maternal disruption of thyroid homeostasis may affect the interpretation of the human epidemiologic study results. Specifically, aside from overt primary hypothyroidism, there are two primary subcategories of hypothyroidism: (1) subclinical hypothyroidism; and (2) hypothyroxinemia. Subclinical hypothyroidism is characterized by *elevated TSH levels with normal serum T_4 and T_3 concentrations*. In contrast, hypothyroxinemia is characterized by *decreased T_4 with normal serum concentrations of TSH and T_3* (Alexander et al., 2017; Choksi et al., 2003). Maternal T_4 is the primary source of thyroid hormone for a developing human fetus in the first trimester (i.e., little if any maternal T_3 is transferred across the placenta primarily due to high levels of deiodinase 3 activity that catabolizes T_3 to a biologically inactive form). The first trimester is also a critical window for central nervous system development (e.g., neural tube, spinal cord, medulla, pons, thalamus/hypothalamus, etc.). It therefore stands to reason that the health implications may be different for early in utero development if associated with a condition where maternal T_4 (and T_3) concentrations are normal (subclinical hypothyroidism) versus one involving decreased levels of T_4 (hypothyroxinemia).

With regard to what level of decrease in thyroid hormone (e.g., T_4) is sufficient for anatomical and/or functional alterations, particularly in neurodevelopment in fetuses or newborns, several studies have identified a range of T_4 decrements associated with neurodevelopmental health outcomes across humans or experimental rodents. For example, neurodevelopmental and cognitive deficits have been observed in children who experienced a 25% decrease in maternal T_4 during the second trimester in utero (Haddow et al., 1999). In other studies, mild to moderate thyroid insufficiency in pregnant women was defined as having serum T_4 levels below the 10th percentile for the study population, which was associated with a 15−30% decrease relative to the corresponding median (Finken et al., 2013; Julvez et al., 2013; Román et al., 2013; Henrichs et al., 2010). In experimental animals, decreases in mean maternal T_4 levels of ~10−17% during pregnancy and lactation have been found to elicit neurodevelopmental toxicity in rat offspring (Gilbert et al., 2016; Gilbert, 2011). With regard to a general diagnostic criterion to delineate hypothyroxinemia from other types of clinical hypothyroidism, the Controlled Antenatal Thyroid Study (CATS), conducted in a large cohort of pregnant women in Europe, resulted in the identification of a condition referred to as “isolated hypothyroxinemia”

and is defined as the presence of free thyroxine (FT_4) below the 2.5th percentile with a thyrotropin (TSH) level within the reference range (Hales et al., 2018; Lazarus et al., 2012; Negro et al., 2011). However, there is no clear or consistent biological threshold for T_4 changes specifically associated with untoward developmental health outcomes, so a BMR of 0.5 SD was therefore identified as a default when performing BMD modeling on thyroid hormone alterations in offspring, consistent with U.S. EPA *Benchmark Dose Technical Guidance* (U.S. EPA, 2012). Further, while total T_4 (TT_4), free T_4 (FT_4), and TSH dose-response data are BMD modeled (see Table 9), important biological considerations are presented in Section 6.1.1.2 that delineate TT_4 as the key hormone metric for a developing fetus/neonate.

Significantly decreased thyroid hormone (e.g., T_4 and T_3) was observed in adult rats exposed twice daily to oral K^+PFBS (NTP, 2019) for 28-days, as well as the P_0 (maternal) mice of the Feng et al. (2017) study. No overt signs of traditional hypothyroidism such as increased TSH and increased thyroid tissue weight or histopathology were observed in either adult population. Adult rodents have a considerable reserve thyroid hormone capacity compared with the developing offspring, which depend on their supply from maternal T_4. While there is concern over decreases in thyroid hormone (i.e., hypothyroxinemia) in developmental life stages due to critical endocrine dependency of in utero and neonatal development, the levels at which there is concern for hypothyroxinemia in euthyroid adults is unclear. Therefore, for euthyroid adult rats and mice, a biologically significant level of change was not determined for the BMR because it is unclear what magnitude of hormone perturbation would be considered adverse. Therefore, for thyroid hormone effects in adult rodents, a default BMR of 1 SD from control mean was applied. Section 6.1.1.2 presents critical distinctions between perturbations in thyroid hormone economy in adults versus developing fetus/neonates, resulting in the use of different BMRs across life stages (e.g., 1 SD for adults, 0.5 SD for newborns).

For kidney hyperplasia data from the subchronic study by Lieder et al. (2009a) and the two-generation reproductive toxicity study by Lieder et al. (2009b), a BMR of 10% extra risk was used because it is the recommended approach for dichotomous data in the absence of information on the minimally significant level of change.

6.1.1.2 Approach for Animal-Human Extrapolation of Perfluorobutane Sulfonic Acid Dosimetry

As discussed in Section 1.3, toxicokinetic data exists for PFBS in relevant animal species (i.e., rats and mice) and humans, such that a data-informed adjustment approach for estimating the dosimetric adjustment factor (DAF) can be used. In *Recommended Use of Body Weight$^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose* (U.S. EPA, 2011b), the U.S. EPA endorses a hierarchy of approaches to derive human equivalent oral exposures using data from laboratory animal species, with the preferred approach being physiologically based toxicokinetic modeling. Other approaches might include using chemical-specific information, without a complete physiologically based toxicokinetic model. In the absence of chemical-specific models or data to inform the derivation of human equivalent oral exposures, the U.S. EPA endorses $BW^{3/4}$ as a default to extrapolate toxicologically equivalent doses of orally administered agents from all laboratory animals to humans for the purpose of deriving an RfD under certain exposure conditions.

The U.S. EPA concluded that data for PFBS are adequate to support derivation of data-informed dosimetric adjustment. Briefly, the ratio of the clearance (*CL*) in humans to

animals, CL_H:CL_A, can be used to convert an oral dose-rate in experimental animals (mg/kg-day) to a human equivalent dose rate. Assuming the exposure being evaluated is low enough to be in the linear (or first order) range of clearance, the average blood concentration (C_{AVG}) that results from a given dose is calculated as:

$$C_{AVG}\left(\text{mg}/\text{mL}\right) = f_{abs} \times \text{dose (mg/kg/hr)} \Big/ CL\ \text{(mL/kg/hr)}$$

where f_{abs} is the fraction absorbed and dose is the average dose rate expressed at an hourly rate. Assuming equal toxicity given equal C_{AVG} in humans as in mice or rats, and that f_{abs} is the same in humans as animals, the equitoxic dose, human equivalent dose (HED) (i.e., the human dose that should yield the same blood concentration (C_{AVG}) as the animal dose from which it is being extrapolated), is then calculated as follows:

$$HED = \frac{POD}{CL_A / CL_H} = POD \times \frac{CL_H}{CL_A}$$

Thus, the DAF could be calculated as simply CL_H:CL_A, the ratio of clearance in humans to clearance in the animal from which the POD is obtained. However, clearance values are not reported for humans in the available toxicokinetic studies for PFBS (Xu et al., 2020; Olsen et al., 2009). Because clearance is a measure of average elimination, to calculate clearance in the absence of the information, one also needs to evaluate a companion variable, the V_d. Neither Olsen et al. (2009) nor Xu et al. (2020) reported the V_d for humans. However, there is evidence suggesting that V_d for PFBS is relatively similar across species, including rodents (e.g., 0.12−0.29 L/kg across male and female rats following 10 mg/kg i.v. dose) and monkeys (e.g., 0.21−0.25 L/kg across male and female cynomolgus macaques following 10 mg/kg i.v. dose) (Chengelis et al., 2009; Olsen et al., 2009). Therefore, it is reasonable to assume V_d for humans is approximately equivalent to V_d for animals (i.e., $V_{d,H} = V_{d,A}$), in which case clearance and half-life are inversely related as follows:

$$CL\ \text{(mL/kg/hr)} = \ln(2) \times \frac{1}{t_{1/2}\text{(hr)}} \times V_d\ \left(\text{mL}/\text{kg}\right)$$

Because reliable measures of half-life in humans and animals are available for PFBS, the ratio of elimination half-life in animals from which the POD is obtained to that in humans, $t_{1/2,A}$:$t_{1/2,H}$, can be used to calculate the DAF, and the human equivalent dose (HED) can be calculated as follows:

$$HED = POD \times \frac{t_{1/2_A}}{t_{1/2_H}}$$

As described in Section 1.3, two studies evaluated the elimination of human serum K^+PFBS in human populations with previous occupational exposure (Xu et al., 2020; Olsen et al., 2009). Initial blood concentrations of PFBS in the population examined by Xu et al. (2020) are more representative of environmental exposure, and the population was larger, including 11 male and 6 female employees when compared to Olsen et al. (2009). While the estimated serum half-life of PFBS reported by Olsen et al. (2009) overlapped with that by Xu et al. (2020)

(mean: 43.8 days; range: 21.9−87.6 days), there is a statistically significant difference between these two studies. As such, the two data sets will not be combined and the half-life estimated by Xu et al. (2020) is presumed to better predict human dosimetry at environmental levels. The average half-life reported by Xu et al. (2020) (mean: 43.8 days or 1,050 hours) was assigned for $t_{½,H}$.

One study evaluated the elimination of serum PFBS in mice. Lau et al. (2020) reported serum terminal half-lives of 5.8 hours in male mice and 4.5 hours in female mice. Because the half-life estimates did not vary significantly between the doses (i.e., 30 and 300 mg/kg), these parameter estimates were combined. However, there was a statistically significant difference in the half-life estimates between sexes (female mice had a slightly shorter half-life [4.5 hours] compared to males [5.8 hours]), so sex-specific half-lives were assigned for $t_{1/2,A}$ for mice.

Two studies were used to calculate serum half-life estimates for dosimetric adjustment in rats (Huang et al., 2019a; Olsen et al., 2009). A numerical average of the terminal half-lives ($t_{1/2,\beta}$) measured in rats after oral and i.v. doses is identified in Olsen et al. (2009) as 4.6 hours in males and 5.7 hours in females. Olsen et al. (2009) reported sex-specific elimination differences in half-life values in rats. A numerical average of the $t_{1/2,\beta}$ measured in male rats after oral and i.v. doses in Huang et al. (2019a) is 4.9 hours. In male rats, half-life values reported in Olsen et al. (2009) and Huang et al. (2019a) are consistent, thus they were averaged for use in dosimetric adjustment, resulting in a geometric mean terminal serum half-life of 4.8 hours. The terminal half-life value reported by Huang et al. (2019a) in female rats after a 4-mg/kg i.v. dose of PFBS was 0.95 hours. Huang et al. (2019a) was not able to fit the data to a two-compartment model, thus they did not report a $t_{1/2,\beta}$ for rats following oral exposure. For this reason, the mean female $t_{1/2,\beta}$ value from Olsen et al. (2009) was used for dosimetric adjustment.

Table 8 presents the DAFs for converting rat and mice PODs to HEDs for PFBS.

Table 8. Mouse, Rat, and Human Half-Lives and Data-Informed DAFs

Species	Sex	Animal $t_{1/2}$ (hr)	Human $t_{1/2}$ (hr)	DAF ($t_{1/2,A}/t_{1/2,H}$)
Mouse	Male	5.8[a]	1,050[b]	0.0055
	Female	4.5[c]		0.0043
Rat	Male	4.8[d]		0.0046
	Female	5.7[e]		0.0054

[a]Terminal serum half-life of combined doses for male mice from Lau et al. (2020).
[b]Mean serum elimination half-life for humans (combined sexes) from Xu et al. (2020).
[c]Terminal serum half-life of combined doses for female mice from Lau et al. (2020).
[d]Geometric mean of terminal serum half-lives ($t_{1/2,\beta}$) measured after all oral and i.v. doses for male rats from Olsen et al. (2009) and Huang et al. (2019a).
[e]Mean of terminal serum half-lives ($t_{1/2,\beta}$) measured after oral and i.v. doses for female rats from Olsen et al. (2009).

DAF = dosimetric adjustment factor; i.v. = intravenous; $t_{1/2}$ = half-life.

Where modeling was feasible, the estimated BMDLs were identified as PODs (summarized in Table 9). Further details, including the modeling output and graphical results for the model selected for each endpoint, can be found in HAWC and are discussed in Appendix F. Where dose-response modeling was not feasible, NOAELs or LOAELs were identified (summarized in Table 9).

Kidney histopathology—papillary epithelial tubular/ductal hyperplasia—Lieder et al. (2009b)	Rat/F_1—male	$BMDL_{10}$ = 0.78	Adequate model fit
	Rat/F_1—female	$BMDL_{10}$ = 0.48	Adequate model fit

[a]Following U.S. EPA (2011b) and U.S. EPA (2014d) guidance, animal doses from candidate principal studies were converted to HEDs by applying a DAF, where HED = dose × DAF.
[b]Fetal endpoints from Feng et al. (2017) were modeled alternatively using dose-group sizes based either on total number of fetuses or dams. Given that Feng et al. (2017) seems not to have used the litter as the statistical unit of analysis, it is unclear whether the study-reported standard errors pertain to litters or fetuses. Alternatively, modeling fetal endpoints using litter *n* or fetal *n* provides two modeling results that bracket the "true" variance among all fetuses in a dose group (i.e., using the fetal *n* will underestimate the true variance while using the litter *n* will overestimate the true variance). Individual animal data were requested from study authors but were unable to be obtained.
[‡]BMD modeling methods and links to modeling inputs and results in HAWC are found in Appendix F. HAWC visualization: Candidate PODs for subchronic and chronic RfD.

$BMDL_{0.5SD}$ = benchmark dose lower confidence limit for 0.5 SD change from the control; $BMDL_{10}$ = 10% benchmark dose lower confidence limit; $BMDL_{1SD}$ = benchmark dose lower confidence limit for 1 SD change from the control; DAF = dosimetric adjustment factor; HAWC = Health Assessment Workspace Collaborative; HED = human equivalent dose; K^+PFBS = potassium perfluorobutane sulfonate; LOAEL = lowest-observed-adverse-effect level; NOAEL = no-observed-adverse-effect level; PND = postnatal day; POD = point of departure; RfD = oral reference dose; SD = standard deviation; T_4 = thyroxine; TSH = thyroid stimulating hormone.

6.1.1.3 Considerations in Selecting the Critical Effect for Deriving Oral Reference Doses

The evidence for the thyroid, developmental, and kidney effect domains *support a hazard* via the oral exposure route (see Table 7). However, there are qualitative and quantitative differences in the strength of evidence between these effect domains (see Table 9). PFBS-induced perturbation of the thyroid was consistently observed across two species, sexes, life stages, and exposure durations in two independent, high-confidence studies. These perturbations involved a coherent pattern of hormonal changes with similar sensitivity in the POD ranges across life stages (e.g., maternal and PND 1/newborn $BMDL_{05}$s of 0.093 and 0.095 mg/kg-day, respectively). Developmental effects (e.g., delayed eyes opening, vaginal opening, or first estrous) were observed in mouse litters in which decrements in thyroid hormone occurred and with similar sensitivity in the ranges of POD estimates (i.e., 0.073−0.21 mg/kg-day) (Feng et al., 2017). However, these developmental effects have been reported in a single study and species (mouse). Kidney effects in adult animals (Lieder et al., 2009a; Lieder et al., 2009b) were observed in adult or developing rats across high- or medium-confidence gavage studies of various duration; however, were less sensitive at 0.27 mg/kg-day and above.

In deriving a subchronic RfD, both the Feng et al. (2017) and NTP (2019) studies were considered as potential principal studies because of the observed sensitivity of thyroid hormone decrements. However, the biological significance of hypothyroxinemia (i.e., decreased T_4) in

adult euthyroid animals, absent additional signs of overt thyroid toxicity (e.g., reflex increase in TSH and/or alterations in tissue weight or histology), is unclear; therefore, the thyroid effects from the NTP (2019) rat study were not selected as a critical effect. The gestational exposure study in mice was selected as the principal study for deriving the subchronic RfD based on thyroid effects. The gestational exposure study conducted by Feng et al. (2017) reported administration of K^+PFBS by gavage in ICR mice (10/dose) from GDs 1 to 20. This study was of good quality (i.e., high confidence) with adequate reporting and consideration for appropriate study design, methods, and conduct (click to see risk of bias analysis in HAWC). Feng et al. (2017) reported statistically significantly decreased total T_3, total T_4, and free T_4, as well as increased TSH in dams and offspring (increased TSH PND 30 only) gestationally exposed to PFBS.

The critical effect from the Feng et al. (2017) study was decreased serum total thyroxine (T_4) in newborn (PND 1) mice. T_4 and T_3 are essential for normal growth of developing offspring across animal species [for review see Forhead and Fowden (2014)]. And, previous studies have shown that exposure to other PFAS during pregnancy results in lower T_4 and T_3 levels in pregnant women and fetuses or neonates (Yang et al., 2016; Wang et al., 2014). The selection of total T_4 as the critical effect is based on a number of key considerations (see below) that account for cross-species correlations in thyroid physiology and hormone dynamics particularly within the context of a developmental life stage.

A key consideration for selecting total T_4 is that this represents the aggregate of potential thyroid endocrine signaling (i.e., free T_4 + protein bound T_4) at any given time. In humans, FT_4 represents approximately 0.03% of circulating hormone, indicating that as much as 99.97% of all T_4 is protein bound (e.g., albumin; TBG). Although T_3 is the active hormone form in respondent somatic tissues, the formation of T_3 is contingent upon the deiodination of free T_4. A critical consideration in pregnant females is that T_4, not T_3, is the thyroid hormone that crosses the placenta of humans and rodents. Although free T_4 might be considered a suitable measure of thyroid hormone status in nondevelopmental (e.g., adult) life stages, there are some important factors associated with maintenance of the microenvironment for developing offspring in utero that supports using total T_4 as the critical effect. A tightly regulated transfer of maternal thyroid hormone to a fetus is paramount to proper development of multiple tissues and organ systems (e.g., nervous system), especially during the early trimesters. The placenta has transporters and deiodinases that collectively act as a gatekeeper to maintain an optimal T_4 microenvironment in the fetal compartment (Fisher, 1997; Koopdonk-Kool et al., 1996). For example, deiodinase 3 (D3) is highly expressed in human uterus, placenta, and amniotic membrane, where it serves a critical role of regulating thyroid hormone transfer to the fetus through the deiodination of T_4 to transcriptionally inactive reverse triiodothyronine (rT_3) or T_3 to inactive 3,5-diiodo-L-thyronine (T_2). Similarly, Wasco et al. (2003) showed that D3 is highly expressed in the rodent uterus and is highly induced during pregnancy. Further, the *Dio3* gene that encodes D3 has been shown to be imprinted in the mouse (Hernandez et al., 2002), suggesting a pivotal role for this specific deiodinase in the mouse as well. Indeed, the human and rodent placenta have been shown to be similarly permeable to T_4 and T_3 (Fisher, 1997; Calvo et al., 1992). Due to placental barrier functionality, free T_4 levels in a pregnant dam might not be entirely representative of actual T_4 status in a developing fetus. Further, the American Thyroid Association published a guidelines document in 2017 in which they stated: “Current uncertainty around FT_4 estimates in pregnancy has led some to question the wisdom of relying on any FT_4 immunoassays during pregnancy. In

contrast, measurement of TT_4 and the calculated FT_4 index do show the expected inverse relationship with serum TSH. This finding suggests that TT_4 measurements may be superior to immunoassay measurement of FT_4 measurements in pregnant women" (Alexander et al., 2017). Thus, decreased total T_4 in offspring (and dams during pregnancy/at delivery) is expected to be more representative of PFBS-mediated thyroid effects and potentially associative developmental effects.

There are some differences in HPT development and functional maturation and regulation during early life stages (e.g., timing of in utero and early postnatal thyroid development) between humans and rodents [for a comprehensive overview see Regulatory Science Associates (2019)]. Human thyroid development occurs in three phases in utero which entails initial development of the gland between Embryonic Day 10 to Gestational Week 11 (Phase I), maturation of the fetal thyroid system from Gestational Weeks 11−35 (Phase II), and further refinement of hypothalamic-pituitary-thyroid axis functionality during the latter portion of gestation up to approximately 4 weeks into the postnatal period (Phase III) (Klein et al., 1982; Fisher and Klein, 1981). Importantly, in utero development of the rodent thyroid gland occurs in the same phases and order as humans, the difference being that rodents are essentially born during Phase II, with Phase III occurring almost exclusively postnatally; whereas in humans, Phase III is well underway in utero and completes postnatally. Accordingly, rodent neurodevelopment in the early postnatal phase is analogous to the third trimester of human development in utero (Gilbert et al., 2012). Further, fetal development of rodents in utero is entirely dependent on maternal thyroid hormone until approximately GD 17−18, whereas in humans, fetal development transitions from complete reliance on maternal thyroid hormone during the first trimester (i.e., thyroid development Phase I) to a mix of fetal thyroid hormone synthesis and maternal transplacental hormone transfer beginning in the second trimester (i.e., thyroid development Phase II) through the in utero portion of Phase III (Fisher and Klein, 1981).

Within the context of early developmental life stages, there are several commonalities in HPT dynamics between humans and rodents such as similar profiles of (1) thyroid hormone binding proteins, (2) hormone functional reserve, and (3) placental deiodinase. For example, two carrier proteins—thyroid binding globulin (TBG) and transthyretin (TTR)—are primarily responsible for storage and transit of T_4 in mammals (Rabah et al., 2019). TBG is the primary carrier of T_4 in humans across all life stages (Savu et al., 1991). Importantly, in fetal and infant rats, TBG is also the primary carrier of T_4 (Savu et al., 1989). As rats transition to adulthood, TTR takes over as the primary carrier of T_4. In addition, as a relatively highly abundant carrier protein, albumin also plays a role in thyroid hormone binding and transit in humans and rodents; however, the relative affinity for binding is lower than either TBG or TTR.

Life-stage-specific differences in thyroid hormone reserve capacity between adults and neonates have been noted. On average, intrathyroidal thyroglobulin stores in adults are on the order of months, whereas in neonates the functional reserve is approximated at less than 1 day (Gilbert and Zoeller, 2010; Savin et al., 2003; van den Hove et al., 1999). This suggests that the adult thyroid has compensatory abilities not present in early life stages, making fetal/neonatal populations particularly sensitive to perturbations in thyroid hormone economy (e.g., hypothyroxinemia). And although the timing of thyroid development can vary between species (Forhead and Fowden, 2014), the dynamic reserve capacity of T_4 between humans and

rodents near birth and in early postpartum might not be significantly different. For example, human neonates have a serum half-life of T_4 of approximately 3 days (Vulsma et al., 1989), and thyroid tissue stores of T_4 are estimated to be less than 1 day (van den Hove et al., 1999). Because the developing rodent thyroid does not begin producing its own hormone until late in gestation (≥GD 17), newborn rodent T_4 levels are primarily a reflection of transplacentally translocated maternal hormone; and adult rats have been shown to have a serum T_4 half-life of 0.5–1 day (Choksi et al., 2003). For this reason, significant differences in functional thyroid reserve capacity between human and rodent neonates are not anticipated.

Accounting for the information presented above, the subchronic RfD, based on the $BMDL_{0.5SD}$ (HED) of 0.095 mg/kg-day for decreased serum total T_4 in newborn (PND 1) mice, is derived as follows:

Subchronic RfD for K^+PFBS = $BMDL_{0.5SD}$ (HED) ÷ UF_C
= 0.095 mg/kg-day ÷ 100
= 0.00095mg/kg-day
= **1×10^{-3} mg/kg-day**

Table 10 summarizes the uncertainty factors for the subchronic RfD for K^+PFBS based on effects in the thyroid.

Table 10. Uncertainty Factors for the Subchronic RfD for Thyroid Effects for K^+PFBS (CASRN 29420-49-3)

UF	Value	Justification
UF_A	3	A UF_A of 3 ($10^{0.5}$) is applied to account for uncertainty in characterizing the toxicokinetic and toxicodynamic differences between mice and humans following oral K^+PFBS/PFBS exposure. Some aspects of the cross-species extrapolation of toxicokinetic and toxicodynamic processes have been accounted for by calculating an HED by applying a DAF as outlined in the U.S. EPA's *Recommended Use of Body Weight$^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose* (U.S. EPA, 2011b). However, some residual uncertainty remains in the relative cross-species sensitivity in toxicodynamics (e.g., thyroid signaling). Thus, in the absence of chemical-specific data to quantify these uncertainties, U.S. EPA's guidance recommends use of a UF_A of 3.
UF_D	3	A UF_D of 3 is applied due to database deficiencies. The oral exposure database contains multiple short-term and subchronic-duration toxicity studies of laboratory animals (NTP, 2019; Bijland et al., 2011; 3M, 2010; Lieder et al., 2009a; 3M, 2001, 2000d), a two-generation reproductive toxicity study in rats (Lieder et al., 2009b), and multiple developmental toxicity studies in mice and rats (Feng et al., 2017; York, 2002). However, the observation of decreased thyroid hormone is known to be a crucial element during developmental life stages, particularly for neurodevelopment, and the database is limited by the lack of developmental neurotoxicity studies. In addition, because other health effect domains such as immunotoxicity and mammary gland development are effects of increasing concern across several members of the larger PFAS family (Grandjean, 2018; Liew et al., 2018; White et al., 2007), the lack of studies evaluating these outcomes following PFBS exposure is a limitation in the database.
UF_H	10	A UF_H of 10 is applied to account for interindividual variability in the human populations because of both intrinsic (toxicokinetic, toxicodynamic, genetic, life stage, and health status) and extrinsic (life style) factors that can influence the response to dose. In the absence of chemical-specific data to quantify this variability in the toxicokinetics and toxicodynamics of K^+PFBS/PFBS in humans, U.S. EPA recommends using a UF_H of 10.

Table 10. Uncertainty Factors for the Subchronic RfD for Thyroid Effects for K^+PFBS (CASRN 29420-49-3)

UF	Value	Justification
UF_L	1	A UF_L of 1 is applied for LOAEL-to-NOAEL extrapolation because the POD is a BMDL and the BMR was selected based on evidence that it represented a minimal biologically significant response level in susceptible populations such as developing offspring.
UF_S	1	A UF_S of 1 is applied because the POD comes from a developmental study in mice. The developmental period is recognized as a susceptible life stage in which exposure during certain time windows (e.g., gestational) is more relevant to the induction of developmental effects than lifetime exposure (U.S. EPA, 1991a).
UF_C	100	Composite UF = $UF_A \times UF_D \times UF_H \times UF_L \times UF_S$

BMDL = benchmark dose lower confidence limit; BMR = benchmark response; DAF = dosimetric adjustment factor; HED = human equivalent dose; K^+PFBS = potassium perfluorobutane sulfonate; LOAEL = lowest-observed-adverse-effect level; NOAEL = no-observed-adverse-effect level; PFAS = per- and polyfluoroalkyl substances; PFBS = perfluorobutane sulfonic acid; POD = point of departure; RfD = oral reference dose; UF = uncertainty factor; UF_A = interspecies uncertainty factor; UF_C = composite uncertainty factor; UF_D = database uncertainty factor; UF_H = intraspecies uncertainty factor; UF_L = LOAEL-to-NOAEL uncertainty factor; UF_S = subchronic-to-chronic uncertainty factor.

The data for K^+PFBS can be used to derive a subchronic RfD for the free acid (PFBS), as K^+PFBS is fully dissociated in water at the environmental pH range of 4–9 (NICNAS, 2005). To calculate the subchronic RfD for the free acid, the subchronic RfD for the potassium salt is adjusted to compensate for differences in MW between K^+PFBS (338.19) and PFBS (300.10). The subchronic RfD for PFBS (free acid) is calculated as follows:

Subchronic RfD for PFBS (free acid) = RfD for K^+PFBS salt × (MW free acid ÷ MW salt)
= 0.00095 mg/kg-day × (300.10 ÷ 338.19)
= 0.00095 mg/kg-day × (0.89)
= 0.00085 mg/kg-day
= **9×10^{-4} mg/kg-day**

Confidence in the subchronic RfD for PFBS and K^+PFBS for thyroid effects is medium, as explained in Table 11.

Table 11. Confidence Descriptors for the Subchronic RfD for PFBS (CASRN 375-73-5) and the Related Compound K^+PFBS (CASRN 29420-49-3)

Confidence Categories	Designation	Discussion
Confidence in study	H	Confidence in the principal study is high because the overall study design, performance, and characterization of exposure was good. Study details and risk of bias analysis can be found in HAWC.

Table 11. Confidence Descriptors for the Subchronic RfD for PFBS (CASRN 375-73-5) and the Related Compound K^+PFBS (CASRN 29420-49-3)

Confidence Categories	Designation	Discussion
Confidence in database	M	Confidence in the oral toxicity database for derivation of the candidate subchronic RfD for thyroid effects is medium because although there are multiple developmental toxicity studies in mice and rats, no studies are available that have specifically evaluated neurodevelopmental, immunological, or mammary gland effects. In addition, available toxicokinetic studies are limited (e.g., one mouse toxicokinetic study) and toxicokinetic data do not exist for PFBS at all life stages, including neonates, infants, and children. Additionally, studies are not available to estimate the relative cross-species sensitivity in toxicodynamics (e.g., thyroid signaling).
Confidence in candidate subchronic RfD	M	The overall confidence in the candidate subchronic RfD for thyroid effects is medium.

H = high; HAWC = Health Assessment Workspace Collaborative; K^+PFBS = potassium perfluorobutane sulfonate; M = medium; PFBS = perfluorobutane sulfonic acid; RfD = oral reference dose.

The subchronic RfD is derived to be protective of all types of effects across studies and species following oral subchronic exposure and is intended to protect sensitive subpopulations and life stages.

6.1.2 Derivation of the Chronic Oral Reference Dose

There are no chronic studies available for PFBS and K^+PFBS. Therefore, based on the same database and similar considerations as the subchronic RfD, the noncancer chronic RfD is derived, based on the same $BMDL_{0.5SD}$ (HED) of 0.095 mg/kg-day for decreased serum total T_4 in newborn (PND 1) mice (Feng et al., 2017), as follows:

Chronic RfD for K^+PFBS $= BMDL_{0.5SD}\text{ (HED)} \div UF_C$
$= 0.095\text{ mg/kg-day} \div 300$
$= 0.00032\text{ mg/kg-day}$
$= \mathbf{3 \times 10^{-4}\text{ mg/kg-day}}$

Table 12 summarizes the uncertainty factors for the chronic RfD for K^+PFBS based on effects in the thyroid.

Table 12. Uncertainty Factors for the Chronic RfD for Thyroid for K^+PFBS (CASRN 29420-49-3)

UF	Value	Justification
UF_A	3	A UF_A of 3 ($10^{0.5}$) is applied to account for uncertainty in characterizing the toxicokinetic and toxicodynamic differences between mice and humans following oral K^+PFBS/PFBS exposure. Some aspects of the cross-species extrapolation of toxicokinetic and toxicodynamic processes have been accounted for by calculating an HED by applying a DAF as outlined in the U.S. EPA's *Recommended Use of Body Weight$^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose* (U.S. EPA, 2011b). However, some residual uncertainty remains in the relative cross-species sensitivity in toxicodynamics (e.g., thyroid signaling). Thus, in the absence of chemical-specific data to quantify these uncertainties, U.S. EPA's guidance recommends using a UF_A of 3.
UF_D	10	A UF_D of 10 is applied to account for database deficiencies. The oral exposure database contains multiple short-term and subchronic-duration toxicity studies of laboratory animals (NTP, 2019; Bijland et al., 2011; Lieder et al., 2009a; 3M, 2001, 2000d), a two-generation reproductive toxicity study in rats (Lieder et al., 2009b), and multiple developmental toxicity studies in mice and rats (Feng et al., 2017; York, 2002). However, because thyroid hormone is known to be critical during developmental life stages, particularly for neurodevelopment, the database is limited by the lack of developmental neurotoxicity studies. Further, because of the lack of chronic studies, there is additional uncertainty regarding how longer-term exposures might affect hazard identification and dose-response assessment for PFBS via the oral route (e.g., potentially more sensitive effects). Lastly, because immunotoxicity and mammary gland development are effects of increasing concern across several members of the larger PFAS family (Grandjean, 2018; Liew et al., 2018; White et al., 2007), the lack of studies evaluating these outcomes following PFBS exposure is a limitation in the database.
UF_H	10	A UF_H of 10 is applied to account for interindividual variability in the human populations because of both intrinsic (toxicokinetic, toxicodynamic, genetic, life stage, and health status) and extrinsic (lifestyle) factors that can influence the response to dose. In the absence of chemical-specific data to quantify this variability in the toxicokinetics and toxicodynamics of K^+PFBS/PFBS in humans, U.S. EPA recommends using a UF_H of 10.
UF_L	1	A UF_L of 1 is applied for LOAEL-to-NOAEL extrapolation because the POD is a BMDL and the BMR was selected based on evidence that it represented a minimal biologically significant response level in susceptible populations such as developing offspring.
UF_S	1	A UF_S of 1 is applied because the POD comes from a developmental study of mice. The developmental period is recognized as a susceptible life stage in which exposure during certain time windows (e.g., gestational) is more relevant to the induction of developmental effects than lifetime exposure (U.S. EPA, 1991b). The additional concern over potential hazards following longer term (chronic) exposures is accounted for under the UF_D above.
UF_C	300	Composite UF = $UF_A \times UF_D \times UF_H \times UF_L \times UF_S$

BMDL = benchmark dose lower confidence limit; BMR = benchmark response; DAF = dosimetric adjustment factor; HED = human equivalent dose; K^+PFBS = potassium perfluorobutane sulfonate; LOAEL = lowest-observed-adverse-effect level; NOAEL = no-observed-adverse-effect level; PFAS = per- and polyfluoroalkyl substances; PFBS = perfluorobutane sulfonic acid; POD = point of departure; RfD = oral reference dose; UF = uncertainty factor; UF_A = interspecies uncertainty factor; UF_C = composite uncertainty factor; UF_D = database uncertainty factor; UF_H = intraspecies uncertainty factor; UF_L = LOAEL-to-NOAEL uncertainty factor; UF_S = subchronic-to-chronic uncertainty factor.

The data for K^+PFBS can be used to derive a chronic RfD for the free acid (PFBS), because K^+PFBS is fully dissociated in water at the environmental pH range of 4−9 (NICNAS, 2005). To calculate the chronic RfD for the free acid, the chronic RfD for the potassium salt is

adjusted to compensate for differences in MW between K^+PFBS (338.19) and PFBS (300.10). The chronic RfD for PFBS (free acid) for thyroid effects is the same as the value for the K^+PFBS salt. The chronic RfD for PFBS (free acid) is calculated as follows:

Chronic RfD	=	RfD for K^+PFBS salt × (MW free acid ÷ MW salt)
for PFBS (free acid)	=	0.00032 mg/kg-day × (300.10 ÷ 338.19)
	=	0.00032 mg/kg-day × (0.89)
	=	0.00028 mg/kg-day
	=	**3×10^{-4} mg/kg-day**

Confidence in the chronic RfD for PFBS and K^+PFBS for thyroid effects is low, as explained in Table 13 below.

Table 13. Confidence Descriptors for Chronic RfD for PFBS (CASRN 375-73-5) and the Related Compound K^+PFBS (CASRN 29420-49-3)

Confidence Categories	Designation	Discussion
Confidence in study	H	Confidence in the principal study is high because the overall study design, performance, and characterization of exposure was good. Study details and risk of bias analysis can be found in HAWC.
Confidence in database	L	Confidence in the oral toxicity database for deriving the chronic RfD is low because, although there are multiple short-term studies and a subchronic-duration toxicity study in laboratory animals, one acceptable two-generation reproductive toxicity study in rats, and multiple developmental toxicity studies in mice and rats, the database lacks any chronic-duration exposure studies or studies that have evaluated neurodevelopmental, immunological, or mammary gland effects. In addition, available toxicokinetic studies are limited (e.g., one mouse toxicokinetic study) and toxicokinetic data do not exist for PFBS at all life stages, including neonates, infants, and children. Additionally, studies are not available to estimate the relative cross-species sensitivity in toxicodynamics (e.g., thyroid signaling).
Confidence in candidate chronic RfD	L	The overall confidence in the candidate chronic RfD for thyroid effects is low.

H = high; HAWC = Health Assessment Workspace Collaborative; K^+PFBS = potassium perfluorobutane sulfonate; L = low; PFBS = perfluorobutane sulfonic acid; RfD = oral reference dose.

The chronic RfD is derived to be protective of all types of effects across studies and species following oral chronic exposure and is intended to protect the population as a whole, including potentially susceptible populations and life stages (U.S. EPA, 2002). This value should be applied in general population risk assessments. Decisions concerning averaging exposures over time for comparison with the RfD should consider the types of toxicological effects and specific life stages of concern. For example, fluctuations in exposure levels that result in elevated exposures during development could potentially lead to an appreciable risk, even if average levels over the full exposure duration were less than or equal to the RfD.

6.2 DERIVATION OF INHALATION REFERENCE CONCENTRATIONS

No published studies investigating the effects of subchronic- or chronic-duration inhalation toxicity of PFBS and the related compound K^+PFBS in humans or animals have been identified.

6.3 CANCER WEIGHT-OF-EVIDENCE DESCRIPTOR AND DERIVATION OF CANCER RISK VALUES

No studies evaluating the carcinogenicity of PFBS or K^+PFBS in humans or animals have been identified. In accordance with the *Guidelines for Carcinogen Risk Assessment* (U.S. EPA, 2005), the U.S. EPA concluded that there is *"Inadequate Information to Assess Carcinogenic Potential"* for PFBS and K^+PFBS by any route of exposure. Therefore, the lack of data on the carcinogenicity of PFBS and the related compound K^+PFBS precludes the derivation of quantitative estimates for either oral (oral slope factor) or inhalation (inhalation unit risk) exposure.

6.4 SUSCEPTIBLE POPULATIONS AND LIFE STAGES

Early life stages as well as pregnant women are potentially susceptible to PFBS exposure. PFBS has been detected in blood serum of nursing mothers, which might indicate a potential for lactational exposure (Glynn et al., 2012); however, information on the kinetics of lactational transfer are lacking and represents a key data gap for future research.

The available information suggests sex-specific variation in the toxicokinetics of PFBS in rodents. Studies in mice and rats generally report clearance and elimination half-lives to be faster for females than for males (see the "Toxicokinetics" section). For example, Lau et al. (2020) reports statistically significant differences in half-life between the sexes with female mice exhibiting a shorter half-life than males. Similar sex-specific variation in elimination has been reported in rats. Olsen et al. (2009) reported a statistically significant difference in the urinary clearance rates ($p \leq 0.01$), with female rats (469 ± 40 mL/hour) having faster clearance rates than male rats (119 ± 34 mL/hour). Huang et al. (2019a) also reported higher clearance in female rats than in male rats given the same dose (26.0−75.5 mL/hour-kg in males, 152−259 mL/hour-kg in females). Chengelis et al. (2009) reported that the mean apparent clearance of PFBS from the serum was approximately eightfold higher for female rats (0.311 L/hour-kg) than for male rats (0.0394 L/hour-kg). Statistically significant sex-related differences in half-life or clearance were not observed between male and female monkeys (Olsen et al., 2009). Differences in the toxicokinetics in rodents could result in sex-specific differences in toxicity studies.

In vivo toxicity studies report that PFBS exposure can alter thyroid hormone levels in parental and F_1 generation animals (see the "Thyroid Effects" section). Thyroid hormones play a critical role in coordinating complex developmental processes for various organs/systems (e.g., reproductive and nervous system), and disruption of thyroid hormone production/levels in a pregnant woman or neonate can have persistent adverse health effects for the developing offspring (Ghassabian and Trasande, 2018; Foster and Gray, 2013; Julvez et al., 2013; Román et al., 2013).

Animal studies also provide evidence that gestationally exposed females might be a susceptible subpopulation because of potential effects on female reproduction, including evidence of altered ovarian follicle development and delayed vaginal opening (see the "Reproductive Effects" section). Furthermore, gestationally exposed females also had significantly reduced BWs and delayed eye opening. These findings suggest that developmental landmarks indicative of adverse responses can be affected after PFBS exposure (see the "Offspring Growth and Early Development" section).

APPENDIX A. LITERATURE SEARCH STRATEGY

This appendix presents the full details of the literature search strategy used to identify primary, peer-reviewed literature pertaining to perfluorobutane sulfonic acid (PFBS) (Chemical Abstracts Service registry number [CASRN] 375-73-5) and/or the potassium salt (K^+PFBS) (CASRN 29420-49-3) and the deprotonated anionic form of PFBS (i.e., $PFBS^-$; CASRN 45187-15-3). Initial database searches were conducted on July 18, 2017 using four online scientific databases (PubMed, Web of Science [WOS], TOXLINE, and TSCATS via TOXLINE) and updated on February 28, 2018; May 1, 2019; and May 15, 2020. The literature search focused on chemical name and synonyms (see Table A-1) with no limitations on publication type, evidence stream (i.e., human, animal, in vitro, and in silico) or health outcomes. Beyond database searches, references were also identified from studies submitted under the Toxic Substances Control Act (TSCA) and from review of other government documents (e.g., Agency for Toxic Substances and Disease Registry [ATSDR]) and combined with the results of the database search. Search results are retained in the U.S. EPA's Health and Environmental Research Online (HERO) database.

APPENDIX B. DETAILED PECO CRITERIA

Table B-1. Population, Exposure, Comparator, and Outcome Criteria

PECO Element	Evidence
Population	**Human:** Any population (occupational; general population including children, pregnant women, and other sensitive populations). The following study designs will be considered most informative: controlled exposure, cohort, case-control, or cross-sectional. Note: Case reports and case series are not the primary focus of this assessment and will be tracked as supplemental material during the study screening process. **Animal:** Nonhuman mammalian animal species (whole organism) of any life stage (including preconception, in utero, lactation, peripubertal, and adult stages). **In vitro models of genotoxicity:** The studies will be considered PECO relevant. All other in vitro studies will be tagged as "non-PECO relevant, but supplemental material." **Nonmammalian model systems/in vitro/in silico NOT related to genotoxicity:** Nonmammalian model systems (e.g., fish, amphibians, birds, and *Caenorhabditis elegans*); studies of human or animal cells, tissues, or biochemical reactions (e.g., ligand binding assays) with in vitro exposure regimens; bioinformatics pathways of disease analysis; and/or high throughput screening data. These studies will be classified as non-PECO relevant, but have supplemental information.
Exposure	**Human:** Studies providing qualitative or quantitative estimates of exposure based on administered dose or concentration, biomonitoring data (e.g., urine, blood, or other specimens), environmental or occupational-setting measures (e.g., water levels or air concentrations), residential location, job title or other relevant occupational information. Human "mixture" studies are considered PECO relevant as long as they have the PFAS of interest. **Animal:** Studies providing qualitative and quantitative estimates of exposure based on administered dose or concentration. Oral and inhalation studies are considered PECO relevant. Nonoral and noninhalation studies are tagged as supplemental. Experimental mixture studies are included as PECO relevant only if they include a PFBS-only arm. Otherwise, mixture studies are tagged as supplemental. All studies must include exposure to PFBS, CASRN 375-73-5. Studies of precursor PFAS that identify any of the targeted PFAS as metabolites will also be included.
Comparator	**Human:** A comparison or reference population exposed to lower levels (or no exposure/exposure below detection levels) or for shorter periods of time. For D-R purposes, exposure-response quantitative results must be presented in sufficient detail such as regression coefficients presented with statistical measure of variation such as RR, HR, OR, or SMR or observed cases vs. expected cases (common in occupational studies); slope or linear regression coefficient (i.e., per unit increase in a continuous outcome); difference in the means; or report means with results of *t*-test, mean comparison by regression, or other mean-comparing hypothesis test. **Animal:** Quantitative exposure versus lower or no exposure with concurrent vehicle control group.
Outcome	Cancer and noncancer health outcomes. In general, endpoints related to clinical diagnostic criteria, disease outcomes, histopathological examination, genotoxicity, or other apical/phenotypic outcomes will be prioritized for evidence synthesis. Based on preliminary screening work and other assessments, the systematic review is anticipated to focus on liver (including serum lipids), developmental, reproductive, neurological, developmental neurotoxicity, thyroid disease/disruption, immunological, cardiovascular, and musculoskeletal outcomes.

D-R = dose-response; HR = hazard ratio; OR = odds ratio; PECO = Population, Exposure, Comparator, and Outcome; PFAS = per- and polyfluoroalkyl substances; PFBS = perfluorobutane sulfonic acid; RR = risk ratio; SMR = standardized mortality ratio

APPENDIX C. STUDY EVALUATION METHODS

For each outcome in a study, in each domain, reviewers reached a consensus judgment of *good, adequate, deficient, not reported,* or *critically deficient*. Questions used to guide the development of criteria for each domain in epidemiology studies are presented in Table C-1 and experimental animal toxicology studies in Table C-3. These categories were applied to each evaluation domain for each study as follows:

- *Good* represents a judgment that the study was conducted appropriately in relation to the evaluation domain and any deficiencies, if present, are minor and would not be expected to influence the study results.
- *Adequate* indicates a judgment that there are methodological limitations relating to the evaluation domain, but that those limitations are not likely to be severe or to have a notable impact on the results.
- *Deficient* denotes identified biases or deficiencies that are interpreted as likely to have had a notable impact on the results or that prevent interpretation of the study findings.
- *Not reported* indicates that the information necessary to evaluate the domain was not available in the study. Generally, this term carries the same functional interpretation as *deficient* for the purposes of the study confidence classification. Depending on the number and severity of other limitations identified in the study, it may or may not be worth reaching out to the study authors for this information.
- *Critically deficient* reflects a judgment that the study conduct introduced a serious flaw that makes the observed effect(s) uninterpretable. Studies with a determination of critically deficient in an evaluation domain will almost always cause the study to be considered overall *uninformative*.

Once the evaluation domains were rated, the identified strengths and limitations were considered to reach a study confidence rating of *high, medium, low,* or *uninformative* for a specific health outcome. This was based on the reviewer judgments across the evaluation domains and included consideration of the likely impact the noted deficiencies in bias and sensitivity, or inadequate reporting, have on the results. The ratings, which reflect a consensus judgment between reviewers, are defined as follows:

- *High*: A well-conducted study with no notable deficiencies or concerns were identified; the potential for bias is unlikely or minimal, and the study used sensitive methodology. *High* confidence studies generally reflect judgments of *good* across all or most evaluation domains.
- *Medium*: A satisfactory (acceptable) study in which deficiencies or concerns were noted, but the limitations are unlikely to be of a notable degree. Generally, *medium* confidence studies will include *adequate* or *good* judgments across most domains, with the impact of any identified limitation not being judged as severe.
- *Low*: A substandard study in which deficiencies or concerns were noted, and the potential for bias or inadequate sensitivity could have a significant impact on the study results or their interpretation. Typically, *low* confidence studies would have a *deficient* evaluation for one or more domains, although some *medium* confidence studies could have a *deficient* rating in domain(s) considered to have less influence on the magnitude or

direction of effect estimates. Generally, *low* confidence results are given less weight than *high* or *medium* confidence results during evidence synthesis and integration and are generally not used as the primary sources of information for hazard identification or derivation of toxicity values unless they are the only studies available. Studies rated as *low* confidence only because of sensitivity concerns about bias towards the null require additional consideration during evidence synthesis. Observing an effect in these studies could increase confidence, assuming the study was otherwise well-conducted.

- *Uninformative*: An unacceptable study in which serious flaw(s) make the study results unusable for informing hazard identification. Studies with *critically deficient* judgments in any evaluation domain will almost always be classified as *uninformative* (see explanation above). Studies with multiple *deficient* judgments across domains might also be considered *uninformative*. *Uninformative* studies will not be considered further in the synthesis and integration of evidence for hazard identification or dose-response but might be used to highlight possible research gaps.

Table C-1. Questions Used to Guide the Development of Criteria for Each Domain in Epidemiology Studies

Core Question	Prompting Questions	Follow-Up Questions
Exposure measurement Does the exposure measure reliably distinguish between levels of exposure in a time window considered most relevant for a causal effect with respect to the development of the outcome?	For all: • Does the exposure measure capture the variability in exposure among the participants, considering intensity, frequency, and duration of exposure? • Does the exposure measure reflect a relevant time window? If not, can the relationship between measures in this time and the relevant time window be estimated reliably? • Was the exposure measurement likely to be affected by a knowledge of the outcome? • Was the exposure measurement likely to be affected by the presence of the outcome (i.e., reverse causality)? For case-control studies of occupational exposures: • Is exposure based on a comprehensive job history describing tasks, setting, time period, and use of specific materials? For biomarkers of exposure, general population: • Is a standard assay used? What are the intra- and interassay coefficients of variation? Is the assay likely to be affected by contamination? Are values less than the limit of detection dealt with adequately? What exposure time period is reflected by the biomarker? If the half-life is short, what is the correlation between serial measurements of exposure?	Is the degree of exposure misclassification likely to vary by exposure level? If the correlation between exposure measurements is moderate, is there an adequate statistical approach to ameliorate variability in measurements? If there is a concern about the potential for bias, what is the predicted direction or distortion of the bias on the effect estimate (if there is enough information)?

Table C-1. Questions Used to Guide the Development of Criteria for Each Domain in Epidemiology Studies

Core Question	Prompting Questions	Follow-Up Questions
Outcome ascertainment Does the outcome measure reliably distinguish the presence or absence (or degree of severity) of the outcome?	For all: • Is outcome ascertainment likely to be affected by knowledge of, or presence of, exposure (e.g., consider access to health care, if based on self-reported history of diagnosis)? For case-control studies: • Is the comparison group without the outcome (e.g., controls in a case-control study) based on objective criteria with little or no likelihood of inclusion of people with the disease? For mortality measures: • How well does cause of death data reflect occurrence of the disease in an individual? How well do mortality data reflect incidence of the disease? For diagnosis of disease measures: • Is diagnosis based on standard clinical criteria? If based on self-report of diagnosis, what is the validity of this measure? For laboratory-based measures (e.g., hormone levels): • Is a standard assay used? Does the assay have an acceptable level of interassay variability? Is the sensitivity of the assay appropriate for the outcome measure in this study population?	Is there a concern that any outcome misclassification is nondifferential, differential, or both? What is the predicted direction or distortion of the bias on the effect estimate (if there is enough information)?
Participant selection Is there evidence that selection into or out of the study (or analysis sample) was jointly related to exposure and to outcome?	For longitudinal cohort: • Did participants volunteer for the cohort based on knowledge of exposure and/or preclinical disease symptoms? Was entry into the cohort or continuation in the cohort related to exposure and outcome? For occupational cohort: • Did entry into the cohort begin with the start of the exposure? • Was follow-up or outcome assessment incomplete, and if so, was follow-up related to both exposure and outcome status? • Could exposure produce symptoms that would result in a change in work assignment/work status ("healthy worker survivor effect")? For case-control study: • Were controls representative of population and time periods from which cases were drawn? • Are hospital controls selected from a group whose reason for admission is independent of exposure? • Could recruitment strategies, eligibility criteria, or participation rates result in differential participation relating to both disease and exposure? For population-based survey: • Was recruitment based on advertisement to people with knowledge of exposure, outcome, and hypothesis?	Were differences in participant enrollment and follow-up evaluated to assess bias? If there is a concern about the potential for bias, what is the predicted direction or distortion of the bias on the effect estimate (if there is enough information)? Were appropriate analyses performed to address changing exposures over time in relation to symptoms? Is there a comparison of participants and nonparticipants to address whether differential selection is likely?

Table C-1. Questions Used to Guide the Development of Criteria for Each Domain in Epidemiology Studies

Core Question	Prompting Questions	Follow-Up Questions
Confounding Is confounding of the effect of the exposure likely?	Is confounding adequately addressed by considerations in… a. …participant selection (matching or restriction)? b. …accurate information on potential confounders and statistical adjustment procedures? c. …lack of association between confounder and outcome or confounder and exposure in the study? d. …information from other sources? Is the assessment of confounders based on a thoughtful review of published literature, potential relationships (e.g., as can be gained through directed acyclic graphing), minimizing potential overcontrol (e.g., inclusion of a variable on the pathway between exposure and outcome)?	If there is a concern about the potential for bias, what is the predicted direction or distortion of the bias on the effect estimate (if there is enough information)?
Analysis Do the analysis strategy and presentation convey the necessary familiarity with the data and assumptions?	• Are missing outcome, exposure, and covariate data recognized and, if necessary, accounted for in the analysis? • Does the analysis appropriately consider variable distributions and modeling assumptions? • Does the analysis appropriately consider subgroups of interest (e.g., based on variability in exposure level, duration, or susceptibility)? • Is an appropriate analysis used for the study design? • Is effect modification considered, based on considerations developed a priori? • Does the study include additional analyses addressing potential biases or limitations (i.e., sensitivity analyses)?	If there is a concern about the potential for bias, what is the predicted direction or distortion of the bias on the effect estimate (if there is enough information)?
Sensitivity Is there a concern that sensitivity of the study is not adequate to detect an effect?	• Is the exposure range adequate? • Was the appropriate population included? • Was the length of follow-up adequate? Is the time/age of outcome ascertainment optimal given the interval of exposure and the health outcome? • Are there other aspects related to risk of bias or otherwise that raise concerns about sensitivity?	
Selective reporting Is there reason to be concerned about selective reporting?	• Are the results needed for the IRIS analysis presented (based on a priori specification)? If not, can these results be obtained? • Are only statistically significant results presented?	

IRIS = Integrated Risk Information System.

C.1. EXPOSURE MEASUREMENT EVALUATION CRITERIA

The criteria used to evaluate exposure measurement for PFBS (Table C-2) are adapted from the criteria developed by the National Toxicology Program (NTP) Office of Health Assessment and Translation for their assessment of the association between perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) and immune effects (NTP, 2016, 2015) and were established prior to beginning study evaluation. Standard analytical methods for evaluating individual per- and polyfluoroalkyl substances (PFAS) in serum or whole-blood using quantitative techniques such as liquid chromatography-triple quadrupole mass spectrometry are preferred (CDC, 2018; U.S. EPA, 2014b, e; ATSDR, 2009; CDC, 2009). The estimated serum half-life of PFBS is approximately 1 month (Lau, 2015; Olsen et al., 2009), so unlike for some other PFAS with longer half-lives, current exposure might not be indicative of past exposures. Little data is available on repeated measures of PFBS in humans over time, so the reliability of a single measure is unclear. The timing of the exposure measurement is considered in relation to the etiologic window for each outcome being reviewed.

Table C-2. Criteria for Evaluation of Exposure Measurement in Epidemiology Studies

Exposure Measurement Rating	Criteria
Good	All of the following: • Evidence that exposure was consistently assessed using well-established methods that directly measure exposure (e.g., measurement of PFAS in blood, serum, or plasma). • Exposure was assessed in a relevant time window for development of the outcome (i.e., temporality is established, and sufficient latency occurred prior to disease onset). • There is evidence that a sufficient proportion of the exposure data measurements are above the limit of quantification for the assay so that different exposure groups can be distinguished based on the analyses conducted. • The laboratory analysis included standard quality control measures with demonstrated precision and accuracy. • There is sufficient specificity/sensitivity and range or variation in exposure measurements that would minimize potential for exposure measurement error and misclassification by allowing exposure classifications to be differentiated (i.e., can reliably categorize participants into groups such as high vs. low exposure).

Table C-2. Criteria for Evaluation of Exposure Measurement in Epidemiology Studies

Exposure Measurement Rating	Criteria
Adequate	• Evidence that exposure was consistently assessed using well-established methods that directly measure exposure (e.g., measurement of PFAS in blood, serum, or plasma), but there were some minor concerns about quality control measures or other potential for nondifferential misclassification. OR • Exposure was assessed using indirect measures (e.g., drinking water concentrations and residential location/history, questionnaire, or occupational exposure assessment by a certified industrial hygienist) that have been validated or empirically shown to be consistent with methods that directly measure exposure (i.e., intermethods validation: one method vs. another). Note: This could be *good* if the validation was sufficient. All studies for PFBS used direct measures. And all of the following: • Exposure was assessed in a relevant time window for development of the outcome. • There is evidence that a sufficient proportion of the exposure data measurements are above the limit of quantification for the assay. • There is sufficient specificity/sensitivity and range or variation in exposure measurements that would minimize potential for exposure measurement error and misclassification by allowing exposure classifications to be differentiated (i.e., can reliably categorize participants into groups such as high vs. low exposure), but there might be more uncertainty than in *good*.
Deficient	Any of the following: • Some concern, but no direct evidence, that the exposure was assessed using poorly validated methods. • There is insufficient information provided about the exposure assessment, including precision, accuracy, and level of quantification, but no evidence for concern about the method used. • Exposure was assessed in a relevant time window for development of the outcome. There could be concerns about reverse causation between exposure and outcome, but there is no direct evidence that it is present. • There is some concern over insufficient specificity/sensitivity and range or variation in exposure measurements that may result in considerable exposure measurement error and misclassification when exposure classifications are compared (i.e., data do not lend themselves to reliably categorize participants into groups such as high vs. low exposure, and/or there is considerable uncertainty in exposure values that do not allow for confidence in the examination of small per unit changes in continuous exposures).

Table C-2. Criteria for Evaluation of Exposure Measurement in Epidemiology Studies

Exposure Measurement Rating	Criteria
Critically deficient	Any of the following: • Exposure was assessed in a time window that is unknown or not relevant for development of the outcome. This could be due to clear evidence of reverse causation between exposure and outcome, or other concerns such as the lack of temporal ordering of exposure and disease onset, insufficient latency, or having exposure measurements that are not reliable measures of exposure during the etiologic window. • Direct evidence that bias was likely because the exposure was assessed using methods with poor validity. • Evidence of differential exposure misclassification (e.g., differential recall of self-reported exposure). • There is evidence that an insufficient proportion of the exposure data measurements are above the limit of quantification for the assay.

PFAS = per- and polyfluoroalkyl substances; PFBS = perfluorobutane sulfonic acid.

Table C-3. Questions Used to Guide the Development of Criteria for Each Domain in Experimental Animal Toxicology Studies

Evaluation Type	Domain– Core Question	Prompting Questions	Basic Considerations
Reporting Quality	**Reporting quality–** Does the study report information for evaluating the design and conduct of the study for the endpoint(s)/outcome(s) of interest? *Notes:* *Reviewers should reach out to study authors to obtain missing information when studies are considered key for hazard evaluation and/or dose-response.* *This domain is limited to reporting. Other aspects of the exposure methods, experimental design, and endpoint evaluation methods are evaluated using the domains related to risk of bias and study sensitivity.*	Does the study report the following? • **Critical information** necessary to perform study evaluation: o Species, test article name, levels and duration of exposure, route (e.g., oral, inhalation), qualitative or quantitative results for at least one endpoint of interest. • **Important information** for evaluating the study methods: o Test animal: strain, sex, source, and general husbandry procedures. o Exposure methods: source, purity, method of administration. o Experimental design: frequency of exposure, animal age, and life stage during exposure and at endpoint/outcome evaluation. o Endpoint evaluation methods: assays or procedures used to measure the endpoints/outcomes of interest.	These considerations typically do not need to be refined by assessment teams, although in some instances the **important information** may be refined depending on the endpoints/outcomes of interest or the chemical under investigation. A judgment and rationale for this domain should be given for the study. Typically, these will not change regardless of the endpoints/outcomes investigated by the study. **In the rationale, reviewers should indicate whether the study adhered to GLP, OECD, or other testing guidelines.** • *Good*: All critical and **important information** is reported or inferable for the endpoints/outcomes of interest. • *Adequate*: All **critical information** is reported but some **important information** is missing. However, the missing information is not expected to significantly impact the study evaluation. • *Deficient*: All **critical information** is reported but **important information** is missing that is expected to significantly reduce the ability to evaluate the study. • *Critically deficient*: Study report is missing any pieces of **critical information**. Studies that are *critically deficient* for reporting are *uninformative* for the overall rating and considered no further for evidence synthesis and integration.

Table C-3. Questions Used to Guide the Development of Criteria for Each Domain in Experimental Animal Toxicology Studies

Evaluation Type		Domain– Core Question	Prompting Questions	Basic Considerations
Risk of Bias	**Selection and performance bias**	**Allocation–** Were animals assigned to experimental groups using a method that minimizes selection bias?	For each study: • Did each animal or litter have an equal chance of being assigned to any experimental group (i.e., random allocation)? • Is the allocation method described? • Aside from randomization, were any steps taken to balance variables across experimental groups during allocation?	These considerations typically do not need to be refined by assessment teams. A judgment and rationale for this domain should be given for each cohort or experiment in the study. • *Good*: Experimental groups were randomized, and any specific randomization procedure was described or inferable (e.g., computer-generated scheme). (Note that normalization is not the same as randomization [see response for *adequate*].) • *Adequate*: Study authors report that groups were randomized but do not describe the specific procedure used (e.g., "animals were randomized"). Alternatively, the study authors used a nonrandom method to control for important modifying factors across experimental groups (e.g., body-weight normalization). • *Not reported* (interpreted as *deficient*): No indication of randomization of groups or other methods (e.g., normalization) to control for important modifying factors across experimental groups. • *Critically deficient*: Bias in the animal allocations was reported or inferable.

Table C-3. Questions Used to Guide the Development of Criteria for Each Domain in Experimental Animal Toxicology Studies

Evaluation Type		Domain– Core Question	Prompting Questions	Basic Considerations
Risk of Bias	**Selection and performance bias**	**Observational bias/blinding–** Did the study implement measures to reduce observational bias?	For each endpoint/outcome or grouping of endpoints/outcomes in a study: • Does the study report blinding or other methods/procedures for reducing observational bias? • If not, did the study use a design or approach for which such procedures can be inferred? • What is the expected impact of failure to implement (or report implementation) of these methods/procedures on results?	These considerations typically do not need to be refined by the assessment teams. (Note that it can be useful for teams to identify highly subjective measures of endpoints/outcomes where observational bias may strongly influence results prior to performing evaluations.) A judgment and rationale for this domain should be given for each endpoint/outcome or group of endpoints/outcomes investigated in the study. • *Good*: Measures to reduce observational bias were described (e.g., blinding to conceal treatment groups during endpoint evaluation; consensus-based evaluations of histopathology lesions).[a] • *Adequate*: Methods for reducing observational bias (e.g., blinding) can be inferred or were reported but described incompletely. • *Not reported*: Measures to reduce observational bias were not described. o Interpreted as *adequate*—The potential concern for bias was mitigated based on use of automated/computer-driven systems; standard laboratory kits; relatively simple, objective measures (e.g., body or tissue weight); or screening-level evaluations of histopathology. o Interpreted as *deficient*—The potential impact on the results is major (e.g., outcome measures are highly subjective). • *Critically deficient*: Strong evidence for observational bias that could have impacted results.

Table C-3. Questions Used to Guide the Development of Criteria for Each Domain in Experimental Animal Toxicology Studies

Evaluation Type		Domain– Core Question	Prompting Questions	Basic Considerations
Risk of Bias	**Confounding/ variable control**	**Confounding–** Are variables with the potential to confound or modify results controlled for and consistent across all experimental groups?	For each study: • Are there differences across the treatment groups (e.g., co-exposures, vehicle, diet, palatability, husbandry, health status, and so forth) that could bias the results? • If differences are identified, to what extent are they expected to impact the results?	These considerations may need to be refined by assessment teams, as the specific variables of concern can vary by experiment or chemical. A judgment and rationale for this domain should be given for each cohort or experiment in the study, noting when the potential for confounding is restricted to specific endpoints/outcomes. • *Good*: Outside of the exposure of interest, variables that are likely to confound or modify results appear to be controlled for and consistent across experimental groups. • *Adequate*: Some concern that variables that were likely to confound or modify results were uncontrolled or inconsistent across groups but are expected to have a minimal impact on the results. • *Deficient*: Notable concern that potentially confounding variables were uncontrolled or inconsistent across groups and are expected to substantially impact the results. • *Critically deficient*: Confounding variables were presumed to be uncontrolled or inconsistent across groups and are expected to be a primary driver of the results.

Table C-3. Questions Used to Guide the Development of Criteria for Each Domain in Experimental Animal Toxicology Studies

Evaluation Type		Domain– Core Question	Prompting Questions	Basic Considerations
Risk of Bias	**Reporting and attrition bias**	**Selective reporting and attrition–** Did the study report results for all prespecified outcomes and tested animals? *Note:* *This domain does **not** consider the appropriateness of the analysis/results presentation. This aspect of study quality is evaluated in another domain.*	For each study: *Selective reporting bias:* • Are all results presented for endpoints/outcomes described in the methods (see note)? *Attrition bias:* • Are all animals accounted for in the results? • If there are discrepancies, do study authors provide an explanation (e.g., death or unscheduled sacrifice during the study)? • If unexplained results, omissions, and/or attrition are identified, what is the expected impact on the interpretation of the results?	These considerations typically do not need to be refined by assessment teams. A judgment and rationale for this domain should be given for each cohort or experiment in the study. • *Good*: Quantitative or qualitative results were reported for all prespecified outcomes (explicitly stated or inferred), exposure groups, and evaluation time points. Data not reported in the primary article is available from supplemental material. If results, omissions, or animal attrition are identified, the study authors provide an explanation, and these factors are not expected to impact the interpretation of the results. • *Adequate*: Quantitative or qualitative results are reported for most prespecified outcomes (explicitly stated or inferred), exposure groups, and evaluation time points. Omissions and/or attrition are not explained but are not expected to significantly impact the interpretation of the results. • *Deficient*: Quantitative or qualitative results are missing for many prespecified outcomes (explicitly stated or inferred), exposure groups and evaluation time points and/or high animal attrition; omissions and/or attrition are not explained and may significantly impact the interpretation of the results. • *Critically deficient*: Extensive results omission and/or animal attrition is identified and prevents comparisons of results across treatment groups.

Table C-3. Questions Used to Guide the Development of Criteria for Each Domain in Experimental Animal Toxicology Studies

Evaluation Type		Domain– Core Question	Prompting Questions	Basic Considerations
Sensitivity	**Exposure methods sensitivity**	**Chemical administration and characterization–** Did the study adequately characterize exposure to the chemical of interest and the exposure administration methods? *Note:* *Consideration of the appropriateness of the route of exposure is not evaluated at the individual study level. Relevance and utility of the routes of exposure are considered in the PECO criteria for study inclusion and during evidence synthesis.*	For each study: • Does the study report the source, purity, and/or composition (e.g., identity and percent distribution of different isomers) of the chemical? If not, can the purity and/or composition be obtained from the supplier (e.g., as reported on the website)? • Was independent analytical verification of the test article purity and composition performed? • Did the study authors take steps to ensure the reported exposure levels were accurate? o For inhalation studies: Were target concentrations confirmed using reliable analytical measurements in chamber air? o For oral studies: If necessary, based on consideration of chemical-specific knowledge (e.g., instability in solution; volatility) and/or exposure design (e.g., the frequency and duration of exposure), were chemical concentrations in the dosing solutions or diet analytically confirmed? • Are there concerns about the methods used to administer the chemical (e.g., inhalation chamber type, gavage volume, etc.)?	It is essential that these criteria are considered and potentially refined by assessment teams, as the specific variables of concern can vary by chemical. A judgment and rationale for this domain should be given for each cohort or experiment in the study. • *Good*: Chemical administration and characterization is complete (i.e., source, purity, and analytical verification of the test article are provided). There are no concerns about the composition, stability, or purity of the administered chemical or the specific methods of administration. For inhalation studies, chemical concentrations in the exposure chambers are verified using reliable analytical methods. • *Adequate*: Some uncertainties in the chemical administration and characterization are identified but these are expected to have minimal impact on interpretation of the results (e.g., source and vendor-reported purity are presented, but not independently verified; purity of the test article is suboptimal but not concerning). For inhalation studies, actual exposure concentrations are missing or verified with less reliable methods. • *Deficient*: Uncertainties in the exposure characterization are identified and expected to substantially impact the results (e.g., source of the test article is not reported, levels of impurities are substantial or concerning, deficient administration methods such as use of static inhalation chambers or a gavage volume considered too large for the species and/or life stage at exposure). • *Critically deficient*: Uncertainties in the exposure characterization are identified, and there is reasonable certainty that the results are largely attributable to factors other than exposure to the chemical of interest (e.g., identified impurities are expected to be a primary driver of the results).

Table C-3. Questions Used to Guide the Development of Criteria for Each Domain in Experimental Animal Toxicology Studies

Evaluation Type		Domain– Core Question	Prompting Questions	Basic Considerations
Sensitivity	**Exposure methods sensitivity**	**Exposure timing, frequency and duration–** Was the timing, frequency, and duration of exposure sensitive for the endpoint(s)/outcome(s) of interest?	For each endpoint/outcome or grouping of endpoints/outcomes in a study: • Does the exposure period include the critical window of sensitivity? • Was the duration and frequency of exposure sensitive for detecting the endpoint of interest?	Considerations for this domain are highly variable depending on the endpoint(s)/outcome(s) of interest and must be refined by assessment teams. A judgment and rationale for this domain should be given for each endpoint/outcome or group of endpoints/outcomes investigated in the study. • *Good*: The duration and frequency of the exposure was sensitive, and the exposure included the critical window of sensitivity (if known). • *Adequate*: The duration and frequency of the exposure was sensitive, and the exposure covered most of the critical window of sensitivity (if known). • *Deficient*: The duration and/or frequency of the exposure is not sensitive and did not include the majority of the critical window of sensitivity (if known). These limitations are expected to bias the results towards the null. • *Critically Deficient*: The exposure design was not sensitive and is expected to strongly bias the results towards the null. The rationale should indicate the specific concern(s).

Table C-3. Questions Used to Guide the Development of Criteria for Each Domain in Experimental Animal Toxicology Studies

Evaluation Type		Domain– Core Question	Prompting Questions	Basic Considerations
Sensitivity	**Outcome measures and results display**	**Endpoint sensitivity and specificity–** Are the procedures sensitive and specific for evaluating the endpoint(s)/outcome(s) of interest? *Note:* *Sample size alone is not a reason to conclude an individual study is critically deficient.*	For each endpoint/outcome or grouping of endpoints/outcomes in a study: • Are there concerns regarding the specificity and validity of the protocols? • Are there serious concerns regarding the sample size (see note)? • Are there concerns regarding the timing of the endpoint assessment?	Considerations for this domain are highly variable depending on the endpoint(s)/outcome(s) of interest and must be refined by assessment teams. A judgment and rationale for this domain should be given for each endpoint/outcome or group of endpoints/outcomes investigated in the study. Examples of potential concerns include: • Selection of protocols that are insensitive or nonspecific for the endpoint of interest. • Use of unreliable methods to assess the outcome. • Assessment of endpoints at inappropriate or insensitive ages, or without addressing known endpoint variation (e.g., due to circadian rhythms, estrous cyclicity, etc.). • Decreased specificity or sensitivity of the response due to the timing of endpoint evaluation, as compared to exposure (e.g., short-acting depressant or irritant effects of chemicals, insensitivity due to prolonged period of nonexposure prior to testing).

Table C-3. Questions Used to Guide the Development of Criteria for Each Domain in Experimental Animal Toxicology Studies

Evaluation Type		Domain– Core Question	Prompting Questions	Basic Considerations
Sensitivity	**Outcome measures and results display**	**Results presentation–** Are the results presented in a way that makes the data usable and transparent?	For each endpoint/outcome or grouping of endpoints/outcomes in a study: • Does the level of detail allow for an informed interpretation of the results? • Are the data analyzed, compared, or presented in a way that is inappropriate or misleading?	Considerations for this domain are highly variable depending on the outcomes of interest and must be refined by assessment teams. A judgment and rationale for this domain should be given for each endpoint/outcome or group of endpoints/outcomes investigated in the study. Examples of potential concerns include: • Nonpreferred presentation such as developmental toxicity data averaged across pups in a treatment group when litter responses are more appropriate. • Failure to present quantitative results. • Pooled data when responses are known or expected to differ substantially (e.g., across sexes or ages). • Failure to report on or address overt toxicity when exposure levels are known or expected to be highly toxic. • Lack of full presentation of the data (e.g., presentation of mean without variance data; concurrent control data are not presented).

Table C-3. Questions Used to Guide the Development of Criteria for Each Domain in Experimental Animal Toxicology Studies

Evaluation Type	Domain– Core Question	Prompting Questions	Basic Considerations
Overall Confidence	**Overall Confidence–** Considering the identified strengths and limitations, what is the overall confidence rating for the endpoint(s)/outcome(s) of interest? *Note:* *Reviewers should mark studies that are rated lower than high confidence only due to low sensitivity (i.e., bias towards the null) for additional consideration during evidence synthesis. If the study is otherwise well-conducted and an effect is observed, the confidence may be increased.*	For each endpoint/outcome or grouping of endpoints/outcomes in a study: • Were concerns (i.e., limitations or uncertainties) related to the reporting quality, risk of bias, or sensitivity identified? • If yes, what is their expected impact on the overall interpretation of the reliability and validity of the study results, including (when possible) interpretations of impacts on the magnitude or direction of the reported effects?	The overall confidence rating considers the likely impact of the noted concerns (i.e., limitations or uncertainties) in reporting, bias, and sensitivity on the results. A confidence rating and rationale should be given for each endpoint/outcome or group of endpoints/outcomes investigated in the study. • *High confidence*: No notable concerns are identified (e.g., most or all domains rated *good*). • *Medium confidence*: Some concerns are identified, but expected to have minimal impact on the interpretation of the results (e.g., most domains rated *adequate* or *good*; may include studies with *deficient* ratings if concerns are not expected to strongly impact the magnitude or direction of the results). Any important concerns should be carried forward to evidence synthesis. • *Low confidence*: Identified concerns are expected to significantly impact the study results or their interpretation (e.g., generally, *deficient* ratings for one or more domains). The concerns leading to this confidence judgment must be carried forward to evidence synthesis (see note). • *Uninformative*: Serious flaw(s) that make the study results unusable for informing hazard identification (e.g., generally, *critically deficient* rating in any domain; many *deficient* ratings). *Uninformative* studies are considered no further in the synthesis and integration of evidence.

[a]For nontargeted or screening-level histopathology outcomes often used in guideline studies, blinding during the initial evaluation of tissues is generally not recommended because masked evaluation can make "the task of separating treatment-related changes from normal variation more difficult" and "there is concern that masked review during the initial evaluation may result in missing subtle lesions." Generally, blinded evaluations are recommended for targeted secondary review of specific tissues or in instances when there is a predefined set of outcomes that is known or predicted to occur (Crissman et al., 2004).

GLP = Good Laboratory Practice; OECD = Organisation for Economic Cooperation and Development.

APPENDIX D. HAWC USER GUIDE AND FREQUENTLY ASKED QUESTIONS

D.1 WHAT IS HAWC AND WHAT IS ITS PURPOSE?

The Health Assessment Workspace Collaborative (HAWC) is an interactive, expert-driven, content management system for human health assessments that is intended to promote transparency, trackability, data usability, and understanding of the data and decisions supporting an environmental and human health assessment. Specifically, HAWC is an interface that allows the data and decisions supporting an assessment to be managed in modules (e.g., study evaluation, summary study data, etc.) that can be publicly accessed online (see Section D.2 below and Figure D-1). Following the literature search and screening that are conducted using HERO and DistillerSR, HAWC manages each study included in an assessment and makes the extracted information available via a web link that takes a user to a web page displaying study-specific details and data (e.g., study evaluation, experimental design, dosing regime, endpoints evaluated, dose-response data, etc., described in further detail below in Sections D.3 to D.6). Finally, all data managed in HAWC is fully downloadable using the blue "Download datasets" link (highlighted in the red box below) also located in the gray navigation bar located on the assessment home page (discussed in Section D.7). Note that a user may quickly navigate HAWC by clicking on the file path (highlighted in the orange, dashed box below) given in the gray row below the HAWC icon and menu bar (see Figure D-1). HAWC aims to facilitate team collaboration by scientists who develop these assessments and enhance transparency of the process by providing online access (no user account required) to the data and expert decisions used to evaluate potential human health hazard and risk of chemical exposures.

Figure D-1. HAWC Homepage for the Public PFBS Assessment

D.2 HOW DO I ACCESS HAWC?

HAWC is an open-source, online application that may be accessed using the following link—https://hawcprd.epa.gov/assessment/public/—and then selecting an available assessment. The following browsers are fully supported for accessing HAWC: Google Chrome (preferred), Mozilla Firefox, and Apple Safari. There are errors in functionality when viewed with Internet Explorer. No user account is required for access to public HAWC assessments. The assessments located in HAWC are meant to accompany a textual expert synthesis of the data managed in HAWC. Each written assessment document contains embedded URL links to the evidence in HAWC (e.g., study evaluation, summary study data, visualizations, etc.) supporting

the assessment text. The links embedded in an assessment document can be accessed by a mouse click (or hover while pressing CTRL + right click).

D.3 WHAT CAN I FIND IN HAWC?

HAWC contains a comprehensive landscape of study details and data supporting an assessment. Note that links are provided in the assessment text to guide the reader, but a user may also navigate to the HAWC homepage for an assessment on their own. Once a user lands on an assessment homepage, all studies included in an assessment can be viewed by clicking the blue "Study list" link (highlighted in the red box below) in the gray navigation pane (see Figure D-2). By clicking the study name listed in blue (under "Short citation") a user can view the full study details, study evaluation, and experimental details and data. For example, in Figure D-2, a user may click on "3M, 2000, 4289992" (highlighted in the orange, dashed box below). This will take the user to the 3M (2000d) study details page that includes a link to the study in HERO along with study details, study evaluation, and available experimental (animal) and study population (epidemiologic) groups.

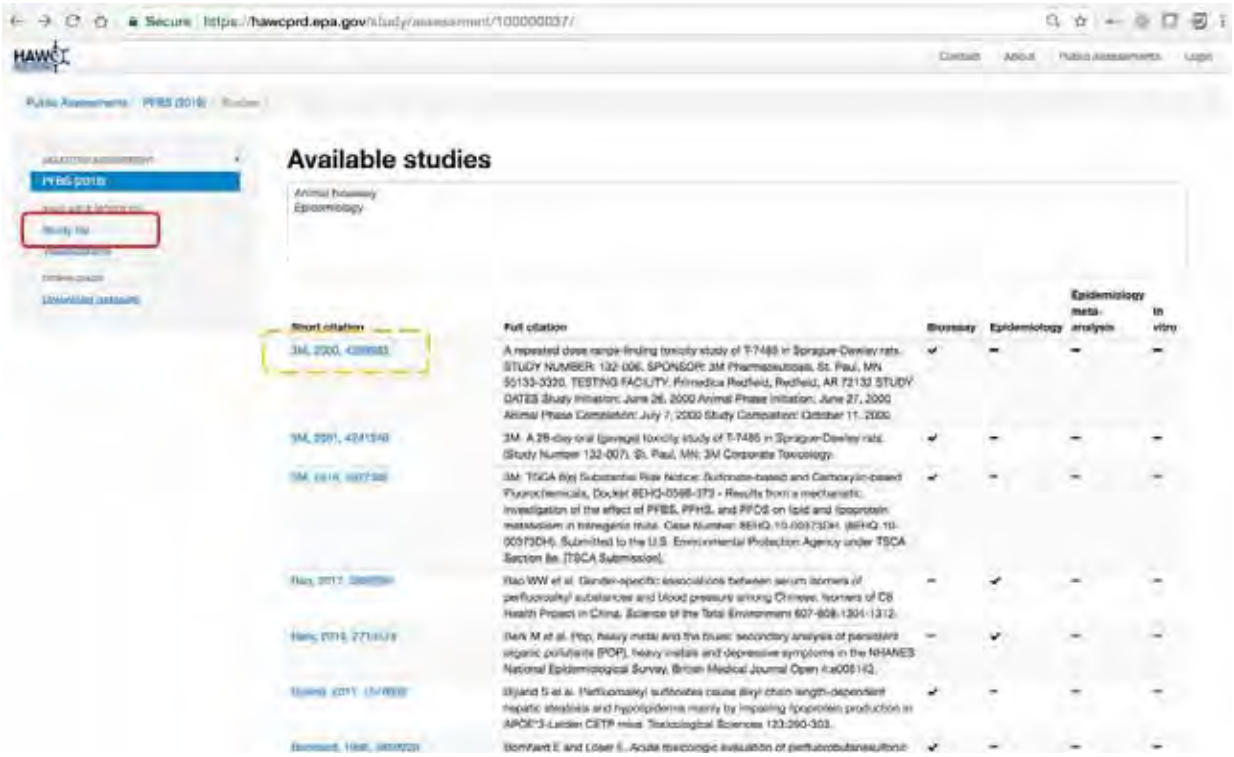

Figure D-2. Representative Study List

D.4 HOW DO I ACCESS STUDY EVALUATION(S)?

Study evaluation is performed to ensure that the studies used in the assessment are conducted in such a manner that the results are credible for each outcome and the ratings are outcome specific. The study evaluation criteria and decisions are fully documented in HAWC and displayed for each study on the study details page. Study evaluation is depicted as a pie chart with each domain and rating making up a piece of the pie that is colored according to the

rating. A user may hover over each piece of the pie, which causes rating metric text to populate to the right of the pie graph (see Figure D-3). For full domain and rating details the user may click the blue "View details" button (highlighted in the red box below). [Note that this example is given for the 3M (2000d)].

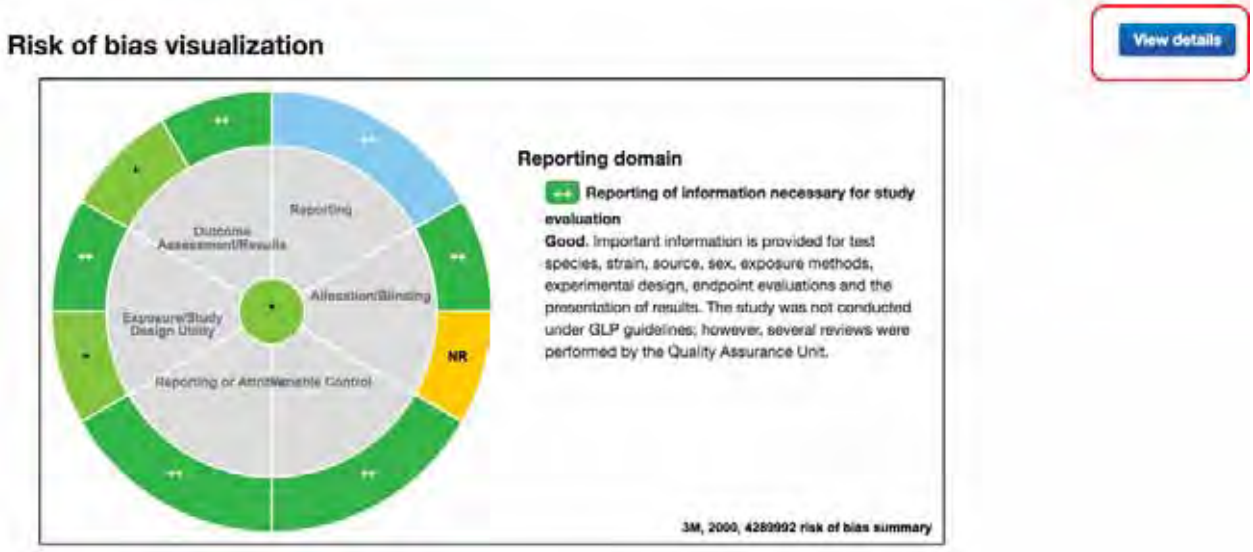

Figure D-3. Representative Study Evaluation Pie Chart with the Reporting Domain Selected and Text Populating to the Right of Pie Chart

D.5 HOW DO I ACCESS STUDY-SPECIFIC INFORMATION ON EXPERIMENTAL AND STUDY POPULATION DETAILS AND EXTRACTED ENDPOINT DATA?

Specific information on experimental design, dosing (if animal bioassay), outcomes and exposure (if epidemiology), and extracted endpoint data can be accessed from the study details page by clicking on [for the 3M (2000d) study] "available animal bioassay experiments" at the bottom of the study details page. A user may click on the experiment name (highlighted in blue, 10-day oral) to view dosing/exposure details and available groups. Clicking on available animal groups (e.g., male Sprague-Dawley or female Sprague-Dawley) will take the reader to a new page with experimental group information (e.g., species/strain/sex, dosing regimen information, and available/additional endpoints information for animal studies; and outcome and exposure information for epidemiologic studies). If a study reports data, then the data are extracted and managed as "available endpoints." If the study authors include endpoints in the methods and results but do not report data, the endpoint is listed under "additional endpoints" without dose-response data. All endpoints are also clickable and contain an endpoint description, methods, and (if data are reported) a clickable data plot (e.g., alanine aminotransferase [ALT]). The description of endpoints, methods, and data are often copied directly from the study report and, therefore, can contain study author judgments and may not necessarily include U.S. EPA judgments on the endpoint data that would be included in the assessment.

D.6 WHAT ARE VISUALIZATIONS AND HOW DO I ACCESS THEM?

The data managed in HAWC is displayed using visualizations that are intended to support textual descriptions within an assessment. All visualizations can be accessed using the blue "Visualizations" link (highlighted in the red box below) also found in the gray navigation pane (see Figure D-4A). *Note that the available visualizations are at the discretion of the chemical manager and are meant to accompany the assessment text*. Visualizations are fully interactive. Hovering and clicking on records in the rows and columns and data points on a plot will cause a pop-up window to appear (see Figure D-5B). This pop-up window is also interactive and clicking on blue text within this pop-up will open a new web page with descriptive data.

Figure D-4A. Visualization Example for PFBS
(Note that the records listed under each column [study, experiment endpoint, units, study design, observation time, dose] and data within the plot are interactive.)

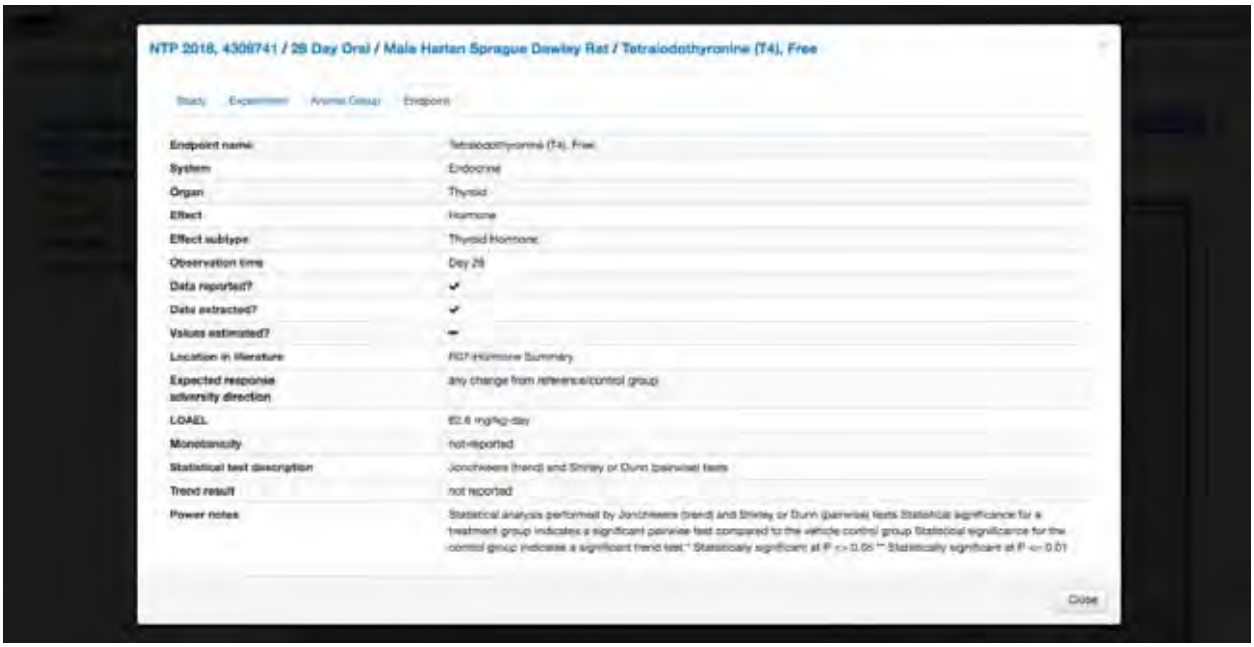

Figure D-4B. Example Pop-Up Window after Clicking on Interactive Visualization Links (In Figure D-4A, the red circle for study NTP (2019); male at a dose of 500 mg/kg-day was clicked leading to the pop-up shown above. Clicking on the blue text will open a new window with descriptive data.)

D.7 HOW DO I DOWNLOAD DATA SETS?

A user may download any available data set by first clicking on the blue "Download datasets" link (highlighted in the red box below) in the gray navigation pane on the assessment homepage. This takes the user to a new page where the desired data set may be selected for download as an Excel file (see representative image in Figure D-6).

Figure D-5. Representative Data Download Page

D.8 HOW DO I ACCESS THE BENCHMARK DOSE MODELING OUTPUTS?

Benchmark dose (BMD) modeling is performed on an endpoint-by-endpoint basis at the discretion of the chemical manager. Those endpoints for which BMD modeling has been completed are referenced in the assessment text and are available for viewing. To access BMD modeling outputs the user can click on links included in the assessment text. Alternatively, the user may navigate to the BMD modeling outputs by clicking on a study [e.g., Feng et al. (2017)] of interest from the study list, an available animal bioassay experiment (in this example, the 20-day oral gestation study), an available animal group (P_0 female ICR mice), and an endpoint of interest (tetraiodothyronine [T_4], free). Next navigate to the blue "Actions" button, click, and scroll to "View session" (highlighted in the red box below) under BMD Modeling (see Figure D-7A). The BMD setup, results, and model recommendation and selection (highlighted in the orange, dashed box in Figure D-8B) are available for viewing. Selecting the BMD setup tab will display the modeled dose-response data, the selected models and options, and all benchmark modeling responses (BMRs). The results tab will display the BMD modeling output summary for all models. A user may hover over a selected model row to visualize the model fit to the data. In addition, a user may obtain the Benchmark Dose Software (BMDS) output text by clicking the "View" button under the "Output" column for each model that was run. The "Model recommendation and selection" tab displays all models, warnings when appropriate, and the recommendation for which models are valid, questionable, or failed to fit.

APPENDIX F. BENCHMARK DOSE MODELING RESULTS

F.1. MODELING OF NONCANCER ENDPOINTS

As discussed in the body of the report under "Derivation of Oral Reference Doses," the endpoints selected for benchmark dose (BMD) modeling were incidence of renal papillary epithelial tubular/ductal hyperplasia in rats from Lieder et al. (2009a) and Lieder et al. (2009b); thyroid hormones in pregnant mice and offspring at Postnatal Days (PNDs) 1, 30, and 60 from Feng et al. (2017) and adult rats from NTP (2019); and developmental effects (i.e., eye opening, first estrus, vaginal opening) from Feng et al. (2017). The animal doses in the study, converted to human equivalent doses (HEDs), were used in the BMD modeling; the data are available for download in Health Assessment Workspace Collaborative (HAWC). BMD modeling was conducted by experts in quantitative Benchmark Dose Software (BMDS) analysis and interpretation. Links to the data and modeling output are included in Table F-1. The selected point of departure (POD) (HED) listed in Table F-1 represents the best-fitting model for each endpoint; if the data were determined not to be amenable to BMD modeling, the no-observed-adverse-effect level (NOAEL) or lowest-observed-adverse-effect level (LOAEL) is listed. Figure F-1 illustrates the doses examined and NOAEL, LOAEL, BMD, and benchmark dose lower confidence limit (BMDL) values for the potential critical effects.

Table F-1. Candidate PODs for the Derivation of the Subchronic and Chronic RfDs for PFBS (CASRN 375-73-5) and the Related Compound K^+PFBS (CASRN 29420-49-3)

Endpoint/Reference	Species/Life Stage—Sex	Selected POD (HED)[a] (mg/kg-d)
Kidney effects		
Kidney histopathology—papillary epithelial tubular/ductal hyperplasia—Lieder et al. (2009a)	Rat—male	$BMDL_{10}$ = 0.489
	Rat—female	$BMDL_{10}$ = 0.300
Kidney histopathology—papillary epithelial tubular/ductal hyperplasia—Lieder et al. (2009b)	Rat/P_0—male	$BMDL_{10}$ = 0.351
	Rat/P_0—female	$BMDL_{10}$ = 0.265
Kidney histopathology—papillary epithelial tubular/ductal hyperplasia—Lieder et al. (2009b)	Rat/F_1—male	$BMDL_{10}$ = 0.776
	Rat/F_1—female	$BMDL_{10}$ = 0.478
Thyroid effects		
Total T_4—NTP (2019)	Rat—male	LOAEL = 0.34
	Rat—female	$BMDL_{1SD}$ = 0.037
Free T_4—NTP (2019)	Rat—male	LOAEL = 0.34
	Rat—female	$BMDL_{1SD}$ = 0.027
Total T_4—Feng et al. (2017)	Mouse/P_0—female	$BMDL_{1SD}$ = 0.093
Free T_4—Feng et al. (2017)	Mouse/P_0—female	NOAEL = 0.21
TSH—Feng et al. (2017)	Mouse/P_0—female	NOAEL = 0.21
Total T_4 PND 1 (fetal *n*)[b]—Feng et al. (2017)	Mouse/F_1—female	NOAEL = 0.21
Total T_4 PND 1 (litter *n*)[b]—Feng et al. (2017)	**Mouse/F_1—female**	**$BMDL_{0.5SD}$ = 0.095 ($BMDL_{1SD}$ = 0.25)**

Table F-1. Candidate PODs for the Derivation of the Subchronic and Chronic RfDs for PFBS (CASRN 375-73-5) and the Related Compound K^+PFBS (CASRN 29420-49-3)

Endpoint/Reference	Species/Life Stage—Sex	Selected POD (HED)[a] (mg/kg-d)
Total T_4 PND 30—Feng et al. (2017)	Mouse/F_1—female	NOAEL = 0.21
Total T_4 PND 60—Feng et al. (2017)	Mouse/F_1—female	NOAEL = 0.21
TSH PND 30—Feng et al. (2017)	Mouse/F_1—female	NOAEL = 0.21
Developmental effects		
Eyes opening (fetal *n*)[b]—Feng et al. (2017)	Mouse/F_1—female	NOAEL = 0.21
Eyes opening (litter *n*)[b]—Feng et al. (2017)	Mouse/F_1—female	$BMDL_{0.5SD}$ = 0.073 ($BMDL_{1SD}$ = 0.16)
Vaginal opening (fetal *n*)[b]—Feng et al. (2017)	Mouse/F_1—female	$BMDL_{0.5SD}$ = 0.15 ($BMDL_{1SD}$ = 0.35)
Vaginal opening (litter *n*)[b]—Feng et al. (2017)	Mouse/F_1—female	$BMDL_{0.5SD}$ = 0.094 ($BMDL_{1SD}$ = 0.22)
First estrous (fetal *n*)[b]—Feng et al. (2017)	Mouse/F_1—female	NOAEL = 0.21
First estrous (litter *n*)[b]—Feng et al. (2017)	Mouse/F_1—female	NOAEL = 0.21

[a]Following U.S. EPA (2011b) guidance, animal doses from candidate principal studies were converted to HEDs through the application of a DAF, where HED = dose × DAF. See Table 8 in the assessment for full details. Links are to the HAWC BMDS session containing full modeling results for that endpoint.
[b]Fetal endpoints from Feng et al. (2017) were modeled alternatively using dose group sizes based either on total number of fetuses or dams. Given that it appears that Feng et al. (2017) did not use the litter as the statistical unit of analysis, it is unclear if the study-reported standard errors pertain to litters or fetuses. Alternatively, modeling fetal endpoints using litter *n* or fetal *n* provides two modeling results that bracket the "true" variance among all fetuses in a dose group (i.e., using the fetal *n* will underestimate the true variance while using the litter *n* will overestimate the true variance). Individual animal data were requested from study authors but were unable to be obtained.

BMDL = benchmark dose lower confidence limit; BMDS = benchmark dose software; DAF = dosimetric adjustment factor; HAWC = Health Assessment Workspace Collaborative; HED = human equivalent dose; K^+PFBS = potassium perfluorobutane sulfonate; LOAEL = lowest-observed-adverse-effect level; NOAEL = no-observed-adverse-effect level; PFBS = perfluorobutane sulfonic acid; PND = postnatal day; POD = point of departure; RfD = oral reference dose; SD = standard deviation; T_4 = total thyroxine; TSH = thyroid-stimulating hormone.

F.2. MODELING PROCEDURE FOR CONTINUOUS NONCANCER DATA

BMD modeling of continuous data was conducted on the HAWC website using the U.S. Environmental Protection Agency's (U.S. EPA's) BMDS (Version 2.7). All continuous models available within the software were fit using a benchmark response (BMR) of 1 standard deviation (SD). For continuous data of effects in developing offspring, including thyroid hormone changes, a BMR of 0.5 SD change from the control mean is used to account for effects occurring in a sensitive life stage. A 1 SD BMR is also presented as the basis for model comparison as directed in the U.S. EPA *Benchmark Dose Technical Guidance* (U.S. EPA, 2012). An adequate fit is judged based on the χ^2 goodness-of-fit *p*-value ($p > 0.1$), magnitude of the scaled residuals in the vicinity of the BMR, and visual inspection of the model fit. In addition to these three criteria for judging adequacy of model fit, a determination is made as to whether the variance across dose groups is homogeneous. If a homogeneous variance model is deemed appropriate based on the statistical test provided by BMDS (i.e., Test 2), the final BMD results are estimated from a homogeneous variance model. If the test for homogeneity of variance is rejected ($p < 0.1$), the model is run again while modeling the variance as a power function of the mean to account for this nonhomogeneous variance. If this nonhomogeneous variance model does not adequately fit the data (i.e., Test 3; $p < 0.1$), the data set is considered unsuitable for BMD modeling. In cases in which a model with # parameters = # dose-groups was fit to the data set, all parameters were estimated, and no *p*-value was calculated, that model was not considered for estimating a POD unless no other model provided adequate fit. Among all models providing adequate fit, the BMDL from the model with the lowest Akaike's information criterion (AIC) was selected as a potential POD when BMDL values were sufficiently close (within threefold). Otherwise, the lowest BMDL was selected as a potential POD from which to derive the oral reference dose/inhalation reference concentration (RfD/RfC).

F.2.1 Modeling Predictions for Serum Total T_4 in PND 1 Female Offspring (litter *n*)

The modeling results for total T_4 in PND 1 female offspring (litter *n*) exposed Gestation Days (GDs) 1−20 are shown in Table F-2. The Exponential 4 model (see Figure F-2) was selected given appropriate fit to the data and that the BMDL values differed by greater than threefold. The output for the U.S. EPA's BMDS model run is also provided below.

Table F-2. Modeling Results for Total T_4 in PND 1 Female Offspring (Litter *n*) Exposed GDs 1−20[a]

Model	Global *p*-Value	AIC	$BMD_{0.5SD}$ (HED) (mg/kg-d)	$BMDL_{0.5SD}$ (HED) (mg/kg-d)	BMD_{1SD} (HED) (mg/kg-d)	$BMDL_{1SD}$ (HED) (mg/kg-d)	Residual of Interest
Linear	0.5652	−4.74898	0.7778	0.5120	1.5557	1.0241	0.348
Polynomial	0.5652	−4.74898	0.7778	0.5120	1.5557	1.0241	0.348
Power	0.5652	−4.74898	0.7778	0.5120	1.5557	1.0241	0.348
Hill	−999	−1.89	0.368	0.0704	0.8677	0.2294	-6.01×10^{-7}
Exponential-M2	0.77	−5.3672	0.5546	0.3017	1.2555	0.6694	−0.5752
Exponential-M3	0.77	−5.3672	0.5546	0.3017	1.2555	0.6694	−0.5752
Exponential-M4[b]	**0.8583**	**−3.8581**	**0.3346**	**0.0951**	**0.8708**	**0.2498**	**−0.08305**
Exponential-M5	−999	−1.89	0.3807	0.0958	0.8669	0.2517	-4.356×10^{-7}

[a]Feng et al. (2017).
[b]Selected model. Exponential 4 model was selected given appropriate fit to the data and that the BMDL values differed by greater than threefold. The Hill and Exponential 5 models were not selected because they did not return a *p*-value.

AIC = Akaike's information criterion; BMD = maximum likelihood estimate of the exposure concentration associated with the selected BMR; BMDL = 95% lower confidence limit on the BMD (subscripts denote BMR: i.e., 0.5 SD = exposure concentration associated with 0.5 SD change from the control mean); BMR = benchmark response; GD = gestation day; HED = human equivalent dose; PND = postnatal day; SD = standard deviation; T_4 = thyroxine.

```
  Other models for which likelihoods are calculated:

    Model A1:        Yij = Mu(i) + e(ij)
                Var{e(ij)} = Sigma^2

    Model A2:        Yij = Mu(i) + e(ij)
                Var{e(ij)} = Sigma(i)^2

    Model A3:        Yij = Mu(i) + e(ij)
                Var{e(ij)} = exp(lalpha + log(mean(i)) * rho)

    Model  R:        Yij = Mu + e(i)
                Var{e(ij)} = Sigma^2

                              Likelihoods of Interest

                    Model      Log(likelihood)      DF         AIC
                   -------    -----------------    ----   ------------
                       A1        5.944999            5     -1.889998
                       A2        8.698072            8     -1.396144
                       A3        5.944999            5     -1.889998
                        R       0.3138778            2      3.372244
                        4        5.929054            4     -3.858109

   Additive constant for all log-likelihoods =     -36.76.   This constant added to
the
   above values gives the log-likelihood including the term that does not
   depend on the model parameters.

                               Explanation of Tests

   Test 1:  Does response and/or variances differ among Dose levels? (A2 vs. R)
   Test 2:  Are Variances Homogeneous? (A2 vs. A1)
   Test 3:  Are variances adequately modeled? (A2 vs. A3)

   Test 6a: Does Model 4 fit the data? (A3 vs 4)

                             Tests of Interest
```

Test	-2*log(Likelihood Ratio)	D. F.	p-value
Test 1	16.77	6	0.01017
Test 2	5.506	3	0.1383
Test 3	5.506	3	0.1383
Test 6a	0.03189	1	0.8583

The p-value for Test 1 is less than .05. There appears to be a difference between response and/or variances among the dose levels, it seems appropriate to model the data.

The p-value for Test 2 is greater than .1. A homogeneous variance model appears to be appropriate here.

The p-value for Test 3 is greater than .1. The modeled variance appears to be appropriate here.

The p-value for Test 6a is greater than .1. Model 4 seems to adequately describe the data.

Benchmark Dose Computations:

Specified Effect = 1.000000

Risk Type = Estimated standard deviations from control

Confidence Level = 0.950000

BMD = 0.87078

BMDL = 0.249811

BMDU = 21400

    Model A2:        Yij = Mu(i) + e(ij)
                Var{e(ij)} = Sigma(i)^2

    Model A3:        Yij = Mu(i) + e(ij)
                Var{e(ij)} = exp(lalpha + log(mean(i)) * rho)

    Model  R:        Yij = Mu + e(i)
                Var{e(ij)} = Sigma^2

                              Likelihoods of Interest

                   Model      Log(likelihood)      DF         AIC
                  -------    -----------------    ----   ------------
                      A1        5.944999           5     -1.889998
                      A2        8.698072           8     -1.396144
                      A3        5.944999           5     -1.889998
                       R       0.3138778           2      3.372244
                       4        5.929054           4     -3.858109

  Additive constant for all log-likelihoods =     -36.76.   This constant added to
the
  above values gives the log-likelihood including the term that does not
  depend on the model parameters.

                               Explanation of Tests

  Test 1:  Does response and/or variances differ among Dose levels? (A2 vs. R)
  Test 2:  Are Variances Homogeneous? (A2 vs. A1)
  Test 3:  Are variances adequately modeled? (A2 vs. A3)

  Test 6a: Does Model 4 fit the data? (A3 vs 4)

                            Tests of Interest

    Test          -2*log(Likelihood Ratio)       D.  F.          p-value
  --------        ------------------------      ------     --------------
    Test 1                        16.77           6             0.01017
    Test 2                        5.506           3              0.1383
```

```
 Test 3                        5.506           3             0.1383
Test 6a                      0.03189           1             0.8583

 The p-value for Test 1 is less than .05.   There appears to be a
 difference between response and/or variances among the dose
 levels, it seems appropriate to model the data.

 The p-value for Test 2 is greater than .1.   A homogeneous
 variance model appears to be appropriate here.

 The p-value for Test 3 is greater than .1.   The modeled
 variance appears to be appropriate here.

 The p-value for Test 6a is greater than .1.   Model 4 seems
 to adequately describe the data.

Benchmark Dose Computations:

  Specified Effect = 0.500000

         Risk Type = Estimated standard deviations from control

  Confidence Level = 0.950000

               BMD =      0.33455

              BMDL =    0.0950923

              BMDU =      1.22544
```

F.3 MODELING PROCEDURE FOR DICHOTOMOUS NONCANCER DATA

BMD modeling of dichotomous noncancer data (see Figure F-1) was conducted on the HAWC website using the U.S. EPA's BMDS Version 2.7. For these data, the Gamma, Logistic, Log-Logistic, Log-Probit, Multistage, Probit, and Weibull dichotomous models available within the software were fit using a BMR of 10% extra risk. The Multistage model is run for all polynomial degrees up to $n - 2$, where n is the number of dose groups including control. Adequacy of model fit was judged based on the χ^2 goodness-of-fit p-value ($p > 0.1$), scaled residuals at the data point (except the control) closest to the predefined BMR (absolute value < 2.0), and visual inspection of the model fit. In the cases where no best model was found to fit to the data, use of a reduced data set without the high-dose group was further attempted for modeling and the result was presented along with that of the full data set. In cases in which a

model with # parameters = # dose-groups was fit to the data set, all parameters were estimated, and no *p*-value was calculated, that model was not considered for estimating a POD *unless* no other model provided adequate fit. Among all models providing adequate fit, the BMDL from the model with the lowest AIC was selected as a potential POD when BMDL values were sufficiently close (within threefold) (see Table F-1). Otherwise, the lowest BMDL was selected as a potential POD.

APPENDIX G. QUALITY ASSURANCE

U.S. EPA has an agency-wide quality assurance (QA) policy, and that policy is outlined in the *EPA Quality Manual for Environmental Programs* (see CIO 2105-P-01-0) and follows the specifications outlined in U.S. EPA Order CIO 2105.0. The goal of the QA policy is to assure that environmental data used to support Agency decisions are of adequate quality and usability for their intended purpose.

As required by CIO 2105.0, ORD maintains a Quality Management Program, which is documented in an internal Quality Management Plan (QMP). The latest version was developed in 2013 using the *Guidance for Developing Quality Systems for Environmental Programs (QA/G-1).* An NCEA-specific QMP was also developed in 2013 as an appendix to the ORD QMP. Quality assurance for products developed within CPHEA is managed under the ORD QMP and applicable appendices.

This assessment has been designated as High Profile and is classified as QA Category A. Category A designations require reporting of all critical QA activities, including audits.

Another requirement of the Agency quality system includes the use of project-specific planning documents referred to as Quality Assurance Project Plans (QAPPs) that describe how specific data collection efforts will be planned, implemented, and assessed. Specific management of quality assurance in this assessment is documented in an Umbrella Quality Assurance Project Plan, which was developed using the U.S. EPA Guidance for Quality Assurance Project Plans (QA/G-5). The latest approved version of the QAPP is dated September 2019. During assessment development, additional QAPPs may be applied for quality assurance management. They include:

Title	Document Number	Date
Program Quality Assurance Project Plan (PQAPP) for the Provisional Peer-Reviewed Toxicity Values (PPRTVs) and Related Assessments/Documents	L-CPAD-0032718-QP	October 2015 (last updated 2020)
Umbrella Quality Assurance Project Plan for NCEA PFAS Toxicity Assessments	B-IO-0031652-QP-1-2	July 2018 (last updated September 2019)
Quality Assurance Project Plan (QAPP) for Enhancements to Benchmark Dose Software (BMDS)	B-003742-QP-1-0	July 2019

During assessment development, this project underwent quality audit:

Date	Type of Audit	Major Findings	Actions Taken
September 18, 2020	Technical System Audit	None	None

During assessment development, the assessment was subjected to external reviews by individual letters from expert peer reviewers and by other federal agency partners including the Executive Offices of the President. Peer-review reports during these review steps are available at https://www.epa.gov/pfas/learn-about-human-health-toxicity-assessment-pfbs. In addition, the assessment underwent public comment from November 21, 2018 to January 22, 2019. The public comments are available in the Docket ID No. EPA-HQ-OW-2018-0614. Prior to release, the final draft assessment was submitted to management and QA clearance. During this step the CPHEA QA director and QA managers review the project QA documentation and ensure U.S. EPA QA requirements have been met.

Acronyms and Abbreviations

bw	body weight
cc	cubic centimeters
CD	Caesarean Delivered
CERCLA	Comprehensive Environmental Response, Compensation and Liability Act of 1980
CNS	central nervous system
cu.m	cubic meter
DWEL	Drinking Water Equivalent Level
FEL	frank-effect level
FIFRA	Federal Insecticide, Fungicide, and Rodenticide Act
g	grams
GI	gastrointestinal
HEC	human equivalent concentration
Hgb	hemoglobin
i.m.	intramuscular
i.p.	intraperitoneal
IRIS	Integrated Risk Information System
IUR	inhalation unit risk
i.v.	intravenous
kg	kilogram
L	liter
LEL	lowest-effect level
LOAEL	lowest-observed-adverse-effect level
LOAEL(ADJ)	LOAEL adjusted to continuous exposure duration
LOAEL(HEC)	LOAEL adjusted for dosimetric differences across species to a human
m	meter
MCL	maximum contaminant level
MCLG	maximum contaminant level goal
MF	modifying factor
mg	milligram
mg/kg	milligrams per kilogram
mg/L	milligrams per liter
MRL	minimal risk level
MTD	maximum tolerated dose
MTL	median threshold limit
NAAQS	National Ambient Air Quality Standards
NOAEL	no-observed-adverse-effect level
NOAEL(ADJ)	NOAEL adjusted to continuous exposure duration
NOAEL(HEC)	NOAEL adjusted for dosimetric differences across species to a human
NOEL	no-observed-effect level
OSF	oral slope factor
p-IUR	provisional inhalation unit risk
p-OSF	provisional oral slope factor
p-RfC	provisional inhalation reference concentration

p-RfD	provisional oral reference dose
PBPK	physiologically based pharmacokinetic
ppb	parts per billion
ppm	parts per million
PPRTV	Provisional Peer Reviewed Toxicity Value
RBC	red blood cell(s)
RCRA	Resource Conservation and Recovery Act
RDDR	Regional deposited dose ratio (for the indicated lung region)
REL	relative exposure level
RfC	inhalation reference concentration
RfD	oral reference dose
RGDR	Regional gas dose ratio (for the indicated lung region)
s.c.	subcutaneous
SCE	sister chromatid exchange
SDWA	Safe Drinking Water Act
sq.cm.	square centimeters
TSCA	Toxic Substances Control Act
UF	uncertainty factor
µg	microgram
µmol	micromoles
VOC	volatile organic compound

PROVISIONAL PEER REVIEWED TOXICITY VALUES FOR COBALT (CASRN 7440-48-4)

Background

On December 5, 2003, the U.S. Environmental Protection Agency's (EPA's) Office of Superfund Remediation and Technology Innovation (OSRTI) revised its hierarchy of human health toxicity values for Superfund risk assessments, establishing the following three tiers as the new hierarchy:

1. EPA's Integrated Risk Information System (IRIS).

2. Provisional Peer-Reviewed Toxicity Values (PPRTV) used in EPA's Superfund Program.

3. Other (peer-reviewed) toxicity values, including:

   - Minimal Risk Levels produced by the Agency for Toxic Substances and Disease Registry (ATSDR),
   - California Environmental Protection Agency (CalEPA) values, and
   - EPA Health Effects Assessment Summary Table (HEAST) values.

A PPRTV is defined as a toxicity value derived for use in the Superfund Program when such a value is not available in EPA's Integrated Risk Information System (IRIS). PPRTVs are developed according to a Standard Operating Procedure (SOP) and are derived after a review of the relevant scientific literature using the same methods, sources of data, and Agency guidance for value derivation generally used by the EPA IRIS Program. All provisional toxicity values receive internal review by two EPA scientists and external peer review by three independently selected scientific experts. PPRTVs differ from IRIS values in that PPRTVs do not receive the multi-program consensus review provided for IRIS values. This is because IRIS values are generally intended to be used in all EPA programs, while PPRTVs are developed specifically for the Superfund Program.

Because new information becomes available and scientific methods improve over time, PPRTVs are reviewed on a five-year basis and updated into the active database. Once an IRIS value for a specific chemical becomes available for Agency review, the analogous PPRTV for that same chemical is retired. It should also be noted that some PPRTV manuscripts conclude that a PPRTV cannot be derived based on inadequate data.

Disclaimers

Users of this document should first check to see if any IRIS values exist for the chemical of concern before proceeding to use a PPRTV. If no IRIS value is available, staff in the regional Superfund and RCRA program offices are advised to carefully review the information provided in this document to ensure that the PPRTVs used are appropriate for the types of exposures and circumstances at the Superfund site or RCRA facility in question. PPRTVs are periodically

updated; therefore, users should ensure that the values contained in the PPRTV are current at the time of use.

It is important to remember that a provisional value alone tells very little about the adverse effects of a chemical or the quality of evidence on which the value is based. Therefore, users are strongly encouraged to read the entire PPRTV manuscript and understand the strengths and limitations of the derived provisional values. PPRTVs are developed by the EPA Office of Research and Development's National Center for Environmental Assessment, Superfund Health Risk Technical Support Center for OSRTI. Other EPA programs or external parties who may choose of their own initiative to use these PPRTVs are advised that Superfund resources will not generally be used to respond to challenges of PPRTVs used in a context outside of the Superfund Program.

Questions Regarding PPRTVs

Questions regarding the contents of the PPRTVs and their appropriate use (e.g., on chemicals not covered, or whether chemicals have pending IRIS toxicity values) may be directed to the EPA Office of Research and Development's National Center for Environmental Assessment, Superfund Health Risk Technical Support Center (513-569-7300), or OSRTI.

INTRODUCTION

The Integrated Risk Information System (IRIS) does not report a Reference Dose (RfD) for cobalt (U.S. EPA, 2007). The Health Effects Assessment Summary Tables (HEAST) (U.S. EPA, 1997a) and Drinking Water Standards and Health Advisories list (U.S. EPA, 2004) likewise do not contain an RfD for cobalt. The Chemical Assessments and Related Activities (CARA) lists (U.S. EPA, 1991, 1994a) report a Health Effect Assessment (HEA) for cobalt (U.S. EPA, 1987). The 1987 HEA derived a chronic RfD of 0.005 mg cobalt/kg-day based on a no-observed-adverse-effect level (NOAEL) of 5 mg cobalt/kg-day for testicular effects in a subchronic rat study (Nation et al., 1983). The Agency for Toxic Substances and Disease Registry (ATSDR) Toxicological Profile for cobalt and its compounds reports an oral Minimal Risk Level (MRL) for intermediate exposure of $1x10^{-2}$ mg/kg-day (ATSDR, 2004), based on a lowest-observed-adverse-effect level (LOAEL) of approximately 1 mg cobalt/kg-day for polycythemia in humans (Davis and Fields, 1958). ATSDR (2004) did not derive an oral MRL for chronic exposure. This MRL for intermediate exposure was based on the polycythemic effect of cobalt exposure (1 mg cobalt/kg-day, Davis and Fields, 1958) by application of an UF of 10 for a LOAEL and an UF of 10 for human variability. The World Health Organization (WHO, 2005) has not published an Environmental Health Criteria (EHC) document on cobalt. An International Agency for Research on Cancer (IARC) Monograph on cobalt and its compounds (IARC, 2006) and the National Toxicology Program (NTP) Status Reports (NTP, 2005) were searched for relevant information.

IRIS (U.S. EPA, 2007) does not report a Reference Concentration (RfC) for cobalt. The HEAST (U.S. EPA, 1997a) likewise does not list an RfC for cobalt. The cobalt HEA (U.S. EPA, 1987) derived a subchronic inhalation RfC of $9x10^{-5}$ mg/m^3 based on a LOAEL of 0.1 mg/m^3 for

respiratory effects in a 3-month study in swine (Kerfoot et al., 1975). A chronic inhalation RfC of $9x10^{-6}$ mg/m^3 was derived from the same study. The ATSDR Toxicological Profile for cobalt and its compounds reports an inhalation MRL for chronic exposure of $1x10^{-4}$ mg/m^3 (ATSDR, 2004), based on a NOAEL of 0.0053 mg cobalt/m^3 for decreased pulmonary function in humans (Nemery et al., 1992). The American Conference of Governmental Industrial Hygienists (ACGIH, 2004) has set a Threshold Limit Value-Time-Weighted Average (TLV-TWA) of 0.02 mg/m^3 for cobalt and inorganic cobalt compounds, expressed as cobalt, based on respiratory and cardiovascular effects. The National Institute for Occupational Safety and Health (NIOSH, 2005) Recommended Exposure Limit (REL) TWA for cobalt is 0.05 mg/m^3, based on effects in the respiratory system. The Occupational Safety and Health Administration (OSHA, 2005) Permissible Exposure Limit (PEL) is 0.1 mg/m^3.

IRIS (U.S. EPA, 2007) does not report a cancer classification, slope factor or unit risk for cobalt. The HEAST (U.S. EPA, 1997a) and Drinking Water Standards and Health Advisories list (U.S. EPA, 2004) likewise do not report carcinogenicity assessments for cobalt. The CARA lists (U.S. EPA, 1991, 1994a) do not report a cancer classification or an estimate of the carcinogenic potency of stable cobalt compounds due to a lack of pertinent data. An IARC Monograph on cobalt and its compounds (IARC, 2006) classified cobalt sulfate and other soluble cobalt (II) salts as "possibly carcinogenic to humans." ACGIH (2004) has classified cobalt in category A3 – confirmed animal carcinogen with unknown relevance to humans.

Literature searches for studies relevant to the derivation of provisional toxicity values for cobalt were conducted initially through 2000 in TOXLINE (supplemented with BIOSIS and NTIS updates), MEDLINE, TSCATS, RTECS, CCRIS, DART, EMIC/EMICBACK, HSDB, GENETOX and CANCERLIT and subsequently from 2000 to August 2005 in MEDLINE, TOXLINE (NTIS subfile), TOXCENTER, TSCATS, CCRIS, DART/ETIC, GENETOX, HSDB, RTECS and Current Contents. An updated literature search was performed in MEDLINE from 2005 to June 2008.

REVIEW OF PERTINENT DATA

Human Studies

Overview

Indicators of adverse health effects in humans following oral exposure to cobalt include increased erythrocyte number and hemoglobin (Taylor et al., 1977; Duckham and Lee, 1976; Davis and Fields, 1958), cardiomyopathy (Morin et al., 1971; Alexander, 1969, 1972) and decreased iodine uptake by the thyroid (Roche and Layrisse, 1956). Cardiomyopathy is an endpoint of concern for cobalt in humans; however, it is highly likely that alcohol consumed in "beer-cobalt cardiomyopathy," as well as other factors, such as smoking, played a role in the effects that were observed. Cobalt is a sensitizer in humans by any route of exposure. Sensitized individuals may react to inhalation of cobalt by developing asthma; ingestion or dermal contact with cobalt may result in development of dermatitis. Several studies have suggested that

cross-sensitization may occur between cobalt and nickel (Shirakawa et al., 1990; Lammintausta et al., 1985; Bencko et al., 1983; Rystedt and Fisher, 1983).

Respiratory effects, including respiratory irritation, wheezing, asthma, pneumonia and fibrosis, have been widely reported in humans exposed to cobalt by inhalation (for review, see Barceloux, 1999; Lison, 1996). Epidemiology studies show decreased pulmonary function in workers exposed to inhaled cobalt (Nemery et al., 1992; Gennart and Lauwerys, 1990). Results of studies investigating cancer incidence in workers exposed to inhaled cobalt are suggestive of a possible association between exposure to cobalt and respiratory tumors (Tuchsen et al., 1996; Mur et al., 1987; Morgan, 1983).

Oral Exposure

In humans, cobalt stimulates production of red blood cells through increased production of the hormone erythropoietin and has been explored for use in the treatment of anemia (Smith and Fisher, 1973; Duckham and Lee, 1976). Increases in red blood cell counts and blood hemoglobin have been reported in non-anemic volunteers (Davis and Fields, 1958) and in anephric anemic patients (Taylor et al., 1977; Duckham and Lee, 1976).

Reversible polycythemia (increase in blood cell number) was reported (see Table 1) in six healthy adult males following treatment with 150 mg cobalt chloride per day for 22 days (Davis and Fields, 1958). Five subjects received 150 mg cobalt chloride/day for the entire exposure period and a sixth subject initially received 120 mg cobalt chloride/day, which was later increased (time not specified) to 150 mg/day. Cobalt chloride was administered as a 2% solution diluted in either water or milk. Assuming an average body weight of 70 kg, 150 mg cobalt chloride/day corresponds to approximately 1 mg cobalt/kg-day. Outcomes assessed in this study were red blood cell count, hemoglobin percentage, leukocyte count, reticulocyte percentage and thrombocyte count. Polycythemia was observed in all six patients within 7 to 22 days of treatment as demonstrated by increases in red blood cell counts ranging from 0.5 to 1.19 million (approximately 16-20% increase above pre-treatment levels) and increases in hemoglobin levels ranging from 6 to 11% above pretreatment values. In five of the six subjects, reticulocyte levels were elevated, reaching at least twice the pre-experiment values. Thrombocyte and total leukocyte counts were not significantly different from pretreatment values. Erythrocyte counts returned to pre-treatment levels within 9 to 15 days after cobalt administration was discontinued. The fact that leucocyte counts remained relatively constant throughout the experiment supports the concept that this is a true polycythemia. As such, based on the results of this study, 1 mg cobalt/kg-day was identified as a LOAEL for cobalt-induced polycythemia in humans.

Table 1. Hematopoietic, Thyroid and Developmental Effects of Cobalt (Co) via Oral Route

Target Organ	Species	Effect	Dosage (mg Co/kg-day)
Hematopoietic Effects	Human Human Rat	Reversible Effect (Polycythemia) ↑ Hemoglobin and ↑ RBC Hematopoietic effect	1.0 0.16 – 0.32* 0.5 – 32.0
Thyroid	Human Mice	↓ Iodine uptake Histopathological changes in thyroid	1.0 48.0
Fetus	Rat	Developmental toxicity	5.2 – 21.0
Heart	Rat	↓ Myocardial function	8.0

*Therapeutic doses for anemic patients

Duckham and Lee (1976) treated 12 anephric patients on dialysis with 25 to 50 mg cobalt chloride daily for approximately 12 weeks. Assuming an average body weight of 70 kg, doses of 25 and 50 mg cobalt chloride/day are equivalent to 0.16 and 0.32 mg cobalt/kg-day, respectively. During the exposure period, patients also received daily treatment with 100 mg ferrous sulfate and 50 mg ascorbic acid. Within approximately 2 months of initiation of treatment with cobalt, an increase in hemoglobin of 26-70% was observed in patients treated with 0.32 mg cobalt/kg-day. Serum cobalt levels appeared to reach steady state within 2 months of exposure (approximately 40-100 μg cobalt/100 mL). In a subgroup of three patients, continuation of treatment with 0.16 mg cobalt/kg-day for approximately 3 months maintained elevated hemoglobin levels. Hemoglobin levels decreased rapidly when cobalt therapy was discontinued. The authors did not report whether therapy with ferrous sulfate and ascorbic acid was discontinued at the same time. Results of this study are difficult to interpret because patients were anephric and on dialysis, which may have altered cobalt pharmacokinetics and dose-effect relationships. Furthermore, since it is well established that treatment with ferrous sulfate alone increases hemoglobin concentration (Hillman, 2001), concomitant therapy with iron is a confounding factor. Since this study did not evaluate the response of patients treated with ferrous sulfate alone, it is not possible to determine the relative contributions of iron and cobalt to the observed increases in hemoglobin. Thus, adverse effect levels cannot be confidently determined for cobalt. In a separate study, a group of eight anephric patients with refractory anemia were treated with 25 to 50 mg cobalt chloride daily for 12 to 36 weeks (Taylor et al., 1977). Increased hemoglobin concentration and decreased requirement for blood transfusions were observed (Taylor et al., 1977). Data on hemoglobin concentrations (or other indicators of polycythemia) were not reported.

Pregnant women given 75 to 100 mg cobalt chloride/day with no other treatment for 90 days to 6 months did not experience pregnancy-induced reductions in hematocrit and hemoglobin levels, compared to untreated controls (Holly, 1955). However, daily treatment with 1 g ferrous sulfate alone or combined daily treatment with 60 to 90 mg cobalt chloride and 0.8 to 1.2 g ferrous sulfate prevented pregnancy-related decreases in hematocrit and hemoglobin levels. The response to combined cobalt chloride and iron therapy was more pronounced than the

response to iron therapy alone. In patients treated with iron only, decreases in hemoglobin and hematocrit were prevented in approximately 80% of patients, compared to 100% of patients treated with combined cobalt chloride and iron.

Cardiomyopathy has been observed in association with consumption of large quantities of beer containing cobalt chloride (introduced into the beer to stabilize the foam) (Alexander, 1969, 1972; Morin et al., 1971). Exposure estimates in reported cases range from 0.04 to 0.14 mg cobalt/kg-day (corresponding to approximately 8-30 pints of beer daily) over a period of years (Alexander, 1969, 1972; Morin et al., 1971). The cardiomyopathy in the beer drinkers, referred to in the literature as "beer-cobalt cardiomyopathy," was fatal to 43% of the subjects within several years, with approximately 18% of these deaths occurring within the first several days following diagnosis. Beer-cobalt cardiomyopathy appeared to be similar to alcoholic cardiomyopathy and beriberi; however, the onset of the beer-cobalt cardiomyopathy was much more abrupt. The practice of adding cobalt to beer to stabilize the foam has been discontinued. It should be noted, however, that the cardiomyopathy may also have been due to the fact that the beer drinkers had protein-poor diets and may have had prior or concurrent cardiac and hepatic damage from alcohol abuse. Due to the potential adverse effects of poor nutrition and/or chronic ethanol exposure on cardiovascular health, it is difficult to delineate the contribution of oral cobalt exposure to the observed cardiomyopathy. As such, no adverse effects levels can be determined for cobalt-induced cardiotoxicity.

The thyroid also appears to be a target organ for cobalt (see Table 1). Treatment of 12 euthyroid (normal thyroid) patients with 150 mg cobalt chloride/day (equivalent to 1 mg cobalt/kg-day, assuming a body weight of 70 kg) for 2 weeks resulted in a greatly reduced uptake of 48-hour radioactive iodine by the thyroid when measured after 1 week of exposure to cobalt, with uptake nearly abolished completely by the second week of exposure to cobalt (Roche and Layrisse, 1956). It should be noted that when cobalt treatment was discontinued, iodine uptake returned to pre-treatment reported values. No other clinical details were provided for the human subjects. Therefore, based on the results of this study, a LOAEL of 1 mg cobalt/kg-day was identified for decreased radioactive iodine uptake in human thyroid following oral cobalt exposure. In another small clinical study (Paley et al., 1958), decreased radioactive iodine uptake was reported in two of four (3 males, 1 female) euthyroid patients orally administered 37.5 mg cobalt/day as cobalt chloride (equivalent to 0.54 mg cobalt/kg-day, assuming a body weight of 70 kg) for 10 to 14 days. One of the two subjects with reported decreased iodine uptake had received i.v. cobalt in addition to oral cobalt intake, and had been previously diagnosed with hyperthyroidism (although was clinically euthyroid at the time of study). The i.v. dosing may have raised the internal cobalt concentration to a level greater than the reported 0.54 mg dosage based upon oral dosing of 37.5 mg/day in other subjects that did not receive i.v. cobalt. Of the remaining three subjects, 24-hour iodine uptake was not significantly decreased following oral cobalt exposure compared to corresponding pre-treatment values (based on pairwise t-test). The oral cobalt dose of 0.54 mg cobalt/kg-day represents a NOAEL for thyroid effects in humans. It should be noted that the Roche and Layrisse (1956) and Paley et al. (1958) studies lack details pertinent to other clinical conditions (e.g. including effects on thyroid stimulating hormone [TSH]) of these patients; thus the mechanism for the effect of cobalt on thyroidal iodine uptake cannot be ascertained. However, cobalt appears to increase thiocyanate-

induced release of radioiodine from the thyroid, suggesting a possible effect on binding of iodine (e.g., iodination of thyroglobulin) in the thyroid gland.

Cobalt has been found to be a sensitizer in humans. Individuals are sensitized following dermal or inhalation exposure, but flares of dermatitis may be triggered following cobalt ingestion. In a small clinical study, several patients with eczema of the hands were challenged orally with 1 mg cobalt sulfate (0.005 mg cobalt/kg-day, assuming a body weight of 70 kg) in tablet form once per week for 3 weeks; this translates to an estimated average daily dose of 0.0007 mg cobalt/kg-day (1 day a week/7 days a week × 0.005 mg cobalt/kg-day). 28/47 patients had a flare of dermatitis following the oral challenge (Veien et al., 1987). All 47 patients had positive dermal patch tests to cobalt (13 to cobalt alone and 34 to nickel and cobalt) and 7 of the 13 patients who had patch-tested positive to cobalt alone reacted to the oral challenge. These results suggest that cobalt allergy can be induced from oral ingestion exposures to cobalt. Although the exposure levels associated with sensitization to cobalt following inhalation or dermal exposure have not been established, interrelationships have been found to exist between cobalt and nickel sensitization (Bencko et al., 1983; Rystedt and Fisher, 1983; Veien et al., 1987). In guinea pigs, nickel and cobalt sensitization appear to be interrelated and mutually enhancing (Lammintausta et al., 1985). Therefore, it is possible that in people sensitized by nickel, exposure to cobalt may result in an allergic reaction.

Inhalation Exposure

Numerous studies have investigated health effects in workers occupationally exposed to cobalt-bearing dust (Linna et al., 2003; Swennen et al., 1993; Auchincloss et al., 1992; Cugell, 1992; Nemery et al., 1992; Prescott et al., 1992; Gennart and Lauwerys, 1990; Meyer-Bisch et al., 1989; Raffn et al., 1988; Shirakawa et al., 1988, 1989; Sprince et al., 1988; Kusaka et al., 1986a,b; Demedts et al., 1984; Davison et al., 1983). However, many of these studies are of limited utility for risk assessment due to inadequate characterization of exposure and/or effects. Four studies were considered to be potentially suitable for RfC derivation. Two of these focused exclusively on respiratory effects (Nemery et al., 1992; Gennart and Lauwerys, 1990); one studied only thyroid effects (Prescott et al., 1992) and one considered multiple endpoints (Swennen et al., 1993). The populations studied included diamond-cobalt saw manufacturers, diamond polishers, plate painters and cobalt production workers. All four studies were cross-sectional design.

Several studies have examined the effects of hard metal, a mixture containing approximately 20% cobalt with the remainder being primarily tungsten carbide. Exposure of humans to hard metal has been shown to result in an increase in cancer mortality (Moulin et al., 1998; Lasfargues et al., 1994) as well as a number of other diseases, including asthma and pulmonary fibrosis (for reviews, see Barceloux, 1999; Lison, 1996). There is substantial evidence from animal studies that tungsten, although it acts as an inert dust by itself, can potentiate the effects of cobalt on the respiratory tract (Lasfargues et al., 1995; Lison et al., 1995, 1996; Swennen et al., 1993). For this reason, studies of hard metal were not given further consideration.

Gennart and Lauwerys (1990) studied ventilatory function in workers at a plant producing diamond-cobalt circular saws. The form of cobalt used in diamond polishing is primarily metallic cobalt powder; specific cobalt species contained in this powder were not identified. The exposed population consisted of 48 workers (34 males and 14 females) who agreed to participate in the study (an additional 27 workers declined). Exposure duration for these workers ranged from 0.1 to 32 years, with an average of approximately 6 years. The work involved weighing and mixing cobalt powder and microdiamond particles (and possibly small amounts of other undisclosed substances), cold pressing, heating and hot pressing. After sintering, the pieces were welded onto steel disks. These operations were performed in two rooms called the mixing room and the oven room, where all the examined workers spent most of their time. Controls consisted of 23 workers (11 males and 12 females) from other factories in the same area who were not exposed to known pneumotoxic chemicals. Personal air samples were collected at different workplaces during half a workshift. Subjects filled out a questionnaire regarding occupational and medical histories, smoking habits and pulmonary symptoms; gave a urine sample for cobalt determination; and participated in lung function tests. Cobalt concentrations varied from 9.4 to 2875 $\mu g/m^3$ in the mixing room (geometric mean=135.5 $\mu g/m^3$) and from 6.2 to 51.2 $\mu g/m^3$ in the oven room (geometric mean=15.2 $\mu g/m^3$). The prevalence of respiratory symptoms, such as cough, sputum and dyspnea, were significantly increased in the exposed workers compared to the control group (numeric data not reported). Mean predicted values of FEV_1 (forced expiratory volume in 1 second adjusted for body size) and FVC (forced vital capacity) were significantly lower, and the prevalence of abnormal values was higher in the cobalt exposed workers (both smokers and non-smokers) compared to the control group. In controls, FEV_1 and FVC were 95.4 and 101.6 percent of predicted values, respectively. Mean percent predicted FEV_1 and FVC in exposed non-smokers were 87.1 and 92.3, respectively, and in exposed smokers were 83.9 and 93.4, respectively. Among non-smokers, all measures of pulmonary function were lower in workers exposed for 5 years or more than in those exposed to cobalt for a shorter period of time.

Nemery et al. (1992) conducted a cross-sectional study of cobalt exposure and respiratory effects in diamond polishers who were primarily exposed to metallic cobalt-containing dust; species of cobalt in the dust samples were not identified. The study group was composed of 194 polishers working in 10 different workshops. In two of these workshops (#1, 2), the workers used cast iron polishing disks almost exclusively, and in the others, they primarily used cobalt-containing disks. The number of subjects from each workshop varied from 6 to 28 and the participation rate varied from 56 to 100%. The low participation in some workshops reflects the fact that only workers who used cobalt disks were initially asked to be in the study; low participation is not due to a high refusal rate (only eight refusals were documented). More than a year after the polishing workshops were studied, an additional three workshops with workers engaged in sawing diamonds, cleaving diamonds or drawing jewelry were studied as an unexposed control group (n=59 workers). Subjects were asked to fill out a questionnaire regarding employment history, working conditions, medical history, respiratory symptoms and smoking habits; to give a urine sample for cobalt determination; and to undergo a clinical examination and lung function tests. Both area air samples and personal air samples were collected (always on a Thursday). Sampling for area air determinations started 2 hours after work began and continued until 1 hour before the end of the work day. Personal air samples were collected from the breathing zone of a few workers per workshop for four successive

1-hour periods. Air samples were analyzed for cobalt and iron. In addition, personal air samplers were used to sample the air 1 cm above the polishing disks. These samples were analyzed for the entire spectrum of mineral and metallic compounds. Air samples were not obtained at one of the polishing workshops (#4); however, this workshop was reported to be almost identical to an adjoining workshop (#3) for which samples were obtained. Urinary cobalt levels were similar between workers in these two workshops, so exposure was considered to be similar as well.

Results of area and personal air sampling were strongly correlated (R=0.92), with area air sampling reporting lower concentrations than personal air samples in all workshops except one (#9) (Nemery et al., 1992). In this workshop, personal air samples appeared to be artificially low in comparison to area air samples and urinary cobalt levels of the workers. When this workshop was excluded, a strong correlation (R=0.85-0.88) between urinary cobalt and cobalt in the air was observed. Based on urinary cobalt levels, the predicted concentration of cobalt expected in personal air samples from workshop #9 was approximately 45 $\mu g/m^3$ (the mean value actually reported was 6 $\mu g/m^3$). The polishing workshops were divided into two groups: those with low exposure to cobalt (#1-5, n=102) and those with high exposure to cobalt (#6-10, n=91). Mean cobalt exposure concentrations were 0.4, 1.6 and 10.2 $\mu g/m^3$ by area air sampling and 0.4, 5.3 and 15.1 $\mu g/m^3$ by personal air sampling in the control, low-exposure and high-exposure groups, respectively. The inclusion of the apparently biased personal air samples from workshop #9 means that the reported mean cobalt exposure in the high-exposure group obtained by personal air sampling (15.1 $\mu g/m^3$) may be lower than the true value. Air concentrations of iron were highest in the two polishing workshops that used iron disks and the sawing workshop (highest value=62 $\mu g/m^3$), and were not correlated with cobalt levels. Analysis of samples taken near the disks showed the presence of cobalt, with occasional traces of copper, zinc, titanium, manganese, chromium, silicates and silicon dioxide. No tungsten was detected. Some workers may have previously been exposed to asbestos since pastes containing asbestos had been used in the past to glue the diamonds onto holders. However, since the asbestos was in its non-friable form, exposure was insufficient to produce functional impairment. Smoking habits were similar in workers from the high-exposure, low-exposure and control groups. Duration of exposure was not discussed.

Workers in the high-exposure group were more likely than those in the other groups to complain about respiratory symptoms; the prevalences of eye, nose and throat irritation and cough, and the fraction of these symptoms related to work, were significantly increased in the high-exposure group (Nemery et al., 1992). Workers in the high-exposure group also had significantly lower lung function compared to controls and low-exposure group workers, as assessed by FVC, FEV_1, MMEF (forced expiratory flow between 25 and 75% of the FVC) and mean PEF (peak expiratory flow rate), although the prevalence of abnormal values did not differ significantly between exposure categories. In controls, FVC, FEV_1 and MMEF were approximately 110, 107 and 94 percent of predicted values, respectively, compared to approximately 105, 104 and 87 percent of predicted values, respectively, in the high-exposure group workers. Results in the low-exposure group did not differ from controls. The effect on spirometric parameters in the high exposure group was present in both men and women. Women seemed to be affected more than men; however, the interaction between exposure and sex was not significant (two-way analysis of variance). Smoking was found to exert a strong effect on

lung function; however, lung function level remained negatively correlated with exposure to cobalt, independent of smoking.

A cobalt dose-effect relationship is evident from the Nemery et al. (1992) study, based on a multivariate regression analysis of urinary cobalt and lung function measurements. Increasing urinary cobalt concentration (approximate range <1-70 μg cobalt/g creatinine) was significantly (p<0.05) associated with co-variate-adjusted decreasing forced expiratory volume (FEV1%) and forced vital capacity (FVC%). Significant co-variates retained in the regression analysis included gender and smoking. The model predicted 3% and 4% decreases in FEV1% and FVC%, respectively, in association with a 10-fold increase in urinary cobalt concentration. The approximate mean urinary cobalt levels of the control and high exposure groups were 2 and 20 μg cobalt/g creatinine, respectively. The magnitude of the cobalt effect was similar to the predicted effect of smoking, approximately 3-4% decrease in FEV1% and FVC%. Cobalt concentration determined from personal air sampling may be more representative of airborne cobalt exposure than area sampling. As such, 5.3 $\mu g/m^3$ and 15.1 $\mu g/m^3$ represent a NOAEL and LOAEL, respectively, for decreased pulmonary function and increased symptoms of airway irritation.

Swennen et al. (1993) conducted a cross-sectional study of workers exposed to metallic cobalt and various inorganic cobalt salts and oxides (specific species not identified) at a cobalt plant producing these materials from cobalt metal cathodes and scrap metal. The study group included 82 male workers from the cobalt plant who had no history of lung disease prior to employment and who had never been exposed to other pneumotoxic chemicals. Methods for selection or exclusion of subjects in constructing the cohort and participation were not reported. The control group comprised 82 age-matched workers from the mechanical workshop of a nearby plant owned by the same company. Workers filled out a questionnaire regarding occupational history, respiratory complaints and smoking habits; received a routine clinical examination; participated in lung function tests; had a chest radiograph taken; and gave blood and urine samples (before and after working on Monday and Friday of one week) for determination of cobalt content as well as hematological and serum chemistry analyses. Exposure was monitored by personal air samplers worn by each cobalt worker for 6 hours on both Monday and Friday.

Workers in the cobalt plant were exposed to cobalt concentrations ranging from 1 to 7772 $\mu g/m^3$ (Swennen et al., 1993). The geometric mean exposure concentration was 125 $\mu g/m^3$. Exposure duration ranged from 0.3 to 39.4 years, with an average exposure of 8.0 years. A significantly higher number of exposed workers reported dyspnea than did controls. The increase occurred primarily among smokers although no significant interaction was found between smoking and exposure to cobalt. Based on a logistic regression model, the probability of dyspnea during exercise was significantly associated with increasing cobalt concentration in the air or urine. The parameters of the model were not reported. The clinical examinations detected significantly increased prevalence of skin disorders (eczema, erythema) (51 vs. 25%) and wheezing (16 vs. 6%) in the exposed group compared to controls. Lung function tests did not differ between the two groups; however, a few significant trends were noted: the FEV_1/VC (forced expiratory volume in one second/vital capacity) ratio decreased with increasing concentration of cobalt in the air and urine, and the RV (residual volume) and TLC (total lung

capacity) increased with increasing duration of exposure. No lung abnormalities were found by chest radiographs in either group. Blood analyses did not show polycythemia, and in fact, there were slight, but significant, decreases in red blood cell count, hemoglobin and hematocrit in the exposed workers. White blood cell counts were significantly increased. Serum levels of the thyroid hormone T3 (triiodothyronine) were slightly (7%), but significantly, decreased in the exposed group, while T4 (thyroxine) and TSH (thyrotropin) were not affected. Serum markers for cardiomyopathy (i.e., myocardial creatine kinase) were unchanged.

Prescott et al. (1992) conducted a cross-sectional study to investigate the effects of cobalt exposure on thyroid volume in female plate painters. The test group included 61 female plate painters exposed to cobalt blue dyes in two porcelain factories. The control group consisted of 48 unexposed women working at the same factories. The dyes used in the two factories differed; factory I (36 workers) used cobalt aluminate, which is insoluble, and factory II (25 workers) used cobalt-zinc silicate, which was reported to be "semi-soluble." Workers were exposed to cobalt during the painting procedure when the plates were spray-painted (under a fume hood) two or three times with the water-based cobalt blue underglaze and when the excess color was removed with a brush after drying. Cobalt concentrations were reported to be approximately 0.05 mg/m^3 in the workplaces (no further details on air levels were reported). The average duration of exposure was 14.6 years in group I workers and 16.2 years in group II workers. Subjects filled out a questionnaire regarding health, use of medicines, day of menstrual cycle, employment information and smoking habits and agreed to give blood and urine samples for determination of thyroid hormone levels (e.g. thyroxine (T4), triiodothyronine (T3), and thyroid stimulating hormone) and cobalt concentration, respectively, and to undergo ultrasonography to determine volume of the thyroid gland.

Urinary cobalt levels were similar in group I exposed workers and controls (Prescott et al., 1992). Group II workers exposed to semi-soluble cobalt-zinc silicate had urinary cobalt levels that were approximately 10-fold higher than controls. Group I workers did not differ from controls for any of the thyroid parameters measured; however, Group II workers had a significant 22% increase in serum T4 (thyroxine) levels. Mean thyroid volume was lower in this group as well, although the difference from controls (16.1 mL in group II vs. 19.2 mL in controls and 18.7 mL in group I) was not statistically significant. The occurrence of respiratory effects in these workers was not reported.

Results of three studies investigating cancer incidence in workers exposed to cobalt by the inhalation route (Tuchsen et al., 1996; Mur et al., 1987; Morgan, 1983) are suggestive of a possible association between exposure to cobalt and respiratory tumors. Morgan (1983) investigated the health and causes of death of 49 men occupationally exposed to cobalt salts and oxides (specific species not identified) in a manufacturing plant in South Wales. During the study period, 33 men died (five with lung cancer and three with cancer at other sites). The expected number of deaths was 3.0 for lung cancer and 4.1 for cancers at other sites, based on national statistics, resulting in mortality ratios of 1.7 and 0.73, respectively (statistical analysis of data not reported).

Mur et al. (1987) analyzed the mortality of a cohort of 1143 workers in a plant that refined and processed cobalt and sodium. The plant workers may have been involved in multiple processing applications utilizing different forms of cobalt including cobalt chloride, oxides and

other salts (specific species not identified). An increase in deaths [Standard Mortality Ratio (SMR) = 4.66; 95% confidence interval (CI) = 1.46-10.64] resulting from lung cancer was observed in workers based on four cases observed in the exposed group and one case expected based on French national statistics. In a study within the cohort that controlled for age and smoking habits, 44% (four workers) in the exposed group and 17% (three workers) in the control group died of lung cancer. The authors indicated that the differences were not statistically significant and that the workers were exposed to arsenic and nickel in addition to cobalt. The exposure levels of cobalt were not reported.

Tuchsen et al. (1996) analyzed the cancer incidence of a cohort of 874 women who worked in one of two factories (382 from one factory, 492 from a second factory) applying a cobalt-based (cobalt-aluminate spinel) plate underglaze. From unexposed areas of factory I, 520 referents were selected. Both groups were compared to statistics for all Danish women in the same calendar year. During the 5-year follow-up period, the overall cancer incidence was only slightly elevated in exposed workers, while the incidence of lung cancers was significantly increased [Standard Incidence Ratio (SIR) = 2.35; 95% CI = 1.01-4.6]. The incidence of lung cancers in the referents (not exposed to cobalt) was greater than that of all Danish women, but the difference was not statistically significant. Exposure characterization prior to 1980 was not described, while exposures after 1980 were variable and reported as a mean concentration for a given year. Exposures were generally in the range of 0-1 mg cobalt/m^3 except for 2 years, during which they were greater.

Animal Studies

Overview

Studies in animals show that oral exposure to cobalt produces effects similar to those observed in humans, including increases in red blood cells and hemoglobin (Domingo et al., 1984; Krasovskii and Fridlyand, 1971; Murdock, 1959; Holly, 1955; Stanley et al., 1947), thyroid effects (Shrivastava et al., 1996) and cardiac effects (Haga et al., 1996; Pehrsson et al., 1991; Mohiuddin et al., 1970). Other findings in animals not reported in humans include neurobehavioral changes (Singh and Junnarkar, 1991; Bourg et al., 1985; Krasovskii and Fridlyand, 1971) and testicular toxicity (Anderson et al., 1992, 1993; Pedigo et al., 1988; Corrier et al., 1985; Mollenhauer et al., 1985; Domingo et al., 1984; Nation et al., 1983). Developmental toxicity studies in rats and mice provide evidence that high oral doses of cobalt may produce developmental effects in animals, in some cases in the absence of overt maternal toxicity (Szakmary et al., 2001; Paternain et al., 1988; Domingo et al., 1985).

Animal data support the conclusion that the respiratory tract is the critical target for inhaled cobalt (NTP, 1991; Bucher et al., 1990; Wehner et al., 1977). Subchronic inhalation exposure to cobalt resulted in cytotoxicity and reparative proliferation in all regions of the respiratory tract in rats and mice (NTP, 1991; Bucher et al., 1990). Available chronic animal studies have demonstrated the carcinogenic potential of inhaled cobalt in male and female rats and mice, with alveolar and bronchiolar tumors being the most prevalent (Bucher et al., 1999; NTP, 1998).

Oral Exposure

Studies in rats show that subchronic oral exposure to cobalt chloride increases red blood cell counts and hemoglobin levels with NOAELs ranging from 0.05 to 0.62 mg cobalt/kg-day (Krasovskii and Fridlyand, 1971; Stanley et al., 1947) and LOAELs ranging from 0.5 to 32 mg cobalt/kg-day (Domingo et al., 1984; Krasovskii and Fridlyand, 1971; Murdock, 1959; Holly, 1955; Stanley et al., 1947). In general, effects in animal studies were observed at higher exposure levels than those reported in humans.

Effects of cobalt on red blood cells and hemoglobin were investigated in Sprague-Dawley rats treated with 2.5, 10, and 40 mg cobalt chloride hexahydrate/kg-day (equivalent to 0.62, 2.5, and 9.9 mg cobalt/kg-day, respectively) for 8 weeks (Stanley et al., 1947). After 8 weeks of exposure, increases in hemoglobin and red blood cell number were observed in the 2.5 and 9.9 mg cobalt/kg-day treatment groups. Statistical significance was not reported.

Hemoglobin and hematocrit were significantly increased in male Sprague-Dawley rats exposed to 500 ppm cobalt chloride in drinking water, equivalent to approximately 32 mg cobalt/kg-day (assuming a water intake of 0.139 L/kg-day for male Sprague-Dawley rats; U.S. EPA, 1988), for 3 months (Domingo et al., 1984). Compared to controls, hematocrit and hemoglobin were both increased by approximately 30% at the end of the 3-month exposure period, with increases observed within the first 2 weeks of exposure (numeric data not presented). Following the 3-month exposure period, histopathological examination showed no treatment-related morphological or ultrastructural changes to any organ. Increased tissue weights were observed for spleen, heart and lungs, and testicular weight was decreased compared to controls. Based on the results of this study, 32 mg cobalt/kg-day was identified as a subchronic LOAEL for increased hematocrit and hemoglobin and decreased testicular weight in rats.

In rats exposed to 40 mg cobalt chloride/kg-day (equivalent to 18 mg cobalt/kg-day) for 4 months, hemoglobin and red blood cell count were increased by 37 and 21%, respectively, compared to controls (Holly, 1955). Similar effects were observed following concomitant administration of 40 mg cobalt chloride/kg-day and 200 mg ferrous sulfate, with increases of 30% for hemoglobin and 32% for red blood cell count, compared to controls. Statistical significance was not reported.

Oral exposure of rats to 10 mg cobalt/kg-day (as cobalt chloride) for 5 months resulted in increases in hemoglobin, hematocrit and red blood cell count compared to untreated controls, with effects reaching a plateau after approximately 60 days of exposure (Murdock, 1959). Statistical significance was not reported. No changes were observed for mean corpuscular hemoglobin concentration and mean cell volume compared to untreated controls, indicating that stimulation of erythropoiesis by cobalt did not result in the production of abnormal red blood cells.

The effects of exposure to 0.05, 0.5, and 2.5 mg cobalt/kg-day (as cobalt chloride) for 7 months were examined in rats (Krasovskii and Fridlyand, 1971). Treatment with 0.5 and 2.5 mg cobalt/kg-day, but not 0.05 mg cobalt/kg-day, for 7 months increased red blood cells and hemoglobin. Stimulation of hematopoiesis was more pronounced in the 2.5 mg cobalt/kg-day

group than in the 0.5 mg cobalt/kg-day group, with polycythemia in the 0.5 mg cobalt/kg-day group described as mild and transient. Results of this study are difficult to evaluate since numeric data and statistical analyses were not reported.

Studies in animals have noted cardiac effects following cobalt (cobalt sulfate) exposure (Haga et al., 1996; Pehrsson et al., 1991; Mohiuddin et al., 1970), although at higher exposure levels than observed in human studies. The effect of cobalt on myocardial function was examined in rats exposed to 8.4 mg cobalt/kg-day for 16 or 24 weeks (Haga et al. 1996). After 24 weeks of exposure, decreased left ventricular systolic and diastolic function was observed. An increase in the ventricular weight to body weight ratio indicates that left ventricular hypertrophy is a contributory factor in cobalt-induced myocardial dysfunction although a mechanism was not identified. Significant effects on cardiac function were not observed following 16 weeks of exposure. In guinea pigs, exposure to 20 mg cobalt/kg-day as cobalt sulfate in the diet for 5 weeks resulted in decreased absolute and relative heart weights and a greater incidence of abnormal electrocardiograms compared to animals fed on diets not supplemented with cobalt (Mohiuddin et al., 1970). Cardiac arrhythmias, including bradycardia, and repolarization abnormalities, were observed in 65% of cobalt-treated animals compared to 5% of control animals. Cellular alterations, observed at the light and electron microscopic levels, in cardiac tissues included pericardial thickening and inflammation, myocardial degeneration and vacuolization, endocardial thickening and myofibrillar damage. In contrast, no effects on cardiac function were observed in male rats (12/group) exposed to protein-restricted diets containing 8.4 mg cobalt/kg-day for 8 weeks (Pehrsson et al., 1991). Treated rats showed a significant decrease in body weight but no differences in left ventricular function relative to animals treated with protein-restricted diets without added cobalt. Although the results from the Pehrsson et al. (1991) and Haga et al. (1996) rat studies conflict, it appears that oral cobalt-induced myocardial injury/dysfunction may have a significant time-dependence. Oral cobalt (as cobalt sulfate) at the same dose level (8.4 mg cobalt/kg-day) did not appear to alter cardiac structure or function following exposure for up to 16 weeks (Pehrsson et al., 1991; Haga et al., 1996). However, ventricular hypertrophy with a concomitant decrease in left ventricular systolic and diastolic function was observed in rats after 24 weeks of oral cobalt (Haga et al., 1996). Thus, based on the results of this study, 8.4 mg cobalt/kg-day represents a subchronic LOAEL for myocardial toxicity in rats; Based on the results of the Mohiuddin et al. (1970) study, a LOAEL of 20 mg cobalt/kg-day was identified for myocardial toxicity in guinea pigs.

Histopathological changes in the thyroid gland have been observed following exposure of female mice to 400 ppm cobalt chloride (~48 mg cobalt/kg-day, assuming an average water intake of 0.265 L/kg-day for female mice; U.S. EPA, 1988) in drinking water for 15 to 45 days (Shrivastava et al., 1996). The severity of effect increased with exposure duration. After 15 days of exposure, a reduction in thyroid epithelial cell height with degenerated nuclei and reduced amount of colloid with peripheral resorption vacuoles was observed, with more pronounced effects after 30 days of exposure. More significant degenerative changes were observed after 45 days of exposure, including necrotic epithelial cells, reduced connective tissue between follicles, lymphocytic infiltrate and larger amounts of colloid within the lumen. Based upon significant thyroid toxicity observed in this study, a LOAEL of 48 mg cobalt/kg-day was identified in mice.

Developmental effects of orally administered cobalt have been studied in rats, rabbits and mice (Szakmary et al., 2001; Pedigo and Vernon, 1993; Paternain et al., 1988; Seidenberg et al., 1986; Domingo et al., 1985; Elbetieha et al., 2008). Szakmary et al. (2001) evaluated the developmental effects of oral cobalt sulfate exposure in rats, mice and rabbits. Exposure of pregnant rats to 5.2-21.0 mg cobalt/kg-day (oral gavage) decreased perinatal growth and survival, retarded skeletal development and produced skeletal and urogenital malformations, with a LOAEL of 5.2 mg cobalt/kg-day. Maternal toxicity (increased relative liver, adrenal, spleen weights; increased BUN, serum creatinine) was only observed at the highest dose (21.0 mg cobalt/kg-day). Thus, embryotoxicity in rats was observed at exposure levels below the LOAEL for maternal toxicity. In pregnant mice exposed to 10.5 mg cobalt/kg-day, retarded skeletal development and malformations of the eye, kidney and skeleton were observed in the absence of maternal toxicity. In pregnant rabbits exposed to 4.2 mg cobalt/kg-day, 20% mortality was observed in dams. Fetal resorptions were observed in 30% of surviving dams. Results of the studies in rats and mice provide evidence that adverse developmental effects can occur in the absence of maternal toxicity, and that rabbits are more sensitive to oral cobalt.

Domingo et al. (1985) treated pregnant female rats (15 animals/group) with 5.4 to 21.8 mg cobalt/kg-day as cobalt chloride from gestation day 14 through lactation day 21. Offspring were examined for mortality, body weight, body and tail length and general signs of toxicity after 1, 4 and 21 days of nursing. In contrast to the study by Szakmary et al. (2001), results of the Domingo et al. (1985) study reported maternal toxicity at all doses that produced adverse developmental effects (specific maternal effects observed were not reported). Fetal effects at 5.4 mg cobalt/kg-day included stunted growth of the pups of both sexes, decreased body length and tail length in male offspring and decreased spleen and liver weight in female offspring. Effects at the 10.9 mg cobalt/kg-day dose included decreased body weight in female pups, while at 21.8 mg cobalt/kg-day, decreased number of living young and decreased survival were seen. Blood parameters (liver enzymes, bilirubin, total protein, uric acid, urea, creatinine, hemoglobin and hematocrit) in pups did not show any treatment-related changes. No signs of toxicity were observed in surviving pups in any of the cobalt exposure groups.

No significant effects on fetal growth or survival were found in rats exposed to 6.2 to 24.8 mg cobalt/kg-day as cobalt chloride (oral gavage) during gestation days 6-15 (Paternain et al., 1988). The incidence of stunted fetuses was higher in the animals treated with 12.4 or 24.8 mg cobalt/kg-day (0.3 stunted fetuses per litter in the 12.4 mg cobalt/kg-day group; 1.0 stunted fetuses per litter in the 24.8 mg cobalt/kg-day group) compared to the control group (0 stunted fetuses per litter); however, the differences were not statistically significant. No treatment-related effects were observed for the number of corpora lutea, total implants, resorptions, the number of dead and live fetuses or fetal size parameters. No gross external abnormalities, skeletal malformations or other signs of fetal toxicity were observed. Maternal effects, including reduced body weight gain and food consumption and altered hematological parameters (increased hematocrit, hemoglobin and reticulocytes), were reported at all exposure levels. No fetal effects were reported in mice exposed to 81.7 mg cobalt/kg-day (oral gavage) during gestation days 8-12 (Seidenberg et al., 1986), but a significant ($p<0.05$) decrease in maternal weight was found. Additional details were not reported.

Pedigo and Vernon (1993) exposed male B6C3F1 mice to 400 ppm cobalt chloride (~45 mg cobalt/kg-day, assuming a water intake of 0.247 L/kg-day for male B6C3F1 mice; U.S. EPA, 1988) in the drinking water for 10 weeks, after which the males were mated with control females to examine for dominant lethal effects. Relative to the control group, the cobalt treatment group had a lower percentage of pregnant females (control, 29/32; cobalt, 18/31), lower number of implantations per female (control, 8.3; cobalt, 6.5) and higher preimplantation losses (control, 0.43; cobalt, 2.4). At the end of the 10-week treatment period, sperm concentration was decreased to 15.3% and motility decreased to 18.3% of controls. Several measures of sperm velocity were also depressed relative to controls. All sperm parameters, except sperm concentration, returned to control levels 8 weeks after the cobalt exposure was terminated. The increase in preimplantation losses in the dominant lethal assay appears related to adverse effects on spermatogenesis rather than to effects on preimplantation development of embryos.

Several studies reported testicular degeneration and atrophy in rats exposed to 11.7 to 46.9 mg cobalt/kg-day as cobalt chloride for 2-3 months in the diet or in the drinking water (Anderson et al., 1992, 1993; Pedigo et al., 1988; Corrier et al., 1985; Mollenhauer et al., 1985; Domingo et al., 1984; Nation et al., 1983). Pedigo et al. (1988) exposed male CD-1 mice to 100, 200 or 400 ppm of cobalt chloride (~11.7, 23.4 or 46.9 mg cobalt/kg-day, respectively, assuming an average water intake of 0.258 L/kg-day for male mice; U.S. EPA, 1988) in the drinking water for 13 weeks. High-dose animals showed a significantly decreased testicular weight beginning at week 9 of treatment and a decreased epididymal sperm concentration by week 11 of treatment. All dose groups showed significantly decreased testicular weight and epididymal sperm concentration and increased serum testosterone levels by week 12 of exposure, with the magnitude increasing with dose. Effects on serum testosterone levels may be secondary to effects on spermatogenesis and related to inhibition of local inhibitory feed-back mechanisms. Based on the results of this study, 11.7 mg cobalt/kg-day was identified as a subchronic LOAEL for decreased testicular weight and epididymal sperm concentration in male rats.

Anderson et al. (1992, 1993) exposed groups of male CD-1 mice to 400 ppm of cobalt chloride (~46.9 mg cobalt/kg-day, assuming an average water intake of 0.258 L/kg-day for male mice; U.S. EPA, 1988) in the drinking water for up to 13 weeks. A decrease in testicular weight and a progressive degeneration of the seminiferous tubules were seen beginning at 9 weeks of exposure. Initial changes were vacuolization of Sertoli cells and abnormal spermatid nuclei, followed by sloughing of cells, shrinkage of tubules and thickened endothelium. No recovery was reported after a 20-week non-exposure recovery period. Co-administration of 800 ppm of zinc chloride provided a partial protection against the effects of cobalt. Based on the results of this study, 46.9 mg cobalt/kg-day was identified as a subchronic LOAEL for decreased testicular weight and degeneration of seminiferous tubules in male mice. Similar histology (degeneration of the testes, particularly the seminiferous tubules) was noted in Sprague-Dawley rats exposed to 20 mg cobalt/kg-day in the diet for up to 98 days (Corrier et al., 1985; Mollenhauer et al., 1985). Decreased testicular weight was seen in Sprague-Dawley rats exposed to 500 ppm cobalt chloride (~32 mg cobalt/kg-day, assuming a water intake of 0.139 L/kg-day for male Sprague-Dawley rats; U.S. EPA, 1988) for 3 months (Domingo et al., 1984).

Elbetieha et al. (2008) examined the potential effects of cobalt on male fertility in forty adult (60 day-old) male Swiss mice exposed to cobalt chloride hexahydrate via drinking water at concentrations of 200, 400, or 800 ppm for 12 weeks. Based on daily water intake reported in the study, daily average doses of cobalt chloride were estimated at 26, 47, or 93 mg/kg-day (equivalent to 6.5, 11.7, or 23 mg cobalt/kg-day); control animals received untreated tap water. Mice were observed daily for signs of clinical toxicity during the exposure period. At the end of the 12-week cobalt exposure period, male mice were separated into individual cages containing two virgin Swiss female mice and given *ad libitum* access to food and untreated tap water. Mice were cohabitated for 10 days during which it was estimated that the females completed two estrus cycles. Male control and cobalt-treated mice were necropsied after day 10 of cohabitation and testes, seminal vesicles, epididymides and preputial glands were harvested, weighed, and prepared for analysis. The left testis and epididymis from each male mouse was processed for determination of sperm count, while the right testis was processed for histopathology. Ten days later, female mice were necropsied and examined for number of pregnancies, number of implantation sites, number of viable fetuses, total number of resorptions, and incidence rate of resorptions.

Ingestion of cobalt chloride was associated with 1/10 and 2/10 deaths in the mid- and high-dose treatment groups, respectively, during week 10 of exposure. Average body weight gain was significantly reduced in all cobalt treatment groups ($p < 0.01$). No other signs of clinical toxicity were observed in surviving male mice. Relative to the control group, the number of pregnant females mated with male mice from the mid- and high-dose groups was significantly ($p < 0.05$) reduced (control, 19/20; mid-dose, 12/18; high-dose, 7/16). The number of implantation sites was significantly ($p < 0.01$) reduced in females mated with low- and mid-dose males (control, 7.89; low-dose, 5.67; mid-dose, 5.42), and the number of viable fetuses was significantly ($p < 0.05$) reduced in females mated with males from all cobalt treatment groups (control, 7.74; low-dose, 5.0; mid-dose, 4.67; high-dose, 5.83). In addition, the total number of resorptions (control, 3/150; low-dose, 9/81; mid-dose, 9/65; high-dose, 10/45) and the number of animals with resorptions (control, 3/19; low-dose, 10/15; mid-dose, 10/16; high-dose, 5/7) were significantly ($p < 0.05$) increased in females mated with males from all three cobalt-treatment groups. Analysis of male reproductive organs revealed a significant ($p < 0.005$) decrease in absolute epididymal weight in mice of the high-dose treatment group. Testes weights were significantly ($p < 0.01$) reduced in males at all doses of cobalt, and a significant ($p < 0.005$) increase in the absolute weight of seminal vesicles of the mid- and high-dose males only. Compared to controls, testicular sperm counts and daily sperm production were decreased in the mid- and high-dose males, but not in the low-dose animals. Epididymal sperm counts were decreased in male mice from all three cobalt treatment groups. Histopathological examination of testis tissue from males of the mid- and high-dose revealed a number of abnormalities including necrosis of the seminiferous tubules and interstitium, congested blood vessels, hypertrophy of the interstitial Leydig cells, and degeneration of the spermatogonial cells; incidence rate of these observations was not reported. These testicular histopathologies were not observed in the testes of control and low-dose treated males. Based on the results of this study, a LOAEL of 6.5 mg/kg-day was identified for decreased testicular weight, epididymal sperm counts, and associated reproductive abnormalities in pregnant females. A NOAEL was not identified.

Nation et al. (1983) exposed groups (n=6) of male Sprague-Dawley rats (weighing 200-210 g) to diets containing 0, 5 or 20 mg cobalt/kg-day as cobalt chloride for a total of 69 days. Following 14 days of exposure, animals were trained for scheduled (operant) or conditioned suppression neurobehavioral tests. Other than two seizures in the same high-dose animal, no overt signs of neurotoxicity were reported at any exposure level. A trend toward a decreased response rate in the schedule training behavior was observed in both the exposed groups but only attained statistical significance in the high-dose animals near the end of the operant testing period (sessions 28-35, on exposure days 44-51). A trend toward decreased conditioned suppression behavior did not attain statistical significance in either group. Animals exposed to 20 mg cobalt/kg-day, but not 5 mg cobalt/kg-day, showed a significantly decreased weight of the testes following 69 days of exposure. Based on the results of this study, a NOAEL of 5 mg cobalt/kg-day and a LOAEL of 20 mg cobalt/kg-day was identified for decreased testicular weight and changes in operant behavior in male Sprague-Dawley rats.

Several other studies have examined the effects of cobalt on neurobehavioral parameters (Singh and Junnarkar, 1991; Krasovskii and Fridlyand, 1971; Bourg et al., 1985). In groups of male Sprague-Dawley rats (n=8) exposed to 20 mg cobalt/kg-day as cobalt chloride for 57 days in the drinking water, cobalt enhanced behavioral reactivity to stress (the animals were less likely to descend from a safe platform to an electrified grid) (Bourg et al., 1985). Singh and Junnarkar (1991) reported a moderate reduction in spontaneous activity and mild hypothermia in rats exposed orally to cobalt chloride (approximately 8 mg cobalt/kg-day) or cobalt sulfate (approximately 35 mg cobalt/kg-day). Krasovskii and Fridlyand (1971) exposed groups of rats (number and sex not specified) to 0.05, 0.5 or 2.5 mg cobalt/kg-day as cobalt chloride for up to 7 months. Neurobehavioral tests showed that treatment with cobalt resulted in a significant (p<0.05) increase in the latent reflex period at 0.5 mg cobalt/kg and above, and a pronounced neurotropic effect (disturbed conditioned reflexes) at 2.5 mg cobalt/kg.

Inhalation Exposure

In a subchronic inhalation study, groups of 10 F344/N rats and 10 B6C3F1 mice of each sex were exposed to cobalt sulfate hexahydrate aerosol (MMAD=0.83-1.10 μm; σ_g not reported) at concentrations of 0, 0.3, 1, 3, 10 or 30 mg/m^3 (equivalent to 0, 0.067, 0.22, 0.67, 2.2 or 6.7 mg cobalt/m^3) 6 hours/day, 5 days/week for 13 weeks (Bucher et al., 1990; NTP, 1991). Although this report indicates that exposure was to cobalt sulfate heptahydrate aerosol, detailed analysis of the cobalt aerosol in the 2-year continuation study (Bucher et al., 1999; NTP, 1998) reports that the aerosol was actually composed of cobalt sulfate hexahydrate; thus, exposure to the hexahydrate form is assumed for the 13-week study. Animals were monitored for body weight and observed for clinical signs during the exposure period. Urine samples for urinalysis and cobalt determination were collected from rats prior to sacrifice. Following termination of exposure, all animals were sacrificed and necropsied. Blood samples were collected and analyzed for hematological parameters (rats and mice) and serum chemistry and thyroid function parameters (rats only). The major organs were weighed. Animals from the control and high-dose groups received comprehensive histopathological examinations, while those from the lower dose groups received more limited examinations focused on the respiratory tissues.

All rats survived until scheduled necropsy (NTP, 1991; Bucher et al., 1990). Gross evidence of toxicity was noted only in rats exposed to 6.7 mg cobalt/m^3, and they displayed clinical signs of toxicity (ruffled fur, hunched posture) and reduced body weights. Polycythemia, indicated by significant increases in red blood cell count, hemoglobin and hematocrit, was noted in males exposed to $\geq$0.67 mg cobalt/m^3 and females exposed to $\geq$2.2 mg cobalt/m^3. In addition, platelets were significantly reduced in rats of both sexes at $\geq$2.2 mg cobalt/m^3 and reticulocytes were increased in females at 6.7 mg cobalt/m^3. Leukocyte counts and differentials were unaffected. Serum cholesterol was significantly reduced in males at $\geq$2.2 mg cobalt/m^3 and females at 6.7 mg cobalt/m^3. No other serum chemistry parameters were affected, including creatine kinase isozymes indicative of damage to cardiac muscle cells. Among the thyroid hormones, T3 (triiodothyronine) was significantly reduced in females at 2.2 mg cobalt/m^3 (83% of control) and males at 6.7 mg cobalt/m^3 (62% of control) and TSH (thyrotropin) was significantly reduced in males at 6.7 mg cobalt/m^3 (30% of control), but T4 (thyroxine) was not affected in either sex at any dose and the researchers concluded that thyroid function was not consistently affected in this study. Urinalysis revealed a dose-related increase in the number of epithelial cells and granular casts in the urine of many exposed male rats (3-7 per group exposed to $\geq$0.67 mg cobalt/m^3) but not in the urine of control male rats. The researchers interpreted this finding as indicating minimal nephropathy in exposed male rats although histopathological lesions were not detected in the kidney. No effects on sperm counts, sperm motility or the incidence of abnormal sperm were noted. Average estrus cycle of females exposed to 6.7 mg cobalt/m^3 was slightly longer than controls, but the difference was not significant. Absolute and relative lung weights were significantly increased in both male and female rats at $\geq$0.22 mg cobalt/m^3. Other organ weights were not affected by treatment. Compound-related lesions were found only in the respiratory tissues of exposed rats. Degenerative, inflammatory and regenerative lesions were found throughout the respiratory tract (see Table 2). Incidence and severity of lesions were similar in males and females. The most sensitive tissue was the larynx, with squamous metaplasia present at all exposure levels.

Among mice, 2/10 males exposed to 6.7 mg cobalt/m^3 died during the study (NTP, 1991; Bucher et al., 1990). The only clinical signs of toxicity observed were rapid breathing and skin discoloration in one of the mice that died. Body weights were reduced throughout the study in both males and females exposed to 6.7 mg cobalt/m^3. No dose-related hematological effects were found. Absolute and relative lung weights were significantly increased in male and female mice exposed to $\geq$2.2 mg cobalt/m^3. Respiratory lesions were similar to those observed in rats. As with rats, the most sensitive tissue was the larynx, with squamous metaplasia present at all exposure levels. Reproductive system effects were more prominent in mice than rats. Males had significantly decreased testicular weight (48% compared to control), decreased epididymal weight (81% compared to control), testicular atrophy consisting of loss of germinal epithelium in the seminiferous tubules and foci of mineralization and an increased percentage of abnormal sperm at 6.7 mg cobalt/m^3 (295% compared to control). Significant reductions in sperm motility of 90, 87 and 54% were observed in the 0.67, 2.2 and 6.7 mg cobalt/m^3 exposure groups, respectively (lower doses were not tested). Females had a significantly increased length of the estrus cycle at 6.7 mg cobalt/m^3 (119% longer compared to control).

Table 2. Rats with Selected Lesions in the 13-Week Cobalt Sulfate Inhalation Study[a]

Site	Lesion	Exposure Group (mg Cobalt (Co) per m^3)					
		Control	0.067 mg Co/m^3	0.22 mg Co/m^3	0.67 mg Co/m^3	2.2 mg Co/m^3	6.7 mg Co/m^3

M: number of males with lesions out of 50 animals.
F: number of females with lesions out of 50 animals.
[a]NTP, 1991; Bucher et al., 1990
[b]$p<0.05$ vs controls by Fisher exact test
[c]$p<0.01$ vs controls by fisher exact test

Other studies in animals have also reported respiratory lesions and altered respiratory function following inhalation exposure to cobalt. Kyono et al. (1992) observed mild pulmonary lesions in rats exposed to 2.12 mg/m^3 of cobalt aerosols (generated from an aqueous suspension of ultrafine metallic cobalt particles) 5 hours/day for 4 days. Lesions were characterized by focal hypertrophy of the epithelium, abnormal macrophages, vacuolization of type I epithelial cells and proliferation of type II epithelial cells, which are indicative of an initial inflammatory response. Kerfoot et al. (1975) exposed groups of five miniature swine to 0, 0.1 or 1.0 mg/m^3 of pure cobalt metal powder for 6 hours/day, 5 days/week for 3 months. Wheezing was observed in animals from both cobalt groups after 4 weeks of exposure (numeric data not reported). Tidal volume was decreased to 73% and 64% of controls in the low and high dose groups, respectively, and total respiratory compliance was decreased relative to controls (low dose, 66% of control; high dose, 56% of control). Statistical significance was not reported. Examination of lung tissue by electron microscopy revealed septa thickened by collagen, elastic tissue and fibroblasts in both exposure groups, with more pronounced effects in the high dose group. Johansson et al. (1987) exposed rabbits (8/group) to 0.4 or 2 mg cobalt/m^3 as cobalt chloride, 6 hours/day, 5 days/week for 14-16 weeks. Nodular accumulation of alveolar type II cells (8/8 rabbits in both cobalt groups), abnormal accumulation of enlarged, vaculolated alveolar macrophages (5/8 in the low dose group and 8/8 in the high dose group) and interstitial inflammation (4/8 rabbits in the low dose group and 8/8 rabbits in the high dose group) were observed, with more pronounced effects in the high dose group.

The carcinogenicity of inhaled cobalt was investigated in groups of 50 F344/N rats and 50 B6C3F1 mice of each sex exposed to cobalt sulfate hexahydrate aerosol (MMAD=1.4-1.6 μm; σ_g=2.1-2.2) at concentrations of 0, 0.3, 1 or 3 mg/m^3 (equivalent to 0,

0.067, 0.22 or 0.67 mg cobalt/m^3) 6 hours/day, 5 days/week for 105 weeks (Bucher et al., 1999; NTP, 1998). Animals were monitored for body weight and observed for clinical signs during the exposure period. Following termination of exposure, all animals were sacrificed and necropsied. At necropsy, all organs and tissues were examined for gross lesions, trimmed and examined histologically.

In F344 rats, there were no changes in survival or mean body weights in males or females of any exposure group (Bucher et al., 1999; NTP, 1998). Irregular breathing was noticed more frequently in female rats exposed to 0.67 mg cobalt/m^3 than in controls or other treatment groups; no changes in clinical signs were noted in any of the treated male rats. Incidence of selected neoplasms and nonneoplastic lesions of the lung in rats is summarized in Table 3. Both male and female rats in all exposure groups showed a high incidence (94% or greater) of squamous metaplasia of the alveolar epithelium, fibrosis of the pulmonary interstitium and granulomatous inflammation, with all lesions increasing in severity with increasing exposure level. Significant increases in alveolar/bronchiolar adenomas or carcinomas were seen in high-dose male rats, while significant increases in alveolar/bronchiolar adenomas or carcinomas were seen in the mid- and high-dose female rats. The combined incidence of alveolar/bronchiolar neoplasms (adenoma and carcinoma) in male rats and female rats was significantly greater than that in control animals, and a significant linear trend occurred in both sexes. Rats of both sexes showed treatment-related increases in hyperplasia of the lateral nasal wall, atrophy of the olfactory epithelium and squamous metaplasia of the larynx. A significant increase in the incidence of pheochromocytoma in 0.67 mg cobalt/m^3 dosed females was also noted (2/48, 1/49, 4/50 and 10/50 in control, 0.067, 0.22 and 0.67 mg cobalt/m^3 groups, respectively). A marginally increased incidence of pheochromocytoma in males exposed to 0.22 mg cobalt/m^3, but not in those exposed to 0.67 mg cobalt/m^3, was considered by the study authors not to be related to treatment.

In B6C3F1 mice, no changes in survival were observed in any exposure group (Bucher et al., 1999; NTP, 1998). Male mice exposed to 0.67 mg cobalt/m^3 showed a decreased mean body weight relative to controls from week 96 through the end of the study (105 weeks). Mean body weights of exposed female mice were generally greater than those of controls throughout the study. Irregular breathing was noted slightly more frequently in female mice exposed to 0.22 mg cobalt/m^3 than in controls or other exposed groups. Incidence of selected neoplasms and nonneoplastic lesions of the lung in mice is summarized in Table 4. A dose-related increase in the occurrence of cytoplasmic vacuolization of the bronchus was seen in both sexes of mice, with incidences at all exposure levels being significantly different from controls. As in rats, both sexes of mice showed a significant linear trend toward increased alveolar/bronchiolar tumors, with the 0.67 mg cobalt/m^3 male and the 0.22- and 0.67 mg cobalt/m^3 female groups attaining statistical significance. Mice of both sexes showed significantly increased incidences of squamous metaplasia of the larynx ($p<0.05$) at all exposure levels examined. In male mice, but not in females, the incidence of hemangiosarcoma was significantly elevated in animals exposed to 0.22 mg cobalt/m^3, but not in other exposure groups (2/50, 4/50, 8/50 and 7/50 in the control, 0.067, 0.22 and 0.67 mg cobalt/m^3 groups, respectively).

Table 3. Incidence of Selected Neoplasms and Nonneoplastic Lesions in the Respiratory Tract of Rats in the 2-Year Inhalation Study of Cobalt Sulfate[a]

Site	Lesion Type	Exposure Group (mg Cobalt (Co) per m^3)			
		Control	0.067 mg Co/m^3	0.22 mg Co/m^3	0.67 mg Co/m^3
Lung	Alveolar epithelium hyperplasia	M: 9 F: 15	M: 20 [b] F: 7	M: 20 [b] F: 20	M: 23 [c] F: 33 [c]

Wehner et al. (1977, 1979) exposed 2-month-old male Syrian golden hamsters to inhaled cobalt oxide at 0 or 10 mg/m^3 (51 animals/group), 7 hours/day, 5 days/week for approximately 15 months. The incidence of tumors in treated hamsters was not statistically different from controls. There was "limited" histopathologic and ultrastructural examination in the study. No developmental toxicity studies were located following inhalation exposure to cobalt.

Other Studies

Parenteral Administration

Heath (1956) injected groups of 10 male and 20 female rats with a single intramuscular 28 mg dose of powdered cobalt in the thigh. Injection-site sarcomas appeared in 18 (60%) of the treated rats within 5-12 months. Similar results were observed in Wistar rats by Gilman (1962) and Gilman and Ruckerbauer (1962), with single intramuscular doses of 20 mg of cobalt oxide and cobalt sulfide. Cobalt oxide and cobalt sulfide given intramuscularly at doses twice those used in rats did not induce sarcomas in mice (Gilman and Ruckerbauer, 1962). Shabaan et al. (1977) observed a high incidence of fibrosarcomas in rats given subcutaneous injections of cobalt chloride at 40 mg/kg-day for 10 days. Tumors developed in 8-12 months. Stoner et al. (1976) tested cobalt acetate in the strain A mouse pulmonary tumor test. Groups of 20 mice/sex

received three times per week intraperitoneal injections for a total of 19 cumulative doses of 0, 95, 237 or 475 mg/kg. Survival was high over the 30-week observation period, and the incidence of lung tumors in treated mice was not statistically different from controls.

Genotoxicity Studies

The genetic toxicity of cobalt was reviewed by Beyersman and Hartwig (1992) and more recently by De Boeck et al. (2003b), Hartwig and Schwerdtle (2002) and Lison et al. (2001). Cobalt compounds have generally tested negative in bacterial mutagenicity assays, with occasional positive results occurring with the addition of an exogenous metabolic system. In contrast, cobalt compounds have generally tested positive in yeast and plant cells. In mammalian cell systems, cobalt has been shown to induce DNA strand breaks, sister-chromatid exchanges and morphological cell transformation.

Results of *in vitro* studies using human peripheral blood mononucleated cells show that cobalt metal and cobalt chloride induced DNA strand breaks at non-cytotoxic concentrations (De Boeck et al., 1998, 2003a). Evidence demonstrating mutagenic activity of cobalt *in vivo* in humans is lacking. No significant change in DNA strand breaks were observed in lymphocytes from nonsmoking workers who had been occupationally exposed to cobalt or hard metal dust although a positive association was observed between DNA strand breaks and smoking (De Boeck et al., 2000).

Experimental data in animals provide evidence of genotoxicity following *in vivo* exposure to cobalt. Single oral exposure of male Swiss mice to 0, 4.96, 9.92 or 19.8 mg cobalt/kg-day, as cobalt chloride, resulted in significantly increased percentages of both chromosomal breaks and chromosomal aberrations in bone marrow cells, with significant linear trends toward increasing aberrations with increased exposure (Palit et al., 1991a,b,c,d). Thirty hours following single intraperitoneal injection of cobalt chloride at doses of 6.19, 12.4, or 22.3 mg cobalt/kg in BALB/c mice, an increase in micronucleus formation was seen in the mid- and high-dose mice but not in low-dose mice (Suzuki et al., 1993). Single injection of 12.4 mg cobalt/kg resulted in significantly increased micronucleus formation at 24 hours post-injection but not at 12, 48, 72 or 96 hours. Pedigo and Vernon (1993) reported that treatment with 400 ppm cobalt chloride (~45 mg cobalt/kg-day, assuming a water intake of 0.247 L/kg-day for male B6C3F1 mice; U.S. EPA, 1988) in the drinking water of male B6C3F1 mice for 10 weeks resulted in an increase in dominant lethal effects as indicated by changes in the number of pregnant females, percentage of live embryos and number of pre-implantation losses per female.

DERIVATION OF PROVISIONAL SUBCHRONIC AND CHRONIC ORAL RfD VALUES FOR COBALT

Indicators of human health effects following oral exposure to cobalt (Co) include increased erythrocyte production and hemoglobin levels, decreased iodine uptake by the thyroid gland, elicitation of dermatitis in sensitized individuals and cardiomyopathy. Observations in humans for effects on the heart, blood and the thyroid gland are supported by results of studies in animals. Other effects, including neurobehavioral, developmental and testicular toxicity were

observed in animals and at relatively high doses; these endpoints were not considered further for the development of the subchronic or chronic provional RfD (p-RfD).

Cardiomyopathy was considered as an endpoint of concern for cobalt exposure in humans; however, it is probable that alcohol consumed in "beer-cobalt cardiomyopathy," as well as other associated factors such as nutritional deficiency, played a role in the cardiotoxic effects observed. Therefore, a dose-response relationship could not be determined for cobalt exposure from these studies. Studies in animals have noted cardiac effects following cobalt exposure at higher exposure levels than observed in human studies of "beer-cobalt cardiomyopathy." On this basis, cardiomyopathy was not selected as the critical endpoint for p-RfD derivation.

Allergic response in cobalt-sensitized workers was considered as a potential critical endpoint for the derivation of an oral p-RfD. However, the available data provide no information on the dose-response relationship of cobalt sensitization, nor is a no observable adverse effect level (NOAEL) for the elicitation of an allergic response in humans defined. Interrelationships also exist between cobalt and nickel (Ni) sensitization so that people sensitized by (Ni) may have an allergic reaction following cobalt exposure. Allergic response was, therefore, not chosen as the critical effect for p-RfD derivation.

Cobalt has been shown to induce polycythemia which is characterized by an increase in erythrocyte number and hemoglobin levels through stimulation of erythropoietin, a hormone produced primarily in the kidney. The hematological effects of cobalt treatment have been reported in healthy, non-anemic adults (Davis and Fields, 1958) and in anephric anemic dialysis patients (Taylor et al., 1977; Duckham and Lee, 1976). However, the effects observed in healthy adults were reversible and erythrocyte counts returned to pre-treatment levels within 9 to 15 days after cobalt administration was discontinued. In anephric dialysis patients, treatment with cobalt resulted in an increase in hemoglobin from levels clinically described as "anemic" to levels at or near "normal." Thus, the effect of cobalt administration in these patients was clinically beneficial. Furthermore, the results of this study are difficult to interpret due to confounding factors, including the anephric status of patients and the concomitant administration of iron. Hematologic effects of cobalt were also found in several studies in rats (Domingo et al., 1984; Krasovskii and Fridlyand, 1971; Murdock, 1959; Holly, 1955, Stanley et al., 1947), supporting the plausibility for the effects observed in humans. However, the effects in animals were generally observed at higher doses than that used in the Davis and Fields (1958) human study. It is not known whether cobalt exposure in humans at higher dose levels would increase erythrocytes sufficiently above normal physiological levels to significantly increase the risk of cardiovascular effects. Therefore, polycythemia was not chosen as the critical effect for p-RfD derivation.

Effects of cobalt on thyroidal iodine uptake were identified as an endpoint of concern in humans, based on a preliminary report by Roche and Layrisse (1956). This report showed that oral exposure to cobalt (1 mg cobalt/kg-day) for 2 weeks markedly inhibited radioactive iodine uptake in the human thyroid. In a smaller human clinical study, reduced iodine uptake was reported in 2 of 4 euthyroid patients exposed to 0.54 mg cobalt/kg-day by the oral route for up to 14 days (Paley et al., 1958). A confounding factor in this study is that one of the two subjects reported to have reduced iodine uptake had received intravenous (i.v.) cobalt in addition to oral cobalt intake. The i.v. loading dose regimen may have raised the internal concentration of cobalt

to a level greater than the estimated 0.54 mg cobalt/kg-day based on oral intake alone, rendering the Paley et al. (1958) study inappropriate for consideration. Importantly, long-term cobalt exposure (up to 7 months) at 2-4 mg/kg-day in anemic children has been reported to cause goiter (Gross et al., 1954; Kriss et al., 1955; Little and Sunico, 1958). Therefore, while reduced iodine uptake is reported in humans following short-term exposures at low doses (Roche and Layrisse, 1956; Paley et al., 1958), potentially more severe thyroid lesions may occur as a function of increased duration or dose. Based on observations from rodent models of cobalt exposure, the severity of thyroid toxicity appears to be related to duration of exposure. Indeed, necrosis and inflammation of the thyroid has been reported in mice exposed to approximately 48 mg cobalt/kg-day with an increase in severity over a period of 15-45 days (Shrivastava et al., 1996).

Subchronic provisional RfD

Although cobalt exposure induces decreased radioactive iodine uptake in the thyroid (Roche and Layrisse, 1956), and polycythemia (Davis and Fields, 1958) in humans at similar daily exposure levels (1 mg/kg-day and 0.97 mg/kg-day, respectively), thyroid toxicity is chosen as the critical effect for derivation of provisional oral reference values. Cobalt-induced polycythemia and decreased iodine uptake by the thyroid were reversible following relatively short-term exposure in humans, however supporting studies indicate the potential for more severe thyroid effects (e.g., Kriss et al., 1955). The point of departure (POD) of 1 mg cobalt/kg-day for decreased iodine uptake in human thyroid is the LOAEL; dividing this POD by a composite uncertainty (UF) of 300 yields a **subchronic p-RfD of 3E-3 mg/kg-day** as follows:

Subchronic p-RfD = LOAEL ÷ UF
= 1 mg/kg-d ÷ 300
= **0.003 or 3E-3 mg/kg-day**

The composite UF of 300 is composed of three uncertainty factors: An UF of 10 for LOAEL to NOAEL extrapolation was applied because the POD is based on a LOAEL. An UF of 10 was applied due to the lack of data regarding inter-individual human variability or information on sensitive subpopulations. Specifically, because the critical study (Roche and Layrisse, 1956) for oral cobalt was based on healthy (euthyroid) adults, an UF of 10 was applied to protect sensitive human populations. The available database includes several short-term human studies, multiple developmental studies in animals and animal studies investigating hematological, cardiac, neurological, neurobehavioral, and thyroid endpoints. The lack of a multi-generation reproductive toxicity study is of particular concern because the database includes several animal studies indicating effects on sperm function and testicular degeneration which raises concerns that cobalt exposure may affect reproductive capability. Therefore, an UF of 3 was applied to account for lack of a multi-generation toxicity study.

Chronic provisional RfD

Using the same LOAEL of 1 mg/kg-day for decreased iodine uptake in humans, and an additional UF of 10 for extrapolating from subchronic to chronic duration (composite UF of 3000), a **chronic p-RfD of 3E-4 mg/kg-day** is derived as follows:

p-RfD = LOAEL ÷ UF
= 1 mg/kg-d ÷ 3000
= **0.0003 or 3E-4 mg/kg-day**

An UF of 10 for extrapolation from subchronic to chronic duration was applied because the critical effect was chosen from a principal study of a relatively short duration (2 weeks) of oral exposure in humans. The temporal relationship between cobalt-induced decreased radioactive iodine uptake and more severe thyroid toxicity should be considered carefully. One postulated temporal relationship is that chronic exposure may have no greater effect than that resulting from short-term exposure, because if the precursor event of inhibition of iodine uptake does not occur, then there may be no change in thyroid function in the short- or long-term. Prolonged cobalt exposure could have less of an effect because of the compensatory response of the pituitary-thyroid axis to iodine deficiency, via increasing iodine uptake. However, although plausible, there are no data to suggest that this postulated temporal relationship exist for cobalt-induced thyroid toxicity. Indeed, a limited number of clinical observations primarily in children exposed to oral cobalt at doses of 2-4 mg/kg-day for up to 7 months suggest the potential for more severe thyroid toxicity (e.g., Kriss et al., 1955). In addition, cobalt may not be readily eliminated from the body; for example, the biological half-life of cobalt chloride in rats is 25 hours (Rosenberg, 1993). Therefore, an UF of 10 for extrapolation from subchronic to chronic duration was applied.

Confidence in the principal study is low-to-medium. Roche and Layrisse (1956) examined twelve subjects over a two-week exposure period. Since only a single dose level was evaluated, a NOAEL for decreased iodine uptake was not identified. Other human and animal studies support the plausibility of cobalt producing thyroid toxicity (Paley et al., 1958; Prescott et al., 1992; Shirivistava et al., 1996). Confidence in the database is low-to-medium. Although some studies (Gross et al., 1954; Kriss et al., 1955; Little and Sunico, 1957) of longer duration reported increased severity of thyroid effects (e.g., goiter) in children exposed to cobalt at higher doses (2-4 mg cobalt/kg-day), critical details of these studies are unavailable for assessment. Therefore, a temporal relationship between prolonged oral cobalt exposure and increased severity of thyroid effects in humans (or experimental animals) is not clear, based upon available data. As such, a low confidence in the provisional subchronic and chronic RfDs results.

DERIVATION OF PROVISIONAL SUBCHRONIC AND CHRONIC INHALATION RfC VALUES FOR COBALT

The human and animal database indicates that respiratory effects are sensitive endpoints of inhaled cobalt. Symptoms of respiratory tract irritation and altered pulmonary function have been widely reported in workers exposed to cobalt-containing airborne media. Of the four human epidemiology studies discussed above, the study by Nemery et al. (1992) provides the strongest basis for derivation of a provisional RfC (p-RfC). Workers in this study were exposed to lower air concentrations of metallic cobalt dust than in the studies by Gennart and Lauwerys (1990), Prescott et al. (1992) and Swennen et al. (1993). The values obtained from personal air samples from the Nemery et al. (1992) study, indicate a NOAEL of 5.3 $\mu g/m^3$ and a LOAEL of 15.1 $\mu g/m^3$. Furthermore, the Nemery et al. (1992) study demonstrated a dose-effect relationship

on lung function which correlated with urinary cobalt-levels, after adjusting for effects of smoking and gender.

Animal data support the conclusion that the respiratory tract is the critical target for inhaled cobalt (NTP, 1991; Bucher et al., 1990; Wehner et al., 1977). Subchronic and chronic inhalation exposure to cobalt resulted in inflammation, fibrosis, and bronchiolar regeneration in all regions of the respiratory tract in both rats and mice (NTP, 1991, 1998; Bucher et al., 1990, 1999) at doses higher than those identified in the Nemery et al. (1992) study. The NTP (1991) study further demonstrated that cobalt can produce testicular effects in male mice following inhalation exposure, but the effects were produced only at high dose levels. Oral studies have also identified the testes as a target for cobalt toxicity. Multi-generation reproduction studies following inhalation or oral exposure to cobalt are not available. Although developmental toxicity studies following inhalation exposure to cobalt are not available, oral studies provide evidence that high oral doses of cobalt may produce developmental effects in animals (Szakmary et al., 2001; Paternain et al., 1988; Domingo et al., 1985).

Decreased pulmonary function and respiratory tract irritation were identified as the co-critical effects for derivation of the subchronic and chronic p-RfCs. Assuming the personal air samples to be more representative of worker exposure than the area air samples, the study by Nemery et al. (1992) identified a NOAEL of 5.3 $\mu g/m^3$ and a LOAEL of 15.1 $\mu g/m^3$ for metallic cobalt for effects on pulmonary function (e.g. forced expiratory volume (FEV), forced vital capacity (FVC) and forced expiratory flow [referred to as MMEF]) and an increased prevalence of symptoms of respiratory tract irritation (e.g. nose/throat irritation, cough, phlegm, dyspnea). Although the LOAEL may be biased low due to inclusion of data from workshop #9, this does not affect the p-RfC derivation. A NOAEL/LOAEL approach is taken for the derivation of inhalation RfC values because the critical effect data are not amenable to benchmark dose modeling. For example, workers in the low cobalt exposure group experienced a slight but non-statistically significant increase in ventilatory function compared to controls, whereas a significant decrease in ventilatory function was observed in the high cobalt exposure group compared to both the control and the low cobalt exposure groups. The NOAEL for occupational exposure was adjusted to continuous exposure as follows:

$$5.3\ \mu g/m^3\ (10\ m^3/day\ /\ 20\ m^3/day)\ (5\ days\ /\ 7\ days) = 1.9\ \mu g/m^3$$

Using the $NOAEL_{ADJ}$ of 1.9 $\mu g/m^3$ as the POD, the subchronic p-RfC and chronic p-RfC for cobalt was derived as shown below.

Subchronic p-RfC

Dividing the $NOAEL_{ADJ}$ of 1.9 $\mu g/m^3$ by a composite UF of 100 yields a **subchronic p-RfC of 2E-5 mg/m^3** for metallic cobalt as follows:

$$\begin{aligned} \text{Subchronic p-RfC} &= NOAEL_{ADJ} \div UF \\ &= 1.9\ \mu g/m^3 \div 100 \\ &= \mathbf{0.00002\ or\ 2E\text{-}5\ mg/m^3} \end{aligned}$$

The composite UF of 100 is composed of two uncertainty factors: 10 for database insufficiencies and 10 for inter-individual variability. Nemery et al. (1992) did not report exposure duration for any worker in this study; an assumption is made that worker exposure was at least of subchronic duration. A factor of 10 was applied to account for database insufficiencies due to the lack of inhalation developmental toxicity studies and a multi-generation reproduction study. A factor of 10 was applied to account for human variability, including sensitive subgroups. Individuals with underlying respiratory diseases (asthma, chronic obstructive pulmonary disease) may be more sensitive to the respiratory effects of inhaled cobalt. This subchronic p-RfC may not be protective for people with hypersensitivity to cobalt.

Chronic p-RfC

Dividing the $NOAEL_{ADJ}$ of 1.9 $\mu g/m^3$ by a composite UF of 300 yields a **chronic p-RfC of 6E-6 mg/m^3** for metallic cobalt as follows:

$$\begin{aligned} \text{Chronic p-RfC} &= NOAEL_{ADJ} \div UF \\ &= 1.9\ \mu g/m^3 \div 300 \\ &= \mathbf{0.000006\ or\ 6E\text{-}6\ mg/m^3} \end{aligned}$$

The composite UF of 300 is composed of three uncertainty factors: 3 to account for extrapolating from an assumed subchronic exposure duration to a chronic exposure duration, 10 for database insufficiencies and 10 for human inter-individual variability. A factor of 3 is applied to account for extrapolating from an assumed subchronic to chronic exposure duration. Since Nemery et al. (1992) did not report duration for any worker in this study, it is possible that exposure duration may have been subchronic or longer for some workers. A factor of 10 is applied to account for database insufficiencies due to the lack of inhalation developmental toxicity studies and a multi-generation reproduction study. A factor of 10 is applied to account for human variability, including sensitive subgroups. Individuals with underlying respiratory diseases (asthma, chronic obstructive pulmonary disease) may be more sensitive to the respiratory effects of inhaled cobalt. This chronic p-RfC may not be protective for people with hypersensitivity to cobalt.

Confidence in the key study (Nemery et al., 1992) is low because this cross-sectional study:

- looked at only respiratory endpoints;
- included a control group that was studied more than 1 year after the exposed population;
- included a study group exposed to iron and diamond dust in addition to cobalt (and possibly to asbestos in the past);
- did not report duration of exposure; and
- encountered a number of procedural difficulties during its course (e.g., construction of control group).

Confidence in the database is medium. The choice of the critical endpoint is well supported by other studies in humans and animals. Subchronic exposure studies in rats and mice (NTP, 1991) found histopathological changes in the upper respiratory tract. Other studies in animals support these findings. Reproductive and developmental effects have not been adequately studied. Furthermore, oral studies reported large doses were required to produce reproductive or

developmental effects. It would be difficult to get a large enough internal dose via inhalation to produce these effects. For these reasons, there is medium-to-low confidence in the subchronic and chronic p-RfCs.

PROVISIONAL CARCINOGENICITY ASSESSMENT FOR COBALT

Weight-of-Evidence Descriptor

Under the 2005 Guidelines for Carcinogen Risk Assessment (U.S. EPA, 2005a), cobalt sulfate (soluble) is described as "likely to be carcinogenic to humans by the inhalation route," based on both the limited evidence of carcinogenicity in humans and sufficient evidence of carcinogenicity in animals as shown by a statistically significant increased incidence of alveolar/bronchiolar tumors in both sexes of rats and mice, pheochromocytomas in female rats, and hemangiosarcomas in male mice (Bucher et al., 1999). While available studies in humans have suggested a possible association between exposure to cobalt and respiratory tumors in cobalt workers (Tuchsen et al., 1996; Mur et al., 1987; Morgan et al., 1983), limitations within these studies, including small numbers of subjects, inadequate exposure assessment and potential exposure to other chemicals make them inadequate for assessing the carcinogenic potential of cobalt. Studies for evaluation of the oral carcinogenic potential for cobalt were not located.

Mode-of-Action Discussion

The U.S. EPA (2005a) Guidelines for Carcinogen Risk Assessment defines mode of action as "a sequence of key events and processes, starting with the interaction of an agent with a cell, proceeding through operational and anatomical changes, and resulting in cancer formation." Examples of possible modes of carcinogenic action, in general, include mutagenic, mitogenic, anti-apoptotic (inhibition of programmed cell death), cytotoxic with reparative cell proliferation, and immunologic suppression.

While the mode of action of cobalt-induced carcinogenicity has not been determined, data suggests a number of potential biological events that might be involved including non-mutagenic genotoxicity (e.g. clastogenicity). A recent review by Lison et al. (2001) of *in vitro* and *in vivo* experiments in animal models indicates that two different mechanisms of genotoxicity may contribute to the carcinogenic potential of cobalt compounds: DNA strand breakage and inhibition of DNA repair. DNA strand breaks have been reported at non-cytotoxic concentrations in human peripheral blood monocytes (De Boeck et al., 1998, 2003a). Furthermore, oral exposure of mice to cobalt chloride resulted in significantly increased percentages of both chromosomal breaks and chromosomal aberrations in bone marrow cells (Palit et al., 1991a,b,c,d). Mechanistic studies suggest cobalt-induced oxidative stress may be involved. Exposure to cobalt compounds increases indices of oxidative stress, including diminished levels of reduced glutathione, increased levels of oxidized glutathione, increased levels of oxygen radicals and increased free-radical-induced DNA damage (Kawanishi et al., 1994; Lewis et al., 1991; Kadiiska et al., 1989; Zhang et al., 1998; Moorehouse et al., 1985). To compound the potential DNA strand breaking effects of cobalt, it appears that cobalt may also inhibit the repair of such genetic damage. A review by Hartwig and Schwerdtle (2002)

concluded that cobalt may specifically target zinc finger structures in DNA repair proteins, interfering with base and nucleotide excision repair. Collectively, while data indicate that cobalt induces DNA damage and repair inhibition, there is weak evidence to suggest direct or indirect mutagenicity in bacterial or mammalian systems.

Potential for a Mutagenic Mode of Action

Key events

The precise mechanism of cobalt-induced carcinogenicity has not been fully determined. There is evidence that cobalt is capable of eliciting genotoxic effects. While evaluations for mutagenic effects in bacteria have generally yielded negative results, results in several mammalian cell systems have suggested that cobalt is genotoxic in mammalian cells. Limited data from *in vivo* animal studies show that cobalt induces genotoxic effects, including chromosomal breaks, chromosomal aberrations and micronucleus formation. The most likely mechanisms for the genotoxic effects of cobalt are DNA strand breakage and the inhibition of DNA repair.

Strength, consistency, specificity of association

Although the carcinogenic potential of inhaled cobalt has been demonstrated in rats and mice by increased incidence of alveolar/bronchiolar tumors (Bucher et al., 1999; NTP, 1998), direct evidence demonstrating that cobalt can induce mutagenic changes in cells of the respiratory tract is lacking. *In vivo* exposure to hard metal dust containing 6.3% cobalt, 84% tungsten and 5.4% carbon induced DNA strand breaks in rat type II epithelial lung cells (De Boeck et al., 2003c). Chromosome/genome mutations were observed within 12 hours of exposure to a single intratracheal instillation of 16.6 mg hard metal dust/kg body weight. Since the mutagenic potential of cobalt alone was not evaluated in this study, a causal relationship between type II epithelial cell mutations and cobalt exposure could not be established. Potential mutagenic changes in respiratory tract cells could also be mediated through activated oxygen species released by inflammatory cells (e.g., macrophages, polymorpohnuclear neutrophils), rather than directly by cobalt (Lison et al., 2001).

Dose-response concordance

A dose-response concordance has not been established between the development of bronchoalveolar tumors and mutagenesis following inhalation exposure to cobalt. Dose-response information on mutagenicity is available for acute oral and parenteral exposure to cobalt in mice (Suzuki et al., 1993; Palit et al., 1991a,b,c,d). No carcinogenicity data are available for the oral or parenteral routes upon which to base a dose-response concordance. Furthermore, no data are available on the mutagenic potential of cobalt in respiratory tract cells following *in vitro* or *in vivo* exposure.

Temporal relationships

In vivo studies in animals show that acute oral and parenteral exposure to cobalt produces genotoxicity to bone marrow cells (Suzuki et al., 1993; Palit et al., 1991a,b,c,d). Due to the lack of data on the mutagenic potential of cobalt in respiratory tract cells, the temporal relationship between potential mutagenic mechanisms and the development of bronchoalveolar tumors cannot be assessed. Development of lung tumors in animals exposed to cobalt occurred following chronic exposure (NTP, 1998).

Biological plausibility and coherence

In vivo mutagenicity studies in mice show that oral and intraperitoneal exposure to single doses of cobalt chloride induced mutagenic changes in bone marrow cells (Suzuki et al., 1993; Palit et al., 1991a,b,c,d). Although it has been hypothesized that the bronchoalveolar tumors are the result of genotoxicity (De Boeck et al., 2003b; Hartwig and Schwerdtle, 2002; Lison et al., 2001), no direct evidence is available linking cobalt-induced mutagenesis to the development of cancer. Carcinogenicity through an indirect mutagenic mode of action may be mediated by activated inflammatory cells (macrophages, polymorpohnuclear neutrophils) (Lison et al., 2001).

Other Potential Mode(s) of Action: Cytotoxicity and Cellular Regeneration

Subchronic and chronic inhalation studies (Bucher et al., 1990, 1999; NTP, 1991, 1998) in rodents provide some evidence that cobalt causes cell injury with subsequent reparative cell proliferation, which may be involved in the development of bronchoalveolar tumors. Following inhalation exposure to cobalt sulfate hexahydrate aerosol at concentrations of 0.3 to 30 mg/m^3 (equivalent to 0.067 to 6.7 mg cobalt/m^3) for 3 months, rats and mice developed several lesions indicative of cell damage and proliferation throughout the entire respiratory tract, including nasal epithelial degeneration and metaplasia, laryngeal inflammation and metaplasia, bronchiolar epithelial regeneration and ectasia, alveolar hyperplasia and lung fibrosis (NTP, 1991; Bucher et al., 1990). Squamous hyperplasia of the larynx was the most sensitive effect (LOAEL=0.067 mg cobalt/m^3). The results of the 2-year carcinogenesis study (Bucher et al., 1999; NTP, 1998) in rats and mice revealed a statistically significant increase in combined alveolar/bronchiolar adenomas and carcinomas in the 0.67 mg cobalt/m^3 group, but not in the 0.067 and 0.22 mg cobalt/m^3 groups for male rats and mice. In female rats and mice, a statistically significant increase in combined alveolar/bronchiolar adenomas and carcinomas was observed in the 0.22 and 0.67 mg cobalt/m^3 groups, but not in the 0.067 mg cobalt/m^3 group. In this same study, granulomatous inflammation of the lung was observed at all exposure levels (0.067, 0.22 and 0.67 mg cobalt/m^3) in rats. Other markers of cell damage and proliferation, including hyperplasia, metaplasia and fibrosis, were observed in the 0.22 and 0.67 mg cobalt/m^3 exposure groups. Compared to rats, mice appeared to be less sensitive to cobalt-induced cytotoxic changes. Results of this study show that bronchoalveolar tumors develop at exposure levels that also produce cell damage and reparative proliferation, although cell damage and repair are also observed at lower exposure levels than tumorigenesis. These observations suggest the possibility that cell injury in the respiratory tract may have preceded the development of cancers although direct evidence for this assertion is lacking.

Although limited evidence of carcinogenicity in humans is available, results of several epidemioloic studies suggest a possible association between exposure to cobalt and respiratory tumors (Tuchsen et al., 1996; Mur et al., 1987; Morgan, 1983). Subchronic exposure studies in cobalt workers show an association between cobalt exposure and diminished pulmonary function (Nemery et al., 1992; Gennart and Lauwerys, 1990). Taken together, results of studies in rodents and humans suggest that inhaled cobalt may produce a cytotoxic response in the respiratory tract that may contribute to decreases in pulmonary function and the development of bronchoalveolar tumors.

Sustained cell proliferation, in response to cytotoxicity, can be a significant risk factor for cancer (Correa, 1996). Sustained cytotoxicity and regenerative cell proliferation may result in the perpetuation of mutations (spontaneous or directly or indirectly induced by the chemical), resulting in uncontrolled growth. It is also possible that continuous proliferation may increase the probability that damaged DNA will not be repaired. No data on cobalt are available to directly evaluate the relationship between cell damage and reparative proliferation and the development of bronchoalveolar tumors.

Conclusions Regarding Cancer Mode of Action

Limited evidence supports genotoxicity and cytotoxicity followed by cellular regeneration as potential modes of action for cobalt tumorigenicity. *In vitro* and *in vivo* studies provide evidence that cobalt is capable of eliciting genotoxic effects in mammalian cells; however, two key uncertainties remain:

(1) No direct evidence linking cobalt-induced mutagenesis to the development of cancer is available and (2) the mutagenic potential of cobalt in respiratory cells has not been evaluated.

Results of the 3-month and 2-year inhalation studies in rats and mice (Bucher et al., 1990, 1999; NTP, 1991, 1998) are also consistent with the hypothesis that cobalt acts through a mode of action involving cytotoxicity and cellular regeneration, based on the observations that these effects occur following subchronic exposure and bronchoalveolar tumors develop at exposure levels that produce cytotoxicity and reparative proliferation. These observations suggest the possibility that cell injury in the respiratory tract may have preceded the development of cancers although direct evidence for this assertion is lacking. No mode of action data are available to explain the statistically significant increases in the incidences of pheochromocytomas and hemangiosarcomas that were observed in female rats and male mice, respectively.

Because a mutagenic mode of action is plausible, but cannot be clearly established for carcinogenicity of inhaled cobalt, it is recommended that an age-dependent adjustment factor not be applied to the unit risk to account for possible age-dependence of carcinogenic potency as described in U.S. EPA (2005b).

Quantitative Estimates of Carcinogenic Risk

Oral Exposure

Human or animal studies examining the carcinogenicity of cobalt following oral exposure were not located. Therefore, derivation of an oral slope factor is precluded.

Inhalation Exposure

As available human inhalation studies were not sufficiently detailed, particularly with regards to analysis of exposure, the NTP (1998; Bucher et al., 1999) 2-year carcinogenicity study in rats and mice was chosen as the principal study for the derivation of an inhalation unit risk, based on the dose-response relationship for statistically significant increased incidences of alveolar/bronchiolar (A/B) neoplasms (adenoma and carcinoma). Although statistically significant increases in the incidences of pheochromocytomas and hemangiosarcomas were observed in female rats and male mice, respectively, these tumors were not considered for the derivation of the inhalation unit risk because a higher and more consistent response across species was observed for alveolar/bronchiolar tumors. The exposure concentrations in this study were adjusted to continuous exposure as follows:

$$Conc_{[ADJ]} = Conc \times \frac{5\ days/\ week}{7\ days/\ week} \times \frac{6\ hours/\ day}{24\ hours/\ day}$$

This adjustment resulted in duration-adjusted concentrations of 0, 0.012, 0.040 and 0.120 mg cobalt/m^3, respectively, for exposure to cobalt sulfate hexahydrate at 0.0, 0.3, 1.0 and 3.0 mg/m^3 exposure levels. Using the RDDR computer program, as specified in the RfC guidelines (U.S. EPA, 1994b), human equivalent concentrations (HECs, in mg cobalt/m^3) were calculated at each exposure level for each species and sex using body weight default values (U.S. EPA, 1994b), assuming exposure to particulates (MMAD=1.5 μm, σ_g=2.2) with effects occurring in the thoracic region of the respiratory tract. Table 5 shows the resulting HECs.

Table 5. Human Equivalent Concentrations (mg Cobalt/m^3) Corresponding to Exposure Concentrations in the NTP (1998; Bucher et al., 1999) Chronic Cancer Bioassay

Study	Male Rat	Female Rat	Male Mouse	Female Mouse
RDDR Multiplier	0.83	0.79	1.48	1.44
Control	0	0	0	0
Low	0.010	0.0095	0.018	0.017
Medium	0.033	0.032	0.059	0.058
High	0.10	0.095	0.18	0.17

All models for quantal data in the U.S. EPA Benchmark Dose (BMD) software (version 1.3.2) were fit to incidence for tumors (combined A/B adenomas and carcinomas), in rats and mice; males and females were modeled separately. All data sets modeled showed a statistical trend for increased tumor incidence with increasing exposure concentration. In accordance with the U.S. EPA (2000) BMD methodology, the default benchmark response (BMR) of 10% increase in extra risk was used as the basis for the BMD, with the BMDL represented by the 95% lower confidence limit on the BMD. Models were run using the default restrictions on parameters built into the BMD software. Table 6 shows the exposure concentration and incidence data that were modeled.

Table 6. Neoplasm Incidence Observed in the NTP (1998; Bucher et al., 1999) Chronic Cancer Bioassay

Animal/Strain/Site	Incidence of Neoplasms			
	Human Equivalent Concentration of Cobalt (mg/m^3)			
F-344 Rats (male)	**0**	**0.010**	**0.033**	**0.10**
Lung: A/B adenoma or carcinoma	1/50	4/50	4/48	7/50
	Human Equivalent Concentration of Cobalt (mg/m^3)			
F-344 Rats (female)	**0**	**0.0095**	**0.032**	**0.095**
Lung: A/B adenoma or carcinoma	0/50	3/49	15/50	15/50
	Human Equivalent Concentration of Cobalt (mg/m^3)			
B6C3F1 Mice (male)	**0**	**0.018**	**0.059**	**0.18**
Lung: A/B adenoma or carcinoma	11/50	14/50	19/50	28/50
	Human Equivalent Concentration of Cobalt (mg/m^3)			
B6C3F1 Mice (female)	**0**	**0.017**	**0.058**	**0.17**
Lung: A/B adenoma or carcinoma	4/50	7/50	13/50	18/50

Table 7 summarizes the BMD modeling results. BMDLs shown were derived from acceptable model fits (p>0.5). As is shown in Table 7, BMDLs were similar across study groups (range: 0.011-0.035 mg/m^3). Lung tumors in female rats were chosen as the endpoint for use as a point of departure for derivation of the inhalation unit risk. The BMDL for this endpoint was the lowest for all study groups (i.e., male and female rats and mice) and was based on a model that showed a good fit to the data (p=0.84), as reflected in the proximity of the BMDL to the BMD, after dropping the high exposure group. Dropping the high exposure group is recommended according to U.S. EPA (2000) procedure when no models achieve adequate fit using all exposure levels. Although this left only two exposure levels (in addition to the control), these exposure levels are in the low-dose portion of the curve within the region of the dose-response relationship in which response is increasing with exposure level (i.e., the region of interest for deriving the point of departure) and bracket the derived BMD. Appendix A presents the results from all model runs used to support this toxicity assessment.

Table 7. Summary of BMD Modeling Results for Cobalt Cancer Data

Tumor	Species	Sex	BMD (mg/m^3)	BMDL (mg/m^3)
Lung: A/B adenoma or carcinoma	rat	male	0.085	0.035
Lung: A/B adenoma or carcinoma	rat	female	0.014[a]	0.011[a]
Lung: A/B adenoma or carcinoma	mouse	male	0.026	0.015
Lung: A/B adenoma or carcinoma	mouse	female	0.038	0.023

[a] Based on control, low and middle exposure levels; high exposure level was dropped due to failure of models to achieve adequate fit using all exposure levels.

In the absence of mode of action data to inform the low dose extrapolation for cobalt, an inhalation cancer unit risk was calculated by linear extrapolation of the BMDL to zero exposure level (U.S. EPA, 2005a). The provisional **inhalation unit risk of 9 $(mg/m^3)^{-1}$** for cobalt sulfate (soluble) was calculated as follows:

$$\begin{aligned} \text{Provisional Unit Risk} &= \text{BMR / BMDL} \\ &= 0.1 / 0.011 \\ &= \mathbf{9\ (mg/m^3)^{-1}} \end{aligned}$$

Table 8 shows continuous life-time exposure concentrations that correspond with specified risk levels (i.e., $1x10^{-4}$, $1x10^{-5}$, $1x10^{-6}$).

Table 8. Continuous Life-time Exposure Concentrations Corresponding to Specified Cancer Risk

Exposure Concentration at $1x10^{-4}$ Risk	$1.1x10^{-5}$ mg/m^3
Exposure Concentration at $1x10^{-5}$ risk	$1.1x10^{-6}$ mg/m^3
Exposure Concentration at $1x10^{-6}$ Risk	$1.1x10^{-7}$ mg/m^3

APPENDIX A: SUMMARY OF BMD MODELING OF TUMOR INCIDENCE DATA IN MALE AND FEMALE RATS AND MICE (NTP, 1998; BUCHER ET AL., 1999)

Male rat – A/B adenoma or carcinoma:

All models show acceptable fit ($p > 0.1$)
Log-logistic model yielded best fit (highest p-value and lowest AIC)
Best estimate of BMDL = 0.035 mg/m^3

Model	p	AIC	BMD mg/m^3	BMDL mg/m^3
gamma (power ≥1)	0.502	111.12	0.087	0.043
logistic	0.446	111.52	0.099	0.066
log logistic (slope ≥1)	0.510	111.07	0.085	**0.035**
2 degree polynomial (pos betas)	0.502	111.12	0.087	0.043
1 degree polynomial (pos betas)	0.502	111.12	0.087	0.043
probit	0.453	111.47	0.098	0.063
log probit (slope ≥1)	0.357	112.11	0.104	0.064
quantal linear	0.502	111.12	0.087	0.043
quantal quadratic	0.373	111.99	0.010	0.069
weibull (power ≥1)	0.502	111.12	0.087	1.043

BMDS MODEL RUN
~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

  The form of the probability function is

  P[response] = background+(1-background)/[1+EXP(-intercept-slope*Log(dose))]

  Dependent variable = INRM
  Independent variable = ECRM
  Slope parameter is restricted as slope ≥ 1

  Total number of observations = 4
  Total number of records with missing values = 0
  Maximum number of iterations = 250
  Relative Function Convergence has been set to 1e-008
```

Parameter Convergence has been set to 1e-008

User has chosen the log transformed model

Default Initial Parameter Values
background = 0.02
intercept = 0.683504
slope = 1

Asymptotic Correlation Matrix of Parameter Estimates

(*** The model parameter(s) -slope
have been estimated at a boundary point or have been specified by the user
and do not appear in the correlation matrix)

	background	intercept
background	1	-0.63
intercept	-0.63	1

Parameter Estimates

Variable	Estimate	Std. Err.
background	0.0398603	0.0231667
intercept	0.272287	0.592931
slope	1	NA

NA - Indicates that this parameter has hit a bound
implied by some inequality constraint and thus
has no standard error.

Nickel, soluble salts; CASRN Various

Human health assessment information on a chemical substance is included in the IRIS database only after a comprehensive review of toxicity data, as outlined in the IRIS assessment development process. Sections I (Health Hazard Assessments for Noncarcinogenic Effects) and II (Carcinogenicity Assessment for Lifetime Exposure) present the conclusions that were reached during the assessment development process. Supporting information and explanations of the methods used to derive the values given in IRIS are provided in the guidance documents located on the IRIS website.

STATUS OF DATA FOR Nickel, soluble salts

File First On-Line 09/30/1987

Category (section)	Assessment Available?	Last Revised
Oral RfD (I.A.)	yes	12/01/1991
Inhalation RfC (I.B.)	not evaluated	
Carcinogenicity Assessment (II.)	not evaluated; message	08/01/1994

I. Chronic Health Hazard Assessments for Noncarcinogenic Effects

I.A. Reference Dose for Chronic Oral Exposure (RfD)

Substance Name — Nickel, soluble salts
CASRN — Various
Last Revised — 12/01/1991

The oral Reference Dose (RfD) is based on the assumption that thresholds exist for certain toxic effects such as cellular necrosis. It is expressed in units of mg/kg-day. In general, the RfD is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. Please refer to the Background Document for an elaboration of these concepts. RfDs can also be derived for the noncarcinogenic health effects of substances that are also carcinogens. Therefore, it is essential to refer to other sources of

information concerning the carcinogenicity of this substance. If the U.S. EPA has evaluated this substance for potential human carcinogenicity, a summary of that evaluation will be contained in Section II of this file.

I.A.1. Oral RfD Summary

Critical Effect	Experimental Doses*	UF	MF	RfD
Decreased body and organ weights **Rat Chronic Oral Study** **Ambrose et al., 1976**	NOAEL: 100 ppm diet (5 mg/kg/day) LOAEL: 1000 ppm diet (50 mg/kg/day)	300	1	2E-2 mg/kg/day

*Conversion Factors -- 1 ppm = 0.05 mg/kg/day (assumed rat consumption)

I.A.2. Principal and Supporting Studies (Oral RfD)

Ambrose, A.M., D.S. Larson, J.R. Borzelleca and G.R. Hennigar, Jr. 1976. Long-term toxicologic assessment of nickel in rats and dogs. J. Food Sci. Technol. 13: 181-187.

Ambrose et al. (1976) reported the results of a 2-year feeding study using rats given 0, 100, 1000 or 2500 ppm nickel (estimated as 0, 5, 50 and 125 mg Ni/kg bw) in the diet. Body weights in the high-dose male and female rats were significantly decreased compared with controls. Body weight was also reduced at 1000 ppm. This reduction was significant for females at week 6 and from weeks 26 through 104, whereas males showed body weight reduction only at 52 weeks. Groups of female rats on the 1000 or 2500 ppm nickel diets (50 and 125 mg Ni/kg bw) had significantly higher heart-to-body weight ratios and lower liver-to-body weight ratios than controls. No significant effects were reported at 100 ppm (5 mg Ni/kg bw). The dose of 1000 ppm (50 mg Ni/kg bw) represents a LOAEL for this study, while the dose of 100 ppm (5 mg Ni/kg bw) is a NOAEL. In this study, 2-year survival was poor, particularly in control rats of both sexes (death: 44/50), raising some concern about the interpretation of the results of this study. A subchronic study conducted by American Biogenics Corp. (ABC, 1986) also found 5 mg/kg/day to be a NOAEL, which supports the Ambrose et al. (1976) chronic NOAEL of 5 mg/kg/day.

Dietary exposure of dogs to 2500 ppm Ni (about 63 mg/kg/day) resulted in depressed body weight gain; no effects were seen at either 100 ppm (about 2.5 mg/kg/day) or 1000 ppm Ni (about 25 mg/kg/day) in the diet (Ambrose et al., 1976). This study demonstrates that rats are the more sensitive of the two species.

ABC (1986) conducted the 90-day study with nickel chloride in water (0, 5, 35 and 100 mg/kg/day) administered by gavage to both male and female CD rats (30 animals/sex/group). The data generated in this study included clinical pathology, ophthalmological evaluations, serum biochemistry, body and organ weight changes and histopathological evaluations of selected organs (heart, kidney, liver).

The body weight and food consumption values were consistently lower than those of controls for the 35 and 100 mg/kg/day dosed males. Female rats in both high-dose groups had lower body weights than controls, but food consumption was unaffected by the test article. Clinical signs of toxicity, such as lethargy, ataxia, irregular breathing, cool body temperature, salivation and discolored extremities, were seen primarily in the 100 mg/kg/day group; these signs were less severe in the 35 mg/kg/day group. The 5 mg/kg/day group did not show any significant clinical signs of toxicity. There was 100% mortality in the high-dose group; 6/30 males and 8/30 females died in the mid-dose group (35 mg/kg/day). Histopathologic evaluation indicated that deaths of 3/6 males and 5/8 females in the mid-dose group were due to gavage errors. At sacrifice, kidney, liver and spleen weights for 35 mg/kg/day treated males and right kidney weights for 35 mg/kg/day treated females were significantly lower than controls. Based on the results obtained in this study, the 5 mg/kg/day nickel dose was a NOAEL, whereas 35 mg/kg/day was a LOAEL for decreased body and organ weights.

I.A.3. Uncertainty and Modifying Factors (Oral RfD)

UF — An uncertainty factor of 10 is used for interspecies extrapolation and 10 to protect sensitive populations. An additional uncertainty factor of 3 is used to account for inadequacies in the reproductive studies (RTI, 1987; Ambrose et al., 1976; Smith et al., 1990) (see Additional Comments section). During the gestation and postnatal development of F1b litters in the RTI (1987) study, temperatures were about 10 degrees F higher than normal at certain times, which makes evaluation of this part of the reproductive study impossible. In the Ambrose et al. (1976) study, statistical design limitations included small sample size and use of pups rather than litters as the unit for comparison. There were also problems with the statistical analysis of the Smith et al. (1990) study.

The Ni dietary study by Ambrose et al. (1976) identifying a NOAEL of 100 ppm (5 mg/kg/day) is supported by the subchronic gavage study in water (ABC, 1986), which indicated the same NOAEL (5 mg/kg/day).

MF — None

I.A.4. Additional Studies/Comments (Oral RfD)

In addition to the effects on organ weights described in the critical study, two other sensitive endpoints exist: neonatal mortality and dermatotoxicity. While no reproductive effects have been associated with nickel exposure to humans, several studies in laboratory animals have demonstrated fetotoxicity. These studies are described below.

Following the reproductive studies is a discussion of nickel-induced dermatotoxicity in hypersensitive humans. While nickel has long been recognized as a contact irritant, many studies have also demonstrated dermal effects in sensitive humans resulting from ingested nickel. The weight-of- evidence from these studies indicates that ingested nickel may invoke an eruption or worsening of eczema; however, a dose-response relationship is difficult to establish. A few representative studies and review articles are cited below.

While the systemic toxicity data (as manifested in organ weight changes) was used as the critical study for the RfD determination, the reproductive/fetotoxicity and the dermatotoxicity were both considered as possible endpoints upon which to base the quantitative risk assessment of nickel. The data for effects on the latter two endpoints do not demonstrate consistent dose-response relationships, and in both cases the available studies are sufficiently flawed so as to prevent their selection as the basis for the oral RfD. It is noted, however, that the RfD based on the Ambrose et al. (1976) study is considered to be protective of all endpoints with the possible exception of hypersensitive individuals as described below.

In addition to the 2-year feeding study used as the basis for the RfD, Ambrose et al. (1976) also reported reproductive toxicity of nickel. The study had some statistical design limitations including small sample size and use of pups rather than litters as the unit for comparison. Furthermore, the results were equivocal and did not clearly define a NOAEL or LOAEL. Because nickel was administered in a laboratory chow diet rather than drinking water, quantifying analogous nickel exposure via drinking water was problematic.

In a 2-generation study (RTI, 1987) nickel chloride was administered in drinking water to male and female CD rats (30/sex/dose) at dose levels of 0, 50, 250 and 500 ppm (0, 7.3, 30.8 and 51.6 mg/kg/day, estimated) for 90 days before breeding (10 rats/sex/group comprised a satellite subchronic nonbreeder group). At the 500 ppm dose level there was a significant decrease in the Po maternal body weight, along with absolute and relative liver weights. Thus, 250 ppm (30.8 mg/kg/day) was a NOAEL for Po breeders. Histopathology was performed for liver, kidney, lungs, heart, pituitary, adrenals and reproductive organs to make this assessment. This NOAEL is

higher than the NOAEL derived from the chronic Ambrose et al. (1976) and subchronic gavage (ABC, 1986) assays.

In the RTI (1987) F1a generation (postnatal days 1-4) at the 500 ppm dose level the number of live pups/litter was significantly decreased, pup mortality was significantly increased, and average pup body weight was significantly decreased in comparison with controls. Similar effects were seen with F1b litters of Po dams exposed to 500 ppm nickel. In the 50 and 250 ppm dose groups increased pup mortality and decreased live litter size was observed in the F1b litters. However, these effects seen with F1b litters are questionable because the room temperature tended to be 10 degrees F higher than normal at certain times (gestation-postnatal days) along with much lower levels of humidity. As evidenced in the literature, temperatures that are 10 degrees F above normal during fetal development cause adverse effects (Edwards, 1986). Therefore, the above results seen at 50 and 250 ppm cannot be considered to be genuine adverse effects.

F1b males and females of the RTI (1987) study were randomly mated on postnatal day 70 and their offspring (F2a and F2b) were evaluated through postnatal day 21. This phase included teratological evaluations of F2b fetuses. Evaluation of the data indicated that the 500 ppm dose caused significant body weight depression of both mothers and pups, and increased neonatal mortality during the postnatal development period. The intermediate dose, 250 ppm nickel, produced transient depression of maternal weight gain and water intake during gestation of the F2b litters. The 50 ppm nickel exposure caused a significant increase in short ribs (11%). However, since this effect was not seen in both the higher dose groups, the reported incidence of short ribs in the 50 ppm group is not considered to be biologically significant.

Schroeder and Mitchener (1971) conducted a 3-generation study in which 5 mating pairs of rats were provided drinking water containing 5 mg Ni/L (estimated as 0.43 mg/kg bw). Results of this study indicated significant increases in neonatal mortality and in the number of runts born to exposed rats compared with controls. The major weakness of this study, however, is that the end result is based on a total of five matings. The matings were not randomized and the males were not rotated. The Schroeder and Mitchener (1971) study was conducted in an environmentally controlled facility where rats had access to food and water containing minimal levels of essential trace metals. Because of the interactions of nickel with other trace metals, the restricted exposure to trace metals (chromium was estimated as inadequate) may have contributed to the toxicity of nickel.

Smith et al. (1990) also studied the reproductive and fetotoxic effects of nickel. Four groups of 34 female Long-Evans rats were given drinking water containing nickel chloride in the following concentrations of nickel: 0, 10, 50 or 250 ppm (0, 1.3, 6.8 or 31.6 mg/kg/day) for 11 weeks prior to mating and during two successive gestation periods (G1, G2) and lactation periods (L1, L2).

Maternal body weight gain was reduced during G1 in mid- and high-dose females. The reproductive performance of the exposed rats was not affected. Pup birth weight was unaltered by treatment, and weight gain was reduced only in male pups exposed to 50 ppm nickel during L1. The most significant toxicological finding was the increased incidence of perinatal mortality. The proportion of dead pups per litter was elevated at the high dose in L1 and at 10 and 250 ppm in L2. While the perinatal mortality reported in this study is consistent with other reproductive studies on nickel, it is hard to define a NOAEL and LOAEL because of the absence of a clear dose-response trend at the lower doses.

Many studies have been published regarding nickel sensitivity in humans. Of the general population, approximately 8-10% of women and 1-2% of men demonstrate a sensitivity to nickel as determined by a patch test (North American Contact Dermatitis Group, 1973; Prystowsky et al., 1979). Initial sensitization to nickel is believed to result from dermal contact, but recurring flares of eczema, particularly of the hands, may be triggered by ingestion.

The human studies described below are difficult to interpret for several reasons: very small numbers of subjects (mostly women already determined to be sensitive to nickel by a patch test) were used in the studies; many investigators reported a placebo effect; many studies were not conducted in a double-blind manner, thereby introducing investigator bias; and it was often not specified whether subjects had been fasted overnight or whether there were other dietary restrictions. It is important to note that the way in which nickel is consumed may greatly affect its bioavailability. Sunderman et al. (1989) demonstrated that 27+/-17% of the nickel in drinking water was absorbed by healthy humans whereas only 0.7+/-0.4% of the same dose of nickel ingested in food was absorbed (a 40-fold difference). One final point to bear in mind in interpreting these studies is that the subjects were generally given a bolus dose of nickel. The absorption and biokinetics following such an exposure may be quite different from an exposure which is given incrementally throughout the day.

Following an overnight fast, groups of 5 nickel-sensitive women were given 100 mL of water along with one oral dose of nickel sulfate containing 0.6, 1.25 or 2.5 mg nickel (Cronin et al., 1980). The clinical response was observed for the next 24 hours. Worsening of hand eczema was reported in 2/5 female subjects that received 0.6 mg, 3/5 at 1.25 mg and 5/5 at 2.5 mg. Erythema was observed in 1/5 (0.6 mg), 4/5 (1.25 mg) and 4/5 (2.5 mg) women. While there appears to be a good dose-response relationship, this study did not report controls. The response observed at the lowest dose may well be within background levels.

Numerous other studies have been conducted to attempt to establish the relationships between nickel exposure and dermal irritation. Kaaber et al. (1978, 1979) reported worsening of eczema following an oral challenge with 2.5 mg nickel. In the 1978 study, 17/28 subjects experienced aggravation of dermatitis following nickel ingestion. Nine of the 17 that experienced adverse

effects from the nickel found that their condition improved when they adopted a low nickel diet. In the 1979 study 9/14 subjects responded negatively to nickel treatment.

Studies conducted by Gawrodger et al. (1986), Burrows et al. (1981) and Jordan and King (1979) offer different results. Jordan and King's double blind, placebo controlled investigation suggested that 0.5 mg supplement to a normal diet was safe with the possible exception of extremely sensitive individuals. Gawrodger et al. (1986) reported that 5/10 women responded to both the 0.4 and 2.5 mg doses of nickel, but 10/26 also reacted to a placebo. They determined the LOAEL of their experiment to be 5.6 mg of nickel, a dose at which 100% of the women responded. Burrows et al. (1981) administered 0.5 mg nickel twice a day on two consecutive days to 22 patients, each of whom served as her own control. There was no significant difference between the number of individuals responding to a placebo as compared to nickel. However, the placebo response was high (12/22). The authors concluded that there is probably no connection between nickel in an ordinary diet and exacerbation of dermatitis but that a higher level may aggravate dermatitis in some individuals.

Nielsen (1989) describes a study in which 12 nickel-sensitive women were challenged for a 4-day period with a diet providing 490 ug Ni/day. No changes were observed before the start of the nickel challenge to day 0 (start of challenge). On day 4, the eczema of 6 patients was considered to be worse according to both the patients' impressions and a dermatologist's evaluation. The delayed reaction in this study may be attributed to the fact that the dose of nickel was ingested in the diet throughout the day as opposed to studies which employed a bolus dose. This difference may greatly affect the pharmacokinetics of ingested nickel.

While the previous studies on humans with a hypersensitivity to nickel were considered in developing the RfD, none of them were adequate to serve as the basis for the quantitative risk assessment. The RfD is believed to be set at a level which would not cause individuals to become sensitized to nickel; however, those who have already developed a hypersensitivity (e.g., from a dermal exposure) may not be fully protected.

One final point to bear in mind in establishing an RfD for nickel is that nickel has been shown to be an essential trace element for several animal species. Rats deprived of nickel exhibit retarded growth and low hemoglobin levels (Schnegg and Kirchgessner, 1977). A requirement for nickel has not been conclusively demonstrated in humans, but nickel is considered to be a normal constituent of the diet. Typical daily intake of nickel ranges from 100-300 ug/day.

I.A.5. Confidence in the Oral RfD

Study — Low
Database — Medium
RfD — Medium

The chronic study (Ambrose et al., 1976) was properly designed and provided adequate toxicological endpoints; however, high mortality occurred in the controls (44/50). Therefore, a low confidence is recommended for the study. The database provided adequate supporting subchronic studies, one by gavage and the other in drinking water (Po animals of the RTI subchronic study, 1986). A medium confidence level in the database is recommended since there are inadequacies in the remaining reproduction data.

I.A.6. EPA Documentation and Review of the Oral RfD

Source Document — U.S. EPA, 1986, 1991

The information contained in the Quantification of Toxicologic Effects for Nickel was reviewed by the Science Advisory Board in August 1990.

Other EPA Documentation — None

Agency Work Group Review — 04/16/1987, 05/20/1987, 07/16/1987, 05/17/1990, 08/14/1991

Verification Date — 07/16/1987

I.A.7. EPA Contacts (Oral RfD)

Please contact the IRIS Hotline for all questions concerning this assessment or IRIS, in general, at (202)566-1676 (phone), (202)566-1749 (FAX) or hotline.iris@epa.gov (internet address).

I.B. Reference Concentration for Chronic Inhalation Exposure (RfC)

Substance Name — Nickel, soluble salts
CASRN — Various

Not available at this time.

II. Carcinogenicity Assessment for Lifetime Exposure

Substance Name — Nickel, soluble salts
CASRN — Various

The U.S. EPA has not evaluated soluble salts of nickel, as a class of compounds, for potential human carcinogenicity. However, nickel refinery dust and specific nickel compounds - nickel carbonyl and nickel subsulfide - have been evaluated. Summaries of these evaluations are on IRIS.

TOXICOLOGICAL REVIEW

OF

ZINC AND COMPOUNDS

(CAS No. 7440-66-6)

In Support of Summary Information on the Integrated Risk Information System (IRIS)

July 2005

U.S. Environmental Protection Agency
Washington D.C.

DISCLAIMER

This document has been reviewed in accordance with U.S. Environmental Protection Agency policy and approved for publication. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

CONTENTS —TOXICOLOGICAL REVIEW OF ZINC AND COMPOUNDS (CAS No. 7440-66-6)

LIST OF TABLES

FOREWORD

The purpose of this Toxicological Review is to provide scientific support and rationale for the hazard and dose-response assessment in IRIS pertaining to chronic exposure to zinc and compounds. It is not intended to be a comprehensive treatise on the chemical or toxicological nature of zinc and compounds.

In Section 6, *Major Conclusions in the Characterization of Hazard and Dose Response*, EPA has characterized its overall confidence in the quantitative and qualitative aspects of hazard and dose response by addressing knowledge gaps, uncertainties, quality of data, and scientific controversies. This discussion is intended to convey the limitations of the assessment and to aid and guide the risk assessor in the ensuing steps of the risk assessment process.

For other general information about this assessment or other questions relating to IRIS, the reader is referred to EPA's IRIS Hotline at 202-566-1676.

REVIEWERS

This document and the accompanying IRIS Summary have been peer reviewed by EPA scientists and independent scientists external to EPA. Comments from all peer reviewers were evaluated carefully and considered by the Agency during the finalization of this assessment. During the finalization process, the IRIS Program Director achieved common understanding of the assessment among the Office of Research and Development; Office of Air and Radiation; Office of Prevention, Pesticides, and Toxic Substances; Office of Solid Waste and Emergency Response; Office of Water; Office of Policy, Economics, and Innovation; Office of Children's Health Protection; Office of Environmental Information, and EPA's regional offices.

Summaries of the external peer reviewers' comments and the disposition of their recommendations are in Appendix A.

1. INTRODUCTION

This document presents background information and justification for the Integrated Risk Information System (IRIS) Summary of the hazard and dose-response assessment of zinc and compounds. IRIS Summaries may include an oral reference dose (RfD), inhalation reference concentration (RfC) and a carcinogenicity assessment.

The RfD and RfC provide quantitative information for use in risk assessments for health effects known or assumed to be produced through a nonlinear (possibly threshold) mode of action. The RfD is an estimate of an oral exposure for [a given duration], to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime. It is derived from a statistical lower confidence limit on the benchmark dose (BMDL), a no-observed-adverse effect-level (NOAEL), a lowest-observed-adverse-effect level (LOAEL), or another suitable point of departure, with uncertainty/variability factors applied to reflect limitations of the data used. The RfD is expressed in units of mg/kg-day. The inhalation RfC is analogous to the oral RfD, but provides a continuous inhalation exposure estimate. The inhalation RfC considers toxic effects for both the respiratory system (portal-of-entry) and for effects peripheral to the respiratory system (extrarespiratory or systemic effects). It is generally expressed in units of mg/m^3.

The carcinogenicity assessment provides information on the carcinogenic hazard potential of the substance in question and quantitative estimates of risk from oral and inhalation exposure. The information includes a weight-of-evidence judgment of the likelihood that the agent is a human carcinogen and the conditions under which the carcinogenic effects may be expressed. Quantitative risk estimates are presented in three ways to better facilitate their use: (1) generally, the *slope factor* is the result of application of a low-dose extrapolation procedure and is presented as the risk per mg/kg-day of oral exposure; (2) the *unit risk* is the quantitative estimate in terms of either risk per µg/L drinking water or risk per $µg/m^3$ continuous airborne exposure; and (3) the 95% lower bound and central estimate on the estimated concentration of the chemical substance in drinking water or air that presents cancer risks of 1 in 10,000, 1 in 100,000, or 1 in 1,000,000.

Development of these hazard identification and dose-response assessments for zinc and compounds has followed the general guidelines for risk assessment as set forth by the National Research Council (1983). EPA guidelines that were used in the development of this assessment

include the following: *Guidelines for the Health Risk Assessment of Chemical Mixtures* (U.S. EPA, 1986a), *Guidelines for Mutagenicity Risk Assessment* (U.S. EPA, 1986b), *Recommendations for and Documentation of Biological Values for Use in Risk Assessment* (U.S. EPA, 1988), *Guidelines for Developmental Toxicity Risk Assessment* (U.S. EPA, 1991), *Interim Policy for Particle Size and Limit Concentration Issues in Inhalation Toxicity* (U.S. EPA, 1994a), *Methods for Derivation of Inhalation Reference Concentrations and Application of Inhalation Dosimetry* (U.S. EPA, 1994b), *Peer Review and Peer Involvement at the U.S. Environmental Protection Agency* (U.S. EPA, 1994c), *Proposed Guidelines for Neurotoxicity Risk Assessment* (U.S. 1995a), *Use of the Benchmark Dose Approach in Health Risk Assessment* (U.S. EPA, 1995b), *Guidelines for Reproductive Toxicity Risk Assessment* (U.S. EPA, 1996), *Science Policy Council Handbook: Peer Review* (U.S. EPA, 1998), and *Guidelines for Carcinogen Risk Assessment* (U.S. EPA, 2005).

The literature search strategy employed for this compound was based on the CASRN and at least one common name. Any pertinent scientific information submitted by the public to the IRIS Submission Desk was also considered in the development of this document. The relevant literature was reviewed through October, 2004.

2. CHEMICAL AND PHYSICAL INFORMATION RELEVANT TO ASSESSMENTS

Some of the chemical and physical properties of zinc and zinc-containing compounds are presented in Table 2-1.

Table 2-1. Chemical and physical properties of zinc and selected zinc compounds

	Zinc	Zinc oxide	Zinc chloride	Zinc sulfate	Zinc sulfide
CAS Registry Number	7440-66-6	1314-13-2	7646-85-7	7733-02-0	1314-98-3

Zinc is ubiquitous in the environment and occurs in the earth's crust at an average concentration of about 70 mg/kg (Thomas, 1991). Zinc metal is not found freely in nature; rather it occurs in the +2 oxidation state primarily as various minerals such as sphalerite (zinc sulfide), smithsonite (zinc carbonate), and zincite (zinc oxide). Fifty-five zinc containing minerals are known to exist. The most important commercial minerals, their molecular composition and zinc percentages are listed in Table 2-2.

Table 2-2. Zinc commercial minerals, molecular composition, and percentage of zinc

Name	Composition	% Zinc
Sphalerite	ZnS	67.0
Hemimorphite	$Zn_4Si_2O_7(OH)_2H_2O$	54.2
Smithsonite	$ZnCO_3$	52.0
Hydrozincite	$Zn_5(OH)_6(CO_3)_2$	56.0
Zincite	ZnO	80.3
Willemite	Zn_2SiO_4	58.5
Franklinite	$(Zn,Fe,Mn)(Fe,Mn)_2O_4$	15-20

Source: Goodwin, 1998.

The primary anthropogenic sources of zinc in the environment are from metal smelters and mining activities (ATSDR, 1995). The production and use of zinc in brass, bronze, die castings metal, alloys, rubbers, and paints may also lead to its release to the environment through various waste streams.

Elemental zinc is a lustrous, blue-white to grey metal that is virtually insoluble in water. It has a melting point of 419.5°C and boiling point of 908°C (ATSDR, 1995). Pure zinc is usually produced by an electrolytic process in which zinc oxide is leached from the roasted or calcined ore with sulfuric acid to form zinc sulfate solution which is electrolyzed in cells to deposit zinc on cathodes (Lewis, 1993). The primary application of zinc in metallurgy is its use as a corrosion protector for iron and other metals.

Zinc salts have numerous applications and are used in wood preservation, catalysts, corrosion control in drinking water systems, photographic paper, vulcanization acceleration for rubber, ceramics, textiles, fertilizers, pigments, batteries, and as nutritional supplements or medicines (ATSDR, 1995). Zinc chloride is a primary ingredient in smoke bombs used for crowd dispersal, in fire-fighting exercises (by both military and civilian communities), and by the military for screening purposes. Zinc chloride, zinc sulfate, zinc oxide, and zinc sulfide have dental, medical, and household applications. Zinc chloride and zinc sulfate are also used in herbicides (ATSDR, 1995). Zinc compounds are usually colorless which is advantageous since

they do not color paints, plastics, rubber, or cosmetics to which they might be added. However, zinc oxide and zinc sulfide exhibit luminescence when excited by UV-Vis radiation.

Zinc ions are strongly adsorbed to soils at pH 5 or greater and are expected to have low mobility in most soils (Christensen et al., 1996; Gao et al., 1997). Zinc is taken up by plants and vegetables and the normal zinc content is in the range of 15 to 100 mg/kg (Thomas, 1991).

In natural waters, zinc can be found in several chemical forms, such as hydrated ions, metal-inorganic complexes, or metal-organic complexes (U.S. EPA, 1979). Hydrated zinc cations may be hydrolyzed to form zinc hydroxide or zinc oxide (U.S. EPA, 1979). In anaerobic environments, Zinc sulfide may be formed (U.S. EPA, 1979). Zinc accumulates in aquatic organisms, and bioconcentration factor values for freshwater fish and marine fish were reported as 1000 and 2000, respectively (U.S. EPA, 1979).

As discussed in Section 4.1, zinc is an essential element in humans. In adults, the greatest dietary sources of zinc are meats, dairy products, grains, and mixed dishes (Pennington et al., 1989), while fruits, nuts, fats, sweeteners, and beverages contribute comparatively small amounts of zinc to the diet.

3. TOXICOKINETICS RELEVANT TO ASSESSMENTS

3.1. ABSORPTION

3.1.1. Gastrointestinal Absorption

Numerous studies have assessed zinc absorption in healthy humans under a variety of dietary conditions. The North American adult diet contains about 8-15 mg Zn/day based on data from the 1988-1994 National Health and Nutrition Examination Survey (IOM, 2001). Zinc uptake from a normal diet ranges from 26-33% (Sandstrom and Abrahamson, 1989; Knudsen et al., 1995; Hunt et al., 1998) when taken with food, but is higher (i.e., 68-81%) when subjects have fasted (Istfan et al., 1983; Sandstrom and Abrahamson, 1989). Within a 5-25 mg dose range, zinc absorption, expressed as a percent of the total dose administered, decreases as the dose increases; for example, in human volunteers, 61% of a 24.5 mg dose of zinc (as zinc chloride) was absorbed, compared to 81% of a 4.5 mg dose (Istfan et al., 1983).

Within the digestive tract, zinc is primarily absorbed in the small intestine. Ligation studies in rats have suggested that absorption is mainly in the duodenum (Methfessel and Spencer, 1973; Davies, 1980), with approximately 60% of the absorption occurring in the duodenum, 30% in the ileum, 8% in the jejunum, and 3% through the colon and cecum (Davies, 1980). However, more recent studies in humans (Lee et al., 1989) have suggested a greater rate of transport across the jejunum than across any other intestinal segment. As discussed in a review by Lönnerdal (2000), it is possible that while there is a greater rate of absorption in the jejunum, the fact that oral zinc first passes through the duodenum allows for a greater absolute absorption in that segment, despite a greater transport rate in the jejunum. However, the quantitative importance of the different intestinal segments is not yet clearly defined. Gastrointestinal absorption of zinc is biphasic, with an initial rapid phase followed by a saturable slow phase (Davies, 1980; Gunshin et al., 1991). It is notable that these studies generally used water-soluble forms of zinc; as zinc appears to be absorbed as zinc ion, less soluble forms would be expected to show a lower level of gastrointestinal absorption.

Zinc appears to be absorbed by both passive diffusion and a saturable carrier-mediated process (Tacnet et al., 1990). The carrier-mediated mechanism appears to be most important at low zinc levels, and involves a saturable cysteine-rich intestinal protein (CRIP) (Hempe and Cousins, 1991, 1992). CRIP binds zinc during transmucosal transport and may function as an intracellular zinc carrier. There is also some evidence that CRIP binds zinc in competition with

metallothionein (Hempe and Cousins, 1991). The binding capacity of CRIP for zinc is limited, and CRIP becomes saturated at high intestinal concentrations of zinc (Hempe and Cousins, 1991). Metallothionein may be involved in zinc homeostasis at higher zinc concentrations (Richards and Cousins, 1975; Hempe and Cousins, 1992). Metallothionein production is increased in response to an increase in zinc levels as well as by other heavy metals (Richards and Cousins, 1975; Cousins, 1985). The exact role of metallothionein in zinc absorption is not known, but it is thought to regulate zinc availability by sequestering it in the intestinal mucosal cells, thereby preventing absorption and providing an exit route for excess zinc as these cells are shed and excreted in the feces (Foulkes and McMullen, 1987). It has been proposed that as zinc enters the cells of the intestinal mucosa it is initially associated with CRIP, with only a small fraction binding to metallothionein, but as zinc concentrations rise, the binding to CRIP becomes saturated, the proportion of zinc binding to CRIP decreases, and more zinc is bound to metallothionein (Hempe and Cousins, 1992).

Evans (1976) proposed that zinc bound to ligands is transported into epithelial cells where the metal is transferred to the binding site on the plasma membrane. Metal-free albumin then interacts with the plasma membrane and removes zinc from the receptor site. The quantity of metal-free albumin available probably determines the amount of zinc removed from the epithelial cell, and thus regulates the quantity of zinc that enters the body. Several dietary factors can influence zinc absorption, including other trace elements (e.g., copper, iron, lead, calcium, cadmium, cobalt; see Section 4.6.2), amino acids, simple and complex carbohydrates, and protein. High levels of phytate or phosphate in the diet can decrease the amount of zinc absorbed (Pecoud et al., 1975; Larsson et al., 1996; Oberleas, 1996). Oberleas (1996) suggested that the phytate in the food provided to test subjects complexes with endogenous zinc ions secreted from the pancreas, thus preventing its reabsorption and increasing fecal zinc elimination. In general, low molecular weight substances, such as amino acids, increase the absorption of zinc (Wapnir and Stiel, 1986). Imidazole, tryptophan, proline, and cysteine increased zinc absorption from various regions of the gastrointestinal tract. Wapnir and Stiel (1986) suggested that the increase was due to the presence of both mediated and non-mediated transport mechanisms for amino acids. Absorption is inhibited by certain proteins (e.g., bovine serum albumin and dephytinized soyabean protein isolate), is unaffected by others (e.g., bovine whey) (Davidsson et al., 1996), and enhanced by others (e.g., casein) (Hunt et al., 1991; Davidsson et al., 1996).

Physiological factors also appear to influence zinc absorption. The primary factor influencing zinc absorption appears to be the body's ability to alter zinc excretion and absorption efficiency in order to maintain zinc homeostasis (Johnson et al., 1993). Zinc absorption is enhanced in humans with low zinc levels; 93% of a 1.19 mg dose of zinc was absorbed in subjects maintained on a low zinc diet (1.4 mg/day) as compared to 81% absorption of the same test dose in subjects on an adequate zinc diet (15 mg/day) (Istfan et al., 1983). A study in mice (He et al., 1991) suggests that zinc absorption decreases with age. Fractional absorption was significantly lower in young adult mice (70 days of age) and in adult mice (100 days of age) compared to weanling mice (1 day of age); fractional absorption in adolescent mice (20 days of age) was similar to that found in weanlings.

3.1.2. Respiratory Tract Absorption

Hamdi (1969) found elevated levels of zinc in the urine and blood of workers exposed to zinc oxide fumes, relative to non-exposed workers. Although this study did not estimate zinc absorption efficiency, it does provide evidence that zinc is absorbed following inhalation exposure. Similarly, Drinker and Drinker (1928) found elevated levels of zinc in the gall bladder, kidney, and pancreas of cats, rabbits, and rats exposed to airborne zinc oxide.

Studies by Sturgis et al. (1927) and Gordon et al. (1992) examined lung retention following inhalation exposure to zinc oxide. Retention is reflective of deposition of zinc oxide in the lung rather than systemic absorption (Hirano et al., 1989). Species differences in retention have been observed; guinea pigs, rats, and rabbits retained 20, 12, and 5%, respectively, following nose-only exposure to 11.3, 4.3, or 6.0 mg/m^3 of zinc oxide, respectively, for 3 hours (guinea pigs and rats) or 6 hours (rabbits) (Gordon et al., 1992).

3.2. DISTRIBUTION

Zinc is an essential human nutrient, a cofactor for over 300 enzymes, and is found in all tissues. In humans, the highest concentrations of zinc have been found in bone, muscle, prostate, liver, and kidneys (Schroeder et al., 1967; Wastney et al., 1986). Similar distributions have been found in animals (Ansari et al., 1975, 1976; Llobet et al., 1988). Less than 10% of the body's total zinc is readily exchanged with plasma (Miller et al., 1994) and most of this is from the slow exchange of zinc located in bone and muscle. In blood, zinc is found in plasma, erythrocytes, leukocytes, and platelets. Approximately 98% of serum zinc is bound to proteins; 85% is bound to albumin, 12% to α_2-macroglobulin, and the remainder to amino acids (Giroux et al., 1976). In

erythrocytes, zinc is predominantly found as a component of carbonic anhydrase (87%) and Cu, Zn-superoxide dismutase (5.4%) (Ohno et al., 1985).

Ansari et al. (1975) examined the heart, liver, kidneys, muscle, tibia, and small intestine for changes in tissue zinc concentration following the addition of 600 ppm supplemental zinc to the diet of male rats for up to 42 days. While small increases in tissue zinc levels relative to controls were reported, only occasionally were the differences statistically significant, and no pattern with increasing tissue zinc with time was noted. In a later study, Ansari et al. (1976) exposed male rats to up to 8400 ppm supplemental zinc as zinc oxide in the diet for 21 days then examined the liver, kidney, heart, tibia, and muscle for tissue zinc concentrations. Exposure to 1200 ppm had no significant effect on tissue zinc levels relative to controls; the amount of stable zinc in liver, kidney, and bone was increased at 2400 ppm and higher, but reached a plateau (2400-7200 ppm; approximately 200-625 mg/kg-day). Exposure at the highest level (8400 ppm) caused additional increases in liver, kidney, and bone, as well as an increase in zinc level in the heart. No changes in zinc concentration were seen in the skeletal muscle. Similar results for the accumulation of zinc in organs have been found in mice (He et al., 1991), rabbits (Bentley and Grubb, 1991), and wood mice *(Apodemus sylvaticus L.*) (Cooke et al., 1990).

In a series of animal experiments carried out by Drinker and Drinker (1928), the fate of inhaled zinc oxide from the lungs of animals (cats, rabbits and rats) was assessed. Increased zinc levels were found in the lungs, pancreas, liver, kidney, and gall bladder.

3.3. METABOLISM

Zinc is a metallic element that is found in the body as a divalent cation. Accordingly, it does not undergo metabolism. It interacts electrostatically with anions (i.e., carbonate, hydroxide, oxalate, phytate) and negatively charged moieties on macromolecules such as proteins. It can also form soluble chelation complexes with amino acids and multidentate organic acids such as ethylenediaminetetraacetic acid.

3.4. ELIMINATION AND EXCRETION

Following oral exposure, zinc is primarily excreted via the gastrointestinal tract and eliminated in the feces; approximately 70-80% of an ingested dose is excreted in the feces (Davies and Nightingale, 1975). Oberleas (1996) found that the pancreas secretes into the

duodenum two to four times the amount of zinc that is typically consumed in an average day; most of this secreted zinc is reabsorbed. Zinc is also excreted in the urine. In humans, approximately 14% of the eliminated zinc was excreted in urine; when zinc intake was increased, urinary excretion accounted for 25% of the eliminated zinc (Wastney et al., 1986). Other minor routes of elimination are sweat (Prasad et al., 1963), saliva secretion (Greger and Sickles, 1979), and incorporation into hair (Rivlin, 1983).

The rate at which zinc is excreted is dependant on both current zinc intake and past zinc intake, probably via an effect on body stores (Johnson et al., 1988). Age also affects the rate at which zinc is excreted. He et al. (1991) reported higher fecal excretion of zinc in adult mice following an intraperitoneal dose of ^{65}Zn, as compared to weanling, adolescent, or young adult mice.

3.5. PHYSIOLOGICALLY-BASED TOXICOKINETIC MODELS

Physiologically based toxicokinetic models have been developed to assess environmental exposure levels for other metals such as cadmium and lead. However, no toxicokinetic models have been developed for zinc in either human or animal species.

4. HAZARD IDENTIFICATION

4.1. ESSENTIALITY OF ZINC

While the focus of this document, and the values derived in Chapter 5, is on the effects of excess zinc exposure, rather than the effects of insufficient zinc intake, a discussion of the importance of zinc as a dietary nutrient is relevant when considering the effects of zinc exposure. The essentiality of zinc was established over 100 years ago. Zinc is essential for the function of more than 300 enzymes, including alkaline phosphatase, alcohol dehydrogenase, Cu, Zn-superoxide dismutase, carboxypeptidase, δ-aminolevulinic acid dehydratase (ALAD), carbonic anhydrase, deoxyribonucleic acid (DNA) polymerases (DNA polymerase alpha, DNA polymerase III), and reverse transcriptase (Vallee and Falchuk, 1993; Sandstead, 1994). A list of key enzymes containing zinc or affected by zinc status are provided in Table 4-1. Zinc has three functions in these metalloenzymes: participation in catalytic functions, maintenance of structural stability, and regulatory functions (Vallee and Falchuk, 1993; Walsh et al., 1994). Zinc is also involved in DNA and ribonucleic acid (RNA) synthesis and cell proliferation. The zinc coordinates with cysteine and histidine residues of certain peptides and produces a tertiary structure which has an affinity for unique segments of DNA in promoter gene regions (Prasad, 1993). The configurations include the zinc finger, the most common zinc motif, and the zinc thiolate cluster (Walsh et al., 1994). Other physiological roles of zinc include enhancement of the affinity of growth hormone for its binding receptors, modulation of synaptic transmissions by interacting with specific sites on ionotrophic neurotransmitter receptor proteins, and induction of metallothionein (Walsh et al., 1994).

A wide range of clinical symptoms have been associated with zinc deficiency in humans (Abernathy et al., 1993; Prasad, 1993; Sandstead, 1994; Walsh et al., 1994). The clinical manifestations of severe zinc deficiency, seen in individuals with an inborn error of zinc absorption or in patients receiving total parenteral nutrition lacking in adequate zinc, include bullous pustular dermatitis, diarrhea, alopecia, mental disturbances, and impaired cell-mediated immunity resulting in intercurrent infections. Symptoms associated with moderate zinc deficiency include growth retardation, male hypogonadism, skin changes, poor appetite, mental lethargy, abnormal dark adaptation, and delayed wound healing. Neurosensory changes (hypogeusia, decreased dark adaptation), impaired neuropsychological functions (dysosmia, irritability, and reduced cognitive function), oligospermia, decreased serum testosterone, hyperammonemia, and impaired immune function (alterations in T-cell subpopulations,

decreased natural killer cell activity) have been observed in individuals with mild or marginal zinc deficiency.

As reviewed by Mahomed et al. (1989), severe zinc deficiency in animals has been associated with reduced fertility, fetal nervous system malformations, and growth retardation in late pregnancy. In humans, labor abnormalities, congenital malformations, and preterm labor have been reported in otherwise healthy women with low maternal serum zinc concentrations. Numerous studies have examined pregnancy outcomes following zinc supplementation. For example, Simmer et al. (1991) found significant intrauterine growth retardation and fewer inductions of labor (generally associated with poor fetal growth), and non-statistically significant decreases in birth weight and placental weights in zinc-deficient women compared to women receiving a supplement containing 100 mg zinc citrate (22.5 mg zinc). The women receiving the supplement had been selected because they were determined to be at risk of delivering small-for-gestational age babies. However, Mahomed et al. (1989) did not find any statistically significant differences in gestation duration, details of labor and delivery, fetal development, or neonatal health among 246 randomly selected pregnant women receiving 20 mg Zn/day as zinc sulfate (66 mg zinc sulfate) tablets beginning before the 20th week of pregnancy as compared to 248 women receiving placebo tablets. While the zinc supplement and placebo group had marginal zinc intake (approximately 10 mg/day) prior to supplementation, the zinc supplementation did not appear to influence pregnancy outcome. The author commented that the women recruited in this study were from mid-socioeconomic groups. Endogenous stores of zinc could possibly have met the need for fetal development.

Table 4-1. Key enzymes containing zinc or affected by zinc status

Enzyme name (symbol)	Alternative titles (symbol)	Reaction catalyzed	Cofactor(s)	Enzyme commission number (EC)[a]
Cu, Zn-superoxide dismutase	Superoxide dismutase, cytosolic; Superoxide dismutase 1	$2\ O_2^{\cdot-} + 2\ H^+ <=> O_2 + H_2O_2$	Copper and zinc	1.15.1.1
Erythrocyte Cu, Zn-superoxide dismutase	Superoxide dismutase, cytosolic; Superoxide dismutase 1	$2\ O_2^{\cdot-} + 2\ H^+ <=> O_2 + H_2O_2$	Copper and zinc	1.15.1.1
Extracellular Cu, Zn-superoxide dismutase	Superoxide dismutase, extracellular	$2\ O_2^{\cdot-} + 2\ H^+ <=> O_2 + H_2O_2$	Copper and zinc	1.15.1.1

The zinc content of a typical mixed diet of North American adults is approximately 10-15 mg/day (IOM, 2001). The U.S. Food and Drug Administration's (FDA) Total Diet Study (Pennington and Schoen, 1996) found zinc intakes of 7.25, 9.74, 15.42, 9.38, and 15.92 mg/day in children (2 years of age), girls (14-16 years), boys (14-16 years), women (25-30 years), and men (25-30 years), respectively. The 2000 recommended dietary allowances (RDAs) for zinc (IOM, 2001) are presented in Table 4-2.

4.2. STUDIES IN HUMANS

Human studies have investigated the effects of dietary zinc supplementation. High doses can cause clinical symptoms of gastrointestinal distress, while low doses primarily affect the status of other essential nutrients such as copper and iron.

4.2.1. Oral Exposure

In a double-blind crossover trial, Samman and Roberts (1987, 1988) gave zinc sulfate tablets (150 mg supplemental Zn/day in three divided doses at mealtimes) to healthy adult volunteers (21 men and 26 women) for 6 weeks; identical capsules containing lactose were given to the same group of volunteers for 6 weeks as the placebo. Using the reported average body weights, the zinc doses averaged 2 mg Zn/kg-day for the men and 2.5 mg Zn/kg-day for the women. Adverse symptoms, including abdominal cramps, vomiting, and nausea, occurred in 84% of the women and 18% of the men. Five females withdrew from the trial because of gastric irritation. A dose-related increase in clinical symptoms was observed when doses were expressed on a mg/kg-day basis. Ingestion of zinc tablets alone (contrary to instructions) or with small meals increased the incidence of adverse effects. Zinc administration for 6 weeks had no effect on plasma levels of copper, total cholesterol, or high-density lipoprotein (HDL)-cholesterol in males or females, but significantly decreased the plasma level of low-density lipoprotein (LDL)-cholesterol in females only. An apparent inverse linear relationship between plasma zinc levels and LDL-cholesterol levels was found in the females. Hematocrit values were unaffected by zinc ingestion in males and females. Specific measures of copper status (ferroxidase activity of serum ceruloplasmin, antioxidant activity of erythrocyte Cu, Zn-superoxide dismutase [ESOD] activity) were apparently unaffected in males. However, females, who received higher mg/kg-day doses of zinc than males, exhibited a significant reduction in the activity of two copper metalloenzymes: serum ceruloplasmin and ESOD. Other indicators of copper status were not affected.

Table 4-2. Recommended dietary allowances (RDA) by life stage group and gender

Life stage group	RDA (mg/day)	
	Male	Female
0 through 6 months	2[a]	2[a]
7 through 12 months	3	3
1 through 3 years	3	3
4 through 8 years	5	5
9 through 13 years	8	8
14 through 18 years	11	9
19 through 50 years	11	8
>51 years	11	8
Pregnancy		
≤18 years		12
19 through 50 years		11
Lactation		
<18 years		13
19 through 50 years		12

[a]Acceptable daily intake. No RDA value was reported.

Fischer et al. (1984) instructed groups of 13 healthy adult male volunteers (ages not specified) to take capsules containing 0 (cornstarch) or 25 mg supplemental zinc (as zinc gluconate) twice daily for 6 weeks; using a reference body weight of 70 kg for an adult male, average daily dose was 0.71 mg supplemental Zn/kg-day. Nonfasting blood samples were taken at the beginning and at biweekly intervals and tested for measures of copper status. Plasma copper levels and levels of ceruloplasmin's ferroxidase activity did not change during the course of the study. However, ESOD activity decreased after 4 weeks in the supplement group and was significantly lower than controls by 6 weeks. An inverse correlation between plasma zinc levels and ESOD activity was also observed at 6 weeks.

A 10-week study of zinc supplementation in 18 healthy women, aged 25-40 years, given zinc gluconate supplements twice daily (50 mg supplemental Zn/day, or 0.83 mg supplemental Zn/kg-day) resulted in a decrease of ESOD activity (Yadrick et al., 1989). ESOD activity declined over the 10-week supplementation period and, at 10 weeks, was significantly different ($p<0.05$) from values during the pretreatment period. By 10 weeks, ESOD activity had declined to 53% of pretreatment levels. This change in enzyme activity is considered a better indicator of altered copper status than a measure of metal concentration in tissue or plasma. This has been documented by studies in rats which were fed copper-deficient or high-zinc diets, in which treatment-related changes in copper metalloenzyme activity are greater and precede changes in plasma or tissue levels of copper (L'Abbe and Fischer, 1984a, b). Ceruloplasmin activity was not altered. Serum zinc was significantly increased. There was also a significant decline in serum ferritin and hematocrit values at 10 weeks. Such a decrease could pose a significant risk to the iron status of women.

Recently, Davis et al. (2000) and Milne et al. (2001) have reported the results of exposure of a group of postmenopausal women (aged 50-76, mean of 64.9 ± 6.7 years) to varying concentrations of zinc and copper in the diet. Average height was 159.6 ± 7.6 cm, and mean body weight was 65.1 ± 9.5 kg. Subjects were kept in a metabolic ward for a 200-day period, and fed a controlled basal diet that contained 0.6 mg copper and 3 mg zinc. For the first 10 days, all subjects consumed an equilibration diet, which consisted of the basal diet supplemented with 1.4 mg copper (2 mg total) and 6 mg zinc (9 mg total). Following an initial 10-day equilibration, one group (n=12) was exposed to the basal diet supplemented with 0.4 mg Cu/day (1 mg Cu/day total) and the other group (n=13) was fed the basal diet supplemented with 2.4 mg Cu/day (3.0 mg Cu/day total). The remaining 190 days were divided into two 90-day study periods for both groups: the copper-supplemented basal diet (1 mg Cu/day, total) with no zinc supplement was fed for the first 90-day period and the copper-supplemented (1 mg Cu/day, total) basal diet supplemented with 50 mg Zn/day was fed for the second 90-day period. The two 90-day periods were separated by an additional equilibration period, identical to the one performed at the beginning of the study.

During each of the equilibration periods, and twice monthly during the exposure periods, blood was drawn from the subjects after an overnight fast, and evaluated for changes in cells and cell elements (erythrocytes, platelets, mononuclear cells [MNC], neutrophils), plasma and blood levels of copper and zinc, and a variety of blood proteins and factors (alkaline phosphatase activity, superoxide dismutase activities [ESOD and extracellular Cu, Zn-superoxide dismutase

(EC-SOD)], 5'-nucleotidase activity, triiodothyronine, thyroxine, and thyroid-stimulating hormone levels, and amyloid precursor protein [APP] levels). Copper and zinc levels were determined for urine, feces, and diet. Alcohol tolerance tests were performed at the end of the first equilibration period and at the end of the low- and high-zinc exposures. Data were analyzed by a two-way (dietary zinc and copper) repeated-measures analysis of variance, and Tukey's contrasts were used to test for differences among means.

Plasma zinc concentrations were significantly lower, relative to the equilibration levels, and platelet zinc concentrations tended to be lower, though not significantly, in subjects fed 3 mg Zn/day than in those fed 53 mg Zn/day; plasma zinc was not lowered from equilibration levels when subjects were fed 3 mg Zn/day, but was elevated in those fed 53 mg Zn/day. Zinc supplementation increased Zn levels in the feces and urine, but did not appear to affect plasma Cu levels. Neither erythrocyte zinc levels nor erythrocyte membrane zinc concentrations were significantly altered by changes in dietary zinc.

High-zinc subjects showed significant increases in bone-specific alkaline phosphatase activity, relative to the equilibration period, but not in plasma alkaline phosphatase or erythrocyte membrane alkaline phosphatase. Zinc supplementation significantly increased mononuclear white cell 5'-nucleotidase activity and decreased plasma 5'-nucleotidase activity; the difference in 5'-nucleotidase activity was apparent when subjects were fed the high-copper diet, but not when they were fed the low-copper diet.

EC-SOD activity, but not ESOD activity, was significantly increased by zinc supplementation; this was more apparent in the low-copper group. ESOD activity was significantly decreased relative to equilibration levels in low-copper subjects and significantly increased in high-copper subjects; in both cases, zinc supplementation caused a statistically insignificant decrease in ESOD activity.

Erythrocyte glutathione peroxidase activity was increased by low dietary zinc and decreased by high dietary zinc; however, the decrease did not result in a return to initial equilibration activity. Plasma free thyroxine concentrations, but not total thyroxine concentrations, were significantly increased in the zinc-supplemented groups; no other effects on thyroid-related endpoints were noted.

During the low-zinc period, there was an increase in total cholesterol; this increase was reversed with high-zinc treatment, resulting in lower total cholesterol. LDL-cholesterol changes were similar to the total cholesterol changes, while HDL-cholesterol, very low density lipoprotein-cholesterol, and triglycerides were not affected. Zinc supplementation significantly decreased platelet APP expression in subjects fed the low-copper diet; however, technical problems prevented many of these samples from being properly analyzed, so the sample size for APP expression was very small. Most indicators of iron status were not affected by the changes in dietary zinc or copper during the 90-day period; the exception was a small drop in hemoglobin (Hb) levels, which the investigators attributed to the effects of accumulated blood loss due to blood draws conducted during the study.

Hale et al. (1988) carried out an epidemiological study of the effect of zinc supplements on the development of cardiovascular disease in elderly subjects who were participants in an ongoing longitudinal geriatric health screening program. Noninstitutionalized, ambulatory subjects between the ages of 65 and 91 (average 78) years were evaluated using questionnaire, electrocardiogram, hematological, and drug-use data. A group of subjects (38 women and 31 men) that had ingested zinc supplements (20 to 150 mg supplemental Zn/day) for at least one year was compared to a control group (1195 women and 637 men) from the same screening program. Approximately 85% of the study group reported taking <50 mg supplemental Zn/day; for the 15% that reported an average intake of 60-150 mg supplemental Zn/day, the average duration was 8 years. The overall duration of zinc usage by the study group was: ≤2 years, 30%; >2≤10 years, 55%; and >10 years, 15%. Based on the results of the questionnaire and hematological parameters, the incidence of anemia was reported to have decreased with an increase in zinc dose. There were no differences between zinc and control groups with respect to electrocardiographic results or the incidence of adverse cardiovascular events (heart attack, heart failure, hypertension, or angina). The zinc group had a lower mean serum creatinine, lower total serum protein, lower serum uric acid, and a higher mean corpuscular Hb. Red blood cell counts were significantly lower in the women, but not in the men, of the zinc group.

Three groups of healthy white men were administered 0 (n=9), 50 (n=13), or 75 (n=9) mg/day supplemental zinc as zinc gluconate for 12 weeks (Black et al., 1988). The subjects were given instructions to avoid foods high in calcium, fiber, and phytic acid, dietary constituents that are known to decrease zinc absorption. Subjects were also told to restrict their intake of zinc-rich foods in order to minimize the variation in daily dietary zinc. Three-day dietary records were collected on a biweekly basis. These records indicated that the dietary zinc intakes of the

three treatment groups were 12.5, 14.0, and 9.5 mg Zn/day for the groups receiving the 0, 50, and 75 mg/day supplements, respectively. Based on the average body weights for each treatment group, total zinc intakes were 0.16, 0.85, and 1.10 mg Zn/kg-day for the 0, 50, and 75 mg/day groups, respectively. Biweekly blood samples were collected from all subjects and analyzed for total cholesterol, HDL-cholesterol, LDL-cholesterol, triglycerides, zinc, and copper. Urinary zinc and copper values were also determined. There was a general decline in the mean serum HDL-cholesterol for the 75-mg supplement group between weeks 6 and 12. HDL values for this group were significantly lower than those for the placebo group at weeks 6 and 12 (p <0.05). There was also a decline in the HDL values for the 50-mg group between weeks 8 through 12; however, this decline was not significantly different from that for the controls until the 12th week of treatment. When the mean HDL-cholesterol level of these subjects was compared to population percentile norms (Simko et al., 1984), there was a decline from the 92nd to the 77th percentile in 6 weeks, followed by a relative stabilization of HDL values for the remaining 6-week test period. Over the 12-week period, the HDL values for the 50-mg supplemental zinc group declined from the 90th to the 77th population percentile norms. Serum zinc, copper, total cholesterol, LDL-cholesterol, and triglycerides did not appear to be affected by treatment.

In another study, 12 healthy men (23 to 35 years) with normal serum cholesterol levels received a zinc sulfate capsule twice a day with meals (160 mg supplemental Zn/day or ~2 mg supplemental Zn/kg-day, assuming a 70 kg reference body weight) for 5 weeks and 8 subjects received placebo capsules (Hooper et al., 1980). Fasting lipid levels were measured weekly for 7 weeks and at week 16 in the zinc group, and biweekly for 6 weeks in the control group. There were no statistically significant differences in total serum cholesterol, triglyceride, and LDL-cholesterol between the zinc and control groups. After 5 weeks of zinc ingestion, serum HDL-cholesterol had been reduced by 17%; although no further zinc was administered, the serum HDL-cholesterol level continued to decline and was reduced by 26% at week 7, relative to the values for the placebo group. The rise in plasma zinc concentration did not correlate with the fall in HDL-cholesterol. Serum HDL-cholesterol returned to near baseline levels 11 weeks after the end of zinc supplementation.

Bogden et al. (1988) exposed groups of healthy elderly (age 60-89) to 0, 15, or 100 mg supplemental Zn/day for 3 months. At the end of the study, blood was drawn, and evaluated for changes in zinc levels in plasma, erythrocytes, MNCs, polymorphonuclear cells, and platelets. Serum samples were also evaluated for cholesterol, HDL cholesterol, alkaline phosphatase, and albumin. No statistically significant changes in any of the evaluated serum parameters were

reported, with the exception of an decrease in the ratio of plasma zinc to plasma copper in the high-dose group.

Chandra (1984) gave 11 healthy men 300 mg of supplemental zinc as zinc sulfate in two divided doses daily for 6 weeks (~4 mg supplemental Zn/kg-day using a 70 kg reference body weight). Fasting blood samples were taken prior to exposure, after 2, 4, and 6 weeks of exposure, and at 2 and 10 weeks following cessation of exposure. Effects of zinc ingestion included a 19% reduction in HDL levels at 4 weeks, and a 30% decrease in HDL levels and a 15% increase in LDL levels at 6 weeks, relative to pre-exposure values. Total serum cholesterol and triglycerides were unchanged. Zinc ingestion also adversely affected several indices of polymorphonuclear leukocyte function: chemotactic migration was reduced by 53% and the amount of phagocytosis of bacteria was reduced by 49%, although the bactericidal capacity was unchanged. In addition, the lymphocyte stimulation response to phytohemagglutinin was reduced by approximately 60-70%.

Freeland-Graves et al. (1982) exposed groups of eight healthy women to 0, 15, 50, or 100 mg supplemental zinc as zinc acetate daily for 60 days (approximately 0, 0.25, 0.83, or 1.7 mg supplemental Zn/kg-day, assuming a reference female body weight of 60 kg) and evaluated effects on serum zinc and cholesterol levels. Zinc exposure resulted in significant, dose-related increases in serum zinc. In the highest exposure group only, plasma HDL-cholesterol was significantly reduced at 4 weeks of exposure, but not at any other timepoint examined. A direct correlation between dietary zinc and whole-blood copper was observed in treated subjects. The study authors noted that in the 50 and 100 mg groups, some bloating, nausea, and abdominal cramps were noted unless the supplement was taken with a large glass of water at mealtime.

Prasad et al. (1978) fed a patient with sickle cell anemia supplements of 150 to 200 mg Zn/day for 2 years. The supplement resulted in copper deficiency; serum copper and plasma ceruloplasmin levels were decreased. When copper was administered, the plasma ceruloplasmin levels became normal. In a follow-up study of 13 patients on zinc therapy (similar treatment levels assumed), 7 patients had ceruloplasmin levels at the lower limit of normal after 24 weeks of dosing.

In a recent study by Prasad et al. (2004), the antioxidant effect of zinc was studied in humans. Twenty healthy subjects (9 males and 11 females, ages 19 - 50 years) were randomly assigned into two groups. Ten subjects received oral placebo, and 10 received oral zinc (45 mg

zinc as zinc gluconate) daily for 8 weeks. Blood was drawn from the subjects both before and after the treatment period, and the following parameters were examined: plasma zinc concentration, lipid peroxidation, DNA oxidation, tumor necrosis factor alpha (TNF-α) and interleukin-1β mRNA levels, and nuclear factor kappa-B (NF-κB) DNA binding. A statistically significant increase in plasma zinc concentrations was observed in the zinc-supplemented group. Plasma markers of lipid peroxidation (i.e., 4-hydroxynonenol and malondialdehyde) and DNA oxidation (i.e., 8-hydroxy-2'-deoxyguanosine) were significantly decreased in the zinc-supplemented group ($p<0.05$). Ex vivo studies were performed to determine the effects of zinc supplementation on the ability of MNCs to modulate relative mRNA levels of pro-inflammatory cytokines (i.e., TNF-α and interleukin-1β) in response to lipopolysaccharide (LPS) stimulation. LPS-treated MNCs from the zinc-supplemented group had a statistically significant decrease in the levels of TNF-α and interleukin-1β mRNA versus placebo controls. The activation and DNA binding of NF-κB following ex vivo treatment of MNCs with TNF-α was used as a model for induction of oxidative stress. A 50% decrease in the DNA binding of NF-κB was shown with MNCs from the zinc-supplemented group compared to placebo controls ($p<0.05$).

4.2.2. Inhalation Exposure

Most of the available information on the toxicity of inhaled zinc focuses on metal fume fever, a collection of symptoms observed in individuals exposed to freshly formed zinc oxide fumes or zinc chloride from smoke bombs. The earliest symptom of metal fume fever (also referred to as zinc fume fever, zinc chills, brass founder's ague, metal shakes, or Spelter's shakes) is a metallic taste in the mouth accompanied by dryness and irritation of the throat. Flu-like symptoms, chills, fever, profuse sweating, headache, and weakness follow (Drinker et al., 1927a, b; Sturgis et al., 1927; Rohrs, 1957; Malo et al., 1990). The symptoms usually occur within several hours after exposure to zinc oxide fumes and persist for 24 to 48 hours. An increase in tolerance develops with repeated exposure; however, this tolerance is lost after a brief period without exposure, and symptoms are most commonly reported at the beginning of the work week and after holidays. There are many reports of metal fume fever in the literature; however, most describe individual cases and exposure levels are not known. It is beyond the scope of this document to describe all of these reports. Below is a discussion of some of the studies which provide useful information on critical exposure levels or describe the clinical sequelae.

Drinker et al. (1927a) described the case of a worker exposed to zinc oxide on two successive days. On the first day, the worker was exposed for 5 hours to an average

concentration of 52 mg Zn/m^3. The worker reported feeling an oncoming fever four hours after exposure began, and elevated temperature, chill, and fatigue were reported several hours after exposure termination. No adverse symptoms were reported after the second day of exposure, even though zinc oxide levels were higher on the second day (330 mg Zn/m^3). To further examine this apparent tolerance, Drinker et al. (1927a) experimentally exposed another man with previous zinc oxide exposure to 430 mg/m^3 for 8 minutes on day 1 and to 610 mg/m^3 for 8 minutes on day 2. On day 1, the subject's temperature gradually increased and peaked 13 hours after exposure (101.2°F versus 98.5°F prior to exposure). The subject reported chills and feeling feverish, weak, and somewhat debilitated 10-15 hours after exposure. As with the occupational exposure, these symptoms were not observed after the second exposure.

Brown (1988) described the case of a shipyard worker who sprayed zinc onto steel surfaces. The worker complained of aches and pains, dyspnea, dry cough, lethargy, a metallic taste, and fever. Chest radiographs taken at the time of admission into a hospital revealed multiple nodules measuring 3-4 mm in size. The symptoms had resolved after 3 days, and the chest radiograph was normal after 4 days.

There is evidence to suggest that exposure to zinc oxide fumes may impair lung function. Malo et al. (1990, 1993) present case reports of two workers exhibiting symptoms of metal fume fever with evidence of functional lung involvement. In the first case (Malo et al., 1990), a worker exposed to zinc oxide fumes reported chills with muscle aches and dyspnea; a chest radiograph revealed diffuse interstitial shadows. After a 10-day period of non-exposure, the chest radiograph was normal. A lung function test was performed after the worker was away from work for 30 days; forced expiratory volume in one second (FEV_1), forced vital capacity (FVC), and the FEV_1/FVC ratio were normal. The worker was then exposed to his usual work environment for 1 hour on two consecutive days. Significant decreases in FEV_1 (16-20%) and FVC (10-11%) were observed on both days, 4-6 hours after exposure; buccal temperature was also increased and the worker experienced malaise and general muscle ache. In the second case (Malo et al., 1993), lung function tests were performed 3 months after the worker left work and after the worker returned to work for 1 day. A decrease in FEV_1 (24%) was observed after the worker returned to work (lung function was normal prior to returning to work). Total zinc concentrations in the work environment were 0.26-0.29 mg/m^3.

In a series of experiments by Drinker et al. (1927b), a group of five men and three women received face-only exposure to various concentrations of zinc oxide for 6-40 minutes.

Two of the men were exposed to several different concentrations; the remaining subjects were exposed to only one concentration. Body temperature was used as an indicator of metal fume fever. The magnitude of the increase in body temperature appeared to be concentration-related. Based on the results of this study and epidemiology data, the study authors concluded that workers exposed to less than 15 mg Zn/m^3 in the air were not likely to develop metal fume fever.

The results of more recent studies suggest that metal fume fever will occur at lower concentrations. In a study by Fine et al. (1997), a group of 13 healthy, non-smoking subjects without any previous exposure to zinc oxide fumes were exposed to 0, 2.5, or 5 mg/m^3 furnace-generated zinc oxide for 2 hours. The subjects were exposed to all three concentrations; each exposure was separated by a 48-hour non-exposure period. Significant increases in oral temperature were observed 6-12 hours after exposure to 2.5 or 5 mg/m^3 zinc oxide fume. A statistically significant increase in the number of symptoms reported was also observed after exposure to 5 mg/m^3. The symptoms occurred 6-9 hours after exposure, and all symptoms were resolved by the next day after exposure. The commonly reported symptoms were fatigue, muscle ache, and cough. Levels of plasma interleukin-6 were significantly increased after exposure to 2.5 or 5 mg/m^3; peak levels were observed 6 hours after exposure.

Gordon et al. (1992) exposed four adults to 5 mg/m^3 zinc oxide fumes or furnace gases for 2 hours. All subjects reported symptoms 4-8 hours after zinc oxide exposure; the symptoms included chills, muscle/joint pain, chest tightness, dry throat, and headache. No significant alterations in lung function were observed following zinc oxide exposure.

Martin et al. (1999) described a cohort of 20 Chinese workers who were exposed to zinc oxide over a single 8-hour workday. Subjects were given an examination by a physician, a spirometric evaluation, and chest radiographs before beginning work, immediately after the shift, and 24 hours after the start of exposure. Exposure concentrations, measured twice per individual during the 8-hour shift, ranged from 0-36.3 mg/m^3. However, as no significant association between airborne zinc measurements and serum zinc levels was present, the reliability of these measurements in reflecting actual zinc exposure is uncertain. No subject showed signs of metal fume fever. Chest radiographs likewise did not reveal any changes over the period examined. Similarly, no changes in respiratory parameters, assessed by spirometry, were reported as a result of exposure.

Zerahn et al. (1999) described the effects of an accidental exposure of 13 soldiers (11 men and 2 women) to an unknown level of zinc chloride smoke during a combat exercise. Blood samples were obtained on day 2, as well as after 1, 2, 4, and 8 weeks. Blood samples from 10/13 subjects were available on day 0, and at week 29. Spirometric analyses of lung function parameters were performed on day 1 postexposure, as well as 1, 2, 4, 8, and 29 weeks after the exposure. Radiographs were taken from day 1 after exposure and during followup. Significant decreases in lung diffusion capacity were observed from 1 week postexposure through the end of the study, with the lowest value occurring at week 4. A significant decrease in total lung capacity was seen at week 4 only, and a decrease in vital capacity at week 2 only. Plasma levels of fibrinogen were also elevated from weeks 1-8 postexposure.

Pettilä et al. (2000) described three cases of patients who inhaled an unknown level of zinc chloride smoke for 1-5 minutes and developed acute respiratory distress syndrome. Two of the three died as a result of exposure; autopsy revealed edema, pulmonary sepsis, emphysematic changes, and necrosis in both cases. The third patient developed respiratory distress on day 2 postexposure, and received supportive therapy. Four months after smoke inhalation, pulmonary function tests were 41-44% of the expected values, and revealed severe restrictive pulmonary dysfunction.

4.3. PRECHRONIC AND CHRONIC STUDIES AND CANCER BIOASSAYS IN ANIMALS—ORAL AND INHALATION

4.3.1. Oral Exposure

As with the human studies, oral animal studies have identified several critical targets of zinc toxicity. The sensitive targets of toxicity include alterations in copper status (Straube et al., 1980; L'Abbe and Fischer, 1984a, b; Bentley and Grubb, 1991), hematology (Straube et al., 1980; Maita et al., 1981; Bentley and Grubb, 1991; Zaporowska and Wasilewski, 1992), and damage to the kidneys (Straube et al., 1980; Maita et al., 1981; Llobet et al., 1988), pancreas (Aughey et al., 1977; Maita et al., 1981), and gastrointestinal tract (Maita et al., 1981).

Maita et al. (1981) exposed groups of 12 male and 12 female Wistar rats and ICR mice to 0, 300, 3000, or 30,000 ppm zinc sulfate (hydration state not reported) in the diet for 13 weeks. The study authors estimated zinc sulfate intakes of male rats to be 23.2, 234, and 2514 mg/kg-day (5.3, 53, and 572 mg supplemental Zn/kg-day). In the case of females, the authors estimated the doses as 24.5, 243, and 2486 mg $ZnSO_4$/kg-day (5.6, 55, and 565 mg supplemental Zn/kg-

day). For male mice the estimated doses were 42.7, 458, and 4927 mg $ZnSO_4$/kg-day (9.7, 104, and 1119 mg supplemental Zn/kg-day) and 46.4, 479, and 4878 mg $ZnSO_4$/kg-day (10.5, 109, and 1109 mg supplemental Zn/kg-day) for female mice. Zinc intakes from the control diet were not estimated.

In rats, no adverse clinical signs or increases in mortality were observed (Maita et al., 1981). Body weight gain was decreased in the high-dose male rats, as was food and water intake. Several statistically significant alterations in hematology and serum clinical chemistry parameters were observed in the high-dose rats; these included decreases in hematocrit and Hb levels in males, decreases in leukocyte levels in males and females, decreases in serum total protein, cholesterol, and calcium levels in males, and decreases in serum calcium levels in females. Significant decreases in absolute and relative liver and spleen weights were observed in the high-dose male rats; decreases in absolute weight were also observed in a number of other organs in the high-dose males which were probably related to the decreased body weight. No other consistent alterations in organ weights were observed. Histopathological lesions were limited to the pancreas of high-dose rats; however, significant increases in the incidence of degeneration and necrosis of acinar cells, decreased number of acinar cells, clarification of centroacinar cells and "ductule-like" metaplasia of acinar cells, and interstitial fibrosis were observed. Incidences of these lesions were not reported.

In mice, an increase in mortality was observed in the high-dose group (5/24 mice died); impairment of the urinary tract and regressive changes (decreased number of acinar cells) in the pancreas were observed in the animals dying early (Maita et al., 1981). Decreases in body weight gain were also observed in both sexes of high-dose mice. In the low- and mid-dose male mice, there were significant increases in Hb and erythrocyte levels. Significant decreases in hematocrit, Hb, and erythrocyte levels were observed in the high-dose male and female mice; a significant decrease in hematocrit level was also observed in the mid-dose male mice. Total leukocyte levels were also decreased in the high-dose male mice. Several statistically significant alterations in serum clinical chemistry parameters were observed in the high-dose mice, including slight-to-moderate decreases in total protein, glucose, and cholesterol and moderate-to-marked increases in alkaline phosphatase and urea nitrogen. Decreases in total protein and increases in alkaline phosphatase and urea nitrogen were also observed in the mid-dose male mice, although the study authors stated that the values were within acceptable historical limits. Histological alterations were observed in the pancreas, gastrointestinal tract, and kidneys of high-dose mice; incidences were not reported. Pancreatic alterations included an increased

number of acinar cells, many displaying necrosis, swollen nuclei, and/or ductule-like metaplasia. Slight-to-moderate ulcerative lesions in the boundary of the forestomach, inflammation of the mucous membranes of the "upper intestine" with proliferation of epithelial cells, and edema at the lamina propria were observed.

In a study by L'Abbe and Fischer (1984a), groups of 10 weanling male Wistar rats were fed a basal diet supplemented with 15, 30, 60, 120, or 240 ppm zinc as anhydrous zinc sulfate for 6 weeks; the 30 ppm group served as the control group. Using a reference body weight of 0.217 kg and food intake of 0.020 kg/day (U.S. EPA, 1988), daily doses of 1.4, 2.8, 5.5, 11, and 22 mg supplemental Zn/kg-day were estimated. Although a linear relationship between zinc intake and serum ceruloplasmin levels was not established, the number of animals with abnormal ceruloplasmin levels increased with increasing doses. Abnormal ceruloplasmin levels were observed in 0, 0, 11, 30, and 100% of the animals in the 15, 30, 60, 120, and 240 ppm groups, respectively. The study authors estimated that the ED_{50} for low ceruloplasmin levels was approximately 125 ppm. Dose-related decreases in liver Cu, Zn-superoxide dismutase and heart cytochrome c oxidase activities were observed at dietary zinc levels greater than 30 ppm, reaching statistical significance in the 120 and 240 ppm groups. Heart Cu, Zn-superoxide dismutase and liver cytochrome c oxidase activities were not affected.

In a second study, L'Abbe and Fischer (1984b) fed groups of 10 weanling male Wistar rats diets containing normal (30 mg Zn/kg diet) or supplemented (240 mg Zn/kg diet) zinc (as zinc sulfate) and normal (6 mg Cu/kg diet) or deficient (0.6 mg Cu/kg diet) copper for up to 6 weeks. Groups of rats were sacrificed at 2, 4, and 6 weeks. Blood, heart, and liver samples were collected for analysis. No significant differences in body weight or food consumption were noted among treated groups. Similarly, no differences were seen in Hb levels. Serum and heart copper levels were significantly decreased in rats fed either zinc-supplemented or copper-deficient diets. In both the high zinc and copper-deficient groups, activity levels of serum ceruloplasmin, liver and heart Cu, Zn-superoxide dismutase, and liver and heart cytochrome c oxidase were significantly reduced relative to control animals by 2 weeks of exposure, and remained reduced throughout the study.

Zaporowska and Wasilewski (1992) exposed groups of 13 male and 16 female Wistar rats to 0 or 0.12 mg Zn/mL as zinc chloride in the drinking water for 4 weeks. The study authors estimated the daily drinking water dose to be 11.66 mg Zn/kg-day in males and 12.75 mg Zn/kg-day for females. Although significant decreases in food and water intake were observed, body

weight gain was not significantly different from controls. Significant alterations were observed in several hematological endpoints including decreases in erythrocyte and Hb levels, increases in total and differential (neutrophils and lymphocytes) leukocyte levels, and increases in the percentage of reticulocytes and polychromatophilic erythrocytes.

Bentley and Grubb (1991) fed groups of seven-eight male New Zealand white rabbits diets containing 0, 1000, or 5000 μg supplemental zinc/g as zinc carbonate (0, 34, 170 mg supplemental Zn/kg-day using an estimated time-weighted-average body weight of 2.5 kg and an allometric equation for food intake [U.S. EPA, 1988]) for 8 (1000 μg/g group) or 22 weeks (5000 μg/g group); the basal diet contained 105.5 μg Zn/g. No adverse alterations in body weight gain were observed. A significant decrease in Hb levels were observed in the 5000 μg/g group. Significant decreases in serum copper and increases in serum and tissue (liver, kidney, brain, testis, pancreas, thymus, skin, bone, and hair) zinc levels were also observed in the 5000 μg/g group. No effects were reported at other dose levels.

de Oliveira et al. (2001) exposed groups of 9 or 12 male and female Swiss mice to 0 or 1% hydrated zinc acetate (0 or 793 mg Zn/kg-day), assuming reference body weight and drinking water consumption values from U.S. EPA (1988), beginning in the first month of life and lasting for 60 days. Animals were evaluated using a shock avoidance behavioral test at the end of their 60-day exposure period. The animals were placed in a two-compartment chamber where one compartment was dark and the other lighted. When placed in the lighted compartment, the mice (who prefer the dark) moved into the dark compartment where they received an electric shock upon contact with the dark room floor. On the next day when the animals were placed in the lighted compartment, the time before they moved into the dark compartment increased significantly from the time on the first day, signifying that they had learned from the adverse day zero experience. There was no significant difference in the time before dark room entry between the control and zinc-exposed animals on test day 1. Entry into the dark chamber did not result in shock treatment on test day 1.

The control and zinc-exposed animals continued to be tested on days 7, 14, 21, and 28. No shock was given on any of these test days. The initial period in the lit room before entering the dark room decreased over time for both the control and the zinc-exposed groups. However, the decrease over time was greater in the zinc-exposed group signifying a more rapid extinction of the learned avoidance response. The time spent in the lighted chamber before entry into the dark room was significantly lower (about half of that for the controls) for the zinc-exposed

animals on day 28. Accordingly, postnatal zinc exposure appeared to have a negative effect on the retention of a learned behavioral response.

Llobet et al. (1988) examined the effects of subchronic oral administration of zinc in Sprague-Dawley rats. Forty female rats were exposed to 0, 160, 320, and 640 mg/kg-day zinc acetate dihydrate in the drinking water (0, 48, 95, and 191 mg Zn/kg-day) for 12 weeks. Sugar was added to all drinking water of all groups to reduce unpalatability. Food and water were provided *ad libitum*. Food and water consumption, volume of urine, and weight of excreted feces were measured daily and body weights were measured weekly. After 12 weeks of treatment, blood samples were collected and analyzed for hematocrit, Hb, glucose, glutamate oxaloacetate transaminase, glutamate pyruvate transaminase, alkaline phosphatase, urea, and creatinine concentrations. The brain, heart, lungs, spleen, liver, and kidneys were weighed, analyzed for zinc concentration, and (all but the brain) examined histologically. Zinc concentrations were also determined for bone, abdominal muscle, and blood. Clinical signs noted were apathy and two deaths in the 640 mg/kg-day group. Statistically significant decreases in water intake and urine output were observed in the 640 mg/kg-day group; a decrease in urine output was also observed in the 320 mg/kg-day group for 3 of the 6 two-week measurement periods. No alterations in body weight gain or organ weights were observed. Increases in blood urea and creatinine levels in the 640 mg/kg-day group were the only significant alterations in hematological or serum clinical chemistry parameters. Zinc concentrations were significantly increased in the liver, kidneys, heart, bone, and blood of rats in the 320 and 640 mg/kg-day groups. The study authors noted that the "most severe histological alterations were observed in kidneys," but it is unclear, from the limited reporting of the histological results, if lesions were observed in other tissues. The described renal lesions included flattened epithelial cells in the Bowman's capsule, desquamation of the proximal convoluted tubules, and pyknotic nuclei in the 640 mg/kg-day group.

Straube et al. (1980) examined the effects of excess dietary zinc in ferrets. Adult ferrets (six males, nine females), weighing 500-700 g, were divided into four groups and fed a basal diet of canned dog food (that contained 27 ppm zinc and 3.3 ppm copper) plus 0 (five animals), 500 ppm (three animals), 1500 ppm (four animals), or 3000 ppm (three animals) supplemental zinc as zinc oxide. Doses of 0, 142, 425, and 850 mg supplemental Zn/kg-day, respectively, are estimated using the midpoint of the range of initial body weights and the amount of food given to each animal (170 g per day, assumed to be consumed completely each day). Animals in the 1500 and 3000 ppm groups showed signs of severe toxicity and were sacrificed or died within

the first 3 weeks. Animals in the 500 ppm group were sacrificed on days 48, 138, and 191, and the controls were sacrificed on days 27, 48, 138, 147, and 197. The following parameters were used to assess toxicity: hematology (Hb, packed cell volume, erythrocyte, leukocyte, and reticulocyte levels), serum clinical chemistry (urea nitrogen, bilirubin, ceruloplasmin oxidase activity, and blood glucose), and histopathology (kidney, liver, pancreas, lung, heart, stomach, intestine, spleen, bone marrow, and brain). Severe decreases in food intake (80%) and body weight loss (12-50%) were observed in the 1500 and 3000 ppm groups. Additional effects observed in the 1500- and 3000-ppm groups included: macrocytic hypochromic anemia, increased reticulocyte count, diffuse nephrosis, and the presence of protein, glucose, blood, and bilirubin in the urine. The 500 ppm group showed no clinical signs of toxicity. Increases in tissue zinc levels, decreases in copper levels, and decreased ceruloplasmin oxidase activity were observed at all three dietary concentrations.

Aughey et al. (1977) investigated the effects of supplemental zinc on endocrine glands in groups of 75 male and 75 female C3H mice by administering 0 or 0.5 g/L zinc (as zinc sulfate) in the drinking water for up to 14 months. The authors reported that the body weight in the control group ranged from 21 to 30 g, and the mean weight of the zinc-fed mice was approximately 1 g higher. Using the midpoint of the body weight range (0.022 to 0.031 kg), a water intake of 0.0069 L/day was calculated (U.S. EPA, 1988), resulting in average daily drinking water doses of 0 or 135 mg Zn/kg-day. At 1 month intervals, five mice in each of the treated and control groups were killed. After 6 months of exposure to zinc, there were no significant changes in plasma insulin or glucose levels as compared to controls. Histological alterations were observed in the pancreas, pituitary gland, and adrenal gland of zinc-exposed mice. The histological changes in the mice were first observed after 3 months of exposure to zinc. In the zinc-supplemented mice, the pancreatic islets were enlarged and had a vacuolated appearance. The β-cells of the pancreatic islets were larger with enlarged mitochondria and prominent Golgi apparatus. The severity of the pancreatic lesions appeared to increase with increasing exposure durations. Pituitary alterations consisted of changes in the adrenocorticotrophic hormone-producing cells that indicated increased synthesis and secretion, including increased number and size of granules and more prominent rough endoplasmic reticulum and Golgi apparatus. Hypertrophy of the adrenal zona fasciculata and increased adrenal cortical lipid and cholesterol deposition were also observed. No tumors were reported in the pancreas, pituitary gland, or adrenal gland of zinc-exposed mice; data on other organs were not reported.

In a 1-year study, an unspecified number of newborn Chester Beatty stock mice (sex not reported) were administered 0, 1000, or 5000 ppm zinc (approximately 0, 170, or 850 mg/kg/day) as zinc sulfate in drinking water (Walters and Roe, 1965). A separate group of mice received zinc oleate in the diet at an initial dose of 5000 ppm supplemental zinc; this dose was reduced to 2500 ppm after 3 months and to 1250 ppm after an additional 3 months because of mortality due to anemia. An epidemic of the ectromelia virus caused the deaths of several mice during the first 8 weeks; consequently, additional control and test-diet groups were established. There was no difference in body weight gain between control and treated groups, except for the dietary zinc group which became anemic. Survival was not reported in treated compared with control groups. An apparent increase in the incidence of hepatomas was observed in treated mice surviving for 45 weeks or longer relative to controls (original and replacement mice were pooled). The hepatoma incidences in the control, low-dose drinking water, high-dose drinking water, and test-diet groups were 3/24 (12.5%), 3/28 (10.7%), 3/22 (13.6%), and 7/23 (30.4%), respectively. Incidences of malignant lymphoma in the control, low-dose drinking water, high- dose drinking water, and test-diet groups were 3/24 (12.5%), 4/28 (14.3%), 2/22 (9%), and 2/23 (8.7%), respectively. Incidences of lung adenoma in the control, low-dose drinking water, high-dose drinking water, and test-diet groups were 10/24 (41.7%), 9/28 (32.1%), 5/22 (22.7%), and 9/23 (39.1%), respectively. None of these were significantly elevated in a statistical analysis of these data performed by the EPA.

Halme (1961) exposed tumor-resistant and tumor-susceptible strains of mice to zinc in drinking water. In a 3-year, 5-generation study, zinc chloride was added to the water of tumor-resistant mice (strain not specified); the groups received 0, 10, 20, 50, 100, or 200 mg Zn/L. The spontaneous tumor frequency for this strain of mice was 0.0004%. The tumor frequencies in the generations were reported as: F0=0.8%, F1=3.5%, F1 and F2=7.6%, and F3 and F4=25.7%. Most of the tumors occurred in the 10- and 20-mg Zinc dose groups. No statistical analyses and no individual or group tumor incidence data were reported. In the tumor-susceptible mice, strains C3H and A/Sn received 10-29 mg Zn/L in their drinking water for 2 years; 33/76 C3H strain mice developed tumors (31 in females) and 24/74 A/Sn strain mice developed tumors (20 in females). Most of the tumors were reported to be adenocarcinomas, but the tissues in which they occurred were not reported. The numbers of specific tumor types were not reported. The overall tumor frequencies (43.4% for C3H and 32.4% for A/Sn, both sexes combined) were higher than the spontaneous frequency (15% for each strain), although no statistical analyses were reported.

4.3.2. Inhalation Exposure

As with most of the human inhalation studies, inhalation studies in animals have focused exclusively on the toxicity of zinc from acute exposures. No relevant subchronic or chronic animal inhalation studies of zinc compounds were located.

In a multispecies study, Gordon et al. (1992) exposed an unspecified number of male Hartley guinea pigs, Fischer 344 rats, and New Zealand rabbits to freshly generated zinc oxide particles. The guinea pigs and rats received nose-only exposure to 0, 2.5, or 5.0 mg/m^3 zinc oxide for 3 hours; the rabbits received nose-only exposure to 0 or 5.0 mg/m^3 zinc oxide for 2 hours. Animals were sacrificed 0, 4, or 24 hours following cessation of exposure. The lungs were lavaged, and the lavage fluid and recovered cells were examined for evidence of inflammation. Significant increases in lavage fluid parameters (lactate dehydrogenase, β-glucuronidase, and protein content) were observed 24 hours after the guinea pigs and rats were exposed to 2.5 or 5.0 mg/m^3. No significant alterations in lavage parameters were observed in the rabbits. The ability of alveolar macrophages to phagocytize particles was assessed in guinea pigs and rabbits. In the guinea pigs exposed to 5.0 mg/m^3, there was a significant reduction in phagocytic capacity (percentage of viable macrophages engulfing four or more particles), but no effect on phagocytic index (percentage of macrophages engulfing particles). Phagocytic ability was not adversely affected in the rabbits. The authors suggested that the reason rabbits were less affected was a lower retention of the inhaled zinc particles (4.7% in rabbits, compared to 11.5% in rats and 19.8% in guinea pigs), resulting in a lower dose per unit tissue mass.

Lam et al. (1988) exposed groups of seven-eight male Hartley guinea pigs to 2.7 or 7 mg/m^3 (average concentrations) freshly formed ultrafine zinc oxide aerosols (count median diameter of 0.05 μm; geometric standard deviation of 2.0) for 3 hours/day for 5 days. Two groups of eight guinea pigs were exposed to furnace gases for 3 hours on one of two days; the two groups were combined and served as the control group. No significant alterations in tidal volume, functional residual capacity, residual volume, respiratory frequency, airway resistance, or compliance were observed. Gradual decreases in total lung capacity (significant after day 4), vital capacity (significant after day 2), and single-breath diffusing capacity for carbon monoxide (significant after day 4), relative to controls, were observed in the 7 mg/m^3 group, but not in the 2.7 mg/m^3 group. Significant increases in relative and absolute lung weights were also observed in the 7 mg/m^3 group.

Lam et al. (1988) also assessed the effect of a single high peak of zinc oxide on lung function. In the first of the two experiments, eight male Hartley guinea pigs were exposed to 4.0 mg/m^3 zinc oxide for 3 hours on day 1; on day 2, the animals were exposed to 34 mg/m^3 for the first hour and to 4.0 mg/m^3 for the remaining 2 hours. Significant decreases in total lung capacity and vital capacity were observed on days 2, 3, 4, and 5; apparent alveolar volume was decreased on day 3. Relative lung weights were decreased on days 2-5. In general, the decrements in lung function parameters and lung weight changes peaked at day 3. Increase in respiratory resistance and decrease in respiratory compliance were observed on days 1 and 2. Increases in absolute and relative lung weights were observed on days 2-5.

In the second experiment, eight male Hartley guinea pigs were exposed to 6 mg/m^3 (average concentration) 3 hours/day for 5 days; the animals were exposed to 25 mg/m^3 during the first hour of exposure on day 1. Several lung function parameters were significantly altered, including decreases in vital capacity and total lung capacity on days 1-5, decreases in functional residual capacity and residual volume on days 2-5, a decrease in apparent alveolar volume on day 3, and increases in single-breath diffusing capacity for carbon monoxide on days 1-5. A gradual, but statistically significant increase in respiratory resistance and decrease in respiratory compliance was observed on days 1-5. Increases in absolute and relative lung weights were observed on days 2-5.

Amdur et al. (1982) exposed groups of 23 male Hartley guinea pigs to 0.91 mg/m^3 freshly-generated zinc oxide for 1 hour. A significant decrease in respiratory compliance was observed immediately after exposure and 1 hour postexposure. No alterations in respiratory frequency, tidal volume, or minute volume were observed. Similar results were observed in another study by this group in which seven guinea pigs were exposed to 0.90 mg/m^3 zinc oxide for 1 hour. This study showed that compliance continued to decrease between the first and second postexposure hours.

4.4. REPRODUCTIVE/DEVELOPMENTAL STUDIES—ORAL AND INHALATION

4.4.1. Oral Exposure

4.4.1.1. *Reproductive and Developmental Studies in Humans*

No human studies were identified which examined the potential of zinc to induce reproductive or developmental effects. Studies which examined the influence of zinc supplementation in pregnant women with marginal zinc intakes are discussed in Section 4.1.

4.4.1.2. *Reproductive Studies in Animals*

The reproductive and developmental toxicity of zinc has been investigated in several animal studies. Studies in rats provide evidence that high oral doses of zinc (>25 mg/kg-day) adversely affect spermatogenesis (Saxena et al., 1989; Evenson et al., 1993) and result in impaired fertility (decreased number of implantation sites and increased number of resorptions) in exposed females (Sutton and Nelson, 1937; Schlicker and Cox, 1968; Kumar, 1976; Pal and Pal, 1987).

In two separate experiments, Saxena et al. (1989) exposed an unspecified number of adult male Sprague-Dawley rats to 0 or 500 ppm of supplemental zinc (zinc form not specified) in the diet for 3 or 6 weeks. Using averages of the weekly body weight and food intake data provided, the supplemental zinc intake is calculated to have been 20 mg/kg-day for the 3-week experiment and 28 mg/kg-day for the 6-week experiment. In general, there were no adverse effects on food intake or body weight gain in the rats fed the high zinc diet for 3 or 6 weeks. The study authors noted an increase in swelling of the cervical and pectoral girdle lymph nodes and lameness of the forelimbs in the zinc-exposed animals, and that the degree of swelling increased with exposure duration; however, no data were provided to assess the statistical significance of this effect. General loss of hair and roughness of fur with subcutaneous hematomas were also noted in the rats exposed for 6 weeks. With the exception of a statistically significant increase in caput epididymis weight in the rats exposed for 3 weeks, there were no significant alterations in relative weights of reproductive tissues (testes, caput epididymis, cauda epididymis, seminal vesicles, prostate). Zinc intake significantly affected enzyme activities in tissues of the male reproductive system. Significant decreases in lactic dehydrogenase were observed in the testes, caput epididymis, cauda epididymis (6 weeks only), seminal vesicles, and prostate (6 weeks only) after 3 or 6 weeks of exposure. Increases in arylsulfatase activity were observed in the seminal vesicles after 3 or 6 weeks of exposure and in the cauda and caput epididymis after 6 weeks of exposure. Leucyl aminopeptidase activity was significantly increased in the testes, caput epididymis (3 weeks only), cauda epididymis, seminal vesicles (3 weeks only), and prostate gland after 3 or 6 weeks of exposure. Histological examination of the gonads of rats consuming increased levels of zinc for 3 weeks revealed meiotic arrest at the primary spermatocyte stage, degenerating secondary spermatocytes, fluid accumulation within the

seminiferous tubules, and reduced epithelial cell height in the epididymis. After 6 weeks of exposure, histological examination of the testes revealed additional evidence of arrested spermatogenesis. The germinal epithelium contained only spermatogonia, one layer of primary spermatocytes, and a few pyknotic secondary spermatocytes; no mature spermatozoa were present in the cauda epididymis. Necrotic nuclei were observed among Sertoli cells, Leydig cells, and in the epithelia of prostatic follicles and seminal vesicles. Fertility tests were not carried out in this study.

Evenson et al. (1993) fed groups of 10 male Sprague-Dawley rats a diet containing deficient, adequate or excessive amounts of zinc (4, 12, or 500 mg total Zn/kg food) for 8 weeks; using the average of the initial and terminal body weight data provided in this paper and an allometric equation for food intake (U.S. EPA, 1988), the average dosages of zinc are estimated to be 0.4, 1, or 49 mg total Zn/kg-day. Body weight gain was directly related to the zinc dose, but there was no effect on the relative testicular weight. Flow cytometric data revealed that excess zinc caused abnormalities in the chromosome structure of sperm. The authors suggested that excess zinc, represented by the highest dose group, destabilizes disulfide bonds and complexes with protamine (a basic protein in the sperm) molecules, leading to a destabilization of sperm chromatin quaternary structure and greater susceptibility to DNA denaturation. No fertility tests were carried out in this study.

Sutton and Nelson (1937) maintained groups of young female (n=3) and male (n=2) rats on basal diets supplemented with 0, 0.10, 0.50, or 1.0% zinc as zinc carbonate for 10-39 weeks. Using reference values for body weight (0.124 kg) and food intake (14 g) (U.S. EPA, 1988), supplemental zinc intake is estimated as 0, 113, 565, or 1130 mg/kg-day. Hematological alterations consisting of a 20% decrease in Hb level in the 0.50% group, a 42-57% decrease in Hb level in the 1.0% group, and 15-28% decrease in erythrocyte level in the 1.0% group were observed. No hematological alterations were observed in the 0.10% group. Growth, reproduction, and development were reported to be normal for the 0.10% group over several generations. Adverse reproductive effects were observed in the 0.50% group; there were several stillbirths in the first pregnancy, after which there were no live young born. Rats in this group ceased to become pregnant after 5 months, although their body weights appeared normal. Reproduction and development were reported to have returned to normal in this group after excess zinc was withheld from the diet. No data were presented in support of this statement, so the timeframe of recovery is not known. Most of the animals on the 1.0% zinc diet failed to grow normally and some died within 4 weeks; no reproduction occurred in this dose group.

Since both males and females were treated with zinc, but no histopathological examination of the gonads was performed, it is not possible to determine the immediate cause of reproductive failure at higher dose levels.

Pal and Pal (1987) added 4000 ppm of zinc as zinc sulfate to the diet of 12 Charles-Foster female rats for 18 days beginning immediately after coitus. Using the reference values for food intake and body weight (U.S. EPA, 1988), supplemental zinc intake is estimated at 450 mg/kg-day. The incidence of conception in the treated group was significantly reduced compared to controls (5/12 vs. 12/12). In those animals that did conceive, the number of implantation sites per pregnant female was not significantly altered. Zinc treatment had no effect on the number of resorption sites and there were no stillbirths or malformations among the offspring of treated rats. In a separate experiment in which female rats were fed 4000 ppm supplemental zinc for 3 weeks prior to mating, the incidence of conception and fetal outcome were not adversely affected by treatment.

In a series of four studies conducted by Schlicker and Cox (1968), groups of 10-20 female Sprague-Dawley rats were fed a control diet or a diet containing supplemental zinc oxide prior to mating and/or during gestation. The exposure protocols for the four studies were as follows: (1) 10 rats fed 0 or 0.4% dietary zinc on gestational days 0 through 15 or 16, (2) 20 rats fed 0 or 0.4% supplemental zinc on gestational days 0 through 18 or 20, (3) 20 rats fed 0 or 0.4% supplemental zinc for 21 days prior to mating through delivery, and (4) 10 rats fed 0 or 0.2% supplemental zinc for 21 days prior to mating through gestational day 15. Using initial body weight data provided and an allometric equation for food intake (U.S. EPA, 1988), excess zinc intake by dams is estimated as 0, 200, or 400 mg/kg-day for the 0, 0.2, and 0.4% dietary concentrations, respectively. Dams were sacrificed on the final day of exposure, and the fetuses removed for examination. A 4-29% fetal resorption rate was observed in the dams exposed to 0.4% zinc beginning on gestational day 0 (studies 1 and 2). In rats exposed to 0.4% zinc prior to mating and during gestation, there was a 100% resorption of the fetuses. Significant decreases in body weight were observed in the fetuses of rats exposed to 0.4% zinc on gestational days 0-15 16, 18, or 20, but not in the 0.2% group exposed prior to mating and during gestational days 0-15. No external malformations were observed in the 0.4% group exposed during gestation or in the 0.2% group exposed prior to and during gestation.

In a single-generation study of reproductive performance, Khan et al. (2001) exposed groups (n=5-7) of male and female Sprague-Dawley rats to 0, 3.6, 7.2, 14.4, or 28.8 mg Zn/kg-

day, as zinc chloride, by gavage. Animals were exposed 7 days per week for 77 days prior to cohabitation and throughout the 21-day cohabitation period; females were also exposed during each of the 21-day gestation and lactation periods. Evaluated reproductive parameters included fertility, viability index, weaning index, litter size, and pup body weight. No significant changes were seen in body weights of the exposed rats prior to birth, but postpartum dam body weights for the mid- and high-dose groups were significantly decreased, relative to controls. The fertility indices in all dose groups were significantly lower than in the control group, though no dose-related trends were noted. At the highest two dose levels, the number of live pups per litter, but not total pups per litter, was significantly decreased, as was live pup weight at postnatal day 21, though not at days 4, 7, or 14. No other changes in reproductive parameters were noted, and no effects on serum clinical chemistry endpoints were reported.

Kumar (1976) compared the effect of different levels of dietary zinc on pregnancy in an unspecified strain of rats. Beginning on day 1 of pregnancy, 12 control rats were fed a basal diet containing 30 ppm of zinc (3.39 mg/kg-day), and 13 rats were fed the basal diet plus 150 ppm supplemental zinc (as zinc sulfate, ~20 mg/kg-day total zinc). The dams were sacrificed on gestational day 18. No alterations in the number of implantation sites were found, but a statistically significant increase in the number of resorptions (9.5%) was observed in the zinc-supplemented group.

Kinnamon (1963) fed groups of five Sprague-Dawley female rats a diet containing 0 or 0.5% supplementary zinc as zinc carbonate for 5 weeks prior to mating with untreated males and for the first 2 weeks of gestation. At the end of the 7-week period, the rats were injected with radiolabelled zinc chloride, then housed in metabolism cages for 4 days prior to sacrifice. Using the body weight data provided and an allometric equation for food intake (U.S. EPA, 1988), supplemental zinc doses of 0 or 500 mg/kg-day were calculated. No significant differences in number of fetuses per litter, wet weight of the litter, or average weight per fetus were observed.

4.4.1.3. *Developmental Studies in Animals*

Several studies have examined the developmental toxicity of zinc. Studies by Schlicker and Cox (1968) and Ketcheson et al. (1969) have found decreases in body weights in the offspring of rats exposed to high doses of zinc in the diet. Additionally, alopecia and achromotrichia have been observed in the offspring of mice and mink exposed to high doses of zinc during gestation and lactation (Bleavins et al., 1983; Mulhern et al., 1986).

Ketcheson et al. (1969) fed groups of 10 pregnant female Sprague-Dawley rats a basal diet containing 9 ppm of zinc or 0.2% or 0.5% supplemental zinc as zinc oxide, throughout gestation and lactation day 14. Using an estimated body weight of 0.300 kg and reported food intake data, estimated maternal supplemental zinc doses are 120 and 280 mg/kg-day during gestation in the 0.2 and 0.5% groups, respectively, and 150 and 400 mg/kg-day during lactation. No significant alterations in maternal body weight or food intake were observed in the zinc-supplemented groups relative to controls. No significant alterations in duration of gestation or the number of viable pups per litter were observed. Significant alterations in newborn and 14-day-old pup body weights were observed; the alterations consisted of an increase in the 0.2% group and a decrease in the 0.5% group. The increase in pup body weight at the 0.2% dietary level suggests that the basal diet did not provide a sufficient amount of zinc to support pregnancy and lactation. No external malformations were reported.

Uriu-Hare et al. (1989) fed groups of eight-nine Sprague-Dawley rats diet containing low, adequate (control group), or high amounts of zinc (4.5, 24.5, or 500 ppm total zinc) during gestational days 1-20. Using estimates of body weight (0.285 kg) and food intake (17 g/day) data presented in graphs, the total dietary intake of zinc is estimated to have been 0.27, 1.45, or 30 mg/kg-day. No adverse effects on maternal body weight gain, hematocrit levels, or the incidences of resorptions, malformations, fetal body weight, or fetal length were observed in the high zinc group, as compared to the adequate zinc group. Adverse effects, including decreases in maternal body weight and increases in resorptions, malformations, and fetal growth were observed in the low-zinc group only.

Mulhern et al. (1986) fed an unspecified number of female weanling C57BL/6J mice a diet containing 50 (normal) or 2000 (high) ppm of zinc as zinc carbonate and, at age 6 weeks, mated them with unexposed males. Each dam and her offspring were assigned to one of 10 groups receiving 50 or 2000 ppm total zinc during gestation, lactation, and postweaning until age 8 weeks. Decreases in hematocrit and body weight were observed in the F_1 mice exposed to 2000 ppm zinc during gestation, lactation, and postweaning. The study authors noted that decreases in body weight gain were observed in other groups; however, the magnitude and statistical significance were not reported. Alopecia was observed in all groups of F_1 mice exposed to 2000 ppm during lactation, regardless of gestational exposure. The mice began to lose hair between 2 and 4 weeks of age, and exhibited severe alopecia at 5 weeks. Exposure to 2000 ppm during lactation and/or post weaning resulted in achromotrichia, which the authors suggest may result from the effects of zinc-induced copper deficiency.

Bleavins et al. (1983) fed groups of adult mink (11 females and 3 males) a basal diet containing 20.2 ppm of zinc or the basal diet supplemented with 500 ppm of zinc as zinc sulfate heptahydrate. After 2 months the animals were mated during an 18-day period; since no clinical signs of zinc toxicity or copper deficiency were noted for the 500-ppm group, 3 days before the end of the mating period, the high dose of zinc was increased to 1000 ppm. Using the reference body weight and an allometric equation for food intake (U.S. EPA, 1988), the intake of zinc is calculated to have been 56 mg/kg-day. Fewer dams (8/11) on the high-zinc diet produced offspring than those on the control diet (11/11); however, gestational length, litter size, birth weights and kit mortality to weaning were not affected. Zinc had no effect on body, liver, spleen or kidney weights, or on hematological parameters (leukocyte, erythrocyte, Hb, hematocrit) in adults. Clinical signs associated with copper deficiency (alopecia, anemia, achromotrichia) were also not observed in adults. However, 3- to 4-week-old kits exhibited achromotrichia around the eyes, ears, jaws, and genitals, with a concomitant loss of hair and dermatosis in these areas. Subsequently, achromotrichia and alopecia spread over much of the body. At 8 weeks, treated kits had lower hematocrit and lower lymphocyte counts, but higher numbers of band neutrophils. At 8 weeks, treated kits exhibited signs of immunosuppression (significantly lowered thymidine incorporation by lymphocytes after stimulation by concanavalin A). Treated male kits had lower body weights than controls at 12 weeks. After weaning, the kits were placed on the basal diet, and within several weeks they recovered.

4.4.2. Inhalation Exposure

No studies examining the reproductive/developmental toxicity of zinc in humans or animals were identified.

4.5. OTHER STUDIES

4.5.1. Acute Toxicity Data

4.5.1.1. *Oral Exposure*

Brewer et al. (2000) reported on the use of zinc supplementation for the treatment of Wilson's disease. Wilson's disease results in an accumulation of copper within the body, eventually leading to hepatic changes and, in some patients, neurologic effects as well. The study authors discussed the results of 26 pregnancies in 19 women with Wilson's disease who received oral zinc acetate (from 25-150 mg Zn/day) prior to and during pregnancy. Urinary

copper, a reliable indicator of body copper status, was able to be maintained within normal levels with zinc supplementation, and hepatic and neurological signs in the affected women returned to normal while treatment continued. Of 26 pregnancies, there were four miscarriages, and two fetal abnormalities; one major (microcephaly) and one minor (surgically correctable heart defect). This study did not include any control subjects; thus these adverse effects cannot be fully correlated to either Wilson's disease or to zinc supplements.

4.5.1.2. *Inhalation Exposure*

Fine et al. (2000) exposed a group of 11 control subjects and a group of 10 sheet metal workers to 5 mg/m^3 of zinc oxide fume for 2 hours on each of 3 consecutive days. Naive subjects showed a number of slight to moderate symptoms following the first exposure, including chills, flushing, fatigue, muscle and stomach aches, dyspnea, and nausea. Following the second and third exposures, the incidence of symptoms among naive subjects were significantly lower than following the first exposure. Similarly, the increase in temperature was greatest among naive subjects after the first exposure, and decreased after the second and third exposures; after the third exposure, the temperature increase was significantly lower than after the first exposure. The temperature changes and incidence of symptoms for sheet metal workers were not significantly different from exposure to control air. Both the response of naive subjects to multiple exposures and the response of sheet metal workers to zinc oxide exposure were cited as evidence of the development of tolerance to zinc fume fever.

4.5.1.3. *Other Methods of Exposure*

In a short-term in vivo assay, Stoner et al. (1976) injected strain A/Strong mice (20/sex/dose) intraperitoneally with zinc acetate 3 times/week for a total of 24 injections (total doses were 72, 180, or 360 mg/kg). Controls (20/sex/group) consisted of an untreated group, a vehicle control group administered 24 injections of saline, and a positive control group administered a single injection of urethane (20 mg/mouse). Mice were sacrificed 30 weeks after the first injection; survival was comparable for all groups. There was no increase in number of lung tumors per mouse in treated animals relative to the pooled controls. While four thymomas were observed in zinc acetate-treated groups and none in controls, the occurrence of these tumors was not statistically significantly elevated.

Guthrie (1956) injected 0.15-0.20 mL of 10% zinc sulfate into the testis of 19 four-month-old rats and 0.15 mL of 5% zinc chloride into the testis of 29 three-month-old rats

(strain not specified). No testicular tumors were observed in either group at sacrifice 15 months after injection. No controls were described.

4.5.2. Genotoxicity

The results of short-term genotoxicity assays for zinc are equivocal. Zinc acetate and/or zinc-2,4-pentanedione have been analyzed in four short-term mutagenicity assays (Thompson et al., 1989). In the Salmonella assay (with or without hepatic homogenates), zinc acetate was not mutagenic over a dose range of 50-7200 μg/plate, but zinc 2,4-pentanedione was mutagenic to strains TA1538 and TA98 at 400 μg/plate. The addition of hepatic homogenates diminished this response in a dose-dependent manner. In the mouse lymphoma assay, zinc acetate gave a dose-dependent positive response with or without metabolic activation; the mutation frequency doubled at 10 μg/mL. In the Chinese hamster ovary cell in vitro cytogenetic assay, zinc acetate gave a dose-dependent positive response with or without metabolic activation, but the presence of hepatic homogenates decreased the clastogenic effect. Neither zinc acetate nor zinc-2,4-pentanedione were positive in the unscheduled DNA synthesis assay in rat hepatocytes over a dose range of 10-1000 μg/mL.

Zinc chloride has been reported to be positive in the Salmonella assay (Kalinina et al., 1977), negative in the mouse lymphoma assay (Amacher and Paillet, 1980), and a weak clastogen in stimulated human lymphocyte cultures (Deknudt and Deminatti, 1978). Zinc sulfate was not mutagenic in the Salmonella/microsome assay (Gocke et al., 1981), and zinc acetate did not induce chromosomal aberrations in unstimulated human lymphocyte cultures (Gasiorek and Bauchinger, 1981). Crebelli et al. (1985) found zinc oxide (99% purity) (1000-5000 μg/plate) not to be mutagenic for reverse mutation in *Salmonella typhimurium*.

Responses in mutagenicity assays are thought to depend on the form (e.g., inorganic or organic salt) of the zinc tested. For example, inorganic salts tend to dissociate and the zinc becomes bound with culture media constituents. Salts that dissociate less readily (i.e., zinc-2,4-pentanedione) tend to be transported into the cell and are postulated to cause a positive response (Thompson et al., 1989).

Zinc deficiency or excessively high levels of zinc may enhance susceptibility to carcinogenesis, whereas supplementation with low to moderate levels of zinc may offer protection (Woo et al., 1988). Zinc deficiency enhanced methylbenzylnitrosamine (MBN)-induced carcinoma of the esophagus in male rats (Fong et al., 1978), but retarded the

development of oral cancer induced by 4-nitroquinoline-N-oxide (4-NQO) in 4-week-old female rats (Wallenius et al., 1979). In a study that examined both zinc deficiency and supplementation, Mathur et al. (1979) found that animals with a deficient diet (5.9 mg/kg) and animals with a diet supplemented with excessively high levels of zinc (200-260 mg/kg) had fully developed carcinomas of the palatial mucosa. While the rats were on the specific diets, the palatial mucosa was painted with 4-NQO, 3 times/week for 20 weeks. In the zinc-deficient group, 2/25 rats developed cancer of the palatial mucosa; 2/25 rats in the excessive zinc group also developed this form of cancer. Animals supplemented with moderate levels of zinc in the diet (50 mg/kg) developed only moderate dysplasia. Thus, zinc's modifying effect on carcinogenesis may be dose-dependent.

4.6. INTERACTIONS

Numerous studies have examined the interactions of zinc and other metals; however, the vast majority of these have examined the effect of co-exposure to zinc on the toxicity of the other metal. The few studies that have been conducted on the effect of other metals on the toxicity of zinc are not adequate to support dose-response assessments for the interactions, or even qualitative assessments of the type or direction of the interaction (e.g., antagonism, synergism), particularly under subchronic or chronic exposure conditions. Interactions between zinc and other metals are highly plausible given that the ligand binding reactions of zinc are similar to those of a variety of other essential or toxic divalent cations (Andersen, 1984). These include a relatively high reactivity with thiolate anions (ionized functional groups from cysteine) and formation of relatively stable chelation complexes with multidentate carboxylic acid ligands (similar to calcium and lead). Thus, competition for reactions with sulfhydryls proteins and ligand exchange reactions are potential mechanisms of interaction that may exert effects at the level of zinc transport, binding, catalysis, or stabilization of zinc-dependent enzymes. The displacement of zinc from ALAD by lead is a good example of such an interaction, and is the basis for one aspect of the toxicity of lead (the inhibition of ALAD and heme synthesis) and the ability of zinc to attenuate this effect of lead (Finelli et al., 1975; Simons, 1995).

Binding to and induction of the synthesis of metallothionein appears to play an important role in the physiologic regulation of zinc levels and, possibly, zinc's reactivity as a potential binder of hydroxyl radicals (Li et al., 1980; Udom and Brady, 1980; Goering and Fowler, 1987; Kelly et al. 1996; Liu et al., 1996). A variety of divalent cations including, cadmium, cobalt,

copper, lead, and zinc bind to metallothionein (Stillman, 1995). Expression of metallothionein resulting from cadmium exposure may result in increased liver content of zinc and decreased plasma zinc concentrations; this could potentially give rise to interactions that have toxicologic consequences. For example, displacement of zinc from weakly bound extracellular proteins by cadmium is thought to be involved in the mechanism by which cadmium (and possibly other divalent metals) induces the synthesis of metallothionein (Palmiter, 1994). When cells are deprived of zinc they become very sensitive to zinc and relatively insensitive to cadmium. The increased sensitivity could be due either to increased transport of zinc or to a change in the relative amounts or affinities of metallothionein. The decreased sensitivity of cadmium is predicted if zinc is the only effective inducer, because during zinc starvation the low affinity pool of extracellular zinc would be depleted first; thus addition of small amounts of cadmium would fill this pool without liberating any zinc. Addition of more cadmium would displace zinc from higher affinity pools; thus further depletion would lead to cell death. Induction of metallothionein by zinc has been shown to alter the physiologic disposition of copper and the toxicity of cadmium (Waalkes and Pérez-Ollé, 2000). Recent characterization of divalent metal ion transporters in epithelia, including that of mammalian small intestine, suggest that zinc may share absorptive mechanisms with a variety of divalent cations, including cadmium, copper, iron, and lead (Gunshin et al., 1997; Fleming et al., 1999). This provides at least one mechanism by which co-exposure with other divalent metals could affect zinc absorption, and possibly transport of absorbed zinc in other tissues.

For the most part, however, definitive evidence for any of the above mechanisms giving rise to antagonism or synergism of the toxicity of zinc has not been reported. Information on interactions relevant to the toxicity of zinc and compounds is presented below.

4.6.1. Interactions with Essential Trace Elements

4.6.1.1. *Copper and Zinc*

As discussed above, the most sensitive effects of high supplementary levels of zinc in humans are alterations in the levels of copper-containing enzymes (e.g., Cu, Zn-superoxide dismutase and serum ceruloplasmin) and plasma LDL cholesterol levels. Although studies by Samman and Roberts (1987, 1988), Fischer et al. (1984) and Yadrick et al. (1989) failed to find decreases in plasma copper levels, these studies did find alterations in serum ceruloplasmin and ESOD activities. As discussed in Fischer et al. (1984), copper metalloenzyme activity is a more sensitive indicator of copper status than plasma copper levels. Animal studies reported by L'Abbe and Fischer (1984a, b) have demonstrated the reduction of Cu, Zn-superoxide dismutase

activity in the liver and heart as the most sensitive indicator of copper status in rats fed high levels of zinc in their diet. These observations were correlated with similar Cu, Zn-superoxide dismutase activities in the liver and heart of animals fed a copper deficient diet. It is believed that the copper deficiency results from a zinc-induced decrease in copper absorption, although the exact mechanisms are not understood. Excess dietary zinc results in induction of intestinal metallothionein synthesis; because metallothionein has a greater binding capacity for copper than for zinc, copper absorbed into the intestinal mucosal cells may be sequestered by metallothionein and not absorbed systemically (Walsh et al., 1994).

The above considerations suggest that increased intakes of copper may decrease toxic effects of zinc that are related to copper deficiency; however, this possibility has not been rigorously explored experimentally. Smith and Larson (1946) reported that co-exposure to copper resulted in a partial attenuation of the microcytic and hypochromic anemia resulting from exposure to high levels of dietary zinc. This would be consistent with copper replenishment after zinc-induced copper depletion. Several studies have demonstrated that increased levels of copper can decrease the absorption of zinc. Oestreicher and Cousins (1985) reported that dietary levels of zinc and copper did not affect absorption of zinc or copper in an isolated, perfused rat small intestine model. However, low levels of copper in the perfusion medium resulted in an increased absorption of zinc, while medium and high copper levels resulted in decreased zinc absorption. Kinnamon (1963) reported a significant decrease in uptake of a single gavage dose of radiolabeled zinc in rats fed a diet high in copper for 5 weeks prior to exposure. Gachot and Poujeol (1992) reported exposure of primary rabbit proximal tubule cells to both 15 and 50 μM copper resulted in noncompetitive inhibition of zinc absorption into the cells. Zinc and copper are substrates for a divalent metal transport protein that has been shown to participate in the absorption of iron (Gunshin et al., 1997). The relative importance of this protein in the absorptive transport of zinc and copper has not been determined. However, Klevay (1973) reported that rats fed a diet with a 40:1 ratio of zinc:copper gained less weight than those fed a normal 5:1 ratio, indicating the importance of the relative levels of both zinc and copper in the diet.

4.6.1.2. *Calcium and Zinc*

Hwang et al. (1999) reported that administration of calcium acetate to hemodialysis patients did not result in changes in hair or serum zinc relative to baseline levels, though both levels were lower than normal controls. A review by Lönnerdal (2000) provides evidence that calcium levels do not directly influence the absorption of zinc. It appears, however, that calcium

aggravates zinc deficiency when it is added to diets based on plant products that might be expected to be high in phytate (reviewed in O'Dell, 1969). Heth and Hoekstra (1965) reported a decreased absorption of zinc when calcium was co-administered in the diet, and that increased dietary calcium resulted in an increased rate of zinc loss (shortened clearance half-time).

4.6.1.3. *Iron and Zinc*

O'Brien et al. (2000) reported that percentage zinc absorption was significantly lower in pregnant women who received iron-containing prenatal supplements (60 mg/day) relative to women who had not received iron-containing supplements. Plasma zinc concentrations were also significantly lower after iron supplementation, but not if the supplement also contained 15 mg of zinc. Bouglé et al. (1999) reported a significant correlation between zinc absorption and iron content in the diet, with increased dietary iron resulting in diminished absorption of zinc. However, Lönnerdal (2000) has suggested that at lower iron intake levels, iron has no effect on the absorption of zinc. Zinc and iron are substrates for a divalent metal transport protein that has been shown to participate in the absorption of iron (Gunshin et al., 1997). The relative importance of this protein in the absorptive transport of zinc has not been determined.

4.6.2. Interactions with Other Heavy Metals

4.6.2.1. *Cadmium and Zinc*

Numerous studies have demonstrated that zinc can decrease the carcinogenicity and toxicity of cadmium (Gunn et al., 1963; Waalkes et al., 1989; Coogan et al., 1992; Brzoska et al., 2001), possibly through decreased cadmium absorption or alterations in metallothionein levels (for review, see Krishnan and Brodeur, 1991). Less is known about the effects of cadmium on the pharmacokinetics and toxicity of zinc.

Toxic levels of cadmium may inhibit zinc absorption (Lönnerdal, 2000). Studies conducted in isolated cells or membranes from kidney proximal tubule or small intestine indicate that zinc and cadmium may share common transport and/or binding mechanisms in transporting epithelia (Tacnet et al., 1990, 1991; Prasad and Nath, 1993; Prasad et al., 1996; Endo et al., 1997). For example, Gachot and Poujeol (1992) assessed the effect of cadmium on the uptake of zinc by isolated rabbit proximal tubule cells. At low concentrations (15 μM), cadmium acts as a competitive inhibitor of carrier-mediated zinc uptake, while at higher concentrations (50 μM) it also exhibits noncompetitive inhibition of an unsaturable pathway. Similar results were reported by King et al. (2000) who found that injection of cadmium chloride in mice reduced the uptake of ^{65}Zn by 56% in testes and 47% in brain. Exposure of rats whose diets contained normal

(12 mg/kg) or elevated (60 mg/kg) levels of zinc to 5 mg Cd/L in the drinking water did not alter the amount of zinc or copper in the plasma or liver (Bebe and Panemangalore, 1996). Levels of copper in the kidneys were decreased in animals that were exposed to high-dosages of zinc and cadmium, but not in animals that received normal zinc diets and cadmium; cadmium had no effect on kidney zinc levels. Brzoska et al. (2001) reported that treatment of rats with cadmium resulted in decreased levels of zinc in the tibia; zinc supplementation restored the levels to normal.

4.6.2.2. *Lead and Zinc*

A sizable database on the effects of zinc on lead toxicity exists. However, a detailed discussion of the effects of exposure to zinc on the toxicity of lead is beyond the scope of this document. The effects of zinc on the toxicity of lead are discussed in a review by Krishnan and Brodeur (1991).

Administration of zinc in the diet, but not through injection, has been shown to decrease the toxicity of dietary lead (Cerklewski and Forbes, 1976; El-Gazzar et al., 1978), possibly due to zinc decreasing the intestinal absorption of lead (Cerklewski and Forbes, 1976; Cerklewski, 1979). It is not known if lead will affect the absorption of zinc. However, exposure of rats whose diets contained normal (12 mg/kg) or elevated (60 mg/kg) levels of zinc to drinking water containing 20 mg Pb/L did not alter the amount of zinc or copper in the plasma, kidney, or liver (Bebe and Panemangalore, 1996). This would suggest, though it is hardly conclusive, that lead exposure does not alter zinc absorption. Both zinc and lead have been shown to bind to the N-methyl-D-aspartate receptor site in rats, but lead does not appear to bind to the zinc allosteric site (Lasley and Gilbert, 1999). As noted previously, zinc and lead are substrates for a divalent metal transport protein that has been shown to participate in the absorption of iron (Gunshin et al., 1997). The relative importance of this protein in the absorptive transport of lead or zinc has not been determined.

4.6.2.3. *Cobalt and Zinc*

Anderson et al. (1993) reported that exposure to 400 ppm cobalt chloride in the drinking water of mice for 13 weeks resulted in seminiferous tubule damage and degeneration (vacuole formation, sloughing of cells, giant cell formation) in the testes. Co-exposure to 800 ppm zinc chloride resulted in 90% of the animals exhibiting complete or partial protection against the testicular toxicity of cobalt. No studies examining the potential effects of cobalt compounds on the toxicity of zinc were identified.

4.7. SYNTHESIS AND EVALUATION OF MAJOR NONCANCER EFFECTS AND MODE OF ACTION – ORAL AND INHALATION

4.7.1. Oral Exposure

The essentiality of zinc was established over 100 years ago. Zinc is essential for the function of more than 300 enzymes, including alkaline phosphatase, alcohol dehydrogenase, Cu, Zn-superoxide dismutase, carboxypeptidase, ALAD, carbonic anhydrase, RNA polymerase, and reverse transcriptase (Vallee and Falchuk, 1993; Sandstead, 1994). A wide range of clinical symptoms have been associated with zinc deficiency in humans (Abernathy et al., 1993; Prasad, 1993; Sandstead, 1994; Walsh et al., 1994). The clinical manifestations of severe zinc deficiency, seen in individuals with an inborn error of zinc absorption or in patients receiving total parenteral nutrition without adequate zinc, include bullous pustular dermatitis, diarrhea, alopecia, mental disturbances, and impaired cell-mediated immunity resulting in intercurrent infections. Symptoms associated with moderate zinc deficiency include growth retardation, male hypogonadism, skin changes, poor appetite, mental lethargy, abnormal dark adaptation, and delayed wound healing. Neurosensory changes, impaired neuropsychological functions, oligospermia, decreased serum testosterone, hyperammonemia, and impaired immune function (alterations in T-cell subpopulations, decreased natural killer cell activity) have been observed in individuals with mild or marginal zinc deficiency. Severe zinc deficiency in animals has been associated with reduced fertility, fetal neurological malformations, and growth retardation in late pregnancy (Mahomed et al., 1989).

Increased zinc consumption, as supplemental zinc, has been associated with changes in health effects in humans, including decreased copper metalloenzyme activity (Fischer et al., 1984; Samman and Roberts, 1987, 1988; Yadrick et al., 1989; Davis et al., 2000; Milne et al., 2001), hematological effects such as anemia, neutropenia (Hale et al., 1988), decreases in cholesterol levels (Hooper et al., 1980; Freeland-Graves et al., 1982; Chandra, 1984; Black et al., 1988; Davis et al., 2000; Milne et al., 2001), immunotoxicity (Chandra, 1984), and gastrointestinal effects (Freeland-Graves et al., 1982; Samman and Roberts, 1987, 1988).

Although the decreased copper metalloenzyme activities and cholesterol levels are not necessarily adverse in themselves, they are likely to be indicators of more severe effects occurring at greater dose levels. Several human studies provide evidence that excess zinc intake may induce copper deficiency. Severe copper deficiency has been observed in individuals

ingesting very high doses of zinc for over one year (Patterson et al., 1985; Hoffman et al., 1988). At lower zinc doses, more subtle signs of impaired copper status, such as alterations in copper metalloenzyme activities, are evident. Copper deficiency is thought to result from a zinc-induced decrease in copper absorption. Excess dietary zinc results in induction of intestinal metallothionein synthesis; because metallothionein has a greater binding capacity for copper than for zinc, copper absorbed into the intestinal mucosal cells is sequestered by metallothionein and not absorbed systemically (Walsh et al., 1994). Zinc and copper may also be substrates for a divalent metal transport protein (i.e., CRIP) induced by copper in the small intestine (Gunshin et al., 1997). Although studies by Davis et al. (2000), Milne et al. (2001), Samman and Roberts (1987, 1988), Fischer et al. (1984), and Yadrick et al. (1989) failed to find decreases in plasma copper levels after zinc supplementation, these studies did find alterations in indicators of body copper status, including decreases in serum ceruloplasmin, EC-SOD, and ESOD activities. As discussed in Fischer et al. (1984), copper metalloenzyme activity is a more sensitive indicator of copper status than plasma copper levels.

While the exact function of HDL is not known, it is thought to function in the transfer of cholesterol from extrahepatic tissue to the liver. Bile acids are synthesized from cholesterol in the liver and carry cholesterol breakdown products to the intestines with the bile, thus providing an excretory pathway for cholesterol. The results of epidemiology studies suggest an association between high concentrations of HDL with a reduced risk of coronary heart disease. As compared to all lipids and lipoproteins measured, HDL may have the largest impact on risk of coronary heart disease in individuals over 50 years old (Simko et al., 1984). Normal levels of HDL-cholesterol are 45.5 mg/dL in men and 55.5 mg/dL in women. HDL-cholesterol levels below 35 mg/dL have been associated with an increased risk of coronary heart disease (Simko et al., 1984). Collectively, the human data suggest that short-term ($\leq$12 weeks) increases in zinc intake result in decreases in HDL-cholesterol levels. In the Hooper et al. (1980) and Chandra (1984) studies, in which subjects received daily doses of 2 or 4 mg supplemental Zn/kg-day for up to 6 weeks, the HDL-cholesterol levels dropped below 35 mg/dL. Although zinc-induced decreases in HDL-cholesterol have been observed, a relationship between increased zinc intake and an increased risk of coronary heart disease has not been established. Additionally, not all human studies have confirmed effects on HDL-cholesterol levels following zinc supplementation (Davis et al., 2000; Milne et al., 2001).

Following high-level oral exposure, zinc appears to exert adverse health effects primarily through interaction with copper. Specifically, high levels of zinc can result in a saturation of the

carrier-mediated pathway of zinc absorption and a shift to metallothionein-mediated absorption (Hempe and Cousins, 1992). It is believed that the copper deficiency results from a zinc-induced decrease in copper absorption. Zinc-induced copper deficiency is consistent with numerous reports of effects of zinc on various biomarkers of copper nutritional status following exposures to elevated levels of zinc in humans and animals, as well as by reports indicating that copper supplementation can result in an attenuation of zinc-induced toxicity.

While co-exposure to zinc has been demonstrated to alter the toxicity of a number of other metals, few studies have been conducted on the effects of co-exposure to metals (other than copper) on zinc toxicity. The available studies suggest the plausibility that co-exposure to other divalent metals may decrease absorption of zinc, but offer only limited insight as to potential effects of these metals on zinc toxicity. The few studies that have been conducted on the effect of other metals on the toxicity of zinc are not adequate to support dose response assessments for the interactions, or even qualitative assessments of the type or direction of the interactions (e.g., antagonism, synergism), particularly under subchronic or chronic exposure conditions.

4.7.2. Inhalation Exposure

Most of the available information on the toxicity of inhaled zinc has focused on metal fume fever, a collection of symptoms observed in individuals exposed to freshly formed zinc oxide fumes or zinc chloride from smoke bombs. The earliest symptom of metal fume fever (also referred to as zinc fume fever, zinc chills, brass founder's ague, metal shakes, or Spelter's shakes) is a metallic taste in the mouth accompanied by dryness and irritation of the throat. Flu-like symptoms, chills, fever, profuse sweating, headache, and weakness follows (Drinker et al., 1927a; Sturgis et al., 1927; Rohrs, 1957; Malo et al., 1990). The symptoms usually occur within several hours after exposure to zinc oxide fumes and persist for 24 to 48 hours. An increase in tolerance develops with repeated exposure; however this tolerance is lost after a brief non-exposure period, and symptoms are most commonly reported on Mondays and after holidays. There are many reports of metal fume fever in the literature; however, most describe individual cases and exposure levels are not known.

In animals, exposure to zinc oxide results in similar effects as those reported in humans. Gordon et al. (1992) examined the effects of zinc oxide in rabbits, rats, and guinea pigs, and reported changes in lavage parameters which appeared to correlate with pulmonary retention of the zinc particles. In a series of studies in guinea pigs, Lam et al. (1988) reported that ultrafine zinc oxide particles resulted in significant respiratory effects, including decreased lung function

and increased lung weight. However, subchronic or chronic studies of the toxicity of zinc following inhalation exposure in animals are not available. Similarly, no studies examining the effects of inhaled zinc on reproductive or developmental endpoints were located.

The mechanisms behind metal fume fever are not known, but are thought to involve several different factors. Exposure to zinc oxide particles has been shown to elicit the release of a number of proinflammatory cytokines, leading to a persistent pulmonary inflammation which could result in some of the reported symptoms of metal fume fever, including decreased lung function and bronchoconstriction. An allergic response to zinc particles, leading to an asthma-like response, has also been proposed as a possible mechanism. However, additional mechanistic information will be required in order to adequately determine the mechanisms involved in the toxicity of inhaled zinc.

4.8. WEIGHT-OF-EVIDENCE EVALUATION AND CANCER CHARACTERIZATION

Under the U.S. EPA *Guidelines for Carcinogen Risk Assessment* (U.S. EPA, 2005), there is *inadequate information to assess carcinogenic potential* of zinc, because studies of humans occupationally-exposed to zinc are inadequate or inconclusive, adequate animal bioassays of the possible carcinogenicity of zinc are not available, and results of genotoxic tests of zinc have been equivocal.

Adequate studies examining the carcinogenicity of zinc in orally-exposed humans are not available. Prasad et al. (1978) reported on sickle cell anemia patients who were treated with zinc for 2 years; however, carcinogenic endpoints were not evaluated. Aughey et al. (1977) did not find pancreatic, pituitary, or adrenal tumors in C3H mice exposed to zinc sulfate in the drinking water for up to 14 months; however, histopathology of other organs was not reported. Additional data on the carcinogenicity of zinc following oral exposure are not available. While a number of studies of the effects of short-term exposure to zinc in the workplace are available, the vast majority of these focus on the more acute effects of zinc, particularly metal fume fever and its resulting sequelae. No studies adequately examining the carcinogenic effects of zinc in humans or animals were located in the available literature.

Either zinc deficiency or excessively high levels of zinc may enhance susceptibility to carcinogenesis, whereas supplementation with low to moderate levels of zinc may offer protection (Mathur, 1979; Woo et al., 1988). For example, zinc deficiency enhanced carcinomas

of the esophagus induced by MBN (Fong et al., 1978) but retarded the development of oral cancer induced by 4-NQO (Wallenius et al., 1979). Thus, zinc's modifying effect on carcinogenesis may depend on the dose of zinc as well as the carcinogen being affected. The mutagenicity of zinc, particularly in *S. typhimurium*, appears to depend greatly on the chemical form.

4.9. SUSCEPTIBLE POPULATIONS

4.9.1. Possible Childhood Susceptibility and Susceptible Diabetics

Data in humans are not available that examine whether children are more susceptible to the toxicity of zinc than adults. However, the RDA for children, expressed in terms of mg/kg-day, is greater than that for adults. Animal studies have, however, suggested that neonates and/or developing animals may be more susceptible to the toxic effects of excess zinc. Bleavins et al. (1983) reported that in minks exposed to 56 mg Zn/kg-day throughout gestation and weaning, no changes were seen in exposed adults, but 3-4 week-old kits exhibited achromotrichia, thought to be associated with copper deficiency. Signs of copper deficiency progressed as zinc exposure continued.

ESOD, formerly known as erythrocuprein, contains two atoms of zinc and copper each as cofactors and acts as a scavenger of singlet oxygen species. As reported by Arai et al. (1987), this enzyme is known to be glycosylated, and glycosylation is significantly increased in diabetics. Furthermore, this glycosylation significantly decreases ESOD activity compared to the activity of non-glycosylated form of ESOD. Thus diabetics may be sensitive to high dietary levels of zinc. Several other studies have examined the effects of zinc exposure in young animals, but have not provided data on adult animals similarly exposed for comparison. Additional data will be required to adequately assess the susceptibility of children to zinc exposure, relative to adults.

4.9.2. Possible Gender Differences

Several studies in humans have suggested that females may be more sensitive to the adverse effects of excess zinc than males. For example, Samman and Roberts (1987, 1988) reported that women experienced adverse symptoms more frequently (84% in women vs. 18% in men) as well as being more susceptible to zinc-induced changes in LDL cholesterol levels, serum ceruloplasmin, and ESOD. However, women in this study received a higher average dose

(2.5 mg/kg-day) than did the corresponding men (2.0 mg/kg-day). In contrast, Hale et al. (1988) reported that in elderly subjects, zinc-exposed women did not experience the same reduction in the incidence of anemia as was seen in zinc-exposed men. The studies of Yadrick et al. (1989) and Fischer et al. (1984) reported similar effect levels on ESOD levels, expressed as mg total Zn/kg-day, in men and women. Further data examining the potential difference in response between men and women were not located.

In animal studies, it appears that if any differences between sexes were noted, the male is the more susceptible gender. For example, Maita et al. (1981) reported changes in body weight, altered clinical chemistry, and decreased liver and spleen weights in male rats, but not in female rats, exposed to 572 mg Zn/kg-day. Studies of reproductive function have demonstrated alterations in spermatogenesis at zinc exposure levels below those inducing alterations in female reproductive parameters (Sutton and Nelson, 1937; Pal and Pal, 1987; Saxena et al., 1989; Evenson et al., 1993). Other studies (Aughey et al., 1977; Zaporowska and Wasilewski, 1992) have not reported significant differences between male and female animals exposed to zinc. Additional studies will be required to determine whether sex-specific differences in adverse responses to zinc exist.

5. DOSE-RESPONSE ASSESSMENTS

5.1. ORAL REFERENCE DOSE (RfD)

The RfD for zinc is based on human clinical studies to establish daily nutritional requirements. Zinc is an essential trace element that is crucial to survival and health maintenance, as well as growth, development, and maturation of developing organisms of all animal species. Thus, insufficient as well as excessive oral intake can cause toxicity and disease and a quantitative risk assessment must take essentiality into account. The principal studies examine dietary supplements of zinc and the interaction of zinc with other essential trace metals, specifically copper, to establish a safe daily intake level of zinc for the general population, including pregnant women and children, without compromising normal health and development.

5.1.1. Choice of Principal Study and Critical Effect

Available studies of oral zinc toxicity have identified a number of zinc-induced physiological changes in humans, including decreased copper metalloenzyme activities (Fischer et al., 1984; Samman and Roberts, 1987, 1988; Yadrick et al., 1989; Davis et al., 2000; Milne et al., 2001), hematological effects (Hale et al., 1988), decreases in HDL-cholesterol levels (Hooper et al., 1980; Freeland-Graves et al., 1982; Chandra, 1984; Black et al., 1988), immunotoxic effects (Chandra, 1984), and gastrointestinal effects (Samman and Roberts, 1987, 1988). The available data indicate that the most sensitive effects of zinc are alterations in copper status. It is thought that the copper deficiency results from a zinc-induced decrease in copper absorption. As discussed in Fischer et al. (1984), copper metalloenzyme activities are a more sensitive indicator of copper status than plasma copper levels. For example, although studies by Samman and Roberts (1987, 1988), Fischer et al. (1984), Yadrick et al. (1989), Davis et al. (2000), and Milne et al. (2001) failed to find significant decreases in plasma copper levels, these studies did find alterations in other indicators of copper status, including activities of serum ceruloplasmin, ESOD, and/or EC-SOD. Some 60% or more of total erythrocyte copper is associated with ESOD. The identity of this protein, originally called erythrocuprein, from human tissues has been reported by McCord and Fridovich (1969). This protein contains two atoms, each, of zinc and copper.

Erythrocuprein functions as a superoxide dismutase having the ability to catalyze the dismutation of monovalent superoxide anion radicals into hydrogen peroxide and oxygen.

These proteins are also present in phagocytic cells and known to act as scavengers of singlet oxygen, thus preventing oxidative tissue damage. It follows that while the decreased copper metalloenzyme activities seen in several of the human studies are not necessarily adverse in themselves, they signal a decrease in the body's defenses against free radical oxidation. The consequences of the decrease in the enzyme activity would vary depending on the status of other components of the free radical defense system, such as the dietary adequacy of vitamins C, E, A, and selenium. Additional support for the selection of the critical endpoint comes from the rat study of L'Abbe and Fischer (1984a), which noted that changes in indicators of copper status (e.g., serum ceruloplasmin and cytochrome c oxidase activity and liver and heart Cu, Zn-superoxide dismutase activity) in rats exposed to supplemental zinc in the diet for 6 weeks were dose-related.

Of the available studies in humans, the studies of Davis et al. (2000), Milne et al. (2001), Fischer et al. (1984), and Yadrick et al. (1989) have identified effects on indicators of copper status at similar daily exposure levels.

In the study reported by Davis et al. (2000) and Milne et al. (2001), a population of postmenopausal women consumed a total of 53 mg Zn/day (3 mg/day in the controlled diet plus 50 mg/day as supplements), resulting in a total average daily dose of 0.81 mg/kg-day (using a mean body weight of 65.1 kg provided in the manuscripts). Bone-specific alkaline phosphatase activity was increased following zinc exposure, and ESOD activity and plasma free thyroxine were significantly decreased following exposure to zinc for 90 days.

Fischer et al. (1984) examined a group of adult male volunteers exposed to 50 mg supplemental Zn/day; adding in an average daily dietary consumption of 15.92 mg Zn/day (from the U.S. FDA Total Diet Study from 1982-1986 [Pennington et al., 1989]), the total exposure level from Fischer et al. (1984) was 65.92 mg Zn/day, or 0.94 mg/kg-day assuming a reference male body weight of 70 kg. ESOD activity was decreased by 4 weeks of exposure, with an inverse correlation between plasma zinc and ESOD activity apparent at 6 weeks.

The study of Yadrick et al. (1989) exposed a group of healthy adult women to 50 mg supplemental Zn/day; adding in an average daily dietary consumption of 9.38 mg/day (from the FDA Total Diet Study from 1982-1986 [Pennington et al., 1989]), the total exposure level from the Yadrick et al. (1989) study was 59.38 mg Zn/day, or 0.99 mg/kg-day assuming a reference

female body weight of 60 kg. ESOD activity declined steadily over the treatment period, and was statistically lower than pretreatment values at the end of the 10-week exposure.

In establishing an RfD for zinc, the data on essentiality were combined with the data on toxicity to define a level that would meet physiological requirements without causing toxic responses when consumed daily for a lifetime. The exposure values that were considered in determining the RfD suggest that there is only one order of magnitude between the minimum amount of zinc that will maintain physiological function (5.5 mg/day, King, 1986) and the amount associated with appearance of potentially adverse effects (60 mg/day, Cantilli et al., 1994).

As the four studies identified physiological changes on similar, sensitive endpoints (indicators of body copper status) at similar dose levels (0.81-0.99 mg Zn/kg-day) in a variety of human subject groups (adult males, adult females, postmenopausal females), the studies of Davis et al. (2000), Milne et al. (2001), Yadrick et al. (1989), and Fischer et al. (1984) were selected as co-principal studies.[1]

5.1.2. Methods of Analysis

A NOAEL/LOAEL approach was applied to derive the RfD. A benchmark dose approach was considered, but was not utilized for this assessment. All of the co-principal studies examined only one dose level, apart from controls, and therefore did not provide sufficient information to describe the dose-response function. Therefore, the studies are not suitable for benchmark analysis.

5.1.3. RfD Derivation—Including Application of Uncertainty Factors (UF)

In selecting the point of departure for the RfD, the effect levels from the principal studies were evaluated. As described in Section 5.1.1 above, the studies identified effect levels of 0.81

[1] The studies by Davis et al. (2000) and Milne et al. (2001) were approved by the Institutional Review boards of the University of North Dakota and the US Department of Agriculture and followed Guidelines of the Department of Health and Human Services and the Helsinki Declaration regarding the use of human subjects. The study by Yadrick et al. (1989) was approved by the Institutional Review Board of Oklahoma State University and informed consent was obtained from each participant. Finally, the study by Fischer et al. (1984) was approved by the Human Studies Committee of the Health Protection Branch, Health and Welfare Canada, and a consent form was signed by all participants.

mg Zn/kg-day (Davis et al., 2000; Milne et al., 2001), 0.94 mg Zn/kg-day (Fischer et al., 1984), and 0.99 mg Zn/kg-day (Yadrick et al., 1989) for changes in indicators of body copper status. Since the four studies have similar methodologies and outcomes with regard to effects, they were averaged together to obtain the point of departure (0.81+0.94+0.99=2.74/3=0.91 mg/kg-day).

The RfD of 0.3 mg/kg-day was derived by dividing the point of departure of 0.91 mg Zn/kg-day by a total uncertainty factor of 3 as follows:

RfD = NOAEL ÷ UF
= 0.91 mg/kg-day ÷ 3
= 0.3 mg/kg-day.

When considered within the context of the RDA and reference daily intake (RDI) values shown in Table 5-1, the RfD allows for some flexibility in the dietary intake (i.e., the RfD is 1.2 to 2.3 times the RDA). For essential elements such as zinc, the RDA provided the lower bound for determination of the RfD.

An interspecies uncertainty factor (UF_A) was not necessary for extrapolation from an animal study to the human population. The principal studies were conducted in human volunteers.

A threefold intraspecies uncertainty factor (UF_H) was applied to account for variability in susceptibility in human populations. The critical effect for zinc is decreased copper uptake, leading to a decrease in the activity of Cu, Zn-SOD enzymes that function as part of the body's system to protect against free radicals and oxidative stress. This system is complex, involving the SOD, catalase, glutathione, glutathione peroxidase, glutathione reductase, and the antioxidant vitamins (A, C, and E) providing several layers of protection. However, there is variability within the human population. Individuals with genetic catalase deficiency and glucose-6-phosphate dehydrogenase deficiencies have reduced capacities to metabolically cope with oxidative stress. Poor nutrition can also compromise the ability to respond to free radicals and oxidative stress. It is, accordingly, prudent to allow a threefold factor for human variability since the individuals used in the critical studies were apparently healthy adults. The use of a 10-fold uncertainty factor for intrahuman variability would result in an RfD below the RDA.

In the case of zinc and other nutritionally required elements, it is important that the RfD not be set at a value that would suggest that people should consume diets with insufficient zinc. Recommended dietary levels, expressed as intake both in mg Zn/day and in mg Zn/kg-day (calculated by adjusting with reference body weights of 13 kg for young children, 61 kg for women [pregnant, lactating, or general adult], or 70 kg for men), are presented in Table 5-1. Use of a threefold factor results in an RfD value that exceeds the dietary values by factors from 1.2 to 2.3. A smaller margin between the RfD and RDA cannot be recommended. RDA values are established for healthy individuals, and thus there are instances when additional dietary zinc is recommended such as during the recovery from surgery and other circumstances where active tissue repair is necessary.

Table 5-1. Estimated nutritional requirements of zinc at various life stages, expressed as mg/day and mg/kg-day

Life stage	Recommended intake (mg Zn/day)	Reference body weight (kg)	Recommended intake (mg Zn/kg-day)
1-3 years	3 (RDA[a])	13	0.23
Adulthood (>18 years) Male Female	 11 (RDA) 8 (RDA)	 76 61	 0.15 0.13
Pregnant women	11 (RDA)	61	0.18
Lactating women	12 (RDA)	61	0.2
U.S. FDA RDI[b] Values Male Female	 15 mg (RDI) 15 mg (RDI)	 70 60	 0.21 0.25

[a]RDA values and reference body weights are from IOM (2001).
[b]RDI values are established by the U.S. FDA and are used in the labeling of nutritional supplements.

An uncertainty factor to account for extrapolation from a subchronic study to estimate chronic exposure conditions (UF_S) was not necessary. Zinc is an essential element and therefore chronic exposures of zinc are required for proper nutrition. Exposure at the level of the RfD is expected to be without adverse effects when zinc is consumed on a daily basis over the life-span of the individual, neither inducing nutritional deficiency nor resulting in toxic effects in healthy non-pregnant adult humans consuming an average American diet.

There is extensive experience with humans receiving chronic dietary exposures from the diet plus nutritional supplements that do not exceed the 15 mg/day RDI which demonstrates that these levels are not adverse. For example, Hale et al. (1988) studied hematological parameters in elderly subjects who were supplemented with zinc for an average duration of 8 years. In general, no significant alterations were found between the zinc-supplemented group and controls. On the other hand, Prasad et al. (1978) studied a patient given 150-200 mg Zn/day for 2 years. The patient developed copper deficiency which was reversed with copper supplementation. Additionally, pharmacokinetic data on zinc absorption, distribution, and elimination suggest that steady-state levels will be reached within the time periods evaluated by the principal studies. Therefore, an uncertainty factor for extrapolation from a study of less than chronic duration to a lifetime exposure scenario was not determined to be necessary.

An uncertainty factor for extrapolation from a LOAEL to a NOAEL (UF_L) was determined to not be necessary. The RfD was based on a minimal effect level for a sensitive biological indicator, i.e., decreased ESOD activity, which is reflection of zinc-associated alterations in copper homeostasis that could lead to oxidative tissue damage. As discussed in the section on intrahuman variability, there is redundancy in the physiological free radical defense system that argues against describing the decreased activity of Cu, Zn-SOD as definitively adverse. Protection for variability in the status of this defense system is accommodated by the threefold factor allowed for intrahuman variability.

The deficit in copper absorption in the presence of excess zinc can also not be categorized as requiring the application of a LOAEL to NOAEL UF. As discussed in Fischer et al. (1984), copper metalloenzyme activities are more sensitive indicators of copper status than plasma copper levels. They are an early biomarker for a subclinical copper deficiency. Most importantly, the application of a threefold UF for a LOAEL to NOAEL adjustment, when combined with a threefold factor for intraspecies variability, would lower the RfD to below the RDA.

A database uncertainty factor (UF_D) to account for uncertainties due to lack of information in the database was not necessary. The database contains a considerable number of well-conducted human studies in a diverse group of human subjects. There are numerous reproductive and developmental toxicity studies performed in different species. Animal studies demonstrate that effects on reproductive and/or developmental endpoints are not the most sensitive endpoints for zinc toxicity.

The additional use of a daily vitamin supplement containing 15 mg zinc, such as is found in a standard multivitamin tablet, in conjunction with a diet adequate in zinc would result in a total adult daily exposure on the order of 0.4 mg Zn/kg-day[2], which is above the RfD. However, daily multivitamins also contain copper (2 mg/day), which could be expected to counteract the effects of excess zinc intake resulting from daily multivitamin use. Therefore, the use of a daily multivitamins, or similar balanced supplements, is not contraindicated by exposure at the level of the RfD.

5.1.4. Previous IRIS Assessment

In the previous assessment for zinc, the oral RfD was based on a single clinical study (Yadrick et al., 1989) which investigated the effects of oral zinc supplements (50 mg/day) on copper and iron balance. The total exposure level in this study (as discussed in Section 5.1.3) was 0.99 mg Zn/kg-day. The RfD of 0.3 mg/kg-day was derived by dividing this dose (0.99 mg/kg-day) by a total uncertainty factor of 3 based on a minimal LOAEL from a moderate-duration study of the most sensitive humans and consideration of a substance that is an essential dietary nutrient.

5.2. INHALATION REFERENCE CONCENTRATION (RfC)

Available data on humans exposed to zinc compounds by inhalation are limited to reports of acute exposures to zinc oxide or zinc chloride. Similarly, available studies in animals have been of acute duration, and, therefore, are not suitable for use in derivation of an RfC. A route-to-route extrapolation from the oral data was considered, but was not attempted as available data from acute inhalation studies suggest that significant portal of entry effects will occur. Lacking suitable data, derivation of an inhalation RfC for zinc compounds is precluded.

[2] A typical over-the-counter zinc supplement, such as a daily multivitamin, contains 15 mg Zn. For a healthy adult male, this would add an additional 0.21 mg Zn/kg-day, or 0.25 mg Zn/kg-day for a healthy adult female; thus, with a zinc-sufficient diet, the total zinc intake for a male consuming one multivitamin daily would be 0.36 mg/kg-day. Values for normal and lactating females consuming the same multivitamin would be 0.38 mg/kg-day and 0.45 mg/kg-day, respectively. Each of these values falls within the order of magnitude range about the RfD and can be considered to be without risk.

5.3. CANCER ASSESSMENT

5.3.1. Oral Slope Factor

Data are inadequate for the derivation of an oral slope factor for zinc. No human studies examining the oral carcinogenicity of zinc or zinc compounds were located. A 1-year study in mice (Walters and Roe, 1965) did not find increases of malignant lymphoma, lung adenoma, or hepatoma. The study did not report on the incidence of any other types of tumors, nor did it perform adequate histologic analysis of other tissues. Similarly, Aughey et al. (1977) did not observe increases in tumors of the pancreas, pituitary gland, or adrenal gland in mice exposed to zinc for 14 months; however, observations from other organs were not reported. A study by Halme (1961) reported potential increases in zinc-induced tumors in a multi-generation study in rats, but was not sufficiently descriptive to allow for a complete evaluation of the study. No other animal studies of the oral carcinogenicity of zinc were identified. Therefore, lack of data precludes the derivation of an oral slope factor.

5.3.2. Inhalation Unit Risk

Data are inadequate for the derivation of an inhalation unit risk for zinc. No suitable human or animal studies were identified which examined the carcinogenicity of zinc following chronic inhalation exposure.

6. MAJOR CONCLUSIONS IN THE CHARACTERIZATION OF HAZARD AND DOSE RESPONSE

6.1. HUMAN HAZARD POTENTIAL

Zinc is an essential element, necessary for the function of more than 300 enzymes. A wide range of clinical symptoms have been associated with zinc deficiency in humans (Prasad, 1993; Sandstead, 1994; Walsh et al., 1994), though generally only with chronically severe or moderately severe deficiency. Oral exposure to high levels of zinc in humans can result in several systemic effects, the most sensitive of which are related to diminished copper status. As discussed in Fischer et al. (1984), copper metalloenzyme activity is a more sensitive indicator of copper status than plasma copper levels. These sensitive indicators of copper status, which may not be adverse in themselves, can be considered as precursor events to more severe copper-deficiency-induced changes.

The majority of the inhalation data on zinc focuses on short-term inhalation of zinc oxide or zinc chloride, resulting in metal fume fever. The earliest symptoms of metal fume fever are a metallic taste in the mouth accompanied by dryness and irritation of the throat. Flu-like symptoms, chills, fever, profuse sweating, headache, and weakness follow (Drinker et al., 1927a, b; Sturgis et al., 1927; Rohrs, 1957; Malo et al., 1990). The symptoms usually occur within several hours after exposure to zinc oxide fumes and persist for 24 to 48 hours. An increase in tolerance develops with repeated exposure; however, this tolerance is lost after a brief non-exposure period. Studies of the health effects of subchronic or chronic exposure to inhaled zinc compounds were not located in the available literature.

Under the *Guidelines for Carcinogen Risk Assessment* (U.S. EPA, 2005) there is *inadequate information to assess carcinogenic potential* of zinc in humans, because studies of humans occupationally exposed to zinc are inadequate or inconclusive, adequate animal bioassays of the carcinogenicity of zinc are not available, and tests of the genotoxic effects of zinc have been equivocal.

6.2. DOSE RESPONSE

6.2.1. Noncancer/Oral

The most sensitive effects of oral exposure to excess zinc in humans involve the copper status of the body. Zinc exposure can result in a decreased absorption of copper, leading to low systemic copper levels and subsequent health effects, including decreased copper metalloenzyme activity, hematological effects, decreases in cholesterol levels, immunotoxicity, and gastrointestinal effects. While changes such as decreased copper metalloenzyme levels may not be adverse in themselves, they have been demonstrated to be precursor events for more severe effects. The study of Yadrick et al. (1989) established a minimal LOAEL of 0.99 mg Zn/kg-day for decreased levels of ESOD, an indicator of body copper status, in women exposed for 10 weeks, while the study of Fischer et al. (1984) established a minimal LOAEL of 0.94 mg Zn/kg-day for the same endpoint in men exposed for 6 weeks, and the study of Davis et al. (2000) and Milne et al. (2001) identified a minimal LOAEL of 0.81 mg Zn/kg-day for changes in ESOD and plasma free thyroxine. These four studies in human volunteers were considered to be co-principal studies, and the minimal LOAEL (0.91 mg Zn/kg-day, average of these LOAELs) was selected as the point of departure. An uncertainty factor of 3 (discussed in Section 5.1.3, above), representing the uncertainties associated with human variability and the need for an adequate dietary level of zinc, was then applied to the minimal LOAEL of 0.91 mg Zn/kg-day to give the RfD of 0.3 mg Zn/kg-day.

6.2.2. Noncancer/Inhalation

Data on the effects of inhaled zinc are primarily limited to short-term studies examining metal fume fever in occupationally-exposed humans. Studies in animals are not sufficient for the derivation of an RfC, owing mainly to insufficient duration or other study limitations. Lacking suitable data, derivation of an inhalation RfC is precluded.

6.2.3. Cancer/Oral and Inhalation

Data in both humans and animals are inadequate to evaluate potential associations between zinc exposure and cancer. Under the *Guidelines for Carcinogen Risk Assessment* (U.S. EPA, 2005), there is *inadequate information to assess the carcinogen potential* of zinc, because studies of humans occupationally-exposed to zinc are inadequate or inconclusive, adequate animal bioassays of the possible carcinogenicity of zinc are not available, and tests of the genotoxic effects of zinc have been equivocal.

APPENDIX A. EXTERNAL PEER REVIEW—SUMMARY OF COMMENTS AND DISPOSITION

The support document and IRIS summary for zinc have undergone both internal peer review performed by scientists within EPA and a more formal external peer review performed by scientists in accordance with EPA guidance on peer review (U.S. EPA, 1998). Comments made by the internal reviewers were addressed prior to submitting the documents for external peer review and are not part of this appendix. Public comments were read and considered. The external peer reviewers were tasked with providing written answers to general questions on the overall assessment and on chemical-specific questions in areas of scientific controversy or uncertainty. All three external peer reviewers recommended that this document and the accompanying assessments were acceptable with minor revisions. A summary of significant comments made by the external reviewers and EPA's response to these comments follows.

(1) General Questions for Peer Reviewers

General Question For the RfD, has the most appropriate critical effect been chosen? For the cancer assessment, are the tumors observed biologically significant? Relevant to human health? Points relevant to this determination include whether or not the choice follows from the dose-response assessment, whether the effect is considered adverse, and if the effect (including tumors observed in the cancer assessment) and the species in which it is observed is a valid model for humans.

Comment All three reviewers agreed that the document is concise and clearly written, and the choice of critical study and critical effects are appropriate. Some of the concerns reviewers presented include: balancing adverse effects with both deficiencies and level of concern for effects of deficiency or the effects below the RfD, specifically for children; adverse effects resulting from other metal interactions, such as iron and or copper; uncertainty associated with a higher RfD than the currently derived RfD, concerns for different forms of zinc exposure, enhancement of NOAEL/LOAEL information from animal studies; clear presentation of zinc status as essential element in IRIS Summary; additional studies recommended by two reviewers.

Response to Comment Section 5.1.3 of the Toxicological Review was added to provide an enhanced discussion of the RfD, relevance to the RDA, and effects below RfD in sensitive populations, such as children. Although limited data are available, information on the potential adverse effects in children were included in Section 4.9 of the Toxicological Review. Table 3 presents diet, age, gender and body-weight-specific zinc requirements followed by a discussion of the effects that may occur below the RfD and the uncertainties associated with the RfD.

An enhanced discussion of the chosen UF of 3 has been added in Section 5.1.3 of the Toxicological Review and clearly describes the rational for the chosen UF; however, the suggested uncertainty factor of 1.5 was not implemented. This decision was based on the threshold effect of decreased ESOD activity and the uncertainty as to whether decreased ESOD activity may predispose a cell to an accumulation of oxidative damage due to decreased

quenching of free radicals. Although the recent antioxidant effects of zinc supplementation have been reported (Prasad et al., 2004), the study did not determine whether the decreased levels of serum markers of oxidative stress (e.g., 8-hydroxy-2'-deoxyguanosine) were due to a decreased level of oxidative DNA damage or a decrease in the removal of this lesion within nucleated cells.

Metal-metal interactions are discussed in Section 4.6 of the Toxicological Review and information on zinc speciation and their relevance to environmental exposure are included Section 3.1 of the Toxicological Review.

Because available animal studies present information on supplementary levels of dietary zinc and no additional dosages, it is not possible to clearly discuss proper NOAEL/LOAELs from these studies; therefore, this was not discussed in Chapter 4 of the Toxicological Review.

Section 5.1 of the Toxicological Review and Section I.A.2 of the IRIS Summary have been revised to include information, as suggested by one reviewer, on the relevance of the RfD and environmental levels of zinc and the significance of zinc as an essential element to help risk assessors and managers make meaningful risk assessment decisions, as follows:

> The RfD for zinc is based on human clinical studies to establish daily nutritional requirements. Zinc is an essential trace element that is crucial to survival and health maintenance, as well as growth, development, and maturation of developing organisms of all animal species. Thus, insufficient as well as excessive oral intake can cause toxicity and disease and a quantitative risk assessment must take essentiality into account. The principal studies examine dietary supplements of zinc and the interaction of zinc with other essential trace metals, specifically copper, to establish a safe daily intake level of zinc for the general population, including pregnant women children, without compromising normal health and development.

Suggested new studies have been added in the Toxicological Review and the relevant literature has been reviewed and updated through October 2004.

(2) RfD Derivation

General Question The RfD for zinc is based on human clinical studies to establish daily nutritional requirements. The human studies examined dietary supplements of zinc and the interaction of zinc with other metals, such as copper, to establish a safe daily intake of zinc for children, adults, and pregnant women. Do you consider this RfD to be protective of adverse effects in children and pregnant women? Do you agree with the method of analysis used to evaluate dose-response data for zinc?

A. Comment Is the RfD protective of adverse effects in children and pregnant women?

Reviewers did not consider the RfD to be protective for adverse effects in children because it was below the RDA and they suggested expanding the discussions in the Toxicological Review.

Response to Comment The paragraph regarding the protective effect of the RfD in children is not accurate and has been removed. An enhanced discussion of the RfD relative to the RDA has been included. For transparency, the dose conversion and body weight have been added in Table 5-1, Section 5.1.3 of the Toxicological Review. As suggested by one reviewer, effects of multivitamins were also included, and a paragraph addressing the relevance of the RfD for children and pregnant woman has been added.

B. Comment Are appropriate uncertainty factors applied to the point of departure?

The reviewers, while suggesting the UF of 1.5 instead of 3, recommended expanding the discussions on uncertainties in the Toxicological Review.

Response to Comment The discussion of the rationale for an uncertainty factor of 3 has been enhanced. Since the RfD was based on a toxicity threshold dose-response, standard uncertainty factors have been used to develop the RfD.

(3) RfC Derivation

General Question Data for derivation of RfC are considered inadequate. Do you agree?

Comment All reviewers agreed. One reviewer suggested that an overview statement be provided in the IRIS Summary regarding the inadequacy of the data.

Response to Comment The summary sheet was modified per reviewer's recommendations, and the following statement was included in Section I.B of the IRIS Summary:

> Available data are not suitable for the derivation of an RfC for zinc. A number of case reports of metal fume fever have been reported in humans, however exposure levels are not known. The data in animals is limited to a few studies of acute duration, no subchronic or chronic inhalation studies of zinc are available at this time.

(4) Cancer Weight-of-Evidence (WOE) Classification

General Question The WOE classification for zinc has been discussed in Chapter 4 of the Toxicological Review. Have appropriate criteria been applied from the EPA draft revised Guidelines for Carcinogen Risk Assessment (U.S. EPA, 1999)?

Comment All reviewers agreed that the application of the guidelines and presentation of data in support of the WOE was appropriate.

Comment Two reviewers had specific editorial comments and one reviewer provided annotated changes in each chapter of the Toxicological Review and IRIS Summary.

Response to Comment All editorial and annotated changes were incorporated.

RECOMMENDATIONS

Comment Two reviewers recommended acceptance with major revisions as suggested for Chapters 5 and 6 of the Toxicological Review and for the IRIS Summary while the third reviewer recommended acceptance with minor revision.

Response to Comment All major editorial changes, addition of new studies, and revisions to the text in both the Toxicological Review and the IRIS Summary were incorporated. Corrections were made to reflect adverse effects at or below the RfD to protect children.

The uncertainty section was completely revised and expanded statements were provided in support of the UF of 3. This value was considered the most protective for preventing zinc deficiency and toxicity. When considered within the context of the RDA and RDI values shown in Table 5-1, Section 5.1.3 of the Toxicological Review, the RfD is 50% greater than the nearest RDA values (for young children and pregnant or lactating women), and 20% greater than the RDI values. For essential elements such as zinc, the RDA provides the lower bound for determination of the RfD. Based on these reasons, the UF of 3 was considered to be protective against adverse effects that may occur from deficiency or excess, and the recommendation by two reviewers to reduce the UF to 1 or 1.5 due to a concern for deficiency were considered to be adequately addressed by the UF of 3.

Attachment

1I

16

cadmium out of its milk, and Miller concluded that most major animal products, including meat and milk, seemed quite well protected against cadmium accumulation.

Interactions of cadmium with several other trace elements (Hill et al. 1963,[172] Gunn and Gould 1967,[160] Mason and Young 1967)[189] somewhat confuse the matter of establishing criteria.

Recommendation

From the available data on the occurrence of cadmium in natural waters, its toxicity, and its accumulation in body tissues, an upper limit of 50 μg/l allows an adequate margin of safety for livestock and is recommended.

Chromium

In a five-year survey of lake and river waters of the United States (Kopp and Kroner 1970),[182] the highest level found in over 1,500 samples was about 0.1 mg/l, the average being about 0.001 mg/l. In another similar survey (Durum et al. 1971)[141] of 700 samples, none contained over 0.05 mg/l of chromium VI and only 11 contained more than 0.005 mg/l. A number of industrial processes however use the element, which then may be discharged as waste into surface waters, possibly at rather high levels.

Even in its most soluble forms, the element is not readily absorbed by animals, being largely excreted in the feces; and it does not appear to concentrate in any particular mammalian tissue or to increase in these tissues with age (Mertz 1967,[194] Underwood 1971[254]).

Hexavalent chromium is generally considered more toxic than the trivalent form (Mertz 1967).[194] However, in their review of this element, McKee and Wolf (1963)[193] suggested that it has a rather low order of toxicity. Further, Gross and Heller (1946)[158] found that for rats the maximum nontoxic level, based on growth, for chromium VI in the drinking water was 500 mg/l. They also found that this concentration of the element in the water did not affect feed utilization by rabbits. Romoser et al. (1961)[226] found that 100 ppm of chromium VI in chick diets had no effect on the performance of the birds over a 21-day period.

In a series of experiments, Schroeder et al. (1963a,[238] 1963b,[239] 1964,[234] 1965[235]) administered water containing 5 mg/l of chromium III to rats and mice on low-chromium diets over a life span. At this level, the element was not toxic, but instead it had some beneficial effects. Tissue levels did not increase significantly with age.

As a result of their review of chromium toxicity, McKee and Wolf (1963)[193] suggested that up to 5 mg/l of chromium III or VI in livestock drinking water should not be harmful. While this may be reasonable, it may be unnecessarily high when the usual concentrations of the element in natural waters is considered.

Recommendation

An upper allowable limit of 1.0 mg/l for livestock drinking waters is recommended. This provides a suitable margin of safety.

Cobalt

In a recent survey of surface waters in the United States (Durum et al. 1971)[141] 63 per cent of over 720 samples were found to contain less than 0.001 mg/l of cobalt. One sample contained 4.5 mg/l, one contained 0.11 mg/l, and three contained 0.05–0.10 mg/l.

Underwood (1971)[254] reviewed the role of cobalt in animal nutrition. This element is part of the vitamin B_{12} molecule, and as such it is an essential nutrient. Ruminants synthesized their own vitamin B_{12} if they were given oral cobalt. For cattle and sheep a diet containing about 0.1 ppm of the element seemed nutritionally adequate. A wide margin of safety existed between the required and toxic levels for sheep and cattle, which were levels of 100 times those usually found in adequate diets being well tolerated.

Nonruminants required preformed vitamin B_{12}. When administered to these animals in amounts well beyond those present in foods and feeds, cobalt induced polycythemia (Underwood 1971).[254] This was also true in calves prior to rumen development; about 1.1 mg of the element per kg of body weight administered daily caused depression of appetite and loss of weight.

Cobalt toxicity was also summarized by McKee and Wolf (1963).[193]

Recommendation

In view of the data available on the occurrence and toxicity of cobalt, an upper limit for cobalt in livestock waters of 1.0 mg/l offers a satisfactory margin of safety, and should be met by most natural waters.

Copper

The examination of over 1,500 river and lake waters in the United States (Kopp and Kroner 1970)[182] yielded, at the highest, 0.28 mg/l of copper and an average value of 0.015 mg/l. These rather low values were probably due in part to the relative insolubility of the copper ion in alkaline medium and to its ready adsorbability on colloids (McKee and Wolf 1963).[193] Where higher values than those reported above are found, pollution from industrial sources or mines can be suspected.

Copper is an essential trace element. The requirement for chicks and turkey poults from zero to eight weeks of age is 4 ppm in the diet (NRC 1971b).[206] For beef cattle on rations low in molybdenum and sulfur, 4 ppm in the diet is adequate; but when these elements are high, the copper requirement is doubled or tripled (NRC 1970).[204] A dietary level of 5 ppm in the forage is suggested for pregnant and

lactating ewes and their lambs (NRC 1968b[203]). A level of 6 ppm in the diet is considered adequate for swine (NRC 1968a).[202]

Swine are apparently very tolerant of high levels of copper, and 250 ppm or more in the diet have been used to improve liveweight gains and feed efficiency (Nutrition Reviews 1966a[210]; NRC 1968a).[202] On the other hand, sheep were very susceptible to copper poisoning (Underwood 1971),[254] and for these animals a diet containing 25 ppm was considered toxic. About 9 mg per animal per day was considered the safe tolerance level (NRC 1968b).[203]

Several reviews of copper requirements and toxicity have been presented (McKee and Wolf 1963,[133] Nutrition Reviews 1966a,[210] Underwood 1971).[254] There is very little experimental data on the effects of copper in the water supply on animals, and its toxicity must be judged largely from the results of trials where copper was fed. The element does not appear to accumulate at excessive levels in muscle tissues, and it is very readily eliminated once its administration is stopped. While most livestock tolerate rather high levels, sheep do not (NRC 1968b).[203]

Recommendation

It is recommended that the upper limit for copper in livestock waters be 0.5 mg/l. Very few natural waters should fail to meet this.

Fluorine

The role of fluorine as a nutrient and as a toxin has been thoroughly reviewed by Underwood (1971).[254] (Unless otherwise indicated, the following discussion, exclusive of the recommendation, is based upon this review.) While there is no doubt that dietary fluoride in appropriate amounts improved the caries resistance of teeth, the element has not yet been found essential to animals. If it is a dietary essential, its requirement must be very low. Its ubiquity probably insures a continuously adequate intake by animals.

Chronic fluoride poisoning of livestock has, on the other hand, been observed in several areas of the world, resulting in some cases from the consumption of waters of high fluoride content. These waters come from wells in rock from which the element has been leached, and they often contain 10–15 mg/l. Surface waters, on the other hand, usually contain considerably less than 1 mg/l.

Concentrations of 30–50 ppm of fluoride in the total ration of dairy cows is considered the upper safe limit, higher values being suggested for other animals (NRC 1971a).[205] Maximum levels of the element in waters that are tolerated by livestock are difficult to define from available experimental work. The species, volume, and continuity of water consumption, other dietary fluoride, and age of the animals, all have an effect. It appears, however, that as little as 2 mg/l may cause tooth mottling under some circumstances. At least a several-fold increase in its concentration seems, however, required to produce other injurious effects.

Fluoride from waters apparently does not accumulate in soft tissues to a significant degree. It is transferred to a very small extent into the milk and to a somewhat greater degree into eggs.

McKee and Wolf (1963)[133] have also reviewed the matter of livestock poisoning by fluoride, concluding that 1.0 mg/l of the element in their drinking water did not harm these animals. Other more recent reports presented data suggesting that even considerably higher concentrations of fluoride in the water may, with the exception of tooth mottling, caused no animal health problems (Harris et al. 1963,[100] Shupe et al. 1964,[246] Nutrition Reviews 1966b,[211] Saville 1967,[231] Schroeder et al. 1968a[237]).

Recommendation

An upper limit for fluorides in livestock drinking waters of 2.0 mg/l is recommended. Although this level may result in some tooth mottling it should not be excessive from the standpoint of animal health or the deposition of the element in meat, milk, or eggs.

Iron

It is well known that iron (Fe) is essential to animal life. Further, it has a low order of toxicity. Deobald and Elvehjem (1935)[128] found that iron salts added at a level of 9,000 mg Fe/kg of diet caused a phosphorus deficiency in chicks. This could be overcome by adding phosphate to the diet. Campbell (1961)[124] found that soluble iron salt administered to baby pigs by stomach tube at a level of 600 mg Fe/kg of body weight caused death within six hours. O'Donovan et al. (1963)[212] found very high levels of iron in the diet (4,000 and 5,000 mg/kg) to cause phosphorus deficiency and to be toxic to weanling pigs. Lower levels (3,000 mg/kg) apparently were not toxic. The intake of water by livestock may be inhibited by high levels of this element (Taylor 1935).[250] However, this should not be a common or a serious problem. While iron occurs in natural waters as ferrous salts which are very soluble, on contact with air it is oxidized and it precipitates as ferric oxide, rendering it essentially harmless to animal health.

It is not considered necessary to set an upper limit of acceptability for iron in water. It should be noted, however, that even a few parts per million of iron can cause clogging of lines to stock watering equipment or an undesirable staining and deposit on the equipment itself.

Lead

Lake and river waters of the United States usually contain less than 0.05 mg/l of lead (Pb), although concentrations in excess of this have been reported (Durum et al. 1971,[141] Kopp and Kroner 1970).[182] Some natural waters in areas where galena is found have had as much as 0.8 mg/l of the

Attachment

17

lactating ewes and their lambs (NRC 1968b[205]). A level of 6 ppm in the diet is considered adequate for swine (NRC 1968a).[202]

Swine are apparently very tolerant of high levels of copper, and 250 ppm or more in the diet have been used to improve liveweight gains and feed efficiency (Nutrition Reviews 1966a[210]; NRC 1968a).[202] On the other hand, sheep were very susceptible to copper poisoning (Underwood 1971),[254] and for these animals a diet containing 25 ppm was considered toxic. About 9 mg per animal per day was considered the safe tolerance level (NRC 1968b).[205]

Several reviews of copper requirements and toxicity have been presented (McKee and Wolf 1963,[196] Nutrition Reviews 1966a,[210] Underwood 1971).[254] There is very little experimental data on the effects of copper in the water supply on animals, and its toxicity must be judged largely from the results of trials where copper was fed. The element does not appear to accumulate at excessive levels in muscle tissues, and it is very readily eliminated once its administration is stopped. While most livestock tolerate rather high levels, sheep do not (NRC 1968b).[205]

Recommendation

It is recommended that the upper limit for copper in livestock waters be 0.5 mg/l. Very few natural waters should fail to meet this.

Fluorine

The role of fluorine as a nutrient and as a toxin has been thoroughly reviewed by Underwood (1971).[254] (Unless otherwise indicated, the following discussion, exclusive of the recommendation, is based upon this review.) While there is no doubt that dietary fluoride in appropriate amounts improved the caries resistance of teeth, the element has not yet been found essential to animals. If it is a dietary essential, its requirement must be very low. Its ubiquity probably insures a continuously adequate intake by animals.

Chronic fluoride poisoning of livestock has, on the other hand, been observed in several areas of the world, resulting in some cases from the consumption of waters of high fluoride content. These waters come from wells in rock from which the element has been leached, and they often contain 10–15 mg/l. Surface waters, on the other hand, usually contain considerably less than 1 mg/l.

Concentrations of 30–50 ppm of fluoride in the total ration of dairy cows is considered the upper safe limit, higher values being suggested for other animals (NRC 1971a).[205] Maximum levels of the element in waters that are tolerated by livestock are difficult to define from available experimental work. The species, volume, and continuity of water consumption, other dietary fluoride, and age of the animals, all have an effect. It appears, however, that as little as 2 mg/l may cause tooth mottling under some circumstances. At least a several-fold increase in its concentration seems, however, required to produce other injurious effects.

Fluoride from waters apparently does not accumulate in soft tissues to a significant degree. It is transferred to a very small extent into the milk and to a somewhat greater degree into eggs.

McKee and Wolf (1963)[197] have also reviewed the matter of livestock poisoning by fluoride, concluding that 1.0 mg/l of the element in their drinking water did not harm these animals. Other more recent reports presented data suggesting that even considerably higher concentrations of fluoride in the water may, with the exception of tooth mottling, caused no animal health problems (Harris et al. 1963,[160] Shupe et al. 1964,[246] Nutrition Reviews 1966b,[211] Saville 1967,[221] Schroeder et al. 1968a[237]).

Recommendation

An upper limit for fluorides in livestock drinking waters of 2.0 mg/l is recommended. Although this level may result in some tooth mottling it should not be excessive from the standpoint of animal health or the deposition of the element in meat, milk, or eggs.

Iron

It is well known that iron (Fe) is essential to animal life. Further, it has a low order of toxicity. Deobald and Elvehjem (1935)[125] found that iron salts added at a level of 9,000 mg Fe/kg of diet caused a phosphorus deficiency in chicks. This could be overcome by adding phosphate to the diet. Campbell (1961)[124] found that soluble iron salt administered to baby pigs by stomach tube at a level of 600 mg Fe/kg of body weight caused death within six hours. O'Donovan et al. (1963)[212] found very high levels of iron in the diet (4,000 and 5,000 mg/kg) to cause phosphorus deficiency and to be toxic to weanling pigs. Lower levels (3,000 mg/kg) apparently were not toxic. The intake of water by livestock may be inhibited by high levels of this element (Taylor 1935).[250] However, this should not be a common or a serious problem. While iron occurs in natural waters as ferrous salts which are very soluble, on contact with air it is oxidized and it precipitates as ferric oxide, rendering it essentially harmless to animal health.

It is not considered necessary to set an upper limit of acceptability for iron in water. It should be noted, however, that even a few parts per million of iron can cause clogging of lines to stock watering equipment or an undesirable staining and deposit on the equipment itself.

Lead

Lake and river waters of the United States usually contain less than 0.05 mg/l of lead (Pb), although concentrations in excess of this have been reported (Durum et al. 1971,[141] Kopp and Kroner 1970).[182] Some natural waters in areas where galena is found have had as much as 0.8 mg/l of the

United States Environmental Protection Agency

2018 Edition of the Drinking Water Standards and Health Advisories Tables

The 2012 Drinking Water Standards and Health Advisories (DWSHA) Tables were amended March 2018 to fix typographical errors and add health advisories published after 2012.

2018 Edition of the Drinking Water Standards and Health Advisories

EPA 822-F-18-001

Office of Water
U.S. Environmental Protection Agency
Washington, DC

March 2018

The Health Advisory (HA) Program, sponsored by the EPA's Office of Water (OW), publishes concentrations of drinking water contaminants at Drinking Water Specific Risk Level Concentration for cancer (10^{-4} Cancer Risk) and concentrations of drinking water contaminants at which noncancer adverse health effects are not anticipated to occur over specific exposure durations - One-day, Ten-day, and Lifetime - in the *Drinking Water Standards and Health Advisories* (DWSHA) tables. The One-day and Ten-day HAs are for a 10 kg child and the Lifetime HA is for a 70 kg adult. The daily drinking water consumption for the 10 kg child and 70 kg adult are assumed to be 1 L/day and 2 L/day, respectively. The Lifetime HA for the drinking water contaminant is calculated from its associated Drinking Water Equivalent Level (DWEL), obtained from its RfD, and incorporates a drinking water Relative Source Contribution (RSC) factor of contaminant-specific data or a default of 20% of total exposure from all sources. Maximum Contaminant Levels (MCLs) and Maximum Contaminant Level Goals (MCLGs) for some regulated drinking water contaminants are also published.

HAs serve as the informal technical guidance for unregulated drinking water contaminants to assist Federal, State and local officials, and managers of public or community water systems in protecting public health as needed. They are not to be construed as legally enforceable Federal standards. EPA's OW has provided MCLs, MCLGs, RfDs, One-Day HAs, Ten-day HAs, DWELs, Lifetime HAs, Drinking Water Specific Risk Level Concentration for cancer (10^{-4} Cancer Risk), and Cancer Descriptors in the DWSHA tables. HAs are intended to protect against noncancer effects. The 10^{-4} Cancer Risk level provides information concerning cancer effects. The MCL values for specific drinking water contaminants must be used for regulated contaminants in public drinking water systems.

The DWSHA tables are revised periodically by the OW so that the benchmark values are consistent with the most current Agency assessments. Reference dose (RfD) values are updated to reflect the values in the Integrated Risk Information System (IRIS) and the Office of Pesticide Programs (OPP) Reregistration Eligibility Decisions (REDs) documents. The associated DWEL is recalculated accordingly. The 2018 DWSHA tables **do not** reflect assessments from IRIS or OPP published from 2012 to 2018. The DWSHA tables are currently undergoing a modernization effort to move the relevant HA information into a web-based format. This posting of the 2018 DWSHA tables is an intermediate step to address typographical errors and include health advisories published since the 2012 tables were published.

A Lifetime noncancer benchmark is made available to risk assessment managers for comparison to the cancer risk level drinking water concentration (10^{-4} Cancer Risk) and to determine whether the noncancer Lifetime HA or the cancer risk level drinking water concentration provides a more meaningful scenario-specific risk reduction. In this regard, the Office of Water defines the Lifetime HA as the concentration in drinking water that is not expected to cause any adverse noncarcinogenic effects for a lifetime of exposure, whereas the 10^{-4} Cancer Risk is the concentration of the chemical contaminant in drinking water that is associated with a specific probability of cancer. The Office of Water also advises consideration of the more conservative cancer risk levels (10^{-5}, 10^{-6}), found in the IRIS or OPP RED source documents, if it is considered more appropriate for exposure-specific risk assessment.

Many of the values on the DWSHA tables have been revised since the original HAs were published. Revised RfDs, 10^{-4} Cancer Risk values, and cancer designations or descriptors obtained from Integrated Risk Information System (IRIS) are presented in **BOLD** type. Revised RfDs, 10^{-4} Cancer Risk values, and cancer designations or descriptors obtained from Office of Pesticide Program's Registration Eligibility Decision (OPP RED) are presented in ***BOLD ITALICS*** type.

The summaries of IRIS Toxicological Reviews from which the RfDs and cancer benchmarks, as well as the associated narratives and references can be accessed at: http://www.epa.gov/IRIS. Those from OPP REDs can be accessed at: http://www.epa.gov/pesticides/reregistration/status.htm.

In some cases, there is an HA value for a contaminant but there is no reference to an HA document. Such HA values can be found in the Drinking Water Criteria Document for the contaminant.

With a few exceptions, the RfDs, Health Advisories, and Cancer Risk values have been rounded to one significant figure following the convention adopted by IRIS.

For unregulated chemicals with current IRIS or OPP REDs RfDs, the Lifetime Health Advisories are calculated from the associated DWELs, using the RSC values published in the HA documents for the contaminants.

The DWSHA tables may be reached from the Water Science home page at: http://www.epa.gov/waterscience/. The DWSHA tables are accessed under the Drinking Water icon.

Copies of the Tables may be ordered free of charge from

Monday thru Friday, 9:00 AM to 5:30 PM EST

DEFINITIONS

The following definitions for terms used in the DWSHA tables are not all-encompassing, and should not be construed to be "official" definitions. They are intended to assist the user in understanding terms used in the DWSHA tables.

Action Level: The concentration of a contaminant which, if exceeded, triggers treatment or other requirements which a water system must follow. For example, it is the level of lead or copper which, if exceeded in over 10% of the homes tested, triggers treatment for corrosion control.

Cancer Classification: A descriptive weight-of-evidence judgment as to the likelihood that an agent is a human carcinogen and the conditions under which the carcinogenic effects may be expressed. Under the 2005 EPA *Guidelines for Carcinogen Risk Assessment*, Cancer Descriptors replace the earlier alpha numeric Cancer Group designations (US EPA 1986 guidelines). The Cancer Descriptors in the 2005 EPA *Guidelines for Carcinogen Risk Assessment* are as follows:

- "carcinogenic to humans" (**H**)
- "likely to be carcinogenic to humans" (**L**)
- "likely to be carcinogenic above a specified dose but not likely to be carcinogenic below that dose because a key event in tumor formation does not occur below that dose" (**L/N**)
- "suggestive evidence of carcinogenic potential" (**S**)
- "inadequate information to assess carcinogenic potential" (**I**)
- "not likely to be carcinogenic to humans" (**N**)

The letter abbreviations provided parenthetically above are now used in the DWSHA tables in place of the prior alpha numeric identifiers for chemicals that have been evaluated under the new guidelines (the 2005 guidelines or the 1996 and 1999 draft guidelines) or whose records in the DWSHA tables have been revised.

Cancer Group: A qualitative weight-of-evidence judgment as to the likelihood that a chemical may be a carcinogen for humans. Each chemical was placed into one of the following five categories (US EPA 1986 guidelines). The Cancer Group designations are given in the Tables for chemicals that have not yet been evaluated under the new guidelines or whose records in the DWSHA tables have been revised.

Group Category

A	Human carcinogen
B	Probable human carcinogen: **B1** indicates limited human evidence **B2** indicates sufficient evidence in animals and inadequate or no evidence in humans
C	Possible human carcinogen
D	Not classifiable as to human carcinogenicity
E	Evidence of noncarcinogenicity for humans

10^{-4} Cancer Risk: The concentration of a chemical in drinking water corresponding to an excess estimated lifetime cancer risk of 1 in 10,000.

Drinking Water Advisory: A nonregulatory concentration of a contaminant in water that is likely to be without adverse effects on health and aesthetics for the period it is derived.

DWEL: Drinking Water Equivalent Level. A DWEL is a drinking water lifetime exposure level, assuming **100%** exposure from that medium, at which adverse, noncarcinogenic health effects would not be expected to occur.

HA: Health Advisory. An estimate of acceptable drinking water levels for a chemical substance based on health effects information; an HA is not a legally enforceable Federal standard, but serves as technical guidance to assist Federal, State, and local officials.

> **One-Day HA:** The concentration of a chemical in drinking water that is not expected to cause any adverse noncarcinogenic effects for up to one day of exposure. The One-Day HA is intended to protect a 10-kg child consuming 1 liter of water per day.
>
> **Ten-Day HA:** The concentration of a chemical in drinking water that is not expected to cause any adverse noncarcinogenic effects for up to ten days of exposure. The Ten-Day HA is also intended to protect a 10-kg child consuming 1 liter of water per day.
>
> **Lifetime HA:** The concentration of a chemical in drinking water that is not expected to cause any adverse **noncarcinogenic effects** for a lifetime of exposure, incorporating a drinking water RSC factor of contaminant-specific data or a default of 20% of total exposure from all sources. The Lifetime HA is based on exposure of a 70-kg adult consuming 2 liters of water per day. For Lifetime HAs developed for drinking water contaminants before the Lifetime HA policy change to develop Lifetime HAs for all drinking water contaminants regardless of carcinogenicity status in this DWSHA update, the Lifetime HA for Group C carcinogens, as indicated by the 1986 Cancer Guidelines, includes an uncertainty adjustment factor of 10 for possible carcinogenicity.

MCLG: Maximum Contaminant Level Goal. A non-enforceable health benchmark goal which is set at a level at which no known or anticipated adverse effect on the health of persons is expected to occur and which allows an adequate margin of safety.

MCL: Maximum Contaminant Level. The highest level of a contaminant that is allowed in drinking water. MCLs are set as close to the MCLG as feasible using the best available analytical and treatment technologies and taking cost into consideration. MCLs are enforceable standards.

Oral cancer slope factor: The slope factor is the result of application of a low-dose extrapolation procedure and is presented as the risk per (mg/kg)/day.

RfD: Reference Dose. An estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime.

Risk Specific Level Concentration: The concentration of the chemical contaminant in drinking water or air providing cancer risks of 1 in 10,000, 1 in 100,000, or 1 in 1,000,000.

SDWR: Secondary Drinking Water Regulations. Non-enforceable Federal guidelines regarding cosmetic effects (such as tooth or skin discoloration) or aesthetic effects (such as taste, odor, or color) of drinking water.

TT: Treatment Technique. A required process intended to reduce the level of a contaminant in drinking water.

Unit Risk: The unit risk is the quantitative estimate in terms of either risk per µg/L drinking water or risk per $\mu g/m^3$ air breathed.

[1] Chemicals evaluated under the 2005 Cancer Guidelines or the 1996 or 1999 drafts are demoted by an abbreviation for their weight-of-the-evidence descriptor (see page iii). If the agency has not completed a new assessment for the chemical, the 1986 Guidelines Group designation (see page iii) is given in the Cancer Descriptor column.

[2] When Acrylamide is used in drinking water systems, the combination (or product) of dose and monomer level shall not exceed that equivalent to a polyacrylamide polymer containing 0.05% monomer dosed at 1 mg/L.

[3] The MCL value for any combination of two or more of these three chemicals should not exceed 0.007 mg/L because of a similar mode of action.

[4] Administrative stay of the effective date.

[5] PAH = Polycyclic aromatic hydrocarbon.

Comprehensive reviews of literature dealing with trace element effects on plants are provided by McKee and Wolf (1963),[436] Bolland and Butler (1966),[278] and Chapman (1966).[386] Hodgson (1963)[417] presented a review dealing with reactions of trace elements in soils.

In developing a workable program to determine acceptable limits for trace elements in irrigation waters, three considerations should be recognized:

- Many factors affect the uptake of and tolerance to trace elements. The most important of these are the natural variability in tolerances of plants and of animals that consume plants, in reactions within the soil, and in nutrient interactions, particularly in the plant.
- A system of tolerance limits should provide sufficient flexibility to cope with the more serious factors listed above.
- At the same time, restrictions must be defined as precisely as possible using presently available, but limited, research information.

Both the concentration of the element in the soil solution, assuming that steady state may be approached, and the total amount of the element added in relation to quantities that have been shown to produce toxicities were used in arriving at recommended maximum concentrations. A water application rate of 3 acre feet/acre/year was used to calculate the yearly rate of trace elements added in irrigation water.

The suggested maximum trace element concentrations for irrigation waters are shown in Table V-13.

The suggested maximum concentrations for continuous use on all soils are set for those sandy soils that have low capacities to react with the element in question. They are generally set at levels less than the concentrations that produce toxicities when the most sensitive plants are grown in nutrient solutions or sand cultures. This level is set, recognizing that concentration increases in the soil as water is evapotranspired, and that the effective concentration in the soil solution, at near steady state, is higher than in the irrigation water. The criteria for short-term use are suggested for soils that have high capacitites to remove from solution the element or elements being considered.

The work of Hodgson (1963)[417] showed that the general tolerance of the soil-plant system to manganese, cobalt, zinc, copper, and boron increased as the pH increased, primarily because of the positive correlation between the capacity of the soil to inactivate these ions and the pH. This same relationship exists with aluminum and probably exists with other elements such as nickel (Pratt et al. 1964)[449] and boron (Sims and Bingham 1968).[495] However, the ability of the soil to inactivate molybdenum decreases with increase in pH, such that the amount of this element that could be added without producing excesses was higher in acid soils.

TABLE V-13—Recommended Maximum Concentrations of Trace Elements in Irrigation Waters[a]

Element	For waters used continuously on all soil	For use up to 20 years on fine textured soils of pH 6.0 to 8.5
	mg/l	mg/l
Aluminum	5.0	20.0
Arsenic	0.10	2.0
Beryllium	0.10	0.50
Boron	0.75	2.0
Cadmium	0.010	0.050
Chromium	0.10	1.0
Cobalt	0.050	5.0
Copper	0.20	5.0
Fluoride	1.0	15.0
Iron	5.0	20.0
Lead	5.0	10.0
Lithium	2.5[b]	2.5[b]
Manganese	0.20	10.0
Molybdenum	0.010	0.050[d]
Nickel	0.20	2.0
Selenium	0.020	0.020
Tin[c]		
Titanium[c]		
Tungsten[c]		
Vanadium	0.10	1.0
Zinc	2.0	10.0

[a] These levels will normally not adversely affect plants or soils.
[b] Recommended maximum concentration for irrigating citrus is 0.075 mg/l.
[c] See text for a discussion of these elements.
[d] For only acid fine textured soils or acid soils with relatively high iron oxide contents.

In addition to pH control (i.e., liming acid soils), another important management factor that has a large effect on the capacity of soils to adsorb some trace elements without development of plant toxicities is the available phosphorus level. Large applications of phosphate are known to induce deficiencies of such elements as copper and zinc and greatly reduce aluminum toxicity (Chapman 1966).[386]

The concentrations given in Table V-13 are for ionic and soluble forms of the elements. If insoluble forms are present as particulate matter, these should be removed by filtration before the water is analyzed.

Aluminum

The toxicity of this ion is considered to be one of the main causes of nonproductivity in acid soils (Coleman and Thomas 1967,[392] Reeve and Sumner 1970,[493] Hoyt and Nyborg 1971a[419]).

At pH values from about 5.5 to 8.0, soils have great capacities to precipitate soluble aluminum and to eliminate its toxicity. Most irrigated soils are naturally alkaline, and many are highly buffered with calcium carbonate. In these situations aluminum toxicity is effectively prevented.

With only a few exceptions, as soils become more acid (pH <5.5), exchangeable and soluble aluminum develop by dissolution of oxides and hydroxides or by decomposition of clay minerals. Thus, without the introduction of aluminum, a toxicity of this element usually develops as soils are acidified, and limestone must be added to keep the soil productive.

20

Selenium

Selenium is toxic at low concentrations in nutrient solutions, and only small amounts added to soils increase the selenium content of forages to a level toxic to livestock. Broyer et al. (1966)[384] found that selenium at 0.025 mg/l in nutrient solutions decreased the yields of alfalfa.

The best evidence for use in setting water quality criteria for this element is application rates in relation to toxicity in forages. Amounts of selenium in forages required to prevent selenium deficiencies in cattle (Allaway et al. 1967)[386] ranged between 0.03 and 0.10 mg/kg (depending on other factors), whereas concentrations above 3 or 4 mg/kg were considered toxic (Underwood 1966).[471] A number of investigators (Hamilton and Beath 1963,[410] Grant 1965,[407] Allaway et al. 1966)[467] have shown that small applications of selenium to soils at a rate of a few kilograms per hectare produced plant concentrations of selenium that were toxic to animals. Gissel-Nielson and Bisbjerg (1970)[406] found that applications of approximately 0.2 kg/hectare of selenium produced from 1.0 to 10.5 mg/kg in tissues of forage and vegetable crops.

Recommendation

With the low levels of selenium required to produce toxic levels in forages, the recommended maximum concentration in irrigation waters is 0.02 mg/l for continuous use on all soils. At a rate of 3 acre feet of water per acre per year this concentration represents 3.2 pounds per acre in 20 years. The same recommended maximum concentration should be used on neutral and alkaline fine textured soils until greater information is obtained on soil reactions. The relative mobility of this element in soils in comparison to other trace elements and slow removal in harvested crops provide a sufficient safety margin.

Tin, Tungsten, and Titanium

Tin, tungsten, and titantium are effectively excluded by plants. The first two can undoubtedly be introduced to plants under conditions that can produce specific toxicities. However, not enough is known at this time about any of the three to prescribe tolerance limits. (This is true with other trace elements such as silver.) Titantium is very insoluble, at present it is not of great concern.

Vanadium

Gericke and Rennenkampff (1939)[405] found that vanadium at 0.1, 1.0, and 2.0 mg/l added to nutrient solutions as calcium vanadate slightly increased the growth of barley, whereas at 10 mg/l vanadium was toxic to both tops and roots and that vanadium chloride at 1.0 mg/l of vanadium was toxic. Warington (1954,[476] 1956[477]) found that flax, soybeans, and peas showed toxicity to vanadium in the concentration range of 0.5 to 2.5 mg/l. Chiu (1953)[383] found that 560 pounds per acre of vanadium added as ammonium metavanadate to rice paddy soils produced toxicity to rice.

Recommendations

Considering the toxicity of vanadium in nutrient solutions and in soils and the lack of information on the reaction of this element with soils, a maximum concentration of 0.10 mg/l for continued use on all soils is recommended. For a 20-year period on neutral and alkaline fine textured the recommended maximum concentration is 1.0 mg/l.

Zinc

Toxicities of zinc in nutrient solutions have been demonstrated for a number of plants. Hewitt (1948)[413] found that zinc at 16 to 32 mg/l produced iron deficiencies in sugar beets. Hunter and Vergnano (1953)[421] found toxicity to oats at 25 mg/l. Millikan (1947)[433] found that 2.5 mg/l produced iron deficiency in oats. Earley (1943)[399] found that the Peking variety of soybeans was killed at 0.4 mg/l, whereas the Manchu variety was killed at 1.6 mg/l.

The toxicity of zinc in soils is related to soil pH, and liming acid soil has a large effect in reducing toxicity (Barnette 1936,[471] Gall and Barnette 1940,[404] Peech 1941,[440] Staker and Cummings 1941,[468] Staker 1942,[467] Lee and Page 1967[426]). Amounts of added zinc that produce toxicity are highest in clay and peat soils and smallest in sands.

On acid sandy soils the amounts required for toxicity would suggest a recommended maximum concentration of zinc of 1 mg/l for continuous use. This concentration at a water application rate of 3 acre feet/acre/year would add 813 pounds per acre in 100 years. However, if acid sandy soils are limed to pH values of six or above, the tolerance level is increased by at least a factor of two (Gall and Barnette 1940).[404]

Recommendations

Assuming adequate use of liming materials to keep pH values high (six or above), the recommended maximum concentration for continuous use on all soils is 2.0 mg/l. For a 20-year period on neutral and alkaline soils the recommended maximum is 10 mg/l. On fine textured calcareous soils and on organic soils, the concentrations can exceed this limit by a factor of two or three with low probability of toxicities in a 20-year period.

PESTICIDES (IN WATER FOR IRRIGATION)

Pesticies are used widely in water for irrigation on commercial crops in the United States (Sheets 1967).[502] Figures on production, acreage treated, and use patterns indicate insecticides and herbicides comprise the major agricultural pesticides. There are over 320 insecticides and 127 herbicides registered for agricultural use (Fowler 1972).[498]

Silver; CASRN 7440-22-4

Human health assessment information on a chemical substance is included in the IRIS database only after a comprehensive review of toxicity data, as outlined in the IRIS assessment development process. Sections I (Health Hazard Assessments for Noncarcinogenic Effects) and II (Carcinogenicity Assessment for Lifetime Exposure) present the conclusions that were reached during the assessment development process. Supporting information and explanations of the methods used to derive the values given in IRIS are provided in the guidance documents located on the IRIS website.

STATUS OF DATA FOR Silver

File First On-Line 01/31/1987

Category (section)	Assessment Available?	Last Revised
Oral RfD (I.A.)	yes	12/01/1991
Inhalation RfC (I.B.)	not evaluated	
Carcinogenicity Assessment (II.)	yes	06/01/1989

I. Chronic Health Hazard Assessments for Noncarcinogenic Effects

I.A. Reference Dose for Chronic Oral Exposure (RfD)

Substance Name — Silver
CASRN — 7440-22-4
Last Revised — 12/01/1991

The oral Reference Dose (RfD) is based on the assumption that thresholds exist for certain toxic effects such as cellular necrosis. It is expressed in units of mg/kg-day. In general, the RfD is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. Please refer to the Background Document for an elaboration of these concepts. RfDs can also be derived for the noncarcinogenic health effects of substances that are also carcinogens. Therefore, it is essential to refer to other sources of

information concerning the carcinogenicity of this substance. If the U.S. EPA has evaluated this substance for potential human carcinogenicity, a summary of that evaluation will be contained in Section II of this file.

I.A.1. Oral RfD Summary

Critical Effect	Experimental Doses*	UF	MF	RfD
Argyria **2- to 9-Year Human i.v. Study** **Gaul and Staud, 1935**	NOEL: None LOAEL: 1 g (total dose); converted to an oral dose of 0.014 mg/kg/day	3	1	5E-3 mg/kg/day

* Conversion Factors: Based on conversion from the total i.v. dose to a total oral dose of 25 g (i.v. dose of 1 g divided by 0.04, assumed oral retention factor; see Furchner et al., 1968 in Additional Comments section) and dividing by 70 kg (adult body weight) and 25,500 days (a lifetime, or 70 years).

I.A.2. Principal and Supporting Studies (Oral RfD)

Gaul, L.E. and A.H. Staud. 1935. Clinical spectroscopy. Seventy cases of generalized argyrosis following organic and colloidal silver medication. J. Am. Med. Assoc. 104: 1387-1390.

The critical effect in humans ingesting silver is argyria, a medically benign but permanent bluish-gray discoloration of the skin. Argyria results from the deposition of silver in the dermis and also from silver-induced production of melanin. Although silver has been shown to be uniformly deposited in exposed and unexposed areas, the increased pigmentation becomes more pronounced in areas exposed to sunlight due to photoactivated reduction of the metal. Although the deposition of silver is permanent, it is not associated with any adverse health effects. No pathologic changes or inflammatory reactions have been shown to result from silver deposition. Silver compounds have been employed for medical uses for centuries. In the nineteenth and early twentieth centuries, silver arsphenamine was used in the treatment of syphillis; more recently it has been used as an astringent in topical preparations. While argyria occurred more commonly before the development of antibiotics, it is now a rare occurrence. Greene and Su (1987) have published a review of argyria.

Gaul and Staud (1935) reported 70 cases of generalized argyria following organic and colloidal silver medication, including 13 cases of generalized argyria following intravenous silver arsphenamine injection therapy and a biospectrometric analysis of 10 cases of generalized argyria classified according to the quantity of silver present. In the i.v. study, data were presented for 10 males (23-64 years old) and for two females (23 and 49 years old) who were administered 31-100 i.v. injections of silver arsphenamine (total dose was 4-20 g) over a 2- to 9.75-year period. Argyria developed after a total dose of 4, 7 or 8 g in some patients, while in others, argyria did not develop until after a total dose of 10, 15 or 20 g. In the biospectrometric analysis of skin biopsies from 10 cases of generalized argyria, the authors confirmed that the degree of the discoloration is directly dependent on the amount of silver present. The authors concluded that argyria may become clinically apparent after a total accumulated i.v. dose of approximately 8 g of silver arsphenamine. The book entitled "Argyria. The Pharmacology of Silver" reached the same conclusion, that a total accumulative i.v. dose of 8 gm silver arsphenamine is the limit beyond which argyria may develop (Hill and Pillsbury, 1939). However, since body accumulates silver throughout life, it is theoretically possible for amounts less than this (for example, 4 g silver arsphenamine) to result in argyria. Therefore, based on cases presented in this study, the lowest i.v. dose resulting in argyria in one patient, 1 g metallic silver (4 g silver arsphenamine x 0.23, the fraction of silver in silver arsphenamine) is considered to be a minimal effect level for this study.

Blumberg and Carey (1934) reported argyria in an emaciated chronically ill (more than 15 years) 33-year-old female (32.7 kg) who had ingested capsules containing silver nitrate over a period of 1 year. The patient reported ingesting 16 mg silver nitrate three times a day (about 30 mg silver/day) for alternate periods of 2 weeks. Spectrographic analysis of blood samples revealed a blood silver level of 0.5 mg/L 1 week after ingestion of silver nitrate capsules ceased, and there was only a small decrease in this level after 3 months. The authors noted that this marked argyremia was striking because even in cases of documented argyria, blood silver levels are not generally elevated to this extent. Normal levels for argyremic patients were reported to range from not detected to 0.005 mg Ag/l blood. Heavy traces of silver in the skin, moderate amounts in the urine and feces, and trace amounts in the saliva were reported in samples tested 3 months after ingestion of the capsules stopped; however, despite the marked argyremia and detection of silver in the skin, the argyria at 3 months was quite mild. No obvious dark pigmentation was seen other than gingival lines which are considered to be characteristic of the first signs of argyria. The authors suggested that this may have been because the woman was not exposed to strong light during the period of silver treatment. This study is not suitable to serve as the basis for a quantitative risk assessment for silver because it is a clinical report on only one patient of compromised health. Furthermore, the actual amount of silver ingested is based on the patient's recollection and cannot be accurately determined.

In a case reported by East et al. (1980), argyria was diagnosed in a 47-year- old woman (58.6 kg) who had taken excessively large oral doses of anti-smoking lozenges containing silver acetate over a period of 2.5 years. No information was provided as to the actual amount of silver ingested. Symptoms of argyria appeared after the first 6 months of exposure. Based on whole body neutron activation analysis, the total body burden of silver in this female was estimated to be 6.4 (plus or minus 2) g. Both the total body burden and concentration of silver in the skin were estimated to be 8000 times higher than normal. In a separate 30-week experiment, the same subject retained 18% of a single dose of orally-administered silver, a retention level much higher than that reported by other investigators. East et al. (1980) cited other studies on this particular anti-smoking formulation (on the market since 1973) which demonstrated that "within the limits of experimental error, no silver is retained after oral administration." However, this may not hold true for excessive intakes like that ingested by this individual. As with the study by Blumberg and Carey (1934), this study is not suitable to serve as the basis for a quantitative risk assessment. It is a clinical report on only one patient and the actual amount of silver ingested can only be estimated.

I.A.3. Uncertainty and Modifying Factors (Oral RfD)

UF — An uncertainty factor of 3 is applied to account for minimal effects in a subpopulation which has exhibited an increased propensity for the development of argyria. The critical effect observed is a cosmetic effect, with no associated adverse health effects. Also, the critical study reports on only 1 individual who developed argyria following an i.v. dose of 1 g silver (4 g silver arsphenamine). Other individuals did not respond until levels five times higher were administered. No uncertainty factor for less than chronic to chronic duration is needed because the dose has been apportioned over a lifetime of 70 years.

MF — None

I.A.4. Additional Studies/Comments (Oral RfD)

In the study by East et al. (1980) (see section 1.A.2.), one human was found to retain 18% of a single oral dose. However, the authors acknowledge that this high level of retention is not consistent with data published in other laboratories. For ethical reasons, the experiment could be not repeated to determine the validity of the results.

Humans are exposed to small amounts of silver from dietary sources. The oral intake of silver from a typical diet has been estimated to range from 27-88 ug/day (Hamilton and Minski, 1972/1973; Kehoe et al., 1940). Tipton et al. (1966) estimated a lesser intake of 10-20 ug/day in two subjects during a 30- day observation period. Over a lifetime, a small but measurable amount of silver is accumulated by individuals having no excessive exposure. Gaul and Staud

(1935) estimated that a person aged 50 years would have an average retention of 0.23-0.48 g silver (equivalent to 1-2 g silver arsphenamine). Petering et al. (1991) estimated a much lower body burden of 9 mg over a 50- year period based on estimated intake, absorption, and excretion values; however, it is not clear how the final estimate was calculated. Furchner et al. (1968) studied the absorption and retention of ingested silver (as silver nitrate, amount not specified) in mice, rats, monkeys and dogs. In all four species, very little silver was absorbed from the GI tract. Cumulative excretion ranged from 90 to 99% on the second day after ingestion, with <1% of the dose being retained in <1 week in monkeys, rats and mice. Dogs had a slightly greater retention. The authors used the data from the dog to estimate how much silver ingested by a 70 kg human would be retained. An "equilibrium factor" of 4.4% was determined by integrating from zero to infinity a retention equation which assumes a triphasic elimination pattern for silver with the initial elimination of 90% coming from the dog data. The first elimination half-time of 0.5 days was used "arbitrarily"; subsequent half-times of 3.5 days and 41 days were taken from a metabolic study by Polachek et al. (1960). Furchner et al. (1968) considered their calculated equilibrium factor of 4.4% to be a conservative estimate for the amount of silver which would be retained by a 70 kg human. This figure was rounded to 4% and was used in the dose conversion (i.v. dose converted to oral intake) for the calculation of the RfD.

In addition to silver arsphenamine, any silver compound (silver nitrate, silver acetate, argyrol, Neosilvol and Collargol, etc.), at high dose, can cause argyria. Another important factor predisposing to the development of argyria is the exposure of the skin to light.

Argyria, the critical effect upon which the RfD for silver is based, occurs at levels of exposure much lower than those levels associated with other effects of silver. Argyrosis, resulting from the deposition of silver in the eye, has also been documented, but generally involves the use of eye drops or make-up containing silver (Greene and Su, 1987). Silver has been found to be deposited in the cornea and the anterior capsule of the lens. The same deposition pattern was seen in the eyes of male Wistar rats following administration of a 0.66% silver nitrate solution to the eyes for 45 days (Rungby, 1986). No toxicological effects were reported.

Toxic effects of silver have been reported primarily for the cardiovascular and hepatic systems. Olcott (1950) administered 0.1% silver nitrate in drinking water to rats for 218 days. This exposure (about 89 mg/kg/day) resulted in a statistically significant increase in the incidence of ventricular hypertrophy. Upon autopsy, advanced pigmentation was observed in body organs, but the ventricular hypertrophy was not attributed to silver deposition.

Hepatic necrosis and ultrastructural changes of the liver have been induced by silver administration to vitamin E and/or selenium deficient rats (Wagner et al., 1975; Diplock et al., 1967; Bunyan et al., 1968). Investigators have hypothesized that this toxicity is related to a silver-induced selenium deficiency that inhibits the synthesis of the seleno-enzyme glutathione

peroxidase. In animals supplemented with selenium and/or vitamin E, exposures of silver as high as 140 mg/kg/day (100 mg Ag/L drinking water) were well- tolerated (Bunyan et al., 1968).

I.A.5. Confidence in the Oral RfD

Study — Medium
Database — Low
RfD — Low

The critical human study rates a medium confidence. It is an old study (1935) which offers fairly specific information regarding the total dose of silver injected over a stated period of time. One shortcoming of the study is that only patients developing argyria are described; no information is presented on patients who received multiple injections of silver arsphenamine without developing argyria. Therefore, it is difficult to establish a NOAEL. Also, the individuals in the study were being treated for syphilis and may have been of compromised health.

Confidence in the database is considered to be low because the studies used to support the RfD were not controlled studies. For clinical case studies of argyria (such as Blumberg and Carey, 1934; East et al., 1980), it is especially difficult to determine the amount of silver that was ingested.

Confidence in the RfD can be considered low-to-medium because, while the critical effect has been demonstrated in humans following oral administration of silver, the quantitative risk estimate is based on a study utilizing intravenous administration and thus necessitates a dose conversion with inherent uncertainties.

I.A.6. EPA Documentation and Review of the Oral RfD

Source Document — This assessment is not presented in any existing U.S. EPA document.

Other EPA Documentation — None

Agency Work Group Review — 10/09/1985, 02/05/1986, 04/18/1990, 02/20/1991, 07/18/1991

Verification Date — 07/18/1991

Screening-Level Literature Review Findings — A screening-level review conducted by an EPA contractor of the more recent toxicology literature pertinent to the RfD for silver conducted in August 2003 did not identify any critical new studies. IRIS users who know of important new

studies may provide that information to the IRIS Hotline at hotline.iris@epa.gov or 202-566-1676.

I.A.7. EPA Contacts (Oral RfD)

Please contact the IRIS Hotline for all questions concerning this assessment or IRIS, in general, at (202)566-1676 (phone), (202)566-1749 (FAX) or hotline.iris@epa.gov (internet address).

I.B. Reference Concentration for Chronic Inhalation Exposure (RfC)

Substance Name — Silver
CASRN — 7440-22-4

Not available at this time.

II. Carcinogenicity Assessment for Lifetime Exposure

Substance Name — Silver
CASRN — 7440-22-4
Last Revised — 06/01/1989

Section II provides information on three aspects of the carcinogenic assessment for the substance in question; the weight-of-evidence judgment of the likelihood that the substance is a human carcinogen, and quantitative estimates of risk from oral exposure and from inhalation exposure. The quantitative risk estimates are presented in three ways. The slope factor is the result of application of a low-dose extrapolation procedure and is presented as the risk per (mg/kg)/day. The unit risk is the quantitative estimate in terms of either risk per ug/L drinking water or risk per ug/cu.m air breathed. The third form in which risk is presented is a drinking water or air concentration providing cancer risks of 1 in 10,000, 1 in 100,000 or 1 in 1,000,000. The rationale and methods used to develop the carcinogenicity information in IRIS are described in The Risk Assessment Guidelines of 1986 (EPA/600/8-87/045) and in the IRIS Background Document. IRIS summaries developed since the publication of EPA's more recent Proposed Guidelines for Carcinogen Risk Assessment also utilize those Guidelines where indicated (Federal Register 61(79):17960-18011, April 23, 1996). Users are referred to Section I of this IRIS file for information on long-term toxic effects other than carcinogenicity.

II.A. Evidence for Human Carcinogenicity

II.A.1. Weight-of-Evidence Characterization

Classification — D; not classified as to human carcinogenicity

Basis — In animals, local sarcomas have been induced after implantation of foils and discs of silver. However, the interpretation of these findings has been questioned due to the phenomenon of solid-state carcinogenesis in which even insoluble solids such as plastic have been shown to result in local fibrosarcomas.

II.A.2. Human Carcinogenicity Data

No evidence of cancer in humans has been reported despite frequent therapeutic use of the compound over the years.

II.A.3. Animal Carcinogenicity Data

Inadequate. Local sarcomas have been induced after subcutaneous (s.c.) implantation of foils and discs of silver and other noble metals. Furst (1979, 1981), however, cited studies showing that even insoluble solids such as smooth ivory and plastic result in local fibrosarcomas and that tin when crumbled will not. He concluded that i.p. and s.c. implants are invalid as indicators of carcinogenicity because a phenomenon called solid-state carcinogenesis may complicate the interpretation of the cause of these tumors. It is difficult to interpret these implantation site tumors in laboratory animals in terms of exposure to humans via ingestion. Within these constraints there are two studies given below in which silver per se appeared to induce no carcinogenic response.

Schmahl and Steinhoff (1960) reported, in a study of silver and of gold, that colloidal silver injected both i.v. and s.c. into rats resulted in tumors in 8 of 26 rats which survived longer than 14 months. In 6 of the 8, the tumor was at the site of the s.c. injection. In about 700 untreated rats the rate of spontaneous tumor formation of any site was 1 to 3%. No vehicle control was reported.

Furst and Schlauder (1977) evaluated silver and gold for carcinogenicity in a study designed to avoid solid-state carcinogenesis. Metal powder was suspended in trioctanoin and injected monthly, i.m., into 50 male and female Fischer 344 rats per group. The dose was 5 mg each for 5 treatments and 10 mg each for 5 more treatments for a total dose of 75 mg silver. The treatment regimen included a vehicle control (a reportedly inert material), and cadmium as a positive control. Injection site sarcomas were found only in vehicle control (1/50), gold (1/50) and

cadmium (30/50); no tumors (0/50) appeared at the site of injection in the silver-treated animals. A complete necropsy was performed on all animals. The authors mentioned the existence of spontaneous tumors in Fischer 344 rats, but reported only injection site tumors. They concluded that finely divided silver powder injected i.m. does not induce cancer.

II.A.4. Supporting Data for Carcinogenicity

Further support for the lack of silver's ability to induce or promote cancer stems from the finding that, despite long standing and frequent therapeutic usage in humans, there are no reports of cancer associated with silver. In a recent Proceedings of a Workshop/Conference on the Role of Metals in Carcinogenesis (1981) containing 24 articles on animal bioassays, epidemiology, biochemistry, mutagenicity, and enhancement and inhibition of carcinogenesis, silver was not included as a metal of carcinogenic concern.

No evidence of the mutagenicity of silver was shown in two available studies. Demerec et al. (1951) studied silver nitrate for the possible induction of back-mutations from streptomycin dependence to nondependence in Eschericha coli. Silver nitrate was considered nonmutagenic in this assay. Nishioka (1975) screened silver chloride with other chemicals for mutagenic effects using a method called the rec-assay. Silver chloride was considered nonmutagenic in this assay.

II.B. Quantitative Estimate of Carcinogenic Risk from Oral Exposure

Not available.

II.C. Quantitative Estimate of Carcinogenic Risk from Inhalation Exposure

Not available.

II.D. EPA Documentation, Review, and Contacts (Carcinogenicity Assessment)

II.D.1. EPA Documentation

Source Document — U.S. EPA, 1988

The 1988 Drinking Water Criteria Document for Silver has received Agency Review.

II.D.2. EPA Review (Carcinogenicity Assessment)

Agency Work Group Review — 09/22/1988

Verification Date — 09/22/1988

Screening-Level Literature Review Findings — A screening-level review conducted by an EPA contractor of the more recent toxicology literature pertinent to the cancer assessment for silver conducted in August 2003 did not identify any critical new studies. IRIS users who know of important new studies may provide that information to the IRIS Hotline at hotline.iris@epa.gov or 202-566-1676.

II.D.3. EPA Contacts (Carcinogenicity Assessment)

Please contact the IRIS Hotline for all questions concerning this assessment or IRIS, in general, at (202)566-1676 (phone), (202)566-1749 (FAX) or hotline.iris@epa.gov (internet address).

' = An enthalpy of vaporization value cannot be derived for the constituent; therefore, a dimensionless Henry's Law Constant value set at 25 degrees Celsius is used for evaluation of its treatment efficiency.
Organic Carbon Partition Coefficient and Dimensionless Henry's Law Constant values derived from U.S. EPA Regional Screening Level (RSL) tables as of May 2021.

Irrigation = The standard is based on beneficial use for irrigation of crops, per "Water Quality Criteria", by National Academy of Sciences.
Livestock = The standard is based on beneficial use for watering livestock, per "Water Quality Criteria", by National Academy of Sciences.
TF = Treatment Factor. A TF of 5 is applied to the Class I groundwater quality standard, based on Illinois EPA's treatment efficiency determination for chemicals whose constituents are not based on an MCL. A constituent's treatment efficiency is based the effectiveness to treat groundwater at an 80% removal efficiency rate for the constituent. A TF of 5 is applied to a constituent having either an organic carbon partition coefficient ("K_{oc}") greater than ethylbenzene's K_{oc} of 446 L/kg for carbon adsorption efficiency, or a constituent having a dimensionless Henry's Law Constant ("H'") greater than dichloromethane's (methylene chloride) H' of 0.11, when set at a groundwater system temperature of 20 degrees Celsius, for air stripping efficiency. If a constituent does not meet the criteria for an 80% removal efficiency, no TF is applied to the Class I groundwater quality standard.

Comprehensive reviews of literature dealing with trace element effects on plants are provided by McKee and Wolf (1963),[436] Bolland and Butler (1966),[375] and Chapman (1966).[386] Hodgson (1963)[417] presented a review dealing with reactions of trace elements in soils.

In developing a workable program to determine acceptable limits for trace elements in irrigation waters, three considerations should be recognized:

- Many factors affect the uptake of and tolerance to trace elements. The most important of these are the natural variability in tolerances of plants and of animals that consume plants, in reactions within the soil, and in nutrient interactions, particularly in the plant.
- A system of tolerance limits should provide sufficient flexibility to cope with the more serious factors listed above.
- At the same time, restrictions must be defined as precisely as possible using presently available, but limited, research information.

Both the concentration of the element in the soil solution, assuming that steady state may be approached, and the total amount of the element added in relation to quantities that have been shown to produce toxicities were used in arriving at recommended maximum concentrations. A water application rate of 3 acre feet/acre/year was used to calculate the yearly rate of trace elements added in irrigation water.

The suggested maximum trace element concentrations for irrigation waters are shown in Table V-13.

The suggested maximum concentrations for continuous use on all soils are set for those sandy soils that have low capacities to react with the element in question. They are generally set at levels less than the concentrations that produce toxicities when the most sensitive plants are grown in nutrient solutions or sand cultures. This level is set, recognizing that concentration increases in the soil as water is evapotranspired, and that the effective concentration in the soil solution, at near steady state, is higher than in the irrigation water. The criteria for short-term use are suggested for soils that have high capacitites to remove from solution the element or elements being considered.

The work of Hodgson (1963)[417] showed that the general tolerance of the soil-plant system to manganese, cobalt, zinc, copper, and boron increased as the pH increased, primarily because of the positive correlation between the capacity of the soil to inactivate these ions and the pH. This same relationship exists with aluminum and probably exists with other elements such as nickel (Pratt et al. 1964)[449] and boron (Sims and Bingham 1968).[465] However, the ability of the soil to inactivate molybdenum decreases with increase in pH, such that the amount of this element that could be added without producing excesses was higher in acid soils.

TABLE V-13—Recommended Maximum Concentrations of Trace Elements in Irrigation Waters

Element	For waters used continuously on all soil	For use up to 20 years on fine textured soils of pH 6.0 to 8.5
	mg/l	mg/l
Aluminum	5.0	20.0
Arsenic	0.10	2.0
Beryllium	0.10	0.50
Boron	0.75	2.0
Cadmium	0.010	0.050
Chromium	0.10	1.0
Cobalt	0.050	5.0
Copper	0.20	5.0
Fluoride	1.0	15.0
Iron	5.0	20.0
Lead	5.0	10.0
Lithium	2.5[a]	2.5[a]
Manganese	0.20	10.0
Molybdenum	0.010	0.050[d]
Nickel	0.20	2.0
Selenium	0.020	0.020
Tin[c]		
Titanium[c]		
Tungsten[c]		
Vanadium	0.10	1.0
Zinc	2.0	10.0

[a] These levels will normally not adversely affect plants or soils.
[b] Recommended maximum concentration for irrigating citrus is 0.075 mg/l.
[c] See text for a discussion of these elements.
[d] For only acid fine textured soils or acid soils with relatively high iron oxide contents.

In addition to pH control (i.e., liming acid soils), another important management factor that has a large effect on the capacity of soils to adsorb some trace elements without development of plant toxicities is the available phosphorus level. Large applications of phosphate are known to induce deficiencies of such elements as copper and zinc and greatly reduce aluminum toxicity (Chapman 1966).[386]

The concentrations given in Table V-13 are for ionic and soluble forms of the elements. If insoluble forms are present as particulate matter, these should be removed by filtration before the water is analyzed.

Aluminum

The toxicity of this ion is considered to be one of the main causes of nonproductivity in acid soils (Coleman and Thomas 1967,[391] Reeve and Sumner 1970,[453] Hoyt and Nyborg 1971a[419]).

At pH values from about 5.5 to 8.0, soils have great capacities to precipitate soluble aluminum and to eliminate its toxicity. Most irrigated soils are naturally alkaline, and many are highly buffered with calcium carbonate. In these situations aluminum toxicity is effectively prevented.

With only a few exceptions, as soils become more acid ($pH < 5.5$), exchangeable and soluble aluminum develop by dissolution of oxides and hydroxides or by decomposition of clay minerals. Thus, without the introduction of aluminum, a toxicity of this element usually develops as soils are acidified, and limestone must be added to keep the soil productive.

3

toxicity in acid sandy soils. A safety margin would be obtained by liming these soils. A concentration of copper at 5.0 mg/l applied in irrigation water at the rate of 3 acre feet of water per year for a 20-year period would add 800 pounds of copper in 20 years.

Recommendations

Based on toxicity levels in nutrient solutions and the limited soils data available, a maximum concentration of 0.20 mg/l copper is recommended for continuous use on all soils. On neutral and alkaline fine textured soils for use over a 20-year period, a maximum concentration of 5.0 mg/l is recommended.

Fluoride

Applications of soluble fluoride salts to acid soils can produce toxicity to plants. Prince et al. (1949)[450] found that 360 pounds fluoride per acre, added as sodium fluoride, reduced the yields of buckwheat at pH 4.5, but at pH values above 5.5 this rate produced no injury.

MacIntire et al. (1942)[435] found that 1,150 pounds of fluoride in superphosphate, 575 pounds of fluoride in slag, or 2,300 pounds of fluoride as calcium fluoride per acre had no detrimental effects on germination or plant growth on well-limed neutral soils, and that vegetation grown on these soils showed only a slight increase in fluoride as compared to those grown in acid soils. However, Shirley et al. (1970)[464] found that bones of cows that had grazed pastures fertilized with raw rock and colloidal phosphate, which contained approximately two to three per cent fluorides, for seven to 16 years averaged approximately 2,900 and 2,300 mg of fluorine per kilogram of bone, respectively. The bones of cows that had grazed on pastures fertilized with relatively fluorine free superphosphate, concentrated superphosphate, and basic slag fertilizer contained only 1400 mg/kg fluorine.

Recommendations

Because of the capacity of neutral and alkaline soils to inactivate fluoride, a relatively high maximum concentration for continuous use on these soils is recommended. Recommended maximum concentrations are 1.0 mg/l for continuous use on all soils and 15 mg/l for use for a 20-year period on neutral and alkaline fine textured soils.

Iron

Iron in irrigation waters is not likely to create a problem of plant toxicities. It is so insoluble in aerated soils at all pH values in which plants grow well, that it is not toxic. In fact, the problems with this element are deficiencies in alkaline soils. In reduced (flooded) soils soluble ferrous ions develop from inherent compounds in soils, so that quantities that might be added in waters would be of no concern. However, Rhoads (1971)[458] found large reductions in the quality of tobacco when plants were sprinkler irrigated with water containing 5 or more mg soluble iron/l, because of precipitation of iron oxides on the leaves. Rhoad's experience would suggest caution when irrigating any crops using sprinkler systems and waters having sufficient reducing conditions to produce reduced and soluble ferrous iron.

The disadvantages of soluble iron salts in waters are that these would contribute to soil acidification, and the precipitated iron would increase the fixation of such essential elements as phosphorous and molybdenum.

Recommendations

A maximum concentration of 5.0 mg/l is recommended for continuous use on all soils, and a maximum concentration of 20 mg/l is recommended on neutral to alkaline soils for a 20-year period. The use of waters with large concentrations of suspended freshly precipitated iron oxides and hydroxides is not recommended, because these materials also increase the fixation of phosphorous and molybdenum.

Lead

The phytotoxicity of lead is relatively low. Berry (1924)[374] found that a concentration of lead nitrate of 25 mg/l was required for toxicity to oats and tomato plants. At a concentration of 50 mg/l, death of plants occurred. Hopper (1937)[418] found that 30 mg/l of lead in nutrient solutions was toxic to bean plants. Wilkins (1957)[479] found that lead at 10 mg/l as lead nitrate reduced root growth. Since soluble lead contents in soils were usually from 0.05 to 5.0 mg/kg (Brewer 1966),[383] little toxicity can be expected. It was shown that the principal entry of lead into plants was from aerial deposits rather than from absorption from soils (Page et al. 1971)[445] indicating that lead that falls onto the soil is not available to plants.

In a summary on the effects of lead on plants, the Committee on the Biological Effects of Atmosphere Pollutants (NRC 1972)[441] concluded that there is not sufficient evidence to indicate that lead, as it occurs in nature, is toxic to vegetation. However, in studies using roots of some plants and very high concentrations of lead, this element was reported to be concentrated in cell walls and nuclei during mitosis and to inhibit cell proliferation.

Recommendations

Recommended maximum concentrations of lead are 5.0 mg/l for continuous use on all soils and 10 mg/l for a 20-year period on neutral and alkaline fine textured soils.

Lithium

Most crops can tolerate lithium in nutrient solutions at concentrations up to 5 mg/l (Oertli 1962,[443] Bingham et al. 1964,[377] Bollard and Butler 1966[378]). But research revealed

that citrus was more sensitive (Aldrich et al. 1951,[309] Bradford 1963b,[381] Hilgeman et al. 1970[415]). Hilgeman et al. (1970)[415] found that grapefruit developed severe symptoms of lithium toxicity when irrigated with waters containing lithium at 0.18 to 0.25 mg/l. Bradford (1963a)[380] reported that experience in California indicated slight toxicity of lithium to citrus at 0.06 to 0.10 mg/l in the water.

Lithium is one of the most mobile of cations in soils. It tends to be replaced by other cations in waters or fertilizers and is removed by leaching. On the other hand, it is not precipitated by any known process.

Recommendations

Recommendations for maximum concentrations of lithium, based on its phytotoxicity, are 2.5 mg/l for continuous use on all soils, except for citrus where the recommended maximum concentration is 0.075 mg/l for all soils. For short-term use on fine textured soils the same maximum concentrations are recommended because of lack of inactivation in soils.

Manganese

Manganese concentrations at a few tenths to a few milligrams per liter in nutrient solutions are toxic to a number of crops as shown by Morris and Pierre (1949),[440] Adams and Wear (1957),[364] Hewitt (1965),[414] and others. However, toxicities of this element are associated with acid soils, and applications of proper quantities of ground limestone successfully eliminated the problem. Increasing the pH to the 5.5 to 6.0 range usually reduced the active manganese to below the toxic level (Adams and Wear 1957).[364] Hoyt and Nyborg (1971b)[420] found that available manganese in the soil and manganese content of plants were negatively correlated with soil pH. However, the definite association of toxicity with soil pH as found with aluminum was not found with manganese, which has a more complex chemistry. Thus, more care must be taken in setting water quality criteria for manganese than for aluminum (i.e., management for control of toxicities is not certain).

Recommendations

Recommended maximum concentrations for manganese in irrigation waters are set at 0.20 mg/l for continued use on all soils and 10 mg/l for use up to 20 years on neutral and alkaline fine textured soils. Concentrations for continued use can be increased with alkaline or calcareous soils, and also with crops that have higher tolerance levels.

Molybdenum

This element presents no problems of toxicity to plants at concentrations usually found in soils and waters. The problem is one of toxicity to animals from molybdenum ingested from forage that has been grown in soils with relatively high amounts of avaiable molybdenum. Dye and O'Hara (1959)[398] reported that the molybdenum concentration in forage that produced toxicity in ruminants was 5 to 30 mg/kg. Lesperance and Bohman (1963)[430] found that toxicity was not simply associated with the molybdenum content of forage but was influenced by the amounts of other elements, particularly copper. Jensen and Lesperance (1971)[423] found that the accumulation of molybdenum in plants was proportional to the amount of the element added to the soil.

Kubota et al. (1963)[426] found that molybdenum concentrations of 0.01 mg/l or greater in soil solutions were associated with animal toxicity levels of this element in alsike clover. Bingham et al. (1970)[376] reported that molybdosis of cattle was associated with soils that had 0.01 to 0.10 mg/l of molybdenum in saturation extracts of soils.

Recommendations

The recommended maximum concentration of molybdenum for continued use of water on all soils, based on animal toxicities from forage, is 0.010 mg/l. For short term use on soils that react with this element, a concentration of 0.050 mg/l is recommended.

Nickel

According to Vanselow (1966b),[474] many experiments with sand and solution cultures have shown that nickel at 0.5 to 1.0 mg/l is toxic to a number of plants. Chang and Sherman (1953)[385] found that tomato seedlings were injured by 0.5 mg/l. Millikan (1949)[437] found that 0.5 to 5.0 mg/l were toxic to flax. Brenchley (1938)[382] reported toxicity to barley and beans from 2 mg/l. Crooke (1954)[395] found that 2.5 mg/l was toxic to oats. Legg and Ormerod (1958)[429] found that 1.0 mg/l produced toxicity in hop plants. Vergnano and Hunter (1953)[473] found that 1.0 mg/l in solutions flushed through sand cultures was toxic to oats. Soane and Saunders (1959)[466] found that tobacco plants showed no toxicity at 30 mg/l, and that corn showed no toxicity at 2 mg/l but showed toxicity at 10 mg/l.

Work by Mizuno (1968)[435] and Halstead et al. (1969)[409] and the review of Vanselow (1966b)[474] showed that increasing the pH of soils reduces the toxicity of added nickel.

Halstead et al. (1969)[409] found the greatest capacity to adsorb nickel without development of toxicity was by a soil with 21 per cent organic matter.

Recommendations

Based on both toxicity in nutrient solutions and on quantities that produce toxicities in soils, the recommended maximum concentration of nickel in irrigation waters is 0.20 mg/l for continued use on all soils. For neutral fine textured soils for a period up to 20 years, the recommended maximum is 2.0 mg/l.

salinities near this limit may be observed, seri-nomic losses or serious physiological disturbances should rarely, if ever, result from their use.

TOXIC SUBSTANCES IN LIVESTOCK WATERS

There are many substances dissolved or suspended in waters that may be toxic. These include inorganic elements and their salts, certain organic wastes from man's activities, pathogens and parasitic organisms, herbicide and pesticide residues, some biologically produced toxins, and radionuclides.

For any of the above, the concentrations at which they render a water undesirable for use for livestock is subject to a number of variables. These include age, sex, species, and physiological state of the animals; water intake, diet and its composition, the chemical form of any toxic element present, and the temperature of the environment. Naturally, if feeds and waters both contain a toxic substance, this must be taken into account. Both short and long term effects and interactions with other ions or compounds must also be considered.

The development of recommendations for safe concentrations of toxic substances in water for livestock is extremely difficult. Careful attention must be given to the discussion that follows as well as the recommendations and to any additional experimental findings that may develop. Based on available research, an appropriate margin of safety, under almost all conditions, of specific toxic substances harmful to livestock that drink the waters and to man who consumes the livestock or their products, is reviewed below. Although the margin of safety recommended is usually large, the criteria suggested cannot be used as a guide in diagnosing livestock losses, since they are well below toxic levels for domestic animals.

Toxic Elements and Ions

Those ions largely responsible for salinity in water (sodium, calcium, magnesium, chloride, sulfate, and bicarbonate) are in themselves not very toxic. There are, however, a number of others that occur naturally or as the result of man's activities at troublesome concentrations. If feeds and water both contain a toxic ion, both must be considered. Interactions with other ions, if known, must be taken into account. Elements or ions become objectionable in water when they are at levels toxic to animals, where they seriously reduce the palatability of the water, or when they accumulate excessively in tissues or body fluids, rendering the meat, milk, eggs, or other edible product unsafe or unfit for human use.

Aluminum

Soluble aluminum has been found in surface waters of the United States in amounts to 3 mg/l, but its occurrence at such concentrations is rare because it readily precipitates as the hydroxide (Kopp and Kroner 1970).[152]

Most edible grasses contain about 250–500 mg of the element. However, there is no evidence that it is essential for animal growth, and very little is found deposited in animal tissues (Underwood 1971).[254] It is not highly toxic (McKee and Wolf 1963,[103] Underwood 1971),[254] but Deobald and Elvehjem (1935)[188] found that a level of 4,000 mg aluminum per kilogram of diet caused phosphorus deficiency in chicks. Its occurrence in water should not cause problems for livestock, except under unusual conditions and with acid waters.

Recommendation

Livestock should be protected where natural drinking waters contain no more than 5 mg/l aluminum.

Arsenic

Arsenic has long been notorious as a poison. Nevertheless, it is present in all living tissues in the inorganic and in certain organic forms. It has also been used medicinally. It is accepted as a safe feed additive for certain domestic animals. It has not been shown to be a required nutrient for animals, possibly because its ubiquity has precluded the compounding of deficient diets (Frost 1967).[149]

The toxicity of arsenic can depend on its chemical form, its inorganic oxides being considerably more toxic than organic forms occurring in living tissues or used as feed additives. Differences in toxicities of the various forms are clearly related to the rate of their excretion, the least toxic being the most rapidly eliminated (Frost 1967,[149] Underwood 1971).[254] Except in unusual cases, this element should occur in waters largely as inorganic oxides. In waters carrying or in contact with natural colloidal material, the soluble arsenic content may be decreased to a very low level by adsorption.

Wadsworth (1952)[260] gave the acute toxicity of inorganic arsenic for farm animals as follows: poultry, 0.05–0.10 g per animal; swine, 0.5–1.0 g per animal; sheep, goats, and horses, 10.0–15.0 g per animal; and cattle, 15–30 g per animal. Franke and Moxon (1936)[148] concluded that the minimum dose required to kill 75 per cent of rats given intraperitoneal injections of arsenate was 14–18 mg arsenic per kilogram, while for arsenite it was 4.25–4.75 mg/kg of body weight.

When mice were given drinking water containing 5 mg/l of arsenic as arsenite from weaning to natural death, there was some accumulation of the element in the tissues of several organs, a somewhat shortened life span, but no carcinogenic effect (Schroeder and Balassa 1967).[233] In a similar study with rats (Schroeder et al. 1968b),[236] neither toxicity nor carcinogenic effects were observed, but large amounts accumulated in the tissues.

Peoples (1964)[220] fed arsenic acid at levels up to 1.25 mg/kg of body weight per day for eight weeks to lactating cows. This is equivalent to an intake of 60 liters of water

ATTACHMENT 2

Pre-filed Testimony of Lynn E. Dunaway, P.G.

My name is Lynn E. Dunaway. I am employed as an Environmental Protection Specialist, have a Bachelor of Science degree in geology and am an Illinois, licensed professional geologist. I work in the Hydrogeology and Compliance Unit, Groundwater Section, Division of Public Water Supplies, Bureau of Water, Illinois Environmental Protection Agency ("Agency"). I have worked in the Groundwater Section since 1988 and have completed multiple courses to enhance my professional knowledge. My curriculum vitae (Attachment 2A), is included for further detail about my training and experience. My duties in the Groundwater Section include: Providing review of hydrogeolgic assessments and reports, and providing technical input on the same as well as special projects requiring geologic expertise; Providing geologic and hydrogeologic expertise to Bureau of Water permit programs (industrial, municipal and mines) and the Public Water Supply, Permit Section; Responding to questions from the regulated community, public and other governmental agencies about the provisions of the Illinois Environmental Protection Act ("Act") and Illinois Pollution Control Board ("Board") rules adopted thereunder; Project management of sites subject to corrective actions under the Act or Board rules; Assist the regulated community with required steps to be compliant with setback zones, technology control regulations (35 Ill. Adm. Code 615 and 35 Ill. Adm Code 616) and minimal hazard certification; Testifying before the Board on proposed rules and setback zone exceptions; assisting in the implementation of source water protection programs and; Mentoring interns and student workers. My pre-filed testimony focuses primarily on changes to the definition of Class I: Potable Resource Groundwater in Section 620.210, additional required submissions with groundwater management zone applications in Section 620.250 and the establishment of site specific numerical groundwater standards within

previously listed Class III: Special Resource Groundwater areas in Section 620.230. I can give further explanation of my pre-filed testimony and answer additional questions as needed.

Section 620.210 Class I: Potable Resource Groundwater

The Agency is proposing to the change methods by which groundwater may be determined to be Class I, in subsection 620.210(a)(4)(B). The Agency is proposing to eliminate the permeameter as method for determining hydraulic conductivity and add the wellhead protection area of a community water supply well or well field.

The permeameter is being proposed for elimination as a method, because samples of earth materials must be collected and transported to the permeameter to run the hydraulic conductivity test. Sample collection may cause a change from the in-situ hydraulic conductivity, because the tool used to collect the sample can cause compaction as it penetrates the geologic formation, thereby reducing the measured hydraulic conductivity. Conversely, removal of the tool from the geologic formation, or subsequent handling can create fractures within the sample, thereby increasing the measured hydraulic conductivity. Further, samples for permeameter tests are usually collected above the saturated zone, and therefore are not representative of material containing groundwater.

The Agency is proposing the addition of the wellhead protection area (Section 620.110) for a community well or well field which is a two dimensional projection on the surface, of a three-dimensional region containing groundwater that will recharge a well or well field within a five-year period. The wellhead protection area is an appropriate region for inclusion as Class I groundwater because these three-dimensional areas have been delineated using site specific hydrogeologic parameters (e.g. transmissivity, specific capacity, gradient, etc.). These site specific

hydrogeologic parameters are measurements that reflect flow conditions within the geologic formations that contain groundwater. See the Illinois "Wellhead Protection Program" incorporated by reference in Section 620.125. The parameters representing groundwater flow conditions can then be used in calculations and models to estimate the area within the geologic formation where groundwater will be flowing towards a well and the region within the geologic formation which is expected to yield groundwater into a well within the next five years. The subsurface regions of groundwater flow towards a community well or well field are then projected onto the overlying ground surface, forming the wellhead protection area, which extends to the depth of the well or wells being delineated. Given the relatively short five-year time-period being predicted, the Agency believes the entire three-dimensional region of the projected two dimensional wellhead protection area should be included as Class I groundwater.

Section 620.250 Groundwater Management Zone

The Agency is proposing the addition of a list of information that must be included with each groundwater management zone (GMZ) application. Though the list of technical documents and submissions the Agency is proposing to add as subsection 620.250(g) have generally been submitted to the Agency as part of the GMZ process, they may only be submitted as the Agency requests the information from the applicant as the Agency's evaluation of the groundwater conditionals and the appropriateness of the proposed corrective action progresses. Adopting a standardized list of technical information, which in the Agency's experience is typically needed to understand the hydrogeologic conditions at a site, will make the GMZ process more effective. The proposed technical submissions are useful for evaluating the adequacy of a proposed correct action as required by subsections 620.250(a) and (b).

The Agency is also proposing to have the GMZ applicant provide a description of the selected corrective action, how the applicant determined the corrective action would effectively achieve the applicable groundwater standards and the monitoring that will be conducted to demonstrate the predicted success of the selected and Agency approved corrective action. The Agency is proposing the inclusion of these additional descriptions and demonstrations in recognition that corrective action is rarely a one step process. For example: removing a storage tank that has caused groundwater contamination is a corrective action, but groundwater contamination will persist, for some period of time, dependent upon site specific conditions. Therefore, monitored natural attenuation or some other additional corrective action will often be necessary to achieve groundwater quality standards. The GMZ application should include explanations of all the steps or phases of corrective action and the amount of time expected to complete them, so that it is clear to anyone reviewing the site when corrective action is complete, and if, or when, the Section 620.450 Alternative Groundwater Quality Standards are applicable.

Therefore, the Agency is proposing new subsection 620.250(g) to make GMZ applications easier to review by requiring submission information typically needed at the beginning of the application process and by requiring a description of the corrective action processes, the amount of time needed to achieve completed corrective action and documentation supporting the efficacy of the selected corrective action.

Section 620.430 Site Specific Standards

Section 620.230 provides the requirements to establish Class III: Special Resource Groundwater within any larger groundwater resource that contributes to a dedicated nature preserve ("DNP"). Since January 1999 when the first, Class III groundwater area was published in the

Environmental Register for final listing, the Agency has completed reviews of the required information and published 30 DNPs for final listing, to create Class III groundwater areas. (Attachment 2B list of nature preserves with Class III areas). Listing a Class III area associated with a DNP establishes a Class III groundwater standard within the Class III groundwater area, equal to the Class I groundwater standard set forth in Section 620.410 and makes the non-degradation provisions of Part 620; Subpart C, applicable to all groundwater within the Class III groundwater area, unless the Board has adopted a different standard pursuant to Section 620.260.

Section 620.230 requires that a general description of the existing groundwater quality at and surrounding a DNP be provided for Agency review prior to listing. While each listed DNP has met this obligation, some DNPs have much more data available than others. The Agency reviewed groundwater monitoring data that was collected by the Illinois State Geological Survey for a number of DNPs. As a first step to evaluate appropriate standards specific to particular DNPs, the Agency statistically evaluated the existing chemical concentrations of available groundwater monitoring data. The power of a statistical analysis increases with the number of valid samples included in the analysis. Therefore, any DNP that did not have at least eight samples in the data set was eliminated from further review for site specific standards, for this proposal.

Of the DNPs for which the Agency was able to find quantitative groundwater quality data, six DNPs met the initial (eight sample minimum) criteria. The DNPs that met the criteria are two wetland DNPs and four cave DNPs. The wetland DNPs are Spring Grove Fen and Cotton Creek Marsh, both in McHenry County, and both listed as Class III groundwater in 2012. The cave DNPs are Fogelpole Cave, Monroe County, listed in 2003; Pautler Cave, Monroe County and Stemler Cave, St. Clair and Monroe Counties, both listed in 2005; and Armin Krueger Speleological, Monroe County, listed in 2010 (Attachments 2C and 2D maps of the DNP and Class III

areas). Statistical methods discussed in the Unified Guidance (March 2009 Unified Guidance) are broad enough to be generally applicable to other groundwater monitoring programs beyond the Resource Conservation and Recovery Act ("RCRA"). The Unified Guidance recommends that false positives for evaluation of groundwater monitoring data not exceed a range of .01 to .05, or inversely, should have a confidence of 99% to 95%, respectively. Since 95% confidence is more environmentally conservative (i.e. more likely to indicate an exceedence of a given concentration when one has not actually occurred) the Agency opted for evaluation methods using 95% confidence. The Agency believes a conservative approach is appropriate since Class III groundwater is intended to protect the groundwater resource contributing to sensitive and unique areas.

The simplest standard is a value to which other values can be directly compared to determine compliance with the standard. Further, the Illinois Groundwater Protection Act ("IGPA") (415 ILCS 55/8) states a preference for numerical standards instead of narrative standards. Therefore, the Agency used statistical methods with existing water quality to calculate a tolerance limit where appropriate, which with 95% confidence, represents the maximum expected groundwater concentration of a given chemical constituent as a single numerical value. Before calculating a tolerance limit, the Agency used the Ryan-Joiner normality test in the Minitab software to determine if the data used was normally distributed. Statistical p-values for data, or log-normal transformed data, equal to or greater than 0.1 were considered to have a normal distribution. Once normality was determined an equation for parametrically (i.e. normally) or an equation for non-parametrically distributed data, as applicable, was used to calculate the tolerance limit for the applicable chemical constituent. In addition to its potential use as a numerical groundwater standard, calculation of tolerance limits allows quantitative and qualitative comparison of expected

maximum results within a Class III area with measured results from relevant research and site specific circumstances. Site specific conditions and scientific research were taken into consideration when proposing standards for the DNPs. The research and site specific circumstances are explained in greater detail in the constituent specific discussions.

The Agency's evaluation of chemical constituents for consideration as site specific Class III groundwater standards took into consideration whether there was an adequate number of samples for statistical analysis, the constituents for which monitoring data is available, the nature of the DNP(s) that the specific groundwater serves, relevant research, site specific conditions and previously adopted Class I groundwater standards. Existence of a Class I standard is significant because it first assures that the criteria for establishment of a groundwater standard as required by Section 8 of the IGPA have been met, and further provides a context within which to assess ambient groundwater conditions within the Class III areas. For example, nitrate monitoring was available for a number of the DNPs. Nitrate can promote the growth of invasive plant species in wetlands and change nutrient cycling within cave systems. Due to the nitrate concentrations and distributions in the available data, the tolerance limits calculated for nitrate at the DNPs, where nitrate data was available, indicated that concentrations of nitrate were likely to exceed the Class I: Potable Resource numeric standard of 10 mg/L with regularity. Therefore, consistently meeting the Class I nitrate standard, which is already applicable within the listed Class III areas, would be a first step towards reducing nutrient levels within the Class III areas assessed. The need for more stringent standards can be assessed and proposed later, after first meeting the Class I, mile stone.

Chloride

The Section 620.410 groundwater standard for chloride is 200 mg/L. Chloride data was available for all of the DNPs that met the Agency's initial data availability assessment. Chloride was the only chemical constituent available for evaluation at Cotton Creek Marsh DNP. The Agency determined a lower site specific standard for chloride would be beneficial to all of the DNPs and the associated Class III areas assessed in this proposal. Fens are wetlands fed primarily by discharging groundwater which is highly mineralized and typically has a neutral to basic pH. According to information from a study by the Illinois State Geological Survey, Native Landscapes and Science and Technology Management, Inc. (Panno et al 1999) (Document 1), the ionic content of groundwater discharging to fens is dominated by calcium and bicarbonate. Both anthropogenic and natural sources of other ions may occur in fens. For example, the Panno et al 1999 study found that sodium and chloride from septic systems or road salt could alter groundwater quality to the point that the groundwater became a sodium and chloride type groundwater instead of a calcium and bicarbonate type. The Panno et al 1999 study correlated the number of chloride tolerant and chloride intolerant plants relative to the ionic charter of the groundwater. The study found that high levels of sodium and chloride favor more salt tolerant, generalist species, such as narrow leaf cattails, to the exclusion of rarer specially adapted species. However, a fen recharged by a calcium and bicarbonate dominated groundwater supported a diverse plant population. The Panno et al 1999 study used a graphical technique to group groundwater into ionic types (e.g. calcium/bicarbonate or sodium/chloride). The concentration of a particular ion that represents an inflection point between groundwater types is called a threshold concentration. The threshold concentration of chloride calculated in the Panno et al 1999 study that would represent a change from a calcium/bicarbonate groundwater to a sodium/chloride groundwater is 45 mg/L chloride. The Agency calculated a tolerance limit (rounded to the nearest whole number) based

on available groundwater monitoring data near Spring Grove Fen and Cotton Creek Marsh of 175 mg/L chloride and 89 mg/L chloride, respectively. Chloride at Spring Grove Fen had a median of 87.4 and a mean of 75.8. This distribution reflects chloride concentrations generally in excess of the 45 mg/L threshold value established by Panno et al 1999, but below the 200 mg/L Class I standard, with some groundwater chloride values still below the threshold. At Cotton Creek Marsh the median chloride was 7.8 mg/L, with a chloride mean of 22.9 mg/L. Chloride distribution at Cotton Creek Marsh represents concentrations generally below the threshold with occasional elevated concentrations of chloride. What the numerical values of the individual samples don't show is the relative volume of groundwater contributed to these two wetlands, from the groundwater flow paths being intercepted by each of the sampling points. The State endangered purple-flowering raspberry (Rubus odoratus), the State threatened bog buckbean (Menyanthes trifoliata) and the State threatened black sandshell mussel (Ligumia recta) occur in both of these wetland DNPs. The presence of these rare wetland species indicates that the averaged flow of groundwater into the DNPs represents groundwater quality which is still generally favorable to a fen environment. Therefore, a lower chloride standard will benefit both Spring Grove Fen and Cotton Creek Marsh, by maintaining and potentially improving groundwater quality.

Accordingly, the Agency is proposing that the Board adopt a site specific groundwater standard of 45 mg/L for both the Spring Grove Fen and Cotton Creek Marsh, Class III groundwater areas to protect the fen environments within the dedicated nature preserves.

Chloride is also being proposed for a lower standard at Stemler, Pautler, Fogelpole and Armin Krueger caves. Data from the Fogelpole Class III area and Armin Krueger Class III groundwater area was considered together because dye tracing tests indicate that under certain flow conditions these cave systems share recharge. Chloride was evaluated for a site specific

standard because there is an existing groundwater quality standard, adequate chloride data exists for each of the cave systems proposed and a more stringent standard in these Class III areas may aid in the protection and potentially the recovery of the federally and State endangered Illinois Cave Amphipod (Gammarus acherondytes). This species exists only in caves in southwestern Illinois. Many other rare species of cave dwelling creatures also inhabit these cave systems. Studies show that the survival of some amphipod species is negatively impacted by increased concentrations of ions such as potassium, sodium and chloride in water (Taylor, Webb and Panno 2000) (Document 2). Changes in these dissolved constituents make it difficult for aquatic creatures to maintain the osmotic balance within their bodies. Even concentrations of these ions that are not immediately lethal to a given species, may cause stress, which when combined with other factors may impact the creatures viability. David Sutcliffe (Sutcliffe 2000) (Document 3) studied Gammarus duebeni a common amphipod in Europe, which occupies environments ranging from hypersaline pools to fresh water streams. Though G. duebeni is recognized as a single species, Sutcliffe found that a number of morphological features exist to regulate osmotic balance within the species depending on the environment inhabited. It therefore stands to reason that over many generations G. acherondytes would adapt to groundwater quality within cave systems. Relatively sudden changes to the chloride content of groundwater caused by urbanization and agriculture would almost certainly cause distress to a creature adapted to live in non-impacted cave groundwater.

Because groundwater within cave systems fluctuates between being dominated by surface infiltration and slower moving longer residence time groundwater, large data sets such as the one available for the Fogelpole/Armin Krueger Class III areas reflect a bimodal distribution. Therefore,

a single tolerance limit doesn't predict cave groundwater quality very well, since it is essentially divided into two different groundwater types.

For example, the Fogelpole/Armin Krueger Class III areas have a large data set, which would, under strictly porous media conditions, yield a useful tolerance limit. However, the data displays different results due to the bimodal groundwater sources. A tolerance limit was calculated for the Fogelpole/Armin Krueger Class III areas, which predicts an upper maximum value, with 95% confidence of 46.5 mg/L. However, the actual measured maximum value was nearly three times that value at 127 mg/L, while the chloride mean and median values were 19.6 and 17.0 mg/L, respectively. The extreme contrast between the maximum detected value, the "average" groundwater quality and a single statistically based calculation suggest that a different metric should be considered to establish Class III groundwater standards for caves. Pautler Cave, which had a population of G. acherondytes when last surveyed, before its entrance was sealed sometime prior to 1993 (Webb 1993) (Document 4), has a mean chloride concentration of 18.3 mg/L, a median concentration of 12.0 mg/L and a maximum concentration of 51 mg/L in its Class III area. In contrast, the Stemler Cave, Class III area has a mean, median and maximum recorded chloride concentration of 51.6 mg/L, 48.0 mg/L and 83.0 mg/L, respectively. These comparative statistics of chloride concentration in the Stemler Class III area result from consistently higher concentrations of chloride than are usually recorded in the Fogelpole/Armin Krueger and Pautler Class III areas. The Agency believes this contrast in chloride concentrations to be important because the Fogelpole/Armin Krueger and Pautler cave systems are reported to have good populations of G. acherondytes, while G. acherondytes has not been found in Stemler Cave since 1965.

Since the Class III areas that contribute to Fogelpole/Armin Krueger and Pautler Caves have generally low chloride concentrations (mean and median concentrations less than 20 mg/L) and chloride has been identified as an ion that may cause stress to the osmotic balance of amphipods, the Agency believes a site specific chloride standard lower than the Class I groundwater standard, that more closely resembles groundwater quality in the cave systems that support G. acherondytes, would be of benefit to the DNPs that contain caves.

With these considerations in mind and to aid in the protection of G. acherondytes in the Fogelpole Cave DNP, the Armin Krueger Cave DNP and the Pautler Cave DNP and potentially assist in the recovery of G. acherondytes in the Stemler Cave DNP, the Agency is proposing that the Board adopt a Class III site specific groundwater standard of 20 mg/L in all four of these listed Class III groundwater areas, since this concentration approximates the mean and median values reported in those cave systems with G. acherondytes populations.

The Agency is aware that private septic systems are common within the Class III areas of Stemler, Fogelpole/Armin Krueger and Pautler Caves, and also exist within the Class III areas of Spring Grove Fen and Cotton Creek Marsh. Septic systems can be a source of contaminants, including chloride, especially in shallow groundwater. To assess the potential economic impact a reduced groundwater standard for chloride might have on the use of private septic systems by residents within Class III areas, the Agency conducted a literature search for documents assessing septic system impacts to groundwater. The Agency found United States Geological Survey, Water Resources Investigations Report 91-4011 (USGS 1991), (Document 5). The USGS 1991 report examines groundwater quality proximate to two different subdivisions, served by private septic systems where highly fractured limestone bedrock is located near the land surface. The subdivisions are located in a suburban area near Nashville Tennessee. Monitoring wells within

the bedrock, domestic wells and springs discharging groundwater down gradient of the subdivisions were sampled to determine if there was a link between groundwater and the septic systems. Since many of the contaminants found in septic effluent occur naturally and may also have other anthropogenic sources the USGS sampled for optical brighteners, which are found in laundry detergents, thus establishing a marker that could be used to evaluate the linkage between septic effluent and groundwater. Optical brighteners were detected in groundwater, thereby establishing a link between septic effluent and groundwater down gradient of the subdivisions. In addition to the optic brighteners, the USGS also monitored for chloride and other water quality parameters. The USGS detected chloride in all samples collected with a range in concentration of 2.1 mg/L to 38 mg/L. The reported groundwater chloride concentrations from USGS 1991 had a mean and median concentration of 13.0mg/L and 12.0mg/L, respectively. These mean and median chloride concentrations are similar to the groundwater in the Fogelpole/Armin Krueger and Pautler Class III areas. The maximum concentration, and the mean and median concentrations reported in USGS 1991, are also below the inflection point used as the proposed site specific chloride standard for Spring Grove Fen and Cotton Creek Marsh. Therefore, groundwater in a karst setting, with more discrete groundwater flow through factures, which is hydraulically connected with septic effluent does not necessarily yield excessive chloride concentrations in groundwater. In comparison to a karst setting, the groundwater flow in sand and gravel is more diffuse. Therefore, average groundwater concentrations of chloride from septic systems in the Spring Grove Fen and Cotton Creek Marsh Class III areas should not be greater than found in a karst setting. Based on this comparison, the Agency does not believe that properly designed and operated private septic systems are implicitly incompatible with Class III groundwater areas. Therefore, adoption of a more stringent chloride standard would not impose an economic burden by precluding the use of

septic systems within the Class III areas. While other anthropogenic sources of chloride may have an impact on groundwater quality, no new groundwater remediation programs are created by these site specific standards, nor are any new groundwater monitoring requirements imposed within the Class III areas by adoption of these site specific standards. Therefore, the Agency believes the economic impact of the site specific chloride standards will be minimal, while the potential benefit to the endangered and threatened species which rely on this groundwater is significant.

pH

The Taylor, Webb and Panno 2000 report identifies pH as a characteristic of groundwater quality that is likely important to the survival of G. acherondytes. The Class I groundwater standard for pH is a range of 6.5 to 9.0 standard units (SU). Groundwater monitoring data was available for assessment of pH within all of the Class III areas that contribute to cave DNPs. As with the chloride analysis, the pH values for the Fogelpole Class III area and the Armin Krueger Class III area were evaluated together since those two cave systems share groundwater under certain flow conditions.

Because groundwater within cave systems fluctuates between being dominated by rapid surface infiltration and slower moving, longer residence time groundwater, large data sets such as the one available for the Fogelpole/Armin Krueger Class III areas reflect this bimodal distribution. A single tolerance limit doesn't predict cave groundwater quality very well, since it is essentially divided into two different groundwater types. Therefore, the Agency has used minimum, maximum and mean pH values to evaluate pH in the cave Class III areas. Comparison of the groundwater pH values for the Class III groundwater areas of the cave systems yield mean pH values of 7.6, 7.1 and 6.7 SU at Fogelpole/Armin Krueger, Pautler and Stemler,

respectively. While the lowest pH recorded within the Fogelpole/Armin Krueger Class III areas (6.1 SU) was below that recorded in the Stemler Class III area (6.4 SU), none of the pH values recorded from the Stemler Class III area were over 7.0 SU (neutral). All pH values recorded for Stemler Cave are on the acidic side of neutral. The maximum pH values were 8.5, 7.4 and 6.9 SU at Fogelpole/Armin Krueger, Pautler and Stemler, respectively. As discussed previously, Fogelpole Cave, Armin Krueger Cave and Pautler Cave have populations of G. acherondytes, while Stemler Cave has no known extant population. As suggested by Taylor, Webb and Panno 2000 the lower pH values in the Stemler Cave Class III groundwater may result from a closer link between surface water and groundwater within the cave. Extended contact with the limestone in which the caves are formed would be expected to raise pH values. Though a modified pH standard can't change the natural conditions, it could insure that surface and subsurface discharges that reach groundwater do not contribute to decreased pH levels. While pH may combine with other factors to determine G. acherondytes survival, it appears, based on available data that pH values consistently below 7.0 SU, at a minimum, may add additional stress to G. acherondytes populations.

Much of the land use contained in the Fogelpole/Armin Krueger, Pautler and Stemler cave Class III groundwater areas is rural, agricultural land and low density residential housing, utilization of septic systems as a means of sanitary waste disposal are common. Therefore, the Agency evaluated available information regarding the pH of septic system effluent. According to the Washington State Department of Health, Wastewater Management Program (2004) (Document 6) the optimum pH for bacterial growth, which septic systems rely on for waste treatment, is between 6.5 and 9.0 SU. The proposed site specific pH standard is 7.0 to 9.0 SU, which is within the operating range for septic systems. None of the reported pH values in groundwater collected by

USGS 1991 were less than 7.0 SU. Taken together, these pieces of information indicate that even though properly operated septic system effluent itself may occasionally be below 7.0 SU, the pH operating range is often higher than 7.0 SU and groundwater would also buffer the pH rather quickly. This suggests that properly installed and operated private septic systems should not adversely impact pH in karst environments. Therefore, use of private septic systems, which are a common waste disposal method in the Fogelpole/Armin Krueger, Pautler and Stemler cave Class III groundwater areas, could continue, and thus not have a negative economic impact on area residents. Further, the site specific pH standard does not create any new remedial action or groundwater monitoring programs. Therefore, the Agency believes the economic impact of the site specific pH standard will be minimal, while the potential benefit to the endangered and threatened species which rely on this groundwater is significant.

Based on the importance of pH attributed by Taylor, Webb and Panno 2000 to the survival of G. acherondytes and the data demonstrating higher pH in the groundwater within the Class III areas that support populations of G. acherondytes, the Agency believes a site specific standard for pH is warranted. Therefore, to aid in the protection of G. acherondytes in the Fogelpole Cave DNP, the Armin Krueger Cave DNP and the Pautler Cave DNP and potentially assist in the recovery of G. acherondytes in the Stemler Cave DNP, the Agency is proposing that the Board adopt a Class III site specific groundwater standard of 7.0 to 9.0 standard units in all four of these listed Class III groundwater areas.

Professional Experience

Illinois Environmental Protection Agency **February 1988 to Present**
Bureau of Water
Division of Public Water Supplies
Groundwater Section
Springfield, Illinois

Environmental Protection Specialist IV **March, 2017 to Present**
Duties include: Currently in this position: provide review and technical input on hydrogeologic assessments and reports to all Bureau of Water Programs and Office of Emergency Response on groundwater issues; regularly respond to questions concerning the Illinois Environmental Protection Act (Act) and associated regulations, from the public, press, other governmental bodies and industry; review and respond to documents submitted pursuant to the regulations; remedial project management at facilities under Bureau of Water permits and unpermitted sites; assist with the development of regulations in support of the Act including testimony before the Illinois Pollution Control Board (Board) and at public hearings; provide technical input for special projects requiring geologic expertise, including pre-trial documents and testimony in court and before the Board; design and routine maintenance of tracking logs and data bases for the support of various groundwater programs; assist in the preparation of routine reports concerning various aspects of the States groundwater protection programs; Participate as mentor in the Graduate Public Service Internship (GPSI) program and the Governor's Environmental Corp (GEC) program.

Environmental Protection Specialist III **April, 1991 to March 2017**
Duties include: Currently in this position: provide review and technical input on hydrogeologic assessments and reports to all Bureau of Water Programs and Office of Emergency Response on groundwater issues; regularly respond to questions concerning the Act and associated regulations, from the public, press, other governmental bodies and industry; review and respond to documents submitted pursuant to the regulations; remedial project management at facilities under Bureau of Water permits and unpermitted sites; assist with the development of regulations in support of the Act including testimony before the Board and at public hearings; provide technical input for special projects requiring geologic expertise, including pre-trial documents and testimony in court and before the Board; design and routine maintenance of tracking logs and data bases for the support of various groundwater programs; assist in the preparation of routine reports concerning various aspects of the States groundwater protection programs; assist in the design of a data base to track and enhance compliance with the regulations under the Act; Participate as mentor in the GPSI program and the GEC program;

Temporary assignment as Unit Supervisor during supervisor's absence.

Environmental Protection Specialist II **June, 1989 to April, 1991**
Duties include: the quality control process used for the Sections ambient groundwater monitoring programs before entry into the SAFE system for periodic transfer to the STORET data base; use the SAFE System; use of the STORET System; assist with the development of regulations in support of the Illinois Groundwater Protection Act (Act); regularly respond to questions concerning the Act; provide technical review of assessments submitted to the Section; provide technical input for special projects requiring geologic expertise; lead worker for the Agency's first Draft submittal for approval of the (WHPP); assist in the preparation of routine combined section 106/319 grant reports; design and routine maintenance of tracking logs and data bases for the support of various groundwater programs; assist in the preparation of routine reports concerning various aspects of the States groundwater protection programs.

Environmental Protection Specialist I **February, 1988 to June, 1989**
Duties include: learn the quality control process used for the Sections ambient groundwater monitoring programs before entry into the SAFE System for periodic transfer to the STORET data base; learn to use the SAFE System; occasionally respond to questions concerning the Act; provide technical input for special projects requiring geologic expertise; routine maintenance of tracking logs for the support of various groundwater programs; assist in the preparation of routine reports concerning various aspects of the States groundwater protection programs.

Analytical Logging Inc. **August, 1982 to January, 1986**
Shreveport Louisiana
South Texas District
Corpus Christi, Texas

Lead Well Site Geologist **March, 1984 to January, 1986**
Duties Included: over site of a two or three man team; provide daily progress reports summarizing drilling activities and important hydrocarbon detections to field office and home office geologists and engineers; correlation and interpretation of geophysical logs; geologic evaluation of lithologic samples to determine geologic formation and hydrocarbon potential; packed column gas chromatography for hydrocarbon analysis; evaluation techniques to predict high pressure zones; routine maintenance of all systems utilized; creating a graphical representation correlating the geology, drilling parameters and hydrocarbon detections for each well.

Well Site Geologist **August, 1982 to February, 1984**
Duties Included: correlation and interpretation of geophysical logs; geologic evaluation of lithologic samples to determine geologic formation and hydrocarbon potential; assist with packed column gas chromatography for hydrocarbon analysis; learn evaluation techniques to predict high pressure zones; learn routine maintenance of all systems utilized; creating a graphical representation correlating the geology, drilling parameters

and hydrocarbon detections for each well.

Other Work Experience

Grain/ Livestock Farm Hand	**February 1986 to July 1986 and October 1987 to December 1987**
Shipping/Receiving Clerk	**August 1986 to November 1986**
Agrichemical Service Company Laborer	**March 1987 to June 1987**
Meat Packing Company Laborer	**July 1987 to September 1987**

Education and Training

Bradley University **August, 1978 to May, 1982**
Peoria, Illinois
Bachelor of Science; Geology

Northern Illinois University **May, 1982 to July, 1982**
Dekalb, Illinois
Post-graduate work; Field Mapping of the Black Hills Region, South Dakota

USEPA Groundwater Monitoring and Restoration **June 1 & 2, 1993**
Short course on behavior of DNAPLs in the subsurface and case studies

USEPA Risk Assessment Guidance for Superfund **October 18-21, 1993**
Environmental response training and case studies

Computer Modeling for Groundwater Systems **August 21, to December 16, 1995**
Basis of groundwater models, Dr. Larry Barrows, Illinois State University

Applied Ground Water Statistics for Landfills Short Course **July 8 & 9, 1997**
Statistical techniques for detection and compliance monitoring

Statistical Methods in Water Resources **August 6-10, 2001**
Application of statistical methods, University of Illinois, Springfield

Ozark Underground Laboratory Karst Short Course **March 12, 2003**
Unique features and case studies in karst geologic settings

Aqueous Geochemistry for Environmental Regulators **March 9 & 10, 2004**
Short Course by Dr. Stephen Van der Hoven, Illinois State University

Overview of Environmental Geophysics **May 6, 2004**
Review of common equipment advantages/disadvantages, by USEPA and Tetra Tech.

Geotechnology for Non-Engineers **April 20, 2005**
Key principles and concepts of Geotechnolgy, by Dr. Timothy Stark, University of Illinois

Fate and Transport Processes and Models **March 29 & 30, 2006**
Key elements of transport, models & assumptions, by Dr. Atul Salhotra, RAM, Inc.

Introduction to ArcGIS I **March 10 & 11, 2008**
Introduction to the features and functions of ArcGIS and use thereof, by Carmen Maso', USEPA

National Groundwater Association Conference **June 26 & 27, 2012**
Day 1: Presentations of general interest for groundwater assessment and protection, Day 2: Presentations related to hydraulic fracturing and groundwater quality

The Environmental Sampling Field Course **August 21-24, 2012**
Classroom and field training collecting soil, surface water and groundwater samples, by David & Gillian Nielson

Practical Geophysics
for Engineering, Archeology and Hydrogeology **September 27 & 28, 2012**
Classroom and hands on field demonstrations of resistivity, seismic, down-hole logging, by Drs. Ismail, Larson and Young, Illinois State Geological Survey

Forty Hour Safety Training with Annual Eight Hour Refresher per 29 CFR 1910.120
Last refresher 3/7/2013

Licenses

Licensed Professional Geologist (Illinois) **March 31, 1998**

License Number: 196.000608
Expiration Date: March 31, 2023

Illinois EPA's Development of Proposed PFAS Groundwater Quality Standards for 35 IAC Part 620

Difference between Groundwater Quality Standards and Maximum Contaminant Levels (MCLs)

Groundwater quality standards and MCLs are NOT the same, other than in some cases the absolute value of the MCL may be used as a basis for the numerical groundwater quality standards under the Illinois Pollution Control Board's (Board) Part 620. Groundwater quality standards apply in-situ and are enforceable numerical standards intended to protect and restore the beneficial uses of resource groundwater.

MCLs apply at the entry point to a public water supply distribution system. Finished or treated drinking water must meet MCLs before distribution to consumers to provide assuredly safe drinking water. MCLs consider not only the toxicity of the contaminant, but also the occurrence, best available treatment (BAT), and laboratory analytical methods.

How Illinois EPA's proposed Groundwater Quality Standards are derived

35 Ill. Adm. Code 620, Appendix A, provides procedures for determining a Human Threshold Toxicant Advisory Concentration (HTTAC) for those substances for which US EPA has not adopted a Maximum Contaminant Level Goal (MCLG). Appendix A, subsection (a) provides an equation required for the calculation of the HTTAC:

$$HTTAC = \frac{RSC \bullet ADE}{W}$$

Where:

HTTAC	=	Human Threshold Toxicant Advisory Concentration (mg/L).
RSC	=	Relative contribution of the amount of the exposure to a chemical via drinking water when compared to the total exposure to that chemical from all sources. If valid chemical-specific data are not available, a value of 20% (= 0.20) must be used.
ADE	=	Acceptable daily exposure of substance in milligrams per day (mg/d).
W	=	Per capita daily water consumption equal to 2 liters per day (L/d).

The equation is consistent with the method used by the US EPA for determining drinking water advisories for chemicals for which a maximum contaminant level (MCL) or maximum contaminant level goal (MCLG) is not prescribed by the US EPA. The Illinois EPA uses the equation for calculating a Class I potable resource groundwater quality standard in the absence of an MCL or MCLG.

Appendix A, subsection (b), provides procedures for determining Acceptable Daily Exposures (ADEs) for Class I groundwater. The ADE represents the maximum amount of a threshold toxicant in milligrams per day (mg/d), which if ingested daily for a lifetime results in no adverse effects to humans. Subsection (b)(2), states that for those substances for which the US EPA has derived a verified oral reference dose (RfD) given in milligrams per kilogram per day (mg/kg/d), the reference dose must be used. The ADE equals the product of multiplying the RfD by 70 kilograms (kg), which is the assumed average weight of an adult human.

When determining the appropriate RfD to use in calculating a HTTAC, the Illinois EPA uses the following hierarchy as its source:

1. US EPA Integrated Risk Information System (IRIS)
2. US EPA Provision Peer-Reviewed Toxicity Values Program (PPRTV)
3. US EPA Office of Pesticide Programs (OPP)
4. US Department of Health and Human Services Agency for Toxic Substances and Disease Registry (ATSDR)

In June of 2018, ATSDR issued a draft Toxicological Profile for Perfluoroalkyls for public comment. The comment period closed on August 20, 2018. The toxicological profile focused on four perfluoroalkyls and recommended the following intermediate oral reference doses:

- Perfluorooctanoic Acid (PFOA) = 3E-06 mg/kg/d
- Perfluorooctane Sulfonic Acid (PFOS) = 2E-06 mg/kg/d
- Perfluorohexane Sulfonic Acid (PFHxS) = 2E-05 mg/kg/d
- Perfluorononanoic Acid (PFNA) = 3E-06 mg/kg/d

In 2014, PPRTV issued a chronic reference dose of 2E-02 mg/kg/d for perfluorobutane sulfonic acid (PFBS).

The RfDs are calculated from animal studies and 35 Ill. Adm. Code 620, Appendix A, subsection (b) allows for the use of subchronic (intermediate) RfDs when chronic values are not available. The Illinois EPA expects ATSDR values to be finalized; therefore, chose the ATSDR RfDs for calculating the proposed groundwater quality standards for PFOA, PFOS, PFHxS and PFNA. The Illinois EPA used the PPRTV RfD for calculating the PFBS groundwater quality standard. As updated data becomes available, reference doses will be adjusted and updated Class I standards will be proposed.

Using the equation and values specified in Appendix A, the Class I groundwater quality standards are calculated as follows:

$$HTTAC = \frac{0.20 \bullet ADE\ (\frac{mg}{d})}{2\ (\frac{L}{d})}$$

Where:

PFOA ADE	=	0.000003 mg/kg/d • 70 kg = 0.00021 mg/d
PFOS ADE	=	0.000002 mg/kg/d • 70 kg = 0.00014 mg/d
PFHxS ADE	=	0.00002 mg/kg/d • 70 kg = 0.0014 mg/d
PFNA ADE	=	0.000003 mg/kg/d • 70 kg = 0.00021 mg/d
PFBS ADE	=	0.02 mg/kg/d • 70 kg = 1.4 mg/d

The resulting groundwater quality standards are as follows:

PFOA	=	0.000021 mg/L (21 ng/L)
PFOS	=	0.000014 mg/L (14 ng/L)
PFHxS	=	0.00014 mg/L (140 ng/L)
PFNA	=	0.000021 mg/L (21 ng/L
PFBS	=	0.14 mg/L (140,000 ng/L)

These values are also protective of developmental and infant exposure through umbilical cord blood and breast-milk/formula feeding, based on US EPA exposure factor assumptions of a 7.8 kg child ingesting 1.13 L/d, with an RSC of 100% coming from umbilical cord or ingestion of breast-milk/formula. The proposed groundwater quality standards equal ATSDR's minimal risk levels for a child.

Proposed Updates to 35 Ill. Adm. Code 620.410 and 620.420

(Class I and Class II Groundwater Quality Standards)

By Carol Hawbaker
Environmental Risk Assessor
Illinois EPA Office of Toxicity Assessment

February 13, 2020

Introduction of New Chemicals

<u>The amendments propose the addition of 9 chemicals:</u>

- Aluminum
- Lithium
- 1-Methylnaphthalene
- Molybdenum
- Perfluorobutane Sulfonic Acid (PFBS)
- Perfluorohexane Sulfonic Acid (PFHxS)
- Perfluorononanoic Acid (PFNA)
- Perfluorooctanoic Acid (PFOA)
- Perfluorooctane Sulfonic Acid (PFOS)

Addition of Atrazine Metabolites

The amendments propose the addition of 3 atrazine metabolites to be included in the total atrazine Class I and Class II groundwater quality standards.

<u>Metabolites</u>

- Desethyl-atrazine (DEA)
- Desisopropyl-atrazine (DIA)
- Diaminochlorotriazine (DACT)

Combination of Radium 226 and 228

The amendments propose combined Radium 226 + 228 Class I and Class II groundwater quality standards.

The proposed value for Class I and Class II is the Federal MCL.

Combined PFOA + PFOS Value

The amendments propose both individual and combined values for PFOA and PFOS.

- Individual:

  PFOA = 21 ng/L

  PFOS = 14 ng/L

- Combined Not to Exceed 21 ng/L

Updates to Carcinogenic Designations

<u>Carcinogen designations updated for the following chemicals:</u>

- para-Dichlorobenzene
- Ethylbenzene
- gamma-Hexachlorocyclohexane (lindane)
- 1,2,4-Trichlorobenzene

Updates to Class I: Potable Resource Groundwater Quality Standards (Section 620.410)

In addition to new chemicals, updated Class I Groundwater Quality Standards are proposed for 19 chemicals presently listed in Section 620.410. Proposed new and updated standards are based on the following factors:

- Updates to US EPA or Illinois Maximum Contaminant Levels (MCLs)
- Updates to Toxicity Values
- Improvements in Laboratory Technologies (allowing for lower levels of quantification)
- Irrigation or Livestock Criteria (used when irrigation or livestock values are more stringent than MCLs or toxicity-based values)
- Correction of Typo from Previous Amendments - Vanadium

Updated Toxicity Values

Illinois EPA Hierarchy for Determining Toxicity Values

Hierarchy is derived from US EPA OSWER Directive 9285.7-53, dated December 5, 2003 and discussed in the Illinois Pollution Control Board Rulemaking R08-18: Proposed Amendments to Groundwater Quality Standards, 35 Ill. Adm. Code 620.

Tier 1: Integrated Risk Information System (IRIS)

Tier 2: Provisional Peer Reviewed Toxicity Values (PPRTV)

Tier 3: Other Toxicity Values

> "Priority given to sources of information that are the most current, the basis for which is transparent and publicly available, and which has been peer-reviewed."
>
> OSWER Directive 9285.7-53

Updated Toxicity Values

Tier 3: Other Toxicity Values

Additional sources referenced in OSWER Directive 9285.7-53, include, but are not limited to:

- California Environmental Protection Agency (Cal EPA) Toxicity Values
- Agency for Toxic Substances and Disease Registry (ATSDR) Minimal Risk Levels
- Health Effects Assessment Summary Table (HEAST)

Methods for Calculating Groundwater Quality Standards for Substances for which US EPA Has Not Adopted a MCL

Methodologies are found at Section 620, Subpart F and Appendix A.

- Human Nonthreshold Toxicant Advisory Concentration (HNTAC) for Carcinogens
- Human Threshold Toxicant Advisory Concentration (HTTAC) for Non-Carcinogens

Human Nonthreshold Toxicant Advisory Concentrations (Carcinogen)

$$HNTAC(\frac{mg}{L}) = \frac{TR \bullet BW \bullet AT \bullet 365 \frac{days}{year}}{SF_o \bullet IR \bullet EF \bullet ED}$$

Where:

TR = Target Risk = 1.0E-06

BW = Body Weight = 70 kilograms

AT = Averaging Time = 70 years

SF_o = Oral Slope Factor ((milligrams/kilogram/day)$^{-1}$) = Chemical-Specific

IR = Daily Water Ingestion Rate = 2 liters/day

EF = Exposure Frequency = 350 days/year

ED = Exposure Duration = 30 years

Human Threshold Toxicant Advisory Concentration (Non-Carcinogen)

$$HTTAC\ \left(\frac{mg}{L}\right) = \frac{RSC \bullet ADE}{W}$$

Where:

RSC = Relative contribution of the amount of the exposure to a chemical via drinking water when compared to the total exposure to that chemical from all sources.

ADE= Acceptable Daily Exposure of substance in milligrams per day. The ADE represents the maximum amount of a threshold toxicant, which, if ingested daily for a lifetime, results in no adverse effects to humans. The ADE equals the product of multiplying a US EPA hierarchy oral reference dose given in milligrams per kilogram per day by 70 kilograms, which is the assumed average weight of an adult human.

W = Per capita daily water consumption equal to 2 liters per day

Livestock and Irrigation Values

Livestock or Irrigation Values are Currently Used as Class I Groundwater Quality Standards for the Following Chemicals:

- Boron - Irrigation
- Cobalt - Livestock
- Nickel - Livestock

Based upon support of a use other than potability (livestock watering, irrigation, industrial use) where the different use requires a more stringent standard.

Proposing livestock values for copper and fluoride, and an irrigation value for selenium.

Updates to Class II: General Resource Groundwater Quality Standards (Section 620.420)

In addition to new chemicals, updated Class II Groundwater Quality Standards are proposed for 40 chemicals presently listed in Section 620.420. Proposed new and updated standards are based on the following factors:

- Updated Class I Groundwater Quality Standards
- Updated Treatment Factors
- Irrigation or Livestock Criteria

Updated Treatment Factors

Criteria for Application of Best Available Technology (BAT) Treatment Factors:

- Dimensionless Henry's Constant (H') Value Greater Than Methylene Chloride's (H') Value of 0.133 at a 20 ^{0}C Groundwater System Temperature.

OR

- Organic Carbon Partition Coefficient (K_{oc}) Value Greater Than Ethylbenzene's (K_{oc}) Value of 446 cm^3/gram.

If a chemical's chemical/physical values meet the criteria, a Treatment Factor of 5 is applied to the Class I Groundwater Quality Standard to calculate a Class II Groundwater Quality Standard.

Source of Values: US EPA Regional Screening Levels

Source of Criteria: Illinois Pollution Control Board R08-18

PFAS

Per and Poly-Fluoroalkyl Substances = PFAS

PFAS are a group of man-made chemicals applied to many consumers products to make them waterproof, stain resistant or non-stick.

- Non-Stick Pans
- Stain-Resistant Carpets and Textiles
- Water-Proof Clothing and Footwear
- Pizza Boxes, Food Wrappers, Microwave Popcorn Bags
- Fire-Fighting Foam

PFAS

PFAS are chemicals of emerging concern:

- "Forever Chemicals": PFAS chemicals do not degrade naturally in the environment
- PFAS chemicals have an affinity for water and can migrate long distances

Health Effects of PFAS

Epidemiology Studies Suggest Associations Between PFAS Exposure and Several Health Effects:

- Pregnancy-Induced Hypertension/Pre-Eclampsia
- Liver Damage
- High Cholesterol
- Thyroid Disease
- Decreased Response to Vaccines
- Decreased Fertility
- Decreased Birth Weight

Source: Agency for Toxic Substance and Disease Registry (ATSDR)

Health Effects of PFAS

Carcinogenic Potential:

The Illinois Environmental Protection Act defines a "carcinogen" as:

a contaminant that is classified as a category A1 or A2 carcinogen by the American Conference of Governmental Industrial Hygienists; a category 1 or 2A/2B carcinogen by the World Health Organization's International Agency for Research on Cancer; a "human carcinogen" or "anticipated human carcinogen" by the United States Department of Health and Human Service National Toxicological Program; or a category A or B1/B2 carcinogen or as "carcinogenic to humans" or "likely to be carcinogenic to humans" *by the United States Environmental Protection Agency in the integrated risk information system or a final rule issued in a Federal Register notice by the USEPA.* [415 ILCS 5/58.2]

Health Effects of PFAS

- PFOA: Designated a Group 2B Carcinogen (possibly carcinogenic to humans) by International Agency for Research on Cancer in 2017. PFOA is considered a carcinogen per the Act's definition of a carcinogen.

- PFOS: Designated as "Suggestive of Carcinogenic Potential" by US EPA Integrated Risk Information System in 2016. PFOS is not considered a carcinogen per the Act's definition of a carcinogen.

Suggestive of Increases in Testicular and Kidney Cancer.

Insufficient Data to Develop Cancer Toxicity Values.

PFAS

The Illinois EPA proposes to add 5 PFAS Chemicals to the 620 Regulations:

- Perfluorohexane Sulfonic Acid (PFHxS):

  Class I and Class II Standards = 0.00014 mg/L (140 ng/L)
- Perfluorononanoic Acid (PFNA):

  Class I and II Standards = 0.000021 mg/L (21 ng/L):
- Perfluorooctanoic Acid (PFOA):

  Class I and II Standards = 0.000021 mg/L (21 ng/L)
- Perfluorooctane Sulfonic Acid (PFOS):

  Class I and Class II Standards = 0.000014 mg/L (14 ng/L)
- Perfluorobutane Sulfonic Acid (PFBS):

  Class I and Class II Standards = 0.14 mg/L (140,000 ng/L)

PFAS

The Illinois EPA proposed the addition of 5 PFAS chemicals to the 620 regulations because toxicity values are available from sources within Illinois EPA and US EPA hierarchy for the selection of toxicity values.

- Agency for Toxic Substances and Disease Registry (ATSDR) – PFOA, PFOS, PFNA, PFHxS
- Provisional Peer Reviewed Toxicity Values (PPRTV) - PFBS

PFAS

- PFOA, PFOS, PFNA, PFHxS Source for Toxicity Values:

  Agency for Toxic Substances and Disease Registry (ATSDR)

  Draft

  Draft Profile is in final review by US Office of Management and Budget (OMB). ATSDR did not make revisions following public comment and peer-review.

  The MRLs proposed in the ATSDR Toxicological Profile are used by US Department of Health and Human Services and Illinois Department of Public Health in human health and risk assessments.

PFAS

ATSDR MRLs Used in the Development of Groundwater Quality Standards:

- PFOA: 0.000003 (3E-06) mg/kg/d
- PFOS: 0.000002 (2E-06) mg/kg/d
- PFNA: 0.000003 (3E-06) mg/kg/d
- PFHxS: 0.00002 (2E-05) mg/kg/d

PFAS

- PFBS Source for Toxicity Values:
  Provisional Peer Reviewed Toxicity Values (PPRTV)

In 2014, PPRTV issued a chronic reference dose of 0.02 (2E-02) mg/kg/d for PFBS.

Date: February 21, 2020

Re: Illinois EPA Tables Describing the Basis for Developing the Proposed Class I and Class II Groundwater Quality Standards (35 Ill. Adm. Code 620.410 and 620.420)

The attachment document consists of 3 tables:

Table 1: Groundwater Quality Standards (GQS) Proposed for Updates at 620.410: Class I Potable Resource Groundwater

Table 2: Groundwater Quality Standards (GQS) Proposed for Updates at 620.420: Class II General Resource Groundwater

Table 3: Sources for Carcinogenicity Updates

A page is also provided for definitions of acronyms used in the tables.

100 W. Randolph Street, Suite 4-500, Chicago, IL 60601

Definitions:

ATSDR: Agency for Toxic Substances and Disease Registry

CalEPA: California Environmental Protection Agency

CAS No.: Chemical Abstract Services Number

HNTAC: Human Non-Threshold Toxicant Advisory Concentration (620.605(b)(2))

HTTAC: Human Threshold Toxicant Advisory Concentration (620.Appendix A(a))

IARC: International Agency for Research on Cancer

IRIS: Integrated Risk Information System

MCL: Federal Maximum Contaminant Level

MRL: Minimal Risk Level (milligrams/kilogram/day) – non-carcinogen toxicity value

PPRTV: Provisional Peer Reviewed Toxicity Values

PQL: Practical Quantitation Limit

RfD: Oral Reference Dose (milligrams/kilogram/day) – non-carcinogen toxicity value

RSC: Relative Source Contribution

SF_o: Oral Slope Factor ((milligrams/kilogram/day)$^{-1}$) – carcinogen toxicity value

Treatability Factor: Treatability Factor is determined by best available treatment technologies for removal efficiency. Criteria discussed at Illinois Pollution Control Board (IPCB) R08-18, Rick Cobb prefiled testimony dated May 29, 2008. Criteria for when a treatment factor of 5 is applied is: a dimensionless Henry's constant greater than methylene chloride at 20 ^{0}C (0.11), or an organic carbon partition coefficient greater than ethylbenzene (446 cm^3/g).

WQC: *Water Quality Criteria*, 1972

	Combined PFOA + PFOS	----	----	----	0.000021	0.000021	----	----	----

[1] The value is the dimensionless Henry's Constant at 25 °C. The enthalpy of vaporization is not known; therefore, an adjustment to the Henry's Constant due temperature changes cannot be calculated.

[2] The proposed update to the Class II total BETX standard is due to proposed updates to ethylbenzene and toluene standards.

Table 3: Sources for Carcinogenicity Updates

CAS No.	Constituent	Carcinogen Classification	Source	Year Classified
106-46-7	para-Dichlorobenzene	2B	IARC	1999
100-41-4	Ethylbenzene	2B	IARC	2000
58-89-9	Hexachlorocyclohexane, gamma-(Lindane)	1	IARC	2018
335-67-1	Perfluorooctanoic Acid (PFOA)	2B	IARC	2017

The Illinois Environmental Protection Act (415 ILCS) defines a carcinogen as:

> "A contaminant that is classified as a category A1 or A2 carcinogen by the American Conference of Governmental Industrial Hygienists; a category 1 or 2A/2B carcinogen by the World Health Organization's International Agency for Research on Cancer; a "human carcinogen" or "anticipated human carcinogen" by the United States Department of Health and Human Service National Toxicological Program; or a category A or B1/B2 carcinogen or as "carcinogenic to humans" or "likely to be carcinogenic to humans" by the United States Environmental Protection Agency in the integrated risk information system or a final rule issued in a Federal Register notice by the USEPA." [415 ILCS 5/58.2]

ATTACHMENT 4

Illinois Environmental Protection Agency Proposed Updates to 35 Ill. Adm. Code 620

By: Carol Hawbaker
Environmental Risk Assessor
Illinois Environmental Protection Agency
Office of Toxicity Assessment

May 26, 2021

Proposed Updates to 35 Ill. Adm. Code 620

The presentation will cover the following topics:

- Introduction of nine new constituents.
- Addition of three metabolites to be evaluated with atrazine for compliance with groundwater quality standards (GQS).
- Combination of radium 226 and radium 228 to form a new constituent: radium (combined 226+228).
- Addition of carcinogen designations for four existing constituents.
- Updates to constituents in the tables at Section 620.310(a)(3)(A)(i) and (ii).

Proposed Updates to 35 Ill. Adm. Code 620

The presentation will cover the following topics (continued):

- Updates of Class I GQS for three inorganic constituents from MCLs to irrigation/livestock water quality standards, based on beneficial use of groundwater.
- For constituents which Class I GQS are based on procedures found in Section 620, Subpart F and Appendix A:
  - Updates to toxicity values and relative source contribution (RSC) values;
  - Updates to exposure factors;
  - Addition of a mutagenic method for the development of a carcinogen Class I GQS for constituents with a mutagenic mode of action.

Proposed Updates to 35 Ill. Adm. Code 620

The presentation will cover the following topics (continued):

- Updates to Class II GQS.
- Introduction of tables (Appendix E) listing constituents that have similar-acting health effects or affect the same target organ.

Introduction of New Constituents

- Aluminum
- Lithium
- 1-Methylnaphthalene
- Molybdenum

- Five Per-and Polyfluoroalkyl Substances (PFAS):
  - PFBS (Perfluorobutanesulfonic Acid)
  - PFHxS (Perfluorohexanesulfonic Acid)
  - PFNA (Perfluorononanoic Acid)
  - PFOA (Perfluorooctanoic Acid)
  - PFOS (Perfluorooctanesulfonic Acid)

Introduction of New Constituents

Proposed Class I and Class II GQS:

CASRN	Constituent	Proposed Class I GQS (mg/L)	Class I Source	Proposed Class II GQS (mg/L)	Class II Source
7429-90-5	Aluminum	1.9	Subpart F	5	Livestock
7439-93-2	Lithium	0.01	Subpart F	2.5	Irrigation
90-12-0	1-Methylnaphthalene	0.27	Subpart F	0.27	Subpart F
7439-98-7	Molybdenum	0.019	Subpart F	0.05	Irrigation

Per and Poly-Fluoroalkyl Substances (PFAS)

PFAS are a group of human-made constituents applied to many consumers products to make them waterproof, stain resistant or non-stick.

- Food packaging - fast food containers, lunch meat paper, disposable plates and bowls, and oil-, water- and grease-resistant coatings on food packaging (pizza boxes);
- Commercial household products - non-stick coated cookware (Teflon), cleaning products, waxes, polishes, and adhesives;
- Clothing and fabric textiles - stain- and water-resistant carpeting and upholstery, water repellant clothing, tents, umbrellas, shoes, and leather goods;
- Cosmetics and personal care products - shampoos, conditioners, sunscreens, cosmetics, and dental floss;
- Building and exterior use products - paints and sealants;
- Industrial use - metal plating and finishing, wire coatings, automotive fluids, and the manufacture of artificial turf;
- Firefighting foam - aqueous film-forming foam (AFFF).

Per and Poly-Fluoroalkyl Substances (PFAS)

PFAS are constituents of emerging concern:

- "Forever Chemicals": PFAS not degrade naturally in the environment.
- PFAS constituents have an affinity for water and can migrate long distances.
- PFAS can bioaccumulate in plants, fish and wildlife, and humans.
- PFAS are a group of chemicals consisting of over 5,000 substances.
- Toxicological studies and assessments are being conducted by several agencies.
- Limited toxicological data for most PFAS.

Per and Poly-Fluoroalkyl Substances (PFAS)

Epidemiology and Animal Studies Suggest Associations Between PFAS Exposure and Several Health Effects:

- Pregnancy-Induced Hypertension/Pre-Eclampsia
- Liver Damage
- High Cholesterol
- Thyroid Disease
- Decreased Response to Vaccines
- Decreased Fertility
- Decreased Birth Weight
- Developmental Delays

Per and Poly-Fluoroalkyl Substances (PFAS)

- PFOA meets Illinois EPA's definition of a carcinogen. The International Agency for Research on Cancer (IARC) classified PFOA as a "2B" carcinogen in 2017.
- A "2B" classification means the constituent is possibly carcinogenic to humans.
- U.S. EPA concluded there was "suggestive potential" for PFOS to be carcinogenic to humans; however, PFOS does not meet Illinois EPA's definition of a carcinogen at this time.
- Possible Cancer Links:
  - Kidney
  - Testicular
  - Prostate
  - Liver
  - Pancreas

Per and Poly-Fluoroalkyl Substances (PFAS)

Proposed Class I GQS are based on proposed procedures for 35 Ill. Adm. Code 620, Subpart F and Appendix A.

CASRN	Constituent	Class I and Class II GQS (mg/L or ppm)	Class I and Class II GQS (ng/L or ppt)	Toxicity Value	Toxicity Value Source	Relative Source Contribution Value for Noncarcinogens
375-73-5	PFBS	0.0012	1,200	3E-04	PPRTV	0.2
355-46-4	PFHxS	0.000077	77	2E-05	ATSDR	0.2
375-95-1	PFNA	0.000012	12	3E-06	ATSDR	0.2
335-67-1	PFOA	0.000002	2	1.4E+02	OEHHA	Not Applicable
1763-23-1	PFOS	0.0000077	7.7	2E-06	ATSDR	0.2

PPRTV: Provisional Peer Reviewed Toxicity Values.

ATSDR: Agency for Toxic Substance and Disease Registry.

OEHHA: California EPA Office of Environmental Health Hazard Assessments.

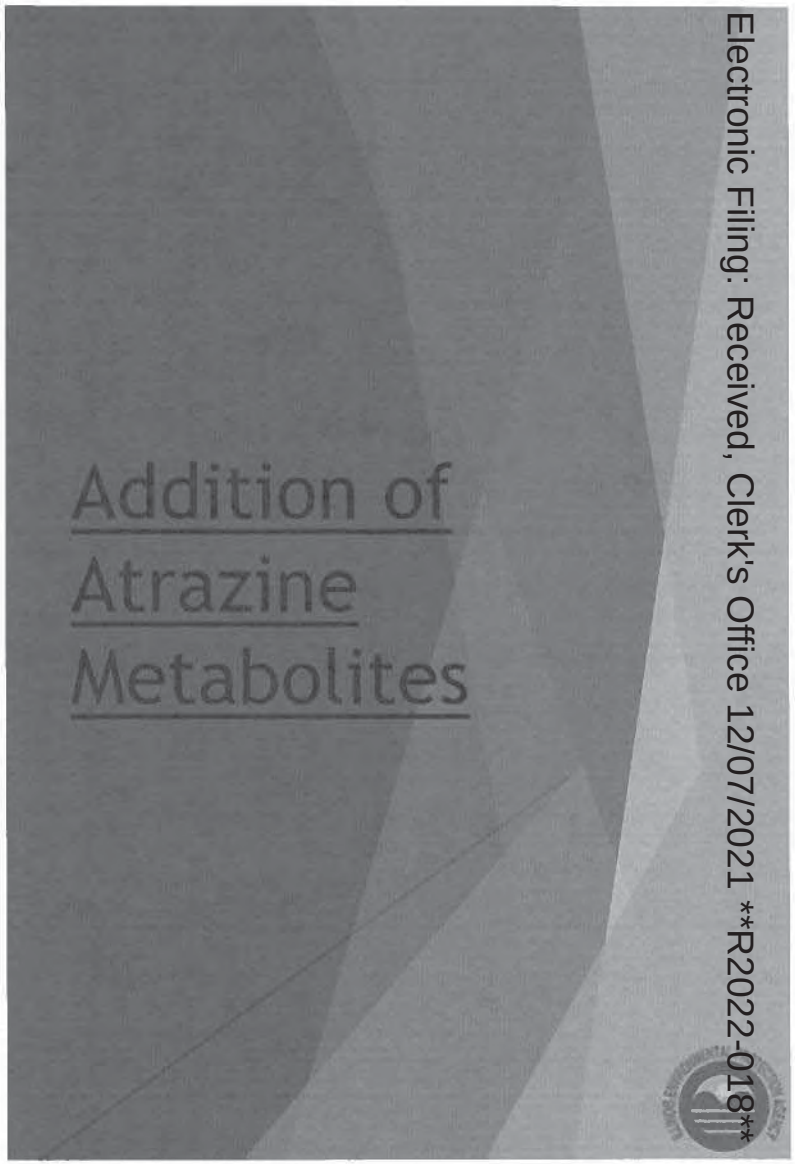
PFBS, PFHxS, PFNA and PFOS toxicity values are oral reference doses (RfDs) for noncarcinogen effects in units of mg/kg-day.

PFOA toxicity value is an oral slope factor (SF_o) for cancer risks in units of $(mg/kg\text{-}day)^{-1}$. The GQS is the minimum reporting level, per Subpart F.

The amendments propose the addition of 3 atrazine metabolites to be included when comparing atrazine concentrations to GQS.

Added Metabolites

- DEA (Desethyl-atrazine)
- DIA (Desisopropyl-atrazine)
- DACT (Diaminochlorotriazine)



Combination of Radium 226 and 228

Presently, radium 226 and radium 228 have individual Class I GQS. They are not listed in the Class II GQS.

The amendments propose radium (combined 226+228) Class I and Class II GQS.

The proposed value for the Class I and Class II GQS is based on the Federal maximum contaminant level (MCL) for radium (combined 226+228) of 5 picocuries per liter (pCi/L).

Proposed Updates to Carcinogen Designations

Carcinogen designations are updated for the following constituents:

- *p*-Dichlorobenzene (1,4-dichlorobenzene)
  - Classified "2B" by International Agency for Research on Cancer (IARC) - 1999
- Ethylbenzene
  - Classified "2B" by IARC - 2000
- *gamma*-HCH (*gamma*-hexachlorocyclohexane, lindane)
  - Classified "1" by IARC - 2018
- Isopropylbenzene (cumene)
  - Classified "2B" by IARC - 2013

Proposed Updates to Constituents in Tables at 35 Ill. Adm. Code 620.310(a)(3)(A)(i) and (ii) – Preventive Response Activities

The following constituents are removed from the tables due to carcinogenicity classifications, based on the Board Note at Section 620.310(a)(3)(A).

- *p*-Dichlorobenzene (1,4-dichlorobenzene)
- Ethylbenzene
- Arsenic
- *gamma*-HCH (lindane)
- Isopropylbenzene (cumene)

MCPP (mecoprop) is removed as the constituent's proposed Class I GQS is based on its lowest level of quantitation (LLOQ) or lowest concentration minimum reporting level (LCMRL), formerly termed practical quantitation limit (PQL).

Proposed Updates to Constituents in Tables at 35 Ill. Adm. Code 620.310(a)(3)(A)(i) and (ii) – Preventive Response Activities

Constituents Added to Tables

- Aluminum
- Molybdenum
- 1-Methylnaphthalene
- PFBS
- PFHxS
- PFNA
- PFOS
- Antimony
- HMX (octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine)
- Nitrobenzene
- RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine
- TNT (2,4,6-trinitrotoluene)
- 1,3,5-Trinitrobenzene

Proposed Updates of Class I GQS for Three Inorganic Constituents Based on More Stringent Irrigation or Livestock Values

Class I potable resource groundwater may also be used for irrigation and watering of livestock. The following constituents are proposed to be updated as follows:

CASRN	Constituent	Current Class I GQS (mg/L)	Current Source	Proposed Class I GQS (mg/L)	Proposed Source
7440-50-8	Copper	0.65	Lead/Copper Rule	0.5	Livestock
7681-49-4	Fluoride	4	U.S. EPA MCL	2	Livestock
7782-49-2	Selenium	0.05	U.S. EPA MCL	0.02	Irrigation

Proposed Updates to Subpart F and Appendix A

Out of 115 total constituents presently listed at 35 Ill. Adm. Code 620.410, 40 utilize the procedures in Subpart F and Appendix A to develop Class I GQS (35% of constituents):

- 30 constituents utilize the Human Threshold Toxicant Advisory Concentration (HTTAC) calculation at Appendix A(a) for noncarcinogens.

- 10 constituents utilize the Human Nonthreshold Toxicant Advisory Concentration (HNTAC) calculation at 35 Ill. Adm. Code 620.605(b)(2), for carcinogens. Of these 10, 7 constituents utilize a practical quantitation limit (PQL), because the calculated HNTAC is less than the PQL.

Proposed Updates to Appendix A

Illinois EPA's Hierarchy for Determining Toxicity Values

Basis for hierarchy is derived from U.S. EPA OSWER Directive 9285.7-53, dated December 5, 2003, and discussed in the Illinois Pollution Control Board Rulemaking R08-18: Proposed Amendments to Groundwater Quality Standards, 35 Ill. Adm. Code 620.

- Tier 1 Toxicity Value Source: Integrated Risk Information System (IRIS)
- Tier 2 Toxicity Value Source: Provisional Peer Reviewed Toxicity Values (PPRTV)
- Tier 3 Other Toxicity Values:

  "Priority given to sources of information that are the most current, the basis for which is transparent and publicly available, and which has been peer-reviewed."

  OSWER Directive 9285.7-53

Proposed Updates to Appendix A

Additional Guidance Regarding the Selection of Tier 3 Toxicity Values derived from U.S. EPA OSWER Directive 9285.7-86, dated May 16, 2013. Tier 3 sources are ranked as follows:

1. Agency for Toxic Substances and Disease Registry (ATSDR) minimal risk levels.
2. California EPA, Office of Environmental Health Hazard Assessment (OEHHA), toxicity values.
3. PPRTV Appendix "Screening Toxicity Values."
4. Health Effect Assessment Summary Table (HEAST) toxicity values.

Proposed Updates to Appendix A

Updates Procedures for Determining an Oral Reference Dose (RfD) When an RfD is Not Available from the Listed Toxicity Values Sources.

- Due to outdated methodology, proposes to update the procedures found at 35 Ill. Adm. Code 620, Appendix A(b)(3)-(c) for when there is no "verified" RfD, The proposed updated method is based on the methodology used by IRIS, U.S. EPA's Tier 1 toxicity source.

- Only 1 constituent (MTBE) utilized the methodology at Appendix A(b)(3)-(c) for developing an RfD.

Proposed Updates to Appendix A

Updates to Exposure Factors in the HTTAC calculation

(updates are applied for a more sensitive receptor population - children)

Current Exposure Factors	Proposed Exposure Factors
Body Weight (BW) = 70 kg (equivalent for an average adult)	Body Weight (BW) = 15 kg (equivalent for a child 0 - 6 years) of age
Daily Water Ingestion Rate (W) = 2 L/day (equivalent for an average adult)	Daily Water Ingestion Rate (W) = 0.78 L/day (equivalent for a child 0 - 6 years of age)

Proposed Updates to Appendix A

Updates to HNTAC Calculation

(moved from 35 Ill. Adm. Code 620.605(b) to Appendix A)

HNTAC calculation for carcinogens is based on methodology found in U.S. EPA's Risk Assessment Guidance for Superfund (RAGs), Part B.

Supplemental Guidance from U.S. EPA updates the carcinogen calculation to account for age-adjusted daily water ingestion rates, as opposed to adult only water ingestion rates currently used in the calculation.

Supplemental Guidance also applies adjustment factors to the age-adjusted daily water ingestion rates for to account for toxicokinetic differences between children of various age groups and adults for carcinogens with a mutagenic mode of action for carcinogenesis.

Updated equations used to calculate U.S. EPA Regional Screening Levels (RSLs) for ingestion of tapwater.

Proposed Updates to Appendix A

Updates to HNTAC Calculation

Illinois EPA proposes to update the HNTAC calculation by incorporating updated guidance to adjust for childhood exposures to carcinogens. This includes:

- Updating the HNTAC carcinogen calculation, including updating exposure factors.

- Adding a HNTAC mutagen calculation for carcinogen constituents which operate by a mutagenic mode of action for carcinogenesis. 11 constituents are classified as mutagens; 6 rely on the HNTAC calculation to determine Class I GQS.

Proposed Updates to Appendix A

Current HNTAC Calculation

$$HNTAC(mg/L) = \frac{TR \bullet BW \bullet AT \bullet 365 \frac{days}{year}}{SF_o \bullet IR \bullet EF \bullet ED}$$

Where:

Symbol (units)	Parameter	Existing Value
TR (unitless)	Target Cancer Risk – 1 in 1 Million Risk	1.0E-06
BW (kg)	Body Weight	70
AT (years)	Averaging Time for Carcinogens	70
SF_o ((mg/kg-day)$^{-1}$)	Oral Slope Factor – Toxicological Value	Chemical-Specific
IR (L/day)	Daily Water Ingestion Rate	2
EF (days/year)	Exposure Frequency	350
ED (year)	Exposure Duration	30

Proposed Updates to Appendix A

Proposed Updated HNTAC Calculation

$$HNTAC\ (mg/L) = \frac{TR \bullet \left(AT \bullet 365 \frac{days}{year}\right)}{SF_o \bullet IFW_{adj}}$$

Where:

Symbol (units)	Parameter	Proposed Value
TR (unitless)	Target Cancer Risk - 1 in 1 million	1.0E-06
AT (years)	Averaging Time for Carcinogens	70
SF_o ((mg/kg-day)$^{-1}$)	Oral Slope Factor - Toxicological Value	Chemical-Specific
IFW_{adj} (L/kg)	Age-Adjusted Daily Water Ingestion Rate	327.95

Proposed Updates to Appendix A

IFW_{adj} Calculation

$$IFW_{adj}(327.95\ L/kg) = \left[\left(\frac{EF_{child} \bullet ED_{child} \bullet IRW_{child}}{BW_{child}}\right) + \left(\frac{EF_{adult} \bullet ED_{adult} \bullet IRW_{adult}}{BW_{adult}}\right)\right]$$

Where:

Symbol (units)	Parameter	Value
EF all (days/year)	Exposure Frequency	350
ED_{child} (years)	Exposure Duration - child (0 - 6 years)	6
IRW_{child} (L/day)	Daily Water Ingestion Rate - child (0 - 6 years)	0.78
BW_{child} (kg)	Body Weight - child (0 - 6 years)	15
ED_{adult} (year)	Exposure Duration - adult	20
IRW_{adult} (L/day)	Daily Water Ingestion Rate - adult	2.5
BW_{adult} (kg)	Body Weight - adult	80

Proposed Updates to Appendix A

Proposed Introduction of an HNTAC Calculation for Mutagens

$$HNTAC_{MUT}\ (mg/L) = \frac{TR \bullet \left(AT \bullet 365\,\frac{days}{year}\right)}{SF_o \bullet IFWM_{adj}}$$

Where:

Symbol (units)	Parameter	Value
TR (unitless)	Target Cancer Risk – 1 in 1 million	1.0E-06
AT (years)	Averaging Time for Carcinogens	70
SF_o ($(mg/kg\text{-}day)^{-1}$)	Oral Slope Factor – Toxicological Value	Chemical-Specific
$IFWM_{adj}$ (L/kg)	Age-Adjusted Daily Water Ingestion Rate for Mutagens	1,019.9

Proposed Updates to Appendix A

$IFWM_{adj}$ Calculation

$$IFWM_{adj}\,(1019.9\,L/kg) = \left[\left(\frac{EF_{0-2} \bullet ED_{0-2} \bullet IRW_{0-2} \bullet 10}{BW_{0-2}}\right) + \left(\frac{EF_{2-6} \bullet ED_{2-6} \bullet IRW_{2-6} \bullet 3}{BW_{2-6}}\right) + \left(\frac{EF_{6-16} \bullet ED_{6-16} \bullet IRW_{6-16} \bullet 3}{BW_{6-16}}\right) + \left(\frac{EF_{16-26} \bullet ED_{16-26} \bullet IRW_{16-26} \bullet 1}{BW_{16-26}}\right)\right]$$

Adjustment Factors of 10, 3 and 1 are used to account for different risks from exposure during different life stages.

Proposed Updates to Appendix A

$IFWM_{adj}$ Calculation

$IFWM_{adj}$ Parameter Values:

Symbol	Parameter	Proposed Value
EF - all (days/year)	Exposure Frequency	350
ED_{0-2} (years)	Exposure Duration: 0-2 years of age	2
ED_{2-6} (years)	Exposure Duration: 2-6 years of age	4
ED_{6-16}, ED_{16-26} (years)	Exposure Duration: 6-16 and 16-26 years of age	10
IRW_{0-2}, IRW_{2-6} (L/day)	Daily Water Ingestion Rate: 0-2 and 2-6 years of age	0.78
IRW_{6-16}, IRW_{16-26} (L/day)	Daily Water Ingestion Rate: 6-16 and 16-26 years of age	2.5
BW_{0-2}, BW_{2-6} (kg)	Body Weight: 0-2 and 2-6 years of age	15
BW_{6-16}, BW_{16-26} (kg)	Body Weight: 6-16 and 16-26 years of age	80

Updates to Class II: General Resource Groundwater Quality Standards (Section 620.420)

In addition to the new constituents, updated Class II GQS are proposed for 74 constituents or mixtures currently listed in Section 620.420. Proposed updated standards are based on the following factors:

- Updated Class I Groundwater Quality Standards
- Irrigation or Livestock Criteria
- Updated Treatment Factors

Updated Treatment Factors

Treatment Factors are applied based on the effectiveness to treat the constituent in the groundwater at an 80% removal efficiency rate:

- For removal via air stripping, an 80% removal efficiency rate is assumed for constituents having a Dimensionless Henry's Law Constant (H') value greater than methylene chloride's (H') value of 0.111 at a 20°C groundwater system temperature.

OR

- For removal via carbon adsorption, an 80% removal efficiency rate is assumed for constituents having an Organic Carbon Partition Coefficient (K_{oc}) value greater than ethylbenzene's (K_{oc}) value of 446 L/kg.

If a constituent's chemical/physical values meet either of the criteria, a Treatment Factor of 5 is applied to the Class I Groundwater Quality Standard to calculate a Class II Groundwater Quality Standard.

- Source of Chemical/Physical Values: U.S. EPA Regional Screening Levels
- Source of Treatment Factor Criteria: Illinois Pollution Control Board R08-18

Proposed Addition of Tables at Appendix E for Similar-Acting Chemicals

- 35 Ill. Adm. Code 620, Appendix B and Appendix C provide procedures for mixtures of similar-acting substances within the groundwater.
  - Table A lists similar-acting constituents based on noncarcinogenic health effects or target organs.
  - Table B lists similar-acting constituents based on cancer effects.

ILLINOIS ENVIRONMENTAL PROTECTION AGENCY
1021 NORTH GRAND AVENUE EAST, P.O. BOX 19276, SPRINGFIELD, ILLINOIS 62794-9276 · (217) 782-3397
JB PRITZKER, GOVERNOR JOHN J. KIM, DIRECTOR

35 Ill. Adm. Code 620; Groundwater Quality
Pre-Filing Public Comment Period
Factsheet and Overview of Proposed Changes

Draft Proposed Rules

The Illinois EPA is proposing draft language to update 35 Ill. Adm. Code 620. The proposed updates include nine new chemicals, three new atrazine metabolites, and procedures for selecting toxicity values consistent with current federal guidance. Definitions are updated and references are consistent with those criteria and practices as incorporated. Site specific groundwater standards for designated Class III Special Resource Groundwater are also added. Exposure factors are updated, and the Human Non-Threshold Toxicant Advisory Concentration model is updated. Tables for similar-acting constituents are added. Finally, this proposal includes groundwater quality standards for five Per- and Polyfluoroalkyl Substances (PFAS): perfluorooctanoic acid (PFOA), perfluorooctanesulfonic acid (PFOS), perfluorononanoic acid (PFNA), perfluorohexanesulfonic acid (PFHxS), and perfluorobutanesulfonic acid (PFBS).

A summary of the key provisions is below. More information concerning the draft proposed rule may be found at
https://www2.illinois.gov/epa/about-us/rules-regs/water/Pages/620-Groundwater-Quality.aspx

Public Comment

Prior to submitting proposed rules to the Illinois Pollution Control Board for review and final adoption, the Illinois EPA is soliciting public comment on draft proposed rules. The Illinois EPA will accept written public comment until **June 25, 2021**. Comments should be submitted to
EPA.620.rulemaking@illinois.gov

All comments, including proposed alternative language, received by Illinois EPA will be considered prior to the Agency filing the proposed rule with Illinois Pollution Control Board. Questions about the process or rulemaking should be submitted to the e-mail address above.

Public Meeting

The Illinois EPA will host a virtual public meeting to review the proposed changes and answer questions concerning the proposal. **The meeting will be held at 1:00 pm on May 26, 2021.**
The meeting link is:
https://illinois.webex.com/illinois/j.php?MTID=m19e9dc943bb9f835453fc6b6e8823826
Computer and telephone connection instructions are provided at the bottom of this Notice. If you have questions about connecting to the meeting, contact Jeff Guy at (217) 785-8724 or by submitting an e-mail to **EPA.620.rulemaking@illinois.gov.**

Key Provisions

1. Updates the methodology located in Appendix A for developing oral reference doses (RfDs), when a verified RfD is not available. The updated methodology is the method used by U.S. EPA Integrated Risk Information System (IRIS), the Tier 1 source for selecting toxicity criteria.
2. Provides the hierarchy for selecting a verified RfD from various sources. The hierarchy is in Appendix A.
3. Updates the Exposure Factors used in the Human Threshold Toxicant Advisory Concentration (HTTAC) equation and the Human Non-Threshold Toxicant Advisory Concentration (HNTAC) equations for both carcinogens and mutagens to be consistent with the U.S. EPA Exposure Factors Handbook (2011) and U.S. EPA Regional Screening Level calculator. Updates the exposure population from an average adult to a child ages 0-6 years for the HTTAC equation.
4. Updates Class I groundwater quality standards in tables at Part 620.410, based on updates to toxicity values, exposure factors and other methodologies.
5. Updates Class II groundwater quality standards in tables at Part 620.420, based on updates to Class I groundwater quality standards and updates to treatment factors, based on updates to dimensionless Henry's Law Constants when calculated at 20 °C and organic carbon partition coefficients.
6. Establishes groundwater quality standards for nine new chemicals, adds three metabolites as a mixture to atrazine, and moves atrazine and its metabolites tables to Part 620.410(c)(2) and Part 620.420(c)(2) for complex mixtures. Combines Radium 226 and 228 to form CASRN 7440-14-4: Radium (combined 226+228), updates the Class I groundwater quality standard for radium (combined 226+228) to an updated standard of 5 pCi/L, equal to the U.S. EPA Drinking Water MCL, and adds a Class II groundwater quality standard for radium (combined 226+228) at Part 620.420(a)(2). Establishes a Class II groundwater quality standard for silver and adds it to the table at Part 620.420(a)(2).
7. Updates constituent tables to include Chemical Abstract Services Registry Numbers (CASRNs) as additional identifiers for the constituents.
8. Adds footnotes to tables identifying the sources or methods for determining the groundwater quality standards.
9. Removes the explosive constituents at Parts 620.410(c) and 620.420(c); integrates the constituents into Parts 620.410(b) and 620.420(b).
10. Adds Appendix E, providing tables for similar-acting non-carcinogenic constituents by health effect (Table A) and similar-acting carcinogen constituents by cancer effect (Table B).
11. Updates the names of eleven constituents.
12. Adds carcinogen designations for four existing chemicals and one new chemical.
13. Adds mutagen designations for eleven chemicals.
14. Updates toxicity values for the constituents whose groundwater quality standards are based on the Human Threshold Toxicant Advisory Concentration (HTTAC) equation for noncarcinogens or the Human Nonthreshold Toxicant Advisory Concentration (HNTAC) equation for carcinogens.

A detailed list of Key Provisions can be found at
https://www2.illinois.gov/epa/about-us/rules-regs/water/Pages/620-Groundwater-Quality.aspx

Proposed Changes to 620 Sub Part A-C

Sub Part	Section	Proposed Changes
Part A	**620.110**	Adds definition of "Chemical Abstract Service Registry Numbers (CASRN)", "Lowest Concentration Minimum Reporting Level", and "Mutagen". Updates definition of "Carcinogen" to be consistent with updates to terminology used by U.S. EPA Integrated Risk Information System, and definition of "Detection" to language currently used in test methods. Removes the definition of "Practical Quantitation Level".
	620.125	Updates CFR references to most recent iteration of the code. Adds Illinois EPA "Integrated Water Quality Report and Section 303(d) List" and National Academy of Science "Water Quality Criteria" (1973) to incorporated references and updates several test methods. Adds references from the U.S. EPA Office of Research and Development, National Center for Environmental Assessment, and reference from U.S. EPA Office of Resource Conservation and Recovery. Updated for groundwater guidance from USEPA 2017.
Part B	**620.210**	Removes permeameter as an acceptable means to determine hydraulic conductivity. Adds the wellhead protection area of a community water supply well or well field as a specific area to which Class I groundwater quality standards are applicable.
	620.250	Lists a standard set of documentation that must be included with all groundwater management zone applications.
Part C	**620.302**	Adds to the list of examples of persons who do groundwater monitoring.
	620.310	Updates table at Part 620.310(a)(3)(A)(i) to include CASRN for each constituent; and removes para-dichlorobenzene and ethylbenzene from the table due to their updated carcinogen classification and the Board Note for 620.310(a)(3)(A). Adds a table at Part 620.310(a)(3)(A)(ii) depicting the constituents in the subsection; and removes *gamma*-HCH (*gamma*-hexachlorocyclohexane, lindane) and isopropylbenzene (cumene) due to their updated carcinogen classification and the Board Note for 620.310(a)(3)(A). Amends Board Note for 620.310(a)(3)(A) to revised outdated language.

Proposed Changes to 620 Sub Part D-F

Sub Part	Section	Proposed Changes
Part D	**620.410**	Adds Class I groundwater quality standards for nine new chemicals. Updates constituent tables to add CASRN for each constituent. Adds footnotes detailing the sources of the standards. Updates Class I groundwater quality standards as applicable. Removes explosive constituents table at 620.410(c) and integrates the constituents into table at 620.410(b). Moves atrazine from 620.410(b) to the complex chemical mixtures tables at 620.410(c) with the addition of atrazine metabolites.
	620.420	Adds Class II groundwater quality standards for nine new chemicals and two chemicals listed in 620.410 without prior Class II groundwater quality standards. Updates constituent tables to add a CASRN for each constituent, and update Class II groundwater quality standards as applicable. Adds footnotes detailing the sources of the standards. Removes explosive constituents table at 620.420(c) and integrates the constituents into table at 620.420(b). Moves atrazine from 620.420(b) to the complex chemical mixtures tables at 620.420(c) with the addition of atrazine metabolites.
	620.430	Establishes site specific Class III groundwater quality standards for chloride and pH at four dedicated nature preserves, which are caves, pursuant to 620.230(b). Establishes site specific Class III groundwater quality standards for chloride at two dedicated nature preserves, which are wetlands, pursuant to 620.230(b).
	620.440	Updates names of explosive constituents.
	620.450	Updates names of explosive constituents.
Part E	**620.510**	Requires that the 2009 Unified Guidance be used to determine background groundwater quality unless other methods are specified by regulation. Replaces the use of the PQL with the LLOQ, LCMRL or MDL, as appropriate to the nature of the chemical.
Part F	**620.601**	(b)-Updates code reference to 604.200.
	620.605	(b)(1) Designates the more stringent toxicity value of the (Human Threshold Toxicant Advisory Concentration (HTTAC) or Human Nonthreshold Toxicant Advisory Concentration (HNTAC) as the guidance value in the absence of a Maximum Contaminant Level (MCL) or Maximum Contaminant Level Goal (MCLG).
		(b)(2) Removes the Human Nonthreshold Toxicant Advisory Concentration (HNTAC) language and equation and relocates it to Appendix A.

Proposed Changes to 620 Appendices

Appendix	Section	Proposed Changes
A	(a)	Updates exposure factors representative of a child for the HTTAC model, which is consistent with Illinois Administrative Code Part 742 and U.S. EPA Regional Screening Levels (per capita daily water consumption = 0.78 liters per day, assumed average weight of a child 0-6 years of age = 15 kg).
	(b)(2)	Incorporates U.S. EPA's hierarchy of toxicity sources from "*Tier 3 Toxicity Value White Paper*", dated May 16, 2013, by U.S. EPA Office of Solid Waste and Emergency Response Human Health Regional Risk Assessors Forum (OSWER) for determining an appropriate verified oral reference dose.
	(b)(3)	Revises methodology used to calculate guidance values when a verified oral reference dose is not available to make language consistent with U.S. EPA Reference Dose Guidance.
	(b)(4)	Clarifies usage of uncertainty factors.
	(c)(1)	Adds equation for calculating HNTAC guidance level for chemicals designated as mutagens.
	(c)(2)	Updates equation for calculating HNTAC guidance levels for chemicals designated as carcinogens that are not designated as mutagens.
B	(c)	Removes language specific to mixtures of ortho-dichlorobenzene and para-dichlorobenzene, and 1,1-dichloroethane and 1,1,1-trichloroethane, and adds reference to Appendix E.
E		Provides tables of similar acting non-carcinogenic and carcinogenic constituents.

ATTACHMENT 5

GAC Recommendations to Proposed 35 Ill. Adm. Code 620

The Illinois Groundwater Advisory Council (GAC) held meetings on June 16, 2021, July 19, 2021, and August 25, 2021 in part to discuss the Illinois Environmental Protection Agency's (Illinois EPA) current draft Part 620 rulemaking proposal and public comments regarding the same. The Illinois EPA has expressed an urgency to file these proposed rules with the Illinois Pollution Control Board (IPCB), but has provided no specific reason for the urgency other than it being over 12 years since Part 620's last update

After the three GAC meetings referenced above and reviewing the public comments submitted before the May 25th deadline, the GAC believes the Illinois EPA has not yet provided the following necessary information:

1. A description of the basis for the Illinois EPA's reluctance to work with all impacted parties during the drafting of these rules, which could have resulted in discussions answering many of the questions raised during the comment period that ended May 25, 2021. Per the 12/17/20 GAC remote meeting call, the Illinois EPA Agency had already started working on the draft proposal.
2. A description of the basis for the Illinois EPA's urgency to file these proposed rules with the IPCB without prior response to all comments submitted during the comment period that ended May 25, 2021.
3. A description of the basis for not following the federal or surrounding state approaches, methodologies, and standards.
4. A description of the basis for justifying Illinois standards to be more stringent than federal and/or surrounding state approaches, as well as why the Illinois EPA is seeking to revise these standards before the US EPA has updated their federal standards.
5. A description of how testing will be performed in state laboratories at the levels recommended in the proposal, including calculation assumptions and technical research references.
6. A description of the methods regulated entities should use to analyze for per/polyfluoroalkyl (PFA's) substances and other materials in wastewater, biosolids, and other products.
7. A description of state and/or federal resources available for regulated entities to treat to the proposed standards.

Based upon Illinois EPA statements at the August 25th meeting that they would not provide responses to raised nor previously submitted questions prior to proposing the amendments to the IPCB, the GAC will not have the benefit of knowing the Illinois EPA's responses and/or how it might revise the proposal. As a result, the GAC cannot offer a recommendation that the Illinois EPA move forward in this filing. Should the Illinois EPA continue to move forward with the proposal, it is the GAC's position that the Illinois EPA sufficiently address these questions in

the Proposed Rulemaking and/or Statement of Reasons to provide the most robust and transparent proposal to the Illinois Pollution Control Board for a more effective and workable standard.

JB PRITZKER, GOVERNOR JOHN J. KIM, DIRECTOR

Memorandum

Date: September 29, 2021

To: Robert Elvert, Chair
Groundwater Advisory Council

From: Michael Summers, P.G.,
Chairman, Intergovernmental Coordinating Committee on Groundwater

Subject: Intergovernmental Coordinating Committee on Groundwater's Response to the Groundwater Advisory Council's Recommendation

---

PURPOSE: The purpose of this Memorandum is to meet the statutory requirements in the Illinois Groundwater Protection Act and to provide a written response to the Groundwater Advisory Council's (GAC or Council) Recommendation. *See 415 ILCS 55/4*

BACKGROUND: The Intergovernmental coordinating Committee on Groundwater (ICCG or Committee) convened a remote meeting (via WebEx) on September 22, 2021 at 1:00pm, with the following members present:

Michael Summers, Chairman - Illinois Environmental Protection Agency (Illinois EPA)
James Bentley, Office of State Fire Marshall
Vickie Broomhead, Department of Natural Resources, Office of Mines and Minerals
Wes Cattoor, Department of Natural Resources, Office of Water Resources
Charles Jones, Department of Public Health
Doug Liniger, Department of Transportation
Randy Locke, Illinois State Geological Survey
Adnan, Khayyat, Office of Emergency Management

Also present at the meeting:
Kari Beckum, Illinois EPA
Gerrin Cheekbutler, Department of Public Health
Alex Davis, Illinois Environmental Regulatory Group
Sara Terranova, Illinois EPA

Representatives from the Department of Agriculture, Department of Nuclear Safety, and Department of Commerce and Economic Opportunity did not attend the meeting.

The purpose of the ICCG meeting was to discuss the proposed changes to the 35 Ill. Adm. Code 620 Groundwater Quality standards, and to discuss the GAC Recommendation concerning these proposed changes. By Statue *"[t]he Committee shall consider findings and recommendations that are provided by the Council and respond in writing regarding such matters. The Chairman of the Committee shall designate a liaison person to serve as a facilitator of communications with the Council."* See 415 ILCS 55/4. The Chairman has designated himself as the liaison with the GAC.

The GAC Recommendation is the result of three GAC remote meetings (June 16, 2021, July 19, 2021, and August 25, 2021), in which GAC members and interested public parties participated. The GAC Recommendations, dated September 19, 2021, was sent directly to ICCG Chairman, Illinois EPA representatives, and GAC members. The ICCG Chairman and Illinois EPA representatives received the GAC Recommendation via email on September 19, 2021 and by hard by copy on September 22, 2021,

The ICCG Chair forwarded a copy of the GAC Recommendations to all Committee members prior to the September 22, 2021 Committee meeting. A copy of the GAC Recommendations is included as an attachment to this Memorandum.

RESPONSE: Discussion of the GAC Recommendation during the Committee meeting resulted in the following statement being unanimously approved by the Committee. The Chair did not voice an opinion:

> "The ICCG as a whole entity does not have the expertise to answer or comment on the GAC questions/comments on the proposed changes to the 35 Ill. Adm. Code 620 Groundwater Quality standards. These changes to the Groundwater Quality standards are being proposed by the Illinois EPA, who has the expertise and knowledge to address this (GAC) Recommendation. Therefore, it is the Committee's stated opinion that the GAC Recommendation should be addressed by the Illinois EPA in the Statement of Reason or before the Illinois Pollution Control Board. Further, this Response by ICCG does not specifically endorse or disapprove of the proposed rule changes and individual ICCG member reserves the right to provide additional comment, questions, or concerns during the rule making process."

CONCLUSION: By providing this written Memorandum and the Response within to the GAC, the ICCG has met its Statutory obligations under the Illinois Groundwater Protection Act.

Subject: GAC - 35 Ill. Adm. Code 620

Mr. Elvert,

The Illinois Environmental Protection Agency (Agency) has received and reviewed the Groundwater Advisory Council's (GAC) Recommendations to Proposed 35 Ill. Adm. Code 620. The Agency believes each applicable point of concern raised by the GAC has been sufficiently addressed in the Statement of Reasons and the accompanied Testimony that is to be filed before the Illinois Pollution Control Board (Board). However, if any outstanding issues remain, each concern may be raised and further addressed during the 35 Ill. Adm. Code 620 rulemaking proceeding before Board.

Thank you,
Sara Terranova
Assistant Counsel
Division of Legal Counsel

TITLE 35: ENVIRONMENTAL PROTECTION
SUBTITLE F: PUBLIC WATER SUPPLIES
CHAPTER I: POLLUTION CONTROL BOARD

PART 620
GROUNDWATER QUALITY

SUBPART A: GENERAL

SUBPART B: GROUNDWATER CLASSIFICATION

SUBPART C: NONDEGRADATION PROVISIONS
FOR APPROPRIATE GROUNDWATERS

SUBPART D: GROUNDWATER QUALITY STANDARDS

SUBTITLE F

SUBPART E: GROUNDWATER MONITORING AND ANALYTICAL PROCEDURES

SUBPART F: HEALTH ADVISORIES

AUTHORITY: Implementing and authorized by Section 8 of the Illinois Groundwater Protection Act [415 ILCS 55/8] and authorized by Section 27 of the Illinois Environmental Protection Act [415 ILCS 5/27].

Reg. 2662, effective February 5, 2002; amended in R08-18 at 36 Ill. Reg. 15206, effective October 5, 2012; amended in R08-18(B) at 37 Ill. Reg. 16529, effective October 7, 2013; amended in _____ at ____ Ill. Reg. _____, effective _____

Section 620.110 Definitions

The definitions of the Environmental Protection Act [415 ILCS 5] and the Groundwater Protection Act [415 ILCS 55] apply to this Part. The following definitions also apply to this Part:

"Act" means the Environmental Protection Act [415 ILCS 5].

"Agency" means the Illinois Environmental Protection Agency.

"Aquifer" means saturated (with groundwater) soils and geologic materials which are sufficiently permeable to readily yield economically useful quantities of water to wells, springs, or streams under ordinary hydraulic gradients. [415 ILCS 55/3(b)]

"BETX" means the sum of the concentrations of benzene, ethylbenzene, toluene, and xylenes.

"Board" means the Illinois Pollution Control Board.

"Chemical Abstract Services Registry Number" or "CASRN" means a unique numerical identifier designated for only one substance, assigned by the Chemical Abstracts Service for that substance.

"Carcinogen" means a contaminant that is classified as a Category A1 or A2 Carcinogen by the American Conference of Governmental Industrial Hygienists; or a Category 1 or 2A/2B carcinogen by the World Health Organization's International Agency for Research on Cancer; or a "Human carcinogen" or "Anticipated Human Carcinogen" by the United States Department of Health and Human Service National Toxicological Program; or a Category A or B1/B2 Carcinogen or as "carcinogenic to humans" or "likely to become carcinogenic to humans" *by the United States Environmental Protection Agency in Integrated Risk Information System or a Final Rule issued in a Federal Register notice by the USEPA.* [415 ILCS 5/58.2]

"Community water supply" means a public supply which serves or is intended to serve at least 15 service connections used by residents or regularly serves at least 25 residents. [415 ILCS 5/3.145]

"Contaminant" means any solid, liquid, or gaseous matter, any odor, or any form of energy, from whatever source. [415 ILCS 5/3.165]

"Corrective action process" means those procedures and practices that may be imposed by a regulatory agency when a determination has been made that contamination of groundwater has taken place, and are necessary to address a potential or existing violation of the standards set forth in Subpart D.

"Cumulative impact area" means the area, including the coal mine area permitted under the Surface Coal Mining Land Conservation and Reclamation Act [225 ILCS 720] and 62 Ill. Adm. Code 1700 through 1850, within which impacts resulting from the proposed operation may interact with the impacts of all anticipated mining on surface water and groundwater systems.

"Department" means the Illinois Department of Natural Resources.

"Detection" means the identification of a contaminant in a sample at a value equal to or greater than the:

"Method Detection Limit" or "MDL" means the minimum measured concentration of a substance that can be ~~measured as~~ reported with 99% ~~percent~~ confidence that the ~~true value is greater than zero~~ measured concentration is distinguishable from method blank results, pursuant to 40 CFR 136, appendix B (2017~~2006~~), incorporated by reference at Section 620.125; or

"Lower Limit of Quantitation ~~Method Quantitation Limit~~" or "LLOQ~~MQL~~" means the minimum concentration ~~of a substance~~ that can be measured or ~~and~~ reported pursuant to "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods," ~~,~~ incorporated by reference at Section 620.125.

"Groundwater" means underground water which occurs within the saturated zone and geologic materials where the fluid pressure in the pore space is equal to or greater than atmospheric pressure. [415 ILCS 5/3.210]

"Hydrologic balance" means the relationship between the quality and quantity of water inflow to, water outflow from, and water storage in a hydrologic unit such as a drainage basin, aquifer, soil zone, lake, or reservoir. It encompasses the dynamic relationships among precipitation, runoff, evaporation, and changes in ground and surface water storage.

"Lowest Concentration Minimum Reporting Level" or "LCMRL" means the lowest spiking concentration such that the probability of spike recovery in the

50% to 150% range is at least 99%.

"IGPA" means the Illinois Groundwater Protection Act. ~~[~~415 ILCS 55~~]~~.

"Lowest observable adverse effect level" or "LOAEL" ~~or "Lowest observable adverse effect level"~~ means the lowest tested concentration of a chemical or substance that produces a statistically significant increase in frequency or severity of non-overt adverse effects between the exposed population and its appropriate control. ~~LOAEL may be determined for a human population (LOAEL-H) or an animal population (LOAEL-A).~~

"Licensed Professional Engineer" or "LPE" means a person, corporation, or partnership licensed under the laws of the State of Illinois to practice professional engineering. [415 ILCS 5/57.2]

"Licensed Professional Geologist" or "LPG" means an individual who is licensed under the Professional Geologist Licensing Act *to engage in the practice of professional geology in Illinois.* [225 ILCS 745/15]

"Mutagen" means a carcinogenic constituent that operates by a mutagenic mode of action for carcinogenesis. Carcinogens with a mutagenic mode of action would be expected to cause irreversible changes to DNA and would exhibit greater effects in early life versus later life exposure.

~~"NOAEL" or~~ "No observable adverse effect level" or "NOAEL" means the highest tested concentration of a chemical or substance that does not produce a statistically significant increase in frequency or severity of non-overt adverse effects between the exposed population and its appropriate control. ~~NOAEL may be determined for a human population (NOAEL-H) or an animal population (NOAEL-A).~~

"Non-community water supply" means a public water supply that is not a community water supply. [415 ILCS 5/3.145]

"Off-site" means not on-site.

"On-site" means on the same or geographically contiguous property that may be divided by public or private right-of-way, provided the entrance and exit between properties is at a crossroads intersection and access is by crossing as opposed to going along the right-of-way. Noncontiguous properties owned by the same person but connected by a right-of-way that he controls and that the public does not have access to is also considered on-site property.

"Operator" means the person responsible for the operation of a site, facility or unit.

"Owner" means the person who owns a site, facility, or unit; ~~or~~ part of a site, facility, or unit; ~~,~~ or who owns the land on which the site, facility, or unit is located.

"Potable" means generally fit for human consumption in accordance with accepted water supply principles and practices. [415 ILCS 5/3.340]

"Potential primary source" means any unit at a facility or site not currently subject to a removal or remedial action which:

Is utilized for the treatment, storage, or disposal of any hazardous or special waste not generated at the site; or

Is utilized for the disposal of municipal waste not generated at the site, other than landscape waste and construction and demolition debris; or

Is utilized for the landfilling, land treating, surface impounding or piling of any hazardous or special waste that is generated on the site or at other sites owned, controlled or operated by the same person; or

Stores or accumulates at any time more than 75,000 pounds above ground, or more than 7,500 pounds below ground, of any hazardous substances. [415 ILCS 5/3.345]

"Potential route" means abandoned and improperly plugged wells of all kinds, drainage wells, all injection wells, including closed loop heat pump wells, and any excavation for the discovery, development or production of stone, sand or gravel. This term does not include closed loop heat pump wells using USP (U.S. Pharmacopeia) *food grade propylene glycol.* [415 ILCS 5/3.350]

"Potential secondary source" means any unit at a facility or a site not currently subject to a removal or remedial action, other than a potential primary source, which:

Is utilized for the landfilling, land treating, or surface impounding of waste that is generated on the site or at other sites owned, controlled or operated by the same person, other than livestock and landscape waste, and construction and demolition debris; or

Stores or accumulates at any time more than 25,000 but not more than 75,000 pounds above ground, or more than 2,500 but not more than 7,500 pounds below ground, of any hazardous substance; or

Stores or accumulates at any time more than 25,000 gallons above ground, or more than 500 gallons below ground, of petroleum, including crude oil or any fraction thereof which is not otherwise specifically listed or designated as a hazardous substance; or

Stores or accumulates pesticides, fertilizers, or road oils for purposes of commercial application or for distribution to retail sales outlets; or

Stores or accumulates at any time more than 50,000 pounds of any de-icing agent; or

Is utilized for handling livestock waste or for treating domestic wastewaters other than private sewage disposal systems as defined in the Private Sewage Disposal Licensing Act [225 ILCS 225]. [415 ILCS 5/3.355]

~~"Practical Quantitation Limit" or "PQL" means the lowest concentration or level that can be reliably measured within specified limits of precision and accuracy during routine laboratory operating conditions in accordance with "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods", EPA Publication No. SW-846, incorporated by reference at Section 620.125.~~

"Previously mined area" means land disturbed or affected by coal mining operations prior to February 1, 1983.

BOARD NOTE: February 1, 1983, is the effective date of the Illinois permanent program regulations implementing the Surface Coal Mining Land Conservation and Reclamation Act [225 ILCS 720] as codified in 62 Ill. Adm. Code 1700 through 1850.

"Property class" means the class assigned by a tax assessor to real property for purposes of real estate taxes.

BOARD NOTE: The property class (rural property, residential vacant land, residential with dwelling, commercial residence, commercial business, commercial office, or industrial) is identified on the property record card maintained by the tax assessor in accordance with the Illinois Real Property

Appraisal Manual (February 1987), published by the Illinois Department of Revenue, Property Tax Administration Bureau.

"Public water supply" means all mains, pipes and structures through which water is obtained and distributed to the public, including wells and well structures, intakes and cribs, pumping stations, treatment plants, reservoirs, storage tanks and appurtenances, collectively or severally, actually used or intended for use for the purpose of furnishing water for drinking or general domestic use and which serve at least 15 service connections or which regularly serve at least 25 persons at least 60 days per year. A public water supply is either a "community water supply" or a "non-community water supply". [415 ILCS 5/3.365]

"Regulated entity" means a facility or unit regulated for groundwater protection by any State or federal agency.

"Regulatory agency" means the Illinois Environmental Protection Agency, Department of Public Health, Department of Agriculture, the Office of Mines and Minerals in the Department of Natural Resources, and the Office of State Fire Marshal.

"Regulated recharge area" means a compact geographic area, as determined by the Board pursuant to Section 17.4 of the Act, *the geology of which renders a potable resource groundwater particularly susceptible to contamination.* [415 ILCS 5/3.390]

"Resource groundwater" means groundwater that is presently being, or in the future is capable of being, put to beneficial use by reason of being of suitable quality. [415 ILCS 5/3.430]

"Saturated zone" means a subsurface zone in which all the interstices or voids are filled with water under pressure greater than that of the atmosphere.

"Setback zone" means a geographic area, designated pursuant to this Act, containing a potable water supply well or a potential source or potential route having a continuous boundary, and within which certain prohibitions or regulations are applicable in order to protect groundwaters. [415 ILCS 5/3.450]

"Site" means any location, place, tract of land and facilities, including but not limited to, buildings and improvements used for the purposes subject to regulation or control by the Act or regulations thereunder. [415 ILCS 5/3.460]

"Spring" means a natural surface discharge of an aquifer from rock or soil.

"Threshold dose" means the lowest dose of a chemical at which a specified measurable effect is observed and below which it is not observed.

"Treatment" means the technology, treatment techniques, or other procedures for compliance with 35 Ill. Adm. Code,- Subtitle F.

"Unit" means any device, mechanism, equipment, or area (exclusive of land utilized only for agricultural production). [415 ILCS 5/3.515]

"U.S. EPA" means the United States Environmental Protection Agency.

"Wellhead protection area" or "WHPA" means the surface and subsurface recharge area surrounding a community water supply well or well field, delineated outside of any applicable setback zones (pursuant to Section 17.1 of the Act [415 ILCS 5/17.1]), and pursuant to Illinois' Wellhead Protection Program, through which contaminants are reasonably likely to move toward such well or well field.

"Wellhead Protection Program" or "WHPP" means the wellhead protection program for the State of Illinois, approved by U.S. EPA under 42 USC 300h-7. BOARD NOTE: Derived from 40 CFR 141.71(b) (2003). The wellhead protection program includes the "groundwater protection needs assessment" under Section 17.1 of the Act [415 ILCS 5/17.1] and 35 Ill. Adm. Code 615-617.

Section 620.210 Class I: Potable Resource Groundwater

Except as provided in Sections 620.230, 620.240, or 620.250, Potable Resource Groundwater is:

a) Groundwater located 10 feet or more below the land surface and within:

1) The minimum setback zone of a well which serves as a potable water supply and to the bottom of such well;

2) Unconsolidated sand, gravel, or sand and gravel which is 5 feet or more in thickness and that contains 12% ~~percent~~ or less of fines (i.e., fines which pass through a No. 200 sieve tested according to ASTM Standard Practice D2487-06, incorporated by reference at Section 620.125);

3) Sandstone which is 10 feet or more in thickness, or fractured carbonate which is 15 feet or more in thickness; ~~or~~

4) Any geologic material which is capable of a:

A) Sustained groundwater yield, from up to a 12-inch borehole, of 150 gallons per day or more from a thickness of 15 feet or less; or

B) Hydraulic conductivity of 1 x 10^{-4} cm/sec or greater using one of the following test methods or its equivalent:

i) Slug test; or~~Permeameter;~~

ii) Pump test~~Slug test; or~~

~~iii) Pump test.~~

5) The wellhead protection area of a community water supply well or well field, as defined in Section 620.110 and delineated pursuant to the methods incorporated by reference in Section 620.125. For the purposes of this Subpart, when a maximum setback zone has been adopted pursuant to Section 14.3 of the Act, the WHPA includes the delineated area within the maximum setback zone.

b) Any groundwater which is determined by the Board pursuant to petition procedures set forth in Section 620.260, to be capable of potable use.

BOARD NOTE: Any portion of the thickness associated with the geologic

materials as described in subsections 620.210(a)(2), (a)(3), or (a)(4) should be designated as Class I: Potable Resource Groundwater if located 10 feet or more below the land surface.

(Source: Amended at ~~36 Ill. Reg. 15206~~, effective ~~October 5, 2012~~)

Section 620.250 Groundwater Management Zone

a) Within any class of groundwater, a groundwater management zone may be established as a three-dimensional region containing groundwater being managed to mitigate impairment caused by the release of contaminants from a site:

1) That is subject to a corrective action process approved by the Agency; or

2) For which the owner or operator undertakes an adequate corrective action in a timely and appropriate manner and provides a written confirmation to the Agency. Such confirmation shall ~~must~~ be provided in a form as prescribed by the Agency.

b) A groundwater management zone is established upon concurrence by the Agency that the conditions as specified in subsection (a) are met and groundwater management continues for a period of time consistent with the action described in that subsection.

c) A groundwater management zone expires upon the Agency's receipt of appropriate documentation which confirms the completion of the action taken pursuant to subsection (a) and which confirms the attainment of applicable standards as set forth in Subpart D. The Agency shall review the on-going adequacy of controls and continued management at the site if concentrations of chemical constituents, as specified in Section 620.450(a)(4)(B), remain in groundwater at the site following completion of such action. The review shall ~~must~~ take place no less often than every 5 years and the results shall be presented to the Agency in a written report.

d) Notwithstanding subsections (a) and (b) above, a groundwater management zone as defined in 35 Ill. Adm. Code 740.120 may be established in accordance with the requirements of 35 Ill. Adm. Code 740.530 for sites undergoing remediation pursuant to the Site Remediation Program. Such a groundwater management zone shall remain in effect until the requirements set forth at 35 Ill. Adm. Code 740.530(c) are met.

e) While the groundwater management zone established in accordance with 35 Ill. Adm. Code 740.530 is in effect, the otherwise applicable standards as specified in Subpart D of this Part shall not be applicable to the "contaminants of concern", as defined at 35 Ill. Adm. Code 740.120, for which groundwater remediation objectives have been approved in accordance with the procedures of 35 Ill. Adm. Code 740.

f) Notwithstanding subsection (c) above, the review requirements concerning the ongoing adequacy of controls and continued management at the site shall not apply to groundwater within a three-dimensional region formerly encompassed by a groundwater management zone established in accordance with 35 Ill. Adm. Code 740.530 while a No Further Remediation Letter issued in accordance with the procedures of 35 Ill. Adm. Code 740 is in effect.

g) All groundwater management zone applications submitted pursuant to subsection (a) shall contain the following:

1) Facility information. This includes the name, address, and county where the site is located.

2) Identification of specific units (operating or closed) present at the facility.

3) Maps and engineering drawings showing the facility and units at the facility.

4) Statement of the groundwater classification(s) at the facility.

5) Identification of the chemical constituents released to the groundwater.

6) Description of how groundwater will be monitored to determine the rate and extent of the release, and if it has migrated off site.

7) Schedule for investigation of the extent of the release.

8) Results of available soil testing and groundwater monitoring associated with a release, locations and depths of samples, and monitoring well construction details with well logs.

9) Remedy

A) Description of selected remedy and why it was chosen;

B) Results of groundwater contaminant transport modeling or calculations showing how the selected remedy will achieve compliance with the applicable groundwater standards;

C) Description of the fate and transport of contaminants with selected remedy over time; and

D) A statement of how groundwater at the facility will be monitored following implementation of the remedy to ensure that the groundwater standards have been attained.

10) Information requested by the Agency, necessary for its review of the groundwater management zone application.

Section 620.302 Applicability of Preventive Notification and Preventive Response Activities

a) Preventive notification and preventive response as specified in Sections 620.305 through 620.310 applies to:

1) Class I groundwater under Section 620.210(a)(1), (a)(2), or (a)(3) that is monitored by the persons listed in subsection (b); or

2) Class III groundwater that is monitored by the persons listed in subsection (b).

b) For purposes of subsection (a), the persons that conduct groundwater monitoring are:

1) An owner or operator of a regulated entity for which groundwater quality monitoring shall ~~must~~ be performed pursuant to State or Federal law or regulation (e.g., section 106 and 107 of the Comprehensive Environmental Response, Compensation and Liability Act (42 USC 9601, et seq.); sections 3004 and 3008 of the Resource Conservation and Recovery Act (42 USC 6901, et seq.); sections 4(q), 4(v), 12(g), 21(d), 21(f), 22.2(f), 22.2(m) and 22.18 of the Act; 35 Ill. Adm. Code 615, 616, 724, 725, 730, 731, 750, 807, 811, ~~and~~ 814, and 815; and 62 Ill. Adm. Code 1780 and 1784);

2) An owner or operator of a public water supply well who conducts groundwater quality monitoring;

3) A State agency that is authorized to conduct, or is the recipient of, groundwater quality monitoring data (e.g., Illinois Environmental Protection Agency, Department of Public Health, Department of Agriculture, Office of State Fire Marshal, or Department of Natural Resources); or

4) An owner or operator of a facility that conducts groundwater quality monitoring pursuant to State or federal judicial or administrative order.

c) If a contaminant exceeds a standard set forth in Section 620.410 or Section 620.430, the appropriate remedy is corrective action and Sections 620.305 and 620.310 do not apply.

(Source: Amended at ~~36 Ill. Reg. 15206~~, effective ~~October 5, 2012~~)

Section 620.310 Preventive Response Activities

a) The following preventive assessment shall~~must~~ be undertaken:

1) If a preventive notification under Section 620.305(c) is provided by a community water supply:

A) The Agency shall notify the owner or operator of any identified potential primary source, potential secondary source, potential route, or community water supply well that is located within 2,500 feet of the wellhead.

B) The owner or operator notified under subsection (a)(1)(A) shall, within 30 days after the date of issuance of such notice, sample each water well or monitoring well for the contaminant identified in the notice if the contaminant or material containing such contaminant is or has been stored, disposed of, or otherwise handled at the site. If a contaminant identified under Section 620.305(a) is detected, then the well shall ~~must~~ be resampled within 30 days of the date on which the first sample analyses are received. If a contaminant identified under Section 620.305(a) is detected by the resampling, preventive notification shall ~~must~~ be given as set forth in Section 620.305.

C) If the Agency receives analytical results under subsection (a)(1)(B) that show a contaminant identified under Section 620.305(a) has been detected, the Agency shall:

i) Conduct a well site survey pursuant to 415 ILCS 5/17.1(d), if such a survey has not been previously conducted within the last 5 years; and

ii) Identify those sites or activities that represent a hazard to the continued availability of groundwaters for public use unless a groundwater protection needs assessment has been prepared pursuant to 415 ILCS 5/17.1(d).

2) If a preventive notification is provided under Section 620.305(c) by a non-community water supply or for multiple private water supply wells, the Department of Public Health shall conduct a sanitary survey within 1,000 feet of the wellhead of a non-community water supply or within 500 feet of the wellheads for multiple private water supply wells.

3) If a preventive notification under Section 620.305(b) is provided by the owner or operator of a regulated entity and the applicable standard in Subpart D has not been exceeded:

A) The appropriate regulatory agency shall determine if any of the following occurs for Class I: Potable Resource Groundwater:

i) The levels set forth below are exceeded or are changed for pH:

CASRN	Constituent	Criteria (mg/L)
	~~Para-Dichlorobenzene~~	~~0.005~~
95-50-1	o~~rtho~~-Dichlorobenzene (1,2-dichlorobenzene)	0.01
	~~Ethylbenzene~~	~~0.03~~

iii) For a chemical constituent of gasoline, diesel fuel, or heating fuel, the constituent exceeds the following:

Constituent	Criterion (mg/L)
BETX	0.095

iv) For pH, a statistically significant change occurs from background.

~~BOARD NOTE: Constituents that are carcinogens have not been~~

~~listed in subsection (a)(3)(A) because the standard is set at the PQL and any exceedence thereof is a violation subject to corrective action.~~

B) The appropriate agency shall determine if, for Class III: Special Resource Groundwater, the levels as determined by the Board are exceeded.

C) The appropriate regulatory agency shall consider whether the owner or operator reasonably demonstrates that:

i) The contamination is a result of contaminants remaining in groundwater from a prior release for which appropriate action was taken in accordance with laws and regulations in existence at the time of the release;

ii) The source of contamination is not due to the on-site release of contaminants; or

iii) The detection resulted from error in sampling, analysis, or evaluation.

D) The appropriate regulatory agency shall consider actions necessary to minimize the degree and extent of contamination.

b) The appropriate regulatory agency shall determine whether a preventive response shall ~~must~~ be undertaken based on relevant factors including, but not limited to, the considerations in subsection (a)(3).

c) After completion of preventive response pursuant to authority of an appropriate regulatory agency, the concentration of a contaminant listed in subsection (a)(3)(A) in groundwater may exceed 50% ~~percent~~ of the applicable numerical standard in Subpart D only if the following conditions are met:

1) The exceedence ~~has~~ been minimized to the extent practicable;

2) Beneficial use, as appropriate for the class of groundwater, has been assured; and

3) Any threat to public health or the environment has been minimized.

d) Nothing in this Section shall in any way limit the authority of the State or of the

United States to require or perform any corrective action process.

Constituent Name and Groundwater Quality Standard Notations

[a] The standard units are milligrams per liter ("mg/L"), except for the radium (combined 226+228) unit of picocuries per liter ("pCi/L").

[b] The standard is calculated using the Human Threshold Toxicant Advisory Concentration ("HTTAC") procedures at Appendix A.

[c] The standard is based on the Maximum Contaminant Level ("MCL"), promulgated by U.S. EPA, Office of Water, and Illinois EPA Primary Drinking

Water Standards at 35 Ill. Adm. Code 611.

[d] The constituent meets the definition of a "carcinogen" at Section 620.110.

[e] The standard is based on beneficial use for irrigation of crops, per "*Water Quality Criteria*", by National Academy of Sciences, incorporated by reference at Section 620.125.

[f] The standard is the 95% confidence concentration stated in Illinois EPA's "*Integrated Water Quality Report and Section 303(d) List*", incorporated by reference at Section 620.125.

[g] The standard is based on beneficial use for watering livestock, per "*Water Quality Criteria*", by National Academy of Sciences, incorporated by reference at Section 620.125.

[h] The standard is 50% of the U.S. EPA "action level" of 0.015 mg/L for lead. The U.S. EPA action level applies at the service connection. The standard is reduced by 50% as a safety margin, based on the assumption that 50% of water would be treated.

[i] The standard is the "LLOQ" or "LCMRL" as defined in Section 620.110.

[j] The standard is promulgated at 35 Ill. Adm. Code 611.300.

b) Organic Chemical Constituents

Except due to natural causes or as provided in Section 620.450 or subsection (d), concentrations of the following organic chemical constituents shall not be exceeded in Class I groundwater:

~~Constituent~~	~~Standard (mg/L)~~
~~Acenaphthene~~	~~0.42~~
~~Acetone~~	~~6.3~~

Constituent Name and Groundwater Quality Standard Notations

[a] The standard is the Human Threshold Toxicant Advisory Concentration ("HTTAC"), calculated using procedures at Appendix A.
[b] The constituent meets the definition of a "carcinogen" at Section 620.110.
[c] The standard is based on the Maximum Contaminant Level ("MCL"), promulgated by U.S. EPA, Office of Water, and Illinois EPA Primary Drinking Water Standards at 35 Ill. Adm. Code 611.
[d] The standard is the Human Nonthreshold Toxicant Advisory Concentration ("HNTAC"), calculated using procedures at Appendix A.
[e] The constituent meets the definition of a "mutagen" at Section 620.110.
[f] The standard is based on the Maximum Contaminant Level Goal ("MCLG"), promulgated by U.S. EPA, Office of Water.
[g] The standard is the "LLOQ" or "LCMRL" as defined in Section 620.110.
[h] The standard in based on 35 Ill. Adm. Code 302.208.

c) ~~Explosive Constituents~~

~~Concentrations of the following explosive constituents must not exceed the Class I groundwater standard:~~

~~Constituent~~	~~Standard (mg/L)~~
~~1,3-Dinitrobenzene~~	~~0.0007~~
~~2,4-Dinitrotoluene*~~	~~0.0001~~
~~2,6-Dinitrotoluene*~~	~~0.00031~~
~~HMX (High Melting Explosive, Octogen)~~	~~1.4~~

~~Nitrobenzene~~	~~0.014~~
~~RDX (Royal Demolition Explosive, Cyclonite)~~	~~0.084~~
~~1,3,5-Trinitrobenzene~~	~~0.84~~
~~2,4,6-Trinitrotoluene (TNT)~~	~~0.014~~

~~*Denotes a carcinogen.~~

~~d)~~ Complex Organic Chemical Mixtures

1) Concentrations of the following chemical constituents ~~of gasoline, diesel fuel, or heating fuel~~ shall ~~must~~ not be exceeded in Class I groundwater:

~~Constituent~~	~~Standard (mg/L)~~
~~Benzene*~~	~~0.005~~
~~BETX~~	~~11.705~~
~~*Denotes a carcinogen.~~	

CASRN	**Constituent**	**Standard (mg/L)**
71-43-2	Benzene[a]	0.005[b]
	Total BETX	11.705[c]

Constituent Name and Groundwater Quality Standard Notations

[a] The constituent meets the definition of a "carcinogen" at Section 620.110.

[b] The standard is based on the Maximum Contaminant Level ("MCL"), promulgated by U.S. EPA, Office of Water, and Illinois EPA Primary Drinking Water Standards at 35 Ill. Adm. Code 611.

[c] The standard is the total combined standard of benzene, ethylbenzene, toluene, and xylenes.

2) Atrazine and Metabolites

The total concentration of Atrazine plus Atrazine metabolites shall be compared to the Atrazine Class I groundwater standard of 0.003 mg/L.

CASRN	**Constituent**	**Standard**

		(mg/L)
1912-24-9	Atrazine	0.003[a]
	Total Atrazine and Metabolites	0.003
6190-65-4	DEA (desethyl-atrazine)	
1007-28-9	DIA (desisopropyl-atrazine)	
3397-62-4	DACT (diaminochlorotriazine)	

Groundwater Quality Standard Notation

[a] The standard is based on the Maximum Contaminant Level ("MCL"), promulgated by U.S. EPA, Office of Water, and Illinois EPA Primary Drinking Water Standards at 35 Ill. Adm. Code 611.

d)~~e)~~ pH
Except due to natural causes, a pH range of 6.5 - 9.0 units shall ~~must~~ not be exceeded in Class I groundwater.

e)~~f)~~ Beta Particle and Photon Radioactivity

1) Except due to natural causes, the average annual concentration of beta particle and photon radioactivity from man-made radionuclides shall not exceed a dose equivalent to the total body organ greater than 4 mrem/year in Class I groundwater. If two or more radionuclides are present, the sum of their dose equivalent to the total body, or to any internal organ shall not exceed 4 mrem/year in Class I groundwater except due to natural causes.

2) Except for the radionuclides listed in subsection (f)(3), the concentration of man-made radionuclides causing 4 mrem total body or organ dose equivalent shall ~~must~~ be calculated on the basis of a 2 liter per day drinking water intake using the 168-hour data in accordance with the procedure set forth in NCRP Report Number 22, incorporated by reference at Section 620.125(a).

3) Except due to natural causes, the average annual concentration assumed to produce a total body or organ dose of 4 mrem/year of the following chemical constituents shall not be exceeded in Class I groundwater:

~~Constituent~~	~~Critical Organ~~	~~Standard (pCi/L)~~
~~Tritium~~	~~Total body~~	~~20,000.0~~

~~Strontium-90 Bone marrow 8.0~~

CASRN	Constituent	Critical Organ	Standard (pCi/L)
10028-17-8	Tritium	Total Body	20,000
10098-97-2	Strontium-90	Bone Marrow	8.0

(Source: Amended at ~~36 Ill. Reg. 15206~~, effective ~~October 5, 2012~~)

Section 620.420 Groundwater Quality Standards for Class II: General Resource Groundwater

a) Inorganic Chemical Constituents

1) Except due to natural causes or as provided in Section 620.450 or subsection (a)(3) or (e) of this Section, concentrations of the following chemical constituents shall ~~must~~ not be exceeded in Class II groundwater:

~~Constituent~~	~~Standard (mg/L)~~
~~Antimony~~	~~0.024~~
~~Arsenic*~~	~~0.2~~
~~Barium~~	~~2.0~~
~~Beryllium~~	~~0.5~~
~~Cadmium~~	~~0.05~~
~~Chromium~~	~~1.0~~
~~Cobalt~~	~~1.0~~
~~Cyanide~~	~~0.6~~
~~Fluoride~~	~~4.0~~
~~Lead~~	~~0.1~~
~~Mercury~~	~~0.01~~
~~Nitrate as N~~	~~100.0~~
~~Perchlorate~~	~~0.0049~~
~~Thallium~~	~~0.02~~
~~Vanadium~~	~~0.1~~

~~*Denotes a carcinogen.~~

CASRN	Constituent	Standard (mg/L)
7440-36-0	Antimony	0.024[a]
7440-38-2	Arsenic[b]	0.2[c]
7440-39-3	Barium	2.0[d]
7440-41-7	Beryllium	0.5[e]
7440-43-9	Cadmium	0.05[f]
7440-47-3	Chromium (total)	1.0[f]
7440-48-4	Cobalt	1[c]

CASRN	Constituent	Standard (mg/L)
143-33-9	Cyanide (sodium cyanide)	0.6[c]
7681-49-4	Fluoride (sodium fluoride)	2[c]
7439-92-1	Lead	0.1[c]
7439-93-2	Lithium	2.5[e]
7487-94-7	Mercury (mercuric chloride)	0.01[c]
7439-98-7	Molybdenum	0.05[e]
14797-55-8	Nitrate as N	100[c]
14797-73-0	Perchlorate	0.0081[d]
7440-28-0	Thallium	0.002[g]
7440-62-2	Vanadium	0.1[c]

Constituent Name and Groundwater Quality Standard Notations

[a] A treatment factor of 4 is applied to the Class I groundwater quality standard. The constituent's treatment efficiency is based on the effectiveness to treat the constituent in the groundwater at an 75% removal efficiency rate for the constituent.

[b] The constituent meets the definition of a "carcinogen" at Section 620.110.

[c] The standard is based on beneficial use for watering livestock, per "*Water Quality Criteria*", by National Academy of Sciences, incorporated by reference at Section 620.125.

[d] The Class II standard is equal to the Class I groundwater quality standard.

[e] The standard is based on beneficial use for irrigation of crops, per "*Water Quality Criteria,*", by National Academy of Sciences, incorporated by reference at Section 620.125.

[f] The standard is based on beneficial use for watering livestock and irrigation of crops, per "*Water Quality Criteria*", by National Academy of Sciences, incorporated by reference at Section 620.125.

[g] A treatment factor of 10 is applied to the Class I groundwater quality standard. The constituent's treatment efficiency is based on the effectiveness to treat the constituent in the groundwater at an 90% removal efficiency rate for the constituent.

2) Except as provided in Section 620.450 or subsection (a)(3) or (e) of this Section, concentrations of the following chemical constituents shall ~~must~~ not be exceeded in Class II groundwater:

~~Constituent~~	~~Standard (mg/L)~~
~~Boron~~	~~2.0~~
~~Chloride~~	~~200.0~~
~~Copper~~	~~0.65~~
~~Iron~~	~~5.0~~
~~Manganese~~	~~10.0~~
~~Nickel~~	~~2.0~~
~~Selenium~~	~~0.05~~
~~Total Dissolved Solids (TDS)~~	~~1,200.0~~
~~Sulfate~~	~~400.0~~
~~Zinc~~	~~10.0~~

CASRN	Constituent	Standard[a]
7429-90-5	Aluminum	5[b]
7440-42-8	Boron	2[c]
16887-00-6	Chloride	200[d]
7440-50-8	Copper	0.5[b]
7439-89-6	Iron	5[d]
7439-96-5	Manganese	10[c]
7440-02-0	Nickel	2[c]
7440-14-4	Radium (combined 226+228)	5[e]
7782-49-2	Selenium	0.02[c]
7440-22-4	Silver	0.058[e]
14808-79-8	Sulfate	400[d]
	TDS (total dissolved solids)	1,200[d]
7440-66-6	Zinc	10[c]

Constituent Name and Groundwater Quality Standard Notations

[a] The standard units are milligrams per liter ("mg/L"), except for the radium (combined 226+228) unit of picocuries per liter ("pCi/L").

[b] The standard is based on beneficial use for watering livestock, per "*Water Quality Criteria*", by National Academy of Sciences, incorporated by reference at Section 620.125.

[c] The standard is based on beneficial use for irrigation of crops, per "*Water Quality Criteria*", by National Academy of Sciences, incorporated by reference at Section 620.125.

[d] The standard is the 95% confidence concentration stated in Illinois

EPA's "*Integrated Water Quality Report and Section 303(d) List*", incorporated by reference at Section 620.125.

[e] The Class II standard is equal to the Class I groundwater quality standard.

3) The standard for any inorganic chemical constituent listed in subsection (a)(2) of this Section, for barium, or for pH does not apply to groundwater within fill material or within the upper 10 feet of parent material under such fill material on a site not within the rural property class for which:

A) Prior to November 25, 1991, surficial characteristics have been altered by the placement of such fill material so as to impact the concentration of the parameters listed in subsection (a)(3) of this Section, and any on-site groundwater monitoring of such parameters is available for review by the Agency.

B) On November 25, 1991, surficial characteristics are in the process of being altered by the placement of such fill material, that proceeds in a reasonably continuous manner to completion, so as to impact the concentration of the parameters listed in subsection (a)(3) of this Section, and any on-site groundwater monitoring of such parameters is available for review by the Agency.

4) For purposes of subsection (a)(3) of this Section, the term "fill material" means clean earthen materials, slag, ash, clean demolition debris, or other similar materials.

b) Organic Chemical Constituents

1) Except due to natural causes or as provided in Section 620.450 or subsection (b)(2) or (e) of this Section, concentrations of the following organic chemical constituents shall ~~must~~ not be exceeded in Class II groundwater:

~~Constituent~~	~~Standard (mg/L)~~
~~Acenaphthene~~	~~2.1~~
~~Acetone~~	~~6.3~~
~~Alachlor*~~	~~0.010~~
~~Aldicarb~~	~~0.015~~
~~Anthracene~~	~~10.5~~

~~Atrazine~~	~~0.015~~
~~Benzene*~~	~~0.025~~

Constituent Name and Groundwater Quality Standard Notations

[a] A treatment factor of 5 is applied to the Class I groundwater quality standard. The constituent's treatment efficiency is based on the effectiveness to treat the constituent in the groundwater at an 80% removal efficiency rate for the constituent.

[b] Illinois EPA's treatment efficiency determination demonstrates a treatment factor is not applicable for the constituent. The standard is equal to the Class I groundwater quality standard.

[c] The constituent meets the definition of a "carcinogen" at Section 620.110.

[d] The constituent meets the definition of a "mutagen" at Section 620.110.

[e] A treatment factor of 10 is applied to the Class I groundwater quality standard. The constituent's treatment efficiency is based on the effectiveness to treat the constituent in the groundwater at a 90% removal efficiency rate for the constituent.

[f] A treatment factor of 2.5 is applied to the Class I groundwater quality standard. The constituent's treatment efficiency is based on the effectiveness to treat the constituent in the groundwater at a 60% removal efficiency rate for the constituent.

[g] A treatment factor of 3 is applied to the Class I groundwater quality standard. The constituent's treatment efficiency is based on the effectiveness to treat the constituent in the groundwater at a 65% removal efficiency rate for the constituent.

[h] A treatment factor of 1.5 is applied to the Class I groundwater quality standard. The constituent's treatment efficiency is based on the effectiveness to treat the constituent in the groundwater at a 30% removal efficiency rate for the constituent.

[i] The standard in based on 35 Ill. Adm. Code 302.208.

2) The standards for pesticide chemical constituents listed in subsection (b)(1) of this Section do not apply to groundwater within 10 feet of the land surface, provided that the concentrations of such constituents result from the application of pesticides in a manner consistent with the requirements of the Federal Insecticide, Fungicide and Rodenticide Act (7 USC 136 et seq.), and the Illinois Pesticide Act [415 ILCS 60].

c) ~~Explosive Constituents~~

~~Concentrations of the following explosive constituents must not exceed the Class II groundwater standard:~~

~~Constituent~~	~~Standard (mg/L)~~
~~1,3-Dinitrobenzene~~	~~0.0007~~
~~2,4-Dinitrotoluene*~~	~~0.0001~~
~~2,6-Dinitrotoluene*~~	~~0.00031~~
~~HMX (High Melting Explosive, Octogen)~~	~~1.4~~
~~Nitrobenzene~~	~~0.014~~
~~RDX (Royal Demolition Explosive, Cyclonite)~~	~~0.084~~
~~1,3,5-Trinitrobenzene~~	~~0.84~~
~~2,4,6-Trinitrotoluene (TNT)~~	~~0.014~~

~~*Denotes a carcinogen.~~

~~d)~~ Complex Organic Chemical Mixtures

1) Concentrations of the following organic chemical constituents ~~of gasoline, diesel fuel, or heating fuel~~ shall ~~must~~ not be exceeded in Class II groundwater:

~~Constituent~~ ~~Standard (mg/L)~~

~~Benzene*~~ ~~0.025~~
~~BETX~~ ~~13.525~~

~~*Denotes a carcinogen~~

CASRN	Constituent	Standard (mg/L)
71-43-2	Benzene[a]	0.025[b]
	Total BETX	13.525[c]

Constituent Name and Groundwater Quality Standard Notations

[a] The constituent meets the definition of a "carcinogen" at Section 620.110.

[b] A treatment factor of 5 is applied to the Class I groundwater quality standard. The constituent's treatment efficiency is based on the effectiveness to treat the constituent in the groundwater at an 80% removal efficiency rate for the constituent.

[c] The standard is the total combined Class II standard of benzene, ethylbenzene, toluene, and xylenes.

2) Atrazine and Metabolites

The total concentration of Atrazine plus Atrazine metabolites shall be compared to the atrazine Class I groundwater standard of 0.015 mg/L.

CASRN	Constituent	Standard (mg/L)
1912-24-9	Atrazine	0.015[a]
	Total Atrazine and Metabolites	0.015
6190-65-4	DEA (desethyl-atrazine)	
1007-28-9	DIA (desisopropyl-atrazine)	
3397-62-4	DACT (diaminochlorotriazine)	

Constituent Name and Groundwater Quality Standard Notations:

[a] A treatment factor of 5 is applied to the Class I groundwater quality

standard. The constituent's treatment efficiency is based on the effectiveness to treat the constituent in the groundwater at an 80% removal efficiency rate for the constituent.

de) pH

Except due to natural causes, a pH range of 6.5 - 9.0 units shall ~~must~~ not be exceeded in Class II groundwater that is within 5 feet of the land surface.

(Source: Amended at ~~37 Ill. Reg. 16529~~, effective ~~October 7, 2013~~)

Section 620.430 Groundwater Quality Standards for Class III: Special Resource Groundwater

Except due to natural causes, concentrations ~~Concentrations of~~ inorganic and organic chemical constituents shall ~~must~~ not exceed the standards set forth in Section 620.410, except for ~~those~~:

a) The chemical constituents for which the Board has adopted a standard pursuant to Section 620.260; and

b) The following standards set forth below for Class III Special Resource Groundwater established in accordance with Section 620.230(b) and depicted in the Environmental Register as indicated for each nature preserve.

1) The following standards are applicable for Pautler Cave Nature Preserve and Stemler Cave Nature Preserve (Environmental Register, May 2005, Num. 611), Fogelpole Cave Nature Preserve (Environmental Register May 2003, Num. 587), and Armin Krueger Speleological Nature Preserve (Environmental Register, December 2009, Num. 666):

Chloride	20 mg/L
pH	range of 7.0-9.0 Standard Units

2) The following standard is applicable for Cotton Creek Marsh Nature Preserve and Spring Grove Fen Nature Preserve (Environmental Register, July 2012, Num 697):

Chloride	45 mg/L

(Source: Amended at __ Ill. Reg. _____, effective _____)

Section 620.440 Groundwater Quality Standards for Class IV: Other Groundwater

a) Except as provided in subsection (b) or (c), Class IV: Other Groundwater standards are equal to the existing concentrations of constituents in groundwater.

b) For groundwater within a zone of attenuation as provided in 35 Ill. Adm. Code 811 and 814, the standards specified in Section 620.420 shall ~~must~~ not be exceeded, except for concentrations of contaminants within leachate released from a permitted unit.

c) For groundwater within a previously mined area, the standards set forth in Section 620.420 shall ~~must~~ not be exceeded, except for concentrations of TDS, chloride, iron, manganese, sulfates, pH, 1,3-dinitrobenzene, 2,4-dinitrotoluene, 2,6-dinitrotoluene, HMX (octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine~~high melting explosive, octogen~~), nitrobenzene, RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine~~royal demolition explosive, cyclonite~~), 1,3,5-trinitrobenzene, or TNT (2,4,6-trinitrotoluene ~~(TNT~~). For concentrations of TDS, chloride, iron, manganese, sulfates, pH, 1,3-dinitrobenzene, 2,4-dinitrotoluene, 2,6-dinitrotoluene, HMX, nitrobenzene, RDX, 1,3,5-trinitrobenzene, or ~~2,4,6-trinitrotoluene (~~TNT~~)~~, the standards are the existing concentrations.

(Source: Amended at ~~36 Ill. Reg. 15206~~, effective ~~October 5, 2012~~)

Section 620.450 Alternative Groundwater Quality Standards

a) Groundwater Quality Restoration Standards

1) Any chemical constituent in groundwater within a groundwater management zone is subject to this Section.

2) Except as provided in subsections (a)(3) or (a)(4), the standards as specified in Sections 620.410, 620.420, 620.430, and 620.440 apply to any chemical constituent in groundwater within a groundwater management zone.

3) Prior to completion of a corrective action described in Section 620.250(a), the standards as specified in Sections 620.410, 620.420, 620.430, and 620.440 are not applicable to such released chemical constituent, provided that the initiated action proceeds in a timely and appropriate manner.

4) After completion of a corrective action as described in Section 620.250(a), the standard for such released chemical constituent is:

A) The standard as set forth in Section 620.410, 620.420, 620.430, or 620.440, if the concentration as determined by groundwater monitoring of such constituent is less than or equal to the standard for the appropriate class set forth in those Sections; or

B) The concentration as determined by groundwater monitoring, if such concentration exceeds the standard for the appropriate class set forth in Section 620.410, 620.420, 620.430, or 620.440 for such constituent, and:

i) To the extent practicable, the exceedence has been minimized and beneficial use, as appropriate for the class of groundwater, has been returned; and

ii) Any threat to public health or the environment has been minimized.

5) The Agency shall develop and maintain a listing of concentrations derived pursuant to subsection (a)(4)(B). This list shall be made available to the public and be updated periodically, but no less frequently than semi-annually. This listing shall be published in the Environmental Register.

b) Coal Reclamation Groundwater Quality Standards

1) Any inorganic chemical constituent or pH in groundwater, within an underground coal mine, or within the cumulative impact area of groundwater for which the hydrologic balance has been disturbed from a permitted coal mine area pursuant to the Surface Coal Mining Land Conservation and Reclamation Act [225 ILCS 720] and 62 Ill. Adm. Code 1700 through 1850, is subject to this Section.

2) Prior to completion of reclamation at a coal mine, the standards as specified in Sections 620.410(a) and (e), 620.420(a) and (e), 620.430, and 620.440 are not applicable to inorganic constituents and pH.

3) After completion of reclamation at a coal mine, the standards as specified in Sections 620.410(a) and (e), 620.420(a), 620.430, and 620.440 are applicable to inorganic constituents and pH, except:

A) The concentration of total dissolved solids ("TDS") shall ~~must~~ not exceed:

i) The post-reclamation concentration or 3000 mg/L, whichever is less, for groundwater within the permitted area; or

ii) The post-reclamation concentration of TDS shall ~~must~~ not exceed the post-reclamation concentration or 5000 mg/L, whichever is less, for groundwater in underground coal mines and in permitted areas reclaimed after surface coal mining if the Illinois Department of Mines and Minerals and the Agency have determined that no significant resource groundwater existed prior to mining (62 Ill. Adm. Code 1780.21(f) and (g)); and

B) For chloride, iron, manganese, and sulfate, the post-reclamation concentration within the permitted area shall ~~must~~ not be exceeded.

C) For pH, the post-reclamation concentration within the permitted area shall ~~must~~ not be exceeded within Class I: Potable Resource Groundwater as specified in Section 620.210(a)(4).

D) For 1,3-dinitrobenzene, 2,4-dinitrotoluene, 2,6-dinitrotoluene, HMX (octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine~~high melting explosive, octogen~~), nitrobenzene, RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine~~royal demolition explosive, cyclonite~~), 1,3,5-trinitrobenzene, and TNT (2,4,6-trinitrotoluene ~~(TNT)~~, the post-reclamation concentration within the permitted area shall ~~must~~ not be exceeded.

4) A refuse disposal area (not contained within the area from which overburden has been removed) is subject to the inorganic chemical constituent and pH requirements of:

A) 35 Ill. Adm. Code 302.Subparts B and C, except due to natural causes, for such area that was placed into operation after February 1, 1983, and before the effective date of this Part, provided that the groundwater is a present or a potential source of water for public or food processing;

B) Section 620.440(c) for such area that was placed into operation prior to February 1, 1983, and has remained in continuous operation since that date; or

C) Subpart D of this Part for such area that is placed into operation on or after the effective date of this Part.

5) For a refuse disposal area (not contained within the area from which overburden has been removed) that was placed into operation prior to February 1, 1983, and is modified after that date to include additional area, this Section applies to the area that meets the requirements of subsection (b)(4)(C) and the following applies to the additional area:

A) 35 Ill. Adm. Code 302.Subparts B and C, except due to natural causes, for such additional refuse disposal area that was placed into operation after February 1, 1983, and before the effective date of this Part, provided that the groundwater is a present or a potential source of water for public or food processing; and

B) Subpart D for such additional area that was placed into operation on or after the effective date of this Part.

6) A coal preparation plant (not located in an area from which overburden has been removed) which contains slurry material, sludge, or other

precipitated process material, is subject to the inorganic chemical constituent and pH requirements of:

A) 35 Ill. Adm. Code 302.Subparts B and C, except due to natural causes, for such plant that was placed into operation after February 1, 1983 and before the effective date of this Part, provided that the groundwater is a present or a potential source of water for public or food processing;

B) Section 620.440(c) for such plant that was placed into operation prior to February 1, 1983, and has remained in continuous operation since that date; or

C) Subpart D for such plant that is placed into operation on or after the effective date of this Part.

7) For a coal preparation plant (not located in an area from which overburden has been removed) which contains slurry material, sludge or other precipitated process material, that was placed into operation prior to February 1, 1983, and is modified after that date to include additional area, this Section applies to the area that meets the requirements of subsection (b)(6)(C) and the following applies to the additional area:

A) 35 Ill. Adm. Code 302.Subparts B and C, except due to natural causes, for such additional area that was placed into operation after February 1, 1983, and before the effective date of this Part, provided that the groundwater is a present or a potential source of water for public or food processing; and

B) Subpart D for such additional area that was placed into operation on or after the effective date of this Part.

c) Groundwater Quality Standards for Certain Groundwater Subject to a No Further Remediation Letter under Part 740. While a No Further Remediation Letter is in effect for a region formerly encompassed by a groundwater management zone established under 35 Ill. Adm. Code 740.530, the groundwater quality standards for "contaminants of concern", as defined in 35 Ill. Adm. Code 740.120, within such area shall be the groundwater objectives achieved as documented in the approved Remedial Action Completion Report.

(Source: Amended at ~~36 Ill. Reg. 15206~~, effective ~~October 5, 2012~~)

Section 620.510 Monitoring and Analytical Requirements

a) Representative Samples
A representative sample shall be taken from locations as specified in Section 620.505.

b) Sampling and Analytical Procedures

1) Samples shall ~~must~~ be collected in accordance with the procedures set forth in the documents pertaining to groundwater monitoring and analysis ~~"Methods for Chemical Analysis of Water and Wastes," "Methods for the Determination of Inorganic Substances in Environmental Samples," "Methods for the Determination of Metals in Environmental Samples," "Methods for the Determination of Organic Compounds in Drinking Water," "Methods for the Determination or Organic Compounds in Drinking Water, Supplement I," "Methods for the Determination of Organic Compounds in Drinking Water, Supplement II," "Methods for the Determination of Organic Compounds in Drinking Water, Supplement III," "Methods for the Determination of Organic and Inorganic Compounds in Drinking Water," "Prescribed Procedures for Measurement of Radioactivity in Drinking Water," "Procedures for Radiochemical Analysis of Nuclear Reactor Aqueous Solutions," "Radiochemical Analytical Procedures for Analysis of Environmental Samples," "Radiochemistry Procedures Manual," "Practical Guide for Ground Water Sampling," "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods" (SW-846), 40 CFR 136, appendix B, 40 CFR 141.80, 40 CFR 141.61, and 40 CFR 141.62, "Techniques of Water Resources Investigations of the United States Geological Survey, Guidelines for Collection and Field Analysis of Ground Water Samples for Selected Unstable Constituents," "Practical Guide for Ground-Water Sampling," "Techniques of Water Resources Investigations of the United States Geological Survey, Guidelines for Collection and Field Analysis of Ground-Water Samples for Selected Unstable Constituents,"~~ incorporated by reference at Section 620.125 or other procedures adopted by the appropriate regulatory agency.

2) Groundwater elevation in a groundwater monitoring well shall ~~must~~ be determined and recorded when necessary to determine the gradient.

3) Unless specified otherwise by regulations, statistical methods used to determine naturally occurring groundwater quality background

concentrations of contaminants shall be conducted in accordance with "Statistical Analysis of Groundwater Monitoring Data at RCRA Facilities, (March 2009 Unified Guidance)," as incorporated by reference in Section 620.125 for use with prediction limits and all other statistical tests including, but not limited to, confidence limits and control charts.

43) The analytical methodology used for the analysis of constituents in Subparts C and D shall ~~must~~ be consistent with both of the following:

A) The methodology shall ~~must~~ have a LLOQ or LCMRL~~PQL~~ at or below the preventive response levels of Subpart C or groundwater standard set forth in Subpart D, whichever is applicable; and

B) "Methods for Chemical Analysis of Water and Wastes," "Methods for the Determination of Inorganic Substances in Environmental Samples," "Methods for the Determination of Metals in Environmental Samples," "Methods for the Determination of Organic Compounds in Drinking Water," "Methods for the Determination of Organic Compounds in Drinking Water, Supplement I," "Methods for the Determination of Organic Compounds in Drinking Water, Supplement II," "Methods for the Determination of Organic Compounds in Drinking Water, Supplement III," "Methods for the Determination of Organic and Inorganic Compounds in Drinking Water," "Prescribed Procedures for Measurement of Radioactivity in Drinking Water," "Procedures for Radiochemical Analysis of Nuclear Reactor Aqueous Solutions," "Radiochemical Analytical Procedures for Analysis of Environmental Samples," "Radiochemistry Procedures Manual," "Practical Guide for Ground Water Sampling," "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods" (SW-846), 40 CFR 136, appendix B, 40 CFR 141.80, 40 CFR 141.61, and 40 CFR 141.62, "Techniques of Water Resources Investigations of the United States Geological Survey, Guidelines for Collection and Field Analysis of Ground Water Samples for Selected Unstable Constituents," "Practical Guide for Ground-Water Sampling", "Techniques of Water Resources Investigations of the United States Geological Survey, Guidelines for Collection and Field Analysis of Ground-Water Samples for Selected Unstable Constituents", or other procedures incorporated by reference at Section 620.125.

c) Reporting Requirements

At a minimum, groundwater monitoring analytical results shall ~~must~~ include information, procedures, and techniques for:

1) Sample collection (including but not limited to name of sample collector, time and date of the sample, method of collection, and identification of the monitoring location);

2) Sample preservation and shipment (including but not limited to field quality control);

3) Analytical procedures (including but not limited to the MDL, LLOQ, ~~method detection limits and~~ or the LCMRL~~PQLs~~); and

4) Chain of custody control.

(Source: Amended at ~~36 Ill. Reg. 15206~~, effective ~~October 5, 2012~~)

SUBPART F: HEALTH ADVISORIES

Section 620.601 Purpose of a Health Advisory

This Subpart establishes procedures for the issuance of a Health Advisory that sets forth guidance levels that, in the absence of standards under Section 620.410, shall ~~must~~ be considered by the Agency in:

a) Establishing groundwater cleanup or action levels whenever there is a release or substantial threat of a release of:

1) A hazardous substance or pesticide; or

2) Other contaminant that represents a significant hazard to public health or the environment.

b) Determining whether the community water supply is taking its raw water from a site or source consistent with the siting and source water requirements of 35 Ill. Adm. Code 604.200~~611.114 and 611.115~~.

c) Developing Board rulemaking proposals for new or revised numerical standards.

d) Evaluating mixtures of chemical substances.

(Source: Amended at, effective)

Section 620.605 Issuance of a Health Advisory

a) The Agency shall issue a Health Advisory for a chemical substance if all of the following conditions are met:

1) A community water supply well is sampled and a substance is detected and confirmed by resampling;

2) There is no standard under Section 620.410 for such chemical substance; and

3) The chemical substance is toxic or harmful to human health according to the procedures of Appendix A, B, or C.

b) The Health Advisory shall ~~must~~ contain a general description of the characteristics of the chemical substance, the potential adverse health effects, and a guidance level to be determined as follows:

1) If disease or functional impairment is caused due to a physiological mechanism for where there is a threshold dose below which no damage occurs, the guidance level for any such substance shall be the Maximum Contaminant Level Goal ("MCLG"), adopted by U.S. EPA for such substance, 40 CFR 136, appendix B, 40 CFR 141.80, 40 CFR 141.61, and 40 CFR 141.62, incorporated by reference at Section 620.125. If there is no MCLG for the substance, the guidance level is either the Human Threshold Toxicant Advisory Concentration or the Human Nonthreshold Toxicant Advisory Concentration for such substance as determined in accordance with Appendix A, whichever is less, unless the lower concentration for such substance is less than the lowest appropriate LLOQ ~~PQL~~ specified in "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods", EPA Publication No. SW-846 (SW-846), incorporated by reference at Section 620.125, or the LCMRL specified in the drinking water methods incorporated by reference at Section 620.125 for the substance. If the concentration for such substance is less than the lowest appropriate LLOQ or LCMRL~~PQL~~ for the substance ~~specified in SW-846~~, incorporated by reference at Section 620.125, the guidance level is the lowest appropriate LLOQ or LCMRL~~PQL~~.

~~2) If the chemical substance is a carcinogen, the guidance level for any such chemical substance is the one-in-one-million cancer risk concentration, unless the concentration for such substance is less than the lowest~~

~~appropriate PQL specified in "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods," EPA Publication No. SW-846 (SW-846), incorporated by reference at Section 620.125 for such substance. If the concentration for such substance is less than the lowest appropriate PQL for the substance specified in SW-846, the guidance level is the lowest appropriate PQL. The one-in-one-million cancer risk concentration, the Human Nonthreshold Toxicant Advisory Concentration (HNTAC), shall be determined according to the following equation:~~

$$\frac{HNTAC}{(mg/L)} = \frac{TR \times BW \times AT \times 365\ days/year}{SFo \times IR \times EF \times ED}$$

~~Where:~~

~~TR = Target Risk = 1.0E-06~~
~~BW = Body Weight = 70 kg~~
~~AT = Averaging Time = 70 years~~
~~SFo = Oral Slope Factor = Chemical-specific~~
~~IR = Daily Water Ingestion Rate = 2 liters/day~~
~~EF = Exposure Frequency = 350 days/year~~
~~ED = Exposure Duration = 30 years~~

(Source: Amended at ~~36 Ill. Reg. 15206~~, effective ~~October 5, 2012~~)

Section 620.APPENDIX A Procedures for Determining Human ~~Threshold~~ Toxicant Advisory Concentrations for Class I: Potable Resource Groundwater

a) Calculating the Human Threshold Toxicant Advisory Concentration for Noncancer Effects

For those substances for which U.S. EPA has not adopted a Maximum Contaminant Level Goal ("MCLG"), the Human Threshold Toxicant Advisory Concentration is calculated as follows:

$$HTTAC = \frac{RSC \bullet ADE}{W}$$

~~$$HTTAC = \frac{RSCxADE}{W}$$~~

Where:

HTTAC = Human Threshold Toxicant Advisory Concentration in milligrams per liter ("mg/L");

RSC = Relative contribution of the amount of the exposure to a chemical via drinking water when compared to the total exposure to that chemical from all sources. Valid chemical-specific data shall be used if available. If valid chemical-specific data are not available, a value of 20% (= 0.20) shall ~~must~~ be used;

ADE = Acceptable Daily Exposure of substance in milligrams per day ("mg/d") as determined pursuant to subsection (b); and

W = Per capita daily water consumption for a child (0-6 years of age, equal to 0.78~~2~~ liters per day ("L/d").

b) Procedures for Determining Acceptable Daily Exposures for Class I: Potable Resource Groundwater

1) The Acceptable Daily Exposure ("ADE") represents the maximum amount of a threshold toxicant in milligrams per day ("mg/d"), which if ingested daily by a child from 0 to 6 years of age~~for a lifetime~~ results in no adverse

effects ~~to humans~~. Subsections (b)(2) through (b)(6) list, in prescribed order, methods for determining the ADE in Class I: Potable Resource Groundwater.

2) ~~For those substances for which the USEPA has derived a Verified Oral Reference Dose for humans, USEPA's Reference Dose given in milligrams per kilogram per day (mg/kg/d), as determined in accordance with methods provided in National Primary and Secondary Drinking Water Regulations, 40 CFR 136, appendix B, 40 CFR 141.80, 40 CFR 141.61, and 40 CFR 141.62, incorporated by reference at Section 620.125, must be used. The ADE equals the product of multiplying the Reference Dose by 70 kilograms (kg), which is the assumed average weight of an adult human.~~ For those substances for which noncancer toxicity values have been derived and presented in units of milligrams per kilogram per day ("mg/kg/day"), the ADE equals the product of multiplying the toxicity value by 15 kilograms ("kg"), which is the assumed average weight of a child 0 to 6 years of age.

3) ~~For those substances for which a no observed adverse effect level for humans (NOAEL-H) exposed to the substance has been derived, the ADE equals the product of multiplying one-tenth of the NOAEL-H given in milligrams of toxicant per kilogram of body weight per day (mg/kg/d) by the average weight of an adult human of 70 kilograms (kg). If two or more studies are available, the lowest NOAEL-H must be used in the calculation of the ADE.~~ For those substances for which an oral reference dose is not available, the ADE equals the value of the most sensitive Point of Departure ("POD") as determined by Benchmark Dose Modeling or the NOAEL/LOAEL approach consistent with current U.S. EPA RfD guidance, followed by the derivation of a Human Equivalent Dose ("HED") using physiologically based pharmacokinetic ("PBPK") modeling or Dose Adjustment Factor ("DAF"), then divided by the total Uncertainty Factor ("UF") and modifying factor ("MF"), if applicable. The value is then multiplied by 15 kg (the assumed average weight of a child 0 – 6 years of age). The equation is depicted below:

$$ADE = \frac{POD}{Total\ UF} \bullet 15kg$$

4) ~~For those substances for which only a lowest observed adverse effect level for humans (LOAEL-H) exposed to the substance has been derived, one-tenth the LOAEL-H must be substituted for the NOAEL-H in subsection~~

~~(b)(3).~~ Uncertainty Factors shall be applied to the Point of Departure ("POD") in increments of 1, 3, or 10, not to exceed a total UF of 10,000, and shall ~~must~~ be used consistent with U.S. EPA guidance. A composite UF of 3 and 10 shall be expressed as 30 whereas a composite UF of 3 and 3 shall be expressed as 10. UFs may be used to account for the following:

A) Interspecies Variability

B) Intraspecies Variability

C) Lowest Observable Adverse Effects Level ("LOAEL") to No Observed Adverse Effects Level ("NOAEL") Uncertainty

D) Database Deficiencies

E) Subchronic to Chronic Duration

~~5) For those substances for which a no observed adverse effect level has been derived from studies of mammalian test species (NOAEL-A) exposed to the substance, the ADE equals the product of multiplying 1/100 of the NOAEL-A given in milligrams toxicant per kilogram of test species weight per day (mg/kg/d) by the average weight of an adult human of 70 kilograms (kg). Preference will be given to animal studies having High Validity, as defined in subsection (c), in the order listed in that subsection. Studies having a Medium Validity must be considered if no studies having High Validity are available. If studies of Low Validity must be used, the ADE must be calculated using 1/1000 of the NOAEL-A having Low Validity instead of 1/100 of the NOAEL-A of High or Medium Validity, except as described in subsection (b)(6). If two or more studies among different animal species are equally valid, the lowest NOAEL-A among animal species must be used in the calculation of the ADE. Additional considerations in selecting the NOAEL-A include:~~

~~A) If the NOAEL-A is given in milligrams of toxicant per liter of water consumed (mg/L), prior to calculating the ADE the NOAEL-A must be multiplied by the average daily volume of water consumed by the mammalian test species in liters per day (L/d) and divided by the average weight of the mammalian test species in kilograms (kg).~~

~~B) If the NOAEL-A is given in milligrams of toxicant per kilogram of~~

~~food consumed (mg/kg), prior to calculating the ADE, the NOAEL-A must be multiplied by the average amount in kilograms of food consumed daily by the mammalian test species (kg/d) and divided by the average weight of the mammalian test species in kilograms (kg).~~

~~C) If the mammalian test species was not exposed to the toxicant each day of the test period, the NOAEL-A must be multiplied by the ratio of days of exposure to the total days of the test period.~~

~~D) If more than one equally valid NOAEL-A is available for the same mammalian test species, the best available data must be used.~~

~~6) For those substances for which a NOAEL-A is not available but the lowest observed adverse effect level (LOAEL-A) has been derived from studies of mammalian test species exposed to the substance, one-tenth of the LOAEL-A may be substituted for the NOAEL-A in subsection (b)(5). The LOAEL-A must be selected in the same manner as that specified in subsection (b)(5). One-tenth the LOAEL-A from a study determined to have Medium Validity may be substituted for a NOAEL-A in subsection (b)(3) if the NOAEL-A is from a study determined to have Low Validity, or if the toxicity endpoint measured in the study having the LOAEL-A of Medium Validity is determined to be more biologically relevant than the toxicity endpoint measured in the study having the NOAEL-A of Low Validity.~~

c) Procedures for Establishing Validity of Data from Animal Studies

1) High Validity Studies

A) High validity studies use a route of exposure by ingestion or gavage, and are based upon:

i) Data from animal carcinogenicity studies with a minimum of 2 dose levels and a control group, 2 species, both sexes, with 50 animals per dose per sex, and at least 50 percent survival at 15 months in mice and 18 months in rats and at least 25 percent survival at 18 months in mice and 24 months in rats;

ii) Data from animal chronic studies with a minimum of 3 dose levels and a control group, 2 species, both sexes, with

40 animals per dose per sex, and at least 50 percent survival at 15 months in mice and 18 months in rats and at least 25 percent survival at 18 months in mice and 24 months in rats, and a well-defined NOAEL; or

iii) Data from animal subchronic studies with a minimum of 3 dose levels and control, 2 species, both sexes, 4 animals per dose per sex for non-rodent species or 10 animals per dose per sex for rodent species, a duration of at least 5% of the test species' lifespan, and a well-defined NOAEL.

B) Supporting studies which reinforce the conclusions of a study of Medium Validity may be considered to raise such a study to High Validity.

2) Medium Validity Studies
Medium validity studies are based upon:

A) Data from animal carcinogenicity, chronic, or subchronic studies in which minor deviations from the study design elements required for a High Validity Study are found, but which otherwise satisfy the standards for a High Validity Study;

B) Data from animal carcinogenicity and chronic studies in which at least 25 percent survival is reported at 15 months in mice and 18 months in rats (a lesser survival is permitted at the conclusion of a longer duration study, but the number of surviving animals should not fall below 20 percent per dose per sex at 18 months for mice and 24 months for rats), but which otherwise satisfy the standards for a High Validity Study;

C) Data from animal subchronic or chronic studies in which a Lowest Observable Adverse Effect Level (LOAEL) is determined, but which otherwise satisfy the standards for a High Validity Study; or

D) Data from animal subchronic or chronic studies which have an inappropriate route of exposure (for example, intraperitoneal injection or inhalation) but which otherwise satisfy the standards for a High Validity Study, with correction factors for conversion to the oral route.

3) Low Validity Studies

Low validity studies are studies not meeting the standards set forth in subsection (c)(1) or (c)(2).

d) Calculating a Human Nonthreshold Toxicant Advisory Concentration ("HNTAC") for Cancer Risk

The Human Nonthreshold Toxicant Advisory Concentration ("HNTAC") is calculated as follows:

1) For chemicals designated by U.S. EPA as "mutagens," the HNTAC is calculated as follows:

$$HNTAC = \frac{TR \bullet \left(AT \bullet 365 \frac{days}{year}\right)}{SF_o \bullet IFWM_{adj}}$$

Where:

HNTAC	=	Human Nonthreshold Toxicant Advisory Concentration, equal to milligrams per liter (mg/L)
TR	=	Target Cancer Risk, equal to one-in-one million cancer risk (1E-06)
AT	=	Averaging Time, equal to 70 years
SF_o	=	Oral Slope Factor (chemical-specific), equal to $(mg/kg\text{-}day)^{-1}$
$IFWM_{adj}$	=	Age-Adjusted Mutagenic Drinking Water Ingestion Rate, equal to 1,019.9 liters per kilogram (L/kg)

2) For chemicals not designated by U.S. EPA as "mutagens," the HNTAC is calculated as follows:

$$HNTAC = \frac{TR \bullet \left(AT \bullet 365 \frac{days}{year}\right)}{SF_o \bullet IFW_{adj}}$$

Where:

HNTAC	=	Human Nonthreshold Toxicant Advisory Concentration, equal to milligrams per liter (mg/L)
TR	=	Target Cancer Risk, equal to one-in-one million cancer risk (1E-06)
AT	=	Averaging Time, equal to 70 years
SF_o	=	Oral Slope Factor (chemical-specific), equal to $(mg/kg\text{-}day)^{-1}$
IFW_{adj}	=	Age-Adjusted Drinking Water Ingestion Rate, equal to 327.95 liters per kilogram (L/kg)

(Source: Amended at ~~36 Ill. Reg. 15206~~, effective ~~October 5, 2012~~)

Section 620.APPENDIX B Procedures for Determining Hazard Indices for Class I: Potable Resource Groundwater for Mixtures of Similar-Acting Substances

a) This appendix describes procedures for evaluating mixtures of similar-acting substances which may be present in Class I: Potable Resource Groundwaters. Except as provided otherwise in subsection (c), subsections (d) through (h) describe the procedure for determining the Hazard Index for mixtures of similar-acting substances.

b) For the purposes of this appendix, a "mixture" means two or more substances which are present in Class I: Potable Resource Groundwater which may or may not be related either chemically or commercially, but which are not complex mixtures of related isomers and congeners which are produced as commercial products (for example, PCBs or technical grade chlordane).

c) The following substances listed in Appendix E~~Section 620.410~~ are ~~mixtures of similar actings~~similar-acting substances:

~~1) Mixtures of ortho-Dichlorobenzene and para-Dichlorobenzene. The Hazard Index (HI) for such mixtures is determined as follows:~~

~~HI = [ortho-Dichlorobenzene]/0.6 + [para-Dichlorobenzene]/0.075~~

~~2) Mixtures of 1,1-Dichloroethylene and 1,1,1-trichloroethane. The Hazard Index (HI) for such mixtures is determined as follows:~~

~~HI = [1,1-Dichloroethylene]/0.007 + [1,1,1-trichloroethane]/0.2~~

d) When two or more substances occur together in a mixture, the additivity of the toxicities of some or all of the substances will be considered when determining health-based standards for Class I: Potable Resource Groundwater. This is done by the use of a dose addition model with the development of a Hazard Index for the mixture of substances with similar-acting toxicities. This method does not address synergism or antagonism. Guidelines for determining when the dose addition of similar-acting substances is appropriate are presented in Appendix C. The Hazard Index is calculated as follows:

$$HI = [A]/ALA + [B]/ALB + \ldots [I]/ALI$$

Where:

HI	=	Hazard Index, unitless.
[A], [B], [I]	=	Concentration of each similar-acting substance in groundwater in milligrams per liter ("mg/L").
ALA, ALB, ALI	=	The acceptable level of each similar-acting substance in the mixture in milligrams per liter ("mg/L").

e) For substances that are considered to have a threshold mechanism of toxicity, the acceptable level is:

1) The standards listed in Section 620.410; or

2) For those substances for which standards have not been established in Section 620.410, the Human Threshold Toxicant Advisory Concentration ("HTTAC") as determined in Appendix A.

f) For substances that are carcinogens, the acceptable level is:

1) The standards listed in Section 620.410; or

2) For those substances for which standards have not been established under Section 620.410, the one-in-one-million cancer risk concentration, unless the concentration for such substance is less than the lowest appropriate LLOQ~~PQL~~ specified in "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods," EPA Publication No. SW-846, incorporated by reference at Section 620.125, or the LCMRL specified in the drinking water methods incorporated by reference at Section 620.125 for the substance, incorporated by reference at Section 620.125, the guidance level is ~~in which case~~ the lowest appropriate LLOQ or LCMRL~~PQL shall be the acceptable level~~.

g) Since the assumption of dose addition is most properly applied to substances that induce the same effect by similar modes of action, a separate Hazard Index shall ~~must~~ be generated for each toxicity endpoint of concern.

h) In addition to meeting the individual substance objectives, a Hazard Index shall ~~must~~ be less than or equal to 1 for a mixture of similar-acting substances.

(Source: Amended at ~~36 Ill. Reg. 15206~~, effective ~~October 5, 2012~~)

Section 620.APPENDIX C Guidelines for Determining When Dose Addition of Similar-Acting Substances in Class I: Potable Resource Groundwaters is Appropriate

a) Substances shall ~~must~~ be considered similar-acting if:

1) The substances have the same target in an organism (for example, the same organ, organ system, receptor, or enzyme).

2) The substances have the same mode of toxic action. These actions may include, for example, central nervous system depression, liver toxicity, or cholinesterase inhibition.

b) Substances that have fundamentally different mechanisms of toxicity (threshold toxicants vs. carcinogens) shall ~~must~~ not be considered similar-acting. However, carcinogens which also cause a threshold toxic effect should be considered in a mixture with other similar-acting substances having the same threshold toxic effect. In such a case, an Acceptable Level for the carcinogen shall ~~must~~ be derived for its threshold effect, using the procedures described in Appendix A.

c) Substances which are components of a complex mixture of related compounds which are produced as commercial products (for example, PCBs or technical grade chlordane) are not mixtures, as defined in Appendix B. Such complex mixtures are equivalent to a single substance. In such a case, the Human Threshold Toxicant Advisory Concentration may be derived for threshold effects of the complex mixture, using the procedures described in Appendix A, if valid toxicological or epidemiological data are available for the complex mixture. If the complex mixture is a carcinogen, the Health Advisory Concentration is the one-in-one-million cancer risk concentration, unless the lower concentration for such substance is less than the lowest appropriate LLOQ~~PQL~~ specified in "Test Methods for Evaluating Solid Wastes, Physical/Chemical Methods," EPA Publication No. SW-846, incorporated by reference at Section 620.125, or the LCMRL specified in the drinking water methods incorporated by reference at Section 620.125 for the substance.~~,~~ If the concentration for such substance is less than ~~in which case~~ the lowest appropriate LLOQ or LCMRL~~PQL~~ for the substance incorporated by reference at Section 620.125, the guidance level is the lowest appropriate LLOQ or LCMRL~~shall be the Health Advisory Concentration~~.

(Source: Amended at ~~36 Ill. Reg. 15206~~, effective ~~October 5, 2012~~)

Section 620.APPENDIX E: Similar-acting Substances

Table A: -Similar-acting Noncarcinogenic Constituents

Cholinesterase Inhibition	
116-06-3	Aldicarb
1563-66-2	Carbofuran
Circulatory System	
7440-36-0	Antimony
7440-38-2	Arsenic
1912-24-9	Atrazine
94-75-7	2,4-D (2,4-dichlorophenoxy acetic acid)
206-44-0	Fluoranthene
86-73-7	Fluorene
13252-13-6	HFPO-DA (hexafluoropropylene oxide dimer acid, GenX)
98-95-3	Nitrobenzene
355-46-4	PFHxS (perfluorohexanesulfonic acid)

117-81-7	Di(2-ethylhexyl)phthalate
121-14-2	2,4-Dinitrotoluene
606-20-0	2,6-Dinitrotoluene
123-91-1	1,4-Dioxane (*p*-dioxane)

58-89-9	*gamma*-HCH (*gamma*-hexachlorocyclohexane, lindane)
76-44-8	Heptachlor
1024-57-3	Heptachlor epoxide
1336-36-3	PCBs (polychlorinated biphenyls as decachloro-biphenyl)
335-67-1	PFOA (perfluorooctanoic acid)
87-86-5	Pentachlorophenol
127-18-4	Tetrachloroethylene
8001-35-2	Toxaphene
79-01-6	Trichloroethylene
75-01-4	Vinyl Chloride
Mammary Gland	
121-14-2	2,4-Dinitrotoluene
606-20-0	2,6-Dinitrotoluene
