The Dunleith Formation (Templeton and Willman, 1963, p. 114), which overlies the Guttenberg Formation and underlies the Wise Lake Formation in the Galena Group, is named for Dunleith Township, Jo Daviess County. The type section is an exposure in the Mississippi River bluffs on the north side of East Dubuque (SE 19, 29N-2W), where the formation is 132 feet thick, including the unexposed lower 20 feet (fig. O-2B). The type section for the lowest strata (the St. James and Buckhorn Members) is at Buena Vista, Stephenson County. The Dunleith Formation is exposed (fig. O-2C) in most of the area described in the discussion of the Galena Group. It is commonly 120-125 feet thick in the northern outcrop area and is 135 feet thick near New London, Missouri, where it is overlain by the Wise Lake Formation. South of New London, where the Wise Lake and upper Dunleith beds are missing, the formation is only about 100 feet thick. At East Dubuque the lower 27 feet is dolomite-mottled lithographic limestone and the upper 85 feet is dolomite. South and east of there, the limestone is progressively replaced by dolomite from the top down, and at Galena and farther east the formation is all dolomite, except for local areas such as north of Morris, Grundy County, in which it is dolomite-mottled limestone. In northwestern Illinois the Dunleith consists of alternating pure and argillaceous units. The pure units are medium to thick bedded and vuggy and the argillaceous units thin to medium bedded and dense. Chert nodules are common, particularly in the argillaceous units. The formation is subdivided into 10 conformable members, most of them consisting of a pure unit overlain by a thinner argillaceous unit. The Buckhorn (at the base) is overlain by the St. James, Beecher, Eagle Point, Fairplay, Mortimer, Rivoli, Sherwood, Wall, and Wyota Members. In Illinois the upper six members are recognized only in the northern dolomite and limestone facies. The argillaceous content decreases eastward and southward, and the member differentiation is less useful in the central northern outcrop area, although most of the members can be identified by such minor characteristics as abundance and types of chert, persistent thin bentonite beds, corrosion zones, fucoidal zones, and common fossils. In subsurface in northeastern Illinois the formation is even purer, contains little or no chert, and its members have not been differentiated (Buschbach, 1964). The southern limestone facies occurs throughout central and southern Illinois but is exposed only at Lowell, La Salle County, at Valmeyer, Monroe County, and near West Point Landing, Calhoun County. The lower four members are recognizable in the outcrops but rarely in subsurface. The overlying part of the Dunleith is divided into only two members, a lower massive calcarenite (Moredock Member) and an upper cherty, thin- to medium-bedded, calcarenitic limestone (New London Member). The Dunleith is sparsely fossiliferous in the dolomite facies, although *Paucicrura* [*Dalmanella*], *Prasopora*, and *Receptaculites* (fig. O-5) characterize certain zones. Bryozoans and crinoidal debris are particularly abundant in the southern limestone facies. The Dunleith Formation is called the "Drab" in the lead-zinc district, and it is equivalent to the upper part of the Decorah Shale and the lower part of the Prosser Limestone in the Mississippi Valley north of Illinois, to the Jessamine, Benson, and Brannon Members of the Lexington Limestone in Kentucky, to the upper part of the Hermitage and most of the Bigby-Cannon Formations in Tennessee, and to the Kirkfield Formation, the Sherman Fall Formation, and the Rust Member of the Coburg Formation in New York.

Buckhorn Member—The Buckhorn Member of the Dunleith Formation (Templeton and Willman, 1963, p. 119), the basal member, is named for Buckhorn Corners, Stephenson County, 2 miles east of the type section in a quarry at Buena Vista (NW SW NE 15, 28N-7E), where the member is 8.3 feet thick. It is commonly 5-8 feet thick but is generally absent in southwestern Illinois, where it is overlapped by the St. James Member. The Buckhorn consists of argillaceous, medi-

um to coarse, blue-gray dolomite heavily speckled with black, particularly at the top. It contains green shale partings and in the northwestern area is slightly sandy. It locally contains several very thin layers of bentonite. *Paucicrura [Dalmanella] rogata* is especially common. The Buckhorn is called the "Blue" in the lead-zinc district. With the overlying St. James Member, it is equivalent to the Ion Member at the top of the Decorah in the region northwest of Illinois.

St. James Member—The St. James Member of the Dunleith Formation (Templeton and Willman, 1963, p. 119), which overlies the Buckhorn Member, is named for St. James Cemetery in Stephenson County, 3 miles northwest of the type section, in the same exposure as the Buckhorn type section, where the St. James is 13.3 feet thick. It is called the "Gray" in the lead-zinc district. The St. James Member commonly is about 14 feet thick in the dolomite facies in northern Illinois and 8-12 feet thick in the southern limestone facies. In northern Illinois it is light tan, pure, medium-bedded, vuggy dolomite, but thin green shale partings are common in the upper 2-4 feet. It has black speckles but not as many as the Buckhorn. *Prasopora simulatrix* (fig. O-5) is common in the upper few inches in the extreme northwestern part of the state but has been found eastward only as far as Rockford, where it is rare. In the southern area the St. James is a coarse-grained, gray to brown, faintly gray-speckled calcarenite that locally has a few inches of conglomerate at the base.

Beecher Member—The Beecher Member of the Dunleith Formation (Templeton and Willman, 1963, p. 120) overlies the St. James Member and is named for Beecher Street in East Dubuque, Jo Daviess County, which is near the type section (part of the Dunleith type section), where the member is 6.3 feet thick. It commonly is about 8 feet thick in the northern outcrop area and 12 feet in the southern area. In the type section the Beecher is lithographic to fine-grained, dolomite-mottled limestone, typical of the northern limestone facies, but in most of northern Illinois it is relatively pure, noncherty, mainly massive, vuggy dolomite. High purity and massiveness differentiate it from the cherty Eagle Point Member above and the more argillaceous St. James below. In the southern limestone facies it is coarse-grained, gray to pink, almost wholly massive, pure calcarenite.

Eagle Point Member—The Eagle Point Member of the Dunleith Formation (Templeton and Willman, 1963, p. 120) overlies the Beecher Member and is named for Eagle Point, a prominent bluff on the west side of the Mississippi Valley in Dubuque County, Iowa, 2 miles north of the type section (part of the Dunleith type section), where the member is 11.8 feet thick. It is commonly 12-18 feet thick in the northern outcrop area and 9-10 feet in the southern area. It is characterized by well defined bands of chert nodules. It consists of slightly argillaceous dolomite-mottled limestone in the type section, but it is dolomite in most of northern Illinois. In the southern outcrop area it is calcarenite containing bands of chert, is finer grained, denser, and more argillaceous than the members above and below.

Fairplay Member—The Fairplay Member of the Dunleith Formation (Templeton and Willman, 1963, p. 121) overlies the Eagle Point Member, and is named for the town of Fairplay, Grant County, Wisconsin, 6 miles northeast of the type section (part of the Dunleith type section), where the member is 19.8 feet thick. It is commonly 14-20 feet thick. In the type section it consists of relatively pure, lithographic limestone and is the top of the northern limestone facies. It is largely free of chert, but scattered nodules appear locally. The upper 1-3 feet is persistently argillaceous or shaly. *Receptaculites oweni* is common in many beds, and the Fairplay is the Lower *Receptaculites* Zone. These characteristics extend into the northern dolomite facies, but the member is not differentiated in the southern limestone facies.

Mortimer Member—The Mortimer Member of the Dunleith Formation (Templeton and Willman, 1963, p. 121) overlies the Fairplay Member and is named for Mortimer Street in East Dubuque, Jo Daviess County, near the type section (part of the Dunleith type section) (fig. O-2B), where the member is 11.3 feet thick. It is commonly 10-13 feet thick. It consists of thick-bedded vuggy dolomite that contains bands of large white chert nodules. Its purity is between that of the pure Fairplay Member below and the argillaceous Rivoli above. It has a 2.2-foot argillaceous zone at the top in the type section, which thins to 5-6 inches in the Dixon and Rockford areas. It contains a few dense argillaceous beds. Thin lenses of bentonite occur along a prominent bedding plane at the top.

Rivoli Member—The Rivoli Member of the Dunleith Formation (Templeton and Willman, 1963, p. 122) overlies the Mortimer Member and is named for Rivoli Street in East Dubuque, Jo Daviess County, near the type section (part of the Dunleith type section) (fig. O-2B), where the member is 19 feet thick. The Rivoli Member thins eastward from the type section and is 13 feet thick in central northern Illinois. It is the most argillaceous of the Dunleith members. The upper 5 feet is a persistent argillaceous zone that is very cherty in the type section. The lower 5-6 feet contains bands of large chert nodules. Corrosion surfaces are strongly developed in the Rivoli. Thin lenses of bentonite are locally present at or near the top and probably occur at other horizons, especially along sharp reentrants. *Receptaculites oweni* is abundant in upper Rivoli strata and the overlying Sherwood Member—the Middle *Receptaculites* Zone.

Sherwood Member—The Sherwood Member of the Dunleith Formation (Templeton and Willman, 1963, p. 123) overlies the Rivoli Member and is named for Sherwood Street in East Dubuque, Jo Daviess County, near the type section (part of the Dunleith type section) (fig. O-2B), where the Sherwood is 13.6 feet thick. The Sherwood Member is 10 feet thick in central northern Illinois. It consists of relatively pure, vuggy dolomite with a strong argillaceous zone in the top 3.6 feet in the type section. Chert is erratic in occurrence, except for an almost continuous bed of chert just above the base in some areas. One of the most persistent bentonites, as much as 3 inches thick, occurs about 3 feet above the base, and another occurs locally at the base of the upper argillaceous zone.

Wall Member—The Wall Member of the Dunleith Formation (Templeton and Willman, 1963, p. 123) overlies the Sherwood Member and is named for Wall Street in East Dubuque, Jo Daviess County, near the type section (part of the Dunleith type section) (fig. O-2B), where the Wall is 9.7 feet thick. The Wall Member is commonly 10-12 feet thick. It is less argillaceous than the Sherwood below and more argillaceous than the Wyota above. The argillaceous zone at the top is not prominent, but the upper 1-3 feet commonly has more argillaceous mottling and thin, wavy shale partings than the beds below. A widespread bentonite bed as much as 4 inches thick occurs near the middle of the member. Chert nodules are common, and the beds above the bentonite are more cherty than those below.

Wyota Member—The Wyota Member of the Dunleith Formation (Templeton and Willman, 1963, p. 124), the uppermost member in northern Illinois, overlies the Wall Member, and is named for Wyota Street in East Dubuque, Jo Daviess County, near the type section (part of the Dunleith type section) (fig. O-2B), where the Wyota is 19.9 feet thick. The Wyota Member is commonly 18-20 feet thick. Most of it is purer than the Wall but less pure than the overlying Sinsinawa Member of the Wise Lake Formation. It is characterized by the persistence of thin beds with argillaceous flecks, particularly in the upper 10 feet, and by abundant chert nodules in well defined bands. The upper 2-4 feet is slightly ar-

 Electronic Filing: Received, Clerk's Office 07/01/2024

gillaceous, locally shaly, and in many exposures makes a strong reentrant that marks the top of the Dunleith Formation.

Moredock Member—The Moredock Member of the Dunleith Formation (Templeton and Willman, 1963, p. 124) occurs in the southern limestone facies, overlying the Eagle Point Member. It is named for Moredock Lake, at Valmeyer, Monroe County, near the type section in the Mississippi River bluff (cen. N line SW 3, 3S-11W), where the member is 58.4 feet thick. The Moredock is commonly 60-70 feet thick where overlain by the New London Member, but in many exposures in the southern outcrop area the Moredock is overlain unconformably by Maquoketa Group strata, as it is at the type section, or by the Cape Limestone, and the upper few feet of the member are missing. The Moredock is exceptionally pure, coarse-grained calcarenite that is massive, cross-bedded, crinoidal, nearly white, and banded with pink, buff, and gray beds. Although the member is generally noncherty, large chert nodules or lenses of chert occur locally. It is distinguishable from the Eagle Point Member, which is finer grained, has bands of chert nodules, and is less pure.

New London Member—The New London Member of the Dunleith Formation (Templeton and Willman, 1963, p. 125) occurs in the southern limestone facies, overlying the Moredock Member and underlying the Wise Lake Formation. It is named for New London, Ralls County, Missouri, 2 miles south of the type section in a roadcut and in the bluff east of U.S. 61 on the north side of Salt River (NE SW 25, 56N-5W), where it is 32.8 feet thick. The top of the member is not exposed in the type section, but it occurs in a roadcut and bluff half a mile south of Frankford, Ralls County, on the north side of Peno Creek (SE NE and NE SE 2, 54N-4W). The New London consists of fine-grained to lithographic, calcarenitic, cherty limestone that contains beds of fine- to medium-grained calcarenite and some thin argillaceous and slightly shaly beds. Red-brown shale partings occur locally. It is finer grained than the Moredock below, coarser than the Wise Lake above, and less pure and thinner bedded than either. A persistent bentonite, as much as 2 inches thick, commonly marks the base of the member. It is believed to be equivalent to the bentonite near the base of the Sherwood Member in the northern area. The entire member is exposed only in the extreme northern part of the southern outcrop area, where it is 35-45 feet thick. South of there it is generally overlapped by Cincinnatian strata, but the lower 3-5 feet, identified by the bentonite at its base, is present locally.

Wise Lake Formation

The Wise Lake Formation (Templeton and Willman, 1963, p. 125) consists of relatively pure dolomite and limestone overlying the cherty Dunleith Formation and underlying the shaly Dubuque Formation. It is named for Wise Lake, a lake on the Mississippi River floodplain near the type section at the north end of a prominent bluff, 6 miles south of Galena, Jo Daviess County (cen. NE 21, 27N-1E), where the formation is 70.9 feet thick. The Wise Lake Formation, persistently 67-75 feet thick, occurs throughout the northern outcrop area (fig. O-2B, C) and southward in subsurface to the central part of the state, where it is sharply truncated by Cincinnatian strata. The Wise Lake consists of noncherty, medium- to thick-bedded, vuggy, pure dolomite in the northern outcrop area. The southern limestone facies is not exposed in Illinois, but in outcrops near New London, in Ralls County, Missouri, it is thick-bedded, fine-grained, to lithographic, pure limestone. The Wise Lake is subdivided into two members; the basal Sinsinawa Member is thinner bedded and slightly less pure than the Stewartville above it. *Receptaculites oweni* (fig. O-5) is abundant and persistently present in the lower 10-15 feet of the Stewartville, called the Upper *Receptaculites* Zone, and is associated with a gastropod-cephalopod fauna. *Maclurites cuneata* and *Hormatoma major* (fig. O-5) are common in some localities. The Sinsinawa Member is less fossiliferous but contains gastropods and, in places, a few *Receptaculites*. The Wise Lake Formation is the purest of the carbonate formations in the Galena Group and is equivalent and lithologically similar to relatively pure formations throughout much of the continent. The Wise Lake is thought to represent the greatest submergence of the continent during Paleozoic time. The Wise Lake Formation consists of strata formerly included in the Stewartville Formation and in the upper part of the Prosser Formation in the Upper Mississippi Valley. It is equivalent to the Steuben Member of the Cobourg Limestone in New York and Ontario, the upper part of the Lexington Limestone in Kentucky, and the upper part of the Bigby-Cannon Formation in Tennessee.

Sinsinawa Member—The Sinsinawa Member of the Wise Lake Formation (Templeton and Willman, 1963, p. 126), the lower member, is named for the Sinsinawa River in Jo Daviess County, along which it is well exposed. The type section is a roadcut along U.S. Highway 20 on the east side of the Galena River at Galena (SW SE NE 20, 28N-1E), where ber is 33 feet thick, although a few feet at the top (exposed in the Wise Lake type section) is missing. The Sinsinawa Member is 35-40 feet thick. Where exposed in the northern outcrop area (fig. O-2B), most of it is medium- to thick-bedded, pure, vuggy dolomite, but it contains a few dense, slightly argillaceous beds. A 1-2 inch bed of bentonite is widely present about 17 feet above the base, and a thin bentonite occurs locally about 7 feet higher. The Sinsinawa Member is equivalent to the upper, noncherty part of the Prosser Limestone of Minnesota.

Stewartville Member—The Stewartville Member of the Wise Lake Formation (Ulrich, 1911, pl. 27), the upper member (originally the Stewartville Formation), is named for Stewartville, Olmstead County, Minnesota, which is half a mile east of the type section, a quarry on the north side of the Root River, where 28 feet of dolomite in the lower part of the member is exposed (Kay, 1935a, p. 567). The Stewartville Member is about 60 feet thick in the type locality, but only 30-35 feet thick in northern Illinois. It is largely thick-bedded, pure dolomite, and many samples from the lower 10-15 feet (the Upper *Receptaculites* Zone) contain almost no insoluble residue. The bedding becomes thinner upward as a gradual transition to the shaly Dubuque Formation above takes place. The top of the Stewartville is placed at the lowest definitely argillaceous or shaly bedding plane. Above this position is the first occurrence of *Pseudolingula iowensis*, which is common in the higher, more shaly part of the Dubuque Formation. The Stewartville Member is the *Maclurea* bed of early reports.

Dubuque Formation

The Dubuque Formation (Sardeson, 1907, p. 193) is the shaly dolomite at the top of the Galena Group. It is named for Dubuque, Dubuque County, Iowa, and the type section is a quarry in Dubuque, east of Columbia College at the top of the West 14th Street hill, where 33 feet of Dubuque, its top eroded, is exposed. In Illinois the Dubuque Formation occurs only in the northwestern part of the state, where it is 40-45 feet thick (Templeton and Willman, 1963, p. 128). It is truncated by Maquoke-

Electronic Filing: Received, Clerk's Office 07/01/2024

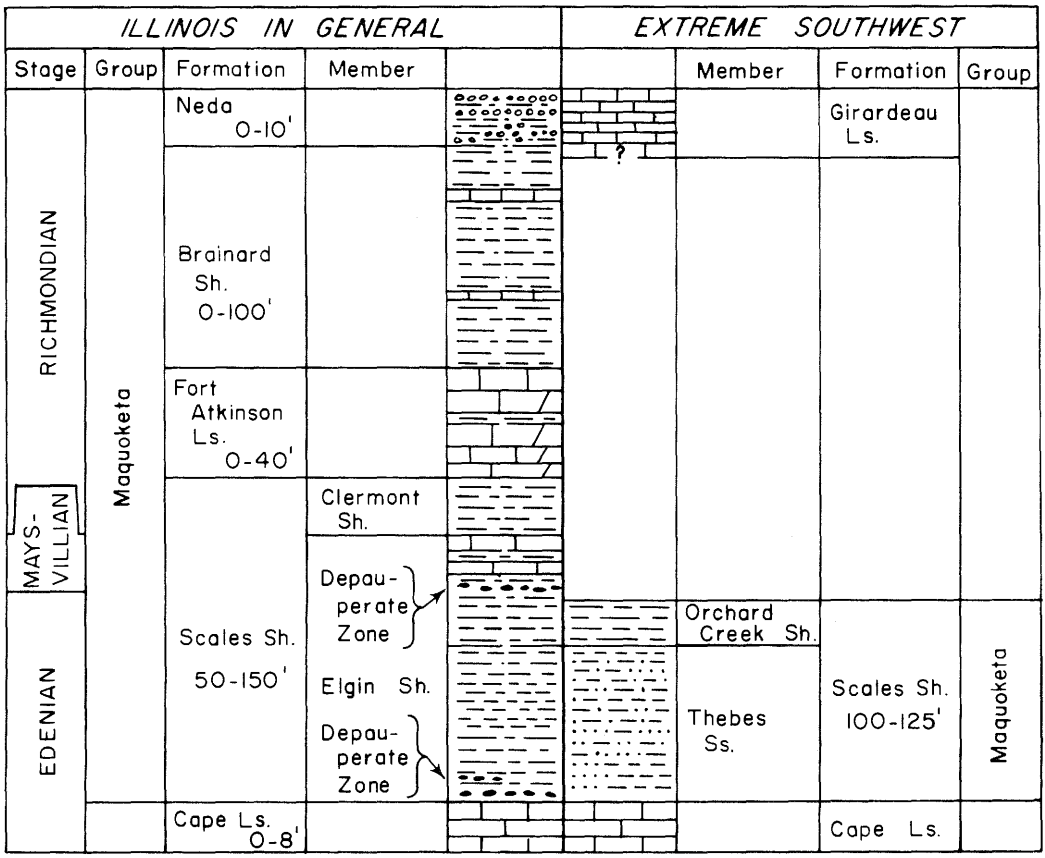

Fig. O-25—Columnar section of the Cincinnatian Series (after Templeton and Willman, 1963).

ta Group strata south of Galesburg in Knox County. It is also absent in subsurface in northeastern Illinois, but equivalent beds may be included in the Wise Lake Formation. The lower 20 feet of the Dubuque Formation grades uniformly from the pure, thick-bedded dolomite of the underlying Wise Lake Formation to shaly dolomite. A 4-inch bed of dolomite set off by relatively strong shale partings occurs 8 feet above the base of the formation and is a widely traceable marker bed. In the upper part of the formation, beds of dolomite 1-6 inches thick that are dense, fine-grained, and argillaceous are interlayered with beds of dolomitic shale 1-8 inches thick. A thin bed of red-brown shale occurs 20 feet below the top. Calcite-filled vugs are common in the upper 2 feet. *Paucicrura [Dalmanella]*, *Sowerbyella, Pseudolingula iowensis,* and crinoid debris are common in the shaly beds in the upper 15 feet. Some beds contain numerous, minute, brown-red, spore-like forms that are probably algae. The Dubuque is overlain unconformably by the Maquoketa Group. Although the contact is sharp, there is slight, if any, truncation of the Dubuque in the outcrop area in Illinois. The Dubuque is equivalent to the *Oxoplecia* Zone of early reports. It is correlated with the Hillier Member at the top of the Cobourg Formation in New York, the Cynthiana Limestone in Kentucky, and the Catheys Formation in Tennessee.

CINCINNATIAN SERIES

The Cincinnatian Series (Meek and Worthen, 1865, p. 155), named for Cincinnati, Ohio, is the uppermost series of the Ordovician System (fig. O-4). It is separated by unconformities from the Champlainian Series below and the Silurian Alexandrian Series above. In Illinois the Cincinnatian Series includes the Cape Limestone, the Maquoketa Group, and the Girardeau Limestone (fig. O-25). Where not affected by sub-Silurian erosion (fig. O-26), the series is 180-350 feet thick.

The Cincinnatian strata in Illinois were long believed to be equivalent to only the uppermost (Richmond) strata in the type region at Cincinnati (fig. O-27) but now are correlated

Electronic Filing: Received, Clerk's Office 07/01/2024

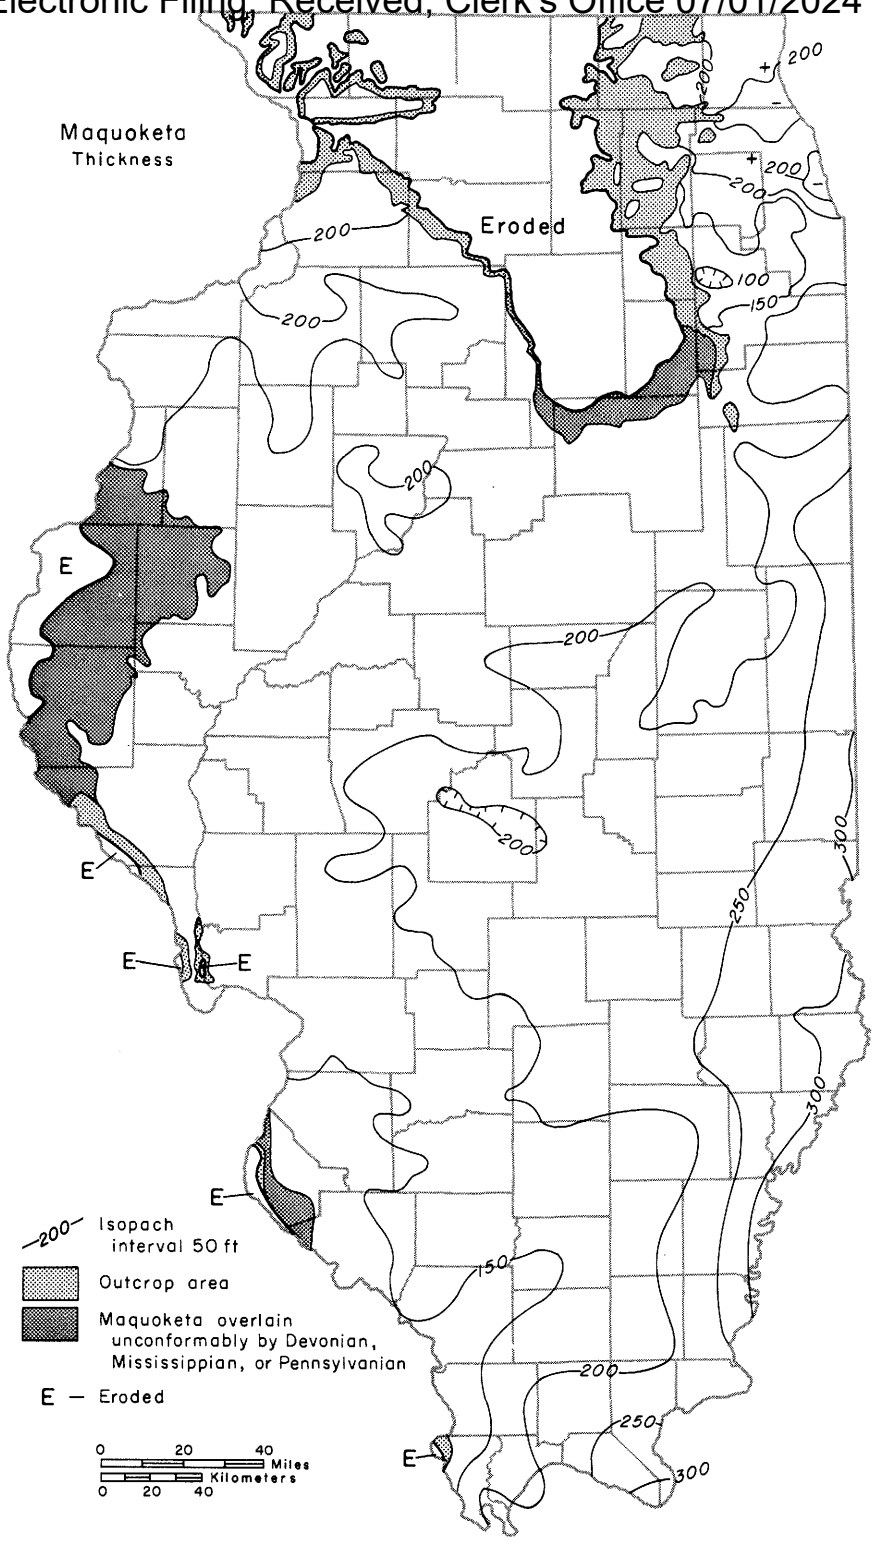

Fig. O-26—Thickness of the Maquoketa Group.

Electronic Filing: Received, Clerk's Office 07/01/2024

with the entire series and are subdivided into the Edenian (earliest), Maysvillian, and Richmondian Stages (Templeton and Willman, 1963). The fauna of the Cincinnatian strata in Illinois has not been studied in sufficient detail to determine the precise position of the stage boundaries.

Despite unconformities at the top and bottom, it appears that almost the entire Cincinnatian Series is represented in Illinois. The Cape Limestone at the base of the Cincinnatian in southern Illinois is as old or older than the oldest Cincinnatian strata at Cincinnati. The Fort Atkinson Limestone, in the middle of the Maquoketa Shale Group, has a fauna that closely matches that of the Richmondian Waynesville Limestone of the type region (Savage, 1925a). The *Cornulites* Zone, which occurs near the top of the Richmondian, is present in the upper part of the Brainard Shale

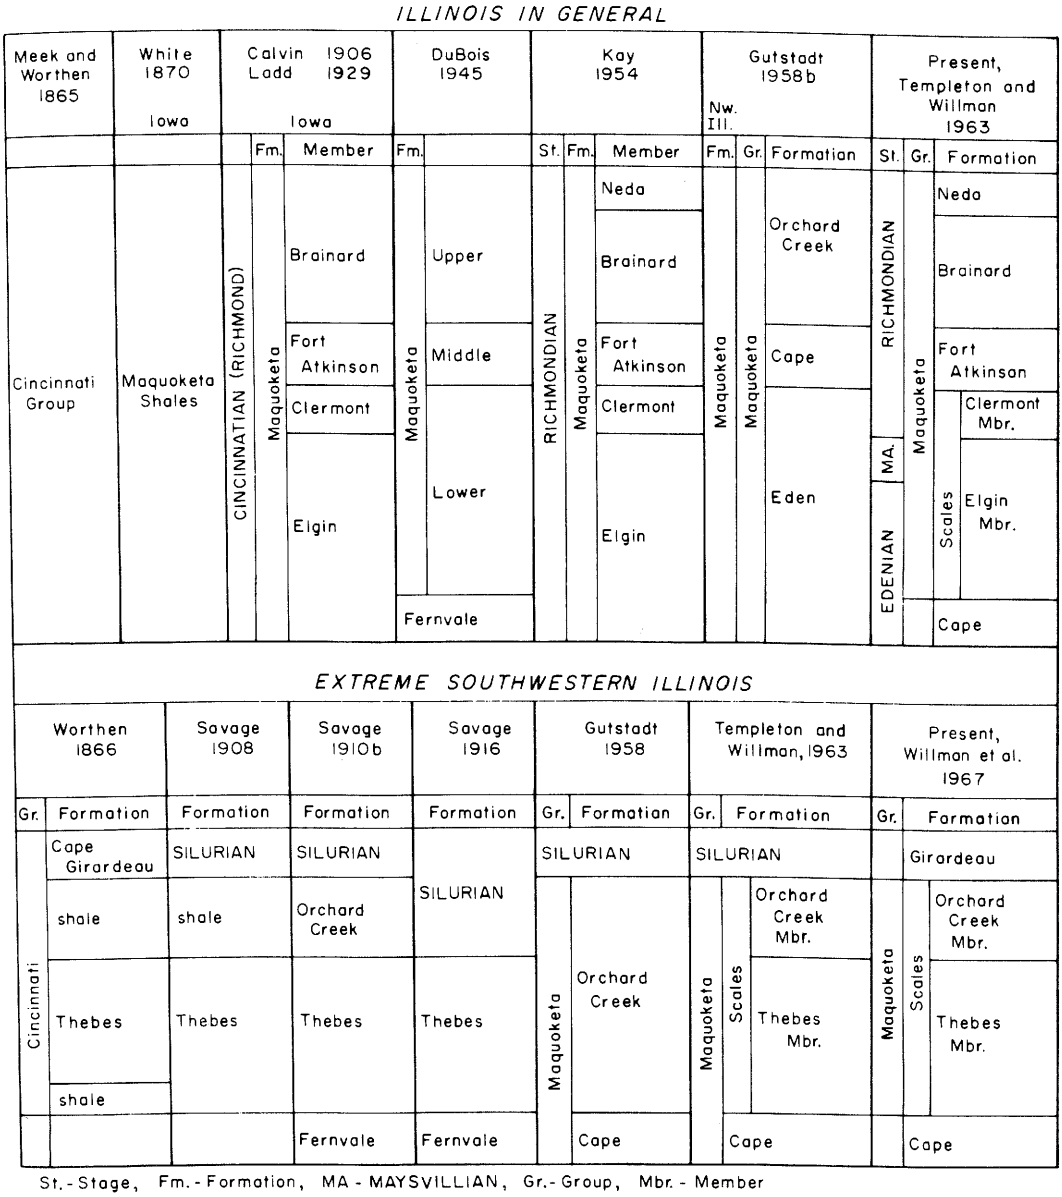

Fig. O-27—Development of the classification of the Cincinnatian Series.

Electronic Filing: Received, Clerk's Office 07/01/2024

in Illinois. The Neda Formation and the Girardeau Limestone at the top may be younger than the youngest strata in the type Cincinnatian.

The unconformity at the base of Cincinnatian strata is marked by the sharp truncation of the upper half of the Trentonian Galena Group limestone and dolomite by the Cincinnatian strata in an east-west belt across central Illinois. The Dubuque and Wise Lake Formations and the upper part of the Dunleith Formation were eroded in this belt and are not known south of there, although they may be present in subsurface in the southeastern part of the state where the Galena Group thickens. The Lower Depauperate Zone at the base of the Maquoketa Group is continuous across the truncated formations. Impact of a large meteorite near Glasford in western Illinois probably accounts for the intensive deformation of the Champlainian and older strata before deposition of the Maquoketa Group in that area (Buschbach and Ryan, 1963).

Edenian Stage

The Edenian Stage of the Cincinnatian Series (Newberry, 1873, table opp. p. 89; Twenhofel et al., 1954, chart), the basal stage, is based on the Eden Group, named for Eden Park in Cincinnati, Ohio. In Illinois it includes the Cape Limestone and the lower part of the Scales Shale (essentially the part underlying the Upper Depauperate Zone), which consists of the Thebes Sandstone Member and probably the Orchard Creek Shale Member in extreme southern Illinois and the middle and lower parts of the Elgin Shale Member elsewhere. The presence of dark brown to nearly black shale is characteristic of the Elgin Shale Member and lower Edenian strata in the type region of the Cincinnatian.

Maysvillian Stage

The Maysvillian Stage of the Cincinnatian Series (Foerste, 1905, p. 150; Twenhofel et al., 1954, chart), which overlies the Edenian Stage, is named for Maysville, Kentucky. In Illinois it consists of strata in the upper part of the Scales Formation, including the Upper Depauperate Zone and the overlying argillaceous limestone beds that contain *Isotelus* in abundance. The Girardeau Limestone in the extreme southwestern part of Illinois is approximately at this position, but its relation to the Upper Depauperate Zone is not known. Its fauna has long been considered to be more closely related to Silurian than to Ordovician faunas (Savage, 1917), and it therefore probably is late Richmondian in age.

Richmondian Stage

The Richmondian Stage of the Cincinnatian Series (Winchell and Ulrich, 1897, p. ciii; Twenhofel et al., 1954, chart), the uppermost stage, is named for Richmond, Indiana. In Illinois it includes the uppermost part of the Scales Shale, the Fort Atkinson Limestone, the Brainard Shale, the Neda Formation, and the Girardeau Limestone. The red shales of the Neda suggest correlation with red shales and sandstones in the Queenston and Juniata Formations at the top of the Cincinnatian Series in the Appalachian region.

Cape Limestone

The Cape Limestone (Templeton and Willman, *in* Gutstadt, 1958b, p. 524), the oldest Cincinnatian formation, is named for Cape Girardeau, Missouri, and the type section is an exposure on Main Street just north of Broadway in Cape Girardeau, where the formation is 8.5 feet thick, the maximum thickness observed (Templeton and Willman, 1963, p. 134). The Cape Limestone has a patchy distribution in the outcrop area in Missouri from St. Louis to Cape Girardeau. It occurs in the southwestern part of Illinois, where Cincinnatian strata deeply truncate the Trentonian Series, but it is exposed only at Valmeyer, Monroe County (SW 3, 3S-11W), where it is 1.5 feet thick. A few small outcrops formerly occurred near Thebes in Alexander County but are now covered. The Cape Limestone occurs mainly in shallow channels eroded in the top of the Dunleith Formation. In the northern part of the area, it is overlain by the Elgin Shale Member of the Scales Shale, as shown by the presence of the Lower Depauperate Zone above it at Valmeyer. In the southern part of the outcrop area, it is overlain by the Thebes Sandstone Member of the Scales. The Cape Limestone is a light gray to reddish gray, coarse-grained, fossiliferous calcarenite. It occurs in medium to thick beds with weak shaly partings. It has a large fauna characterized by brachiopods, particularly *Lepidocyclus capax*, and crinoids. The Cape Limestone was for many years called the Fernvale Limestone. It is correlated with the Fernvale Limestone in Arkansas and Oklahoma but not with the type Fernvale in Tennessee, which, being Richmondian in age, is much younger.

Maquoketa Shale Group

The Maquoketa Shale Group (White, 1870, p. 180-182) is named for exposures on the Little Maquoketa River in Dubuque County, Iowa. It underlies most of Illinois (fig. O-26), unconformably overlying the Galena Group and truncating the upper half of the Galena in the southern part of the state, except for the southwestern area where it rests conformably

Electronic Filing: Received, Clerk's Office 07/01/2024

on the Cape Limestone. It is unconformably overlain by Silurian strata, which locally truncate the upper half of the Maquoketa, except in the southwestern area where it is overlain conformably by the Girardeau Limestone. In western Illinois the sub-Kaskaskia unconformity at the base of the Middle Devonian rocks cuts through the Silurian strata and into the Maquoketa, and farther west near the Mississippi River it completely truncates the Maquoketa (fig. O-26). The sub-Absaroka unconformity at the base of the Pennsylvanian rocks locally cuts through the Maquoketa along the La Salle Anticline (fig. P-4). Except where thinned by the unconformities, the Maquoketa is 180 to nearly 350 feet thick.

Throughout most of Illinois the Maquoketa Shale Group (fig. O-25) consists of a lower unit, dominantly shale (the Scales Shale), overlain by a middle limestone (the Fort Atkinson Limestone), and an upper shale (the Brainard Shale) (DuBois, 1945; Gutstadt, 1958b; Templeton and Willman, 1963; Buschbach, 1964). In northern Illinois, the Neda Formation (red shale and hematitic oolite) is locally present at the top of the group. In extreme southwestern Illinois, the Maquoketa Group includes only the Scales Shale. Some of the complex facies variations within the Maquoketa Group in Illinois have been shown by DuBois (1945, fig. 3), but his middle zone is not equivalent in all areas to the Fort Atkinson Limestone, which is now restricted to the section in which limestone or dolomite is dominant.

The Maquoketa Shale contains two zones with distinctive pyritic and phosphatic beds, called depauperate zones because they contain only small fossils, largely a coquina of mollusks. The Lower Depauperate Zone, at the base of the Scales Shale, is widely present throughout the state, but the Upper Depauperate Zone, near the top of the Scales, has been found only locally in central and northeastern Illinois. The limestone beds and the calcareous shale beds in the Maquoketa Group generally contain a large and varied fauna (fig. O-5). Large brachiopods are common, and branching bryozoans are especially abundant. In a zone near the top in northwestern Illinois, specimens of *Phragmopora* that reach 4 inches in diameter are locally abundant. Some beds of calcarenite consist largely of bryozoan and crinoidal debris.

Various group and formation names have been used in differentiating the type Cincinnatian (Weiss and Norman, 1960). In southeastern Indiana, part of the type region, the Cincinnatian strata are assigned to the Maquoketa Group (Gray, 1972). The Maquoketa Group is equivalent to Collingwood and Queenston strata in Ontario and New York, to the Sylvan Shale to the southwest, and to the Reedsville Shale and the Sequatchie Formation to the south and southeast of Illinois.

Scales Shale

The Scales Shale (Templeton and Willman, 1963, p. 135, in which it was called the Scales Formation), the "lower shale" formation in the Maquoketa Group in most of Illinois, is named for Scales Mound, Jo Daviess County, and the type section is a railroad cut on the west side of the town (SW NE SW 26, 29N-2E). Only the lower 30 feet, overlying the Dubuque Formation, is exposed in the type section, but the upper 18 feet is exposed 5 miles east in another railroad cut (SW SW SW 15, 29N-3E). The Scales Shale is extensive but is exposed only in northwestern Illinois and in small areas near West Point Landing in Calhoun County, Valmeyer in Monroe County, and Thebes in Alexander County. The formation is generally 75-100 feet thick, but it ranges from 50-150 feet thick. The lower part is generally dark gray to dark brown shale, which is differentiated as the Elgin Shale Member. At the top of the Scales is a gray shale—the Clermont Shale Member—that contains beds of argillaceous limestone. In the southwestern part of Illinois, brown sandstone and siltstone at the base of the Scales is differentiated as the Thebes Sandstone Member, and the shale overlying it is the Orchard Creek Shale Member. The Scales Shale has been called "the lower brown shale member" (Willman and Payne, 1942), "the lower shale zone" (DuBois, 1945), or the Scales Formation (Templeton and Willman, 1963).

Elgin Shale Member—The Elgin Shale Member of the Scales Shale (Calvin, 1906, p. 60, 98) is named for Elgin, Fayette County, Iowa. It forms the major part of the formation and is partly exposed in many localities in northwestern Illinois and locally in the other outcrop areas of the Maquoketa Group. Although dominantly shale, and in some areas almost entirely shale, the member contains beds of dolomite, limestone, siltstone, and sandstone. The lower two-thirds of the shale is commonly dark gray or dark brown, and locally in eastern Illinois it is nearly black. The shale generally becomes lighter in color to the northwest, and in the Scales type section only a few beds are dark. The Lower Depauperate Zone consists of one or several thin depauperate beds at the base or in the lower few feet of the Elgin Shale. At Valmeyer, Monroe County, depauperate beds occur at the base of the shale and as much as 9 feet above the base. A similar depauperate bed, the Upper Depauperate Zone, occurs in the upper part of the Elgin Shale Member. It was formerly exposed in the Goose Lake clay pit in Grundy County but is now covered. At Goose Lake it is 60 feet above the base of the Scales Shale, is 20 feet below the top, and is overlain by shale and argillaceous limestone containing *Isotelus*, which forms the top of the member. The Upper Depauperate Zone has been encountered in borings only in central and northeastern Illinois.

Clermont Shale Member—The Clermont Shale Member of the Scales Shale (Calvin, 1906, p. 60, 98), the upper member, is named for Clermont, Fayette County, Iowa. It is dominantly gray shale overlying the zone of interbedded shale and limestone in the upper part of the Elgin Shale Member. Where that zone cannot be distinguished, which is commonly the case in subsurface, it is not differentiated. It is generally

Electronic Filing: Received, Clerk's Office 07/01/2024

15-20 feet thick but thickens in central and southeastern Illinois.

Thebes Sandstone Member—The Thebes Sandstone Member of the Scales Shale (Worthen, 1866, p. 139; Savage, 1909, p. 515) is named for Thebes, Alexander County, and the type section consists of exposures in the Mississippi River bluffs in Thebes (SW SE 8, 15S-3W). The Thebes Sandstone Member is exposed in Illinois only in the vicinity of Gale and Thebes, and it occurs in subsurface only in the extreme southwestern part of the state. It overlies the Cape Limestone and grades or intertongues eastward and northward into the lower part of the Elgin Shale Member. It is overlain by the Orchard Creek Shale Member, which probably is also laterally equivalent to part of the Elgin Shale Member. About 65 feet of the Thebes Sandstone Member is exposed in the bluff north of Thebes (SE 5, 15S-3W), but it has a maximum thickness of about 160 feet. The Thebes consists of dark brown, silty, fine-grained sandstone, largely medium to thick bedded and locally cross bedded. In places it is largely brown siltstone, but it locally contains beds of gray to brown shale several feet thick. Several types of fucoid marks are common in the upper 35 feet.

Orchard Creek Shale Member—The Orchard Creek Shale Member of the Scales Shale (Savage, 1909, p. 515) is named for a small exposure along Orchard Creek, 2 miles south of Thebes, Alexander County. This section is now covered, but the Orchard Creek is exposed in the Mississippi River bluffs a mile north of Thebes (SE 5, 15S-3W), where it is 27 feet thick, overlies the Thebes Sandstone Member, and is overlain by the Girardeau Limestone. The Orchard Creek Shale Member is exposed locally in and near the Mississippi bluffs in Alexander County from Gale southward almost to Fayville. It is 10-30 feet thick in the outcrop area. It is largely blue-gray shale, but in the thickest exposures the upper part is interbedded with fine-grained limestone. The Orchard Creek is probably a lateral equivalent of part of the Elgin Shale Member, but its precise position is uncertain, and it could be equivalent even to the Brainard Shale. It is differentiated only where it overlies the Thebes Sandstone Member. The Orchard Creek contains a large fauna (Savage, 1917). It was long assigned to the Silurian System, but the presence of *Climacograptus putillus* indicates Cincinnatian age (Pryor and Ross, 1962).

Fort Atkinson Limestone

The Fort Atkinson Limestone (Calvin, 1906, p. 60, 98), the "middle limestone" formation in the Maquoketa Group, is named for exposures at Fort Atkinson, Winneshiek County, Iowa. It is exposed in northeastern Illinois, particularly at Wilmington, Will County (SE SW NW 25, 33N-9E) and near the Dresden Island Dam, Grundy County (SE NE NW 34, 34N-8E). The Fort Atkinson Limestone has been called the Divine Limestone (Lamar and Willman, 1931) and the "middle limestone" (DuBois, 1945). It is widely distributed in subsurface in Illinois and is commonly 15-40 feet thick. However, in some areas, for instance in much of the Maquoketa outcrop area in northwestern Illinois, it becomes very shaly and is inseparable from the shales above and below. In other areas it includes limestone laterally equivalent to the shale formations above and/or below. The Fort Atkinson changes within short distances from white or pink, coarse-grained, crinoidal limestone to brown fine-grained dolomite or gray argillaceous limestone. In some localities the upper part is limestone, the lower part dolomite. The amount of interbedded shale varies greatly. The Fort Atkinson is generally fossiliferous with a large fauna of brachiopods and bryozoans (Savage, 1925a). It correlates with the Waynesville Limestone in Ohio and Kentucky.

Brainard Shale

The Brainard Shale (Calvin, 1906, p. 60, 97), the "upper shale" formation in the Maquoketa Group, is named for an exposure near Brainard, Fayette County, Iowa. It occurs throughout the area of the Maquoketa Group, except in local areas where it is truncated by the sub-Silurian unconformity. Although widely present near the surface in the mounds and ridges in northwestern Illinois, it is generally covered by slumped material from the overlying Silurian dolomite formations, and actual outcrops are small and scarce. It is exposed locally in northeastern Illinois, particularly near Channahon and Ritchey in Will County, near Elgin in Kane County, and in small areas in Calhoun and Jersey Counties. The Brainard Shale is 75-100 feet thick where it is not deeply truncated by the sub-Silurian unconformity. In the outcrops it consists of greenish gray to green shale, partly dolomitic, and locally silty. In subsurface it contains beds of siltstone, and locally limestone or dolomite. It is generally much lighter colored and softer than the Scales Shale. Two thin bentonite beds locally occur near the top in southeastern Illinois. The Brainard is commonly fossiliferous, and the presence of *Cornulites* in the upper part suggests equivalence to the Elkhorn Formation at the top of the Richmondian strata in Indiana and Ohio.

Neda Formation

The Neda Formation (Savage and Ross, 1916, p. 193, in which it was called Neda iron ore), the youngest formation in the Maquoketa Group in northern Illinois, is named for exposures near Neda, Dodge County, Wisconsin. The Neda Formation occurs in local areas in northern Illinois and is exposed along the Kankakee River southeast of Ritchey, Will County (26, 27, 35, 36, 32N-10E, particularly in NE NW SW 36). In that area it is 4-8 feet thick, overlies the green Brainard Shale, and is overlain by the Kankakee Formation or, locally, by 1-2 feet of the Wilhelmi Formation of Silurian age. The Neda is generally less than 10 feet thick in Illinois. It is largely red shale interbedded with red-brown or black oolite consisting of flattened spheroids of geothite or hematite that average about 0.5 mm across. In places it contains a few beds of gray or green shale. Athough it rests sharply on the underlying Brainard Shale, there is no evidence of an unconformity. The upper contact, however, is sharp and erosional. The basal Silurian rocks in places contain streaks of reddish shale and black oolites that were probably reworked from the Neda. The Neda occurs only in areas where the Brainard Shale is relatively thick and where the basal Silurian formations, the Wilhelmi and Elwood Formations, which generally occur in channels eroded in the top of the Brainard, are absent or very thin. The major unconformity, therefore, is on top of the Neda Formation, which favors its assignment to the Maquoketa Group (Workman, 1950; Buschbach, 1964) rather than to the basal Silurian Noix Oolite Member (Athy, 1928). The Neda is not fossiliferous in Illinois, but Savage and Ross (1916) reported a Cincinnatian fauna in the Neda in its type region. The Neda is believed to be a thin western tongue of the Queenston delta of the Appalachian region.

Girardeau Limestone

The Girardeau Limestone was originally named the Cape Girardeau Limestone (Swallow, 1855, p. 109) for outcrops at Cape Point, 1.5 miles northeast of Cape Girardeau, Missouri (SW NE SE 28, 31N-14E), but the shorter form "Girardeau" has been used since the late 1800s (Savage, 1909). In Illinois it occurs only in the extreme southwestern part, and it is exposed only near Thebes, Alexander County. About 30 feet is exposed along Orchard Creek south of Thebes (SW SE NW 21, 15S-3W), which is about its maximum thickness, although the base is not exposed. The base appears to be conformable on the Orchard Creek Shale, the upper part of which contains a few limestone beds like the Girardeau. The top is a prominent unconformity that northward from Thebes completely truncates the Girardeau before reaching Gale. The Girardeau Limestone consists of unevenly bedded, fine-grained to lithographic, dark brown limestone. It has shaly partings and silicified silty interbeds that commonly contain black chert nodules. The Girardeau contains a large fauna, most of it preserved on the bedding planes (Savage, 1917). Although Savage considered the fauna had affinities closer to the Silurian than the Ordovician, the strong unconformity at the top and the transitional, local character of the fauna have caused many to favor its classification as Ordovician, a practice followed in Illinois since 1967 but still considered tentative. The relation of the Girardeau to the Maquoketa elsewhere in Illinois is not known. Judged on the basis of thickness of the underlying Maquoketa strata, it could be approximately equivalent to the Fort Atkinson Limestone, but it does not resemble it. It could be as young or younger than the Neda Formation, the interpretation at present favored.

SILURIAN SYSTEM

H. B. Willman and Elwood Atherton

The Silurian System (Murchison, 1835, p. 48-49; Lapworth, 1879, p. 12-14), named for the Silures, a tribe of people who lived in the type area in Wales during Roman times, underlies most of Illinois and is the surface of the bedrock in four areas (fig. S-1). Silurian strata are well exposed in all four areas (fig. S-2). In northeastern Illinois, Silurian rocks are exposed in large, deep quarries in the Chicago region and in the bluffs of the Des Plaines, Kankakee, Du Page, and Fox Valleys, but in the northern half of that area they are deeply buried by glacial drift. In northwestern Illinois, the Silurian strata are the resistant rocks that cap nearly all the mounds, and they are well exposed in the Mississippi River bluffs from the Galena area southward to the Rock Island vicinity and also along tributary valleys for several miles east of the bluffs. In western Illinois, the Silurian System has been uplifted along the Lincoln Anticline and the Cap au Grès Faulted Flexure and is well exposed in the Mississippi and Illinois River bluffs in Jersey and Calhoun Counties. In southern Illinois, the exposures are limited to the Mississippi bluffs and tributary valleys in Alexander County and southern Union County. The Silurian rocks in all these areas were long called Niagara Limestone (Worthen, 1866; Bannister, 1868; Shaw, 1873).

The Silurian System has a maximum thickness of nearly 1000 feet in and below some pinnacle reefs in the area east of East St. Louis. However, the system is more commonly 400-600 feet thick in that area and farther north (fig. S-1). South of the pinnacle reefs the Silurian rocks are generally only 300-400 feet thick.

The Silurian System is subdivided into three series—the Alexandrian Series (below), which is based on exposures in Alexander County, Illinois, and the Niagaran and Cayugan Series, both based on exposures in the Niagara Falls area in New York and Ontario. Because of pronounced changes in lithology, different rock-stratigraphic classifications have developed in the widely separated outcrop areas in Illinois, and 15 formations and 10 members are now recognized (figs. S-3 to S-10). The subsurface correlations between the outcrop areas have not been firmly established for some units.

The Silurian rocks are dominantly carbonates—almost entirely dolomite in the northern part of the state (Willman, 1943, 1973) but

Electronic Filing: Received, Clerk's Office 07/01/2024

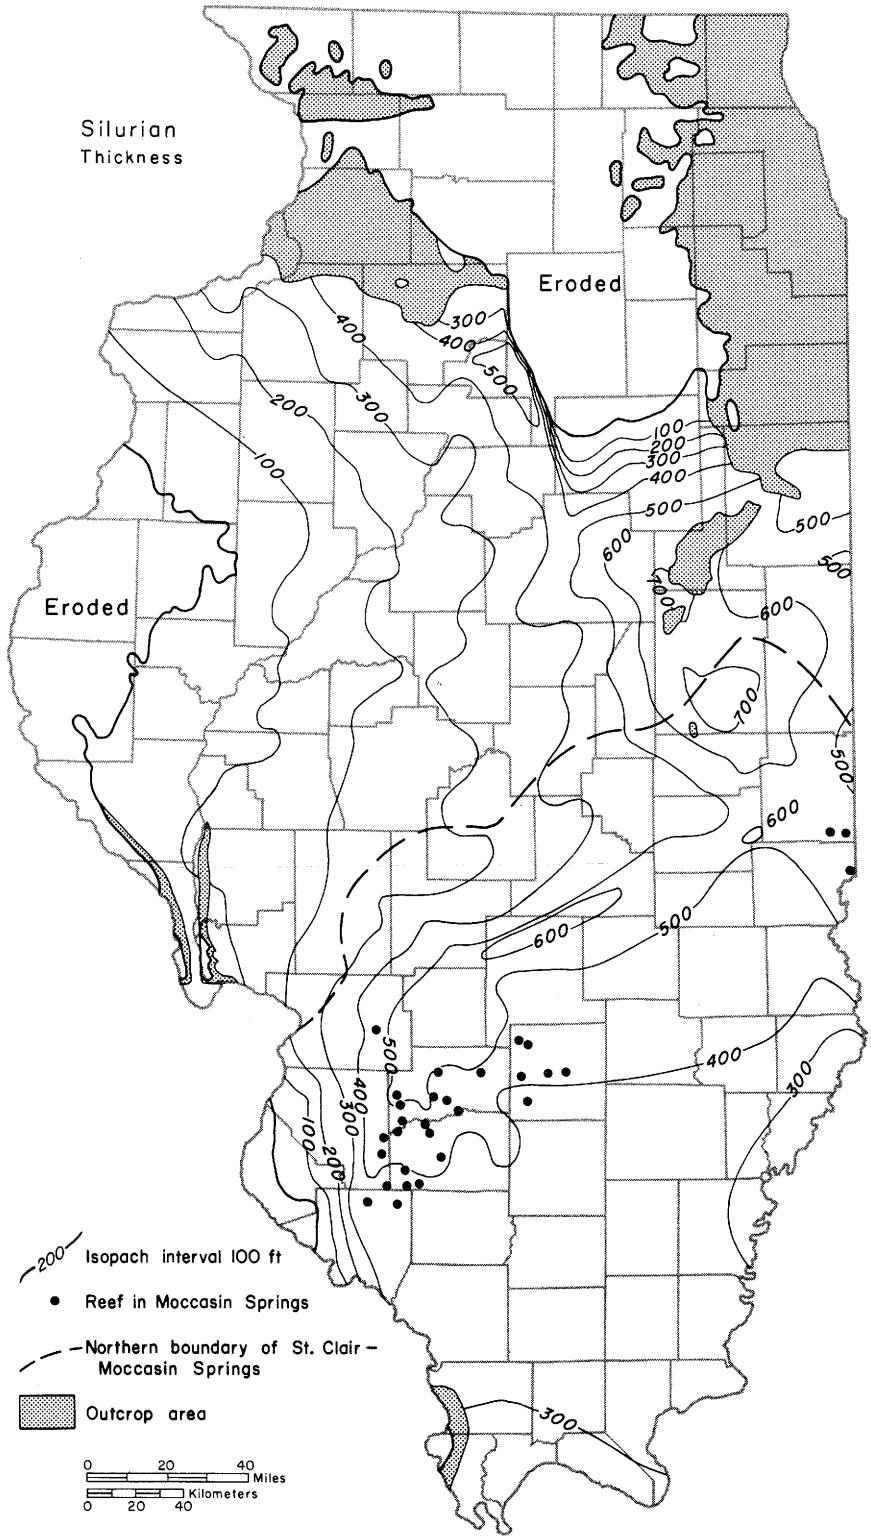

Fig. S-1—Silurian System thickness, outcrop areas, nomenclature boundary, and reefs in the Moccasin Springs Formation.

largely limestone, siltstone, and shale in the southern part (Lowenstam and DuBois, 1946; Lowenstam, 1949). With the overlying Devonian carbonate rocks, they form the Hunton Limestone Megagroup.

The Alexandrian formations, the lower Niagaran rocks, and all of the Silurian rocks south of the reefs maintain distinctive characteristics and lateral continuity for long distances (fig. S-11), but where reefs are present the sediments have abrupt lateral variations in lithology, and few units can be widely traced. The reefs are very pure carbonate. The northern reefs, in the Racine Formation, are mainly dolomite, but the southern reefs, in the Moccasin Springs Formation, are largely limestone. The interreef rocks are less pure, varying from cherty silty dolomite to argillaceous dolomite around the Racine reefs and from argillaceous limestone to calcareous shale and siltstone around the Moccasin Springs reefs. However, in northwestern Illinois the interreef rocks, except in local areas, are nearly pure dolomite and are similar in lithology to the reef rock.

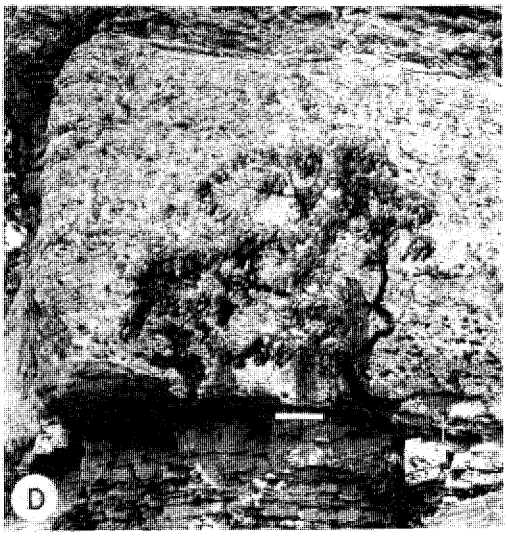
Illinois was almost continuously beneath the sea during Silurian time. The most striking features in the Silurian sea were the reefs that formed in Niagaran time in a broad area reaching from the Ozark region northeastward across Illinois, Indiana, and Ohio to Ontario (Lowenstam, 1949, 1957). Another group of reefs in northwestern Illinois, Iowa, northeastern Illinois, and eastern Wisconsin may have been part of an archipelago bordering the Wisconsin Arch. The two belts of reefs essentially meet in the Kankakee Arch area and form part of a barrier around the Michigan Basin.

In the relatively deep water south of the reef front and around the southernmost reefs, the sediments that were deposited during the growth of the reefs are largely red, green, gray, impure, noncherty limestone, siltstone, and shale; farther north, the reefs are surrounded by gray, cherty, silty dolomite. The red sediments are more dominant to the southwest and probably were derived from that direction.

In the southern reef area, the oldest reefs probably began to grow during deposition of the upper part of the St. Clair Formation, as indicated by the presence of local lenses of pure sediments, probably wash from reefs. However, the major reefs began to grow a little later, at or just above the base of the Moccasin Springs Formation. In the northern areas, major reef growth began at approximately the same time as in the south, the beginning of Racine deposition. The great thickness of the southern reefs appears to be related to the progressive sinking of the deep part of the Illinois Basin, the Fairfield Basin (fig. 12).

The reefs continued as prominent features through Silurian time, although the presence of Niagaran fossils in the upper parts of some reefs suggests that reef growth did not extend into Cayugan time. However, as all of the reefs are overlain unconformably by Middle Devonian or younger sediments, the Cayugan, and perhaps even the early Devonian, parts of the reefs could have been present and eroded. In either case, the sea continued to occupy the Illinois Basin around and south of the reefs into Devonian time, and several hundred feet of Lower Devonian sediments were deposited in the basin and largely filled it.

In the classification based on major unconformities, the Silurian rocks belong to the Tippecanoe Sequence (fig. 14). They are separated from the underlying Ordovician rocks by an unconformity, as previously described. In the part of the Illinois Basin south of the reefs, deposition appears to have been essentially continuous from Silurian to Devonian time, but the sub-Kaskaskia unconformity at the base of the Middle Devonian rocks truncates the reefs and the Niagaran, Lower Devonian, and Cayugan rocks on the flanks of the reefs. Cayugan and Lower Devonian sediments may not have been deposited north of the area of the Moccasin Springs Formation (fig. S-1), but if they were present they must have been eroded, because the unconformity cuts deeply into Niagaran strata in that area. Well rounded, medium-grained quartz sand found locally in upper Silurian rocks in subsurface is largely Middle Devonian sand introduced along joints (Summerson and Swann, 1970). In extreme western Illinois, the Silurian strata were entirely eroded before the Middle Devonian limestone was deposited. No major unconformities are recognized within the Silurian System, although sharp contacts and channeling between the Kankakee and Edgewood Formations in western Illinois and the Sexton Creek and Edgewood Formations in southern Illinois may indicate movements on local structures on the flank of the Ozarks. The Alexandrian and Niagaran rocks are separated by a widespread, smooth surface that probably indicates a diastem.



Fossils are generally abundant in the relatively pure carbonate rocks of the Silurian System (fig. S-12) but are scarce in the more

argillaceous and silty strata. Five faunal zones are extensive. (1) The *Platymerella* Zone at the base of the Kankakee Formation is essentially equivalent to the *Virgiana* Zone found to the north in Wisconsin, Michigan, and Ontario. The two fossils are closely related pentamerids. (2) The *Microcardinalia* Zone at the top of the Kankakee Formation and in the upper part of the Sweeney Formation is widely present at the top of Alexandrian rocks. (3) A zone of abundant arenaceous Foraminifera, characterized by Ammodiscidae, occurs at the base of Niagaran strata, although it has not been found in northwestern Illinois. (4) The *Pentamerus* Zone, which in Illinois occurs only in the northwestern part of the state, is regionally present at or near the base of the Niagaran Series. (5) The uppermost Niagaran reefs in northeastern Illinois contain distinctive fossils characteristic of the Guelph Formation of New York and Ontario, referred to as the Guelph fauna, or the *Megalomus* Zone. *Megalomus* is present but not common in the youngest Niagaran strata in both northeastern and northwestern Illinois. Fossils characteristic of the Guelph are also found in the top of the reef at Marine, Madison County (Lowenstam, 1949).

The Niagaran reefs are very fossiliferous and contain a great variety of invertebrates, especially stromatactis-like forms, corals, stromatoporoids, bryozoans, brachiopods, and crinoids (Lowenstam, 1949, 1950, 1957; Ingels, 1963; and others), whereas the interreef rocks are sparsely fossiliferous and the fauna, principally sponges, crinoids, and brachiopods, differs in many aspects from that of the reefs (Lowenstam, 1948a).

Fig. S-2—Exposures and textures of Silurian rocks.

A—Massive dolomite in the core of a Racine (Niagaran) reef, at the top of the Material Service Corporation (Stearns) quarry on Archer Avenue at 28th Street, Chicago.

B—Steeply dipping, well bedded dolomite forming the flank of a Racine (Niagaran) reef, in the Material Service Corporation quarry at Thornton, Cook County.

C—Massive Marcus Dolomite in a quarry 3 miles east of Fulton, Whiteside County.

D—Massive Tete des Morts Formation overlying the Mosalem Formation at the top of Silurian escarpment, 4 miles southeast of Galena, Jo Daviess County.

E—Mottled, porous, pure dolomite characteristic of Racine reef facies in the Chicago area (×1).

F—Dense, argillaceous dolomite containing chert nodules characteristic of Racine interreef facies in the Chicago area. The outer, porous parts of the nodules are blackened by air pollutants.

HUNTON LIMESTONE MEGAGROUP

The Hunton Limestone Megagroup (Taff, 1902, p. 3; Swann and Willman, 1961, p. 478), named for the former hamlet of Hunton, Coal County, Oklahoma, comprises dominantly carbonate rocks of Silurian and Devonian age that in Illinois lie between the late Ordovician clastic rocks (Maquoketa Shale Group) and the late Devonian clastic rocks (New Albany Shale Group) at the base of the overlying Knobs Megagroup (fig. 14). In local areas, siltstone and shale in the base of the Silurian System are not included in the megagroup, whereas limestone in the uppermost Ordovician strata is included. At the top of the Hunton, shale of Middle Devonian age, locally present, is excluded, but basal Upper Devonian limestone is included.

Hunton strata occur throughout most of Illinois, but are absent in the central northern region and in small areas in western and southern Illinois where Ordovician and older

rocks are exposed. The megagroup thickens from those areas to over 1800 feet in the southeastern part of the state (fig. S-13). It varies from being almost entirely dolomite in northern Illinois to limestone in southern Illinois. It contains some thin or local noncarbonate units—particularly the Devonian chert units in the extreme southwestern part of Illinois, some shaly strata in the Silurian Moccasin Springs Formation, and the patchy Dutch Creek Sandstone at the base of the Middle Devonian Series.

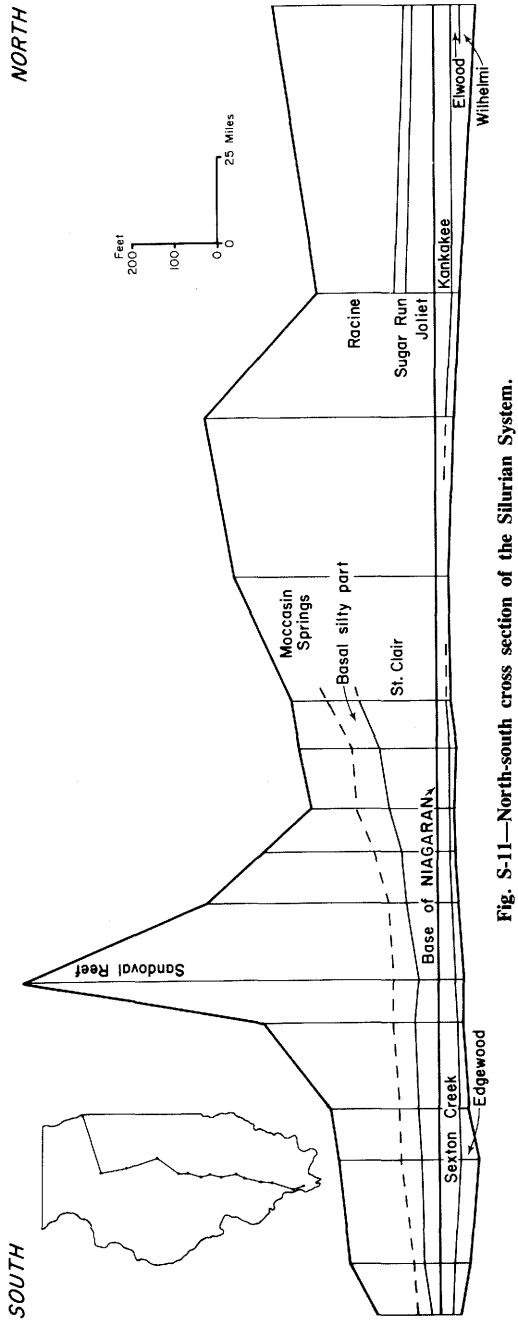

Fig. S-11—North-south cross section of the Silurian System.

The Hunton Megagroup includes within it the sub-Kaskaskia unconformity, along which in some areas Middle Devonian strata completely truncate Lower Devonian and Silurian strata, leaving only Middle Devonian strata in the Hunton Megagroup. In other areas, the sub-Absaroka unconformity, at the base of the Pennsylvanian System, truncates all the Devonian strata, so that the megagroup consists entirely of Silurian carbonates. In a few places the sub-Absaroka unconformity cuts out the Hunton entirely. In a small area in northwestern Schuyler County, the Upper Devonian New Albany Shale Group truncates the Hunton Megagroup and rests on the Ordovician Maquokota Shale Group.

ALEXANDRIAN SERIES

The Alexandrian Series (Savage, 1908, p. 110; 1916, p. 312; Weller, 1940, p. 19; Willman et al., 1967), named for exposures in Alexander County, consists of early Silurian strata including and underlying the *Microcardinalia* Zone and overlying Ordovician rocks. Alexandrian strata occur throughout most of the area of Silurian rocks (fig. S-14) and, where they fill erosional channels in the Maquoketa Shale Group, are locally as much as 150 feet thick. The Alexandrian strata were included in the Niagaran until Savage (1908) recognized that they contain a fauna older than that in the lower part of the Niagaran type section in New York (fig. S-10). At first the Alexandrian Series included only the Girardeau and Edgewood Formations, but later Savage expanded the series to include the Orchard Creek Shale below and the Sexton Creek Limestone above. Weller (1940) returned the Orchard Creek to the Ordovician, and later Willman et al. (1967) followed suggestions by several authors and placed the Girardeau, also, in the Ordovician. Alexandrian strata throughout Illinois are generally argillaceous limestone or dolomite at the base, overlain by purer glauconitic limestone or dolomite that is very cherty in some areas. The series is divisible into two parts by a zone of *Platymerella manniensis* that is present at the base of the Kankakee Formation in northeastern and western Illinois but has not been found elsewhere.

Fig. S-13—Thickness of the Hunton Limestone Megagroup (modified from Bond et al., 1971).

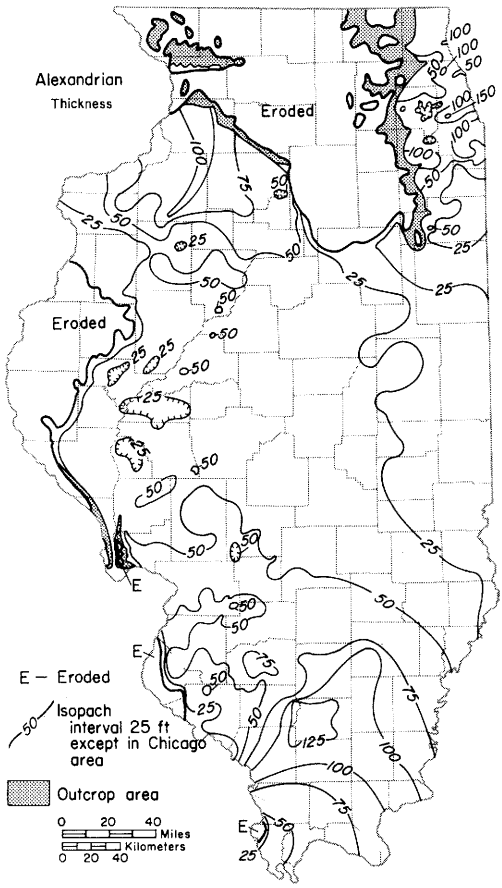

Fig. S-14—Thickness of the Alexandrian Series.

Wilhelmi Formation

The Wilhelmi Formation (Willman, 1973, p. 12) is the basal formation in the Alexandrian Series in northeastern Illinois (fig. S-3) and is named for Wilhelmi Airport on the south side of Joliet, Will County, which is about 5 miles northeast of the type section (railroad cut in SE SW SE 35, 35N-9E). Earlier it had been referred to as the lower shaly part of the Edgewood Formation. It is as much as 100 feet thick where it fills deep channels in the Maquoketa Shale Group, but it is thin or absent in other areas. The lower part of the Wilhelmi Formation is medium to dark gray, very argillaceous dolomite and dolomitic shale. This unit is differentiated as the Schweizer Member and is present only where the formation is thick. The overlying moderately argillaceous dolomite, differentiated as the Birds Member, is characteristic of the relatively thin part of the formation. In some areas the basal dolomitic shale is difficult to differentiate from shale of the underlying Maquoketa Group, but the latter generally is greenish gray. The Wilhelmi is lithologically similar to the Mosalem Formation in northwestern Illinois. It probably correlates with the lower part of the Edgewood Formation in western Illinois but is more argillaceous than the latter. It is absent in southern Illinois. Strata of similar lithology occur in the basal Edgewood in Iowa and are locally present in the base of the Mayville in Wisconsin and the Brassfield in Indiana and Kentucky. The Wilhelmi contains early Llandoverian graptolites (Ross, 1962a).

Schweizer Member—The Schweizer Member of the Wilhelmi Formation (Willman, 1973, p. 13), the basal member, is named for Schweizer School a mile east of the type section, which is part of the type section of the Wilhelmi Formation. Although widely present in subsurface in northeastern Illinois and as much as 80 feet thick, the Schweizer Member is well exposed only in and near the type section, where it is 25 feet thick. It consists of medium to dark gray dolomitic shale at the base that grades to very argillaceous, silty dolomite at the top. A thin bed of limestone conglomerate marks the base in the type section.

Birds Member—The Birds Member of the Wilhelmi Formation (Willman, 1973, p. 13), which overlies the Schweizer Member, is named for the railroad siding at Birds, 2 miles northwest of the type section, which is part of the Wilhelmi Formation type section. The uppermost part of the member and its contact with the overlying Elwood Formation are ex-

Electronic Filing: Received, Clerk's Office 07/01/2024

posed in a ravine half a mile northeast (NW NW SE 36, 35N-9E). The Birds Member consists of 10-20 feet of slightly to moderately argillaceous, slightly cherty, thin-bedded, medium-gray dolomite. It is distinguished by several thin beds of relatively pure, finely laminated, fossiliferous dolomite.

Elwood Formation

The Elwood Formation (Willman, 1973, p. 14), which overlies the Wilhelmi Formation in northeastern and north-central Illinois (fig. S-3), is named for the town of Elwood, Will County. The type section, which is 5 miles north of the town, lies in a ravine 3 miles southwest of Joliet, on the southeast side of the Des Plaines River Valley (NW NW SE 36, 35N-9E), where the formation is 27 feet thick. The Elwood, which previously was referred to as the upper cherty zone of the Edgewood Formation, is a slightly argillaceous, light brownish gray, thin- to medium-bedded, fine-grained dolomite that contains layers of dense white chert as much as 4 inches thick. Chert forms 40-50 percent of the upper part of the formation but is less abundant downward. Although widely present in the Joliet area, it is erratic in occurrence elsewhere. It is exposed locally along the Fox River Valley north of Aurora (SE SW 3, 38N-8E) and has been traced westward in subsurface as far as Peru, La Salle County. The abundance of chert decreases laterally, and in places equivalent beds may not be separable from the Wilhelmi Formation. In some areas, particularly in subsurface, very cherty strata previously correlated with the Kankakee Dolomite probably belong to the Elwood Formation. The Elwood Formation appears to be conformable to the Wilhelmi below and the Kankakee above. It is lithologically similar to the Blanding Formation in northwestern Illinois and to strata included in the Mayville Formation in Wisconsin.

Kankakee Formation

The Kankakee Formation (Savage, 1916, p. 316), the uppermost formation in the Alexandrian Series in northeastern, central, and western Illinois (figs. S-3, S-5), is named for the Kankakee River in Will County, and the type section is in Cowan's Quarry and adjacent bluffs of the river 3.5 miles southeast of Ritchey (SE SW NW 26, 32N-10E), where the formation is 18 feet thick. The Kankakee Formation is commonly about 40 feet thick where exposed along the Des Plaines River Valley southwest of Joliet (Willman, 1973) and in subsurface elsewhere in northeastern Illinois. It has a similar thickness in exposures in Calhoun and Jersey Counties in western Illinois (Rubey, 1952), but in part of western Illinois it is completely truncated by Middle Devonian strata. In the type area the Kankakee Formation consists largely of greenish to pinkish gray, fine- to medium-grained, slightly cherty, glauconitic dolomite, generally in wavy beds 2-4 inches thick that are separated by thin green clay partings. It is differentiated into four members. The Drummond Member (at the base) is the most massive, and commonly contains a few rounded quartz sand grains and the most glauconite. The overlying Offerman Member is very thin bedded, slightly argillaceous, and weathers lighter in color than the other members. The overlying Troutman Member makes up the greater part of the formation and has the typical character of the formation. It is overlain by the nearly white Plaines Member, which is massive except for a few thin clay partings near the base. The top of the Plaines is a distinctive, flat surface that is smooth except for small sharp-sided pits about half an inch deep that form a roughly evenly spaced pattern at 3-6 inch intervals. The pits are filled with bright green clay. This surface has been interpreted as an unconformity at the base of the Niagaran Series, but there is slight if any truncation of the Plaines Member, which is only 2-3 feet thick, and the surface is more likely a corrosion surface on which strata may be absent because of nondeposition rather than subaerial erosion. The Kankakee Formation is generally fossiliferous, and corals, particularly *Halysites* and *Favosites* (fig. S-12), are common to abundant throughout the formation (Savage, 1926). Although the basal Drummond Member contains the *Platymerella* Zone, these fossils are also locally common in the upper few feet of the underlying Elwood Formation. The Plaines Member at the top of the formation contains the *Microcardinalia* Zone where that fossil, along with *Pentamerus oblongus* (fig. S-12), occurs in dense clusters, most commonly in the lower part of the member and occasionally as scattered individuals in the Troutman Member below. The Kankakee Formation is traced in subsurface from the type region to exposures in Calhoun and Jersey Counties in western Illinois, where the formation is somewhat purer and the wavy bedding and green clay partings are less conspicuous. The formation varies from fine-grained, gray limestone in the north part of the western Illinois outcrop area to porous brown dolomite in the south part. The Kankakee is not differentiated into members in western Illinois, but the *Platymerella* Zone is present at the base and the *Microcardinalia* Zone at the top. The Kankakee is lithologically similar to the Sweeney Formation in northwestern Illinois. Although fossils indicate the equivalence of the Kankakee to the Sexton Creek Limestone in southern Illinois, the type Sexton Creek does not closely resemble the Kankakee. It lacks both the upper and lower faunal zones, and may be equivalent to only part of the Kankakee. The Kankakee Formation is essentially equivalent to the Brassfield of Indiana, Kentucky, and Ohio, but the Brassfield locally includes strata equivalent to the Wilhelmi and Edgewood in Illinois. The Kankakee is equivalent to the Mayville, Byron, and Hendricks Formations in eastern Wisconsin. However, the Mayville and Byron locally include strata equivalent to the Wilhelmi and Elwood Formations.

Drummond Member—The Drummond Member of the Kankakee Formation (Willman, 1973, p. 17), the basal member, is named for Drummond, Will County, 5.5 miles southwest of the type section in a railroad cut on the southeast side of the Des Plaines River Valley, 2 miles southwest of Joliet, Will County (NW SE SW 30, 35N-10E), where the member is 8.5 feet thick. It is as much as 11 feet thick in the Joliet area but thins to only 1 foot thick along the Kankakee River. The Drummond Member is pure, vesicular to coarsely vuggy, gray dolomite that generally contains abundant grains of glauconite, scattered grains of well rounded quartz sand, relatively large chert nodules, and large colonies of corals. The *Platymerella* Zone occurs in the lower part, with the fossils most common in lenses of chert.

Offerman Member—The Offerman Member of the Kankakee Formation (Willman, 1973, p. 17), which overlies the Drummond Member, is named for Offerman School, three-fourths of a mile southeast of the type section, which is in the same exposure as the Drummond Member. In the type section the member is only 2.5 feet thick, a minimum thickness, but

it more commonly is about 3 feet thick along the Kankakee River and 6-11 feet thick in quarries at Joliet, Elmhurst, and Hillside. The Offerman Member differs from the underlying and overlying members in being more argillaceous, less vesicular, and thinner bedded, and in having smoother bedding surfaces and a lighter colored weathered surface.

Troutman Member—The Troutman Member of the Kankakee Formation (Willman, 1973, p. 18), which overlies the Offerman Member, is named for Troutman Grove Cemetery, Will County, 2 miles south of the type section, the lower part of which is in the same exposure as the Drummond Member, whereas the upper part is in a small quarry one-fourth of a mile east (SW NW SE 30, 35N-10E). The two sections are correlated by a thin bed of white clay that occurs near or slightly above the middle of the member in both sections and also in nearly all exposures of the member in northeastern Illinois. The Troutman is 27 feet thick in the type locality but thins to 11 feet along the Kankakee River. The Troutman Member has the typical lithology of the Kankakee Formation. It contains a few widely scattered nodules of chert.

Plaines Member—The Plaines Member of the Kankakee Formation (Willman, 1973, p. 18), the uppermost member, is named for Plaines Station, a railroad switching point on the southeast side of the Des Plaines River 1.75 miles southwest of Joliet, Will County. The type section is at the top of a small quarry, where it overlies the type section of the upper part of the Troutman Member. The Plaines Member is 2.2 feet thick in the type section but elsewhere is 1.5-3.4 feet thick. It is widely exposed along the Kankakee and Des Plaines Rivers. The dolomite is pure, massive, medium grained, and nearly white, and the top is the smooth surface that marks the top of the formation. The *Microcardinalia* Zone is largely in the Plaines Member.

Mosalem Formation

The Mosalem Formation (Brown and Whitlow, 1960, p. 36) is the basal formation in the Alexandrian Series in northwestern Illinois (fig. S-4) and is named for Mosalem Township in Dubuque County, Iowa. The type section, a roadcut south of the village of King (E1/2 SE 27, 88N-3E) exposes the upper 60 feet, nearly the entire thickness. Brown and Whitlow named the Mosalem and the overlying Tete des Morts as members of the Edgewood Formation, but, because they are distinctly different in lithology, Willman (1973, p. 31) made them separate formations and discontinued the use of Edgewood in northwestern Illinois. The Mosalem strata were originally named "Winston" (Savage, 1914) for exposures at the east end of the railroad tunnel at Winston, Jo Daviess County, but later were included in the Edgewood Formation (fig. S-8). The Mosalem is well exposed in many places in northwestern Illinois north of the Savanna Anticline and is as much as 100 feet thick where it fills channels eroded into the Maquoketa Shale Group. Typical thick exposures can be seen in the Mississippi River bluffs 6 miles south of Galena (SE SW SE 21, 27N-1E) and south of Pearl City, Stephenson County (NE cor. 17, 26N-6E). The formation is generally much thinner and is only 7 feet thick in Mississippi Palisades State Park north of Savanna, Carroll County (SW NE SE 28, 25N-3E). The Mosalem grades from very argillaceous, medium to dark gray dolomite and dolomitic shale at the base in the thick sections, to moderately argillaceous, fine-grained, dense, gray, yellow-brown-weathering dolomite at the top. It differs from the overlying Tete des Morts Formation in being more argillaceous and thinner bedded and in containing a few bands of white chert nodules and several thin, pure, vesicular, fossiliferous, laminated beds. Where thin, the Mosalem is slightly to moderately argillaceous and thick bedded. The formation is largely nonfossiliferous, but Savage (1914) listed a small fauna. The Mosalem is similar in character to the Wilhelmi Formation in northeastern Illinois and probably is equivalent to part of the Edgewood Formation in western and southern Illinois.

Tete des Morts Formation

The Tete des Morts Formation (Brown and Whitlow, 1960, p. 39) (fig. S-4), named for Tete des Morts Creek, Dubuque County, Iowa, overlies the Mosalem Formation in northwestern Illinois north of an east-west line through Hanover, Jo Daviess County. The type section is in the same exposure as the type section of the Mosalem Formation. The formation was originally designated a member of the Edgewood Formation but was later classified as a formation in Illinois (Willman, 1973, p. 33). It is the prominent cliff-forming unit at or near the top of many mounds and ridges in the Driftless Area in northwestern Illinois (fig. S-2D). The underlying Mosalem Formation and the Maquoketa Shale Group below are generally covered in the slopes below the Tete des Morts. The Tete des Morts is about 24 feet thick in the type locality, but in Illinois it is commonly about 20 feet thick, with a range of 18-22 feet, except where it thins to absence within a short distance at its southern limit. The Tete des Morts Formation is mainly pure, fine- to medium-grained, vesicular, massive, gray dolomite in which corals, particularly *Favosites*, are common. It generally contains little chert, but a persistent band of chert nodules and chert lenses occurs in a thin, slightly argillaceous, well bedded zone 1-2 feet thick 7-8 feet below the top. Scattered chert nodules occur locally in the lower part of the formation, and thin vein-like lenses of white chert are common, particularly in the upper part. Glauconite is common to abundant in the upper part and common to rare in the lower part. Weathered surfaces are deeply etched and exceptionally rough. Except for corals, fossils are scarce. The Tete des Morts most closely resembles the glauconitic Drummond Member at the base of the Kankakee Formation in northeastern Illinois, but if the nearly identical Elwood and Blanding Formations, which have conspicuous layers of chert, are equivalent, the Tete des Morts must be older than the Drummond, and it may be laterally equivalent to upper beds of the Wilhelmi Formation.

Blanding Formation

The Blanding Formation (Willman, 1973, p. 35) (fig. S-4), which overlies the Tete des Morts Formation in northwestern Illinois, is named for the village of Blanding, Jo Daviess County, 3 miles south of the type section in the upper part of the Mississippi River bluffs (SE SW SE 21, 27N-1E), where the formation is 51.5 feet thick. The formation was originally named "Waucoma" (Savage, 1914) but later was assigned to the Kankakee Dolomite (Savage, 1926). The Blanding Formation is commonly 35-50 feet thick, and is widely exposed both north and south of the Savanna Anticline, along which it is eroded. It consists of brownish to pinkish gray, fine-

grained, slightly argillaceous to pure dolomite in 2-6 inch beds. It contains layers of white chert, most of them 1-3 inches thick and commonly separated by 4-6 inches of dolomite. In some localities chert forms 50 percent of the upper part of the formation. The cherty residuum above the Tete des Morts Formation on many of the mounds in the Driftless Area is derived from the Blanding Formation. The basal 3-8 feet of the formation at some places contains only a little chert, largely in scattered nodules. The dolomite in this basal zone is slightly more argillaceous than that above, and it may be equivalent to a thicker well bedded zone quarried for building stone, the "quarry beds," farther west in Iowa. Silicified corals are common in the Blanding, and Savage (1926) listed other fossils. The Blanding Formation is similar in lithology to the Elwood Formation in northeastern Illinois, but the latter has been traced in subsurface westward only to Peru, La Salle County, and the equivalence of the two units is not considered established.

Sweeney Formation

The Sweeney Formation (Willman, 1973, p. 36) (fig. S-4), which overlies the Blanding Formation in northwestern Illinois, is named for the Sweeney Islands in the Mississippi River, a short distance west of the type section, an exposure in the bluffs in Mississippi Palisades State Park, north of Savanna, Carroll County (SW SE NE 33, 25N-3E), where the formation is 55 feet thick. It is also well exposed in the Mississippi River bluffs south of the Savanna Anticline and in quarries at Fulton in Whiteside County (cen. NE SW 21, 22N-3E). Savage (1926) correlated this unit with the Niagaran Joliet Formation in northeastern Illinois, but it has slight lithologic resemblance to the Joliet, is similar to the Kankakee Formation, and contains the *Microcardinalia* Zone characteristic of the upper Kankakee. The Sweeney Formation is commonly 45-55 feet thick and occurs throughout the Silurian outcrop area in northwestern Illinois, although it is eroded from most of the mounds north of Hanover. The Sweeney Formation is light pinkish to brownish gray, vesicular, pure dolomite in tight beds 1-4 inches thick with thin, green clay partings. Near the base and in a zone near the middle of the formation, the partings become thicker and are shaly. In places the formation contains no chert, but scattered nodules are not rare, and in a zone 3-5 feet thick 15-20 feet above the base the chert occurs in layers, lenses, and nodules. *Microcardinalia* and *Pentamerus oblongus* are common in this zone, generally in the chert. Silicified corals are common throughout the formation. It is equivalent to the upper part of the Hopkinton in Iowa and it is tentatively correlated with the Kankakee and the Sexton Creek Formations elsewhere in Illinois.

Edgewood Formation

The Edgewood Formation (Savage, 1909, p. 517-518) (figs. S-5, S-6), the basal Alexandrian formation in western and southern Illinois, is named for exposures near Edgewood, Pike County, Missouri. The Edgewood is as much as 50 feet thick where exposed along the Lincoln Anticline in Calhoun and Jersey Counties, but in places it is reduced to 10 feet or less where it is truncated by the Kankakee Formation (Rubey, 1952). The upper 33 feet is well exposed in a quarry at Monterey School, Calhoun County (NE SW 11, 12S-2W), and at Twin Springs in Pere Marquette State Park in Jersey County (NW SE 9, 6N-13W) (Collinson et al., 1954). The formation varies from a soft, fine-grained, thin- to medium-bedded, argillaceous, brown, dolomitic limestone containing disseminated fine sand in the northern part of the outcrop area, to a hard, massive, porous, brown dolomite or very dolomitic limestone in the southern part. In the northern part the lower few feet is a massive gray oolite or oolitic limestone—the Noix Oolite Member. The oolite is fossiliferous in places, but the remainder of the formation contains few fossils (Savage, 1913). The Edgewood Formation is also exposed along and near the Mississippi River in Alexander County in southern Illinois, where its maximum thickness is about 4 feet and it is locally absent. It thickens eastward in subsurface to as much as 60 feet. Good exposures occur in roadcuts near Gale (NE NE NW 4, 15S-3W) (Pryor and Ross, 1962). In that area the Edgewood is a massive, gray, crystalline limestone. The lower 2 feet is a conglomerate of pebbles from the Girardeau Limestone, mixed with oolites and fine quartz sand in a clear calcite matrix. The oolitic bed is assigned to the Noix Oolite Member. The oolite is also locally present in subsurface throughout southern Illinois.

Noix Oolite Member—The Noix Oolite Member of the Edgewood Formation (Keyes, 1898, p. 59, 62) is named for exposures along Noix Creek near Louisiana, Pike County, Missouri. It is generally at or close to the base of the Edgewood Formation but is lenticular and absent in some areas. It commonly is 1.5-3.5 feet thick in western Illinois (Rubey, 1952), and it is as much as 2 feet thick in southern Illinois (Pryor and Ross, 1962).

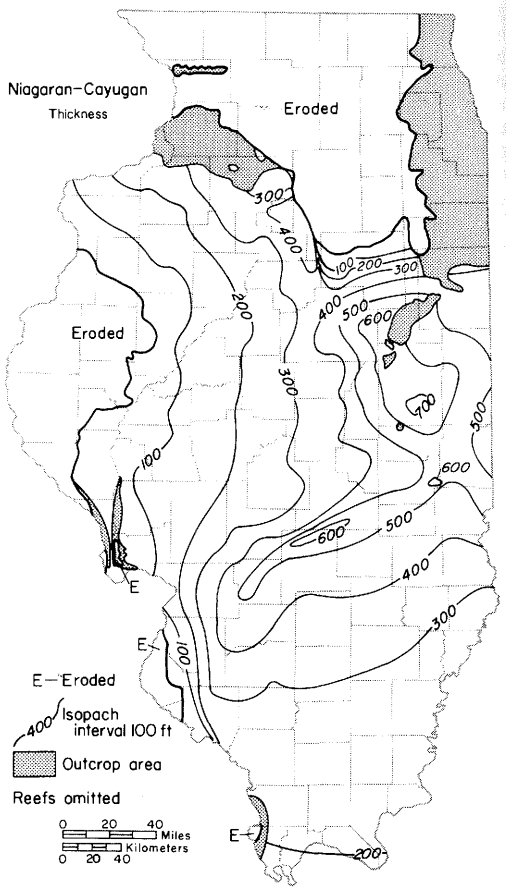
Sexton Creek Limestone

The Sexton Creek Limestone (Savage, 1909, p. 518; Ulrich, 1911), which overlies the Edgewood Formation in southern Illinois (fig. S-6), is named for exposures in the Mississippi River bluff at the mouth of Sexton Creek in Alexander County (SW 27, 14S-3W), where it is about 40 feet thick, but it is best exposed 4 miles northeast, just north of the mouth of Dongola Hollow (SW SE NW 12, 14S-3W). It was originally defined to include higher strata, now differentiated as the St. Clair Limestone, but was restricted to its present boundaries by Ulrich (1911). The Sexton Creek locally truncates the Edgewood Limestone to rest directly on the Girardeau Limestone. The Sexton Creek and its contact with the Edgewood Limestone are exposed in a roadcut a quarter of a mile southeast of Gale (NE NE NW 4, 15S-3W) (Pryor and Ross, 1962). The formation is a thin-bedded, fine-grained, cherty, gray limestone. The upper part is thicker bedded and is mottled red. In the areas where it is relatively thick, the Sexton Creek commonly contains persistent bands of black chert nodules. The formation is correlated with the Kankakee Formation in northern Illinois on the basis of its fossils, although the faunal zones that mark the top and bottom of the Kankakee Formation have not been found in the Sexton Creek. The Sexton Creek is approximately equivalent to the Brassfield Limestone in Indiana and Kentucky.

 Electronic Filing: Received, Clerk's Office 07/01/2024

NIAGARAN SERIES

The Niagaran Series (Hall, 1842, p. 57; Swartz et al., 1942, chart 3) is based on the Niagara Falls section in New York, as restricted by differentiation of the pre-Clinton strata as the Alexandrian Series (Savage, 1908, p. 434). It consists of the strata above the *Microcardinalia* Zone (*Stricklandinia* or *Stricklandia* Zone of early reports) up to and including the faunal zone characteristic of the Guelph Formation in New York and Ontario, which is commonly identified as the *Megalomus* Zone. According to Berry and Boucot (1970, pl. 2), the Niagaran in Illinois is equivalent to most of the Upper Llandovery, the Wenlock, the Ludlow, and part of the Pridoli Series in Europe (figs. S-7 to S-10). Niagaran strata crop out in all four outcrop areas of Silurian rocks in Illinois (fig. S-1) and are present in subsurface throughout most of the Illinois Basin (S-15). They are overlain by the Cayugan Series only in southern Illinois, where the position of the top of the Niagaran is not definite but at present is placed in the upper part of the Moccasin Springs Formation. Elsewhere in Illinois the top of the Niagaran Series is truncated by Middle Devonian or younger strata. Niagaran strata have a maximum thickness of a little more than 1000 feet in Marion County, where the Sandoval Reef stood high above the surrounding interreef Niagaran (fig. S-11). Three facies were recognized in the Niagaran strata by Lowenstam (1949). A dominantly shaly facies (Bainbridge Group) occurs in the southern part of the state and also surrounds numerous reefs in the northern part of that area. A facies of intermediate purity (Thorn Group) extends from western Illinois to the Chicago region, and in it the reefs are surrounded by cherty, generally silty dolomite. A relatively pure facies (Coe Group) occurs in northwestern Illinois where the reefs are surrounded by dolomite that is generally purer than it is in the other facies. These units are at present recognized as facies, not groups, and different rock-stratigraphic classifications are used within the three facies (figs. S-3 to S-6). The boundary between the southern and northern facies is transitional through a broad zone entirely in subsurface, but, for practical purposes of changing nomenclature, it is placed at the northern boundary of the area in which a distinctive electric log marker, the "two-kick, three-kick zone," can be recognized (figs. S-1, S-16). The position of the boundary of the northwestern facies is not as well known and



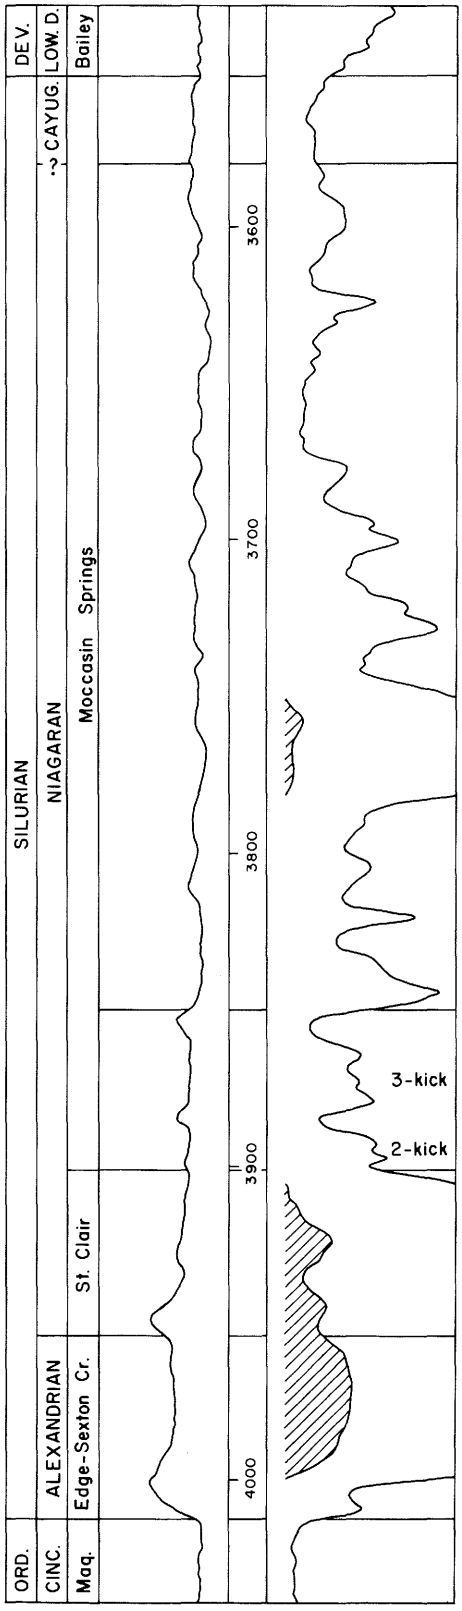


Fig. S-15—Thickness of the Niagaran Series; includes the Cayugan Series in southern Illinois.

the rock-stratigraphic units have not as yet been traced far from the outcrop area.

Joliet Formation

The Joliet Formation (Savage, 1926, p. 522) (figs. S-3, S-5) is named for Joliet, Will County, and the type section is in the National Stone Company quarry on the south side of Joliet (NE SE 21, 35N-10E), where the formation is 68 feet thick. The Joliet Formation is differentiated as the basal formation of the Niagaran Series in an area extending from Chicago to Calhoun County in western Illinois (fig. S-1). It is 70-80 feet thick in exposures along the Des Plaines River Valley, but only about 40 feet along the Kankakee River. It is 35-40 feet thick along the Mississippi River at Grafton in Jersey County, but farther west the top is truncated by Middle Devonian strata, and in southern Calhoun County the formation is entirely eroded. In exposures in northeastern Illinois along the Des Plaines, Kankakee, Du Page, and Rock Rivers, the Joliet Formation is differentiated into a basal shaly, red, green, and gray member (the Brandon Bridge

Member), overlain by nearly white, generally cherty dolomite that is silty at the base, grades to slightly silty at the top (the Markgraf Member), and is, in turn, overlain by nearly white, locally red-mottled, pure dolomite (the Romeo Member). In western Illinois, much of the Joliet is similar to the Romeo Member, although there is a weakly shaly zone at the base. The Romeo Member is prominent on electric logs and has been traced widely in subsurface. The basal shaly zone of the Joliet Formation is characterized by an abundance of arenaceous Foraminifera, among which Ammodiscidae are prominent (Dunn, 1942). This zone is also present at the base of the Joliet in Jersey County (Collinson et al., 1954) and at the base of the St. Clair Limestone in southern Illinois. It has not been found in northwestern Illinois or in Wisconsin north of Milwaukee, but eastward it is well represented in the Osgood Formation of Indiana. Outside the area where the Joliet is differentiated, the position of its top is not well established, but in northwestern Illinois the Marcus Formation may in part be equivalent to the Joliet, and in southern Illinois the top of the Joliet correlates to a horizon within the St. Clair Limestone.

Brandon Bridge Member—The Brandon Bridge Member of the Joliet Formation (Willman, 1973, p. 20), the basal member, is named for Brandon Bridge over the Des Plaines River on the southwest side of Joliet, Will County, and the type section is in the Lincoln Stone Company quarry southwest of the bridge (S1/2 SE 20 and N1/2 NE 29, 35N-10E), where the member is 29 feet thick. The Brandon Bridge thins southward and is only 10.5 feet thick where exposed along the Kankakee River east of the Warner Bridge in Kankakee County (NW SE SW 31, 32N-11E). In the Joliet area the Brandon Bridge Member is differentiated into two parts by a bed of green to black shale as much as a foot thick, but generally only an inch or two thick. The lower part is the more shaly and contains beds of red crinoidal dolomite interbedded with very argillaceous gray and red dolomite. The upper part is less shaly and most of it is gray, mottled with red and green. The top is placed at the highest strong shaly parting. The abundance of arenaceous Foraminifera in the member has been noted, and *Bumastus* (fig. S-12) is locally present, particularly in the middle shale.

Markgraf Member—The Markgraf Member of the Joliet Formation (Willman, 1973, p. 21), which overlies the Brandon Bridge Member, is named for the abandoned Markgraf quarry on the north side of the Des Plaines River, on the southwest side of Joliet, Will County (SW SW 16, 35N-10E), where the member is 22.1 feet thick. It thins southward and is only 12.3 feet thick where exposed along the Kankakee River at the mouth of Rock Creek Canyon (SW SE SW 32, 32N-11E). The Markgraf Member is light gray, nearly white, medium-bedded dolomite. Along the Des Plaines River the member consists of three approximately equal units—a basal very silty dolomite, a middle moderately silty and argillaceous dolomite with bands of chert nodules, and an upper slightly argillaceous dolomite that also contains bands of chert nodules. Along the Kankakee River, where the member is relatively thin, the dolomite all resembles the upper unit along the Des Plaines Valley.

Romeo Member—The Romeo Member of the Joliet Formation (Willman, 1973, p. 22), the top member, is named for Romeo, Will County, where part of the member is exposed at the top of quarries now largely filled with water. The type section is in the National Stone Company quarry, 6 miles south of Romeo, on the southwest side of Joliet, where it is part of the type section for the Joliet Formation, and is 20.2 feet thick. It ranges from 18 feet in Rock Creek Canyon

Fig. S-16—Electric log of the Silurian System.

Electronic Filing: Received, Clerk's Office 07/01/2024

along the Kankakee River to 34 feet thick in a quarry at Elmhurst in Du Page County. The member consists of light gray to white, gray-weathering, pure, vesicular, thin- to medium-bedded dolomite, commonly with tight stylolitic bedding surfaces. It locally has pink mottling. It contains silicified fossils and several bands of chert nodules in the type locality, but in many exposures it exhibits little or no chert. Corals are common and locally abundant.

Marcus Formation

The Marcus Formation (Willman, 1973, p. 37) is the basal Niagaran unit in northwestern Illinois (fig. S-4). It is named for Marcus, Carroll County, 4 miles northwest of the type section, which is in an abandoned quarry in the southern part of Mississippi Palisades State Park (SW SE SE 33, 25N-3E), where it is 40.3 feet thick. It was differentiated as the "*Pentamerus* beds" in early studies and later was named "Waukesha" (Savage, 1926). The Marcus Formation occurs in northwestern Illinois both north and south of the Savanna Anticline, along which it is eroded. North of the anticline it occurs only in the deepest part of the syncline, but it extends eastward to Shannon, Carroll County, and is well exposed north of Mt. Carroll, Carroll County (SE NW NW 25, 25N-4E). South of the anticline it is well exposed in quarries east of Fulton (SW NE NW 19, 22N-4E). The Marcus is uniformly close to 40 feet thick. It consists of pure, vesicular, brown, massive dolomite (fig. S-2C). The lower 10-20 feet is generally crowded with the shells of *Pentamerus oblongus* (fig. S-12), which is also common in the upper part along with other fossils, especially corals. The Marcus Formation occurs at the position occupied by the Joliet Formation farther east and south, but it does not resemble it lithologically, and strata equivalent to the Marcus may be missing at the corrosion surface that marks the base of the Joliet. The abundance of *Pentamerus* suggests correlation of the Marcus with the Schoolcraft in Wisconsin and the Reynales in New York.

Sugar Run Formation

The Sugar Run Formation (Willman, 1973, p. 22), which overlies the Joliet Formation in northeastern Illinois (fig. S-3), is named for Sugar Run, a stream on the south side of Joliet, Will County, along which it is well exposed. The type section, just south of the stream, is in the National Stone Company quarry, which is also the location of the type section for the Joliet Formation. The lower 26 feet of the Sugar Run is exposed at the top of the east face of the quarry. The Sugar Run strata, informally called the "building stone beds," were originally included with overlying interreef Racine strata in the Waukesha Formation (Savage, 1926), but later the Waukesha was restricted to the lower beds (Willman, 1943) (fig. S-7); recently Waukesha was replaced with Sugar Run (Willman, 1973). The Sugar Run Formation is about 30 feet thick in the Joliet area and its contact with the overlying Racine Formation is exposed on the north side of Joliet, particularly where State Highway 4A ascends the east bluff of the Des Plaines Valley (NW NW SE 34, 36N-10E). The Sugar Run Formation is exposed along the Des Plaines River from Joliet to Sag Bridge, in quarries at Elmhurst and Hillside, along the Du Page River at Naperville, along the Fox River Valley at Aurora and Batavia, and along the Kankakee River from Rock Creek Canyon to Wiley Creek. It is absent in subsurface in some areas, in which it may be laterally equivalent to interreef strata included in the Racine Formation. The Sugar Run is slightly to moderately argillaceous and silty, very fine-grained, dense to slightly vesicular, light greenish gray, buff-weathering dolomite that occurs in medium to thick smooth-surfaced beds. It has been extensively quarried for building stone. Rock from quarries near Lemont was called "Athens Marble" and that from Joliet was called "Joliet Marble." The basal 7 feet of the Sugar Run grades uniformly into the pure Romeo Member of the Joliet Formation below. The Sugar Run generally has few macrofossils, but trilobites, particularly *Calymene*, are found in the Lemont area and elsewhere, and a varied fauna has been described (Lowenstam, 1948a).

Racine Formation

The Racine Formation (Hall, 1861), the uppermost Niagaran Formation in northern and western Illinois (figs. S-3, S-4, S-5), is named for exposures in quarries at Racine, Wisconsin. The quarries at Racine are in reefs, and the term "Racine" was introduced in northeastern Illinois for similar rocks (Savage, 1926, p. 524). Savage gave the name "Waukesha" to the impure cherty dolomite thought to underlie the reefs but in fact equivalent to them. He also included in the Waukesha the strata under the reefs that were used for building stone. Later, Waukesha was restricted in northeastern Illinois to the latter strata, and the overlying reef and interreef strata were combined in the Racine (Willman, 1943). At the same time the Racine was redefined to include the uppermost Niagaran strata that had been differentiated by Savage on the basis of their fossils as being equivalent to the Port Byron Formation of northwestern Illinois, although similar in lithology to the Racine. For the same reason, the term "Port Byron" was discontinued in northwestern Illinois, and Racine was extended to include the entire sequence of reef-bearing rocks. The Racine is well exposed in the Chicago area (fig. S-2A, B), especially in the large quarries at Thornton, McCook, La Grange, Hillside, and Elmhurst (Bretz, 1939; Willman, 1943, 1962, 1973; Willman et al., 1950; Lowenstam et al., 1956). In northwestern Illinois it is well exposed at the top of the Mississippi bluffs in Palisades State Park north of Savanna, in the bluffs south of Fulton to Port Byron, and at Morrison, Whiteside County (Sutton, 1935; Willman, 1943, 1973). In western Illinois it is exposed only in a small area at Grafton, Jersey County. The Racine is as much as 300 feet thick. In some areas it is almost entirely pure reef rock (fig. S-2E); in others it is largely silty or argillaceous, cherty interreef rock (fig. S-2F). In places the two types of rocks intertongue. Dark gray to black shaly beds are present locally. At Blue Island, a thickness of several feet of such beds was encountered during the digging of the Calumet Sag Channel and they have been informally called the "Blue Island beds" or "*Lecthaylus* shale" (Lowenstam, 1948a). Reefs start at various levels in the Racine. Many are well defined reefs with flank beds dipping steeply away from a central massive core. In other areas the reef bodies overlap. The Racine reef rock is exceptionally pure dolomite, largely vesicular to coarsely vuggy, medium grained and light gray to white. It commonly is mottled with various shades of gray. In some reefs, many of the vugs are filled with asphaltum. The

Electronic Filing: Received, Clerk's Office 07/01/2024

steeply dipping flank beds are generally pure dolomite, but some beds grade into argillaceous dolomite as the slopes diminish. The Racine reefs are highly fossiliferous. In northwestern Illinois much of the Racine consists of flat-lying, pure, reef type of dolomite, and reef structures do not appear to be as common as they are in northeastern and central Illinois. No reefs are present in the small area where the Racine is exposed at Grafton in Jersey County, western Illinois. About 45 feet of Racine is exposed at Grafton, but immediately west of there the formation is truncated by Middle Devonian strata. The interreef rocks in northeastern Illinois are largely impure, varying from moderately silty to very silty or very argillaceous, and lenticular bodies of shale are locally present on the flanks of some reefs. The interreef rocks are commonly very cherty, the chert generally in irregularly scattered nodules. The interreef rocks in many places contain beds of relatively pure dolomite, probably wash from the reefs. Near the reefs some beds have a strongly nodular character, suggesting deposition in water that was subject to frequent agitation. The Racine is equivalent to the upper part of the St. Clair and to all except the youngest part of the Moccasin Springs in southern Illinois. It is correlated with and is similar in lithology to the Gower in Iowa, the Engadine in northern Wisconsin, and the Wabash in Indiana.

St. Clair Limestone

The St. Clair Limestone (Penrose, 1891a, p. 102-103) (fig. S-6), named for St. Clair Springs, 8 miles northeast of Batesville, Independence County, Arkansas, is the basal formation of the Niagaran Series in southern Illinois. It is well exposed in the Mississippi River bluffs north of the mouth of Dongola Hollow, in Alexander County (SW SE NW 12, 14S-3W). Although only 10-20 feet thick where exposed in Alexander County, it thickens northward to 80-100 feet in the deeper part of the Illinois Basin, and it is as much as 150 feet thick at its northern margin, where it grades into the Joliet and Racine Formations. The strata now included in the St. Clair were originally in the upper part of the Sexton Creek (Savage, 1909), but Weller later (1940) included them in the lower part of the Bainbridge Formation (fig. S-10). Lowenstam (1949), noting that the pink crinoidal limestone of the lower Bainbridge is almost identical to that of the St. Clair in Arkansas, extended the St. Clair to Illinois and introduced Moccasin Springs for the upper, red, shaly part of the Bainbridge and elevated Bainbridge to a group. The St. Clair consists of coarsely crystalline calcite grains and abundant pink crinoidal remains in a fine-grained limestone matrix. The amount of crinoidal debris decreases upward. The matrix contains a small amount of silt, clay, and some very fine sand. The limestone occurs in medium to thick beds and is generally free of chert. It contains an abundance of arenaceous Foraminifera. The St. Clair Limestone is thought to be equivalent to the Joliet Formation and the lower part of the Racine Formation in northern Illinois. The Brandon Bridge Member of the Joliet, like the St. Clair, contains a few thin beds of pink crinoidal dolomite and abundant Foraminifera. Pink mottling also occurs in the Romeo Member of the Joliet and locally also in the Racine. The St. Clair is correlated with the Osgood, Laurel, Waldron, and Louisville Formations in Indiana.

Moccasin Springs Formation

The Moccasin Springs Formation (Lowenstam, 1949, p. 16) (fig. S-6) overlies the St. Clair Limestone in southern Illinois and is named for the village of Moccasin Springs, which is 9 miles north of Cape Girardeau, Cape Girardeau County, Missouri, and 3 miles north of the type section, a ravine in the Mississippi River bluffs (SE SE NW 24, 32N-14E). The formation is 100-130 feet thick in the outcrop area, and a thick section is exposed along Sammons Creek (Salamans on some maps), Alexander County (cen. S line 2, 15S-3W) (Pryor and Ross, 1962). The formation thickens northeastward and is commonly 160-200 feet thick, but it is as much as 400 feet thick bordering the reefs. The Moccasin Springs is dominantly red, or red- and gray-mottled, very silty, argillaceous limestone and calcareous siltstone, with shale common near the top. Beds that lack the red mottling become more abundant upward and northward. The Moccasin Springs contains numerous reefs (fig. S-1), some as much as 1000 feet thick (Lowenstam, 1949) (fig. S-11). The Moccasin Springs reefs are dominantly limestone, have well defined flank structures, and many have been large producers of oil. The interreef Moccasin Springs is differentiated into three members that have not been formally named. The lower is red- and gray-mottled shale and silty limestone that grades eastward from the outcrop area into alternating beds of mottled argillaceous limestone and red calcareous siltstone that have a characteristic and widely traceable electric log curve described as the "2-kick, 3-kick zone" (fig. S-16) throughout much of the basin and bordering the reefs. The overlying member is more uniformly red to greenish gray limestone, but it has some argillaceous and silty beds. The uppermost member is dominantly green shale, but it contains beds of red-brown siltstone and limestone. The position of the St Clair–Moccasin Springs contact in the northern Illinois Niagaran is uncertain, and the Moccasin Springs may be equivalent to only the upper part of the Racine Formation, including and above the "*Lecthaylus* shale" that is approximately 200 feet above the base of the Racine. Ross (1962b) reported a lower Ludlovian *Monograptus* from about 50 feet below the top of the Moccasin Springs, which makes it possible that much of the formation above that position may be Cayugan in age. The interreef facies of the Moccasin Springs Formation is similar to the Mississinewa Shale Member of the Wabash Formation in Indiana and the Henryhouse Formation in Arkansas and Oklahoma.

CAYUGAN SERIES

The Cayugan Series (Clarke and Schuchert, 1899; Swartz et al., 1942, chart 3) is based on the Cayugan Group of New York and includes all the strata of Silurian age above the contact of the Guelph and Salina Formations in the New York type section. As the uppermost Racine strata in northern Illinois have been correlated with the Guelph Formation, no Cayugan age strata are recognized in that area. However, the generally accepted interpretation that the reefs isolated the basin in which the Salina evaporites accumulated in-

Electronic Filing: Received, Clerk's Office 07/01/2024

troduces the possibility that some of the highest reefs may have continued to grow in Cayugan time. Reefs of Cayugan age could have been eroded from Illinois before they were overlapped by Middle Devonian strata. In the deeper part of the Illinois Basin, the Moccasin Springs Formation appears in places to grade upward into the Bailey Formation, which is largely of Lower Devonian age (Collinson and Schwalb, 1955), but in the outcrop area in Illinois the contact is sharp (Pryor and Ross, 1962). As the conodonts suggest that the lowermost beds of the Bailey are upper Silurian (Collinson, 1967), the Cayugan Series probably includes the upper part of the Moccasin Springs and the lower part of the Bailey Formation. Late Silurian graptolites have been reported from strata equivalent to the upper part of the Moccasin Springs in Missouri (Berry and Satterfield, 1972).

DEVONIAN SYSTEM

Charles Collinson and Elwood Atherton

The Devonian System (Sedgwick and Murchison, 1839), named for Devonshire, England, may originally have covered all of Illinois, but if so it was eroded from the northern part of the state, largely before Pennsylvanian time (fig. D-1). The upper and lower boundaries of the system in Illinois have been controversial, but in recent years they have become more precise, mainly because of zonation of the conodonts (Collinson, 1961, 1967; Collinson et al., 1971). The lower boundary is now placed in the lower part of the Bailey Formation rather than at its base (fig. D-2). The upper boundary is placed as high as the lower few feet of the otherwise Mississippian Hannibal Formation or, where those beds are missing, on the top of the Louisiana Limestone or the Saverton Shale. In many earlier reports, the upper boundary was placed as low as the top of the Cedar Valley Limestone or the Lingle Limestone, thus putting nearly all the New Albany Shale Group into the Mississippian System.

The Devonian is less than 100 feet thick in a large part of central and western Illinois, but it thickens into the deep part of the Illinois Basin to more than 1800 feet thick (fig. D-1). It is exposed only in limited areas along and near the Mississippi and Ohio Valleys, principally where the valleys truncate anticlinal areas (fig. D-3).

The Devonian System is subdivided into three series, Lower, Middle, and Upper. It is the only system in Illinois for which these terms have not been replaced by geographic names. Major stages in the development of the classification are shown in figures D-4 and D-5. The development of separate classifications for the northern and southern parts of the state results from the rise of the Sangamon Arch (fig. D-10) across north-central Illinois during, or at least by the end of, Lower Devonian time. Because the Sangamon Arch, rather than the Mississippi River Arch (fig. 12), formed a barrier in the Middle Devonian seas, the formations deposited in central and southern Illinois differ from those in northwestern Illinois. During late Devonian time, the Sangamon Arch subsided, and the seas spread entirely across the area.

The Lower Devonian rocks are dominantly siliceous limestone, dolomite, and chert; the Middle Devonian strata are largely pure limestone and dolomite; and the Upper Devonian sediments are dominantly black, gray, and green shale, although smaller amounts of limestone and siltstone are present. The Lower and Middle Series, with the underlying Silurian carbonates, compose the Hunton Limestone Megagroup, whereas the overlying clastic rocks form the basal part of the Knobs Megagroup (fig. D-2).

The large amount of silica in the Lower Devonian formations appears to have originated partly as finely divided quartz silt that was physically transported to the seas, and partly as a product of intensive weathering of the bordering upland areas, of transportation to the seas in solution, and of deposition as primary or diagenetic chert.

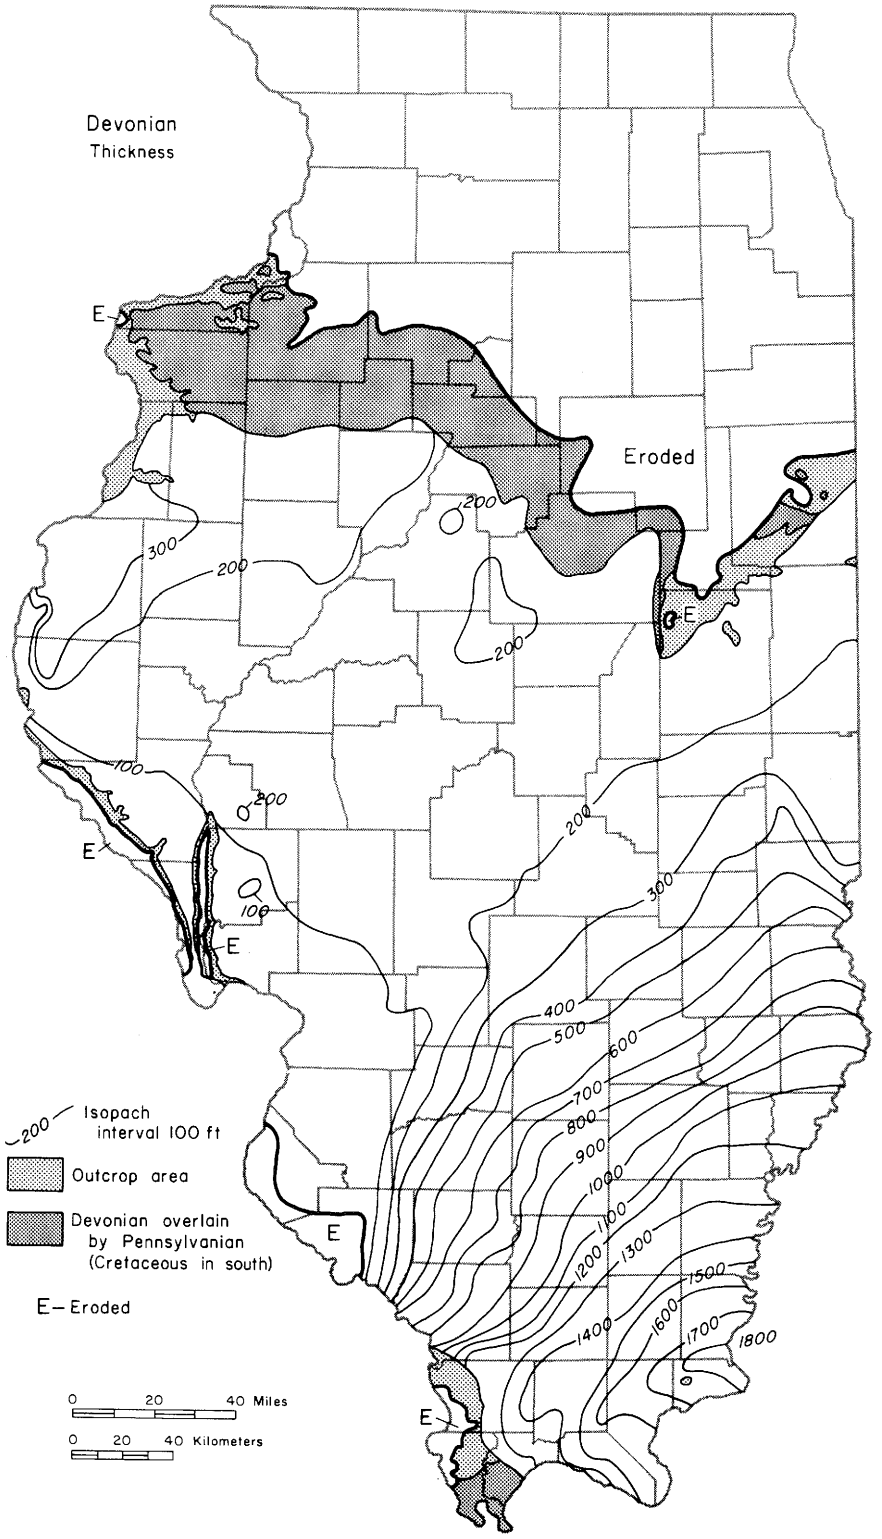

Fig. D-1—Thickness of the Devonian System.

Electronic Filing: Received, Clerk's Office 07/01/2024

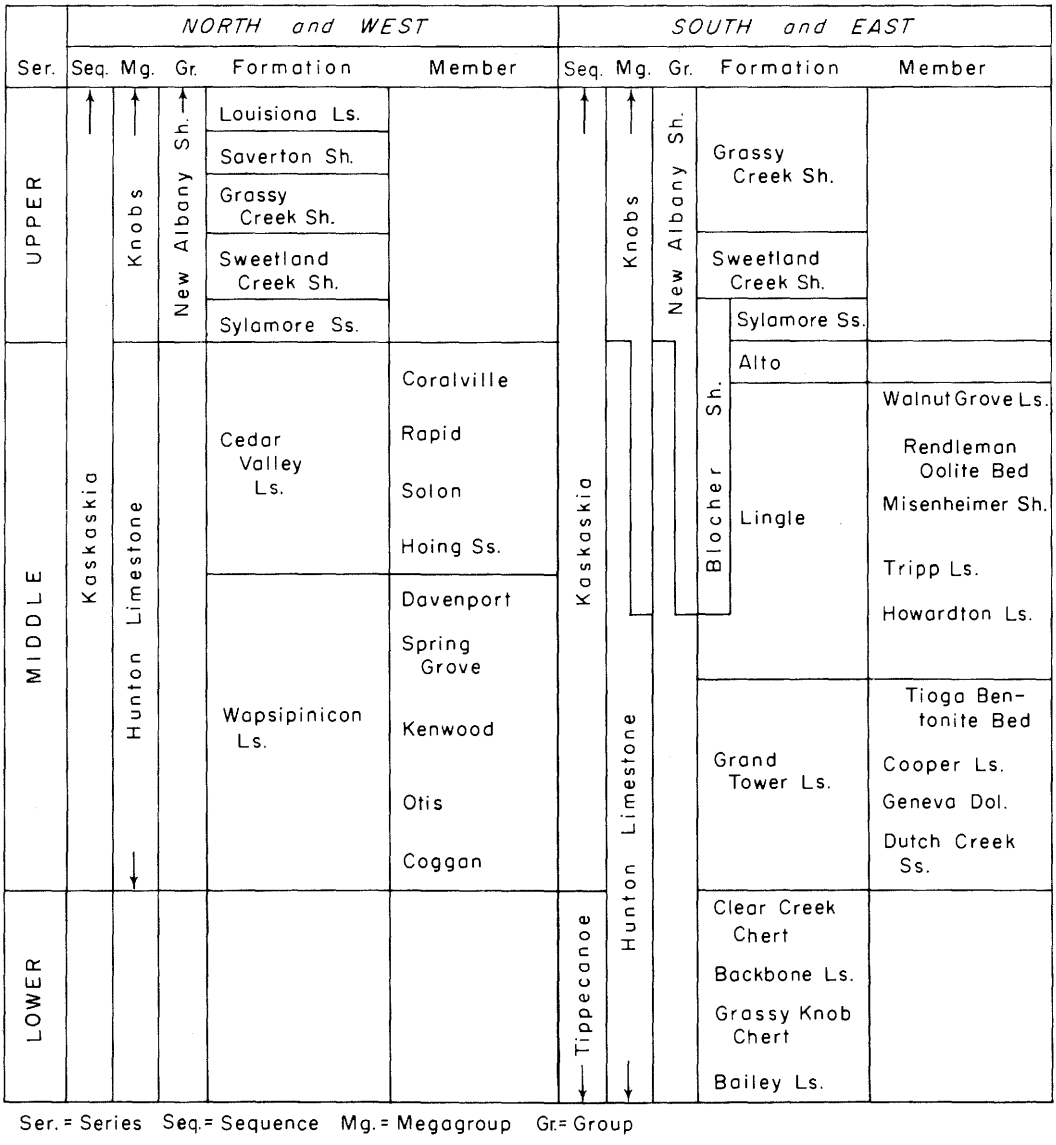

Fig. D-2—Classification of the Devonian System.

Most Middle Devonian rocks in Illinois are normal marine limestone, but north of the Sangamon Arch the normal sediments are interbedded with evaporites. By late Middle Devonian time, argillaceous sediments rich in spores and in finely disseminated organic debris were being deposited in the relatively deep seas in the southern part of the Illinois Basin, forming black, laminated, fissile shale. The conditions favoring this type of sedimentation were widespread during late Devonian time and black sediments covered the entire basin, although at times the supply of organic material was reduced and gray and green shales were deposited. On the flanks of the positive areas, calcareous sediments accumulated and, in places, are interbedded with black shale.

Middle Devonian rocks, particularly on and near the flanks of the basin, contain beds, lenses, and "floating grains" of quartz sand (Summerson and Swann, 1970). Most of the

Electronic Filing: Received, Clerk's Office 07/01/2024

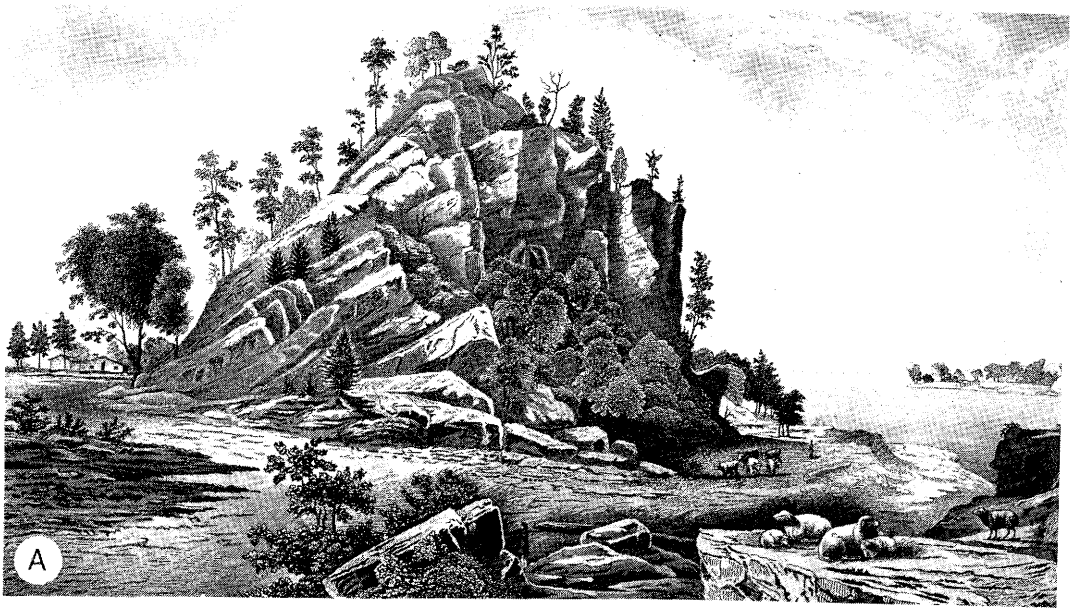
sand is well rounded and was derived by erosion from earlier Paleozoic formations (such as the St. Peter Sandstone) that were exposed on the Ozark Uplift and the Wisconsin Arch. These sands are thin and discontinuous but they are present throughout the basin. A thin bed of bentonite, the Tioga Bentonite, that originated from volcanoes in the eastern United States is widely traceable in late Middle Devonian rocks.

Fossils are common in only a few local beds of the siliceous Lower Devonian rocks, but they are common to abundant in the normal marine Middle Devonian limestones. Brachiopods and corals are the most common and best preserved of the macrofossils (figs. D-6, D-3E). Virtually no fossils are found in the widespread hypersaline limestones. In the Upper Devonian Series, macrofossils are abundant in the limestones but sparse in the shales. However, *Tasmanites* are abundant and conodonts are common to abundant in the series. The ranges of many Devonian fossils are given by Collinson et al. (1967a).

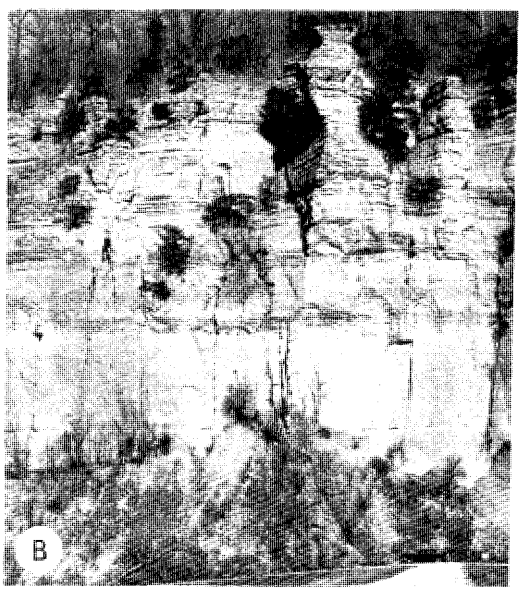
In the Illinois Basin, sedimentation was continuous from Silurian into Devonian time and from Devonian into Mississippian time. The major unconformity in the Devonian System is at the base of the Middle Devonian, where an extensive unconformity resulted from regional uplift, withdrawal of the seas, and minor warping. As a result, the Middle Devonian Series successively overlies Lower Devonian, Silurian, and Ordovician strata (fig. D-7) along what is termed the sub-Kaskaskia unconformity—the base of the Kaskaskia Sequence.

The regional correlations of the Devonian formations of Illinois have been discussed by Weller (1944b), Cooper (1944), and Collinson et al. (1967a, b).

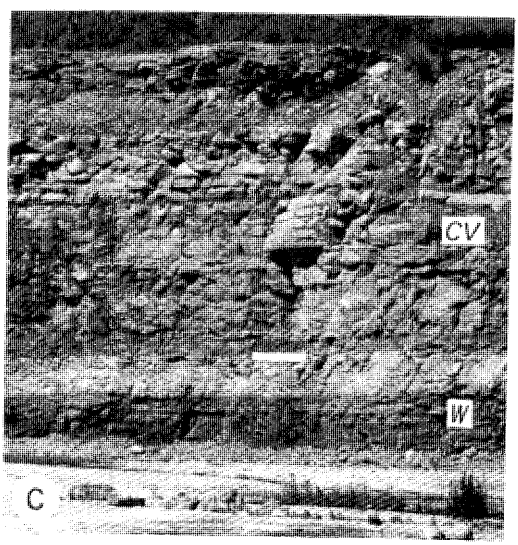
LOWER DEVONIAN SERIES



As in most of the Mississippi Valley region, Lower Devonian rocks in Illinois are largely siliceous—cherty, silty limestone and dolomite, and chert formations. They have long been called the Lower Devonian Series (Bassett, 1925), although the New York terms "Helderbergian," "Helderbergian and Oriskanian," and "Ulsterian" have been used at times in Illinois and are still used in other regions (fig. D-5). The name "Lower Devonian" is generally applied to Devonian strata older than the Onondaga Group of the New York section. They are correlated with Emsian and older strata of Europe (Collinson et al., 1967a).

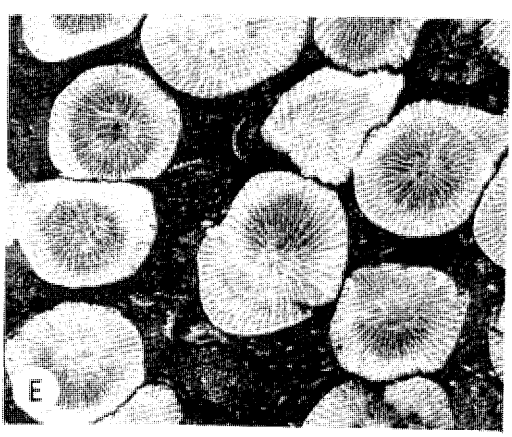


In Illinois the Lower Devonian underlies the southern third of the state, thickening southward from its northern boundary to 1200 feet in the extreme south (fig. D-8). Near the northern boundary the Lower Devonian rocks surround and partially overlap middle Silurian reefs, north of which they are truncated by the sub-Kaskaskia unconformity. They may have originally extended over all of Illinois, unless the Sangamon Arch and the positive areas bordering Illinois were above sea level during this epoch. South of the Silurian reefs, Lower Devonian strata are successively truncated by the unconformity. Along the western edge of the state, the Lower Devonian strata are truncated by the present surface on the flanks of the Ozark Uplift, and they are well exposed in Jackson, Union, and Alexander Counties (Weller, 1944a; Weller and Ekblaw, 1940; Pryor and Ross, 1962).



The Lower Devonian Series includes the Bailey Limestone (siliceous and cherty) at the base, the Grassy Knob Chert, the Backbone Limestone (pure), and the Clear Creek Chert (fig. D-9). The Bailey grades downward into the shale at the top of the Silurian Moccasin Springs Formation. Fossils are scarce in the Bailey, but the few conodonts found there suggest that the base of the Lower Devonian Series is within the lower part of the Bailey (Collinson et al., 1967a).

Bailey Limestone



The Bailey Limestone (Ulrich, *in* Buckley and Buehler, 1904, p. 110) is named for Bailey's Landing on the Mississippi River, Perry County, Missouri, a settlement long abandoned but thought to have been at or near the village of Grand Eddy. As the original type section is not exposed, Croneis (1944) designated as a neotype the outcrops in the river bluffs at and north of Red Rock Landing, half a mile east of Grand Eddy (11, 35N-12E). The Bailey Limestone underlies much of the deep part of the Illinois Basin and it has a maximum thickness of as much as 500 feet. It is 200-300 feet thick in the Illinois outcrop area, which extends from the south line of Jackson County to Olive Branch, Alexander County. It is exposed in high cliffs in the Mississippi River bluffs, especially in the Pine Hills area in Union County about 5 miles southeast of Grand Tower, where about 400 feet of Bailey, Grassy Knob, and Backbone is exposed (fig. D-3B). The Bailey is dominantly gray to greenish gray, silty, cherty, thin-bedded, very hard limestone. Some beds are argillaceous. The chert is black to dark gray and occurs in bands of nodules and in beds, some of which are 1-2 feet thick. Beds of calcareous and silicified siltstone occur in places. In the northern area, bordering the Silurian reefs, the Bailey is less cherty and is greenish gray, argillaceous dolomite. An upper zone, 0-100 feet thick, is pure, white, coarsely crystalline, only slightly cherty

limestone similar to the Backbone Limestone, from which it is separated by the Grassy Knob Chert. It has been traced widely in subsurface and referred to as the "unnamed limestone" (Collinson et al., 1967a). The sparse fauna of the Bailey includes *Leptaena rhomboidalis, Dalmanites* sp. (pygidia), several species of rhynchonellid brachiopods, crinoids, and conodonts. Most of the fauna occurs in the upper part. The presence of *Scyphocrinus elegans* low in the formation has been interpreted as indicating that the lower part is uppermost Silurian in age and that no break in sedimentation occurred between the Silurian and Devonian Systems in this region. The Bailey is overlain conformably by the Grassy Knob Chert and in many localities is not readily differentiated from it (Weller et al., 1952; Pryor and Ross, 1962).

Grassy Knob Chert

The Grassy Knob Chert (Savage, 1925b, p. 139-144), which overlies the Bailey Limestone, is named for Grassy Knob, a prominent high area on the Mississippi River bluffs 4 miles east of Grand Tower, Jackson County. The type section is in the west face of the knob (SW SW 27, 10S-3W). The formation is exposed in and near the Mississippi River bluffs in Jackson, Union, and Alexander Counties and occurs in subsurface through the deep part of the Illinois Basin (Collinson et al., 1967a). It is about 200 feet thick in the outcrop area but thickens to about 300 feet in the basin to the east. The Grassy Knob differs from the Bailey Formation below in being lighter colored and in containing more thick beds of solid chert, especially in the middle part of the formation (Weller, 1940), which is well exposed 2 miles southeast of Reynoldsville, Union County (NW cor. 32, 13S-2W). The Grassy Knob is gradational to the Bailey Limestone below. It is more sharply differentiated from the Backbone Limestone above, although no unconformity is evident. In the southern part of the Devonian outcrop area, where the Backbone is absent, the Grassy Knob is not readily separated from the Clear Creek Chert. Fossils are rare in the Grassy Knob Chert.

Backbone Limestone

The Backbone Limestone (Savage, 1920, p. 169-178), which overlies the Grassy Knob Chert, is named for an

isolated ridge called the Backbone along the Mississippi River north of Grand Tower, Jackson County. The type section is in a quarry at the south end of the ridge (SE SW SW 24, 10S-4W), where only the upper 38 feet of the formation, overlain by the Clear Creek Chert, is exposed. The Backbone Limestone appears to be as much as 200 feet thick where it rims the deep part of the Illinois Basin, but it becomes thinner within the deeper part and in places is absent (Collinson et al., 1967a). In the outcrop area in Jackson and Union Counties, the Backbone Limestone is about 100 feet thick, but it thins southward and is absent (or becomes cherty and is not recognized) in the Devonian outcrop area in Alexander County. The Backbone Limestone consists of light gray, massive, crystalline, pure limestone that commonly contains many large crinoid stems and a few scattered chert nodules. It has a large fauna that is dominated by brachiopods, notably *Acrospirifer murchisoni* and *Costispirifer arenosus*, but gastropods, bryozoans, conodonts, and trilobites are common. The fossils indicate a correlation with the Oriskany in New York. The Backbone is continuous with the Little Saline Limestone in Missouri.

Clear Creek Chert

The Clear Creek Chert (Worthen, 1866, p. 126-129; Savage, 1920, p. 174-175), the uppermost Lower Devonian formation, is named for Clear Creek in Union County, along which the formation is exposed for about 5 miles (T11-12S, R2W), although no specific type section has been designated. As originally defined by Worthen (1866), the Clear Creek may have included the Backbone Limestone and possibly the Grassy Knob Chert, but Savage (1920) restricted the name to the chert formation above the Backbone. The Clear Creek Chert is exposed along the Mississippi Valley from the south end of the Backbone in Jackson County, south to the vicinity of Tamms, Alexander County. It is well exposed in a quarry on the west bluff of Cache Valley northwest of Tamms

Grassy Knob Chert		200-300
Bailey Ls.		200-500

Fig. D-9—Columnar section of the Lower Devonian Series.

(NE NW 36, 14S-2W). The thickness of the Clear Creek is difficult to determine, but it is at least 300 feet thick in the outcrop area. Bald Knob, the highest point in southern Illinois, rises 600 feet above Clear Creek and appears to be all Clear Creek Chert, but the thickness is complicated by structure. The formation thickens eastward from the outcrop area to about 600 feet in the southern part of the basin. The Clear Creek is dominantly chert; much of it is white, or generally lighter in color than the chert in the lower formations (Weller, 1940). It contains some beds of gray, very fine-grained, siliceous limestone, which in places are separated from the chert beds by stylolitic partings. Such partings are also common in the chert. The proportion of limestone is generally small in most outcrops, but it is larger near the top of the formation and increases in subsurface north and east from the outcrop area. Solution of the limestone beds and fracturing of the chert beds has produced modifications of the original deposit that are variously described as novaculite, ganister, and tripoli (Lamar, 1953). The novaculite and ganister have been used for gravel and for making silica brick. The tripoli, which consists of finely divided particles of silica in vein-like bodies, is used in abrasives. The Clear Creek is much more fossiliferous than the Grassy Knob, and some chert beds are largely casts of fossils, particularly of the brachiopod *Eodevonaria melonicus*.

MIDDLE DEVONIAN SERIES

The term "Middle Devonian Series" has been commonly used in Illinois since 1925 (Bassett), but previously the New York terms "Ulsterian," "Erian," and "Senecan" were used for these rocks. As now defined, the Middle Devonian Series is based on the boundaries established in Europe and is equivalent to the Eifelian and Givetian Stages (Collinson, 1967).

The Middle Devonian Series underlies much of the southern two-thirds of Illinois and, although commonly less than 100 feet thick in the central and western parts, it thickens to more than 400 feet in the southeastern part (fig. D-10). It is exposed in small areas in southern, western, and northwestern Illinois (fig. D-3).

In Illinois the Middle Devonian Series includes strata from the base of the Grand Tower or the Wapsipinicon to the top of the Alto or Cedar Valley Formations (fig. D-11), although evidence from the conodont fauna indicates that in some places the upper boundary may lie within the upper part of the Cedar Valley and the Blocher. Lowermost Middle Devonian rocks may be absent in Illinois because of the major unconformity at the base.

A broad, gentle arch, the Sangamon Arch (Whiting and Stevenson, 1965), extended

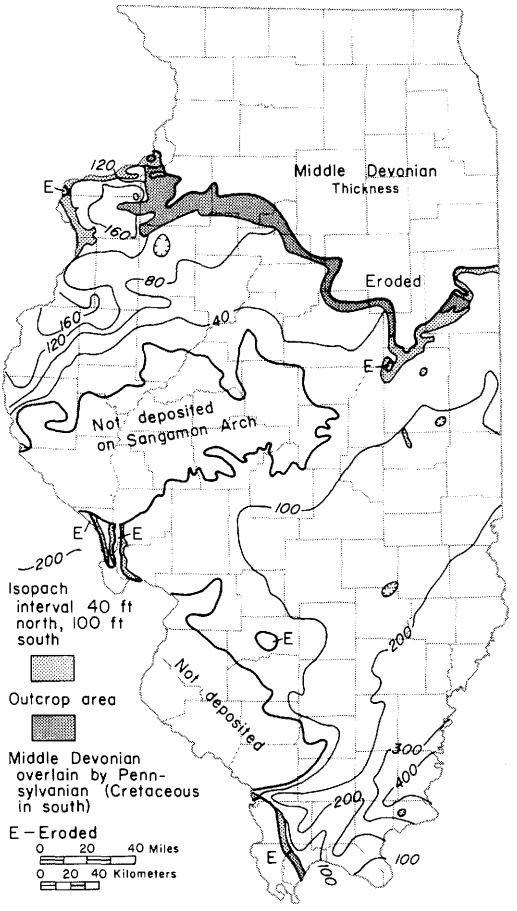

Fig. D-10—Thickness of the Middle Devonian Series.

northeast-southwest across north-central Illinois (fig. D-10) and served as a barrier in the Middle Devonian seas. The formations north of the arch were long considered to be uppermost Middle Devonian or Upper Devonian and younger than the formations south of the arch (Cooper et al., 1942), but more recent studies have indicated the general equivalence of the sediments on both sides (Collinson, 1967).

The Middle Devonian Series is dominantly limestone, although it is dolomitic in some areas. The upper part grades laterally to black shale in the deep part of the Illinois Basin, and a thin sandstone or sandy limestone occurs at the base in many areas. The top of the limestone or dolomite is the top of the Hunton Megagroup.

The Middle Devonian strata are generally very fossiliferous, and the large fauna is domi-

Electronic Filing: Received, Clerk's Office 07/01/2024

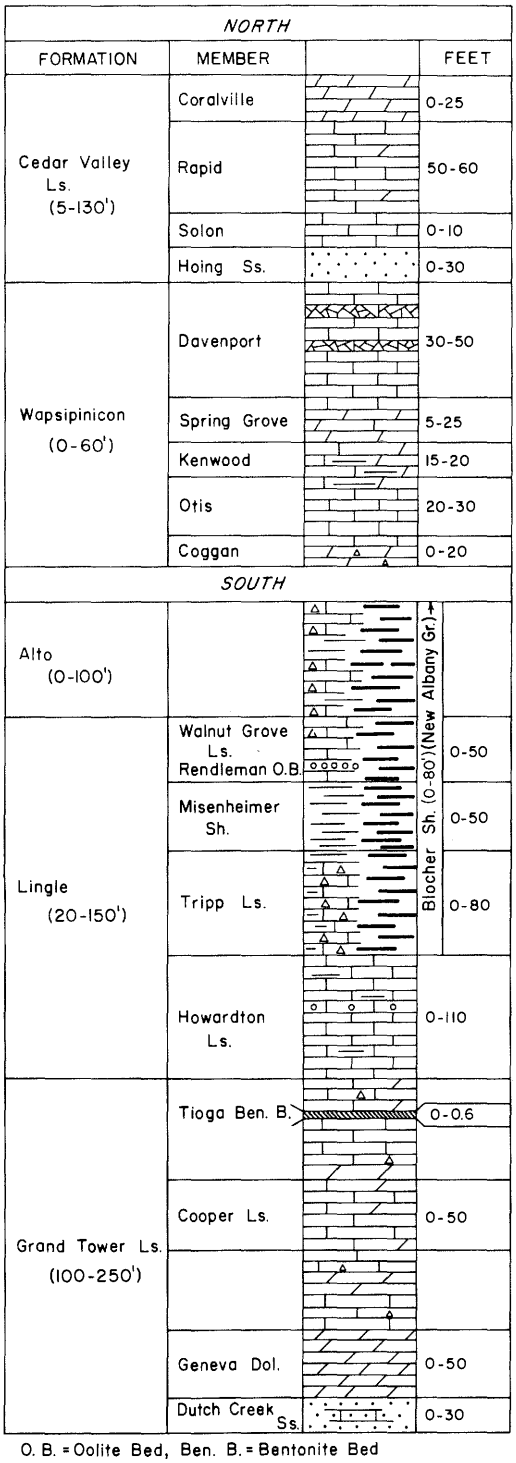

Fig. D-11—Columnar section of the Middle Devonian Series.

nated by brachiopods, corals, and conodonts, although other forms are common. Because of the sub-Kaskaskia unconformity, the Middle Devonian strata truncate Lower Devonian, Silurian, and uppermost Ordovician strata (fig. D-7).

KASKASKIA SEQUENCE

The major unconformity at the base of the Middle Devonian Series, or in some areas the base of the Upper Devonian Series, is widely present throughout the eastern part of the United States, and the strata between the unconformity and the next higher major unconformity (which in Illinois is at the base of the Pennsylvanian System) are called the Kaskaskia Sequence (Sloss et al., 1949) (fig. 14). The Kaskaskia Sequence is named for the Kaskaskia River in south-central Illinois. The original definition of the sequence placed its top at the base of the Mississippian Aux Vases Sandstone, excluding the Chesterian Series. However, because the sub-Aux Vases unconformity is confined to the margin of the basin and the Chesterian strata generally have the same structural attitude as the underlying Valmeyeran Series, the Kaskaskia was extended upward to the base of the Pennsylvanian System (Swann and Willman, 1961).

Wapsipinicon Limestone

The Wapsipinicon Limestone (Norton, 1895, p. 127, 155-166) is named for the Wapsipinicon River in Iowa, along which the type section consists of exposures between Troy Mills and Central City, Linn County, Iowa. It occurs in the basin northwest of the Sangamon Arch (fig. D-12), where it unconformably overlies Silurian and Ordovician strata (fig. D-7) and is overlain by the Cedar Valley Limestone. It has a maximum thickness of about 60 feet near the Mississippi River and thins southeastward. It lenses out on the flanks of the Sangamon Arch, where it is overlapped by the Cedar Valley Limestone. The Wapsipinicon is exposed in Illinois only in the vicinity of Rock Island, and the principal exposures are in quarries and outcrops at Milan (fig. D-3C), Rock Island, and Andalusia in Rock Island County, and at Cleveland in Henry County (Savage, 1921b; Savage and Udden, 1921; Collinson et al., 1967b; Edmund and Anderson, 1967). The Wapsipinicon is dominantly fine-grained to lithographic, pure limestone, but some beds are argillaceous and dolomitic. Beds of anhydrite and gypsum occur locally in the subsurface in the westernmost part of the area, particularly in Hancock County. They are probably equivalent to the prominent brecciated beds that occur in the outcrop sections. Pods and lenses of sandstone occur in places, especially at and near the base. In the type region six members are differentiated, but in Illinois only the upper five are recognized (fig. D-11)—the Coggan Member (cherty dolomite) at the base, the Otis Member

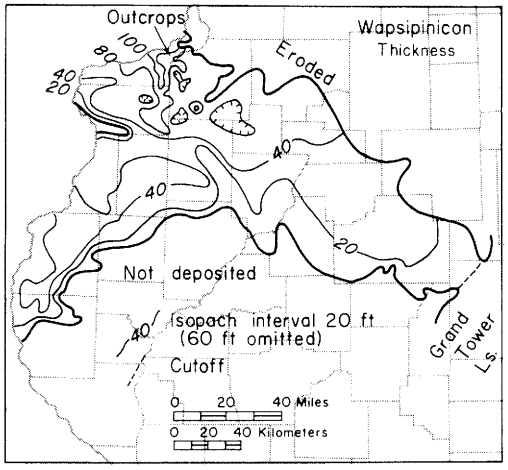

Fig. D-12—Thickness of the Wapsipinicon Limestone (after James, 1968).

(lithographic limestone), the Kenwood Member (argillaceous dolomitic limestone), the Spring Grove Member (dolomite and dolomitic limestone), and the Davenport Member (lithographic limestone) at the top. The Wapsipinicon apparently was deposited in hypersaline waters and fossils are very rare.

Coggan Member—The Coggan Member of the Wapsipinicon Limestone (Norton, 1894, p. 23-24), at the base of the Wapsipinicon in Illinois, is named for Coggan, Linn County, Iowa, where the type section is at the Illinois Central Railroad crossing of the Buffalo River. The Coggan Member is not exposed in Illinois, but it occurs locally in subsurface and is as much as 20 feet thick in the area between Galesburg, Knox County, and Muscatine, Iowa. It consists of massive, buff, cherty dolomite. It also contains a thin bentonite that has been correlated with the Tioga Bentonite Bed, which occurs near the top of the Grand Tower Formation southeast of the Sangamon Arch.

Otis Member—The Otis Member of the Wapsipinicon Limestone (Norton, 1894, p. 22-24), which overlies the Coggan Member (or Silurian dolomite where the Coggan is absent), is named for the railway junction called Otis, east of Cedar Rapids, Linn County, Iowa. The Otis Member is 26 feet thick where exposed in a quarry at Cleveland, Henry County (S1/2 31, 18N-2E). It is fine-grained to lithographic, light gray to brown limestone with a few lenses of chert. In the region where it thins out on the flanks of the Sangamon Arch, lenses of quartz sandstone as much as 5 feet thick occur at the base.

Kenwood Member—The Kenwood Member of the Wapsipinicon Limestone (Norton, 1894, p. 23; Stainbrook, 1935, p. 251), which overlies the Otis Member, is named for Kenwood Park in the northern part of Cedar Rapids, Linn County, Iowa, where the type section is an exposure along Indian Creek. As originally defined, the Kenwood included strata later differentiated as the Spring Grove Member (Stainbrook, 1935). The Kenwood is 15-20 feet thick in the outcrop area. It is 10 feet thick where exposed at the base of a quarry half a mile southeast of Milan, Rock Island County (NW 25, 17N-2W), and 16 feet in the quarry on the south side of Rock Island, Rock Island County (SE 14, 17N-2W), but the base is not exposed in either quarry. The Kenwood consists of laminated or thin-bedded, argillaceous, dolomitic limestone with strongly brecciated beds and pockets of clay.

Spring Grove Member—The Spring Grove Member of the Wapsipinicon Limestone (Stainbrook, 1935, p. 251-252) formerly was the upper part of the Kenwood. It is named for Spring Grove Township, Linn County, Iowa, where the type section is on the right bank of the Wapsipinicon River (cen. 24, 86N-7W). It is probably as much as 25 feet thick in subsurface, but it is only 5-10 feet thick in the outcrop area, where it is exposed in the quarries at Milan and Rock Island. The Spring Grove Member is brown laminated dolomite and dolomitic limestone that weathers into thin plates. It is nonfossiliferous.

Davenport Member—The Davenport Member of the Wapsipinicon Limestone (Norton, 1894, p. 24; Stainbrook, 1935, p. 252), the uppermost member, overlies the Spring Grove Member and is overlain by the Cedar Valley Limestone. It is named for Davenport, Scott County, Iowa, near which it is exposed, but no type section has been designated. As originally used, the name "Davenport" was applied to a Lower Davenport Member and an Upper Davenport Member. However, the upper, fossiliferous member was later assigned to the Cedar Valley, and the lower member was renamed the Davenport Member (Stainbrook, 1935). The Davenport is 40-50 feet thick in subsurface, but is 30 feet thick where exposed in the quarries at Milan and Rock Island and only 18 feet thick across the river near Linwood, Iowa. It consists of pure, hard, light gray to brownish gray, fine-grained to lithographic limestone. It contains many beds of limestone breccia and, in subsurface, anhydrite and gypsum. No fossils have been found in it.

Cedar Valley Limestone

The Cedar Valley Limestone (McGee, 1891, p. 314), named for the valley of Cedar River, Iowa, overlies the Wapsipinicon Limestone and underlies the New Albany Shale Group of the Upper Devonian Series. No type section has been designated. The Cedar Valley underlies a large area in north-central and northwestern Illinois (fig. D-13). It is exposed in the Rock Island area where the Mississippi River and its tributaries have cut into the Mis-

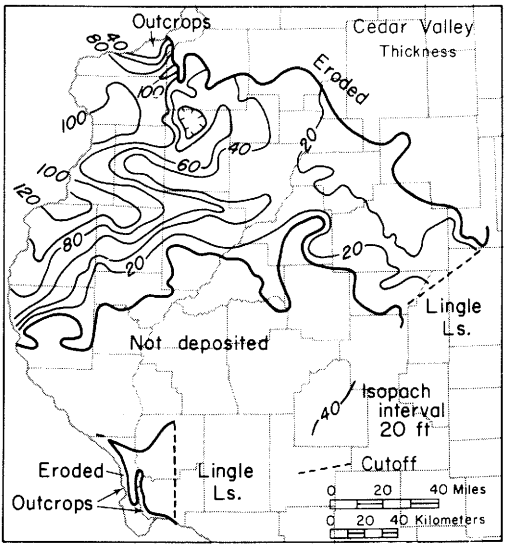

Fig. D-13—Thickness of the Cedar Valley Limestone (after James, 1968).

Electronic Filing: Received, Clerk's Office 07/01/2024

sissippi River Arch (fig. D-3C). Southward, the Cedar Valley overlaps the Wapsipinicon Limestone and thins out on the flank of the Sangamon Arch, except at the northeastern and southwestern ends of the arch where the Middle Devonian seas temporarily covered the arch, and the Cedar Valley sediments are continuous with strata included in the Lingle Limestone. The strata deposited immediately south of the southwestern part of the Sangamon Arch are exposed in Calhoun and Jersey Counties, and, because they are more like the Cedar Valley than the Lingle, the name Cedar Valley has long been used in that area (Rubey, 1952). The Cedar Valley has a maximum thickness of about 130 feet in the subsurface in Hancock County, but it generally thins to the east and south (fig. D-13). It is about 60 feet thick in exposures near Rock Island. In the Calhoun and Jersey County outcrops it is 4-40 feet thick, but in most of the area it is less than 15 feet thick. The Cedar Valley is largely a highly fossiliferous, crystalline, light gray limestone (fig. D-3D), but it contains some fine-grained, argillaceous beds, thin shaly partings, and sandstone. In the northern outcrop area it is subdivided into four members—the Hoing Sandstone Member at the base, the Solon Member (pure, very fossiliferous), the Rapid Member (argillaceous, partly fossiliferous), and the Coralville Member (pure, very fossiliferous) at the top. In the area south and southwest of Rock Island, the Cedar Valley is medium-grained, detrital limestone that in Hancock and Adams Counties locally contains fine-grained, rounded quartz sand. The Solon and Rapid Members are not differentiated in that area. In the southern outcrop area the Cedar Valley grades from brown, thin-bedded, fine-grained, cherty, argillaceous, sandy limestone at the base to thick-bedded, pure, crystalline, highly fossiliferous limestone in the upper part. The Cedar Valley apparently has conformable relations to the Wapsipinicon below. Its sharp erosional contact with the New Albany above indicates a minor unconformity, although the faunal evidence indicates only a brief interruption in sedimentation. In places the Cedar Valley is overlain unconformably by Pennsylvanian strata. The fauna of the Cedar Valley is very large (Savage, 1920, 1921b; Cooper and Cloud, 1938; Rubey, 1952; Collinson and Scott, 1958b; and others) and is characterized by abundant brachiopods and corals (fig. D-6). The Cedar Valley has a large conodont fauna that indicates the Upper Devonian age of the uppermost beds in some areas. In general, the fauna correlates the Cedar Valley with Hamilton strata in New York and the upper part of the North Vernon Limestone in Indiana (Collinson et al., 1967b).

Hoing Sandstone Member—The Hoing Sandstone Member of the Cedar Valley Limestone (Hinds, 1914, p. 12), the basal member, was originally called the "Hoing oil sand" for its occurrence in a well on the Hoing Farm, near Colmar, McDonough County, the discovery well of the Colmar-Plymouth oil field (Blatchley, 1914). It was called the Hoing sand, or the "Hoing" sandstone, until formally designated the Hoing Sandstone (Howard, 1961). The Hoing is patchy in western Illinois. Although it is commonly only a few inches thick, it reaches 30 feet thick in the Colmar-Plymouth oil field. Where well developed it is a clean, friable sandstone composed of well rounded, fine to medium quartz grains. However, where it directly overlies the Silurian dolomite it commonly contains residual debris from erosion of the dolomite. At the exposure at the Monterey School, Calhoun County (NE SW 11, 12S-2W), the Hoing Member is 0-2 feet thick and consists of sandstone, shale, and chert conglomerate overlying the deeply eroded Silurian dolomite (Collinson et al., 1954). Thin lenses of sand also occur locally higher in the Cedar Valley Limestone.

Solon Member—The Solon Member of the Cedar Valley Limestone (Norton, 1897, p. 148; Keyes, 1913, p. 205-206), the basal member where the Hoing is not present, is named for Solon, Johnson County, Iowa, but no type section has been designated. In Illinois the Solon Member has a maximum thickness of about 10 feet but is absent locally. It is 6-8 feet thick where exposed in quarries southeast of Milan and on the south side of Rock Island. It is a fine- to medium-grained, grayish brown, very fossiliferous limestone with brecciated beds. It is characterized by an abundance of brachiopods, mainly *Atrypa independensis*, and corals, notably biostromes of *Hexagonaria profunda* (fig. D-6). Conodonts also are abundant and indicate correlation with the upper Hamilton in New York (Collinson et al., 1967b).

Rapid Member—The Rapid Member of the Cedar Valley Limestone (Keyes, 1912, p. 149; 1913, p. 205-206), which overlies the Solon, is named for a locality in Johnson County, Iowa, not specified by Keyes. The Rapid is the most widespread and thickest member. It is as much as 60 feet thick in the Rock Island area, but it thins to the east and south. It forms the upper 53 feet of the quarry southeast of Milan. The member consists of gray to buff, fine-grained, argillaceous, locally dolomitic limestone. Most of it is thick bedded, but the upper and lower parts are thin bedded and have shaly partings. Some beds, especially near the top and bottom, are very fossiliferous. Brachiopods and corals are most common, particularly *Atrypa, Stropheodonta, Chonetes, Spirifer, Schizophoria, Pentamerella, Hexagonaria, Favosites,* and *Heliophyllum* (Edmund and Anderson, 1967) (fig. D-6). Conodonts indicate a late Middle Devonian age (Collinson et al., 1967b).

Coralville Member—The Coralville Member of the Cedar Valley Limestone (Keyes, 1912, p. 149; 1913, p. 205-206), the uppermost member, is named for Coralville, Johnson County, Iowa, and the type section is in quarries 1 mile northeast of Coralville. The Coralville is present in Illinois only in the western part of the area of the Cedar Valley. It is as much as 25 feet thick and is unconformably overlain by the Sweetland Creek Shale of the New Albany Group. It consists of brown, medium-grained dolomite that in places is a stromatoporoid reef. The Coralville is abundantly fossiliferous; brachiopods, corals, bryozoans, and stromatoporoids are the most common fossils. The conodonts indicate that in places the boundary of the Middle and Upper Devonian Series lies within the Coralville (Collinson et al., 1967b), but most, if not all, of the Coralville in Illinois is Middle Devonian in age.

Grand Tower Limestone

The Grand Tower Limestone (Keyes, 1894, p. 30, 42), which forms the lower part of the Middle Devonian Series in Illinois south of the Sangamon Arch, is named for Grand Tower, Jackson County (fig. D-3A). The type section, not designated by Keyes, was probably intended to be, and currently is accepted as, the exposure in the Devil's Bake Oven, an isolated hill half a mile north of Grand Tower (SW SE NE 23, 10S-4W), where the formation is 157 feet thick. The Grand Tower thins out northward against the Sangamon Arch, westward against the Ozark Uplift, and southward at the southern margin of Illinois (fig. D-14). It apparently was not deposited on the Sparta Shelf, an eastward projection of the Ozarks, but it does occur in the Wittenberg Trough, along the south side of the Sparta Shelf, and it is as much as 160 feet thick there (Meents and Swann, 1965). From the

Electronic Filing: Received, Clerk's Office 07/01/2024

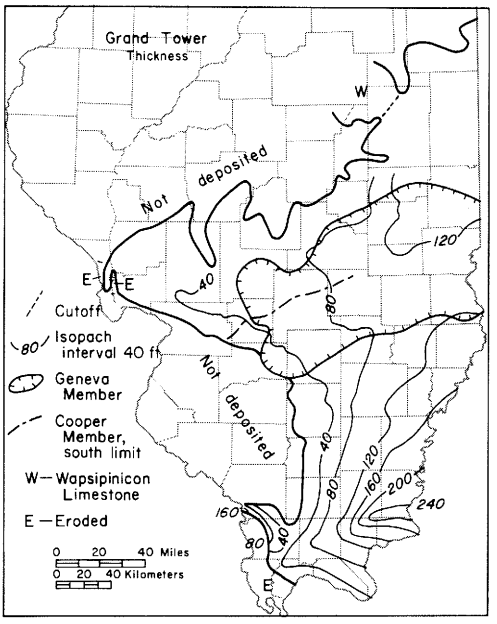

Fig. D-14—Thickness of the Grand Tower Limestone (after North, 1969).

Sparta Shelf it thickens eastward to reach a maximum of 250 feet. The Grand Tower is mostly coarse-grained, light gray, medium- to thick-bedded, cross-bedded, pure, fossiliferous limestone, but it also contains lithographic limestone, which becomes more abundant upward (North, 1969). At the base a calcareous sandstone or sandy limestone with sandstone beds is differentiated as the Dutch Creek Sandstone Member. In the central and eastern parts of the state the Grand Tower is largely dolomite, the lower part of which is brown dolomite differentiated as the Geneva Dolomite Member, and the upper part is a laminated, gray to tan, fine-grained dolomite that has not been named. In the northern part of its area, the Grand Tower is represented primarily by a light gray, lithographic limestone differentiated as the Cooper Limestone Member. A thin bentonite widely present near the top of the formation is the Tioga Bentonite Bed. The Grand Tower Limestone is abundantly fossiliferous, and a large macrofauna (S. Weller, 1897; Savage, 1920; Grimmer, 1968) and conodont fauna (Orr, 1964; Collinson et al., 1962) have been described. The base of the Grand Tower is a major unconformity—the base of the Kaskaskia Sequence—and in the northern part of its area the Grand Tower sharply overlaps the entire Lower Devonian Series and rests on the Silurian System. The Grand Tower correlates with all but the upper part of the Wapsipinicon Limestone in northern Illinois and Iowa, with the Geneva Dolomite and Jeffersonville Limestone in Indiana, and with the Onondaga in New York (Collinson et al., 1967a).

Dutch Creek Sandstone Member—The Dutch Creek Sandstone Member of the Grand Tower Limestone (Savage, 1920, p. 170-171, 175; Meents and Swann, 1965, p. 6) is named for Dutch Creek, a tributary of Clear Creek in central Union County, but no type section has been designated. An exposure along a secondary road 1.1 miles northwest of its junction with Illinois Highway 127 (W1/2 NW 27, 11S-2W), about 2 miles north of Dutch Creek, has been used as a reference section (Meents and Swann, 1965). There the gradation of the member to the overlying part of the Grand Tower and the unconformable contact on the underlying Clear Creek can be seen. The Dutch Creek was originally called the Oriskany Sandstone by Worthen (1866). Because of the discontinuous nature of the sandstone and its lateral and vertical gradation to sandy dolomite or limestone, Meents and Swann (1965) restricted the Dutch Creek to localities where beds of sandstone are present and classified it as a member of the Grand Tower Limestone. The Dutch Creek is exposed at many localities in Union, Alexander, and Jackson Counties (Weller and Ekblaw, 1940), and it is present in subsurface at many places throughout the area of the Grand Tower Limestone. However, the principal occurrences are in the outcrop area and in Wayne and adjacent counties of eastern Illinois (Collinson et al., 1967a). The Dutch Creek is as much as 30 feet thick in the outcrop area but is more commonly less than 15 feet, in many areas only a foot or two thick. It is a fossiliferous, calcareous sandstone composed of well rounded, well sorted, medium to fine quartz grains. In many areas the sandstone is interbedded with sandy limestone. The abundant fauna is principally brachiopods and corals. The fossil mold of the coral *Pleurodictyum problematicum* is an especially distinctive indicator of the member. Prominent brachiopods include *Amphigenia curta, Rhipidomella* cf. *R. penelope,* and *Protoleptostrophia perplana.*

Geneva Dolomite Member—The Geneva Dolomite Member of the Grand Tower Limestone (Collett, 1882, p. 63, 81-82), named for Geneva, Shelby County, Indiana, is continuous from its type locality westward into eastern and central Illinois, where it is as much as 50 feet thick but is not exposed. In Illinois it is the basal member of the Grand Tower Limestone, wherever the patchy Dutch Creek Sandstone Member is not present, but in Indiana it is classified as a formation (Shaver et al., 1970). The Geneva is dark brown, crystalline, porous, pure dolomite. It contains finely disseminated organic material and produces oil in several fields (Schwalb, 1955). In some localities floating grains of rounded, coarse to fine quartz sand occur in the Geneva, particularly in its lower part. The Geneva is essentially nonfossiliferous but contains a few chitinozoans and scolecodonts (Collinson et al., 1967a). The member grades laterally into the lower part of the Grand Tower (Meents and Swann, 1965; North, 1969).

Cooper Limestone Member—The Cooper Limestone Member of the Grand Tower Limestone (Swallow, 1855, p. 108, 196) is named for Cooper County, Missouri, where it is classified as a facies of the Calloway Limestone (Koenig, 1961). In Illinois it is as much as 50 feet thick in a belt 60-90 miles wide that extends eastward across the state south of the Sangamon Arch (fig. D-14). It is exposed only in Calhoun County (Meents and Swann, 1965), where it previously was considered part of the Cedar Valley Limestone. It is sparsely fossiliferous, gray, dense, lithographic, pure limestone, but it contains scattered grains of quartz sand in some localities. On its northern margin it is overlapped by the Lingle Limestone, and on the south it grades laterally to the light-colored dolomite that overlies the Geneva Dolomite Member. It is similar to the Wapsipinicon Limestone north of the Sangamon Arch and probably is continuous with it west of Illinois.

Tioga Bentonite Bed—The Tioga Bentonite Bed of the Grand Tower Limestone (Ebright et al., 1949, p. 10), named for Tioga County, Pennsylvania, where it was first discovered in drill cuttings from the Tioga gas field, is widely present in Illinois 10-30 feet below the top of the formation, but no outcrops have been found (Meents and Swann, 1965), except re-

Electronic Filing: Received, Clerk's Office 07/01/2024

cently in a quarry at Tuscola in Douglas County. Although possibly as much as 6-8 inches thick in southeastern Illinois, it most commonly is only 1-2 inches thick. Its occurrence is patchy, but it has been observed in more than 100 wells and can be recognized on sonic logs even in areas where it is only a quarter of an inch thick. It is greenish to brownish gray shale that contains biotite flakes and an abundance of mixed-layer clay minerals that distinguish it from the normal shales.

Lingle Formation

The Lingle Formation (Savage, 1920, p. 171, 176; Weller, 1944a, p. 95-96; North, 1969, p. 14-22) is named for Lingle Creek in southern Union County. The type section is a poorly exposed outcrop on a branch of Lingle Creek (SE SW SW 26, 13S-2W). A more complete exposure occurs 3.25 miles west of Cobden, Union County (NW NE 34, 11S-2W). Because the sequence is complex and the exposures poor and widely scattered (Weller, 1940), the Lingle has been variously interpreted (fig. D-5). Savage (1920) differentiated a shale at the base—the Misenheimer Shale—as a separate formation, but Weller (1944a) included the shale in the Lingle and abandoned the name "Misenheimer." Grimmer (1968) and North (1969) related the type Misenheimer to a shale well above the base of the Lingle and reinstated Misenheimer but made it a member of the Lingle. The Lingle occurs throughout a large area south of the Sangamon Arch, generally overlapping the Grand Tower (fig. D-15), and it has a maximum thickness of about 110 feet. The Lingle Formation is an interval of mixed limestone and shale. It is more argillaceous, more shaly, darker colored, and finer grained than the Grand Tower below, and less silty and dolomitic than the Alto Formation above. North (1969) subdivided the Lingle into the Howardton Limestone Member (argillaceous, shaly) at the base, the Tripp Limestone Member (argillaceous, silty, cherty), the Misenheimer Shale Member, and the Walnut Grove Limestone Member (cherty, very silty, glauconitic) at the top. The Walnut Grove is characterized by the Rendleman Oolite Bed near its base. Of the four members, the Misenheimer and Walnut Grove occur only near the outcrop area in southwestern Illinois (fig. D-15). North interpreted these two members and the more extensive Tripp Member below as grading laterally eastward into the New Albany Shale Group, with the Tripp Member essentially equivalent to the Blocher Shale. However, the relations are not clearly demonstrable, and faunal evidence suggests that all three members plus the overlying Alto and Sylamore Formations may be equivalent to the Blocher. Some of the Lingle strata are very fossiliferous, and both macrofossils (Savage, 1920; Grimmer, 1968) and conodont faunas (Orr, 1964) have been described. Characteristic fossils include *Microcyclus discus* (fig. D-6), *Devonochonetes coronatus*, and *Mucrospirifer mucronatus*. They relate the Lingle to the upper half of the Hamilton in New York (Collinson et al., 1967a).

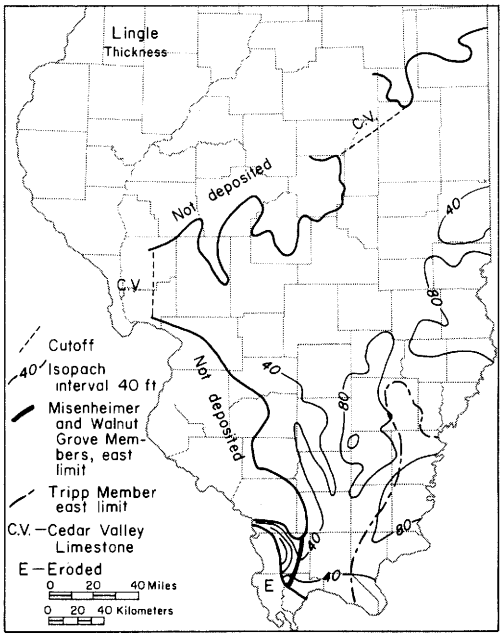

Fig. D-15—Thickness of the Lingle Formation (compiled from North, 1969).

Howardton Limestone Member—The Howardton Limestone Member of the Lingle Formation (North, 1969, p. 22-25), the basal member, is named for Howardton, Jackson County, 2 miles east of the type section, which is in a quarry in the Backbone ridge north of Grand Tower (NE NE SE 23, 10S-4W), where it is 33 feet thick. The Howardton extends throughout much of the area of the Lingle, but it is overlapped by the Tripp Member in the northern part. It is as much as 110 feet thick in southeastern Illinois and generally thins northward and westward. It is gray, fine-grained, slightly silty, argillaceous limestone, most of which has thin, shaly partings. The basal few feet is characterized by a small, button-shaped coral, *Microcyclus*, and the top by a thin intraformational microbreccia with light-colored limestone fragments in a dark matrix. The base of the Howardton is the original Grand Tower–Lingle contact of Savage (1920).

Tripp Limestone Member—The Tripp Limestone Member of the Lingle Formation (North, 1969, p. 25-28) overlies the Howardton Limestone Member and is named for Tripp School, 200 yards northwest of the type section, an outcrop on the south side of Kratzinger Hollow, 1 mile northwest of Jonesboro, Union County (N1/2 NE NW 23, 12S-2W). The upper 17 feet of the member is exposed at the type section and 22-foot thicknesses are found in near-by wells. The Tripp is widespread and reaches 80 feet thick in south-central Illinois, although it is absent in southeastern Illinois (fig. D-15). The member contains limestone, dolomite, chert, siltstone, and shale. It is largely cherty, argillaceous, silty limestone, but beds of shale are abundant near its base and top. About half of the member is dolomite on the margin of the Sparta Shelf. Glauconite, quartz sand, oolite, and beds of phosphate pellets are locally abundant in the northern and western parts of the member. Crinoids, brachiopods, and corals are abundant in some beds.

Misenheimer Shale Member—The Misenheimer Shale Member of the Lingle Formation (Savage, 1920, p. 169-178; Grimmer, 1968, p. 407-415) overlies the Tripp Member and is named for Misenheimer Creek in Union County. Grimmer (1968) described the type section as an exposure 3 miles west of Mill Creek (SW NW 35, 13S-2W) in the south branch of a tributary of Cooper Creek. He designated an exposure on the south bank of Green Creek, 33 feet southwest of Illinois Highway 146, 1.75 miles northwest of Jonesboro (NE NW 23, 12S-2W), where the shale is about 25 feet thick, as a

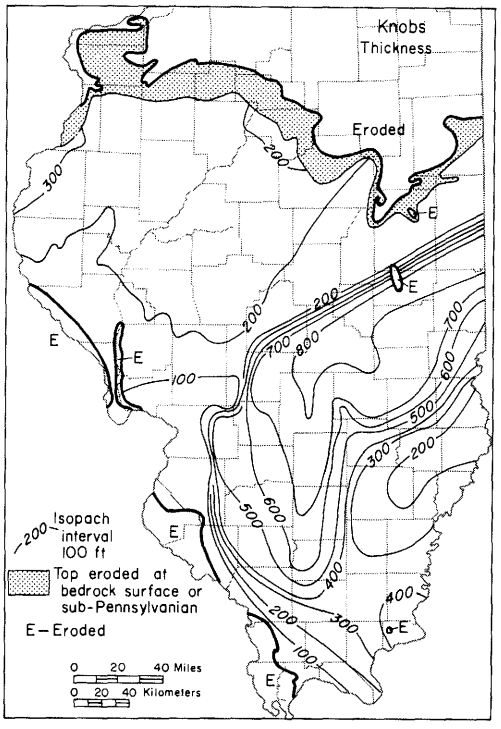

Fig. D-16—Thickness of the Knobs Megagroup.

principal reference section. Both Grimmer (1968) and North (1969) placed the type Misenheimer well above the base of the Lingle (where Savage had placed it), but Grimmer assigned the strata below the Misenheimer to the St. Laurent Formation of Missouri, whereas North subdivided them into the Howardton and Tripp Members of the Lingle. The Misenheimer occurs only in and near the outcrop region in Jackson, Union, and Alexander Counties (fig. D-15). It consists of as much as 50 feet of dark gray to gray-brown, calcareous, spore-bearing shale that contains a few macrofossils.

Walnut Grove Limestone Member—The Walnut Grove Limestone Member of the Lingle Formation (North, 1969, p. 29-30), the uppermost member, is named for Walnut Grove Church, Union County, 1 mile southeast of the type section, an outcrop near the head of a small tributary of Clear Creek (SE SE SW 22, 11S-2W), where the member is 29 feet thick. The Walnut Grove occurs only in and near the outcrop area in Jackson, Union, and Alexander Counties (fig. D-15), and its maximum thickness is about 50 feet. It is cherty, very silty, glauconitic, spore-bearing, fine-grained, fossiliferous limestone locally interbedded with very dark brown, calcareous shale. The Rendleman Oolite Bed near the base is a distinctive key bed. Fossils include crinoids, corals, brachiopods, and sporangites.

Rendleman Oolite Bed—The Rendleman Oolite Bed (North, 1969, p. 30-31) is named for Rendleman School, 1 mile east of the type section (part of the Walnut Grove type section), where it is 1.5 feet thick and occurs 4 feet above the base of the Walnut Grove Member. It is a persistent, distinctive bed. The ooliths, which are poorly sorted and have a maximum diameter of 1 mm, occur in a fine-grained limestone matrix.

Alto Formation

The Alto Formation (Savage, 1920, p. 168-178), which overlies the Lingle Formation in southwestern Illinois, is named for Alto Township, Union County, where the type section is along a creek (cen. N½ NE NE 34, 11S-2W). The Alto Formation is in essentially the same area as the Misenheimer and Walnut Grove Members of the Lingle Formation (fig. D-15). It is as much as 100 feet thick. The lower part consists of dolomitic and calcareous shale and siltstone; the shale resembles the Misenheimer. The upper part is silty, cherty, gray to dark gray dolomite that grades from coarsely crystalline at the top to finely crystalline at the base. White, gray, and black chert nodules are abundant. On the basis of its few macrofossils (*Devonochonetes* sp., *"Reticularia" laevis* and *Mucrospirifer mucronatus)*, Savage assigned the Alto to the Upper Devonian, but the conodont fauna (Orr, 1964), which includes *Polygnathus cristata*, relates the Alto to the uppermost Middle Devonian (Collinson et al., 1967a). Although Savage (1920) and Workman and Gillette (1956) believed the Alto extended under the oldest part of the New Albany Shale, Weller (1940) and North (1969) interpreted both the Lingle and Alto as grading laterally into the New Albany. North correlated the Alto with the upper part of the Sweetland Creek Shale in the deep part of the Illinois Basin, but Collinson et al. (1967a) interpreted the uppermost conodont faunas of the Blocher Shale, below the Sweetland Creek, as Upper Devonian in age, in which case both the Alto and the part of the Lingle Formation above the Howardton Member are probably equivalent to the Blocher.

KNOBS MEGAGROUP

The Knobs Megagroup (Swann and Willman, 1961, p. 480-481) consists of the Devonian and Mississippian clastic rocks that overlie the Hunton Limestone Megagroup and underlie the Mammoth Cave Limestone Megagroup throughout the Illinois Basin (fig. 14). It is named for the Knobs, an area of highly dissected Devonian and Mississippian shales that partially surrounds the Bluegrass Region and lies in front of the Highland Rim Escarpment of Kentucky and Indiana. In much of the Illinois Basin, the Knobs Megagroup includes shale, siltstone, and sandstone from the base of the Blocher Shale of the New Albany Group to the top of the Borden Siltstone; but on the flanks of the basin, where shallow-water carbonates were deposited, the stratigraphic interval is restricted at both top and bottom. The Knobs has a maximum thickness of about 1000 feet, but it is much thinner in western Illinois and it thins out in places (fig. D-16). The Knobs is mainly black shale in most of the basin, but in central Illinois it is dominated by the great volume of gray siltstone and silty shale in the Borden delta.

Electronic Filing: Received, Clerk's Office 07/01/2024

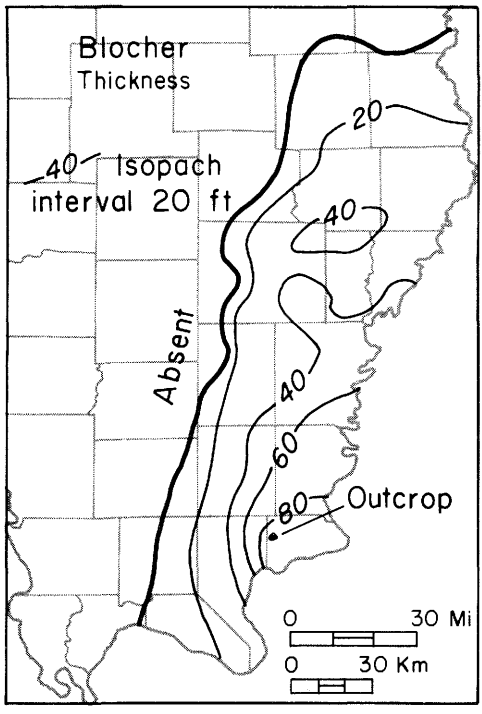

Fig. D-17—Thickness of the Blocher Shale (after North, 1969).

New Albany Shale Group

The New Albany Shale Group (Borden, 1874, p. 158) is named for New Albany, Floyd County, Indiana, where it is largely black shale that overlies the Sellersburg Limestone (Lingle Formation in Illinois) and is overlain by the Rockford Limestone (Chouteau Limestone in Illinois). The unit, originally called the New Albany black slate, is classified as a formation in the type region (Shaver et al., 1970). It consists of the essentially continuous body of Middle and Upper Devonian and Kinderhookian (lower Mississippian) black, gray, and green shale. It includes the Blocher, Sweetland Creek, Grassy Creek, Saverton, and Hannibal Shales (figs. D-2, M-3). It has a maximum thickness of about 400 feet and is exposed in western and southern Illinois. Lineback (1968a) differentiated the New Albany in Indiana into the Blocher Member (calcareous to dolomitic, pyritic shale rich in organic matter) at the base, the Selmier Member (greenish gray mudstone), the Morgan Trail Member (black, fissile, siliceous, pyritic shale), the Camp Run Member (alternating greenish gray mudstone and black shale), and the Clegg Creek Member (black, silty or dolomitic, pyritic shale) at the top. These units have been recognized in subsurface in eastern Illinois, but, except for the Blocher, they have not been traced widely. Black shale containing Devonian sharks' teeth has been found in crevices in the Silurian dolomite in the Chicago area (Bretz, 1939), indicating that the New Albany formerly extended across the Kankakee Arch. The name "Mountain Glen Shale," formerly used for the New Albany in southwestern Illinois (Savage, 1920; Weller, 1940), was replaced by "New Albany" (Workman and Gillette, 1956). The New Albany has now been extended to include comparable shales in western Illinois, and the term "Champ Clark Group" used by Workman and Gillette (1956) is no longer needed for the Upper Devonian formations. The New Albany, particularly the dark shale, contains an abundance of brown resinous spores, *Tasmanites*, which are called *Sporangites* in many reports. Conodonts are common, but normal marine macrofossils are scarce, except in a few limestone beds near the base and top. The New Albany is correlated with the Antrim and Ellsworth Shales of Michigan and the Chattanooga of Tennessee (Collinson et al., 1967a).

Blocher Shale

The Blocher Shale (Campbell, 1946, p. 840; Lineback, 1968a, p. 1295-1298), the basal formation in the New Albany Group, is named for Blocher, Scott County, Indiana, and the type section is 1.5 miles southeast of Blocher on Highway 50, 1 mile east of the Baltimore and Ohio Railroad. It originally included only the lower 8-10 feet of black shale in the type area, but Lineback (1968a) extended it upward about 6 feet to the base of the *Spathiocaris* Zone, which is a gray shale more easily traced, and that position is now accepted. The Blocher Shale extends from the type locality into eastern Illinois (Workman and Gillette, 1956), where it is as much as 80 feet thick, but it thins out in the central part of the state (fig. D-17). North (1969) correlated it with the Tripp Member of the Lingle Formation, but the conodont fauna suggests that it is equivalent also to higher parts of the Lingle, the Alto Formation, and the earliest Upper Devonian strata (Collinson et al., 1967a).

UPPER DEVONIAN SERIES

The term "Upper Devonian Series" has been in general use in Illinois since 1925 (Bassett), prior to which the New York terms "Senecan" and "Chautauquan" had been used in addition to Upper Devonian (figs. D-4, D-5). Upper Devonian sediments underlie

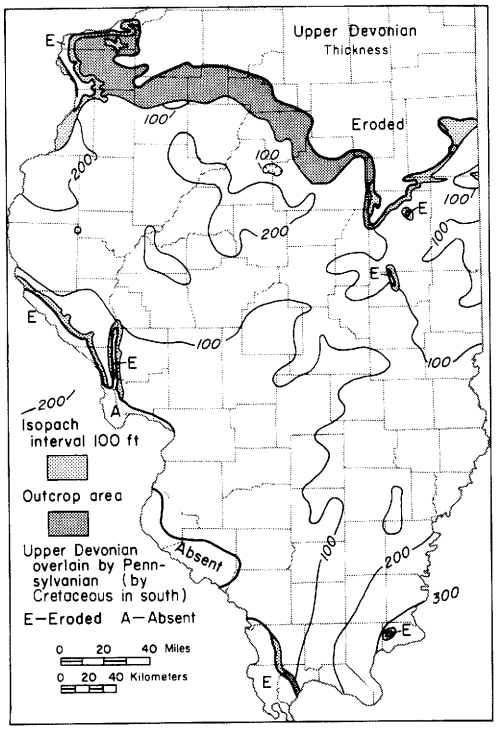

Fig. D-18—Thickness of the Upper Devonian Series.

most of southern and western Illinois. They completely overlap the then subsiding Sangamon Arch, on which Middle Devonian sediments had not been deposited (fig. D-18). They are more than 300 feet thick in Hardin County and as much as 275 feet thick in Mercer County, but elsewhere they are generally less than 200 feet.

In the Devonian type region in England, Upper Devonian applies to the Frasnian (lower) and Famenian (upper) Stages. Conodont studies by Collinson (1967) placed the base of the Frasnian at the base of the Sylamore Sandstone in central and western Illinois, at the top of the Alto Formation in southwestern Illinois, and a few feet below the top of the Blocher Shale in southeastern Illinois. Savage (1920) included the Alto and younger Devonian rocks in the Upper Devonian, as did Weller (1940), Cooper et al. (1942), Cooper (1944), and Orr (1964). However, Weller (1944b), on sedimentational evidence, and Collinson et al. (1967a), on the basis of conodont faunas, tentatively placed the Alto in the Middle Devonian, which is the current practice. The position of the top of the Upper Devonian Series was long debated, as described under the discussion of the Devonian System, but the top of the Louisiana Limestone (or a few feet above it in the Hannibal Shale) in western Illinois, the top of the Grassy Creek Shale in southwestern Illinois, and a position near the top of the New Albany Group in eastern Illinois are now generally accepted as the top of the Upper Devonian.

In the major part of the Illinois Basin the Upper Devonian Series consists largely of the black and gray shale of the New Albany Group, but on the flanks of the Ozark Uplift and on the Mississippi River Arch it also includes limestone, sandstone, and siltstone (fig. D-19). The Louisiana Limestone contains a large variety of macrofossils (Williams, 1943), but the shales generally contain few. Zonation in the series, therefore, is based largely on the conodonts, which, along with abundant *Tasmanites*, are common in the shale formations.

The Upper Devonian rocks are generally conformable on the Middle Devonian strata, but in western and southwestern Illinois a minor unconformity occurs at the base of the Sylamore Sandstone, of the Sweetland Creek Shale, or of the Grassy Creek Shale.

Sylamore Sandstone

The Sylamore Sandstone (Penrose, 1891b, p. 113, 114), the basal Upper Devonian formation in central and western Illinois (Workman and Gillette, 1956), is named for Sylamore Creek, Stone County, central northern Arkansas. It is widely but sporadically present in Illinois, is rarely more than 5 feet thick, and generally varies from a few inches to a mere thin layer of sand embedded in the base of the Sweetland Creek Shale or the Grassy Creek

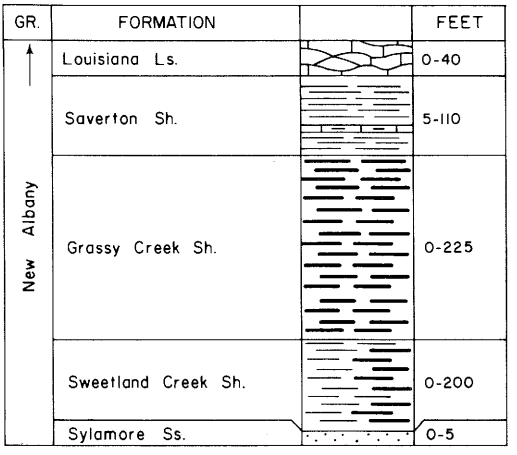

Fig. D-19—Columnar section of the Upper Devonian Series.

Electronic Filing: Received, Clerk's Office 07/01/2024

Shale. It consists of well rounded, fine to medium, quartz sand grains, like those in the older Paleozoic sandstones. It varies from friable sandstone to grains cemented with pyrite, calcite, or dolomite. In the western part of Illinois, it rests unconformably on the Middle Devonian Cedar Valley Formation or Wapsipinicon Limestone, on Silurian dolomite, or locally on Ordovician limestone. In eastern Illinois it probably is equivalent to thin sandy beds in the upper part of the Blocher Shale and the lower part of the Sweetland Creek Shale. It is more or less continuous through Missouri, north and west of the Ozark Uplift, to the type locality, and it is correlated with the Hardin Sandstone east of the Ozarks in Kentucky and Tennessee.

Sweetland Creek Shale

The Sweetland Creek Shale (Udden, 1899, p. 65-78; Collinson et al., 1967a, p. 960-961) is named for Sweetland Creek, Muscatine County, Iowa, and the type section is an exposure along that creek, 4 miles northeast of Muscatine (cen. N1/2 27, 77N-1W), where it is 14 feet thick and is overlain by 6 feet of Grassy Creek Shale. As originally defined, the Sweetland Creek included all the Devonian shale at the type locality. It therefore was essentially equivalent to Grassy Creek Shale (Workman and Gillette, 1956). As now defined (Collinson et al., 1967a), the Sweetland Creek Shale is restricted to the dominantly gray and green shale that underlies the black Grassy Creek and extends throughout much of the Illinois Basin (Collinson, 1961; North, 1969). The Sweetland Creek Shale is only a few inches thick in southwestern Illinois, but reaches 50 feet thick in northwestern Illinois and 200 feet in southeastern Illinois, where it appears to be essentially continuous with the Selmier Member of the New Albany Shale in Indiana. Although dominantly gray in the western part of Illinois, the Sweetland Creek contains some dark gray to black beds. In the central and eastern parts of Illinois, it is generally dark and not readily separated in well samples from the Blocher Shale below and the Grassy Creek Shale above. However, in that area it is easily identified on geophysical logs, which show persistent variations that permit key beds to be widely traced within the formation (North, 1969). Macrofossils are scarce, but the conodonts have been studied in considerable detail and indicate ages ranging from early to middle Upper Devonian (Klapper and Furnish, 1962; Collinson et al., 1962).

Grassy Creek Shale

The Grassy Creek Shale (Keyes, 1898, p. 59-63; 1912, p. 149; Collinson et al., 1967a, p. 961) is named for Grassy Creek, a stream in Pike County, Missouri. It originally included all the black, gray, and green shale below the Louisiana Limestone and above the Cedar Valley or older formations, but in 1912 Keyes differentiated the upper gray shale as the Saverton Shale, and Collinson et al. (1967a) restricted the Grassy Creek further by assigning the lower gray and green shale to the Sweetland Creek Shale. No type section was designated and some of the sections referred to by Keyes include Maquoketa Shale (Weller, 1936). Mehl (1960) named a section in the Mississippi bluffs several hundred feet north of the Champ Clark Bridge at Louisiana, Pike County, Missouri, as the type locality (SW NW NE 18, 54N-1W). In Illinois the Grassy Creek was at first restricted to the western part of the state, but in 1956 Workman and Gillette extended it to central and southwestern Illinois in place of the Mountain Glen Shale, a name long used in that area (Savage, 1920; Weller, 1940). Still later it was extended to eastern Illinois (Collinson et al., 1967a; North, 1969). The Grassy Creek occurs in nearly all the area in which Upper Devonian strata appear. It is well exposed in Pike, Calhoun, and Jersey Counties in western Illinois and in Union County and locally in Hardin County in southern Illinois (fig. D-18). In subsurface its high resistivity on electric logs serves to differentiate it from the Saverton Shale above and from the Sweetland Creek Shale below.

Saverton Shale

The Saverton Shale (Keyes, 1912, p. 149), a gray shale overlying the black Grassy Creek Shale and underlying the Louisiana Limestone, is named for Saverton, Ralls County, Missouri. No type section was designated by Keyes, but Mehl (1960) named an exposure in the Mississippi River bluff at Louisiana, Pike County, Missouri, as the type section, the same exposure named as the type for the Grassy Creek Shale. Because the Louisiana Limestone is limited to a small area in Illinois (fig. D-20), the Saverton is more commonly overlain by the Mississippian "Glen Park" or Hannibal Formations. The Saverton is well exposed in western Illinois in and near the Mississippi and Illinois River bluffs in Pike, Calhoun, and Jersey Counties. It is 5-110 feet thick in western Illinois, but is generally less than 10 feet thick where overlain by the Louisiana Limestone. In eastern and southern Illinois, it is commonly not differentiated and is included in the Hannibal Formation. The Saverton is a bluish to greenish gray, silty shale that contains both thin sandy beds and calcareous beds and grades to calcareous siltstone in the upper part. It grades into the overlying Louisiana Limestone, the lower part of which in places grades laterally into the uppermost Saverton. The few macrofossils present in the Saverton include *Spirifer marionensis* and *Orbinaria puxidata*. Conodonts are abundant, especially in the siltstone at the top, and *Palmatolepis minuta, P. gracilis, P. glabra,* and *P. quadratinodosa marginifera* indicate an Upper Devonian age (Scott and Collinson, 1961; Collinson et al., 1967a).

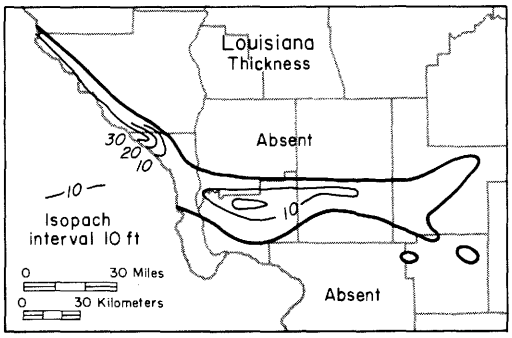

Fig. D-20—Thickness of the Louisiana Limestone.

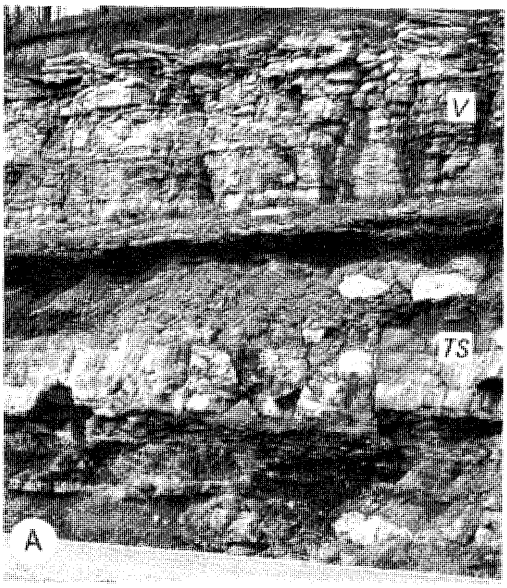
Electronic Filing: Received, Clerk's Office 07/01/2024

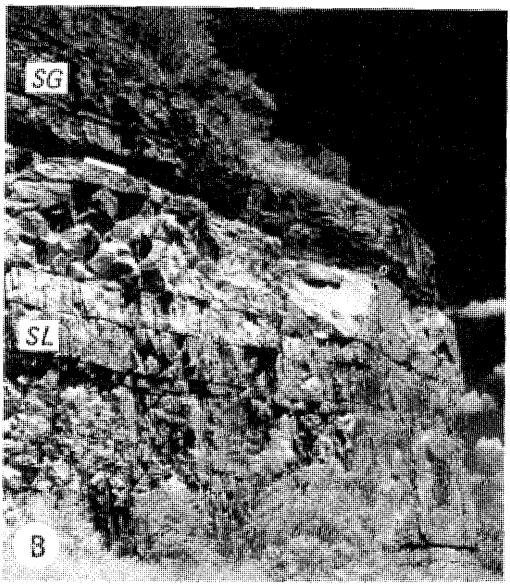
Louisiana Limestone

The Louisiana Limestone (Keyes, 1892, p. 289) is named for Louisiana, Pike County, Missouri, where it is well exposed in the Mississippi River bluffs. No type section was designated, but a prominent exposure on the south side of Louisiana, where it is underlain by the Saverton Shale and overlain by the Hannibal Shale, is commonly accepted as the type section. The Louisiana occurs in an area 10-25 miles wide extending eastward from the Mississippi River into west-central Illinois (fig. D-20). It is a lenticular body as much as 40 feet, but more commonly 10-20 feet thick. It is exposed along the Mississippi and Illinois Valleys in Pike, Calhoun, and Jersey Counties. The formation is light gray to buff, lithographic limestone with thin shale partings and dolomite interbeds. The limestone is very pure and is probably a chemical precipitate. It contains a large variety of macrofossils dominated by small brachiopods, particularly *Schuchertella, Chonetes, Cyrtina,* and *Ambocoelia*, but microcrinoids, bryozoans, and ostracodes also are common (Williams, 1943). The Devonian or Mississippian age of the Louisiana Limestone and its relation to the similar McCraney Limestone, which is exposed in Illinois essentially within sight of the type Louisiana in Missouri, were major controversies for many years (Collinson, 1961; Scott and Collinson, 1961). Studies of the conodont faunas demonstrated that the Louisiana was of Upper Devonian age and the McCraney was of Mississippian age, resolving both problems and substantiating field tracing of the units in the Mississippi River bluffs in Illinois. The Louisiana is unconformably overlain by the "Glen Park" Formation, but, as the faunas indicate only a short interruption in sedimentation, the unconformity appears to be related to minor uplift on the flank of the Lincoln Anticline.

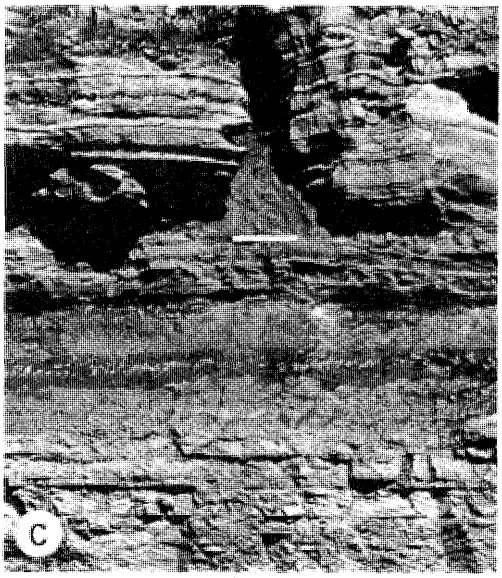
MISSISSIPPIAN SYSTEM



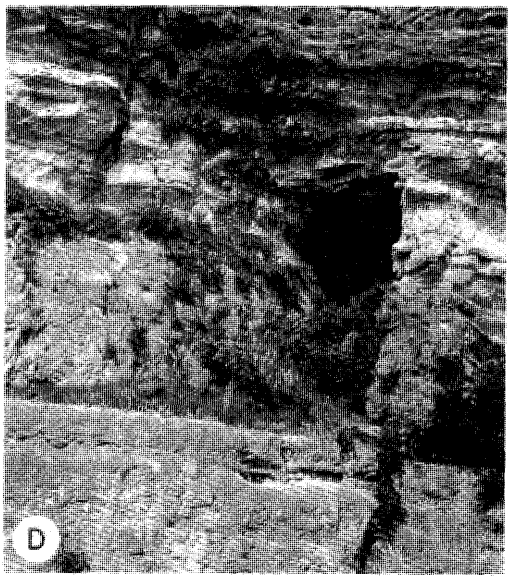
Elwood Atherton, Charles Collinson, and Jerry A. Lineback



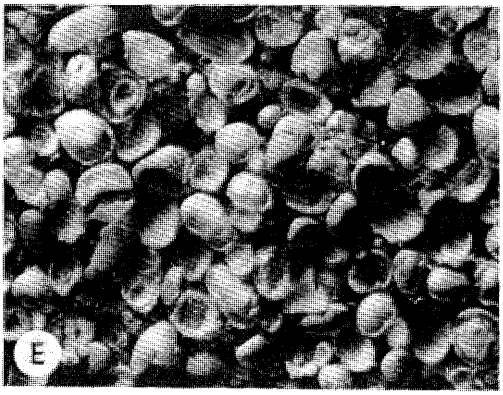
The Mississippian System (Winchell, 1869; Williams, 1891), which overlies the Devonian System and underlies the Pennsylvanian System, is named from exposures in the bluffs of the Mississippi River in Iowa, Illinois, and Missouri (fig. M-1). In earlier reports these strata were called "Carboniferous limestone," or "Lower Carboniferous" (Worthen, 1866) to differentiate them from the upper Carboniferous or "Coal Measures," that are now called the Pennsylvanian System. "Carboniferous" continues to be used in other countries, and the U.S. Geological Survey recognizes the Mississippian and Pennsylvanian Systems as the Carboniferous Systems (Keroher, 1970).



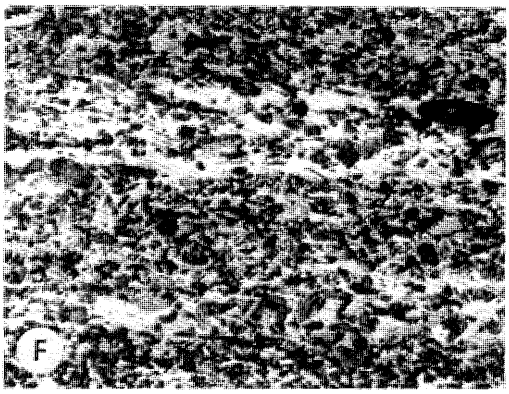
The Mississippian System is well developed in the Illinois Basin east of the type exposures, and it covers most of Illinois south of a line running roughly from Monmouth, Warren County, to Hoopeston, Vermilion County (fig. M-2). It crops out in a belt around the western and southern rim of the Illinois Basin from Henderson County on the west through Hardin County on the southeast, but on the north side of the basin it is overlapped by Pennsylvanian strata and does not crop out. In northeastern Illinois it is at the top of the bedrock but is covered by glacial drift. The system is over 3200 feet thick in southern Illinois but thins northward because of truncation and because of depositional thinning of many of its component formations (fig. M-3).



Although limestone is the dominant rock type in the Mississippian System, a large siltstone delta is present in central and eastern Illinois, and shale and sandstone formations are prominent in parts of the system. The lowest part of the system consists mainly of shale and siltstone and is included in the upper part of the Knobs Megagroup (fig. 14). Limestone, which makes up most of the middle part of the system, is referred to the Mammoth Cave Limestone Megagroup. The alternating limestone-shale and sandstone-shale formations of the upper part compose the Pope Megagroup. Three major varieties of limestone occur in the system—(1) very fine-grained or lithographic, dense, medium-gray, mostly cherty limestone; (2) medium- to coarse-grained, light gray, crinoidal or bryozoan limestone, part of it very cherty; and (3) medium- to coarse-grained, light gray to white, oolitic limestone. The shales are mainly dark greenish gray, but thin beds of red and green shale are extensive. The sandstones are very fine to fine grained and light gray or light greenish gray. The siltstones are light greenish gray.



Electronic Filing: Received, Clerk's Office 07/01/2024



Electronic Filing: Received, Clerk's Office 07/01/2024

Much of the limestone and shale is exceedingly fossiliferous (fig. M-4). Brachiopods are particularly numerous, with spiriferids and productids most abundant. The Burlington Limestone, and, to a lesser extent, the Keokuk Limestone consist mainly of crinoidal debris and are zoned on the basis of crinoid genera and species. Fenestrate bryozoan debris, mostly of *Archimedes*, is abundant in some beds in the Warsaw, Salem, and Ullin Formations. Blastoids, particularly pentremitids, are characteristic of some limestone units in the Chesterian Series, as are *Schizoblastus* and *Metablastus* in the Valmeyeran and *Orophocrinus* and *Globocrinus* in the Kinderhookian. Shark teeth are common in some beds of the Burlington and Keokuk Limestones, and Foraminifera, particularly endothyrids, are abundant in the Salem Limestone. Conodonts are common to abundant throughout the Mississippian and provide a basis for biostratigraphic zonation (Collinson et al., 1962). Thin beds of coal occur in the Chesterian (late Mississippian) sandstones, and the megaspores in the coals indicate dominance of a lepidocarp-lepidodendrid flora (Winslow, 1959).

Three series, all with type localities in Illinois, are differentiated at time planes established by differences in faunas. The Kinderhookian Series, at the base, is dominantly shale and is relatively thin. The Valmeyeran, in the middle, is relatively thick and is dominantly limestone and siltstone. The Chesterian, at the top, is also thick and consists of alternations of limestone-shale and sandstone-shale formations.

The main sources of the siliceous clastic sediments in the Mississippian System appear to have been northeast of Illinois, although some sediment came from the northwest and minor quantities from the Ozark region. The delta represented by the Borden Siltstone grew southeastward into the Illinois Basin. The Chesterian sands were carried into the basin by the Michigan River, which also came from the northeast (fig. M-31). The sands are moderately angular and lack the high degree of rounding characteristic of older sandstones, which were probably beneath the seas or buried by younger formations during Mississippian time.

The boundary between the Devonian and Mississippian Systems occurs in the New Albany Shale Group. Its exact position has long been controversial, but it is now widely accepted, on the basis of conodont evolution, as probably occurring near the base of the Hannibal Shale, above the Louisiana Limestone, and probably in or below the highly variable "Glen Park" Formation (Collinson et al., 1971). The Louisiana Limestone is present in only a small area, and the Devonian-Mississippian boundary commonly occurs within the shale sequence. The contact is generally conformable, but in western Illinois a minor unconformity marks the contact of the "Glen Park" Formation on the Louisiana Limestone.

The contact between the Mississippian and Pennsylvanian Systems is one of the major unconformities in Illinois and is the boundary between the Absaroka Sequence and the Kaskaskia Sequence (fig. 14). Strata in the Illinois Basin were warped, faulted, and truncated by erosion at the close of the Mississippian Period. Valleys as much as 450 feet deep were cut into Chesterian strata and subsequently were filled with Pennsylvanian sediments (Bristol and Howard, 1971). The Pennsylvanian rocks progressively overlap older Mississippian formations northward and westward from the southern part of the Illinois Basin. Around the margin of the basin the Pennsylvanian rocks overlap older systems.

KINDERHOOKIAN SERIES

The Kinderhookian Series (Meek and Worthen, 1861b, p. 288; Collinson, 1961, p. 102) is named for the village of Kinderhook, northwestern Pike County, where the type section consists of exposures in the Mississippi River bluffs. There Kinderhookian strata overlie the Devonian Saverton Shale, and the McCraney Limestone is at the top of the section. The younger Kinderhookian strata, which lie be-

tween the Burlington Limestone (above) and the McCraney (below), are exposed near by (Collinson, 1961). The Kinderhookian extends throughout most of western, central, and southern Illinois (fig. M-5) but is well exposed only along the Mississippi and Illinois Valleys in western Illinois. Small exposures occur around Hicks Dome in Hardin County

Fig. M-3—Classification of the Mississippian System.

The Kinderhookian is as much as 167 feet thick in western Illinois, where the North Hill Group (fig. M-6) is well developed, and 100 to 120 feet thick in a belt running east from Calhoun County where the "Glen Park" is well developed. It is thin in the eastern and southern parts of the Illinois Basin. The Kinderhookian Series is dominantly shale but has a thin, extensive limestone at the top and a limestone-siltstone-shale formation locally developed at the base.

As originally defined (fig. M-7), the Kinderhook Group included all the strata between the black shale (Grassy Creek) and the Burlington Limestone, strata previously correlated with the Devonian Chemung Group of New York. Later, the black shale was also included in the Kinderhook Group, which was assigned to the Mississippian System. After the Kinderhookian was made a series, the position of the Mississippian-Devonian boundary became controversial (Stainbrook, 1935; Weller, 1939). Studies of the conodont faunas resulted in a redefinition of the Kinderhookian Series to include only those strata overlying the Louisiana Limestone and underlying the Meppen Limestone, or the Burlington where the Meppen is absent (Collinson, 1961). As thus defined, the Kinderhookian Series includes the upper part of the New Albany Group, the widespread Chouteau Limestone, and, in a small area in western Illinois, the North Hill Group.

The Kinderhookian Series is generally conformable with the Upper Devonian Series (below) and the Valmeyeran Series (above), but in western Illinois both contacts are marked by local unconformities that resulted from minor uplifts on the flanks of the Ozarks.

"Glen Park" Formation

The "Glen Park" Formation (Ulrich, 1904, p. 110; Moore, 1928, p. 138-140) is named for Glen Park Sta-

Fig. M-5—Thickness of the Kinderhookian Series.

tion, about 25 miles south of St. Louis, Jefferson County, Missouri, where 1.4 feet of fossiliferous oolitic limestone was named Glen Park. Stuart Weller (1914, p. 464-467) gave the name "Hamburg Oolite" to exposures of the oolitic limestone at Hamburg that he considered to be younger than the type Glen Park, but the name was preempted and Moore (1928) redefined the name "Glen Park" to include the strata at Hamburg. However, studies of the conodonts indicate that the two units are not of the same age—the type Glen Park being Devonian and the Hamburg strata Mississippian—but the name "Glen Park" has been retained pending introduction of a new name.

The "Glen Park" is exposed in and near the Mississippi River bluffs in Calhoun, Pike, and Jersey Counties, and in the lower Illinois Valley in Calhoun and Jersey Counties. It is restricted to western Illinois where its thickness varies greatly but does not exceed 25 feet in the outcrop area. Much of the thick brown shale included in the "Glen Park" by Workman and Gillette (1956) is now included in the Hannibal Shale. The lithology of the "Glen Park" varies considerably and may be almost any combination of sandy, silty, brown or buff limestone, buff siltstone, silty shale, oolitic limestone, limestone conglomerate, or thin sandstone beds. In Gresham Hollow, about a mile southeast of Hamburg, Calhoun County (NW 1, 10S-3W), it consists of calcareous, blue-gray siltstone overlying light gray to buff, silty, dense, fine-grained limestone. The limestone contains beds of dolomitic siltstone bearing *Tasmanites* and also lenses of highly fossiliferous, white to buff, conglomeratic, oolitic, cross-bedded limestone. Stuart Weller (1906b) described the fauna. The "Glen Park" rests with apparent erosional contact on the Louisiana Limestone, or on the Saverton Shale where the Louisiana is not present. However, no unconformity is generally recognizable where the "Glen Park" is absent.

Hannibal Shale

The Hannibal Shale (Keyes, 1892, p. 289) is named for Hannibal, Missouri, where about 75 feet of sandy shale between the Louisiana Limestone (below) and the Burlington Limestone (above) was included in the forma-

Fig. M-7—Development of the classification of the Kinderhookian Series.

tion. The formation is now defined as the shale overlying the "Glen Park" Formation and underlying the Chouteau Limestone, both of which are absent in the Hannibal type section. It is included in the New Albany Group. The Hannibal Shale was called Maple Mill by Workman and Gillette (1956), but Collinson (1961) found that the Maple Mill Shale in Iowa correlates with the Saverton Shale of the Upper Devonian, and the original name was reinstated. The Hannibal Shale is widely exposed in the Mississippi and Illinois Valleys in western Illinois, and it extends eastward in subsurface across the state. It has a maximum thickness of about 100 feet in Calhoun County, but it thins eastward and is difficult to differentiate from the underlying Devonian shale in the deeper part of the basin. The Hannibal, as exposed in the McCraney North Section, Pike County (NE NE 15, 4S-7W), is almost entirely a green to gray, argillaceous siltstone in the northern part of the outcrop area (Collinson, 1964). The lower part becomes increasingly argillaceous southward and consists of silty shale in Calhoun and Jersey Counties—for example, at Teneriffe School, Jersey County (NW cor. 9, 7N-13W). In the southern part of the outcrop area, the Hannibal contains a lens of black shale as much as 40 feet thick that is differentiated as the Nutwood Member. A siltstone facies formerly called the English River Formation (Workman and Gillette, 1956) is well developed in the upper part of the Hannibal in Adams and Hancock Counties. The Hannibal Shale contains abundant conodonts, which show that the upper part of the formation is equivalent to the Chouteau Limestone in the area where the Chouteau and the North Hill Group are absent. Megafossils are scarce, but the brachiopod *Chonopectus* is abundant in some beds of the siltstone facies. "Roostertail" markings (*Taonurus caudagalli*) and irregular tubular markings (*Scalarituba missouriensis*) are common features, and they are the reason the Hannibal Shale was originally known as the "Vermicular Sandstone and Shales."

Nutwood Shale Member—The Nutwood Shale Member of the Hannibal Shale (Workman and Gillette, 1956, p. 27) is named for Nutwood, Jersey County, where the type section is exposed along a creek through "The Narrows," just northeast of the village (SE NW 34, 8N-13W), where the Nutwood is 13 feet thick. The Nutwood occurs in a limited area from Calhoun County east to Christian County and south to Bond and northern St. Clair Counties. It is as much as 40 feet thick but is less than 20 feet thick within most of its extent. It is a silty, slightly calcareous or noncalcareous, dark brown to black, spore-bearing (*Tasmanites*) shale that grades laterally and vertically into gray Hannibal Shale. It commonly is in the lower part of the Hannibal, but in places it is at the base and rests on the "Glen Park" Formation or on Devonian strata.

MAMMOTH CAVE LIMESTONE MEGAGROUP

The Mammoth Cave Limestone Megagroup (Miller, 1917, p. 3; Swann and Willman, 1961, p. 481) consists of the dominantly limestone groups and formations that overlie the siliceous clastic rocks of the Knobs Megagroup and occur below the lowest well developed sandstone formations of late Valmeyeran

or early Chesterian age at the base of the Pope Megagroup. It is named for Mammoth Cave, Kentucky. The name was introduced, first as a formation name and later as a series name, for the relatively pure limestone in the interval from the base of the St. Louis Limestone to the base of the Big Clifty Sandstone. The Mammoth Cave is entirely Mississippian in age, but both upper and lower contacts are time-transgressive and are marked by a series of step-like, vertical cut-offs (figs. 14, M-3). It occurs throughout the area of Mississippian rocks in Illinois, but it thins from nearly 2000 feet in extreme southern Illinois to little more than 100 feet in east-central Illinois (fig. M-8). It crops out extensively along the Mississippi and Illinois Valleys in western Illinois and along the Mississippi and Ohio Valleys in southern Illinois.

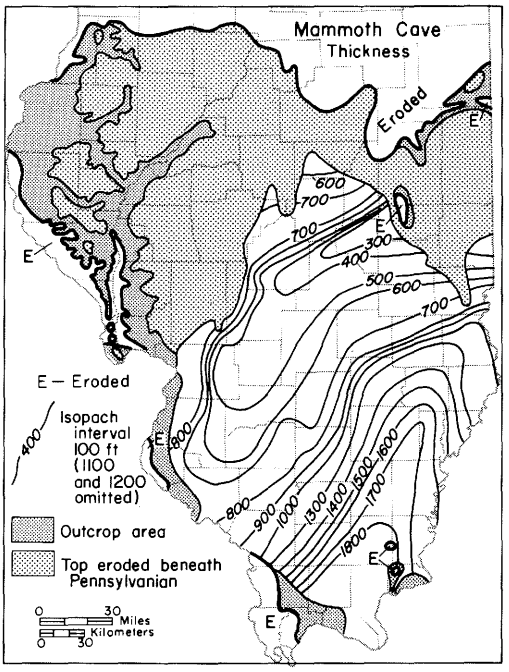

Fig. M-8—Thickness of the Mammoth Cave Limestone Megagroup. Thickness is shown where Chesterian strata are present.

Chouteau Limestone

The Chouteau Limestone (Swallow, 1855, p. 101), the uppermost formation in the Kinderhookian Series, is named for Chouteau Springs, Cooper County, Missouri, where the name was applied to 70 feet of limestone between the "Encrinital Limestone" (Burlington) and the "Vermicular Sandstone" (Hannibal). The name "Rockford," which was applied to the formation in Indiana, was used in southeastern Illinois until the older name, Chouteau, was accepted for all of Illinois (Buschbach, 1952). The Chouteau extends over almost all of Illinois south of a line from Calhoun County to northern Vermilion County (fig. M-9), but it is exposed only in Calhoun and Jersey Counties (Buschbach, 1952; Rubey, 1952; Collinson et al., 1954) and in a small area around Hicks Dome in Hardin County (Weller et al., 1952). It is well exposed in Pere Marquette State Park, southwestern Jersey County, and in the Meppen North Section, Calhoun County (SW NE 23, 12S-2W), where it is about 60 feet thick (Collinson, 1957, 1969). The Chouteau is generally less than 20 feet thick, but it thickens to nearly 80 feet in southern Calhoun County. The Chouteau consists of irregular beds of light brownish or greenish gray, lithographic to very fine-grained limestone with wavy bedding planes. The beds vary from a few inches to nearly 1 foot thick. Locally it is fine-grained dolomite. In a narrow belt extending northeastward from the Ozark region it is red or pink. Gray and buff chert nodules are present and locally abundant where the formation is more than 30 feet thick, but where it is less than 20 feet thick chert is absent. Geodes 1-8 inches in diameter and filled with calcite are common. Macrofossils also are common and conodonts are present in nearly all beds (Collinson, 1961). The Chouteau Limestone normally overlies the Hannibal Formation with apparent conformity, and in places the lower part grades laterally into the upper part of the Hannibal Shale, but in southwestern Illinois the Chouteau locally overlaps the Hannibal and lies unconformably on Devonian to Ordovician formations. In central and eastern Illinois the Chouteau is overlain by the Borden Siltstone, in western Illinois by the Burlington

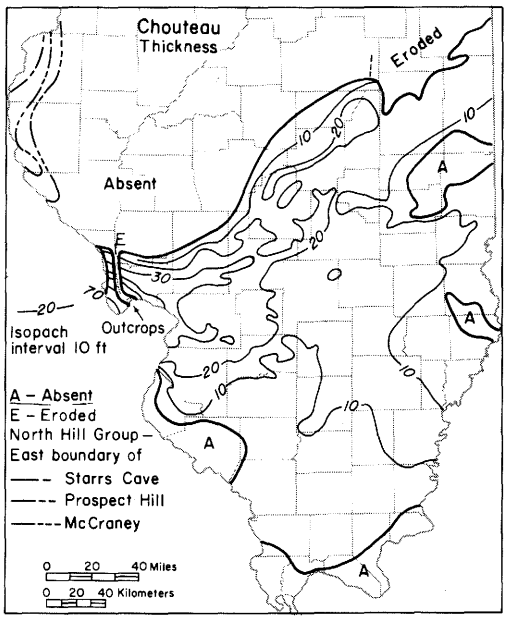

Fig. M-9—Thickness of the Chouteau Limestone and areal extent of the formations of the North Hill Group (after Buschbach, 1952; Workman and Gillette, 1956).

Electronic Filing: Received, Clerk's Office 07/01/2024

Limestone, in southwestern Illinois by the Meppen or Fern Glen Formations, and in Union County and vicinity by the Springville Shale (Buschbach, 1952).

North Hill Group

The North Hill Group (Laudon, 1931, p. 344) is named for the North Hill area of Burlington, Iowa. The name was introduced for the oldest member of the Hampton Formation, but Laudon later (1935) made the unit a formation. Workman and Gillette (1956) made it a group to include the McCraney Limestone at the base, the Prospect Hill Siltstone, and the Starrs Cave Limestone. These formations, extensive in Iowa, are confined in Illinois to a narrow belt east of the Mississippi River in extreme western Illinois (fig. M-9), where they have a maximum thickness of about 110 feet. The group is conformable on the Hannibal Shale but is overlain unconformably by the Burlington Limestone. Conodonts and other fossils indicate that the North Hill Group correlates with the Chouteau Limestone (Collinson, 1961).

McCraney Limestone

The McCraney Limestone (Moore, 1928, p. 20) is named for McCraney Creek (misspelled McKerney in the original publication), near which the limestone crops out in the Mississippi River bluffs north of Kinderhook, northwestern Pike County. It was originally designated a member of the Hannibal Formation, but Workman and Gillette (1956) made it the basal formation in the North Hill Group. The McCraney occurs only in extreme western Illinois (fig. M-9). It has a maximum thickness of 58 feet near the Mississippi River but thins eastward, and within 15-20 miles it is entirely absent. It is well exposed along Fall Creek, southern Adams County (SE 23, 3S-8W). The McCraney Limestone consists of alternating thin layers of light gray to buff lithographic limestone with buff to brown, very fine-grained dolomite. A bed of coarsely oolitic limestone forms the top of the McCraney where the formation is thick. The McCraney is conformable with the underlying Hannibal and the overlying Prospect Hill, but where the latter is absent the McCraney is unconformably overlain, and in places completely truncated, by the Burlington Limestone. The conodont fauna shows that the McCraney correlates with the lower part of the Chouteau and the upper part of the Hannibal (Collinson, 1961; Scott and Collinson, 1961).

Prospect Hill Siltstone

The Prospect Hill Siltstone (Moore, 1928, p. 20; Workman and Gillette, 1956, p. 30), named for Prospect Hill, near Burlington, Iowa, was originally designated a member of the Hannibal Formation, but Workman and Gillette (1956) differentiated the uppermost beds as the Starrs Cave Formation and made the Prospect Hill a formation in the North Hill Group. It occurs in extreme western Illinois within the area underlain by the McCraney Limestone (fig. M-9). It has a maximum thickness of 29 feet but thins eastward to its boundary. It is exposed above the McCraney along Fall Creek in southern Adams County (SE 23, 3S-8W). The siltstone is light gray to buff, calcareous, pyritic, massive, and friable. It is con-

Electronic Filing: Received, Clerk's Office 07/01/2024

formable with the underlying McCraney and the overlying Starrs Cave, but where the latter is absent it is overlain unconformably by the Burlington Limestone. It contains few macrofossils, but the abundant conodonts show a close correlation with the upper part of the Chouteau Limestone (Collinson, 1961, 1964).

Starrs Cave Limestone

The Starrs Cave Limestone (Collinson, *in* Workman and Gillette, 1956, p. 31), the uppermost formation in the North Hill Group, is named for Starrs Cave on the Flint River near Burlington, Iowa, where the type section consists of 2.7-3.5 feet of oolitic, very light gray limestone containing many brachiopods and corals (NW NW 19, 70N-2W). Laudon (1931) referred to this unit as the *Schellwienella* Zone. In Illinois the Starrs Cave occurs only in western Hancock County (fig. M-9), where it is 2-12 feet thick but is not exposed. It is a buff to light brownish gray, coarsely oolitic, locally dolomitic limestone. It conformably overlies the Prospect Hill Siltstone and is unconformably overlain by the Burlington Limestone. It has an abundant macrofauna dominated by brachiopods and is correlated with the Chouteau Limestone (Collinson, 1961).

VALMEYERAN SERIES

The Valmeyeran Series (Weller and Sutton, *in* Moore, 1933, p. 261-262) is named for Valmeyer, Monroe County, near which much of the series is exposed. It is the middle series of the Mississippian System and includes formations assigned to two series (Osagian and Meramecan) in other areas. The Valmeyeran Series underlies most of central and southern Illinois (fig. M-10) and includes strata from the top of the Chouteau Limestone upward to the base of the Shetlerville Member of the Renault Limestone (Swann, 1963) (figs. M-3, M-11, M-12, M-13). The series is thickest, over 1800 feet, in southeastern Illinois, and it thins to 600 feet or less before being truncated by erosion in northern Illinois (fig. M-10). It probably originally covered all of northern Illinois, as 200 feet of Valmeyeran strata are preserved in fault blocks in the Des Plaines Disturbance (Emrich and Bergstrom, 1962).

The Valmeyeran is characterized by lateral changes due to depositional pinchouts and lateral gradation. In the type area along the Mississippi River near St. Louis, the Valmeyeran is predominantly carbonate formations. In central Illinois the Burlington and Keokuk Limestones pinch out eastward and the lower part of the Valmeyeran consists of the thick Borden Siltstone (fig. M-14). Eastward, in southeastern Illinois, the Borden is replaced as the dominant unit by the very thick Ullin Limestone and then by thick siliceous limestone of the Fort Payne Formation. The sediment of the Borden Siltstone was transported from the northeast by a major river and deposited in the inland sea as a delta that spread to and overlapped the Keokuk and Burlington carbonates. The deep-water, sediment-starved basin adjacent to the delta was later filled with Fort Payne and Ullin sediments (Swann et al., 1965; Lineback, 1966, 1968a, 1968b).

The overlying Salem and St. Louis Limestones are more persistent across the basin than the underlying units, but they, too, show facies that reflect water depth. Massive biocalcarenitic Salem grades laterally northward into fine-grained evaporite-bearing carbonates of the St. Louis (Lineback, 1972). Near the top of the Valmeyeran Series, the members of the Ste. Genevieve Limestone show rapid facies changes and the contact with the underlying St. Louis Limestone is stepped up and down in response to local lithologic changes.

Because of the complex facies variations in the Valmeyeran Series, knowledge of the relations between the many units has grown slowly, and the classification has been repeatedly changed (fig. M-15).

Borden Siltstone

The Borden Siltstone (Cumings, 1922, p. 487) is named for Borden, Clark County, Indiana, where it is well exposed. It forms an elongate, tongue-shaped delta immediately east of the pinchout of the Burlington and Keokuk Limestones. It is continuous with the Borden Group of Indiana. The formation reaches more than 650 feet thick (fig. M-16), but it does not crop out in Illinois. The Borden in Illinois is dominantly gray to brownish gray, argillaceous, slightly calcareous, glauconitic, fine-grained siltstone, with lesser amounts of silty shale, some greenish gray coarse siltstone or fine sandstone, and light-colored, fossiliferous, cherty limestone. A persistent bed of coarse siltstone and fine sandstone is differentiated as the Bilyeu Member. Beds of fine sandstone and coarse siltstone near the base of the Borden are informally called the "Carper sand" (Moulton, 1926), and the name has been extended to similar beds in the Springville Shale (Lineback, 1968a). Some of the sandstones contain oil (Stevenson, 1964). The Borden Siltstone delta was deposited as a series of southward-developing imbricate topset, foreset, and bottomset beds (Swann et al., 1965; Lineback, 1966). Depositional dips of foreset bedding planes range from 25-120 feet per mile toward the delta margin. The delta was built into a deep-water basin. The "Carper sand" is now believed to have been deposited by multiple turbidity flows off the mouths of distributaries. At least six major turbidite systems as much as 300 feet thick have been recognized, some of which extend for many miles and lens out or grade into the Springville Shale. The Borden is laterally equivalent to the Warsaw Shale and is separated from it by a vertical cut-off at the

Electronic Filing: Received, Clerk's Office 07/01/2024

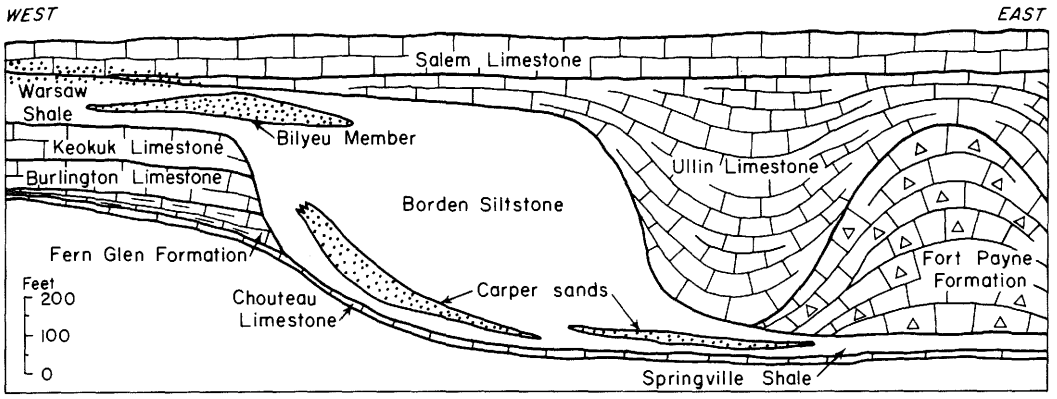

Fig. M-14—Diagrammatic east-west cross section across central Illinois showing the Borden Siltstone delta (after Lineback, 1968b).

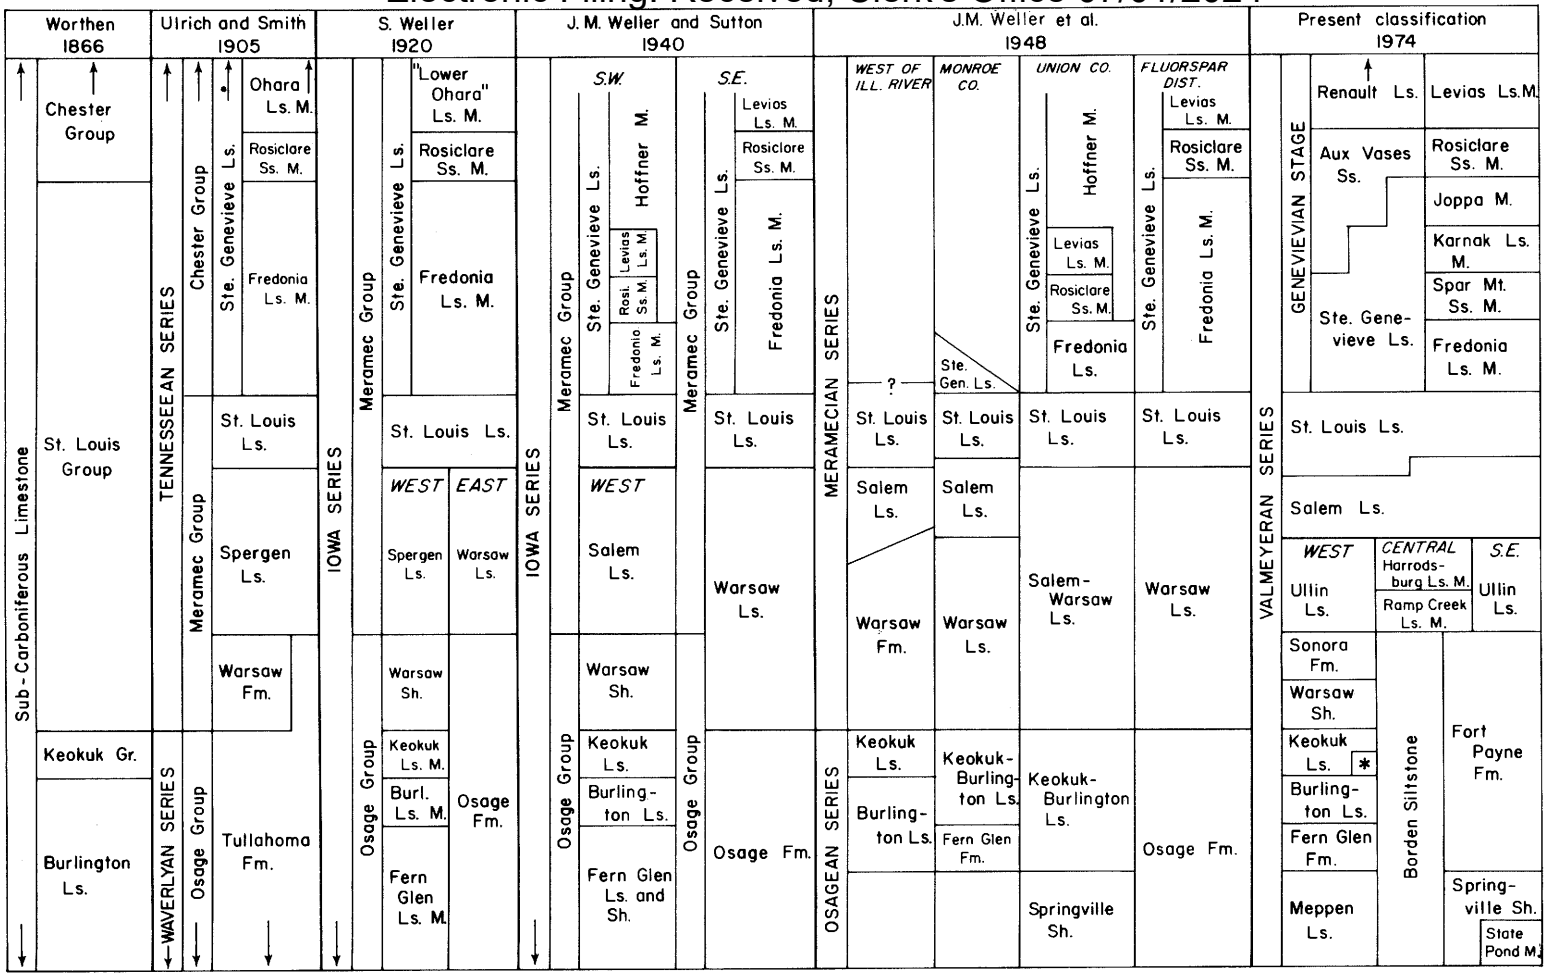
position of the eastern pinchout of the Burlington and Keokuk Limestones (fig. M-14). In southern and southeastern Illinois, the Borden is separated from the equivalent Springville Shale by a vertical cut-off where the siltstone thins to less than 100 feet thick. The Borden overlies the Chouteau Limestone and is overlain by the Fort Payne Formation, or the Ullin, Salem, or St. Louis Limestones.

Bilyeu Member—The Bilyeu Member of the Borden Siltstone (Lineback, 1968a, p. 5) is named for Bilyeu Cemetery, Christian County, about 2 miles north of the type section, which is in the National Petroleum Company No. 1-A Bilyeu, Haldon et al., south well (NW NW SW 10, 13N-1E), where the member is 102 feet thick, extending from 1616 to 1718 feet deep. The Bilyeu consists of siltstone that is coarser than most of the Borden and also of fine sandstone. It is 0-150 feet thick and extends in the subsurface through Piatt, De Witt, Macon, Christian, Montgomery, Sangamon, and parts of adjacent counties in central Illinois. The Bilyeu Member extends westward beyond the eastern pinchout of the Burlington and Keokuk Limestones and, therefore, in that area is a member of the Warsaw Shale.

Springville Shale



The Springville Shale (Savage, 1920, p. 169-178; Collinson and Scott, 1958a, p. 11), the basal formation of the Valmeyeran Series in southern Illinois, is named for the now abandoned village of Springville, Union County, which was located a short distance southeast of the type exposures in the bed and banks of a creek 4 miles southeast of Anna (SE 3, 13S-1W). Savage included in the Springville the thin Chouteau Limestone and the shale in the upper part of the New Albany Group, but these were removed by Collinson and Scott (1958a). The Springville Shale crops out discontinuously northward from the type exposures to Jonesboro, in a fault slice along the Shawneetown Fault in Saline County, and on the flanks of Hicks Dome in Hardin County. The Springville is as much as 100 feet thick, but in most of southern Illinois it is less than 50, and in some places it is absent. The formation consists of greenish gray to dark brownish gray, clayey shale. A bed of soft glauconitic shale at the base is differentiated as the State Pond Member. In places, the Springville is mottled red and green and has been informally called the "calico shale." Lenses of the "Carper sand" are present in the areas of thicker shale. The shale is the deep-water equivalent of the Borden delta, and it is separated from the Borden Siltstone by vertical cut-off where the Borden thins to 100 feet (Lineback, 1966) (fig. M-14). The Springville overlies the Chouteau Limestone or, where the Chouteau is absent, the New Albany Group. It is overlain by the Fort Payne Formation or the Ullin Limestone.

State Pond Member—The State Pond Member of the Springville Shale (Collinson and Scott, 1958a, p. 5), at the base of the formation, is named for State Pond, an artificial lake a mile northwest of Jonesboro, Union County. The type section is in the south bank of the stream, below the spillway of the dam (NW SE 14, 12S-2W), where the member is 14-15 inches thick. It is a greenish gray, soft, glauconitic shale containing phosphate nodules. It has yielded conodonts and ostracodes typical of the Fern Glen, Burlington, and Keokuk Limestones and probably is a deep-water equivalent of all three formations.

Meppen Limestone

The Meppen Limestone (Collinson, 1969, p. 12) is named for the village of Meppen, Calhoun County, and the type section is in a quarry 0.6 mile north of Meppen (SW NE 23, 12S-2W), where the formation is 7 feet thick, consists of buff, massive dolomite containing numerous small calcite geodes, and stands out as a distinct buff band in the quarry face. The formation occurs along the western edge of Illinois in an area extending from Calhoun County to Monroe County. It is well exposed in Calhoun and Jersey Counties and has a maximum thickness of 22 feet at Chautauqua, Jersey County (SE SE NE 13, 6N-12W). The Meppen is a tan or buff, very fine-grained, slightly crinoidal, dolomitic limestone or calcareous dolomite that commonly contains many calcite geodes 0.5-2 inches in diameter. The Meppen rests unconformably on the Chouteau Limestone, and at Chautauqua the relation is clearly angular. The Meppen is overlain conformably by the Fern Glen Formation, but north of the Lincoln Anticline the Fern Glen grades into the Burlington, and the Burlington overlaps the Meppen. The Meppen Limestone was called Sedalia in Illinois for many years (Rubey, 1952; Collinson et al., 1954) be-

Fig. M-16—Thickness of the Warsaw Shale, Borden Siltstone, and Springville Shale.

cause of its lithologic similarity to the upper dolomitic portion of the Chouteau Limestone in Missouri, which had been named Sedalia by Moore (1928). However, the conodont faunas have shown that the Missouri Sedalia is Kinderhookian, whereas the Illinois "Sedalia" is Valmeyeran. The Meppen contains lower Valmeyeran conodonts, such as *Pseudopolygnathus multistriatus, Polygnathus communis carinus,* and *Bactrognathus hamatus,* but no diagnostic Kinderhookian species. The conodont *Gnathodus semiglaber–Pseudopolygnathus multistriatus* Zone occurs in the Meppen Formation (Collinson et al., 1962). Lithologically and faunally, the Meppen correlates better with the Pierson Limestone of central Missouri than with the Sedalia.

Fern Glen Formation

The Fern Glen Formation (S. Weller, 1906b, p. 438) is named for Fern Glen Station on the Missouri Pacific Railroad, 20 miles west of St. Louis, where the type section, in the Missouri River bluffs, consists of 30-40 feet of red and green calcareous shale, shaly limestone, and a basal bed of massive, yellowish gray, magnesian limestone. The Fern Glen occurs in western Illinois from Randolph County north to Jersey County and in a belt extending northeast to southwestern Champaign County. It is typically exposed in the Chautauqua West Section, southern Jersey County (SW NE 13, 6N-12W), where it includes about 20 feet of calcareous shale, crinoidal limestone, and greenish gray chert (Collinson, 1969). It is also well exposed near Valmeyer, Monroe County (SE SE 3, 3S-11W). Throughout most of its extent, the Fern Glen is less than 50 feet thick, but in a few small areas in St. Clair, Sangamon, and Christian Counties, it approaches 100 feet. The formation consists of green and red calcareous shale and of gray, green, and red limestone and dolomite that is partly argillaceous. The lower part is generally shaly and noncherty, while the upper part is mainly limestone containing small nodules of greenish gray chert. The Fern Glen overlaps the underlying Meppen Limestone to rest on truncated older rocks, as old as the Maquoketa Shale Group. It grades vertically and laterally into the overlying Burlington Limestone, and the boundary is ordinarily drawn at the top of the youngest red or green bed. Fossils are abundant, notably brachiopods, corals, and crinoids. The more common fossils include the brachiopods *Spirifer vernonensis, S. rowleyi, Athyris lamellosa,* and *Leptaena rhomboidalis*, the bryozoan *Evactinopora sexradiata*, and the coral *Cyathaxonia arcuata.* The conodont *Bactrognathus–Polygnathus communis* Zone occurs in the Fern Glen Formation and the lower part of the Burlington Limestone.

Burlington Limestone

The Burlington Limestone (Owen, 1852, p. 90-140; Hall, 1857, p. 190; Van Tuyl, 1925, p. 120) is named for the city of Burlington, Des Moines County, Iowa, where the formation is well exposed and about 70 feet thick. Owen used the term "Encrinital group of Burlington," Hall called it the Burlington Limestone, and Van Tuyl gave it its present definition by transferring the "beds of passage" (Montrose Chert Member) from the Burlington to the Keokuk. The Burlington extends from Henderson County in the northwest across a roughly triangular area southward to Jackson County and eastward to Iroquois County (fig. M-17). Good outcrops are found in the Mississippi River bluffs from Quincy, Adams County, to near Alton, Madison County (Collinson, 1964). In the vicinity of Quincy the lower 25 feet is relatively pure and is quarried as the "Quincy Lime." The

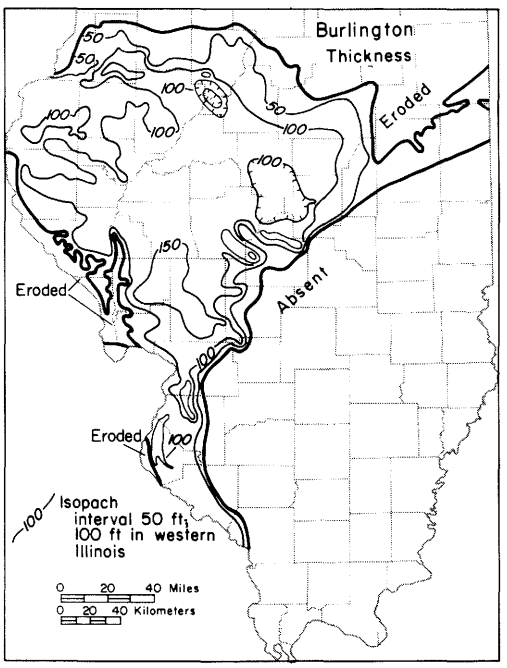

Fig. M-17—Thickness of the Burlington Limestone.

Electronic Filing: Received, Clerk's Office 07/01/2024

formation is commonly 100-150 feet thick, but it is as much as 200 feet thick in western Christian County. It terminates sharply to the east where overlapped by the Borden Siltstone (fig. M-14). In the northwestern part of its extent the Burlington consists largely of very pure, coarsely crystalline, light gray limestone in medium to thick beds. It contains a few beds of fine-grained, brownish gray, dolomitic limestone. Beds and nodular masses of light gray or white chert are common, especially in the middle and upper parts of the formation. Some beds are glauconitic. Large crinoid stems are abundant, and many beds are almost entirely crinoidal debris. The top of the Burlington is marked throughout a wide area by a bed 2-10 inches thick that contains many fish teeth and spines. Farther south the Burlington becomes more cherty, the crystalline limestone beds are few and fine-grained beds more common, and fossils are much less abundant. Chert in some places forms as much as 50 percent of the formation, but the chert is exceedingly lenticular and the amounts vary greatly (Rubey, 1952). In the southern area the Burlington and the overlying Keokuk can be distinguished only by their fossils and are generally referred to as the Burlington-Keokuk Limestone. The Burlington lies conformably on the Fern Glen and Meppen Formations, and unconformably on older beds where the Fern Glen and Meppen are absent. Among the common fossils restricted to the Burlington are *Cryptoblastus melo, Globoblastus norwoodi, Dictyoclostus burlingtonensis, Rhipidomella burlingtonensis, Stenocisma bisinuata, Spirifer grimesi, S. forbesi,* and *Spiriferella plena* (Weller and Sutton, 1940). Many crinoids have been described. The lower part of the Burlington Formation is in the conodont *Bactrognathus-Polygnathus communis* Zone, and the upper half is in the conodont *Bactrognathus-Taphrognathus* Zone (Collinson et al., 1971). The Burlington and the overlying Keokuk represent a shallow-water, largely clastic, carbonate sediment that was deposited on the western flank of the Illinois Basin while the Borden delta was expanding into the basin from the northeast.

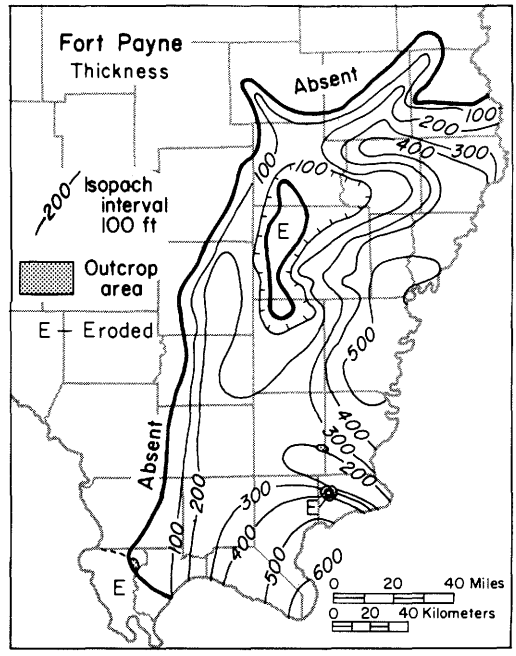

Fig. M-18—Thickness of the Fort Payne Formation.

Keokuk Limestone

The Keokuk Limestone (Owen, 1852, p. 91, 92; Hall, 1857, p. 190; Van Tuyl, 1925, p. 142) is named for Keokuk, Lee County, Iowa. At the type locality about 70 feet of Keokuk Limestone overlying the Burlington Limestone is well exposed along Soap Creek and in the Mississippi River bluff near the mouth of the creek. The Keokuk occurs throughout much the same area as the underlying Burlington (fig. M-17), and it is well exposed along the Mississippi and Illinois Rivers in western Illinois. The Keokuk is 60-80 feet thick for much of its extent. Like the Burlington, the Keokuk is primarily a biocalcarenite. In the type region the lower 30 feet is very cherty and is differentiated as the Montrose Chert Member (Collinson, 1964). The part of the Keokuk above the Montrose is composed of beds of fossiliferous, crinoidal limestone interbedded with fine-grained limestone, argillaceous dolomite, and calcareous gray shale. The shale beds increase upward in number and thickness. The limestone is light gray, speckled with darker gray, brown, or black, and contains beds and nodules of chert. It is generally thinner bedded and darker than limestone of the Burlington, and the shale partings are more numerous. The contact with the overlying Warsaw Shale is gradational. In contrast to the crinoidal limestone of the Burlington, the Keokuk shows a great heterogeneity of skeletal remains, with abundant bryozoans, corals, and brachiopods. The Keokuk contains bryozoans in much greater abundance and diversity than does the Burlington, with *Archimedes* and *Worthenopora* especially common. Distinctive brachiopods include *Spirifer logani, Dictyoclostus crawfordsvillensis, Orthotetes keokuk,* and *Rotaia subtrigonia* (Weller and Sutton, 1940). The conodont *Gnathodus texanus—Taphrognathus* Zone essentially coincides with the Keokuk Formation (Collinson et al., 1971).

Montrose Chert Member—The Montrose Chert Member of the Keokuk Formation (Keyes, 1895, p. 320) is named for Montrose, Lee County, Iowa, and the type section consists of 30 feet of very cherty limestone at the base of the Keokuk Limestone where it is exposed along the Mississippi River between Montrose and Keokuk. Earlier, these beds had been termed the "Keokuk cherty limestones" (Owen, 1852) or the "cherty beds of passage" separating the Keokuk and Burlington (Hall, 1857). The Montrose Chert Member is generally about 30 feet thick and consists of gray, medium- to coarse-grained, fossiliferous limestone and light gray dolomite in beds 2-10 inches thick. It contains nodules and beds of blue-gray chert. The chert is dominant in many places and commonly is strongly brecciated (Collinson, 1964).

Warsaw Shale

The Warsaw Shale (Hall, 1857, p. 54-56) is named for Warsaw, Hancock County, and the exposure in Geode Glen at Warsaw has become the type section (NW NW 10, 4N-9W) (Collinson, 1964). The Warsaw is widely

Electronic Filing: Received, Clerk's Office 07/01/2024

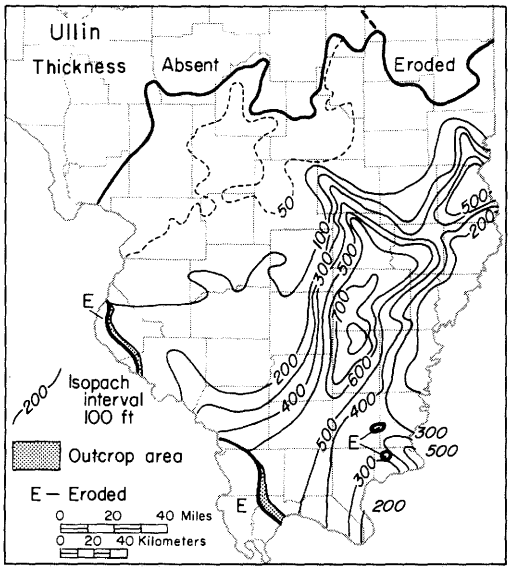

Fig. M-19—Thickness of the Ullin Limestone.

present in the bluffs of the Mississippi and Illinois Valleys in western and southwestern Illinois. It consists of as much as 300 feet of siltstone in west-central Illinois (fig. M-16), but it thins to less than 100 feet in the outcrop area, where it consists of gray shale containing beds of argillaceous limestone. Quartz geodes are common and locally abundant; some are replacements of fossils. Some contain petroleum. The Warsaw is fossiliferous, with brachiopods, bryozoans, and crinoids especially common. The corkscrew bryozoan, *Archimedes* (fig. M-4), is so abundant that the formation was called the *Archimedes* limestone in early reports. Coarse silt and fine sandstone differentiated as the Bilyeu Member of the Borden Siltstone in central Illinois continues westward into the Warsaw Shale, where it becomes a member of the Warsaw. The Warsaw is overlain by the Sonora Formation or by the Ullin, Salem, or St. Louis Limestones. The Warsaw Shale overlies the Keokuk Limestone, and where the Keokuk and Burlington Limestones pinch out eastward the Warsaw is separated from the Borden Siltstone by a vertical cut-off (Lineback, 1966) (fig. M-14).

Sonora Formation

The Sonora Formation (Keyes, 1895, p. 320) is named for the now extinct village of Sonora, Hancock County, about a mile north of the type section of the formation in the Sonora quarries (SE NW 31, 6N-8W), where about 20 feet of sandy, cross-bedded dolomite grades to porous, dolomitic sandstone. The Sonora crops out most widely in the Mississippi River bluffs and along tributary valleys in Adams and Hancock Counties. It is typically exposed at Jackson Cemetery, Hancock County (SE NW 14, 7N-8W), where it is more than 20 feet thick and consists of beds of argillaceous and dolomitic, cross-bedded sandstone alternating with sandy shale. The Sonora is generally about 20 feet thick between Niota and Hamilton, but elsewhere it is thinner, becoming only 2-3 feet thick in the Warsaw area (Collinson, 1964). Although characteristically a sandy formation, the lithology varies laterally and vertically. The dolomite is arenaceous to argillaceous and sparsely fossiliferous, but fragments of fenestellid bryozoans occur throughout. The sandstone is generally light buff, dolomitic, argillaceous, and fine grained. The shale is generally greenish gray and sandy. Both Salem and St. Louis overlie the Sonora in places. The contact with the overlying St. Louis varies from conformable to erosional. In most localities where the contact is exposed, the lower part of the St. Louis is brecciated, possibly by the solution of a layer of gypsum or anhydrite. The Sonora grades laterally into the Salem Limestone and the upper part of the Warsaw Shale (Collinson, 1964). The Sonora lies within the conodont *Taphrognathus varians—Apatognathus* Zone (Collinson et al., 1971).

Fort Payne Formation

The Fort Payne Formation (Smith, 1890, p. 155-156) is named for Fort Payne, De Kalb County, Alabama. It consists of dark, very fine-grained, siliceous, cherty limestone. The Fort Payne is confined to southern Illinois. It is over 610 feet thick in Pope County, and thins northward and westward (fig. M-18). The best exposure of the Fort Payne in Illinois is in a fault slice along the Shawneetown Fault near the former community of Horseshoe, Saline County, where at least 150 feet of steeply dipping beds are exposed. The Fort Payne is also exposed on the flanks of Hicks Dome in Hardin County, where it is largely weathered to chert. Eleven feet of chert exposed in the bluff in Alexander County west of Ullin, Pulaski County, is also assigned to the Fort Payne. In the subsurface the Fort Payne consists of quartz and carbonates in silt- and clay-sized particles. In the lower part it contains nodular chert and fossils, especially crinoids, and some clay minerals. The dark color is caused by pyrite and organic matter. The Fort Payne overlies the Springville Shale, the Chouteau Limestone, or the lower portion of the foreset slope of the Borden Siltstone delta in southern Illinois. It is overlain by the Ullin Limestone. The Fort Payne occurs as an irregular tongue-shaped body that partially filled a deep-water basin bordered by the foreset slopes of the Borden delta in southern Illinois and southeastern Indiana (Lineback, 1966). It is the northernmost extension of a large body of siliceous and cherty rocks that extends through western Kentucky to Mississippi and Alabama and eastward to the Appalachian Mountains.

Ullin Limestone

The Ullin Limestone (Lineback, 1966, p. 29-34) is named for Ullin, Pulaski County, near which the type section was compiled from three exposures (secs. 14, 21, and 22, 14S-1W), which have a total thickness of about 630 feet. Its maximum thickness is more than 800 feet in Hamilton County and it thins generally northward (fig. M-19). It is exposed in the Mississippi River bluffs in Monroe, St. Clair, and Madison Counties and in southern Illinois in Union, Pulaski, and Hardin Counties. The Ullin Limestone is largely light-colored, fine- to coarse-grained limestone (fig. M-1F) that is rich in bryozoans and crinoids. It overlies the Fort Payne Formation, or the Borden, Springville, Warsaw, or Chouteau Formations

Electronic Filing: Received, Clerk's Office 07/01/2024

where the Fort Payne is absent. It underlies the Salem Limestone and pinches out beneath it in western Illinois. The Ullin can generally be subdivided into two members, the Harrodsburg Limestone Member, above, and the Ramp Creek Limestone Member, below. The Harrodsburg is generally lighter colored, coarser grained, less cherty and less argillaceous than the Ramp Creek, whereas the Ramp Creek contains more crinoidal debris and is glauconitic in places. However, the Harrodsburg and Ramp Creek Members are similar in many places, and in about one-third of the area of the Ullin they cannot be differentiated. Where the Ullin is thickest, in Hamilton County, both members are light-colored calcarenite rich in bryozoans. Where the Ullin is thin, as it is on the crest of the Borden delta and on the highest parts of the Fort Payne tongue, both members become more crinoidal and are indistinguishable. The Ullin Limestone filled deep-water trenches bordered by depositional slopes of the Borden delta and the Fort Payne Formation.

Ramp Creek Limestone Member—The Ramp Creek Limestone Member of the Ullin Limestone (Stockdale, 1929, p. 233-242) is named for the village of Ramp Creek, Monroe County, Indiana, and the type section is a near-by exposure of 21 feet of siliceous and argillaceous limestone (NW NW 35, 8N-1W). The name "Ramp Creek" was originally applied to the lower part of the Harrodsburg Limestone, but Harrodsburg was later restricted to the upper, purer limestone (Smith, 1965). The Ramp Creek in Illinois is the lower, cherty, argillaceous limestone of the Ullin (Lineback, 1966). The Ramp Creek is 0-490 feet thick. It includes the brachiopod *Marginirugus magnus* Zone.

Harrodsburg Limestone Member—The Harrodsburg Limestone Member of the Ullin Limestone (Hopkins and Siebenthal, 1897, p. 296-297; Stockdale, 1939, p. 72-73; Smith, 1965, p. 11; Lineback, 1966, p. 33) is named for Harrodsburg, Monroe County, Indiana. The original type section was destroyed by highway construction, but an exposure 1 mile north of Harrodsburg is used as a standard reference section (Shaver et al., 1970). The Harrodsburg Member is exposed along the Mississippi Valley in western and southwestern Illinois and in Hardin County in southeastern Illinois. It is over 800 feet thick in Hamilton County, but it thins northward and pinches out at the margin of the formation. It consists of light-colored bryozoan and crinoid debris. In Monroe County the Harrodsburg strata were included in the Kidd Member of the Salem by Baxter (1960a), but they were excluded from the Kidd by Lineback (1972).

Salem Limestone

The Salem Limestone (Cumings, 1901, p. 233) is named for Salem, Washington County, Indiana, where it is extensively quarried for Indiana building stone. It was called "Spergen Hill" or "Spergen" limestone in early reports. No type section was designated, but a quarry 0.8 mile east of Salem is considered the principal reference section (Shaver et al., 1970). The Salem Limestone forms prominent outcrops in Illinois in parts of Hardin County, along the Mississippi River in Randolph (fig. M-1D), Monroe, and Madison Counties, and in places in western Illinois. It is over 500 feet thick in southeastern Illinois and thins northward (fig. M-20). Small patches occur northwest of the area mapped. The Salem generally overlies the Ullin, but where the Ullin pinches out northward the Salem rests on the Warsaw Shale or the Sonora Formation. The Salem is overlain by the St. Louis Limestone. The Salem is a biocalcarenite consisting of rounded, broken, fossil fragments and whole small fossils, commonly with banded, oolitic-like overgrowths, that are imbedded in a matrix that ranges from micrite to sparite. Endothyrid foraminifers are commonly abundant (fig. M-4). Minor lithologies in the Salem include biocalcilutite, biocalcirudite, sucrosic dolomite, dolomitic limestone, fine-grained limestone, fossiliferous crystalline limestone, sandstone, chert, and the evaporites anhydrite and gypsum. Some fine-grained, silty, dolomitic beds weather yellow and form reentrants on the weathered faces. The Salem differs from the underlying Ullin by having a greater variety of fossils and fossils with banded overgrowths. In the outcrop area in Monroe County and extending from Prairie du Rocher, Randolph County, to Dupo, St. Clair County, the Salem is divided into the Kidd (at the base), Fults, Chalfin, and Rocher Members, largely on the basis of differences in textures (Baxter, 1960a). The Kidd and Fults Members are lithologically and faunally similar to the type Salem in Indiana. The upper part of the Salem grades laterally into the St. Louis Limestone in Madison County and northward (Lineback, 1972). The lower part can be identified into Christian County and northward, but the biocalcarenite grades laterally into dolomitic limestone and fossiliferous limestone that contain evaporites and sandstone in places. The lateral gradation is the result of the southward deepening of the water from shallow water near the shore in north-central Illinois to deeper water near the center of the Illinois Basin.

Kidd Member—The Kidd Member of the Salem Limestone (Baxter, 1960a, p. 19-22; Lineback, 1972, p. 5), the basal member, is named for Kidd, Monroe County, and the type section is in the Mississippi River bluffs east of the village (NE NE 1, 5S-10W). As originally defined, it included the Harrodsburg Member of the Ullin Limestone, but it was

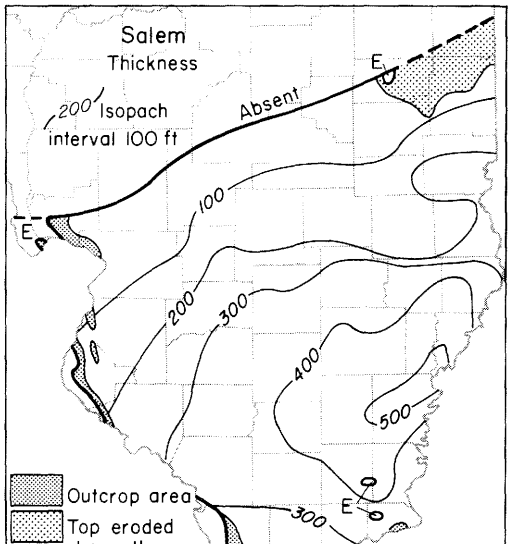

Fig. M-20—Thickness of the Salem Limestone.

Electronic Filing: Received, Clerk's Office 07/01/2024

restricted by Lineback to the biocalcarenite below the Fults Member and above the Ullin. In the type section the Kidd consists of about 22 feet of chert-free, high-calcium biocalcarenite, largely made up of medium and coarse grains of fragmented fossils, mostly crinoid columnals and bryozoan detritus, in beds 2-3 feet thick. The foraminifers *Endothyra* sp., *Tournayella* sp., and *Globoendothyra* sp. are present. *Globoendothyra baileyi* is common and becomes more common in the upper half of the member.

Fults Member—The Fults Member of the Salem Limestone (Baxter, 1960a, p. 22-24) is named for Fults, Monroe County, and the type section is in the bluffs three-fourths of a mile northwest of the town (SE NE 20, 4S-10W), where the member is 29.4 feet thick. It is 25-34 feet thick in the outcrop area in Monroe and St. Clair Counties. The Fults Member consists largely of thin- to medium-bedded, fine-grained, silty, cherty, more or less dolomitic limestone, but it contains beds of medium-grained limestone composed of fragmented fossils. *Globoendothyra baileyi* and *Eoendothyranopsis spiroides* are common.

Chalfin Member—The Chalfin Member of the Salem Limestone (Baxter, 1960a, p. 24-27) is named for the village of Chalfin Bridge, Monroe County, and the type section is in the Mississippi River bluffs 1 mile southwest of the village (NE SW 7, 4S-10W), where the member is 39.5 feet thick. It is 26-57 feet thick in the outcrop area. The Chalfin consists of varying thicknesses of fine-grained limestone; fine- to medium-grained, fossiliferous, locally oolitic limestone; and semilithographic limestone, some of it brecciated. The lower 10 feet is predominantly a calcarenite composed of bryozoan detritus, crinoid columnals, microcrystalline pellets, and a few oolites. *Eoendothyranopsis* group *pressus-rarus, Koninckopora sahariensis, K. inflata, Septabrunsiina,* and profuse *Calcisphaera* characterize the Chalfin.

Rocher Member—The Rocher Member of the Salem Limestone (Baxter, 1960a, p. 27-29), the uppermost member, is named for Prairie du Rocher, Randolph County, and the type section is in the Mississippi River bluffs above a large spring 1 mile northwest of the town, where the member is 69.3 feet thick. It thins northward to 10-15 feet at Valmeyer, Monroe County. The Rocher is mined for high-calcium limestone just north of the type section. It is composed largely of marine fossils, predominantly Foraminifera, but it also includes crinoid and bryozoan fragments, brachiopods, corals, and echinoids. Endothyrids and calcareous spheres with calcite centers, questionable fossils classified as *Calcisphaera*, are abundant (Baxter, 1960b). The microfauna is similar to that of the Chalfin and the lower part of the St. Louis. The limestone varies from slightly oolitic to oolite. It occurs in thick, cliff-forming beds, broken by an occasional thin bed.

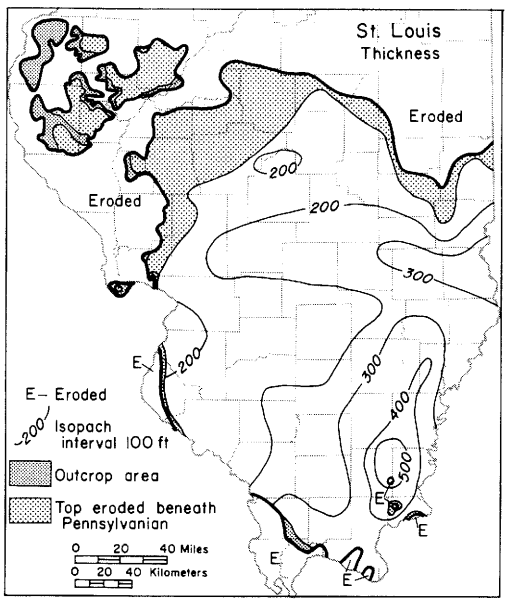

Fig. M-21—Thickness of the St. Louis Limestone.

St. Louis Limestone

The St. Louis Limestone (Engelmann, 1847, p. 119-120; Ulrich, 1904, p. 103) is named for St. Louis, Missouri, where it is extensively exposed. No type section was designated. The St. Louis is typically exposed in Illinois in the Mississippi River bluffs at Alton, Madison County (Collinson et al., 1954) (fig. M-1B). It is also well exposed in the Mississippi and Illinois Valleys in western and southern Illinois (fig. M-1D) and along the Ohio River in Hardin County (fig. M-21). The St. Louis is 500 feet thick in southeastern Illinois and thins northwestward to less than 200 feet before being truncated by pre-Pennsylvanian erosion. The St. Louis Limestone in Illinois is characterized by fine-grained, micritic to lithographic, cherty limestone, but it contains beds of dolomite, crystalline limestone, fossiliferous limestone, and evaporites. The evaporites are represented in the outcrop areas by limestone breccias. The outcrop areas of the St. Louis are characterized by abundant sink holes. The St. Louis overlies the Salem Limestone except in the parts of western Illinois where it lies on the Warsaw Shale or the Sonora Formation. It is overlain by the Ste. Genevieve Limestone. The lower part of that formation grades laterally into the St. Louis Limestone, and in those places the formations are separated by a vertical cut-off. The rugose coral *Lithostrotionella* is common and characteristic (fig. M-4). In the St. Louis–Alton area the lower part of the St. Louis is included in the conodont *Taphrognathus varians–Apatognathus* Zone and the upper part in the *A. scalenus—Cavusgnathus* Zone. The upper St. Louis has common *Eoendothyranopsis, Koninckopora pruvosti,* and large archaediscids.

Genevievian Stage

The Genevievian Stage (Swann, 1963, p. 20-21) is named for the Ste. Genevieve Limestone, the type section for which is at Ste. Genevieve, Missouri. It is the only stage at present differentiated in the Valmeyeran Series and covers only the latest part of Valmeyeran time (fig. M-3). It consists of all the strata contemporaneous with the Ste. Genevieve Limestone where its top corresponds with the last occurrence of *Platycrinites penicillus*. The *Platycrinites–Talarocrinus* boundary is the basis for the time plane separating the Valmeyeran and Chesterian Series. It falls within the Renault Limestone at the top of the Levias Member. The base of the Genevievian Stage is less well defined, but in the Illinois Basin it is placed at the top of the St. Louis

 Electronic Filing: Received, Clerk's Office 07/01/2024

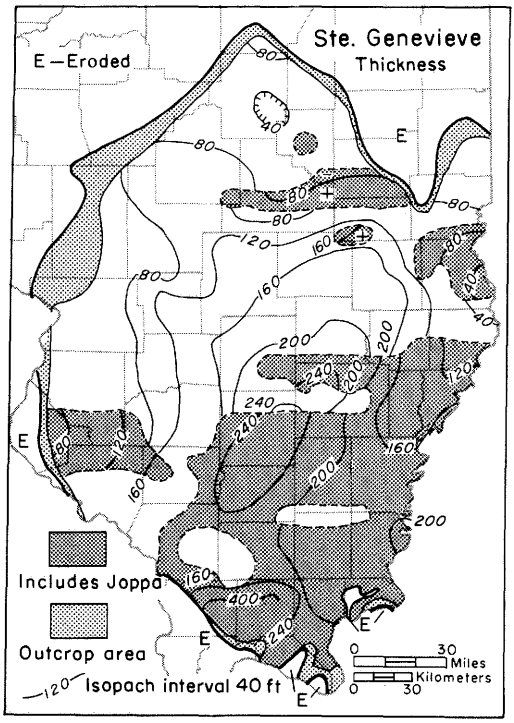

Fig. M-22—Thickness of the Ste. Genevieve Limestone.

Limestone, which is the base of the *Gnathodus bilineatus—Cavusgnathus charactus* Zone, somewhat higher than the disappearance of *Lithostrotion* and *Lithostrotionella* with large corallites, where it was originally placed.

Ste. Genevieve Limestone

The Ste. Genevieve Limestone (Shumard, 1860, p. 406) is named for Ste. Genevieve, Missouri, where it is about 100 feet thick, and the type section consists of outcrops in the bluffs along the Mississippi River 1-4 miles southeast of Ste. Genevieve. The Ste. Genevieve overlies the St. Louis Limestone and underlies the Aux Vases Sandstone throughout much of the southern half of the Illinois Basin. It crops out from the vicinity of Alton, Madison County (fig. M-1B), south along the Mississippi Valley to Randolph County and from Union County, where it is about 300 feet thick, eastward across southern Illinois to Hardin County, where it averages about 250 feet thick (fig. M-22). The Ste. Genevieve is generally light gray, but some beds of oolite (fig. M-1E) are nearly white. Chert is common and is generally gray, but in some places it is black. Thin beds of sandstone and sandy limestone, some traceable for many miles, occur mainly in the upper half of the formation. The sandstone is generally calcareous, light greenish gray, and very fine grained. A little shale, mainly dark greenish gray but locally red, purple, or green, occurs in the upper part of the formation. The Ste. Genevieve is subdivided into four members: the Fredonia Limestone Member at the base, the Spar Mountain Sandstone Member, the Karnak Limestone Member, and the Joppa Member (sandstone, limestone, dolomite, and shale). Near its western border the Ste. Genevieve has a conglomeratic bed at its base and rests unconformably on the eroded top of the St. Louis Limestone. Elsewhere the two formations appear to be conformable and, in the transition zone, beds with Ste. Genevieve lithology intertongue with beds with St. Louis lithology. The contact is placed below the lowest prominent oolitic bed. The contact between the Ste. Genevieve and the overlying Aux Vases Sandstone is conformable, but it is marked by a series of downward steps to the west as the upper limestone beds grade westward into sandstone. Weathered surfaces of the Ste. Genevieve generally show abundant fossils, mainly crinoid fragments. *Platycrinites ("Platycrinus") penicillus* and *Pugnoides ottumwa* are characteristic, although they occur rarely in older or younger strata. The Ste. Genevieve is in the lower part of the *Gnathodus bilineatus—Cavusgnathus charactus* Zone (Collinson et al., 1971). The Ste. Genevieve Formation extends into eastern Missouri, southwestern Indiana, and western Kentucky. The Pella beds of Iowa are correlated with the Ste. Genevieve.

Fredonia Limestone Member—The Fredonia Limestone Member of the Ste. Genevieve Limestone (Ulrich and Smith, 1905, p. 24, 40; Swann, 1963, p. 27, 66), the lowest and thickest member, is named for Fredonia, Caldwell County, Kentucky (14-I-18). The Fredonia originally included the dominantly limestone section from the base of the Rosiclare Sandstone to the top of the underlying St. Louis Limestone, but it was restricted by Swann (1963) to the limestone between the base of the Spar Mountain Member and the St. Louis Limestone. The Fredonia is generally 80-100 feet thick, but from Effingham County north to Coles County it thins rapidly to 20 feet or less. The limestone is light gray, mainly oolitic, cross-bedded, and crinoidal, but it includes some darker lithographic limestone beds like those in the St. Louis below.

Spar Mountain Sandstone Member—The Spar Mountain Sandstone Member of the Ste. Genevieve Limestone (Tippie, 1945, p. 1657), which overlies the Fredonia Limestone Member, is named for Spar Mountain, Hardin County, where the type section, on the south-facing slope (NE 4, 12S-9E), consists of 8-15 feet of light gray to greenish gray, calcareous, glauconitic sandstone or siltstone grading to very sandy limestone. The Spar Mountain extends throughout most of the area of the Ste. Genevieve (fig. M-22). Lenses of similar sandstone and sandy calcarenite occur sporadically at other levels in the Ste. Genevieve, and the Spar Mountain is difficult to differentiate from them in some areas. It is erratic in thickness and has a varied lithology, including beds of dolomite, limestone, sandy limestone, sandstone, and thin shale. In the northern part of its extent, it is as much as 40 feet thick. In the western part of the basin—for example, in western Washington County—the Spar Mountain grades laterally into the Aux Vases Sandstone and is separated from it by vertical cut-off.

Karnak Limestone Member—The Karnak Limestone Member of the Ste. Genevieve Limestone (Swann, 1963, p. 28-29, 71) is named for Karnak, Pulaski County, about 4 miles southeast of the type section in Johnson County (SW SW 32, 13S-2E, and NW NW 5, 14S-2E), where the top 16 feet of an estimated 20-25 feet of limestone is exposed in cuts on Illinois Highway 37. The Karnak is a persistent unit and is generally traceable throughout the area of the Ste. Genevieve (fig. M-22), but in western Washington County it thins and grades laterally into the Aux Vases Sandstone. The Karnak is generally 10-35 feet thick. The limestone is relatively pure, oolitic, crinoidal, mostly light gray, and cross-bedded.

Electronic Filing: Received, Clerk's Office 07/01/2024

Joppa Member—The Joppa Member of the Ste. Genevieve Limestone (Swann, 1963, p. 29, 71), the uppermost member, is named for Joppa Junction, Johnson County, about half a mile west of the type section (SW SW 32, 13S-2E), where the member comprises 32 feet of shale and limestone overlying the Karnak Limestone Member. In southeastern Illinois the Joppa generally includes prominent limestones that allow it to be readily separated from the Aux Vases Sandstone. However, in most of the western and northern parts of the basin it is impractical to separate the Joppa from the Aux Vases, and there the Joppa is terminated by a vertical cut-off. The Joppa is 20-50 feet thick. Most of the limestone is sandy and oolitic, and part of it is red and hematitic. The sandstone is generally very fine grained and calcareous, resembling that of the Aux Vases. The shale is largely dark greenish gray, but red and green shales are common.

POPE MEGAGROUP

The Pope Megagroup (Swann and Willman, 1961, p. 481-482), named for Pope County in southern Illinois, comprises sandstone-shale units alternating with limestone-shale units of late Valmeyeran and Chesterian age that overlie the Mammoth Cave Limestone Megagroup and underlie the Pennsylvanian System and younger rocks (fig. 14). The lateral extent of the Pope Megagroup in Illinois is the same as that of the base of the Ste. Genevieve Limestone to the north (fig. M-22) and that of the Aux Vases Sandstone to the south (fig. M-23). The outcrop area runs along and near the Mississippi and Ohio Rivers from Alton, Madison County, south to Grand Tower, Jackson County, and then eastward through Hardin County. The Pope thickens from its truncated edge on the north to about 1300 feet near its southern border, only slightly thicker than the Chesterian Series (fig. M-26). The Pope Megagroup is roughly equivalent to the Chesterian Series, but it includes the Spar Mountain Member of the Ste. Genevieve (Valmeyeran) to the north and the Aux Vases (Valmeyeran) in most of its extent. Near its southeastern border the base of the Pope is locally a little higher than that of the Chesterian. The Pope is generally conformable on the Mammoth Cave Megagroup, except for minor erosional channels at the base of the Aux Vases Sandstone. It is separated from the overlying Pennsylvanian System by a major unconformity that has a relief of as much as 450 feet.

Aux Vases Sandstone

The Aux Vases Sandstone (Keyes, 1892, p. 295) is named for the Aux Vases River in Ste. Genevieve County, Missouri, and the type section consists of outcrops in the Mississippi River bluffs at the mouth of the Aux Vases River (N1/2 NW1/4 13, 37N-9E). The Aux Vases consists of sandstone, siltstone, and minor amounts of shale and, locally, dolomite and limestone. It occurs in much

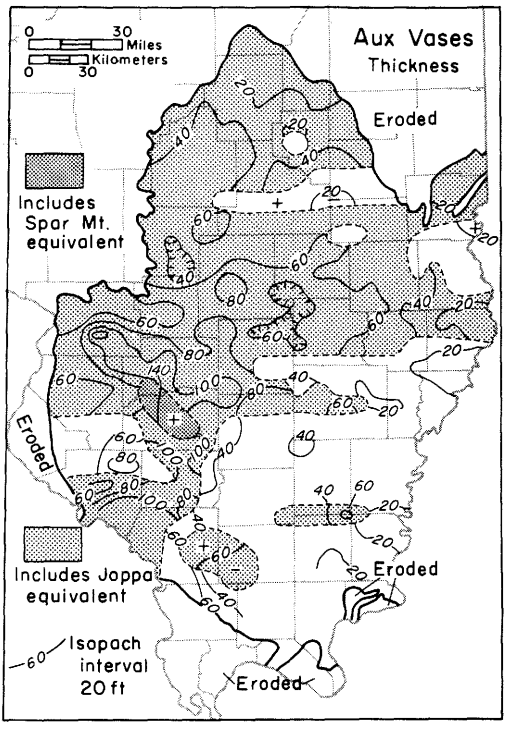

Fig. M-23—Thickness of the Aux Vases Sandstone.

of the area of the Chesterian Series (fig. M-23). It crops out along the Mississippi River Valley in St. Clair, Monroe, and Randolph Counties, being particularly well exposed in the bluffs 2-3 miles southeast of Prairie du Rocher, Randolph County. In southern Illinois it crops out principally in Union, Johnson, and Hardin Counties. The thickness map of the Aux Vases (fig. M-23) shows discontinuities because in some areas the base is dropped to include the equivalents of the underlying Joppa Member of the Ste. Genevieve Limestone where the Joppa grades to sandstone and shale. In a much smaller area, the base is dropped to include equivalents of the Spar Mountain Sandstone Member where the Karnak Member lenses out or grades to sandstone (Swann and Atherton, 1948; Swann, 1963). In the area where the Joppa Member is present, all of the Aux Vases is assigned to the Rosiclare Sandstone Member. In southeastern Illinois the Aux Vases is commonly 20-40 feet thick, but north and west of there, where it includes Joppa equivalents, it is 60-80 feet thick. It thickens to the west and reaches a maximum of 130-160 feet in the small area where it includes Joppa and Spar Mountain equivalents. The sandstone is light gray to greenish gray, locally pink or red, hematitic, calcareous, very fine to fine grained. In many places it grades to coarse siltstone. Lenses of brown dolomite occur in the lower part. The shale in the Aux Vases is dark gray and sandy, and the siltstone is green or gray. Where it includes Joppa equivalents, the Aux Vases commonly contains beds or lenses of gray, yellow, brown, pink, or red oolitic limestone.

Rosiclare Sandstone Member—The Rosiclare Sandstone Member of the Aux Vases Sandstone (Ulrich and Smith,

Electronic Filing: Received, Clerk's Office 07/01/2024

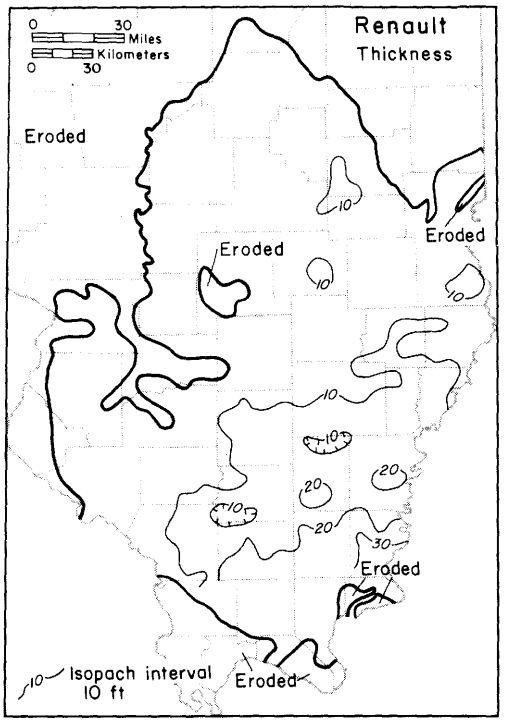

Fig. M-24—Thickness of the Renault Limestone.

1905, p. 24, 40; Swann, 1963, p. 80) is named for Rosiclare, Hardin County; its type section is in the Ohio River bluffs just below the town (NW SE and SW SE 5, 13S-8E). As originally defined, the Rosiclare Sandstone was a member of the Ste. Genevieve Limestone, and the name was widely misapplied to the sandstone now called the Spar Mountain Sandstone Member of the Ste. Genevieve. However, the type Rosiclare was found to be equivalent to the Aux Vases Sandstone (Swann and Atherton, 1948; Swann, 1963). The Rosiclare Sandstone has long been correctly correlated throughout the eastern part of the Illinois Basin, where it is an important oil producer. Consequently, the name "Rosiclare" is retained for a member of the Aux Vases. The Rosiclare is the main body of the Aux Vases in the area where it overlies the Joppa Member of the Ste. Genevieve and, therefore, does not include lateral equivalents of the Ste. Genevieve Limestone. It is commonly 20-40 feet thick.

Cedar Bluff Limestone Group

The Cedar Bluff Limestone Group (Swann, 1963, p. 63) is named for the quarry of the Cedar Bluff Limestone Company, formerly the Ohara quarry, southeast of Princeton, Caldwell County, Kentucky (S1/2 21-H-20). It consists of the Downeys Bluff, Yankeetown, and Renault Formations in areas where these formations are dominantly limestone (fig. M-25). It occurs in southeastern Illinois and is exposed in Hardin County. It was originally called the Ohara Limestone, but the name Ohara is widely used for the Karnak Member of the Ste. Genevieve in the subsurface. The Valmeyeran-Chesterian contact falls within the Cedar Bluff Group at the top of the Levias Limestone Member of the Renault Formation.

Renault Limestone

The Renault Limestone (S. Weller, 1913, p. 120, 122; Swann, 1963, p. 79), the lower part of which is Valmeyeran in age and the upper part Chesterian, is named for Renault Township, Monroe County, and the type section consists of exposures in the valley of Horse Creek. A typical exposure 4 miles northeast of the village of Renault on the south side of Dry Fork (SE SW 23, 4S-9W) is accepted as the type section (Swann, 1963). The interbedded sandstone and shale unit overlying the limestone portion in the type area was originally regarded as the upper part of the Renault but now is assigned to the Yankeetown. The Renault is a widespread, relatively thin formation, averaging only about 8 feet thick (fig. M-24), but it ordinarily stands out as a high-resistive unit on electric logs. The Renault thickens to more than 40 feet in part of Johnson County. It consists of a lower relatively pure limestone, the Levias Member (Valmeyeran), and an upper sandy limestone, the Shetlerville Limestone Member (Chesterian), which in turn includes a persistent sandstone bed (Popcorn Sandstone Bed) at its base. In some earlier reports the Levias Member was miscorrelated with strata below the Aux Vases Sandstone and it was therefore classified as a member of the Ste. Genevieve Formation.

Levias Limestone Member—The Levias Limestone Member of the Renault Formation (Sutton and J. M. Weller, 1932, p. 430, 439) is named for Levias, Crittenden County, Kentucky, and the type locality is just east of the town (10-J-16). It was originally the uppermost member of the Ste. Genevieve Limestone and was introduced as a replacement of the earlier name "Lower Ohara," but it was assigned to the Renault Limestone when it was found to overlie the Aux Vases Sandstone. The Levias is well developed in and near Hardin County, but north and west of there it is not easily distinguished and it is recognized only sporadically north of Lawrence County and west of Franklin County. In Hardin County the Levias commonly is 10-25 feet thick, but it has a maximum thickness of 35 feet. The limestone is relatively pure, cross-bedded, medium- to coarse-grained, white oolite containing some pink and light green ooliths. It contains some fine-grained limestone, and a few feet at the base is sandy. The Levias Limestone contains *Platycrinites penicillus* and is the top of the Valmeyeran Series.

Shetlerville Limestone Member—The Shetlerville Limestone Member of the Renault Formation (S. Weller, *in* S. Weller et al., 1920, p. 123; Swann, 1963, p. 82) is named for Shetlerville, Hardin County. Weller designated it a formation, citing exposures of about 30 feet of limestone just east of Shetlerville as the type section. Swann (1963) put the upper shaly part in the Yankeetown, restricted the Shetlerville to 15 feet of limestone exposed in a quarry one-fourth of a mile south of Shetlerville (SE NE SW 35, 12S-7E), and classified it as a member of the Renault. Most of the limestone is dark greenish or brownish gray, sandy, and oolitic. The basal portion grades to sandstone and is named the Popcorn Sandstone Bed. Some beds are light colored and resemble the underlying Levias Member. The basal contact is sharp and may be unconformable. The Shetlerville contains the crinoid *Talarocrinus* (fig. M-4) and is the basal part of the Chesterian Series.

Popcorn Sandstone Bed—The Popcorn Sandstone Bed in the base of the Shetlerville Member of the Renault Limestone (Swann, 1963, p. 32) is named for Popcorn Spring, 700 feet

Electronic Filing: Received, Clerk's Office 07/01/2024

north of Popcorn Church in Lawrence County, Indiana (SE SE SW 5, 6N-2W), where it forms the base of the Paoli Formation. It is a bed of sandstone, shale, or impure limestone a few inches or a few feet thick. It occurs in Hardin County, but it is not widely recognized in Illinois.

CHESTERIAN SERIES

The Chesterian Series (Worthen, 1860, p. 312-313; Swann, 1963, p. 20), the uppermost series of the Mississippian System, is named for Chester, Randolph County, where it is well exposed in the bluffs of the Mississippi River. It was originally called the Kaskaskia Limestone (Hall, 1857) and the *Archimedes* Limestone (Swallow, 1858) before it was named the Chester Limestone. Later it was made the Chester Group, and since 1948 has been the Chesterian Series (J. M. Weller et al., 1948). The Aux Vases Sandstone, long considered to be the base of the Chesterian, is excluded from the series because it is in the *Platycrinites penicillus* Zone near the top of the Valmeyeran Series (Swann, 1963).

The Chesterian Series consists of limestone-shale formations alternating with sandstone-shale formations (fig. M-25). It extends from the major unconformity at the base of the Pennsylvanian System (sub-Absaroka unconformity) down to the base of the Shetlerville Member of the Renault Formation, which is the top of the Valmeyeran Series.

The Chesterian Series occupies much of the southern half of Illinois (fig. M-26). It is a little more than 1400 feet thick in Johnson County in the southern part of the Illinois Basin and thins outward to its truncated edge. The thickness pattern reflects sub-Pennsylvanian valleys that generally run from northeast to southwest and cut into the Chesterian rocks. Chesterian strata crop out in western and southern Illinois from near Valmeyer south to Grand Tower and then eastward through Hardin County to the Ohio River.

The Chesterian Series is subdivided into three stages, the Gasperian (below), Hombergian, and Elviran (Swann, 1963). These units were derived from the New Design, Homberg, and Elvira Groups, which had been used like provincial time-stratigraphic units (figs. M-27 and M-28). The series includes five groups, 20 formations, and 14 members, and it forms the major part of the Pope Megagroup (fig. 14).

Many of the Chesterian limestones and shales are abundantly fossiliferous. The sandstones are much less fossiliferous, but contain some plant fossils. Coals, a few inches thick at most, occur in some of the Chesterian sandstones. Many of the limestones contain abundant crinoidal fragments, and the series is characterized by the presence of *Talarocrinus*, which distinguishes it from the underlying Valmeyeran containing *Platycrinites penicillus*. Blastoids and the corkscrew bryozoan, *Archimedes*, are common and characteristic (fig. M-4). Several conodont assemblage zones, shown in figure M-25, are useful in differentiating Chesterian rocks (Collinson et al., 1971).

Many of the Chesterian formations have distinctive characters on electric logs (fig. M-29), but the sandstone bodies, although widely traceable, have great lenticularity (fig. M-30).

The clastic sediments in the Chesterian Series were transported by the ancient Michigan River from the northeast and were deposited in deltaic bodies in the marine embayment in the Illinois Basin (Potter, 1962a; Swann, 1963, 1964). The alternation of limestone and sandstone formations resulted from lateral shifts in the mouth of the river and in the position of the shoreline (fig. M-31) during the progressive sinking of the basin (fig. M-32).

On the thickness maps of the Chesterian Series, the eroded margins of the formations from Alton, Madison County, south and east to the Ohio River in Hardin County are largely at the present surface, but the margins trending northeast across the state from the Mississippi Valley are beneath Pennsylvanian strata.

Gasperian Stage

The Gasperian Stage (Swann, 1963, p. 21-22, 67), the oldest stage of the Chesterian Series, is derived from the Gasper Limestone of Kentucky (Butts, 1917), which is named for the Gasper River, northwest of Bowling Green, Kentucky. It includes rocks from the base of the Shetlerville Member of the Renault Limestone to the top of the Beech Creek Limestone (fig. M-25). The upper part of the Cedar Bluff Group is included in the Gasperian, but the lower part is Valmeyeran and the group was described under Valmeyeran. Sandstone predominates in the Gasperian Stage. In the Anna district of southwestern Illinois, sandstone of the Cypress alone constitutes about half of the Gasperian Stage. In the fluorspar district, where the Gasperian Stage is about 300 feet thick, about 200 feet is sandstone. Marine fossils occur in limestones

and shales of the Paint Creek Group and the Renault Limestone. The bryozoan *Cystodictya labiosa* Zone and the crinoid *Talarocrinus* Range Zone are the most definitive faunal zones of the Gasperian Stage, although the *Talarocrinus* Zone does not include the Beech Creek Limestone.

Yankeetown Sandstone

The Yankeetown Sandstone (S. Weller, 1913, p. 120) is named for Yankeetown School, Monroe County, near which the type section (NE cor. SE 26, 4S-9W) consists of cherty sandstone grading to chert. The Yankeetown is a sandstone-shale unit in western Illinois that grades into a limestone-shale unit in eastern Illinois. Although only about 20 feet thick in the outcrop area, it can be traced northeastward into the upper part of a thick sandstone in Washington County, where it is separated by a thin limestone (Renault) from the Aux Vases Sandstone below. As thus differentiated, the Yankeetown Sandstone includes sandstone and shale formerly regarded as being in the upper part of the Renault. The Yankeetown is about 60 feet thick in much of the central part of its extent (fig. M-33). To the north it thins to less than 20 feet, and to the south and southwest it thickens in places to a little over 100 feet. Red shale is extensively developed near the top of the Yankeetown, but other shales present are dark greenish gray, green, and variegated. The sandstone is much like that in the Bethel, mainly white or light gray to light greenish gray, very fine, angular, and incoherent. Chert occurs only in, and close to, the western outcrop belt. Southeastward the sandstone facies changes to a limestone-shale facies, the change occurring near the northwestern corner of Hamilton County (Swann and Atherton, 1948). At about the same place, the Bethel Sandstone, which is predominantly shale to the northwest, becomes predominantly sandstone to the southeast, which misled many into thinking that the Bethel and Yankeetown were equivalent (fig. M-7). The sandstone of the Yankeetown was commonly called "Benoist," and the names "Benoist" and "Bethel" were mistakenly regarded as being interchangeable. In the limestone-shale facies, most of the shales are dark greenish gray and green, with some red in the upper part. The limestones are light gray, buff, brown, or gray. Some are oolitic, some crinoidal, some silty, and some lithographic.

Paint Creek Group

The Paint Creek Group (S. Weller, 1913, p. 120; Swann, 1963, p. 76) is named for Paint Creek, a stream in Randolph County,

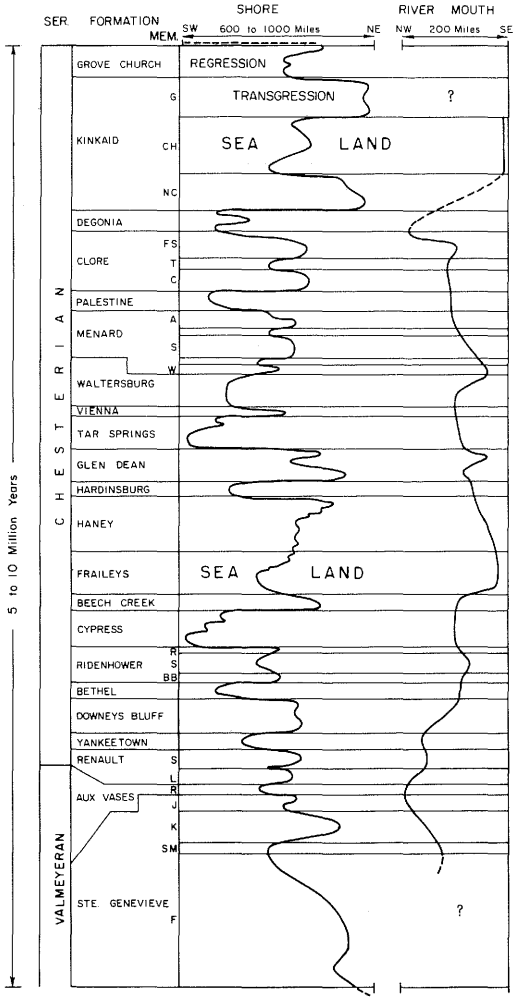

Fig. M-32—Changes in position of the shoreline and the position of the Michigan River during late Valmeyeran and Chesterian times (after Swann, 1963).

Electronic Filing: Received, Clerk's Office 07/01/2024

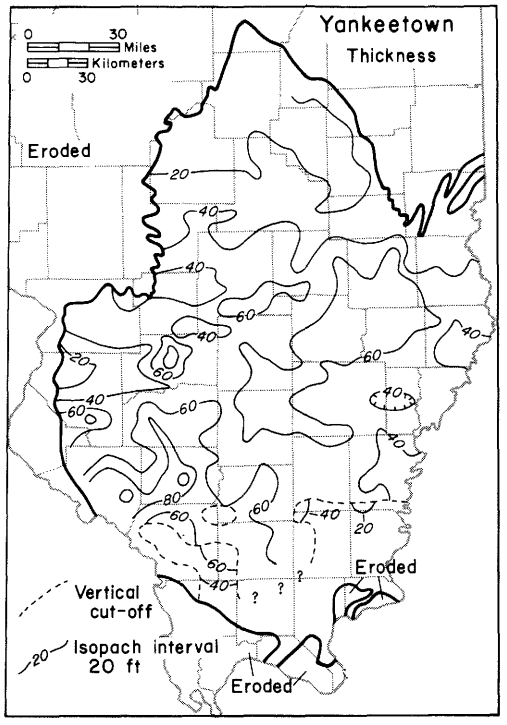

Fig. M-33—Thickness of the Yankeetown Sandstone.

and the type section is along a tributary west of McCuen School (E1/2 2, 5S-9W). It is recognized only in western Illinois, where it is dominantly shale and limestone and consists of the Downeys Bluff, Bethel, and Ridenhower Formations (fig. M-25). Although the Bethel is normally a sandstone, it is shale in that area and includes a bed of bright red shale. The name was formerly used in southeastern Illinois for the strata now included in the Ridenhower Formation.

Downeys Bluff Limestone

The Downeys Bluff Limestone (Atherton, 1947, p. 129) is named for Downeys Bluff, Hardin County, and the type section is in a bluff along the Ohio River (NW SE 5, 13S-8E). It was originally regarded as a member of the Paint Creek Formation in southwestern Illinois and of the Renault Formation in southeastern Illinois, but it was later traced across the Illinois Basin (Dana and Scobey, 1941). It is now a formation at the base of the Paint Creek Group in southwestern Illinois and at the top of the Cedar Bluff Group in southeastern Illinois (fig. M-25). The Downeys Bluff generally is 20-30 feet thick in Gallatin, Saline, and parts of Jackson and adjacent counties (fig. M-34), where it consists of two limestone benches separated by a thin shale. Elsewhere the Downeys Bluff consists of only the upper of the two benches, generally 5-10 feet thick but locally 10-20 feet thick. Where two benches of the Downeys Bluff are present, the upper is typically cherty and the lower is slightly silty or very finely sandy. Limestone of the Downeys Bluff is white or light brownish gray and crinoidal. Many crinoid segments are replaced by pink chert. The pink crinoids are an excellent diagnostic characteristic that is better developed in the western than in the eastern part of Illinois.

West Baden Group

The West Baden Group (Cumings, 1922, p. 514; Gray et al., 1960, p. 44) is named for West Baden, Orange County, Indiana, and consists of the Bethel, Ridenhower, and Cypress Formations. It occurs in southeastern Illinois and is most useful in an area where the Ridenhower is dominantly sandstone and separation of the formations is difficult—in places impractical (Swann, 1963).

Bethel Sandstone

The Bethel Sandstone (Butts, 1917, p. 63-64) is named for Bethel School, 3.5 miles west of Marion, Crittenden County, Kentucky. It is dominantly sandstone in much of Illinois, but it grades to shale to the west. The Bethel is 20-40 feet thick in much of its northwestern area (fig. M-35), but locally it is thinned by pre-Cypress erosion. The formation thickens to the southeast, reaching just over 100 feet in eastern Gallatin County. The sandstone of the Bethel is, in general, the coarsest grained of the Chesterian sandstones. Locally, it includes a few small quartz pebbles and a basal conglomerate of limestone and shale pebbles. Most of the sandstone is light gray to light

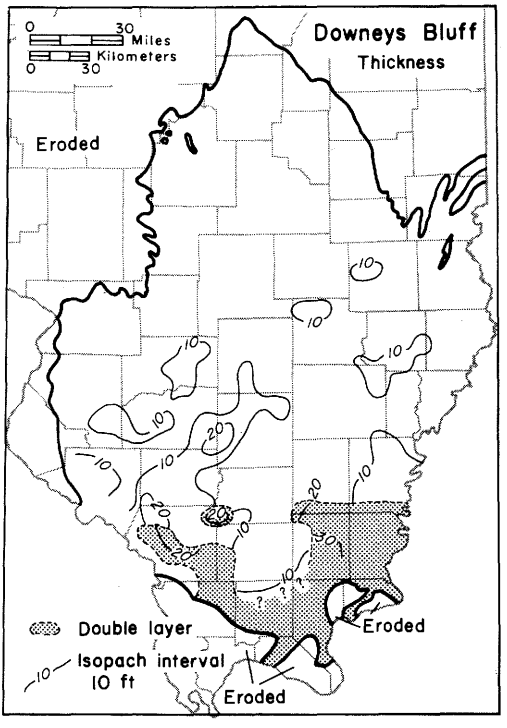

Fig. M-34—Thickness of the Downeys Bluff Limestone.

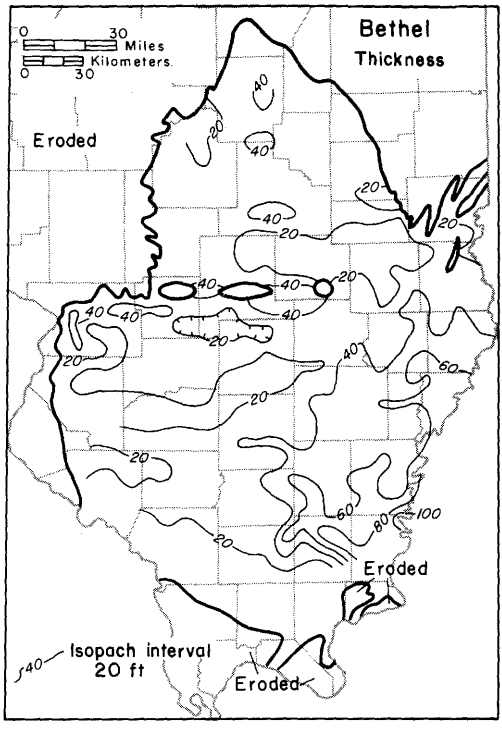

Fig. M-35—Thickness of the Bethel Sandstone.

greenish gray, but a few thin lenses are green or medium gray. Dark greenish gray shale partings are common, and some contain carbon and mica flakes. As the sandstone grades westward to shale, red and green shales become more noticeable. Along the outcrop belt in southwestern Illinois, a persistent bed of deep red, structureless clay about 15 feet thick is prominent. In places, numerous fragmentary plant fossils, including *Lepidodendron*, are present.

Ridenhower Formation

The Ridenhower Formation (Butts, 1917, p. 73) is named for Ridenhower School, Johnson County, and the type section is at Indian Point, 5 miles south of Vienna (SE SW 32, 13S-3E), where the formation is 60 feet thick and consists of shale with beds of fossiliferous limestone. The formation is a markedly varied unit that is mainly shale but contains beds of limestone and sandstone. It occurs between two clastic formations, dominantly sandstone. Locally, in parts of central and eastern Illinois, the formation is subdivided into the Beaver Bend Limestone Member (below), the Sample Sandstone Member, and the Reelsville Limestone Member, but in most of Illinois these units cannot be differentiated. They are well developed in Indiana and Kentucky, where they were named. The average thickness of the Ridenhower Formation in southern Illinois is about 33 feet, but at several places it is more than 80 feet thick (fig. M-36). The contact of the Ridenhower with the overlying Cypress Sandstone is generally sharp. In some places the Ridenhower is absent and the Cypress rests on the Bethel Sandstone. The shale of the Ridenhower is mainly dark greenish gray, but red, green, and brown shales are common. Much of the shale is calcareous and fossiliferous. The limestone includes sandy, oolitic, crinoidal, and lithographic beds, most of which are light to dark gray and brown, but buff, green, pink, and yellow beds are present. Some distinctive beds can be traced for several tens of miles. The proportion of limestone in the formation increases westward, so that near its western limit the formation is almost all limestone. In contrast, the proportion of sandstone is greatest in southeastern Illinois from Hardin County north-northeast along the Wabash River. The fauna of the Ridenhower resembles that of the Renault. The bryozoans *Cystodictya* and *Archimedes* and the blastoid *Pentremites* are common.

Beaver Bend Limestone Member—The Beaver Bend Limestone Member of the Ridenhower Formation (Malott, 1919, p. 9-10), the lowermost member, is named for a prominent bend in Beaver Creek, Lawrence County, Indiana, and the type section is a railroad cut half a mile east of Huron. The Beaver Bend is classified as a formation in Indiana. It consists of limestone and shale, and in southeastern Illinois it can be differentiated from the Reelsville Member only locally, where the intervening Sample Sandstone is present.

Sample Sandstone Member—The Sample Sandstone Member of the Ridenhower Formation (Butts, 1917, p. 70-73), the middle member, is named for the town of Sample, Breckenridge County, Kentucky, and the type section is in a railroad cut on the north bank of Sinking Creek, 1 mile east of Sample. The Sample Sandstone Member is dominantly sandstone and shale. It occurs locally in southeastern Illinois.

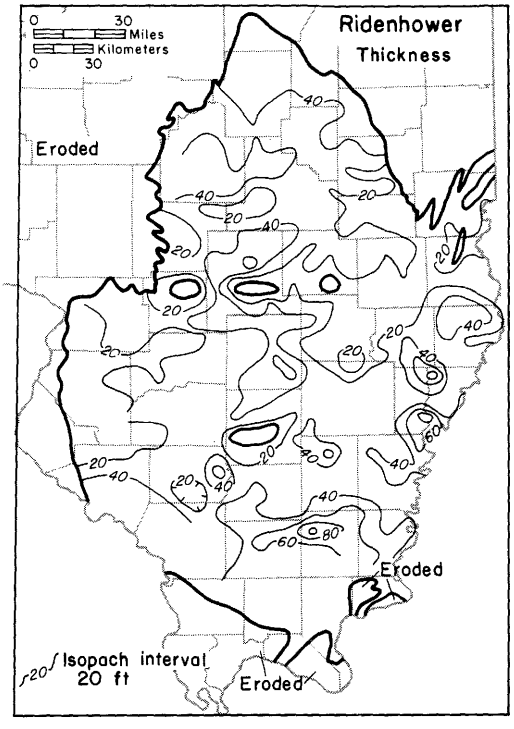

Fig. M-36—Thickness of the Ridenhower Formation.

Electronic Filing: Received, Clerk's Office 07/01/2024

Reelsville Limestone Member—The Reelsville Limestone Member of the Ridenhower Formation (Malott, 1919, p. 10-11), the uppermost member, is named for Reelsville, Putnam County, Indiana, and the type section is on the Eel River, just south of Reelsville, where the member is 2.5 feet thick. It is classified as a formation in Indiana. It is dominantly limestone but contains beds of shale. It is not differentiated in the type section of the Ridenhower Formation, and it has limited distribution in southeastern Illinois, mostly in subsurface. The *Agassizocrinus* cf. *leavis* Peak Zone is equivalent to the Reelsville Member.

Cypress Sandstone

The Cypress Sandstone (Engelmann, 1863, p. 189-190) is named for Cypress Creek, Union County, and the type section is in bluffs along the creek about 6 miles southeast of Anna (T12 and 13S-1E). The name Ruma, now abandoned, was given to equivalent strata in Randolph County (S. Weller, 1913). The Cypress and the Tar Springs Sandstone are the thickest and most persistent sandstone formations of the Chesterian Series. In the central part of southern Illinois, the Cypress is generally well over 100 feet thick, and it reaches 200 feet thick (fig. M-37). It thins outward from that area, and it is only 20-30 feet thick near the outcrops in southern Randolph County. It varies from thick bodies of sandstone to shale and sandy shale interbedded with some thin beds of sandstone. The massive sandstone in the Cypress is white to light gray, fine to medium grained, angular, and generally friable. It makes up about half of the formation and typically is in a single body at the base of the formation. Some wells encounter two sandstone bodies, usually in the lower part of the formation, and others, mostly in the north and southwest but sporadically elsewhere, encounter only shale. Typically the upper part of the Cypress is more shaly than the lower, and commonly 5-30 feet of shale or sandy shale occurs at the top. Locally a few thin beds of sandstone lie immediately below the overlying Beech Creek Limestone. Sandstone beds near the top are generally cemented with calcite or dolomite. The shale in the Cypress is largely dark greenish gray, but some of the top beds are green, and a moderately persistent bed of red shale occurs about 10 feet below the top of the formation. In Randolph County in western Illinois, where the Cypress is almost entirely shale, the formation includes a considerable proportion of red and green shale. Beds of gray or green siltstone are present in the upper part of the Cypress, and a thin, dark green, quartzitic siltstone occurs near the top. Coal beds a few inches thick are sporadically present near the top of the Cypress, especially near its southern limit. The base of the Cypress and, to a lesser extent, surfaces in the middle part of the formation tend to parallel underlying structure more closely than they do the overlying Beech Creek Limestone, which suggests slight warping during Cypress time. Plant fossils, including *Lepidodendron* trunks, are present in the Cypress.

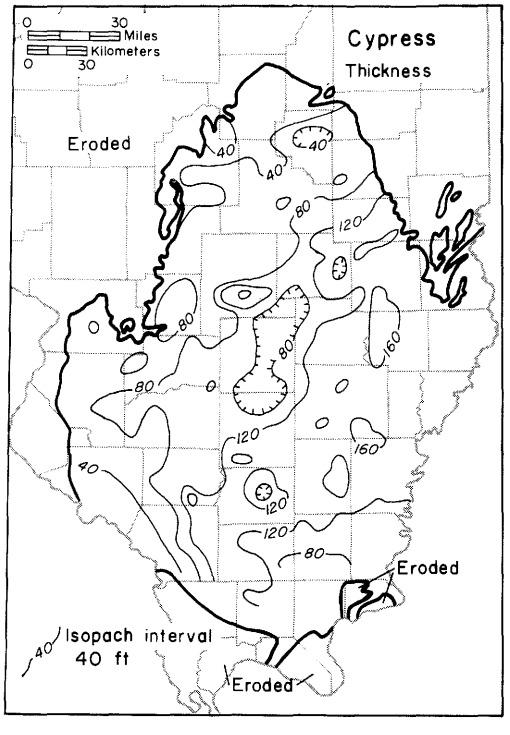

Fig. M-37—Thickness of the Cypress Sandstone.

Golconda Group

The Golconda Group (Brokaw, 1916, pl. 3; Ulrich, *in* Butts, 1917, p. 91-95; Swann, 1963, p. 68) is named for Golconda, Pope County, and the type section is in the bluffs of the Ohio River above Golconda (secs. 5, 8, 18, 13S-7E). It is a limestone-shale unit, but it has a sandstone member locally present in its lower part in the northeastern part of its area. It consists of the Beech Creek Limestone at the base, the Fraileys Shale, and the Haney Limestone (fig. M-25). The Golconda Group ranges from about 60 feet thick near its northern limit to over 180 feet near its southern limit.

Okaw Group

The Okaw Group (S. Weller, 1913, p. 120; S. Weller and J. M. Weller, 1939, p. 12; Swann, 1963, p. 76) is named for the Okaw River, now the Kaskaskia River, and the type section consists of exposures along the river in Randolph County (T4, 5, and 6S, R7 and 8W). The name is used only in western Illinois for formations from the Beech Creek through the Glen Dean (fig. M-25) in an area where the clastic units of the Hardinsburg are poorly developed and it is difficult to assign many small limestone outcrops to the proper formation.

Beech Creek Limestone

The Beech Creek Limestone (Malott, 1919, p. 11-15) is named for Beech Creek, Greene County, Indiana, and

Electronic Filing: Received, Clerk's Office 07/01/2024

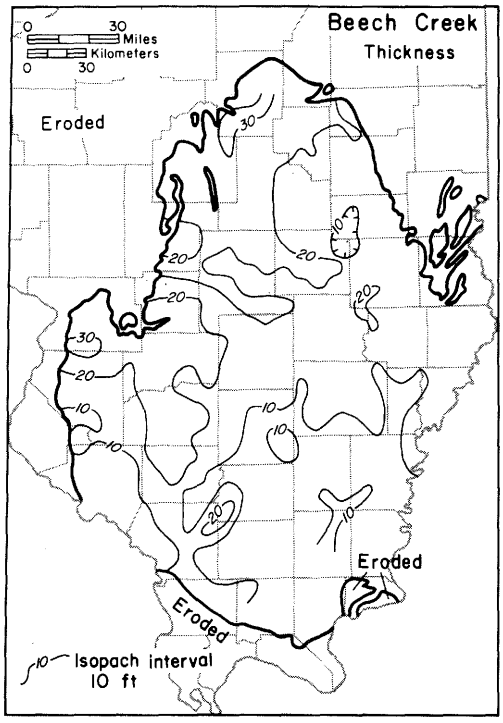

Fig. M-38—Thickness of the Beech Creek Limestone.

the type section is at the mouth of Ray's Cave, one-fourth of a mile south of Beech Creek. It is a relatively thin limestone unit, commonly called the "Barlow lime." It is very persistent and is widely used as a horizon for structure contour maps of the Illinois Basin (Bristol, 1968). The Beech Creek is unusual in that it thickens from south to north, counter to the trend of other Chesterian formations (fig. M-38). It is as much as 35-40 feet thick in the north but in areas in Hardin County it is thin, shaly, and difficult to identify. In some places the changes in thickness are abrupt and probably result from fusion of the formation with limestone beds that elsewhere are in the lower part of the Fraileys Shale. The lower part of the Beech Creek is argillaceous, dark brownish gray, dense to lithographic limestone, usually with scattered, black, rounded grains and a few fossils. The upper part is light brownish gray, fine to coarse grained, fossiliferous, and similar to much of the limestone higher in the Golconda Group. Some thin beds of oolitic limestone are present. The Beech Creek becomes somewhat sandy eastward, and in the vicnity of Saline and southern Hamilton Counties it seems to be represented locally by a bed of calcareous sandstone. *Euphemia randolphensis*, a pelecypod, and *Martinia contracta*, a brachiopod, are characteristic of some beds in the Beech Creek.

Hombergian Stage

The Hombergian Stage (Swann, 1963, p. 22, 70), the middle stage of the Chesterian Series, derived from the Homberg Group (J. M. Weller, 1939), is named for Homberg, Pope County. The Hombergian Stage includes strata from the top of the Beech Creek up to the top of the Glen Dean (fig. M-25). The limestones in this stage are typically light brownish gray, light gray, or buff to gray and many of them and their associated shales are abundantly fossiliferous. Red shales in the upper part of the Fraileys and the lower part of the Hardinsburg are extensive marker beds. The bryozoan *Prismopora serrulata* and the crinoid *Pterotocrinus* (fig. M-4) are typical Hombergian fossils.

Fraileys Shale

The Fraileys Shale (McFarlan et al., 1955, p. 18) is named for Fraileys Landing (abandoned), Hardin County, about a mile northeast of the type section in a bluff along Haney Creek (NE NE SE 9, 12S-10E), where the formation is 94 feet thick. It is dominantly shale, with minor amounts of limestone and, locally, sandstone. The Fraileys Shale is 80-100 feet thick in most of Williamson County, and it thins irregularly northward to 30-40 feet in the northern and northeastern areas (fig. M-39). Great variations in thickness within short distances have a reciprocal relation with units above and below. The Fraileys is dominantly dark gray shale. A bed of red shale a few feet below the top and a bed of siltstone just below the shale are persistent in the southern area. Limestone beds occur sporadically at numerous levels. A bed about 15 feet below the top is fairly persistent, but the others, mostly lenticular accumulations of fossil debris, thin rapidly and disappear within a short distance. Some of these beds

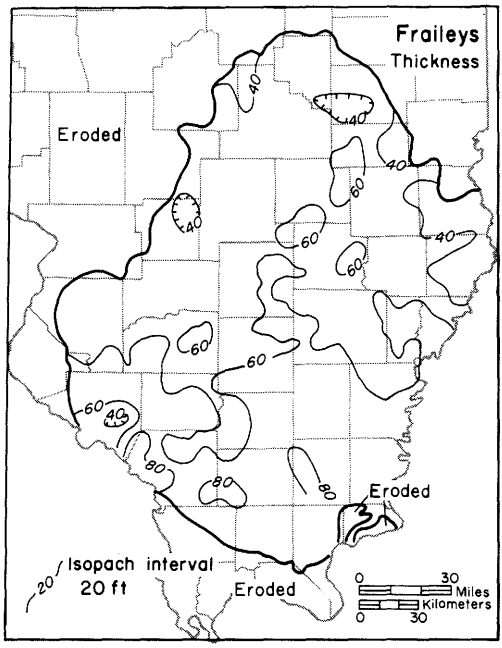

Fig. M-39—Thickness of the Fraileys Shale.

contain abundant fragments of bright red, orange, and green fossils, mainly bryozoans but also a few oolites and other detrital grains. In the north, limestone is fairly abundant locally in the Fraileys, particularly in the lower part, and in places it is difficult to distinguish limestone at the base of the Fraileys from the underlying Beech Creek Limestone. Sandstone in the Fraileys, where present in significant amount, is assigned to the Big Clifty Sandstone Member. The corkscrew-like axes of the bryozoan *Archimedes* reach a peak in number of species and abundance of specimens in the Fraileys and Haney Formations. A brachiopod faunal zone, the *"Camarophoria"—Stenoscisma explanata* Range Zone, extends from the Fraileys upward to the top of the Chesterian strata. The *Pterotocrinus capitalis* Range Zone is equivalent to the lower half of the Fraileys Shale.

Big Clifty Sandstone Member—The Big Clifty Sandstone Member of the Fraileys Shale (Norwood, 1876, p. 405) is named for Big Clifty Creek, Grayson County, Kentucky, and the type section is along the creek, 2 miles southwest of the village of Big Clifty. The Big Clifty enters Illinois from the east and wedges out within a few tens of miles. Many wells in Lawrence, northern and eastern Jasper, and southern Cumberland Counties encounter 15-20 feet of Big Clifty. It is near the middle of the Fraileys or, less commonly, near the base. A few sporadic occurrences have been found in Marion County and east of there. In Indiana the Big Clifty occupies nearly the whole of the interval represented by the Fraileys Shale in Illinois.

Haney Limestone

The Haney Limestone (McFarlan et al., 1955, p. 18) is named for Haney Creek, Hardin County. It is 35.5 feet thick in the type section, which overlies the type section of the Fraileys Shale (NE NE SE 9, 12S-10E). It is dominantly limestone, with a little interbedded shale. The formation thickens from north to south (fig. M-40). It is

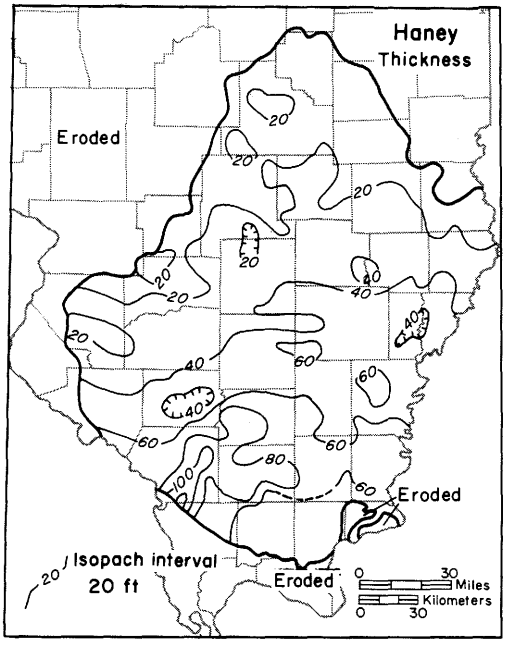

Fig. M-40—Thickness of the Haney Limestone.

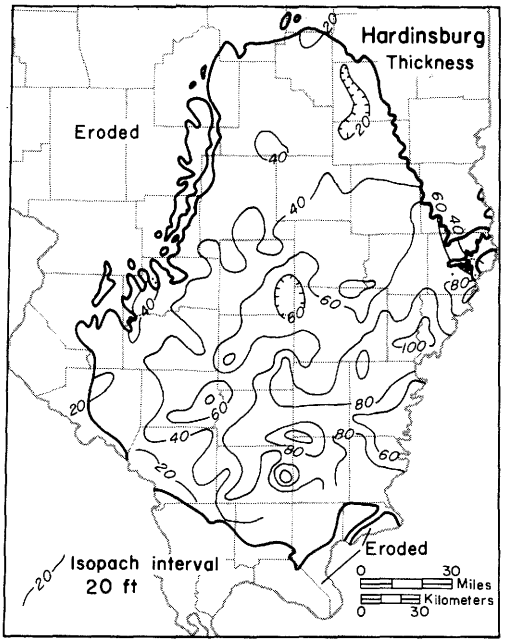

Fig. M-41—Thickness of the Hardinsburg Sandstone.

80-100 feet thick in much of Williamson County and even thicker in southern Jackson County, but it generally thins to less than 15 feet thick in Moultrie, Coles, and Cumberland Counties. In Washington County, the lower part of the Haney grades northwestward to shale, and the base of the Haney shifts to a higher horizon—the formation thinning from 60 feet or more to 35-40 feet. The limestone of the Haney is typically light gray to brownish gray or dark gray, coarse grained, and fossiliferous. Much of it is oolitic. In Randolph County a zone of white oolite about 20 feet thick in the Haney is informally called the "Marigold Oolite" (Sutton, 1934) for the village of Marigold, near which it is well exposed (SE 20, 5S-8W). In many places the oolitic beds alternate with non-oolitic beds or with shale. A little chert is commonly present in the Haney, and much of the limestone is shaly. The shale is dark gray and generally calcareous and fossiliferous. The individual limestone beds generally are markedly lenticular and are much less persistent laterally than are beds in the younger Chesterian limestones. In the southern part of the area, the Haney is characterized by an upper limestone unit about 25 feet thick, a middle shale up to 10 feet thick, and a lower limestone about 50 feet thick, the upper part of which is more shaly than the lower. To the northwest the Haney grades to a shale that cannot be readily distinguished from the overlying shale of the Hardinsburg or the underlying Fraileys.

Hardinsburg Sandstone

The Hardinsburg Sandstone (Brokaw, 1916, pl. 3; Butts, 1917, p. 23) is named for Hardinsburg, Breckenridge County, Kentucky, and it is 30 feet thick in the type section, which is near the town. It is a clastic unit commonly 50-100 feet thick but thinner to the north and west (fig. M-41). In Lawrence County, the Hardinsburg

Electronic Filing: Received, Clerk's Office 07/01/2024

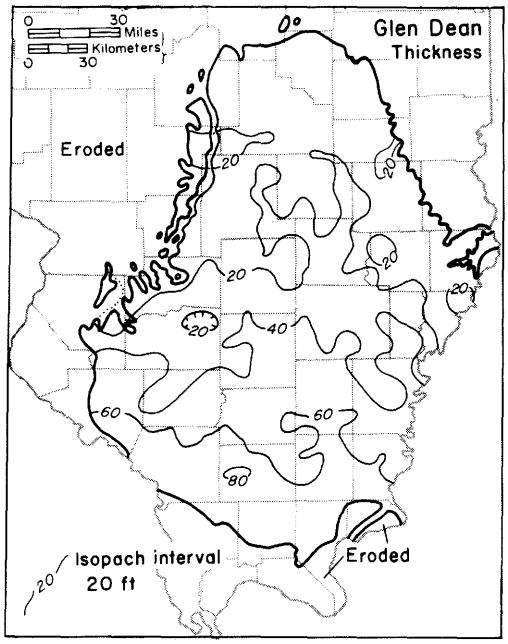

Fig. M-42—Thickness of the Glen Dean Limestone.

locally cuts entirely through the underlying Golconda Group and into the uppermost part of the Cypress Sandstone to attain a thickness of more than 240 feet. The formation has a thick-bedded sandstone facies and a thin-bedded, flaggy, shaly sandstone and shale facies, both exposed in the southern outcrop belt. Well developed sandstone bodies lens in and out of the section within fairly short distances at various horizons and locally make up almost the entire formation. The sandstone in the Hardinsburg is largely light gray, very fine grained, friable, and in part calcareous. The thick sandstone bodies are white and fine grained, whereas the thin bodies are generally gray or green and compact, some of them grading to siltstone. The sandstone bodies show a complex deltaic pattern with braids, tributaries, and distributaries (Potter, 1963). Much of the system is to the east in Indiana and Kentucky, but bifurcating arms extend into Illinois. Thin beds of coal occur locally in the upper part of the sandstone. The shale in the Hardinsburg is mainly dark gray or dark greenish gray. At the base of the Hardinsburg, red, green, and dark gray shale as much as 30 feet thick contains beds and nodules of lithographic, red and brown limestone and dolomite. In most places an erosional surface separates the shale from the upper part of the Hardinsburg, and in some places the surface cuts entirely through the shale, so that sandstone rests directly on the underlying Golconda Group.

Glen Dean Limestone

The Glen Dean Limestone (Butts, 1917, p. 97-102) is named for the town of Glen Dean, Breckenridge County, Kentucky, and the type section is in exposures along a railroad (abandoned) on both sides of the town. The Glen Dean is a limestone-shale unit that thickens from 5-15 feet in the north to 65-80 feet in the south (fig. M-42). In subsurface the top and base of the Glen Dean are put at the limits of well defined limestone strata. In the south, the Glen Dean typically has a threefold division into upper and lower limestone units separated by shale. In a few places a shale lens occurs in the lower limestone. Farther north only the lower limestone unit is generally present, and the formation is correspondingly thinner. In general, where the Glen Dean is relatively thick it contains a higher proportion of shale. The Glen Dean has fairly rapid lateral variations in thickness and in limestone-shale ratio, particularly in the upper two units, and boundaries between the subdivisions are not consistent throughout large areas. The Glen Dean is composed of limestone and various amounts of dolomite and shale. The limestone is light to medium brownish gray, coarse grained, and fossiliferous. Parts of it are oolitic and some beds are cherty. Well developed oolitic limestone is rare in younger Chesterian limestones. The shales are dark greenish gray and are generally fossiliferous. The bryozoan *Prismopora serrulata* is abundant and the blastoid *Pentremites spicatus* is also characteristic of the Glen Dean. The *Pterotocrinus acutus—P. bifurcatus* Assemblage Zone is equivalent to the Glen Dean.

Elviran Stage

The Elviran Stage (Swann, 1963, p. 23, 65), the youngest stage of the Chesterian Series, originally called the Elvira Group (J. M. Weller, 1939), is named for Elvira Township, Johnson County (12S-2E). It includes the nine formations younger than the Glen Dean Limestone (fig. M-25). The limestones of the Elviran Stage are generally darker and finer grained and contain more silt and argillaceous material and less abundant fossils than the older Chesterian limestones. Representative fossils include *Pentremites fohsi, Pterotocrinus menardensis, Composita subquadrata, Eumetria costata,* and *Sulcatopinna missouriensis.*

Tar Springs Sandstone

The Tar Springs Sandstone (Owen, 1856, p. 174; Butts, 1917, p. 103-105) is named for Tar Springs, Breckenridge County, Kentucky, and the type section is an exposure in a cliff at the town, where the sandstone is about 50 feet thick. It is one of the thickest and most persistent sandstone formations of the Chesterian Series. The Tar Springs is 75-130 feet thick for most of its extent in Illinois, thinning to about 50 feet near its northwestern limits (fig. M-43). It is locally more than 150 feet thick, and in the thicker portions the ratio of sandstone to shale is relatively high. Locally the formation is almost entirely sandstone or almost entirely shale (fig. M-1A). The sandstone is white to light gray, very fine grained to fine grained, locally medium grained, angular, and friable to well cemented. Conglomerate with coarse sand grains and limestone pebbles occurs at the base but is rare. In general, one to three well developed sandstone bodies make up a little more than half the formation. Commonly, a sandstone body occurs at the base of the formation, but sand-

Electronic Filing: Received, Clerk's Office 07/01/2024

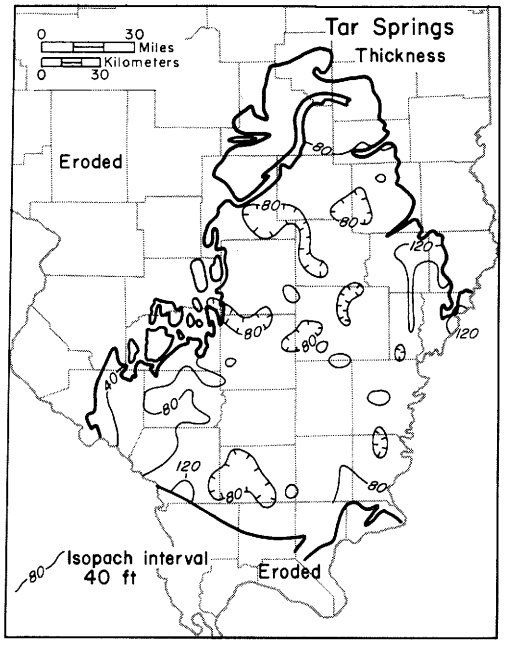

Fig. M-43—Thickness of the Tar Springs Sandstone.

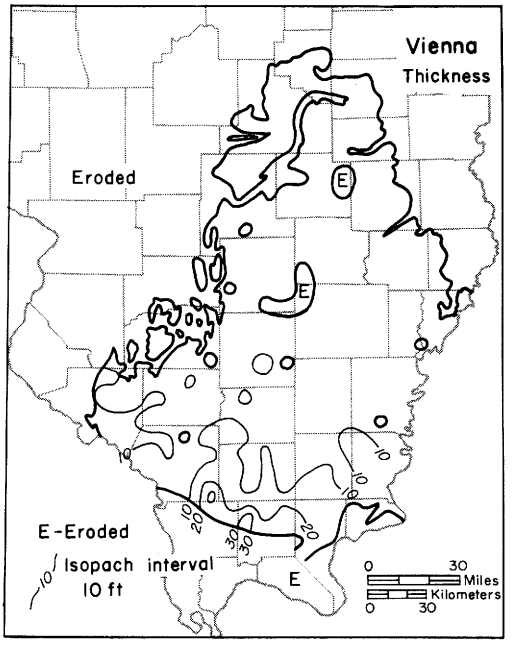

Fig. M-44—Thickness of the Vienna Limestone.

stones also occur at the middle and at the top. The sandstone bodies in the Tar Springs thicken or thin rapidly, and they have a deltaic distributary pattern similar to that of other Chesterian sandstones (Swann, 1963). The remainder of the formation is shale, siltstone, and shaly sandstone. The shale is dark gray and slightly carbonaceous. The siltstones and some of the thin-bedded sandstones are medium to dark olive gray. Commonly there is 3-15 feet of shale at the base and a little more than that at the top. Thin beds of coal occur locally near the top and middle of the formation, especially near the southern limit.

Vienna Limestone

The Vienna Limestone (S. Weller, 1920, p. 396-398) is named for Vienna, Johnson County, and the type section is in an old quarry west of the town (NE SW NW 5, 13S-3E), where the formation is 14 feet thick. It is a thin limestone, rarely more than about 8 feet thick and commonly only 3 or 4 feet (fig. M-44). However, in extreme southern Illinois the limestone thickens rapidly to 30 feet (fig. M-1A). Until recently, the calcareous shale locally present above and below the limestone bed was assigned to the Vienna (Swann, 1963). The limestone is mainly dark brownish gray, but some is brown or dark gray. It is generally very fossiliferous, with crinoid fragments predominating. It contains dark chocolate-brown chert nodules in the outcrop, but chert is rare in subsurface. Locally some beds are sandy. In places thin beds and partings of shale are interbedded with the limestone. The fauna includes the bryozoan *Prismopora serrulata*, which is also abundant in the Glen Dean, and the pelecypod *Sulcatopinna missouriensis*, which is abundant in the Menard.

Waltersburg Formation

The Waltersburg Formation (S. Weller, 1920, p. 398) is named for Waltersburg, Pope County, which is near the type section (SE cor. 17, 13S-6E). It is a clastic unit consisting mainly of shale, but it has beds of siltstone and

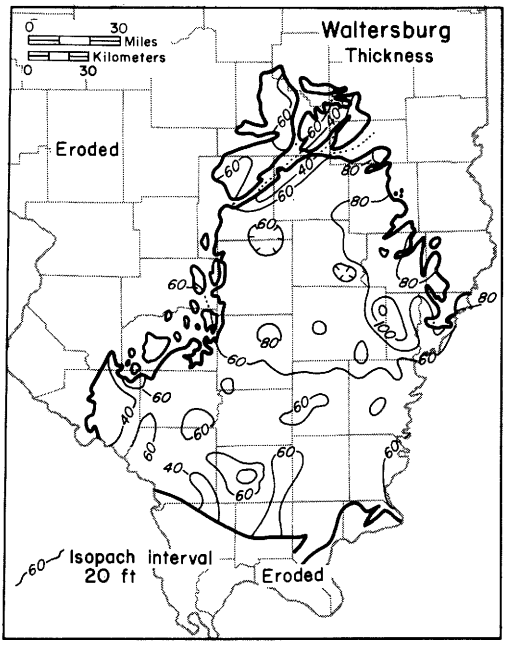

Fig. M-45—Thickness of the Waltersburg Sandstone.

Electronic Filing: Received, Clerk's Office 07/01/2024

sandstone. The Waltersburg is 50-75 feet thick throughout most of Illinois (fig. M-45), but it thins to about 30 feet to the west in Randolph County and thickens to 80-100 feet to the northeast in Jasper and Richland Counties. The thickness increases at the edge of the Walche Member at the base of the Menard, where the top of the Waltersburg steps up from the base of the Walche to the base of the Scottsburg Limestone Member. The Waltersburg Formation is mainly dark gray, slightly carbonaceous shale, in part silty and sandy. Green shale occurs in the upper part of the Waltersburg, and a thin coal is present near the top of the formation close to its southern edge. In the south, some of the shale at the top and bottom of the formation is calcareous and fossiliferous, and until recently it was assigned to the Menard above or the Vienna below (Swann, 1963). The Waltersburg includes beds and laminae of dark gray and dark olive siltstone and beds of gray to white sandstone that is very fine to fine grained, locally quartzitic, and characteristically well jointed. Most of the thick sandstone bodies in the Waltersburg are within 30 miles of the Wabash River (Swann, 1951; Potter, 1963), are strongly linear, and trend northeast-southwest. They are well exposed on Bay Creek between Simpson and Grantsburg, near the Pope-Johnson county line.

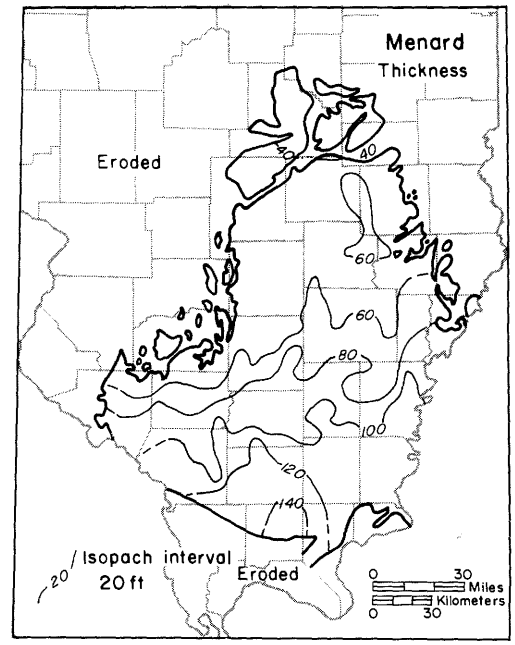

Fig. M-46—Thickness of the Menard Limestone.

Menard Limestone

The Menard Limestone (S. Weller, 1913, p. 120, 128) is named for Menard, Randolph County, where the type section is in the quarry at the Menard State Hospital (NE 23, 7S-7W). The formation is also well exposed in the Mississippi River bluffs at Menard and from Chester to Rockwood, Randolph County. It is a limestone-shale formation, generally 100-150 feet thick in the southern area, 80-100 feet in the central part, and 45-60 feet in the northern and northwestern area, beyond which it is truncated by pre-Pennsylvanian erosion (fig. M-46). The Menard is readily divisible into three limestone members—the Walche (below), the Scottsburg, and the Allard—which are separated by unnamed shale members; a third shale occurs at the top. The limestone of the Menard is argillaceous, dark brownish gray to brown and buff, dense, and fine grained to lithographic. Some beds are oolitic, and many beds contain fine to coarse, dark, rounded grains that give the rock a characteristic speckled aspect. The limestone members are more or less shaly, and they include beds of shale as thick as 5 feet. Chert is present in some places. The shale of the Menard Formation is calcareous, dark gray, and fossiliferous, and it contains thin beds and nodules of limestone. The shale between the Walche and Scottsburg Limestone Members is 3-10 feet thick in most of the area underlain by the Walche Member, beyond which it is not recognized. It thickens in the northeast to about 20 feet or more in Wabash County. The shale between the Scottsburg and Allard Limestone Members is 30-40 feet thick in the far south and thins to about 5 feet in the north. Beds of green shale and green dolomite occur in this unit, and in the south a limestone about 10 feet thick is present in the lower half. The shale at the top of the Menard is generally 20-30 feet thick in the southern part of its extent and 10-20 feet in the northern part. It includes, at the top, a bed of limestone about 5 feet thick. This bed is persistent south of about T6S, but it is generally very thin or absent farther north. Locally, especially in the north, the erosional surface at the base of the Palestine cuts into the shale and in places entirely through it. The initial appearance of *Spirifer increbescens* and *Composita subquadrata* is in the Menard (S. Weller, 1920). The pelecypod *Sulcatopinna missouriensis* is very abundant in places. The *Pentremites fohsi* Range Zone occurs in the lower part of the Menard (S. Weller, 1926).

Walche Limestone Member—The Walche Limestone Member of the Menard Formation (Swann, 1963, p. 38-39) is named for Walche's cut on the Illinois Central Railroad in Caldwell County, Kentucky, where the type section is exposed. Previously it was called the "Little Menard." It is 3-9 feet thick, generally gray to dark gray limestone, typically silty or sandy, and pyritic in part. The Walche is overlapped by the Scottsburg Member, and it is not recognized north of a curve running approximately from northern Wabash County through Wayne County to southwestern Franklin County, beyond which it appears to grade laterally into siltstone that is included in the Waltersburg Formation.

Scottsburg Limestone Member—The Scottsburg Limestone Member of the Menard Formation (Swann, 1963, p. 38-39) is named for Scottsburg, Caldwell County, Kentucky, which is 3 miles southwest of the type section in Walche's cut on the Illinois Central Railroad. It has commonly been referred to as the "Massive Menard." The member is 30-40 feet thick in the far south, but it thins northward to about 5 feet. Much of the limestone is dense and fine grained to lithographic. Some beds are dolomitic.

Allard Limestone Member—The Allard Limestone Member of the Menard Formation (Swann, 1963, p. 38-40) is named for Allard College School, Johnson County, 2.2 miles northeast of the type section, which is in a cut at the south end of the Illinois Central Railroad tunnel (SW NW NE 1, 13S-4E). The Allard Member is dominantly limestone, and it ranges from a little more than 30 feet in the far south to 10-12 feet in much of the northern area of the Menard.

Electronic Filing: Received, Clerk's Office 07/01/2024

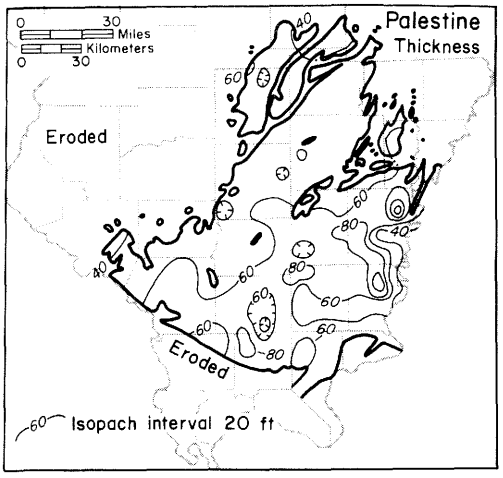

Fig. M-47—Thickness of the Palestine Sandstone.

Palestine Sandstone

The Palestine Sandstone (S. Weller, 1913, p. 120) is named for Palestine Township, Randolph County, where the type section occurs along tributaries of Tyndall Creek (29, 30, 6S-6W). It is a clastic unit that includes sandstone, shale, and siltstone. The Palestine tends to thicken southward (fig. M-47) but not as markedly as other Chesterian formations. It is commonly 50-60 feet thick, but it ranges from 25 to over 100 feet. It is thickest where massive (channel-phase) sandstone bodies are present. Much of the sandstone is gray, very fine grained, and more or less shaly. The thicker sandstone bodies are lighter colored and coarser grained, and grade to white, medium-grained sandstone. The shale is dark gray and generally silty or sandy. The siltstone is mainly dark gray with a little dark green. Much of the Palestine Sandstone is slightly carbonaceous. An underclay and coal bed mark the top of the Palestine at several localities in western Illinois (Swann, 1963). The Palestine does not have persistent traceable beds, such as characterize the younger Chesterian formations. The sandstone bodies lens rapidly in and out, but in most places the sandstone is in the upper and/or lower parts of the formation, rarely in the middle. Well developed channel sands in the lower part of the formation generally cut into the Menard Limestone. The sandstone bodies in the Palestine have the pattern of a deltaic distributary system (Potter, 1963). Fossil tree trunks of *Lepidodendron* are perhaps more common in the Palestine than in any of the other Chesterian sandstones.

Clore Formation

The Clore Formation (S. Weller, 1913, p. 120) is named for Clore School, Randolph County, and the type section is in gullies near the school (SE cor. 20, 7S-6W). The formation includes three members, a lower limestone and shale member (Cora), a middle sandstone and shale member (Tygett), and an upper limestone and shale member (Ford Station). Early geologists in places confused the Tygett Sandstone Member with either the Degonia Sandstone or the Palestine Sandstone and confined the Clore Formation to either the Cora or the Ford Station Member (Swann, 1963). The Clore is 40-60 feet thick near its northern and northwestern limits, and it thickens southward to a little more than 120 feet in parts of Pope and Johnson Counties (fig. M-48). The Clore is thinned by sub-Degonia channels in many more places than are shown in figure M-48. In several areas, sub-Pennsylvanian channels also cut into the Clore. The formation is dominantly shale throughout most of its extent, but the proportion of limestone increases southward. Near the southern outcrop belt the top is stepped up a few feet to include limestone equivalent farther north to the basal portion of the Degonia. At about the same place, the base is stepped down to include limestone equivalent to the uppermost portion of the Palestine. Fossils are generally abundant in the Clore. The fauna is made up mainly of bryozoans and brachiopods. The genera *Archimedes*, *Batostomella*, and *Rhombopora* (fig. M-4) are conspicuous among the bryozoans, and *B. nitidula* is an index fossil. The brachiopods *Spirifer increbescens* and *Composita subquadrata* are especially abundant.

Cora Limestone Member—The Cora Limestone Member of the Clore Formation (Swann, 1963, p. 40-41), the lowest member, is named for Cora, Jackson County, and the type section is near by at the mouth of Degonia Creek Hollow (SW SE 16, 8S-5W). The Cora is 15-45 feet thick. It varies from dominantly limestone to dominantly shale. In both facies it is interbedded limestone and shale and locally contains sandstone lenses. A zone in the Cora Member in which the limestone surfaces are covered with delicate branching bryozoans is the *Batostomella nitidula* Peak Zone (S. Weller, 1926).

Tygett Sandstone Member—The Tygett Sandstone Member of the Clore Formation (Swann, 1963, p. 40, 42), the middle member, is named for Tygett School, Union County, and the type section is on Bradshaw Creek, 1.5 miles north of the school (NE NW 24, 11S-1W), where it is 26 feet thick. It consists of sandstone and minor amounts of shale. *Sigillaria* trunks and fragments are common in some beds.

Ford Station Limestone Member—The Ford Station Limestone Member of the Clore Formation (Swann, 1963, p. 40, 42), the upper member, is named for the Ford Station siding of the Missouri Pacific Railroad, Randolph County, where the type section is in an abandoned quarry (NW SE

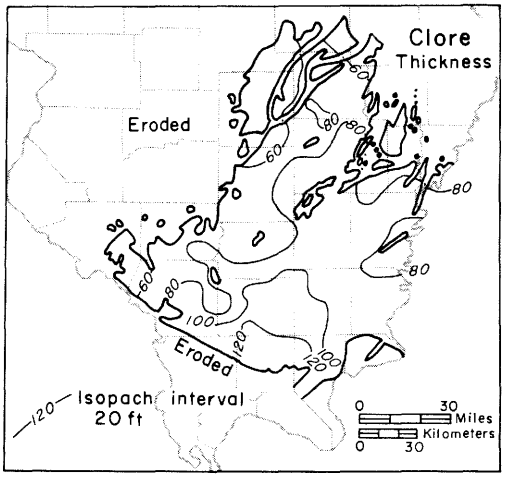

Fig. M-48—Thickness of the Clore Formation.

Electronic Filing: Received, Clerk's Office 07/01/2024

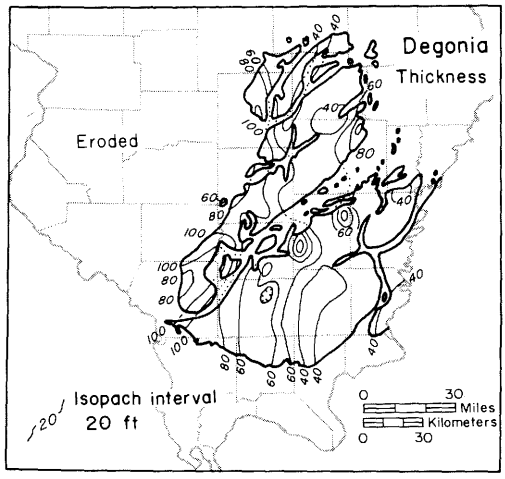

Fig. M-49—Thickness of the Degonia Sandstone.

33, 7S-6W). It is 38 feet thick in the type section but ranges from 20-50 feet thick. It consists of interbedded limestone and shale that include rare lenses of sandstone. Most of the shale in the Ford Station Member is dark gray to dark greenish gray and is generally calcareous and fossiliferous. The limestone is gray, buff, drab, or dark brownish gray, argillaceous, and shaly. Dolomite occurs irregularly.

Degonia Sandstone

The Degonia Sandstone (S. Weller, 1920, p. 281-290) is named for Degonia Township, Jackson County, where the type section is in the bluffs of the Mississippi River and small tributaries (12-16, 21-25, 8S-5W). It is a clastic unit, dominantly sandstone, that ranges from 150 feet of massive sandstone in western Illinois to as little as 20 feet of shale in the southeast (fig. M-49). Typically, it includes two well developed, lenticular beds of massive sandstone. The upper overlaps the lower and both are absent locally. Most of the shale is gray to dark gray, but an extensive bed of red shale occurs at the top of the formation. Thick elongate and thin sheet sand bodies occur in a dendritic pattern (Potter, 1963). A north-south sandstone body, locally more than 15 miles wide, is joined from the east by southwest-trending bodies that fill channel distributaries. In the thick bodies, the sandstone typically is white and fine grained (Atherton, 1947). In southwestern Illinois thin coal beds occur locally near the top and middle of the formation. The Degonia contains plant remains, with *Lepidodendron* the most common.

Kinkaid Limestone

The Kinkaid Formation (S. Weller, 1920, p. 281-290; Swann, 1963, p. 42) is named for Kinkaid Creek, Jackson County, where the type section is in exposures along the creek (SE NW NW 6, 8S-4W). It is a limestone-shale unit (fig. M-1C) and is one of the thicker Chesterian formations, commonly 120-160 feet thick. However, pre-Pennsylvanian erosion of valleys trending northeast-southwest has cut the formation, and particularly its upper member, into isolated areas (Bristol and Howard, 1971, 1974). The formation appears to have been highly resistant to erosion, because it caps the Chesterian Series in large areas, and slump blocks of Kinkaid occur on the slopes of steep-walled pre-Pennsylvanian valleys. The formation ranges from about 100 feet thick in the north to a little more than 170 feet near its southern margin (fig. M-50). It is divided into three members—the Negli Creek Limestone Member (below), the Cave Hill Shale Member, and the Goreville Limestone Member. The fauna of the Kinkaid is dominantly brachiopods, bryozoans, and blastoids and resembles that of several older Chesterian limestone formations, although it is less prolific. A species of *Martinia* is very common.

Negli Creek Limestone Member—The Negli Creek Limestone Member of the Kinkaid Formation (Logan, 1924, p. 11, 125; Malott, 1925, p. 112-114; Swann, 1963, p. 75), the lowermost member, is named for Negli Creek, Perry County, Indiana, along which the type section is an exposure of 12 feet of limestone (NW 36, 6S-3W). In Illinois it is a massive limestone very similar in thickness and lithology to the Goreville Limestone Member but more extensive. It thickens southward from 16 feet in Effingham County to 37 feet in Franklin County. Most of the limestone is brownish gray, but it has some light gray and brown beds. It is very fine grained but includes coarse grains of fossils. In places the lower part is lithographic. It is cherty, particularly in the upper part, but generally less cherty than the Goreville Member. Algal growths (*Girvanella*) are common in the lower part of the Negli Creek, and large gastropods and small biserial Foraminifera occur near the middle.

Cave Hill Shale Member—The Cave Hill Shale Member of the Kinkaid Formation (Swann, 1963, p. 42-43), the middle member, is named for Cave Hill, Saline County, where the type section is on the west slope of the hill (SE SW NW 5, 10S-7E). It is 108 feet thick in the type section, but is over-thickened 25-30 feet by tectonic squeezing. It is a limestone-shale unit about 65 feet thick in the northern area, thickening southward to a little more than 90 feet in the south. The proportion of limestone increases southward, and in the southern area the shale is largely limited to the top and bottom few feet (fig. M-1C). The upper shale, about 15 feet thick, consists of calcareous, dark gray and greenish gray shale at the top and red and green shale below. The red shale makes a fairly extensive marker bed. The middle limestone part contains a variety of carbonate rocks, mainly light brownish gray lithographic limestone, dark shaly limestone,

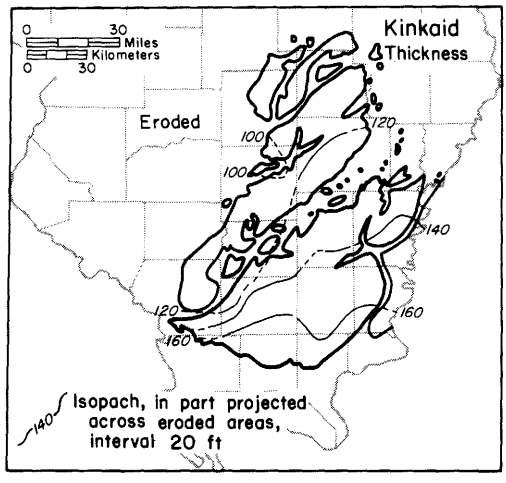

Fig. M-50—Thickness of the Kinkaid Limestone.

Electronic Filing: Received, Clerk's Office 07/01/2024

and buff dolomite. The interbedded shale is mainly dark gray, but locally some is very dark gray or black. The basal shale, about 15 feet thick, consists of dark gray shale and locally some black shale. The lower third of the Cave Hill commonly includes some silty shale, a little gray to dark gray and green siltstone, and, in places, more or less shaly sandstone.

Goreville Limestone Member—The Goreville Limestone Member of the Kinkaid Formation (Swann, 1963, p. 43-44), the uppermost member, is named for Goreville, Johnson County, and the type section is in a quarry at Buncombe, 4 miles south of Goreville (SW SW SE 10, and NW NW NE 15, 12S-2E) (fig. M-1C), where the member is 40.5 feet thick. It is a resistant and relatively uniform, massive limestone about 30 feet thick, but it ranges from about 25 feet in the north to nearly 50 feet in the south. Most of the limestone is brownish gray but some of it is light gray or gray. It is very fine grained but includes coarse fossil grains, mostly crinoidal fragments. It is cherty to slightly cherty nearly everywhere.

Grove Church Shale

The Grove Church Shale (Swann, 1963, p. 44-45), the uppermost formation in the Chesterian Series in Illinois, is named for Cedar Grove Church, Johnson County, and the type section is in a roadcut and near-by gullies, 1.25 miles east of Lick Creek (W line NE NW 31, 11S-2E), where the formation is 16 feet thick. The formation has been largely eroded from Illinois by pre-Pennsylvanian erosion, and it occurs only in patches in Johnson, Pope, and Saline Counties, and probably in parts of adjacent counties. The maximum known thickness is 67 feet in the northern half of Johnson County. The Grove Church is a gray, fossiliferous shale and includes interbedded fossiliferous limestone. It was originally part of the Kinkaid Formation, but it was split off because it is dominantly shale. As a result, the Kinkaid is a dominantly limestone formation. It also has a distinctive fauna; some species have affinities to Pennsylvanian fossils, particularly the fusuline *Millerella* and some ostracodes (Cooper, 1947). The conodont fauna differs strikingly from that of the Kinkaid (Rexroad and Burton, 1961). The genus *Streptognathodus* comprises over one-third of the fauna of the Grove Church and there is a marked decrease in *Cavusgnathus*. Transitional forms show that the change is evolutional, rather than being a migratory influx.

PENNSYLVANIAN SYSTEM

M. E. Hopkins and J. A. Simon

Strata of the Pennsylvanian System constitute the bedrock in about two-thirds of the area of Illinois (36,806 out of 56,400 square miles) and underlie all or parts of 86 of the 102 counties of the state (fig. P-1). The name "Pennsylvanian Series" was introduced by H. S. Williams in a report on Washington County, Arkansas (Simonds, 1891, p. xiii), to designate strata generally called "Coal Measures." Later, the coal fields of Pennsylvania were named as the type area (Williams, 1891, p. 83). The name "Pennsylvanian" has been used in Illinois since the first report of the present Geological Survey (Weller, 1906a), but the terms "Coal Measures" and/or "Upper Carboniferous" were still used in many early reports of the Survey. The Pennsylvanian was classified as a series in Illinois until about 50 years ago and since then has been regarded as a system (fig. P-2).

Throughout most of the area they cover in Illinois, Pennsylvanian strata are concealed by unconsolidated Pleistocene deposits, but in many areas they have been exposed by stream erosion (fig. P-3). The lowermost Pennsylvanian strata are prominently exposed in escarpments that generally face south along the southernmost boundary of the Pennsylvanian, beyond the maximum advance of Pleistocene glaciers. The upper two-thirds of the Pennsylvanian section occurs in relatively flat areas, where the best exposures are generally in artificial cuts made in mining or in highway or railroad construction.

Although the maximum thickness of the Pennsylvanian in Illinois is about 2500 feet, the maximum composite thickness of the individual formations is more than 3300 feet. The formations generally thicken from northern and western Illinois toward the south and southeast. Thickness is also affected by progressive overlap to the north and northwest as lower units pinch out. In much of the Pennsylvanian area of western and northern Illinois, most of the members of the three lowest formations are relatively thin or missing. In places on the La Salle Anticline, these formations are absent and the Colchester (No. 2) Coal at the base of the Carbondale Formation rests directly on the St. Peter Sandstone of Ordovician age. In the extreme northwestern area of Pennsylvanian rocks, however, the

P-2—Classification of the Pennsylvanian System. In the graphic column, blank space indicates gray shale. Named members are listed to the right of the graphic column. Figure is continued on next two pages.

three lowest formations are all well developed, particularly in Rock Island and Mercer Counties.

A major unconformity underlies the Pennsylvanian System (fig. P-4) and separates the Absaroka Sequence, which includes all the Pennsylvanian strata, from the Kaskaskia Sequence below. Pennsylvanian rocks overlie the youngest strata of the Mississippian System in extreme southern Illinois and progressively overlap older strata northward. In the extreme northern part of the coal basin, Pennsylvanian rocks directly overlie rocks of Ordovician and Silurian age.

The upper surface of the Pennsylvanian rocks is an eroded post-Pennsylvanian, pre-Pleistocene surface modified in part by further erosion during the Pleistocene (fig. 10). In a relatively small area in Adams, Pike, and Brown Counties in western Illinois, the Pennsylvanian is overlain by Gulfian (upper Cretaceous) rocks (Frye et al., 1964).

The Pennsylvanian System is characterized by many vertical changes in lithology, commonly abrupt, that produce 500 or more distinguishable units of sandstone, siltstone, shale, limestone, coal, and clay (Kosanke et al., 1960). Many of these units are laterally extensive, and even though others vary lithologically they can be correlated widely because of their positions in relation to continuous marker units, usually limestones, black fissile shales, or coals.

Typically, 90-95 percent of the system consists of clastic rocks. Sandstones commonly constitute 60 percent of the lower part of the section (McCormick Group). Most of the remainder is siltstone and shale, and less than 1 percent is coal and limestone. Sandstones constitute about 25 percent of the middle and

upper parts of the system, although the percentage may be somewhat higher in the upper strata. In the upper part of the section, shale (dominantly of various shades of gray with smaller amounts of red, green, and black) and underclay commonly form 65-70 percent of the sequence. In general, 5-10 percent of the upper two-thirds of the sequence is limestone, the largest percentage in the Bond Formation.

Because of the abrupt and distinct vertical variations in lithology and the widespread lateral continuity of many of the Pennsylvanian units, their classification has undergone many changes (fig. P-5). The present Pennsylvanian classification was adopted (Kosanke et al., 1960) to make it conform to the Illinois State Geological Survey policy on stratigraphic nomenclature (Willman et al., 1958) (fig. 16). The multiple classification adopted by the Survey permitted recognition of cycles as a separate and distinct classification, thus removing cyclothems from the rock-stratigraphic classification, where they had been used in place of formations. After several alternatives for formations had been considered, the entire system was subdivided into seven formations, each a bundle of Pennsylvanian strata characterized by certain gross lithologic characteristics and separated from the overlying and underlying strata by the top or bottom of generally widely traceable members. The formations are differentiated by the relative abundance, character, and distribution of four basic lithologies—sandstone, shale, coal, and limestone. Adjacent formations that have closely related lithologic characteristics are combined into a group and three groups are recognized.

The present time-stratigraphic classification of the Pennsylvanian System in Illinois (fig. P-2) is based on that developed in the Midcontinent Region and was first published by the Illinois State Geological Survey on the Geologic Map of Illinois (Willman et al., 1967). Correlations with Midcontinent strata are based on both biostratigraphy and rock stratigraphy, and many biozones and rock units of the Midcontinent Region can be identified in the Illinois Basin. The sediments were continuous before the two regions were separated by post-Pennsylvanian erosion. A time-stratigraphic classification of the Pennsylvanian System in Illinois based on ostracodes (Cooper, 1946) used Midcontinent terms, but the correlations were not definitive and the classification was not followed.

The most common invertebrate macrofossils are brachiopods, crinoids, gastropods, and pelecypods, but corals, cephalopods, trilobites, foraminifers, bryozoans, and worms occur in some beds (fig. P-6) (Wanless, 1958). Biostratigraphic zones in the Pennsylvanian in Illinois are based on fusulinids (Dunbar and Henbest, 1942; Thompson et al., 1959; Thompson and Shaver, 1964), ostracodes (Cooper, 1946), and spores (Kosanke, 1950; Peppers, 1964, 1970; Winslow, 1959). Moore et al. (1944) discussed ranges of all fossil types in the Pennsylvanian of the United States. Floral zones for the nation as a whole were described by Read and Mamay (1964).

Coal-bearing Pennsylvanian strata have been fairly precisely correlated from spores and pollen in the coals. Palynological studies of other lithologic units, however, have not been extensive. Major time-stratigraphic intervals are delineated by their most abundant spore taxa and by the occurrence of certain genera and species that have relatively short stratigraphic ranges. Some of these fossils are limited to two or three coals, whereas others extend through one or more series. A coal can generally be precisely correlated with a named coal member, or at least placed within an interval containing two or three named coal members.

The Pennsylvanian of Illinois includes strata belonging to the recognized series of the Midcontinent, from oldest to youngest: Morrowan, Atokan, Desmoinesian, Missourian,

Fig. P-5—Development of the classification of the Pennsylvanian System (after Kosanke et al., 1960). In Wanless (1939) and Weller (1940), the McLeansboro and Carbondale Groups were subdivided into cyclothems, and the Caseyville and Tradewater Groups in southern Illinois were subdivided into seven formations. In several reports from 1940 to 1950 the base of the McLeansboro was put at the top of the No. 6 Coal. Cyclothems are retained in a separate cyclical classification. Units bounding the groups and formations are in italics.

Fig. P-7—Arrangement of lithologic units in a cyclothem (after Willman and Payne, 1942).

and Virgilian (fig. P-2). Older strata of problematical age, sometimes referred to as the Springeran Series (Pennsylvanian and/or Mississippian), have not been recognized in Illinois. However, certain sink-hole or cave deposits lying on or in older carbonates in western and northeastern Illinois contain very early Pennsylvanian strata that have not been correlated with strata in other areas, although they are at present considered Morrowan. Because of the overlapping relations on the unconformity at the base of the Pennsylvanian, the basal Pennsylvanian strata vary in age, generally from Morrowan in southern Illinois to Atokan and Desmoinesian in western, northern, and eastern Illinois. The youngest Pennsylvanian strata in Illinois, found only at the top of the deepest part of the Fairfield Basin, belong in the lower part of the Virgilian Series. The spores of several coals preserved in down-faulted blocks in western Kentucky and adjacent southeastern Illinois suggest that most of the Virgilian may be represented in this part of the basin. Within the Pennsylvanian System in Illinois, no major, widespread unconformities with either large-scale overlaps or structural discordances are evident. Numerous erosional episodes, however, occurred during the development of fluvial and deltaic sandstones.

The many individual units of the Pennsylvanian generally occur in an orderly sequence, and the sequences are repeated many times throughout most of the succession. Although the idealized sequence shown in figure P-7 is rarely complete, the units that are present have the same relative position in the sequence. These sequences were early recognized as cycles of sedimentation (Udden, 1912; Weller, 1930, 1931) and were subsequently termed "cyclothems" (Wanless and Weller, 1932).

Cyclothems have been used extensively in geologic reports in the past 40 years (Wanless, 1929 [called suites], 1931a [called cyclical formations], 1957; Willman and Payne, 1942), but they are not entirely adequate for rock-stratigraphic classification. They are much smaller units than the formations and are most useful in detailed differentiation and field mapping of the Pennsylvanian sediments. The named cyclothems are listed in table 3.

Pennsylvanian sediments of the Illinois Basin were deposited in a gently subsiding trough that was open toward the south until post-Pennsylvanian time, when it was closed by uplift of the Pascola Arch south of Illinois. The greatest subsidence took place in the southeastern part of the state where the system is thickest.

Because of subsidence during and after the Pennsylvanian, the base of the Pennsylvanian is as much as 2500 feet lower in the deeper part of the basin than at the surface around the margin, and the Herrin (No. 6) Coal is as much as 1400 feet lower (fig. P-8). The major structural features within the Illinois Basin that influence the present distribution of Pennsylvanian strata are the La Salle Anticlinal Belt, the Fairfield Basin, the Du Quoin Monocline, and the Eagle Valley Syncline, which is in southeastern Illinois south of the Shawneetown Fault (fig. 12). Faulting is most prominent in southeastern Illinois, where the faults of the fluorspar district have caused Pennsylvanian strata to be preserved in grabens south of the principal margins of the Pennsylvanian. The distribution of Pennsylvanian formations is also influenced by the Shawneetown Fault, the Cottage Grove Fault System, and the Wabash Valley Fault System. Pennsylvanian outliers in southern Calhoun County are related to the Cap au Grès Faulted

Flexure. Numerous other flexures in the Pennsylvanian rocks in the basin are commonly related to structures that have greater relief in pre-Pennsylvanian strata. Domal structures in Pennsylvanian strata overlie many Silurian reefs.

The Pennsylvanian section is generally thinner in the area of the Sparta Shelf west of the Du Quoin Monocline in southwestern Illinois and in the shelf area north and west of the Illinois River. In both areas much of the section is present, but the lowermost or oldest strata were not deposited there and the youngest strata probably have been eroded from the area.

During Pennsylvanian time clastic sediments were generally carried into the seas occupying the Illinois Basin area by rivers flowing from the north, northeast, and east, and to a lesser extent from the northwest. When the seas withdrew, most of the major rivers flowed southwestward across Illinois. Much of the sedimentation occurred in large deltas on the gently subsiding basin (Wanless et al., 1963). The marine, brackish water, and delta-plain sediments have complex relations, and there is little agreement on interpretations of the environment of deposition of some strata.

Sandstones occur in two broad general types—channel facies and sheet facies (Andresen, 1961; Hopkins, 1958; Potter, 1962b,

Electronic Filing: Received, Clerk's Office 07/01/2024

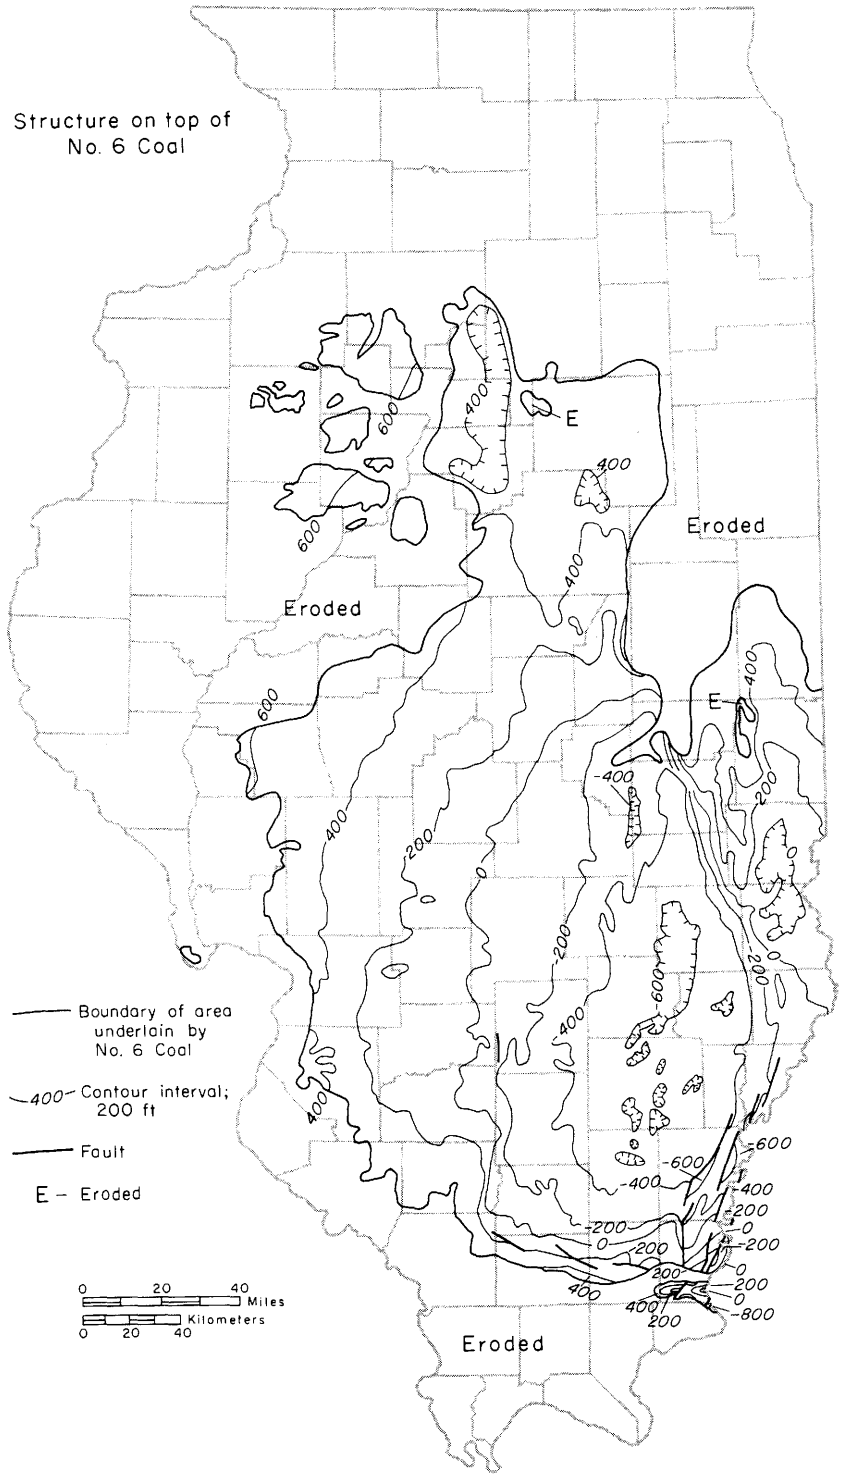

Fig. P-8—Structure of the top of the Herrin (No. 6) Coal Member (based on map by K. E. Clegg).

1963; Siever, 1957). Sandstones in channels are generally less than 100 feet thick, but where channels cross and two or more sandstones are in vertical juxtaposition, thicknesses of more than 100 feet are found. Some channel sandstones abruptly truncate lower strata in long, winding courses, suggesting that the sand filled valleys that had been subaerially eroded. The lower surface of the channel sandstone generally truncates sharply the strata below, but the upper surface commonly grades into the overlying rocks, which are generally siltstone. Most sandstones appear to be nonmarine, although some are clearly marine. The sheet sandstones are thinner than the channel sandstones and occur in widely traceable layers that commonly are conformable with strata above and below. Siltstones are common but generally are not as thick as the channel sandstones or some shales.

The shales that overlie limestones in the normal cyclical sequence are generally marine. The black fissile shales, which commonly occupy a position between a marine limestone and the top of the underlying coal, were marine muds deposited in restricted deoxygenated bottom waters. The gray shales that occur in several areas as large wedges or lenses between the black fissile shale and the coal were deposited in transitional environments, which probably ranged from prodelta to delta front to valley flat. The underclays below most coals or coal positions probably were deposited in relatively fresh water. Claystones other than underclays, commonly associated with the lighter colored marine limestones, generally are also marine.

Nearly 50 coals have been named in the Pennsylvanian of Illinois, but other coals, which are known to be present although as yet unnamed, bring the total to at least 75. Many of the coals are very widespread. The coals accumulated on broad delta plains in fresh-water environments, probably only slightly above sea level (Wanless et al., 1969). Some interstratified partings of mineral matter, mostly clay, also are extensive. The most notable example is the so-called "blueband" in the lower part of the Herrin (No. 6) Coal Member, a 1- to 3-inch clay parting that has been traced almost continuously throughout thousands of square miles.

Most limestones in the cyclical sequence above the coals were deposited in a marine environment and contain a large variety of fossils. Some limestones are relatively pure, particularly in younger Pennsylvanian strata, but most are characteristically argillaceous. Most of the nodular limestones that occur in a clay matrix in or below underclays are generally nonfossiliferous but some of them contain algal remains, ostracodes, and the worm *Spirorbis*. They are generally regarded as freshwater deposits, but some grade into marine limestone in a few areas.

Conglomerates composed of granules and pebbles of locally derived rocks are present at places in the channel sandstone deposits. Lenses and beds of conglomerate consisting of quartz pebbles derived from outside the Illinois Basin occur in sandstones in the Caseyville Formation. The Covel Conglomerate Member is a thin, unique, widespread limestone conglomerate that occurs a short distance below the Springfield (No. 5) Coal Member in northern Illinois. Claystone conglomerates or breccias altered to almost pure kaolinite commonly occupy the stratigraphic position of coals in channel fill in a few local areas (Smith and O'Brien, 1965).

MORROWAN SERIES

The Morrowan Series of the Pennsylvanian System (Adams, 1904, p. 28) is named for Morrow, Washington County, Arkansas, which lies a short distance from the type exposure on Hale Mountain. The series consists of marine and nonmarine rocks. The Caseyville Formation of the McCormick Group (fig. P-2) constitutes the entire Morrowan Series in Illinois (Willman et al., 1967). The top of the series may not correlate precisely with the top in the Midcontinent section.

Marine fossils are rare in the Caseyville, but the Sellers Limestone Member in southeastern Illinois contains a Morrowan fauna. The type region of the Morrowan in many places contains *Millerella*, a nonfusiform fusulinid that is also found in the Chesterian Series and in younger Pennsylvanian sediments and is the most advanced fusulinid found in Morrowan rocks. However, no fusulinids have been found in the Illinois Morrowan. The upper limit of the Morrowan in fusulinid-bearing rocks is placed at the base of the first strata containing *Profusulinella*.

The compression plant fossils of the Morrowan Series are in Zone 6 (*Neuropteris tennesseeana* and *Mariopteris pygmaea*) of Read and Mamay (1964). The roof shale of the Baldwin coal, which occurs in the Morrowan type section, contains a plant-impression flora similar to that above the Gentry Coal Member in southeastern Illinois. The relative ages of strata within the Morrowan Series in Illinois can best be determined from the spores,

which are abundant in Caseyville sediments, especially the coals. The Morrowan Series in Illinois is dominated by the genus *Lycospora*, which in some coals makes up as much as 80 percent of the spore population. Spores of herbaceous lycopods—*Densosporites*, *Cristatisporites*, and *Radiizonates*—are also abundant. *D. sinosus*, *R. striatus*, and *R. irregularis* are useful guide fossils for the lower part of the Morrowan, whereas *C. indignibundus* is typically found in the upper part. *Schulzospora* ranges up to the top of the Morrowan. *Triquitrites*, *Laevigatosporites*, and *Endosporites* are found in the lower part of the Morrowan but are very rare.

ABSAROKA SEQUENCE

The major unconformity at the base of the Pennsylvanian System marks the base of the Absaroka Sequence (Sloss et al., 1949, p. 121) (fig. 14), which is named for the Absaroka Mountains in northwestern Wyoming and southern Montana. In Illinois the sequence includes only the strata of the Pennsylvanian System, and its top is the major unconformity at the base of the Cretaceous System (Swann and Willman, 1961). Clastic sediments—shale, sandstone, and siltstone—dominate the sequence. Minor unconformities consisting of deeply entrenched valley systems occur within the Absaroka, but many of the erosional channels in the sequence were produced by entrenchment of river distributaries in deltaic sediments. Except for minor sedimentational dips on local structures, the strata in the sequence are essentially parallel. In the Appalachian Basin and the Midcontinent areas, this sequence continues upward into the Permian System, but no Permian rocks have been found in Illinois. The basal unconformity separating the Absaroka from the underlying Kaskaskia Sequence (fig. P-3D) has been characterized (Siever, 1951; Wanless, 1955; Bristol and Howard, 1971) as an erosion surface formed by streams draining to the south and southeast in western Illinois and to the southwest in central and southern Illinois. The surface has local relief of as much as 450 feet and relatively steep-sided valleys. It truncates all the older Paleozoic systems except the Cambrian (fig. P-4).

McCormick Group

The McCormick Group (Kosanke et al., 1960, p. 28) is named for McCormick in northwestern Pope County, where the various units of this group are prominently exposed. In Illinois the McCormick Group comprises strata of the Caseyville and Abbott Formations, from the base of the Pennsylvanian to the top of the Bernadotte Sandstone Member (fig. P-2). The McCormick Group comprises strata formerly included in the Tradewater and Caseyville Groups (Wanless, 1939; Weller, 1940). The McCormick Group in Illinois thickens from about 200 feet at the northwestern extent of the Pennsylvanian to at least 600 feet in southern Illinois, but it is absent in substantial areas in both western and northern Illinois. Lithologically, this group is almost entirely detrital. It is made up of 50-60 percent massive, predominantly cross-bedded, relatively pure quartz sandstone and 40 percent or more sandy shale and siltstone. The sandstones are seldom more than 100 feet thick. A few thin, nonpersistent coals and rare fossiliferous limestones occur locally. Several of the fine-grained sandstones and a few shales are calcareous in places and contain marine invertebrate fossils, but the bulk of the units of the McCormick Group are barren of animal fossils.

Caseyville Formation

The Caseyville Formation of the McCormick Group (Owen, 1856, p. 48) is named for Caseyville, on the Ohio River in southwestern Union County, Kentucky, near the type locality, "measured from outcrops on the Illinois shore of the Ohio River between the mouth of the Saline River and Gentry's Landing below Battery Rock," in Hardin County (Lee, 1916, p. 15-16). A well exposed reference section has been described along the Illinois Central Gulf Railroad in Pope County (NW SW SE 31, 11S-5E to NE SE NE 18, 12S-5E) (Kosanke et al., 1960, p. 28, 61-62). The Caseyville includes strata from the base of the Pennsylvanian to the top of the Pounds Sandstone Member. The top of the Pounds is generally difficult to recognize in the subsurface north of its outcrop.

The Caseyville Formation is widespread in southern Illinois, and rocks of similar age have been reported in northwestern Illinois in parts of Mercer and Rock Island Counties (fig. P-9). In southern Illinois the Caseyville Formation is as much as 500 feet thick, but 350 feet is a common maximum elsewhere. The Caseyville varies abruptly in thickness because the unconformable surface on which it was deposited has a relief of a few hundred feet—from the bottom of large valleys to the flat upland divides (Siever, 1951; Wanless, 1955; Bristol and Howard, 1971). To the north the Caseyville thins to zero and is overlapped by the Abbott Formation (fig. P-9). In Mercer and Rock Island Counties, the formation varies in thickness; it locally exceeds 100 feet.

The Caseyville Formation is primarily sandstone (fig. P-3A), siltstone, and shale. The sandstones are composed of quartz and very little clay or mica. Most contain quartz granules and pebbles, commonly less than half an inch (12 mm) in diameter, which occur either scattered throughout the sandstone or concentrated in beds of con-

Electronic Filing: Received, Clerk's Office 07/01/2024

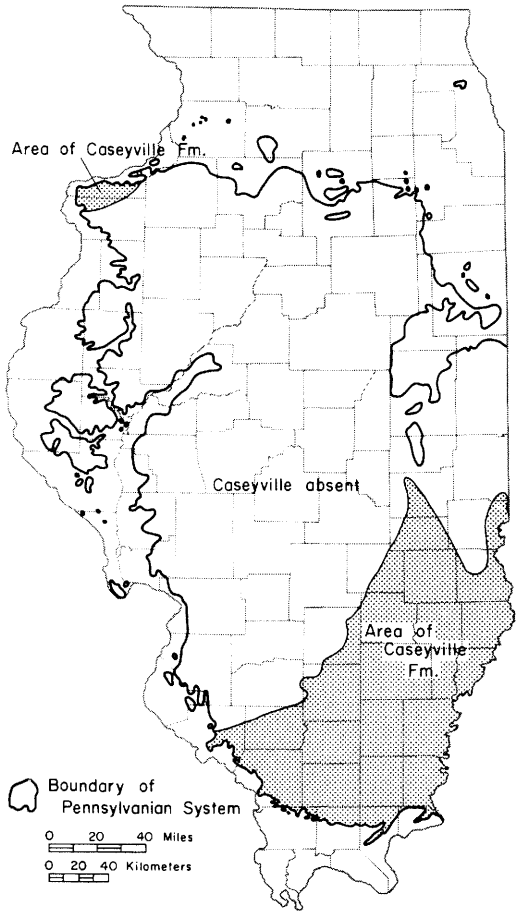

Fig. P-9—Extent of the Caseyville Formation (after Wanless, 1955).

glomerate (fig. P-3F). The coarser sandstones reach about 100 feet thick and show relatively uniform cross-bedding with dip directions to the west, south, or southwest (Potter and Olsen, 1954; Potter, 1962b, 1963) parallel to the direction of elongation of the sandstone bodies. In the finer grained sandstone units, which are usually less than 25 feet thick, the most prevalent sedimentary structure is ripple bedding (fig. P-3E). Shale or siltstone interbeds are common. Considerable oil has been produced for many years in the La Salle Anticlinal Belt in eastern Illinois from sandstones in the Caseyville.

The shales and siltstones are not as widely exposed. The thicker shale units in the Lusk and Drury Members are sandy and contain several beds of sandstone, some relatively coarse grained. A few shales associated with coals are dark, relatively fine and uniform, and their clay mineral content is high. Most of the Caseyville in northwestern Illinois is composed of medium gray to dark gray brittle shales interbedded with silty shales and a few clean quartz sandstones.

Several coal seams, most of them somewhat lenticular, are found in the Caseyville Formation, although only one—the Gentry Coal Member in southeastern Illinois—is named. In Rock Island and Mercer Counties, as many as seven impure coals up to 2 feet thick occur in the Caseyville (Searight and Smith, 1969).

Limestones are rare in the Caseyville Formation, the only one named being the Sellers Limestone Member, which is exposed in only one small area along the Ohio River Valley. Marine invertebrate fossils are found in this limestone, as well as in a few calcareous sandstone units, some of which contain reworked Mississippian fossils. The formation is otherwise barren of animal fossils.

The upper limit of the Caseyville, which is the top of the Pounds Sandstone Member, is commonly difficult to recognize in the subsurface north of its outcrop belt. Consequently, no separate map of the Caseyville thickness was prepared, but figure P-10 shows the combined thickness of the Caseyville, Abbott, and Spoon Formations. Included are strata from the base of the Pennsylvanian up to the base of the Colchester (No. 2) Coal, a widely recognizable key member that has been traced throughout the state. The Caseyville of Illinois correlates with all but the upper few feet of the Caseyville Formation of western Kentucky and with the lower part of the Mansfield Formation of Indiana.

Lusk Shale Member—The Lusk Shale Member of the Caseyville Formation (Weller, 1940, p. 36), the basal unit of the Pennsylvanian System in southeastern Illinois, is named for Lusk Creek in Pope County. The type section consists of exposures along the creek north of Waltersburg (12, 13S-6E). The thickness of the Lusk varies from zero to over 200 feet. The member is composed of various amounts of silty shale, siltstone, and sandstone. Quartz pebbles are common to abundant in some sandstone units as much as 25 feet or more thick, and these units are similar to the Battery Rock and Pounds Sandstone Members. Other sandstone units as much as 50 feet thick are fine grained. The Lusk contains a few thin, unnamed, nonpersistent coal seams and a few zones with marine fossils, most of them fragmentary. In general, all the Pennsylvanian rocks in southern Illinois below the Battery Rock Sandstone are assigned to either the Lusk Shale or the Wayside Sandstone.

Wayside Sandstone Member—The Wayside Sandstone Member of the Caseyville Formation (Lamar, 1925, p. 84-85) is named for Wayside, Johnson County, and the type section consists of outcrops near the village (N1/2 30, 11S-2E) (Wanless, 1956, p. 9). The Wayside is the lowermost unit of the Pennsylvanian System on the western side of the southern Illinois outcrop belt and is equivalent, at least in part, to the Lusk Shale to the east. Like the Lusk, it is a complex unit of interbedded lenticular sandstones as much as 50 feet thick that are separated by silty or sandy shales and siltstones, all part of a fluvial-deltaic complex. In the area south of Carbondale the thickness of the Wayside varies but averages about 70 feet.

Battery Rock Sandstone Member—The Battery Rock Sandstone Member of the Caseyville Formation (Cox, 1875, p. 204) is named for Battery Rock, a bluff of massive sandstone on the west bank of the Ohio River in Hardin County, the type section (26, 11S-10E). The Battery Rock Sandstone, a prominent bluff-forming unit (fig. P-3A), is very well developed in Gallatin, Hardin, and Pope Counties, where it is 50-100 feet thick in a large area. It is also as much as 100 feet thick in the western part of the southern Illinois outcrop belt, but there it is more lenticular. Along the southwestern side of the Illinois Basin, the sandstone extends only as far north as Randolph County. In the subsurface to the north and northeast of the outcrop belt, the Battery Rock is difficult to trace because several other thick sandstone units occur in the

Fig. P-10—Combined thickness of the Caseyville, Abbott, and Spoon Formations (after Wanless, 1955).

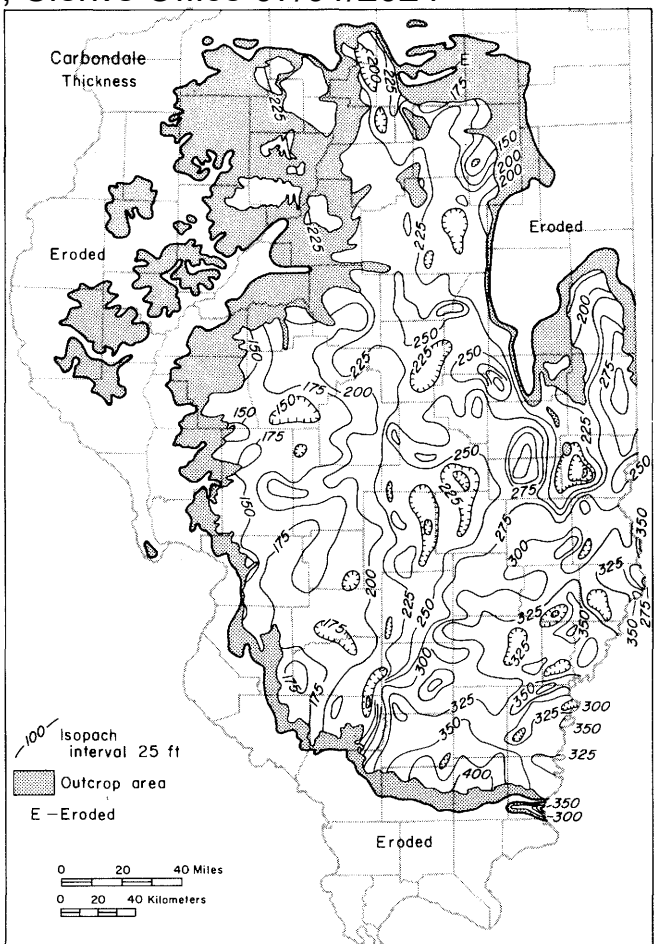

Fig. P-11—Thickness of the Carbondale Formation (based on map by K. E. Clegg).

Electronic Filing: Received, Clerk's Office 07/01/2024

lower part of the McCormick Group. The Battery Rock is generally medium-grained sandstone, but at places it becomes coarse; almost everywhere it contains scattered quartz granules and pebbles, which in places form conglomerate beds. Although the Caseyville sandstones have been called conglomerates, the term "conglomeratic" is more appropriate. The Battery Rock is correlated with the lower Caseyville conglomerate, or Kyrock Sandstone Member, of western Kentucky and with the lower part of the Mansfield Sandstone of Indiana.

Drury Shale Member—The Drury Shale Member of the Caseyville Formation (Lamar, 1925, p. 91-95) is named for Drury Creek in Jackson County, and the type section consists of exposures along the creek south of Makanda (33, 34, 10S-1W). The Drury is a complex unit of sandy or silty shale, siltstone, and lenticular massive sandstone units, and is much like the Lusk Shale. It contains at least two thin, nonpersistent coals. The Drury is as much as 100-150 feet thick in places near the type area, but the thickness varies somewhat, partly because of differential erosion prior to deposition of the overlying Pounds Sandstone. All strata lying between the Battery Rock and Pounds Sandstones are considered equivalent to the Drury, but, for the sake of clarity in classification, the name "Drury" is not used in parts of southeastern Illinois where two other members of the Caseyville Formation—the Sellers Limestone and the Gentry Coal—occur within the Drury interval. Although rocks of Drury age are present in the subsurface of the southern part of the Illinois Basin, the Battery Rock and Pounds Sandstones cannot generally be differentiated in well logs, which makes it impractical to differentiate the Drury. The Drury is equivalent to part of the Mansfield Sandstone of Indiana.

Sellers Limestone Member—The Sellers Limestone Member of the Caseyville Formation (Wanless, 1939, p. 36, 101) is named for Sellers Landing, Hardin County, on the west bank of the Ohio River, near the type section (21, 11S-10E) (Wanless, 1956, p. 9). The Sellers Limestone is known only at the type locality, where about 10 feet is exposed. It is a major marine deposit in a complex fluvial-deltaic sequence. Part of the limestone is sandy and coarse grained and contains a varied marine fauna, but most of the Sellers is composed of beds of very fine-grained, argillaceous limestone interbedded with gray shale. No fusulinids, ostracodes, or conodonts have been found in the Sellers. It is equivalent to part of the Drury Shale, but no limestone correlatives are known.

Gentry Coal Member—The Gentry Coal Member of the Caseyville Formation (Kosanke et al., 1960, p. 29) is named for Gentry Landing, Hardin County, and the type locality consists of exposures near the landing (SW 26, 11S-10E). It previously was called the Battery Rock Coal (Owen, 1856, No. 1 vertical section). The Gentry Coal has been identified as a thin coal in several scattered localities in southeastern Illinois but is apparently not persistent. It was mined more than 100 years ago in small mines near the settlement of Lamb in Hardin County. It is underlain by a thin underclay, which overlies a thick, gray, silty shale that is equivalent to part of the Drury Shale. It is overlain by a shale that also is equivalent to part of the Drury Shale. Its exact relation to the Sellers Limestone has not been established, although field relations suggest that the Gentry is slightly above the Sellers.

Pounds Sandstone Member—The Pounds Sandstone Member of the Caseyville Formation (Weller, 1940, p. 38), the uppermost member, is named for Pounds Hollow in Gallatin County, and the type section consists of exposures along the hollow (35, 36, 10S-8E). The Pounds Sandstone is lithologically similar to the Battery Rock Sandstone and reaches 100 feet thick, forming long, abrupt bluffs in southern Illinois, usually north of the Battery Rock bluff. The Pounds is also known as far north as Rock Castle Creek in Randolph County (33, 6S-5W). Like other members of the Caseyville Formation, the Pounds Sandstone has not been widely traced in the subsurface north of the outcrop belt, although strata of this age and lithologic character are known to be present (fig. P-9). The Pounds is correlated with part of the Mansfield Sandstone of Indiana and the upper Caseyville conglomerate, or Bee Springs Sandstone Member, of western Kentucky.

ATOKAN SERIES

The Atokan Series of the Pennsylvanian System (Taff and Adams, 1900, p. 273) is named for Atoka, Atoka County, Oklahoma. No type section was designated, but the area near Atoka contains a sequence of a few thousand feet of sandstones and shales generally devoid of invertebrate fossils and truncated at the top by a major fault. In Illinois the Atokan Series consists of the strata composing the Abbott Formation of the McCormick Group (Willman et al., 1967) (fig. P-2). The base and top have not been defined by fossils, although fossiliferous zones are present within the series.

Where marine rocks are abundant, the Atokan is generally characterized as the two subzones of the earliest fusiform fusulinids, *Profusulinella* and *Fusulinella*, and the top is defined as the strata below the first appearance of *Fusulina* and *Wedekindellina*, although some confusion has arisen because *Fusulina* has been reported in the Atokan of the type area.

Plant fossil zones for the Atokan Series are Zones 7 (*Megatopteris* spp.) and 8 (*Neuropteris tenufolia*) of Read and Mamay (1964). Spore assemblages are the best means for correlating the Atokan strata in the Illinois Basin with Atokan strata of other areas. They are of greater diversity and their genera are more abundant and more evenly distributed than is true in the Morrowan Series. *Laevigatosporites*, *Calamites*, *Florinites*, and *Punctatisporites* increase in the upper part at the expense of *Lycospora*, which, with *Densosporites*, especially *D. annulatus*, and *Cristatisporites indignibundus*, is common in the lower part of the Atokan. Certain species of *Radiizonates* and *Torispora* are useful in defining the upper part.

Abbott Formation

The Abbott Formation of the McCormick Group (Kosanke et al., 1960, p. 30, 44) is named for Abbott Station on the Illinois Central Gulf Railroad, Pope County, along which the type section is exposed (5, 6, 7, 18, 19, 11S-5E). The Abbott Formation overlies the Caseyville and extends from the top of the Pounds Sandstone Member to the top of the Bernadotte Sandstone Member of western Illinois, which has been correlated with the Murray Bluff Sandstone Member of southern Illinois (fig. P-2). In subsurface, both the top and base of the Abbott are commonly difficult to determine. Only the sandstones and some

Electronic Filing: Received, Clerk's Office 07/01/2024

of the coals have been named. In southern Illinois the Abbott overlaps the Caseyville Formation northward and is the basal formation of the Pennsylvanian System throughout most of the state outside the area of Caseyville strata. The Abbott is overlain by the Spoon Formation, which overlaps it in northern and northeastern Illinois and on some prominent anticlinal structures. The Abbott Formation has a maximum thickness of 300-350 feet in southern Illinois, but in western Illinois even where it is well developed it is generally less than 100 feet thick. It is similar to the Caseyville Formation in being composed primarily of detrital rocks, but it differs from the Caseyville in containing thicker, more widespread coals and in the character of the sandstones. The sandstones in the Abbott are generally finer grained, thinner in maximum development, contain more interstitial clay and mica flakes, and have no more than a few quartz granules and pebbles. These characteristics are transitional; the lower sandstones in the Abbott more closely resemble those in the Caseyville and the upper are similar to the impurer sandstones of the overlying Spoon Formation. Abbott shales are similar to those of the Caseyville but are in general less sandy. About half of the formation is shale; no named limestone units occur in the Abbott Formation. Calcareous sandstones, sandy limestones, and a few shale units contain marine fossils locally. Two marine limestones in southwestern Indiana (the Fulda and Ferdinand Members) and the Lead Creek Limestone Member in western Kentucky occur in strata equivalent to the lower part of the Abbott Formation in Illinois, as the associated coal floras show. The Abbott Formation is equivalent to the uppermost part of the Caseyville Formation and the lower part of the Tradewater Formation in western Kentucky and to the upper part of the Mansfield and essentially all of the Brazil Formation in Indiana.

Reynoldsburg Coal Member—The Reynoldsburg Coal Member of the Abbott Formation (Weller, 1940, p. 39), the lowermost named member in southern Illinois, is named for Reynoldsburg, Johnson County, and the type locality is north of Cedar Creek (W1/2 32, 11S-4E). The Reynoldsburg is well known only in a relatively small area in the central part of the southern Illinois outcrop belt, where the thickness of the coal is very irregular but is as much as 3 feet. It varies in character, apparently grading to a canneloid black shale near the type locality. The Reynoldsburg Coal has been mined locally in the type area. It is well exposed along Interstate 24 in the northernmost of a series of large highway cuts, which exposes all the Caseyville Formation and the lowermost part of the Abbott Formation. No coal at this position has been identified in western Illinois, but the No. 2 coal in western Kentucky is thought to be equivalent to the Reynoldsburg.

Grindstaff Sandstone Member—The Grindstaff Sandstone Member of the Abbott Formation (Butts, 1925, p. 44) is named for Grindstaff Hollow in Gallatin County, and outcrops along the hollow (NE cor. 28, 10S-8E) are the type section. The Grindstaff is similar in appearance and characteristics to the other two sandstones of the Abbott Formation in southern Illinois. It is best developed east of the Du Quoin Monocline. The Grindstaff is generally fine or medium grained, most of it is slightly micaceous, and it varies considerably in thickness up to 60 feet. It sometimes contains quartz granules and pebbles in the western part of the southern Illinois outcrop belt but generally fewer than occur in the underlying Caseyville sandstones. The sandstone is thickest and coarsest where it was deposited in local distributary or fluvial channels. It grades laterally into and overlies gray, silty or sandy shale. In a few places a very impure, sandy, clastic limestone or calcareous sandstone, formerly called the Boskydell Marine Zone or Boskydell Sandstone, is found at or near the position of the Grindstaff Sandstone in southwestern Illinois. The Grindstaff Sandstone is correlated with the Babylon Sandstone of western Illinois.

Babylon Sandstone Member—The Babylon Sandstone Member of the Abbott Formation (Wanless, 1931a, p. 189-190, 192-193), the lowest named member in western Illinois, is named for Babylon, Fulton County. The type locality is half a mile north of Babylon in the west bank of the Spoon River (NE NE 14, 7N-1E) (Wanless, 1957, p. 65, 205). The Babylon Sandstone is widely present in western Illinois and at its maximum is about 25 feet thick. In many places it is the lowest unit of the Pennsylvanian System and unconformably overlies Mississippian limestones. The sandstone is made up of relatively pure, subangular, medium to coarse quartz grains, most of which have been secondarily enlarged by quartz overgrowths that sparkle in sunlight (Wanless, 1957). The Babylon in western Illinois becomes thinner and sporadic in occurrence to the south. It is correlated with the Grindstaff Sandstone of southern Illinois.

Manley Coal Member—The Manley Coal Member of the Abbott Formation (Kosanke et al., 1960, p. 31) is named for Manley, Fulton County. It previously was called the Babylon Coal (Wanless, 1931a, p. 189-190, 192-193). It shares the type locality of the Babylon Sandstone Member (Wanless, 1957, p. 66, 205). The Manley Coal is widely distributed in western Illinois but occurs sporadically. It ranges up to 4 feet thick and has been mined in a few places. It varies from banded coal to cannel coal, and at one mine in Fulton County cannel coal 2.5-3 feet thick was once mined (Wanless, 1957). The Manley has not been identified in southern Illinois. It is correlated with the Shady Lane Coal Member of Indiana.

Willis Coal Member—The Willis Coal Member of the Abbott Formation (Butts, 1925, p. 62-63) is named for the Willis Mine in Gallatin County (SE SW 30, 10S-9E). The coal is present at widely scattered localities in the outcrop area in southern Illinois. It has been mined locally in southeastern Illinois, where it is 3-3.5 feet thick. In the type area the Willis is closely underlain by the Grindstaff Sandstone Member and is immediately overlain by about 40 feet of Finnie Sandstone. It is correlated with the Tarter Coal of western Illinois and the Lower Block Coal Member of Indiana.

Tarter Coal Member—The Tarter Coal Member of the Abbott Formation (Wanless, 1939, p. 15, 103) is named for Tarter Bridge over the Spoon River, Fulton County, and the type section consists of exposures near the bridge (SE 2, 5N-1E) (Wanless, 1956, p. 9; 1957, p. 67, 202). The Tarter Coal is thin and discontinuous throughout its outcrop area in western Illinois (Wanless, 1957), attaining a maximum thickness of slightly over 1 foot in many scattered outcrops. The interval from the Tarter Coal up to the Pope Creek Coal is usually only a few feet, and both coals are present in several outcrops. The Tarter is correlated with the Willis Coal of southern Illinois and the Lower Block Coal Member of Indiana.

Finnie Sandstone Member—The Finnie Sandstone Member of the Abbott Formation (Owen, 1856, No. 1 vertical section) is named for Finnie Bluff at the type locality, which is "along road for less than 2 miles north of Mulfordtown, Union County, Kentucky" (Glenn, 1912, p. 14). "Finnie" was adopted in Illinois to replace "Delwood Sandstone" (Kosanke et al., 1960, p. 31). The Finnie is widespread throughout much of southern Illinois east of the Du Quoin Monocline. Its bedding varies widely, as does its thickness (up to 60-70 feet). It is similar in appearance to other sandstones in the Abbott Formation and in a few localities contains scattered marine fossils. The distribution of the Finnie in the deeper part of the Illinois Basin has not been determined.

Delwood Coal Member—The Delwood Coal Member of the Abbott Formation (Weller, 1940, p. 40) is named for Delwood, Pope County, and the type locality consists of exposures near the village (NW NW 3, 11S-6E) (Wanless, 1956, p. 9). The Delwood Coal has been identified in several wide-

ly scattered outcrops in southern Illinois and in places is more than 3 feet thick. It is probably not continuous and locally may have been removed by channeling during development of a younger sandstone. Very little is known of the distribution of the Delwood in subsurface north of the outcrop belt. The name may have been applied to more than one coal and, in fact, recent palynological studies indicate the type Delwood may be equivalent to the Bidwell Coal Member of the lower part of the Spoon Formation. The Delwood has been correlated with the Pope Creek Coal of western Illinois, the Upper Block Coal Member of Indiana, and the No. 3 (Ice House) coal of western Kentucky.

Pope Creek Coal Member—The Pope Creek Coal Member of the Abbott Formation (Wanless, 1931a, p. 189-190, 192) is named for Pope Creek in Mercer County, and the type locality is along the creek (cen. 33, 14N-2W) (Wanless, 1929, p. 52; 1956, p. 9). The Pope Creek Coal is widespread in the western Illinois outcrop belt, where it is as much as 3 feet thick and averages about 1 foot (Wanless, 1957). The upper part of the coal is truncated in places by the Bernadotte Sandstone, but more commonly the coal is overlain by a gray shale several feet thick. The Pope Creek has been correlated with the Delwood Coal of southern Illinois, the Upper Block Coal Member of Indiana, and the No. 3 (Ice House) coal of western Kentucky.

Bernadotte Sandstone Member—The Bernadotte Sandstone Member (Savage, 1927, p. 307-316), which forms the top of the Abbott Formation in western Illinois, is named for the former town of Bernadotte, Fulton County, near the type locality (SW 19, 5N-2E) (Wanless, 1956, p. 9; 1957, p. 70-72, 103). The Bernadotte Sandstone is fairly extensive in western Illinois and attains thicknesses of 18 feet, though it commonly averages about 5 feet. It is very fine grained, only slightly micaceous, and the upper part is commonly cemented with silica. The Bernadotte differs from most Pennsylvanian sandstones in generally having a flat base and an uneven top, on the thicker parts of which overlying stratigraphic units tend to wedge out (Wanless, 1957). The Bernadotte is correlated with the Murray Bluff Sandstone of southern Illinois.

Murray Bluff Sandstone Member—The Murray Bluff Sandstone Member of the Abbott Formation (Weller, 1940, p. 40), the top member of the formation in southern Illinois, is named for the hill called Murray Bluff in Saline County, where the type section occurs (NE 35, 10S-5E). In the type section the sandstone is at least 60 feet thick and contains many liesegang rings (secondary iron-oxide diffusion banding). It is relatively thick in channel facies and thinner in nonchannel facies. The Murray Bluff has been identified at numerous localities throughout the outcrop area in southern Illinois, but its northward extent in the subsurface is generally not recognized. A sandstone occurs at this position in the areas where the Litchfield and Assumption Coals of the Spoon Formation are present. The Murray Bluff has been correlated with the Bernadotte Sandstone of western Illinois and the Aberdeen Sandstone Member of western Kentucky.

DESMOINESIAN SERIES

The Desmoinesian Series of the Pennsylvanian System (Keyes, 1893, p. 86-114) is named for the Des Moines River in Iowa, along which the strata of the series are exposed. No specific type section was designated. In Illinois the Desmoinesian includes all of the Spoon and Carbondale Formations of the Kewanee Group and the lower part of the Modesto Formation of the McLeansboro Group—up to the top of the Trivoli Sandstone Member (Willman et al., 1967) (fig. P-2). The Desmoinesian is the most widely developed series of the Pennsylvanian in the United States.

Fusulinids are abundant in many of the limestones in Illinois (Dunbar and Henbest, 1942), and the Desmoinesian is the *Fusulina* Zone. That genus is confined to the Desmoinesian Series, except for the one reported occurrence in Atokan rocks. Several other invertebrates, such as *Mesolobus*, *Chaetetes*, and *Prismopora*, are seldom found above the top of the Desmoinesian, and certain of their species are confined to this series. The exact upper boundary is difficult to determine in much of the Illinois Basin because an interval at the top of the Desmoinesian and the base of the Missourian is barren of fusulinids.

Floral Zones 9 (*Neuropteris rarinervis*) and 10 (*Neuropteris flexuosa* and *Pecopteris* spp.) of Read and Mamay (1964) are included in the Desmoinesian Series. In Illinois the series contains the thickest, most widespread coals, the spores of which are dominated by *Lycospora*. That genus suddenly disappears at the top of the Desmoinesian. *Thymospora pseudothiessenii*, which appears in the bottom third, also disappears at the top of the Desmoinesian. *Densosporites* occurs only in the lower half of the Desmoinesian, and *Schopfites* is diagnostic of approximately the middle third. There is a marked change in the spore flora at the Desmoinesian-Missourian boundary.

Kewanee Group

The Kewanee Group (Kosanke et al., 1960, p. 31) is named for Kewanee, Henry County, in western Illinois in the outcrop belt of its two formations—Spoon and Carbondale (fig. P-2). It includes strata previously classified as the Carbondale Formation or Group plus older and younger strata (P-5). The Kewanee Group is continuously recognized in all of the Illinois Basin within the confines of its outcrop limits. It normally lies above the Abbott Formation, but in northern and northeastern Illinois where the Abbott is missing it lies on rocks ranging in age from Valmeyeran (middle Mississippian) to Champlainian (middle Ordovician). It is overlain by the McLeansboro Group. The Kewanee Group contains the best developed cyclothems and more than 99 percent of the mapped coal reserves of the state (Cady et al., 1952). Lateral continuity of many of the lithologic units, especially the marine limestones, black fissile shales, coals, and underclays is remarkably extensive. The

Electronic Filing: Received, Clerk's Office 07/01/2024

limestones, generally less than 5 feet thick, were deposited during marine transgressions from the west and southwest. Along with marine shales they alternate with fluvial and deltaic sediments that include siltstones, silty shales, elongate "channel" sandstones, and coals. The limestones are usually gray and argillaceous, and they contain a diverse marine fauna dominated by brachiopods, gastropods, crinoids, pelecypods, and Foraminifera (including fusulinids). The sandstones are texturally and mineralogically less mature than those of the McCormick Group in that they contain much more clay matrix, mica flakes, and feldspar grains, and their sand grains are less rounded and not as well sorted.

Spoon Formation

The Spoon Formation of the Kewanee Group (Kosanke et al., 1960, p. 32, 45) is named for the Spoon River, Fulton County, about a quarter of a mile east of the type section, which is in a roadcut and a railroad cut (NE SE 22, 6N-1E). The formation consists of strata from the top of the Bernadotte Sandstone of western Illinois or the Murray Bluff Sandstone of southern Illinois to the base of the Colchester (No. 2) Coal (fig. P-2), rocks formerly included in the upper part of the Tradewater Group. The Spoon Formation is present throughout most of the area in which Pennsylvanian strata occur. It is as much as 350 feet thick in southern Illinois but ranges from a few feet to less than 100 feet in northern and western Illinois. The formation is characterized by less sandstone and more coal and limestone than the Abbott Formation below and by less limestone and coal than the Carbondale Formation above. Sandstones are well developed in both elongate and sheet facies but do not constitute as much of the total section as they do in the lower formations. The sandstones show the general upward increase in the amount of argillaceous matrix and mica flakes that began in the sandstones in the Abbott Formation, from which they differ only slightly. The formation contains the first widespread limestones and coals, but they are thinner than those in the younger Pennsylvanian of Illinois. The coals of the Spoon are thicker and more extensive than those of the lower formations. The Spoon Formation correlates with the upper part of the Tradewater Formation and the lower part of the Carbondale Formation in western Kentucky and the very uppermost part of the Brazil Formation, all the Staunton Formation, and the lower part of the Linton Formation in Indiana.

Rock Island (No. 1) Coal Member—The Rock Island (No. 1) Coal Member of the Spoon Formation is the basal named member of the formation in western Illinois. It was first called Coal Number 1 (Worthen, 1868, p. 6, 10, 11) because it was believed to be the oldest (the first deposited) minable coal in Fulton, Morgan, Scott, and Schuyler Counties. It is typically exposed in the Spoon River Bluff near Seville, Fulton County (Worthen, 1870, p. 194). This exposure was designated the type section (SW SW 23, 6N-1E) by Wanless (1957, p. 72, 201). As that coal was correlated with the coal mined at Rock Island (Worthen and Shaw, 1873, p. 221, 229-232), the name Rock Island (No. 1) Coal came into general use. In western Illinois the Rock Island (No. 1) Coal occurs only in widely scattered areas. It attains a maximum thickness of about 8 feet in belts trending east-west or northeast-southwest (Wanless, 1965, p. 27, 29-30; Searight and Smith, 1969, p. 13), in other places only a few inches to a foot or two of coal is present, and it is absent throughout broad areas. The Rock Island Coal is tentatively correlated with the Assumption and the Litchfield Coals of west-central Illinois. It has been correlated with the Murphysboro Coal (Wanless, 1957), but the floras indicate it is lower than the Murphysboro (Kosanke, 1950). It is correlated with the Minshall Coal Member of Indiana.

Litchfield Coal Member—The Litchfield Coal Member of the Spoon Formation (Kay, 1915, table 9 and footnote, p. 139) is named for Litchfield, Montgomery County, where the coal was mined at a depth of 684 feet in the Litchfield Collieries Company Mine No. 7, which is the type section (SE NE NE 32, 9N-5W). In the mine, the Litchfield Coal occurs about 150 feet below the Lowell Coal and is 2-7 feet thick. It is not widely recognized throughout southern Illinois but has been found in a few drill holes. The Litchfield Coal is probably equivalent to the lower bench of the Assumption Coal and to the Rock Island (No. 1) Coal.

Assumption Coal Member—The Assumption Coal Member of the Spoon Formation (Cady, 1935, p. 53) is named for Assumption, Christian County, where the coal was mined at a depth of 1002 feet in the long-abandoned Assumption Coal and Mining Company Mine, which is the type section (NE NW SE 2, 12N-1E). In the mine the coal was 3-4 feet thick and was commonly split into 2 benches. In part of the mine the coal was overlain by limestone correlated with the Seville Limestone, which overlies the Rock Island Coal. The two benches were within 2 feet of each other in some parts of the mine. Where the coal seam was more widely split, the limestone formed the roof of the lower bench, and the interval to the upper bench, as much as 25 feet, consisted of sandstone and carbonaceous shale. The lower bench is the Assumption Coal Member. The extent of the Assumption Coal has not been ascertained, but a coal at approximately this position has been encountered in a few borings scattered throughout the Illinois Basin. The lower of the two benches is tentatively correlated with the Litchfield Coal of southwestern Illinois and the Rock Island (No. 1) Coal of western Illinois.

Seville Limestone Member—The Seville Limestone Member of the Spoon Formation (Wanless, 1931a, p. 189, 192) is named for Seville, Fulton County, where the type locality is in the southwest bank of the Spoon River (SW SW 23, 6N-1E) (Wanless, 1956, p. 9; 1957, p. 72-73, 201). The Seville Limestone is dark gray and argillaceous, and it contains a well preserved and diverse marine fauna. It is sporadic in occurrence and varies in thickness. It is seldom more than 4 feet thick, but more than 30 feet has been reported near Cuba, Fulton County. In several quarries in Rock Island and Mercer Counties, thicknesses up to 16 feet occur. The thicker occurrences are in narrow belts believed to have been estuaries, and in those areas the underlying Rock Island (No. 1) Coal is also thicker than elsewhere. The Seville Limestone is correlated with the Curlew Limestone Member of western Kentucky, the Lower Mercer Limestone of Ohio and Pennsylvania, and the Verne Shaly Limestone Member of Michigan (Wanless, 1957, p. 73). The name "Seville" has also been applied to this limestone in Missouri and Oklahoma.

Curlew Limestone Member—The Curlew Limestone Member of the Spoon Formation (Owen, 1856, No. 1 vertical section) is named for Curlew, Union County, Kentucky, where the type locality is an exposure on Indian Hill (Glenn, 1912, p. 24). The Curlew is gray, fine-grained, locally cherty limestone that seldom is more than 4 feet thick. It contains an abundant open-marine fauna. It is widespread, though sporadic, in southern Illinois and western Kentucky. The Curlew is correlated with the Seville Limestone.

Hermon Coal Member—The Hermon Coal Member of the Spoon Formation (Kosanke et al., 1960, p. 33) is named for Hermon, Knox County. The unit formerly was called the Lower De Long Coal (Wanless, 1931a, p. 188-192). The type locality is along Brush Creek in Knox County, where the Hermon is the lowest of three thin coals (6, 8, 9N-2E) (Wanless, 1956, p. 9; 1957, p. 73-74). The Hermon Coal is found in many parts of western Illinois but is discontinuous. At most places it is represented by 2 inches or less of carbonaceous shale or bony coal. Near Canton in Fulton County, where it occurs locally over thick Rock Island Coal and thick Seville Limestone, the coal is as much as 4 feet thick. It is generally underlain by as much as 4 feet of gray underclay. No coal equivalent to the Hermon Coal has been recognized in southern Illinois.

Bidwell Coal Member—The Bidwell Coal Member of the Spoon Formation (Kosanke et al., 1960, p. 32, 65) is named for Bidwell School in Johnson County, which is near the type locality (NE SE SW 5, 11S-4E). The Bidwell Coal, although discontinuous, is more widespread than most of the coals in the lower part of the Spoon Formation in southern Illinois and is 4 feet thick in places, although generally thinner. It has been identified in only a few drill holes north of the outcrop belt. The Bidwell has not been recognized in western Illinois.

O'Nan Coal Member—The O'Nan Coal Member of the Spoon Formation (Kosanke et al., 1960, p. 32) is named for Dennis O'Nan Ditch, which flows across the tip of Indian Hill, Union County, Kentucky, the type locality (Glenn, 1912, p. 25). It previously was called the Curlew Coal (Owen, 1856, p. 47). The O'Nan Coal is generally thin, seldom over 1 foot thick in its scattered occurrences in southern Illinois. It is now believed to be equivalent to the Bidwell Coal.

New Burnside Coal Member—The New Burnside Coal Member of the Spoon Formation (Weller, 1940, p. 42) is named for New Burnside, Johnson County, which is near the type locality (SE SE SW 5, 11S-4E) (Kosanke et al., 1960, p. 32). The New Burnside Coal is well developed in scattered localities in southern Illinois and is as much as 5 feet thick where mined; however, in most of the area it is generally thinner. It occurs 15-25 feet above the Bidwell Coal. The New Burnside is correlated with the Brush Coal of western Illinois.

Brush Coal Member—The Brush Coal Member of the Spoon Formation (Kosanke et al., 1960, p. 33) is named for Brush Creek, Knox County, where it is the middle of three thin coals. It previously was called the Middle De Long Coal (Wanless, 1931a, p. 188-192). The type locality is along the creek (6, 8, 9N-2E) (Wanless, 1956, p. 9; 1957, p. 74-75). The Brush Coal, widely recognized in western Illinois, consists primarily of carbonaceous shale or bony coal only a few inches thick, which is generally overlain by the underclay of the De Long Coal and underlain by a very persistent, purplish gray underclay that is commonly 3-5 feet thick. The Brush Coal is correlated with the New Burnside Coal of southern Illinois.

Cheltenham Clay Member—The Cheltenham Clay Member of the Spoon Formation (Wheeler, 1896, p. 247; White, 1909, p. 293) is named for the Cheltenham district in the southern part of St. Louis, Missouri. In Illinois, the name is applied locally to a complex claystone member that results from the thinning out of many units and the merging of several underclay units. The stratigraphic interval occupied by this member varies. The youngest deposits are at or immediately below the underclay of the Colchester (No. 2) Coal and the oldest are near the base of the underclay below the Brush (New Burnside) Coal. The Cheltenham is developed primarily in northern, western, and southwestern Illinois, areas where the Pennsylvanian section below the Colchester Coal is relatively thin. The Cheltenham Clay Member in Illinois is considered to be part of the Desmoinesian Series, but in Missouri similar deposits (Cheltenham Formation) are considered part of the Atokan Series (Howe and Koenig, 1961).

Granger Sandstone Member—The Granger Sandstone Member of the Spoon Formation (Kosanke et al., 1960, p. 32) is named for Grangertown, near Indian Hill, Union County, Kentucky, the type locality (Glenn, 1912, p. 24-26). It was originally called the Curlew Sandstone (Owen, 1856, No. 1 vertical section). The Granger Sandstone is widespread in southern Illinois, occurring in channel and nonchannel facies and varying considerably in thickness and bedding characteristics. About 40 feet of Granger Sandstone is well exposed in the Creal Springs Quarry in Williamson County (25, 10S-3E). The sandstone is probably present in much of the deeper part of the Illinois Basin.

Murphysboro Coal Member—The Murphysboro Coal Member of the Spoon Formation (Worthen, 1868, p. 11-12) is named for Murphysboro, Jackson County, where the type locality is in mines (SE 9, 9S-2W) (Wanless, 1956, p. 9). The Murphysboro Coal is well developed only in Jackson County and western Williamson County, where it has been reported to be locally more than 7 feet thick. In places it occurs in several benches separated by shale (Shaw and Savage, 1912). Mining started in this area around 1810, and the coal was sent to New Orleans in flatboats via the Big Muddy and Mississippi Rivers. Where the Murphysboro Coal is thick it is overlain by 40 or more feet of gray silty shale. In these areas the coal contains much less sulfur than elsewhere and resembles the Herrin (No. 6) and Harrisburg (No. 5) Coals, which also have low-sulfur contents where they have thick roof shales. Where relatively thin, the Murphysboro Coal contains much more sulfur, chiefly in the mineral pyrite. In early reports the Murphysboro Coal was correlated with the Colchester (No. 2) Coal, but its position was later found to be lower (Wanless and Weller, 1932), and it is now known to be between the No. 1 and No. 2 Coals.

Creal Springs Limestone Member—The Creal Springs Limestone Member of the Spoon Formation (Kosanke et al., 1960, p. 32, 64, 65) is named for Creal Springs, Williamson County. The type section consists of exposures in the sandstone quarry east of Creal Springs (NE SE SE 25, 10S-3E). The Creal Springs Limestone is gray, argillaceous, and in places cherty. It is seldom over 2 feet thick and contains an open-marine fauna. In the type area the Creal Springs lies on the Granger Sandstone, but throughout much of its extent it is separated from the underlying Murphysboro Coal by several feet of gray shale. The Creal Springs is lenticular and occurs sporadically in a large part of southern Illinois. In some places it was once correlated with the Curlew Limestone, but the fusulinids it contains indicate it is younger than the Curlew (Thompson et al., 1959).

Mt. Rorah Coal Member—The Mt. Rorah Coal Member of the Spoon Formation (Kosanke et al., 1960, p. 33) is named for Mt. Rorah Church, which is about 2 miles north of the type locality (SE 25, 10S-4E; erroneously listed as section 35 in Wanless, 1956, p. 9, and Kosanke et al., 1960, p. 45). It previously was called the Bald Hill Coal (Cady, 1926, p. 259-260). The Mt. Rorah Coal occurs sporadically in a large part of southern Illinois, but it is seldom over 2 feet thick, generally no more than a few inches. It is correlated with the De Long Coal of western Illinois

De Long Coal Member—The De Long Coal Member of the Spoon Formation (Wanless, 1931a, p. 188-192), named for De Long, Knox County, is the uppermost of three thin coals that crop out about 1 1/2 miles southwest of De Long along Brush Creek, the type locality (6, 8, 9N-2E) (Wanless, 1956, p. 9; 1957, p. 188-192). It was called the Upper De Long Coal until "De Long," which had been applied to three coals, was restricted to the uppermost coal (Kosanke et al., 1960, p. 33). The De Long Coal is widespread in western Illinois but is not known to be more than a few inches thick. It

Electronic Filing: Received, Clerk's Office 07/01/2024

is commonly made up of two thin coal seams separated by as much as 2 feet of claystone. The coal is separated from the overlying Seahorne Limestone by soft, poorly laminated shale 1-15 feet thick, and from the underlying Brush Coal by 1-3.5 feet of claystone and, commonly, a few inches of soft, light gray shale immediately over the Brush Coal. The De Long Coal is correlated with the Mt. Rorah Coal of southern Illinois.

Wise Ridge Coal Member—The Wise Ridge Coal Member of the Spoon Formation (Kosanke et al., 1960, p. 33) is named for Wise Ridge, a hill about 3 miles west of the type section—a roadcut in Stonefort, Williamson County (NE SE 25, 10S-4E). It previously was called the Stonefort Coal (Wanless, 1939, p. 30, 103). The coal is lenticular but is widely present in southern Illinois. It is generally less than 3 feet thick and is very thin at some places. It is commonly separated from the Stonefort Limestone (above) by 1-2 feet of black fissile shale.

Stonefort Limestone Member—The Stonefort Limestone Member of the Spoon Formation (Henbest, 1928, p. 70-71) is named for Stonefort, Williamson County. The type locality consists of a roadcut and near-by ravines (NE SE 25, 10S-4E), a correction of the location given by Wanless (1956, p. 9) (Kosanke et al., 1960, p. 33). The Stonefort is a gray, fine-grained, marine limestone, seldom over 3 feet thick, that extends throughout the greater part of southern Illinois. It has been identified on geophysical logs of oil tests in much of the southern part of the Illinois Basin.

Vergennes Sandstone Member—The Vergennes Sandstone Member of the Spoon Formation (Shaw and Savage, 1912, p. 7) is named for Vergennes, Jackson County, and the type locality is near the town (N½ 11, 7S-3W). The outcrops indicate that the Vergennes is a channel sandstone at least 30 feet thick, but units above and below it are poorly exposed and its stratigraphic position is in question. The name Vergennes has not been extended beyond the type area, and recent studies by T. K. Searight suggest that the Vergennes may be equivalent to the Palzo Sandstone.

Seahorne Limestone Member—The Seahorne Limestone Member of the Spoon Formation (Wanless, 1931a, p. 191) is named for Seahorne Branch in Fulton County, and the type section consists of exposures along that stream (S½ SE 5, 3N-3E) (Wanless, 1956, p. 9; 1957, p. 76, 200). The Seahorne is best known in western Illinois, where it varies from limestone nodules in claystone to a solid ledge of limestone more than 6 feet thick. It is usually light gray. In some places it is conglomeratic or brecciated and consists of dark gray fragments that contain abundant brachiopods embedded in a light gray matrix that is dominated by a diverse gastropod fauna. Another fauna, *Spirorbis* and ostracodes, is found at places and is generally considered nonmarine. The Seahorne is not persistent but occurs at many places in Illinois and adjacent states. It is the caprock of the Tebo coal in Missouri (Wanless, 1957).

Davis Coal Member—The Davis Coal Member of the Spoon Formation (Owen, 1856, p. 41) is named for the Davis Mine, located half a mile east of Dekoven Station, Union County, Kentucky (Lee, 1916, p. 19, 30). It has also been called the No. 6 coal in western Kentucky. In Illinois the Davis Coal has about the same distribution as the De Koven Coal, which it underlies by as much as 30-40 feet. The Davis averages about 4 feet thick across much of southern Illinois, where it has been mined by surface methods (Butts, 1925). To the north and west the coal, as a rule, is thinner. It is correlated with the Wiley Coal of western Illinois.

Wiley Coal Member—The Wiley Coal Member of the Spoon Formation (Wanless, 1931a, p. 191) is named for Wiley School, Fulton County, near the type section (SW NW 16, 7N-2E) (Wanless, 1956, p. 9; 1957, p. 79, 206). The Wiley is a widespread coal in western Illinois. It is seldom more than 2 feet thick, although local occurrences of up to 3 feet are known. It is correlative with the Davis Coal of southern Illinois and western Kentucky. It may be equivalent to the Mineral coal of Missouri and Kansas (Wanless, 1957).

De Koven Coal Member—The De Koven Coal Member of the Spoon Formation (Lee, 1916, p. 30, 31) is named for Dekoven Station, Union County, Kentucky, near which it is well exposed. The De Koven Coal, also called the No. 7 coal in western Kentucky, occurs from a few to about 40 feet above the Davis Coal and is widespread throughout Williamson, Saline, and Gallatin Counties, averaging about 3 feet thick (Butts, 1925). It is also present to the north in the deeper part of the Illinois Basin, but there it is generally thinner. In Williamson County the De Koven Coal is split by a few feet of dark shale. The De Koven is correlated with the Greenbush Coal of western Illinois.

Greenbush Coal Member—The Greenbush Coal Member of the Spoon Formation (Wanless, 1931a, p. 191) is named for Greenbush Township, Warren County, the type locality (E½ 24, 8N-1W) (Wanless, 1956, p. 10; 1957, p. 81, 205). The Greenbush Coal is seldom more than a few inches thick, and it grades into a thin carbonaceous shale in some localities. It is correlated with the De Koven Coal of southern Illinois and western Kentucky.

Seelyville Coal Member—The Seelyville Coal Member of the Spoon Formation (Kosanke et al., 1960, p. 33; incorrectly spelled "Seeleyville") is named for Seelyville, Vigo County, Indiana, where the type locality is in mines (12N-7 and 8W). It was originally named Indiana Coal III (Ashley, 1899, p. 106-107) but informally called Seelyville in Indiana. In Illinois the Seelyville is known primarily in Edgar, Clark, and Crawford Counties, where it as much as 6 feet thick. It occurs locally in southern Illinois between the De Koven and Colchester Coals. In Indiana it is now called Seelyville Coal Member (III).

Palzo Sandstone Member—The Palzo Sandstone Member of the Spoon Formation (Cady, 1942, p. 9; Weller et al., 1942a, p. 10, footnote) is named for Palzo, Williamson County, and the type locality consists of exposures near the village (SE 16, 10S-4E) (Wanless, 1956, p. 10). The Palzo Sandstone is well developed throughout the state in both channel and nonchannel facies and is locally more than 50 feet thick. It is similar in appearance to other sandstones in the Spoon Formation in southern Illinois and is correlated with the Isabel Sandstone of western Illinois and the Sebree Sandstone Member of western Kentucky.

Isabel Sandstone Member—The Isabel Sandstone Member of the Spoon Formation (Wanless, 1931a, p. 192) is named for Isabel Township, Fulton County, which includes the type section (NW NE 16, 4N-3E) (Wanless, 1956, p. 10; 1957, p. 83, 199). The name is used in western Illinois for a sandstone that generally is relatively thin, fine-grained, micaceous, feldspathic, and cemented with various amounts of calcium carbonate. The Isabel and younger sandstones differ from the stratigraphically lower sandstones in western Illinois in that they are less quartzose, contain much more mica and feldspar, are not as well sorted, and do not show the abundant quartz overgrowths that produce the "sparkling sandstones." A sandstone is present at this position essentially throughout Illinois. In southern Illinois it is called the Palzo Sandstone.

Abingdon Coal Member—The Abingdon Coal Member of the Spoon Formation (Culver, 1925, p. 75) is named for Abingdon, Knox County, near the type locality (cen. 6, 9N-2E) (Weller et al., 1942b, p. 1589). The Abingdon is recognized only in western Illinois, where it varies in thickness but only locally exceeds 2 feet. It is absent from extensive areas. Although the Abingdon is not definitely recognized in other parts of the state, coals locally present near this position in northern and southern Illinois may be equivalent to the Abingdon Coal.

Browning Sandstone Member—The Browning Sandstone Member of the Spoon Formation, the youngest named member (Wanless, 1939, p. 14, 78), is named for Browning

Township, Schuyler County, which includes the type locality (18, 2N-1E) (Wanless, 1956, p. 10; 1957, p. 86). The Browning Sandstone has been recognized only in western Illinois (Wanless, 1957), where it occurs in both channel and sheet facies and ranges from less than 3 to as much as 80 feet thick. In some places the channel facies is almost entirely sandstone that grades upward into shale, but in other places most of it is silty shale and siltstone.

Carbondale Formation

The Carbondale Formation of the Kewanee Group (Shaw and Savage, 1912, p. 6; Wanless, 1939, p. 79; Willman and Payne, 1942, p. 86-87; Kosanke et al., 1960, p. 34) is named for Carbondale, Jackson County, which lies near the outcrop belt of these rocks. A type section consisting of three outcrops was established in Fulton County, western Illinois (SE NE 1, 7N-4E; NW NE NW 20, 8N-3E; and SW cor. 21, 8N-3E) by Kosanke et al. (1960, p. 34, 46). The Carbondale includes strata from the base of the Colchester (No. 2) Coal Member to the top of the Danville (No. 7) Coal Member (fig. P-2). Shaw and Savage included in the Carbondale the strata from the base of the Murphysboro Coal to the top of the Herrin (No. 6) Coal. The Murphysboro was thought to be equivalent to the Colchester (No. 2) Coal of western Illinois, and the intent was to make the Colchester Coal the base of the formation. Wanless (1939) redefined the Carbondale as a group (fig. P-5), and Willman and Payne (1942) included strata from the base of the Palzo Sandstone to the base of the Anvil Rock Sandstone in the Carbondale Group. The Carbondale Formation consists of a large number of named members, many of which possess remarkable lateral persistence in thickness and lithologic character. In the sandstones and gray silty shales, however, rapid lateral changes are common and are primarily responsible for local and regional changes in thickness. The formation varies from less than 150 feet in western and northeastern Illinois to more than 400 feet near its outcrop belt in southern Illinois (fig. P-11). The Carbondale sandstones occur in elongate, channel facies up to about 100 feet thick and also in thinner sheets. Most of the sandstones are subgraywackes and are more argillaceous than older Pennsylvanian sandstones, although only slightly more so than sandstones of the Spoon Formation. Gray shales are the most abundant type of sediment in Carbondale rocks. Some contain only marine fossils and others only plant fossils. Most of the thicker gray shales probably are either delta front or prodelta deposits. Sideritic nodules and bands are common, especially in the lower parts of the shales. The widespread limestones (fig. P-3B) are gray to dark gray, argillaceous, and normally fossiliferous. Associated with the marine limestones are extensive black fissile shales (fig. P-3C) that are generally less than 2 feet thick and contain marine fossils. Light gray nodular limestones, commonly without fossils, occur in the bottom part of the widespread underclays. The Carbondale Formation contains the principal economic coals of Illinois, the Herrin (No. 6) (fig. P-13), the Springfield-Harrisburg (No. 5) (fig. P-12), the Colchester (No. 2), and the Danville (No. 7) Coal Members, in order of importance as reserves. The Carbondale Formation correlates with the upper portion of the Carbondale Formation and approximately the lower 50 feet of the Sturgis Formation in western Kentucky, where the boundaries are the base of the Kentucky No. 6 coal and the top of the Kentucky No. 11 coal. Essentially the same interval is called the Carbondale Group in Indiana.

Colchester (No. 2) Coal Member—The Colchester (No. 2) Coal Member of the Carbondale Formation, the lowest member, was designated No. 2 by Worthen (1866, p. 59) for the coal in a mine shaft at Highland, Madison County. Worthen also used the name Colchester for the same coal at Colchester, McDonough County (1868, p. 11), and also (1870, p. 96-97) for an exposure 1.5 miles west of Vermont, Fulton County. Wanless (1956, p. 10) designated exposures near Colchester as the type section (12, 13, 5N-4W). The coal has also been called the La Salle (No. 2) Coal or the "Third Vein" coal in northern Illinois. The Colchester Coal is a normal, bright-banded coal (fig. P-3C). It is very extensive in Illinois and is thought to be one of the most widespread coals in the United States. It is generally thin, varying from a fraction of an inch to 18 inches in southern, central, and eastern Illinois, and is rather uniformly 2-3.5 feet thick throughout much of northern and western Illinois, where it has been extensively mined. It is overlain directly by either the black Mecca Quarry Shale Member, or, in parts of western and most of northern Illinois, by the gray Francis Creek Shale Member. It is underlain by a well developed underclay. It is correlated with the Croweburg coal of Missouri and Kansas, the Schultztown of western Kentucky, the Broken Arrow or Croweburg of Oklahoma, the Whitebreast of Iowa, the Colchester Coal Member (IIIa) of Indiana, and tentatively with the Lower Kittanning Coal of the Appalachian field (Wanless, 1957).

Cardiff Coal Member—The Cardiff Coal Member of the Carbondale Formation (Cady, 1915) is named for Cardiff, Livingston County, and the type locality is in mines at Cardiff (22, 23, 30N-8E). The name was not in general use until re-introduced by Peppers (1970). The Cardiff Coal is known only in northeastern Livingston, southeastern Grundy, and western Kankakee Counties, where it occurs in channels trending northeast-southwest eroded in gray shale. It generally is not more than 10 feet above the Colchester (No. 2) Coal. At a few localities the Cardiff directly overlies the Colchester Coal. The Cardiff Coal is highly lenticular and was reported in one mine to be 12 feet thick. It commonly is in more than one major bench, the benches separated by gray shale. Peppers (1970) described the flora and concluded that the Cardiff Coal is a little older than the Lowell Coal.

Francis Creek Shale Member—The Francis Creek Shale Member of the Carbondale Formation (Savage, 1927, p. 309) is named for Francis Creek in Fulton County and the type locality is along the creek (NE SW 22, 5N-1E) (Wanless, 1929, p. 89; 1956, p. 10; 1957, p. 88, 203). The shale is medium gray, silty, and more than 80 feet thick in northeastern Illinois. It forms a large clastic wedge that extends across the northern part of the area of Pennsylvanian rocks and thins out to the west and south (Smith, 1970). It has not been recognized in southern Illinois. The shale is best known for the famous Mazon Creek sideritic concretions that are found in the Kankakee-Will-Grundy Counties area and have yielded what is probably the best known Pennsylvanian flora in the United States (Noé, 1925). In Will County and at one place in Fulton County, concretions in the shale have a diverse fauna (Johnson and Richardson, 1970). The upper part of the Francis Creek commonly contains a few sandstone beds, probably equivalent to the Jake Creek Sandstone.

Jake Creek Sandstone Member—The Jake Creek Sandstone Member of the Carbondale Formation (Wanless, 1957, p. 85, 89, 204) is named for Jake Creek in Fulton County, and the type section is along the upper part of the creek (NE 13, 4N-1E). The Jake Creek is recognized only in western Illinois, where it attains a maximum thickness of 18 feet along a north-south belt about 1 mile wide and appears to be on top

Electronic Filing: Received, Clerk's Office 07/01/2024

of the Francis Creek Shale. It may correlate with thin sandstones in the upper part of the Francis Creek Shale in other parts of the state.

Mecca Quarry Shale Member—The Mecca Quarry Shale Member of the Carbondale Formation (Zangerl and Richardson, 1963, p. 25) is named for Mecca, Parke County, Indiana, where the type section is in a small quarry that was excavated for study of the shale (SW NE 29, 15N-8W). The Mecca Quarry Shale is a hard, black fissile shale that locally is as much as 4 feet thick but more normally is 1-2 feet thick. It contains a varied marine fauna dominated by nektonic and planktonic forms. Large limestone concretions and small phosphatic lenses and nodules are common locally (fig. P-3C). The unit is very extensive in Illinois and adjacent states. It lies immediately above the Colchester (No. 2) Coal in much of southern and eastern Illinois and above the Francis Creek Shale in much of western and northern Illinois. Where the Francis Creek is more than about 30 feet thick, the Mecca Quarry is absent. The Mecca Quarry is generally overlain by the Oak Grove Limestone.

Oak Grove Limestone Member—The Oak Grove Limestone Member of the Carbondale Formation, originally called the Oak Grove beds (Wanless, 1931a, p. 184, 187, 192), is named for Oak Grove School in Fulton County, and the type section is in a ravine just north of the school (SW SE 6, 5N-3E) (Wanless, 1956, p. 10; 1957, p. 91, 197). In western and northern Illinois the Oak Grove consists of a remarkably persistent sequence of thin, lithologically and paleontologically distinctive limestone beds. Most of them are only a few inches thick, but some are a few feet thick. They are interbedded with dark gray and black shale beds that also have characteristic properties (Wanless, 1957, p. 91-94). The total thickness of the Oak Grove seldom exceeds 15 feet. Limestone units are less abundant in the Oak Grove in southern Illinois. The Lowell and Shawneetown Coals appear to occur within strata equivalent to the Oak Grove. Limestones equivalent to the Oak Grove are present in western Indiana, southern Iowa, and western Missouri.

Lowell Coal Member—The Lowell Coal Member of the Carbondale Formation (Willman and Payne, 1942, p. 102-105) is named for Lowell, La Salle County, where the coal is 10 inches thick in the type section, an exposure on the Vermilion River (SE SW 8, 32N-2E). It is a bright-banded, rather shaly coal underlain by a silty to sandy underclay and overlain by several feet of gray shale that contains two limestone beds, which are equivalent to upper units of the Oak Grove Limestone. The underclay overlies a siltstone containing plant root impressions, which in turn is underlain by gray shale containing additional limestone units equivalent to the Oak Grove Limestone. The Lowell Coal is present in northern Illinois and in the southern part of western Illinois. It is equivalent to the Shawneetown Coal in southwestern, southern, and eastern Illinois.

Shawneetown Coal Member—The Shawneetown Coal Member of the Carbondale Formation (Kosanke et al., 1960, p. 34-35) is named for Shawneetown, Gallatin County, where the type section is at a depth of 482.6 feet (erroneously given originally as 543.8 feet) in Union Colliery Company drill hole 28 (NW SW NW 23, 9S-9E) (Peppers, 1970, p. 43). It is the upper of two coals in southeastern Illinois lying between the Colchester (No. 2) and Summum (No. 4) Coals that had previously been called Coal 2A. The Shawneetown Coal is persistent in southern and eastern Illinois, but is known to crop out only in a strip mine near Mitchellsville, Saline County. It normally is thin, but in a few scattered drill holes it has been reported to be as much as 8 feet thick. It is overlain by dark shale and underlain by underclay. It is correlated with the Lowell Coal of northern and western Illinois and with the Survant Coal Member (IV) in eastern Indiana.

Purington Shale Member—The Purington Shale Member of the Carbondale Formation (Wanless, 1931a, p. 184, 188, 192) is named for the Purington Brick Company pit at East Galesburg, Knox County, which exposes the type section (SW 17, 11N-2E) (Wanless, 1956, p. 10). The Purington is a widespread gray shale that overlies the Oak Grove Limestone and attains a maximum thickness of about 50 feet in western and northern Illinois. It commonly contains marine fossils and sideritic concretions in the bottom part and becomes silty and sandy toward the top.

Pleasantview Sandstone Member—The Pleasantview Sandstone Member of the Carbondale Formation (Wanless, 1929, p. 90) is named for Pleasantview (now Pleasant View), Schuyler County, and the type locality is along Mill Creek (31, 2N-1E) (Wanless, 1956, p. 10; 1957, p. 190). The sandstone occurs as sheet facies 20 feet or less thick and as channel facies as much as 80 feet thick. In the channel facies the sandstone cuts through underlying strata down to, and locally through, the Colchester (No. 2) Coal (Ekblaw, 1931; Rusnak, 1957). The sandstone is best developed in western Illinois, but a sandstone commonly present a short distance below the Summum (No. 4) Coal throughout the Illinois Basin is probably equivalent to the Pleasantview. It is generally overlain by several feet of shale, which separates it from the underclay of the Summum Coal.

Kerton Creek Coal Member—The Kerton Creek Coal Member of the Carbondale Formation (Ekblaw, 1931, p. 391) is named for Kerton Creek in Fulton County, along which the type section is exposed (NE NE 15, 3N-2E) (Wanless, 1956, p. 10; 1957, p. 98, 189). This coal is recognized only in Fulton County, where it occurs in channels that had been only partially filled with the underlying Pleasantview Sandstone. The coal is up to 5 feet thick and is either canneloid or quite high in ash. The Summum (No. 4) Coal, which also thickens in the same unfilled channels, overlies the Kerton Creek by only a few feet. The Kerton Creek does not have an underclay but rests directly on the Pleasantview Sandstone. It is believed to correlate with the Roodhouse Coal of Greene County.

Roodhouse Coal Member—The Roodhouse Coal Member of the Carbondale Formation (Siever, *in* Wanless, 1956, correlation chart, pl. 1) is named for Roodhouse, Greene County, near the type section (NW 21, 12N-11W) (Kosanke et al., 1960, p. 35, 47). The coal is canneloid and, like the Kerton Creek Coal of southern Fulton County, occurs immediately above a channel facies of the Pleasantview Sandstone, apparently in channels that were not completely filled by the sandstone (Wanless, 1957, p. 98). The coal is as much as 5 feet thick near the center of the channels but is not present outside them. It directly overlies the Pleasantview Sandstone, without an underclay. It probably correlates with the Kerton Creek Coal in Fulton County.

Breezy Hill Limestone Member—The Breezy Hill Limestone Member of the Carbondale Formation (Pierce and Courtier, 1937, p. 17) is named for Breezy Hill, Crawford County, Kansas, where the type section is exposed. The Breezy Hill Limestone occurs in the lower part of the underclay of the Summum (No. 4) Coal in western and northern Illinois (Inden, 1968; Nance, 1970). The member is widespread, though sporadic. It occurs either as an irregular, silty limestone, rarely over 1 foot thick, or as nodular masses in claystone. The only fossils found in it in western Illinois are micritic patches and filaments, probably algal. This limestone is interpreted as fresh-water in Illinois and open-marine to the west in Kansas and Oklahoma, where it is several feet thick and contains a varied marine fauna. In Missouri it occurs at the base of the underclay of the Mulky coal (Inden, 1968; Nance, 1970).

Summum (No. 4) Coal Member—The Summum (No. 4) Coal Member of the Carbondale Formation (Wanless, 1931a, p. 182, 192) is named for Summum, Fulton County, near the type locality (NE 3, 3N-2E) (Wanless, 1956, p. 10; 1957, p. 204). The term "No. 4" was first used by Lesquereaux (1866, p. 213) for this coal near Shawneetown, Gallatin County. It was also applied incorrectly by Worthen (1870) to the Springfield (No. 5) Coal in parts of Fulton County. The coal, or the recognized position of the coal, is one of the

Electronic Filing: Received, Clerk's Office 07/01/2024

most widespread stratigraphic markers in the state, but it is generally thin and has been mined only locally in Grundy, Kankakee, Fulton, and Saline Counties. It normally is overlain by the black Excello Shale and overlies an underclay. It is correlated with the Mulky coal of Missouri and Kansas, the Houchin Creek Coal Member (IVa) in Indiana, and the No. 8b coal in western Kentucky.

Excello Shale Member—The Excello Shale Member of the Carbondale Formation (Searight et al., 1953) is named for Excello, Macon County, Missouri. In Illinois, the Excello is composed of black fissile shale that is generally 1-3 feet thick and similar in character to the member in Missouri (Nance, 1970, p. 77). Large black limestone concretions commonly occur in the lower part. It generally directly underlies the Hanover Limestone, but in some places in western Illinois a lighter colored shale a few feet thick intervenes. The Excello immediately overlies the Summum (No. 4) Coal, except locally in northern Illinois where a few feet of gray shale separates them.

Hanover Limestone Member—The Hanover Limestone Member of the Carbondale Formation (Wanless, *in* Lamar et al., 1934, p. 84; 1957, p. 101) is named for Hanover School, Greene County, near the type locality (NE SW 27, 10N-11W) (Wanless, 1956, p. 10; 1957, p. 101). The Hanover is a thin marine limestone that is seldom more than 4 feet thick and in places is represented only by nodules of limestone or a thin concentration of marine fossils in which brachiopods are dominant. It is a persistent bed of gray, argillaceous, brecciated or nodular limestone in most of western and northern Illinois, where it overlies the black Excello Shale. It is poorly developed in southern Illinois. The Hanover is one of the most widespread Pennsylvanian limestones in the central United States and is equivalent to the Blackjack Creek Limestone of Kansas, Oklahoma, and Missouri (Wanless, 1957, p. 101).

Covel Conglomerate Member—The Covel Conglomerate Member of the Carbondale Formation (Willman, 1939, p. 174-176) is named for Covel Creek in La Salle County, and the type section is along the creek near its mouth (SE SW 26, 33N-3E) (Willman and Payne, 1942, p. 116; Wanless, 1956, p. 10). This unit is remarkably persistent in northern Illinois and is locally present in western and eastern Illinois. It is composed of rounded, dark gray to black, phosphatic limestone pebbles and water-worn marine fossils in a matrix of lighter gray limestone or of pyrite. In many places the member is covered with laminated algal growths. The Covel is generally 1-3 inches thick and is an easily recognized stratigraphic marker. It is also present in southern Iowa and western Indiana (Wanless, 1957).

Springfield and Harrisburg (No. 5) Coal Members—The Springfield (No. 5) Coal Member and the Harrisburg (No. 5) Coal Member of the Carbondale Formation are the same unit, but separate names are retained because of long-established usage—"Springfield" in central, northern, and western Illinois and "Harrisburg" in southern and eastern Illinois. The term "No. 5" was first applied to this coal by Worthen (1870, p. 93) in his description of the geology of Fulton County. It was later applied to the coal mined in the Springfield, Sangamon County, district (Shaw and Savage, 1913, p. 3), and underground exposures in coal mines were made the type section (16, 16N-4W) (Wanless, 1956, p. 10). The Harrisburg (No. 5) Coal Member (Shaw and Savage, 1912, p. 7) is named for Harrisburg, Saline County, where it is mined. The No. 5 Coal is second only to the Herrin (No. 6) Coal in commercial importance in Illinois. It is commonly 4-8 feet thick (fig. P-12). In southwestern Illinois it has been strip mined in a few pits where the Herrin is the principal coal. The coal is absent along the northern margin of the Pennsylvanian rocks. It is normally overlain by a black fissile shale, but in southeastern Illinois, in a belt several miles wide that trends southwestward, the coal is thick and it is overlain by the gray silty Dykersburg Shale. In that belt the coal is more commonly split by shale partings, and contains less pyrite than where it is overlain by the black fissile shale (Hopkins, 1968). The No. 5 Coal is the most important coal in Indiana, where it is now called the Springfield Coal Member (V), and in western Kentucky, where it is called the No. 9 (Mulford) coal. It is correlated with the Summit coal in Missouri.

Dykersburg Shale Member—The Dykersburg Shale Member of the Carbondale Formation (Hopkins, 1968, p. 4) is named for Dykersburg (called Absher on some maps), Williamson County, near which the type section is in the highwall of an abandoned coal strip pit (SE SE NE 34, 9S-4E). The Dykersburg is confined to a belt 3-15 miles wide that extends southwestward from Wabash County to the outcrop in Saline County. Most of it is gray silty shale containing some sandstone, particularly one major channel sandstone that replaces the Harrisburg Coal along a narrow band. The Dykersburg is as much as 100 feet thick in places. Where overlain by the Dykersburg Shale, the Harrisburg Coal is thicker, is commonly characterized by several shale splits, and contains much less sulfur (less pyrite) than in areas where it is overlain by black fissile shale or the St. David Limestone. The Dykersburg is also well developed in an adjacent area in western Indiana.

St. David Limestone Member—The St. David Limestone Member of the Carbondale Formation (Savage, 1927, p. 309) is named for St. David, Fulton County, and the type section consists of outcrops near the village (SE SE 17, 6N-4E) (Wanless, 1956, p. 10; 1957, p. 105, 197). The St. David is a thin, dark gray, argillaceous limestone containing an abundant open-marine fauna dominated by brachiopods; it also contains a few fusulinids. It is almost invariably present where the Springfield-Harrisburg (No. 5) Coal occurs, although the limestone and coal are generally separated by 1-3 feet of black fissile shale. The St. David is widespread in western Illinois, where its thickness is generally less than 1 foot but locally reaches 2 feet. In eastern and southwestern Illinois also it is persistent and locally is 3-4 feet thick. In southeastern Illinois and western Kentucky, it is continuous but is commonly no more than a few inches of very fossiliferous calcareous shale or impure limestone. The underlying black fissile shale is widely characterized by an abundance of *Dunbarella rectilaterarius* (fig. P-6) in its lower few inches. The St. David is usually absent where the gray Dykersburg Shale, which underlies it in places, is more than 25 or 30 feet thick.

Canton Shale Member—The Canton Shale Member of the Carbondale Formation (Savage, 1921a, p. 240-241) is named for Canton, Fulton County, and the type section consists of outcrops along Big Creek (cen. 9, 6N-4E). The Canton is a gray, rather uniform shale that tends to be decidedly silty in its upper part. In western and northern Illinois, where it is primarily recognized and is as much as 50 feet thick, the lower few feet is dark gray and contains a varied marine fauna and several layers of fossiliferous, calcareous concretions. In northern Illinois a 4-6 inch bed of canneloid coal occurs locally about 10 feet above the base of the Canton. In central and western Illinois, from south of Springfield to the vicinity of Du Quoin in Perry County, the interval between the Herrin (No. 6) and Springfield-Harrisburg (No. 5) Coals thins, and the Canton Shale is only a foot or so thick or is absent. In southern Illinois the shale above the St. David Limestone and the shale either immediately or a few feet above the Briar Hill Coal may be in part equivalent to the Canton.

Briar Hill (No. 5A) Coal Member—The Briar Hill (No. 5A) Coal Member of the Carbondale Formation (Glenn, 1912, p. 38) is named for Briar Hill, a hill near Dekoven Station, Union County, Kentucky. The name was adopted in Illinois (Cady, 1919a, p. 20; 1926, p. 255), and a locality in Saline County (9S-7E) was designated as representative for Illinois (Wanless, 1956, p. 10). In Kentucky, this coal is now referred to as the No. 10 coal. In Illinois, the Briar Hill is fairly continuous in southeastern Illinois and has been recognized as far as Clark County on the northeast and Mt. Vernon on the northwest. It is generally thin and has been mined only on a small scale in the state. The coal is overlain by a dark

Electronic Filing: Received, Clerk's Office 07/01/2024

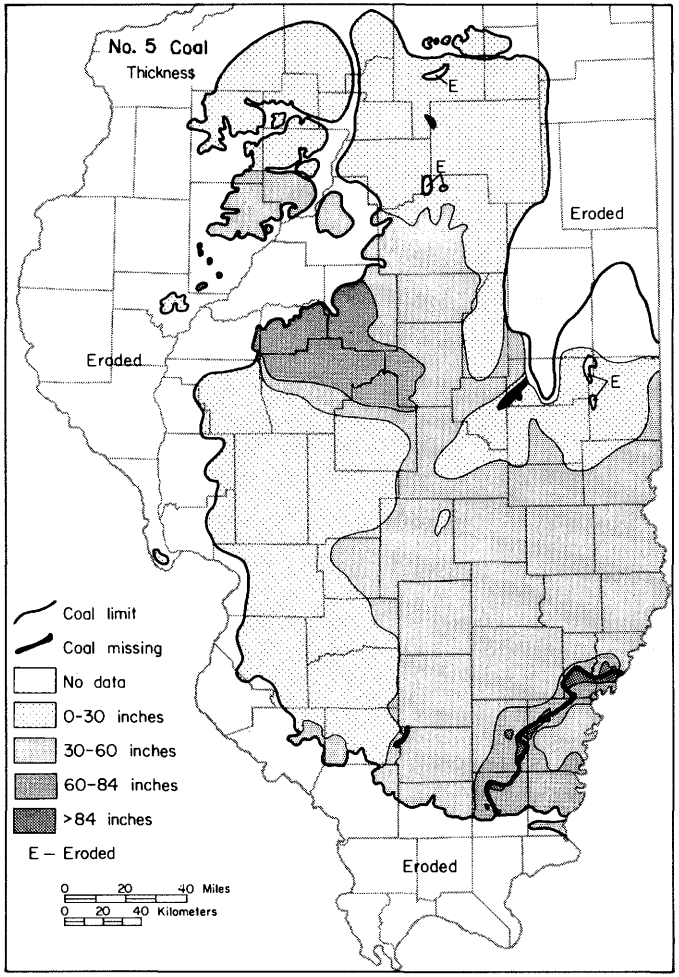

Fig. P-12—Thickness of the Harrisburg (No. 5) and Springfield (No. 5) Coal Members (based on map by K. E. Clegg).

Electronic Filing: Received, Clerk's Office 07/01/2024

gray to black shale that is fissile in places and is seldom over 2 feet thick. It is underlain by a hard silty underclay. It extends into southwestern Indiana.

Vermilionville Sandstone Member—The Vermilionville Sandstone Member of the Carbondale Formation (Cady, 1915, p. 29) is named for Vermilionville, La Salle County, and the type locality is west of the village, along the Vermilion River (SE 9, 32N-2E) (Wanless, 1956, p. 10). The Vermilionville is an argillaceous to silty, fine-grained sandstone that in places occupies channels cut into the underlying strata. In such channels it is as much as 80 feet thick. It is well developed in northern and western Illinois, where it occurs in the interval between the Herrin (No. 6) and the Springfield (No. 5) Coals. It is probably present in southern Illinois, where three sandstone units, all of which locally occur in channels, are present in this interval. One sandstone is below the Herrin Coal, another is below the Briar Hill (No. 5A) Coal, and a third is associated with the Dykersburg Shale. The Vermilionville is generally overlain by a few feet of the Big Creek Shale and is underlain by the Canton Shale. The Vermilionville was formerly called Cuba Sandstone in western Illinois (Savage, 1927) and Waupecan Sandstone in northeastern Illinois (Culver, 1922a).

Big Creek Shale Member—The Big Creek Shale Member of the Carbondale Formation (Savage, 1927, p. 309, 313, 315) is named for Big Creek in Fulton County, along which the type section occurs (7N-4E) (Wanless, 1957, p. 108). The shale is gray, soft, and sandy, is 10-30 feet thick, and grades into the underlying Vermilionville Sandstone. A shale is present at this position throughout much of the state, but the name has been used only in western Illinois.

Spring Lake Coal Member—The Spring Lake Coal Member of the Carbondale Formation (Cady, 1948, p. 5; Peppers, 1970, p. 59) is named for Spring Lake, La Salle County. The type section consists of exposures on the east bank of the Vermilion River on the northwest side of Streator, about three-fourths of a mile northeast of the lake (SE SW SW 23, 31N-3E) (Willman and Payne, 1942, p. 130, 295; Peppers, 1970, p. 59). The coal was described from several outcrops and mines in a small area near Streator, where it has a maximum thickness of 2.5 feet (Willman and Payne, 1942, Unit 43). It is separated from the overlying Herrin (No. 6) Coal by 11-17 feet of strata, the lower part of which consists of black fissile shale and gray shale. *Estheria* and *Leaia* are found in the gray shale. Spore analyses by Peppers (1970) suggest that its position is slightly above the Briar Hill Coal.

Herrin (No. 6) Coal Member—The Herrin (No. 6) Coal Member of the Carbondale Formation was originally named No. 6 Coal (Worthen, 1870, p. 93) and later called Herrin (No. 6) Coal (Shaw and Savage, 1912, p. 6) for Herrin, Williamson County, where the coal is extensively mined. It formerly was called the Brereton (No. 6) coal in western Illinois, the "Second Vein" (No. 5) coal in the La Salle area, and the Streator (No. 7) coal in the Streator area. The coal is a normal bright-banded coal. Its lower portion contains a prominent claystone parting (the "blue band") that normally is 1-3 inches thick. The Herrin Coal is present throughout much of the area of Pennsylvanian rocks (fig. P-13). It averages more than 6 feet thick in extensive areas and locally reaches 15 feet. It is thin in much of central Illinois but has been extensively mined in western, west-central, southern, and northern Illinois, as well as in the southern part of the Danville region of eastern Illinois. In some places the coal is cut out by channels filled with the Anvil Rock Sandstone Member. In parts of Illinois, silty gray shale as much as 100 feet thick overlies the Herrin Coal. Associated with this shale is a channel sandstone commonly as much as a mile wide and 60-80 feet thick that was mapped as Anvil Rock Sandstone (Hopkins, 1958; Potter and Simon, 1961), but later unpublished studies suggest that it may be in part contemporaneous with the coal. In areas where the coal is overlain by relatively thick bodies of the gray shale, the coal generally varies in thickness, locally contains gray shale lenses up to a few tens of feet thick, and has a much lower sulfur content than it does elsewhere (Gluskoter and Simon, 1968; Gluskoter and Hopkins, 1970). The gray shale overlies the coal in four areas, principally in parts of the following counties: (1) Williamson, Franklin, and Jefferson, (2) Madison and St. Clair, (3) eastern Macoupin, and (4) southern Vermilion. Except in these areas the Herrin Coal is generally overlain by either the Anna Shale Member (black fissile shale) or the Brereton Limestone Member. The Herrin Coal rests on a well developed underclay. The coal extends into western Indiana, where it is now called the Herrin Coal Member. It is extensively mined in western Kentucky, where it is known as the No. 11 coal, and it is correlated with the Lexington coal in Missouri and the Mystic Coal Member in Iowa.

Anna Shale Member—The Anna Shale Member of the Carbondale Formation (Jewett, 1941, p. 316-317) is named for Anna, Bourbon County, Kansas. It is a fissile, black, hard, carbonaceous shale that seldom is as much as 4 feet thick. Locally it contains dark gray, impure limestone concretions up to a foot thick. The Anna has a nektonic and planktonic marine fauna and many of the shells are fragmentary and pyritized. The Anna is persistent and generally accompanies the overlying Brereton Limestone, but in parts of southern Illinois the Anna lenses out and the Brereton Limestone lies directly on the Herrin (No. 6) Coal. The Anna otherwise generally lies in abrupt contact with the Herrin Coal, except where the thick wedges of silty gray shale intervene. The Anna Shale and the Brereton Limestone, and locally even higher units, thin to zero over the gray shale wedges.

Brereton Limestone Member—The Brereton Limestone Member of the Carbondale Formation (Savage, 1927, p. 309, 313-315) is named for Brereton, Fulton County, and the type section is along the east bank of Middle Copperas Creek (SE NE 1, 7N-4E) (Wanless, 1956, p. 10; 1957, p. 107, 111, 112, 195). It was formerly called the Herrin Limestone in southern Illinois. The Brereton Limestone is a distinctive marker unit widely developed throughout much of the Illinois Basin (fig. P-3B). It is usually dark gray, argillaceous, fine grained, and commonly less than 5 feet thick, but in places it is as thick as 18 feet. In northern Illinois it contains black phosphatic nodules. It has an open-marine fauna dominated by brachiopods, crinoids, and fusulinids. It is absent in areas where cut by channels in which the Anvil Rock Sandstone was deposited. It thins and disappears over thick deposits of the silty gray shale that locally overlies the Herrin (No. 6) Coal. In parts of southwestern, western, and eastern Illinois, the Brereton Limestone or the Anna Shale are lenticular and pinch out in places. Where both are absent, the overlying Lawson Shale or strata associated with the Jamestown Coal locally form the roof of the Herrin Coal. In southern and parts of west-central Illinois the Brereton is commonly overlain by a few inches to a few feet of the dark gray calcareous shale that underlies the Jamestown Coal. In the rest of the state the limestone is overlain by the Lawson Shale. The Brereton Limestone is present in southwestern Indiana and is quite persistent in western Kentucky, where it is called the Providence Limestone Member. It is correlated with the Myrick Station Member of Missouri.

Jamestown Coal Member—The Jamestown Coal Member of the Carbondale Formation (Bell et al., 1931, p. 3) is a widespread but thin coal in southern Illinois named for Jamestown, Perry County, which is near the type locality (NW NE 34, 5S-4W) (Wanless, 1939, p. 17, 19, 88; 1956, p. 10). The coal is seldom more than a few inches thick in southern Illinois (fig. P-3B), but in southern Clark County and adjacent Crawford County in eastern Illinois it is reported in drill records to be as much as 6 feet thick. The Jamestown Coal is equivalent to the Hymera Coal Member (VI), which is an im-

Electronic Filing: Received, Clerk's Office 07/01/2024

portant commercial coal in Indiana, and to the No. 12 coal in western Kentucky.

Conant Limestone Member—The Conant Limestone Member of the Carbondale Formation (Kosanke et al., 1960, p. 35) is named for Conant, Perry County, near the type locality (NW NE 34, 5S-4W) (Wanless, 1939, p. 17, 88; 1956, p. 10). It previously was called the Jamestown Limestone (Bell et al., 1931, p. 3). The Conant is widespread from St. Clair to Gallatin Counties in southern Illinois (fig. P-3B) but is not recognized a short distance north of that area. It is also present locally in eastern Illinois. For most of its extent the limestone is less than 1 foot thick and lies immediately above the thin Jamestown Coal, but in Perry County it is as much as 4 feet thick in places and is separated from the Jamestown Coal by an equal thickness of dark gray shale. It is overlain by gray silty shale. The limestone is quite argillaceous and locally resembles the Brereton Limestone. It is characterized by an open-marine fauna dominated by the large productid brachiopod *Dictyoclostus*.

Pokeberry Limestone Member—The Pokeberry Limestone Member of the Carbondale Formation (Wanless, 1939, p. 17, 98) is named for Pokeberry School, Schuyler County, which is near the type locality (NW 26, 2N-1W) (Wanless, 1956, p. 11; 1957, p. 113, 188). The limestone is known only in the type area, where it is 15 feet above the Herrin Coal and 9 feet below the Danville (No. 7) Coal. It is a gray, dense, locally conglomeratic or brecciated limestone containing large fossils, most of them brachiopods. It has a very knobby upper surface. It was correlated by Wanless (1957, p. 113) with the Conant Limestone, but its position and correlation are uncertain. It may correlate with the Bankston Fork Limestone. The Pokeberry Limestone is not shown on the geologic column (fig. P-2).

Lawson Shale Member—The Lawson Shale Member of the Carbondale Formation (Kosanke et al., 1960, p. 35) is named for Lawson Creek in Bureau County, about a mile west of the type section (cen. 24, 16N-6E) (Wanless, 1956, p. 10; 1957, p. 112). It previously was called Sheffield Shale (Wanless, 1939, p. 102; 1956, p. 10; 1957, p. 112). The Lawson is typically a gray silty shale as much as 25 feet thick in western Illinois. It probably correlates with a similar shale that underlies the Anvil Rock Sandstone in southern Illinois. The upper part of the Lawson is in some places interbedded with sandstone that grades laterally into the Copperas Creek Sandstone. At other places the Copperas Creek lies unconformably on the shale. In much of west-central and southwestern Illinois the Lawson is a weak, gray and green mottled shale. It is underlain throughout most of western Illinois by the Brereton Limestone or, locally, by either the Anna Shale or Herrin (No. 6) Coal.

Copperas Creek Sandstone Member—The Copperas Creek Sandstone Member of the Carbondale Formation (Savage, 1927, p. 309) is named for Copperas Creek in Fulton County, along which the sandstone is well exposed (Wanless, 1957, p. 114), but no type section was designated. The Copperas Creek occurs in western Illinois as a widespread, thin-bedded sheet sandstone and as a channel sandstone. It is correlated with the Anvil Rock Sandstone of southern Illinois. The Copperas Creek channels appear to be part of a south-to-southeast drainage system that connects with the Anvil Rock Sandstone channels of the deeper part of the Illinois Basin.

Anvil Rock Sandstone Member—The Anvil Rock Sandstone Member of the Carbondale Formation (Owen, 1856, p. 45) is named for an anvil-shaped float block along a bluff 1.5 miles north of Dekoven Station, Union County, Kentucky. The sandstone underlies the Bankston Fork Limestone and overlies the gray shale above the Conant Limestone throughout southern Illinois, where it occurs as a channel sandstone as much as 80 feet thick. The name "Anvil Rock" was applied by Hopkins (1958) and Potter and Simon (1961) to a major channel sandstone, which replaces the Herrin Coal along a sinuous band extending through Montgomery, Bond, Clinton, Washington, Jefferson, and Franklin Counties (fig. P-13), which is now considered to be in part contemporaneous with the Herrin Coal and the immediately overlying gray silty shale. East of the Du Quoin Monocline the Anvil Rock occurs as a channel sandstone or, more commonly, as a sheet sandstone up to 20 feet thick (Hopkins, 1958; Potter and Simon, 1961). In the sheet facies it is normally a fine-grained, relatively impure, quartz sandstone incorporating considerable argillaceous material, but in the channel facies it is medium grained and less argillaceous. In the deeper channels the sandstone cuts through several underlying stratigraphic units, including the Herrin (No. 6) Coal. Some channels are only a few hundred feet across, but the major ones are up to 2 miles wide. In the sheet facies the dominant sedimentary structure is ripple bedding. In the channel facies, planar and trough cross-bedding are common.

Bankston Fork Limestone Member—The Bankston Fork Limestone Member of the Carbondale Formation (Cady, 1926, p. 261-262) is named for Bankston Creek in Saline County, where the type section consists of outcrops along the south side of the creek (NE NW 19, 9S-5E). The Bankston Fork is a fine-grained, argillaceous, thick-bedded limestone that is dolomitic in places (fig. P-3B). It is commonly nodular in the upper and lower portions and is generally divided into two benches by a greenish gray shale several inches thick. It is sparsely fossiliferous, its open-marine fauna dominated by brachiopods, fusulinids, and a few crinoids. It occurs in southwestern, central, eastern, and southeastern Illinois, where it is commonly several feet thick but seldom over 6 feet. It does not occur west of the Illinois River or in northern Illinois. It commonly is not present over the thick portions of the Anvil Rock Sandstone. The Bankston Fork correlates with the Universal Limestone Member of Indiana and is present in parts of western Kentucky, where it locally is as much as 8 feet thick.

Allenby Coal Member—The Allenby Coal Member of the Carbondale Formation (Kosanke et al., 1960, p. 35, 48) is named for Allenby, Saline County, and the type locality is in Williamson County, half a mile northeast of the village along the roadside east of a railroad crossing (NE NW 24, 9S-4E) (Kosanke, 1950, p. 79), where it occurs 1-2 feet above the Bankston Fork Limestone. It was formerly called the Bankston Coal (Wanless, 1939, p. 14, 76). It is a thin coaly zone occurring in much of Williamson, Saline, and Gallatin Counties. It is generally overlain by a greenish gray or gray shale and is underlain by underclay. It is minable locally in western Kentucky, where it is called the Baker coal.

Galum Limestone Member—The Galum Limestone Member of the Carbondale Formation (Bell et al., 1931, p. 3) is named for Galum Creek, Perry County, along which the type section occurs (near cen. N line 13, 6S-4W) (Wanless, 1956, p. 11). It is recognized only in and near Perry County. It is generally an impure, argillaceous, nodular, nonfossiliferous limestone that is seldom more than 3 feet thick. It is overlain by the underclay of the Danville (No. 7) Coal and underlain by a few feet of greenish gray shale that separates the Galum from the Bankston Fork Limestone.

Danville (No. 7) Coal Member—The Danville (No. 7) Coal Member of the Carbondale Formation (Bradley, 1870, p. 250-252), the uppermost member of the formation, is named for Danville, Vermilion County, near the type section (E½ 7, 19N-11W) (Wanless, 1956, p. 11), where it is an important commercial coal that has been mined since the latter part of the 1800s. In the type locality it is 6 feet thick and occurs 20 feet above the Herrin (No. 6) Coal. It previously was called the Sparland (No. 7) coal in western Illinois and the "First Vein" (No. 7) coal in northern Illinois. The Danville Coal is extensive and has been mined in Livingston, McLean, La Salle, and Marshall Counties in addition to Vermilion County. In most of the remainder of the state it is a thin coal, generally from a few inches to less than 3 feet thick. The position of the coal is easily recognized in the subsurface in both lithologic and geophysical logs. The No. 7 Coal is generally overlain by the Farmington Shale Member

Electronic Filing: Received, Clerk's Office 07/01/2024

of the Modesto Formation, but in places the immediate roof is 1-2 feet of black fissile shale. It is underlain by a relatively thick underclay, which has been mined in La Salle and Marshall Counties as ceramic clay. The Danville Coal correlates with the Danville Coal Member (VII) of Indiana and is present as a thin coal in western Kentucky.

McLeansboro Group

The McLeansboro Group (DeWolf, 1910, p. 181; Weller, 1940, p. 36) is named for McLeansboro, Hamilton County, and the type section consists of strata in a diamond drill core from a boring near McLeansboro (SE SW SW NE 25, 4S-5E), where 811 feet of Pennsylvanian strata was encountered above the top of the Danville (No. 7) Coal, which defines the base of the group. The McLeansboro includes all Pennsylvanian rocks in Illinois above the No. 7 Coal and is made up of three formations—the Modesto, Bond, and Mattoon (fig. P-2). DeWolf originally applied formation status to the McLeansboro, but Weller (1940) elevated it to a group and Willman and Payne (1942) defined it as including all the Pennsylvanian strata in Illinois above the base of the Copperas Creek (Anvil Rock) Sandstone Member. About 400 feet of additional Pennsylvanian strata younger than those encountered in the type section drill hole are present in the deeper part of the Illinois Basin in Jasper County, and even younger Pennsylvanian rocks are present in western Kentucky. Lithologically the McLeansboro is similar to the Kewanee Group, but it contains more marine members, including thicker, less argillaceous limestones. Coals are not as thick and probably not as extensive in the McLeansboro. Most are less than 1 foot thick, although some coals are up to 4 feet thick. Variegated claystones, many of them dominantly red, occur several feet above and below some of the limestones. They are much less common in other Pennsylvanian groups. Light olive or tan argillaceous limestone units up to 3-4 feet thick and bearing only ostracodes, *Spirorbis*, and very few pelecypods are present in the McLeansboro, particularly in the upper part. They are similar to thicker limestones in the upper part of the Pennsylvanian in the Appalachian Basin. The Dix Limestone is the only one of these units that has been named. The McLeansboro Group extends into Indiana, and is equivalent to all but the lowest part of the Sturgis Formation of Kentucky.

Modesto Formation

The Modesto Formation of the McLeansboro Group (Kosanke et al., 1960, p. 36, 48, 67-70) is named for Modesto, Macoupin County, near which four outcrops described by Payne (1942) and Ball (1952) constitute the type locality and expose nearly all the formation (SW SE 35, 10N-7W and NE NW 2, 9N-7W; W1/2 NE NW 35, 10N-7W; SW SW SE 7, 12N-8W to NE SE SW 1, 12N-9W; and NE SW SW 16 to NE 17, 12N-9W). The Modesto Formation includes strata from the top of the Danville (No. 7) Coal to the base of the Shoal Creek Limestone Member or the La Salle Limestone Member (fig. P-2). It is overlain by the Bond Formation and underlain by the Carbondale Formation. The Modesto Formation thickens from less than 125 feet along the La Salle Anticlinal Belt in east-central Illinois to over 200 feet in northern Illinois and over 450 feet in southern Illinois, averaging about 350 feet (fig. P-14). It consists of sediments somewhat similar to those of the underlying Carbondale Formation, but the coals are thinner, the limestones are generally thicker and less argillaceous, and several red claystones and shales are associated with the open-marine limestones. With the exception of the Lonsdale, Piasa, and West Franklin Limestones, most of the limestones of this formation, however, are thin and argillaceous. Even though the coals are thin, many are widespread. The sandstones in places are thick channel deposits up to 80 feet thick. Gray shales in this formation are particularly thick and constitute by far the greater part of the formation. The Modesto Formation correlates with the Shelburn Formation and the overlying Patoka Formation of Indiana and a portion of the Sturgis Formation of western Kentucky.

Farmington Shale Member—The Farmington Shale Member of the Modesto Formation (Savage, 1927, p. 309) is named for Farmington Township, Fulton County, which is the type locality (8N-4E) (Wanless, 1956, p. 11). The Farmington is the lowest named unit of the Modesto Formation in most of the state. It is commonly gray shale that becomes coarser grained upward, and the lower part generally contains marine fossils. It generally occurs immediately above the Danville (No. 7) Coal Member, but in several places a dark gray, very impure limestone, usually less than a foot thick, lies directly on the coal. In other places black fissile shale, seldom more than 2 feet thick, overlies the coal or occurs between the limestone and the Farmington Shale. The Farmington ranges from a few feet to as much as 50 feet thick in eastern, western, and southern Illinois and to as much as 100 feet or more in southeastern Illinois. It has been extensively mined for clay in the Danville region, Vermilion County.

Piasa Limestone Member—The Piasa Limestone Member of the Modesto Formation (Culver, 1925, p. 20) is named for Piasa Creek in Jersey County and the type section consists of exposures along the creek (E1/2 25, 8N-10W) (Wanless, 1956, p. 11). The Piasa, which occurs in southwestern and southern Illinois, was formerly called the Cutler Limestone in southern Illinois. In much of southwestern Illinois the Piasa lies only a few feet above the Danville (No. 7) Coal and is separated from it by either variegated claystone, gray shale, or, in places, black fissile shale. The Piasa is commonly light gray, fine-grained, argillaceous limestone containing an open-marine fauna dominated by crinoids (mainly in the lower part) and brachiopods. In many places it contains numerous fusulinids, especially at the base. It is generally less than 4 feet thick and is commonly associated with red and variegated claystone. Correlations with other units in Illinois are not definite, but the Piasa appears to be equivalent to the lower part of the West Franklin Limestone Member of southeastern Illinois and southwestern Indiana and to the Madisonville Limestone Member of western Kentucky.

Electronic Filing: Received, Clerk's Office 07/01/2024

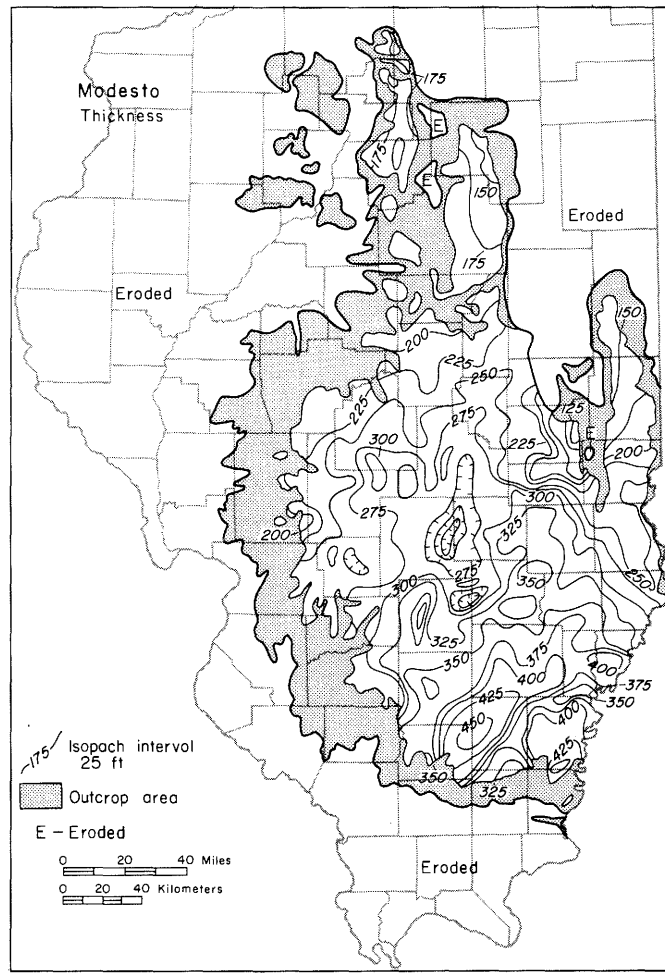

Fig. P-14—Thickness of the Modesto Formation (based on map by K. E. Clegg).

West Franklin Limestone Member—The West Franklin Limestone Member of the Modesto Formation (Collett, 1884, p. 61-62) is named for West Franklin, Posey County, Indiana. The type section consists of outcrops near the town (24, 7S-12W) (Wanless, 1956, p. 11). The member is recognized largely in southeastern Illinois. It is a fine-grained limestone generally less than 15 feet thick and occurs in one to three benches, each generally less than 10 feet thick and separated by a few feet of greenish gray to variegated claystone. The number of limestone benches decreases to the west as the underlying shale, probably the Farmington Shale, thins from east to west. In the eastern part of its area the West Franklin is closely overlain by the Chapel (No. 8) Coal, and it is likely that the West Franklin Limestone is equivalent to the entire interval from the Piasa Limestone upward through the Lake Creek Coal in southern Illinois and through the Scottville Limestone in southwestern Illinois. The Piasa Limestone also may be equivalent to the lower bench of the West Franklin (Andresen, 1956). The West Franklin is probably also equivalent to the interval including the Lonsdale and Exline Limestones of western Illinois and to the Madisonville Limestone of western Kentucky.

De Graff Coal Member—The De Graff Coal Member of the Modesto Formation (Cady, *in* Kosanke et al., 1960, p. 37) is named for De Graff School, Perry County. It previously was informally called the First Cutler Rider coal. The type section consists of exposures along Galum Creek, near De Graff School (SE cor. NE SW 21, 5S-4W). This thin, lenticular coal occurs a few feet above the Piasa Limestone in southern Illinois.

Rock Branch Coal Member—The Rock Branch Coal Member of the Modesto Formation (Kosanke et al., 1960, p. 37) is named for Rock Branch in Macoupin County. It previously was called the Scottville Coal (Payne, 1942, p. 4). The type section consists of exposures along Rock Branch (SW SW NW 16, 12N-9W). This thin coal occurs in southwestern Illinois and may be equivalent to the Pond Creek Coal of southern Illinois.

Electronic Filing: Received, Clerk's Office 07/01/2024

Gimlet Sandstone Member—The Gimlet Sandstone Member of the Modesto Formation (Wanless, 1931a, p. 182, 183, 190, 192) is named for Gimlet Creek in Marshall County, and the type section consists of exposures along the creek (N1/2 SE 16, 12N-9E) (Wanless, 1956, p. 11; 1957, p. 116). The Gimlet Sandstone is locally developed as a fine- to medium-grained channel sandstone 50-60 feet thick, which cuts down from 50 feet above the Danville Coal to within a few feet of the Brereton Limestone. In other places the sandstone is only a few feet thick or is absent. The Gimlet Sandstone has been recognized principally in northern and western Illinois.

Lonsdale Limestone Member—The Lonsdale Limestone Member of the Modesto Formation (Worthen, 1873, p. 328) is named for the old Lonsdale quarries, Peoria County. The original type section in the old quarry (N1/2 6, 8N-7E) is no longer accessible, and an outcrop near by (14, 8N-7E) is a supplementary type section (Wanless, 1957, p. 194). The Lonsdale is a well developed limestone in western and northern Illinois, where it averages 6-8 feet thick and locally is as much as 25 feet thick. It is a very fine-grained, light gray limestone, conglomeratic in part. Throughout much of its area of occurrence the upper part is nodular. It contains a large and diversified marine fauna locally rich in fusulinids. It is correlative with at least a part of the West Franklin Limestone of southeastern Illinois, the Cooper Creek Limestone of Iowa, and the Madisonville Limestone Member of western Kentucky.

Pond Creek Coal Member—The Pond Creek Coal Member (Kosanke et al., 1960, p. 37) is named for Pond Creek in Williamson County. It previously was informally called the Second Cutler Rider coal. The type section of the Pond Creek Coal is at a depth of 125 feet in Consolidated Coal Company drill hole 91 (SW NE NE 21, 8S-3E). The Pond Creek is more extensive than either the De Graff Coal or the Lake Creek Coal, which, respectively, lie just a few feet above and below the Pond Creek, but the Pond Creek is recognized only in southern Illinois. It may be equivalent to the Rock Branch Coal of southwestern Illinois.

Lake Creek Coal Member—The Lake Creek Coal Member of the Modesto Formation is named for Lake Creek Township, Williamson County (Cady, *in* Kosanke et al., 1960, p. 37). It previously was informally called the Third Cutler Rider coal. The type section of the Lake Creek Coal is at a depth of 86.6 feet in the Consolidated Coal Company drill hole 91 (SW NE NE 21, 8S-3E), located in Lake Creek Township. The coal is lenticular and occurs in southern Illinois.

Athensville Coal Member—The Athensville Coal Member of the Modesto Formation (Kosanke et al., 1960, p. 37) is named for Athensville, Greene County. It previously was called Upper Scottville (Kosanke, 1950, p. 85). The type section consists of exposures near the town (SE NW SW 16, 12N-9W, Macoupin County). The Athensville Coal generally lies less than 10 feet below the Scottville Limestone. It occurs in southwestern Illinois, and it may correlate with the Lake Creek Coal of southern Illinois.

Scottville Limestone Member—The Scottville Limestone Member of the Modesto Formation (Payne, 1942, p. 4) is named for Scottville, Macoupin County. The type section consists of exposures along Apple Creek near the town (W1/2 SW 16, 12N-9W) (Wanless, 1956, p. 11). The Scottville Limestone occurs in southwestern Illinois, where it is as much as 3 feet thick. It is a light gray, fine-grained limestone that locally contains abundant *Osagia*, phylloid algae, and a diverse open-marine fauna. It is probably equivalent to part of the West Franklin Limestone of southeastern Illinois.

Exline Limestone Member—The Exline Limestone Member of the Modesto Formation (Cline, 1941, p. 65-66) is named for Exline, Appanoose County, Iowa, which is near the type section (SE 6, 67N-17W). The Exline occurs in western Illinois, where it is dark gray to black, thin- and even-bedded limestone that contains well preserved plant stems and leaves, the worm tube *Spirorbis*, and a few marine pelecypods (Wanless, 1957, p. 120). In Iowa, the Exline contains a normal marine fauna. In Illinois it usually is less than 3 feet thick, is underlain by black fissile shale, and is overlain by gray marine shale. In some places the Exline lies immediately on the Lonsdale Limestone, but in others it is as much as 30 feet above the Lonsdale.

Trivoli Sandstone Member—The Trivoli Sandstone Member of the Modesto Formation (Wanless, 1931a, p. 182, 183, 190, 192), the top of which is the Desmoinesian-Missourian Series boundary, is named for Trivoli, Peoria County. The type section consists of exposures in a ravine northeast of Pea Ridge School, near Trivoli (SW 3, 9N-5E) (Wanless, 1956, p. 11; 1957, p. 121, 193). The Trivoli Sandstone is found both as a sheet facies generally less than 20 feet thick and as a channel facies that thickens to more than 80 feet, primarily at the expense of underlying strata (Andresen, 1961). The Trivoli is present throughout much of Illinois and marks one of the periods of major stream development during Pennsylvanian time in Illinois.

(Modesto Formation continued on page 196.)

MISSOURIAN SERIES

The Missourian Series of the Pennsylvanian System (Keyes, 1893, p. 114-116; Moore, 1931) is named for the state of Missouri, where strata containing much limestone and a very little coal overlie the Desmoinesian rocks. In Illinois the Missourian includes rocks from the top of the Trivoli Sandstone Member up to a position a few feet below the coal that lies below the Shumway Limestone Member (Willman et al., 1967). It therefore includes the upper part of the Modesto Formation, all of the Bond Formation, and about half of the Mattoon Formation, all in the McLeansboro Group (fig. P-2).

Where fusulinids are present, as they are in many units in Illinois, the Missourian is characterized by earlier forms of the genus *Triticites*, which is the sub-genus *Kansanella* of Thompson. Floral zones are not as well defined in the Illinois Basin and the Midcontinent area, where the Missourian and overlying Virgilian together constitute Zones 11 and 12 (zone of *Odontopteris* sp.) (Read and Mamay, 1964). Delineation of the ranges of spore taxa in the Missourian and Virgilian Series has not been determined with the same degree of accuracy as is true for the remainder of the Pennsylvanian because the stratigraphic relation of many of the coals has not been worked out in detail. Small spores of ferns and seed ferns, many less than 30 microns in diameter, are prolific in most of the Missourian and Virgilian coals. The taxa are classified as *Punctatisporites minutus, Laevigatosporites minutus*, and species of *Cyclogranisporites* and *Apiculatisporis*. *Endosporites* is very abundant in many of the coals.

Electronic Filing: Received, Clerk's Office 07/01/2024

Modesto Formation (continued)

Chapel (No. 8) Coal Member—The Chapel (No. 8) Coal Member of the Modesto Formation (Kosanke et al., 1960, p. 38), the oldest named unit in the Missourian Series, is named for Graham Chapel, Peoria County. It previously was called Trivoli (No. 8) coal (Wanless, 1931a, p. 181-182, 190, 192). The type section consists of exposures in a ravine northeast of Pea Ridge School, about 2 miles south of Graham Chapel (SW 3, 8N-5E) (Wanless, 1956, p. 11; 1957, p. 121, 193). The name "No. 8" was first given to this coal by Lesquereux (1866, p. 213) for an exposure near Shawneetown, Gallatin County. Worthen (1870) also applied the name to this coal in outcrops near Springfield, Sangamon County. The Chapel Coal is a thin, bright-banded coal that is persistent throughout most of the area of the state that is underlain by the Modesto Formation. It occurs above the widespread Trivoli Sandstone or the West Franklin Limestone and is correlated with the Ditney Coal Member of southwestern Indiana.

Cramer Limestone Member—The Cramer Limestone Member of the Modesto Formation (Kosanke et al., 1960, p. 38) is named for Cramer, Peoria County. It previously was called Trivoli Limestone (Wanless, 1931a, p. 182, 190, 192). The type section consists of exposures in a ravine northeast of Pea Ridge School, 1.3 miles northeast of the village of Cramer (Wanless, 1956, p. 11; 1957, p. 121, 193). The Cramer Limestone is normally very argillaceous and is generally less than 1 foot thick. It is lenticular but widespread and is commonly found throughout the same area as the underlying Chapel (No. 8) Coal, from which it is commonly separated by 1-2 feet of black fissile shale. The Cramer contains an abundant open-marine fauna. It is correlated with the Sniabar Limestone of southern Iowa, Missouri, and eastern Kansas.

Inglefield Sandstone Member—The Inglefield Sandstone Member of the Modesto Formation (Fuller and Ashley, 1902, p. 3) is named for Inglefield, Vanderburgh County, Indiana, and the type locality consists of exposures in a railroad cut south of the town. The sandstone occurs above the Chapel (No. 8) Coal and below the Womac Coal (Andresen, 1961). It is known primarily in eastern Illinois, but it was reported by Andresen to split into two distinct sandstones in southwestern Illinois, the lower unit occurring below the Carlinville Limestone. The Inglefield Sandstone locally exceeds 80 feet in channels oriented south-southwest, but it is relatively widespread as a much thinner sheet sandstone in most of the Illinois Basin.

Carlinville Limestone Member—The Carlinville Limestone Member of the Modesto Formation (Worthen, 1873, p. 290-301) is named for Carlinville, Macoupin County. The type section consists of outcrops along Macoupin Creek (SW SW 35, 10N-7W) (Wanless, 1956, p. 11). The limestone is recognized only in part of southwestern Illinois, where it is thick-bedded, up to 5 feet thick, and contains an open-marine fauna.

Burroughs Limestone Member—The Burroughs Limestone Member of the Modesto Formation (Ball, *in* Cooper, 1946, p. 12; 1952, p. 37, 38, 85; Kosanke et al., 1960, p. 38) is named for Burroughs Branch, a tributary of Macoupin Creek, in Macoupin County. The type section consists of outcrops along the branch on the west side of Carlinville (NW SW 27, 10N-7W). The Burroughs is recognized in only a small area in west-central Illinois, where it is a dark gray, sandy, clastic limestone that contains crinoid columnals and brachiopods and ranges from a fraction of an inch to more than 5 feet thick. Its position is 14-17 feet above the Carlinville Limestone and 18 feet or less below the Macoupin Limestone.

Womac Coal Member—The Womac Coal Member of the Modesto Formation (Kosanke et al., 1960, p. 38) is named for Womac, Macoupin County. It previously was called the Macoupin Coal (Wanless, 1931b, p. 810-811). The type section consists of exposures in a ravine draining into Macoupin Creek 3 miles southwest of Womac (Wanless, 1956, p. 11). This thin coal is widely traced in the Illinois Basin along with the overlying Macoupin Limestone, from which it is separated by 1-2 feet of black fissile shale. It is correlated with the Raben Branch Coal Member in Indiana.

Macoupin Limestone Member—The Macoupin Limestone Member of the Modesto Formation (Wanless, 1931b, p. 810-811) is named for Macoupin Creek in Macoupin County, along which the type section is exposed (NE NW 2, 9N-7W) (Wanless, 1956, p. 11; Ball, 1952, p. 85-86). It is a widespread unit, found throughout much of the Illinois Basin. The limestone is generally less than 2 but locally as much as 5 feet thick. In the type area it is composed of thin, even beds of crinoidal limestone separated in places by shale partings. Most of it is dark gray and very argillaceous.

Hall Limestone Member—The Hall Limestone Member of the Modesto Formation (Willman, *in* Cooper, 1946, p. 12) is named for Hall Township, Bureau County. The type section consists of exposures in a ravine west of the coal mine refuse pile in the western part of the town of Spring Valley (NW SW 33, 16N-11E) (Wanless, 1956, p. 12). The Hall is recognized only in northern Illinois. In the type section it lies about 45 feet below the La Salle Limestone Member and consists of a 3-foot ledge of fine-grained, green, gray, and red limestone containing numerous brachiopods, crinoid columnals, and bryozoans. It is underlain by a persistent black shale. The Hall is correlated with the Macoupin Limestone of southern and eastern Illinois.

New Haven Coal Member—The New Haven Coal Member of the Modesto Formation (Kosanke, 1950, p. 88-89), the uppermost named member of the formation, is named for New Haven, Gallatin County. The type section is an outcrop along the Little Wabash River (SE SW SE 17, 7S-10E; incorrectly given as NW 19, 7S-10E, by Kosanke, 1950). The New Haven is a thin coal, generally separated by only 1-2 feet of black fissile shale from the overlying Shoal Creek Limestone Member of the Bond Formation. It is widespread in southeastern, southwestern, and central Illinois and is absent in parts of eastern Illinois. It is correlated with a thin coal below the La Salle Limestone in northern Illinois and with the Parker Coal Member of Indiana.

Bond Formation

The Bond Formation of the McLeansboro Group (Kosanke et al., 1960, p. 39, 50, 70-73) is named for Bond County, where exposures are prominent. Seven separate outcrops in three counties constitute the type section (NE NE NE 3, 10N-2W, Montgomery County; SE NE 28, 12N-1W, Christian County; NE NW SE 7, 8N-2W, Montgomery County; east-central 24, 6N-5W, S1/2 7, 6N-4W, E edge 6, 7, 6N-4W, and SW NW 29, 7N-4W, Bond County). The Bond Formation varies from less than 150 feet thick in eastern Illinois to over 300 feet in southeastern Illinois and averages about 250 feet (fig. P-15). It includes all strata from the base of the Shoal Creek Limestone Member or the La Salle Limestone Member to the top of the Millersville Limestone Member or the Livingston Limestone Member (fig. P-2) and is characterized by a high percentage of limestone and calcareous clays and shales. The limestone members that bound the formation are the thickest and purest limestones in the Pennsylvanian System of Illinois. The upper limestone is as much as 50 feet thick and the lower is in places as much as 30 feet thick. Both are extensively quarried. In southern Illinois, south of the area of prominent development, there is no major single bench of the Millersville, and the equivalent strata are difficult to identify. Red claystones and

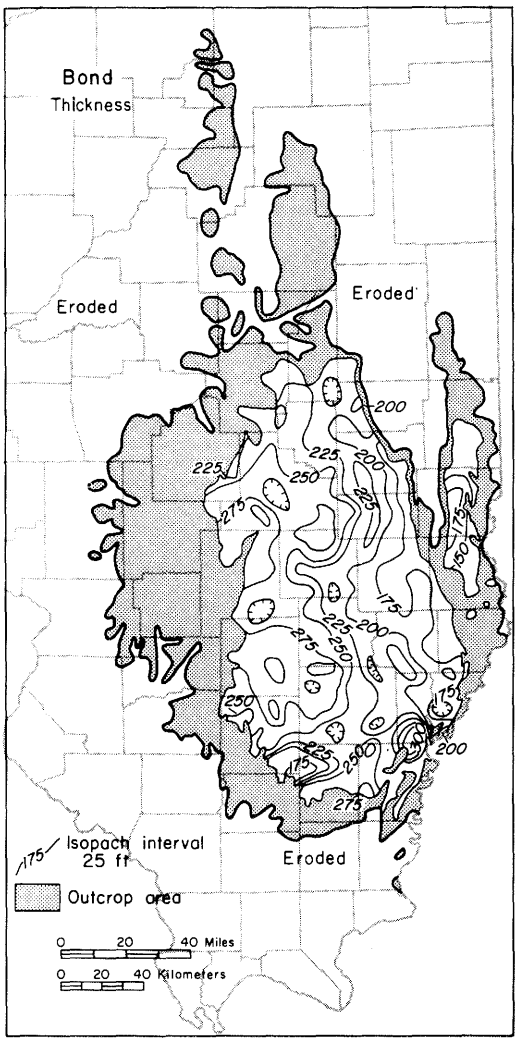

Fig. P-15—Thickness of the Bond Formation (based on map by K. E. Clegg).

shales are present in the Bond and are best developed in northern Illinois. Other units of the formation—gray shales, siltstones, and sandstones—are similar to those in the underlying Modesto Formation. Gray shales constitute the greatest portion of the formation, but thick channel sandstones are developed locally. The formation is also called Bond in Indiana, and it is equivalent to a portion of the Sturgis Formation in western Kentucky.

Shoal Creek Limestone Member—The Shoal Creek Limestone Member of the Bond Formation (Engelmann, 1868, p. 175, 177-183), the base of which is the base of the formation in all except northern Illinois, is named for Shoal Creek in Clinton County, and the type locality consists of exposures along the stream (3N-4W). The limestone is commonly 6-8 feet thick, locally as much as 20 feet. It is generally light gray, thick bedded, and fine grained, and it contains a diverse open-marine fauna. It persists throughout most of the Illinois Basin and is quarried in southwestern Illinois. The Shoal Creek is an easily recognized marker on geophysical logs in most of the deeper part of the Illinois Basin. It is locally cut out by the Mt. Carmel Sandstone or the McWain Sandstone. It is correlated with the La Salle Limestone of northern Illinois, the lower part of the Winterset Limestone Member of Missouri, and the Carthage Limestone Member of western Kentucky. The Shoal Creek Limestone Member is also recognized in Indiana.

La Salle Limestone Member—The La Salle Limestone Member of the Bond Formation (Cady, 1908, p. 128-134), the base of which is the base of the formation in northern Illinois, is named for La Salle, La Salle County. The type section consists of exposures near Bailey's Falls, south of La Salle (14, 33N-1E) (Wanless, 1956, p. 12). The La Salle Limestone is well developed in northern Illinois, where it has been quarried extensively (Cady, 1919b). It is as much as 30 feet thick in exposures near La Salle along the west flank of the La Salle Anticline, but it thins westward to about 12 feet west of Spring Valley, Bureau County. In a belt 1-2 miles wide along its eastern margin, it is a fine-grained, thick-bedded, light gray, nodular limestone containing a few shale partings and a large and diverse marine fauna, mainly brachiopods and gastropods. It grades westward to a fine-grained, argillaceous, tan, brown-weathering limestone that occurs mostly in even beds 4-8 inches thick separated by strong shale partings and containing a restricted marine fauna characterized by large brachiopods, mostly productids. It formerly was correlated with the Millersville and Livingston Limestone Members but is now correlated with the Shoal Creek Limestone.

McWain Sandstone Member—The McWain Sandstone Member of the Bond Formation (Ball, 1943, p. 150) is named for the McWain Farms, Macoupin County. The type section consists of exposures along Macoupin Creek (SE 25, 10N-7W) (Ball, 1952, p. 44). The McWain occurs as a channel sandstone in southwestern Illinois, where it locally rests on the Shoal Creek Limestone or on strata between the Shoal Creek and the Macoupin Limestone. It has been correlated with the Mt. Carmel Sandstone.

Mt. Carmel Sandstone Member—The Mt. Carmel Sandstone Member of the Bond Formation (Worthen, 1875, p. 52, 55) is named for Mt. Carmel bluff on the Wabash River at Mt. Carmel, Wabash County (W1/2 21, 1S-12W). The Mt. Carmel Sandstone is well developed in eastern and southeastern Illinois, where it is the first major channel sandstone above the Shoal Creek Limestone, and it is as much as 80 feet thick in places. It occurs about 10 feet below the Flannigan Coal. The Mt. Carmel Sandstone has been correlated with the McWain Sandstone of southwestern Illinois.

Sorento Limestone Member—The Sorento Limestone Member of the Bond Formation (Simon, *in* Wanless, 1955, p. 1764) is named for Sorento, Bond County. The type section consists of outcrops along the south-flowing tributary of Dry Fork just southwest of Sorento (NE NE 6, 6N-4W) (Kosanke et al., 1960, p. 39). The Sorento Limestone and the underlying unnamed coal have been recognized throughout much of the Illinois Basin. The limestone is generally fine grained, medium gray, less than 2 feet thick, and contains an open-marine fauna composed primarily of brachiopods, crinoids, and gastropods. In southwestern Illinois the Sorento generally lies 15-20 feet above the Shoal Creek Limestone. In the deeper part of the Illinois Basin the interval is usually 20-40 feet, but locally it may be as much as 100 feet. The Sorento is tentatively correlated with the Little Vermilion Limestone of northern Illinois.

Little Vermilion Limestone Member—The Little Vermilion Limestone Member of the Bond Formation (Willman, *in* Cooper, 1946, p. 14) is named for the Little Vermilion River in La Salle County, along which the type section is exposed (SW SW 11, 33N-1E) (Wanless, 1956, p. 12). The Little Vermilion Limestone lies about 25 feet above the La Salle Limestone and is as much as 4 feet thick locally. The limestone is dark gray, argillaceous, and shaly. It is very fossili-

Electronic Filing: Received, Clerk's Office 07/01/2024

ferous, with brachiopods (particularly *Rhipidomella*), bryozoans, and crinoids abundant. In the type area a coal, generally less than 1 foot thick, is found about a foot below the limestone. The Little Vermilion is tentatively correlated with the Sorento Limestone.

Bunje Limestone Member—The Bunje Limestone Member of the Bond Formation (Simon, *in* Kosanke et al., 1960, p. 39) is named for Bunje Station, Bond County, and the type section is about 1 mile south, along Dry Fork (SE SW 7, 6N-4W). The Bunje is known only in the type locality, where it is generally less than 2 feet thick. It is very fossiliferous, having a fauna dominated by large pelecypods, and the upper few inches is characterized by cone-in-cone structure. It is underlain by an unnamed sandstone unit and is commonly about 40 feet above the Sorento Limestone. The Bunje is separated from the Flat Creek Coal above by a few feet of shale and underclay.

Flat Creek Coal Member—The Flat Creek Coal Member of the Bond Formation (Simon, *in* Wanless, 1955, p. 1764) is named for Flat Creek in Bond County, along which the type section is exposed (NE SE 24, 6N-5W) (Kosanke et al., 1960, p. 39). The Flat Creek is a thin, widespread coal readily recognized on geophysical logs in southwestern Illinois. The coal is widely overlain by a thin black shale and a marine limestone. It is correlated with the Flannigan Coal of southeastern and eastern Illinois and the Fairbanks Coal Member of Indiana.

Flannigan Coal Member—The Flannigan Coal Member of the Bond Formation (Newton and Weller, 1937, p. 9) is named for Flannigan Township, Hamilton County, where the type section is an exposure along a southwest-flowing tributary of the Middle Fork Saline River (SW NE NE 17, 7S-5E; erroneously reported as 6S-5E by Kosanke et al., 1960). In the type area, the Flannigan Coal is about 1 foot thick and is overlain by a thin, black fissile shale. The Flannigan occurs in southeastern and eastern Illinois and is correlated with the Flat Creek Coal of southwestern Illinois.

Reel Limestone Member—The Reel Limestone Member of the Bond Formation (Worthen, 1875, p. 55) is named for Reel's Corner, Wabash County (NE? 8, 1S-12W). The Reel Limestone occurs in eastern and southeastern Illinois where it is the first limestone above the Shoal Creek Limestone and lies 85-100 feet above it. The Reel Limestone is dark gray, contains many small gastropods, pelecypods, brachiopods, and incrusting Foraminifera, and is 1-3 feet thick. It is generally underlain by a thin, black fissile shale that directly overlies the Flannigan Coal.

Witt Coal Member—The Witt Coal Member of the Bond Formation (Gluskoter, *in* Kosanke et al., 1960, p. 43) is named for Witt, Montgomery County. The type section consists of exposures along the East Fork of Shoal Creek, about 6.5 miles south of Witt (NE NW SE 7, 8N-2W). The Witt Coal is generally less than 1 foot thick and is recognized only in southwestern Illinois. In the Witt type area the coal lies approximately 45 feet above the Flat Creek Coal. It has been tentatively correlated with a persistent, unnamed, thin coal that occurs about 35 feet above the Reel Limestone throughout eastern and southeastern Illinois.

Coffeen Limestone Member—The Coffeen Limestone Member of the Bond Formation (Gluskoter, *in* Kosanke et al., 1960, p. 39) is named for Coffeen, Montgomery County, and the type section consists of outcrops along the East Fork of Shoal Creek, about 4.5 miles northeast of Coffeen (NE NW SW 7, 8N-2W). The Coffeen Limestone is less than 2 feet thick in the type area and contains a varied marine fauna dominated by brachiopods, crinoids, and bryozoans. It is 8 feet above the Witt Coal in the type area and may be fairly widespread, but it has been recognized only in the northern part of southwestern Illinois. It occurs about 80 feet below the base of the Millersville Limestone. The Coffeen Limestone probably correlates with the Riverview Limestone Member, which lies about 40 feet above the Fairbanks Coal Member of Indiana.

Millersville Limestone Member—The Millersville Limestone Member of the Bond Formation (Taylor and Cady, 1944, p. 22), the top of which defines the top of the formation in central and southern Illinois, is named for Millersville, Christian County. The type locality consists of exposures near the village (SE NE 28 and NW NW 31, 12N-1W) (Payne and Cady, 1944, p. 12-13). In the type area the Millersville is 50 feet thick and is divided into two or three benches by shale partings as much as 2-3 feet thick. It is the thickest limestone in the Pennsylvanian System in Illinois. The limestone is light gray, fine grained, and contains a diversified open-marine fauna. The Millersville has been extensively quarried in central Illinois. In southern Fayette, Effingham, and Jasper Counties and farther south it is not well developed, although thin limestones in that area are considered as correlatives of part of the Millersville. East of the La Salle Anticlinal Belt, the Livingston Limestone is correlated with the Millersville, as is the Argentine Limestone Member of Missouri.

Livingston Limestone Member—The Livingston Limestone Member of the Bond Formation (Worthen, 1875, p. 11-19), the top of which forms the top of the formation in eastern Illinois, is named for Livingston, Clark County. The type section consists of exposures along Big Creek, about 2 miles northwest of Livingston (SE NW 6, 11N-11W) (Wanless, 1956, p. 12). The Livingston occurs in two or three benches separated by shale beds 1-6 feet thick and has a maximum thickness of about 25 feet. It is generally fine grained and medium to thick bedded, and each bench thins to the south as the shale partings become thicker. The Livingston is well developed in Vermilion, Edgar, Clark, and eastern Coles Counties, where it has been extensively quarried. It thins southward into Crawford County. The Livingston is correlated with the Millersville Limestone west of the La Salle Anticlinal Belt.

Mattoon Formation

The Mattoon Formation of the McLeansboro Group (Kosanke et al., 1960, p. 39, 40), the youngest Pennsylvanian formation in Illinois, is named for Mattoon, Coles County, which lies in the general outcrop area of the formation. No type section has been designated, but a good reference section of the lower 300 feet of the formation is available in a detailed sample study and an electrical log for the Illinois Geological Survey Coal Section control well 191, an oil test boring in Clay County (SE SE SE 10, 4N-5E) on file at the Survey (Kosanke et al., 1960, p. 40, 83, 84). The formation is underlain by the Bond Formation (fig. P-2), and the top is an erosional surface overlain, for the most part, by Pleistocene glacial deposits. A maximum of slightly more than 600 feet of Mattoon is preserved in the central part of the Illinois Basin in Jasper County (fig. P-16). Lithologically the Mattoon Formation is a complex unit of thin limestones, coals, black fissile shales, underclays, thick gray shales, and several well developed sandstones. Outcrops are widely scattered, and reliable subsurface data, except for electrical logs of oil tests, are scarce. Consequently, the lateral extent of many of the named units has not been determined. However, many of the coals and limestone units in the Mattoon are believed to be no less persistent than others in the McLeansboro Group. The Omega and Greenup Limestone Members are well developed and

Electronic Filing: Received, Clerk's Office 07/01/2024

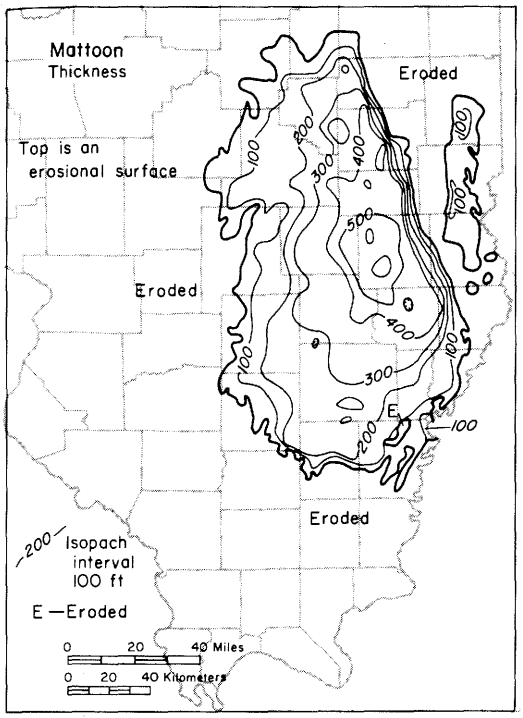

Fig. P-16—Thickness of the Mattoon Formation (based on map by K. E. Clegg).

contain abundant marine fossils, but others are thin and argillaceous. A few tan argillaceous limestones, which contain only ostracodes and *Spirorbis*, are usually less than 5 feet thick. The lower 150 feet of the Mattoon extends into Indiana. The Mattoon correlates with the upper part of the Sturgis Formation in western Kentucky but the top several hundred feet of the Sturgis is younger than the youngest Mattoon of Illinois.

Friendsville Coal Member—The Friendsville Coal Member of the Mattoon Formation (Fuller and Clapp, 1904, p. 2) is named for Friendsville, Wabash County. The type locality consists of several abandoned mines near Friendsville (13, 24, 1N-13W) (Kosanke, 1950, p. 89). The Friendsville Coal is present only in the western two-thirds of Wabash County, where it is as much as 4 feet thick. Near McCleary's Bluff in southern Wabash County it is overlain by an unnamed lenticular limestone up to 6 feet thick that contains abundant phylloid algae. The Friendsville Coal lies about 160 feet above the Reel Limestone, and its position is thought to be in the lower part of the Mattoon Formation. However, its exact relation to the Millersville (Livingston) Limestone has not been determined. In Wabash County, strata that may be equivalent to the Millersville are a complex of limestone, shale, and a few coal streaks, one of which may be equivalent to the Friendsville Coal.

Cohn Coal Member—The Cohn Coal Member of the Mattoon Formation (Newton and Weller, 1937, p. 18) is named for Cohn (now called Livingston), Clark County. The type section consists of an exposure on the south side of Big Creek, about 2.5 miles from Livingston (NE 1, 11N-12W). The Cohn Coal occurs in eastern Illinois, where it is generally less than 10 inches thick. At its type locality it is only 2 inches thick, and it lies 22 feet above the Livingston Limestone and 12 feet below the base of the Merom Sandstone. A 16-inch thick nodular limestone containing numerous *Spirorbis* occurs 2 feet above the coal. To the south in Crawford County, the Cohn Coal is correlated with a thin coal that has been mined in the vicinity of Flat Rock. In that area the Cohn Coal lies at or very near the base of the Merom Sandstone, which may have eroded the coal in some areas.

McCleary's Bluff Coal Member—The McCleary's Bluff Coal Member of the Mattoon Formation (Kosanke, 1950, p. 89; Kosanke et al., 1960, p. 40, 51) is named for McCleary's Bluff, Wabash County. The type section consists of a 3-inch coal seam exposed on the bluff overlooking the Wabash River (NW SW SE 29, 2S-13W). Its stratigraphic position is approximately 50 feet above the Friendsville Coal (Kosanke et al., 1960). It was erroneously placed below the Friendsville Coal by Kosanke (1950) and Siever (*in* Wanless, 1956). The only known exposures of the McCleary's Bluff Coal occur on McCleary's Bluff and at Keys Hill in Wabash County (NE SW 25, 1S-13W). An unnamed coal member approximately 1 foot thick lies 7 feet above the McCleary's Bluff Coal in its type area.

Merom Sandstone Member—The Merom Sandstone Member of the Mattoon Formation (Collett, 1871, p. 199) is named for Merom Hill, Sullivan County, Indiana, and the type section is along the Wabash River Bluff near the town of Merom (7, 7N-10W). At the type locality the Merom Sandstone occurs directly below glacial drift and has a maximum observed thickness of approximately 55 feet. It lies directly on top of a limestone 2-4 feet thick, which is correlated with the Livingston Limestone of eastern Illinois. The sandstone is dominantly a fluvial channel deposit, and at its type locality it has eroded the Cohn Coal, which normally lies 20-30 feet above the Livingston Limestone. The Merom Sandstone is the uppermost named member of the Pennsylvanian System in the Marshall Syncline (fig. 12), where it is approximately 100 feet thick. The stratigraphic position of the Merom Sandstone has not been definitely determined.

Dix Limestone Member—The Dix Limestone Member of the Mattoon Formation (Bradbury, 1965, p. 4) is named for Dix, Jefferson County, where it has been quarried locally. The type section consists of exposures on a southwest-flowing tributary to Casey Fork, about 2 miles south of Dix (NW SE NW 25, 1S-2E). In that area the Dix is a brownish gray argillaceous limestone as much as 6 feet thick that contains only *Spirorbis* and numerous ostracodes. It lies about 50 feet above the position of the Millersville Limestone and 300 feet above the Shoal Creek Limestone. The Dix may correlate with the fresh-water limestone found at the base of the underclay below the Opdyke Coal.

Opdyke Coal Member—The Opdyke Coal Member of the Mattoon Formation (Cady et al., 1952, p. 90-91) is named for the village of Opdyke, Jefferson County, where the type section is in small mines in the vicinity of Belle Rive and Opdyke (3S-4E). In the type locality the Opdyke is fairly extensive and as much as 2 feet thick locally. It crops out in eastern and southeastern Jefferson County and northwestern Hamilton County. It lies about 430 feet above the Shoal Creek Limestone and is tentatively correlated with a 12-inch coal that crops out on the Louden Anticline in eastern Fayette County, 60-70 feet above the Millersville Limestone, and is believed to be extensive in the subsurface of central Illinois.

Shelbyville Coal Member—The Shelbyville Coal Member of the Mattoon Formation (Broadhead, 1875, p. 169-171, used the term "Shelby"; Worthen, 1875, p. 49, used the term "Shelbyville") is named for Shelbyville, Shelby County. The type section is in natural exposures and in drift and shaft mines in the vicinity of Shelbyville (11N-3-4E) (Kay,

Electronic Filing: Received, Clerk's Office 07/01/2024

1915, p. 215, 216). The coal is locally as much as 3 feet thick and can be traced in the subsurface in most of the area in which the Mattoon Formation occurs. It is normally 80-120 feet below the Omega Limestone.

Calhoun Coal Member—The Calhoun Coal Member of the Mattoon Formation (Noé, 1934, p. 103) is named for Calhoun, Richland County, and the type section is in a roadcut about 2 miles southeast of Calhoun (NE NE NE 6, 2N-14W) (Kosanke et al., 1960, p. 40, 82). The Calhoun Coal is widespread in eastern Illinois, where it is 2 feet thick or less and is overlain by the Bonpas Limestone. It lies about 525 feet above the Shoal Creek Limestone. The Calhoun is also present on the western side of the deeper part of the Illinois Basin, where it occurs a foot or two below the Omega Limestone.

Omega Limestone Member—The Omega Limestone Member of the Mattoon Formation (Weller and Wanless, *in* Lamar et al., 1934, p. 128) is named for Omega, Marion County. The type locality consists of exposures in an abandoned limestone quarry (NW NW NE 30, 3N-4W) (Weller and Bell, 1936, p. 29-32; Wanless, 1956, p. 12; Kosanke et al., 1960, p. 81, 82). The Omega is almost 11 feet thick in the type locality and reaches 15 feet in Effingham and Shelby Counties. In Shelby County it varies in thickness and character and is very argillaceous and sandy in areas where it is thick. Although sporadic in occurrence, it appears in a wide area. It is correlated with the Bonpas Limestone in eastern Illinois.

Bonpas Limestone Member—The Bonpas Limestone Member of the Mattoon Formation (Kosanke et al., 1960, p. 41) is named for Bonpas Creek, Richland County. It previously was called Calhoun Limestone (Weller, *in* Dunbar and Henbest, 1942, p. 27). The type section is in a roadcut exposure about 1.5 miles west of Bonpas Creek, the same location as the Calhoun Coal type section (Kosanke et al., 1960, p. 41, 82). The Bonpas is 3 feet thick in the type locality and is widely distributed in eastern Illinois. It contains a varied open-marine fauna and is correlated with the Omega Limestone of the western side of the area covered by the Mattoon Formation.

(Mattoon Formation continued in next column)

VIRGILIAN SERIES

The Virgilian Series of the Pennsylvanian System (Moore, 1931, correlation chart) is named for Virgil, Greenwood County, Kansas, which lies in the outcrop belt of these rocks. In Illinois it includes all Pennsylvanian strata above a position a few feet below the coal that occurs just below the Shumway Limestone Member (Willman et al., 1967). It thus includes the upper half of the Mattoon Formation of the McLeansboro Group (fig. P-2). Where marine rocks are found, as they are in Illinois and the Midcontinent Region, the Virgilian includes strata containing fusulinids of the genus *Triticites* that are more advanced than the subgenus *Kansanella* found in lower strata. The upper limit is placed just below the first appearance of the Permian genera *Pseudoschwagerina* and/or *Schwagerina*, but neither have been found in the Illinois Basin. The spores and plant-compression fossils in Virgilian rocks are not well known.

Mattoon Formation (continued)

Shumway Limestone Member—The Shumway Limestone Member of the Mattoon Formation (Weller, *in* Dunbar and Henbest, 1942, p. 28; Wanless, 1956, p. 12) is named for Shumway, Effingham County. The type locality consists of exposures along Shoal Creek about 2 miles east of Shumway (SE SE SW 26, 9N-5E) (Kosanke et al., 1960, p. 81). The Shumway is the upper, most persistent of two marine limestones. At the type locality it is 2 feet thick and contains an abundant open-marine fauna dominated by brachiopods and containing a few solitary corals. The Shumway and the thin coal a few feet under it are exposed in Effingham County. It is directly underlain by a black fissile shale and overlain by gray shale.

Effingham Limestone Member—The Effingham Limestone Member of the Mattoon Formation (Wanless, 1956, p. 7, 12) is named for Effingham, Effingham County. The type section consists of outcrops in the east-flowing tributary to Salt Creek just south of Effingham (S line NW 33, 8N-6E). This limestone has not been recognized far from the type area, where it is a 1-foot bed of granular conglomeratic limestone containing numerous brachiopods, gastropods, crinoids, and a few corals. A thin, black fissile shale occurs about 3 feet above the Effingham Limestone.

Trowbridge Coal Member—The Trowbridge Coal Member of the Mattoon Formation (Cady, 1948, p. 5, footnote 4) is named for Trowbridge, Shelby County. The type locality consists of outcrops about 1 mile northeast of the town (S line 11, 10N-6E). The Trowbridge attains a maximum thickness of 2.5-3 feet and is a normally banded coal that is high in ash. It occurs about 150-180 feet above the Omega Limestone. It has not been traced far from the type area.

Bogota Limestone Member—The Bogota Limestone Member of the Mattoon Formation (Newton and Weller, 1937, p. 9) is named for Bogota, Jasper County. The type section consists of exposures along Big Muddy Creek about 6 miles southwest of Bogota (NE NE 7, 5N-8E) (Kosanke et al., 1960, p. 44, 79, 80). The Bogota is known definitely only in the type locality, but the name has been questionably applied to many limestone outcrops in the central part of the area of the Mattoon Formation. In the type section the Bogota is 1.5 feet of gray, fossiliferous, nodular limestone in a yellowish brown clay matrix, and it overlies about 1 foot of black fissile shale.

Reisner Limestone Member—The Reisner Limestone Member of the Mattoon Formation (Kosanke et al., 1960, p. 41, 51) is named for Reisner School, Jasper County. It previously was called Newton Limestone (Newton and Weller, 1937, p. 9, 24-25). The type section consists of exposures along West Crooked Creek, 1.5 miles northeast of the abandoned Reisner School (NE NE 16, 7N-10E). Near its type locality the Reisner Limestone is argillaceous and contains fragments of small brachiopods. It is generally less than 1 foot thick, is overlain by 1.5 feet of black fissile shale, and is underlain by claystone containing argillaceous and generally unfossiliferous (with local exceptions of *Spirorbis*) limestone as much as 3 feet thick in places. The Reisner Limestone lies 60-80 feet above the Bogota Limestone Member and 40-45 feet above an unnamed coal that was mined from a few shallow shafts in the vicinity of Newton and was reported to be approximately 2 feet thick. Kosanke et al. (1960) stratigraphically placed the Reisner Limestone as the youngest named member in the Mattoon Formation. However, recent studies indicate that the Reisner Limestone occurs below the Greenup Limestone, as had been stated by Newton and Weller (1937).

Gila Limestone Member—The Gila Limestone Member of the Mattoon Formation (Newton and Weller, 1937, p. 27) is named for Gila, Jasper County. The type section consists of exposures about 1.5 miles south of Gila along Mint Creek (NE SW 31, 8N-9E) (Kosanke et al., 1960, p. 41, 51, 78,

Electronic Filing: Received, Clerk's Office 07/01/2024

79). The Gila has not been recognized outside the type area, where it is a gray, fine-grained, dense limestone 2.5 inches thick in which fish scales and teeth are the only fossils found.

Woodbury Limestone Member—The Woodbury Limestone Member of the Mattoon Formation (Newton and Weller, 1937, p. 9, 28-30) is named for Woodbury, Cumberland County. The type section consists of exposures on a tributary to Webster Branch about 2 miles southwest of Woodbury (S1/2 SE 32, 9N-8E). In the type section the Woodbury is a hard, gray, calcareous ironstone layer 3-4 inches thick that contains numerous brachiopods, crinoids, and a few corals. It is separated from an underlying 5-inch coal by a few inches of black coaly shale. The Woodbury has not been recognized outside the type area.

Greenup Limestone Member—The Greenup Limestone Member of the Mattoon Formation (Newton and Weller, 1937, p. 9, 26), the youngest named member of the formation, is named for Greenup, Cumberland County. The type section consists of exposures along the valley wall of the Embarras River just west of Greenup (cen. W1/2 NE 3, 9N-9E) (Kosanke et al., 1960, p. 41, 51, 79). The Greenup is known from several outcrops in the northern part of the area of the Mattoon Formation in Jasper, Cumberland, and Coles Counties, where it is as much as 8 feet thick and has been quarried locally. The Greenup is a relatively pure limestone with an abundant open-marine fauna dominated by brachiopods and crinoids but also including a few corals and locally abundant fusulinids. It represents a major marine transgression into Illinois.

MESOZOIC ERATHEM

H. B. Willman and John C. Frye

The Mesozoic Erathem—the rocks deposited during the Mesozoic Era (Phillips, 1840)—is represented in Illinois only by the Cretaceous System, the youngest deposits of the era. As the youngest of the Paleozoic rocks (the Permian System), the Mesozoic, Triassic, and Jurassic Systems and the Comanchean Series of the Cretaceous System are not represented in Illinois, the base of the Cretaceous System is a major unconformity (fig. 1). However, the general distribution of the marine Permian rocks over the continental United States suggests that Permian seas covered much of Illinois and that their absence is attributable to erosion, either in latest Permian time or during the early and middle parts of the Mesozoic Era. There is no evidence to suggest that extensive deposits, either marine or continental, accumulated in Illinois during the pre-Cretaceous periods of the Mesozoic Era. Although such deposits could have been present and entirely eroded, the development of the sub-Cretaceous unconformity required a long interval of erosion, and it seems likely that Illinois was continuously in an erosional environment during early Mesozoic time. The Little Bear Soil, which developed on the Paleozoic rocks and is present at the base of the Cretaceous sediments in southern Illinois (fig. K-2), probably formed during the later part of this interval.

The Mesozoic rocks, which are largely unconsolidated sand incorporating some silt and clay, occur only in extreme southern Illinois and locally in western Illinois (figs. K-3, K-4). The southern Illinois Cretaceous strata are part of the deposits at the head of the Mississippi Embayment of the Gulf Coastal Plain. With the overlying Tertiary formations, they compose a distinctive unit differentiated as the Embayment Megagroup.

The Mesozoic Era, the interval of "middle life," formerly called the "Secondary Group" of rocks, is also known as the Age of Reptiles, and the huge dinosaurs of that time may have been common in Illinois, although no remains have been found. The era also saw the first appearance of birds, mammals, and angiosperms.

Little Bear Soil

The Little Bear Soil (Mellen, 1937, p. 8-20), a soil locally preserved at the base of the Cretaceous System, is named for Little Bear Creek, Tishomingo County, Mississippi. It is the only soil-stratigraphic unit that has been named in Illinois in pre-Quaternary strata (Pryor and Ross, 1962; Ross, 1963). It consists of remnants of an iron-rich residual soil developed on Paleozoic rocks. Isolated remnants have been found throughout the eastern part of the Mississippi Embayment. In Illinois it consists of red and brown clays with lenses and nodules of brown to black limonite and, generally, a few angular chert pebbles. It is included in the lower part of the Tuscaloosa Formation. It is well exposed along the Post Creek Cutoff in Pulaski County (cen. 2, 15S-2E), where it is 7 feet thick, rests on the St. Louis Limestone, and is overlain by gravel of the Tuscaloosa Formation. The Little Bear Soil was developed during early Cretaceous time, after the erosional truncation of the Paleozoic rocks by the sub-Cretaceous unconformity.

Electronic Filing: Received, Clerk's Office 07/01/2024

EMBAYMENT MEGAGROUP

The Embayment Megagroup (Swann and Willman, 1961, p. 482), named for the Mississippi Embayment, the northward extension of the Gulf Coastal Plain into southernmost Illinois, consists in Illinois of the dominantly clastic formations of Cretaceous and Tertiary age that differ markedly in character from the underlying Paleozoic and the overlying Quaternary formations and are separated from both by major unconformities. The Embayment Megagroup includes seven formations (figs. K-2, T-2) that occur largely south of the Cache Valley in Pulaski and Massac Counties but also extend westward across Alexander County from the Cache River Valley to the Mississippi River Valley. The megagroup thickens rapidly southward into the Embayment area and has a maximum thickness of nearly 1000 feet in subsurface near Cairo, Alexander County.

CRETACEOUS SYSTEM

The Cretaceous System (D'Halloy, 1822), named for the chalk formations of France, is restricted in Illinois to five counties in extreme southern Illinois and to areas in Pike and Adams Counties in western Illinois.

The Cretaceous rocks in southern Illinois (Glenn, 1906; Lamar and Sutton, 1930; Stearns, 1958; Pryor, 1960; Pryor and Ross, 1962; Ross, 1963, 1964) (figs. K-1, K-2) are at the north end of the Mississippi Embayment of the Gulf Coastal Plain (fig. K-3). They are entirely clastic rocks—the nonmarine part of a large delta built where a river from the east discharged into the head of the embayment. A thin marine deposit occurs at the top. The Cretaceous rocks are as much as 500 feet thick near Cairo, where they are overlain by Paleocene sediments, but they thin rapidly northward as they are truncated by younger Tertiary and Pleistocene sediments.

The Cretaceous rocks in western Illinois (Frye et al., 1964) (fig. K-4) also are clastic rocks, largely sand, and as much as 100 feet thick. They are the easternmost outliers of Cretaceous sediments that formerly covered the region east of the Rocky Mountains and north of the Ozarks. The outliers in Illinois are nearly 200 miles from the nearest Cretaceous exposures in west-central Iowa. They appear to be beach and nearshore sediments deposited in the advancing Cretaceous sea.

Although the deposits are dominantly quartz sand in both areas, they differ noticeably in other mineral constituents. The two regions were separated by a barrier, probably a low eastern extension of the Ozark Uplift across southern Illinois.

The Cretaceous sediments in southern Illinois terminate northward as they are truncated by Tertiary deposits. The presence of Cretaceous-type gravel and white clays in possible sink holes as far north as Kaolin, northwest of Anna, Union County, suggests that Cretaceous deposits formerly were more extensive than they are now, although they probably did not extend significantly north of their present area. Cretaceous rocks in western Illinois terminate southward against an area of higher Mississippian formations, indicating that Cretaceous sediments may never have been deposited in the area between there and extreme southern Illinois.

The southern Illinois Cretaceous rocks are largely nonmarine sand containing beds of lignitic silt and clay, lignite, and gravel. The major part of the Cretaceous in this area is assigned to the McNairy Formation, but the patches of gravel at the base are assigned to the Tuscaloosa Formation, and a thin, marine sandy silt at the top is assigned to the Owl Creek Formation (fig. K-2). The heavy minerals of the sands are characterized by a high content of kyanite and by appreciable amounts of staurolite, tourmaline, sillimanite, zircon, and rutile. The clay minerals in the nonmarine sediments are largely kaolinite, whereas those in the marine sediments are dominantly montmorillonite (Pryor and Glass, 1961). The mineralogy indicates the sediments were derived from the metamorphic rocks of the Piedmont region to the east or southeast. The sediments were carried into the Embayment region by a river on the sub-Cretaceous erosional surface.

Cretaceous rocks in western Illinois, all assigned to the Baylis Formation, are largely sand and clayey sand that are generally nearly white, although they are rusty brown where weathered. They commonly contain a bed of gravel at the base and, in some localities, beds of gray to dark gray silty clay. The heavy minerals in the sands are dominantly

Electronic Filing: Received, Clerk's Office 07/01/2024

zircon, tourmaline, and staurolite, in percentages close to those in the Cretaceous deposits of Iowa and Kansas. The dominant clay mineral varies from bed to bed, from montmorillonite to illite to kaolinite, indicating the mixed compositions of nearshore environments and derivation largely from northern sources. Similar compositions were found in samples of the Cretaceous in Iowa. The mineral composition and sediment characteristics distinguish these deposits from glacial deposits.

The Cretaceous rocks in western Illinois appear to have been deposited on a nearly flat surface eroded across various Mississippian and Pennsylvanian formations. In southern Illinois, variations in thickness of the Cretaceous sediments have commonly been interpreted as indicating significant relief on the pre-Cretaceous surface because the outcropping Cretaceous rocks show none of the intensive faulting found in the Paleozoic rocks immediately north of the Cretaceous area. However, Ross (1963) questioned this interpretation because subsurface information showed that the basal thin gravel and the Little Bear Soil beneath it are more widespread than originally thought and that the thickness variations of the Cretaceous parallel the structures in the Paleozoic rocks. Consequently, he related the irregularities of the sub-Cretaceous surface to Cretaceous and possibly post-Cretaceous movements of some of the major faults.

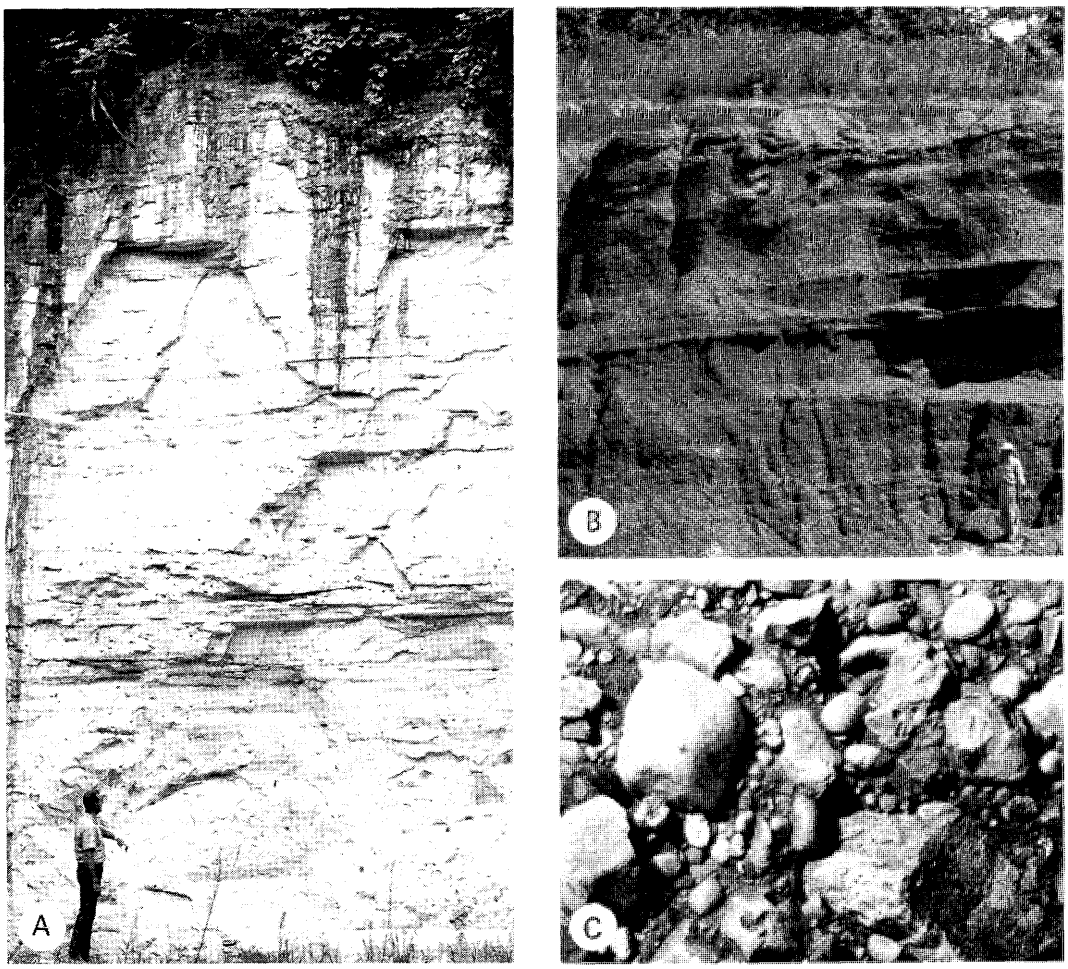

Fig. K-1—Exposures of Cretaceous and Tertiary rocks.

C—Bedding surface of Mounds Gravel in same pit as exposure B (×1 1/2).

Electronic Filing: Received, Clerk's Office 07/01/2024

The Cretaceous age of the southern Illinois deposits is indicated by the presence of a few distinctive Foraminifera in the Owl Creek Formation, by abundant plant fossils in the lignitic beds, and by the equivalence of the deposits to the abundantly fossiliferous marine sediments south of Illinois. No fossils have been found in the western Illinois deposits, but the composition of the gravels, the heavy minerals in the sands, and the clay mineral assemblages are all similar to those of the Cretaceous rocks in Iowa. From their stratigraphic position, the sediments could be Tertiary in age, but they appear to have been deeply eroded before the near-by late Tertiary gravel was deposited.

GULFIAN SERIES

The Gulfian Series (Hill, 1887, p. 298, 300) is named for its occurrence along the Coastal Plain of the Gulf of Mexico, and is presumed to include all Cretaceous rocks in Illinois. In southern Illinois most of the Cretaceous rocks were deposited during the youngest part of the Gulfian, although the basal Tuscaloosa Formation may represent early deposits of the series. Cretaceous rocks in western Illinois were probably deposited during early Gulfian time.

Tuscaloosa Formation

The Tuscaloosa Formation (Smith and Johnson, 1887, p. 18, 95-117) (fig. K-2), is named for exposures along the Tuscaloosa (Black Warrior) River near Tuscaloosa, Alabama. It is exposed only locally in extreme southern Illinois and appears to have a patchy distribution (Pryor, 1960; Pryor and Ross, 1962; Ross, 1964). It has a maximum thickness of 20 feet but is generally much thinner. The Tuscaloosa is well exposed along the Post Creek Cutoff, Pulaski County (cen. 2, 15S-2E), and in railroad cuts in the Thebes Gorge, 1 mile south of Rock Springs Hollow, Alexander County (SW 21, 15S-3W). It is largely chert gravel, generally moderately cemented with fine silica or white clay. The chert pebbles, in a matrix of coarse quartz sand, are mainly white or gray, but black pebbles are locally common. Beds of pebbly sand and white clay also are common. The clays are dominantly kaolinite (Pryor and Glass, 1961). The Little Bear Soil occurs in deposits at the base of the Tuscaloosa Formation. Gravel found northeast of Elco in northern Alexander County (SW SE 7, 14S-1W) is probably Tuscaloosa Gravel preserved in sink holes. Local concentrations of gray and black chert pebbles on the upland bedrock surfaces as far north as Kaolin, Union County (SW NW 2, 12S-2W), are probably residual or reworked from the Tuscaloosa. The Tuscaloosa in Illinois is similar in lithology and stratigraphic position to the Tuscaloosa of Kentucky and Tennessee, but it is a transgressive deposit and may be younger than the type Tuscaloosa.

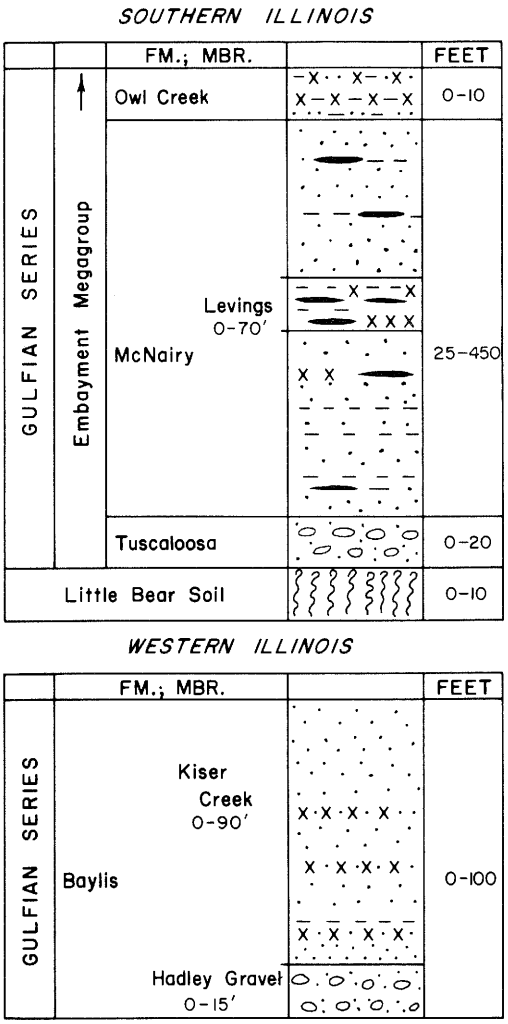

Fig. K-2—Classification of the Cretaceous System.

McNairy Formation

The McNairy Formation (Stephenson, 1914, p. 18, 22) (fig. K-2) is named for McNairy County, Tennessee, where the type section is a railroad cut 1.5 miles west of Cypress Station. It was formerly called a member of the Ripley Formation (Lamar and Sutton, 1930) but was designated a formation by Pryor (1960). The McNairy is widely exposed in extreme southern Illinois, largely south of the Cache River Valley in Massac and Pulaski Counties but also farther west in the southern part of the hills from Olive Branch to Fayville in Alexander County (fig. K-1A). The lower part of the formation is widely exposed in roadcuts in the hills 2-4 miles north of Unionville, Massac County (Ross, 1964), and the upper part in the Ohio River bluffs in the vicinity of U.S. Dam 53 in Pulaski County (Pryor and Ross, 1962). The formation is at least 450 feet thick, perhaps locally a little thicker. Along its northern limit it is truncated by the Mounds Gravel.

Electronic Filing: Received, Clerk's Office 07/01/2024

The McNairy Formation is a deltaic deposit at the northern end of the Mississippi Embayment and consists largely of nonmarine sand deposited by rivers and of lignitic clays and silts deposited in interdistributary areas. The lower part consists of fine, white to light gray, cross-bedded, micaceous sand. A middle section, which is gray to black silt with beds of lignite, is named the Levings Member. The upper part is similar to the lower. In the areas where the McNairy is overlain by the Mounds Gravel, the upper 25-50 feet is commonly stained red by iron oxide. South of Illinois, the McNairy Formation grades into the marine sediments of the Selma Formation.

Levings Member—The Levings Member of the McNairy Formation (Pryor and Ross, 1962, p. 19) is named for Levings, Pulaski County, which is 1.5 miles northeast of the type section along a creek southwest of U.S. Dam 53 (NW SW 18, 15S-2E). The Levings Member is largely lignitic silt and clay with thin beds of lignite. It occurs in the middle part of the McNairy Formation, is 0-70 feet thick, and is generally present throughout the northern part of the Mississippi Embayment.

Owl Creek Formation

The Owl Creek Formation (Hilgard, 1860) (fig. K-2), named for exposures along Owl Creek, 3 miles northeast of Ripley, Tippah County, Mississippi, is the uppermost Cretaceous Formation in southern Illinois. It is exposed in Illinois only in Pulaski County along the Ohio River near U.S. Dam 53 (SE NW NE 13, 15S-1E) and along the Cache River near Unity (NE 7, S1/2 6, 16S-1W) (Pryor and Ross, 1962). It consists of glauconitic, very micaceous, sandy, silty clay and silt 0-10 feet thick. It overlies the McNairy Formation conformably. A weathered zone at its top, marked by concentrations of hematitic nodules and a sharp upper contact, indicates an unconformity that separates the Owl Creek from the overlying Tertiary Clayton Formation. The Owl Creek indicates a brief advance of the sea over the McNairy delta.

Baylis Formation

The Baylis Formation (Frye et al., 1964, p. 4) (fig. K-2), which comprises all the sediments of Cretaceous age in western Illinois, is named for Baylis, Pike County, 4 miles north of the type section, which is an exposure and small pit along a branch of Kiser Creek (NW SW SE 31, 4S-4W). The Baylis occurs in Pike and Adams Counties in a prominent ridge that extends for about 20 miles northwest of the Pittsfield area, and it also appears 10 miles farther northwest in a smaller, less prominent area south of Mendon in Adams County (fig. K-4). The Baylis has a maximum thickness of about 100 feet near Baylis, but the top of the formation is eroded and it may originally have been much thicker. The Baylis is largely fine to medium quartz sand and clayey sand. In places it contains lenses of silty clay and pebbles of chert, quartz, and quartzite. The basal few feet is generally gravel and is differentiated as the Hadley Gravel Member. The upper, sandy part of the formation is the Kiser Creek Member. The sands are generally white, but in places some beds are stained brown by limonite. The basal part of the gravel is locally strongly cemented with iron and manganese minerals, although most of the formation is uncemented and soft. The Baylis rests unconformably on Mississippian and Pennsylvanian rocks and is overlain unconformably by Pleistocene deposits, generally only loess in the main ridge northwest of Pittsfield but elsewhere by Kansan drift and, locally, by Illinoian drift (fig. K-4). Most

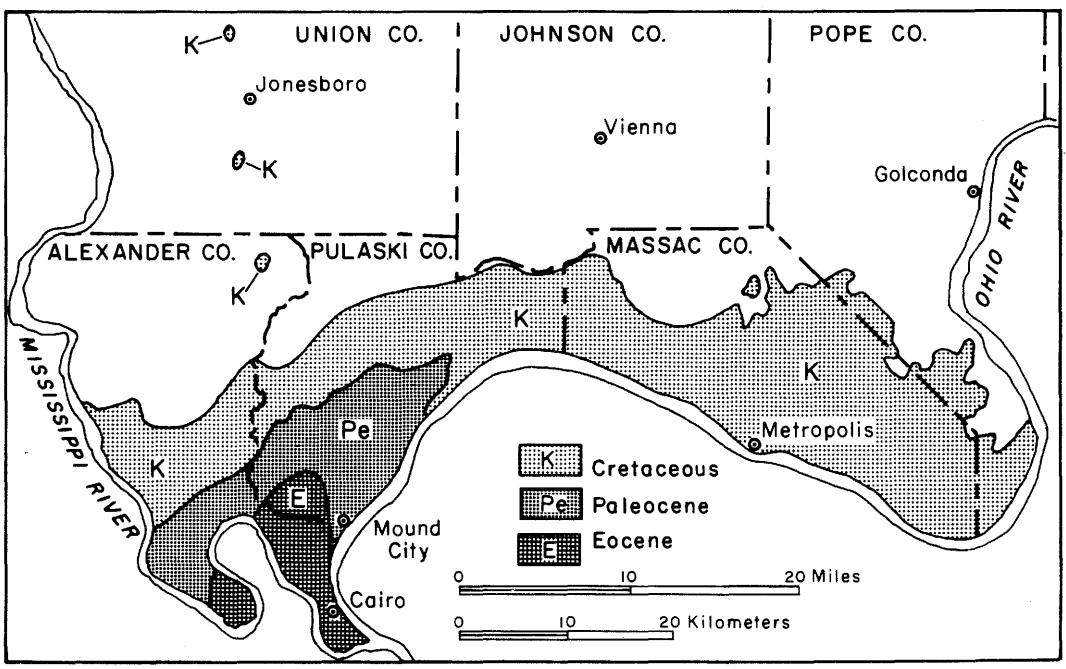

Fig. K-3—Distribution of Cretaceous, Paleocene, and Eocene strata in southern Illinois (after Willman et al., 1967).

Fig. K-4—Distribution of Cretaceous strata in western Illinois (after Frye et al., 1964).

of the formation is similar in lithology to the Cretaceous Dakota Formation in west-central Iowa, but the Hadley Gravel Member closely resembles the Windrow Formation in Iowa and Wisconsin (Andrews, 1958).

Hadley Gravel Member—The Hadley Gravel Member of the Baylis Formation (Frye et al., 1964, p. 4, 8), the basal member, is named for Hadley, Pike County, 4 miles northwest of the type section, which is also the type section for the Baylis Formation. The member is generally present in the outcrop area of the formation. It is as much as 15 feet thick but is generally less than 10 feet and in places is only a layer of pebbles. It is predominantly pebbles and small cobbles of brown, dark gray, and red chert, but 20-30 percent of the pebbles are quartz, and 1-2 percent are quartzite. It differs only slightly from the Grover Gravel of the Tertiary System, which probably was largely reworked from the Cretaceous gravels, but in the Grover Gravel the brown chert pebbles are more abundant, rounder, and more highly polished. Some of the isolated patches of chert gravels long assigned to the Tertiary may be remnants of the Hadley Gravel Member, which originally may have had wide distribution in western and northern Illinois.

Kiser Creek Member—The Kiser Creek Member of the Baylis Formation (Frye et al., 1964, p. 4, 10), the upper member, is named for the East Branch of Kiser Creek, a tributary of which exposes the type section, the same section described for the Baylis Formation. The member constitutes the greater part of the formation and is dominantly sand and clayey sand, as described for the formation. The sands and clays of the Kiser Creek Member differ from glacial sands in their uniformity, lack of carbonates, distinctive clay mineral assemblages, and the absence of the variety of heavy minerals that characterizes the glacial deposits.

CENOZOIC ERATHEM

H. B. Willman and John C. Frye

The Cenozoic Erathem—the strata deposited during the Cenozoic Era (Phillips, 1840)—consists of the Tertiary and Quaternary Systems, which comprise all deposits in Illinois younger than those of the Cretaceous System of Mesozoic age, including those now being deposited. Except for small areas, mainly in western and northern Illinois, rocks of Tertiary age are restricted to extreme southern Illinois (figs. K-1, T-1), whereas deposits of Quaternary age occur throughout the state (fig. 11).

Only a minor unconformity separates the oldest Cenozoic (Tertiary) strata from the youngest Mesozoic (Cretaceous). As the Oligocene and Miocene Series are not present in Illinois, a prominent unconformity separates the oldest Tertiary (Paleocene and Eocene) from the youngest Tertiary (Pliocene) rocks. A major unconformity also separates the Tertiary from the Quaternary. However, because the Cretaceous and Tertiary Systems are missing in much of Illinois, the Quaternary System, which covers more than 95 percent of the state, lies directly and unconformably on Paleozoic rocks in most places.

The older Tertiary rocks include marine deposits of the Mississippi Embayment, whereas the younger are entirely continental. The Quaternary strata include the glacial deposits that cover 80 percent of Illinois, the loess that mantles nearly all of the state, floodplain alluvium along the rivers and streams, lake and swamp deposits in some lowland areas, sand dunes on terraces and bordering uplands, and the soils that have been developed on most of these deposits.

Many of the Cenozoic rocks are abundantly fossiliferous, and even the oldest have many species nearly like those of the present day. The term Cenozoic means "recent life."

TERTIARY SYSTEM

The Tertiary System (Arduino, 1760), a name retained from one of the earliest classifications of rocks, is extensive only in the extreme southern part of Illinois (figs. K-3, T-1), but it also occurs in small widely scattered areas in western and northern Illinois (fig. T-1). Tertiary sediments in southern Illinois are included with Cretaceous sediments in the Embayment Megagroup.

The Paleocene and Eocene Series (fig. T-2) are present as Coastal Plain sediments in extreme southern Illinois, where they are separated from overlapping Pliocene deposits by a major unconformity. Late Eocene, Oligocene, and Miocene sediments are absent, although some sediments of these series could have been deposited and later eroded during development of the sub-Pliocene unconformity. The Jackson Formation of the late Eocene occurs in Kentucky only a short distance south of Illinois, and Oligocene and Miocene deposits occur in the Coastal Plain Embayment area farther south.

Progressive sinking of the embayment area resulted in the relatively rapid southward thickening of the pre-Pliocene Cretaceous and Tertiary deposits and gave them a southward dip significantly greater than that of the Pliocene sediments. Tertiary sediments have a maximum thickness of about 400 feet in the vicinity of Cairo, Alexander County.

The Paleocene sediments are largely marine clays and sands, whereas the Eocene sands and silty clays indicate a return to nonmarine deltaic sedimentation like that operating during the Cretaceous. The Pliocene sediments are mostly fluvial deposits of a continental environment.

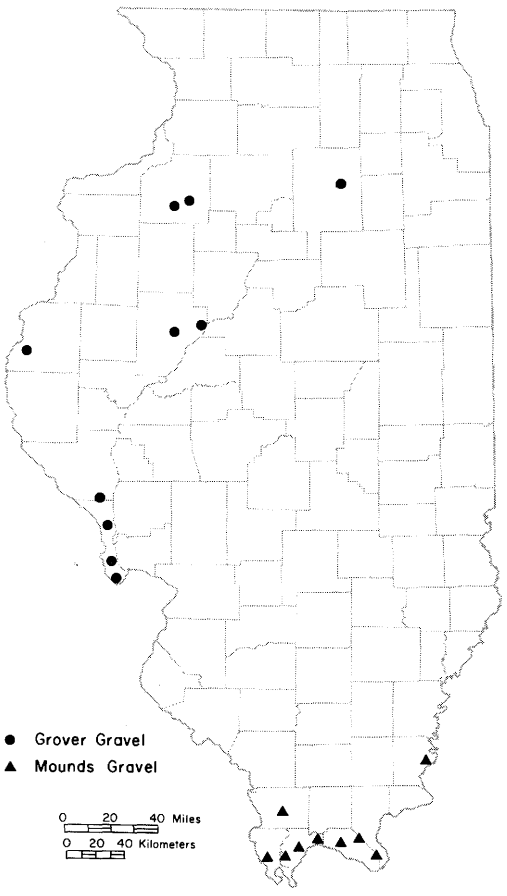

Fig. T-1—Distribution of the Mounds and Grover Gravels.

PALEOCENE SERIES

The Paleocene Series (Schimper, 1874) was differentiated from the Eocene because the floras of the sediments were believed to be sufficiently different from those of the younger Eocene to merit establishing a separate series. The floras of the Paleocene bridge the gap between typical Cretaceous and Eocene floras. Paleocene means "ancient and recent." In Illinois, the Paleocene Series occurs only in the extreme southern counties—Alexander and Pulaski. Paleocene deposits there have a maximum thickness of about 170 feet and are well exposed along the Ohio River near Olmsted and along the Cache River near Unity. The Paleocene consists of the Clayton (below) and Porters Creek Formations. Both formations include marine clays, but the Clayton is sandy and strongly glauconitic. The clays are dominantly montmorillonite (Pryor and Glass, 1961). Paleocene rocks are fossiliferous, but most of the fossils are microfossils or poorly preserved macrofossils. The heavy minerals in the Paleocene sediments are similar to those in the Cretaceous and indicate their source was the metamorphic rocks of the

Piedmont region far to the east. South of Illinois, the two formations are classified as the Midway Group.

Clayton Formation

The Clayton Formation (Landon, 1891, p. 594) (fig. T-2), named for exposures near Clayton, Barbour County, Alabama, is persistently present at the base of the Paleocene Series in southern Illinois (Pryor and Ross, 1962). It is well exposed in a small ravine northwest of U.S. Dam 53 in Pulaski County (SE NW NE 13, 15S-1E). It is commonly 15-20 feet thick and consists of glauconitic, micaceous, green to buff silty clay that is sandy and pebbly at the base. Foraminifera are the main fossils in the Clayton Formation, but the remains of radiolarians and other plankton also are present. The Clayton is generally less sandy and more glauconitic than the Owl Creek Formation below, and the contact, which is unconformable, is marked by pebbles of white and black chert and iron oxide in the base of the Clayton.

Porters Creek Formation

The Porters Creek Formation (Stafford, 1864, p. 361, 368) (fig. T-2) is named for exposures on Porters Creek in Hardeman County, Tennessee. It is present in Alexander and Pulaski Counties in southern Illinois (Lamar, 1928b; Pryor and Ross, 1962) and is well exposed in pits south of Olmsted, Pulaski County (NE SE 27, 15S-1E), in the Ohio River bluffs near U.S. Dam 53, and along the Cache River near Unity. It is 50-150 feet thick, but north of the Cache Valley it is completely truncated by the Mounds Gravel. The Porters Creek is largely massive, compact, essentially unbedded or weakly bedded, dark gray to nearly black clay that has a blocky fracture. It is gray-tan to white where weathered. Because it does not readily become plastic when wet, it can stand in steeper faces than most clays. It is more than 80 percent montmorillonite. Microfossils (Radiolaria, Hystrichospheridae, and Foraminifera) are abundant, but fish scales, shark teeth, and casts and molds of pelecypods and gastropods are also common. The Porters Creek is overlain unconformably by the Wilcox Formation, which locally cuts deeply into the Porters Creek. The Porters Creek is a marine deposit representing an advance of the sea over essentially the entire area of the embayment. Because the clay has the absorptive and filtering properties of fuller's earth, it has been mined commercially south of Olmsted, Pulaski County.

EOCENE SERIES

The Eocene Series (Lyell, 1833) in Illinois occurs in a small area in Pulaski and Alexander Counties. It is exposed only in Pulaski County in the hills from Mounds west to Cache Valley. The Eocene sediments are all assigned to the Wilcox Formation. The Eocene, which means "dawn of the recent," was so named because its flora and fauna contained only a small proportion of recent species.

Wilcox Formation

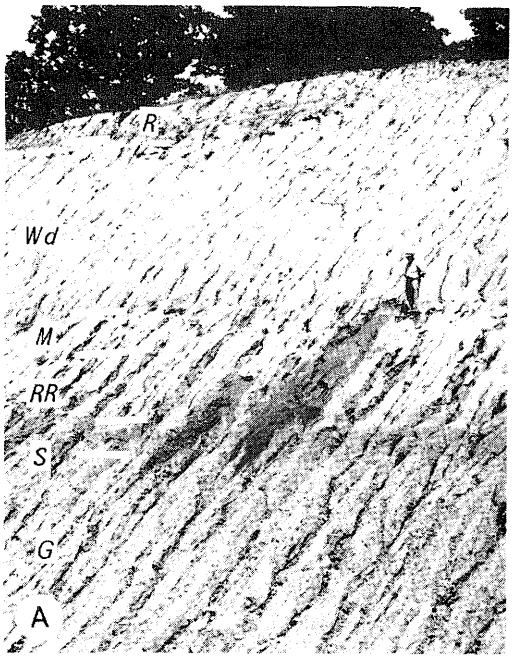
The Wilcox Formation (Crider and Johnson, 1906, p. 5, 9) (fig. T-2) is named for Wilcox County, Alabama. It was formerly called Lagrange in Illinois (Lamar and Sutton, 1930). It is exposed in Illinois only in Pulaski County (Pryor and Ross, 1962), along the east side of the Cache River south of Unity, particularly in a pit where 20 feet of sand of the Wilcox Formation overlies the Porters Creek Formation and is overlain by the Mounds Gravel (SE SW SW 7, 16S-1W) (Pryor and Ross, 1962). The Wilcox varies from white, fine to medium, slightly micaceous sand to gray, nearly white, silty or sandy clay. It is only 20-30 feet thick in the outcrop area, but it thickens southward and is as much as 250 feet thick in subsurface near Cairo, Alexander County. The Wilcox was deposited in a delta at the head of the embayment. It probably is equivalent to only part of the Wilcox farther south in Kentucky and Tennessee.

PLIOCENE SERIES

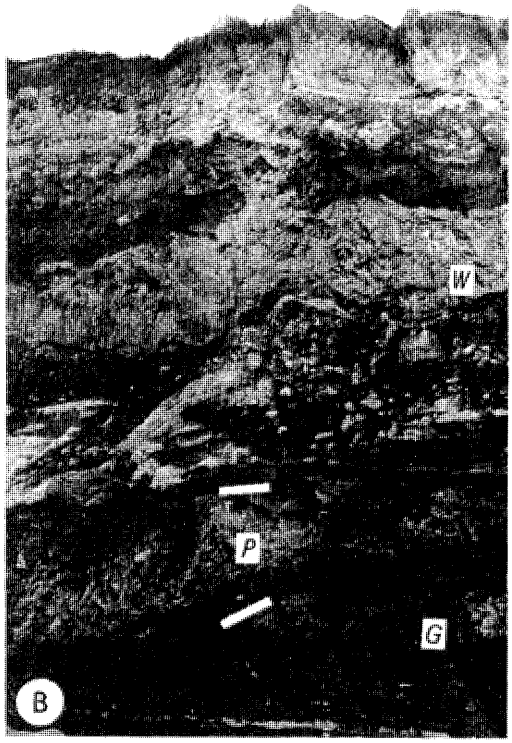
The Pliocene Series (Lyell, 1833), translated as "more recent," was so named because the major part of the invertebrate fossils are

Electronic Filing: Received, Clerk's Office 07/01/2024

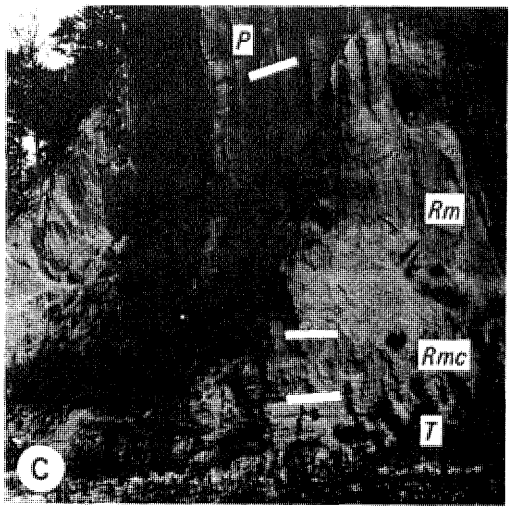
referable to modern species. It is represented in Illinois by the widespread brown chert gravel deposits of southern Illinois—the Mounds Gravel—and the similar but scattered deposits in western Illinois—the Grover Gravel. All of these deposits were previously called "Lafayette," "Lafayette-type," or "Tertiary" gravel. Both formations probably contain some deposits reworked during the early Pleistocene that are not readily differentiated from those deposited during the late Tertiary. Consequently, both the Mounds and Grover Formations are assigned a Pliocene-Pleistocene age (Willman and Frye, 1970).



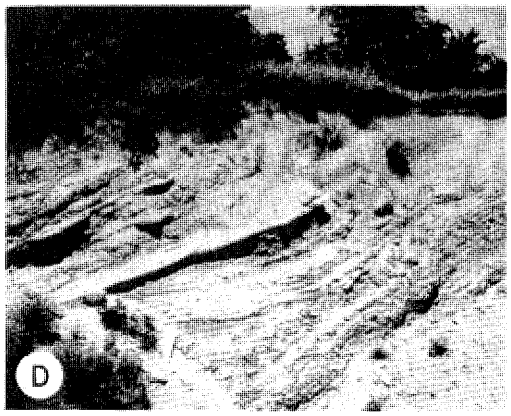
Mounds Gravel



The Mounds Gravel (Willman and Frye, 1970, p. 20) (fig. T-2) is named for Mounds, Pulaski County, which is 3 miles east of the type section in a gravel pit on the east side of Cache Valley (SE SW SW 7, 16S-1W). The formation is widely present and is exposed in numerous gravel pits and roadcuts in the area south of Cache Valley and westward from Cache Valley to the Mississippi River (fig. T-1). Good exposures also occur in pits in the hills 8 miles northeast of Metropolis, Massac County (SW SW 28, 14S-5E) (fig. K-1B). An isolated remnant of the gravel lies on top of the Shawneetown Hills in Gallatin County. The gravel is found in three terraces, the upper at an elevation of 580-620 feet, a middle terrace at 450-500 feet, and a lower terrace at 380-400 feet. The gravel underlying these surfaces is rarely as much as 40 feet thick, more commonly less than 20 feet. It is dominantly medium to dark brown chert pebbles with a glossy surface in a matrix of coarse red sand, but in places it is largely pebbly sand. Most of the pebbles are partly rounded and many are well rounded (fig. K-1C). Many of the chert pebbles are 2-3 inches in diameter, or even larger, in places. Quartz pebbles, also well rounded, are common and are generally less than half an inch in diameter. The lithology of the gravel has been well described by Lamar and Reynolds (1951) and Potter (1955). Crossbedding and heavy-mineral content indicate that the Mounds Gravel in southern Illinois was largely deposited by streams flowing from the east or southeast, probably down the Tennessee River Valley on the east side of the embayment area. However, the deposits near the Mississippi River at the head of the embayment and on its west side contain chert, agate, and purple quartzite pebbles characteristic of the Lake Superior region, which indicates some contribution from the north. The Mounds Gravel truncates the older Tertiary and Cretaceous sediments. It, in turn, was deeply dissected and weathered before the oldest Pleistocene deposit in the area, the Illinoian Loveland Silt, was deposited on it. The rivers and streams have entrenched themselves at least 300 feet since the earliest of the gravels was deposited on the highest bedrock surfaces. Although the highest deposits are believed to be Pliocene in age, similar deposits on the lowest surfaces may have been reworked from the higher levels during the early part of the Pleistocene. The Mounds Gravel does not contain the igneous and carbonate rocks or the heavy minerals characteristic of the glacial deposits of the Upper Mississippi and Ohio River Valleys, but such materials would not be found in sediments from the upper Tennessee River Valley. The age of the gravels is controversial (Fisk, 1944; Leighton and Willman, 1950; Potter, 1955; Willman and Frye, 1970), and the Mounds Gravel is therefore now classified as Pliocene-Pleistocene.



Grover Gravel



The Grover Gravel (Rubey, 1952, p. 61) (fig. T-2) is named for Grover, St. Louis County, Missouri, near which it is well exposed on the highest upland surface as overburden in several clay pits (SE NW SW 3, 44N-3E). The formation is as much as 50 feet thick in the type area. It also occurs widely, however, as small relict patches of chert gravel or scattered pebbles at the base of the loess on the upland surface of Calhoun County, Illinois. Isolated patches of similar chert gravel also are found in western and northern Illinois (fig. T-1). The gravel is mainly rounded, brown chert pebbles with some red hematitic chert, purple quartzite, and white and pink quartz pebbles. The matrix is largely red to tan quartz sand, the heavy minerals in which are dominantly zircon and tourmaline. Boulders of purple and pink quartzite as much as 2 feet in diameter occur in the Grover area and in one locality near Golden Eagle, Calhoun County (NE NE SE 36, 13S-2W). The isolated gravel patches included in the Grover Formation (Horberg, 1950b) because of their stratigraphic position on the bedrock in the uplands and beneath Pleistocene deposits of glacial drift or loess are probably not all of the same age. Some may be remnants of Cretaceous gravel, others of Tertiary gravel that perhaps was reworked from the Cretaceous gravel, and still others may have been reworked from the Tertiary gravel in early Pleistocene time. A few deposits contain rare pebbles of igneous and metamorphic rocks, reduced by weathering to clay with coarse mica flakes (Leighton and Willman, 1949), and these most likely are Pleistocene in age. Although the Mounds Gravel near the Mississippi River in southern Illinois contains some materials from the Upper Mississippi River Valley, similar gravel has not been found between the St. Louis area and the southern Illinois area. The connecting valley apparently has been eroded, probably as a result of uplift of the Ozark Dome. The Grover Gravel has long been interpreted as Tertiary, generally Pliocene, in age (Salisbury, 1892). Rubey (1952) considered the gravel to be as old as Miocene because of the amount of erosion that had taken place after it was deposited and because the gravel appears to be displaced more than 100 feet by movement along the Cap au Grès Faulted Flexure in Calhoun County. Because of the large quartzite boulders in the gravel, Willman and Frye (1958, 1970) suggested that the gravel may be early Pleistocene. As definitive faunal evidence is unavailable, the Grover Gravel is classified as Pliocene-Pleistocene in age.

QUATERNARY SYSTEM

John C. Frye and H. B. Willman

The Quaternary System was proposed in 1829 by Desnoyers (Wilmarth, 1925, p. 43), who recognized it as a unit distinct from the Tertiary System. Its definition depends on the placement of the end of Tertiary time. The Pleistocene Series also began at that time, and in Illinois classification the Quaternary System is equivalent to that one series. In 1925 the Pleistocene was classified as a system in Illinois, and the term "Quaternary" was not used until 1950 when the Pleistocene was reduced to a series and the Quaternary reinstated as a system. The Quaternary System includes the rocks being deposited at present.

PLEISTOCENE SERIES

The term "Pleistocene" was introduced by Lyell in 1839 (p. 616-621) as a replacement for "Newer Pliocene" (Lyell, 1833, p. 52-53) to apply to the marine strata of the Mediterranean region, in which more than 70 percent of the fossils represent living species. In 1846 Forbes applied "Pleistocene" to the "glacial epoch" in the British Isles, and in 1925 Wilmarth defined the Pleistocene in North America as including glacial and contemporaneous deposits of the "Great Ice Age." A report to the International Geological Congress in 1952 suggested worldwide adoption of a definition of the base of the Pleistocene as the base of the Villafranchian or of the equivalent marine Calabrian as exposed in Italy. However, as correlations of this proposed type area with marine strata in North America are not firmly established, the Pleistocene Series in Illinois and the rest of the continental interior continues to be defined as the glacial sequence plus the contemporaneous deposits laid down beyond the limit of continental glaciation. The Pleistocene Series includes the Holocene (Recent), which is classified as a stage rather than as a separate series, the usage accepted by many others.

Deposits of Pleistocene age are the surficial materials in virtually all of Illinois (fig. Q-1). Nearly 80 percent of the state was covered at least once by continental glaciers that left characteristic deposits (drift). Both glaciated and unglaciated areas were largely covered by wind-deposited silt (loess), by lacustrine deposits, or by deposits from streams. The only areas that were not covered by glaciers are the extreme northwestern corner, the southernmost part, and relatively small areas along the western border (fig. Q-2).

The thickness of the Pleistocene deposits in Illinois ranges from zero to approximately 600 feet (fig. Q-3), and variations in thickness occur sharply in relatively small areas. The drift is thick where major valleys in the older rocks have been filled by Pleistocene deposits and where stillstands of a glacier front have built thick ridges (moraines) of glacial debris. Drift thicknesses are greatest where glacial moraines cross the filled valleys. The loess deposits, which were derived largely from glacial outwash in the major valleys by the action of winds, are thickest along the margins of those valleys and thin rapidly away from them, in some places thinning from as much as 100 feet to less than 20 feet thick in a distance of 10 miles. Loess disappears en-

tirely on the surfaces of alluvial valleys and some of the lake plains. Dune sands vary abruptly in thickness and do not display the regular, linear pattern of the loess deposits.

The Pleistocene deposits in Illinois also have a wide range in lithology—bouldery glacial tills, well sorted silts, accretion-gley, and fine-grained lacustrine clays. Glacial tills strongly reflect their mode of origin and their source areas. Glacial regimen changes with the temperature and thickness of the ice, the rate of ice flow, and the manner in which the ice disappeared. In some areas excess of marginal melting over forward motion caused retreat of the ice front. In other areas the ice lost forward motion, stagnated, and melted down from the top. All of these factors influence the resulting deposit. Glacial tills range from dominantly sand and gravel with only a small fraction of clay and silt and a few small boulders to mixtures dominantly clay or silt, with some sand, pebbles, and dispersed boulders.

Alluvial deposits are the product of normal stream action, of meltwaters in, on, or below glacial ice, or of meltwaters flowing from glaciers to a considerable distance (outwash). These deposits range from coarse, bouldery gravel to sand and silt.

Eolian deposits of loess and dune sand result from the action of winds on exposed surfaces of nonindurated materials, mostly glacial outwash. Eolian sediments are well sorted, consisting largely of medium-grained sand in the dunes and coarse to fine silt in the loess deposits. Loess deposits progressively thin and become finer grained away from their source areas in the major valleys. They range from coarse silt containing fine sand immediately adjacent to their source to fine silt containing significant amounts of clay in remote areas.

During Pleistocene time lakes formed along glacial fronts, between morainic ridges, in valleys dammed by glaciers, and in tributary valleys blocked by rapidly alluviating master streams that were receiving large quantities of outwash. The lacustrine deposits are predominantly well bedded silt, clay, and fine to medium sand. Although most lacustrine sediments are largely silt, some are predominantly sand, and others are interbedded silt, sand, and clay.

Colluvium and gravity deposits are produced by the influence of gravity on slopes. The materials in such deposits strongly reflect the local source from which they were derived, which is always up-slope from the deposit. The two categories are differentiated largely by rate of transport and particle size. Colluvial deposits move slowly down-slope, commonly contain a significant percentage of silt, clay, and some coarser fragments, and may or may not have a well defined slip plane separating them from the older rocks below. Gravity deposits are generally composed of angular fragments, are more poorly sorted, are coarser, and are associated with steeper slopes than colluvium. They include talus deposits. Both colluvium and gravity deposits are poorly sorted unless the source material is a uniform and well sorted sediment, such as loess.

Man-made deposits are extensively exposed at the surface in strip-mined areas, filled areas, and artificially created islands. Sanitary landfills also are man-made surficial deposits. Such deposits have no predictable lithology and range from refuse and stripped overburden of mines to relatively uniform sand or silt.

The mineral composition of Pleistocene deposits strongly reflects the source areas of the sediments. Source areas of colluvial and gravity deposits are close at hand, but glacial deposits reflect sources hundreds of miles away. Glacial till contains rocks and minerals picked up by the ice as the glaciers advanced; the heavy minerals of the sands were commonly derived from the crystalline rocks of southern Canada and the clay minerals and carbonates from the Paleozoic rocks farther south. The mineral compositions of the older rocks vary widely from east to west, and, consequently, the direction of ice flow and the correlation of many units can be determined by mineral analysis of the tills. As the sediments of the outwash were derived largely from the glacially transported material, their mineral composition and that of the eolian deposits derived from them also reflect the sources of the glacial deposits.

The tills from a northwestern source (Keewatin Lobe) are characterized by high montmorillonite content, more calcite than dolomite, and more epidote than garnet. Tills from the north and northeast (Lake Michigan Lobe) have a high illite content, much more dolomite than calcite, and nearly equal amounts of garnet and epidote. Tills from farther east (Saginaw, Huron, Erie Lobes) have a high illite content, generally more calcite than dolomite, and much more garnet than epidote.

Pleistocene deposits in Illinois are classified in four basic hierarchies—time-stratigraphic,

Electronic Filing: Received, Clerk's Office 07/01/2024

rock-stratigraphic, soil-stratigraphic, and morphostratigraphic. Time-stratigraphic and rock-stratigraphic classifications are used for Pleistocene deposits in the same manner they are used in the rest of the stratigraphic sequence (fig. 16) and will not be redescribed here. The chart in figure Q-4 shows all time-stratigraphic, rock-stratigraphic, and soil-stratigraphic terms currently in use in Illinois and this report. The surface distribution of the dominantly till formations and members is shown in figure Q-5. Figure Q-6 shows graphically the historical development of the time-stratigraphic classification of the Wisconsinan Stage in Illinois.

Soil-stratigraphic and morphostratigraphic units are virtually unique to the Pleistocene. Soils form at the land surface as a result of the effects of weathering and of plants and animals on the sediments that underlie the surface. In most places soil forms in situ, that is, by the progressive downward alteration of sediments below a relatively stable surface. In some places, however, soils have formed by slow accumulation of fine sediment on the surface, with or without organic material. Soils buried by younger sediments are part of the stratigraphic sequence. Soil-stratigraphic classification, consisting of only one rank

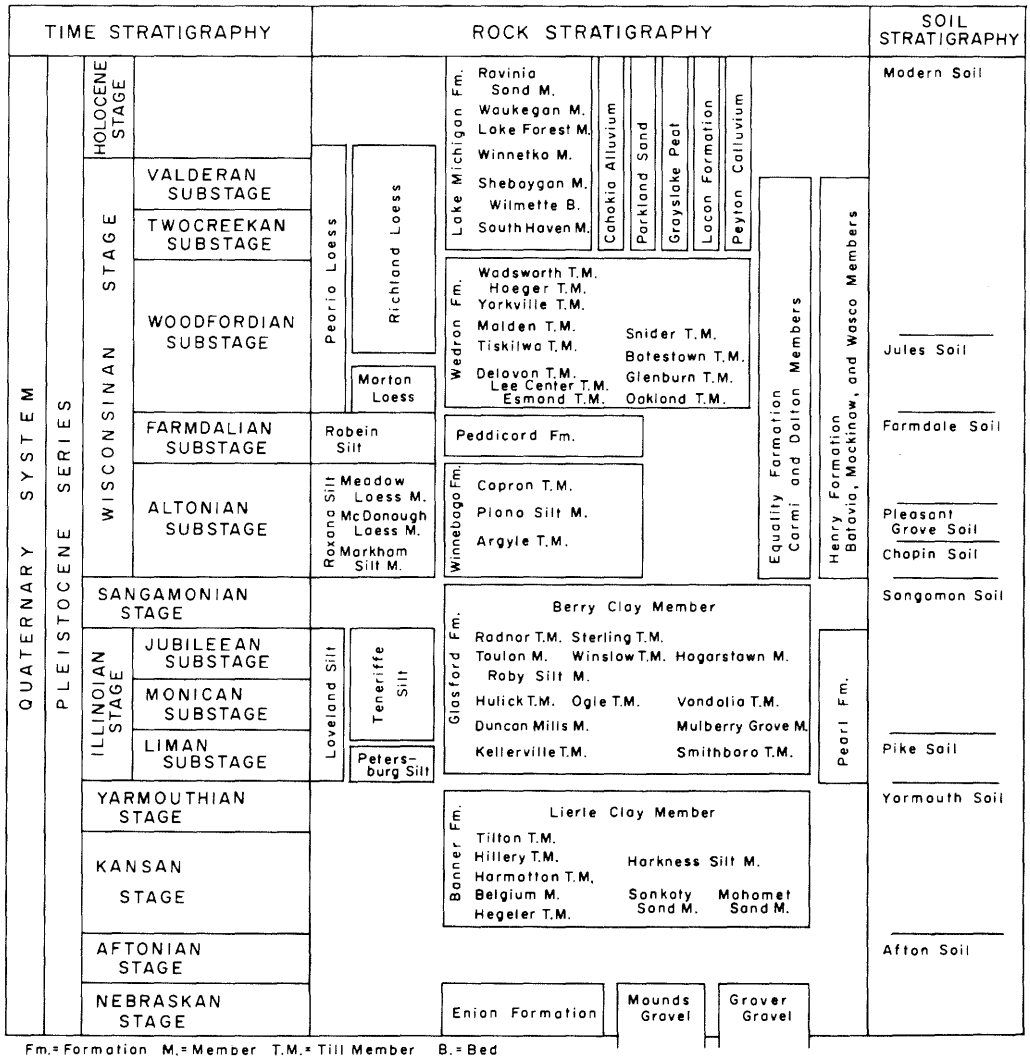

Fig. Q-4—Classification of the Pleistocene Series.

 Electronic Filing: Received, Clerk's Office 07/01/2024

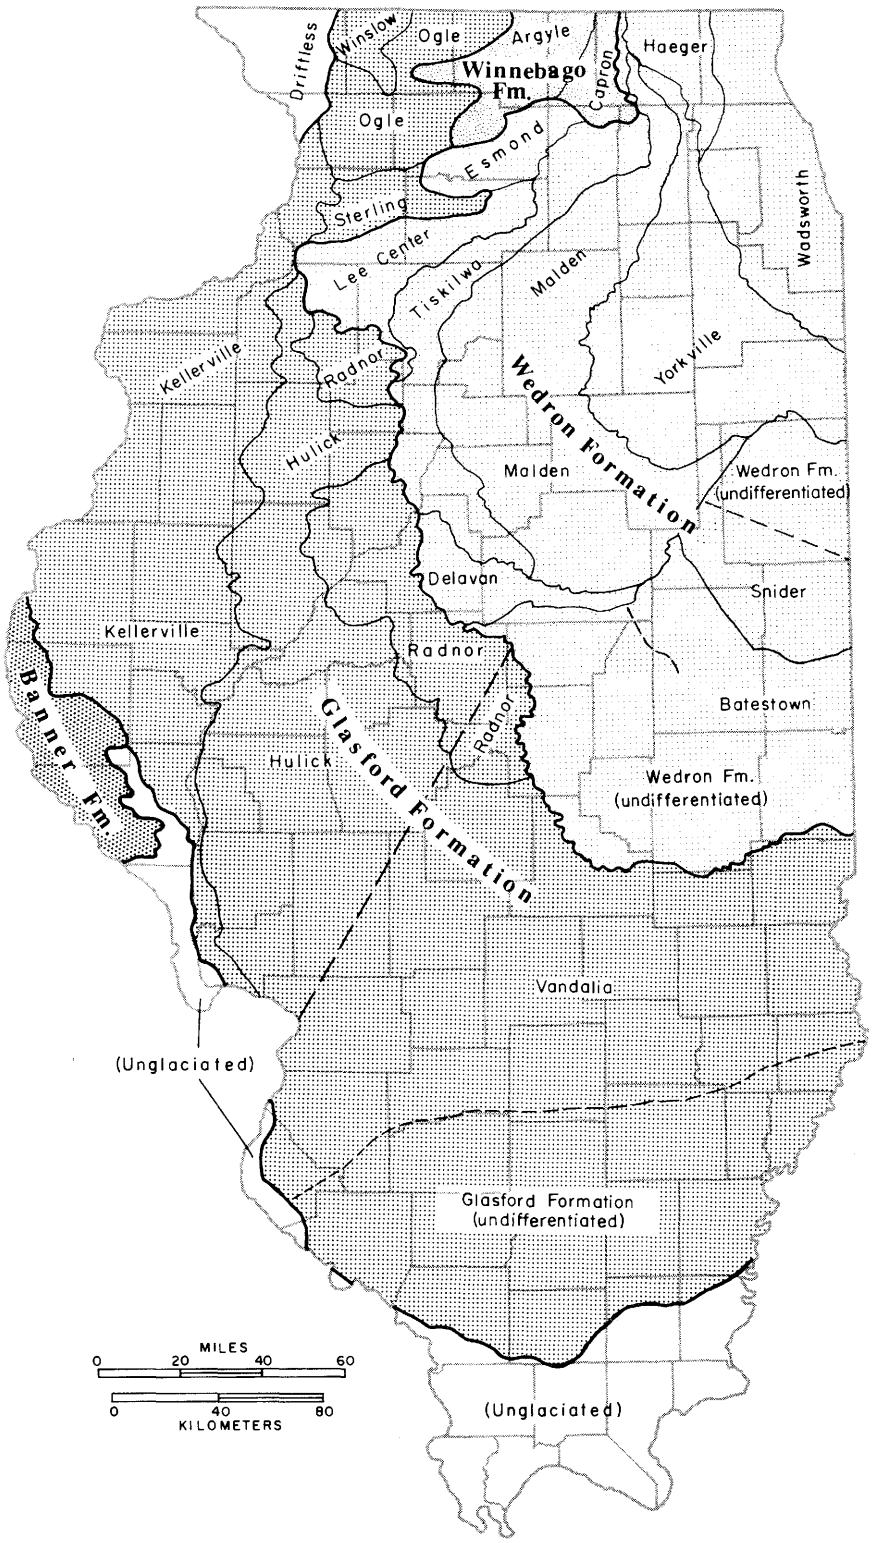

Fig. Q-5—Areal distribution of the dominantly till formations and members of Illinois (after Willman and Frye, 1970; Johnson et al., 1972).

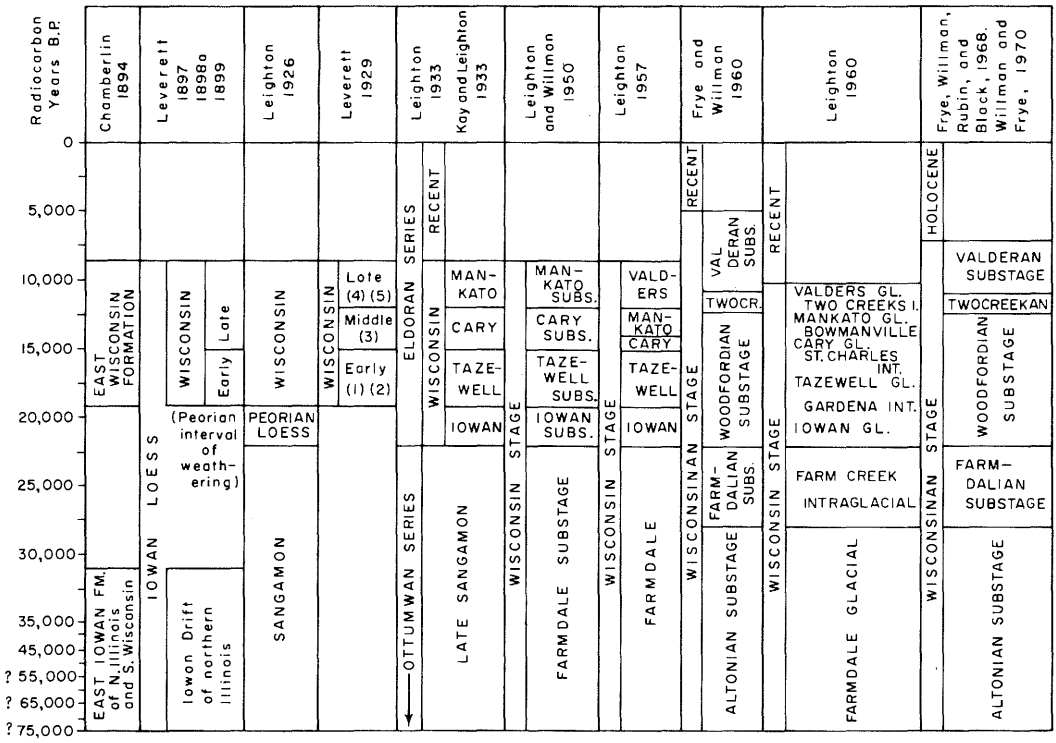

Fig. Q-6—Development of the classification of the Wisconsinan Stage in Illinois.

(soil), is a means of naming, describing, and correlating the soils in the sediment sequence. Soils do not replace the rock-stratigraphic units they are developed on; commonly, each soil is developed on several units. Only the upper surface of a soil presents a definable stratigraphic plane, because the lower part of a soil is gradational. The physical and mineral characteristics of a soil profile are generally useful in its recognition and correlation.

Morphostratigraphic units, as the name implies, are bodies of rock that are recognized and named on the basis of their surface form. Glacially produced morainic ridges, the materials in which are called drifts, and dissected alluviated surfaces, called alluvial terraces, are the two types of morphostratigraphic units recognized in Illinois. Only the drifts are formally named. Drifts are recognized not only in the surface areas but also wherever they can be identified in buried sequences. Such units are particularly useful in classification and mapping of glacial deposits in areas where a single rock-stratigraphic unit, such as glacial till, includes several morainic ridges.

The stratigraphic relations of Pleistocene deposits in Illinois are complex and contrast sharply with the more regular and uniform succession of predominantly marine Paleozoic rocks that they overlie. The complexity is caused by the different modes of deposition, the multiple sources of sediment, and the lack of regional continuity of many of the stratigraphic units. The loesses and the soil-stratigraphic units have the greatest regional continuity, although some of the glacial till units are traceable for more than 100 miles. Outwash and alluvial deposits, in general, occur along present and buried valleys, lacustrine deposits are found along segments of ponded valleys and on low areas of the till plain surfaces, and colluvium and gravity deposits are restricted to localized areas along valley margins. An idealized representation of stratigraphic relations of deposits of the Illinoian Stage in west-central and western Illinois is shown by figure Q-7, and another of Wisconsinan deposits from northeastern to west-central Illinois by figure Q-8.

Fossils are not abundant in most of the Pleistocene deposits of Illinois. None have

Electronic Filing: Received, Clerk's Office 07/01/2024

thus far been found in the Nebraskan Stage, and assemblages of fossil mollusks have been collected and described from less than a dozen localities of the Kansan Stage. Several silt units of the Illinoian Stage contain relatively abundant assemblages of fossil mollusks at localities in the central and western parts of the state. The Wisconsinan and Holocene Stages contain abundant assemblages of both aquatic and terrestrial mollusks. Fossil vertebrates have also been collected from Pleistocene deposits at many localities. Although the remains of large proboscidians, such as mammoths and mastodons, have attracted the most attention, remains of smaller mammals, particularly rodents, have been recovered from several localities.

Nebraskan Stage

The name "Nebraskan" was proposed by Shimek (1909, p. 408) for the lowermost till at the Afton Junction–Thayer exposures in Union County, Iowa, based on its supposed extension into eastern Nebraska. Willman and Frye (1970, p. 118) proposed two reference sections for Illinois, the Zion Church Section in Adams County, and the Enion Section in Fulton County. The base of the Nebraskan Stage is defined by the contact of glacial or glacial-derived deposits with Tertiary or older deposits below, and its upper limit is the top of the in-situ Afton Soil that developed on the Nebraskan deposits (fig. Q-4). The Nebraskan Stage contains the deposits left by the first episode of continental glaciation in the Midwest. The deposits in western Illinois are genetically related to a glacial advance that crossed Iowa from the Keewatin center west of Hudson Bay in Canada. No Nebraskan-age glacial deposits from a northeastern center have been identified with certainty in Illinois. The Enion Formation contains deposits of Nebraskan age, and the Mounds Gravel of southern Illinois and the Grover Gravel of western and northern Illinois, described in the discussion of the Tertiary System, may be, in part, of Nebraskan age.

Enion Formation

The Enion Formation (Willman and Frye, 1970, p. 48) is named for Enion, Fulton County, half a mile east of the type section (NW SW SE 32, 4N-3E). The formation includes glacial till, outwash sand and gravel, and beds of silt that occur in both the uppermost part and at the base. It is exposed at only a few places, mostly in the west-central part of the state (fig. Q-1F). It differs from older Cretaceous and Tertiary deposits in that it contains crystalline rocks from the Canadian area and a heavy mineral suite that includes abundant ferromagnesian minerals.

Aftonian Stage

The Aftonian Stage (Chamberlin, 1894) is named for Afton Junction, Iowa, where Chamberlin interpreted deposits in a gravel pit as being interglacial. During subsequent years, usage transferred the name to accretion-gley deposits and to the deeply developed in-situ Afton Soil on the Nebraskan-age till of southern Iowa. Although there is now reasonable doubt concerning the age of Chamberlin's type gravels near Afton Junction, the name Aftonian has been retained because of its long-accepted use. The time span of the Aftonian is defined as the time of development of the in-situ Afton soil profile, and a reference section for Illinois has been designated as the Zion Church Section of Adams County (Willman and Frye, 1970).

Afton Soil

The name "Afton Soil" was proposed by Frye and Leonard (1952, p. 24, 68) for the soil on deposits of Nebraskan age in northeastern Kansas because of its presumed Aftonian age. They designated the Iowa Point Section in Doniphan County, Kansas, as a reference section, and Willman and Frye (1970, p. 82) suggested the Zion Church Section, Adams County (fig. Q-1F), as a reference for Illinois. It is a deeply developed in-situ soil profile in deposits of Nebraskan age, but it has been correlated with accretion-gley, or accretionary soils, on the Nebraskan till plain and with soils developed in older rocks that are overlain by deposits of Kansan age. It has been identified at only a few places in Illinois.

Kansan Stage

The name "Kansan" was proposed by Chamberlin (1894, p. 754), but the drift was assigned to its present stratigraphic position by Calvin (1897) and Bain (1897) because of the continuity of the deposits described by Chamberlin in Union County, Iowa, with the surface drift in northeastern Kansas. Frye and Leonard (1952, p. 74) proposed three reference sections for type Kansan in Atchison and Doniphan Counties, Kansas, and included within the stage both the proglacial sands below the till (Atchison Formation) and the retreatal outwash gravels above the till, in which the Yarmouth Soil is developed. It was defined as including the span of rocks between the top of the Afton Soil (below) and the top of the in-situ Yarmouth Soil (above). Willman and Frye (1970, p. 119) suggested as reference sections for Illinois the Enion

Electronic Filing: Received, Clerk's Office 07/01/2024

Section of Fulton County, the Tindall School Section of Peoria County, and the Zion Church Section of Adams County. All the deposits of Kansan age found in Illinois are in the Banner Formation.

Banner Formation

The Banner Formation (Willman and Frye, 1970, p. 48) is named for Banner, Peoria County, near which the type section is in the Tindall School Section (SW SW NE 31, 7N-6E). It includes the glacial tills and underlying and intercalated sands, gravels, and silts overlying the Afton Soil and is terminated at the top by the top of the Yarmouth Soil (fig. Q-1E, F). In a few places the formation is as much as 300 feet thick, but it is discontinuous. In west-central Illinois it was deposited by glaciers from the northwest, but in eastern Illinois it was deposited by glaciers from the northeast. Its mineral content reflects the contrasting source areas, and in both regions its mineral content helps to distinguish it from the overlying deposits of Illinoian age. The uppermost part locally contains deposits of clay and silt that accumulated on the till plain surface as accretion-gley, in part during Yarmouthian time, but elsewhere the top of the formation is marked by the in-situ Yarmouth Soil developed in Kansan age deposits. Nine members are recognized in the Banner Formation (fig. Q-4), which is the surface drift in part of western Illinois (fig. Q-5).

Sankoty Sand Member—The Sankoty Sand Member of the Banner Formation (Horberg, 1950a, p. 34) is named for the Sankoty water-well field along the Illinois River on the north side of Peoria, Peoria County, where the type section is in a well (NW SE 15, 9N-8E). It is well sorted, medium- and coarse-grained sand, distinguished by an abundance of highly polished pink quartz grains. It occurs above Paleozoic rocks in the deepest part of the Ancient Mississippi Valley, where it is commonly 100 feet thick but locally is as much as 300 feet thick. It is overlain by tills of the Banner Formation except where they have been removed by erosion. It occurs in central and northwestern Illinois.

Mahomet Sand Member—The Mahomet Sand Member of the Banner Formation (Horberg, 1953, p. 18, 19) is named for Mahomet, Champaign County, near which it is encountered in numerous wells. The Mahomet Sand Member consists of sand and gravel with many silt beds. It lacks the pink quartz grains that occur in the Sankoty Sand. It occupies the deeper parts of the filled Mahomet Valley and its tributaries, mainly in De Witt, Macon, Piatt, and Champaign Counties. It commonly rests on Paleozoic rocks, attains a maximum thickness of 150 feet, and is overlain by till of the Banner Formation.

Harkness Silt Member—The Harkness Silt Member of the Banner Formation (Willman and Frye, 1970, p. 51) is named for Harkness Creek, Adams County, near which the type section is in the Zion Church Section (SE SE SW 9, 3S-8W) (fig. Q-1F). It consists of massive, calcareous, gray and tan silt that contains sparse molluscan fossils. It rests on the Afton Soil and is overlain by glacial till that also is of Kansan age. The member is generally less than 10 feet thick and is exposed at only a few places in central western Illinois.

Hegeler Till Member—The Hegeler Till Member of the Banner Formation (Johnson, 1971, p. 8) is named for the town of Hegeler, Vermilion County, and the type section is in the Harmattan Strip Mine No. 2 (SE SW SW 34, 20N-12W). The unit consists of two zones; the lower is outwash with gravelly till and the upper is silty till. It is up to 8 feet thick, greenish gray, weakly calcareous, generally massive, and compact. It is known in only the one locality, where it rests on rocks of Pennsylvanian age and is overlain by the Belgium Member.

Belgium Member—The Belgium Member of the Banner Formation (Johnson, 1971, p. 10) is named for the town of Belgium, Vermilion County, and the type section is in the same exposure as the Hegeler Till Member. The Belgium Member consists of two units; the lower is massive, tan to dark gray-brown, carbonaceous, calcareous, fossiliferous silt 0.5-2.5 feet thick (Leonard et al., 1971), and the upper is brown calcareous clay 0.5-1.5 feet thick. The Belgium Member is bounded below by the Hegeler Till Member or bedrock and above by the Harmattan Till Member. It is known in only the one locality in central eastern Illinois.

Harmattan Till Member—The Harmattan Till Member of the Banner Formation (Johnson et al., 1971, p. 194) is named for the Harmattan Strip Mine near Danville, Vermilion County (NE 4, 19N-12W). The member is largely gray, calcareous, dense, hard till, but the upper part contains lenticular bodies of gravelly sand. It is bounded at the base by the Belgium Member, or bedrock, and at the top by the Hillery Till Member. In the type area it is 8 feet thick, and it is known definitely only in the Danville area.

Hillery Till Member—The Hillery Till Member of the Banner Formation (Johnson et al., 1971, p. 195) is named for Hillery, Vermilion County, and its type locality is in the Power Plant Section (NW SW SW 21, 20N-12W). The Hillery Till Member is reddish brown, calcareous, massive, hard till. The lower part is slightly darker, and the upper commonly contains streaks of silt. The member is 14 feet thick in the Harmattan Strip Mine Section, where it overlies the Harmattan Till Member and is overlain by the Tilton Till Member. It is best known in the Danville area, where it generally rests directly on the bedrock.

Tilton Till Member—The Tilton Till Member of the Banner Formation (Johnson et al., 1971, p. 196) is named for Tilton, Vermilion County, and the type locality is the School House Branch Section (SE NE NE 2, 19N-12W). Where unoxidized, the Tilton Till Member is gray, calcareous, hard, silty, sandy till. The unit contains considerable silt, sand, and gravel, particularly near the upper and lower boundaries. The Tilton Till is commonly overlain at the top by a truncated weathered zone, or an oxidized zone, and in the Harmattan Strip Mine Section it overlies the Hillery Till Member. In Vermilion County the member is about 15 feet thick.

Lierle Clay Member—The Lierle Clay Member of the Banner Formation (Willman and Frye, 1970, p. 52) is named for Lierle Creek, Adams County (SE cor. SW 33, 1S-6W). It is predominantly accretion-gley consisting of gray clay, silt, and some sand. The Lierle is noncalcareous and is characterized by abundant pedogenic montmorillonite. It overlies the till of the Banner Formation and is overlain by deposits of Illinoian age. It is discontinuous, is less than 10 feet thick, and is exposed at many localities in western Illinois, where the surface drift is Kansan. The unit is part of the Yarmouth Soil but is an accretionary deposit made largely throughout Yarmouthian time.

Yarmouthian Stage

The Yarmouthian Stage is based on the Yarmouth Soil, described by Leverett (1898c, p. 176) from its occurrence in a well section near Yarmouth, Des Moines County, Iowa. It was described as the interval of weathering and organic accumulation separating the Kansan and Illinoian glacial deposits. The adjec-

Electronic Filing: Received, Clerk's Office 07/01/2024

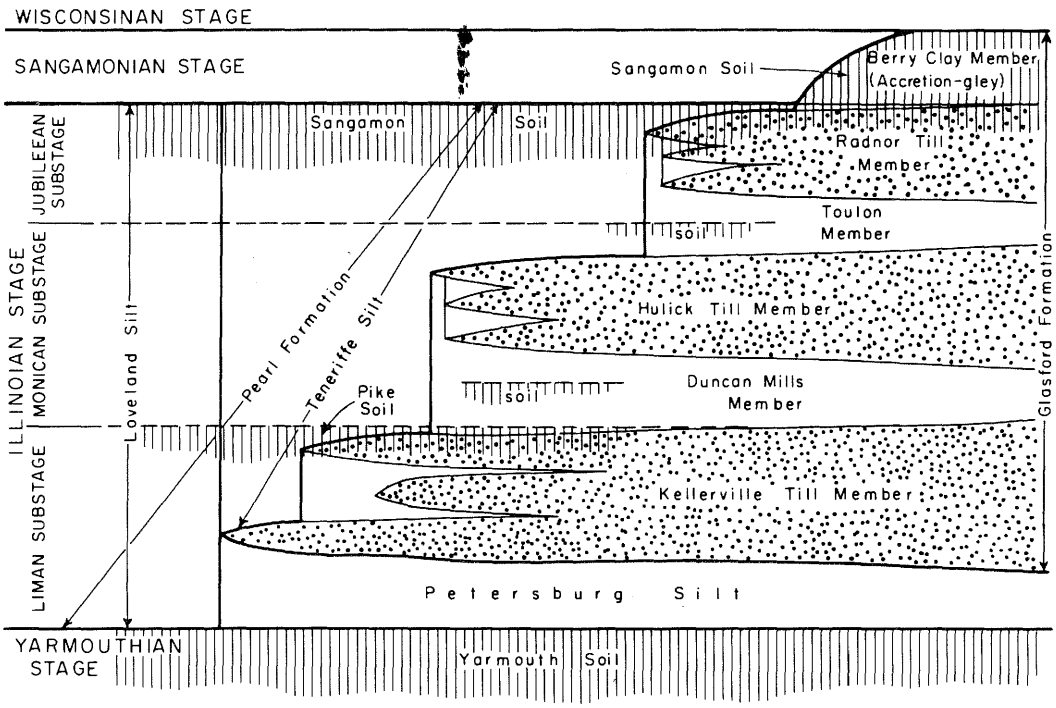

Fig. Q-7—Diagrammatic cross section showing the relations of the formations and members of Illinoian age in central and western Illinois (Willman and Frye, 1970).

tival ending was added (Frye et al., 1948) to distinguish the stage from the soil. As the original type section has not been accessible for 75 years, Willman and Frye (1970) suggested as paratype the Fort Madison Section, Lee County, Iowa (Willman et al., 1966, p. 63). The Yarmouthian Stage in Illinois is represented by the accretion-gley of the Lierle Clay Member of the Banner Formation and by the in-situ Yarmouth Soil (fig. Q-4).

Yarmouth Soil

The Yarmouth Soil was named and described by Leverett (1898c, p. 176) from its occurrence in a well at Yarmouth, Des Moines County, Iowa. He described the soil as the weathered zone on the Kansan drift, overlain by Illinoian deposits. In some places the soil is an in-situ profile developed in earlier deposits (fig. Q-1E), but in others it consists of accretionary deposits of fine sediment and organic material that accumulated in poorly drained areas on the surface of Kansan deposits. Such deposits are as much as 10 feet thick. This soil has been observed at many localities in Illinois, most of them in the western and central parts of the state.

Illinoian Stage

Leverett (*in* Chamberlin, 1896) named the Illinois till sheet for the Illinois Glacial Lobe and later introduced the name Illinoian Stage (Leverett, 1899, p. 20-23). He included within the stage all of the deposits between the Yarmouthian and Sangamonian Stages of present usage. As Leverett did not specify a type section within the lobe, Willman and Frye (1970, p. 120) designated as paratype the Tindall School Section, Peoria County (SW SW NE 31, 7N-6E) (Willman et al., 1963, p. 54-55). In this section the Illinoian Stage is bounded at the base by the truncated Yarmouth Soil and at the top by the top of the Sangamon Soil, an in-situ soil profile in the uppermost Illinoian deposits. The Illinoian Stage is subdivided into three substages—the Liman at the base, the Monican, and the Jubileean. The three substages are all present in the paratype section. The deposits are differentiated into five formations (figs. Q-4, Q-7).

Liman Substage

The Liman Substage (Frye et al., 1964, p. 16) is named for Lima Township, Adams County, and the type section is in the Pryor School Section (NE NE SE 11, 2N-8W). At the type section the substage is represented by the Petersburg Silt at the base with the Kellerville Till Member of the Glasford Formation

Electronic Filing: Received, Clerk's Office 07/01/2024

above it. In the type locality its base is defined by the contact of Petersburg Silt on the Yarmouth Soil developed in Kansan deposits, and its top is the truncated surface of the Pike Soil, which is overlain by loess deposits. At the paratype section for the Illinoian Stage (the Tindall School Section), deposits of the Liman Substage are overlain by glacial deposits of the Monican Substage.

Pike Soil

The Pike Soil (Willman and Frye, 1970, p. 84) is named for Pike County, Illinois, and its type section is in the New Salem Northeast Section (NW NE SW 11, 4S-4W). In the type section the Pike Soil is developed in sediments of Liman age—the Kellerville Till Member of the Glasford Formation—and it is overlain by the Teneriffe Silt, which has the Sangamon Soil in the top. The Sangamon Soil is overlain by Wisconsinan loesses. The Teneriffe Silt at this locality is Monican and/or Jubileean in age, but from regional relations the termination of formation of the Pike Soil is inferred to be in early Monican time. The Pike Soil has a deeply developed profile, but it has been observed at only a few places in western and central Illinois.

Petersburg Silt

The Petersburg Silt (Willman et al., 1963, p. 6) is named for Petersburg, Menard County, and the type section is in the Petersburg Section (NW NW NE 23, 18N-7W). The Petersburg ranges from gray to yellow-tan to purplish tan calcareous silt. The upper part is commonly massive and loess-like and contains fossil mollusks, whereas the lower part has indistinct bedding and locally contains fine sand. It rests on the top of the Yarmouth Soil, or older deposits, and is overlain by the Glasford Formation at the many localities in central and western Illinois where it occurs. In the type section it is 20 feet thick, but at most places it is less than 12 feet thick. Beyond the area of the Glasford, deposits equivalent in age to the Petersburg are part of the Loveland Silt (fig. Q-7).

Loveland Silt

The Loveland Silt (Shimek, 1909, p. 405) is named for Loveland, Iowa, where it is exposed in the bluff of the Missouri River Valley. It is dominantly clayey silt, but locally contains some fine sand. It is tan to reddish brown, massive, and in most places is leached of carbonate minerals. It is bounded at the base by the top of the Yarmouth Soil, or older deposits, and at the top by the top of the Sangamon Soil (Willman and Frye, 1970). It commonly is entirely within the Sangamon Soil (fig. Q-1E). It occurs only beyond the limit of Illinoian glaciation—in extreme southern, western, and northwestern Illinois—and in most places is less than 10 feet thick. The Loveland Silt is continuous with both the Petersburg and Teneriffe Silts, which occur inside the glaciated area (fig. Q-7).

Pearl Formation

The Pearl Formation (Willman and Frye, 1970, p. 60) is named for Pearl, Pike County, and the type section is in the Pearl Prairie Section (SE SW NE 16, 7S-2W) (Frye and Willman, 1965, p. 14). The unit includes Illinoian outwash that occurs beyond the limit of Illinoian glaciation or overlies Illinoian till. It ranges from medium sand to gravel and sand and is commonly tan to gray-tan. It generally has more oxidized and cemented beds than the younger outwash. It is terminated upward by the top of the Sangamon Soil, which is commonly overlain by Wisconsinan loesses. In most places the formation is less than 40 feet thick, but in major valleys it may be significantly thicker. Geographic distribution is primarily along major valleys in central and western Illinois.

Glasford Formation

The Glasford Formation (Willman and Frye, 1970, p. 52) is named for Glasford, Peoria County, and the type section is in the Tindall School Section (SW SW NE 31, 7N-6E). The formation includes glacial tills, intercalated outwash deposits of gravel, sand, and silt, and the overlying accretion-gley deposits (figs. Q-1A, B, D). It overlies the Petersburg Silt or, in the absence of that formation, the top of the Yarmouth Soil or older rocks. It is terminated upward by the top of the Sangamon Soil, where the soil is an in-situ profile developed in the top of the glacial deposits and also where the soil is an accretion deposit. Fourteen members have been described within the Glasford Formation (fig. Q-4), many of which have limited regional extent. The formation is the surface drift and almost continuously present in a large part of Illinois (fig. Q-5). It is also widely present below glacial deposits in the outer 40 miles of the region covered by Wisconsinan glaciers (Horberg, 1953). The Glasford Formation is 35 feet thick in its type section, but it ranges from a few feet to more than 150 feet thick.

Kellerville Till Member—The Kellerville Till Member of the Glasford Formation (Willman and Frye, 1970, p. 55) is named for Kellerville, Adams County, and the type section is in the Washington Grove School Section, 2 miles southwest of Kellerville (NW NW SW 11, 2S-5W), an exposure at the front of the Mendon Moraine. The member is till with intercalated, discontinuous zones of sand and gravel outwash and silt. It is more varied and has a higher percentage of clay minerals and a higher ratio of calcite to dolomite than the overlying members. It is as much as 150 feet thick but commonly less than 50 feet thick. It overlies the Petersburg Silt, or older deposits, and it is overlain by the Duncan Mills Member or, where it extends beyond the margins of later Illinoian glacial advances, by the Teneriffe Silt. It is differentiated in west-central, western, and northwestern Illinois.

Duncan Mills Member—The Duncan Mills Member of the Glasford Formation (Willman and Frye, 1970, p. 56) is named for Duncan Mills, Fulton County, and the type section is in the Enion Section, 4 miles south of Duncan Mills (NW SW SE 32, 4N-3E). In the type section the Duncan Mills Member consists of outwash sand, gravel, and some silt, and is generally deeply weathered. It is recognized as a member only where it is bounded by the Kellerville Till Member below and the Hulick Till Member above. It attains a maximum thickness of 30 feet and has been observed only in central western and west-central Illinois.

Hulick Till Member—The Hulick Till Member of the Glasford Formation (Willman and Frye, 1970, p. 56) is named for Hulick School, Fulton County, and the type section is in the Lewistown Section (SW SE SE 21, 5N-3E). The member, consisting of till and intercalated sand and gravel outwash, is locally more than 100 feet thick. It is bounded at the top in various areas by the Toulon, Radnor Till, or Berry Clay Members, the Teneriffe Silt, or the Pearl Formation. At

Electronic Filing: Received, Clerk's Office 07/01/2024

some places its top is the top of the Sangamon Soil. It rests on the Duncan Mills Member, the Kellerville Till Member, or older rocks. The clays and carbonates of the Hulick indicate derivation from the Paleozoic rocks of north-central and northeastern Illinois, and the heavy mineral assemblage is indicative of a source in western Ontario, Canada. The member occurs in central western and southwestern Illinois.

Toulon Member—The Toulon Member of the Glasford Formation (Willman and Frye, 1970, p. 57) is named for Toulon, Stark County, and the type section is in the Toulon Section (NW NW SW 24, 13N-5E), a borrow pit three-fourths of a mile west of Toulon. The member consists of glacially derived sand, gravel, and silt. It is differentiated only when it occurs between the Radnor Till Member above and the Hulick Till Member below. In its type section it is 9 feet thick, and it exceeds this thickness at only a few places. It has been observed in west-central and western Illinois. A minor soil in the Toulon Member forms the top of the Monican Substage.

Radnor Till Member—The Radnor Till Member of the Glasford Formation (Willman and Frye, 1970, p. 57) is named for Radnor Township, Peoria County, and the type section is in the Jubilee College Section (SW SW SW 7, 10N-7E). In the type section the Radnor Till is bounded at the top by the top of the Sangamon Soil, which is overlain by Wisconsinan loesses, and at its base by the Toulon Member. It consists of massive, calcareous, gray till characterized by a high illite content. It appears to be a stratigraphic equivalent of the Sterling Till Member of northwestern Illinois. In the type section it is 22 feet thick, and it exceeds this thickness only in the end moraine at its outer margin. The member occurs in central and east-central Illinois.

Smithboro Till Member—The Smithboro Till Member of the Glasford Formation (Jacobs and Lineback, 1969, p. 9) is named for Smithboro, Bond County, and its type locality is in the Mulberry Grove Section, 5 miles east of the town (SW SW 31, 6N-1W), where it is about 12 feet thick. The member consists of gray, compact, silty till. It is bounded below by its contact on the top of the Yarmouth Soil, or older rocks, and at the top by the overlying Mulberry Grove Member of the Glasford. It occurs widely in south-central and central eastern Illinois.

Mulberry Grove Member—The Mulberry Grove Member of the Glasford Formation (Jacobs and Lineback, 1969, p. 12) is named for Mulberry Grove, Bond County, and its type section is in the Mulberry Grove Section (SW SW 31, 6N-1W), where it is about 3 feet thick. The member is calcareous gray silt and fine sand containing some fossil mollusks (Leonard et al., 1971). It is bounded below by the Smithboro Till Member and above by the Vandalia Till Member. It occurs in south-central and central eastern Illinois.

Vandalia Till Member—The Vandalia Till Member of the Glasford Formation (Jacobs and Lineback, 1969, p. 12) is named for Vandalia, Fayette County, and the type section is in the Vandalia Bridge Section, along the Kaskaskia River, at Vandalia (NW NE SE 16, 6N-1E), where it is about 20 feet thick. The member consists of sandy till with thin lenticular bodies of silt, sand, and gravel. It is calcareous, except where weathered, generally gray, and moderately compact. It is bounded below by the Mulberry Grove, Smithboro, or older rocks, and at the top by the Hagarstown Member, younger beds, or the top of the Sangamon Soil. It commonly is 25-50 feet thick, and it occurs widely in south-central and central eastern Illinois.

Hagarstown Member—The Hagarstown Member of the Glasford Formation (Jacobs and Lineback, 1969, p. 12) is named for Hagarstown, Fayette County, 5 miles west of the type section, the Hickory Ridge Section (SW NW 30, 6N-1E). The member consists of gravelly till, poorly sorted gravel, well sorted gravel, and sand (fig. Q-1D). Stratigraphically it lies above the Vandalia Till Member and is bounded at the top by the top of the Sangamon Soil. It commonly occurs in elongate ridges in south-central Illinois. In the type locality it is about 30 feet thick, but it is more than 100 feet thick in some of the higher ridges.

Roby Silt Member—The Roby Silt Member of the Glasford Formation (Johnson, 1964, p. 8) is named for Roby, Christian County, and the type section is in the Roby Section, Sangamon County (NW SE NE 14, 15N-3W). The member consists of tan and gray calcareous silt and silty clay and contains fossil mollusks (Leonard et al., 1971). It is bounded below by the Hulick Till Member, or the Vandalia Till Member, and is overlain by the Radnor Till Member. The unit is commonly 2-5 feet thick, and it is widely distributed in central Illinois.

Ogle Till Member—The Ogle Till Member of the Glasford Formation (Frye et al., 1969, p. 24) is named for Ogle County, Illinois, and the type section is in the Haldane West Section (NE NE NE 25, 24N-7E). The member consists largely of till that varies in mineral and textural compositions. The till is generally sandy and silty, tan to gray-brown, and discontinuously interstratified with sand and gravel. The member is generally less than 20 feet thick, and it is extensively eroded. It occurs primarily in Winnebago, Stephenson, Carroll, and Ogle Counties. In most places it rests directly on bedrock. Where the Ogle Till is the surface drift, the Sangamon Soil was developed in its top, and the soil is overlain by loesses of Wisconsinan age. In many places, however, the soil was eroded before deposition of the loesses. Locally the Ogle has been found beneath the Argyle Till Member of the Winnebago Formation.

Winslow Till Member—The Winslow Till Member of the Glasford Formation (Frye et al., 1969, p. 25) is named for Winslow, Stephenson County, and the type section is in roadcuts west of Winslow (SW SE SW 21, 29N-6E). In the type section it consists of 12 feet of dark gray clayey till resting directly on bedrock and overlain by thin loesses of Wisconsinan age. At a few places the Sangamon Soil occurs in the top, but the soil has been eroded from much of the area. The Winslow is limited to Stephenson and Jo Daviess Counties. It may be a lithologic variant of the Ogle Member or a stratigraphic equivalent of the Sterling Member, but it is distinctly different from both in composition.

Sterling Till Member—The Sterling Till Member of the Glasford Formation (Frye et al., 1969, p. 25) is named for Sterling, Whiteside County, and the type section is in the Emerson Quarry Section 2 miles west of Sterling (SE NW SE 13, 21N-6E). The unit consists of gray, silty, calcareous till with an exceptionally high illite content. It overlies the Ogle Till Member, or older rocks, and is bounded at the top by the Sangamon Soil. It is overlain by the Winnebago Formation, the Wedron Formation, or loesses of Wisconsinan age. The Sterling occurs primarily in Whiteside and Lee Counties. It is as much as 40 feet thick in the Sterling area but generally is thinner. It is stratigraphically equivalent to the Radnor Till Member to the south.

Berry Clay Member—The Berry Clay Member of the Glasford Formation (Willman and Frye, 1970, p. 54) is named for Berry, Sangamon County, and the type section is in the Rochester Section, 3 miles west of Berry (NW SE NW 34, 15N-4W). The member is an accreted soil of clay and silt containing a few small pebbles. It is gray to dark gray, leached of carbonate minerals, and generally 2-5 feet thick. It is bounded at the top by the top of the Sangamon Soil and at the base by weathered till of the Glasford Formation. It occurs at isolated localities throughout the area of Illinoian drift (figs. Q-5, Q-7).

Monican Substage

The Monican Substage of the Illinoian Stage (Willman and Frye, 1970, p. 120) is

Electronic Filing: Received, Clerk's Office 07/01/2024

named for Monica, Peoria County, and its type section is in the Jubilee College Section (SW SW SW 7, 10N-7E). In the type section, the deposits of the substage are the Hulick Till Member and the lower part of the Toulon Member of the Glasford Formation. The latter is outwash sand, silt, and gravel, which is oxidized and locally leached in the top. At the type section, the deposits rest unconformably on Pennsylvanian shales, but at the paratype for the Illinoian Stage (Tindall School Section) they occur between sediments of the Liman and Jubileean Substages. The Monican Substage is defined as consisting of the Illinoian deposits above the Pike Soil, and its top is a minor unnamed soil in the Toulon, which is overlain by deposits of the Jubileean Substage.

Teneriffe Silt

The Teneriffe Silt (Willman and Frye, 1970, p. 60) is named for Teneriffe School, Pike County, and the type section is in the New Salem Northeast Section (NW NE SW 11, 4S-4W). The formation contains all the silts overlying till of the Glasford Formation and is bounded at the top by the top of the Sangamon Soil. Locally it rests on the top of the Pike Soil. It is assigned to both the Monican and Jubileean Substages. The unit is fine to coarse silt and locally contains some sand and clay. The Teneriffe is not differentiated beyond the limit of Illinoian glaciation (fig. Q-7), where it is equivalent to the upper part of the Loveland Silt. The formation occurs in central western and south-central Illinois (fig. Q-1C) and at many places is overlain by the Roxana Silt.

Jubileean Substage

The Jubileean Substage of the Illinoian Stage (Willman and Frye, 1970, p. 120) is named for Jubilee College State Park, Peoria County, and its type section is in the Jubilee College Section (SW SW SW 7, 10N-7E). At the type section it consists of the upper silts of the Toulon Member and the overlying Radnor Till Member of the Glasford Formation. It overlies a minor soil developed in deposits of Monican age, and its top is the top of the in-situ Sangamon Soil, which is overlain by Wisconsinan deposits.

Sangamonian Stage

The name "Sangamon interglacial stage" was proposed by Leverett (1898b, p. 176) for exposures in Sangamon County. The name "Sangamonian Stage" was adopted in Illinois in 1960 (Frye and Willman, 1960, p. 4). The interglacial stage was based on a soil that occurs on tills of Illinoian age and is overlain by loesses of Wisconsinan age. Leverett's (1898b) type section was a locality in northwestern Sangamon County described by Worthen (1873, p. 307), but it has not been accessible for three-quarters of a century. For that reason Willman and Frye (1970, p. 121) proposed two paratype sections, the Rochester Section in Sangamon County (an accretion-gley) (NW SE NW 34, 15N-4W) and the Chapin Section in adjacent Morgan County (an in-situ soil profile) (SW NE NW 8, 15N-11W). The stage is based on the soil-stratigraphic unit, typified by these two localities, that serves to define the interval separating the Illinoian and Wisconsinan glacial stages. Sangamonian deposits are predominantly accretion-gley of the Berry Clay Member of the Glasford Formation, which also is part of the Sangamon Soil. Minor amounts of organic debris are associated with the accretion-gley deposits, but the peat and peaty silt beds called Sangamon in early reports are Wisconsinan and are assigned to the Farmdalian Substage.

Sangamon Soil

The Sangamon Soil was defined by Leverett (1898b) on the basis of a soil described by Worthen (1873) from a well in Sangamon County, Illinois. The soil is characterized by both a deeply developed in-situ profile on deposits of Illinoian age (Chapin Section) and a soil composed of accretion deposits above tills of Illinoian age (Rochester Section). The soil ranges from an in-situ solum more than 5 feet deep with a red-brown B-horizon (fig. Q-1A, E) to an accretion deposit of gray leached silt and clay containing a few small pebbles. The soil is developed in deposits of a wide range of ages and character. It is almost continuously present on the Illinoian drift (fig. Q-2), and in places it occurs on older deposits where the Illinoian is absent. It is also found in many localities where it is overlain by Wisconsinan drift.

Wisconsinan Stage

The term "Wisconsinan Stage" is derived (fig. Q-6) from the East-Wisconsin formation proposed by Chamberlin (1894, p. 763). In 1895 (p. 275) he changed the name to Wisconsin formation, and in 1899 (p. 20, 185) Leverett proposed the change to Wisconsin stage. The initial definition was based largely on the pattern of end moraines from the Lake Michigan glacial lobe and included only part of the sequence now included in the stage (fig. Q-2). In 1948 Leighton (*in* Wascher et al., 1948, p. 390) applied the name "Farmdale" to the loess previously called Late Sangamon loess and included it in the Wisconsin stage. In 1960 (p. 5) Frye and Willman proposed an expanded definition of the stage, and the present definition of the Wisconsinan

Electronic Filing: Received, Clerk's Office 07/01/2024

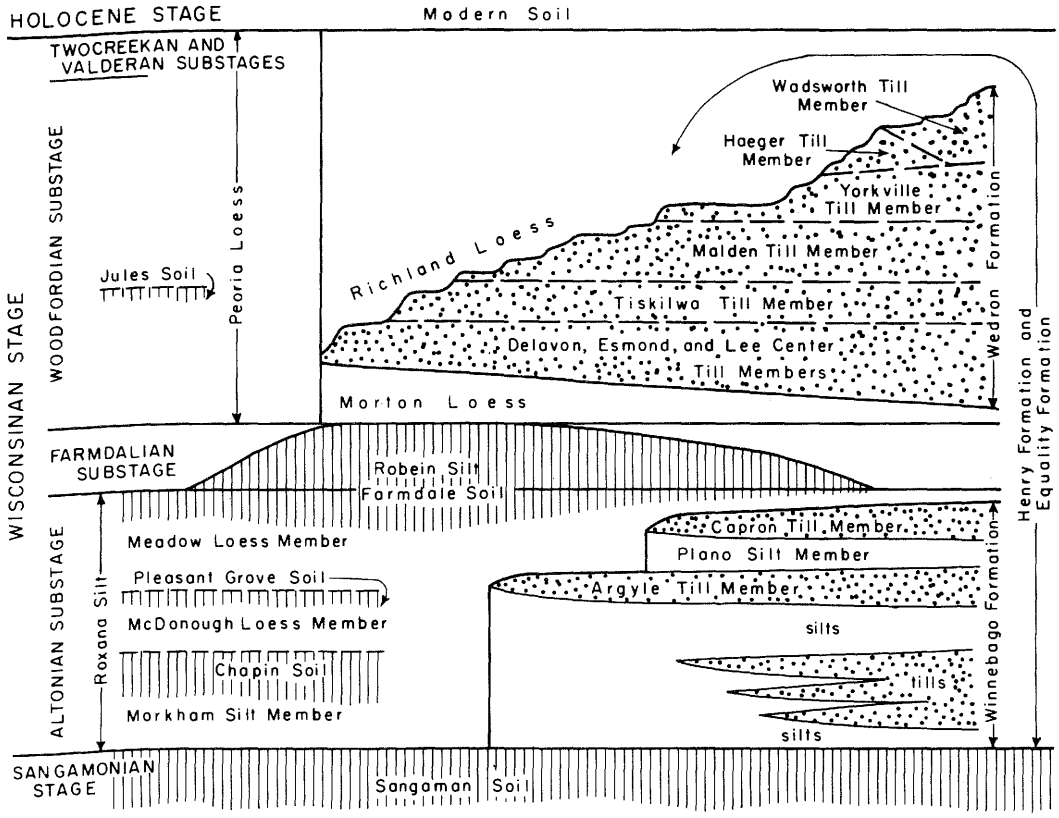

Fig. Q-8—Diagrammatic cross section showing the relations of the formations and members of Wisconsinan age in northern and western Illinois (Willman and Frye, 1970).

Stage was proposed in 1968 (Frye et al., 1968b, p. E1). The Wisconsinan Stage is bounded at the base by the contact of the Roxana Silt on the top of the Sangamon Soil (approximately 75,000 radiocarbon years B.P. [Frye et al., 1974a, p. 12]), and at the top by the contact of the youngest glacial tills with overlying lacustrine deposits in northeastern Wisconsin (approximately 7000 radiocarbon years B. P. [Frye and Willman, 1970, p. 126]). The Cottonwood School Section in Cass County (cen. E line 11, 18N-11W) was suggested by Willman and Frye (1970, p. 121) as a paratype for the stage in Illinois. The Wisconsinan Stage is subdivided into five substages, and the deposits are differentiated into 16 formations, but six of them are dominantly Holocene in age (figs. Q-4, Q-8). The Wisconsinan Stage is represented in all parts of Illinois.

Altonian Substage

The Altonian Substage (Frye and Willman, 1960, p. 5), the oldest subdivision of the Wisconsinan Stage, is named for Alton, Madison County, and the type section, which consists of Roxana Silt, is in the Alton Quarry Section (SE SW NE 10, 5N-10W) (Leonard and Frye, 1960, p. 24). In the type locality the base of the Altonian Substage is at the contact of the Markham Silt Member of the Roxana Silt with the top of the Sangamon Soil. The top of the Altonian is the contact of the Robein Silt and the Roxana Silt, or the top of the Farmdale Soil developed in Roxana Silt. Elsewhere in Illinois the substage includes deposits of till (Winnebago Formation), outwash (Henry Formation), and lacustrine deposits (Equality Formation). Deposits of Altonian age are widely distributed over Illinois.

Electronic Filing: Received, Clerk's Office 07/01/2024

Roxana Silt

The Roxana Silt (Frye and Willman, 1960, p. 5) is named for Roxana, Madison County, and the type section is the Pleasant Grove School Section in the bluff of the Mississippi River Valley (SW NE SE 20, 3N-8W) (fig. Q-1C). The formation rests on the top of the Sangamon Soil (developed in Teneriffe Silt or older deposits), and it terminates upward at the base of the Robein Silt or the top of the in-situ Farmdale Soil (developed in the Roxana), which is overlain by Peoria Loess. The Roxana Silt and the overlying Robein Silt were called Late Sangamon Loess in early reports and later named Farmdale Loess and assigned to the Wisconsin Stage (Leighton, *in* Wascher et al., 1948; Leighton and Willman, 1949, 1950). The member is largely loess, but it contains some colluvium at the base and locally some eolian sand. It is pinkish tan to yellow-gray (Frye et al., 1962) and has a distinctive mineral composition (Glass et al., 1968). It is 48 feet thick in the type section, but it thins rapidly back from bluff exposures. Where thick, it contains a distinctive molluscan fauna (Leonard and Frye, 1960), and it has been subdivided into three members, the Markham Silt Member at the base, the McDonough Loess Member, and the Meadow Loess Member. Where the Roxana is thinner than 7-8 feet thick the members generally cannot be differentiated because of pedological alteration (figs. Q-1A, E). Even where only a foot or two thick, it is generally darker brown and more clayey than the Peoria Loess. The formation occurs extensively outside the limits of Woodfordian glaciation and locally is found buried by Woodfordian drift.

Markham Silt Member—The Markham Silt Member of the Roxana Silt (Willman and Frye, 1970, p. 62) is named for the town of Markham, 4 miles west of Jacksonville, Morgan County, and the type section is in the Chapin Section (SW NE NW 8, 15N-11W). The unit generally consists of colluvium of silt with some sand and a few small pebbles (Frye et al., 1974a), but locally it may be entirely silt or sand. It rests on the top of the Sangamon Soil or on an erosional surface truncating the Sangamon Soil, and it is terminated at the top by the top of the Chapin Soil, which is overlain by the McDonough Loess Member. The Markham is gray-brown, lies within the profile of the Chapin Soil, is commonly 1-3 feet thick, and is widely present in western and central Illinois.

McDonough Loess Member—The McDonough Loess Member of the Roxana Silt (Willman and Frye, 1970, p. 62) is named for McDonough Lake on the Mississippi River floodplain in Madison County, and the type section is in the Pleasant Grove School Section, the same as for the formation (fig. Q-1C). The member consists of gray to tan loess, commonly leached, bounded at the base by the top of the Chapin Soil or older deposits and at the top by the top of the Pleasant Grove Soil, which is overlain by the Meadow Loess Member. The member is generally recognizable only in the thick loess deposits adjacent to the major valleys of central, southern, and western Illinois, and it is 5 feet or less thick.

Meadow Loess Member—The Meadow Loess Member of the Roxana Silt (Willman and Frye, 1970, p. 63) is named for Meadow Heights, part of Collinsville, Madison County, and the type section, like that of the formation, is in the Pleasant Grove School Section (fig. Q-1C). The member is loess, and where thick along the bluffs of the Illinois and Mississippi Rivers of central and southern Illinois it has three recognizable zones—pink-tan zones at the top and base and a gray-tan zone in the middle. Where thick and calcareous, it contains a distinctive fauna of fossil mollusks that has been radiocarbon dated at several localities (Leonard and Frye, 1960). Its heavy mineral suite and clay mineral composition differ from those of other loess deposits (Frye et al., 1962). It rests on top of the Pleasant Grove Soil developed in the McDonough Loess Member, or on older deposits, and it is bounded at the top by the in-situ Farmdale Soil, by the Robein Silt, or by younger formations. The member is 43 feet thick at its type locality, but it thins to a few feet at distances of 15 miles or more from the source valleys.

Chapin Soil

The Chapin Soil (Willman and Frye, 1970, p. 86) is named for Chapin, Morgan County, and the type section is in the Chapin Section (SW NE NW 8, 15N-11W). It is an in-situ soil developed in the colluvium and silt of the Markham Silt Member of the Roxana Silt. The soil generally is grayish brown and rests either on the A-horizon of the Sangamon Soil or on a truncated Sangamon Soil. The profile rarely is more than 2 feet thick, in contrast to the thicker Sangamon profile below (Frye et al., 1974a). The Chapin Soil occurs in western and central Illinois.

Pleasant Grove Soil

The Pleasant Grove Soil (Willman and Frye, 1970, p. 87) is named for Pleasant Grove School and the type section, like that of the Roxana Silt, is in the Pleasant Grove Section, Madison County. The soil at the type locality is an immature, or A-C, profile developed in silt of the McDonough Loess Member of the Roxana Silt. The solum is generally gray to gray-brown and lacks a textural B-horizon. The soil has been observed only adjacent to the major valleys of central and western Illinois.

Winnebago Formation

The Winnebago Formation (Frye and Willman, 1960, p. 5; Frye et al., 1969, p. 25) is named for Winnebago County, and the type section is on the east side of Rockford in the Rock Valley College Section (SW NW SW 10, 44N-2E) and in cores of near-by borings (Nos. 2 and 5) on the Northwest Tollway (Kempton, 1963). The name Winnebago was introduced as a replacement for the term "Farmdale" (Shaffer, 1956). The formation includes glacial till and intercalated silt, gravel, and sand. It is subdivided into three named members, the Argyle Till Member at the base, the Plano Silt Member, and the Capron Till Member, which overlie unnamed till, sand, and gravel members that occur in the buried valleys and are not exposed. The formation is bounded below by the top of the Sangamon Soil, and at the top by the top of the in-situ Farmdale Soil. It ranges from a few feet to as much as 400 feet thick where it is the filling of deep bedrock valleys. The formation is exposed at the surface only in central northern Illinois (fig. Q-5). The Lemont drift (Bretz, 1955), tentatively assigned to this formation, is discussed with the Valparaiso Drift.

Argyle Till Member—The Argyle Till Member of the Winnebago Formation (Frye et al., 1969, p. 26; Willman and Frye, 1970, p. 63) is named for Argyle, Winnebago County, and the type section is in the Rock Valley College Section, the same as the type section for the formation. The till is exceptionally sandy, pinkish tan or salmon colored, massive, and calcareous. It is overlain by the Plano Silt Member, and it overlies unnamed silts and tills of the Winnebago Formation. It occurs only in central northern Illinois (fig. Q-5).

Electronic Filing: Received, Clerk's Office 07/01/2024

Plano Silt Member—The Plano Silt Member of the Winnebago Formation (Kempton and Hackett, 1968, p. 31; Willman and Frye, 1970, p. 64) is named for Plano, Kendall County, and the type section is in the Big Rock Creek Section (SE NE 1, 37N-6E) where the member is 7 feet thick. The member consists of silt, silt rich in organic material, and peat. It overlies the Argyle Till and underlies the Capron Till, and it is recognized only in the area where the Capron Till is present.

Capron Till Member—The Capron Till Member of the Winnebago Formation (Frye et al., 1969, p. 26; Willman and Frye, 1970, p. 64) is named for Capron, Boone County, and the type section is in the Capron North Section (NE SE SE 23, 46N-4E). Its upper part is gray, calcareous sandy till and the lower part is silty till. It rests on Plano Silt or Argyle Till and is topped by an immature soil profile (Farmdale Soil) overlain by Peoria Loess. It occurs only in central northern Illinois (fig. Q-5).

Henry Formation

The Henry Formation (Willman and Frye, 1970, p. 70) is named for Henry, Marshall County, and the type exposure is in a gravel pit along Illinois Highway 29, 2 miles north of Henry (SE SE 32, 14N-10E), where 30 feet of sand and gravel overlain by 2 feet of the Richland Loess and the Modern Soil are exposed. The formation consists of glacial outwash of sand and gravel. In places it contains a few thin silt beds. The thickness of the formation varies greatly; in the major valleys it locally exceeds 100 feet. The formation rests on Woodfordian or older rocks, and it is overlain by Richland or Peorian Loess, the Equality Formation, or Holocene deposits. Although in some areas the formation is continuous with sand and gravel deposits that intertongue with tills of the Winnebago and Wedron Formations, vertical cut-offs are used to put the tongues in the Wedron or Winnebago Formations, and the Henry Formation is never overlain by till (fig. Q-8). Ideally, the formation is bounded at the base by the top of the Sangamon Soil, but such exposures are rarely observed; in some valleys it contains deposits older than Wisconsinan in its lower part. The formation is subdivided into three members, which are genetic units that differ in lithology—the Batavia Member (outwash plains), the Mackinaw Member (valley trains), and the Wasco Member (ice-contact deposits). The Henry Formation occurs extensively in the area of Wisconsinan glaciation and beyond that area along the outwash-carrying valleys (fig. 11).

Batavia Member—The Batavia Member of the Henry Formation (Willman and Frye, 1970, p. 71) is named for Batavia, Kane County, and the type exposure is in a gravel pit, 8 miles north of Batavia (SW 1, 40N-8E), in outwash deposited in front of the West Chicago Moraine. The Batavia Member is an upland unit of outwash sand, gravel, and silt, largely deposited along the fronts of many Wisconsinan moraines in discontinuous sheet-like deposits. The member rarely exceeds 30 feet thick, and it has sharp local variations in both thickness and texture. It rests on units of the Wedron Formation, or older deposits, and is commonly overlain only by a few feet of Richland Loess. It occurs in and bordering the area of Wisconsinan glaciation.

Mackinaw Member—The Mackinaw Member of the Henry Formation (Willman and Frye, 1970, p. 71) is named for Mackinaw, Tazewell County, and the type section is in a gravel pit on the southwest side of Mackinaw (NE NW 19, 24N-2W). The member consists of sand, pebbly sand, and gravel deposited as outwash valley trains leading outward from Wisconsinan glacier fronts and now preserved in terraces and beneath Holocene deposits. The materials are well sorted and regularly bedded. At the type locality the member is 30 feet thick, but at places it is more than 100 feet thick. The member rests on rocks ranging from the Wedron Formation to Paleozoic bedrock. It is generally overlain only by thin Richland Loess in the area of Wisconsinan glaciation and by the Peoria Loess outside that area. It occurs along many valleys throughout Illinois (fig. Q-2).

Wasco Member—The Wasco Member of the Henry Formation (Willman and Frye, 1970, p. 72) is named for Wasco, Kane County, and the type section is in a gravel pit along the Chicago Great Western Railroad (SE NW 24, 40N-7E). The Wasco consists of ice-contact sand and gravel, largely in kames, eskers, and deltas, and is characterized by lateral and vertical variations in grain size, sorting, bedding, and structure. At some localities the deposit is largely cobbles and boulders. Lenses of till and beds of silt occur in some deposits. The thickness varies greatly. The member generally rests on the Wedron Formation but locally overlies older deposits. It is commonly overlain by thin Richland Loess. It occurs discontinuously throughout the area of Wisconsinan glaciation.

Equality Formation

The Equality Formation (Willman and Frye, 1970, p. 72) is named for Equality, Gallatin County, and the type section is in the Saline River Section (SE cor. SW 27, 9S-7E). The formation consists of lacustrine silt, clay, and sand underlying a lake plain or beach complex of the present land surface. It was deposited during Wisconsinan time in (1) slackwater lakes, principally in valleys tributary to the Mississippi, Wabash, and Ohio Rivers in southern Illinois, (2) in shallow lakes produced by flooding between moraines, and (3) in ice-front lakes in northern Illinois (fig. 11). The formation is subdivided into the Carmi Member, dominantly silt and clay, and the Dolton Member, dominantly sand. It includes deposits of Altonian and Woodfordian age. Extensive molluscan faunas have been described from the lacustrine deposits (Frye et al., 1972). In the type region, the thickest sequence of Equality deposits available for study was 52 feet in the Equality Northeast Section (Frye et al., 1972), but well logs suggest that the formation may exceed 100 feet locally. The formation rests on Woodfordian or older deposits and its top is at the surface, except in local areas where Holocene formations cover it. In southern Lake Michigan it is overlain by the Lake Michigan Formation. Many individual glacial lakes, shorelines, spits, bars, and beaches have been named, but they are not stratigraphic units (Willman and Frye, 1970).

Carmi Member—The Carmi Member of the Equality Formation (Willman and Frye, 1970, p. 74) is named for Carmi, White County, and the type section is an exposure along Crooked Creek 4 miles north of Carmi (NE cor. SW 21, 4S-10E). The type section of this member occurs in the deposits of glacial Lake Little Wabash. However, the deposits, their fauna, and clay mineral composition have been much more intensively studied in the deposits of Lake Saline in Gallatin County to the south (Frye et al., 1972). The deposits there are clay and silt, with some sand, commonly 20-40 feet thick but locally as much as 100 feet. They partially fill, or drown, an extensive system of valleys that were dammed by aggradation of the Ohio and Wabash Valleys. The Carmi occurs throughout the state in large areas covered by Wisconsinan lakes and also in many smaller areas in the region of Wisconsinan glaciation in northern Illinois.

Electronic Filing: Received, Clerk's Office 07/01/2024

Dolton Member—The Dolton Member of the Equality Formation (Willman and Frye, 1970, p. 74) is named for Dolton, Cook County, and the type section is an exposure of 8 feet of sand at the top of a clay pit (S1/2 NE 3, 36N-14E). The Dolton is dominantly sand with local beds of silt and gravel, and most of it was deposited in beaches and bars. It is differentiated only where it is the surficial deposit of the Equality Formation. It is best developed in Cook County, where it is associated with the several beaches of Lake Chicago (Bretz, 1955).

Farmdalian Substage

The Farmdalian Substage (Leighton and Willman, 1950, p. 602; Frye and Willman, 1960, p. 6) is named for Farmdale, Tazewell County, and the type section is in the Farm Creek Section (NE SW SE 30, 26N-3W). The substage was defined in more detail in 1968 (Frye et al., 1968b, p. E15) and in 1970 (Willman and Frye, p. 125). The substage includes the deposits made during the span of time represented by the Robein Silt at the type section (28,000-22,000 radiocarbon years B.P.), where the Robein Silt overlies the Roxana Silt and is terminated upward by the top of the Farmdale Soil. It is overlain by the Morton Loess. The substage also comprises the Peddicord Formation and the Farmdale Soil. The deposits have been extensively radiocarbon dated in Illinois.

Robein Silt

The Robein Silt (Willman and Frye, 1970, p. 64) is named for Robein, Tazewell County, and the type section is in the Farm Creek Section (NE SW SE 30, 26N-3W) (fig. Q-1B). It was called Farmdale Silt in some reports (Frye and Willman, 1960). The Robein is brown, gray, dark gray to black, leached silt. It contains abundant organic material, which differentiates it from the Roxana Silt below. It is part of the Farmdale Soil and is Farmdalian in age. It rests on the Roxana Silt, the Peddicord Formation, or the Winnebago Formation, and it is overlain by the Peoria Loess, Morton Loess, or the Wedron Formation. The Robein ranges from a few inches to more than 5 feet thick. It is discontinuous but widely distributed in Illinois.

Peddicord Formation

The Peddicord Formation (Willman et al., 1971, p. 4) is named for Peddicord School, La Salle County, and the type section is in the Wedron Section (SE SW 9, 34N-4E) (Willman and Frye, 1970) (fig. Q-1B). The formation consists of gray and pinkish tan, calcareous, lacustrine silts, and it contains fossil mollusks (Leonard and Frye, 1960). It is Farmdalian in age. The formation has been observed only in the upper Illinois Valley, where it overlies the Sangamon Soil or bedrock and is overlain by the Robein Silt or the Wedron Formation.

Farmdale Soil

The Farmdale Soil was named for Farmdale, Tazewell County (Willman and Frye, 1970, p. 87), and the type section is in the Farm Creek Section (NE SW SE 30, 26N-3W). In the type section it is an organic soil represented by the Robein Silt. It is brown to black and lacks a textural B-horizon. This unit occurs widely over Illinois and occurs both as an organic soil and as an in-situ profile developed in Roxana Silt. It is overlain by the Morton Loess, by the Peoria Loess, or by the Wedron Formation.

Woodfordian Substage

The Woodfordian Substage (Frye and Willman, 1960, p. 6-7) is named for Woodford County, Illinois, where it is the surface deposit over nearly the entire county. Glaciers of the Lake Michigan and Erie Lobes (figs. Q-9, Q-10) covered northeastern Illinois during Woodfordian time. The substage is based on the sequence of deposits above the contact of the Morton Loess on the Robein Silt in the type locality of those formations and extending upward to the base of the Two Creeks deposits, as typically exposed in east-central Wisconsin (Thwaites and Bertrand, 1957; Frye et al., 1968b). The substage includes the deposits of six formations, as well as parts of several dominantly Holocene formations (figs. Q-4, Q-8). Two of the six formations (Henry and Equality) include earlier Wisconsinan deposits and were described under the Altonian Substage. The molluscan fauna of the Woodfordian Substage, largely from the Peoria Loess, has been described (Leonard and Frye, 1960). Many radiocarbon dates have been determined from several deposits of the substage, including those adjacent to the lower and upper contacts, and they indicate a time span from 22,000 to 12,500 radiocarbon years B.P. The Woodfordian includes deposits that earlier were assigned to the Iowan, Tazewell, Cary, and Mankato Substages (fig. Q-6).

Peoria Loess

The Peoria Loess (Leverett, 1898a, p. 246; Kay and Leighton, 1933, p. 673) is named for Peoria, Peoria County, from exposures in the bluffs of the Illinois River Valley. The term "Peorian" was first used by Leverett (1898a) for an interglacial stage. Kay and Leighton (1933) restricted Peorian to the loess deposits outside the Shelbyville Morainic System, as is still the practice. Frye and Leonard (1951, p. 128) made it a rock-stratigraphic unit—Peoria Loess—which use subsequently was adopted in Illinois (Frye and Willman, 1960, p. 7). As a type section had not been described, Willman and Frye (1970, p. 65-66, 188-189) designated the Tindall School Section, south of Peoria in the west bluff of the Illinois Valley, as the type section (SW SW NE 31, 7N-6E). The formation consists of massive, well sorted silt, ranging from coarse in the valley bluffs to fine in uplands distant from the bluffs. It locally contains some fine to medium sand in the bluff areas. Where thick it is calcareous, except in the Modern Soil profile at the top; where thin it is all noncal-

Electronic Filing: Received, Clerk's Office 07/01/2024

careous. The zone from which carbonates are leached varies from 3-4 feet thick at the northern end of the state to 15-20 feet at the southern end. In thick sections along the Illinois Valley, the Jules Soil occurs in the upper part, several feet below the Modern Soil. The Peoria Loess ranges in thickness from as much as 100 feet to only a foot or two, thinning away from the bluffs (figs. 11, Q-1C) (Smith, 1942; Willman and Frye, 1970). The fossil mollusks (Leonard and Frye, 1960) and clay mineral composition (Frye et al., 1962, 1968a) have been described, and a group of radiocarbon dates indicate a span of time from approximately 22,000 B.P. to 12,000 B.P. Peoria Loess is physically continuous with both the Morton Loess and the Richland Loess (fig. Q-8), which occur within the area of Woodfordian glaciation. The Peoria Loess occurs on the upland areas and valley walls of nearly all of Illinois outside the area of Woodfordian glaciation.

Morton Loess

The Morton Loess (Frye and Willman, 1960, p. 7) is named for Morton, Tazewell County, and the type section is in the Farm Creek Railroad-cut Section (cen. 31, 26N-3W) (fig. Q-1A). The unit was formerly called Peorian loess (Alden and Leighton, 1917) and later Iowan loess (Leighton, 1933; Leighton and Willman, 1950). It occurs above the Robein Silt or the Farmdale Soil developed in Roxana Silt and lies below the Wedron Formation. It is massive, calcareous silt, gray to gray-tan and locally fossiliferous (Leonard and Frye, 1960). It ranges up to 10 feet thick. It occurs only within the area of Woodfordian glaciation, but it is physically continuous with the lower part of the Peoria Loess, which lies outside that area (fig. Q-8). Radiocarbon dates indicate a time span from 20,000 to 22,000 years B.P.

Wedron Formation

The Wedron Formation (Frye et al., 1968b, p. E16) is named for Wedron, La Salle County, and the type section is in the Wedron Section (fig. Q-1B) in the Wedron Silica Company pit (SE SW 9, 34N-4E) (Willman and Payne, 1942, p. 148, 307; Willman and Frye, 1970, p. 190). The formation consists of those deposits of glacial till and outwash that extend upward from their contact on the Morton Loess to the top of the till below the Two Creeks deposits at Two Creeks, Wisconsin (Thwaites and Bertrand, 1957). Although largely till, the Wedron contains numerous intercalated beds of outwash gravel, sand, and silt (fig. Q-1A, B). In Illinois the formation is subdivided into 12 members (fig. Q-4) on the basis of the lithology of successive sheets of till. Before 1968, the deposits included in the Wedron Formation were subdivided into drifts or drift formations, lithologically distinct units named for the moraine marking the outer margin of the particular drift (Culver, 1922a; Fisher, 1925; Willman and Payne, 1942; Frye et al., 1965). The gray silty till of the Esmond, Lee Center, and Delavan Till Members was the Shelbyville drift; the pink sandy till of the Tiskilwa Till Member was the Bloomington drift; the yellow-gray silty to sandy till of the Malden Member was the Normal and Cropsey drifts; the medium to dark gray clayey till of the Yorkville Till Member was the Marseilles and Minooka drifts; and the yellow-gray gravelly to clayey till of the Haeger and Wadsworth Till Members was the Valparaiso and Lake Border drifts. The youngest, or uppermost, beds of the Wedron do not occur in Illinois but are exposed in eastern Wisconsin. The formation spans all but the earliest part of the Woodfordian Substage of the Wisconsinan Stage. Its thickness ranges widely, up to as much as 250 feet. Approximately 60 feet of deposits is exposed in the type section. The formation is widely distributed in the northeast quadrant of Illinois (fig. Q-5), where it includes most of the materials of the many prominent Woodfordian moraines, which are described as drift units in the section on morphostratigraphic classification (fig. Q-10).

Esmond Till Member—The Esmond Till Member of the Wedron Formation (Frye et al., 1969, p. 26; Willman and Frye, 1970, p. 67) is named for Esmond, De Kalb County. The type section is in roadcuts 10 miles north of Esmond (NW SW NW 27, 43N-2E, Winnebago County) and borings at Greenway School, near Esmond. The upper part of the till is silty, but the lower part is more clayey. It is gray and calcareous, and its clay mineral content is characterized by being exceptionally high in illite. The member overlies the Morton Loess, or the sandy Argyle Till Member of the Winnebago Formation where the Morton is absent. It is overlain by the pink-tan deposits of the Tiskilwa Till Member of the Wedron Formation or by Richland Loess. It is discontinuous, rarely exceeds 25 feet thick, and it is the surface drift only in the Dixon Sublobe in north-central Illinois (figs. Q-5, Q-9).

Lee Center Till Member—The Lee Center Till Member of the Wedron Formation (Frye et al., 1969, p. 26; Willman and Frye, 1970, p. 68) is named for Lee Center, Lee County, and the type section is a roadcut 5 miles northwest of Lee Center (SE SW NW 31, 21N-10E). In the type section it consists of 8 feet of calcareous, gray, silty till that underlies 4 feet of leached, brown silt of the Richland Loess. The Lee Center Till is bounded at the top by the sharply contrasting pink-tan Tiskilwa Till Member. It overlies the Morton Loess. It occurs primarily in the Green River Sublobe (figs. Q-5, Q-9), where it is thin, discontinuous, and extensively eroded by the meltwaters of Woodfordian glaciers.

Delavan Till Member—The Delavan Till Member of the Wedron Formation (Willman and Frye, 1970, p. 68) is named for Delavan, Tazewell County, and the type section is in roadcuts along Illinois Highway 121, 4 miles east of Delavan (SW 16, 22N-3W). The member consists of gray, calcareous, silty, illitic till that attains a maximum thickness of about 200 feet in the Shelbyville Morainic System. It overlies the Morton Loess and is overlain by the distinctive pinkish tan till of the Tiskilwa Till Member. It is judged to be equivalent to the Lee Center and Esmond Till Members farther north. Beyond the limit of the Tiskilwa Till Member, the Delavan is overlain by Richland Loess. It occurs in the Peoria Sublobe and is best exposed in Tazewell and McLean Counties (figs. Q-1A, Q-5).

Tiskilwa Till Member—The Tiskilwa Till Member of the Wedron Formation (Willman and Frye, 1970, p. 68) is named for Tiskilwa, Bureau County, and the type section is the Buda East Section (SE SE SW 31, 16N-8E). The till is sandy, pink-tan to reddish tan-brown, and commonly is 100-150 feet thick in the higher parts of the Bloomington Morainic System. It is bounded above by the more illitic, tan to yellow-gray till of the Malden Till Member, and below by the gray till of the Delavan, Lee Center, or Esmond Till Members. It is one of the most extensive members of the Wedron Formation, extending from Bloomington in McLean County northward to the Wisconsin state line (fig. Q-5).

Malden Till Member—The Malden Till Member of the Wedron Formation (Willman and Frye, 1970, p. 69) is named for Malden, Bureau County, and the type section is in the Malden South Section (SW SE SE 5, 16N-10E). The member consists of silty and sandy, yellow-gray to gray-tan till, with discontinuous beds and lenses of gravel and sand. In some

areas it grades upward to clayey till. It is bounded at the base by the Tiskilwa Till Member and is overlain by the clayey Yorkville Till Member or, where the Malden Member is the surface drift, by the Richland Loess. At the type locality the member is 25 feet thick, but it is 50-100 feet thick under the crests of some moraines. It is extensively exposed from McLean County northward to Kane County (fig. Q-5).

Yorkville Till Member—The Yorkville Till Member of the Wedron Formation (Willman and Frye, 1970, p. 69) is named for Yorkville, Kendall County, and the type section is in roadcuts at the intersection of Illinois Highways 47 and 71, 1 mile south of Yorkville (SE SE SE 5, 36N-7E). The member is a clayey, greenish gray to dark gray till characterized by abundant small dolomite pebbles. The Yorkville Member is as much as 200 feet thick in the Marseilles Morainic System, in and east of which it is extensively exposed (fig. Q-5). It overlies the Malden Till Member and is overlain by the Wadsworth and Haeger Till Members, the Richland Loess, or in extensive areas by the lake deposits of the Equality Formation (fig. Q-2).

Haeger Till Member—The Haeger Till Member of the Wedron Formation (Willman and Frye, 1970, p. 69) is named for Haegers Bend, a village on the Fox River in McHenry County, and the type section is in roadcuts half a mile northwest of the village (NW NE 23, 43N-8E). In the type exposure the Haeger Member consists of 12 feet of calcareous, gravelly, silty, yellow-gray till overlying the Yorkville Till Member and overlain by the Richland Loess. In some isolated hills the member may be as much as 50-100 feet thick, but it is generally thinner. It is overlain by the Wadsworth Till Member east of the area where the Yorkville is the surface drift. It occurs only in the northeastern part of the state (fig. Q-5).

Wadsworth Till Member—The Wadsworth Till Member of the Wedron Formation (Willman and Frye, 1970, p. 70) is named for Wadsworth, Lake County, and the type section is in roadcuts at the intersection of Illinois Highway 131 and Wadsworth Road (SE SE SW 30, 46N-12E). The member consists of the clayey gray tills of the Lake Border Morainic System, the Tinley Moraine, and much of the Valparaiso Morainic System. The member occurs above the Haeger and Yorkville Till Members, and it is overlain by very thin Richland Loess. It is the youngest till member of the Wedron Formation exposed in Illinois, and it is marginal to the Lake Michigan shore (fig. Q-5). It is also present under most of southern Lake Michigan, where it forms the floor of the lake east of Chicago. It is overlain by the Equality and Lake Michigan Formations in the center of the southern part of the lake.

Oakland Till Member—The Oakland Till Member of the Wedron Formation (Ford, *in* Johnson et al., 1972, p. 15) is named for Oakland, Coles County, where it is the surface drift, but it has been described only from its occurrence in the Harmattan strip mine in Vermilion County (NE NE NW 4, 19N-12W). In the Harmattan strip mine it ranges from 0 to more than 30 feet thick. It is a coarse, blocky, calcareous, brown till containing wood fragments and mollusk shells (dated at 20,800 ± 130 radiocarbon years B.P.; sample ISGS-81). It locally contains thin beds of silt, sand, and gravel at the base. It occurs above Robein Silt and is overlain by the Glenburn Till Member.

Glenburn Till Member—The Glenburn Till Member of the Wedron Formation (Johnson et al., 1971, p. 202) is named for Glenburn, Vermilion County, and the type section is in the Emerald Pond Section (NE SW SW 33, 20N-12W) (Johnson et al., 1972, p. 42). In the type section it is 17 feet thick and consists of pinkish brown to dark brown, calcareous, somewhat sandy till. At the type section it occurs above the Banner Formation of Kansan age and it is overlain by the Batestown Till Member of the Wedron Formation, but elsewhere in Vermilion and adjacent counties it has been described as overlying the Robein Silt and the Oakland Till Member of the Wedron Formation. It occurs in central eastern Illinois.

Batestown Till Member—The Batestown Till Member of the Wedron Formation (Johnson et al., 1971, p. 202) is named for Batestown, Vermilion County, and the type section is in the Emerald Pond Section (NE SW SW 33, 20N-12W) (Johnson et al., 1972, p. 42). In the type section the Batestown is 14 feet thick and consists of light olive brown to dark gray, calcareous, sandy to silty till that contains beds of sand and silt and one bed of boulders. The Batestown is bounded by the Glenburn Till Member below and the Snider Till Member above, or, where the Snider is absent, by the Richland Loess. The member occurs in central eastern Illinois (fig. Q-5).

Snider Till Member—The Snider Till Member of the Wedron Formation (Johnson et al., 1971, p. 204) is named for Snider, Vermilion County, and the type section is in the Emerald Pond Section (NE SW SW 33, 20N-12W) (Johnson et al., 1972, p. 42). In the type section the member is 16 feet thick and consists of light olive-brown to gray-brown, calcareous, blocky, jointed, clayey till and a basal zone of silt, sand, and gravel. It occurs in central eastern Illinois (fig. Q-5), where it overlies the Batestown Till Member and is commonly overlain by thin Richland Loess. The uppermost part of the Snider Till is leached and within the B-horizon of the Modern Soil.

Richland Loess

The Richland Loess (Frye and Willman, 1960, p. 7) is named for Richland Creek, Woodford County, and the type section is in a roadcut north of the creek (NW SE SW 11, 28N-3W). The formation is massive tan silt that is calcareous below the leached zone of the Modern Soil and is locally fossiliferous (Leonard and Frye, 1960). It is as much as 20 feet thick on the east bluff of the Illinois Valley north of Peoria, but it thins to 1-2 feet in the Chicago area. This loess was formerly called Tazewell loess (Leighton, 1933). It rests on deposits of the Wedron, Henry, and Equality Formations inside the area of Woodfordian glaciation (fig. Q-1A), and it is terminated upward by the Modern Soil. It is not differentiated outside that area, but it is continuous with the upper part of the Peoria Loess (fig. Q-8).

Jules Soil

The Jules Soil (Willman and Frye, 1970, p. 88) is named for Jules, Cass County, and the type section is in the Jules Section (SE SE NE 13, 18N-11W) (Frye et al., 1968a, p. 21). This soil is generally an immature, or A-C, profile with a dark gray solum that lacks a textural B-horizon. It occurs within the Peoria Loess and at a few places within the Richland Loess, but only in the thick loess sequences near the Illinois River Valley of central Illinois. It represents an interruption in loess deposition between the deposition of the Tiskilwa and Malden Till Members of the Wedron Formation (Frye et al., 1974b).

Twocreekan Substage

The Twocreekan Substage (Frye and Willman, 1960, p. 8) is named for Two Creeks, Manitowoc County, Wisconsin, and the type section is in the Two Creeks Section, 2 miles east of the town in the bluff of Lake Michi-

Electronic Filing: Received, Clerk's Office 07/01/2024

gan (Thwaites and Bertrand, 1957, p. 859-864; Frye et al., 1965, p. 57). At the type locality, lake deposits of silt and sand and the forest bed overlie till and, in turn, are overlain by till. Many radiocarbon dates have been obtained from wood of the forest bed in the upper part of the Two Creeks deposits (Black and Rubin, 1968), and the time span for the substage is from 12,500 to 11,000 radiocarbon years B.P. Deposits of the Twocreekan Substage have not been specifically differentiated in Illinois, although they occur in the Equality Formation sediments of Lake Chicago and other glacial lakes and in the various surficial formations that are dominantly of Holocene age.

Valderan Substage

The Valderan Substage (Thwaites, 1943; Frye and Willman, 1960, p. 9) is named for Valders, Manitowoc County, Wisconsin, and the type section was designated as the drift in a quarry at Valders (Thwaites and Bertrand, 1957, p. 864-866). The base of the substage is defined (Frye et al., 1968b, p. E18) as the contact of the Valders till on the Two Creeks forest bed at the Two Creeks Section, eastern Wisconsin, and the top is defined as the top of the Cochrane till below post-Cochrane deposits in the James Bay Lowland of Ontario, Canada (Hughes, 1956)—a time span from 11,000 to 7,000 radiocarbon years B.P. Recent studies (Evenson, 1973) suggested that the till in the quarry at Valders is equivalent to the till beneath the Two Creeks forest bed and is therefore Woodfordian in age. If that finding is confirmed, the Two Creeks exposure, the type section of the Twocreekan Substage, should preferably be designated as the reference section for the Valderan Substage as well. The name "Valderan Substage," now well established for the drift younger than Twocreekan, as clearly intended by Thwaites (1943), Leighton (1957), and others, can then be retained. The rock-stratigraphic name for the post-Twocreekan till in eastern Wisconsin may conveniently be changed from Valders till to Two Rivers Till, as proposed by Evenson (1973) and Lineback et al. (1974). In Illinois, deposits of the Valderan Substage occur in the Equality Formation, particularly in the deposits of Lake Algonquin in the Lake Michigan Basin, in the Henry Formation along the Mississippi Valley, and in the various surficial formations that are dominantly of Holocene age.

Holocene Stage

The Holocene Stage, although based on a term and a concept that developed more than a century ago, has never been properly defined as a time-stratigraphic unit. It has been accepted as a replacement for "Recent" by the U. S. Geological Survey (Cohee, 1968) but without formal stratigraphic definition. For formal use in Illinois, Holocene Stage has replaced Recent Stage as the youngest time-stratigraphic subdivision of the Pleistocene Series (Willman and Frye, 1970, p. 126). In that sense it is defined as embracing all deposits younger than the top of the Wisconsinan Stage. The Holocene Age, therefore, extends from approximately 7000 radiocarbon years B.P. to the present. Six formations in Illinois are dominantly of Holocene age, but in many localities these surficial deposits began to accumulate and the Modern Soil began to develop as soon as the glaciers melted from the area; consequently, the lower parts of the deposits are Wisconsinan in age (fig. Q-4). These deposits are generally overlain only by the Modern Soil developed in their tops, but along marginal areas there is some overlapping and intertonguing. To avoid repetition of a formation in a single section or the occurrence of formations in different orders, each surficial formation can be overlain only by the surficial formations that are specified in the description given for that formation. The order is based on the most common relations. In complex relations the formations are terminated laterally by a vertical cut-off. Holocene deposits are abundant throughout Illinois.

Cahokia Alluvium

The Cahokia Alluvium (Willman and Frye, 1970, p. 75) is named for Cahokia, St. Clair County, which is located on the floodplain of the Mississippi River, and the type section is in a boring drilled 3 miles southwest of Cahokia (4300 feet south of lat. 38°32′30″ N and 5200 feet east of long. 90°15′ W) (Bergstrom and Walker, 1956, test hole No. 2). In the boring, the Cahokia consists of 45 feet of silt, clay, and silty sand, overlying 60 feet of sand and gravel of the Henry Formation, which rests on bedrock. The Cahokia Alluvium includes the deposits in the floodplains and channels of present rivers and streams, and the name replaces the long-used informal term "Recent Alluvium." Although largely of Holocene age, the formation in many places probably contains some deposits as old as Woodfordian. It consists mainly of poorly sorted silt, clay, and silty sand but locally contains lenses of sand and gravel. Its thickness varies greatly but rarely exceeds 50 feet. The formation rests on rocks of many ages. It generally is terminated upward by the surface of the floodplain and the Modern Soil, but locally it is overlain by the Parkland Sand, the Grayslake

Electronic Filing: Received, Clerk's Office 07/01/2024

Peat, the Lacon Formation, or the Peyton Colluvium. The Cahokia Alluvium occurs throughout Illinois in valley bottoms (fig. 11),

Parkland Sand

The Parkland Sand (Willman and Frye, 1970, p. 78) is named for Parkland, Tazewell County, and the type section is in a roadcut 5 miles west of Parkland (SW SE SW 2, 23N-7W). The formation consists of windblown sand in dunes and sheet-like deposits. The thickness ranges sharply—some dunes reach 100 feet high—but the range is commonly 20-40 feet. The Parkland Sand is a surficial deposit, but it is locally overlain by the Richland Loess, the Peyton Colluvium, or the Lacon Formation. It occurs in large areas along the Illinois River Valley of central Illinois, the Green River Lowland and the Mississippi Valley of northwestern Illinois, the Kankakee Valley in northeastern Illinois, and in smaller areas elsewhere.

Grayslake Peat

The Grayslake Peat (Willman and Frye, 1970, p. 77) is named for Grayslake, Lake County, and the type section is in a pit 1 mile southeast of Grayslake (NE SE NE 2, 44N-10E), where 14 feet of peat is exposed (Hester and Lamar, 1969). The formation consists of peat, sandy and silty peat, muck rich in organic material, and a foot or two of silt at the top. In some places it contains beds of marl, silt, and clay. It rarely exceeds 20 feet thick. Although it is a surficial formation, it is locally overlain by the Cahokia Alluvium, the Parkland Sand, the Peyton Colluvium, or the Lacon Formation. It occurs as a filling of ponds and poorly drained areas, principally in the region of Wisconsinan glaciation, and in the bottomlands of the major valleys.

Lacon Formation

The Lacon Formation (Willman and Frye, 1970, p. 77) is named for Lacon, Marshall County, and the type locality is a landslip area along the bluffs of the Illinois River Valley, 2 miles northwest of Lacon (E1/2 2, 12N-9E) (Ekblaw, 1932). The formation consists of gravity-initiated deposits, such as landslides, slumps, slips, and rock falls, most of which are triggered by seasonal increases in pore-water pressure and move over surfaces lubricated by infiltrated water. The material is unsorted and reflects a local source. It is a surficial formation, and where it locally interfingers with the Cahokia Alluvium and the Peyton Colluvium it is considered part of those formations. It occurs in the many parts of the state where valley bluffs are prominent.

Peyton Colluvium

The Peyton Colluvium (Willman and Frye, 1970, p. 79) is named for Peyton Creek, Peoria County, and the type section is along the creek at the base of the Illinois Valley bluffs, 1.5 miles southwest of Glasford (NW NE 32, 7N-6E). The locality is mapped as slopewash and alluvial fans (Wanless, 1957). The formation includes the widely distributed but narrow belts of poorly sorted debris that have accumulated on the lower slopes and at the base of slopes by processes of creep, slopewash, and mudflow. The many small cones and fans that occur at the mouths of gullies and rest on floodplain or terrace surfaces, generally interfingering with colluvium, are included in the formation. The Peyton is a surficial formation and is not overlain by other formations. Where it intertongues with the Cahokia Alluvium it is included in that formation.

Lake Michigan Formation

The Lake Michigan Formation (Willman and Frye, 1970, p. 78), named for Lake Michigan, consists of the surficial lacustrine and beach deposits of the southern part of the lake. A cross section of the lake sediments along a line 12-32 miles east of Waukegan, Lake County, is the type locality (Gross et al., 1970). The formation also includes the deposits in the basins of other natural lakes in Illinois. It overlies Paleozoic rocks, glacial deposits of Wisconsinan age, or the Equality Formation, and it is overlain only by water or, on the beaches, by air. The sediments of the Lake Michigan Formation in the southern part of the lake have been described (Gross et al., 1970; Lineback et al., 1970, 1972; Lineback and Gross, 1972), and the chemical composition and trace element content of the sediments have been analyzed (Shimp et al., 1970, 1971; Ruch et al., 1970; Schleicher and Kuhn, 1970; Kennedy et al., 1971; Frye and Shimp, 1973). The formation attains a maximum thickness of more than 60 feet, but generally it is less than 40 feet thick. It is composed of clay, silt, a small proportion of sand, and local accumulations of organic matter. Seven members have been differentiated in the formation (fig. Q-4), all but one (Ravinia) of which have been defined from cores taken from the southern part of Lake Michigan.

South Haven Member—The South Haven Member of the Lake Michigan Formation (Lineback et al., 1970, p. 11) is named for South Haven, Ottawa County, Michigan, and the type section is the interval from 219.3 cm to the base of core 143 (lat. 42°21.8′ N, long. 78°10.8′ W, at a water depth of 390 feet). It is the lowest member of the formation and consists of reddish gray clay, generally less than 3.5 feet thick, on the east side of the lake. The member rests on the Wedron Formation, Equality Formation, or bedrock.

Sheboygan Member—The Sheboygan Member of the Lake Michigan Formation (Lineback et al., 1970, p. 11) is named for Sheboygan, Sheboygan County, Wisconsin, and the type section is the interval 112-219.3 cm in core 143, the same core as the type of the South Haven Member. The member consists of two reddish brown to brown clay units separated by a thin, persistent layer of gray clay. The member ranges up to 4 feet thick, is overlain by the Winnetka Member, and rests on the South Haven Member or the Equality Formation. Its maximum development is in the mid-lake area and it occurs only where water depth exceeds 230 feet. It thins shoreward to the east, south, and west. It is absent from the southwestern part of the lake.

Wilmette Bed—The Wilmette Bed of the Sheboygan Member of the Lake Michigan Formation (Lineback et al., 1970, p. 11) is named for Wilmette, Cook County, and the type section is in the type section of the Sheboygan Member. It is a bed of gray clay, with some silt and sand, in the middle of the Sheboygan Member. It is 3-9 inches thick, and it occurs only in the area of southern Lake Michigan where water depth exceeds 270 feet.

Winnetka Member—The Winnetka Member of the Lake Michigan Formation (Lineback et al., 1970, p. 8) is named for Winnetka, Cook County, and the type section is the interval 35.5-112 cm in core 143, the same core as the type of the South Haven Member. The member consists of brownish gray clay with a few interspersed black beds. It becomes somewhat sandy near the shore, but generally it is finer grained

Electronic Filing: Received, Clerk's Office 07/01/2024

than the overlying members. It is 1-6 feet thick. It rests on the South Haven and Sheboygan Members and the Equality Formation, and it is overlain by the Lake Forest and Waukegan Members. The Winnetka is absent where the Wedron or Equality Formations are near the sediment surface.

Lake Forest Member—The Lake Forest Member of the Lake Michigan Formation (Lineback et al., 1970, p. 8) is named for Lake Forest, Lake County, and the type section is the interval 16-35.5 cm in core 143, the same core as the type of the South Haven Member. The member is dark gray silty clay that usually contains many thin beds of black clay. The black beds contain more organic matter than the enclosing deposits and have been radiocarbon dated at 6920 ± 200 radiocarbon years B.P. (sample ISGS-33) and 7050 ± 200 radiocarbon years B.P. (sample ISGS-36). The member is generally siltier than the Winnetka and Sheboygan Members below and less sandy and more compact than the Waukegan Member above. It is 0-4 feet thick. It is present on the western and southern sides of southern Lake Michigan but is absent from the central and eastern areas.

Waukegan Member—The Waukegan Member of the Lake Michigan Formation (Lineback et al., 1970, p. 6) is named for Waukegan, Lake County, and the type section is the interval 0-16 cm in core 143, the same core as the type of the South Haven Member. It is the surficial sediment of the formation in large areas in the center and along the eastern side of southern Lake Michigan. It is distributed widely over the offshore lake floor except at a few places where bedrock or till form the lake bottom. It consists of soft sandy silt, silty clay with a high water content, sand, and gravel. It is 0.1-30 feet thick. The member becomes sandier near shore and in the southwestern part of the lake. A gray silt facies occurs on the east side of the lake where the member is thickest, and a brown silt facies is on the west side where the member thins to less than a foot thick (Lineback and Gross, 1972).

Ravinia Sand Member—The Ravinia Sand Member of the Lake Michigan Formation (Willman and Frye, 1970, p. 78) is named for Ravinia, in the southern part of Highland Park, Lake County, where the type exposure is an accessible section of the Lake Michigan beach (W1/2 31, 43N-13E). It consists of well sorted, largely medium-grained, nearly white beach sand containing local lenses of gravel. It is relatively clean, except for man-made litter and driftwood. Smaller areas of beach sand present along the shores of other natural lakes in Illinois are included in the Ravinia. The Ravinia Member includes only beach sand and is separated from the rest of the formation at the base of the low-water swash zone. Sands occurring offshore are included in the Waukegan Member. The character of the beach sands and adjacent deposits in extreme northeastern Illinois and the history of their development have been described by Hester and Fraser (1973).

Modern Soil

As a soil-stratigraphic unit, the term "Modern Soil" (Willman and Frye, 1970, p. 89) is applied to any soil profile genetically related to the present topographic surface. It underlies the surface of most of Illinois. The soil ranges from very shallow to several feet in depth and is developed in any sediment that immediately underlies the existing land surface. The type section is the uppermost five units in the Buda East Section in Bureau County (SE SE SW 31, 16N-8E) (Frye et al., 1968a, p. 20). The term carries no implication of soil type in the soil science classification.

Morphostratigraphy

The morphostratigraphic units called drifts, which are based on glacial moraines, are described for each of the glacial lobes (fig. Q-9). A few moraines are continuous from one lobe into another, and a unit is described in the lobe where it is first mentioned. The extent of the named moraines of the Wisconsinan Stage is shown in figure Q-10. The Illinoian moraines and ridged drift areas are shown in figure Q-2. The fact that the drift is based on the moraine is not repeated in the description of each drift. The original namer of the moraine is cited as the namer of the drift. Alluvial terraces are classified as informal morphostratigraphic units. Those named were listed by Willman and Frye (1970).

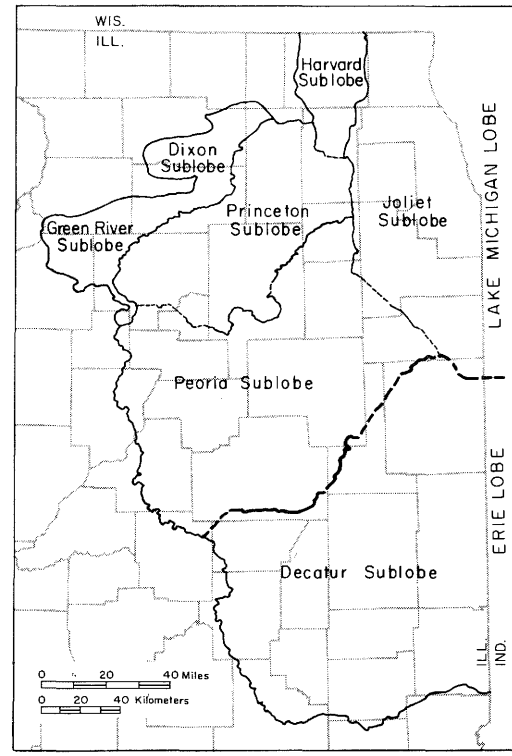

Fig. Q-9—Woodfordian lobes and sublobes in Illinois (Willman and Frye, 1970).

ERIE LOBE

Drift deposited by glaciers that invaded Illinois from the east is assigned to the Erie Lobe (fig. Q-9), although the lobe probably includes contributions by ice from the Lake Huron and Saginaw Lobes, which merged with the Erie Lobe. Erie Lobe glaciers ad-

Electronic Filing: Received, Clerk's Office 07/01/2024

vanced into Illinois during the Kansan, Illinoian, and Wisconsinan Stages, and their drifts are characterized in general by larger amounts of garnet than epidote, by dominance of illite, by the presence of both kaolinite and chlorite, and by more calcite than dolomite. In the Erie Lobe, morphostratigraphic units are differentiated only in the Wisconsinan Stage and are part of the Decatur Sublobe.

Decatur Sublobe Drifts

The Decatur Sublobe drifts are related to two morainic systems and 22 named moraines (figs. Q-9, Q-10). The drift is divided into the Oakland, Glenburn, Batestown, and Snider Till Members of the Wedron Formation.

Shelbyville Drifts (Leverett, 1897, p 17)—The Shelbyville Morainic System is named for Shelbyville, Shelby County. The drift is the outer and oldest Woodfordian drift in both the Decatur and Peoria Sublobes. The massive morainic system represents successive deposits of a fluctuating ice front that in the eastern part of the Decatur Sublobe produced three closely related moraines—Westfield, Nevins, and Paris. The morainic system extends west from the Indiana state line and then northwest about 200 miles to Peoria. In the Decatur Sublobe the drift consists of pinkish gray till of the Glenburn Till Member. In the Peoria Sublobe it is gray till that, with the Le Roy Drift, forms the Delavan Till Member of the Wedron Formation, and it is generally readily distinguishable from the overlying pink till of the Tiskilwa Till Member.

Westfield Drift (Willman and Frye, 1970, p. 92)—The Westfield Moraine, named for Westfield, Clark County, is the outermost moraine of the Shelbyville Morainic System and is traced for about 40 miles.

Nevins Drift (Willman and Frye, 1970, p. 92)—The Nevins Moraine, named for Nevins, Edgar County, the middle moraine of the Shelbyville Morainic System, is separated from the other moraines by narrow depressions and is traced for about 40 miles.

Paris Drift (Willman and Frye, 1970, p. 92)—The Paris Moraine, named for Paris, Edgar County, is the inner moraine of the Shelbyville Morainic System. It is traced from near the Indiana state line westward for about 50 miles.

Heyworth Drift (Willman and Frye, 1970, p. 92)—The Heyworth Moraine is named for Heyworth, McLean County. It is a weakly morainic area east and north from Clinton. In shape and orientation it differs from other Woodfordian moraines, and it may be an Illinoian moraine mantled with Woodfordian drift.

Turpin Drift (Willman and Frye, 1970, p. 92)—The Turpin Moraine is named for Turpin, Macon County. The moraine is a sharp ridge that extends only about 6 miles from Turpin northeast to the front of the Cerro Gordo Moraine. Because its orientation is parallel to Illinoian ridges and normal to the Woodfordian moraines, it, like the Heyworth, may be a mantled Illinoian ridge.

Cerro Gordo Drift (Leverett, 1899, p. 218)—The Cerro Gordo Moraine, named for Cerro Gordo, Piatt County, is a strongly lobate ridge extending for about 80 miles. It probably represents a major readvance of the ice front.

Arcola Drift (Leighton and Brophy, 1961, fig. 1)—The Arcola Moraine, named for Arcola, Douglas County, extends for about 50 miles and forms two well defined lobes. The western lobe once enclosed a large lake called Lake Douglas.

Pesotum Drift (Leighton and Brophy, 1961, fig. 1)—The Pesotum Moraine, named for Pesotum, Champaign County, is a relatively weak ridge, in part flat-topped, that is traced for about 25 miles.

West Ridge Drift (Leverett, 1899, p. 223)—The West Ridge Moraine, named for West Ridge, a small village 3 miles southwest of Villa Grove, Douglas County, extends for about 50 miles.

Hildreth Drift (Willman and Frye, 1970, p. 94)—The Hildreth Moraine, named for Hildreth, Edgar County, extends from the Indiana state line westward for about 25 miles.

Ridge Farm Drift (Willman and Frye, 1970, p. 94)—The Ridge Farm Moraine, named for the town of Ridge Farm, Vermilion County, extends westward from the Indiana state line for about 25 miles.

Champaign Drift (Leverett, 1897, p. 18)—The Champaign Moraine, named for Champaign, Champaign County, was originally called the Champaign Morainic System and included the Pesotum, Hildreth, Ridge Farm, and Urbana Moraines. As those drifts have overlapping relations, they are now considered separate moraines (Willman and Frye, 1970). The Champaign Moraine is restricted to the ridge extending from Champaign to the Bloomington Morainic System, about 30 miles.

Rantoul Drift (Willman and Frye, 1970, p. 94)—The Rantoul Moraine, named for Rantoul, Champaign County, is a broad morainic ridge extending 15 miles southwest from the Newtown Moraine to the Champaign Moraine. Because of its alignment on the trends of earlier Woodfordian moraines, it may be a buried moraine mantled with Champaign Drift.

Urbana Drift (Ekblaw, 1941)—The Urbana Moraine, named for Urbana, Champaign County, extends from Rantoul through Urbana to the Indiana state line, about 50 miles.

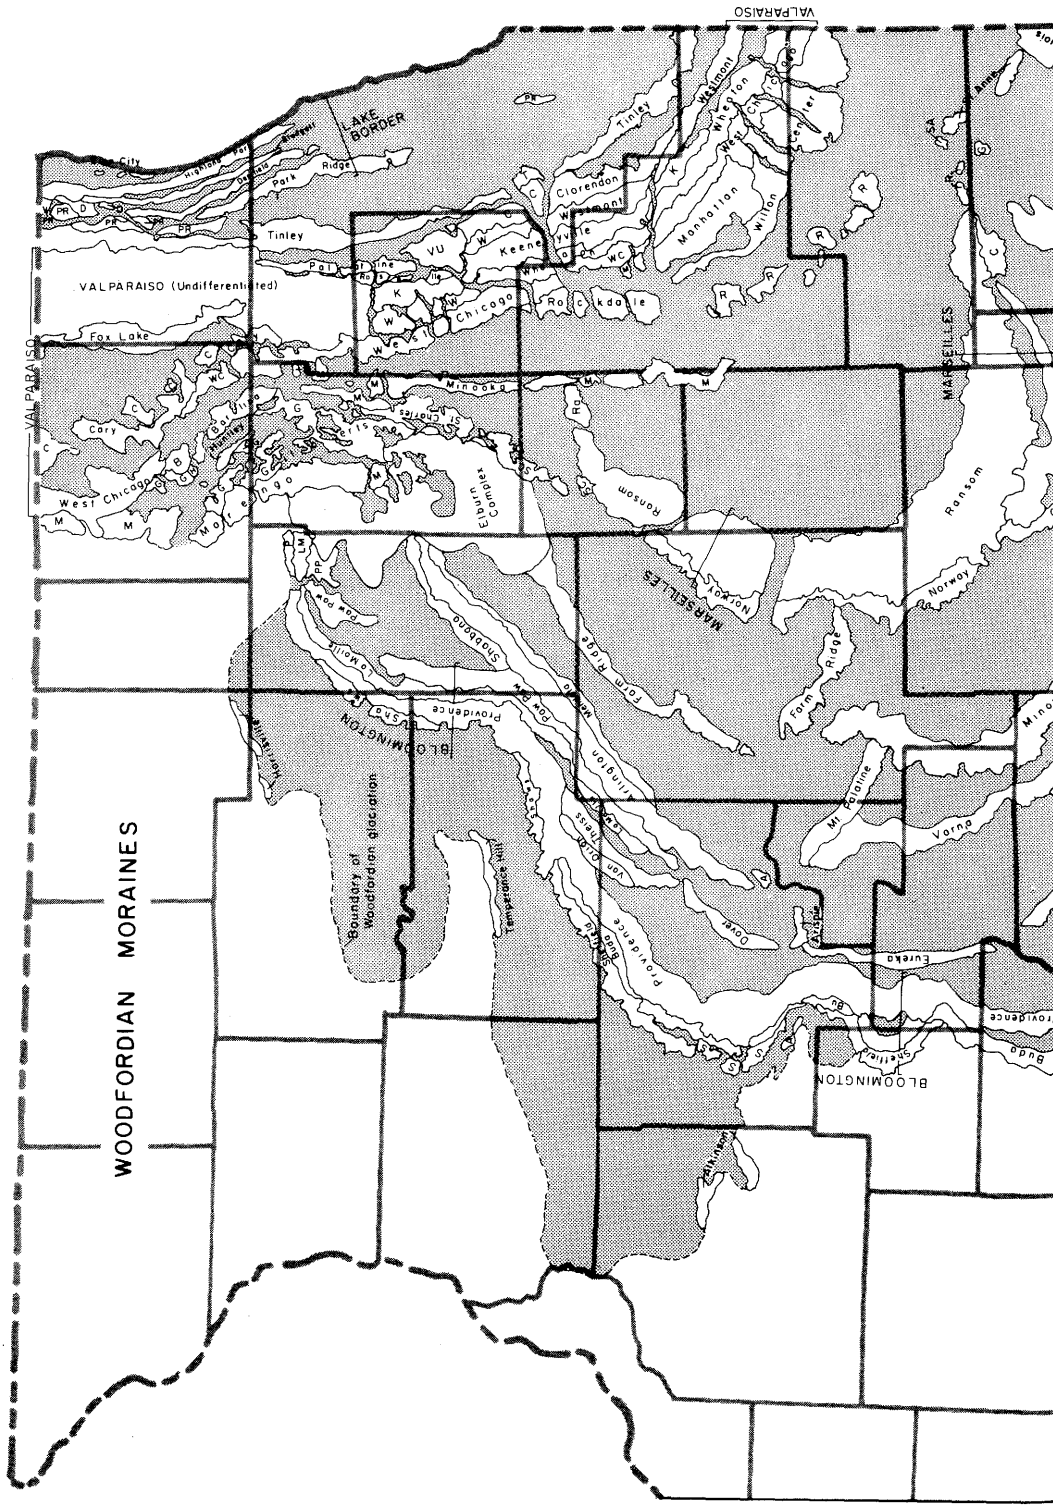
Illiana Drifts (Willman and Frye, 1970, p. 95)—The Illiana Morainic System, formerly considered part of the Bloomington Morainic System, is named for Illiana, Vermilion County, on the Illinois-Indiana state line. The system consists of two closely parallel moraines differentiated as the Newtown and Gifford Moraines, and it extends eastward from the Gibson City interlobate area about 50 miles to the state line.

Newtown Drift (Willman and Frye, 1970, p. 95)—The Newtown Moraine, named for Newtown, Vermilion County, is the frontal moraine of the Illiana Morainic System.

Gifford Drift (Leighton and Brophy, 1961, p. 95)—The Gifford Moraine, named for Gifford, Champaign County, is the inner and higher moraine of the Illiana Morainic System.

Paxton Drift (Willman and Frye, 1970, p. 95)—The Paxton Moraine, named for Paxton, Ford County, extends eastward across the Decatur Sublobe from the Gibson City reentrant to the Indiana state line, about 55 miles. It previously was considered the frontal moraine of the discontinued Chatsworth Morainic System.

Ellis Drift (Willman and Frye, 1970, p. 96)—The Ellis Moraine, named for Ellis, Vermilion County, was formerly classified as part of the Chatsworth Morainic System. It is a relatively weak moraine but is traced for about 45 miles.



Chatsworth Drift (Leverett, 1899, p. 259)—The Chatsworth Moraine, named for Chatsworth, Livingston County, is a prominent moraine 75 miles long with strong relief. It occurs in both the Decatur and Peoria Sublobes.

Gilman Drift (Willman and Frye, 1970, p. 96)—The Gilman Moraine, named for Gilman, Iroquois County, is a broad but weak lobate ridge about 40 miles long, partially covered by the deposits of glacial Lake Watseka.

St. Anne Drift (Willman and Frye, 1970, p. 96)—The St. Anne Moraine, named for St. Anne, Kankakee County, is a weak morainic ridge extending only about 15 miles from Mt. Langham, a large kame, to the Iroquois Moraine.

Iroquois Drift (Leverett, 1899, p. 258, 336)—The Iroquois Moraine, named for Iroquois County, is the youngest deposit of the Erie Lobe, though possibly a contribution of

Fig. Q-10—Woodfordian glacial moraines in Illinois (Willman and Frye, 1970).

 Electronic Filing: Received, Clerk's Office 07/01/2024

the Saginaw Lobe, in Illinois. It is the deposit of a glacier that invaded Illinois from the east for about 8 miles along a 15-mile front.

LAKE MICHIGAN LOBE

Drift deposited by glaciers that followed the Lake Michigan Basin and spread westward and southwestward across Illinois is referred to the Lake Michigan Lobe (fig. Q-9). Morphostratigraphic units are differentiated in the Lake Michigan Lobe drifts of Illinoian and Wisconsinan age. Moraines are widely spaced and discontinuous in the Illinoian drift (fig. Q-2), but are locally useful in morphostratigraphic classification. In the Wisconsinan Woodfordian drift, the moraines are more useful in classification because of their continuity (fig. Q-10) and because many represent readvances of the ice front that produced layered sequences in the drift. After the Woodfordian ice overflowed the Lake Michigan Basin, it was diverted by topographic irregularities and contact with the Erie Lobe glaciers into several sublobes that controlled the distribution of the moraines deposited during the fluctuating withdrawal of the ice front. The major groups of nearly parallel moraines are differentiated as the Peoria, Green River, Dixon, Princeton, Harvard, and Joliet Sublobes. The drift consists of tills and interlayered water-laid deposits that, in the rock-stratigraphic classification, are assigned to the Wedron Formation and divided into eight members on the basis of differences in till composition (fig. Q-5).

Illinoian Drifts

Mendon Drift (Leighton and Brophy, 1961, pl. 1, p. 15; Frye et al., 1964, p. 14)—The Mendon Moraine, named for Mendon, Adams County, marks the outer limit of the Illinoian drift of the Lake Michigan Lobe. It extends from the Mississippi River Valley near Warsaw to the Illinois River Valley at Pearl, about 90 miles. South of Pearl it is absent along the Illinois Valley for many miles, but it is probably represented by morainic topography in Jersey County north of the confluence of the Illinois and Mississippi Rivers. However, that area may also include an extension of the Table Grove Moraine. The Mendon Drift is largely the Kellerville Till Member of the Glasford Formation.

Table Grove Drift (Willman and Frye, 1970, p. 114)—The Table Grove Moraine, named for Table Grove, Fulton County, is a distinctly morainic ridge extending through the middle part of the area of Illinoian drift in western Illinois. Although continuous for about 75 miles, its continuation east of the Illinois Valley and north of southern Knox County is uncertain. It marks the front of the Hulick Till Member of the Glasford Formation

Oneida Drift (Willman and Frye, 1970, p. 115)—The Oneida Moraine, named for Oneida, Knox County, is a weak morainic ridge traced for about 15 miles in Knox and Henry Counties.

Williamsfield Drift (Willman and Frye, 1970, p. 115)—The Williamsfield Moraine, named for Williamsfield, Knox County, is a weak morainic ridge that extends southward from Williamsfield for about 7 miles.

Oak Hill Drift (Willman and Frye, 1970, p. 115)—The Oak Hill Moraine, named for Oak Hill, Peoria County, is a continuous ridge extending northwest from the front of the Wisconsinan drift for about 20 miles. It may mark the front of a significant readvance because it is the outer limit of the Radnor Till Member of the Glasford Formation.

Jacksonville Drift (Ekblaw, *in* Ball, 1938, p. 219)—The Jacksonville Moraine, named for Jacksonville, Morgan County, is a discontinuous belt of morainic hills and crevasse deposits, without a well defined front, in Morgan and Montgomery Counties.

Buffalo Hart Drift (Leverett, 1899, p. 74-76)—The Buffalo Hart Moraine, named for Buffalo Hart, Sangamon County, is a broad area of morainic topography, crevasse deposits, and kames. It has the mineral composition of the Radnor Till and probably correlates with the Oak Hill Moraine west of the Illinois Valley.

Wisconsinan (Woodfordian) Drifts

Peoria Sublobe Drifts

The Peoria Sublobe drifts include three morainic systems and 20 individual moraines (figs. Q-9, Q-10). The outermost moraine is part of the Shelbyville Morainic System, already described as being largely in the Erie Lobe, which extends northward in the Peoria Sublobe to Peoria.

Le Roy Drift (Ekblaw, 1941)—The Le Roy Moraine, named for Le Roy, McLean County, is a lobate ridge that is traced for about 70 miles and may represent a significant readvance of the ice that was probably equivalent to the strongly lobate readvance of the Decatur Sublobe glacier that deposited the Cerro Gordo Moraine.

Shirley Drift (Willman and Frye, 1970, p. 98)—The Shirley Moraine, named for Shirley, McLean County, is a minor moraine about 25 miles long.

Kings Mill Drift (Willman and Frye, 1970, p. 98)—The Kings Mill Moraine, named for Kings Mill Creek in McLean County, is a weak morainic ridge extending for only 10 miles near the front of the Bloomington Morainic System.

Bloomington Drifts (Leverett, 1897, p. 19)—The Bloomington Morainic System, named for Bloomington, McLean County, is one of the most prominent morainic features of the Lake Michigan Lobe drift and it forms the front of the Peoria, Princeton, and Harvard Sublobes. The major part of the drift is the pink till of the Tiskilwa Member of the Wedron Formation, which distinguishes it from the older gray tills and the younger yellow-tan tills of Woodfordian age. North of Peoria the system consists of three well defined moraines, but in other places only one or two crests are recognizable. Five ridges are named in the Peoria Sublobe—the Washington, Metamora, Sheffield, Buda, and Providence Moraines.

Washington Drift (Willman and Frye, 1970, p. 99)—The Washington Moraine, named for Washington, Tazewell County, is a minor morainic area back of the main ridge of the Bloomington Morainic System and can be traced for about 10 miles in the southern part of the Peoria Sublobe.

Metamora Drift (Ekblaw, 1941)—The Metamora Moraine, named for Metamora, Woodford County, is a well defined ridge about 10 miles long that probably marks the eastern margin of a narrow lobe that extended into the Illinois River Valley during the final stages of the building of the Bloomington Morainic System.

Electronic Filing: Received, Clerk's Office 07/01/2024

Sheffield Drift (MacClintock and Willman, 1959, p. 23)—The Sheffield Moraine, named for Sheffield, Bureau County, is the outermost moraine of the Bloomington Morainic System in the Peoria Sublobe and in the southern part of the Princeton Sublobe. It is about 60 miles long.

Buda Drift (MacClintock and Willman, 1959, p. 23)—The Buda Moraine, named for Buda, Bureau County, is a prominent morainic ridge about 65 miles long that extends from Peoria northward into the Princeton Sublobe. It generally is the middle ridge of the Bloomington Morainic System.

Providence Drift (MacClintock and Willman, 1959, p. 24)—The Providence Moraine, named for Providence, Bureau County, forms the crest of the Bloomington Morainic System and rises as much as 200 feet above the frontal outwash plain. In many areas it has a very rough knob and kettle topography. It is traced from Peoria northeastward for about 125 miles in the Peoria and Princeton Sublobes. It is probably equivalent to the Metamora Moraine east of the Illinois Valley.

Normal Drift (Leighton and Ekblaw, 1932, p. 13)—The Normal Moraine, named for Normal, McLean County, is the first moraine back of the Bloomington Morainic System. It is traced for about 35 miles in the southern part of the Peoria Sublobe, in which area it is the front of the gray to tan silty till differentiated as the Malden Till Member of the Wedron Formation.

Eureka Drift (Willman and Frye, 1970, p. 100)—The Eureka Moraine, named for Eureka, Woodford County, extends for about 100 miles, entirely across the Peoria Sublobe. It formerly was correlated with the Normal Moraine, but it overlaps the Normal and forms the front of the Malden Till Member.

Fletchers Drift (Willman and Frye, 1970, p. 100)—The Fletchers Moraine, named for Fletchers, a railroad siding 3 miles southwest of Cooksville, McLean County, also was formerly included in the Normal Moraine. It has a well defined front and is traced westward from the Gibson City reentrant for about 20 miles.

El Paso Drift (Leighton and Brophy, 1961, fig. 1)—The El Paso Moraine, named for El Paso, Woodford County, previously considered the frontal ridge of the discontinued Cropsey Morainic System, is traced westward from the Gibson City reentrant for about 45 miles.

Varna Drift (Willman and Frye, 1970, p. 100)—The Varna Moraine, named for Varna, Marshall County, was previously part of the discontinued Cropsey Morainic System. The Varna is traced for 40 miles but is eroded at the Illinois River Valley.

Minonk Drift (Willman and Frye, 1970, p. 101)—The Minonk Moraine, named for Minonk, Woodford County, was previously part of the discontinued Cropsey Morainic System. It extends for 65 miles, entirely across the Peoria Sublobe.

Strawn Drift (Willman and Frye, 1970, p. 101)—The Strawn Moraine, named for Strawn, Livingston County, is a weak morainic ridge between the Minonk and Chatsworth Moraines and was previously included in the discontinued Cropsey Morainic System. It is traced for only about 15 miles.

Marseilles Drifts (Leverett, 1897, p. 20)—The Marseilles Morainic System, named for Marseilles, La Salle County, is a massive ridge that generally exhibits a distinct lower frontal ridge. The frontal ridge is not continuous; the north part is named Norway and the south part Cullom. The higher, continuous crest is differentiated as the Ransom Moraine. The Ransom is largely greenish gray clayey till, which is part of the Yorkville Till Member of the Wedron Formation. It forms the innermost drift of the Peoria Sublobe and extends entirely across the sublobe.

Norway Drift (Willman and Frye, 1970, p. 102)—The Norway Moraine, named for Norway, La Salle County, extends for about 40 miles along the front of the northern part of the Marseilles Morainic System.

Cullom Drift (Leighton and Brophy, 1961, fig. 1)—The Cullom Moraine, named for Cullom, Livingston County, occupies a position similar to that of the Norway Moraine for about 35 miles along the southern part of the Marseilles Morainic System.

Ransom Drift (Willman and Frye, 1970, p. 102)—The Ransom Moraine, named for Ransom, La Salle County, forms the main crest of the Marseilles Morainic System and is traced for about 100 miles.

Green River and Dixon Sublobes Drifts

Because of their position outside the Bloomington Morainic System, the drifts of the Green River and Dixon Sublobes (figs. Q-9, Q-10) are probably equivalent to the Shelbyville Drift in the Decatur and Peoria Sublobes. The Woodfordian drift is thin, and only three areas of morainic topography along the margins of the sublobes are named.

Temperance Hill Drift (Willman and Frye, 1970, p. 103)—The Temperance Hill Moraine, named for Temperance Hill School, 3 miles northwest of Lee Center, Lee County, is a ridge traced for about 12 miles along the northern side of the Green River Sublobe.

Atkinson Drift (Willman and Frye, 1970, p. 103)—The Atkinson Moraine, named for Atkinson, Henry County, consists of patches of morainic hills along the southern side of the Green River Sublobe.

Harrisville Drift (Willman and Frye, 1970, p. 102)—The Harrisville Moraine, named for Harrisville, Winnebago County, extends for about 10 miles along the north side of the Dixon Sublobe.

Princeton Sublobe Drifts

The Princeton Sublobe (figs. Q-9, Q-10) includes one morainic system, 16 named moraines, and one complex—an area with variously oriented morainic ridges. The pink sandy till of the Tiskilwa Till Member of the Wedron Formation characterizes the outer part of the drift, followed successively eastward by the gray-tan silty till of the Malden Till Member and the gray clayey till of the Yorkville Till Member.

Bloomington Drifts—The southern moraines of the Bloomington Morainic System, the Sheffield, Buda, and Providence Moraines that were previously described for the Peoria Sublobe, extend northward into the Princeton Sublobe, but five other moraines are differentiated locally in the system in the Princeton Sublobe—the Shaws, Van Orin, Theiss, La Moille, and Paw Paw Moraines—all of which consist largely of the pink till of the Tiskilwa Till Member.

Shaws Drift (Willman and Frye, 1970, p. 105)—The Shaws Moraine, named for Shaws, Lee County, is the outermost ridge of the Bloomington Morainic System, occupying a position in the northern part of the sublobe similar to that of the Sheffield Moraine farther south. It has been traced for about 25 miles.

Van Orin Drift (Willman and Frye, 1970, p. 105)—The Van Orin Moraine, named for Van Orin, Bureau County, is a well defined ridge but is traced for only about 10 miles before it blends into the back slope of the Providence Moraine.

Theiss Drift (Willman and Frye, 1970, p. 105)—The Theiss Moraine, named for Theiss Cemetery, 3 miles southwest of Sublette, Lee County, is a distinct ridge for about 16 miles, but it, too, blends into the back slope of the Providence Moraine.

 Electronic Filing: Received, Clerk's Office 07/01/2024

La Moille Drift (Willman and Frye, 1970, p. 105)—The La Moille Moraine, named for La Moille, Bureau County, is a narrow ridge that is traced for about 50 miles. In its southern part it separates from the Bloomington Morainic System.

Paw Paw Drift (Willman and Frye, 1970, p. 106)—The Paw Paw Moraine, named for Paw Paw, Lee County, is the inner moraine of the northern part of the Bloomington Morainic System and is traced for about 50 miles. It is a prominent moraine that, southward, separates from the Bloomington Morainic System, and in part of that area it has a thin overlapping cover of yellow-tan till of the Malden Till Member.

Shabbona Drift (Willman and Frye, 1970, p. 106)—The Shabbona Moraine, named for Shabbona, De Kalb County, is a weakly morainic area about 18 miles long that consists largely of a thin deposit of the Malden Till Member. It marks a major readvance of the ice front.

Dover Drift (Cady, 1919b, p. 24, 81)—The Dover Moraine, named for Dover, Bureau County, is traced for about 12 miles. It marks the front of the Malden Till Member and is probably equivalent to the Shabbona Moraine, but cannot be traced directly to it.

Arispie Drift (Willman and Frye, 1970, p. 106)—The Arispie Moraine, named for Arispie Township, Bureau County, is an east-west ridge only 4 miles long, eroded at the Illinois River Valley, but it probably is a connecting link between the Varna Moraine in the Peoria Sublobe and the Dover Moraine in the Princeton Sublobe.

Arlington Drift (Cady, 1919b, p. 24, 81)—The Arlington Moraine, named for Arlington, Bureau County, is a prominent moraine that is traced northeastward from the Illinois River Valley for 55 miles.

Mt. Palatine Drift (Leighton and Brophy, 1961, fig. 1)—The Mt. Palatine Moraine, named for Mt. Palatine, Putnam County, is a prominent ridge on the south side of the Princeton Sublobe, where it is traced for about 15 miles. It probably correlates with the Arlington Moraine on the north side of the lobe.

Mendota Drift (Willman and Frye, 1970, p. 107)—The Mendota Moraine, named for Mendota, La Salle County, is a weakly morainic ridge that can be traced on the back slope of the Arlington Moraine for about 40 miles.

Farm Ridge Drift (Leverett, 1899, p. 260)—The Farm Ridge Moraine is named for Farm Ridge, which is now called Grand Ridge, La Salle County. It has a lobate configuration and extends for 35 miles north of the Illinois River Valley and for 15 miles south of the valley.

Elburn Drift (Willman and Frye, 1970, p. 107)—The Elburn Complex, named for Elburn, Kane County, is an area of variously oriented morainic ridges, kames, eskers, and lake basins at the junction of the Princeton and Harvard Sublobes.

St. Charles Drift (Willman and Frye, 1970, p. 108)—The St. Charles Moraine, named for St. Charles, Kane County, is a weakly morainic area traced for 25 miles from the front of the Marseilles Morainic System to the northern part of the Minooka Moraine. It marks the front of the very clayey till characteristic of the Yorkville Till Member.

Harvard Sublobe Drifts

The Harvard Sublobe (figs. Q-9, Q-10) includes six moraines that have a slightly westward bulge north of the Princeton Sublobe. They consist of the Tiskilwa, Malden, Yorkville, and Haeger Till Members of the Wedron Formation.

Marengo Drift (Leverett, 1899, p. 290)—The Marengo Moraine, named for Marengo, McHenry County, is a massive moraine that is largely pink till. It extends southward from the Wisconsin state line for about 40 miles, terminating at the Elburn Complex.

Gilberts Drift (Leighton and Ekblaw, 1932, p. 48)—The Gilberts Moraine, named for Gilberts, Kane County, is a low area about 30 miles long behind the Marengo Moraine and is largely pinkish gray till, gravel, and lacustrine sediments. It is assigned to the Malden Till Member, but it is pinker than the Malden in the Princeton Sublobe.

Huntley Drift (Leighton and Willman, 1953, p. 53)—The Huntley Moraine, named for Huntley, McHenry County, is a low, discontinuous ridge about 8 miles long that is largely till of the Yorkville Till Member.

Barlina Drift (Willman and Frye, 1970, p. 109)—The Barlina Moraine, named for Barlina Road, northwest of Lake-in-the-Hills, McHenry County, is a rough-surfaced ridge about 16 miles long, which, like the Huntley, consists largely of till of the Yorkville Till Member.

Valparaiso Drifts (Leverett, 1897, p. 26)—The Valparaiso Morainic System is largely in the Joliet Sublobe, but the West Chicago and Cary Moraines curve northwestward into the Harvard Sublobe, and the drifts are part of the Haeger Till Member.

Joliet Sublobe Drifts

The Joliet Sublobe (figs. Q-9, Q-10) consists of the moraines that trend essentially parallel to the Lake Michigan shore. The lobe contains two morainic systems and 19 named moraines. The moraines in the northwest part of the lobe consist of the gravelly till of the Haeger Till Member, but the others are gray clayey till of the Yorkville and Wadsworth Till Members.

Minooka Drift (Leverett, 1897, p. 20)—The Minooka Moraine, named for Minooka, Grundy County, forms the outer ridge of the Joliet Sublobe for about 50 miles. It ends at the head of Illinois River, where its southward extension was widely eroded by the Kankakee Flood. It is mainly the gray clayey till of the Yorkville Till Member.

Rockdale Drift (Fisher, 1925, p. 87)—The Rockdale Moraine, named for Rockdale, Will County, has a well defined front for 15 miles north of the Des Plaines River Valley and is represented by isolated, weakly morainic areas for 25 miles south of the valley.

Wilton Center Drift (Willman and Frye, 1970, p. 110)—The Wilton Center Moraine, named for Wilton Center, Will County, is traced for about 35 miles, from the vicinity of the Des Plaines Valley to the Indiana state line.

Manhattan Drift (Fisher and Ekblaw, *in* Fisher, 1925, p. 89)—The Manhattan Moraine, named for Manhattan, Will County, extends southward from Joliet for about 20 miles.

Valparaiso Drifts—The part of the Valparaiso Morainic System that is in the Joliet Sublobe is a complex of morainic ridges representing temporary stands of the ice front during the building of the system. Many ridges are indistinctly traced through parts of the complex but are undifferentiated in other parts. The Valparaiso Drift includes a buried drift of questionable age, informally called the Lemont drift (Bretz, 1955), which consists of yellow-gray silty till, sand and gravel, and dune sand, highly contorted in places. The Lemont drift occurs locally in the Worth, Sag Bridge, and Lemont areas in Cook County. It may be Woodfordian in age, but a leached zone on the gravel has been interpreted as possibly being the Sangamon Soil (Horberg and Potter, 1955) or the Farmdale Soil (Frye and Willman, 1970). It was tentatively assigned to the Winnebago Formation (Willman, 1971).

West Chicago Drift (Leighton, 1925, p. 69)—The West Chicago Moraine, named for West Chicago, Du Page County, forms the frontal ridge of the Valparaiso Morainic System from the Wisconsin border to the Indiana state line, about 100 miles. It is a rough-surfaced, gravelly moraine in the north but is more clayey south of West Chicago.

Electronic Filing: Received, Clerk's Office 07/01/2024

Cary Drift (Leighton, 1925, p. 69)—The Cary Moraine, named for Cary, McHenry County, occurs in both the Harvard Sublobe and the northern part of the Joliet Sublobe. It is about 30 miles long and consists of gravelly till assigned to the Haeger Till Member.

Fox Lake Drift (Powers and Ekblaw, 1940, p. 1331)—The Fox Lake Moraine, named for the town of Fox Lake, Lake County, is a kame-moraine traced for about 25 miles south from the Wisconsin state line. Most of it is gravel, and it is assigned to the Haeger Till Member, although the till in places is clayey and more like that in the Wadsworth Till Member.

Wheaton Drift (Ekblaw, *in* Suter et al., 1959, fig. 5)—The Wheaton Moraine, named for Wheaton, Du Page County, is traced for about 60 miles. It may be equivalent to the Cary Moraine, but cannot be traced in the intervening area.

Keeneyville Drift (Ekblaw, *in* Suter et al., 1959, fig. 5)—The Keeneyville Moraine, named for Keeneyville, Du Page County, is traced for about 40 miles. Its position in the Valparaiso Morainic System is similar to that of the Fox Lake Moraine farther north.

Roselle Drift (Ekblaw, *in* Suter et al., 1959, fig. 5)—The Roselle Moraine, named for Roselle, Du Page County, is a narrow ridge traced for about 10 miles.

Palatine Drift (Powers and Ekblaw, 1940, p. 1331)—The Palatine Moraine, named for Palatine, Cook County, is a relatively weak moraine traced for about 18 miles.

Westmont Drift (Willman and Frye, 1970, p. 112)—The Westmont Moraine, named for Westmont, Du Page County, is a poorly defined moraine traced for about 40 miles.

Clarendon Drift (Leighton, *in* Leighton and Willman, 1953, pl. 3)—The Clarendon Moraine, named for Clarendon Hills, Du Page County, is a poorly defined moraine traced for about 25 miles. It is the innermost moraine of the Valparaiso Morainic System.

Tinley Drift (Leighton and Ekblaw, 1932, p. 15; Bretz, 1939, p. 50)—The Tinley Moraine, named for Tinley Park, Cook County, the first moraine back of the Valparaiso Morainic System, extends from Wisconsin to Indiana, about 80 miles. It has a well defined front, except in the 25 miles south of the Wisconsin state line where it overlaps the Valparaiso Morainic System.

Lake Border Drifts (Leverett, 1897, p. 42)—The Lake Border Morainic System, named for its position near the shore of Lake Michigan, consists of five closely spaced moraines that are parallel except near the Wisconsin state line where they somewhat overlap. The moraines all consist of the gray clayey till of the Wadsworth Till Member.

Park Ridge Drift (Bretz, 1939, p. 55)—The Park Ridge Moraine, named for the city of Park Ridge, Cook County, is the outermost ridge of the Lake Border Morainic System and is traced from the Wisconsin state line southward for about 40 miles, where it ends at the Lake Chicago Plain. It recurs 12 miles farther south in an isolated segment at Blue Island.

Deerfield Drift (Bretz, 1939, p. 55)—The Deerfield Moraine, named for Deerfield, Lake County, is traced about 30 miles.

Blodgett Drift (Bretz, 1939, p. 56)—The Blodgett Moraine, named for Blodgett, Lake County, is traced for about 20 miles.

Highland Park Drift (Bretz, 1939, p. 56)—The Highland Park Moraine, named for Highland Park, Lake County, is traced for about 30 miles. The moraine terminates at the Lake Chicago Plain and the Lake Michigan beach.

Zion City Drift (Ekblaw, *in* Suter et al., 1959, fig. 5)—The Zion City Moraine, named for Zion (formerly called Zion City), Lake County, consists of patches of weak morainic topography near the Wisconsin state line. It is eroded at the Lake Michigan beach and is the youngest moraine in Illinois.

INDEX TO STRATIGRAPHIC UNITS

A

Abbott Formation 21, 165, 180, **181**, 184
Aberdeen Sandstone Member 183
Abernathy Member 61, **65**
Abingdon Coal Member 166, **186**
Abingdon Cyclothem 174
Absaroka Sequence 26, 94, 125, 165, 168, 170, **178**
Afton Soil 210, **218**
Aftonian Stage **218**
Agassizocrinus cf. *leavis* Zone 155
Albion Series 93
Alexandrian Series 10, 91, 92, **94**, 112
Allard Limestone Member 146, 150, **160**
Allenby Coal Member 166, **192**
Alto Formation 114, 118, **119**, 121
Altonian Substage 212, 217, **224**
Ancell Group 49, **61**
Anna Shale Member 166, **191**
Antrim Shale 120
Anvil Rock Sandstone Member 166, **192**
Apatognathus scalines-Cavusgnathus Zone 141
Aphelaspis Zone 38
Arbuckle Limestone 41, 51
Archimedes Limestone 139, 145, 149
Arcola Drift **233**
Arenaceous Foraminifera Zone 91, 101
Argentine Limestone Member 198
Argyle Till Member 216, 224, **225**
Arispie Drift **238**
Arlington Drift **238**
Arsenal Member **55**, 56
Assumption Coal Member 166, **184**
Atchison Formation 218
"Athens Marble" 102
Athensville Coal Member 167, **195**
Atkinson Drift **237**
Atokan Series 10, 165, **181**
Augusta Member 61, **65**
Aux Vases Sandstone 133, 142, **143**, 146 150, 151

B

Babylon Coal 182
Babylon Cyclothem 174
Babylon Sandstone Member 165, **182**
Backbone Limestone **109**, 112
Bactrognathus-Polygnathus communis Zone 137, 138
Bactrognathus-Taphrognathus Zone 138
Bailey Limestone 101, 104, **107**, 108, 112
Bainbridge Group 93, 100, 103
Baker coal 192
Bald Hill Coal 185
Baldwin coal 177
Baldwin Formation 149
Bankston Coal 192
Bankston Cyclothem 174
Bankston Fork Limestone Member ... 166, 168, **192**
Banner Formation 210, 216, **219**
Barlina Drift **238**
Barlow lime 156
Batavia Member **226**
Batestown Till Member 216, **229**, 233
Batostomella nitidula Zone 161
Battery Rock Coal 181
Battery Rock Cyclothem 174
Battery Rock Sandstone Member 165, 168, **179**
Bayfield Sandstone 40
Baylis Formation 204, **205**
Beaver Bend Limestone Member 146, **154**
Bee Springs Sandstone Member 181
Beech Creek Limestone 146, 150, 151, **155** 170
Beecher Member 74, **79**
Beekmantown Limestone 51
Belgium Member **219**
Bellwood Formation 92
"Benoist" sand 152
Benson Member 78
Bernadotte Sandstone Member 165, **183**
Berry Clay Member 220, **222**, 223
Bethel Sandstone 146, 150, 151, **153**
Bidwell Coal Member 166, **185**
Big Clifty Sandstone Member 131, 146, **157**
Big Creek Shale Member 166, **191**
Bigby-Cannon Limestone 78, 80
Bilyeu Member 133, **135**, 139
Birds Member 91, **96**
Birdsville Limestone 148, 149
Black River Limestone 67
Black Rock Formation 57
Blackjack Creek Limestone 189
Blackriveran Stage 49, **60**
Blanding Formation 91, 97, **98**
Blocher Shale 113, 114, 118, 119, **120**, 122
Blodgett Drift **239**
Blodgett Member **55**, 56
Blomeyer Member 68, **69**
Bloomington Drifts 228, **236**, **237**
"Blue" 79
Blue Island beds 102
Blue Limestone 58
Bogota Cyclothem 174
Bogota Limestone Member 167, **200**
Boles Member 61, **65**
Bond Formation 21, 167, **196**
Bonneterre Formation 39, 42, 43
Bonpas Limestone Member 167, **200**
Borden Siltstone 125, 133, **134**, 137
Boskydell Marine Zone 182
Boskydell Sandstone 182
Bowling Green Member 93
Bowmanville Intraglacial 217
Brainard Shale 81, **86**
Brandon Bridge Member 91, **101**
Brannon Member 78
Brassfield Formation 92, 93, 97, 99
Brazil Formation 182, 184
Breezy Hill Limestone Member 166, **188**
Brereton Cyclothem 174
Brereton Limestone Member 166, 168, **191**
Brereton (No. 6) Coal 191
Brewerville Sandstone 149
Briar Hill Cyclothem 174
Briar Hill (No. 5A) Coal Member 166, **189**
Brickeys Member 68, **69**
Briton Member 68, **70**
Broken Arrow coal 187
Browning Sandstone Member 166, **186**
Brush Coal Member 166, **185**
Brush Cyclothem 174
Buckhorn Member 74, **78**
Buda Drift **237**
Buelter Member 37, **44**
Buff Member 58
Buffalo Hart Drift **236**
Bunje Cyclothem 174

Electronic Filing: Received, Clerk's Office 07/01/2024

Bunje Limestone Member 167, **198**
Burlington Limestone 125, 132, 135, **137**
Burroughs Limestone Member 167, **196**
Byron Formation 97

C

Cahokia Alluvium 22, **230**
Calabrian Series 211
Calciferous Group 14
Calhoun Coal Member 167, **200**
Calico Shale 135
Calloway Limestone 117
"Camarophoria"-Stenoscisma explanata Zone 157
Cambrian System 10, 21, 25, 26, 32, **34**
Camp Nelson Formation 69, 70
Camp Run Member 120
Canadian Series 10, 49, **51**
Canton Shale Member 166, **189**
Cape Girardeau Limestone 87
Cape Limestone 80, 81, **84**
Capron Till Member 216, 224, **226**
Carbondale Formation 21, 166, 168, 171 180, 184, **187**
Carboniferous System 13, 14, 33, 123, 163
Cardiff Coal Member 166, **187**
Carimona Limestone 75
Carlinville Cyclothem 174
Carlinville Limestone Member 167, **196**
Carmi Member **226**
Carper Sand 134, 135
Carters Limestone 71, 72
Carthage Limestone Member 197
Cary Drift **239**
Cary Substage 217, 227
Caseyville Conglomerate 181
Caseyville Formation 21, 165, 168, 171, 177 **178**
Castlewood Member 74, **75**
Catheys Formation 81
Cave Hill Shale Member 124, 146, 150, **162**
Cavusgnathus naviculus Zone 146
Cayugan Series 10, 89, 92, 100, **103**
Cedar Bluff Limestone Group **144**, 145, 146
Cedar Valley Limestone 104, 108, 113, 114 **115**, 118, 122
Cedaria Zone 38
Cenozoic Erathem 10, 19, 23, **206**
Cerro Gordo Drift **233**
Chalfin Member 133, **141**
Champ Clark Group 109, 120
Champaign Drift **233**
Champlainian Series 10, 49, **58**
Chana Member **68**
Channahon Limestone 92
Chapel (No. 8) Coal Member 167, **196**
Chapin Soil 224, **225**
Charter Member 37, **41**
Chatsworth Drift **233**
Chattanooga Shale 120, 130
Chaumont Formation 67, 71, 72
Chautauquan Series 110, 120
Chazyan Stage 58, **60**
Cheltenham Clay Member 166, **185**
Chemung Group 13, 127
Chepultepec Formation 55
Chester Group 136, 148
Chesterian Series 10, 125, **145**
Chouteau Limestone 120, 129, **131**, 135
Cincinnatian Series 10, 14, 49, **81**
Clarendon Drift **239**
"Clay bed" 58
Clayton Formation **208**
Clear Creek Chert **112**
Clegg Creek Member 120
Clement Member 68, **71**
Clermont Shale Member 81, **85**
Clinton Formation 100
Clore Formation 146, 150, **161**
Coal Measures 13, 14, 163, 171
Coburg Formation 78, 80, 81
Cochrane till 230
Coe Group 100
Coffeen Limestone Member 167, **198**
Coggan Member 114, **115**
Cohn Coal Member 167, **199**
Cohn Cyclothem 174
Colbert Cyclothem 174
Colchester (No. 2) Coal Member 166, 168, **187**
Collingwood Formation 85
Comanchean Series 23, 201
Conant Limestone Member 166, 168, **192**
Cooper Creek Limestone 195
Cooper Limestone Member 114, **117**
Copperas Creek Sandstone Member 166, **192**
Cora Limestone Member 146, 150, **161**
Coralville Member 114, **116**
Cordova Formation 93
Cornulites Zone 83, 86
Cotter Dolomite 56, 57
Covel Conglomerate Member 166, 177, **189**
Crab Orchard Cyclothem 174
Cramer Limestone Member 167, **196**
Crane Member 37, **40**
Creal Springs Limestone Member 166, **185**
Crepicephalus Zone 38
Cretaceous System 10, 21, 22, 25, 27, 105 112, 113, **202**
Croixan Series 10, **37**
Cropsey drift 228, 237
Croweburg coal 187
Ctenodonta bed 77
Cuba Sandstone 191
Cullom Drift **237**
Curdsville Limestone 75
Curlew Limestone Member 166, **184**
Cutler Cyclothem 174
Cutler Limestone 193
Cynthiana Limestone 81
Cypress Sandstone 145, 146, 150, 151, 154 **155**, 170
Cyrene Member 93
Cystodictya labiosa Zone 152

D

Dakota Formation 206
Dalmanella Zone 77, 78
Dane Member **68**
Danville (No. 7) Coal Member 166, **192**
Darty Limestone 130
Davenport Member 114, **115**
Davis Coal Member 166, **186**
Davis Formation 44
Davis Member 37, 38, **45**
Daysville Dolomite Member 61, 62, **64**
De Graff Coal Member 167, **194**
De Koven Coal Member 166, **186**
De Koven Cyclothem 174
De Long Coal Member 166, **185**
De Long Cyclothem 174
Decorah Subgroup 58, 74, **75**, 78, 79
Deerfield Drift **239**
Defiance Member 61, **67**
Degonia Sandstone 146, 150, **162**, 170
Delavan Till Member 210, 216, 224, **228**
Delwood Coal Member 165, **182**
Delwood Cyclothem 174
Delwood Sandstone 182
Dement Member 68, **70**
Depauperate Zone 81, 84, 85
Derby-Doerun Member 37, 38, **45**
Desmoinesian Series 10, 166, 167, **183**
Devonian System 10, 21, 25, 26, 34, **104**
Dikelocephalus postrectus Zone 43
Ditney Coal Member 196
Divine Limestone 86
Dix Limestone Member 167, **199**
Dolton Member **227**
Dover Drift **238**
Downeys Bluff Limestone 146, 150, 151, **153**
"Drab" 78

Electronic Filing: Received, Clerk's Office 07/01/2024

Dresbach Sandstone 38, 39, 42, 43
Dresbachian Stage 37, **38**
Drummond Member 91, **97**
Drury Shale Member 165, **181**
Dubuque Formation 74, 76, 77, **80**
Duncan Mills Member 220, **221**
Dunleith Formation 50, 74, 76, 77, **78**
Dutch Creek Sandstone Member 114, **117**
Dutchtown Limestone 49, 61, 62, 63, **64**
Dykersburg Shale Member 166, **189**

E

Eagle Point Member 74, **79**
Early Wisconsin 217
Easley Group 130
East Iowan Formation 217
East Wisconsin Formation 217
Eau Claire Formation 35, 37, 38, **41**
Edenian Stage 81, **84**
Edgewood Formation 92, 94, 97, 98, **99**, 101
Effingham Limestone Member 167, **200**
Eifelian Stage 113
El Paso Drift **237**
Elburn Drift **238**
Eldena Member 68, **71**
Eldoran Series 217
Elgin Shale Member 81, **85**
Elkhorn Formation 86
Ellenberger Formation 41
Ellis Drift **233**
Ellsworth Shale 120
Elm Member 68, **71**
Elmhurst Sandstone Member 37, **42**
Elvinia Zone 38, 43, 44
Elvins Group 45
Elviran Stage 146, **158**
Elwood Formation 91, 94, **97**, 99
Embayment Megagroup 201, **202**, 204, 208
Eminence Formation 37, 38, **46**, 59
Emsian Stage 107
Encrinital Limestone 131, 137
Engadine Formation 103
English River Siltstone 130
Enion Formation 210, **218**
Eocene Series 10, 207, **208**
Equality Formation 22, 224, **226**, 230
Erian Series 109, 110, 113
Esmond Till Member 216, 224, **228**
Essex Limestone 92
Establishment Member 68, **70**
Eureka Drift **237**
Everett Member 68, **72**
Everton Dolomite 56, **60**, 62
Excello Shale Member 166, **189**
Exline Limestone Member 167, **195**

F

Fairbanks Coal Member 198
Fairplay Member 74, **79**
Famenian Series 121
Farm Creek Intraglacial 217
Farm Ridge Drift **238**
Farmdale drift 225
Farmdale Loess 217, 225
Farmdale Soil 224, **227**
Farmdale Substage 217
Farmdalian Substage 217, 224, **227**
Farmington Shale Member 167, **193**
Ferdinand Member 182
Fern Glen Formation 132, 135, **137**
Fernvale Limestone 83, 84
Ferruginous Sandstone 149
Finnie Sandstone Member 165, **182**
First Cutler Rider coal 194
"First Vein" (No. 7) Coal 192
Fithian Cyclothem 174
Flannigan Coal Member 167, **198**
Flannigan Cyclothem 174
Flat Creek Coal Member 167, **198**
Flat Creek Cyclothem 174
Fletchers Drift **237**
Floral Zone 6 177
Floral Zone 7 181
Floral Zone 8 181
Floral Zone 9 183
Floral Zone 10 183
Floral Zone 11 195
Floral Zone 12 195
Foerstephyllum halli Zone 71
Fond du Lac Sandstone 39, 40
Ford Station Limestone Member 146, 150, **161**
Forreston Member 68, **71**
Fort Atkinson Limestone 81, **86**
Fort Payne Formation 134, 135, **139**
Fox Lake Drift **239**
Fox Valley Member 37, **44**
Fraileys Shale 146, 150, 151, **156**
Francis Creek Shale Member 166, **187**
Franconia Formation 37, 38, **44**, 59
Franconian Stage 37, **43**
Frasnian Series 121
Fredonia Limestone 133, 134, **142**, 146, 151
Friendsville Coal Member 167, **199**
Fulda Member 182
Fults Member 133, **141**
Fusulina Zone 181, 183
Fusulinella Zone 181

G

Galena Group 49, 52, 58, 66, 73, **74**, 112, 170
Galesville Sandstone 37, 38, **42**
Galum Limestone Member 166, **192**
Gardena Intraglacial 217
Garnavillo Member 74, **77**
Gasconade Formation 55
Gasperian Stage **145**, 146
Geneva Dolomite Member 114, **117**
Genevievian Stage **141**, 146
Gentry Coal Member 165, 177, **181**
Gifford Drift **233**
Gila Cyclothem 174
Gila Limestone Member 167, **200**
Gilberts Drift **238**
Gilman Drift **233**
Gimlet Cyclothem 174
Gimlet Sandstone Member 167, **195**
Girardeau Limestone 81, 83, **87**, 93, 99
Givetian Stage 113
Glasford Formation 210, 216, 220, **221**
"Glassrock" 58, 72
Glen Dean Limestone 146, 150, **158**, 170

Hadley Gravel Member 204, **206**
Haeger Till Member 216, 224, **229**, 238, 239
Hagarstown Member 210, **222**
Hall Cyclothem 174
Hall Limestone Member 167, **196**
Hamburg Oolite 109, 129, 130
Hamilton Limestone 13, 109, 110, 116, 118
Hampton Formation 132
Haney Limestone 146, 150, 151, **157**
Hannibal Shale 104, 120, 122, 125, **129**
Hanover Limestone Member 166, **189**
Hardin Sandstone 122
Hardinsburg Sandstone 146, 150, **157**
Harkness Silt Member 210, **219**
Harmattan Till Member **219**
Harmony Hill Shale Member 61, 62, **64**
Harrisburg (No. 5) Coal Member 166, **189**, 190
Harrisville Drift 237
Harrodsburg Limestone Member 133, 140
Hazel Green Member 68, **72**
Hazelwood Member 68, **70**
Hegeler Till Member **219**
Helderbergian Series 93, 107, 110
Hely Member 68, **71**
Hendricks Formation 97
Hennepin Member **68**
Henry Formation 22, 224, **226**, 230
Henryhouse Formation 103
Hermitage Limestone 75, 76, 77, 78
Hermon Coal Member 166, **184**
Hermon Cyclothem 174
Herrin Limestone 191
Herrin (No. 6) Coal Member 166, 168, 176 177, 190, **191**
Heyworth Drift **233**
Hicks Cyclothem 174
High Bridge Group 67
Highland Park Drift **239**
Hildreth Drift **233**
Hillery Till Member **219**
Hillier Member 81
Hoffner Member 136
Hoing Sandstone Member 114, **116**
Holocene Stage 212, 224, **230**
Hombergian Stage 146, **156**
Hopkinton Dolomite 93, 99
Houchin Creek Coal Member (IVa) 189
Howardton Limestone Member 114, **118**
Hulick Till Member 216, 220, **221**, 236
Huntley Drift **238**
Hunton Limestone Megagroup 26, 89, 91, **92** 96, 104, 106, 113
Hymera Coal Member (VI) 191

I

Ice House coal 183
Illiana Drifts **233**
Illinoian Stage 22, 212, **220**, 236
Indiana Coal III 186
Inglefield Sandstone Member 167, **196**
Ion Formation 58, 79
Iowa Series 136
Iowan Loess 217, 228
Iowan Substage 217, 227
Ironton Sandstone 35, 37, 38, **43**
Iroquois Drift **233**
Isabel Sandstone Member 166, **186**

J

Jackson Formation 207
Jacksonville Drift **236**
Jacobsville Sandstone 40
Jake Creek Sandstone Member 166, **187**
Jamestown Coal Member 166, 168, **191**
Jamestown Cyclothem 174
Jamestown Limestone 192
Jefferson City Dolomite 57, 58
Jeffersonville Limestone 117
Jessamine Member 78
Joachim Dolomite 49, 50, 61, 62, 63, **65**
Joliet Formation 91, 92, 94, **100**, 102
"Joliet Marble" 102
Joppa Member 133, 142, **143**, 146
Jordan Sandstone 37, 38, **46**
Jubileean Substage 220, **223**
Jules Soil 224, **229**
Juniata Formation 84
Jurassic System 27, 201

K

Kankakee Formation 86, 91, 92, 94, **97**, 99
Kansan Stage 22, 210, 212, **218**
Karnak Limestone Member 133, **142**, 146
Kaskaskia Limestone 145, 148
Kaskaskia Sequence 26, 107, 112, **114**, 125
Keeneyville Drift **239**
Kellerville Till Member 216, 220, **221**, 236
Kentucky No. 3 coal 183
Kentucky No. 6 coal 186, 187
Kentucky No. 7 coal 186
Kentucky No. 8b coal 189
Kentucky No. 9 coal 189
Kentucky No. 10 coal 189
Kentucky No. 11 coal 187, 191
Kentucky No. 12 coal 192
Kenwood Member 114, **115**
Kenyon Member 37, **40**
Keokuk Limestone 125, 132, 135, **138**
Kerton Creek Coal Member 166, **188**
Kewanee Group 166, 171, **183**
Kidd Member 133, **140**
Kimmswick Subgroup 74, **78**
Kinderhook Group 130
Kinderhookian Series 10, **125**, 170
Kingdom Sandstone Member 61, 62, **64**
Kings Lake Formation 74, **76**
Kings Mill Drift **236**
Kinkaid Limestone 124, 146, 150, **162**, 168, 170
Kirkfield Formation 78
Kiser Creek Member 204, **206**
Kladognathus primus Zone 146
Knobs Megagroup 26, 104, **119**, 123
Knox Dolomite Megagroup 26, 36, 37, **41**, 51
Kress Member 61, 62, **63**
Kyrock Sandstone Member 181

L

La Moille Drift **238**
La Salle Cyclothem 174

Electronic Filing: Received, Clerk's Office 07/01/2024

Prepared by
The Interstate Technology & Regulatory Council
Vapor Intrusion Team

ABOUT ITRC

Established in 1995, the Interstate Technology & Regulatory Council (ITRC) is a state-led, national coalition of personnel from the environmental regulatory agencies of some 46 states and the District of Columbia, three federal agencies, tribes, and public and industry stakeholders. The organization is devoted to reducing barriers to, and speeding interstate deployment of better, more cost-effective, innovative environmental techniques. ITRC operates as a committee of the Environmental Research Institute of the States (ERIS), a Section 501(c)(3) public charity that supports the Environmental Council of the States (ECOS) through its educational and research activities aimed at improving the environment in the United States and providing a forum for state environmental policy makers. More information about ITRC and its available products and services can be found on the Internet at www.itrcweb.org.

DISCLAIMER

ITRC documents and training are products designed to help regulators and others develop a consistent approach to their evaluation, regulatory approval, and deployment of specific technologies at specific sites. Although the information in all ITRC products is believed to be reliable and accurate, the product and all material set forth within are provided without warranties of any kind, either express or implied, including but not limited to warranties of the accuracy or completeness of information contained in the product or the suitability of the information contained in the product for any particular purpose. The technical implications of any information or guidance contained in ITRC products may vary widely based on the specific facts involved and should not be used as a substitute for consultation with professional and competent advisors. Although ITRC products attempt to address what the authors believe to be all relevant points, they are not intended to be an exhaustive treatise on the subject. Interested parties should do their own research, and a list of references may be provided as a starting point. ITRC products do not necessarily address all applicable health and safety risks and precautions with respect to particular materials, conditions, or procedures in specific applications of any technology. Consequently, ITRC recommends also consulting applicable standards, laws, regulations, suppliers of materials, and material safety data sheets for information concerning safety and health risks and precautions and compliance with then-applicable laws and regulations. The use of ITRC products and the materials set forth herein is at the user's own risk. ECOS, ERIS, and ITRC shall not be liable for any direct, indirect, incidental, special, consequential, or punitive damages arising out of the use of any information, apparatus, method, or process discussed in ITRC products. ITRC product content may be revised or withdrawn at any time without prior notice.

ECOS, ERIS, and ITRC do not endorse or recommend the use of, nor do they attempt to determine the merits of, any specific technology or technology provider through ITRC training or publication of guidance documents or any other ITRC document. The type of work described in any ITRC training or document should be performed by trained professionals, and federal, state, and municipal laws should be consulted. ECOS, ERIS, and ITRC shall not be liable in the event of any conflict between ITRC training or guidance documents and such laws, regulations, and/or ordinances. Mention of trade names or commercial products does not constitute endorsement or recommendation of use by ECOS, ERIS, or ITRC. The names, trademarks, and logos of ECOS, ERIS, and ITRC appearing in ITRC products may not be used in any advertising or publicity, or otherwise indicate the sponsorship or affiliation of ECOS, ERIS, and ITRC with any product or service, without the express written permission of ECOS, ERIS, and ITRC.

ACKNOWLEDGMENTS

The members of the Interstate Technology & Regulatory Council (ITRC) Vapor Intrusion Team wish to acknowledge the individuals, organizations, and agencies that contributed to this technical and regulatory guidance document.

As part of the broader ITRC effort, the Vapor Intrusion Team effort is funded primarily by the U.S. Department of Energy. Additional funding and support have been provided by the U.S. Department of Defense and the U.S. Environmental Protection Agency. ITRC operates as a committee of the Environmental Research Institute of the States (ERIS), a Section 501(c)(3) public charity that supports the Environmental Council of the States (ECOS) through its educational and research activities aimed at improving the environment in the United States and providing a forum for state environmental policy makers.

The team co-leaders, Bill Morris (Kansas Department of Health and Environment) and John Boyer (New Jersey Department of Environmental Protection), also wish to recognize the individual efforts of the following state team members:

- Delonda Alexander, North Carolina Department of Environment and Natural Resources
- Tonia R. Burk, Georgia Environmental Protection Division
- Mary Camarata, Oregon Department of Environmental Quality
- Craig Dukes, South Carolina Department of Health and Environmental Control
- Peter Eremita, Maine Department of Environmental Protection
- Richard Galloway, Delaware Department of Natural Resources and Environmental Control
- Jerry Grimes, Virginia Department of Environmental Quality
- Marilyn Hajicek, Colorado Department of Labor and Employment
- Jeanene Hanley, Arizona Department of Environmental Quality
- Jim Harrington, New York Department of Environmental Conservation
- Tom Higgins, Minnesota Pollution Control Agency
- Greg Johnson, Colorado Department of Labor and Employment
- Allan V. Jones, Utah Department of Environmental Quality
- Bheem R. Kothur, Florida Department of Environmental Protection
- Diedre Lloyd, Florida Department of Environmental Protection
- William McKercher, Mississippi Department of Environmental Quality
- John S. Mellow, Pennsylvania Department of Environmental Protection
- Robin Mongeon, New Hampshire Department of Environmental Services
- Evelina Morales, Oklahoma Department of Environmental Quality
- Susan Newton, Colorado Department of Public Health and Environment
- Richard Olm, Arizona Department of Environmental Quality
- Nelly F. Smith, Alabama Department of Environmental Management
- Neil Taylor, Utah Department of Environmental Quality
- Rod Thompson, Indiana Department of Environmental Management

The co-leaders also wish to thank the industry and federal agency team members who contributed in various forms to the guidance:

- Leah Alejo, U.S. Naval Facilities Engineering Service Center
- Harry Anderson, Andre Brown, Jay Hodny, and Jim Whetzel, W.L. Gore & Associates, Inc.
- Vanessa J. Bauders, U.S. Army Corps of Engineers
- Tom Biksey, Environmental Strategies Consulting, LLC
- Anita Broughton, Haley & Aldrich, Inc
- Richard Burns, Connestoga Associates
- Douglas Cox, Mitretek Systems
- Dianne Easly, U.S. Environmental Protection Agency Region 7
- Diana Marquez & Stephen Hoffine, Burns and McDonnell Engineering Company, Inc.
- Amy L. Edwards, Holland & Knight, LLP
- Bart Eklund, URS Corporation
- Rachel Farnum, GE Global Research
- Mark J. Fisher, U.S. Army Corps of Engineers
- Douglas M. Fitton and Eric M. Nichols, LFR Inc.
- David J. Folkes, EnviroGroup Limited
- Kimberly Gates, U.S. Naval Facilities Engineering Service Center
- Ken Gilland, Buck Engineering
- Sandra Gaurin, BEM Systems, Inc
- Johnathan Gledhill, Policy Navigation Group
- Annette Guiseppi-Elie and Jenny Liu, DuPont Engineering
- Blayne Hartman, H&P Mobile Geochemistry
- Harley Hopkins, American Petroleum Institute
- Alana Lee, U.S. Environmental Protection Agency Region 9
- Ronald J. Marnicio, Tetra Tech, EC
- Todd McAlary, GeoSyntec Consultants
- Denise Miller, ARCADIS
- Ian T. Osgerby, U.S. Army Corps of Engineers New England District
- Gina M. Plantz, Newfields
- Henry Schuver, U.S. Environmental Protection Agency Office of Solid Waste
- Fred Tillman, U.S. Environmental Protection Agency Ecosystems Research Division
- Matthew Traister, O’Brien & Gere
- Robert S. Truesdale, RTI
- Yvonne Walker, Navy Environmental Health Center

Special thanks to the community stakeholders, Lenny Siegel (Center for Public Environmental Oversight) and Peter Strauss (PM Strauss and Associates), for their insightful contribution to the value of the community and residents of facilities being investigated for the vapor intrusion pathway. And finally thanks to Andrea Futrell, Stacey Kingsbury, Gleness Knauer, and Steve Hill for their support and guidance in the preparation of this document.

Electronic Filing: Received, Clerk's Office 07/01/2024

EXECUTIVE SUMMARY

This guideline was developed by the Interstate Technology & Regulatory Council (ITRC) Vapor Intrusion Team and represents the combined effort of more than 100 professionals from state and federal regulatory agencies, consultants, industry, and stakeholders. It is a practical, easy-to-read, how-to guideline for assessing the vapor intrusion pathway. Supplemental information is contained in appendices and in a companion document, *Vapor Intrusion Pathway: Investigative Approaches for Typical Scenarios* (VI-1A) to assist the practitioner when using the guideline. Due to variations in policy among regulatory agencies, this document does not provide a single prescriptive approach for assessing the vapor intrusion pathway. Rather, the purpose of this guideline is to provide a generalized framework for evaluating the pathway and a description of the various tools available for investigation, data evaluation, and mitigation. The guideline is intended to be used in conjunction with any applicable federal or state vapor intrusion policy or guidance.

The ITRC *Vapor Intrusion Pathway* guidance series consists of two documents—this *Practical Guideline* and its supplement, *Investigative Approaches for Typical Scenarios*. This document, *A Practical Guideline*, consists of four chapters:

1. An overview of vapor intrusion
2. Preliminary screening of sites
3. Site investigation
4. Mitigation

Chapter 1 provides basic information on the vapor intrusion pathway. Although the document is written for the environmental professional who has some general knowledge of vapor intrusion, it is still important to discuss the essential key points that must be understood to investigate and mitigate the pathway. Thus, Chapter 1 touches on conceptual site models, multiple lines of evidence, background contamination, preferential pathways, and community outreach.

The framework of the document presents a 13-step approach that leads the investigator from Step 1 (Is there an acute exposure?) to Step 13 (Is mitigation warranted?), using a lines-of-evidence approach. The first seven steps (Chapter 2) apply to the screening of sites based upon preexisting conditions and data. The user is prompted to consider whether adequate data are available for screening, whether volatile and toxic compounds are present in the subsurface near buildings, and whether concentrations of these compounds exceed any applicable screening levels. Discussions on issues applicable to the preliminary screening process, such as development of screening levels and building design considerations, are included as appendices.

Unless the vapor intrusion pathway is determined to be incomplete during the preliminary screening steps, six steps follow that describe the vapor intrusion investigative process (see Chapter 3). The process begins with selection of an investigation strategy and development of a work plan, followed by execution of the work plan, and ending with an evaluation of the need for mitigation. Chapter 3 is augmented by detailed appendices (e.g., Appendix D. Toolbox), which

give a comprehensive treatment of the investigatory methods used for vapor intrusion assessments. Methods include groundwater sampling, active and passive soil gas sampling, subslab soil gas sampling, indoor air sampling, and supplemental tools such as flux chambers and forensics. Summary tables, charts, and checklists facilitate the use of the methods described in the toolbox.

Chapter 4 provides a comprehensive treatment of mitigation strategies. This chapter begins with an overview of three general approaches to addressing vapor intrusion—site remediation, institutional controls, and building mitigation. While the chapter focuses on building mitigation, it does include discussions on the differences between site remediation and building mitigation. The chapter also provides a description of eight building mitigation approaches, each including technology selection, design and installation considerations, operation, maintenance, performance monitoring, and mitigation system closure. Summary tables comparing the various options and costs are included.

Appendices include checklists for conceptual site models and reviewing soil gas data, a discussion of building types, a toolbox of investigative methods, quality assurance considerations, guidance for development of screening levels, an indoor air survey form, and a discussion of community stakeholder concerns. An extensive reference list is also included.

To illustrate how to use this *Practical Guideline* document, the Vapor Intrusion Team has also prepared a companion document. *Investigative Approaches for Typical Scenarios* describes applicable approaches for evaluating the vapor intrusion pathway under the following scenarios:

1. An active service station in a residential neighborhood
2. A dry cleaner in a strip mall adjacent to a neighborhood
3. A large industrial facility with a groundwater plume under several hundred receptors
4. A vacant lot with proposed brownfield development over a groundwater plume
5. A vacant large commercial building with warehouse space and office space
6. An apartment building with a parking garage over contamination

The scenarios follow the step-by-step approach described in the guidance document, focus on the decision process and alternatives chosen, identify key issues about each scenario, highlight lessons learned during process, and describe the next steps to be followed.

The ITRC *Vapor Intrusion Pathway* guidance series provides the reader with a logical, flexible framework, the variety of tools and remedial approaches, and the practical rationale for developing an investigative strategy when assessing vapor intrusion. Working within the regulatory framework, this difficult and ever-evolving pathway can be properly evaluated and the risks associated with indoor air contamination from vapor intrusion effectively mitigated.

Electronic Filing: Received, Clerk's Office 07/01/2024

TABLE OF CONTENTS

ACKNOWLEDGMENTS i

EXECUTIVE SUMMARY iii

1. STRATEGIC OVERVIEW 1

    1.1 Introduction 1
    1.2 Conceptual Model for Vapor Intrusion 2
    1.3 Defining the Pathway 3
    1.4 General Framework for Vapor Intrusion Investigations 5
    1.5 Lines of Evidence 5
    1.6 Special Factors Influencing Vapor Intrusion Assessments 6
    1.7 Community Concerns 9
    1.8 Remediation 10
    1.9 Regulatory Considerations/Drivers 10

2. PRELIMINARY SCREENING PHASE 11

    2.1 Developing a Conceptual Site Model 12
    2.2 Preliminary Screening Steps 13
    2.3 Step 1: Does the Site Represent an Acute Exposure Concern? 15
    2.4 Step 2: Are There Sufficient Characterization Data to Evaluate this Pathway? 15
    2.5 Step 3: Are Any of the Site Chemicals of Concern Both Volatile and Toxic? 16
    2.6 Step 4: Are Buildings Located in Close Proximity to Volatile Chemicals in Soil, Soil Gas, or Groundwater? 16
    2.7 Step 5: Identify the Appropriate Occupant Exposure Scenarios and Generic Screening Levels for the Site 17
    2.8 Step 6: Do the Data Exceed the Appropriate Generic Screening Levels? 18
    2.9 Step 7: Does an Exceedance of the Generic Screening Level Warrant Further Investigation? 18
    2.10 Data Usability for Preliminary Screening 19

3. SITE INVESTIGATION PHASE 19

    3.1 Investigative Process 19
    3.2 Common Vapor Intrusion Scenarios 20
    3.3 Site Investigation Phase 21
    3.4 Step 8: Choose an Investigative Strategy 21
    3.5 Step 9: Design a Vapor Intrusion Investigative Work Plan 26
    3.6 Step 10: Implement the Vapor Intrusion Investigative Work Plan 34
    3.7 Step 11: Evaluate the Data 34

1. STRATEGIC OVERVIEW

This section provides a brief overview of the vapor intrusion pathway—the typical model and special factors that influence soil gas movement, the phased approach to investigation and remediation, the interpretation of the data, multiple lines of evidence, and interaction with the local community through a site-specific outreach program. Regulatory issues are identified, and key considerations are summarized for assessing the vapor intrusion pathway.

1.1 Introduction

Vapor intrusion is the migration of volatile chemicals from the subsurface into overlying buildings (USEPA 2002b). Volatile chemicals may include volatile organic compounds, select semivolatile organic compounds, and some inorganic analytes, such as elemental mercury and hydrogen sulfide. Methane should be considered where it is appropriate.

Degradation of indoor air quality causes more apprehension and anxiety among building occupants than are typically associated with other environmental problems. In a residential community, these concerns over vapor intrusion are often magnified. Regulators commonly encounter a series of questions from concerned occupants such as the following:

- Is the air that our children breathe safe, not only in our houses, but outside and in our local school or day care?
- What effect will this contamination have on our property values?

These concerns often become “hot button” issues, at times driving the strategy that regulators will take in addressing the vapor intrusion pathway. Public education and community outreach are crucial to how people react to a potential finding of vapor intrusion.

Why has vapor intrusion become such a significant environmental issue for regulators, industry leaders, and concerned residents alike? For more than a decade, environmental scientists and risk assessors viewed contaminated groundwater as a threat principally to the drinking water supply. As long as individuals didn’t drink the water, the risk of exposure to the contamination was believed eliminated. It wasn’t until investigative work of the Massachusetts Department of Environmental Protection (MassDEP) in the 1990s that regulators began to understand the significance of vapor intrusion. State and federal regulators are now in the process of examining older remedial decisions involving groundwater contamination to assess whether the vapor intrusion pathway warrants reopening closed cases. A multidisciplinary team can best evaluate and discuss the occurrence and potential impacts of the vapor intrusion pathway.

In addition, most other exposure pathways are assessed using “exterior” investigative tools to characterize and delineate contamination. While the actions to characterize and remediate contaminated groundwater or sediments may be apparent to the community, they typically are not invasive to the personal lives of individuals. Vapor intrusion, on the other hand, may involve the collection of environmental samples inside or immediately outside a structure. Thus, the process of investigating the vapor intrusion pathway often directly affects occupants.

Electronic Filing: Received, Clerk's Office 07/01/2024

For example, the Redfield site in Colorado was one of the first major sites to bring the vapor intrusion issue to the attention of the U.S. Environmental Protection Agency (USEPA) and the nation in the late 1990s. Relatively low concentrations of 1,1-dichloroethene (1,1-DCE) in groundwater were found to have impacted indoor air in a large number of homes overlying the solvent plume. Indoor air testing was required in almost 800 homes and apartments at the Redfield site, leading to mitigation of almost 400 residential buildings. Subsequent monitoring of both mitigated and unmitigated homes has continued over the past eight years, resulting in more than 7000 indoor air tests to date in the site vicinity. The essential interaction with residents in this neighborhood is extensive and ongoing.

Finally, vapor intrusion is a significant issue to building occupants due to the personal public health concerns related to the degradation of indoor air quality. While a health officer can provide bottled water for occupants to drink when potable water has been contaminated, what can be done when contaminants from vapor intrusion are found in the air of their buildings?

1.2 Conceptual Model for Vapor Intrusion

Vapor intrusion is typically conceptualized as shown Figure 1-1. Chemicals volatilize from impacted soil and/or groundwater beneath a building and diffuse toward regions of lower chemical concentration (e.g., the atmosphere, conduits, basements). Soil gas can flow into a building due to a number of factors, including barometric pressure changes, wind load, thermal currents, or depressurization from building exhaust fans. The rate of movement of the vapors into the building is a difficult value to quantify and depends on soil type, chemical properties, building design and condition, and the pressure differential. Upon entry into a structure, soil gas mixes with the existing air through the natural or mechanical ventilation of the building. While Figure 1-1 schematically depicts houses and commercial/industrial buildings, other structures (e.g., apartments, schools) also can be of concern. This guidance is generally applicable to all building scenarios.

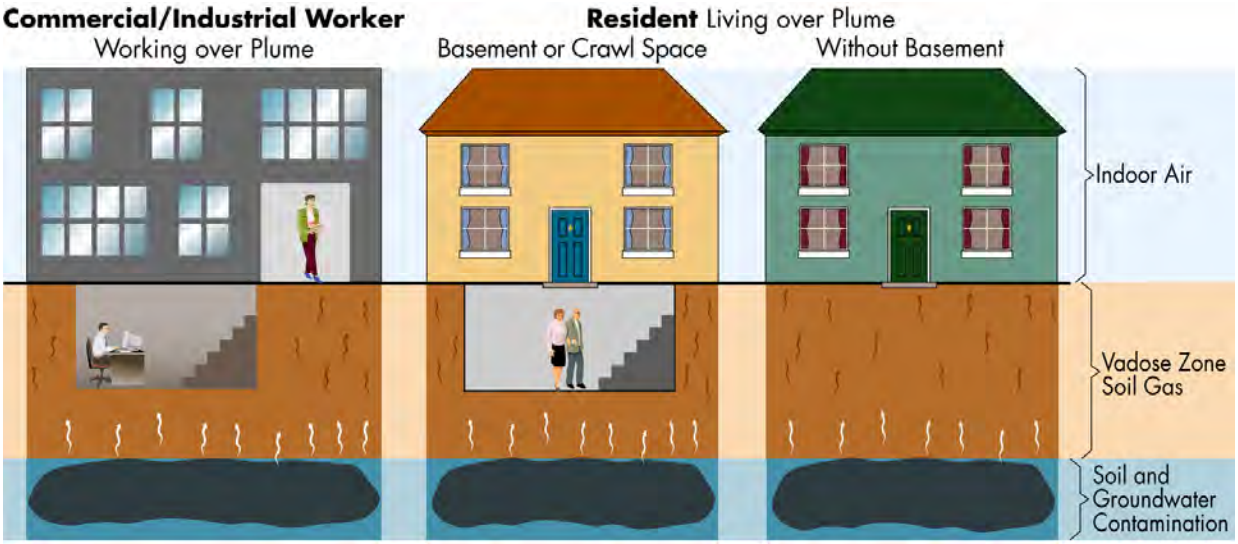

Figure 1-1. Typical conceptual model of vapor intrusion.

Electronic Filing: Received, Clerk's Office 07/01/2024

Both diffusion and advection are mechanisms of transport of subsurface soil gas into the indoor air environment. Diffusion is the mechanism by which soil gas moves from high concentration to low concentration due to a concentration gradient. Advection is the transport mechanism by which soil gas moves due to differences in pressure. These pressure differences can be generated by atmospheric pressure changes, temperature changes creating natural convection in the soil, or forced pressure changes due to building ventilation systems. Advective transport is likely to be the most significant in the region very close to a basement or a foundation, and soil gas velocities decrease rapidly with increasing distance from the structure (USEPA 2004b). Once soil gases enter the "building zone of influence," they are generally swept into the building through foundation cracks by advection due to the indoor-outdoor building pressure differential. The reach of the "building zone of influence" on soil gas flow is usually less than a few feet, vertically and horizontally.

A good source of information on the conceptual model and the migration of soil gas in the subsurface can be found in the New Jersey Department of Environmental Protection (NJDEP) *Vapor Intrusion Guidance* (2005b). For additional references, see the Vapor Intrusion Resources and Links page on the Interstate Technology & Regulatory Council (ITRC) Web site (www.itrcweb.org/vaporintrusion).

1.3 Defining the Pathway

To define the vapor intrusion pathway as a complete exposure pathway, a source, migration route, and receptor must be identified (Figure 1-2). Specifically, this assessment entails the identification of all known or suspected vapor sources of contamination; consideration of the contaminant migration routes (mobility) including an evaluation of methods and manner of access, and identification of those likely to be affected by the contaminants (receptors).

The physical source of the contamination should be determined. The initial or primary sources (e.g., a leaking tank or a surface spill) or secondary sources (e.g., contaminated soil gas, soil, or groundwater) may assist in the vapor intrusion investigation. Factors in identifying likely sources include the following:

- product type, chemical composition, and location of contamination
- contaminated media
- constituents of interest present in each medium
- distribution and concentrations of contaminants in each medium

The type and location of the release can be determined by evaluating previous industrial processes employed at a site and historical site use information. The historical data can indicate chemicals used and storage locations. Also, preliminary sampling may yield analytical results that would clarify the type and location of release.

Electronic Filing: Received, Clerk's Office 07/01/2024

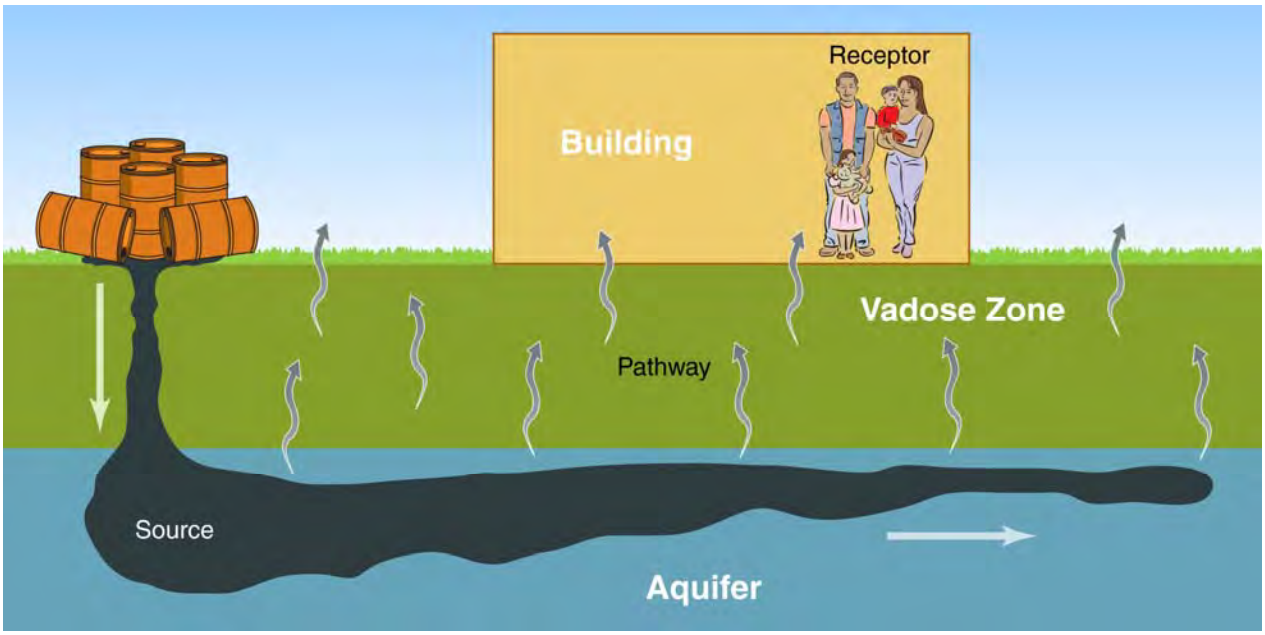

Figure 1-2 Potential source, migration route, and receptor for vapor intrusion.

The movement of contaminants from the source to the receptor is a complicated process in the vapor intrusion pathway. Building depressurization may cause soil gas from soil and/or groundwater contamination to be drawn into buildings through holes and cracks in the foundation. Heating systems, basements, and strong winds promote vapor intrusion into buildings by reducing the internal air pressure and creating a vacuum effect that enhances advective flow from underlying soils and/or groundwater into buildings ("the stack effect").

Receptors are the people that may be exposed to the site related contaminants. Typical receptors include adults and children exposed in a residential setting, adults exposed in an occupational environment, and adults and children exposed in a nonresidential setting. Other site-specific exposure scenarios (e.g., schools, day care facilities) may be identified.

Identification of possible receptors can be determined using the locality of the facility data, land use data, and demographics. Specific considerations might include the following:

- future site use and surrounding area use
- utilities in the area
- zoning criteria (commercial, industrial, residential, and industrial) and zoning exceptions (e.g., commercial zones that allow residential, multifamily residential, second-story residential)—some industrial zones allow a caretaker to live on the site; other commercial zones allow unique uses, such as day care facilities
- land use constraints
- site vicinity and conditional uses typically allowed

Electronic Filing: Received, Clerk's Office 07/01/2024

1.4 General Framework for Vapor Intrusion Investigations

For the vapor intrusion pathway to be complete, there must be three components—a source of volatile compounds in the subsurface environment (groundwater and/or soil), inhabited buildings or the potential for future inhabited buildings, and a migration route to connect them (as discussed above). Once the pathway is identified, a "phased" approach is recommended to evaluate whether exposures present significant risk to the receptors, as defined by the regulatory agencies. Where there are obvious signs of vapor intrusion, such as odors or explosive hazards, these potential acute risks should be addressed immediately. For probable chronic exposure, the site may be evaluated on either a generic or site-specific basis in a timely manner. However, there may be precluding factors that limit the use of a generic screen (e.g., wet basements, sumps).

This section presents a general framework for evaluating vapor intrusion from subsurface media contamination that builds on the premise of conservative but flexible guidance, within the confines of the regulatory agency. Ultimately, the intent is to be able to differentiate sites where the pathway presents or does not present an unacceptable risk, while erring on the side of caution when there is uncertainty.

Some key principles that guide this framework are summarized below, with further detail in Chapters 2 and 3:

- implementation of a community outreach program that provides timely information to concerned citizens and property owners
- use of a phased approach that allows for the collection and use of both generic and site-specific information/data
- development of an accurate conceptual site model (CSM) that is representative of site conditions to assist with the investigative strategy and ensure proper use of the data
- application of an iterative process (i.e., starts with available data and collects additional data only to meet the needs of making informed decisions)
- allowance for a site-specific evaluation using modeling, soil gas sampling, indoor air sampling, or mitigation at any point in the process
- evaluation of multiple lines of evidence that result in decisions based on professional judgment
- consideration of current and future site use
- use of screening levels based on the appropriate exposure scenario (e.g., residential, nonresidential, occupational) consistent with the regulatory agency

1.5 Lines of Evidence

Attribution of chemicals in indoor air to vapor intrusion can become a relatively complex and difficult task. It is important to use multiple lines of evidence to reach decisions based on professional judgment. The following are some lines of evidence, listed in no particular order:

Electronic Filing: Received, Clerk's Office 07/01/2024

- soil gas spatial concentrations, including subslab and exterior (some distance outside the perimeter of the foundations) soil gas data with some level of vertical profiling, if appropriate (see Appendix D)
- groundwater spatial data, with vertical profiling, if appropriate (see Appendix D)
- background, internal and external, sources (see Section 1.6.1)
- building construction and current conditions (see Appendix C)
- subslab (or crawl-space) soil gas data
- indoor air data (see Section 3.7.3)
- concurrent outdoor air data (see Section 3.7.3)
- constituent ratios (see Section 3.7.3)

Other lines of evidence may be available depending on the site-specific circumstances. Conversely, regulatory frameworks of individual states may limit the ability to use some or all of these lines.

In addition to using a phased approach, it is recommended that all available data (e.g., analytical results, building type, and ventilation rates) be used in making a determination about whether vapor intrusion is occurring and whether there are potential health concerns as a result. It should be noted there will likely be some uncertainty associated with such an assessment, regardless of the number of lines of evidence considered. Decisions should be made in consultation with the regulatory agency and based on what professional judgment deems to be reasonable and logical for the specific site.

Soil Gas and Soil Vapor
In many vapor intrusion guidance documents, "soil gas" and "soil vapor" are used interchangeably. In this document, "soil gas" refers to the gaseous elements and compounds in the small spaces between particles of soil. Once the gaseous elements or compounds migrate into a structure, they are referred to as "vapor."

It is important to point out there may be multiple sources of chemicals affecting the overall quality of the indoor air that may not be associated with the investigated chemical release, confounding the interpretation of indoor air sample results. These other sources may be from building materials, heating/cooling energy sources, residual volatile components of stored items, household activities (cooking/cleaning), and consumer products used in the building or background contaminants from ambient outdoor air (Locus Technologies 2006). Thus, indoor air sampling is generally recommended only after identifying the buildings most likely to be impacted to limit the difficult task of evaluating the data and avoiding false positive results.

1.6 Special Factors Influencing Vapor Intrusion Assessments

Numerous conditions may be important considerations either in addition to or instead of the typical conceptual model. Several are described briefly in the subsections below.

1.6.1 Background Air Concentrations

Indoor air quality often contains measurable concentrations of volatile and semivolatile compounds from household activities, consumer products, building materials, and outdoor air sources. In some cases, these background contributions exceed health-based target

Electronic Filing: Received, Clerk's Office 07/01/2024

concentrations, especially for benzene, where background indoor air quality often represents an incremental cancer risk greater than 10^{-5} (one in one hundred thousand) for a residential scenario. It is generally advisable to obtain outdoor ambient air samples when collecting indoor air samples. In this way, outdoor air quality can act as a baseline, to which interior and subsurface sources are additive. In many cases, the site-specific chemicals of concern (COCs) may be limited to a few chemicals, which may not be present at significant background levels, so it may be possible to conduct indoor air monitoring for a target list of analytes and avoid complications associated with background contributions. Otherwise, a forensic analysis may be required to assess the relative contribution from subsurface and background sources, possibly requiring multiple lines of evidence and multiple methods of interpretation. Several studies (NJDEP, MassDEP, New York State Department of Health [NYSDOH]) of indoor air quality at homes unaffected by subsurface contamination are currently being conducted to provide a statistical basis for assessing background air quality. Data from such studies should prove to be valuable as one line of evidence, although personal preferences and consumer products will vary between properties. Information on New York State's background database studies can be found at www.health.state.ny.us/nysdoh/gas/svi_guidance/svi_appendc.htm.

Prior to indoor air sampling, efforts should be made to address sources of background contamination. Some background sources will occur on a fairly constant basis and are difficult to eliminate (e.g., off-gassing from furniture and treated wood surfaces, volatiles released from long-term stored chemicals or fuels). However, other sources are intermittent and have the potential to skew the data (e.g., cigarette smoke, off-gassing from dry cleaning, exhaust from attached garages). Even a simple activity like a hot shower can strip volatiles from the water, producing a spike in the concentrations of trihalomethanes. It is appropriate to conduct a building walkthrough in advance of any interior sampling events to identify potential background sources, eliminate them, and educate the occupants on those activities that should be avoided immediately before and during the sample collection. A sample building survey form can be found in Appendix G.

1.6.2 Biodegradation

Many hydrocarbons (notably petroleum-based hydrocarbons) are readily degraded to carbon dioxide (CO_2) in the presence of oxygen (O_2) by ubiquitous soil microbes. Oxygen is supplied from the atmosphere by vapor diffusion and barometric pumping and as a dissolved solute in infiltrating rainwater. Aerobic degradation is a rapid process and frequently occurs in a relatively thin (a few feet thick) zone where the concentrations of O_2 and hydrocarbons are most ideal for microbial processes. The bioattenuation of hydrocarbons can potentially reduce soil gas concentrations and vapor intrusion by several orders of magnitude.

Like petroleum hydrocarbons, chlorinated solvents also can be biodegraded, but the process tends to occur under anaerobic conditions and is slower than aerobic degradation of petroleum hydrocarbons like benzene, toluene, ethylbenzene, and xylenes (BTEX). In both cases, degradation occurs via oxidation-reduction reactions that are used by the microbes as an energy source.

Electronic Filing: Received, Clerk's Office 07/01/2024

For vapor intrusion studies, the importance of biodegradation of chlorinated solvents is that additional compounds of interest are created, with obvious implications for selecting target compounds. These daughter compounds may be considered worse than the parent compound because of increased carcinogenicity.

1.6.3 Preferential Pathways

Spatially, the permeability of subsurface materials can be highly variable. Conditions such as fractured geologic media and gravel lenses or channels may allow an atypical preferential soil gas flow through high-permeability pathways (in some cases opposite to the groundwater flow). If such a migration route connects a source directly to a building or allows higher levels of groundwater contamination to migrate under a building, vapor intrusion may be exacerbated.

Most buildings have subsurface utility penetrations, so their presence alone is not considered "preferential." For this guidance (consistent with the vapor intrusion pathway in general and the Johnson and Ettinger [J&E] model specifically), some increased component of soil gas flow into the building is usually required to consider the pathway to be preferential. Anthropogenic preferential pathways include building sumps or drainage pits (that can serve as conduits for soil gas to enter buildings) or subsurface utility conduits or drains (that intersect vapor sources or soil gas migration routes and a building foundation). Natural preferential pathways include vertically fractured bedrock where the fractures are interconnected and in direct contact with the building foundation and the vapor contaminant source. Interestingly, the Georgia Environmental Protection Division had a case where rodent tracks or tunnels up to a building foundation allowed vapors to migrate into a basement.

Elevator Shafts
Elevators may constitute a vertical preferential pathway into a building since they may be constructed with subbasement perforations to allow water to drain. Elevators may also allow vapor impact on unexpected floors due to vertical migration up the shaft.

In addition, investigators must consider that preferential pathways may not be apparent based on external building inspections. According to Henry Schuver (USEPA), some communities with unexpectedly high concentrations of indoor contaminants were observed during indoor surveys to have uncapped pipes through the basement floor connected to "dry wells" designed to dispose of fluids through openings surrounded by very permeable fill materials. Thus, they served as preferential pathways by allowing an unexpected amount of vapor to migrate into the structures.

Another example is waste lines without functioning vapor traps. Petroleum compounds often biodegrade before causing vapor intrusion problems. However, one community had elevated petroleum-related concentrations in indoor air traced back to homes connected to sewer lines without vapor traps. These untrapped sewer lines formed a preferential pathway for contaminant vapors that had entered the sewer lines from openings elsewhere along the lines. It is important to note that reports of sewer odors are typically found with vapor traps that have dried out or are no longer operating properly.

The possibility of these conditions highlights the importance of an interior inspection of potentially impacted buildings before the screening process is finalized.

Electronic Filing: Received, Clerk's Office 07/01/2024

1.6.4 Undeveloped Land

Assessing the potential for vapor intrusion in a future building upon land that is currently vacant poses unique challenges. Some of the investigative tools of the vapor intrusion pathway (e.g., subslab soil gas or indoor air samples) are not possible when there is no slab or structure present on the property. Alternative approaches are required in these circumstances.

Future-use exposure scenarios may involve the evaluation of municipal zoning criteria (commercial, residential) and zoning exceptions (e.g., commercial zones that allow residential, multifamily residential, second-story residential). Other considerations include commercial zones that allow day care facilities and industrial zones that allow on-site caretaker residence.

The use of institutional controls (e.g., deed restrictions, environmental covenants) may be appropriate to ensure that future use of an affected property is protective of human health through the vapor intrusion pathway. Institutional controls could include land use restrictions, future building design requirements to address the potential for vapor intrusion, notification requirements for land owners/developers, or stipulations for further investigation of the vapor intrusion pathway during evaluation of specific future use scenarios.

When institutional controls are not appropriate (or not permitted by the regulatory agency), investigators must delve deeper into their "toolbox" to assess vapor intrusion at undeveloped lands. In the end, it may be preferable to incorporate a vapor barrier and/or subslab venting system into the building design as a proactive approach.

1.7 Community Concerns

Vapor intrusion investigators must be trained to deal with community concerns. Informing residents or business owners that chemicals may have entered their buildings is a delicate situation. Usually, people are just learning that the groundwater and/or soil near their properties have been contaminated by releases from a local company or individual. Communities may be skeptical or unsure of what will happen next. How will the vapors affect their health or that of their co-workers and families? It is important to learn from experiences of other investigators who have overcome similar challenges with impacted communities.

Communication is an essential component of any community outreach program. For example, it is generally not a good idea for building occupants to learn about a vapor intrusion investigation for the first time when someone knocks on their door asking permission to drill holes in their floors or inquire about their personal activities (e.g., smoking, dry-cleaning clothes).

Redfield, Colorado Site

To facilitate public education and communication with the residents, investigators went door to door providing information packets and discussed the program directly with each resident when requesting access for testing. Testing personnel were selected, in part, for their ability to communicate and work well with the residents. Consider situations regarding language barriers and residents. Other community relation efforts included frequent public meetings, periodic mailing of project newsletters, articles published in local community newsletters, door-to-door surveys, and development of a project Web site (www.redfieldsite.org) posting fact sheets and the most recent results of groundwater and indoor air testing.

Electronic Filing: Received, Clerk's Office 07/01/2024

To be successful, agencies conducting or overseeing vapor intrusion (VI) investigations need to develop a strong community outreach program to educate and reassure the local community about vapor intrusion in a meaningful, sensitive, and effective manner. Unlike any other contaminant pathway, vapor intrusion merits effective education of the affected community regarding the risk of soil gas migrating from the subsurface as well as background sources typically found in the building.

Community Advisory Groups (CAGs) may assist in this process. CAGs are generally small groups of residents who meet regularly with agencies and responsible parties. They provide an opportunity for the public to gradually gain an understanding of the complexities of vapor studies. In such settings, initial adversarial relationships usually break down, and community members often come up with constructive advice.

1.8 Remediation

Some vapor intrusion investigations will indicate that actions (remedies or mitigations) should be taken to reduce the amount of vapor intrusion into a building. "Remediation" commonly refers to an action that reduces the level of contamination in the environmental medium (e.g., groundwater) that is acting as the source of the indoor air vapors. "Mitigation," on the other hand, is generally applied to actions that prevent or minimize exposure. While the two terms are used interchangeably in this industry, the differences should be understood by the investigator. When an action is needed, a remedy or combination of remedies should be selected, implemented, operated, maintained, and monitored to properly respond to the vapor intrusion problem and bring the site to closure.

Chapter 4 of this document covers sitewide remediation, institutional controls, and building controls. Of these, building control remedies are discussed in the most detail because they include those active mitigation methods most commonly implemented at structures impacted by vapor intrusion.

1.9 Regulatory Considerations/Drivers

As indicated by the ITRC Vapor Intrusion Survey (ITRC 2004b), existing policies, regulations, and guidance regarding the methods for evaluation of the vapor intrusion pathway vary widely among jurisdictional agencies. Prior to developing a site-specific approach for the evaluation of the vapor intrusion pathway, consideration should be given to applicable local, state, and federal policies, regulatory requirements, and available guidance. Regulatory policies may offer specific approaches and screening levels for the evaluation of the vapor intrusion pathway. Coordination of vapor intrusion investigations with the appropriate jurisdictional agencies early in the planning process may allow for a more focused vapor intrusion assessment and ensure that regulatory compliance criteria are met.

Stay Ahead of the Curve

A review of the developing science relating to the vapor intrusion pathway should be conducted on a regular basis. As the state-of-the-practice for evaluating the vapor intrusion pathway develops, additional guidance, investigative tools, and case study information will be available at the ITRC Vapor Intrusion Web page (www.itrcweb.org/vaporintrusion).

Electronic Filing: Received, Clerk's Office 07/01/2024

The agency with oversight responsibility will offer regulatory guidance that is applicable for a given investigation. In an ideal world, the best technical approach for any given situation is defined in the applicable regulatory guidance. In reality, vapor intrusion is an evolving science with many variables. Thus. investigators must be prepared to justify their technical approach.

Since various states express a wide range of comfort about the data types that are acceptable for screening a site from further consideration, this guidance is not prescriptive as to what data types present an appropriate methodology for screening purposes. Rather, this guidance is intended to assist the investigator in understanding the factors and methodologies that may be used to assess the vapor intrusion pathway. To refine the approach, the investigator is encouraged to consult the individual state's guidance on the subject of vapor intrusion. Check the ITRC's Vapor Intrusion Web site (www.itrcweb.org/vaporintrusion) for updated links on VI guidance documents and related information from the various states, federal government, industry and other interested parties.

2. PRELIMINARY SCREENING PHASE

The initial step in assessing the vapor intrusion pathway is developing a conceptual site model based on all available data. Once prepared, the CSM becomes a primary developmental method used by investigators when conducting a preliminary screening of a contaminated site. This chapter provides a fundamental seven-step approach to assessing the vapor intrusion pathway through this early phase of data evaluation. (The remaining six steps of the total 13-step vapor intrusion assessment are discussed in Chapter 3, Site Investigation Phase.) The role of generic screening levels and the importance of groundwater data usability are discussed as they relate to the preliminary screening phase.

As noted in Chapter 1, evaluating the potential for vapor intrusion at a site of concern should be approached as a sequential process extending from the evaluation of initially available data through the determination of no further action or mitigation. This section is intended to help the investigator evaluate existing data and make decisions regarding the need to proceed to the investigative phase to collect additional data. Given that regulator-defined screening levels are often close to background levels for many compounds and that spatial/temporal variability and sampling bias are often present, the ultimate risk management decisions should be based upon multiple lines of evidence rather than upon a single line of evidence (Section 1.5).

An appropriate initial screening process will ensure that those sites most likely to pose unacceptable risk from vapor intrusion are retained for more detailed evaluation. It is also expected that some sites will be removed from further evaluation if it is demonstrated that

- the exposure pathway is and will remain incomplete,
- the COCs are not deemed sufficiently volatile (as defined by the regulatory agency) to pose a hazard, or
- the concentrations of the volatile chemicals fall below generic screening levels.

Electronic Filing: Received, Clerk's Office 07/01/2024

2.1 Developing a Conceptual Site Model

The goal for developing a CSM in the assessment of the vapor intrusion pathway is to assemble a three-dimensional concept of the site that is as comprehensive as possible. This is based on available, reliable data describing the sources of the contamination, the release/transport mechanisms, the possible subsurface migration routes, and the potential receptors, as well as historical uses of the site, cleanup concerns expressed by the community, and future land use plans. All the important features relevant to characterization of a site should be included in a CSM, and any irrelevant ones excluded. The CSM should present both a narrative and a visual representation of the actual or predicted relationships between the contaminants at the site and receptors (building occupants), as well as reflect any relevant background levels. Appendix B is a CSM checklist to assist in preparing this important component of the vapor intrusion assessment.

A CSM typically contains information on soils, geology, hydrogeology, the relative amount of heterogeneity, groundwater quality data, regional groundwater flow direction, well records, boring logs, and surficial features suggestive of whether the area is in a groundwater recharge or discharge area (e.g., ground cover, surface water bodies). Sources to check for this data are county soil surveys; state or federal water supply or geologic reports/maps; U.S. Geological Survey (USGS) topographic maps; geographic information systems; and federal, state, and local government or quasi-government agency records.

A preliminary CSM documents current site conditions, such as site geology, hydrogeology, and volatile organic compound (VOC) distribution and composition relevant to soil gas migration, and should be supported by maps, cross sections, and site diagrams. A narrative description should clearly distinguish what aspects are known or determined and what assumptions have been made in its development. The CSM should provide all interested parties with a conceptual understanding of the potential for exposure to compounds of concern at a site. It is an essential tool to aid management decisions associated with the site and also serves as a valuable communication tool both internally with the site team and externally with the community.

Sources of CSM Information

- "Conceptual Site Model Checklist" (Appendix B)
- *Vapor Intrusion Guidance* (NJDEP October 2005b)
- *Collecting and Interpreting Soil Gas Samples from the Vadose Zone: A Practical Strategy for Assessing the Subsurface Vapor-to-Indoor Air Migration Pathway at Petroleum Hydrocarbon Sites* (API 2005)

The CSM is a dynamic tool to be updated as new information becomes available, and therefore it should be amended, as appropriate, after each stage of investigation. It is especially important that the site be reasonably well characterized for the purposes of sampling plan development. The updated CSM should then contain the following information:

- Types of volatile COCs (e.g., chlorinated solvents, gasoline, jet fuel, diesel) currently or previously stored or handled at the site
- COCs and their concentrations in soil and groundwater—the future use of the data and the regulatory requirements that will be applied to the data are used to determine the appropriate laboratory analytical methods

Electronic Filing: Received, Clerk's Office 07/01/2024

- Potential sources and source areas of vapors (e.g., soil; groundwater; nonaqueous-phase liquid [NAPL])
- Geology and hydrogeology in the area of the site
- Approximate location of vapor sources in the subsurface and the distances (lateral and vertical) between the sources and the building
- Current subsurface soil gas–to–indoor air migration routes (e.g., utility conduits, sewers, diffusion through vadose zone soils, see Figure 2-1)
- Construction features of existing buildings (e.g., size, age, presence of foundation cracks, entry points for utilities, and number of distinct enclosed units)
- Potential future uses for undeveloped lands based on municipal zoning laws

Appendix D of the USEPA draft vapor intrusion guidance (USEPA 2002b) explains the relationship of the CSM to the USEPA data quality objective (DQO) process.

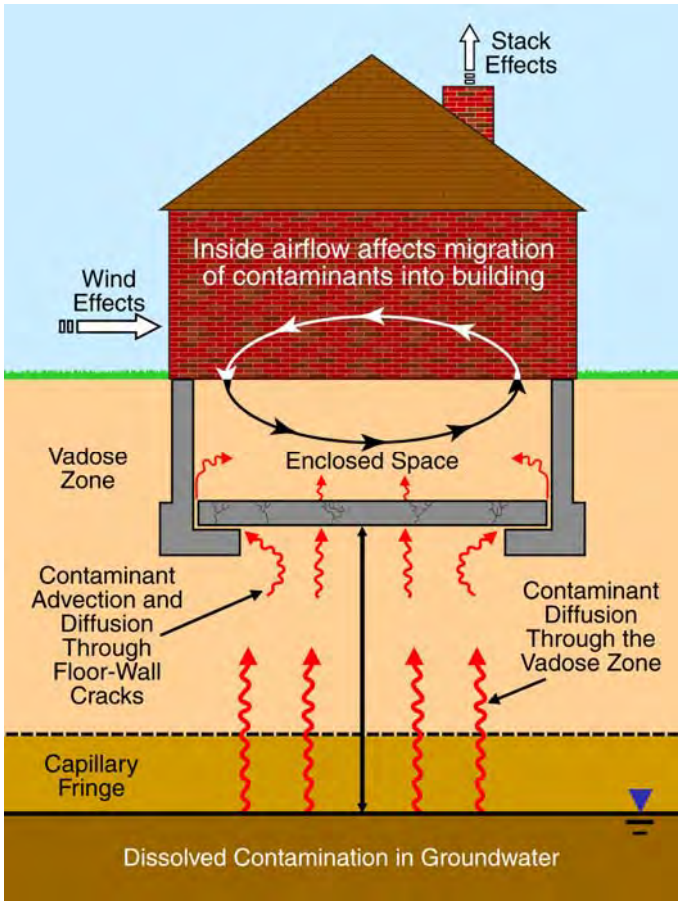

Figure 2-1. CSM illustrating vapor intrusion from groundwater contamination.

2.2 Preliminary Screening Steps

The preliminary screening process presented below comprises seven specific steps to initially assess a contaminated site. Even after the preliminary screening phase is completed, the investigator is advised that data collected in subsequent rounds of investigation may necessitate revisiting these screening steps. Thus, the iterative process discussed earlier in the document is reflected even in the preliminary stages. Refer to the preliminary screening flowchart (Figure 2-2) for additional guidance.

- Step 1: Does the site represent an acute exposure concern?
- Step 2: Are there sufficient characterization data to evaluate this pathway?
- Step 3: Are any of the site COCs both volatile and toxic?
- Step 4: Are buildings located in close proximity to volatile chemicals in soil, soil gas, or groundwater?
- Step 5: Identify the appropriate occupant exposure scenarios and generic screening levels for this site.
- Step 6: Do the data exceed the appropriate generic screening levels?
- Step 7: Does an exceedance of the generic screening level warrant further investigation?

Electronic Filing: Received, Clerk's Office 07/01/2024

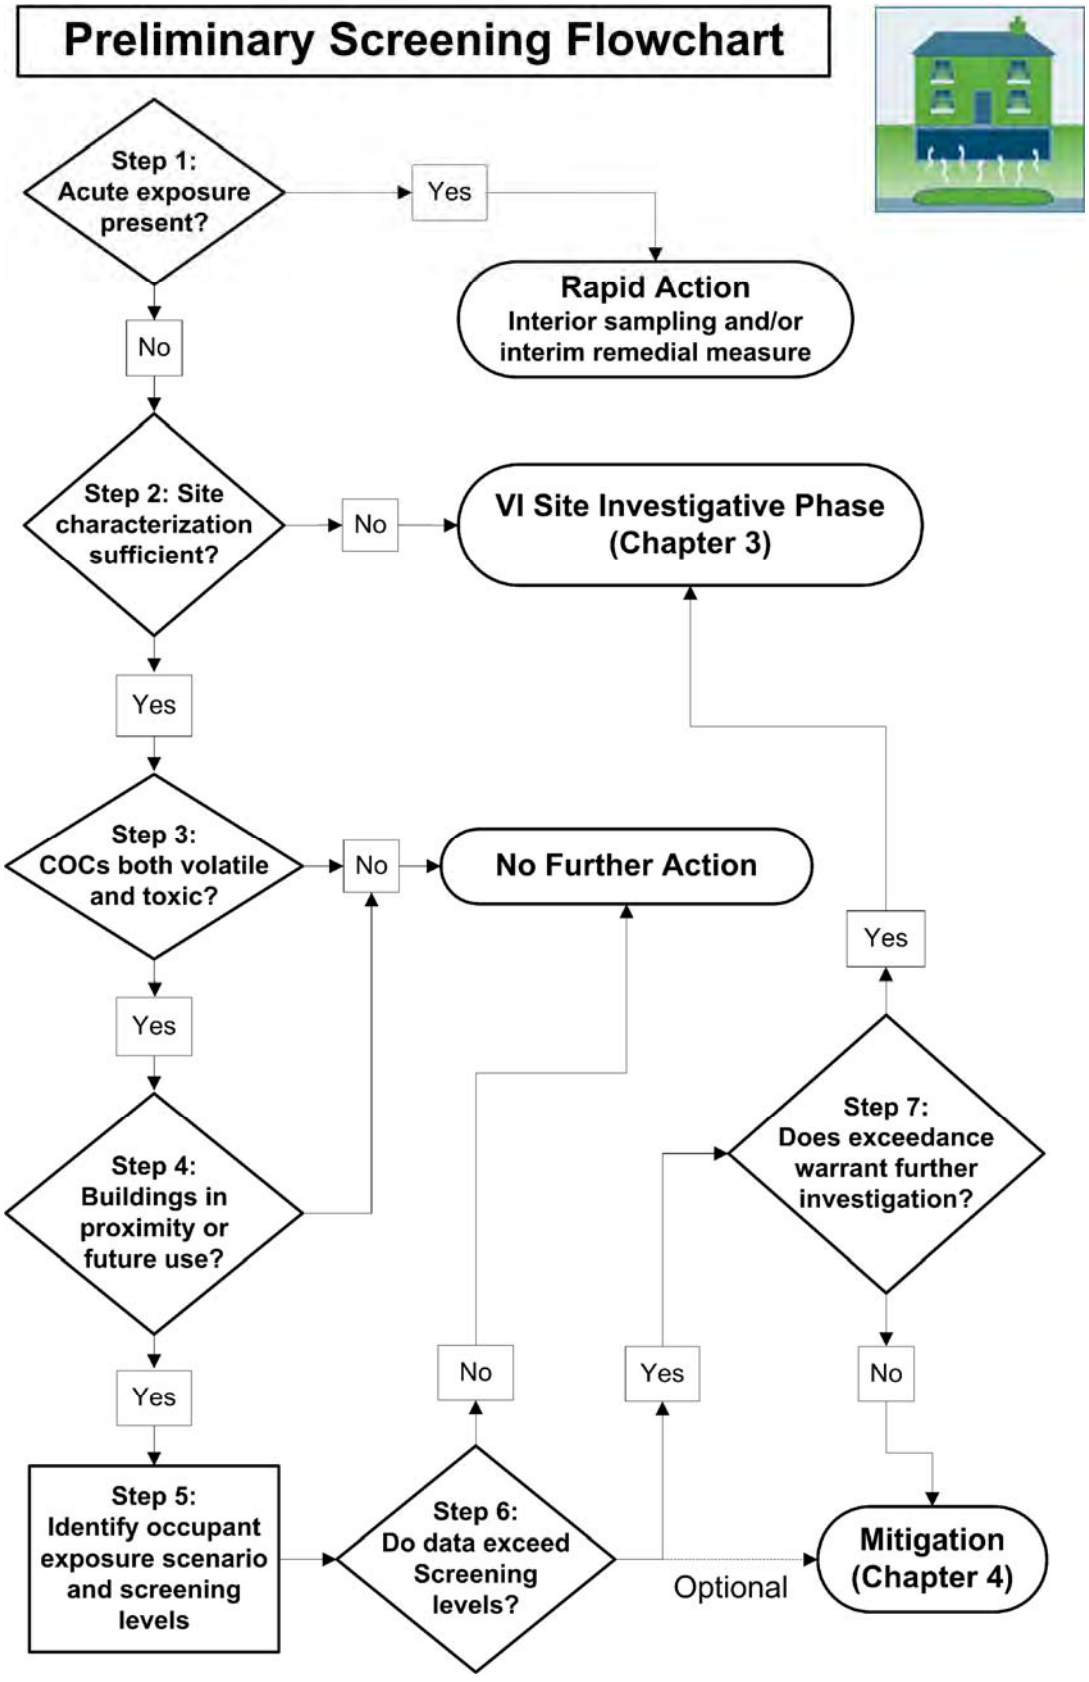

Figure 2-2. Decision-making process for VI preliminary screening.

Electronic Filing: Received, Clerk's Office 07/01/2024

2.3 Step 1: Does the Site Represent an Acute Exposure Concern?

When an acute or emergency hazard resulting from vapor intrusion is suspected, the initial priority should be the immediate safety of the building occupants. Unless the indicators are unambiguous in nature (odors, physiological symptoms, etc.), it is unlikely that a significant decision such as evacuation could be made without interior measurements (subslab soil gas and/or indoor air samples). The judgment to conduct an interior investigation should be made on a site-specific basis. Each regulatory agency has its own preferences as to when subslab soil gas and indoor air sampling is warranted.

If the prompt collection of interior samples is warranted, several sampling techniques may be employed to make an acute/emergency decision. An investigator may choose to use a photoionization detector (PID), combustible gas indicator (CGI), or similar field screening device to determine whether volatile gases are present at substantial levels that could indicate an immediate hazard. Other investigative methods may be preferable to obtain more accurate determinations of VOC concentrations.

Conversely, it may be determined an interim remedial measure (IRM) would either remove the receptors from acute exposure (e.g., evacuation of the affected buildings) or disrupt the migration route (e.g., subslab depressurization or similar remedial systems).

Whichever option is selected, it must be made on a case-by-case basis, using the agencies' best judgment, and must be done rapidly. In general, vapor concentrations of this magnitude are not common.

As part of the iterative process for the vapor intrusion pathway, the investigator must always consider the potential for acute exposure when evaluating data from any subsequent investigative phases.

2.4 Step 2: Are There Sufficient Characterization Data to Evaluate this Pathway?

Preliminary screening for the vapor intrusion pathway is conducted in the context of the available data. Most contaminated sites fail to have sufficient data at this preliminary stage to conclusively eliminate the vapor intrusion pathway. Alternately, the data may not meet the quality assurance/quality control (QA/QC) level required by the regulatory agency. The investigator must determine whether adequate investigation has been conducted to identify all COCs and at their highest concentrations likely present (worst-case pathway or receptor) at the site.

If there are insufficient data to eliminate a site, then additional investigation is warranted. Thus, characterization is called for when the VI pathway may be present or inadequate results are available to make that determination. Supplemental investigation may or may not involve actual media sampling. Chapter 3 provides additional information on the investigative process of site characterization.

Investigate Source
In general, if there are no contaminants of concern at the source (e.g., soil gas at the groundwater table below a building), there may be no need for further characterization. So check the source first!

Electronic Filing: Received, Clerk's Office 07/01/2024

2.5 Step 3: Are Any of the Site Chemicals of Concern Both Volatile and Toxic?

A vapor intrusion assessment typically begins with collecting information about the release. Site assessment reports, interviews with site owners and operators, spill reports from federal and state environmental agencies, and state fire marshal records may contain information and maps about sources. The COCs are typically those compounds that have been used at a site or released into the environment. The project manager should remain cognizant that some volatile chemicals may naturally degrade into other compounds (e.g., trichloroethene [TCE] can break down to vinyl chloride), so the suite of chemicals that are of potential concern may be more extensive than just the compounds released at the site.

Defining "Volatiles"

Regulatory agencies have different ways to define volatile chemicals for the VI pathway.

- The USEPA (2002b) defines volatiles as chemicals with a Henry's law constant greater than 10^{-5} atm m^3 mol^{-1} at room temperature.
- NJDEP (2005b) considers a chemical to be volatile if its Henry's law constant is greater than 10^{-5} atm m^3 mol^{-1} and its vapor pressure is greater than 1 mm Hg at room temperature.

For the most part, only compounds of sufficient volatility and toxicity are a concern for the vapor intrusion pathway. Table 1 of USEPA's draft VI guidance (2002b) lists some of the more common chemicals of sufficient volatility and toxicity. If other volatile chemicals are present at the site, Appendix D of the draft guidance presents an approach to evaluate these chemicals.

In addition, there may be other potentially explosive or toxic chemicals (e.g., methane and hydrogen sulfide) that can represent a subsurface soil gas threat and should be investigated. If the COCs do not meet these criteria, further consideration of the vapor intrusion pathway is not warranted. Otherwise, the investigator moves onto the next step in the preliminary screening phase.

2.6 Step 4: Are Buildings Located in Close Proximity to Volatile Chemicals in Soil, Soil Gas, or Groundwater?

Preliminary screening Step 4 is useful in establishing potential vapor intrusion impact areas around releases. Often, significant contaminant concentrations are found only in relatively close proximity to the original source. USEPA guidance establishes an area within 100 feet vertically or laterally from a volatile concentration of regulatory concern as a potential impact area (USEPA 2002b). Some states have established buffers of 30 feet. Others states, such as New Jersey (NJDEP 2005b), established different distance criteria based on the contaminant type (petroleum versus chlorinated hydrocarbons). Recent work (Lowell and Eklund 2004) suggests that even for sites with the presence of pure petroleum product and contamination a couple of meters below the surface, VOC emissions will tend to be insignificant at lateral distances of about 100 feet transgradient to groundwater flow from a source. Hydrocarbons probably will not migrate as far laterally if oxygen is present. Check with your local regulatory agency as to the applicable distance criterion.

Distance Criterion

USEPA (2002b) suggests that buildings within 100 feet of a contamination plume or source should be evaluated for vapor intrusion unless a significant conduit (preferential pathway) exists, in which case, the area to evaluate should extend to some unspecified distance. States have developed their own distance criterion. Check with the local regulatory agency before evaluating the existing data.

Electronic Filing: Received, Clerk's Office 07/01/2024

At this step, the investigator is assumed to have sufficient information to map the subsurface contaminated soil gas distribution. Otherwise, the site has not been properly characterized (Step 2).

The length of time between the release date and the time of soil gas collection will affect the magnitude of the contaminant concentrations at a location away from a release point. The time required for soil gas to reach near-steady concentrations at any point increases with the square of the distance from the source. Soil gas concentrations measured near a source will in most cases be representative of near-steady conditions. Near-surface concentrations or soil gas concentrations measured several meters away from a source may or may not be representative of near-steady conditions. Additional information can be found in API Publication 4674 (1998).

Answering the Step 4 question requires a judgment call based on confidence in the accuracy of the data and the CSM versus the potential risk to the receptors. Investigators should consider the likely level of heterogeneity and whether or not the applicable distance criteria is conservative, given the site-specific conditions.

Finally, consider the future use of the area under investigation. While the property may be undeveloped at this time, potential developments may expose future occupants to unacceptable risk based on vapor intrusion.

2.7 Step 5: Identify the Appropriate Occupant Exposure Scenarios and Generic Screening Levels for the Site

An evaluation of the vapor intrusion pathway requires consideration of the use of the buildings in proximity of contaminated media (e.g., groundwater, soil, soil gas). For sites that have measurable sources of volatile chemicals and a viable migration route to the building, the ultimate risk decisions may depend on the use of the buildings under current conditions. Future use of current buildings and undeveloped parcels may also need to be considered in light of the probable future exposure patterns.

For preliminary screening purposes, an evaluation of building occupancy scenarios should be conducted. Occupancy scenarios include evaluating building use (e.g., residential, commercial, industrial, schools and day care) as well as potentially exposed populations (e.g., children or adults).

The approach in the USEPA draft VI guidance (2002b) is designed primarily to ensure protection of the public in residential settings but may be adjusted to evaluate nonresidential human exposures which occur in commercial, industrial, and recreational settings. Most state agencies are now making that distinction in their screening levels. According to the Vapor Intrusion Survey (ITRC 2004b), of those states that have developed vapor intrusion screening levels, 69% differentiate between residential and nonresidential values.

It is important to note that exposure to the “general public” in public buildings is usually not the most significant risk driver if there are any full-time workers in the building. USEPA’s draft VI

Electronic Filing: Received, Clerk's Office 07/01/2024

guidance may be interpreted to recommend that people exposed in occupational settings should be evaluated under Occupational Safety and Health Administration (OSHA) using occupational standards rather than by current risk-based screening approaches. This position appears to be going through a reconsideration based on recent draft revisions to the USEPA VI guidance.

Many state agencies now require that occupational exposure be based on risk-based screening values and not OSHA standards when the COCs are not used in the building being investigated. Again, check with your state agency for guidance in this area. In all cases, consider the potential future use of the building, not just the current function.

2.8 Step 6: Do the Data Exceed the Appropriate Generic Screening Levels?

Existing data can be compared to generic screening levels for an initial evaluation to determine whether the pathway is complete and whether there is a potential for risk associated with the inhalation of vapors from subsurface media contamination. The generic screening levels are typically conservative, non-site-specific values. Refer to Appendix H for more information on screening levels.

USEPA included a series of groundwater, soil gas, and indoor air generic screening levels as part of its draft VI guidance (2002b). These values are still being used by the federal government and many state agencies pending revisions in the USEPA guidance document. In addition, numerous state agencies have developed their own generic screening or remediation levels for the vapor intrusion pathway.

At this stage, if the data do not exceed the applicable screening levels, no further action would be warranted (assuming proper characterization has been completed per Step 2). However, an exceedance of a generic screening level generally requires the investigator to move on to Step 7. The one exception may be the option to move directly to mitigation or long-term monitoring.

It should be noted that some state agencies allow modeling of site conditions as part of the preliminary screening to prepare site-specific screening levels.

2.9 Step 7: Does an Exceedance of the Generic Screening Level Warrant Further Investigation?

Exceedance of the applicable screening levels does not automatically mean that a remedial action is appropriate. A determination will have to be made whether additional data are necessary as part of the investigative phase (Chapter 3). Refer to the Preliminary Screening Flowchart (Figure 2-2) for further guidance.

For many regulatory agencies, an exceedance of the state's vapor intrusion criteria simply identifies the need for further investigation (especially at the preliminary screening phase). In fact, 73% of the state agencies surveyed by ITRC in January 2006 acknowledged their criteria as "screening" rather than "action" levels.

Electronic Filing: Received, Clerk's Office 07/01/2024

If there is enough information to confirm VI at a concentration that adversely impacts human health (possible acute exposure), the investigator moves onto the Mitigation Phase (Chapter 4). Otherwise, further characterization is required as part of the Site Investigation Phase (Chapter 3). Of course, the investigator may elect to be proactive and move directly to the mitigation phase at any point in the process, irrespective of the information collected to date.

2.10 Data Usability for Preliminary Screening

In moving from preliminary screening to the investigative phase, it should be clear that the following questions have been answered:

- Have adequate groundwater, soil, soil gas data been collected from the applicable locations?
- Do the results meet the minimum data quality requirements of the DQOs established for the site or of the regulatory agency?

The data usability of the groundwater, soil, soil gas, and/or indoor air results is a critical consideration when making a determination on the vapor intrusion pathway.

3. SITE INVESTIGATION PHASE

This chapter continues the 13-step approach to assessing the vapor intrusion pathway with the site investigation phase. During this phase the majority of the field data are collected according to investigative strategies and work plans developed following early data evaluation.

3.1 Investigative Process

When the preliminary screening phase (Chapter 2) fails to eliminate a site from further consideration of the vapor intrusion pathway, additional evaluation may be conducted during the site investigation phase.

Before conducting a site-specific investigation and evaluation of the vapor intrusion pathway, the investigator must first decide on the general approach (i.e., the information needed and acceptable for determining whether or not the pathway is complete at a specific building or site). Different investigation approaches are available based on the environmental medium being investigated. These distinctive investigation methodologies may be followed in a progressive or phased manner.

As indicated in Table 3-1, each investigative approach has uncertainties, resulting in the potential for false positives (due to conservative assumptions) or the risk of false negatives (if less conservative assumptions are used). Specific investigation tools for each of these media and the advantages and disadvantages of each approach are discussed in more detail in Appendix D. It is common to use several investigative approaches during an investigation. The data gathered from several approaches in the decision-making process is considered as using multiple lines of evidence.

Electronic Filing: Received, Clerk's Office 07/01/2024

Table 3-1. General approaches for vapor intrusion investigations

Media Investigated	Evaluation Method	Principal Issues
Groundwater	Attenuation factor or modeling based on site-specific conditions used to predict indoor air concentration	Imprecision of attenuation factors or modeling requires very conservative assumptions. Henry's law must be corrected for the aquifer temperature.
Soil gas	Attenuation factor or modeling based on site-specific conditions used to predict indoor air concentration	Fewer pathway assumptions required than groundwater, but the accuracy and representativeness of measurements may be an issue
Subslab soil gas	Attenuation factor estimated or measured (e.g., using radon) to predict indoor air concentration	Fewest pathway assumptions required, but intrusive and attenuation factors may still be conservative for many buildings.
Indoor air	Indoor air concentrations directly measured	Intrusive, and background sources may confound data interpretation. Seasonal variations are also an issue.

Many investigators and state agencies prefer to begin the investigation process outdoors (i.e., exterior groundwater or soil gas measurements) in the hope that vapor intrusion can be ruled out without having to test indoors (subslab and/or indoor air samples). An exterior assessment also allows the properties most likely affected to be identified prior to interior sampling. This approach results in less inconvenience to building occupants and avoids the complexities of potential background sources of COCs. For example, if conservative attenuation factors or modeling fail to eliminate vapor intrusion based on exterior data, then interior sampling would be the next step in the areas identified as having the highest soil gas concentrations. Alternatively, preemptive mitigation or other risk management decisions could be based on the results of any of the steps prior to interior testing.

Other investigators and some states prefer going directly to interior testing, combining indoor air and subslab soil gas sampling, or just conducting indoor air sampling. The usual reason given for adopting this approach is concern over the reliability of exterior measurements or assumptions/models used to predict indoor air concentrations versus taking direct indoor air measurements. Perhaps the most reliable approach is to base the investigation and determination of pathway completeness on site-specific conditions and multiple lines of evidence with offsetting strengths and weaknesses.

3.2 Common Vapor Intrusion Scenarios

Innumerable variations of vapor intrusion scenarios are possible, based on the multitude of COCs and sources, geologic and groundwater conditions, and potentially impacted properties and buildings. Differences in these conditions could lead to numerous investigation issues, constraints, and options, all of which impact the investigation work plan and its implementation. While it's impossible to describe each and every scenario that could result from varying circumstances, experience has shown that a few situations tend to occur more frequently than others. Therefore, *Vapor Intrusion Pathway: Investigative Approaches for Typical Scenarios*

Electronic Filing: Received, Clerk's Office 07/01/2024

(VI-1A, ITRC 2007), developed as a supplement to this guidance document, describes six different hypothetical, yet common vapor intrusion scenarios and the investigation approaches that might be followed. Key decision points and alternatives that may be chosen during that stage of the investigative process are identified in the scenarios.

Typical VI Scenarios

The supplement to this document, *Vapor Intrusion Pathway: Investigative Approaches for Typical Scenarios,* discusses the following VI scenarios:

1. Gas station in residential neighborhood
2. Dry cleaner in strip mall located adjacent to neighborhood
3. Large industrial facility with long plume under several hundred buildings
4. Vacant lot with proposed brownfield development over groundwater plume
5. Vacant large commercial building with warehouse space and office space
6. Apartment building with parking garage over groundwater plume

Vapor intrusion investigations can be very complex, and the scenarios are tools in themselves. The main theme of each of the scenarios is to highlight the decision process and the reasoning behind the decision, the selection of a specific tool versus an alternative investigative strategy, and how the tool was used in the hypothetical scenario. Review of the hypothetical case histories presented in the scenarios supplement may help users better understand the nuances of various investigative procedures, particularly for a site similar to one of the six scenarios.

3.3 Site Investigation Phase

For many contaminated sites, assessing vapor intrusion involves collecting additional data to make a determination on the completeness of the pathway. In the Preliminary Screening Flowchart (Figure 2-2), the decision points at Step 2 and Step 7 may lead the investigator to the site investigation phase. In both cases, further investigation is warranted due to insufficient data to properly characterize the site or delineate COCs. The site investigation process presented below continues the progressive approach to assessing a site for the vapor intrusion pathway. It comprises six specific steps to complete the evaluation of a contaminated site:

- Step 8: Choose an investigative strategy.
- Step 9: Design a vapor intrusion investigative work plan.
- Step 10: Implement the vapor intrusion investigation work plan.
- Step 11: Evaluate the data.
- Step 12: Is additional investigation warranted?
- Step 13: Is mitigation warranted?

Each of the site investigation steps (see Figure 3-1) is discussed in greater detail below.

3.4 Step 8: Choose an Investigative Strategy

Before the process can begin, investigators must decide on the technical approach that they believe is acceptable for assessing the vapor intrusion pathway and making risk-management decisions (Step 8). This decision dictates the media to be investigated and the tools that are available. Of course, investigators may have preferences for or against specific tools or evaluation procedures available for each media, as discussed later in this section.

Electronic Filing: Received, Clerk's Office 07/01/2024

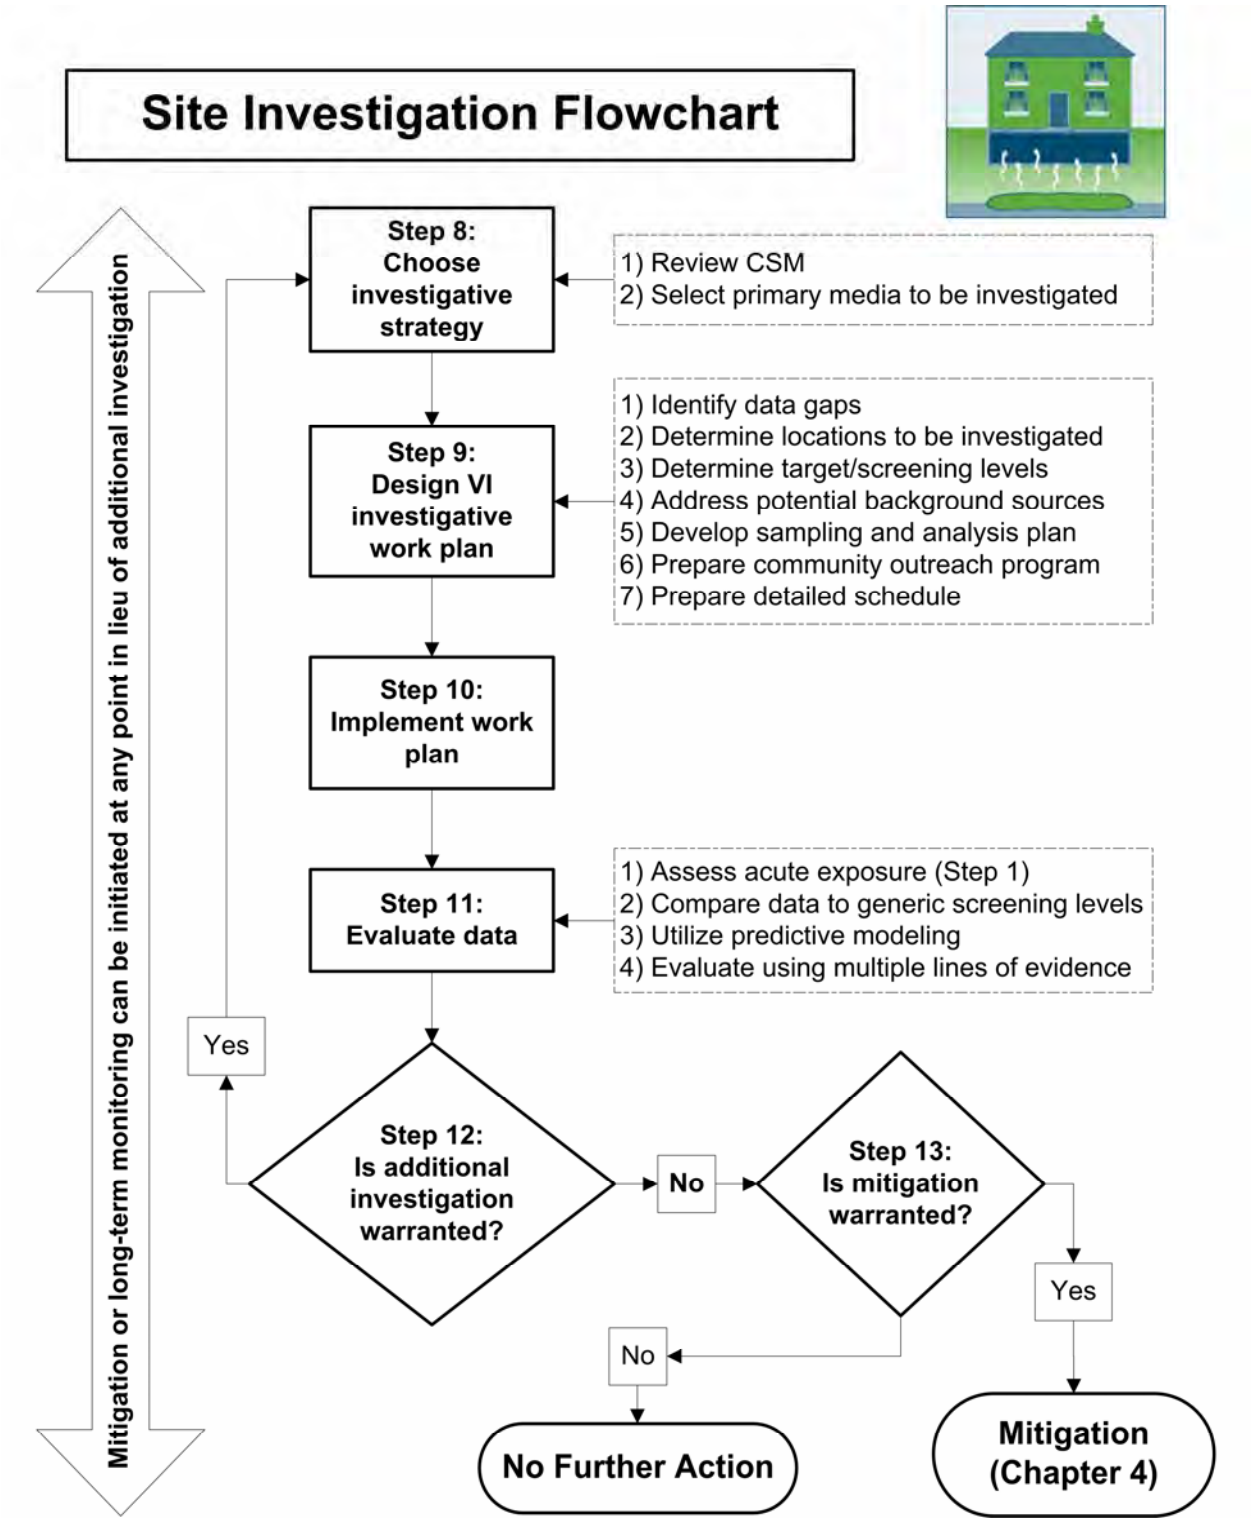

Figure 3-1. Decision-making process for VI site investigation.

The best method for a given application depends on various site-specific factors; therefore, no specific recommendations will be provided here. It should also be noted that strategic approaches

Electronic Filing: Received, Clerk's Office 07/01/2024

can be altered during the investigative phase. For example, the procedures used to determine whether the worst-case building in a group of buildings is impacted may not be the same as those used to determine whether neighboring buildings are also impacted. Thus, the investigative approach used for one site may not be the best for the next site or even the next structure or neighborhood at the same site. Section 3.5.10 discusses in more detail the delineation of the nature and extent of vapor intrusion contaminants.

The investigative processes available for vapor intrusion sites are split into two broad categories—exterior and interior measurements. Supplemental data are used to enhance these two categories. Typically, investigations start with exterior measurements and then move to interior measurements to further evaluate the pathway. The choice of one of these two categories reflects the investigative strategy (Step 8) and should be based on the stage of the investigation and the guidance or policies of the regulatory agency. Appendix D further explains each of the following investigative strategies in greater detail.

3.4.1 Exterior Measurements

Groundwater

Groundwater contaminant plumes migrating under or near buildings may be a source of vapor intrusion. Because of the distance interval between groundwater monitoring wells, it is often necessary during the early stages of a site investigation to estimate the contaminant concentrations at locations that are closer to the building(s) of potential concern. While the concentrations between monitoring wells may be interpolated based on the distance between the wells, it is generally safer to use the higher concentration found in the nearby wells initially to estimate the contaminant levels that may partition into the soil pore space, possibly leading to vapor intrusion. Since water concentrations at the top of the water table are the potential source of vapor partitioning, understanding the well construction and how groundwater samples were collected can be beneficial in making more accurate determinations. The vertical profile of concentrations and water table fluctuations may be necessary data for assessing the potential for off-gassing.

Soil

Soil matrix data are less than ideal for evaluating vapor intrusion risk because of the uncertainty associated with using partitioning equations to calculate soil gas concentrations and the potential loss of VOCs during sample collection. Numerous studies have identified sampling biases, and USEPA (1993a) has determined that the scale of the biases can be as large as several orders of magnitude. Scientific studies have failed to show a good correlation between soil and soil gas sampling and analysis on a consistent basis. Consequently, soil data should be used as a screening or secondary line of evidence in vapor intrusion assessments. Soil data may be available from previous investigations and therefore assist in the development of a CSM (e.g., source location and distribution).

Electronic Filing: Received, Clerk's Office 07/01/2024

Soil Gas

Measurement of soil gas is a common approach around the country for evaluating the vapor intrusion pathway. Soil gas data are reflective of subsurface properties and allow for real-time results. Risk-based screening levels for soil gas are usually higher than indoor air screening levels. Drawbacks to this method include the lack of knowledge of the proper attenuation factor to apply when interpreting soil gas data; debate over the number, location, and method of sample collection; and uncertainty over temporal and/or spatial variations in soil gas concentrations. Soil gas data are recommended over other data, specifically soil matrix and groundwater data, because soil gas data represent a direct measurement of the contaminant that can potentially migrate into indoor air.

Two methods are available to measure soil gas contamination in the unsaturated zone, active and passive soil gas sampling. More details of the soil gas measurement methods can be found in Appendix D.

Soil gas samples can be further differentiated by the location of the samples. Near-slab soil gas samples are collected outside a structure but within a short distance (usually 10 feet) of the building's foundation. Soil gas samples collected 10 feet or more from the perimeter of the building are generally referred to as "exterior" samples. Finally, subslab soil gas samples are collected from below the building foundation or slab. This interior measurement is discussed below.

3.4.2 Interior Measurements

Subslab

Subslab soil gas sampling is the preferred approach of many regulatory agencies for investigating vapor intrusion, primarily because of the proximity of the sample location to the receptor and the elimination of background interferences (when proper sampling methods are employed). Subslab soil gas sampling involves collecting soil gas from the space immediately under a slab or basement. It is distinct from shallow (e.g., 5 feet below ground surface [bgs]) soil gas samples that are collected outside and either next to (near slab) or some distance (exterior) from a slab.

Subslab soil gas concentrations, by themselves, do not necessarily indicate the extent to which vapor intrusion is occurring or, if it is occurring, whether vapor intrusion represents a health risk. However, if subslab soil gas concentrations are more than 1,000–10,000 times the target indoor air levels, the probability of unacceptable vapor intrusion is likely sufficient to warrant proactive mitigation without further investigation. Conversely, if the concentrations in the subslab soil gas are not higher than the regulatory soil gas screening levels (if available), there may be no further need for assessment. This principle alone may help to constrain the number of properties subjected to costly indoor air monitoring programs.

Electronic Filing: Received, Clerk's Office 07/01/2024

Indoor Air

Measuring indoor air is the most direct approach, but may not be the simplest. It is intrusive, and background contaminant sources in the building must be considered. Many commonly used household products contain some of the same target COCs (e.g., tetrachloroethene [PCE] from dry-cleaned clothes, trichloroethane [TCA] from degreasing cleaners). In some areas, especially urban centers, outdoor ambient concentrations (e.g., benzene) may exceed allowable indoor risk based levels, further complicating this approach. When doing indoor air sampling, a household inventory should be performed to find sources of indoor air contaminants. In addition the occupants should be instructed on appropriate actions that should be taken prior to and during the sampling event. Indoor air sampling may still be the method of choice if the COC is not one commonly found in household products or ambient air (e.g., 1,1-DCE, carbon tetrachloride). Agencies may find that residents prefer indoor air sampling over other investigative methods, and the data can be directly compared to screening values rather than having to be predicted or modeled.

Crawl Space

There are several approaches to investigating crawl spaces that involve collecting either air or soil gas samples using both active and passive methods. Typically, crawl-space air samples are collected following protocols similar to those for indoor air samples for a period of up to 24 hours. Ambient air can confound analytical results because of the uncertainty of outdoor air contribution to the crawl space. Soil gas collection can also be performed in the crawl space by inserting the probe rod or sampling tube horizontally through the crawl-space access ports or vertically through the overlying structure. Additionally, flux chambers can be used to determine the surface flux of the contaminant that may be moving into the crawl space. There are little data available to assess the attenuation from crawl space to indoor air.

Ambient

When indoor air sampling is performed as part of a vapor intrusion study, coincident outdoor ambient air samples should also be collected. Ambient air samples are important to characterize site-specific outdoor air contaminants. Depending on building air exchange rates, contaminants from outdoor ambient air may make up a large percentage of indoor air contaminants. Ambient air typically contains numerous VOCs, such as benzene, PCE, and TCE, that often exceed indoor air risk-based screening levels. Some compounds, however, that are not typically found in ambient air (e.g., vinyl chloride or 1,1-DCE) may be a concern for vapor intrusion studies. For residential structures, outdoor air samples should be collected from a representative upwind location, away from wind obstructions such as trees and buildings. The typical intake would be at about 3–5 feet off the ground (at the approximate midpoint of the ground level of the building) and about 5–15 feet away from the building. For commercial structures, outdoor air samples should be collected in representative locations for the intakes of the building heating, ventilating, and air conditioning (HVAC) systems.

Representative samples should be located to minimize bias toward obvious sources of volatile chemicals (e.g., automobiles, lawn mowers, oil storage tanks, gasoline stations, industrial

Electronic Filing: Received, Clerk's Office 07/01/2024

facilities). Outdoor air samples should be collected and analyzed by the same method as for indoor air samples and generally for the same time periods. Consider collecting basic meteorological data during the sampling event.

3.4.3 Supplemental Data

A number of different supplemental data collection tools may be useful when evaluating the vapor intrusion pathway to further define the site-specific CSM. Some of the available tools are listed below and discussed further in Appendix D:

- emission flux chambers
- determination of slab-specific attenuation using conservative tracers (e.g., naturally occurring radon)
- determination of room ventilation rate using tracers
- indoor/subslab differential pressure measurements
- real-time analyzers
- forensics (e.g., constituent ratios, isotopes)
- meteorological data
- pneumatic testing
- manipulating pressure differentials

3.5 Step 9: Design a Vapor Intrusion Investigative Work Plan

Once the investigative strategy is selected (or established by state policy/guidance), a work plan is developed (Step 9) to assess the vapor intrusion pathway. Key components of any vapor intrusion work plan include updating the CSM, identifying data gaps, addressing background contaminant sources, developing the sampling and analysis plan, formulating a schedule, and preparing a community relations plan.

3.5.1 Conceptual Site Model

As discussed in Section 2.1, the CSM should be considered in the preparation of the vapor intrusion investigative work plan. In addition, any deficiencies in the CSM should be identified as data gaps and incorporated into the work plan. For example, consider whether any geophysical investigative techniques are feasible and whether they would help evaluate site lithology and stratigraphic features prior to additional invasive investigations. Critical components of the CSM include the following:

- the location and nature of the source of COC found in the subsurface
- COC properties, including degradation products, solubility, vapor pressure, diffusivity in air and water, and Henry's law constant
- COC screening levels in indoor air and other media, as applicable
- a basic understanding of lithology and stratigraphic features that influence the occurrence and movement of groundwater, NAPL (if any), and soil gas
- depth to groundwater and groundwater flow directions (including vertical gradients or recharge that might lead to a clean groundwater lens at the water table

Electronic Filing: Received, Clerk's Office 07/01/2024

- general nature and extent of COCs in groundwater and/or soil gas
- locations and depths of major underground utilities (particularly storm sewers)
- potential background sources of COC and typical indoor/ambient air concentration ranges
- locations, ownership, and general use of buildings (current and potential future) within the area potentially impacted

Refer to Section 2.1 for more information on CSM development. In addition, Appendix B contains a CSM checklist that should assist investigators in identifying the key components of a CSM.

3.5.2 Data Gaps

The information in the previous section is required to evaluate the potential for vapor intrusion, regardless of the investigation approach, and constitutes a data gap if not known to a reasonably conservative degree. Additional data gaps may exist based on the selected investigative strategy (Step 8). For example, approaches that rely to at least a certain extent on modeling of groundwater concentrations require site-specific information on the geology and nature/extent of COCs in groundwater below the building of concern. On the other hand, strategies that rely primarily on interior measurements for risk management decisions (including background contaminant sources) may require only general information on the nature and extent of groundwater contamination to help guide the sampling program.

3.5.3 Locations to Be Investigated

The specific properties and/or buildings that require investigation should be identified in the work plan. This is a relatively straightforward decision when only one property or building is of concern (e.g., Scenario 1 in ITRC 2007). However, when a large number of off-site buildings are potentially impacted, selection of the property or building for initial investigations can be more challenging (e.g., Scenario 3, ITRC 2007).

Spatial Patterns
It may be discovered that buildings with a specific design feature may be more susceptible to vapor intrusion and warrant closer attention or proactive mitigation. The building does not necessarily need to be located over the most highly contaminated area.

USEPA's draft VI guidance (2002b) suggests selecting the worst-case building(s)—those most likely to be impacted by vapor intrusion—for the initial investigations. The worst-case building, however, is not always readily apparent due to the large number of factors that contribute to vapor intrusion migration, including COC concentrations in groundwater or soil gas, depth to groundwater, soil types, building construction and ventilation, and groundwater flow direction.

In many cases, it may be appropriate to collect additional groundwater and/or soil gas data to narrow down the area with the highest concentrations before selecting individual properties or buildings for site-specific evaluation (e.g., Scenario 3, ITRC 2007). Select several buildings for the initial investigation to account for uncertainty and ensure that the varying factors potentially affecting soil gas migration are addressed. For example, the building overlying groundwater or soil gas with the highest concentrations, as well as the building with the most susceptible

Electronic Filing: Received, Clerk's Office 07/01/2024

foundation conditions (but not necessarily overlying the highest concentrations) might both be investigated.

At some sites, a statistical approach has been adopted for selecting properties or buildings to begin investigations. Buildings might be selected based on the magnitude of underlying concentrations, with bias toward grid cells overlying higher groundwater concentrations (stratified, systematic sampling approach). This method is most appropriate when concentrations are fairly similar over a broad area and there is little to distinguish the most susceptible building or area. The investigator should work with the community outreach coordinator in these cases since the apparently random nature of properties selected for sampling will raise concerns with the local building occupants.

3.5.4 Background

Background contamination is generally defined by anthropogenic (e.g., soils) or upgradient/upstream sources (e.g., groundwater, surface water). However, background indoor air contamination is everything unrelated to the subsurface soil gas that migrates into a structure. (See Appendix G for important questions to ask during an indoor air sampling program.)

One of the initial steps when conducting an indoor air sampling program is to define which chemicals have been released into the subsurface and which are COCs with regard to the vapor intrusion pathway. These COCs may be both primary chemical constituents and their degradation products. Background indoor air sources of volatile chemicals in residential structures include consumer products, supplies used for personal hobbies, household cleaners, paints, and building supplies. These background sources should be identified and, if practical, removed prior to indoor air sampling. Information on common household products that cause measurable levels of volatile chemicals in indoor air can be found on the National Institutes of Health Household Products Database (http://householdproducts.nlm.nih.gov/) and include the following:

- adhesives (automotive, household, craft, plumbing)
- household cleaners
- lubricants
- bonders
- adhesive removers
- antistatic aerosols
- automotive parts cleaners
- paint strippers
- “spot removers” for fabrics
- jewelry polish
- water repellants
- spray paints
- dry-cleaned materials (e.g., clothing containing residual dry-cleaning solvents)

“Background” Structures

In unique circumstances, investigators can determine indoor background air concentrations as one part of a multiple-lines-of-evidence approach in the assessment of vapor intrusion. Using data from structures of similar construction but located outside the contaminant soil gas or groundwater plume, investigators can compare results with buildings impacted by VI. This is particularly useful in reoccupancy scenarios. For example, at a petroleum hydrocarbon site in Colorado, vapor intrusion caused the evacuation of two schools. Indoor air samples were collected in another school located outside of the influence of the contaminated plume. Following mitigation activities, the students were allowed to return to the formerly impacted school when contaminant concentrations in indoor air were in the range of concentrations detected in the unaffected school.

Electronic Filing: Received, Clerk's Office 07/01/2024

- caulks and sealants
- cosmetics including hair spray, nail polish and nail polish remover, perfume, cologne
- air fresheners and odor eliminators
- insect repellants

As a general rule of thumb, these products should not be used inside the building at least 24–48 hours before and during the indoor air sampling activities, if practical. Investigators should consider the sorptive nature of some materials (e.g., carpeting, drapes, upholstery) to retain VOCs, slowly releasing them to the indoor environment over a period of weeks or more.

Other background sources include outdoor ambient sources such as those related to automotive exhaust, smoking indoors (e.g., benzene) and commonly emitted solvents (PCE, TCE, etc.). Before concluding that a chemical is present only as a result of background contamination, consideration should be given to the possibility that detected non-COC may also be attributed to vapor intrusion from other unknown subsurface sources. The likelihood of this possibility would largely depend on how adequately the nature and extent of contamination has been defined at a site. Subslab sampling as part of the indoor air sampling may also help with identifying chemicals migrating into the structure.

Additional information on background contamination and multiple lines of evidence can be found in Boyer 2004.

3.5.5 Sampling and Analysis Plan

Once the data gaps have been identified and the investigative locations (i.e., properties or buildings) selected, sampling methodologies and DQOs should be developed in conjunction with the preparation of the sampling and analysis plan. Keep in mind this is an iterative process and you may have to continually revise and update your investigative strategy based on new data (e.g., for larger sites preliminary soil gas samples may be used to pinpoint structure sampling). The CSM should be consulted (and updated) in parallel with the sampling and analysis plan.

Sampling plans should be reviewed to ensure that the objectives are consistent with the DQOs for the vapor intrusion pathway. Detection limits associated with the available data should be reviewed to ensure that methods chosen provide sufficient sensitivity to detect volatile chemicals at levels of concern. As previously noted, the CSM and its relationship to the USEPA DQO process are presented in Appendix B of the USEPA draft VI guidance (USEPA 2002b).

The definition of the nature and extent of contamination in groundwater and/or the vadose zone should be assessed to ensure that all COCs and areas of contamination have been identified. Groundwater concentrations should be measured or reasonably estimated using samples collected at the top of the water column from wells screened at or across the top of the water table. Soil gas, indoor air, and ambient sampling should be performed in accordance to any relevant standard operating procedures (SOPs). See Appendix D for information regarding sampling methodologies.

Electronic Filing: Received, Clerk's Office 07/01/2024

3.5.6 Groundwater Sampling Issues

Preferably, groundwater monitoring data should reflect the concentration at the groundwater-vadose interface (top of the water table) as that is the point where partitioning from the groundwater to soil gas occurs. In the event that sampling shows no contamination at the groundwater-vadose interface, the project manager may correctly interpret this as indicating no vapor intrusion risk to overlying buildings unless other sources of the contaminant are known in the vadose zone sufficiently near the building of potential concern.

Surficial recharge that occurs along the predominantly horizontal flow path of a groundwater plume will tend to establish a downward vertical hydraulic gradient and cause the affected groundwater plume to also migrate downward in proportion to the amount of recharge and in relation to total flow in the hydraulic unit. This effect is often referred to as a "diving" or "sinking" plume. While it is most apparent in situations where a groundwater plume has migrated over a significant lateral distance, in some situations plumes may start to dive relatively close to their source area. The value of techniques that sample from the upper horizon (with the zone of seasonal water table fluctuations) of the groundwater cannot be minimized. Where rainfall is abundant, sinking plumes can occur even with dissolved contaminants that are traditionally thought of as "floaters." Targeting collection of groundwater samples from the top of the water table can provide significant data that will drastically reduce the extent of area over which one should consider vapor intrusion to be an issue, regardless of climate (wet, arid, etc.). For additional information, refer to NJDEP 2005b, Chapters 2 and 6.

In practice, many groundwater monitoring wells are screened in portions of the aquifer other than the interface. In addition to not revealing the conditions at the groundwater-vadose interface, purging and sampling these wells results in average contaminant concentrations that may under/overestimate soil gas concentrations and subsequently the vapor intrusion risk. Where possible, groundwater data from a relatively narrow interval across the water table should be used in the vapor intrusion assessment. The California Department of Toxic Substances Control states that a screen length of 10 feet or less will yield representative groundwater data suitable for vapor intrusion assessment (Cal DTSC 2004).

The investigator may be asked to determine whether vapor intrusion may pose a risk beyond the known plume boundaries for groundwater plumes that have not reached steady-state conditions. Information regarding the groundwater flow direction and gradient is often useful in determining the potential for contaminant migration. Groundwater characterization can entail groundwater flow direction; vertical and horizontal gradients, including as appropriate, seasonal variation, tidal influences, and the effects of groundwater withdrawal; the rate of groundwater flow movement; and the integrity of any confining units or other barriers to migration of groundwater. Groundwater movement and its associated impact upon distance from the source to the receptor should be considered. Three factors that affect contaminant levels in groundwater that affects contaminant levels in soil gas are dispersion, dilution, and recharge.

Electronic Filing: Received, Clerk's Office 07/01/2024

3.5.7 Community Outreach and Information Plan

Throughout the process, investigators should keep in mind that vapor intrusion will affect communities and individuals. Learning about vapor intrusion can be stressful. In the scientific world, there are many unknowns. Communities want facts and answers. After being told about the potential for vapor intrusion in their community, homes, and businesses, it is only natural for individuals to be concerned about the air they breathe, their health and welfare, the effect of vapor intrusion on property value, and retaining clean and healthy environments. Investigators must be ready to work with communities and share findings in a respectful, understanding, and clear manner. Thus, it is critical that a community outreach plan be prepared and implemented at vapor intrusion sites. Depending on the size and complexity of the site, the plan can be anything from a one-page contact sheet to a highly detailed plan of action.

Below are some of the most common techniques for raising public awareness at contaminated sites.

- **Holding public meetings**. Public meetings may be required if further characterization is planned at any given site. This is a chance to explain the purpose as well as the potential consequences of the investigation. If there are going to be presentations about specific chemicals and risk, expect questions about how risk is calculated and what the numbers really mean. Remember, it is unrealistic to expect that people will leave the meeting with a clear understanding of the technical and policy issues associated with the site. Vapor intrusion is too "new" and complicated for many members of the general public to absorb the most important lessons in one sitting, even with the best of presentations.

- **Contacting mass media**. The mass media, including newspapers, TV, radio and the Internet, can be a positive tool to let people know about contamination issues. Take time to meet the reporters and share the facts. If there are unknowns, just state that you are unsure of certain issues (and make sure you follow up with them when you get the information). Clearly give the print media no more than three main messages. Take the time to educate the reporter on the key issues. Thus, there will be less chance of inaccuracy or sensationalism quoted in the paper. For a TV interview, consider the amount of time the broadcaster will provide to ensure that the most important message gets through.

- **Establishing Community Advisory Groups.** CAGs are generally small groups of residents who meet regularly with agencies and responsible parties. They have no decision-making authority, but they often prove influential. They provide an opportunity for the public to gradually gain an understanding of the complexities of vapor intrusion investigations. In such settings, initial adversarial relationships usually break down, and community members often come up with constructive advice.

- **Newsletters and Web Site.** An excellent tool for communicating with local residents or workers is to prepare periodic newsletters or establish a Web site with site-related information (e.g., www.redfieldsite.org).

Electronic Filing: Received, Clerk's Office 07/01/2024

Investigators should also develop contingency plans for responding to public concerns as they arise. What if contamination is found in sensitive areas, such as schools or day care centers? If evidence shows that the public has been exposed to levels of contamination in drinking water or air that are considered unacceptable, will there be a way to address their likely demands for an independent health study? What if the groundwater plumes extend farther than previously believed? How are results going to be delivered to the occupants and the community as a whole?

3.5.8 Requesting Access

Effective public involvement is an important part of any environmental investigation, but because vapor intrusion investigations often require sampling near, in, or under the places where people live or work, building trust and cooperation is a critical path item for a successful project. To maximize chances of getting permission to sample in areas where existing data suggest that it should be done, it is necessary to target the outreach. This is usually a difficult, time-consuming process, but it can be made easier by a successful community-wide program of education, as described above. A typical community potentially affected by vapor intrusion contains all types of people with a variety of attitudes. Some people insist that their homes be tested even though they live a good distance from known contamination. Others refuse to permit anything that might show a health risk and/or lower their property values. Some want to cooperate, but they may find that sampling, as proposed, is impractical or inconvenient. Conversely, investigators will meet individuals that are cooperative and friendly, wanting to assist in anyway possible.

Access Issues: Be Prepared

Questions that typically need to be answered:

- Are the occupants owners or the renters?
- Who has the authority at a large commercial structure?
- Who is responsible for any common areas?
- Is access different for invasive activity, such as drilling holes in floors or wells in lawns, versus passive sampling?

Answers may vary from state to state, and in some cases the questions will not get clear answers.

The first stage in gaining permission is to determine who is authorized to give permission. The second stage is preparing materials that explain the purpose and extent of the permission. Any right-of-entry document should be written in plain language, and people should not be asked to authorize anything more than is necessary to conduct the investigation. The final stage, contacting people to gain permission, will vary from community to community. Contact by telephone or by "door knocking" is a matter of discretion. CAGs or local leaders working with the regulatory agency can often advise the best approach. They can also advise whether the outreach team should include speakers of languages other than English. In some communities, it may be best to enlist or hire a community-based organization with a continuing relationship with community members. These groups have experience in assisting with issues of mistrust, risk of deportation, and language barriers. Field personnel should be polite and considerate of the assistance that the homeowner/tenant is providing.

Once contact is made, it's essential that household members understand what is entailed in the investigation. Homeowners are likely to ask numerous questions. Will holes be drilled? Will it be necessary to remove certain household products or recently dry-cleaned clothes (background sources)? Will it be necessary to close up the house or turn on/off heating or cooling systems? Will family members or pets be moved out of the home during the sampling? A good program

Electronic Filing: Received, Clerk's Office 07/01/2024

should figure out how to achieve sampling objectives while minimizing disruption of family life. The same is true in commercial structures. Will the investigation interfere with day-to-day business? Will it scare away customers or clients? Will fact sheets be necessary to inform casual entrants to the property what is going on? How long will it take to get the results, and how will they be communicated?

Finally, it should be clear from the start what the long-term implications of the study are. How many times, over what length of time, will sampling occur? What are the response options if unacceptable indoor air levels are found? Who will pay the costs? When, if ever, will things be back to normal?

3.5.9 Implementation and Scheduling

For vapor intrusion investigations, it is critical that a schedule be developed that coordinates all the various activities necessary to complete the work plan. Since the investigation is likely to involve accessing off-site properties, schedules have to be flexible, adjusting to changes that will happen. Anticipate potential pitfalls and be prepared to resolve them. It is also advisable to develop a decision logic in advance of data collection so there will no arguments over responses in the "heat of the moment."

Some of the activities that need to be reflected in the schedule are as follows:

- regulatory approvals
- permits and local approvals
- community education and access
- scheduling tests and potential logistical challenges
- evaluating data and determining if data are adequate
- reporting and communicating results
- being ready to make risk management decisions

3.5.10 Identifying Impacted Structures

The investigator may first delineate the extent of the subsurface contamination using exterior investigative tools. For a large site involving a significant number of buildings, identify primary, secondary, and tertiary buildings based on the magnitude of groundwater and/or soil gas concentrations. Then, as necessary, implement an interior investigation (e.g., subslab soil gas sampling, indoor air sampling) initially in the primary buildings. Some states may start with an interior sampling effort, targeting a primary, secondary, and tertiary zone, based solely on groundwater concentrations. If some of the primary buildings reveal evidence of unacceptable vapor intrusion, the interior investigation is expanded to the secondary buildings. This approach is referred to as a "step-out process," where buildings adjacent to impacted buildings are investigated in an

Building Triage

Sampling all structures for VI may be impractical for larger sites, so existing data can be used to determine which buildings should be targeted first. The building triage approach involves assessing the magnitude of the subsurface concentrations (e.g., soil gas, groundwater) into zones to assist in targeting initial investigations. The zones are primary, secondary, tertiary.

Electronic Filing: Received, Clerk's Office 07/01/2024

outward, sequential manner until a perimeter with no impacts (or below screening levels) is established.

When vapor intrusion impacts are discovered, there is usually significant pressure from the community and other stakeholders to test and mitigate (or take other appropriate action) as quickly as possible. This should be done, of course, but not at the expense of good science or wise use of resources. For example, testing of a large number of buildings or properties beyond the known area of impact may result in unnecessary tests and wasted time and resources. This is particularly harmful when testing proceeds in the wrong direction due to a lack of data to guide the investigation. Therefore, a step-out process to delineate the impacted area should be developed, at least conceptually, prior to beginning the investigations. At some sites, a two-house rule has been followed—testing does not proceed more than two houses in any direction beyond the buildings known to be impacted. Refer to the Colorado indoor air guidance (CDPHE 2004a) for additional information.

In addition, the approach to the step-out testing program does not necessarily have to be the same as the initial testing program. Once the occurrence of vapor intrusion has been established at the initial building(s), knowledge gained from these investigations may suggest that soil gas tests, subslab soil gas tests, or other approaches may be sufficient to make risk management decisions. Testing of multiple buildings or properties often results in spatial patterns and other data correlations that can be used to evaluate the results of individual tests, potentially reducing the number of tests required to make decisions.

3.6 Step 10: Implement the Vapor Intrusion Investigative Work Plan

Once the vapor intrusion investigative work plan has been approved by the regulatory agency, it's time to implement it. The investigator needs to be prepared to adjust the schedule based on field modifications that are bound to occur. Unlike groundwater investigations where the drilling crew works consistently installing monitor wells until they're done, vapor intrusion investigations are dictated by schedules often outside the control of the field samplers. Off-site access agreements may stipulate specific hours when exterior or interior fieldwork can be completed. Collecting indoor air or subslab soil gas samples is dependent on the occupants' being available to let the field samplers into the building. Since interior sampling may involve either very early morning or late evening hours, field samplers should consider appropriate safety concerns.

Heavy rains can delay the collection of exterior soil gas samples. Thus, the investigator needs to have contingency plans in place to avoid falling too far behind in the schedule. In addition, the investigator must be responsive to the results as they are received, showing flexibility to accommodate stakeholder concerns. Verification testing may have to be implemented immediately to address unexpected data.

3.7 Step 11: Evaluate the Data

Before evaluating the analytical results for chronic risk to occupants, a review of Step 1 from the preliminary screening phase is appropriate. At all stages of the assessment, the investigator has

Electronic Filing: Received, Clerk's Office 07/01/2024

to consider the potential for acute exposure of building occupants to contaminants from the vapor intrusion pathway. Although the potential for acute exposure (Step 1) is minimal, it has to be evaluated whenever additional data are obtained.

Both the preliminary screening (Step 6) and data evaluation (Step 11) stages require the use of various decision-making tools to assess the potential for human health risks. For example, in the preliminary screening step, existing site groundwater data can be compared to generic screening levels as means of evaluating whether subslab soil gas and/or indoor air samples should be collected. Similarly, as part of the data evaluation step, subslab data can either be compared to generic screening levels or used in a predictive model to determine whether indoor air samples should be collected or mitigation measures should be implemented. The regulatory agency should be consulted prior to making decisions from the data evaluation steps.

The three primary decision-making tools discussed below are generic screening, predictive modeling, and data evaluation using multiple lines of evidence. In general, generic screening will most commonly be used as part of the preliminary screening process, while predictive modeling and evaluation of multiple lines of evidence will be used to evaluate data collected during preliminary screening or site characterization phases. In addition, many states use generic screening levels in combination with the multiple-lines-of-evidence approach to make remedial decisions.

3.7.1 Comparison with Generic Screening Levels

In generic screening, it is assumed that all detected volatile chemicals in subsurface media samples above applicable generic screening levels are COCs. The applicable generic screening levels (in those states where they exist) are typically conservative, non-site-specific values. Appendix H provides a more detailed discussion of the types and sources of generic screening levels available.

If all detected chemical concentrations are less than the generic screening levels, no significant human health risks would be expected, and further assessment is not required, as long as the analytical data are sufficient and reliable. While an applicable, generic screening can indicate the absence of unacceptable health risks under many circumstances, the presence of chemical concentrations exceeding the screening levels may not definitively identify unacceptable human health risks (due to the conservative assumptions utilized in developing the screening levels). Due to the generic nature of the screening levels, an exceedance could simply be an indication that further site-specific evaluation is needed. For example, if a review of groundwater (or deep soil gas) data resulted in an exceedance of the screening level, it would be appropriate to collect subslab or indoor air samples for further evaluation.

Mitigation Versus More Investigation

Despite the lack of verifying data, choosing to mitigate based on exceeding generic screening levels may be acceptable as a proactive, protective measure.

Electronic Filing: Received, Clerk's Office 07/01/2024

3.7.2 Predictive Modeling

If any of the data collected during the vapor intrusion evaluation indicate concentrations greater than generic screening levels, predictive modeling may be used to assess whether the subsurface media concentrations are high enough to potentially migrate into overlying structures. Groundwater, soil gas, and subslab data can be used to estimate indoor air concentrations in buildings using vapor intrusion contaminant transport modeling. Alternatively, indoor air samples may be collected to obtain direct measurements of chemical concentrations in indoor air. However, there are typically confounding factors when using indoor air sampling results to assess the likelihood that vapor intrusion is occurring.

Models provide predictive capability, but their reliability is difficult to defend with limited site-specific data (Johnson et al. 2002, Hers et al. 2003). The use of models should be approved by the regulatory agency. It is often be helpful to start with a screening level model using mostly generic and conservative input parameters at the early stages of a site assessment to understand, in general terms, the relative magnitude and significance of vapor intrusion. As additional site information becomes available during the course of the site investigation, these data can be incorporated into the model, yielding progressively more site-specific and typically less conservative results. It is recommended that investigators (working with regulators) determine the critical parameters (Johnson et al. 2002) and conduct sensitivity analysis whenever predictive modeling is employed. The use of extreme and nonrepresentative assumptions is the most common weakness of predictive modeling.

As noted in the Vapor Intrusion Survey (ITRC 2004b), the USEPA spreadsheet version of the Johnson and Ettinger (J&E) model is the most commonly used model for estimating chemical concentrations in indoor air (www.epa.gov/Athens/learn2model/part-two/onsite/JnE_lite.htm). With input of groundwater or soil gas concentrations, the model estimates the associated indoor air concentration. The USEPA J&E model is a simple, deterministic model, having single-point inputs and outputs. It is based on the basic principles of contaminant fate and transport, contaminant partitioning between media, and the physical and chemical properties of the contaminants themselves. The model incorporates both diffusion and advection as mechanisms of transport of subsurface soil gas into the indoor air environment. Diffusion is the dominant mechanism for vapor transport within the vadose zone. Once the soil gas enters into the "building zone of influence," the soil gas is swept into the building through foundation cracks by advection due to the indoor-outdoor building pressure differential. The distance of the building zone of influence is usually less than a few feet. The USEPA J&E model uses the conservation-of-mass principle and is based, in part, on the following assumptions:

- Steady state conditions exist.
- An infinite source of contamination exists.
- Air mixing in the building is uniform.
- Preferential pathways do not exist.
- Biodegradation of soil gas does not occur.
- Contaminants are homogeneously distributed laterally beneath the building.
- Contaminant vapors enter a building primarily through cracks in the foundation and walls.

Electronic Filing: Received, Clerk's Office 07/01/2024

- Buildings are constructed on slabs or with basements.
- Ventilation rates and soil gas flow into the building are assumed to remain constant.

The USEPA J&E model is most suitable under homogeneous site conditions with uniform building construction features. Conversely, the model is weakest under variable conditions and cannot evaluate significant preferential pathways; wet basements; substantial lateral transport of soil gas; tall buildings in cold climates; large buildings with potential localized sources of vapors beneath them; and shallow, fractured-bedrock conditions. Each of these conditions has the potential to significantly increase the rate of vapor intrusion beyond the model's predictions. With an understanding of the above-mentioned limitations and the use of conservative input parameters (see USEPA 2004b for typical parameter ranges and conservative values), the USEPA J&E model can enable users to quickly screen sites for vapor intrusion risk.

To facilitate its use in evaluating potential risk due to the inhalation of vapor in indoor air, USEPA has programmed into the J&E model a health risk component that calculates the human health risk from inhaling a specific chemical at the concentration estimated in indoor air. An updated version of the spreadsheet will soon be released that offers significant advantages over versions released in 2001 and 2003. The spreadsheets allow the use of either groundwater or soil gas data; soil matrix data are not allowed). The spreadsheet contains a number of default parameters that can be changed to site-specific values. Typically, agencies customize the spreadsheet by changing the default values and putting limitations on the parameters that can be changed with site-specific data. When using the USPEA J&E model, the input parameters for a given site must be appropriately conservative and match site-specific conditions. Model details are presented in the USEPA 2004b.

The USEPA J&E model should be used only when site conditions match the model assumptions using reasonable, site-specific, or regulator-approved input parameters (USEPA 2004b). Less used, one-dimensional analytical models are also available to simulate the effects of biodegradation, source depletion of contaminants in soils, and various building construction types, such as crawl spaces. Although not included in the current (2004) version of the USEPA J&E model, future revisions are expected to include an option for evaluating buildings with crawl spaces (i.e., dirt floors). For more complex sites, multidimensional numerical models can evaluate spatial and temporal processes in the vapor intrusion pathway.

3.7.3 Evaluation of Indoor Air Data Using Multiple Lines of Evidence

Indoor air data may be collected from existing buildings at any time during a vapor intrusion evaluation. For some states, it is recommended that indoor air samples be the primary sample media and basis for evaluating vapor intrusion. In other states, indoor air sampling is not recommended or is collected as the final data type in the evaluation of vapor intrusion, if warranted based on exterior and/or subslab soil gas data. For instance, if the cumulative health risk using soil gas data and an attenuation factor calculated using the USEPA J&E model for a future building scenario is considered unacceptable, institutional or engineering controls may be warranted. If the cumulative health risk for an existing building scenario is considered unacceptable, the model results can be verified by collecting subslab and/or indoor air samples.

Electronic Filing: Received, Clerk's Office 07/01/2024

If measured indoor air concentrations are greater than the screening levels, it is necessary to assess whether the measured chemical concentrations are due to subsurface vapor intrusion, interior background sources, or ambient outdoor air.

Background Concentrations

A complicating factor in evaluating the potential for vapor intrusion using indoor air data is the potential presence of some of the same chemicals at or above background concentrations separately or in combination with chemicals that may be associated with vapor intrusion. There may be multiple sources of chemicals in indoor air that are not associated with the investigated chemical release (from the ambient air and/or background sources in the building). These other sources may confound the interpretation of indoor air samples results. Thus, attribution of measured chemicals in indoor air can become a relatively complex and difficult task.

When volatile chemicals with multiple potential sources are measured in indoor air, it may be necessary to gather multiple lines of evidence to support a remedial decision either to include or exclude certain chemicals from the risk evaluation. The premise is that if it can be demonstrated through multiple lines of evidence that an indoor air concentration above a remediation goal is not derived from a subsurface source, no remediation is warranted because the indoor air concentrations are due to background source(s). The more evidence gathered to support such a conclusion, the stronger the justification for the resulting decision. Site-specific decisions should be made as to the number and types of information employed. The use of many lines of evidence may not be required if only a few or even one provide clear evidence of either background or vapor intrusion sources.

It should be noted there is some uncertainty associated with such an assessment, regardless of the number of lines of evidence considered. The relative strength or significance of each line of evidence is also a factor to consider. The importance of a line of evidence based on one or two data points (or sample results) is quite different than that of evidence using 20–30 data points. Decisions should be made based on reasonable and logical professional judgment. Clearly, a successful exit strategy is more likely if a site-specific plan is developed and consensus reached with decision makers prior to implementing the investigation.

The following lines of evidence, listed in no particular order, may be used to identify whether measured indoor air contamination is derived from subsurface impacts or background sources. Other lines of evidence may be available depending on the site-specific circumstances.

Chemicals of Concern

The easiest and probably most important line of evidence is the identification of COCs at the site. Provided sufficient characterization has occurred, the investigator should be able to establish the principal contaminants associated with the original discharge or spill. Using this information, along with any degradation products related to these chemicals, the COCs can be identified. Thus, an investigator can limit the scope of the data evaluation and the analytical parameters for any future sampling events.

Electronic Filing: Received, Clerk's Office 07/01/2024

Building Construction and Current Condition

Information regarding the construction and operation of a building may be used to establish the likelihood of subsurface soil gas entering. For example, if a building's HVAC system generates positive air pressure within the structure, it may be reasonable to conclude that this system will minimize or prevent soil gas from migrating into the building from a subsurface source (if positive pressure is the remedy chosen, see Section 4.3.1.6).

Other building factors that should be considered are age; foundation and slab type; building materials; the presence of sumps, perimeter drains, elevators; the height of buildings (particularly in cold climates); basement details; crawl spaces; vapor barriers or radon remediation systems; and surface cover outside the building. Refer to Appendix C for additional information. Facts regarding the building construction and current condition may help with assessing the potential for soil gas contamination to migrate into a building.

Subslab Data

Soil gas measurements collected from beneath a building will provide a good indication of what volatile chemicals could migrate into it. If COCs in the subslab soil gas or crawl-space vapor samples are not observed to be equal to or higher than indoor air concentrations in the building, it is reasonable to conclude that any measured constituent in the indoor air samples is derived in part from other background sources. (Note: Some structures subslab samples will vary in concentration.) The difficulty with this line of evidence is ensuring that representative soil gas samples are collected from beneath the structure. Since soil gas naturally attenuates to some degree in the migration from the subsurface into an overlying structure, a detection of a chemical in the subslab soil gas sample supports, but does not necessarily confirm, that the chemical observed in indoor air is attributable to the subsurface source. Barometric pressure fluctuations can cause reversible vapor flow and can contribute vapors from interior sources to subslab samples. Thus, other lines of evidence may be important to evaluate to establish the presence of concentration gradients inside and outside the structure.

Constituent Ratios

Evaluating the ratio between concentrations of different COCs in groundwater, soil gas, subslab and/or indoor air may help to identify potential vapor intrusion contributions or to screen out background sources. For many volatile chemicals, the background concentration ratios are distinct from groundwater-derived volatile chemical ratios. This characteristic allows the volatile chemical ratios from other media to be used to eliminate indoor air constituents.

Concentration Ratios of Different Chemicals
Example: If the concentration of TCE is 10 times higher than that of PCE in groundwater, deep soil gas, and/or subslab soil gas but PCE has a higher concentration than TCE in indoor air, it is reasonable to conclude there is an interior or background source of PCE (e.g., dry-cleaned clothes, carpet spot remover). Check with the regulatory agency when using constituent ratios.

It is possible that, even if the ratio analysis suggests that indoor or ambient sources are likely responsible for some of the measured indoor air concentrations, subsurface sources may still be contributing to indoor air concentrations. Conversely, if the ratios of

Electronic Filing: Received, Clerk's Office 07/01/2024

constituents in the indoor air sample are similar to the ratios observed in the subslab soil gas sample, one may conclude that the two are linked and that there is a contribution from the subsurface sources, especially if subsurface concentrations are significantly higher than indoor air concentrations.

Comparison of chemical ratios in groundwater to ratios in indoor air may also be considered. However, these ratios should be adjusted for different relative volatilities of the COC using their Henry's law constants and, if significant, different rates of retardation and/or biodegradation in the vadose zone. The comparison of soil gas ratios to Henry's law adjusted groundwater ratios may be another line of evidence for assessing background contributions or vadose zone sources. It should be recognized that background sources might result in ratios that fall within the range predicted for groundwater or measured in soil gas data. Therefore, ratios can screen out obvious background sources but will not necessarily confirm vapor intrusion or eliminate the potential for background contributions.

The presence of marker chemicals (those constituents that are associated with the subsurface contamination but not typical background air sources, such as 1,1-DCE) in indoor air samples is a good indication that intrusion is occurring and that the observed constituents are derived from the subsurface. The converse assumption may also be true—the absence of a marker chemical in indoor air samples is a good indicator that little to no contamination is coming from the subsurface, suggesting that any air contaminants observed are from background sources. However, this second assumption will depend on the relative abundance, volatility, diffusivity, and reporting limit of the marker chemical compared to other COC.

In theory, if a marker chemical is found in the subsurface and indoor air, the indoor air concentrations of other chemicals can be estimated by multiplying the subsurface concentration ratio (nonmarker/marker) by the indoor air concentration of the marker chemical. If the measured indoor air concentrations of the second chemical are greater than that predicted by this method, the additional amounts found in indoor air may be due to background contributions.

Spatial Correlation

The use of spatial correlation is another tool for differentiating vapor intrusion sources from background. For example, use of COC ratios might eliminate a number of background outliers but still leave buildings with ratios that are consistent with either vapor intrusion or background source. Spatial analysis might show that a cluster of such ratios is consistent with a groundwater plume, whereas in other area buildings the ratios appear to be randomly distributed and are more likely associated with background levels. Also, evaluate the results of the ambient (outdoor) air sample. If the data reveal measurable concentrations of multiple chemicals in ambient air, compare these concentrations and concentration ratios with similar chemicals and ratios in indoor and subsurface soil gas samples.

The spatial distribution of volatile chemicals measured within a building may also help with the identification of the source of the vapor. For instance, concentration gradients or hot spots may indicate indoor air sources. The results of air samples taken in various parts of a building can be reviewed and compared to assess whether there are any contaminant concentration gradients or

Electronic Filing: Received, Clerk's Office 07/01/2024

hot spots among the various floors or rooms in a building. In general, if basement concentrations are elevated above background and there is a decreasing contamination gradient from the source (e.g., basement) area on up, there is a relatively good chance that detected concentrations are due to a subsurface source of contamination. However, it is also possible that other sources (e.g., stored products) may be present in the basement and possibly even in the living area, potentially confounding site-related concentration gradients. Ultimately, though, this approach is both expensive and not very practical.

3.7.4 Assessment of Potential Human Health Risks

Exposure to a volatile chemical due to vapor intrusion does not necessarily mean that health effects will occur. Whether or not a person experiences health effects depends on several factors, including the length of exposure, the amount of exposure, the frequency of exposure, the toxicity of the volatile chemical, and the individual's sensitivity to the chemical. The main concern is whether the chemicals may pose an unacceptable risk of chronic health effects due to long-term exposure. It should be noted that the vapor intrusion pathway may not be the only complete pathway for a particular receptor. Each potentially complete pathway (e.g., dermal contact, ingestion, etc.) may be assessed in a risk assessment prior to determining whether and what remediation may be warranted. Some regulatory agencies may mitigate a structure to interrupt completed pathways, (e.g., install a carbon system on a well or install a subslab depressurization system on the house).

Once the COCs and their representative exposure point concentrations are identified and a risk assessment is determined to be the next step, the potential for significant health risk can be assessed. The identified exposure point concentrations should be used in conjunction with appropriate exposure assumptions to complete a site-specific risk assessment. The risk assessment provides a quantitative estimate of the excess lifetime cancer risk and the potential for noncancer health effects. These estimates are then compared to USEPA and/or state-defined screening levels or are evaluated on a case-by-case basis by the regulatory agency to make a risk management decision to determine whether mitigation measures are needed. When evaluating the potential for human health risk, it is important to note that vapor intrusion may not be the only complete exposure pathway for a particular receptor. A site-specific risk assessment should consider all potentially complete exposure pathways for each receptor to make appropriately protective risk management decisions.

Extensive guidance on conducting risk assessments is available from USEPA and many state agencies. The individual state agencies should be consulted to identify any state-specific guidance and/or regulations that should be addressed. These guidance documents should be consulted when completing a site-specific risk assessment. Some of the primary references that provide guidance for the assessment of risk to public health are USEPA 1989, 1996a, 1996b, and 2002d).

3.8 Step 12: Is Additional Investigation Warranted?

Step 12 highlights the iterative process of the vapor intrusion investigation. Upon execution of the work plan and review of the results, the investigator determines whether the site has been

Electronic Filing: Received, Clerk's Office 07/01/2024

adequately characterized. Have the COCs been properly delineated? Has the potential for vapor intrusion at all possibly affected buildings been assessed? Are there sufficient data to reach a remedial decision at the site?

If the answers to these and similar questions are "yes," the investigator can move on to Step 13. However, if the evaluation of the investigative results identifies data gaps that prevent reaching a final conclusion at the contaminated site, additional investigations are warranted, and the process returns to Step 8 to develop a new work plan for the next round of investigation.

To expedite this iterative process, supplemental stages of investigation can be built into the original work plan to avoid long delays while new work plans are developed and approved by the regulatory agency. For example, a standard investigative approach can be developed for assessing vapor intrusion at each building at a site where a large number of structures may be impacted. This way, the initial investigation can center on the worst-case buildings, with subsequent rounds of sampling targeting adjacent buildings (the step-out process). Keep in mind that subsequent work plans can focus on the scope of work and rely on previously approved methods.

At any point in the process, many state and federal agencies will allow a responsible party to implement a remedial action to address vapor intrusion, even prior to confirming the pathway is complete. This proactive approach can be viewed as both responsive to the concerns of public health and economically rationale when compared to the cost of a full investigation.

Alternatively, the decision may be made to conduct long-term monitoring, particularly for undeveloped parcels, until such time as the vapor intrusion pathway source is remediated or future development will likely introduce receptors (people) that could be exposed to unacceptable indoor contaminants from vapor intrusion.

3.9 Step 13: Is Mitigation Warranted?

If the vapor intrusion investigation is complete, the review of the data must be made to determine whether some form of remedial action is appropriate at the site. Step 13 is the final decision point in the assessment of the vapor intrusion pathway. The investigator must reach a conclusion on the status of the site—no further action, additional monitoring, or mitigation. This decision is often left to the regulatory agency. Mitigation is discussed further in Chapter 4.

4. REMEDIATION

Remediation of vapor intrusion impacts may be required when the results of the site investigation phase (Chapter 3) indicates that indoor air concentrations of volatile compounds exceed screening levels in existing buildings or are likely to exceed screening levels in future buildings. When remedial action is required, a remedy or combination of remedies must be selected, implemented, operated, maintained, and/or monitored to control vapor intrusion until the source of the vapors is eliminated.

Electronic Filing: Received, Clerk's Office 07/01/2024

Remedies may address two possible scenarios: emergencies and nonemergencies. This document focuses on chronic exposure concerns and does not discuss appropriate responses to emergency situations where immediate safety is the primary concern. Remedies can be further separated into three types: sitewide remediation, institutional controls, and building controls. Of these, building control remedies are discussed in the most detail because they are most commonly implemented at sites impacted by vapor intrusion.

4.1 Sitewide Remedies

Sitewide remedies address the source of vapors found in buildings, such as contaminated soil and groundwater, rather than controlling the entry of vapors in buildings. Sitewide remedies may be sufficient in situations where the vapor concentrations in buildings are very low or where source remediation can be conducted very quickly. In most cases, however, sitewide remedies are considered to be the long-term solution to vapor intrusion (and other) impacts, while institutional or building control remedies are considered to be short-term or interim remedies, implemented until the long-term or sitewide remedy is complete.

Sitewide remediation of soil and groundwater contamination may include technologies to reduce contaminant concentrations in soils and soil gas, such as soil vapor extraction, or technologies which would reduce concentrations in the groundwater, such as in situ bioremediation or pump-and-treat remedies. For sitewide remedies to be protective, exposures to unacceptable levels of vapor intrusion must be controlled until concentrations in soil and/or groundwater reach acceptable levels. Therefore, until the remedy has met its cleanup goals, the vapor intrusion pathway must be effectively controlled in all potentially impacted and inhabited structures.

In general, source removal and soil vapor extraction sitewide remedies are likely to have the potential to reduce or eliminate soil gas migration in the short term and thus preempt the need for interim control (e.g., institutional or building control) remedies. Sitewide remedies are not the focus of this document.

4.2 Institutional Control Remedies

In the event that sitewide remedies are not immediately effective in reducing or eliminating the potential for vapor intrusion, institutional controls may be put in place on either an interim or permanent basis to protect human health while longer-term sitewide remedies are being developed and implemented. An example of such a control would be legal actions to limit the use of certain parcels. If risks associated with vapor intrusion were unacceptable for unrestricted use of the property, for example, restrictions could be established to allow only those land/building uses that would be associated with acceptable health risks. These legal actions can take many forms, including restrictive covenants, zoning, excavation prohibitions, and groundwater advisories.

At undeveloped sites, or at sites where land use may change in the future, institutional controls may be necessary to ensure that the vapor intrusion pathway is effectively addressed in the future. Institutional controls at undeveloped sites could include mechanisms to require the preemptive installation of vapor intrusion controls, such as subslab depressurization systems, in

Electronic Filing: Received, Clerk's Office 07/01/2024

new buildings This step would avoid some of the difficulties associated with attempting to predict the potential for vapor intrusion prior to building construction (because soil gas concentrations and distributions might change due to construction of the building). Installation and operation of fans, however, might not be required unless post-construction testing or other evaluations indicated this measure to be necessary.

A significant drawback to institutional controls is that they can be difficult to implement and enforce over time in many states that do not have adequate statutory authority to implement them. Institutional controls that incorporate periodic inspections and monitoring may be required to ensure that engineering controls are operated and maintained over time to retain their effectiveness.

Institutional controls, like sitewide media remedies, are not the focus of this document; however, they are often integral to vapor intrusion remedies. The investigator should refer to other guidance documents that have been developed to address the use of institutional controls as part of environmental remediation.

4.3 Building Control Remedies

Building control remedies are typically required at vapor intrusion sites (in both existing and new buildings) until long-term, sitewide remedies reduce soil and/or groundwater concentrations to acceptable levels. The following sections discuss various vapor intrusion building control technologies, factors affecting technology selection, and design and installation issues.

4.3.1 Building Control Technologies

Several building control technologies are identified below that can reduce or eliminate the potential for vapor intrusion impacts in new and existing buildings. A brief summary of each technology is provided, along with some of the advantages and disadvantages of each system. In addition, a typical range of installed costs for each technology is provided. Because vapor intrusion controls are often added to older buildings, the potential need for and additional costs of lead paint and asbestos abatement should be considered on a case-by-case basis. In some cases, excessive costs associated with these issues could affect technology selection. For a quick summary of the typical attributes of each technology, refer to Table 4-1.

Table 4-1. Comparison of mitigation methods

Technology	Typical applications	Challenges	Range of installed costs*
Passive barrier	• New construction • Crawl spaces • Often combined with passive or active venting, sealing openings in the slab, drains, etc.	• Preventing tears, holes • May not suffice as a stand-alone technology • Some states do not accept • Ensuring caulking seals cracks in floors, etc.	• \$0.50–\$5/ft^2 • Thinner, less-expensive barriers likely to be inadequate
Passive venting	• New construction • Low soil gas flux sites • Should be convertible to active system if necessary	• Relies on advective flow of air due to wind and heat stack effects • Air flows and suction typically far less than achieved by fans	• \$0.75–\$5/ft^2

Electronic Filing: Received, Clerk's Office 07/01/2024

Technology	Typical applications	Challenges	Range of installed costs*
Subslab depressurization (SSD)	• New and existing structures • Sumps, drain tiles, and block wall foundations may also be depressurized if present	• Low permeability and wet soils may limit performance • Otherwise, highly effective systems	• $1–$5/ft^2 • Residential systems typically in the $1–2/ft^2 range
Submembrane depressurization	• Existing structures • Crawl spaces	• Sealing to foundation wall, pipe penetrations • Membranes may be damaged by occupants or trades people accessing crawl space	• $1–$6/ft^2 • Residential systems typically in the $1.50–2/ft^2 range
Subslab pressurization	• Same as SSD • Most applicable to highly permeable soils	• Higher energy costs and less effective than SSD • Potential for short-circuiting through cracks	• $1–$5/ft^2
Building pressurization	• Large commercial structures, new or existing • Sensitive receptors	• Requires regular air balancing and maintenance • May not maintain positive pressure when building is unoccupied	• $1–$15/ft^2 • Heavily dependent on size and complexity of structure
Indoor air treatment	• Specialized cases only	• Typically generates a waste disposal stream • Effective capture of air contaminants may be difficult • Energy-intensive, with significant operation, maintenance, and monitoring burden	• $15K–$25K per application not atypical • Actual costs heavily dependent upon type of technology employed
Sealing the building envelope	• Cracks and holes in existing buildings	• Access to perforations • Permanence	• Highly dependent on the extent of sealing required

*Square footage costs based on building footprint.

4.3.1.1 Passive Barriers

Passive barriers are materials or structures installed below a building to physically block the entry of vapors. Passive barriers ideally cause soil gas that would otherwise enter the building under diffusion or pressure gradients to migrate laterally beyond the building footprint. In reality, it may be very difficult to completely prevent (or even substantially prevent) the entry of vapors into a building by passive barriers alone (see Table 4-2). Therefore, passive barriers are generally not recommended by themselves for vapor intrusion control, although they may enhance or increase the efficiency of other technologies, such as subslab depressurization (SSD) systems.

Table 4-2. Passive barrier pros and cons

Advantages	Disadvantages
• Low to moderate capital cost • No mechanical parts	• Even small holes can render ineffective • Likely not effective without venting • Limited applications for existing structures

Electronic Filing: Received, Clerk's Office 07/01/2024

Most passive barriers consist of thermoplastic or elastomeric flexible membranes or spray-on rubberized asphalt emulsions. In new structures, barriers are placed beneath the floor slab to prevent subslab soil gas from entering the structure through cracks or construction joints in the slab. In existing structures, membranes can be used to retard the intrusion of vapors in crawl spaces or over dirt floors.

To be effective, passive barriers must provide a complete barrier to vapor intrusion since, by definition, passive barriers do not include any active measures to control the movement of soil gas. Even small imperfections in the barriers (e.g., due to holes, tears, or incomplete seals at the footings or pipe penetrations) may provide a significant migration route for soil gas when buildings are underpressurized. Occupants may accidentally penetrate the barrier as part of general building maintenance. No standard criteria have been developed for minimum passive barrier thickness or physical properties, such as puncture resistance and tear strength. Nevertheless, thin polyethylene films (often called "vapor barriers" because they have been traditionally used to prevent moisture from accumulating behind drywall walls) are easily damaged and are unlikely to survive normal construction abuse, even when cushioned by sand (ASTM 1998). Even thicker (e.g., 10–20 mil) polyvinyl chloride membranes are likely to be damaged during construction, particularly if placed below concrete slabs. Workers are likely to step onto and force aggregate and other sharp objects into the membrane and may actually poke holes into the membrane to encourage water drainage during concrete placement and curing. Studies of flexible membrane liners used for liquid containment in impoundments have shown that even placement of sand and other earth materials is likely to cause a certain amount of puncturing.

The potential for punctures may be reduced by using thicker membranes (e.g., 60–100 mil high-density polyethylene [HDPE] or similar materials); thick (e.g., ¼-inch) layers of spray-on rubberized asphalt emulsions; and cushioning materials above and/or below the membrane, such as geotextiles, sand, or fine rounded gravel (pea gravel). Some proprietary vapor barrier products incorporate cushioning, barrier, and sealing material layers in one material. Nevertheless, no specific criteria have been developed for passive vapor intrusion barriers, and some degree of imperfection (e.g., punctures, incomplete seals at seams and edges) should be expected in virtually all applications. The potential for high concentrations of certain chemicals to adversely impact membrane or solvent seam integrity should also be considered.

Key Elements of Passive Barrier Systems

- Do not expect complete elimination of vapors
- Select barriers that are thick enough to withstand normal construction abuse
- Include thorough quality control procedures to minimize barrier damage
- Inspect barrier seals at all edges, penetrations, and seams
- Test barrier integrity and performance after installation
- Have contingencies to enhance passive barriers if not adequate

In addition to specifying reasonably adequate membrane thicknesses, passive barrier designs should include QA/QC plans that address the potential for damage to the membranes during installation, subsequent concrete pours, and building construction activities and protocols for minimizing such damage. Specifications should require thorough inspection of liner seals along all edges and at penetrations, observation during concrete pouring, and detailed procedures for testing the efficacy of the passive barrier after the slab is placed (e.g., pressure tests, smoke tests,

Electronic Filing: Received, Clerk's Office 07/01/2024

post-construction indoor air tests). See ASTM Standard E 1643-98 (ASTM 1998) for more information regarding the use of water vapor barriers, although these standards may not be sufficient to address chemical vapor intrusion or associated low indoor air screening levels.

Figure 4-1. Liquid Boot® being applied during construction. Courtesy LBI Technologies, Inc.

Passive barrier designs that rely on complete elimination of vapor intrusion are unlikely to succeed, for the reasons discussed above. If only low reductions in vapor intrusion rates are required, passive barriers may be sufficient; however, some method of measuring the performance of the passive barrier should be specified, and the design should allow for the addition of venting or other measures to address inadequate performance. In most cases, however, passive barriers without venting layers are not likely to be effective unless subsurface conditions are conducive to natural venting. For example, experience shows that in existing structures sealing alone reduces radon levels only 0%–50%, often due to some points of vapor entry that are obscured from view or have no access. Therefore, in most situations, at least passive venting should be combined with passive barriers, as discussed below.

Estimated costs for flexible membranes range \$4–\$50/m^2 (about \$0.50–\$5/ft^2) of building area. Less expensive (and thinner) materials are probably inadequate to be relied on alone as a passive barrier. Spray-on asphaltic emulsions (Figure 4-1) have been installed for \$21–\$32/m^2 (\$2–\$3/ft^2). Price ranges vary based on several factors, including overall area to be covered, number of protrusions that require sealing, and the material used. The barrier thickness and QC measures likely necessary for a passive barrier design to succeed on its own (e.g., without venting) may well result in costs that exceed the ranges quoted above. On the other hand, when passive barriers simply augment other active systems (see below) and are not required to be 100% effective, costs may be closer to the lower end of these ranges.

4.3.1.2 Passive Venting

Passive venting involves the placement of a venting layer below the floor slab to allow soil gas to move laterally beyond the building footprint under natural diffusion gradients (resulting from the buildup of soil gas below the building) or pressure (thermal or wind-created) gradients. Therefore, passive venting is generally feasible in only new construction (see Table 4-3). Because passive venting relies, in part, on soil gas not entering the building before it can vent laterally, passive vents should be combined with passive barriers, as discussed above. Passive venting layers must be permeable enough to allow unimpeded lateral migration of soil gas. Sands or pea gravel (i.e., nonangular materials that will not damage the membrane) are generally preferred below liners. Nonwoven geotextiles with sufficient vapor transmissivity or geogrids may also function as passive venting materials; however, care must be taken to ensure that

Electronic Filing: Received, Clerk's Office 07/01/2024

concrete and fine-grained soils do not penetrate and block the pores of thin geosynthetic materials. Similarly, no venting media will function properly if saturated by water due to high groundwater tables or surface drainage problems (see Section 4.3.2.6). In addition to the venting layer, perforated collection pipes are typically routed at the periphery or through the venting media to collect soil gas and convey it to an exhaust point outside the building (Figure 4.2). Note that collection pipes are generally not required in the venting layer when active depressurization systems are installed. USEPA 1995 provides architectural drawings of passive venting systems for residential homes, including a drawing showing the additional components needed for activation of a passive system (i.e., the addition of a fan).

Figure 4-2. Passive sump mitigation system.
Courtesy Kansas Department of Health and Environment

Table 4-3. Passive venting pros and cons

Advantages	Disadvantages
• Often applied when vapor intrusion is possible but has not occurred • Can be modified to an active venting system if designed accordingly • More applicable to new than to existing buildings • Avoids the long-term operating and maintenance costs of active venting	• Not as effective as active venting • Ambient temperatures and winds can adversely impact success • Not suitable for existing structures unless very modest concentration reductions are required • Upgrade to active venting likely to be necessary for new structures when large reductions in concentrations (e.g., greater than ~90%) are required)

Passive venting designs rely on natural diffusion or pressure gradients to cause soil gas to migrate to collection pipes and exhaust to the atmosphere. Advective flow due to pressure gradients is preferred over diffusion due to chemical gradients in passive venting systems because significant concentrations of soil gas will have to build up below the building before chemical gradients will result in lateral diffusion of soil gas. The elevated concentrations that drive lateral soil gas migration may also cause vertical migration into the building through any imperfections in the passive barrier (see Section 4.3.1.1). Advective flow will occur if the venting layer is depressurized with respect to ambient or atmospheric pressures outside the building and indoor air pressures.

Passive venting systems rely on natural thermal and wind effects to achieve a lower subslab air pressure relative to indoor and outdoor air pressures. For example, by routing the vent pipe through the heated space of the building, the natural thermal stack effect of the house may create enough suction to depressurize the venting layer and draw soil gas up the pipe. However, air may sink down through vent pipes in air-conditioned houses in the summer (a reverse-stack effect). Wind blowing over the tops of exhaust pipes may also create sufficient suction to depressurize

Electronic Filing: Received, Clerk's Office 07/01/2024

passive venting layers. However, air will not necessarily vent from a passive system at all times; hence the need for a sound passive barrier (see above) without significant leaks.

Passive venting systems generally result in less depressurization and lower air flow rates than active depressurization systems with fans (USEPA 1993b). As a result, passive venting systems require more permeable venting media, more suction pits for a given building area, more distributed collection pipes, and tighter passive barriers than active venting systems, all things being equal. Even so, consistent depressurization of the venting layer should not be expected, and passive venting systems are unlikely to perform as well as active systems in most buildings (USEPA 1993b). In existing buildings, where installation of venting media and passive barriers is generally not practicable (except in crawl spaces), only moderate reductions in vapor intrusion concentrations (30%–70%) are expected (USEPA 1993b). Slightly better but still variable performance is reported for some new construction passive systems, with maximum reductions still no greater than 90% (USEPA 1993b).

Key Elements of Passive Venting Systems

- Generally not adequate for existing structures (except crawl spaces)
- Do not expect complete elimination of vapors
- Should be combined with sound passive barrier
- Venting layer must be highly permeable with distributed collection pipe system
- Allow for addition of fan if necessary to meet performance objectives
- Test system integrity and performance after installation

It may be possible to rely on wind-driven ventilation to augment passive systems, particularly in areas where relatively sustained winds are common. In this case, wind-driven turbines are used to depressurize the pipe and venting layer.

Some jurisdictions may not allow the use of passive barrier designs for vapor intrusion mitigation, preferring to go directly to active designs. However, for new construction sites, where vapor intrusion has only the potential to occur, it may be reasonable to begin with a passive design (saving the cost of fans and electricity) and upgrade to an active system only if necessary. In all cases, criteria should be developed, preferably in advance of construction, for determining when passive systems need to be upgraded to active (e.g., when subslab soil gas exceeds certain concentrations based on conservative, assumed attenuation factors). Smoke or tracer gas could also be injected into the passive venting layer while the building is depressurized through operation of building ventilation fans. The detection of smoke or tracer gas inside the building would then indicate the need for an active system.

Installed passive venting system costs for new structures range \$10–\$50/m^2 (about \$1–\$5/ft^2), not including the cost of a passive barrier (see above). Most of the system cost is associated with the venting media material and installation; collection and riser pipes are generally a relatively small part of the overall cost. Some vendors have developed geosynthetic venting materials that can be applied in strips along foundation walls. In general, for roughly equivalent performance, passive venting systems cost more to install than active venting layers because passive systems rely more heavily on transmissivity of the venting layer and the integrity of the barrier layer to function. Nevertheless, when they perform adequately, passive venting systems lack the long-term operation and maintenance costs of active system fans.

Electronic Filing: Received, Clerk's Office 07/01/2024

4.3.1.3 Subslab (Active) Depressurization

Figure 4-3. Active subslab depressurization system.
Courtesy Kansas Department of Health and Environment

Subslab depressurization (SSD) is widely considered the most practical vapor intrusion mitigation strategy for most existing and new structures, including those with basement slabs or slab-on-grade foundations (see USEPA 1993b). SSD systems function by creating a pressure differential across the slab that favors movement of indoor air down into the subsurface. This is accomplished by pulling soil gases from beneath the slab and venting them to the atmosphere at a height well above the outdoor breathing zone and away from windows and air supply intakes (Figure 4-3). In new construction, SSD systems are similar to passive venting systems except that a fan is used to draw soil gas through the subslab venting layer prior to discharging it to the atmosphere. In existing structures, SSD systems entail the cutting of one or more holes in the existing slab, the removal of a quantity of soil from beneath the slab to create an open hole or "suction pit" (6–18 inch radius), and the placement of vertical suction pipes into the holes. These pipes are then manifolded together and connected to a fan, which draws soil gas from the subslab area through the piping and vents it outdoors.

In new construction, permeable venting layers and passive barriers may be placed under the slab to increase the efficiency of the SSD system, essentially by extending the suction field and reducing the number of suction pits. However, venting layers and passive barriers do not have to be as robust for active SSD systems as they do for passive systems.

Key Elements of SSD Systems

- Most widely applied and effective systems for vapor intrusion control
- Applicable to new and existing construction
- One or two suction pits adequate in most existing single-family homes
- Typically combined with venting layer and passive barrier in new construction
- Performance may be limited by low-permeability subsoils
- May be combined with drain tile or block wall depressurization

Active SSD systems are the most reliable, cost effective, and efficient technique for controlling vapor intrusion in the majority of cases, with concentration reductions in the 90%–99% range (USEPA 1993b) and 99.5% or greater in carefully designed and installed systems (Folkes 2002). Subslab depressurization in the range of 0.025–0.035 inches H_2O is generally sufficient to maintain downward pressure gradients (USEPA 1993b).

Experience has shown that one or two suction pits are adequate to depressurize typical residential homes unless tight or wet soils or unusual foundation conditions inhibit the propagation of the suction field (USEPA 1993b). The suction pit location is usually not critical, but the system may perform better when pits are located near the perimeter of the home, closer to the major air entry routes (construction joints and utility penetrations). In tight

Electronic Filing: Received, Clerk's Office 07/01/2024

soils, more permeable backfill materials around the footings may also allow suction fields to extend further around the slab perimeter (USEPA 1993b).

When present, sumps and associated drain tile systems may also be depressurized. Interior (i.e., inside the foundation wall) drain tile systems can help distribute the suction field under the slab. Since most drain tiles are located near the foundation wall, depressurization of the drain tile should help control vapor entry at the joint between the foundation wall and slab. Depressurization of exterior drain tile systems may also control vapor intrusion around the slab perimeter but may be less effective toward the center of the slab (USEPA 1993b).

Hollow block wall or cinder block foundation walls may act as migration routes for vapor to enter homes, particularly if the holes in the top row of blocks are open. Therefore, mitigation techniques for block wall foundations include sealing the holes at the top, as well as actual depressurization of the block wall (USEPA 1993b). Block wall depressurization is usually combined with subslab depressurization systems. However, because uniform depressurization of block walls can be difficult and, in some cases, cause basement depressurization and enhanced vapor intrusion (or back-drafting of fireplaces and combustion appliances) block wall depressurization is suggested only when subslab or drain tile depressurization prove inadequate to control intrusion (USEPA 1993b).

A number of factors must be considered when designing and installing SSDs to ensure the safe and effective performance of the systems (Table 4-4). It is beyond the scope and intent of this document to provide detailed design and construction standards. However, extensive guidance is available for the design, sizing, installation, and testing of SSDs for radon control in existing homes (USEPA 1993b, ASTM 2002b, MassDEP 1995), new residential construction (USEPA 1994a), and schools and other large buildings (USEPA 1994b). The general recommendations of these guidance documents should be followed for mitigation of vapor intrusion, with appropriate modifications for site-specific conditions and regulatory or building code permit requirements. While these guidance documents were developed specifically for radon control, experience at a number of chlorinated solvent sites has shown that SSDs can also effectively reduce VOC concentrations, achieving the relatively lower mitigation criteria currently in effect for these compounds (Folkes and Kurz 2002). SSDs should be designed and installed by qualified persons, typically consisting of environmental professionals and licensed radon contractors.

Table 4-4. Subslab depressurization pros and cons

Advantages	Disadvantages
• Successful track record of performance, 90%–99% reductions typical, 99.5% or greater reduction possible with well-designed systems • Adaptable technology, applicable to a wide variety of site conditions and geology • Simple gauges show whether the system is working	• Requires periodic maintenance • Wet and low-permeability soils retard soil gas movement • Building-specific conditions may limit options for suction pit, riser pipe, and fan locations

Although the capital cost of this technology is a function of building size and condition, a reasonable estimate of installed capital costs for these units is \$10–\$50/m^2 (\$1–\$5/ft^2). Material costs, especially for residences, are quite low and include little more than the cost of the fan,

Electronic Filing: Received, Clerk's Office 07/01/2024

piping, strapping, and cement. Typical installed costs for SSDs in residential homes range about $1000–$2500, including electrical and mechanical permit fees.

Although the fans for houses are low wattage and rarely require separate electrical circuits, they are commonly installed by an electrician and usually require inspection before operation. Annual operation and maintenance costs for these systems are typically very low. Running a 90-watt fan typically costs less than $100 per year, and most fans have an expected life span of 5–15 years, with a replacement cost of about $100 plus labor.

Commercial/industrial systems may use larger, more expensive blowers, which consume more power, often requiring a separate 120 or 240 V AC circuit.

4.3.1.4 Submembrane Depressurization

Submembrane depressurization (SMD), where a membrane is used as a surrogate for a slab to allow depressurization of the soil, has been demonstrated to be the most effective mitigation method in crawl spaces (USEPA 1993b). Properly installed SMD systems have resulted in concentration reductions of up to 99.5%, similar to SSD systems (Folkes and Kurz 2002). An impermeable membrane covers the exposed dirt surface of a crawl space while the depressurization system withdraws soil gas from beneath the membrane and prevents its intrusion into the space above. Table 4-5 lists the pros and cons of this technology, and Figure 4-4 illustrates its application.

Table 4-5. Submembrane depressurization pros and cons

Advantages	Disadvantages
• Similar to SSD's • Applied in situations (e.g., crawl spaces) where SSD is not practicable • Can be combined with SSD	• Similar to SSDs • Membranes can be easily damaged and must be sealed well at edges to prevent leaks • System needs to be periodically inspected to confirm leaks are not present

Figure 4-4. Crawl-space mitigation using submembrane depressurization. Courtesy Kansas Department of Health and Environment

The membrane must be sealed well along all edges of the foundation wall or footings and to any pipe penetrations through the membrane, with enough slack to prevent tearing of the membrane under stress. Because many homes have furnaces or utilities in the crawl space, it may be necessary to place pads or other protective materials over the liner to allow residents and technicians to access the crawl space without damaging the membrane. Membranes can easily be damaged or lose their seal at the edges; therefore, periodic inspection of membranes (or other performance testing) is important for SMDs.

Electronic Filing: Received, Clerk's Office 07/01/2024

When membranes are placed directly on low-permeability soils, it may be necessary to extend the soil gas extraction pipe to more than one point below the membrane using either a perforated intake pipe or a manifold system with multiple suction points (USEPA 1993b). Nonwoven geotextiles may also help extend the suction field of the system while protecting the membrane from angular objects in the soil. When the system is operating, the vacuum created by the mitigation fan should flatten the membrane against the ground. As for SSDs, USEPA guidance (1993b) for the design and installation of SMDs in crawl spaces is recommended.

Key Elements of SMD Systems

- Most widely applied and effective systems for crawl space homes
- Applicable to new and existing construction
- Suction field extension (e.g., perforated pipe) may be required for tight soils
- Liners should be sealed to foundation walls and footings
- Liners should be protected against damage where access (e.g., to service furnaces or plumbing) is expected
- Performance may be limited by low-permeability subsoils
- May be combined with SSD, drain tile, and/or block wall systems

A variation of this technology involves placing the membrane over the crawl-space surface and using a fan to gently withdraw the air within the space above (crawl-space depressurization). These systems, while presumably effective in venting portions of the crawl space, tend to be less effective than SMD systems at preventing vapor intrusion since subsurface soil gas is not actually removed. Crawl-space depressurization also typically results in higher heating and air conditioning costs. Natural crawl-space ventilation may be an option in warm climates but may result in higher heating costs and problems with freezing pipes in colder climates. The performance of natural crawl-space ventilation is variable, however, and typically does not result in more than 50% reduction in vapor intrusion (USEPA 1993b).

Costs for SMD systems are generally consistent with those of passive barriers and SSD: \$10–\$50/m^2 (\$1–\$5/ft^2). Typical costs for installation of SMDs in residential homes range about \$1000–\$2500. Annual operating and maintenance costs for these systems are similar to those for SSD, though post-mitigation monitoring, inspection, and repair costs may be higher.

4.3.1.5 Subslab Pressurization

Subslab pressurization (SSP) systems are similar to SSD systems except that fans are used to push air into the soil or venting layer below the slab instead of pulling it out. The intention is to increase the subslab air pressure above ambient levels, forcing soil gas from the subsurface to the sides of the building. USEPA 1993b suggests that this technology is most effective in highly permeable soils, where it may be difficult to pull enough air to depressurize the subslab region by SSD. SSP systems are applicable to both existing and new structures (Table 4-6).

Table 4-6. Subslab pressurization pros and cons

Advantages	Disadvantages
• Does not require soil gas to be collected within structure • May be more efficient than SSD in highly permeable soils	• More energy-intensive than SSD • Cracks or slab openings may result in short-circuiting, leading to vapors inside structure • May not be appropriate for tight soils

Electronic Filing: Received, Clerk's Office 07/01/2024

Key Elements of SSP Systems
- Generally less effective than SSD systems
- May be appropriate in high-permeability subsoils
- Higher energy costs than SSD systems

Cracks or openings in the slab or foundation walls could cause short-circuiting of the system so that air forced below the slab reenters the building, potentially pulling in some of the vapors that the system intended to keep out. Since indoor air is typically used to force air below the slab, fans should be equipped with a filter to prevent buildup of debris in the vent system. Other researchers (EPA 1993b) have observed that small pits at the discharge end of the vent system have improved performance of SSP systems; however, this represents yet another design challenge associated with implementing this technology at an existing structure.

Limited cost information is available for SSP systems, but costs are expected to be similar to those for SSD systems: \$10–\$50/m^2 (\$1–\$5/ft^2. Energy costs of a SSP systems are typically higher than those of SSD systems.

4.3.1.6 Building Pressurization/HVAC Optimization

In some instances, it may be advantageous to positively pressurize the building interior (relative to the subslab), thereby preventing vapor intrusion (Table 4-7). This effect is typically achieved through mechanical means and is frequently employed at commercial buildings with "clean rooms" where no amount of outside air (or vapor intrusion) is acceptable. It may be possible to tune the building's existing HVAC system to achieve this positive pressurization, or a new system can be installed. Typically, only small increases in building pressure (e.g., <0.001 inches H_2O) are required to prevent vapor intrusion (EPA 1994b). Building pressurization is applicable to both existing and new buildings, although it may be easier to achieve and more cost-effective in new buildings.

Table 4-7. Building pressurization pros and cons

Advantages	Disadvantages
• Can be applied equally well to both new and existing structures • May be the most effective technology at preventing vapor intrusion	• Generally more costly than other techniques • Regular maintenance and air balancing needed to maintain consistent, positive pressure • Not commonly an option for single-family residences

Positive pressurization of buildings is usually practicable only when the building is relatively tight, i.e., when there are few doors or other openings. Therefore, warehouses with large bay doors are not good candidates for positive pressurization. On the other hand, well-ventilated buildings are less likely to have vapor intrusion problems. Typically, only the lower floor of the building will require positive pressurization, although this will be a benefit only if airflow between floors is limited.

This technology is effective if regular maintenance and air balancing of the system is undertaken. Appropriate pressure tests and monitoring should be incorporated in the design of HVAC remedies for vapor intrusion to ensure that sufficient positive pressures are maintained throughout the areas of the building that could be subject to vapor intrusion.

Electronic Filing: Received, Clerk's Office 07/01/2024

The HVAC systems of many buildings operate during normal working hours and are shut off during the night and on weekends. In these cases, vapor intrusion could occur while the systems are off, contaminating indoor air. The degree of impact on indoor air quality during this time and the length of time the impact persists after the HVAC system is restarted must therefore be evaluated in determining the measure's effectiveness. Further, care should be taken to ensure that soil gas is not simply deflected to adjacent, unprotected areas (e.g., into a strip mall or multiunit commercial facility).

Key Elements of Building Pressurization

- Generally practicable only in commercial buildings
- Requires relatively "tight" buildings to limit airflow and energy costs
- Only the bottom floor (e.g., basement) requires pressurization
- May be cost-effective if existing HVAC equipment can be used without significant modifications
- Energy costs typically increased due to higher replacement-air flow rates

Typically applied to large commercial structures, building pressurization may be the most cost-effective method of vapor intrusion mitigation if the HVAC system already creates positive pressures. In other cases, positive HVAC pressures can be achieved with minor adjustments to existing systems, resulting in small or negligible capital costs but potentially increasing energy costs. The increased energy costs associated with positive HVAC system operation will be building-specific, depending on the additional airflow required to achieve positive pressures and heating and/or air conditioning requirements, but could exceed $\$1/ft^2$ annually. Computer-controlled systems may minimize increased energy costs by limiting the amount of airflow to that needed to maintain positive pressures.

Some new building HVAC systems range in cost $100K–$500K or more, depending on the size and complexity of the structure. Moreover, newer building designs are "tighter" and can be more cost-effectively modified than older structures.

4.3.1.7 Indoor Air Treatment

As an alternative to other forms of vapor intrusion mitigation, air within the structure can also be directed to air pollution control equipment (e.g., carbon adsorption systems) to remove toxic air contaminants from the building interior. This technique is not widely practiced since it encourages the collection of contaminant vapors within the structure and is dependent on the treatment system's uninterrupted performance to protect receptors (Table 4-8). However, it can be an effective mitigation strategy when combined with other techniques to control vapor concentrations in problem rooms. Indoor air treatment is an alternative to whole-building pressurization (see above) when subsurface depressurization and/or pressurization methods are not feasible (e.g., high water tables and wet soils). Indoor air treatment is generally only applied in existing buildings, since more cost-effective systems can generally be installed in new buildings.

Electronic Filing: Received, Clerk's Office 07/01/2024

Table 4-8 Indoor air treatment pros and cons

Advantages	Disadvantages
• Results in the physical removal and disposal of the air contaminant, not simple redirection • Less susceptible to malfunction or leaks than most other technologies	• Less effective than other control methods (when applicable) • Very maintenance-intensive and costly to install and operate • System leaks, should they occur, may result in higher exposures than no control

Depending on the specific treatment method, there may be an ancillary waste stream that requires disposal. In addition, to the extent treatment of air is required, it may be more advantageous to treat the air exhausted from another treatment technique (e.g., SSD) rather than treating the indoor air of a structure. This advantage is associated with the smaller volumetric rate of air that would require treatment with SSD than if the entire indoor space required treatment.

Indoor air treatment is expensive compared to other mitigation strategies. It requires large amounts of energy and/or may present waste disposal concerns. Capital costs in the range of $20K and annual operating expenses of $15K–$20K are not uncommon (ITRC 2003). Operation and maintenance costs for these systems vary by type of equipment but can easily approach $15K–$30K or more, annually.

Key Elements of Indoor Air Treatment

- Less effective than other vapor intrusion control methods
- Expensive to install, operate, and maintain
- Typically generates waste (e.g., spent carbon)

4.3.2 Factors Affecting Building Control Technology Selection

As discussed below, a number of factors may affect technology selection for vapor intrusion mitigation of buildings, including building type and use, foundation type, subsurface conditions, the COCs, and the degree of reduction required.

4.3.2.1 New Versus Existing Buildings

More mitigation options are typically available for new buildings than for existing buildings. In general, subsurface features such as passive barriers and venting layers cannot be "installed" below existing buildings, although depressurization technologies have been shown to work well in existing buildings without the benefit of these features. In addition, the presence of lead paint or asbestos may make more intrusive technologies less cost-effective in older, existing buildings. On the other hand, new buildings may incorporate subslab venting layers, collection pipes, and vapor barriers (membranes) to enhance the performance of SSDs. These features may increase the efficiency of depressurization systems and reduce the number of suction points and fans required to achieve desired performance levels. In some cases, these enhancements may be sufficient to allow effective use of passive mitigation systems, although passive system performance will be case-specific and should be critically evaluated during system design and verified during post-mitigation diagnostic testing (see Section 4.3.3.4). New buildings can also incorporate foundation features that enhance the collection of subslab soil gas, such as conduits

Electronic Filing: Received, Clerk's Office 07/01/2024

through grade beams and foundation walls (thereby reducing the number of required suction points). New construction may also incorporate design features that reduce the potential for building depressurization and/or the "stack effect," such as limiting openings that allow vertical movement of air from floor to floor, ventilation of crawl spaces, installation of HVAC systems that allow positive pressurization (commercial buildings), and outside air supply for gas furnaces and water heaters. Some of these items can be retrofitted into existing buildings. Finally, new buildings can incorporate suction points, collection and riser pipes, and other features into the design, allowing optimal location of systems without the aesthetic problems often encountered with existing buildings.

Therefore, if possible, mitigation should occur at the time that the building is constructed, rather than retrofitted after it is constructed. Such decisions may confront property owners wishing to develop property where contaminated shallow groundwater or soils pose a potential threat to indoor air quality via vapor intrusion. While the owner may choose to wait and test indoor air after the building is constructed, hoping that no mitigation will be needed, it is generally preferable for the owner and responsible parties to agree in advance on building modifications during the design phase. Costs for the mitigation can then be minimized, and it can be better integrated with other building features.

4.3.2.2 Building Size

The building size may have some effect on technology selection and system design, though in many cases larger buildings simply require larger systems, often with greater economies of scale. Larger commercial or industrial buildings, such as warehouses, may be less susceptible to poor indoor air quality resulting from vapor intrusion due to the larger building air volume, higher air exchange rates, open bay doors, positive air pressures (depending on HVAC system operation), and thicker floor slabs. These buildings or portions of these buildings, therefore, may not require mitigation. But office areas with low ceilings and a number of dividing walls may have air exchange rates and volumes that are similar to those of residential homes. So when deciding what type of mitigation is best for the building of concern, thought must also be given to which portions of the building the system must effectively mitigate.

Radon mitigation experience suggests that buildings up to 50,000 ft^2 can be mitigated by SSDs with one suction point, provided that subslab materials are permeable and the suction field is not short-circuited by cracks or other penetrations through the slab (USEPA 1993b). However, in most cases such a large building would likely require multiple SSD suction points and either multiple in-line fans or one larger blower. Multiple suction points can be connected to one large fan or blower on the roof, using interior walls or columns to locate riser pipes. However, joints between slab sections, cracks, and other penetrations through the slab between suction points should be sealed to prevent short-circuiting of the suction field.

Horizontal pipes may allow efficient depressurization and collection of soil gas over large areas below new building slabs. Horizontal pipes may also be drilled below existing large buildings, although the economies of this approach versus multiple suction points should be examined carefully. The potential impact of multiple horizontal drill holes on the foundation integrity of any shallow footings or weight-bearing slabs should also be considered.

Electronic Filing: Received, Clerk's Office 07/01/2024

4.3.2.3 Building Use

Current and likely future building use should be considered when selecting mitigation technologies. Reliance on positive HVAC pressures is more suitable for commercial and industrial buildings than for residential homes because commercial HVAC systems are more readily adapted to provide continuous positive pressures and are more likely to receive routine maintenance and monitoring to ensure that positive pressures are maintained. Buildings that are occupied only for short periods or during working hours may not require the same degree of reduction, depending on the assumptions used to develop risk-based indoor air screening levels, if applicable. Building use may affect how and where mitigation piping is routed. Piping arising from the middle of warehouse areas may be in the way of operations and be at risk from damage caused by forklift or other vehicle traffic. Institutional controls—supplemental to a mitigation system or as the mitigation itself (such as building occupancy or use restrictions)—may also be feasible in commercial and industrial buildings, as long as these also ensure that any change in use will trigger a reevaluation of mitigation requirements.

4.3.2.4 Foundation Type and Condition

Foundation types include basements, crawl spaces, slabs on grade, and any number of combinations of these basic types. Foundation type affects design of only those mitigation systems that function by depressurizing soils below the building. SSD systems can be applied in any situation where a slab overlies soil, while SMD systems can be used in crawl spaces or anywhere that expanses of soil are exposed and future use of the area will not damage the membrane. Many buildings require both SSD and SMD systems, which can often be connected to the same fan.

Subslab features such as grade beams, footings, and foundation walls may interrupt the development of suction fields below the slab, requiring installation of suction points in each area. In some cases, existing drain pipes and sump systems may be used as suction points, sealed, and converted into efficient depressurization systems in existing residential and commercial/ industrial buildings. In rare cases, heating and ventilation ducts may be present below the slab, providing a preferential pathway for vapor intrusion and short-circuiting subslab depressurization fields. Building-specific designs may be necessary to overcome this situation.

Certain building features, such as elevator shafts and sumps, may enhance the potential for vapor intrusion unless properly sealed to prevent entry of both soil gas and groundwater containing VOCs. Elevator operations might enhance building depressurization and increase the rate of vapor entry into the building. Elevator shafts and other vertical conduits might also increase the movement of vapors throughout the building.

The foundation *condition* may also affect mitigation options. Excessive cracks, utility penetrations, or other openings may cause short-circuiting of the depressurization field, limiting the areal influence of a particular suction point. Solutions may include sealing of cracks and penetrations and creating additional suction points for SSD systems. Fieldstone foundation walls may be too permeable for depressurization remedies to be effective without grouting or

Electronic Filing: Received, Clerk's Office 07/01/2024

otherwise sealing the wall. In extreme cases, alternative mitigation strategies may be necessary, such as building pressurization or slab replacement.

The condition of the foundation wall may also affect mitigation techniques. Cinder block foundation walls may provide vapor migration routes through the interconnected voids in the blocks, particularly if not sealed at the top of the wall. Mitigation strategies for such conditions include installation of suction points and depressurizing of the wall, as well as sealing of the openings at the top of the wall. In some homes, dugout basements may have exposed earthen walls. Typically, these must be covered by membranes or walled off to enable effective operation of depressurization systems. Basements with exposed earth or rock floors may require placement of a concrete slab or false floor with a membrane to enable depressurization.

In some cases, crawl-space areas are not accessible for installation of SMDs (Section 4.3.1.4). Options may include digging out the crawl space to allow access, installation of outside air vents to enhance natural ventilation of the crawl space (in warmer climates and where freezing of pipes in the crawl space is not a concern), installation of horizontal soil gas extraction pipes below the crawl space, and positive pressurization of the crawl space to inhibit vapor entry.

4.3.2.5 Soil Conditions

Foundation soil conditions may affect the design of depressurization systems. In the absence of a permeable venting layer below the slab, low-permeability soils restrict the extent of suction fields, increasing the number of suction points required below slabs and membranes. In some cases high-vacuum/low-flow fans may be required. Larger voids or suction pits may also be sufficient to improve SSD system operation in tight soils (Folkes and Kurz 2002).

Depressurization systems are generally very effective in permeable soils; however, large venting layers may require low-vacuum/high-flow fans to move enough air through the system. Fan selection and pipe sizing is discussed in USEPA 1993b and Fowler et al. 1990. The mitigation contractor chosen for the project should have experience installing systems in the type of subsurface soils encountered below the building(s) of concern. In very permeable soils where depressurization is difficult, subslab pressurization (where air is pumped into a permeable layer or natural soils below the slab to create positive subslab pressures that divert subsurface soil gas around the structure) may be more effective (see Section 4.3.1.5 and USEPA 1993b).

4.3.2.6 High Water Table Conditions

Saturated soils may prevent effective depressurization of the subslab region by filling soil pores and making them unavailable for vapor transport. Soils beneath the building can become saturated due to various conditions and may stay wet for relatively long periods. In these situations, it may be necessary to first solve the water problem before addressing vapor mitigation. If the wet conditions are due to a high groundwater table containing volatile COCs, actions directed to keeping the water away from the building must take precedence over intrusion concerns associated with subsurface soil gas.

Electronic Filing: Received, Clerk's Office 07/01/2024

In cases where soils are damp but there is no continuing supply of water, air flow generated by an SSD system may dry the soils out sufficiently to allow effective depressurization. In cases where high water tables are controlled by drain tile or French drain systems, depressurization of the air space in the drain tile may be sufficient to control vapor intrusion (see Section 4.3.1.3). If French drain systems are retrofitted in existing structures, the drain pipes should be sufficiently large to drain the water and still leave a headspace for depressurization.

If high water table conditions are episodic, risk assessments may indicate that occasional loss of vapor intrusion control (due to loss of depressurization) does not result in a significant increase in long-term risk. Alternatively, the SSD system could be augmented by a fan that either ventilates or pressurizes the basement with outside air whenever the sump pump switches on, provided that flooding only occurs during warmer weather.

If dewatering is not practicable, then basement and/or crawl-space pressurization may be the most cost-effective method of vapor intrusion control. However, if water is actually entering the basement or crawl space, pressurization will not prevent direct partitioning of volatile compounds into the basement or crawl-space air, which would then flow into other parts of the building. In these cases, it may be necessary to depressurize the basement or crawl space, although energy costs due to heat loss may be high. In some cases, it may be possible to install a false floor above a slab or earth floor and create a thin venting layer that could be depressurized.

Finally, high water table conditions may be due to “clean water” that is infiltrating the ground after precipitation events. In this case, the water below the floor slab may actually provide a clean water lens that prevents or minimizes vapor intrusion into the building. Therefore, the SSD would need to operate during only low water table periods, when depressurization would be feasible.

4.3.2.7 Chemicals of Concern

The COCs may affect mitigation system design in at least three ways. First, potentially combustible vapors (i.e., those that may approach combustible concentrations) require intrinsically safe blowers and monitoring or alarm systems. Second, certain vapors may cause degradation of membranes, pipes, or the solvents used to join pipes. Third, COC action levels, if any, will affect the degree of concentration reduction required inside the building. Reductions of 80% or less may be possible with passive systems, while higher reductions generally require active depressurization or pressurization systems (USEPA 1993b). Standard radon SSD and SMD systems generally perform well when reductions of up to 95% are required, while more rigorous attention to installation details, enlarged suction pits, and/or increased numbers of suction points and fans may be required for higher reductions (Folkes and Kurz 2002).

4.3.3 Design and Installation of Building Controls

The following sections discuss the general approach to design of building controls, pre- and post-diagnostic testing, and other design issues, including access, owner preferences, lead-based paint and asbestos, and back-drafting potential.

Electronic Filing: Received, Clerk's Office 07/01/2024

4.3.3.1 Design Approach

Design of vapor intrusion controls for new buildings should consider all of the factors discussed in the previous section. Vapor intrusion control requirements should be integrated into the overall building design process as soon as possible, since varying the locations of elevator shafts, basements, and even the building itself might help reduce the risk of vapor intrusion. Foundations can be designed to enhance, rather than inhibit, suction field extension below slabs. Similarly, building pressurization systems can be optimized by designing tighter bottom floors and installing HVAC systems capable of creating and maintaining positive pressures during all seasons. Vapor intrusion control designs should include system layout drawings, minimum material specifications, installation procedures, construction QC procedures, and post-installation testing procedures.

Design of vapor intrusion mitigation systems in existing buildings should begin with a visual inspection of the building. For existing residential homes where SSD systems are applicable and the mitigation contractor is familiar with the houses in the area, this is likely the only step required before installation (USEPA 1993b, Folkes 2002). However, for larger commercial buildings, or if subsurface or building characteristics indicate that an SSD system may not work well, premitigation diagnostic testing may be required (see Section 4.3.3.3).

For most existing residential homes, it is usually sufficient to install a relatively standard system without building-specific designs or premitigation diagnostic tests, relying on the mitigation contractor's experience in the area (USEPA 1993b). While this "standard design" approach allows systems to be installed more quickly (which may be important at larger sites with a number of homes requiring mitigation), some form of post-mitigation testing is required to verify that the standard design is adequate. Experience at the Redfield Site in Colorado indicated that only about 10% of homes requiring a 95% or less reduction in concentration needed adjustments after installation of a standard SSD system, and in most cases these adjustments were modest and inexpensive (Folkes 2002).

For larger, more complex buildings or when visual inspections indicate SSD systems may not function well, detailed diagnostic tests prior to mitigation and prepare building-specific designs may be appropriate. Commercial building owners may provide access only if they can review the mitigation design before it is installed. Some states may also require approval of building-specific designs before installation. Designs may also be needed to apply for preinstallation permits and/or to provide the public opportunity for preimplementation review and comment.

Both the standard design and custom design approaches are effective, but the best approach depends on site-specific circumstances, priorities, and to some extent, the preferences of the regulatory agency and the building owner. Table 4-9 summarizes the advantages and disadvantages of each approach.

Electronic Filing: Received, Clerk's Office 07/01/2024

Table 4-9. Mitigation design approach considerations

Approach	Advantages	Disadvantages
Detailed diagnostic testing and design followed by installation and testing	• Post-installation adjustments less likely to be required • May be more effective for unique building types or unusual conditions • May be more effective when a high degree of reduction (e.g., >95%) is required • May be required if multiple reviewers/stakeholders must agree on design specifics	• Higher initial design and testing costs • More site visits required for design and initial installation • Likely to be more expensive for multiple residential mitigations (it takes longer to install systems via this approach if there are a large number of homes to be similarly mitigated)
Standard system installation based on experience and inspection followed by testing, and adjustments, if needed	• Lower initial design and installation costs • Fewer visits required to install system, less disruption to occupants • A larger number of systems can be installed per time period (although some may require adjustments) • Standard design can be adjusted over life of project based on performance of first group of systems • Most appropriate for homes and when mitigators (and regulatory reviewers) have prior experience with similar homes in the same area	• System adjustments may be required in more homes (most likely a minority of homes, if based on prior experience and standard design adjusted as necessary over life of project) • Costs for system adjustments may result in higher total costs than if these "adjustments" had been initially installed, although making such adjustments may be less expensive than detailed diagnostic testing • Additional post-mitigation tests may be necessary to demonstrate adjusted systems working adequately

4.3.3.2 Owner/Tenant Preferences

While the investigator and regulatory agency may be primarily concerned with the performance, cost-effectiveness, and reliability of any mitigation system, the tenant in the mitigated building must live (or work) with that system, and its owner will want to maintain it investment value, regardless of how many pipes, fans, and holes in the floor are deemed necessary by others. What the tenant and owner prefer, then, in terms of mitigation design features, should be taken into account as they would in any radon mitigation installation. Owners/tenants will often have strong opinions about where fans and piping are located, what level of fan noise is acceptable, how readable different system-operation gauges and meters are, and what quality of construction craftsmanship is satisfactory. If the mitigation contractor is considering an attic location for a fan, owners and tenants will need to be questioned about the current and near-future use of that space. When there are multiple mitigation options (for example, at a large commercial building where the mitigation could be based on SSD or could, alternatively, be an adjustment to the HVAC system to pressurize the building) the responsible party should fairly present the options to the building owner and tenant, explaining the advantages and disadvantages associated with each and describing why the preferred alternative should be the option installed.

Electronic Filing: Received, Clerk's Office 07/01/2024

4.3.3.3 Premitigation Diagnostic Tests

When necessary, premitigation tests can be conducted in existing buildings to measure the potential extent of the suction field for SSD systems. These tests, which are often referred to as "communication" or "suction field extension" tests, indicate whether SSD systems are viable and aid in the selection of suction pit locations and fan size. They may also indicate whether any conditions (soil or building) exist that might preempt the use of active depressurization systems. The test typically involves applying suction to a centrally located hole drilled through the floor slab (using a shop vacuum or a portable radon fan) and observing the movement of smoke downward into construction joints and/or small holes drilled at locations surrounding, but distal to, the suction point. Digital micromanometers or other types of small differential-pressure monitoring devices can also be used to assess the extent to which the suction system can achieve sufficient vacuum. Diagnostics should include testing under stressed conditions, such as during operation of furnaces and vent fans that tend to depressurize the building. In most cases, suction field extension tests are the only premitigation diagnostic testing necessary prior to design and installation of SSD systems (USEPA 1993b).

Suction field extension tests may also be conducted during installation of SSD systems, rather than prior to installation, using the first suction point to apply a vacuum and determine whether additional suction points (and/or larger fans) are required.

In many cases, mitigation contractors have sufficient experience with soil conditions and building types to accurately judge the size and locations of mitigation components. If a large number of mitigation systems need to be installed as quickly as possible, it may be more expedient to install standard systems, test these systems as they are being installed, and, when necessary, enhance or modify the systems to meet performance criteria (see Section 4.3.3.4).

4.3.3.4 Post-Mitigation Diagnostic Tests and System Modifications

Post-mitigation diagnostic tests are generally recommended to ensure that mitigation systems are meeting performance objectives and criteria. Some states have required indoor air tests shortly after mitigation systems are installed to ensure that action levels are being achieved. The number and timing of required tests varies, from a minimum of two (MassDEP 2002) to long-term indoor air testing programs (CDPHE 2004). When only two post-mitigation indoor air tests are performed, at least one of the tests is generally performed during cooler months. Post-mitigation indoor air tests should not be conducted immediately after the system has been installed because time is required for vapors that have already entered the structure to dissipate. Some state guidance documents suggest that indoor air sampling not be conducted for at least 30–45 days after installation and, preferably, during the heating season, although experience at sites in Colorado suggests that indoor testing may be conducted within two weeks of system installation (unless extenuating circumstances suggest waiting for a longer period of time).

In some cases, no indoor air testing is required, and post-mitigation suction field testing is considered sufficient to demonstrate SSD performance, assuming downward pressure gradients are measured or observed at all points over the slab. Post-mitigation suction field extension testing can be conducted immediately after system installation or after a short period of

Electronic Filing: Received, Clerk's Office 07/01/2024

operation. In cases of widespread contamination in the state of New York, indoor testing of a representative number of buildings may be considered (NYSDOH 2006).

When long-term indoor air testing is used to monitor mitigation system performance, other forms of diagnostic testing are generally not necessary (except when action levels are not being achieved). On the other hand, when no indoor air testing is performed, perhaps due to concerns about background sources of contamination, more rigorous suction field testing is warranted.

If post-installation diagnostic tests indicate an inadequate suction field, a number of system modifications or enhancements have been shown to be effective (Folkes and Kurz 2002), including the following:

- improved sealing of cracks, construction joints, loose membrane seals, and other penetrations in slabs or membranes that may be short-circuiting the system (as indicated by smoke tests)
- enlarging suction pits below floor slabs
- extending suction points further under membranes, using a pipe tee, perforated pipe, or nonwoven geotextiles
- adding additional suction points, with or without addition fans
- increasing fan size

4.3.3.5 Access and Scheduling

Whether the structure to be mitigated is a commercial or institutional structure or a private residence, arranging for access to the property can prove difficult. Commercial building tenants may not want construction activities disrupting business operations, and some homeowners may resist granting access to their home for a variety of reasons, including privacy issues. Scheduling indoor tests may also be difficult since access is required for both placing canisters and picking them up 24 hours later. Homeowners will often want to schedule tests before or after work. To address these concerns, it is highly advisable that an access agreement between the property owner and the investigating/mitigating entity be executed.

4.3.3.6 Lead-Based Paint/Asbestos

Depending on the age of the structure being investigated, other environmental hazards such as lead-based paint or asbestos may be present and can potentially delay mitigation activities. Generally speaking, structures built before 1990 may pose a hazard with respect to lead-based paint, while asbestos may be present in buildings built before 1980.

The presence of one or more of these materials may delay construction activities within the structure until the hazard is adequately addressed or the appropriate safeguards are in place. Addressing these hazards adds to the cost of mitigation and may negatively impact the overall project schedule. Fortunately, most SSD systems are installed in basements and crawl spaces and, whenever possible, in unfinished portions of the house, limiting the potential for disturbing lead paint or materials containing asbestos.

Electronic Filing: Received, Clerk's Office 07/01/2024

4.3.3.7 HVAC Issues

When one or more ventilation techniques are used to address vapor intrusion, these systems affect the overall balance of air flow within the structure. If the ventilation equipment and combustion devices within a structure (e.g., furnaces, wood stoves, clothes dryers, and water heaters) are not properly balanced, exhaust gases from the combustion units may collect within the structure. This situation is often referred to as "back-drafting" or "spillage."

In buildings with natural draft combustion equipment, a back-draft test may be indicated prior to installation of mitigation systems involving active ventilation (e.g., SSD). If back-drafting is occurring, it should be corrected prior to installation to avoid safety hazards.

Most residential mitigations utilizing pressurization and/or ventilation techniques add little to the potential for overall building depressurization. Typically, SSD fans operate at low flow rates and induce a minimum pressure differential across the slab. SSD systems should be installed by licensed radon contractors familiar with the potential for back-drafting. Although not currently required of radon contractors, USEPA has *recommended* (USEPA 1993b) that the following procedures be undertaken to investigate the possibility of back-drafting:

- Close all windows and doors, both internal and external.
- Open all HVAC supply and return air duct vents/registers.
- Close fireplace and wood stove dampers.
- Turn on all exhaust and air distribution fans and combustion appliances except the appliance being tested for back-drafting.
- Wait five minutes.
- Test to determine the indoor/outdoor pressure differential in the room where the appliance being tested is located. If the pressure differential is –5 pascals or more, assume that a potential for back-drafting exists.
- To begin a test for actual entrainment of flue gases, turn on the appliance being tested. If the appliance is a forced-air furnace, ensure that the blower starts to run before proceeding.
- Wait five minutes.
- Using either a smoke tube or a carbon dioxide gas analyzer, check for flue gas entrainment near the vent hood.
- Repeat the last six steps for each natural draft appliance being tested for back-drafting. Extreme or unusual weather conditions need to be considered when evaluating these data.

Although cold (outside) air supply vents for gas furnaces or water heaters are typically required by building codes in newer homes, older homes may not have them, resulting in greater negative pressures when furnaces turn on and greater potential for both back-drafting and vapor intrusion. In some cases, providing cold air vents alone may mitigate very minor vapor intrusion problems and in all cases should enhance the performance of SSD systems.

4.4 Operation, Maintenance, and Monitoring

Before or shortly after mitigation systems are installed, a building or site-specific operation, maintenance, and inspection/monitoring (OM&M) plan should be prepared. The plan should

Electronic Filing: Received, Clerk's Office 07/01/2024

identify what must be done following start-up of the system, as well as a schedule for conducting these activities. If a large number of systems are installed (e.g., a multihome vapor intrusion site), a standard OM&M plan could be prepared to cover all of the systems, with house-specific drawings and details contained in an appendix.

Indoor air testing is often part of a long-term performance monitoring program, although long-term indoor air monitoring may not be warranted for every system installed. Once proper operation of the system has been confirmed by physical tests and/or post-mitigation indoor air testing (see Section 4.3.3.4), indoor air testing may be warranted only in instances where the system design was complex or the construction problematic. In situations where premitigation levels were very high, however, more frequent monitoring may be necessary. Long-term indoor air testing could also be considered for a portion (e.g., 10%) of systems as QA check on installation. If, during inspections, the inspector believes that the building foundation or components of the mitigation itself have been modified by the owner/tenant since the last inspection, indoor air or suction field extension testing should be considered to ensure that performance expectations are being realized.

Mitigation systems should be inspected periodically. Maintenance should include a visual inspection to confirm the integrity of the system and (by checking manometer readings) that original suction levels are being maintained. Crawl-space membranes should look as if they are being sucked down against the soil, particularly close to suction points. Suction field extension testing may be warranted if manometer readings indicate reduced suction levels or indoor air tests show increasing trends. SSD system fans generally do not require routine maintenance; however, fans should be replaced as necessary throughout the operating life of the system. Noisy fans typically indicate problems with ball bearings and should be replaced. Routine inspections should also include an evaluation of any significant changes made to the building (e.g., remodeled basement, new floor penetrations, new furnace) that would impact the design of the mitigation system or the environment in which it is operated.

The need for air permits and/or exhaust gas controls for SSDs and SMDs should be determined on a site-by-site basis, in compliance with applicable state or local air quality control regulations. In certain cases, particularly those that involve large numbers of structures requiring mitigation within a certain area or those where the mitigation creates high vapor flux rates, it is possible that redirection of soil gases from beneath the building to the ambient air may result in unacceptably high cumulative air quality impacts at receptor points within the community. In such cases, therefore, it may be necessary to apply emission controls on mitigation systems to reduce the concentrations of VOCs being discharged to the atmosphere. Generally, when there appears to be the potential for unacceptable ambient air impacts, a dispersion modeling analysis of the emissions point(s) may be used to estimate whether resulting ambient air quality impacts exceed applicable state toxic thresholds or other health-based standards. Finally, in rare instances, a community ambient air monitoring network may be established to demonstrate that the local population is not being exposed to unacceptable levels of air contaminants resulting from the vapor intrusion mitigation processes. Evaluation of the issue to date in New York has indicated that a requirement for vapor phase controls on these systems is unnecessary, but ambient air studies are ongoing to confirm this conclusion.

Electronic Filing: Received, Clerk's Office 07/01/2024

4.5. Closure

At most sites, long-term cleanup efforts will eventually reduce volatile compound concentrations in soil or groundwater to levels that no longer result in vapor intrusion impacts requiring mitigation. At this point, vapor mitigation systems could be turned off and/or removed, depending on the preferences of the building owners and obligations of responsible parties. Likewise, institutional controls could presumably be retired. This is what is meant by "closure" in the following paragraphs. For the most part this section refers to active, not passive, systems used to prevent vapor intrusion, although passive system piping could be removed if accessible. Unless there is something to "turn off" and/or take away, the concept of closure is primarily an administrative one.

Regulatory personnel and responsible parties should consider early on in the project how to determine when vapor mitigation is no longer required, as this will affect the type of data that will need to be collected during the operating period of the mitigation system. For example, the decision to stop mitigation could be based on indoor air "confirmation tests," which would be conducted after temporarily shutting down the system. The number, location, and frequency of confirmation tests could be the same as those used to identify vapor intrusion impacts; however, a smaller number of confirmation tests might be justified by an improved understanding of site conditions. In any case, the decision to no longer require vapor mitigation in a building will likely be based first on groundwater, soil, and/or soil gas concentrations, which may indicate that the vapor source has been effectively eliminated. However, just as it is difficult to predict vapor intrusion impacts in any particular building based only on media concentrations, it may also be difficult to predict when subsurface media concentrations have become sufficiently low to curtail vapor intrusion mitigation.

Therefore, responsible parties may wish to develop correlations between subsurface media and indoor air concentrations early on in the project to use as a tool for deciding when to commence closure evaluations, if consistent with applicable regulatory requirements. As long as some form of confirmation testing is eventually conducted to determine whether closure is appropriate, the decision to begin such testing could be based on a conservative but not extreme correlation values. For example, if correlation data indicated that a certain percentage of the homes at a site were not unacceptably impacted by vapor intrusion when groundwater or soil gas concentrations were below a certain level, it might be cost-effective to commence confirmation tests at this level, with the expectation that the same percentage of the time confirmatory results would indicate that continued system operation was no longer necessary to mitigate vapor intrusion. The selection of the media concentration that triggers closure (confirmation) testing is largely a matter of economics and site-specific considerations. The length of time that the media must remain below these levels will also be site-specific decision, based on judgments of whether the media has been permanently remediated and how many environmental measurements over time are needed to demonstrate this condition. Of course, if there is good documentation that the source of the contaminated vapors has been completely cleaned up (e.g., excavation of soils to below detection or conservative vapor intrusion-based screening levels), then no or limited confirmation testing may be warranted. Although the time required for soil gas fluxes to diminish after source removal vary site to site, evaluations by Johnson et al. (2002) indicate that

Electronic Filing: Received, Clerk's Office 07/01/2024

soil gas concentrations (and, therefore, indoor air concentrations due to vapor intrusion) are likely to decrease in a relatively short period of time.

Mitigation systems must be shut down before confirmation tests can be conducted. Indoor air testing of mitigated buildings while the system is in operation cannot indicate whether vapor mitigation is still required. One option may be to turn off the mitigation system for a few weeks and then sample indoor air to determine whether the system is still currently needed. This approach is recommended only if the lines of evidence indicate that short-term exposures to conservatively estimated indoor air concentrations (from vapor intrusion) are not likely to result in unacceptable health impacts and if this approach is acceptable to the building occupants and owners.

Alternatively, subslab soil gas samples could be collected as a surrogate for indoor air tests. Collecting soil gas from immediately beneath the slab will reduce (but not eliminate) the potential impacts of indoor or background sources on measured COC concentrations. However, this approach requires estimation of the slab attenuation factor, as discussed in Appendix D. In some cases, comparison of soil gas profiles with baseline data may also indicate that vapor intrusion is no longer occurring. In the absence of indoor air measurements, however, subslab and soil gas to indoor air attenuation are commonly conservatively estimated. As a result indoor air concentrations and the potential for vapor intrusion based on soil gas and subslab soil gas data may be overestimated.

SSD system exhaust gases or subslab soil gas may be measured while the mitigation system is operating. However, at this point there is little if any information available indicating how well these measurements compare to subslab concentrations when the system is turned off. For example, system exhaust gases may include ambient air from outside the foundation wall, which could dilute the COC concentrations in the system exhaust stream. Subslab soil gas concentrations may be different while the system is operating due to the more rapid movement of the soil gas through the soil. Therefore, investigators may wish to develop data allowing correlations between exhaust gases and indoor air and/or subslab concentrations during the initial investigation and operation and monitoring phases of a site, to provide another potential line of evidence for closure evaluations.

The decision to close vapor mitigation systems may be made on a building-by-building basis or, in some cases, it may be made by testing only worst-case buildings at the site (or in certain areas of a larger site). If the mitigation systems at these worst-case buildings can be closed and there is high confidence in the hypothesis that if these buildings are no longer at risk, other buildings at the site will not be at risk either, then closure decisions for the entire area may be based on the results of confirmation tests for this subset of buildings.

Finally, even if regulators decide that systems may be turned off, some building owners may choose to continue operation of their mitigation systems to provide radon control, or as a preemptive measure to control vapor intrusion due to any sources that might occur in the future. Regulatory agencies may wish to promote the continued operation of vapor mitigation systems by building owners for radon control. However, the responsible party that originally installed

Electronic Filing: Received, Clerk's Office 07/01/2024

and operated the vapor mitigation system would probably not be held responsible for the system under the applicable regulatory program once controls were no longer required.

4.6 Other Issues

In the case of undeveloped or redeveloped property, new construction presents an opportunity to deal with one of the more vexing VI problems: mitigating subsurface conduits that may become migration routes for soil gas. For example, sewer, water, underground cable and electrical lines are often placed on porous gravel or soil to maintain good drainage. Yet this practice also fosters inadvertent vapor transport requiring construction provisions that contain barriers to vapor transport, either through the design of the conduit or the use of nonporous materials. Currently, the National Aeronautics and Space Administration (NASA) requires this for new construction at the NASA Research Park, located at Moffett Field in California.

APPENDIX A

Community Stakeholder Concerns

Electronic Filing: Received, Clerk's Office 07/01/2024

COMMUNITY STAKEHOLDER CONCERNS

This appendix was written by stakeholders who represent communities affected by vapor intrusion to give invesitgators an understanding of the issues building occupants may be concerned with regarding vapor intrusion.

As stated in the text, when communities become aware of vapor intrusion, many concerns are raised involving not only a person's own residence, intrusive sampling, and remedies, but also the air that their children breathe while playing out of doors and at school and secondarily the retention of property values and a clean and healthy environment. At many sites, these issues become "hot button" issues, driving the discussion and sometimes the strategy that regulators will take in addressing vapor intrusion.

Based on discussions and experience of community stakeholders at various sites and the experience of stakeholder team members, the following is a brief description of major concerns that communities, property owners and others have voiced. It should be noted, however, that this list of concerns is not exhaustive. As this issue continues to develop, other issues will undoubtedly arise. It should also be noted that many of the issues below are touched on in the preceding text. However, we believe that it is important to articulate these concerns, as they would be presented from a community's point of view.

- **It is important to develop a complete CSM.** Communities want the CSM to consider all sources, receptors, and migration routes. Often, the conceptual model is restricted because the regulating agency has authority to address only some of the sources and/or migration routes. This problem requires state agencies to work together with city and county health departments, as well as with air quality management districts.

- **The quality of outdoor air is important to consider in the conceptual model and in remedy selection.** Some agencies limit their definitions of vapor intrusion to indoor exposure. To many communities, outdoor contamination through subsurface volatilization or direct discharge into the air is part of the same problem. Most guidance addresses vapors intruding into indoor spaces. Yet children spend long periods of their day in backyards, school yards, and playgrounds. This is an important consideration for communities and should be given attention at many sites. Residents also want to minimize discharges from building ventilation systems and groundwater treatment systems.

- **Communities want health-conservative analysis and standards.** Potentially impacted residents want vapor intrusion investigations and remedies to err on the side of caution. Residents want investigations to use very low screening levels and even to require mitigation and response based on the most stringent standards.

- **Cumulative and synergistic risk from multiple contaminants should be considered.** Often, more than one contaminant is the subject of vapor intrusion. Communities are concerned that the cumulative and synergistic effects of these combinations are not well understood or addressed. When it is not possible to understand or estimate these effects, risk assessment procedures should err on the side of caution.

- **Understanding transformation products and the half-lives of contaminants is often not considered in decision making.** Communities are concerned there is not enough care paid to the transformation products and the half-lives of various contaminants. For example, volatile organic compounds are transformed in groundwater and soil. Likewise, as vapors are exposed to the atmosphere, they are also converted. It is important to fully understand the half-lives of the various contaminants that are in the air, as well as considering all of the transformation products.

- **Screening programs and modeling tools are often suspect.** Initial site screening programs that eliminate sites on the basis of modeling and attenuation factors are not well understood by communities and should be used together with site-specific information. Communities are suspicious of the most common model used (J&E) as it sometimes misses the problem, either from improper use or due to shortcomings in the model. For example, there have been reports that the J&E model does not account for lateral transport of soil gas or directly consider preferential pathways. If the issue of vapor intrusion is raised, site-specific information is often required to allay a community's concerns, regardless of the models used by regulators. In addition, soil gas and groundwater plumes should be fully characterized prior to eliminating sites. There have been instances where the plume definition data indicate that no vapor intrusion could be present (assuming standard attenuation factors and vapor modeling), yet samples taken inside of residences indicate that vapor intrusion has occurred. History has reinforced many communities' distrust of models, and many want direct measurements taken.

- **Indoor air sampling is often desired by communities before a site can be eliminated.** Communities generally question findings of acceptable risk based solely on models. There has been sufficient evidence that indoor air concentrations are sometimes substantially above modeled levels. Recognizing that it would be impossible to test the air of every residence, communities that have any sign of vapor intrusion will often demand that indoor air sampling be done. Some occupants are willing to put up with the inconvenience of sampling, as well as a survey of chemicals within their homes. Indoor air samples should also include those buildings occupied by the most vulnerable among us, including day care centers and schools. Often, communities are asking that every room be sampled because of extreme variations in results due to vapor migration routes.

- **Sampling and analysis procedures should be done as quickly as possible and should follow proper procedures.** Near-real-time or real-time sampling techniques (e.g., trace atmospheric gas analyzer) that help identify sources and migration routes are preferred by community stakeholders. Stakeholders often want to know the results of any tests involving their homes as soon as possible. It's also important that good and consistent practices be followed when conducting indoor air sampling. Sometimes windows have been left open or heating systems turned off when conducting indoor air sampling, both of which cause improper readings.

- **Accelerated remediation is often the best long-term solution for vapor intrusion problems.** In most cases where vapor intrusion is caused by groundwater and soil contamination that is being actively remediated, the long-term solution to vapor intrusion is

to accelerate cleanup. At sites where subslab membranes or soil gas ventilation systems are in place to prevent indoor vapor intrusion, residents do not think of these methods as a long-term solution. Settling, earthquakes, power outages, aging, and new construction at existing buildings are barriers for these mitigation techniques. As long as there is potential exposure, health is at risk. The best way to ensure that subsurface contamination does not enter homes or other structures is to remove and/or destroy the toxic compounds. Historically, this process has been slow and difficult, but vapor intrusion sites are ideal candidates for the deployment of innovative remedial technologies.

- **Monitoring, backed by institutional controls and contingency plans, is needed to reinforce both passive and active mitigation.** In all cases where there is vapor intrusion, mitigation techniques (barriers, venting, etc.) should include a long-term monitoring plan and a contingency plan. Monitoring should be supported by institutional controls until such time that it can be shown that vapor intrusion is no longer a threat. Furthermore, the costs of such long-term management activities over the life of the contamination should be weighed against permanent treatment or removal costs (i.e., accelerated cleanup) in the selection of remedies. If in new development, consideration should be given to requiring some type of financial assurance, such as a security bond.

- **New development on sites with vapor intrusion potential should be carefully regulated.** Vapor intrusion hazards should be identified and addressed before new construction occurs. At a number of sites, new development is being proposed where vapor intrusion is likely, even in areas with ongoing vapor intrusion investigation and mitigation efforts. Regulatory agencies should work with cities and other local planning jurisdictions to screen development sites for potential vapor intrusion, ensure maximum cleanup before construction, alter building design to minimize risk, and require the installation of reliable mitigation before the fact. Potential residents should be notified of possible risks. Where necessary, notification requirements should be enforced by institutional controls. A proactive strategy toward property reuse at contaminated sites should cut down on the litigation that typically occurs once the news about vapor intrusion rises to the surface.

  Where sites have the *potential* for vapor intrusion, prophylactic measures such as requiring passive barrier systems that can be monitored and actively vented if post-construction monitoring shows the need. This “precautionary” approach would increase costs somewhat, but less than the costs of investigation and remediation. The precautionary approach also reduces downstream human health and litigation (and therefore financial) risk. Cities and developers may also take proactive measures such as ensuring that sewer and utility conduits are built to avoid typical vapor migration.

- **Retaining property values is an important component of public outreach and remedy selection.** It is apparent that many community members regard first reports of vapor intrusion as an insult not so much to their health as to their pocketbooks. It is crucial that this component of a potential vapor intrusion problem not be overlooked.

APPENDIX B

Conceptual Site Model Checklist

Electronic Filing: Received, Clerk's Office 07/01/2024

CONCEPTUAL SITE MODEL CHECKLIST

The information included in this checklist may be useful for developing a site-specific conceptual migration model and in planning soil gas sampling. The investigator may use this checklist to compile information for each site.

Utilities and Process Piping

☐ Locate and map out all underground utilities near the soil or groundwater impacts. Pay particular attention to utilities that connect impacted areas to occupied buildings.

☐ Locate and map out all underground process piping near the soil or groundwater impacts.

Buildings (Receptors)

☐ Locate and map out existing and potential future buildings.

☐ Identify the occupancy and use of the buildings (e.g., residential, commercial). You may need to interview occupants to obtain this information.

☐ Describe the construction of the building including materials (e.g., wood frame, block), openings (e.g., windows, doors), and height (e.g., one story, two story, multistory). Determine whether there is an elevator shaft in the building.

☐ Describe the foundation construction:

- Type (e.g., basement, crawl space, slab on grade)
- Floor construction (e.g., concrete, dirt)
- Depth below grade

☐ Describe the HVAC system in the building:

- Type (e.g., forced air, radiant)
- Equipment location (e.g., basement, crawl space, utility closet, attic, roof)
- Source of return air (e.g., inside air, outside air, combination)
- System design considerations relating to indoor air pressure (e.g., positive pressure is often the case for commercial buildings)

☐ Describe subslab ventilation systems or moisture barriers present on existing buildings, or identify building- and fire-code requirements for subslab ventilation systems (e.g., for methane) or moisture barriers below foundations.

Source Area

☐ Locate and map out the source area for the vapor-phase contaminants related to the subsurface vapor intrusion pathway.

☐ Describe the presence, distribution, and composition of any NAPL at the site.

☐ Identify the vapor-phase contaminants that are to be considered for the subsurface vapor intrusion pathway.

☐ Describe the status and results for the delineation of contamination in environmental media, specifically soil and groundwater, between the source area and the potential impacted buildings.

☐ Describe the environmental media (e.g., soil, groundwater, both) containing contaminants.

☐ Describe the depth to source area.

☐ Describe the potential migration characteristics (e.g., stable, increasing, decreasing) for the distribution of contaminants.

Geology/Hydrogeology

☐ Review all boring logs, monitoring well construction, and soil sampling data to understand the following:

- Heterogeneity/homogeneity of soils and the lithologic units encountered and the expected/observed contaminant migration:
  - Depth and lateral continuity of any confining units that may impede contaminant migration
  - Depth and lateral continuity of any highly transmissive units that may enhance contaminant migration
- Depth of vadose (unsaturated) zone, capillary fringe, and phreatic (saturated) zone:
  - Note any seasonal water table fluctuations and seasonal flow direction changes (hydraulic gradient).
  - Note the depth interval between the vapor source and the ground surface.

- Note the presence of any perched aquifers.
- Note where the water table intersects the well screen interval or the presence of submerged screen.

☐ Describe distinct strata (soil type and moisture content, e.g., moist, wet, dry) and the depth intervals between the vapor source and ground surface.

☐ Describe the depth to groundwater.

☐ Describe groundwater characteristics (e.g., seasonal fluctuation, hydraulic gradient).

Site Characteristics

☐ Estimate the distance from edge of groundwater plume to building.

☐ Determine nearby potential sources.

☐ Estimate the distance from vapor source area to building.

☐ Describe the surface cover between the vapor source area and the potentially impacted building.

APPENDIX C

Building Types

Electronic Filing: Received, Clerk's Office 07/01/2024

BUILDING TYPES

Basements

Buildings completed below grade with a basement or partial basement may be prone to vapor intrusion for several reasons. Floor and walls may have small voids and cracks that allow soil gas to enter the building. Buildings with earthen floors (as one would find in a cellar) are especially problematic because there is a large surface area for migration of soil gas into the overlying structure and ventilation may not be present to dilute any significant vapor intrusion. Finished basements (with living spaces) are of concern because of the combination of insufficient ventilation and because the residential space is closer to the subsurface contaminant source than is living space completed at the surface. Other “red flag concerns” should be raised with basements if sumps are present or the walls are built with moisture barriers or are wet during the rainy season. Evidence of drywells, cisterns, or other voids below the basement should be identified.

Wet Basements

In areas of shallow water tables, there may not be an unsaturated zone of any significant thickness beneath the building. Building practice typically incorporates a drain around the perimeter of the footings and often a sump pump to prevent flooding of the basement. Nevertheless, this scenario is often referred to as a “wet-basement” condition. Obviously, it is not possible to assess vapor transport through the unsaturated zone beneath a building if there is no unsaturated zone. Depending on the amount of groundwater removed by the perimeter drain and sump pump, a wet-basement scenario may disrupt the formation of a clean water lens.

Slab on Grade

Slabs with cracks, utility piping, and drains may act as conduits for vapor intrusion. In some areas, homes are built with “floating slabs” where the floor is poured separately from the foundation wall. Vapors can enter the building through the perimeter crack between the wall and the floor. In areas where swelling and shrinking soils are a concern, the floor is designed to move independently of the footwalls, and the perimeter gap may be as large as 1–2 inches around the perimeter of the building.

Crawl Spaces

In some regions of the country, houses with crawl spaces may be the least likely candidates for vapor intrusion, whereas in other regions, house with crawl spaces may be especially prone to vapor intrusion problems. In warmer, humid regions, homes are often built over crawl spaces that are well ventilated to prevent the floors from rotting. While the foundation walls may have vents with movable covers, these are usually left open most of the year and may not seal tightly when closed. The extra ventilation may dilute vapor that accumulates in the crawl space. There is a further attenuation of the vapor concentration moving into the living space. Vapor transport studies of similar structures in Holland and Australia suggest that only 10%–25% of the air in the

living space enters by way of the crawl space (Turczynowicz and Robinson 2001, Waitz et al. 1996). By nature of its design, a structure such as this may have a low attenuation factor and hence may be an unlikely candidate for vapor entering the living spaces of the home, although an investigator must consider other lines of evidence as well before excluding a structure from further consideration based upon this factor alone.

In contrast, buildings in colder, dry climates may be constructed to be energy efficient for cooling and/or heating purposes and hence be more airtight. In some regions, homes may be constructed with crawl spaces that exist as large open patches of soil within an enclosed basement. Foundation walls may be built without vents or designed to seal tightly against the cold to prevent frozen pipes. Buildings of newer construction tend to be designed to allow for relatively less ambient air exchange, contributing to the problem of vapor buildup. Depending on furnace configuration, etc., most of the air in the living space enters by way of the crawl space. In these cases, vapor may easily enter the structure.

A common fallacy in evaluating vapor intrusion into crawl spaces comes in considering plastic “vapor barrier” membranes laid over the ground in the crawl space as a suitable layer of prevention against vapor intrusion. Vapor barriers may not form a complete seal and are often made of plastics that are permeable to many of the contaminants commonly encountered as vapor intrusion problems. Unless specifically designed and installed to prevent organic vapors from entering the crawl space, the presence of vapor barriers should not factor into any decision not to proceed further with evaluation.

Row Houses (Multiple Residential Units on a Single Floor Slab)

Row houses or townhouses may be constructed with multiple units on a single floor slab. It may seem reasonable to assess the potential for vapor intrusion by selecting a single unit as representative of the entire row, but experience has shown that vapor intrusion may be dominated by a discontinuity in the slab (e.g., a poorly sealed utility penetration), which may not be visible, and therefore a given unit may or may not be representative of the entire row. Additional consideration should be given to the potential for preferential pathways within the structure that may create dissimilar vapor migration routes between units.

Tall Buildings

Tall buildings in cool or cold climates generally have a significant stack effect caused by thermal convection currents. Air inside the building is heated, and hot air rises, causing a net upward flow, pressure in the upper floors, and a vacuum in the lower floors. The magnitude of the vacuum in the lower floors is proportional to the height of the building and the temperature difference between the indoor and outdoor air. This pressure differential may contribute to vapor intrusion from the subsurface and increase the potential for vapor intrusion into upper floors.

Mobile Homes and Portable Buildings

USEPA and others have offered little to no guidance on how to deal with vapor intrusion with regard to mobile homes and portable buildings. As with houses constructed over crawl spaces,

there may be a wide range of mobile-home building practices across the country, leading to a wide variation in the indoor vapor intrusion risk. The investigator evaluating vapor intrusion sites potentially affecting mobile homes should strive to factor in the building practices that are most prevalent in the area.

The undersides of mobile homes are usually sealed during manufacture with impermeable bituminous paper to protect the floor insulation during transport. Normally, this seal remains in place after the mobile home is installed at a site and can provide an extra measure of protection against vapor intrusion.

Mobile homes can be placed with or without permanent foundations. Mobile homes placed without permanent foundations or on raised concrete pilings are not likely to pose vapor intrusion risks. Even if these foundations are enclosed with metal or vinyl underskirting, which are typically attached for cosmetic purposes or to keep animals from under the mobile home, the natural ventilation though gaps and joints in the underskirting may sufficient to dilute any contaminant soil gas emanating from the subsurface.

In some areas, mobile homes are placed directly on concrete slabs, which offer more protection against vapor intrusion if no cracks are present. Even if the slab has cracks, vapor intrusion into the living space is unlikely to occur because the metal beams on the mobile home bottom typically hold the bottom of the home several inches above the slab. The resulting horizontal channels move any soil gas away from the slab instead into the overlying mobile home.

At the other end of the spectrum, mobile homes placed on permanent foundations may be somewhat susceptible to vapor intrusion depending largely on the foundation type. In some parts of the country, mobile homes are placed on raised perimeter foundations that essentially form an enclosed crawl space under the mobile home. These mobile homes are subject to many of the same considerations as conventional houses built over crawl spaces. With this construction type, the primary factor affecting vapor intrusion into the mobile home is whether the crawl space is ventilated or not, depending on local building practices. However, even mobile homes attached to unventilated crawl spaces may have less vapor intrusion than similarly constructed conventional housing by virtue of the sealed undersides. Also, air-handling systems in mobile homes typically do not draw air from the crawl spaces, as can occur with some systems in conventional construction.

Parking Structures

Buildings may contain enclosed first-floor aboveground or subsurface parking. In accordance with Unified Building Codes, the ventilation (air exchange rates) for these parking areas is generally higher than those for other occupied building floors. These parking areas also generally have ventilation systems that are separate from the overlying occupied floors, if present. In these cases, these floors of parking act as barriers to potential vapor migration into overlying occupied floors (e.g., commercial and/or residential areas). The receptors for potential vapor intrusion evaluation for these types of parking areas would be users of the parking structures and parking attendants.

Other Building Characteristics

Ventilation

The conceptual model for vapor transport assumes that vapor is drawn into the building through openings by the pressure difference between the soil and the interior of the building. The pressure differential is induced by a combination of wind and stack effects due to building heating and mechanical ventilation. Therefore, consideration should be given to the ventilation regimes within a building, including furnace/air conditioning type (e.g., forced air, radiant), furnace/air conditioning location (e.g., basement, crawl space, utility closet, attic, roof), source of return air (e.g., inside air, outside air, combination), and system design considerations relating to indoor air pressure (e.g., positive pressure is often the case for commercial buildings). Additional consideration should be given to the operational period of the ventilation systems, including daily and seasonal variations.

Vapor Barriers

Some buildings are constructed with passive vapor barriers that may reduce vapor flux into a building. More information on passive barriers can be found in Section 4.3.1.1.

Preferential Pathways

USEPA guidance (2002b) suggests that buildings within 100 feet of a contamination plume or source should be evaluated for vapor intrusion unless a significant conduit (preferential pathway) exists (in which case, the area to evaluate should extend to some unspecified distance). Refer to Section 1.6.3 for examples of preferential pathways for the vapor intrusion pathway.

Elevators may also constitute a preferential pathway, since they are typically required by building codes to have perforations to allow water to drain and the elevator may act as a piston to induce an intermittent air-pressure gradient. Most buildings have subsurface utility penetrations, so their presence alone is not considered “preferential.” Some increased component of vapor flow into the building is usually required to consider the migration route to be “preferential.”

Surface Cover

Surface cover (e.g., asphalt pavement) between the vapor source area and building should be considered for the potential vapor capping effect that may affect subsurface vapor migration.

Electronic Filing: Received, Clerk's Office 07/01/2024

APPENDIX D

Toolbox

Electronic Filing: Received, Clerk's Office 07/01/2024

TOOLBOX

This appendix discusses in greater detail the investigative methods or "tools" used in vapor intrusion investigations. Each section is designed to give the investigator a better understanding of how to use a tool and when it is appropriate. References are provided in case the investigator wants additional information about a tool. The tools are broken down in two categories, exterior and interior. Soil gas sampling is the principal investigative tool for potential VI sites; therefore, supplemental information regarding soil gas sampling is provided. Additional details are also provided on groundwater sampling since groundwater is often the principal source of contaminated soil gas and data are usually available on groundwater concentrations. Interior sampling generally refers to data that require entry into buildings of interest, including subslab, crawl-space, and indoor air data. Ambient outdoor air sampling is usually coupled with indoor air and crawl-space sampling. Several additional tools are also discussed.

It should be noted that during any sampling activities certain objectives should always be considered. These include using the appropriate sampling methodologies, containers, sample locations and frequency, and DQOs. Most of these objectives are defined within the discussion for the specific tools since they may vary according to the tool chosen. Basic DQO principles apply to all of the tools discussed below.

A summary of the various quantitative options utilized to evaluate the vapor intrusion pathway are provided in a matrix in Table D-4, near the end of this appendix. In addition, Table D-5, at the end of this appendix, provides the advantages and disadvantages of various investigative strategies. Please refer to these tables during the development of a vapor intrusion investigative work plan.

D.1 DATA QUALITY OBJECTIVES

It is necessary to establish DQOs before sampling is conducted. These are usually addressed during the work plan preparation. Some typical DQOs that should be addressed are listed below. This list is not complete, as special circumstances at any given site may dictate very specific DQOs.

- Define study goals.
- Identify COCs and screening levels.
- Choose sampling and analysis method with appropriate reporting limits.
- Complete presampling building survey (interior sampling).
- Establish appropriate sampling conditions, number of samples, and duration of sampling.
- Collect QC samples (e.g., field blanks, duplicates).
- Establish data validation procedures.

D.2 GROUNDWATER (EXTERIOR)

D.2.1 Use of Preexisting Groundwater Data

In many situations shallow groundwater data that are already available prior to initiation of a VI investigation are sufficient to use as part of the investigation, especially if groundwater contamination has been delineated and the plume has reached steady state conditions (i.e., is no longer expanding). In deciding whether existing data are sufficient, consideration should be given to the site-specific CSM. Groundwater data should be from wells screened across the water table at the time of sampling. In addition, the likelihood of significant vertical changes in groundwater quality near the water table, the sampling method used, the construction of existing wells sampled (e.g., screen length and placement across water table), the type of contaminants present, and heterogeneity of the vadose zone and shallow saturated zone media will likely be the most important factors in determining whether existing data are sufficient to be used for vapor intrusion assessment.

Drinking water supply wells may or may not be appropriate, depending upon how they are constructed and screened. In most situations, it is likely that few drinking water wells are screened/open across the water table. Therefore, the presence of volatiles in private or public drinking water wells should be considered a possible basis for further investigation, but in most situations the data should not be used to determine whether the pathway is complete.

D.2.2 Interpolation of Nearby Data

If groundwater data *immediately* upgradient from the structure are not available, surrounding data points can be used to construct contaminant isoconcentration maps. However, this step should be done only if data points are available on at least two sides of a structure. Complex geologic settings or the anticipated presence of steep concentration gradients warrants a denser sampling grid. Groundwater contours should consider the rate and direction of groundwater flow and the time since chemicals were released to compare the expected length of the plume to measured concentration data. In general, the distribution of chemicals in groundwater will elongate in the direction of groundwater flow (shaped like a feather, hence the term “plume”) with relatively little vertical or transverse dispersion.

D.2.3 Obtaining New Groundwater Data to Evaluate the VI Pathway

If new or additional groundwater data are needed to complete the VI investigation, the goal of the sampling effort should be to determine volatile concentrations in the uppermost groundwater beneath or near potential structures.

USEPA (2002c) and various state agencies (NJDEP 2005a) provide specific guidance and procedures for the installation of groundwater monitoring wells and the acquisition of high-quality groundwater VOC sample data. Some of the recommendations for collecting groundwater data suitable for vapor intrusion assessment (Cal DTSC 2005) are as follows:

- Proper Screen Intervals. Contaminants at the top of the water table, rather than deeper contamination, are responsible for causing potential vapor intrusion problems. Hence, monitoring wells used to make vapor intrusion evaluations should be screened across the air-water interface, meaning the well screens should not be submerged below the top of the water table.
- Proper Screen Lengths. Monitoring wells with excessively long well screens, regardless of screen placement, should not be used to make vapor intrusion evaluations. When sampling long well screens, clean water entering the well screen at depth may dilute the contaminated groundwater near the top of the screen, biasing the sampling results and the associated risk determination. Hence, short screen lengths are preferred for monitoring wells that will be used to make vapor intrusion evaluations. Ideally, the thickness of the water column in the well should be 10 feet or less. For new water table wells installed as part of a VI investigation, a 5–10-foot screen is generally recommended unless this approach conflicts with other site investigation objectives. Additional construction recommendations are discussed in NJDEP 2005b.
- Proper Well Installation. Monitoring wells should be designed and installed to yield representative samples of groundwater conditions. Monitoring wells should have proper filter packs, slot sizes, and annular seals. Direct-push sampling methods and alternative/temporary groundwater sampling techniques are often well suited for VI investigations especially if attempting to determine the depth of the interface between a shallow clean water lens and an underlying plume or for determining vertical gradients. Repeated sampling over time at the same locations may be necessary for some sites to determine whether shallow groundwater quality has changed due to water table elevation fluctuations or other factors. If bedrock wells are installed as part of a VI investigation, open hole intervals should generally be 10 feet or less and should target the most shallow water-bearing zone. In highly weathered/fractured bedrock formations, shallow groundwater flow and contaminant migration can exhibit patterns more typical of unconsolidated formations. In those situations, local heterogeneity of the bedrock may not have as much influence on whether volatiles in groundwater can off-gas into the vadose zone and diffuse up to structures at the surface. Therefore, construction of monitoring wells in such settings can be part of a VI investigation.
- Proper Well Development. Monitoring wells should be developed to create an effective filter pack around the well screen, rectify damage to the formation caused by drilling, optimize hydraulic communication between the formation and well screen, and assist in the restoration of natural water quality of the aquifer near the well.
- Proper Well Purging. Prior to sampling, monitoring wells should be purged to remove stagnant casing water from the well that is not representative of aquifer conditions. Wells can be purged by removing the traditional three casing volumes prior to sampling or the well can be purged with low-flow techniques as described below. Wells should not be purged dry because this practice will drain the filter pack and introduce potential for volatilization losses during recovery. If adequate purging cannot be conducted without excessive drawdown because of low permeability, consider using passive diffusive samplers, which do not require purging.
- Proper Well Sampling. Sampling methods that minimize the loss of VOCs during sample collection and handling, such as bladder pumps or submersible pumps, are preferred. Other methods, such as peristaltic pumps and bailers, may cause unacceptable volatilization of chemicals if not properly implemented (USEPA Technology Verification Program,

www.epa.gov/etv/verifications/verification-index.html). Passive diffusion samplers may be useful, as described below.

D.2.4 Groundwater Spatial Sampling Locations

Groundwater samples should be collected as close, horizontally and vertically, to the structures as possible because concentrations are not always uniform within a plume due to heterogeneities in source areas and in the subsurface media. Given the distance criterion between vapor source and potentially affected structures (check with your regulatory agency for the appropriate distance), a more detailed delineation of the extent of groundwater contamination may be appropriate in some situations.

Changes in surface cover that significantly affect the amount of infiltration upgradient from structures should be considered in choosing sampling locations. For example, if there is an area of groundwater recharge (e.g., storm water retention pond or a transition from a mostly paved surface to a vegetated park/open field) located between the upgradient edge of a plume and a structure, a sampling location downgradient of the recharge area should be selected to be representative of any fresh water lens that may be present.

D.2.5 Perched Water Tables and Vertical Profiles of the Groundwater

If a perched water table exists above the regional water table, it may be appropriate to collect samples from both the perched zone and regional shallow aquifer. Perched saturated zones that are laterally contiguous under/near structures, exist year-round, and are below nearby building foundations should be sampled if they are of sufficient thickness that a sample can be obtained. Professional judgment must be used in more complex situations, but in the above scenario sampling of the regional water table may not be vital to investigating the VI pathway. In some situations, vertical profiles of shallow groundwater contamination may enable a more precise evaluation of the current and potential future risk of VI.

D.2.6 Ongoing Groundwater Monitoring

After an initial VI investigation has been completed, long-term groundwater monitoring to reevaluate the VI pathway may be appropriate in some situations. Groundwater monitoring should be done where groundwater concentrations exceeding screening levels are close to, but not currently within, the applicable distance criterion to a potential receptor.

D.2.7 Groundwater Sampling Methods

Table D-1, prepared by NJDEP (2005b), summarizes some alternative groundwater sampling methods that may apply to VI investigations. Sampling guidance for VI investigations may differ from other guidance in the documents because of the objective to determine very shallow groundwater quality.

Table D-1. Groundwater sampling methods for vapor intrusion investigations

Method	Example guidance documents	Advantages or disadvantages
Direct-push and alternative groundwater sampling methods	NJDEP *Field Sampling Procedures Manual* (2005a), Section 6.9.2.1, www.nj.gov/dep/srp/guidance/fspm	• Can do vertical profiling • Can do discrete interval sampling at defined depth intervals • Rapid sampling at multiple locations • More difficult to repeat sampling in same locations • Some methods limited to unconsolidated formations
Passive diffusion bag samplers	• NJDEP *Field Sampling Procedures Manual* (2005a), www.nj.gov/dep/srp/guidance/fspm • USGS *User's Guide for Polyethylene-Based Passive Diffusion Bag Samplers to Obtain Volatile Organic Compound Concentrations in Wells*, Part 1, www.itrcweb.org/gd_DS.asp • ITRC *Technical and Regulatory Guidance for Using Passive Diffusion Bag Samplers to Monitor Volatile Organic Compounds in Groundwater* (2004a), www.itrcweb.org/gd_DS.asp	• Can use existing wells for ongoing monitoring • May not be adequate where/for: o VOC highly soluble in water, such as methyl tertiary-butyl ether o in-well vertical flow occurs o permeability is very low
Low-flow purging and sampling	NJDEP *Field Sampling Procedures Manual* (2005a), Sections 6.9.2.2 and 6.9.2.3, www.nj.gov/dep/srp/guidance/fspm	• May generally target interval closer to the water table in some settings • Discrete interval sample not obtained
Volume-averaged purge and sample collection	NJDEP *Field Sampling Procedures Manual* (2005a), Section 6.9.2.4, www.nj.gov/dep/srp/guidance/fspm.	• Not recommended to generate new groundwater data specifically for VI investigations because of the potential for vertical averaging

D.2.8 Passive Diffusion Samplers

Passive diffusion samplers come in several varieties, as described in ITRC 2004a. Passive diffusion bag samplers (PDBSs) may be the most common for VOCs. PDBSs should be deployed just below the water level in a well for a minimum of two weeks to equilibrate with the well water. Significant water table fluctuations during that period will affect the appropriate depth intervals for the samplers. If the water level drops below the uppermost sampler, transfer of volatiles from the sampler water into less contaminated well air space would occur. If the upper sampler is exposed to the air space, the upper sampler should be resuspended 2 feet below

the current water level and retrieved after an additional two-week equilibration period. In any event, the depth to water in the well should be measured when the PDBSs are installed and removed, and the position of the samplers relative to the water level should be clearly described in the report presenting the PDBS data. PDBSs are not applicable to all compounds (e.g., semivolatile organic compounds [SVOCs] and soluble compounds such as acetone, styrene, methyl tertiary-butyl ether [MTBE], and 4-methyl-2-pentanone [MIBK]), so the target analytes must be confirmed.

D.2.9 Low-Flow Purging and Sampling

If evaluating the VI pathway is the *only* sampling objective, it is recommended that two modifications to the typical low-flow purging and sampling procedure be employed:

- Set the pump intake level as close to the water table as possible without significant risk that the water level will drop and expose the pump intake. For wells in formations with average or high permeability, about 1.5–2 feet below the static water level should be an adequate intake location.
- The purging objective is to flush two volumes of groundwater through the sampling array (tubing and pump, etc.). While measuring water quality indicator parameters is preferred (but not necessary), drawdown should be measured and not excessive.

D.3 SOIL (EXTERIOR)

At most sites soil matrix data are available. However, these data are less than ideal for evaluating vapor intrusion risk because of the uncertainty associated with using partitioning equations and the potential loss of VOCs during sample collection. Field extraction with methanol or hexane is good for reducing volatilization losses, but it results in elevated detection limits.

To evaluate vapor intrusion, soil matrix must be converted to soil gas concentrations using assumptions about the partitioning of the contaminant into the gas phase. Soil solid–to–soil gas partitioning equations are readily available, but using them increases the uncertainty in evaluating vapor intrusion.

Hartman (2002) has found that in the case of hydrocarbons, calculated soil gas values from soil solid data often overestimate actual soil gas concentrations. Conversely, soil solid data for chlorinated hydrocarbons often underestimates soil gas concentrations.

When soil is sampled for VOCs, soil samples should be collected using procedures specifically designed to minimize volatilization losses, such as SW-846 Method 5035A and augmented USEPA Method 5035A (Cal DTSC 2004). More details on the interpretation of soil data and phase partitioning calculations can be found in the Cal DTSC vapor intrusion guidance (2005). Existing soil data should be used as part of the line-of-evidence approach. In general, soil matrix data are not recommended as a stand-alone screening tool for a vapor intrusion investigation. They can be used to delineate sources or “screen in” sites for vapor intrusion assessment, but not to eliminate sites from further assessment.

D.4 ACTIVE SOIL GAS METHODS (EXTERIOR)

Active soil gas methods consist of the withdrawal of the soil gas from the subsurface and subsequent analysis. These methods give concentration data (e.g., $\mu g/m^3$), which can be directly compared to risk-based screening levels or used in predictive models. Soil gas sampling is the preferred sampling and investigative tool for most vapor intrusion investigations.

Soil gas sample collection techniques for vapor intrusion applications require much greater care than techniques historically used for typical site assessment applications (e.g., assessing whether a underground storage tank has leaked) because risk-based concentration levels for vapor intrusion scenarios are so low (1,000–10,000 times lower than concentration levels previously of concern). The quality of soil gas data depends greatly on the collection protocols. The following overview attempts to identify alternatives, express advantages and disadvantages, and provide appropriate flexibility and cautions where warranted by the current available knowledge and experience. Some of the primary factors that can influence the measured results are summarized below. A checklist summarizing some of the key QA/QC issues is provided in Appendix E. For supplemental or up-to-date references, please refer to the ITRC Vapor Intrusion Web page (www.itrcweb.org/vaporintrusion).

Two techniques are most commonly used to install soil gas probes to collect external active soil gas samples: driven probe rod and burial of soil gas sampling tubes. Both methods have been shown to give reliable, reproducible data in moderate- to high-permeability soils (DiGiulio et. al. 2006a).

D.4.1 Driven Probe Rod (Temporary Method)

This method consists of the insertion of a hard rod (probe) driven to a target depth, collection of soil gas through the rod while it is in the ground, and subsequent removal of the rod (Figure D-1). Soil gas probes can be constructed of a variety of materials and installed by a variety of techniques. Typically, probes are constructed of hollow steel rods with an external diameter typically ranging 12.5–50 mm. Small-diameter, inert, replaceable tubing runs down the center of the drive rod to eliminate potential contamination from the inside of the rod. The probes can be driven by hand, direct-push systems, or larger drill rigs using the wire-line hammer. The driven rod method is typically faster than the buried tube method and also does not leave any materials in the ground. Probe installation can be difficult in consolidated or coarse-grained soils, especially at greater depths, where the rods are more susceptible to deflection. A surface seal is usually employed, but this does not prevent cross-flow at greater depths, so driven probes are most applicable in relatively uniform moderate- to high-permeability materials (generally not in low-permeability soils). A tracer may help to verify the absence of atmospheric air entry during sampling.

Figure D-1. Hollow rod used to collect soil gas.
Courtesy H&P Mobile Geochemistry

D.4.2 Burial of Soil Gas Sampling Tubes (Semipermanent or Permanent Method)

This method consists of the burial of a small-diameter (typically 1/8- to 1-inch outside diameter) inert (e.g., stainless steel, Teflon®, HDPE, polyetheretherketone, Nylaflow®) tube or pipe to a target depth with subsequent sampling of the soil gas after a period of time. Tubing may be buried in holes created with hand-driven rods, direct-push systems, hand augers, drills (for subfoundation samples), or drill rigs for deeper samples. Sand is used as backfill around the tip, and the remainder of the borehole annulus is sealed, usually with bentonite and water slurry. This method is sometimes referred to as the "semipermanent" method (if the tubes are removed after a short period of time) or "permanent" method (if the tubes are left in the ground for a longer period of time) but can equally be used for temporary sampling. This method offers significant advantages when repeated sampling events are needed or where the geology is not conducive to driven probes. Multiple tubes can be "nested" in the same borehole (as shown in Figure D-2), providing the seals between intervals are tight and are often referred to as "multilevel" soil gas wells or probes. They can also be installed in nearby individual boreholes (nested soil gas wells or probes).

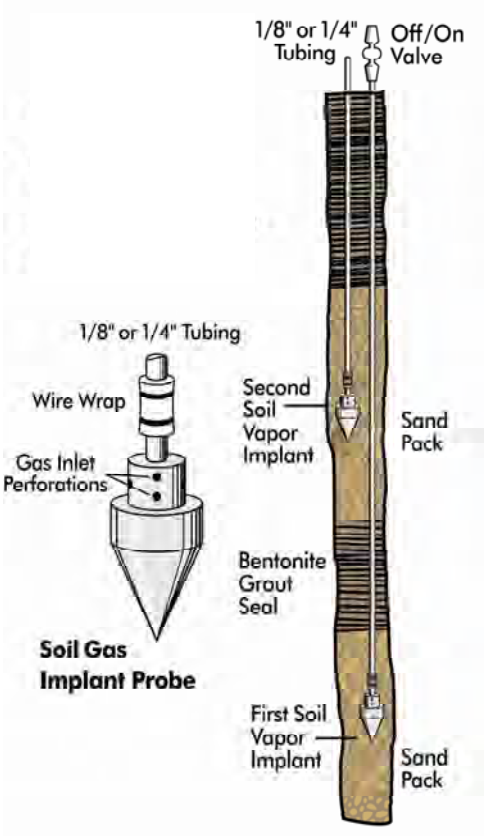

Figure D-2. Typical configuration of nested well.
Courtesy H&P Mobile Geochemistry

D.4.3 Soil Gas Sampling from Existing Groundwater Wells

Soil gas samples can be collected from groundwater wells that are screened across the water table. If 3–5 times the well casing gas volume is purged prior to sampling, the resulting soil gas sample should reflect the soil gas in the vadose zone outside of the well screen. If the casing volume is not purged, the soil gas sample will reflect contributions from both the vadose zone and from soil gas emanating from the standing water column within the lower part of the well, which is difficult to interpret and is therefore not recommended. In the first case, three to five casing volumes should be extracted prior to sampling to ensure the sample is representative. Field screening can be conducted to demonstrate stable readings before sample collection. Groundwater monitoring wells typically have vented caps, so a retrofit will be required to cap the well with an airtight cap and valve.

D.4.4 Purge Volume

Sampling systems with small internal volumes minimize potential sample-integrity problems compared to sampling systems with larger internal volumes, although reliable samples can be collected with the latter, especially when the probes are deeper than 5 feet. Stagnant air inside soil gas probes and sampling trains must be purged prior to sample collection. Three to four

system purge volumes are recommended as a minimum value. The dead volume of the sand pack should be purged if samples are collected within a few hours of installation. Larger purge volumes may result in a more integrated soil gas concentration under some conditions, providing the concentration versus purge volume is assessed using handheld meters (PID, flame ionization detector [FID], O_2, CO_2) or a mobile laboratory. If air rotary drilling is used to emplace the tubes, longer periods of time are required for the sand pack to equilibrate with the soil gas. API 2004 gives an equation to estimate the time required to reach steady state conditions. A test of concentration versus time can be used to determine when values stabilize.

D.4.5 Sample Volume and Purge Volume Tests

To reduce the uncertainty of where the soil gas sample is from and potential breakthrough from the surface, smaller volume samples (<1 L) and proper seals are recommended, especially for soil gas samples collected at shallow depths (<3 feet bgs or subslab). However, three recently published studies compared soil gas concentrations collected from volumes ranging 0.5–100 L (DiGiulio et. al. 2006a, McAlary and Creamer 2006, DiGiulio et. al. 2006b). The results of these studies, done in relatively course-grained soils, show no significant differences in concentrations. If the investigator is concerned about withdrawing larger (>3 L) sample volumes, a test of the sample concentration versus amount withdrawn might be appropriate to demonstrate there is no relationship between soil gas concentration and volume withdrawn. This can be done similar to the purge volume test described in the preceding paragraph.

D.4.6 Flow Rate and Vacuum

To minimize the potential desorption of contaminants from the soil, soil gas samples should be collected using techniques that minimize the vacuum applied to the soil. Higher vacuums also increase the potential for leaks in the sampling system. Most agencies are requiring flows less than 200 mL/min.

This conservative approach limiting flow rate may not be necessary in soils permeable enough to maintain vacuums less than 15% of atmospheric pressure (~5 inches of Hg, 60 inches of H_2O). A recent study by McAlary and Creamer (2006) actually measured soil gas concentrations over different flow rates ranging from 100 mL/min to 100 L/min at a hydrocarbon-contaminated site. They saw no significant difference in measured concentration. This study suggests that for relatively course-grained soils, flow rate does not appear to be an important variable on soil gas concentration.

D.4.7 Leak Tests

To ensure that valid soil gas samples are collected with no breakthrough of air down the probe rod or through leaks in the sampling train, a tracer compound may be applied at the base of the probe where it contacts the surface and near all connections in the sampling train. Connections can also be leak-tested using a “shut-in” test (API 2004). Seal integrity is then confirmed by analyzing collected soil gas samples for the tracer. Gaseous compounds (propane, butane, helium, SF_6) using shrouds or liquid compounds (isopropyl alcohol, pentane, freons) applied to towels are commonly used. Both types of tracers have pros and cons. Gaseous tracers offer some

advantages but are harder to use, especially to cover leakage in the sampling train. Helium offers a nice advantage in that it is readily measured on site with a field meter. Volatile liquid tracers offer logistical simplicity but are more qualitative. Liquid tracers are easily and quickly supplied at multiple locations (i.e., probe, sampling rod, sampling train, etc.) simultaneously. Liquid tracer methods are better suited for sampling through the probe rod since it can be applied to multiple leak points that may not be close to each other.

A small amount of tracer in a sample does not necessarily indicate an unreliable sample. Some agencies, such as the New York State Department of Environmental Conservation, allow tracer concentrations up to 10% of the starting concentration before considering the soil gas sample compromised. For gaseous tracers, the starting concentration is the measured concentration under the shroud. For liquid tracers, the starting concentration either is assumed as equal to the vapor pressure of the compound at ambient temperature or can be measured if on-site analysis is available. For liquid tracers such as isopropanol, a 10% leak would give a value in the sample of approximately 10,000 μg/L, assuming a starting concentration equivalent to its vapor pressure. To account for the possibility that the starting concentration is not equal to the vapor pressure, some agencies have established a specific concentration level, such as 100 μg/L, that can not be exceeded. This value corresponds to a 0.1% leak, assuming a starting concentration equal to the vapor pressure of the compound or a 1% leak if the starting concentration is only 10% of the vapor pressure, a conservative assumption. Table D-2 lists common tracers with their relative advantages and disadvantages.

Prevent Atmospheric Short-Circuiting

- Soil gas probes should be sealed above the sampling zone with a bentonite slurry for a minimum distance of 3 feet to prevent outdoor air infiltration and the remainder of the borehole backfilled with clean material.
- For multiple probe depths, the borehole should be grouted with bentonite between probes to create discrete sampling zones (Figure D-2) or separate nested probes should be installed.
- Set a protective casing around the top of the probe tubing and grout in place to the top of bentonite; slope the ground surface to direct water away from the borehole.

—from NYSDOH (2006) guidance

Table D-2. Common tracers

Tracer	Advantages	Disadvantages
Helium	• Can to check for leaks on site with handheld detector • Can quantify amount of leakage accurately • Does not interfere in TO-15 analysis	• Party-grade helium may have low ppbv VOC contamination • Process is more cumbersome than some others • Cannot be analyzed by TO-15 • Can be difficult to apply to sampling train connections
Liquid tracers	• Easy to use in identifying leaks • Can be detected by VOC analytical methods • Easier to apply to sampling train connections	• Concentration introduced to leak is estimated • Large leak may lead to VOC analysis interferences • No simple field screening method • May leave residual contamination on sampling train

Tracer	Advantages	Disadvantages
Sulfur hexafluoride	• Can check for leaks with on-site instrument with very low detection limits	• Very expensive • Field instrument subject to interference with chlorinated solvents • Cannot be analyzed by TO-15 • Is a greenhouse gas

D.4.8 Collection of Samples with Sampling Assemblies

Sampling assemblies (connecting tubing, fittings, gauges, flow controllers, etc.) should be ensured to be leak-tight using a shut-in test or tracer compound as described in the previous section and should be cleaned (and possibly blank-tested) between soil gas samples if reused. Sample tubing should generally not be reused.

D.4.9 Collection of Samples on Adsorbents

An alternative approach to collecting soil gas in a sample container is to concentrate the soil gas on an adsorbent. This type of method is required for SVOCs (generally compounds heavier than naphthalene). Typically, a pump is used to draw soil gas through the adsorbent, and the adsorbent is then analyzed by a laboratory. A variety of adsorbent cartridges and pumping systems are available from commercial vendors. All of the collection issues and criteria discussed in this section apply when using adsorbents. In addition, it is essential that the soil gas be drawn through the adsorbent by the pump, not pumped through the adsorbent to eliminate the chance for cross-contamination by the pump. It is often recommended to use two tubes in series to avoid breakthrough losses in areas of suspected higher concentrations. The adsorbent, purge rate, and sample volume must be determined by discussion with the analytical laboratory.

D.4.10 Variations in Soil Gas Values Due to Temporal Effects

Variations in soil gas concentrations due to temporal effects are principally due to temperature changes, precipitation, and activities within any overlying structure. Variations are greater in samples taken close to the surface and dampen with increasing depth. In 2006 there were a number of studies on temporal variation in soil gas concentrations, and more are under way or planned in 2007 by USEPA and independent groups. To date these studies have shown that short-term variations in soil gas concentrations at depths 4 feet or deeper are less than a factor of 2 and that seasonal variations in colder climates are less than a factor of 5 (Hartman 2006). Larger variations may be expected in areas of greater temperature variation and during heavy periods of precipitation, as described below.

IBM, Endicott, New York
Recent data from a large site in Endicott, New York collected over a 15-month period showed soil gas concentration variations of less that a factor of 2 at depths greater than 5 feet bgs.

- Temperature. Effects on soil gas concentrations due to actual changes in the vadose zone temperature are minimal. The bigger effect is due to changes in an overlying building's

heating or HVAC system and the ventilation of the structure due to open doors and windows. In colder climates, worse-case scenarios are most likely in the winter season. The radon literature suggests that temporal variations in soil gas are typically less than a factor of 2 and that seasonal effects are less than a factor of 5. If soil gas values are more than a factor of 5 below acceptable levels, repeated sampling is likely not necessary regardless of the season. If the measured values are within a factor of 5 of allowable risk levels, then repeated sampling may be appropriate.

- Precipitation. Infiltration from rainfall can potentially impact soil gas concentrations by displacing the soil gas, dissolving VOCs, and by creating a "cap" above the soil gas. In many settings, infiltration from large storms penetrates into only the uppermost vadose zone. In general, soil gas samples collected at depths greater than about 3–5 feet bgs or under foundations or areas with surface cover are unlikely to be significantly affected. Soil gas samples collected closer to the surface (<3 feet) with no surface cover may be affected. If the moisture has penetrated to the sampling zone, it typically can be recognized by difficulty in collecting soil gas samples. If high vacuum readings are encountered when collecting a sample or drops of moisture are evident in the sampling system or sample, measured values should be considered as minimum values.

- Barometric Pressure. Barometric pressure variations are unlikely to have a significant effect on soil gas concentrations at depths exceeding 3–5 feet bgs unless a major storm front is passing by. A recent study in Wyoming (Luo et al. 2006) has shown little to no relationship between barometric pressure and soil gas oxygen concentrations for a site with a water table at ~15 feet bgs.

In summary, temporal variations in soil gas concentrations, even for northern climates, are minor compared with the conservative nature of the risk-based screening levels. If soil gas values are a factor of 5–10 times below the risk-based screening levels, there likely is no need to do repeated sampling unless a major change in conditions occurs at the site (e.g., elevated water table, significant seasonal change in rainfall).

D.4.11 Choosing an Appropriate Analytical Method

A variety of analytical methods are available to measure soil gas samples, all of which can give accurate results when followed with appropriate QA/QC. Table D-3 (at the end of this appendix) summarizes the most common methods. The primary criteria for choosing the appropriate method are as follows:

- the COCs
- concentrations that may be encountered during sampling
- required detection level and other DQOs
- sampling logistics
- cost

The planning stages of the investigation should include discussions with your laboratory to ensure the appropriate analytical method is utilized.

D.4.12 Sample Containers and Storage

For fuel-related compounds (BTEX, total petroleum hydrocarbons [TPH]) and biogenic gases (CH_4, CO_2, O_2), allowable containers include Tedlar® bags, gas-tight (glass or stainless steel) vials, and passivated (Summa) stainless steel canisters. Tedlar bags are generally not considered to be reliable for more than 48 hours, but some agencies may have different requirements.

For halogenated compounds (e.g., TCE, TCA, PCE), allowable containers must be gas tight but also dark to eliminate potential photodestructive effects.

Adsorbents are suitable for most VOCs and SVOCs. However, multiple adsorbents may be required to deal with complex mixtures.

If stored samples are to be subjected to changes in ambient pressure (e.g., shipping by air), gas-tight vials or canisters are recommended. Tedlar bags to be shipped by air should be only partially filled to prevent rupture.

Allowable storage times in canisters vary among states, ranging from 3 days (Cal DTSC 2005) to 30. Most agencies require analysis within 14 days of collection.

It is not necessary to chill soil gas samples during shipping and storage.

D.4.13 On-Site Analysis

On-site analysis provides real-time detection of VOCs from any vapor migration sources or pathways, allows additional sampling locations to be added (spatially or vertically), allows recognition of spurious data, and enables measurement of the leak-test compound to ensure valid soil gas samples are collected.

Simple portable instruments can provide both qualitative and quantitative data, depending upon the compound and the required detection levels. Field screening with handheld PIDs or FIDs enable rapid screening for vapor migration routes around and into structures. However, most field-screening instruments are limited to the ppmv range, which may not provide sufficient resolution. Quantitative oxygen, carbon dioxide, and methane data are possible from handheld portable meters for concentrations in the percentage range. Helium detectors are available with a range of 0.01%–100% by volume.

For lower detection limits, mobile laboratories equipped with laboratory-grade instruments, including gas chromatographs and mass spectrometers, are capable of fully quantitative results meeting method required QA/QC and detection limits as low as 1–100 $\mu g/m^3$.

D.4.14 Recommended Soil Gas Sample Locations for Vapor Intrusion Assessments

The initial criteria to apply in determining where to collect soil gas samples for vapor intrusion assessments are the location of the contamination source relative to the receptor, the depth of the contamination source, and the type and construction of the receptor. The following sections give brief recommendations on where to collect soil gas samples both laterally and vertically for some typical situations. Additional suggestions can be found in API 2005, NYSDOH 2006, NJDEP 2005b, and EPRI 2005. For supplemental or up-to-date references, refer to the ITRC Vapor Intrusion Team Web page (www.itrcweb.org/teampublic_Vapor.asp).

D.4.15 Sample Density

Sufficient soil gas samples should be taken to make appropriate decisions. When subsurface contamination is encountered near buildings, soil gas samples should be collected to assess the contaminant distribution in sufficient detail to identify buildings that may have unacceptable levels of vapor intrusion. Characterization should continue until concentrations of VOCs meeting acceptable risk-based levels are encountered in the subsurface laterally and vertically between the source and potential receptors.

The exact number and spacing of samples (i.e., sample density) will vary on a site-specific basis. Ideally, there should be a soil gas sample for every existing or future building for smaller sites (i.e., houses surrounding a dry cleaner or a gas station) and sufficient spatial coverage to be representative for larger distributions (e.g., groundwater plume under hundreds of houses). For sites where current and future land use will be restricted by a land use covenant, the soil gas sampling density can be modified as a function of the size of the current and future buildings pursuant to the covenant.

When sampling near or under individual structures, collect enough samples to get a representative value of the soil gas concentration (analogous to placing enough borings on a typical site). If statistical averaging methods are being used to process the data, a minimum number of locations might be required depending upon the statistical method employed.

D.4.16 Selection of Lateral Soil Gas Sampling Locations

It is important to consider the following parameters when selecting lateral sample locations.

Subsurface Contamination Adjacent to a Structure: If the contamination source is not directly below the structure, collect samples on the side of the structure closer to the source. Collect samples in any known subsurface migration routes, such as sewers or utility lines that extend towards the contamination. If concentrations exceeding screening levels are detected, it may be appropriate to proceed to interior sampling (e.g. subslab).

Subsurface Contamination underneath a Structure: If the contamination source is directly below the structure, collect samples directly underneath the structure foundation if possible and/or indoor air samples. If possible, collect enough samples to get a representative value under the footprint of the structure and locate them to provide an indication of the spatial distribution of

the contamination. If subslab samples are not possible, collect near slab soil gas samples around all sides of the structure to determine the concentration distribution and get an idea of the possible concentration under the structure. An alternative approach may be required for very large buildings.

Surface Contamination Within or Immediately Adjacent to a Structure: This situation is most likely applicable to commercial facilities with adjoining businesses (e.g., dry cleaners at strip malls) or industrial settings with partitioned or immediately adjacent buildings. The contamination enters the shallow vadose zone from the surface, as a dense vapor or as a liquid spill, and then migrates laterally underneath the building slab. Collect samples directly underneath the structure slab covering the area of concern in the structure.

D.4.17 Selection of Vertical Soil Gas Sampling Locations Exterior to the Building

The closer to the ground surface or structure foundation, the greater the chance that surface processes such as atmospheric pumping, precipitation, and advective flow induced from the overlying structure will affect the soil gas concentration. In general, the effects due to these processes are considered to be minimized at depths 3–5 feet below the ground surface or building foundation, and measured soil gas concentrations are less likely to fluctuate. However, some processes, such as bioattenuation, oxygen replenishment, and substructure flushing, occur primarily at shallower depths (<3 feet), so sampling in this zone should not necessarily be precluded. If soil gas data from depths <3–5 feet bgs or below the level of the foundation are collected, additional sampling events may be appropriate to ensure representative values, especially if the measured values yield risks that are near acceptable levels.

Multiple-depth samples should be collected as needed to define vertical trends in soil gas concentrations or to determine maximum concentrations at the contamination source. Deeper samples tend to minimize temporal variations. The tension-saturated zone above the water table (capillary fringe) should be avoided if possible because high water saturation makes soil gas sampling difficult.

Exterior soil gas samples collected from just above the source or about 10 feet below the lowest floor slab are expected to provide a conservative estimate of subslab concentrations, as described further in Section D.6.

Some general recommendations regarding selection of vertical samples follow:

Subsurface Contamination Adjacent to a Structure. Collect samples between the structure and the source at about 3–5 feet below the lowest floor or shallower if the contamination source is shallower. For structures with basements, at least one vertical profile along the basement wall facing the contamination is advised.

Subsurface Contamination Underneath a Structure. If accessible, collect samples immediately below the structure’s foundation. For hydrocarbons, collect near-structure samples at about 3–5 feet below the lowest floor or shallower if the contamination source is shallower. For chlorinated hydrocarbons, collect samples near the source and at least 10 feet below the foundation (but no

deeper than the top of the capillary fringe). If concentrations exceeding screening levels are detected, either collect additional samples around the structure to allow better determination of the concentration distribution around the structure or proceed to interior sampling (subslab and/or indoor air).

Surface Contamination Within or Immediately Adjacent to Structure. As described in the prior section, this situation is most likely applicable to commercial facilities with adjoining businesses (e.g., dry cleaners at strip malls) or industrial settings with partitioned or immediately adjacent buildings. Collect samples directly underneath the slab covering the area of concern in the structure.

D.4.18 Applications of Vertical Profiles of Soil Gas Concentrations

Vertical profiles of soil gas concentrations can be useful for the following situations:

- determining the source of the contamination if not previously known
- determining the attenuation of contaminants in the soil gas in the vadose zone due to bioattenuation or other processes

Depending on the depth of groundwater, vertical profiles should consist of a minimum of three sampling depths, fewer for shallower aquifers. If repeated data are desired, install soil gas monitoring tubes for easy re-sampling.

D.5 PASSIVE SOIL GAS METHODS

Passive soil gas methods consist of the burial of an adsorbent in the ground (Figure D-3) with subsequent retrieval and measurement of the adsorbent. With passive sampling, there is no forced movement of soil gas. Instead, as the vapors migrate, the sorbent acts as a sink for the organic compounds in the soil gas. This method gives a time-integrated measurement and therefore reduces the uncertainty due to temporal variations.

Passive soil gas methods directly measure a mass of contaminant that has diffused onto an adsorbent media. Reporting units are typically in terms of mass (e.g., micrograms). Using relative mass levels, passive soil gas can be a viable, cost-effective, and simple screening tool to determine potential areas of concern. While published methods exist that describe the procedures to generate contaminant concentration data from a passive sorbent-based sampler in air in the absence of soil (ASTM 2002a, 2003), no published data or documents have demonstrated the applicability of the

Figure D-3. Installing a passive soil gas module.
Courtesy W.L. Gore & Associates, Inc.

method to soil gas. The fundamental difference is that the gas-phase diffusivity is known in the air, enabling a calculation of concentration from the adsorbed mass, but it is unknown in the vadose zone.

Field studies to calibrate the passive method to actual soil gas concentrations are still too limited to validate the use of this method for quantitative soil gas concentrations. For this reason, passive soil gas is not presently considered to be applicable for stand-alone assessment of vapor intrusion risk. However, passive soil gas sampling does have applications in vapor intrusion assessments. Passive methods offer a quick and relatively inexpensive method to find vapor migration pathways into a structure or around a structure, such as utility corridors. The composition of subsurface soil gases can be determined from passive soil gas samples, and the location of sources and subsurface plumes can be mapped, particularly edges of plumes to determine whether contamination is near current or future buildings. Passive soil gas sampling methods can also be useful in situations where active methods may not be applicable, e.g., low-permeability areas and high-moisture settings. Further, they are capable of detecting and reporting compounds present in very low concentrations.

Special considerations for passive soil gas surveys include the following:

- The adsorbent material should be hydrophobic to minimize water vapor uptake.
- Exposure time—The sampler must be deployed long enough to adsorb a detectable mass, but not so much as to allow the adsorbent to become saturated.
- Desorption and analytical method—The adsorbed compounds can be removed from the adsorbent by thermal desorption or solvent extraction and analyzed using gas chromatography (GC) or GC-mass spectrometry (GC/MS). Methods using thermal desorption have the benefit of greater method sensitivity than those using solvent extraction.
- Sampler installation—For subslab sampling, a narrow-diameter hole is drilled through the slab, and the sampler is slipped into the hole beneath the slab, while the hole itself is sealed. Deeper soil gas sampling generally involves drilling a narrow-diameter hole at least 3–5 feet bgs. The passive sampler is inserted to depth and the installation hole is secured. (See Section 6.0 below for special considerations regarding drilling through slabs.)
- Passive samplers should be transported in a sealable container to preserve cleanliness prior to use and to prevent additional adsorption during return shipment to the analytical laboratory.

Appendix E provides a checklist summarizing additional QA/QC issues.

D.6 SUBSLAB SOIL GAS SAMPLES (INTERIOR)

Subslab samples are soil gas samples collected from immediately below a slab on grade or a basement floor slab. The procedure involves drilling through the concrete slab and collecting a soil gas sample for field or laboratory analysis. Subslab soil gas samples are sometimes collected concurrently with indoor air samples so that the subslab concentrations can be directly compared to indoor air concentrations collected at the same time.

A typical subslab probe is constructed from small-diameter (e.g., ⅛- or ¼-inch outside diameter) stainless steel or another inert material and stainless steel compression fittings. The probes are

cut at a length to either float in the slab or to extend just to the base of the slab (Figure D-4). If repeated sampling is anticipated, surface completions may need to be flush with the surface (trip-proof) and cosmetically clean, especially in residences.

Figure D-4. Installation of subslab soil gas sample port. Courtesy Kansas Department of Health and Environment

Special considerations for subslab soil gas samples include:

- Subslab samples should be avoided in areas where groundwater might intersect the slab.
- Underground utilities (e.g., electric, gas, water, tension rods or sewer lines) should be located and avoided.
- If a vapor barrier already exists under the slab, subslab sampling might puncture the barrier, so the hole must be carefully resealed after monitoring is complete.
- For basements, primary entry points for vapors might be through the sidewalls rather than from below the floor slab, so subslab samples might need to be augmented with samples through the basement walls.
- Sample collection and analysis are analogous to those in other types of soil gas sampling; however, risk-based screening levels for subslab samples are lower than those for deeper soil gas samples, requiring an analytical method with lower detection limits.
- Recent studies have confirmed that temporal variations in subslab soil gas concentrations are usually minimal.

USEPA published an SOP for subslab sampling (USEPA 2006) in March 2006. The NJDEP guidance document (2005b) has a modified version of these procedures. There is also an SOP in the EPRI (2005) handbook. For supplemental or up-to-date references, please refer to the ITRC Vapor Intrusion Web site (www.itrcweb.org/vaporintrusion).

D.7 NEAR-FOUNDATION (EXTERIOR) VERSUS SUBSLAB (INTERIOR) SAMPLING

Subslab sampling is intrusive and sometimes impossible due to access limitations or disturbances to the occupants. In many situations, soil gas samples near the foundation at a depth of ~3–5 feet below the lowest floor may be an appropriate surrogate for subslab sampling for screening purposes, with approval of the regulatory agency. However, there is no consensus regarding the conditions under which near-slab soil gas samples collected around a structure can be used to predict subslab concentrations beneath a structure. Data presented by Diguilio, Wertz, and Abreu at the March 2006 Association for Environmental Health and Sciences workshop indicate that exterior shallow soil gas samples (<10 feet below foundation) may underestimate subslab concentrations for nonbiodegradable compounds. Existing data for hydrocarbons (Davis 2006) suggest otherwise. More studies are currently in progress comparing exterior soil gas concentrations at various depths to subfoundation concentrations.

When subslab soil gas sampling is not possible, it is conservatively recommended to collect multiple near-slab soil gas samples at some depth below the bottom of the lowest floor of the building. See presentations posted at the Indoor Air Vapor Intrusion Database (http://www.iavi.rti.org/WorkshopsandConferences.cfm).

In general, the subslab soil gas concentration cannot be higher than the source concentration. If the soil gas concentrations at the source are below acceptable levels for subslab samples, then subslab samples should not be necessary. In areas of shallow (<25 feet) groundwater, soil gas samples from just above the capillary fringe should be readily obtainable.

For biodegradable hydrocarbons, recent data compiled by Utah Department of Environmental Protection (Davis 2006) indicate that if oxygen levels in the vadose zone are >5% and the source is at least 3–5 feet below the receptor, than the vapor pathway is complete in less than 6% of the sites. Hence, in this situation, if adequate soil porosity exists and areas for air penetration (e.g., lawns and gardens) exist around the structure, it is likely that bioattenuation is occurring under the slab, and near-slab data might be considered to adequately reflect subslab levels, especially for structures with small slabs such as single-family homes.

D.8 MEASUREMENT OF INDOOR AIR (INTERIOR)

Indoor air samples are normally collected after subsurface soil gas characterization and other environmental samples (e.g., groundwater and/or soil gas) indicate the need to conduct an internal site-specific assessment. The analyte list should minimally focus on compounds identified in subsurface samples at concentrations above screening levels, their possible breakdown products, and potentially compounds that may be useful as marker compounds. Since some state agencies require full parameter analysis, confirm the parameter list with the appropriate regulators.

Temporal variability will depend on the duration of the sample. Grab (instantaneous) samples are generally not recommended. For residential settings, air samples are typically collected over a 24-hour period. Air samples for commercial and industrial settings are normally collected over 8 hours to correspond to an average workday. The sample duration should be evaluated and agreed upon during work plan preparation. In addition, confirm the appropriate ventilation conditions with the regulatory agency. Some states require that sampling be performed only in areas where windows and doors have not been opened and air-handling systems have not been operating for several hours.

Short-term temporal variability in subsurface vapor intrusion occurs in response to changes in weather conditions (temperature, wind, barometric pressure. etc.), and the variability in indoor air samples generally decreases as the duration of the sample increases because the influences tend to average out over longer intervals. Published information on temporal variability in indoor air quality shows concentrations with a range of a factor of 2–5 for 24-hour samples (Kuehster, Folkes, and Wannamaker 2004; McAlary et al. 2002). If grab samples are used to assess indoor air quality, a factor of safety (at least a factor of 5) should be used to adjust for short-term fluctuations before comparing the results to risk-based target concentrations. Long-term integrated average samples (up to several days) are technically feasible, using a slower flow rate

(this is the USEPA recommended approach for radon monitoring). Indoor air sampling during unusual weather conditions should generally be avoided.

Specific situations may warrant the need to collect indoor air samples before completing the subsurface soil gas characterization due to an immediate need. Examples of such situations may include, but are not limited to, the following:

- in response to a spill event when there is a need to qualitatively and/or quantitatively characterize the contamination
- if high readings are obtained in a building when screening with field equipment (e.g., PID, organic vapor analyzer, or explosimeter) and the source is unknown
- if significant odors are present and the source is unknown
- if groundwater beneath the building is contaminated, the building is prone to groundwater intrusion or flooding (e.g., sump pit overflows), and subsurface soil gas sampling is not feasible
- regulatory agency requires indoor air sampling
- presence of light, nonaqueous-phase liquid directly below the building
- fractured bedrock potentially creating a preferential pathway into the structure

D.8.1 Presampling Building Surveys

Assessing the vapor intrusion pathway using indoor air analysis may be complicated by the impact of background contaminant sources. Differentiating the common household sources of poor indoor air quality from those associated with contaminated groundwater or subsurface soil is a legal and fiscal dilemma facing both regulatory agencies and potential responsible parties throughout the country.

One of the tools used to identify background sources in the indoor air environment is the “Indoor Air Quality Questionnaire and Building Inventory” prepared by NYSDOH (2006) and provided herein as Appendix G. The questionnaire enables the investigator to document various information on the building, the occupants, and potential sources of indoor air contamination. The questionnaire has been revised and updated over the years by numerous state agencies, including NJDEP, New Hampshire Department of Environmental Services, Vermont Department of Health, and MassDEP. Handheld field screening instruments can be useful to evaluate these types of VOC sources that are unrelated to vapor intrusion.

As part of the presampling site visit, typical entry points should also be evaluated for each building that is to be sampled. Utility corridors can act as contaminant migration pathways allowing VOCs to travel long distances. Any foundation penetrations such as water, sewer, gas, electric and telecommunication lines, as well as sumps, should be screened during the presampling site visit.

D.8.2 Sample Collection Methods

Time-integrated sampling is typically used when conducting indoor air exposure assessments associated with vapor intrusion investigations. A time-integrated sample represents a sample taken at a known sampling rate over a fixed period of time. Two methods are commonly employed: collection of samples in an evacuated canister and collection of samples on adsorbent media.

Collection of Samples in an Evacuated Canister

The sampling canister (Figure D-5) is a passivated or specially lined inert container (e.g., Summa, Silco®) sent to the field under vacuum and certified clean and leak-free. The canister fills with air at a fixed flow rate over a preset period of time with use of a flow controller calibrated and set in the laboratory. Initial and final vacuums are recorded for each canister. The main advantages of canister sample collection are the capability of analyzing multiple samples from the same canister and the ease of deployment and retrieval. Canister methods are most commonly employed in North America. To ensure the canisters are filling at the proper rate, they should be rechecked after deployment. Canisters with dedicated vacuum gauges facilitate this effort and are strongly recommended. The canister must be retrieved prior to being completely filled (with some residual vacuum remaining) to ensure proper collection period.

Figure D-5. Stainless steel canisters.

Collection of Samples on Adsorbents

Sample collection on an absorbent—an option for VOCs and a requirement for SVOCs—can be done actively or passively. Active sampling requires drawing air at a calibrated flow rate through a tube containing adsorbent media over a specified time period. The flow rate and sampling volume used are determined based on the adsorbent used, the COCs, and the amount (mass) of adsorbent contained in the tube. The samples are taken to the laboratory for thermal or chemical desorption and subsequent analysis. Reporting limits are based upon the amount of air that is passed through the tube. It is important to use a sorbent that is certified clean and that can be reliably used for the collection and analysis of the COCs. A primary disadvantage of adsorbent sampling is that typically only one analysis is possible from a tube. Other complications of sorbent sampling are potential compound breakthrough and sorbent contamination from passive adsorption of VOCs.

Passive sampling of indoor air is similar to active sampling methods in which vapor constituents are collected onto adsorbents, but the collection of constituents is based on the diffusion of the compound onto the adsorbent and does not rely on pumps. As an advantage, the passive sampler is simply hung in the indoor air space to be sampled and left for a predetermined period of time. After the exposure period the sampler is placed into an airtight container until analysis of the

media. Exposure times must be determined based on estimated sample concentrations such that the sampler does not reach a state of equilibrium (or saturation) with the environment, a common source of low bias.

D.8.3 Sample Locations and Frequency

A typical single-family residential dwelling (approximately 1500 ft^2) should have one indoor air sample collected from the first floor and one from the basement or crawl space (if present). Significantly larger buildings may require additional samples, especially if there are separate air spaces or separate air-handling units. Multifamily residential units and commercial or retail buildings require a careful review of the building features. Subsurface structures may be present that would facilitate VI and thus degrade indoor air quality in one portion of the building and not another (e.g., partial crawl spaces, sumps, elevators). Any sampling approach should take into account the different exposure scenarios (e.g., day care, medical facilities) that exist within the building and any sensitive populations that may be exposed to the contaminated vapors. Multiple indoor air sample locations are necessary for multifamily residential units and commercial or retail buildings.

Additional sampling considerations include the following:

- Samples should be collected in the breathing zone, ~3–5 feet off the ground, in high-use areas.
- In structures with basements, both the occupied living areas and basement areas may be sampled from a risk management perspective.
- For multistory residential buildings, consideration should be given to collecting one sample on each floor or other appropriate sample locations.
- If indoor air samples are being collected as a stand-alone determination of the VI pathway, a second confirmation sample may be necessary in colder climates due to seasonal variations. One of the two sampling events should take place during the months between November and March, since these are generally worst-case conditions for VI.
- However, in those cases where the results are an order of magnitude below the appropriate screening levels, a second round of sampling is likely not necessary.

D.8.4 Analysis Methods

The most common contaminants of potential concern for VI investigations are VOCs though SVOCs are also of concern. Table D-3 (at the end of this appendix) lists available methods for VOCs and SVOCs.

The TO-14A and TO-15 methods are commonly used for VOCs in indoor and ambient air samples. A driver behind using these methods is the ability to achieve very low reporting limits (RLs). Using the method that can achieve the lowest RLs is not always the best or most viable option. TO-15 utilizes a GC/MS as the detector. The MS can be run in two different modes: full scan and selective ion monitoring (SIM). (Note: Some compound selectivity and the ability to identify unknowns may be lost in the use of SIM analysis due to limiting the masses scanned.) Standard TO-15 is normally run in the full-scan mode and can give a large list of approximately

70 compounds with RLs ranging 0.2–0.5 ppbv. This analyte list and RLs are generally more than sufficient when analyzing soil gas. In the SIM mode, TO-15 has the ability to reach RLs ranging 0.002–0.010 ppbv for a smaller list of (12–15) compounds. (Check with your laboratory, which may have its own list of compounds.) Because soil gas samples generally have COCs at higher concentrations than the SIM method can calibrate to, the SIM method is appropriate for only indoor and ambient air samples.

It is important to note that QA/QC protocols may vary greatly among laboratories, so the practices should be reviewed and specified in the work plan prior to data collection. Data validation methods (when required by the regulatory agency) should also be specified and approved in advance.

D.9 SAMPLING OF CRAWL SPACES (INTERIOR)

Many crawl spaces are designed with vents and may allow outdoor air exchange, so the concentration in the crawl space may be inversely proportional to the ventilation rate, which is not usually controlled. This effect can influence sampling results, as well as the vapor intrusion migration pathway analysis. Other types of crawl spaces have limited access, making it more difficult to collect samples.

Typically, crawl-space samples are collected following protocols similar to those for indoor air samples. For crawl spaces with limited access, a sampling tube is typically inserted horizontally through the crawl-space sidewall access ports or vertically through the overlying floor. As with soil gas or indoor air samples, enough measurements should be collected to get a representative value in the crawl space.

There are several options for sampling air from the crawl space. Crawl spaces can be sampled by collecting soil gas samples (active or passive), air samples (with canisters or adsorbents), or soil gas samples with flux chambers (identified as a supplemental data tool later in this appendix).

D.10 AMBIENT (OUTDOOR) AIR SAMPLING

When sampling indoor air as part of a vapor intrusion study, outdoor ambient air samples should be also collected to characterize site-specific outdoor air background conditions. Ambient air could possibly contain numerous volatile compounds, especially in highly populated or industrialized areas. The outdoor ambient air levels of some volatile compounds can often exceed indoor air risk-based screening levels.

Outdoor air samples should be collected from a representative location, preferably upwind and away from wind obstructions such as trees and buildings. The intake should be at ~3–5 feet off the ground (at the approximate midpoint of the ground-story level of the building) and ~5–15 feet away from the building.

Representative samples should be placed to minimize bias toward obvious sources of volatile chemicals (e.g., automobiles, lawn mowers, oil storage tanks, gasoline stations, industrial

facilities, etc.). Outdoor air samples should be collected and analyzed by the same method as indoor air samples.

For determining ambient air concentrations, USEPA recommends that ambient sampling begin at least 1 hour and preferably 2 hours before indoor air monitoring begins and continue until at least 30 minutes before indoor monitoring is complete. This practice is recommended since most buildings have an hourly air exchange rate in the range of 0.25–1.0, and thus air entering the building in the period before indoor sampling remains in the building for a long time.

D.11 SUPPLEMENTAL TOOLS/DATA USEFUL FOR VI INVESTIGATIONS

D.11.1 Emission Flux Chamber Method

Flux chambers are enclosures placed directly on the surface (e.g., ground, floor) for a period of time, and the contaminant concentration in the enclosure is measured. In theory an effective room concentration can be calculated from the measured flux by assuming the measured flux is constant over time and over the floor area of the room and assuming a room ventilation rate. The calculated room concentration can be compared directly to allowable room concentrations for the volatiles of interest. This method offers advantages in some cases because it yields the actual flux of the contaminant out of the ground, which eliminates some of the assumptions required when using other types of subsurface data. The method has long been used by regulatory agencies at hazardous waste sites and it is widely used for measuring trace emissions from natural soils, but its application to vapor intrusion assessments is relatively limited.

The testing is typically conducted in one of two modes: dynamic or static. In dynamic systems, a sweep gas is introduced into the chamber to maintain a large concentration gradient across the emitting surface. The effluent air from the chamber is collected using canisters and analyzed for COCs. This method is best suited for situations where large fluxes are anticipated. In static systems, a chamber is emplaced, and the contaminant concentration buildup is measured over time. This method is best suited for situations where lower fluxes are anticipated.

Flux chambers are not well suited for structures with covered floor surfaces such as single family residences because the primary entry points of soil gas into the structure (cracks, holes, sumps, etc.) are often concealed by floor coverings, walls, stairs, etc. For structures, the method has more application to larger industrial and commercial buildings with slab-on-grade construction where the slab is mostly uncovered. A building survey using a real-time analyzer or on-site GC can be used to attempt to identify the primary locations of vapor intrusion.

Flux chambers are best suited for situations where measurement from bare soils is desired, such as the following:

- homes with dirt basements or crawl spaces
- mobile homes above unfinished slabs or soil
- evaluation of future-use scenarios at sites without existing buildings
- to demonstrate the occurrence of bioattenuation from areas with shallow soil gas contamination (<5 feet bgs)

Flux chambers can also be used as a qualitative tool to locate surface fluxes of VOC contamination and entry points into structures.

Regardless of the method used, enough chamber measurements should be collected to get a representative value under the footprint of the building (analogous to placing enough borings on a typical site), near edges where the slab meets the footing, over any zones with cracks or conduits, and over the center of the contamination if known. In all cases, it is recommended that chambers be deployed for long enough periods to enable temporal variations to be assessed, similar to indoor air measurements (8–24 hours depending upon the conditions; 24 hours if large temperature differences exist between day and night (County of San Diego *Site Assessment Manual*).

More details on the flux chamber method can be found in Kienbusch 1986, Eklund 1992, and Hartman 2003.

D.11.2 Determination of Slab-Specific Attenuation Factor Using Tracers

Measurement of a conservative tracer inside the structure and in the subslab soil gas can enable calculation of a site-specific attenuation factor. The calculated attenuation factor can then be used to estimate the indoor air concentration of other COCs by multiplying the measured subslab soil gas concentration by the attenuation factor for the tracer (or "marker compound"). This method assumes that all subslab vapor phase contaminants are entering the building at equal rates, a relatively safe assumption for most situations. Naturally occurring radon is the most commonly used conservative tracer. Other potential tracers include breakdown products such as 1,1-DCE or cis-1,2-DCE, which are generally not found in consumer products, building materials, or outdoor air. Complications to this technique include the presence of indoor sources of the tracer (if any) and any temporal variations. However, if subslab samples are being collected, concurrent collection of radon or another tracer data may prove useful and is generally not too expensive. Determination of radon concentration using adsorbents is possible for indoor air samples but not for soil gas samples including subslab samples. Soil gas methods exist for the collection of subslab radon concentration measurements (USEPA 2006), but analysis of the samples may not be readily available from most commercial laboratories.

D.11.3 Determination of Room Ventilation Rate Using Tracers

The indoor air concentration is inversely proportional to the room ventilation rate: doubling the ventilation rate halves the indoor air concentration. The default ventilation rates used by USEPA and many other agencies are conservative: room exchange rates of once every 1–4 hours for residences and once every hour for commercial buildings. For some structures, typically commercial buildings, the actual ventilation rate can be determined from the HVAC system or building design specifications, keeping in mind that the air exchange rate should be calculated from the make-up volume, not the total air-handling volume. For other structures, typically residences, this information is not readily available, so the ventilation rate must be either measured or assumed at the default value. ASTM Method E 741 describes techniques for measuring ventilation rates using gaseous tracers such as helium or sulfur hexafluoride (SF_6).

Typically, a pulse input of tracer gas is applied, and the decay in concentration versus time is measured. The inverse of the air exchange rate is the slope of a plot of natural logarithm of the normalized concentration (Ct = n / Ct = 0) versus time. If a subsurface tracer gas is used, this can serve as the pulse input. Alternatively, a tracer gas can be released at a constant rate and the concentration measured once steady state conditions are reached (i.e., typically after three or four air exchanges).

The techniques are quick and relatively inexpensive. For colder climates, measurement during the cold and warm seasons may be prudent if the ventilation rate during the more conservative case (cold season) suggests unacceptable indoor air concentrations.

D.11.4 Differential Pressure Measurements

Models and look-up values used by USEPA and many state regulatory agencies are based on assumed advective flow into the structure due to a pressure gradient of 4 pascals. This assumption can be checked in the field to provide another line of evidence to evaluate vapor intrusion using a digital micromanometer attached to a subslab soil gas probe. It is often advisable to use one with data-logging capabilities and assess the response to wind speed and barometric pressure changes if these data are collected.

Measurement of the pressure gradient between the structure and outdoors can assist in interpreting measured indoor concentrations of contaminants. A correlation between indoor air concentration and relative pressure could provide information on the contaminant source. For example, if a building is overpressured relative to the subsurface, measured indoor concentrations might be more likely attributable to aboveground sources. Conversely, if the building is underpressured relative to the subsurface, measured indoor concentrations might be more likely attributable to subsurface sources. Commercial buildings with large HVAC systems, and perhaps residences with air-conditioning units, may fall into the former category. Many structures in cold environments, especially residences, will fall into the latter category when the heaters are running. These data will usually be used as a secondary line of evidence in support of indoor air quality data or other lines of evidence.

D.11.5 Real-Time and Continuous Analyzers

As with any type of site investigation, it is difficult to reach any conclusions with any degree of confidence with only a handful of data points. Vapor intrusion data sets consisting of one soil gas and/or indoor air analysis per structure may be very difficult to interpret, but cost and access limitations often preclude multiple analyses. Real-time analyzers can be used less expensively to collect multiple sampler that can be used to locate problem structures, vapor migration routes into structures, and volatile sources inside the structures. Continuous analyzers that collect data automatically over a period of time can sort out background scatter and determine temporal variations both indoors and below ground. Larger data sets allow trends in the results to be recognized and correlated to other variables such as pressure differentials, wind speed, and HVAC systems. Larger data sets allow forensic approaches to be applied.

A variety of real-time analyzers exist, including handheld logging instruments (PID, FID, thermal conductivity detector [TCD], infrared analyzers, z-Nose®, and ppbRAE), automated GCs, portable MSs, and USEPA's own Trace Atmospheric Gas Analyzer (TAGA). Many of these will have applicability that is limited by their sensitivity or cost.

D.11.6 Forensic Data Collection and Analysis

Forensic approaches attempt to determine the source of any detected volatiles through a detailed study of the nature of contamination with focus on lines of evidence to potential sources. Traditional environmental site assessments focus on the nature and extent of contamination as determined by common methodologies developed to provide data for regulatory purposes. The environmental forensics approaches are more sophisticated analytical techniques that have the ability to produce chemical fingerprints that are source specific. Potential fingerprinting strategies include the following:

Forensics Used at Colorado's Redfields Site

Forensic approaches were used at the Redfield Rifles site in Colorado to determine whether the source of subslab contaminants was in the vadose zone or the overlying structure (McHugh, De Blanc, and Pokluda 2006).

- Using compound ratios (e.g., DCE/TCE) and comparing them in the soil gas and indoor air results
- Distinguishing between different types of hydrocarbons (e.g., diesel, gasoline, jet fuels) using comprehensive analysis of the samples, including total chromatographic patterns
- Using isotope ratios (e.g., Cl-36, C-13) to distinguish between chlorinated solvent manufacturers and identify multiple sources in comingled groundwater plumes

Environmental forensics is a developing approach that will likely be increasingly important in regulatory enforcement actions and cost-recovery litigation.

D.11.7 Soil Physical Properties

Site-specific soil properties such as bulk density, grain density, total porosity, moisture content, and fraction organic carbon can be measured from soil samples and the results used to replace default input parameters when models are employed. Air permeability of the vadose zone can be determined from either in situ or laboratory measurements. In situ measurements test a larger portion of the subsurface than a laboratory measurement of a small core sample. In situ measurements of air permeability should be conducted in the shallow vadose zone, the area of the vadose zone subject to advection by building-driven depressurization, or to assess the presence of low-permeability layers in the unsaturated zone, which may act as partial vapor barriers.

D.11.8 Meteorological Data

A variety of weather conditions can influence soil gas or indoor air concentrations. The radon literature suggests that temporal variations in the soil gas are typically less than a factor of 2 during a season and less than a factor of 5 from season to season). Recent soil gas data from

Endicott, New York and Casper, Wyoming are in agreement with the radon results. For soil gas, the importance of these variables will be greater the closer the samples are to the surface and are unlikely to be important at depths greater than 3–5 feet below the surface or structure foundation.

Indoor air may be more susceptible to weather conditions, so collection of meteorological data can be helpful to assessing the vapor intrusion risk:

- Rainfall events—Precipitation can affect vapor intrusion rates and possible soil gas concentrations. Percolation of water through the soil can displace soil gas and lead to a short-term spike in vapor intrusion. The increased soil moisture after a rain event can reduce vapor transport through the soil due to reduced effective porosity and permeability. Measurements made during or immediately after a significant rain event (e.g., >1 inch) may not be representative of long-term average conditions. For other sites, however, frequent rainfall is common, and testing soon after a rain event is both representative and inevitable.

- High wind speed—High wind speed can create pressure differentials around a structure causing an advective flow in the shallow soil gas around and beneath a structure. This condition can create a number of situations including an inflow of air into the vadose zone on the windward side of a building, outflow of soil gas on the leeward side, and overpressurization of the area under the building versus the building itself. Such a flow pattern can lead to higher oxygen concentrations at deeper depths on one side of a building than on the other, which is relevant at sites with hydrocarbon contamination. Recent studies by the American Petroleum Institute suggest that horizontal flow of the soil gas under slab-on-grade foundations can be rapid in areas with sandy soils, which is also likely coupled to wind speed. Unusually windy conditions should be avoided for sampling to the extent possible.

- Frozen ground or permafrost—The inflow of air into the vadose zone or soil gas out of the vadose zone may be restricted if the ground surface is frozen and snow-covered, so these conditions should be noted where applicable.

- Major storm events—Changes in barometric pressure can create movement in the near surface vadose zone, a process known as “barometric pumping.” For most normal climatic conditions, the effect on soil gas concentrations will be minimal; however it may be significant near or during major storm events or for sites with very deep unsaturated zones, especially if the geologic materials are fractured (Parker 2003).

D.11.9 Pneumatic Testing

In some cases, geologic layers can form partial or complete barriers to upward vapor transport toward overlying buildings, particularly laterally continuous, fine-grained soil layers that retain sufficient moisture to be saturated or nearly saturated. It may be possible to identify the presence of such geologic barriers using pneumatic testing, analogous to a groundwater pumping test, where one well is used for extraction and other wells are used for monitoring the vacuum response. If the extraction well is screened below the fine-grained layer and the monitoring probe is screened above the fine-grained layer, the pneumatic test can be analyzed to assess

whether and to what extent there is pneumatic connection between the intervals. Alternatively, a test can be conducted using two wells screening in the geologic layer below the fine-grained unit, where the vacuum versus time data collected at the monitoring well is analyzed using the Hantush-Jacob (1955) leaky-aquifer solution to calculate the vertical leakage (or absence thereof) through the fine-grained "confining" layer, as described by Thrupp, Gallinatti, and Johnson (1996). These pneumatic tests provide information within the subsurface region that is stressed during the test, which can span hundreds of feet, but knowledge of the geology is important prior to inferring conditions farther from the test location.

D.11.10 Manipulating Pressure Differentials

One possible method for distinguishing subsurface vapor intrusion from background sources is to collect indoor air samples with and without manipulating the pressure differential from the subsurface to indoor air. This can be accomplished by pressurizing the building or depressuring the region beneath the floor slab. In both cases, if the applied pressure differential is sufficient to prevent subsurface vapor intrusion, the concentrations of chemicals intruding from the subsurface will be reduced and the concentrations of chemicals from background sources will be largely unaffected. Folkes (2000) reported measured indoor air concentrations for several chlorinated hydrocarbons before and after the operation of a subsurface depressurization system to mitigate subsurface vapor intrusion.

Table D-3. Summary of analytical methods for soil gas, indoor and ambient air samples[a]

Parameter	Method	Sample media/storage	Description[b]	Method holding time	Reporting limit[c]
VOCs					
BTEX, MTBE, TPH	TO-3	Tedlar bag or canister/ambient temperature	GC/FID	30 days for canister	1–3 μg/m^3
Nonpolar VOCs	TO-14A	Canister/ambient temperature	GC/ECD/FID or GC/MS	30 days for canister	1–3 μg/m^3
Polar and nonpolar VOCs	TO-15	Canister/ambient temperature	GC/MS	30 days for canister	1–3 μg/m^3
Low-level VOCs	TO-15 SIM	Canister/ambient temperature	GC/MS	30 days	0.011–0.5 μg/m^3
Polar and nonpolar VOCs	TO-17[d]	Sorbent tube, chilled <4°C	GC/MS	30 days	1–3 μg/m^3
VOCs	8021B modified[e]	Syringe, Tedlar bag, glass vial/ ambient temperature	GC/PID	On-site analysis or up to 30 days (depending on container)	10–60 μg/m^3
VOCs	8260B modified[e]	Syringe, Tedlar bag, glass vial/ ambient temperature	GC/MS	On-site analysis or up to 30 days (depending on container)	50–100 μg/m^3
SVOCs					
SVOCs	TO-13A[d]	High-volume collection (may require large sample volume, e.g., 300 m^3)/PUF/XAD media, chilled <4°C	GC/MS	Extracted within 7 days of collection and analyzed within 40 days of extraction	5–10 μg/sample
Low-level olycyclic aromatic hydrocarbons (PAHs)	TO-13A SIM[d]	High-volume collection (may require large sample volume, e.g., 300 m^3)/PUF/XAD media, chilled <4°C	GC/MS	Extracted within 7 days of collection and analyzed within 40 days of extraction	0.5–1 μg/sample
Pesticides and polychlorinated biphenyls (PCBs)					
Pesticides and PCBs	TO-4A[d] or TO-10A[d]	High-volume collection (may require large sample volume, e.g., 300 m^3)/PUF media, chilled <4°C	GC/ECD	Extracted within 7 days of collection and analyzed within 40 days of extraction	Pesticides: 0.5–1 μg/sample, PCBs: 1–2 μg/sample
Fixed gases					
Fixed gases (methane, nitrogen, oxygen)	USEPA 3C	Canister or Tedlar bag/ambient temperature	GC/FID	3 days for Tedlar bag, 30 days for canister	1000–2000 μg/m^3

Parameter	Method	Sample media/storage	Description[b]	Method holding time	Reporting limit[c]
Fixed gases (methane, nitrogen, oxygen, carbon dioxide, carbon monoxide)	ASTM D-1946	Canister or Tedlar bag/ambient temperature	GC/TCD/FID	3 days for Tedlar bag, 30 days for canister	1000–2000 μg/m^3
Natural gases	ASTM D-1945	Canister or Tedlar bag/ambient temperature	GC/FID	3 days for Tedlar bag, 30 days for canister	1000–2000 μg/m^3
TPH–alkanes					
C4–C24	8015 mod.	Canister or Tedlar bag/ambient temperature	GC/FID	3 days for Tedlar bag, 30 days for canister	10 ppmv
C4–C12	8260	Canister or Tedlar bag/ambient temperature	GC/MS	3 days for Tedlar bag, 30 days for canister	1 ppmv[d]
C4–C12	TO-15	Canister or Tedlar bag/ambient temperature	GC/FID	3 days for Tedlar bag, 30 days for canister	0.1 ppmv

[a] This is not an exhaustive list. Some methods may be more applicable in certain instances. Other proprietary or unpublished methods may also apply.

[b] ECD = electron capture detection, FID = flame ionization detection, GC = gas chromatography, MS = mass spectrometry, PID = photoionization detection, TCD = thermal conductivity detection

[c] Reporting limits are compound specific and can depend upon the sample collection and the nature of the sample. Detection limits shown are for the range of compounds reported by the analytical methods.

[d] The indicated methods use a sorbent-based sampling technique. The detection limits will depend on the amount of air passed through the media.

[e] Method is generally applicable only for on-site analysis of soil gas samples.

Table D-4. Matrix of various quantitative options to evaluate vapor intrusion

Measurement approach	Source at depth (> 5 feet) directly under building				Shallow source (<5 feet) under building				Source in vadose zone adjacent to building				Special conditions			
	Undeveloped site	Residential with basement or slab-on-grade floor	Residential with dirt floor or crawl space	Commercial/ industrial	Undeveloped site	Residential with basement or slab-on-grade floor	Residential with crawl space or dirt floor	Commercial/ industrial	Undeveloped site	Residential with basement or slab-on-grade floor	Residential with crawl space or dirt floor	Commercial/ industrial	Petroleum hydrocarbons	Vapor migration routes	Wet basement	Very-low-permeability soils
Shallow groundwater (near water table)	P	P	P	P	P	O	O	O	O	O	O	O	S	O	P	O
Deep (> 5 feet) soil gas	P	P	P	P	N	N	N	N	P	P	P	P	P	O	N	N

Meteorological data	O	O	O	O	O	O	O	O	O	O	O	O	O	O	O	O

This rating indicates that each tool can be used for the category lower in the hierarchy.

P = primary investigative tool, can potentially be used as a principal tool for assessing VI.

S = secondary investigative tool, can be used to develop CSM and/or as a line of evidence in support of another line of evidence.

O = Optional investigative tool, may be useful to further define VI pathway or as means to focus primary investigative tools.

N = not usually appropriate as an investigative tool for vapor intrusion assessment.

Table D-5. Pros and cons of various investigative strategies

Measurement	Relative Advantages	Relative Disadvantages	Comments
Deep soil gas (>5 feet below slab)	• Existing data may already be available for some sites • Less chance of short-circuiting by atmospheric air • Temporal variations in concentration minimal	• Data may not be representative of soil gas concentrations at shallower depths due to intervening soil layers • Does not account for aerobic biodegradation in shallower soil layers	When combined with other data, deep soil gas data can provide evidence of attenuation as a function of vertical transport distance. However, deep soil gas sampling is conservative for screening purposes.
Shallow soil gas (<5 feet below slab or basement floor)	• Standard equipment and approaches have been developed • Media most likely to intrude into receptors • Data can be collected outside the building	• Rate of vapor transport to the building must be estimated • May not reflect subslab concentrations • Greater temporal variability than deeper soil gas data	Building zone of influence must be taken into consideration in sampling design. Shallow soil gas sampling may not be conservative for screening purposes.
Subslab soil gas	• Provides more representative subsurface data for sites with surface releases (e.g., spills and leaks) • Gives concentrations immediately below building and receptors	• May contain contaminants from interior sources • Highly intrusive; requires building access and drilling through slab/floor • Rate of vapor transport into the building must be estimated • Conservative screening levels	Preferred approach of many regulatory agencies. Concurrent determination of slab-specific attenuation factor may be useful to interpret data.
Emission flux	• Measure actual contaminant emissions from subsurface • Takes into account all subsurface processes such as biodegradation, advection, sorption • Eliminates interpretation using attenuation factor or model	• Equipment and experienced staff may be difficult to find • Selection of representative sampling locations may be difficult • Biased low results if emission “hot spots” are not sampled • Not considered by most regulatory agencies	This approach is best suited for evaluating future-use scenarios on undeveloped land, houses with dirt floor basements or crawl spaces, and to confirm bioattenuation in shallow vadose zone (<3 feet bgs).
Soil gas attenuation (α) factors	• Quick and very easy	• Attenuation factors used for this purpose tend to be very conservative (e.g., $<50^{th}$ percentile) • Empirical attenuation factors may be biased high due to sources other than vapor intrusion • No agreed-upon attenuation factors for many regulatory jurisdictions	Attenuation factors may be based on empirical measurements of concentration ratios at other sites or on assumed Q_{soil} and building ventilation flow rates.

Measurement	Relative Advantages	Relative Disadvantages	Comments
Slab-specific attenuation factor determination (from subsurface tracer)	• Naturally occurring compounds (e.g., Rn-222) can be used in some cases • Provides a direct measure of attenuation across a slab • Typical values often >10 times lower than default values	• Usually requires separate analytical method than that used for target compounds • If radon is used, investigator may find indoor concentrations exceeding health-risk levels • Radon not present everywhere at levels distinguishable from background	Method assumes that the tracer and subsurface contaminants move into the building at the same rate.
Indoor air	• Relatively simple to collect samples • Direct measurement of contaminant concentrations in buildings • May be more convincing to occupants	• Background sources complicate data interpretation • Requires access to indoor space • For residential sites, a building survey prior to sampling is often necessary • Very low reporting limits may be required for some compounds (e.g., TCE) • One-time sampling results may not be representative of long-term average concentrations • Poor sample control	Time-integrated samples are typically collected (e.g., 24-hour samples for residential sites and 8-hour samples for industrial sites).
Crawl-space air	• Simple to measure	• Background sources from overlying structure may complicate data interpretation	Most guidance uses an attenuation factor of 1.0 between crawl space and indoor air.
Pressure differential	• Relatively simple to measure • Can provide evidence of direction of vapor transport (in or out)	• Requires subslab port or other subsurface sampling point • Temporal variations complicate interpretation and often requires multiple sampling events	Detection levels down to 1 pascal can be obtained using inexpensive 0–0.25 inch H_2O magnahelic gauge.
Building ventilation rate	• Very simple to measure (standard ASTM method exists) • For many commercial buildings, rate is already known from design specifications • Value can be >10 times default parameters allowed in models	• For residences, seasonal variations may be large	Fewer sampling locations are needed if additional mixing of air within building is provided. Most commonly used for commercial receptors.

Measurement	Relative Advantages	Relative Disadvantages	Comments
Forensics	• Can differentiate sources of contaminants	• Typically requires a significant amount of data • Methods still being developed • Background sources can complicate interpretation	Forensic approaches are not likely to be used until later rounds of an investigation.
Continuous analyzers	• Provide large amounts of data • Can help sort out temporal variations and background scatter	• Limited use	Larger data sets allow correlation to other variables such as pressure differentials, wind speed, and HVAC systems.
Soil physical properties	• Easy to measure • Enable site-specific values to be used in predictive models • Values can be >10 times default parameters in models	• Data collected near a building may not be representative of zone beneath building • Difficult to get rig near most residential buildings (e.g., lawns, landscaping, trees)	Most sensitive soil physical properties to measure are percentage of water content and permeability.
Groundwater data	• Monitoring wells already exist for many sites (previous data) • Acceptable to most agencies • Familiar media to most investigators • Temporal effects minimal	• Look-up values, attenuation factors, or models tend to be extremely conservative, so VI risk is often overestimated • Existing data may be from a well that is not optimally screened for upper water table	This approach often used as an initial screen.
J&E model with groundwater or soil gas data	• Quick and easy • Model can account for various site-specific factors • Potential future scenarios can be evaluated	• Default input values to model tend to be very conservative • Pressure differential always assumed to be present (i.e., Q_{soil} assumed to be positive value) • Model does not account for biodegradation of BTEX or other compounds • Model is designed to evaluate residential scenarios and has some added limitations if used for other scenarios • Regulators may not accept results if depth to groundwater is <5 feet	The accuracy of the model output is best if the pollutant transport distance is at a minimum (i.e., shallow soil gas is better than deep soil gas) and no partitioning calculations are needed (soil gas data are better than groundwater data).

APPENDIX E

Quality Assurance Considerations

Electronic Filing: Received, Clerk's Office 07/01/2024

QUALITY ASSURANCE CONSIDERATIONS

Quality assurance and quality control procedures should be implemented in every step of the assessment process to ensure the collection of data of acceptable quality. This appendix discusses some general QA/QC considerations for field and laboratory activities.

QA/QC for Active Sampling

The majority of the soil gas and indoor air sampling conducted for the investigation of the vapor intrusion pathway is for VOCs. This section focuses on USEPA Method TO-15, which uses specially treated, certified clean, leak-free canisters for the collection of air samples in the field. Canisters are shipped to the field under vacuum of approximately –30 inches Hg. Flow controllers, calibrated in the laboratory, are sent with the canisters to allow the canisters to collect the samples over a set time period.

Below are *examples* of QA/QC procedures that should be considered. This list is not meant to be exhaustive:

- Analyte list and reporting limits—Discuss your program-required analyte list and reporting limits with the laboratory to ensure they will be met.
- Determine from the laboratory whether its reporting limit refers to a method detection limit (MDL), practical quantitation limit (PQL), or some other reporting limit.
  - MDL = 99% confidence that data is distinguishable from background noise
  - PQL = an estimated value usually 3–5 times the MDL
  - RL = concentration ≥ the lowest calibration standard > MDL

  (www.depweb.state.pa.us/landrecwaste/lib/landrecwaste/land_recycling/workshops/usingyourlabwisely.ppt#349,14,How)
- Laboratory certification—Many regulatory agencies across the country require laboratories to be certified to conduct air analysis.
- Certified canisters—The laboratory must certify that the canister is leak-free and clean below the RL for the VOCs of concern.
- Flow controllers—The laboratory provides a flow controller that is clean and calibrated to collect a sample over a specified time frame (e.g., 30 minutes to 24 hours).
- SOPs—Ensure that the sampling crew follows documented, reproducible field procedures.
- System leak checks for soil gas samples–Use a tracer gas to check for leakage around the sampling probe and analytical sampling train.
- Initial and final vacuum readings—The sampler should take the canister vacuum reading before and after sampling to ensure that the canister was leak-free upon receipt in the field and that the flow controller collected the sample over the specified amount of time.
- Precautions should be taken to avoid sample interference such as fueling vehicles prior to sampling or using permanent marking pens in the field.
- Required laboratory QC samples—Mass spectral tuning, initial calibration, continuing calibration verification, laboratory control spike, and method blank.

- Additional QC samples (if needed):
  - Trip blanks refer to canisters sent out with the canister batch to test for the presence of contaminants introduced during transit and storage.
  - Method blanks refer to purified gas (air, nitrogen) samples collected through the sampling system to test for the presence of contaminants introduced by the sampling methods.
- Analytical holding time per USEPA TO-15—Analysis of canister samples for VOCs must be completed within 30 days from collection; check with the state or region to verify holding time requirements.

QA/QC for Passive VOC Sampling

As with any site investigative tool, passive sampling requires adequate QA/QC to provide data of sufficient quality to ensure proper decision making. Modified USEPA Methods 8260 and 8270 may be used for analysis, or USEPA TO-17 using thermal desorption followed by GC/MS may be used. QA/QC requirements are based more on DQOs than on prescriptive procedures. Specific QA/QC procedures vary depending on the manufacturer of the sampler and on the analytical laboratory. Therefore, it is important to understand what procedures will be used and to determine whether they are adequate to meet DQOs.

At a minimum QA/QC procedures should consider the following:

- Passive sampler installation, retrieval, and handling—To ensure consistency of deployment and sample integrity prior to analysis.
- Units of measure—Concentration or mass (or some other relative) units. If concentration data are to be provided, are there sufficient data to verify sampling rates, indifference to changing air flow, and sampler capacity?
- Detection limit—Are the sampler and analytical method of sufficient sensitivity?
- Cleanliness of sampler—Are procedures in place to verify the cleanliness of the sampler? The sampler background must be sufficiently less than RLs.
- Instrument tuning—Applicable if MS detection is used.
- Instrument calibration—Are target compounds used for calibration and concentration ranges adequate to cover COCs and suspected sample levels?
- Control samples—Method, trip, and field blanks to verify integrity of samples during shipment and potential levels of background.
  - Method blanks are clean adsorbent material analyzed by the applicable analytical method to determine any potential background levels of target compounds contributed by the analytical method.
  - Trip blanks are unexposed passive samplers that accompany samplers during transport to the field and then to the laboratory to determine any potential background levels of target compounds that may have been contributed during transport.
  - Field blanks (for soil gas sampling only) are passive samplers exposed to ambient conditions for the same amount of time field-exposed samplers are exposed to ambient conditions prior to installation in the subsurface, intended to determine the potential

contribution of background levels of target compounds contributed by ambient air and not soil gas.

- Replicate analyses—If replicate analysis is required, does that sampler allow for multiple analyses or do multiple samplers need to be co-located?
- Are matrix spikes required?

Other QA/ QC Considerations

- Passive samplers should be transported in a sealable container to preserve cleanliness prior to use and to prevent additional adsorption during return shipment to the analytical laboratory.
- For subsurface applications, the samplers should also have a design that keeps soil, microbes, liquid water, and other contaminants from coming in direct contact with the adsorbent.
- The adsorbent material should be hydrophobic to minimize water vapor uptake.
- Accurate time recording is essential for comparison of results, and all samplers in a given medium should be deployed for a consistent amount of time. The time may vary for different media. For example, if soil gas concentrations are expected to be higher than indoor air concentrations, the soil gas samplers may approach saturation before the indoor air samplers have sufficient mass to reach analytical detection limits, in which case, the indoor air samplers should be deployed for a longer period than the subsurface samplers.

APPENDIX F

Regulator’s Checklist for Reviewing Soil Gas Data

Electronic Filing: Received, Clerk's Office 07/01/2024

REGULATOR'S CHECKLIST FOR REVIEWING SOIL GAS DATA

ITRC Vapor Intrusion Pathway Overview

SAMPLE COLLECTION ISSUES

Active Soil Gas Surveys

- □ Did the probe rod have an inert internal tube (stainless steel, Teflon®, nylon)?
- □ Was the probe adequately decontaminated between samples?
- □ Were at least three dead volumes of the probe purged?
  - ⇨ *Avoid excessive purging, unless field screening (O_2, CO_2, PID, or FID and tracer gas) conducted to demonstrate absence of atmospheric air intrusion.*
- □ Were samples collected deep enough to minimize air infiltration?
  - ⇨ *At least 5 feet bgs unless special precautions used to minimize purge volume and confirm absence of atmospheric air.*
- □ Did it rain shortly before the sampling event?
  - ⇨ *Soil gas sampling should be avoided following significant precipitation.*
  - ⇨ *Generally, there is no consensus on how much rain can fall or how long you should wait. It depends on soil type, amount of rain, and previous soil moisture content.*
- □ Was a reliable method used to ensure the absence of atmospheric air leakage?
  - ⇨ *Probe sealed at the surface and throughout the borehole annulus?*
  - ⇨ *Tracer compound used to demonstrate no leakage down or around probe and at all sample train fittings?*
- □ Were samples collected close to the surface (<3 feet bgs) repeated?
- □ Were small sample volumes collected?
- □ Were samples collected in appropriate containers for the COC(s)?
- □ If canisters were used, was each canister certified clean or batch-tested?
- □ Were flow controllers and sample trains reused?
  - ⇨ *If yes, they should be cleaned between samples.*
- □ Were vacuum pumps used in the sample collection?
- □ Were excessive vacuums required to obtain a sample?
  - ⇨ *>10 inches of H_20 should be avoided.*
- □ Were samples collected upstream of the vacuum pump?
- □ Were samples analyzed on or off site?
- □ For canisters, were samples stored at ambient air temperature?
- □ Were samples analyzed within recommended holding times?
- □ If both on-site and off-site analyses were performed, do the results generally agree?

Passive Soil Gas Surveys

- □ Were method and trip blanks analyzed?
  - ⇨ *Needed to show absence of contaminants from laboratory or transportation back and forth to site.*
- □ Were samplers left in the ground for consistent and sufficient time?
  - ⇨ Generally a few days to two weeks.
  - ⇨ Collect in same sequence as deployed.
- □ Were duplicate samples collected, and how do they compare?
- □ Are data used appropriately?
  - ⇨ For what purpose?
  - ⇨ Were active soil gas samples collected for comparison?
  - ⇨ How well do passive and active samples compare?
- □ Could measured values be from infiltration of contaminated atmospheric air or from an overlying surface (e.g., asphalt, dirty soil)?
- □ Are relative concentrations of compounds detected consistent with expectations from other media (soil gas, groundwater, bulk soil)?

Flux Chamber Surveys

- □ Were the sample locations representative?
  - ⇨ Near vapor migration routes?
  - ⇨ Open ground, covered ground, cracked ground covers?
- □ How long was the deployment time? Was it long enough to average temporal variations?
  - ⇨ Match indoor air default collection times.
- □ Was a sweep gas used? Was the outflow balanced to the inflow to ensure no leaks?
  - ⇨ If outflow lower than inflow, sweep gas exiting bottom.
  - ⇨ Pressure measurements not adequate to test this.
- □ Did the chamber concentration reach high enough values to influence the flux?
  - ⇨ Should be no more than 20% of risk-based maximum flux value.
- □ What volume of vapor was collected from the chamber?
  - ⇨ Volume collected should be less than 20% of chamber volume.
- □ How fast was it collected? Did it create advective flow from the subsurface or sides?
  - ⇨ Flow should be less than 200 mL/min.
- □ Was the chamber subjected to temperature extremes?
  - ⇨ Shield from direct sunlight.
  - ⇨ Chamber surface must stay above dew point.

SAMPLE ANALYSIS ISSUES

The following questions should be asked when examining the analysis of any type of soil gas sample—active, passive, or flux chambers.

- □ What methods are being used? Can they detect the target compounds at the required levels of sensitivity?
- □ Have the method required calibration standards been analyzed?
- □ Are the reported values within the documented calibration range of the instrument?
- □ Are any compounds coeluting on a non-halogen-specific detector?
- □ Have the method required QA/QC samples been analyzed (blanks, duplicates, etc.)?
- □ Are the calibration standards within method-required holding times and traceable to a certified source?
- □ In what units are the data reported (μ/L, μg/m^3, ppbv, ppmv)?
- □ For high concentrations, have large dilutions been performed?

Passive Soil Gas Samples

In addition to the analytical issues summarized above, the following issues should be examined with passive soil gas samples:

- □ How are the samples desorbed from the collector?
- □ Is the desorption process quantitative, and does it fractionate?
- □ What units are the data reported in (mass, concentration in headspace, etc.)?

Surface Flux Chamber Samples

In addition to the analytical issues summarized above, the following issues should be examined with surface flux chamber samples:

- □ Is the method detection limit low enough to reach the expected chamber concentrations for the acceptable flux?

Electronic Filing: Received, Clerk's Office 07/01/2024

APPENDIX G

Indoor Air Sampling Questionnaire

NEW YORK STATE DEPARTMENT OF HEALTH
INDOOR AIR QUALITY QUESTIONNAIRE AND BUILDING INVENTORY
CENTER FOR ENVIRONMENTAL HEALTH

This form must be completed for each residence involved in indoor air testing.

Preparer's Name _____ Date/Time Prepared _____

Preparer's Affiliation _____ Phone No._____

Purpose of Investigation_____

1. OCCUPANT:

Interviewed: Y / N

Last Name: _____ First Name: _____

Address: _____

County: _____

Home Phone: _____ Office Phone: _____

Number of Occupants/persons at this location _____ Age of Occupants _____

2. OWNER OR LANDLORD: (Check if same as occupant ___)

Interviewed: Y / N

Last Name: _____ First Name: _____

Address: _____

County: _____

Home Phone: _____ Office Phone: _____

3. BUILDING CHARACTERISTICS

Type of Building: (Circle appropriate response)

Residential	School	Commercial/Multi-use
Industrial	Church	Other: _____

If the property is residential, type? (Circle appropriate response)

Ranch	2-Family	3-Family
Raised Ranch	Split Level	Colonial
Cape Cod	Contemporary	Mobile Home
Duplex	Apartment House	Townhouses/Condos
Modular	Log Home	Other:_____

If multiple units, how many? _____

If the property is commercial, type?

Business Type(s) _____

Does it include residences (i.e., multi-use)? Y / N If yes, how many? _____

Other characteristics:

Number of floors_____ Building age_____

Is the building insulated? Y / N How air tight? Tight / Average / Not Tight

4. AIRFLOW

Use air current tubes or tracer smoke to evaluate airflow patterns and qualitatively describe:

Airflow between floors

_____

_____

_____

Airflow near source

_____

_____

_____

Outdoor air infiltration

_____

_____

_____

Infiltration into air ducts

_____

_____

_____

5. **BASEMENT AND CONSTRUCTION CHARACTERISTICS** (Circle all that apply)

a. Above grade construction:	wood frame	concrete	stone	brick
b. Basement type:	full	crawlspace	slab	other _____
c. Basement floor:	concrete	dirt	stone	other _____
d. Basement floor:	uncovered	covered	covered with _____	
e. Concrete floor:	unsealed	sealed	sealed with _____	
f. Foundation walls:	poured	block	stone	other _____
g. Foundation walls:	unsealed	sealed	sealed with _____	
h. The basement is:	wet	damp	dry	moldy
i. The basement is:	finished	unfinished	partially finished	
j. Sump present?	Y / N			
k. Water in sump?	Y / N / not applicable			

Basement/Lowest level depth below grade: _____(feet)

Identify potential soil vapor entry points and approximate size (e.g., cracks, utility ports, drains)

_____

_____

6. **HEATING, VENTING and AIR CONDITIONING** (Circle all that apply)

Type of heating system(s) used in this building: (circle all that apply – note primary)

Hot air circulation	Heat pump	Hot water baseboard	
Space Heaters	Stream radiation	Radiant floor	
Electric baseboard	Wood stove	Outdoor wood boiler	Other _____

The primary type of fuel used is:

Natural Gas	Fuel Oil	Kerosene
Electric	Propane	Solar
Wood	Coal	

Domestic hot water tank fueled by: _____

Boiler/furnace located in:	Basement	Outdoors	Main Floor	Other_____
Air conditioning:	Central Air	Window units	Open Windows	None

Are there air distribution ducts present? Y / N

Describe the supply and cold air return ductwork, and its condition where visible, including whether there is a cold air return and the tightness of duct joints. Indicate the locations on the floor plan diagram.

_____

_____

_____

_____

7. OCCUPANCY

Is basement/lowest level occupied? Full-time Occasionally Seldom Almost Never

Level	General Use of Each Floor (e.g., familyroom, bedroom, laundry, workshop, storage)
Basement	_____
1st Floor	_____
2nd Floor	_____
3rd Floor	_____
4th Floor	_____

8. FACTORS THAT MAY INFLUENCE INDOOR AIR QUALITY

a. Is there an attached garage?	Y / N	
b. Does the garage have a separate heating unit?	Y / N / NA	
c. Are petroleum-powered machines or vehicles stored in the garage (e.g., lawnmower, atv, car)	Y / N / NA	Please specify_____
d. Has the building ever had a fire?	Y / N	When?_____
e. Is a kerosene or unvented gas space heater present?	Y / N	Where? _____
f. Is there a workshop or hobby/craft area?	Y / N	Where & Type? _____
g. Is there smoking in the building?	Y / N	How frequently? _____
h. Have cleaning products been used recently?	Y / N	When & Type? _____
i. Have cosmetic products been used recently?	Y / N	When & Type? _____

j. Has painting/staining been done in the last 6 months? Y / N Where & When? _____

k. Is there new carpet, drapes or other textiles? Y / N Where & When? _____

l. Have air fresheners been used recently? Y / N When & Type? _____

m. Is there a kitchen exhaust fan? Y / N If yes, where vented? _____

n. Is there a bathroom exhaust fan? Y / N If yes, where vented? _____

o. Is there a clothes dryer? Y / N If yes, is it vented outside? Y / N

p. Has there been a pesticide application? Y / N When & Type? _____

Are there odors in the building? Y / N
If yes, please describe: _____

Do any of the building occupants use solvents at work? Y / N
(e.g., chemical manufacturing or laboratory, auto mechanic or auto body shop, painting, fuel oil delivery, boiler mechanic, pesticide application, cosmetologist

If yes, what types of solvents are used? _____

If yes, are their clothes washed at work? Y / N

Do any of the building occupants regularly use or work at a dry-cleaning service? (Circle appropriate response)

Yes, use dry-cleaning regularly (weekly) No
Yes, use dry-cleaning infrequently (monthly or less) Unknown
Yes, work at a dry-cleaning service

Is there a radon mitigation system for the building/structure? Y / N Date of Installation: _____
Is the system active or passive? Active/Passive

9. WATER AND SEWAGE

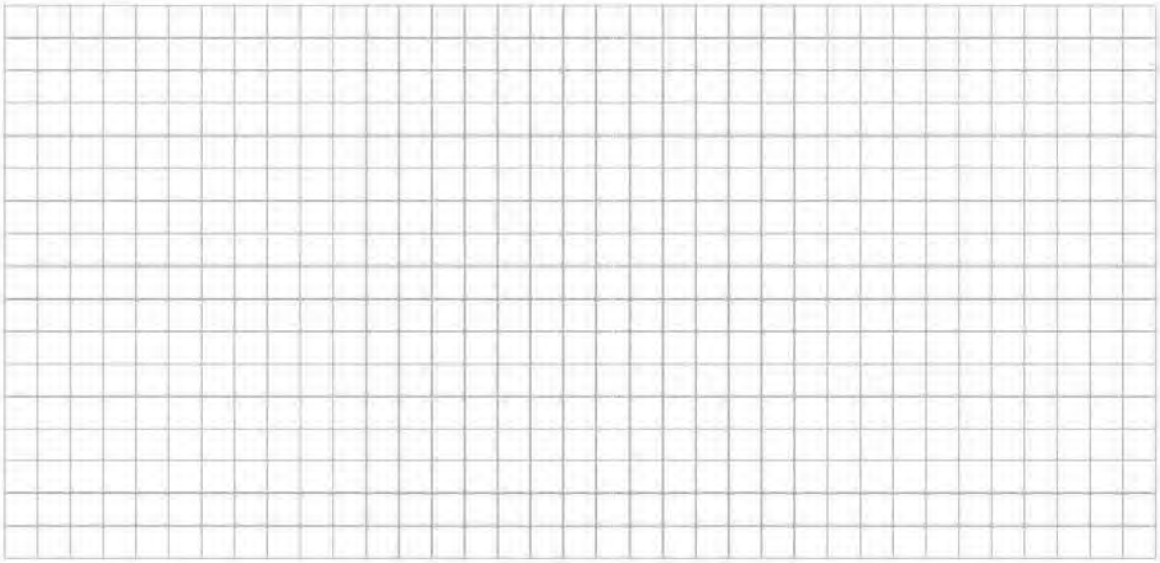
Water Supply: Public Water Drilled Well Driven Well Dug Well Other: _____

Sewage Disposal: Public Sewer Septic Tank Leach Field Dry Well Other: _____

10. RELOCATION INFORMATION (for oil spill residential emergency)

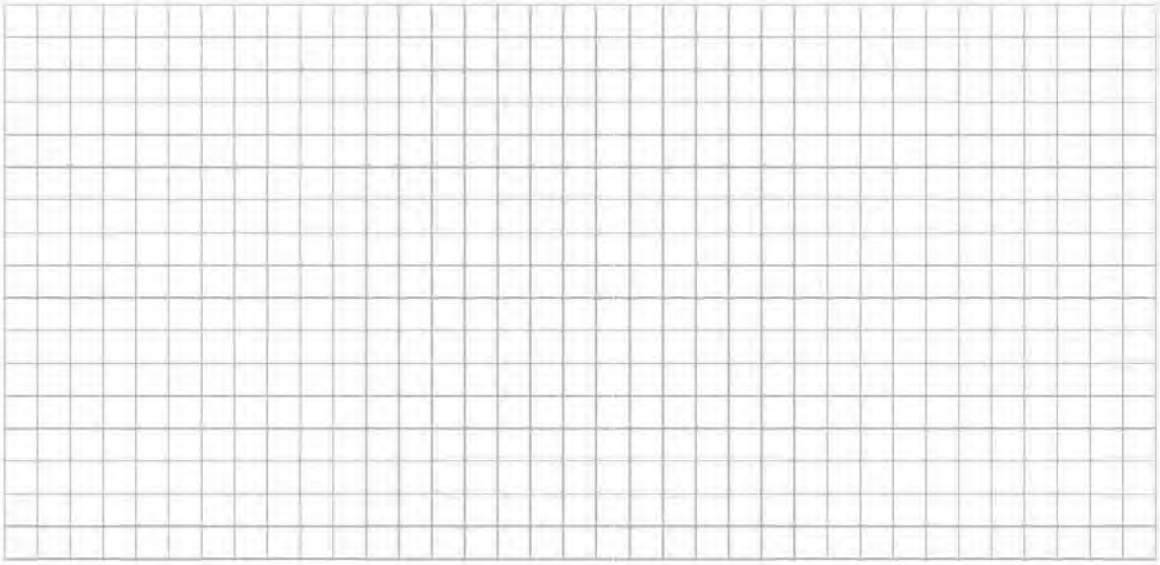
a. Provide reasons why relocation is recommended: _____

b. Residents choose to: remain in home relocate to friends/family relocate to hotel/motel



c. Responsibility for costs associated with reimbursement explained? Y / N

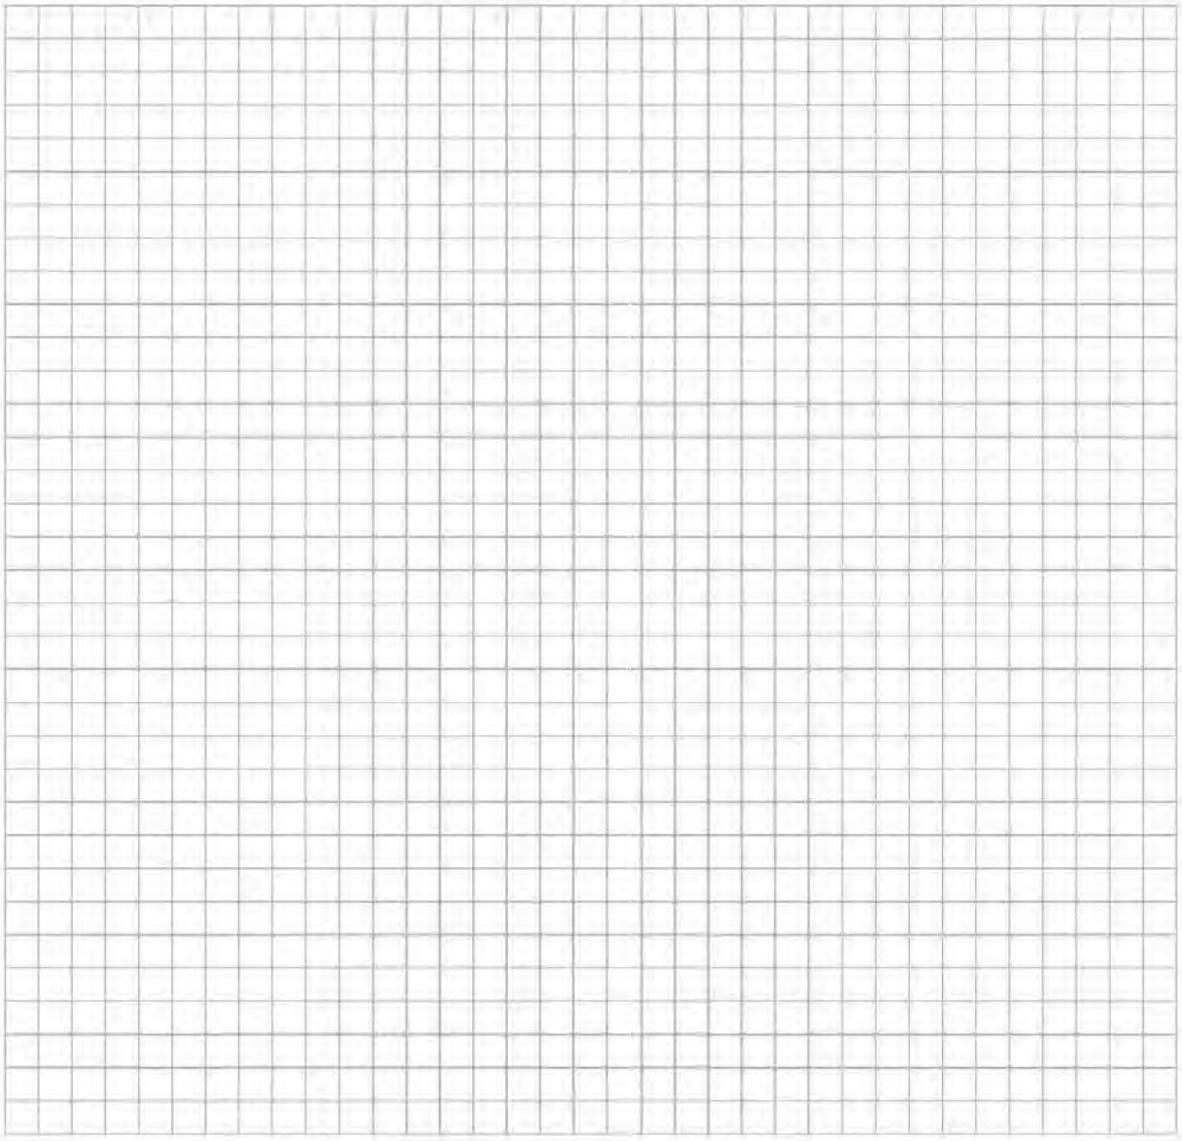
d. Relocation package provided and explained to residents? Y / N



11. FLOOR PLANS

Draw a plan view sketch of the basement and first floor of the building. Indicate air sampling locations, possible indoor air pollution sources and PID meter readings. If the building does not have a basement, please note.

Basement:



First Floor:

12. OUTDOOR PLOT

Draw a sketch of the area surrounding the building being sampled. If applicable, provide information on spill locations, potential air contamination sources (industries, gas stations, repair shops, landfills, etc.), outdoor air sampling location(s) and PID meter readings.

Also indicate compass direction, wind direction and speed during sampling, the locations of the well and septic system, if applicable, and a qualifying statement to help locate the site on a topographic map.

13. PRODUCT INVENTORY FORM

Make & Model of field instrument used: _____

List specific products found in the residence that have the potential to affect indoor air quality.

Location	Product Description	Size (units)	Condition*	Chemical Ingredients	Field Instrument Reading (units)	Photo** Y / N

* Describe the condition of the product containers as **Unopened (UO), Used (U), or Deteriorated (D)**
** Photographs of the **front and back** of product containers can replace the handwritten list of chemical ingredients. However, the photographs must be of good quality and ingredient labels must be legible.

Electronic Filing: Received, Clerk's Office 07/01/2024

APPENDIX H

Development of Screening Levels

Electronic Filing: Received, Clerk's Office 07/01/2024

DEVELOPMENT OF SCREENING LEVELS

H.1 GENERIC SCREENING LEVELS

In general, generic screening levels are used to determine whether the potential exists for subsurface contaminants to be present in indoor air at levels that could result in adverse health effects to exposed receptors. If the screening levels for the selected medium are not exceeded, then it is possible that no further evaluation of the vapor intrusion pathway is necessary. A screening approach should be protective of human health, while limiting unnecessary investigative cost. This appendix describes methodologies for the development of generic screening levels for various environmental media, including indoor air, crawl-space air, subslab soil gas, soil gas, groundwater, and soil.

Typically, the development of a screening level begins with a target concentration in indoor air. Indoor air target concentrations can be risk-based indoor air concentrations derived using USEPA consensus toxicity criteria, indoor air literature background values, or other agency-established values. Target indoor air concentrations can be used as a basis to establish screening levels in soil, soil gas, and groundwater. Indoor air target levels can be developed for residential and nonresidential exposure scenarios. For industrial sites, the OSHA-acceptable workplace levels (e.g., permissible exposure levels [PELs]) or other acceptable workplace levels may be applicable as indoor air target concentrations, depending on the circumstances and established policies of the regulatory agency. (As previously stated, the oversight regulatory agency should be consulted when determining any value or other actions at sites within their oversight.)

Next, an allowable concentration in a subsurface medium is calculated from a target indoor air concentration, assuming a certain amount of attenuation and dilution through the vadose zone and the building floor slab. The amount of vapor attenuation/dilution from the subsurface media concentration to the indoor air concentration, known as the “attenuation factor,” can be based on either a model or empirical data. Generic attenuation factors derived using a vapor intrusion model—primarily the USEPA version of the Johnson and Ettinger model (USEPA 2004b) or variations—incorporate default soil and building parameters. In addition, specific considerations may be applicable to petroleum hydrocarbons due to biodegradation.

Existing numerical criteria developed by various federal and state agencies to evaluate potential indoor air impacts were reviewed. While this appendix focuses on the development of values to be used in a screening-level evaluation of the vapor intrusion pathway, it is important to note that the existing numerical criteria are developed to serve different purposes. More conservative assumptions are included in screening levels that, when exceeded, indicate the potential for risk and a need for further evaluation (USEPA 2002b). More realistic assumptions specific to an exposure scenario may be made in the development of risk-based cleanup standards (CTDEP 2003) or action levels (CDPHE 2004) that, when exceeded, trigger remedial action or mitigation. A point-by-point comparison (in other words, comparison of maximum site data) may be appropriate for a screening-level evaluation using generic screening levels, while cleanup standards are typically compared with an exposure point concentration (such as an average concentration or 95th percentile upper concentration limit of the mean). Some agencies conduct

screening-level evaluations using vapor intrusion models instead of or in addition to numerical screening levels. Other agencies provide generic attenuation factors (discussed below), which are used with subsurface media concentrations to predict indoor air concentrations (Cal DTSC 2004). In addition to a generic screening phase, some agencies have a more site-specific or semi-site-specific screening phase in which generic numerical criteria can be modified using site-specific soil and building parameters and the J&E model (Health Canada 2004, MassDEP 2004, USEPA 2002b).

H.1.1 Attenuation Factors

The attenuation factor represents the ratio of the target indoor air concentration within a building to the vapor-phase concentration in subsurface media underlying or adjacent to a building. Attenuation factors are used by a number of agencies to calculate media-specific screening levels or predict indoor air concentrations. These attenuation factors can be derived either empirically or through the use of vapor intrusion models.

An alpha factor is a unitless empirical attenuation factor relating the indoor air concentration to either a subsurface soil gas concentration (α_{sg}) or to a groundwater concentration (α_{gw}) as follows:

$$(\alpha_{sg}) = C_{indoor}/C_{soil\ gas}$$

and

$$(\alpha_{gw}) = C_{indoor}/(C_{water} \times H) \ ,$$

where H = the compound's unitless Henry's law constant.

In a more practical sense, the attenuation factor is the measure of how soil and building properties can limit the intrusion of organic vapors as they migrate into a structure (Gerrard 2006).

Generic screening levels and attenuation factors generally assume the following conditions for use in evaluating the potential for vapor intrusion into an existing, or in some cases, future building:

- The site is adequately characterized.
- The subsurface is reasonably homogeneous.
- No significant fractures exist in the subsurface.
- Groundwater is greater than a certain depth (varies by agency).
- There is no standing water inside the building.
- NAPL is not present on the water table.
- Preferential pathways for soil gas migration do not exist.
- Biodegradation of soil gas contaminants is not occurring.
- Contaminants are homogeneously distributed.

- The building does not have a dirt floor.
- Contaminant vapors enter a building primarily through cracks in the foundation and walls.
- Building ventilation rates and the indoor-outdoor pressure differentials are constant.
- Model assumptions are representative of site conditions.

USEPA has conducted some testing of the reliability of the attenuation factors to estimate indoor air concentrations (Dawson 2005). Selected data sets of indoor air, groundwater data, and subsurface soil gas concentrations were compared, and an attenuation factor calculated. It was found that for volatile chlorinated hydrocarbons, an attenuation factor of 1000 is a conservative estimate of actual indoor air concentrations from calculated soil gas concentrations derived from volatilization from groundwater. This attenuation factor may not be applicable for very shallow groundwater (<5 feet below foundation) or shallow groundwater (<feet below foundation) if there are significant openings to the subsurface (e.g., earthen floors, crawl spaces, sumps), preferential pathways, low building air exchange rates, or very high sustained indoor/outdoor pressure differentials. It was also found that there are insufficient data to draw definite conclusions about generic soil gas–indoor air attenuation factors.

H.1.2 Key Differences

Key differences in the numerical screening levels used to evaluate the vapor intrusion pathway may include the following:

- receptor-specific screening levels (some agencies have developed residential screening levels only, so levels specific to nonresidential exposure scenarios can be derived)
- toxicity values (some states have approved toxicity value that differ from the approved federal toxicity values)
- use of modeled or empirical data to develop attenuation factors and numerical screening levels
- incorporation of background quantitatively into screening levels
- consideration of hypothetical future buildings (California specifies different modeling or exposure point concentrations assumptions depending on whether the building being evaluated is an existing or future structure)

Target indoor air concentrations can vary by several orders of magnitude due to differences in target carcinogenic and noncarcinogenic risk levels, toxicity values, indoor air background values, odor thresholds, analytical quantitation limits, exposure factors (e.g., exposure duration, inhalation rate, body weight), and not-to-exceed ceiling values, if used. Target indoor air concentrations serve as an input in the development of screening levels for subsurface media. In addition to the variability in target indoor air concentrations, groundwater-to-indoor air, soil gas–to–indoor air, and soil–to–

Application of Screening Levels

- There may be state-specific screening levels, as opposed to defaulting to federal values
- Screening levels are promulgated values in some states, so there is little or no ability for site-specific revision.
- States may have different hierarchies for media preference.
- Consideration of possible future land use changes may be required when identifying the most appropriate receptor-specific screening levels.

indoor air numerical screening levels can vary for a number of other reasons. Regional geology, hydrogeology, climate, and building construction vary and therefore affect default assumptions and model input parameters regarding depth to groundwater, soil type, building air exchange rate, building-outdoor pressure differential, building size, and other variables. Some agencies include a dilution or degradation factor for certain petroleum hydrocarbons to account for the biodegradation in the vadose zone.

H.2 INDOOR AIR TARGET VALUES

Risk-based concentrations are concentrations of chemicals within a building that are not expected to cause adverse health effects from long-term exposure. Risk-based indoor air concentrations are generally developed for chronic exposures to generally low-level vapor concentrations. This appendix does not specifically address acute hazards.

Target indoor air screening levels are generally risk-based and are derived using standard risk assessment equations and the following input parameters:

- acceptable target risk thresholds for individual chemicals or cumulative effects
- appropriate toxicity values (federal or state toxicity values for carcinogenic and noncancer toxicity endpoints)
- exposure assumptions such as inhalation rate, exposure duration, and exposure frequency

Standard risk assessment equations and typical default assumptions are identified in various USEPA and state risk assessment guidance such as USEPA 1989, 1996a, 1996b and 2002d. The following equations generally apply:

- For noncarcingens:

$$\text{target indoor air concentration } (\mu g/m^3) = \frac{THQ \times RfD \times BW \times AT \times 1000\ \mu g/mg}{EF \times ED \times IRA},$$

where

THQ = target hazard quotient (see Section 2.1)
RfD = reference dose (mg/kg-day, see Section 2.2)
BW = body weight (kg)
AT = averaging time (days)
EF = exposure frequency (days/year)
ED = exposure duration (years)
IRA = inhalation rate (m^3/day)

- For carcinogens:

$$\text{target indoor air concentration } (\mu g/m^3) = \frac{TR \times BW \times AT \times 1000\ \mu g/mg}{EF \times ED \times IRA \times CSF},$$

where

TR = target incremental lifetime cancer risk (see Section 2.1)
BW = body weight (kg)
AT = averaging time (days)
EF = exposure frequency (days/year)
ED = exposure duration (years)
IRA = inhalation rate (m^3/day)
CSF = cancer slope factor ($[mg/kg\text{-}day]^{-1}$, see Section 2.2)

Alternatively, the indoor air target concentration may be established as the practical quantitation limits using standard methods or indoor air literature background values. For buildings regulated under OSHA, the indoor air target concentrations may be OSHA-derived screening levels (PELs). Consideration of background concentrations is important in the evaluation of potential subsurface media contributions to indoor air given the presence of other sources of VOCs inside buildings. Some agencies use literature or agency-collected indoor air background values as target indoor air concentrations (NYSDOH 2006), while others use a background value if it exceeds a risk-based concentration on a compound-specific basis (CTDEP 2003, MassDEP 2004). Most agencies set the target indoor air concentration at the PQL if it is higher than a risk-based concentration. Some agencies evaluate PQLs on a chemical-specific basis, while others select one value to represent the PQL for all compounds for a specific medium. For example, the Connecticut Department of Environmental Protection sets a "floor" for the soil gas volatilization criteria at 0.5 ppb (CTDEP 2003).

H.2.1 Acceptable Target Risk Thresholds

Cancer risk is generally described as an incremental lifetime cancer risk (ILCR), and noncancer risk is generally described as a hazard quotient (HQ) or total hazard index (HI), which is the sum of HQs for evaluating noncancer effects for multiple chemicals. Acceptable ILCR values are also identified as individual chemical risk or multiple (cumulative) chemical risk. There is some variability in acceptable target ILCRs established by various regulatory agencies, although the acceptable target level for HQ or total HI is less $\leq$1.0. Most target cumulative ILCRs considered acceptable lie within the risk range of 10^{-6}–10^{-4}.

A total HI of less than 1.0 indicates that it is unlikely that adverse human health affects will occur during a lifetime in an exposed population, including sensitive subpopulations (USEPA 1989). Cumulative ILCRs of 10^{-6}–10^{-4} correspond to theoretical probabilities of 1 chance in 1 million to 1 chance in 10 thousand in addition to or in excess of the background cancer risk. It is generally widely accepted in the regulatory community that cumulative ILCR estimates that are equal or less than 10^{-6} do not require remediation or mitigation measures. Risk estimates that are greater than 10^{-4} generally require remediation or mitigation to reduce potential exposures. Under the Resource Conservation and Recovery Act Corrective Action Environmental Indicators (EI) program (USEPA 2005), USEPA indicates that "For the purposes of making Current Human Exposure under Control EI determinations with respect to vapor intrusion, EPA generally

recommends the use of 10^{-5} levels for carcinogens (incremental individual lifetime cancer risk), and a Hazard Quotient (HQ) of 1 for noncancer risk."

H.2.2 Toxicity Values

Commonly, the equations that are used to calculate risk, screening levels, or acceptable concentrations use the inhalation cancer slope factor, CSF $(mg/kg\text{-}day)^{-1}$ and the inhalation reference dose, RfD (mg/kg-day) as the main indicators of potency or toxicity. Some years ago the Integrated Risk and Information System (IRIS) and the USEPA Office of Air Programs began using, and advocating the use of, a reference concentration (RfC) in $\mu g/m^3$ to describe an acceptable airborne concentration protective of the general public and sensitive subpopulations and a unit risk factor (URF) in $(\mu g/m^3)^{-1}$ is to represent the risk of exposure from 1 $\mu g/m^3$. RfCs and URFs are toxicity values developed assuming only an adult receptor. Adult exposure assumptions are included in their derivation, whereas RfDs and CSF may be used to estimated risk or develop screening levels for adults or children.

H.2.3 Receptors and Exposure Parameters

USEPA 1989 provides general guidance on how to characterize exposures and risks when conducting risk assessments. Characterization of potentially exposed populations involves the identification of the current populations at the site in question, activity patterns of these populations, consideration of future land usage at the property, and an evaluation of sensitive populations (i.e., potentially at an increased risk from exposure to a contaminant due to activity and/or behavioral patterns). The following land use categories may be applicable for the development of screening levels for generic exposure scenarios:

- residential
- nonresidential (e.g., commercial/industrial)
- recreational

The exposure assumptions for different exposure scenarios can change, for example in terms of: hours per day, days per year, and years of exposure as well as inhalation rates and body weights, depending on the applicable receptor(s). Screening levels for a residential receptor is generally considered to be the most conservative and thus protective of sensitive populations as well as adults and children in a residential land use scenario. The exposure assumptions for nonresidential receptors (e.g., commercial and industrial workers) are generally less conservative than those in a residential exposure scenario since for nonresidential exposure scenarios only adult receptors with lesser exposure durations are typically considered. Exposure assumptions may be modified to account for regional conditions.

<u>Residential</u>

This category applies if the primary activity of the property is residential in nature and includes single-family dwellings, condominiums, or apartment buildings. Residential screening levels may also apply to facilities deemed to have similar exposure potential as a residence (such as a day care center, school, or elderly care facility). Receptors for the residential land use must

include the general population, including adults and children of various ages. A pregnant female may also be considered a relevant receptor. Default exposure assumptions for the residential scenario are typically 30-year residence time, daily exposure for 350 days/year, with an inhalation rate of 20 m^3/day for a 70-kg adult over 24 years and 10 m^3/day for a 15-kg child over 6 years.

Nonresidential (Commercial)

Activities and uses are extremely variable within the nonresidential land use category. Nonresidential/commercial land uses may range from more sensitive uses such as day care centers and schools to less sensitive uses such as gas stations and warehouse operations. Potential exposures to children are considered for day care centers and schools. For other commercial scenarios, a commercial worker is considered to be the most sensitive receptor. Default exposure assumptions for the commercial worker are typically 25-year employment time, daily exposure for 250 days/year, with an inhalation rate of 20 m^3/day for a 70-kg adult. Some agencies reduce the default inhalation rate per day to reflect a shorter exposure time during the time the worker is in the work place (e.g., from 20 m^3/day to 10 m^3/day, CTDEP 2003).

Nonresidential (Industrial)

Industrial land use is typically applied when the primary activity at the property is and will continue to be industrial in nature. Inactive or abandoned properties can be included in this category if the use was and/or will be industrial and access is controlled as necessary to ensure unacceptable exposures (i.e., exposures more consistent with a residential exposure setting) do not occur. The industrial category does not typically include establishments where children may commonly be present. For industrial sites, the OSHA-acceptable workplace levels (PELs) or other acceptable workplace levels may be used as indoor air target concentrations. Note: Many regulatory agencies use a risk-based value rather than OSHA PELs when vapor intrusion is occurring and the COC is not being used in the facility.

Default exposure assumptions for the industrial worker are generally similar to a commercial worker: 25-year employment time, daily exposure for 250 days/year, with an inhalation rate of 20 m^3/day for a 70-kg adult. However, some agencies may adjust the inhalation rate to account for increased breathing rates during the workday exposure period.

Recreational

Receptors in structures used for recreational purposes may also include adult and child receptors. Default exposure assumptions for the recreational worker are generally similar to a commercial or industrial worker: 25-year employment time, daily exposure for 250 days/year, with an inhalation rate of 20 m^3/day for a 70-kg adult. Default exposure assumptions for the child recreator may be similar to those for a residential child with shorter exposure durations. However, as above, some agencies may adjust the inhalation rate to account for increased breathing rates during typical recreational activities.

Sensitive Populations

The potential for sensitive populations at a vapor intrusion site should be considered. Facilities where sensitive populations may be located include day care centers, schools, and elderly care facilities. The target indoor air concentration for a residential scenario, which includes children, is often considered adequately protective for sensitive populations. Some agencies include adjustments to screening levels based on adult receptors for the derivation of appropriate screening levels for children. For example, the Connecticut Department of Environmental Protection includes in its residential volatilization criteria (CTDEP 2003) a twofold adjustment factor for children's increased inhalation exposure rate relative to adults (due to a greater respiratory rate per body weight and lung surface area) and a twofold adjustment factor for children's increased sensitivity when exposed to genotoxic carcinogens.

H.3 CRAWL-SPACE AIR SCREENING LEVELS

Few agencies currently have generic screening levels for air within building crawl spaces. Screening levels for crawl-space air may only be applicable in certain regions of the country where crawl-space construction is common for residential buildings. Based on the preliminary results of the agency's vapor intrusion database review process, USEPA has concluded there is limited empirical data from which to develop an attenuation factor for crawl-space air (Dawson 2004).

The following equation can be used to calculate generic screening levels for crawl-space air:

$$C_{CA} = C_{IA}/\alpha \ ,$$

where

C_{CA} = crawl-space air screening concentration ($\mu g/m^3$)
C_{IA} = target indoor air concentration ($\mu g/m^3$)
α = crawl-space air attenuation factor (dimensionless)

The crawl-space air screening levels reviewed are based on empirical attenuation factors and generally range 0.1–1.0. An attenuation factor of 1.0 assumes no attenuation of compound concentrations from crawl-space air to indoor air and is considered to be an upper bound value (Dawson 2004).

H.4 SUBSLAB SOIL GAS SCREENING LEVELS

For both subslab soil gas and soil gas measured at deeper depths beneath a building or outside a building footprint, the soil gas screening levels are the target indoor air concentrations multiplied by an attenuation factor. The attenuation factors should be supported by empirical observations and represent the attenuation of vapors as they migrate from the source through the vadose zone to beneath the floor slab, through the floor slab, or from the exterior into the interior of a building and equilibrating in the indoor air space. Specific considerations may be applicable to petroleum hydrocarbons due to biodegradation.

Several agencies, including USEPA, include soil gas collected from a depth of 5 feet or less (outside a building or below a building floor slab) and subslab soil gas collected below a building floor slab in the same category (typically designated "shallow soil gas") when evaluating the vapor intrusion pathway.

The following equation can be used to calculate subslab soil gas screening levels:

$$C_{SS} = C_{IA}/\alpha \ ,$$

where

C_{SS} = subslab soil gas screening concentration ($\mu g/m^3$)
C_{IA} = target indoor air concentration ($\mu g/m^3$)
α = subslab soil gas attenuation factor (dimensionless)

Attenuation factors for subslab soil gas are typically based on empirical data and generally range 0.01–0.1 for residential buildings. As part of its ongoing review of the agency's vapor intrusion database, USEPA has determined that its current OSWER draft subslab attenuation factor of 0.1 may be overly conservative and is reportedly revisiting this number (Dawson 2004).

H.5 SOIL GAS SCREENING LEVELS

As discussed above, several agencies currently include soil gas collected from a depth of 5 feet or less (outside a building or below a building floor slab) and subslab soil gas collected below a building floor slab in the same category (typically designated "shallow soil gas") when evaluating the vapor intrusion pathway. Due to differences in the nature of sampling, and the need to gain access into a building to conduct subslab sampling, it may be preferable to have soil gas screening levels apply to all soil gas samples collected outside a building at a certain depth below ground surface.

The following equation can be used to calculate soil gas screening levels:

$$C_{SG} = C_{IA}/\alpha \ ,$$

where

C_{SG} = soil gas screening concentration ($\mu g/m^3$)
C_{IA} = target indoor air concentration ($\mu g/m^3$)
α = soil gas attenuation factor (dimensionless)

Both empirical and modeled attenuation factors are available for soil gas. The reported range of attenuation factors, both empirical and modeled, for a residential building scenario is 0.002–0.1. These attenuation factors apply to either shallow (typically <5 feet bgs) or deep (>5 feet) soil gas samples taken at or in proximity to the current structures. Attenuation factors for future

residential buildings are also available for some agencies and typically range 0.0009–0.01. The attenuation factors used by the agencies for nonresidential/commercial buildings typically range 0.0005–0.1. One agency, California Environmental Protection Agency, provides a soil gas attenuation factor for future commercial buildings of 0.0004 (Cal DTSC 2004). Health Canada provides semi-site-specific soil gas attenuation factors for residential and commercial buildings (Health Canada 2004).

H.6 GROUNDWATER SCREENING LEVELS

The groundwater screening levels include established groundwater standards, such as maximum contaminant levels, as well as health-based groundwater concentrations calculated to be protective of indoor air quality.

Groundwater screening levels developed for the vapor intrusion pathway are applicable to groundwater concentrations obtained from monitoring wells screened at or near the water table. Groundwater samples collected from deeper aquifers or well screen intervals are not appropriate for evaluating the vapor intrusion pathway and should not be compared with groundwater screening levels for the purposes of site screening since chemical volatilization and subsequent upward vapor migration occur from chemical concentrations in groundwater at the water table. When nonimpacted shallow groundwater lies above an impacted groundwater zone, the shallow groundwater acts as a barrier for volatilization from groundwater at deeper depths. However, the application of groundwater screening levels is state specific. For instance, Michigan requires that groundwater screening levels be compared to concentrations throughout the affected aquifer.

The following equation is often used to develop generic screening levels to evaluate the groundwater–to–indoor air exposure pathway:

$$C_{GW} = C_{IA}/(H \times \alpha \times 1000\ L/m^3) \ ,$$

where

C_{GW} = groundwater screening level (μg/L)
C_{IA} = target indoor air level (μg/m^3)
H = Henry's law constant (dimensionless)
α = groundwater attenuation factor (dimensionless)

Henry's law constant is used to convert the groundwater concentration in the aqueous phase to a vapor-phase concentration at equilibrium. According to USEPA (2002b), "Field data suggest that this conversion may result in over prediction of the soil gas concentration (by as much as a factor of ten) directly above the contaminated groundwater. However, this is not always the case and consequently Henry's Constant is used [in the USEPA-OSWER Draft Vapor Intrusion Guidance] without a correction factor." Henry's law constants can be obtained from USEPA for many VOCs (USEPA 2004a).

Both empirical and modeled attenuation factors are available from the various agencies for groundwater. Some states calculate chemical-specific attenuation factors using the J&E model

(MassDEP 2004). The range of groundwater–to–indoor air attenuation factors is typically 0.0007–0.0008 (chemical specific) to 0.001 for residential buildings. Generic groundwater attenuation factors are not available for nonresidential/commercial buildings. Health Canada provides semi-site-specific groundwater attenuation factors for residential and commercial buildings (Health Canada 2004). Additional information regarding the use of the J&E model can be found in the EPA 2005.

H.7 SOIL SCREENING LEVELS

Screening levels based on soil concentrations are generally not derived for assessing the vapor intrusion pathway. Most states and USEPA regions do not use or encourage the use of soil–to–indoor air screening levels. The USEPA Office of Solid Waste and Emergency Response draft guidance cites uncertainties related to soil partitioning calculations and analytical limitations when sampling and evaluating VOCs in the soil matrix which reduce the defensibility of soil screening levels (USEPA 2002). Further, nondetect analytical soil concentration results do not necessarily indicate a lack of a soil gas source (due to potential volatilization during sample collection, handling, and analysis) but may be interpreted as such.

Generally, soil gas measurements are recommended as an alternative to bulk soil measurements to evaluate potential vapor migration from a soil medium. There are situations, though, in which it is not feasible to collect a defensible soil gas sample. For instance, the presence of a shallow water table or clay-rich soils may preclude soil gas sampling. In these situations, where contaminants originate from a soil source (as compared to a groundwater source), bulk soil measurements may be used to evaluate the vapor intrusion pathway.

Few states have derived soil–to–indoor air screening levels. Pennsylvania Department of Environmental Protection (PADEP 2004) has developed and promulgated soil screening levels based on the application of the J&E model.

H.8 BIODEGRADABLE COMPOUNDS

Some agencies include a dilution or degradation factor in the development of screening levels for certain petroleum hydrocarbons to account for the biodegradation in the vadose zone. Several apply a dilution/degradation factor of 0.1 (or 10-fold dilution) to petroleum compounds, including BTEX (Health Canada 2004, NJDEP 2005, MADEP 2004). USEPA generic attenuation factors are based largely on data for less-degradable chlorinated compounds (USEPA 2002b). Empirical data suggests that a 3- to 10-fold decrease in the attenuation factor is appropriate for biodegradable BTEX compounds compared with chlorinated compounds (USEPA 2002b, Appendix F, Section 5). Recent American Petroleum Institute guidance suggests 0.01 as a low-end soil gas attenuation factor and that soil gas–to–indoor air attenuation factors of 0.0001–0.00001 may be reasonable for BTEX compounds (API 2004).

ABSTRACT

EPRI is researching coal combustion product (CCP) porewater chemistry to improve predictions of chemical evolution over the long term, particularly post-closure. An EPRI-member company made a large volume of porewater chemistry data available to EPRI, which was used to improve our understanding of porewater chemistry and how it varies between and within CCP units. This data set also provided information on the efficacy of USEPA's SW-846 1313 and 1316 leaching methods (also known as *LEAF 1313* and *LEAF 1316*) for evaluating porewater chemistry.

The objective of this research was to provide information on the chemistry of CCP porewater and how it may vary to help inform decision making on porewater evaluations. The specific objectives of this project were to:

- Evaluate the relationship of total (unfiltered) concentrations versus dissolved (filtered) concentrations in CCP porewater
- Assess the variability of porewater properties within and between CCP units
- Identify whether there are relationships between the laboratory leaching tests and measured porewater concentrations

Product Type: Technical Report

Product Title: Evaluation and Comparison of Leach Test and Porewater Variability for Multiple Coal Combustion Product Management Units

PRIMARY AUDIENCE: Subject matter experts and project managers responsible for closure or groundwater remediation at coal combustion product (CCP) management units.

SECONDARY AUDIENCE: Groundwater and geochemical modelers responsible for predicting the long-term effects of closure or groundwater remediation at CCP management units.

KEY RESEARCH QUESTION

EPRI is researching CCP porewater chemistry to improve predictions of chemical evolution over the long term, particularly post-closure. The objective of this research was to provide information on the chemistry of CCP porewater and how it may vary to inform decision making when characterizing porewater concentration for groundwater and geochemical models. The specific objectives of this project were to:

- Evaluate the relationship of total (unfiltered) concentrations versus dissolved (filtered) concentrations in CCP porewater
- Assess the variability of porewater properties within and between CCP units
- Identify whether there are relationships between the laboratory leaching tests and measured porewater concentrations

RESEARCH OVERVIEW

CCP porewater data were collected and provided by an EPRI-member company. The porewater data were collected from porewater monitoring points (PMPs) installed at 29 CCP management units between 2015 and 2021. In addition, CCP solids samples from the same location and depth as the PMPs at four units were subjected to leach testing using USEPA SW-846 methods 1313 (LEAF 1313) and 1316 (LEAF 1316). EPRI researchers used graphical and statistical methods to evaluate the data with respect to the project objectives.

KEY FINDINGS

- A comparison of total versus dissolved porewater sample results indicated:
  - Total and dissolved measurements are generally more comparable at concentrations elevated well above the reporting limit where laboratory analytical variability is less significant relative to concentration.
  - Major ions (Ca, Mg, Na, K), certain minor ions (Ba, B, Mn, Mo, Sr, Li), and elements with low detection frequency (Cd, Hg) were least likely to be affected by sample filtration.
  - Elements most likely to be affected by sample filtration were Al, Cr, Cu, Fe, and V.
- A comparison of intra-unit and inter-unit porewater variability results indicated:
  - There does not appear to be an overall pattern to define which parameters exhibit high or low variability. However, parameters of interest—either because they are CCP tracers (B and SO_4) or potential remediation drivers (As, Sb, B, Cr, Co, Li, Mo, and Se)—mostly have medium to high intra-unit variability, which suggests that more extensive porewater evaluation may be helpful to characterize a unit when developing a source term to model these parameters. Lithium was the only remediation driver with low intra-unit variability.

  - As, B, Co, Li, Mo, Se, and SO_4 had high inter-unit variability. Sb and Cr had medium and low inter-unit variability, respectively, which was attributed to their relatively low concentration in the porewater samples.
- Comparing leach test eluates to porewater samples, EPRI researchers observed:
  - LEAF 1313 and 1316 eluate concentrations were usually more than 25% higher or 25% lower than their paired median porewater concentrations. This observation was made for 1313 eluates at natural pH and the broader pH range for all porewaters as well as for 1316 results at low and high L/S.
  - Elements often controlled by available content—such as B, Ca, Cl, Li, Sr, and SO_4—tended to be underpredicted by the LEAF tests.
  - As, Fe, and Mn were also underpredicted, even though they tend to be solubility controlled, because the LEAF testing was performed under oxic conditions when the solubility of these elements is low.
  - Conversely, Se and Cr, which are most soluble under oxic conditions, tended to be overpredicted by the LEAF testing performed under oxic conditions.
  - Sb, Tl, and V tended to be overpredicted by the leach tests while other elements were overpredicted or underpredicted depending on test-specific and site-specific factors.

WHY THIS MATTERS

This research helps stakeholders understand that LEAF tests produce valuable information for comparing CCPs and understanding their geochemistry but are not reliable for predicting in-field porewater quality. This research also helps stakeholders understand CCP porewater variability, which can be used to improve characterization of source terms used in fate and transport or geochemical models and resulting predictions of groundwater quality in response to closure or remediation alternatives evaluated with these models.

HOW TO APPLY RESULTS

The conclusions of this research are stated in this executive summary. Readers interested in more detailed information for specific constituents can reference the body of this report.

LEARNING AND ENGAGEMENT OPPORTUNITIES

Previous research results published by EPRI related to porewater variability and the ability of leach tests to predict porewater chemistry are:

2
SUMMARY OF DATA

Coal Combustion Product Units

CCP porewater and leach test data were provided for 14 power plants in North Carolina (Synterra, 2021). The 14 power plants and 29 associated CCP management units are summarized in Table 2-1. Porewater data were collected from porewater monitoring points (PMPs) installed at all 29 units between 2015 and 2021. Additional data from laboratory leaching tests were provided for four plants (Allen, BCSS, Cliffside, and Marshall), based on cores collected at the time of PMP installation in 2018. Operational periods are summarized in Table 2-1 and illustrated in Figure 2-1.

All units contain coal ash and are primarily a mix of fly ash and bottom ash. Several units were excavated within the last 15 years (that is, Asheville units 1964 and 1982, Cliffside units 1–4 and ash storage area, Dan River ash basin, Riverbend ash basin and cinder storage area, and Weatherspoon 1979 ash basin).

Leach test data were obtained by LEAF 1313[1] and LEAF 1316.[2] Synthetic precipitation leaching procedure (SPLP) was also performed, but final values for eluate pH were not available, so the SPLP results are not further considered.

Data Preparation and Refinement

Data were provided in two separate files: one containing the porewater data and the other containing LEAF leach test eluate data. Due to differences in how these two files reported data, slightly different data preprocessing and quality assurance steps were taken for the porewater data file and the LEAF eluate data file. For both data files, concentrations reported in units of µg/L were converted to mg/L for consistency across the data set. Radium activities reported as negative values were set to zero for both data files. Quality control replicate sample analyses were removed from the porewater data set to avoid bias because those results are not independent.[3] In the porewater data, non-detect results were identified as those samples flagged with a "U" qualifier, and the method detection limit was used as the result. QA/QC samples were excluded from the LEAF eluate data. In the LEAF eluate data, non-detect results were identified

[1] LEAF 1313 (SW-846, USEPA 2019) is a standardized, parallel batch extraction method used to evaluate the liquid-solid partitioning (LSP) of inorganic constituents as a function of eluate pH.
[2] LEAF 1316 (SW-846, USEPA 2019) is an equilibrium-based leaching test intended to provide eluate solutions over a range of liquid-to-solid ratios (L/S). This method consists of five parallel batch extractions of a particle-size-reduced solid material in reagent water over a range of L/S values from 0.5 to 10 mL/g-dry material.
[3] The data set included four categories of duplicate samples, which combined represented a small fraction of the data set. In the absence of information about the nature of those duplicate sample categories, they were excluded from the data set used in this analysis.

as those samples with analytical results less than method detection limit (MDL), and the MDL was used as the result.

Notes:

[1] Dry ash handling may include units constructed on top of the footprint of ash basins.

[2] Excavation of the unit has been performed (complete) or is ongoing (in progress) as of the date the information was provided.

[3] Based on review, these locations are likely within the Active Ash Basin but were kept separate because of their distinction in the database.

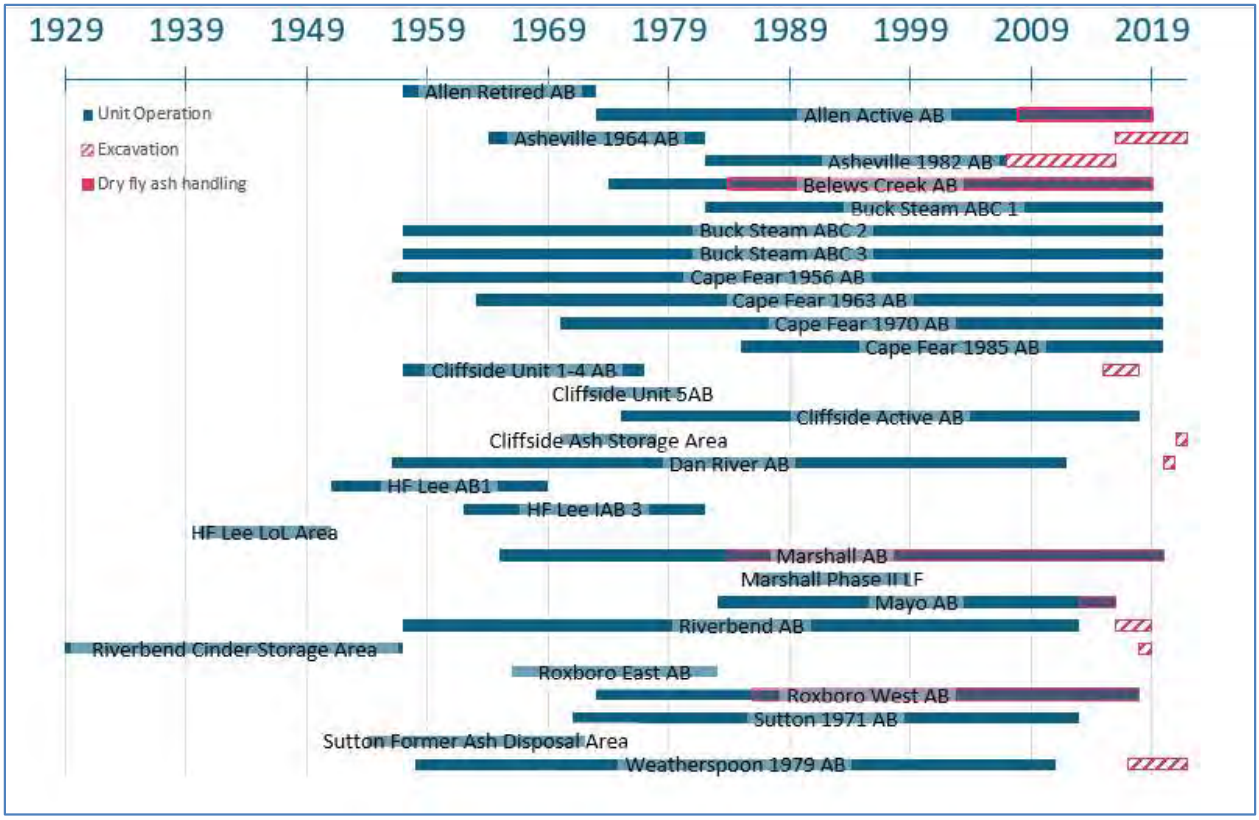

Figure 2-1
Operational history CCP units with available porewater data

Porewater Data

The porewater data set contained 111 parameters (including both total and dissolved fractions for most inorganic parameters) reported at a total of 100 individual PMPs. The porewater data set was refined prior to further analysis based on number of measurements for each parameter and degree of relevance in CCP porewater. Most parameters with fewer than 1,000 measurements were excluded from this analysis. This included redox speciation measurement, dissolved samples filtered at a 0.1 µm level, and some radioactive parameters. Some parameters with fewer than 1,000 total measurements were retained due to their relevance for CCP (fluoride, lithium, and isotopes of radium) or to facilitate comparisons between total and dissolved concentrations. In addition, dissolved oxygen (often unreliable due to contamination during sampling) and oxidation-reduction potential (ORP) (redundant with Eh) measurements were excluded. After refinement, the porewater data set contained 71 parameters measured at 100 PMPs (see Table 2-2 for a list of parameters analyzed in porewater and Appendix A for sample counts and basic statistics).

Leach Test Data

The LEAF data set contained 30 parameters and final eluate pH values for tests performed on CCP samples from 18 PMP boreholes. The LEAF and porewater data were paired based on co-location of station and depth of sample (Table 2-3).[4] For cases in which multiple LEAF samples were collected from multiple depths within the borehole spanning the corresponding porewater screen interval, the LEAF results were paired with the same porewater data. Parameters with no corresponding results in the porewater data set (U), three or fewer samples (Hg), and indicator parameters (ORP, specific conductance, and total dissolved solids [TDS]) were not included in the analysis. The combined leach test data set contained 25 parameters and final eluate pH values reported at 18 PMPs. LEAF 1313 testing was performed at pH values of about 4, 6, 8, and 10 and at natural pH. LEAF 1316 testing was performed at L/S ratios of 0.5, 1, 2, 4, 5, 6, 8, and 10.

[4] LEAF test data that did not have porewater data available from the same PMP and at the screened depth interval are not included in the analysis.

Table 2-3

Notes:

[1] Each row represents one set of paired porewater and leach test data.

[2] Assumed to be a relevant comparison in the absence of depth interval information.

Porewater Results

An overview of the refined porewater data set is presented in Table 2-4. Sample sizes for each parameter varied from 70 samples (dissolved measurements for major ions), to between 100 and 1,000 samples (Ra isotopes, F, and Li), to over 1,000 samples (the rest of the parameters). Most of the major ions were detected in more than 90% of samples, except for NO_2+NO_3, (detected in 49% of samples) and ALK-CO_3 (detected in 12% of samples). Many minor and trace elements (total Al, total and dissolved As, Ba, B, Co, Fe, Li, Mn, Mo, Ni, Sr, and V) were detected in more than 75% of samples. Other minor trace elements were detected in between 25% and 75% of samples, including dissolved Al; total Cd and Pb; and both total and dissolved Sb, Be, Cr, Cr(VI), Cu, Se, Tl, and Zn. Total organic carbon (TOC) and total suspended solids (TSS) were also detected in between 25% and 75% of samples. Dissolved Cd, dissolved Pb, and both total and dissolved Hg were detected in 25% or fewer samples. Sulfide (S^{2-}) was also detected in very few samples (8%).

Table 2-5 shows the results of comparing porewater concentrations to a threshold value based on a regulatory standard, specifically the maximum contaminant level (MCL; 40 C.F.R.§141), secondary maximum contaminant level (SMCL; USEPA, 2022a), or regional screening level (RSL; USEPA, 2022b), where a standard was available. Although **these standards are not directly applicable to porewater data,** they provide useful thresholds for evaluating porewater concentrations. For example, if porewater concentrations are consistently below the threshold value for a parameter, the CCP unit would be an unlikely source of downgradient groundwater protection standard (GWPS) exceedances for that parameter. The statistics presented in this table are comparable to a similar tabulation by EPRI (2021a) for a larger, more widely distributed, porewater data set. However, there are differences in the tabulations. The current data set was compiled to determine the percentage of all samples with a concentration higher than a benchmark. The EPRI (2021a) data set is based on the average concentration of all porewater samples collected at a unit (range from as few as 1 to more than 100 samples per unit).

Both data sets show that As and Li have concentrations higher than a GWPS-based threshold in more than 50% of the sample and site average tabulations. In addition, Mn is greater than its SMCL-based threshold in more than 50% of the two tabulations.[5] Conversely, many of the tested constituents (Al, Sb, Ba, Be, Cr, Cu, F, Pb, Hg, Ra, Sr, Tl, and Zn) were unlikely (<15%) to have a concentration higher than their respective thresholds in both tabulations.

[5] The SMCL is based on aesthetic considerations to drinking water quality rather than on health-based considerations.

Leach Test Results

An overview of the LEAF test eluates is presented in Tables 2-6 (LEAF 1313) and 2-7 (LEAF 1316). Each individual sample represents the result for one test condition (that is, a specific pH for LEAF 1313 or a specific liquid-to-solid ratio for LEAF 1316) applied to one CCP solid sample. For summary purposes, the LEAF 1313 natural pH values (no acid/base added; sometimes referred to as the *natural pH*) and LEAF 1316 results at liquid-to-solid ratio (L/S) = 1.0 are compiled for table statistics. The proportion of detected results for all parameters in both LEAF tests is higher than those reported in the porewater measurements due to lower detection

limits used for most analytes in the LEAF tests. However, Cd was usually not detected and Hg was not detected in the LEAF 1313 samples, and Be was usually not detected and Pb and Hg were not detected in the LEAF 1316 samples.

3
POREWATER ANALYSIS

Summary

This section presents an evaluation of the porewater data set that included a comparison of total and dissolved concentrations as well as an evaluation of the variability observed in porewater concentrations.

Total versus dissolved sample results:

- Total and dissolved measurements are generally more comparable at concentrations elevated well above the reporting limit where laboratory analytical variability is less significant relative to concentration.
- Major ions (Ca, Mg, Na, K), certain minor ions (Ba, B, Mn, Mo, Sr, Li), and elements with low detection frequency (Cd, Hg) were least likely to be affected by sample filtration.
- Elements most likely to be affected by sample filtration were Al, Cr, Cu, Fe, and V.

Intra-unit and inter-unit variability results:

- There does not appear to be an overall pattern to define which parameters exhibit high or low variability. However, parameters of interest—either because they are CCP tracers (B and SO_4) or potential remediation drivers (As, Sb, B, Cr, Co, Li, Mo, and Se)—mostly have medium to high intra-unit variability, which suggests that more extensive porewater evaluation may be helpful to characterize a unit when developing a source term to model these parameters. Li was the only remediation driver with low intra-unit variability.
- As, B, Co, Li, Mo, Se, and SO_4 had high inter-unit variability. Sb and Cr had medium and low inter-unit variability, respectively, which, as previously noted, can be attributed to their relatively low concentration (medians lower than 0.001 mg/L; see Appendix A) in the porewater samples reviewed in this analysis.

Analysis of Total Versus Dissolved Concentrations

Background

Porewater samples from CCP may be unfiltered or filtered[6] in the field, resulting in determinations of total or dissolved concentrations, respectively. The presence of suspended solids in porewater samples has the potential to affect total porewater measurements and can cause analytical results to not be representative of actual porewater concentrations. Geochemical modeling studies generally assume that the samples are field-filtered, while samples collected for

[6] Dissolved data represent field filtration using a 0.45-µm filter.

other purposes may not be filtered. Therefore, it is useful to understand the similarity and dissimilarity between total and dissolved measurements in CCP porewater samples.

A dissolved concentration lower than the total concentration suggests desorption of chemical constituents from small particles (>0.45 µm) in the sample when a total sample is acidified. There is no environmental explanation for a dissolved concentration higher than a total concentration. However, additional variability could be a result of heterogeneity in the samples themselves. Although paired total and dissolved samples are collected from the same location in the same sample event, they are often collected sequentially and therefore may represent slightly different fractions of porewater.

Methods

The porewater data set described in Section 2 was refined to include only samples that had both total and dissolved fractions analyzed (that is, samples with paired total and dissolved data). For samples in which either result was a non-detect, the MDL was used to calculate the ratio. The total versus dissolved concentration comparison plots are provided in Appendix B.

Data were evaluated by determining if total and dissolved concentrations were effectively similar for each sample. Total and dissolved concentrations for a sample were considered similar when the difference was within a predefined range of error. A difference of up to 20% was set as the predefined error—a percentage that is typically acceptable to meet quality control standards in a laboratory for a set of duplicate samples (USEPA, 2020). Therefore, a difference of 20% between the total and dissolved measurements was considered similar because it is within the range of accepted typical analytical variability. The overall degree of similarity for a parameter was then quantified by the percent of samples in the entire data set that had a difference of less than 20% between the total and dissolved concentrations.

Results and Discussion

The results of the total versus dissolved concentration comparison are presented in Table 3-1. For each parameter, the percentage of samples for which dissolved results were similar to totals is presented as well as the percent of samples above and below the defined range. The degree to which dissolved and total concentrations were similar ranged from 42% to 97% (Table 3-1). When there was a difference, the dissolved sample usually (63% of sample pairs with a difference) had the lower concentration, but this was not always the case.

Table 3-1
Summary of total versus dissolved concentration comparison

Parameter	Number of Samples Compared	Number Where Total and Dissolved Both Non-Detect	Dissolved Lower Than Total	Dissolved Higher Than Total	Similar Total and Dissolved Concentrations[1]
Al	1199	236	39%	10%	50%
Sb	1185	440	11%	11%	78%
As	1215	6	14%	6%	80%
Ba	1157	8	6%	2%	93%
Be	1164	560	20%	18%	62%
B	1216	19	3%	2%	95%
Cd	1140	794	7%	7%	86%
Ca	84	0	6%	0%	94%
Cr	1209	311	36%	22%	42%
Co	1212	163	21%	9%	71%
Cu	1076	330	28%	28%	44%
Fe	1209	64	35%	6%	59%
Pb	1078	653	19%	9%	72%
Li	136	5	2%	6%	92%
Mg	70	0	4%	0%	96%
Mn	1216	57	6%	3%	90%
Hg	1108	1037	2%	4%	95%
Mo	1162	67	6%	6%	88%
Ni	1176	122	17%	13%	70%
K	70	2	0%	4%	96%
Se	1194	569	14%	11%	75%
Na	70	0	1%	1%	97%
Sr	1216	1	2%	1%	97%
Tl	1204	403	17%	11%	72%
V	1213	41	40%	9%	52%
Zn	1081	448	18%	20%	62%

Note:

[1] Percentages may not add up to 100% due to rounding.

The similarity between total and dissolved results is visualized by plotting the dissolved concentration (y axis) against the total concentration (x axis) (Figure 3-1; Appendix B). Each sample pair is represented by one data point. If total and dissolved concentrations are identical in a sample, that point will fall on the 1:1 line. The 20% range of variability is illustrated by the dashed lines surrounding the 1:1 line. Any points that fall outside of the area between those lines are considered to have different total and dissolved concentrations. Points below the defined range of comparability have lower dissolved than total concentrations, while points above the defined range have higher dissolved than total concentrations (which, as discussed previously, is likely an artifact of sample and/or laboratory variability). The color of each point reflects the turbidity measured for that sample.

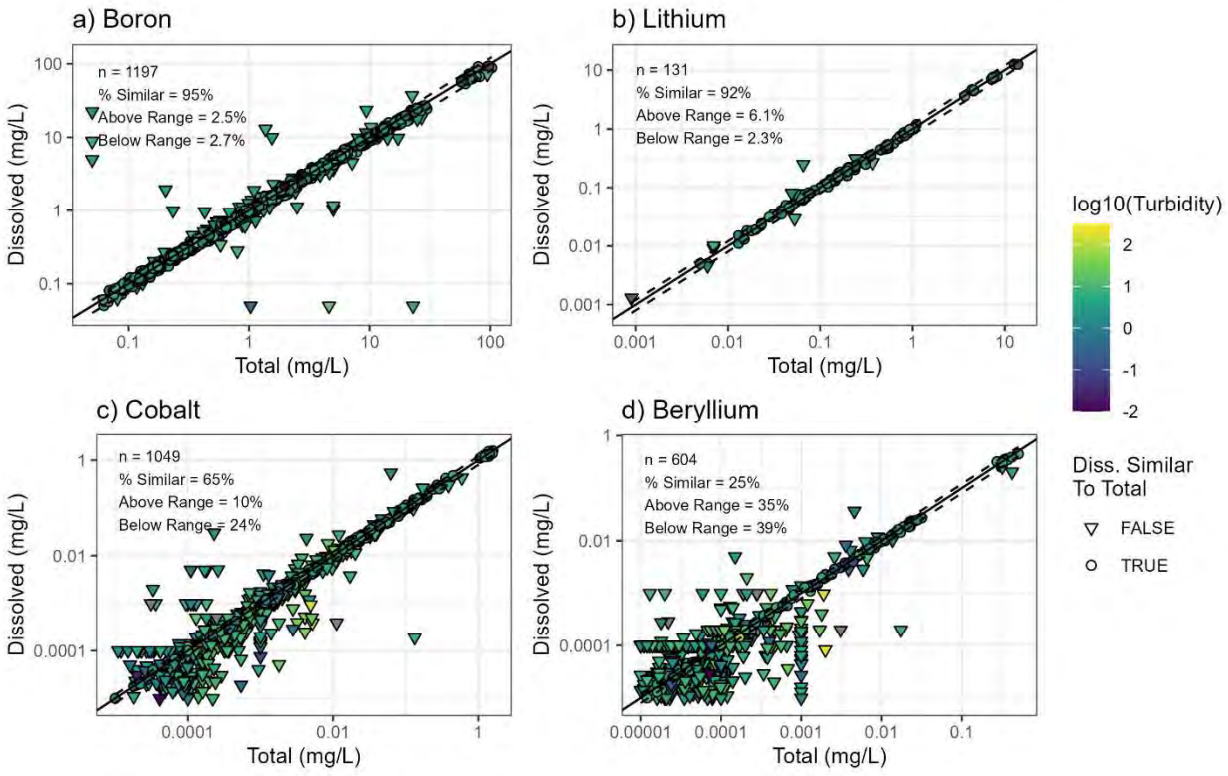

Figure 3-1
Comparison of total versus dissolved measurements for selected parameters when detected in one or both of the paired samples

The statistics on the graphs are for sample pairs where a concentration is detected in one or both samples and differs from Table 3-1 because samples where both results are non-detect were not considered.

Parameters such as Co, which sorb strongly to particulates and therefore have total concentrations more heavily influenced by the presence of turbidity, tend to have a greater proportion of samples below the defined range used for comparison. In contrast, Be does not sorb as strongly to particulates and instead has relatively equivalent proportions of points above and below the defined range. For both Co and Be, fewer samples fall outside the defined range of similarity at higher total concentrations. This suggests that total and dissolved measurements are generally more comparable at concentrations elevated well above the reporting limit (that is, where laboratory analytical variability is less significant relative to concentration).

For both Co and Be, the samples with the highest turbidity typically fall below the defined range. This observation is consistent with turbidity potentially contributing to higher total than dissolved concentrations due to the presence of sorbed ions, although this relationship is qualitative, and turbidity is not the only factor causing differences between dissolved and total concentrations (because not all samples with lower dissolved concentrations compared to totals have elevated turbidity).

Table 3-2 groups the results presented in Table 3-1. This grouping shows that major ions (Ca, Mg, Na, K), certain minor ions (Ba, B, Mn, Mo, Sr, Li), and elements with low detection frequency (Cd, Hg) were least likely to be affected by sample filtration. It is worth noting that Cd and Hg have much lower percentages for similarity (54% and 17%, respectively) when detected in one or both of the total and dissolved samples (see Appendix B). Elements most likely to be affected by sample filtration were Cr, Cu, Al, Fe, and V.

Table 3-2
Grouping of total vs. dissolved sample results

Concentration Tendency for Pairs That Were Not Similar	Percent of Paired Total and Dissolved Samples with Similar Concentration					
	40% to 50%	50% to 60%	60% to 70%	70% to 80%	80% to 90%	>90%
Dissolved more often had lower concentration	Cr	Al, Fe, V	Be, Ni	As, Co, Pb, Se, Tl		Ca, Mg, Ba, B, Mn, Sr
Similar frequency for lower and higher concentration	Cu			Sb	Cd, Mo	Na
Dissolved more often had higher concentration			Zn			K, Li, Hg

Analysis of Variability in Porewater

Background

Porewater composition variability between different CCP units (inter-unit variability) and within the same CCP unit (intra-unit variability) was evaluated in this task. Variability between different units may be due to different operational histories and different CCP source materials. Variability within a single unit may reflect different CCP composition if more than one CCP is managed in the unit (particularly for landfills), differences associated with chemical evolution over time for older vs. newer portions of the unit (particularly for landfills), and, in the case of

sluiced CCPs, the differences in chemistry associated with particle size, because coarse CCP particles will settle near the discharge pipe into the pond, and fine CCP particles will settle near the outfall structure where water exits the pond. This section uses porewater data from 29 CCP units of different sizes and ages (Section 2) to characterize inter-unit and intra-unit variability for a wide range of porewater parameters. The aim of this analysis is not to identify individual causes of variability within and between each of these CCP units; instead, the goal is to describe the variability of different parameters to help inform the characterization of porewater variability within other CCP units.

Methods

Figure 3-2 illustrates how inter-unit and intra-unit variability were evaluated for each parameter. Inter-unit differences were quantified by comparing the highest and lowest medians calculated at the units. Intra-unit differences were quantified using the 25th and 75th percentiles of the data. The 25th and 75th percentiles of the data are visually represented by the lower and upper bounds of the box in a boxplot, and the interquartile range (the difference between the 25th and 75th percentiles) is often used to characterize variability of data.

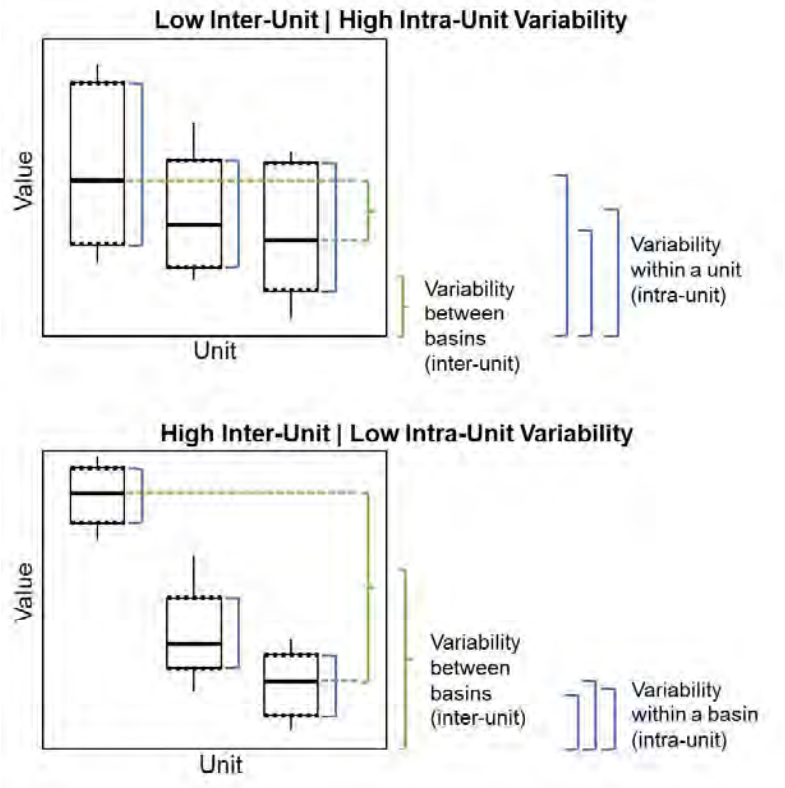

Figure 3-2
Conceptual drawing illustrating how inter- and intra-unit variability were assessed

Electronic Filing: Received, Clerk's Office 07/01/2024

A median range ratio (MRR) was calculated by taking the ratio between highest and lowest medians to allow for comparison of inter-unit variability across different parameters. For example, an MRR of 10 indicates an order of magnitude difference between the highest and lowest medians regardless of the actual concentrations of a given parameter. One MRR was calculated for each parameter based on the medians for all the units. An MRR could not be meaningfully calculated for Eh because the lowest median was a negative value, resulting in a negative ratio.

Intra-unit variability was quantified by taking the ratio between the 25th and 75th percentile of the data (interquartile ratio [IQR]). By calculating the IQR instead of the interquartile range, differences due to absolute concentration measurements are removed. Because IQRs were calculated by unit, as many as 29 IQRs are calculated for each parameter. The median IQR for each parameter is used in this comparison to represent the overall intra-unit variability.

For parameters with both total and dissolved concentrations available, this analysis uses only total concentrations. Data for most parameters were available for all 29 units, although some parameters were not available for all units (Table 3-3).

Results and Discussion

A summary of inter- and intra-unit variability is presented in Table 3-3. The MRR ranges from 1.6 to 80,000, with half the parameters having an MRR between 14.75 and 150. The IQR ranges from 1.0 to 5.0, with half the parameters falling between 1.4 and 2.6. High, moderate, and low variability were categorized based on approximately the top, middle, and bottom third of results, as shown in Table 3-4.

Table 3-3
Results of inter- and intra-unit variability analysis

Category	Parameter	Number of Units	Sample Count	MRR[1]	Median IQR

	TOC	29	1281	74	1.3
	TSS	29	1118	54	2.1
Radiologic	^{226}Ra	23	393	26	3.0
	^{228}Ra	23	393	9.8	2.9
	Ra	8	114	3.3	2.4

Note:

[1] The MRR describes the inter-unit variability, and the median IQR describes the intra-unit variability. A higher value indicates greater variability. Dark green indicates low variability, light green indicates moderate variability, and yellow indicates high variability according to the ranges described in Table 3-4.

Table 3-4
Values for variability group cutoff

Value Type	Range[1]	Quantitative Assessment	Parameter Count
Median IQR	[1 to 1.5]	Low intra-unit variability	15
	(1.5 to 2.3]	Medium intra-unit variability	15
	(2.3 to 5]	High intra-unit variability	15
MRR	(1 to 20]	Low inter-unit variability	16
	(20 to 100]	Medium inter-unit variability	14
	(100 to 80,000]	High inter-unit variability	14

Note:

[1] Square brackets are inclusive of the number shown; round brackets are exclusive

Figure 3-3 illustrates examples of low and high values of inter- and intra-unit variability using boxplots for the results from each unit, ordered based on each unit's median value. The units are identified in the x axis by numerical code (the numbers are non-sequential and were derived from the database provided to EPRI). Results for selected parameters are presented and discussed in the text. Similar figures for all parameters that were evaluated are provided in Appendix C.

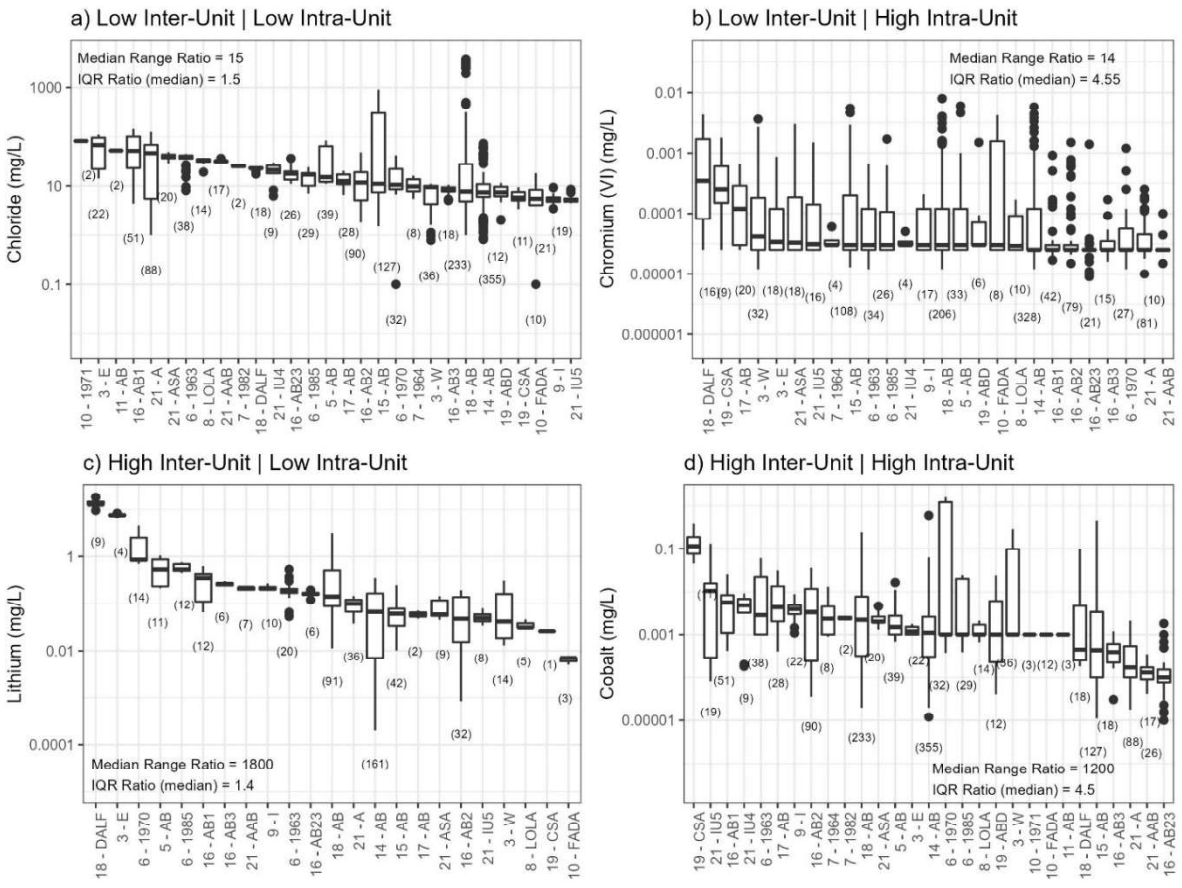

Figure 3-3
Boxplots illustrating both high and low inter- and intra-unit variability for selected parameters

Cl is presented as an example of low inter-unit and low intra-unit variability. An MRR of 15 indicates less than two orders of magnitude variability across all the units. A median interquartile ratio of 1.5 shows that Cl concentrations are relatively consistent within each unit, with units having less than twofold difference in concentration. Few parameters have low inter-unit and intra-unit variability; others with low variability include several field parameters (pH, specific conductance, and temperature) in addition to ALK-CO_3 and Hg, both of which were detected infrequently (Table 3-5).

Cr (Figure 3-3) and Cr(IV) have low inter-unit variability but high intra-unit variability, which may be attributed to the very low concentrations of these parameters. Other parameters with this pattern of variability include Cu, ^{228}Ra, and total Ra (Table 3-5). The maximum and minimum medians are similar because most individual sample results are non-detects, while the occasional detection creates high variability within each unit.

Li is presented as an example of high inter-unit and low intra-unit variability (Figure 3-3). The highest and lowest medians span three orders of magnitude (MRR of 1,800), while concentrations within a unit generally have less than a twofold difference in concentration. This indicates that within a unit there is generally little variability in Li concentration, so a small number of porewater samples may sufficiently characterize Li concentrations. Although no other parameters were observed to have high inter-unit and low intra-unit variability (suggesting that it may be an artifact of a small Li sample size), B and SO_4 (common CCP indicators) along with Mo, alkalinity, and Se had high inter-unit variability and medium intra-unit variability (Table 3-5).

Co is presented in Figure 3-3 as an example of high inter-unit and high intra-unit variability. The medians span three orders of magnitude (MRR of 1,200), and there is over fourfold variation within most units. This suggests that concentrations of Co in porewater may be difficult to predict for a CCP unit and that they may change over time or vary spatially throughout the unit. Other parameters with this distribution include As, Fe, V, Al, and Mn (Table 3-5).

Table 3-5
Inter-unit and intra-unit variability parameter groups

Intra-Unit Variability	Inter-Unit Variability		
	Low (MRR <=20)	**Medium (MRR >20 and <=100)**	**High (MRR >100)**
Low (IQR <=1.5)	pH, EC, TEMP, ALK-CO_3, Cl, Hg	F, Ca, K, Na, Cd, Pb, S^{2-}, TOC	Li
Medium (IQR >1.5 and <=2.3)	NO_2+NO_3, Be, Sr, Zn	Sb, Ba, Tl, TSS	ALK, ALK-HCO_3, Mg, SO_4, B, Mo, Se
High (IQR >2.3)	TURB, Cr, Cr(VI), Cu, ^{228}Ra, Total Ra	Ni, ^{226}Ra	Al, As, Co, Fe, Mn, V

Note: Eh is not shown because MRR was not calculated for this parameter.

There does not appear to be an overall pattern to define which parameters exhibit high or low variability, likely because the porewater concentrations are determined by a combination of the composition of the stored CCP, the operating history of the unit (for example, degree of sluicing), and the *in situ* geochemical conditions as well as the geochemical characteristics of each parameter. Of particular interest are the results for the common CCP tracers (B and SO_4), as well as potential remediation drivers (As, Sb, B, Cr, Co, Li, Mo, and Se; as defined by EPRI, 2021b).

Most of the tracers and remediation drivers have medium to high intra-unit variability, suggesting that more extensive porewater evaluation may be helpful to characterize a unit when developing a source term to model these parameters. Li was the only remediation driver with low intra-unit variability. Except for Sb and Cr, the tracers and potential remediation drivers had high inter-unit variability. Sb and Cr had medium and low inter-unit variability, respectively, which, as previously noted, can be attributed to their relatively low concentration (medians lower than 0.001 mg/L; see Appendix A) in the porewater samples reviewed in this analysis.

4
COMPARISON OF LEAF LEACH TEST ELUATE CONCENTRATIONS TO POREWATER CONCENTRATIONS

Summary

LEAF 1313 (pH-dependent) and 1316 (L/S-dependent) eluate concentrations were compared to median porewater concentrations taken from PMPs screened at the same location and depth as samples used in the LEAF testing for 18 PMPs spread across four CCP management units. This analysis indicated:

- LEAF 1313 and 1316 eluate concentrations were usually more than 25% higher or 25% lower than their paired median porewater concentrations. This observation was made for 1313 eluates at natural pH and the broader pH range for all porewaters and for 1316 results at low and high L/S.
- Elements often controlled by available content—such as B, Ca, Cl, Li, Sr, and SO_4—tended to be underpredicted by the leach tests.
- As, Fe, and Mn were also underpredicted, even though they tend to be solubility controlled, because the LEAF testing was performed under oxic conditions when the solubility of these elements is low.
- Conversely, Se and Cr, which are most soluble under oxic conditions, tended to be overpredicted by the LEAF testing performed under oxic conditions.
- Sb, Tl, and V tended to be overpredicted by the leach tests while other elements were overpredicted or underpredicted depending on test-specific and site-specific factors.
- No bias was detected for Hg because most porewater and all the LEAF test results were non-detect.
- Overall, these observations confirm the observations from EPRI 2020 and 2021c that LEAF tests do not reliably predict porewater concentrations observed in the field.

Background

Laboratory leaching tests can be used to estimate how environmental conditions, the length of exposure to leaching conditions, and material composition affect the release of inorganic constituents from CCP. However, the ability of leaching tests to predict concentrations of inorganic constituents in field porewater depends on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field (EPRI, 2020 and 2021c).

Traditional leach tests expose a solid material to a single eluent, which is intended to be representative of *in situ* porewater concentrations. These traditional leach tests include USEPA Method 1311 (Toxicity Characteristic Leaching Procedures; TCLP), USEPA Method 1312 (Synthetic Precipitation Leaching Procedure; SPLP), and ASTM D3987 (Shake Extraction of Solid Waste with Water; ASTM). A more robust approach to leaching tests is the Leaching Environmental Assessment Framework (LEAF) (USEPA, 2019), which uses a gradient of eluent compositions designed to evaluate leaching behavior across a range of environmental conditions. Different LEAF methods alter different controlling variables (for example, pH, liquid-to-solid ratio [L/S]) in their experimental design.

In 2020 and 2021, EPRI published research that compared the results of traditional leaching tests (TCLP, SPLP, and ASTM) to two of the four LEAF leaching methods: USEPA Method 1313 (Liquid-Solid Partitioning as a Function of Eluate pH Using a Parallel Batch Procedure) and USEPA Method 1314 (Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using an Up-Flow Percolation Column Procedure) (EPRI, 2020 and 2021c). The 2020 and 2021 research compared porewater to leach test eluates from samples collected from the screened intervals of the PMPs. The results indicated that traditional leaching tests were not reliable predictors of measured porewater concentrations because of the relatively high L/S used in these tests and because they do not necessarily reproduce field pH and redox conditions within a CCP unit.

LEAF testing is designed to span the range of pH and L/S encountered in the field although it can be difficult to determine in advance which pH or L/S will best predict the field concentration—and that point varies by element. In general, EPRI (2020 and 2021c) found that low L/S eluates from USEPA Method 1314 were better indicators for constituents where liquid-solid partitioning (LSP) is limited by the content in the CCP solids (available content LSP). Examples of constituents controlled by available content LSP are B, Cl, Mo, and SO_4. Traditional leaching methods and USEPA Method 1313 use higher L/S ratios and tended to underpredict these constituents. Constituents with porewater concentrations controlled by their solubility (solubility-controlled LSP), such as As and Sb, were better predicted by USEPA Method 1313 although the pH at which the test best predicted field conditions did not always correspond to the field pH, in part because redox also affects leaching of these elements and because it is challenging to duplicate field redox conditions in the laboratory—especially for strongly reducing conditions. EPRI (2020 and 2021c) also found that site-specific conditions influence whether some constituent concentrations are available content–controlled, solubility-controlled, or controlled by wash-off (present in an easily dissolved form that is rapidly removed by initial contact with water).

This research expands on the previous findings by evaluating the effectiveness of two LEAF test methods (1313 and 1316) at predicting porewater concentration across multiple CCP storage units using paired LEAF and porewater data (as described in Section 2). Similar to EPRI (2020 and 2021c), the laboratory leaching tests were performed on solid samples extracted from the location and depth interval within the CCP deposit where the screened interval of the PMP was placed.

Methods

Eluate concentrations from the LEAF tests were normalized by dividing by the median porewater concentration for the paired samples. Due to the high variability in the resulting ratios, the $\log_{10}$ of each ratio was used for analysis and visualization. If a leach method predicted a porewater concentration to complete accuracy, the ratio between the eluate concentration and porewater concentration would be equal to one (for a $\log_{10}$ ratio of zero).

To quantitatively assess how well the LEAF methods predicted porewater concentrations at any pH or L/S, a predefined range of variability between leach test eluate and porewater concentrations was established. Concentrations in leach test eluates and porewater samples were considered "within range" if the $\log_{10}$ of the ratio was within half an order of magnitude of zero (that is, a $\log_{10}$ ratio between -0.5 and 0.5, or approximately a threefold difference in concentrations between the leach test and median porewater results). Note that this criterion was applied to all pH and L/S eluates from Methods 1313 and 1316, respectively, and therefore provides insight on whether the leach test was comparable to field porewater concentrations at any point in the tested pH or L/S range. This criterion provided a broad measure of leach test performance relative to porewater concentrations.

However, being "within range" is not necessarily a reasonable approximation of field conditions. For example, a plus or minus threefold difference (half an order of magnitude) for a porewater constituent with a concentration of 1,000 mg/L would mean that the leach test eluate was either within or outside a range between about 320 mg/L and 3,100 mg/L. Therefore, a follow-up tabulation was performed following the approach of EPRI (2020, 2021c) using the following criteria:

- For LEAF 1313, was the natural pH (no acid or base added) eluate within 25% of the median porewater concentration?
- For LEAF 1316, were eluates at low (<1.0) or high (>1.0) L/S within 25% of the median porewater concentration?

Results and Discussion

Evaluation of LEAF Test Bias

The comparison of LEAF test results to observed porewater concentrations for all pH and L/S is presented in Table 4-1. The proportion of samples with LEAF 1313 test results within half an order of magnitude around the median porewater concentration ranged from 0% (Cr(VI)) to 100% (Hg) although the "within range" result for Hg is a reflection on detection limits because most porewater and all leach test results were lower than detection limits. The proportion of samples with LEAF 1316 test results within half an order of magnitude around the median porewater concentration spanned a range, from 0% (Cr(VI)) to 100% (Be and Hg), although the Be and Hg results were mostly non-detect.

F was the only commonly detected element with more than two-thirds of LEAF results within range for both the 1313 and 1316 tests, while Sb, Cl, Cr(VI), Fe, Mn, Se, and V had fewer than one-third of the results within range for both tests.

Table 4-1
Summary of LEAF 1313 and LEAF 1316 comparison to porewater results

Param	LEAF 1313				LEAF 1316			
	Sample Count	Samples in Range (%)	Samples Above Range (%)	Samples Below Range (%)	Sample Count	Samples in Range (%)	Samples Above Range (%)	Samples Below Range (%)
Sb	88	33	66	1.1	95	8.4	92	0
As	88	34	4.5	61	95	32	4.2	64

Fe	88	18	6.8	75	95	12	1.1	87
Pb	88	59	30	11	95	83	1.1	16
Li	88	30	0	70	95	37	1.1	62
Mn	88	24	15	61	95	13	2.1	85
Hg	88	100	0	0	95	100	0	0
Mo	88	25	8	67	95	46	25	28
Ni	49	49	41	10	55	67	22	11
^{226}Ra	29	59	17	24	30	67	10	23
^{228}Ra	29	59	10	31	30	53	0	47
Se	88	10	90	0	95	4.2	96	0
Sr	88	36	2.3	61	95	39	0	61
SO_4	88	18	0	82	95	43	14	43
Tl	88	59	36	4.5	95	62	35	3.2
V	78	18	81	1.3	85	2.4	98	0

Note: A green highlight indicates that >67% of the tests were within range, a yellow highlight indicates 33% to 66% within range, and no highlight indicates <33% within range.

The leach test to median porewater ratios are graphically illustrated in Figure 4-1. Each bar on the histogram shows the number of sample points within a given range of $\log_{10}$ median porewater ratio. If a particular leach method sample perfectly predicted porewater concentrations, the data point would fall on the x = zero line (equivalent to a ratio of 1). The half an order of magnitude range of defined variability is illustrated by the dashed lines at x = -0.5 and x = 0.5. The distribution of samples outside the area between those lines indicates bias. The color of the boxes represents results from the two LEAF tests (because the total number of samples differed between leach test methods, the absolute height of the bars will be different). Figures for selected parameters are presented in Figure 4-1 to illustrate a range of observed outcomes. Similar figures for all parameters are provided in Appendix D.

Sb provides an example where both LEAF 1313 and LEAF 1316 results are biased high (more of the ratios fall to the right of 0.5 than to the left of -0.5 in Figure 4-1a). Most of the LEAF 1316 results for Sb fall outside the half order of magnitude criterion.

Ba is an example in which LEAF 1313 is biased high and LEAF 1316 is biased low (Figure 4-1b). For both tests, the distribution of data is centered close to zero and most samples have a $\log_{10}$ ratio between -0.5 and 0.5, but there are substantially more ratio results to one side of the range compared to the other side.

The distribution for Mo LEAF 1316 data is centered close to zero (Figure 4-1c), with a similar number of ratios on either side of the range, indicating no bias. LEAF 1313 results are mostly to the left of the range, indicating a bias low in the 1313 testing.

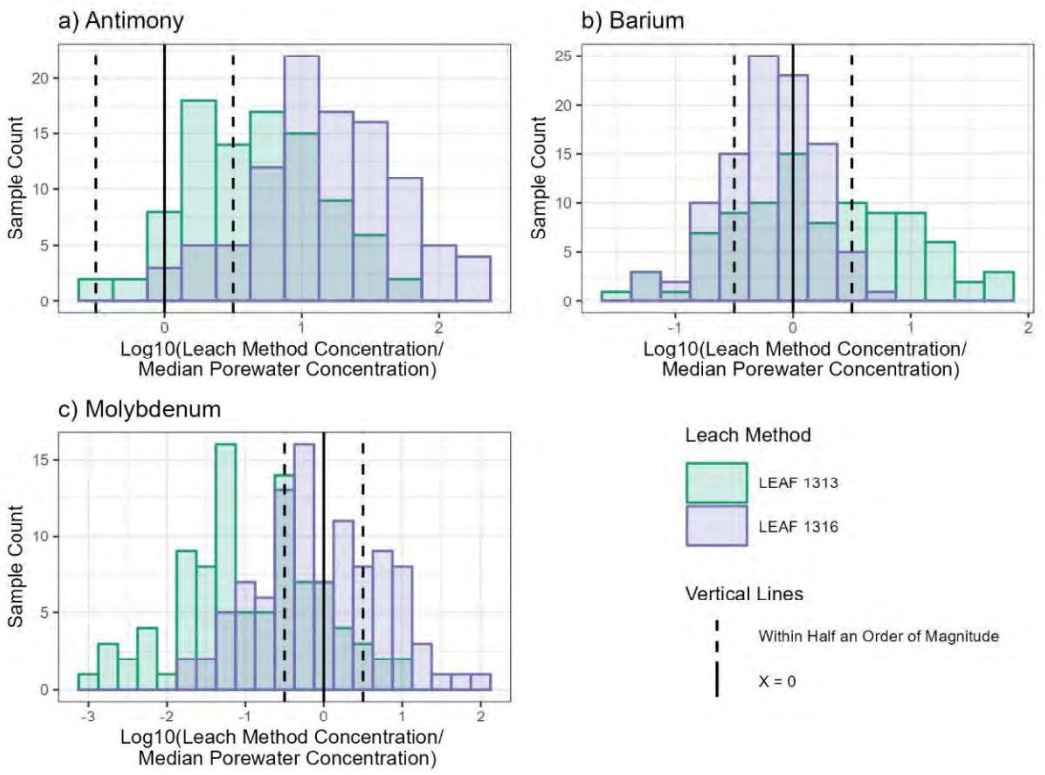

Figure 4-1
Histograms comparing the concentrations predicted by the LEAF 1313 and LEAF 1316 to the median observed porewater concentrations

Sample bias is summarized by element in Table 4-2. A test was considered to impart a bias toward higher concentration (overpredict porewater concentrations) if more than 50% of the samples were above range **or** if at least 20% of the results were above range and there were more than twice as many results above range compared to results below range. Bias low (test underpredicts porewater concentration) was assigned if more than 50% of the samples were below range **or** if at least 20% of the results were below range and there were more than twice as many results below range compared to results above range. The results of this comparison show:

- Elements often controlled by available content—such as B, Ca, Cl, Li, Sr, and SO_4—tend to be underpredicted (bias low) by the leach tests.
- As, Fe, and Mn were also underpredicted, even though they tend to be solubility controlled, because the LEAF testing was performed under oxic conditions when the solubility of these elements is low.
- Conversely, Se and Cr, which are most soluble under oxic conditions, tended to be overpredicted by the LEAF testing performed under oxic conditions.
- Sb, Tl, and V tend to be overpredicted (bias high) by the leach tests while other elements may be overpredicted or underpredicted depending on test-specific and site-specific factors.
- No bias was detected for Hg because most porewater and all the LEAF test results were non-detect.

Table 4-2
Summary of LEAF test bias compared to porewater concentrations

	Bias Low	No Bias	Bias High
LEAF 1313	As, B, Ca, Cl, F, Fe, Li, Mn, Mo, ^{228}Ra, Sr, SO_4	Co, Hg, ^{226}Ra	Sb, Ba, Be, Cd, Cr, Cr(VI), Pb, Ni, Se, Tl, V
LEAF 1316	As, B, Ba, Ca, Cl, Co, Fe, Li, Mn, ^{226}Ra, ^{228}Ra, Sr, SO_4	Be, Cd, F, Pb, Hg, Mo, Ni	Sb, Cr, Cr(VI), Se, Tl, V

Direct Comparison of LEAF Eluate Concentrations to Porewater Concentrations

Figures 4-2 and 4-3 illustrate how leach test concentration varied under the range of pH and L/S conditions imposed by the LEAF 1313 and LEAF 1316 leach tests, respectively. The $\log_{10}$ ratios of leach test sample to median porewater concentrations (y axis) are plotted against the measured sample pH (Figure 4-2) or against the L/S ratio (Figure 4-3). As shown in Figure 4-1, the zero line and predefined range of $\log_{10}$ ratios (-0.5 to 0.5) are shown. In addition, shaded areas represent the order of magnitude and 25% criteria used in EPRI (2020 and 2021c). The same three analytes discussed previously are shown in Figures 4-2 and 4-3 to illustrate a range of potential outcomes. These same figures for all analytes are presented in Appendix E (LEAF 1313, pH dependent) and Appendix F (LEAF 1316, L/S dependent).

Figure 4-1a indicates a tendency for Sb to be overpredicted by LEAF 1313. Figure 4-2a shows this to be the case across the pH range, with some underpredictions at the lowest pH tested. Figure 4-3a shows that porewater Sb tended to be overpredicted at all L/S, especially at low L/S.

Figure 4-1b indicates that Ba was overpredicted by LEAF 1313 and underpredicted by LEAF 1316. Figure 4-2b shows that the 1313 tests for Ba tended to be biased high at low pH and biased

low at high pH. Figure 4-3b shows that Ba can be underpredicted at any L/S and can also be overpredicted at higher L/S.

Figure 4-2c shows that Mo, while biased low across the LEAF 1313 pH range, had more results within range at pH >7.0 SU than at lower pH. Figure 4-3c illustrates that even though the sum of results for Mo testing using Method 1316 showed no bias, the samples at low L/S were biased high, and the samples at high L/S were biased low.

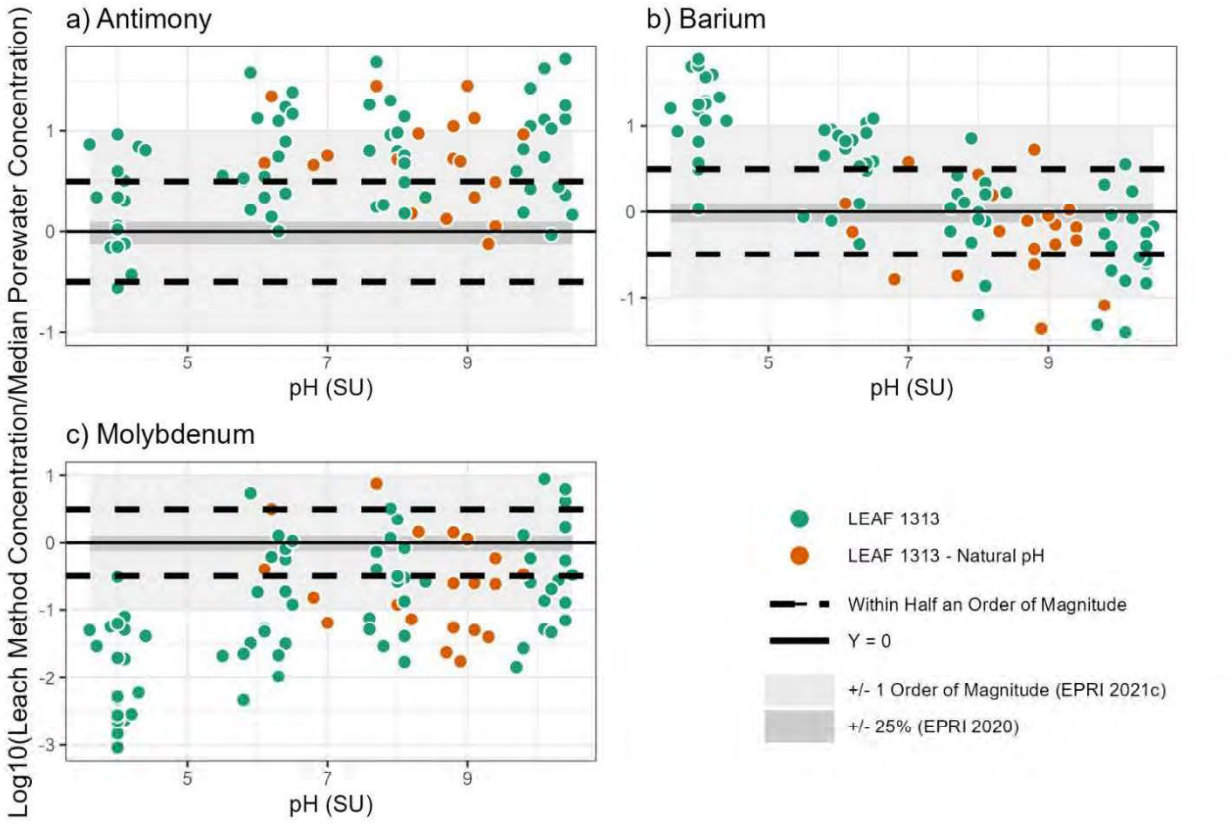

Figure 4-2
Comparison of LEAF 1313 results (normalized to median porewater concentration) across the range of pH levels tested

Electronic Filing: Received, Clerk's Office 07/01/2024

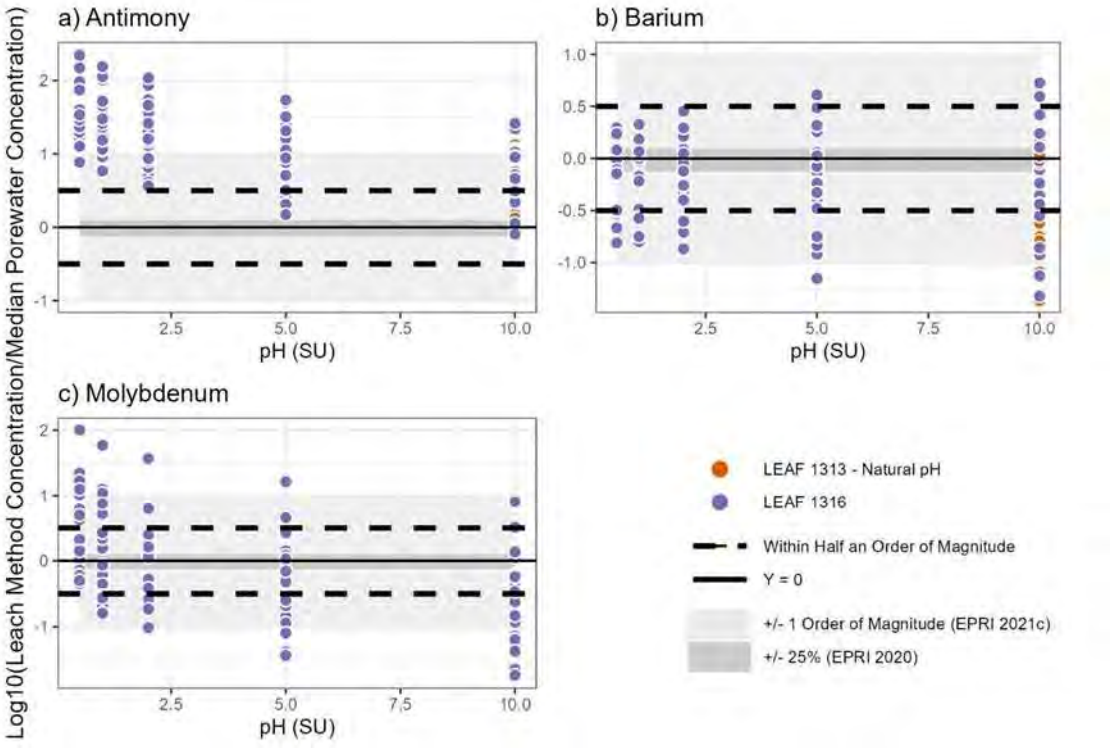

Figure 4-3
Comparison of LEAF 1316 results (normalized to median porewater concentration) across the range of L/S levels tested

Results from the LEAF 1313 test measured at natural porewater pH are included for comparison.

Focusing on natural pH results, the LEAF 1313 tests usually yielded eluate concentrations at natural pH that were higher (>25%) or lower (<25%) than the median porewater concentrations from their paired PMPs (Table 4-3). Taking this comparison a step further, examination of the plots in Appendix E indicates that all LEAF 1313 eluates (natural pH or not) at pH between 6 and 10 were more likely to be outside than inside the ±25% range.[7] The only exception to this observation is for lead, because it was often not detected and the detection limits for the porewater analysis and LEAF 1313 analysis were similar. Similarly, the 1316 eluate concentrations were usually not within ±25% of their paired porewater concentrations. Lead was most likely to yield a concentration within the ±25% criteria but only because the MDLs used for the LEAF 1316 analysis and porewater analyses were similar for this element, which was usually not detected in either porewater or eluates. These results confirm the observations from EPRI 2020 and 2021c that LEAF tests do not reliably predict porewater concentrations observed in the field.

[7] The median porewater concentrations for the ash basins were mostly between 6 and 10 (see pH plot in Appendix C), and the natural pH range for all PMPs was between 6 and 10.

Table 4-3
Tabulation of LEAF 1313 and 1316 eluate concentrations at natural pH and low or high L/S

Parameter	1313 Natural pH Eluates Within ±25%	1313 Natural pH Eluates Outside ±25%	1316 Eluates at L/S <1 Within ±25%	1316 Eluates at L/S >=1 Within ±25%	1316 Eluates Outside ±25%

ADDITIONAL DATA EXPLORATION

This report has discussed porewater composition on a parameter-by-parameter basis. Advanced statistical methods could be used in the future to help characterize entire porewater signatures. Multivariate statistical methods can evaluate the relationships between more than two variables simultaneously, allowing for easier interpretation of entire porewater signatures. Potentially applicable multivariate statistical methods include principal component analysis (PCA), cluster analysis, and linear discriminant analysis (the use of which is discussed in detail in EPRI, 2022).

PCA is a common dimensionality reduction method (Abdi and Williams, 2010; Shlens, 2014). The principal components calculated are essential new "variables," which are linear combinations of the original data that separate the data points and reduce redundancy in the data. In EPRI 2022, PCA was used to distinguish CCP porewater from coal pile runoff water (a potential alternative source of downgradient exceedances). Similar multivariate analyses could be used to assess how parameters co-vary within and between units as well as how successful laboratory leach testing is at determining entire porewater signatures.

B
TOTAL VERSUS DISSOLVED CONCENTRATION COMPARISON

The figures in this appendix (Figures B-1 through B-26) compare total vs. dissolved concentrations in filtered and unfiltered sample pairs when a concentration is detected in one or both samples. For clarity, samples where concentrations are below detection limits in both samples are not shown. The statistics on the graphs are for sample pairs where a concentration is detected in one or both samples and will therefore differ from the statistics shown in Table 3-2.

C
POREWATER VARIABILITY

The figures in this appendix illustrate inter- and intra-unit variability using boxplots. Intra-unit variability was based on the ratio of the 75th to 25th percentile (as illustrated by each individual box; a longer box indicates greater intra-unit variability than a shorter box). Inter-unit variability was determined based on the difference between median concentrations (horizontal line within each box) for each parameter across all sites.

D
HISTOGRAM COMPARISON OF LEAF 1313 AND LEAF 1316 LEACH TEST METHODS

Figures D-1 through D-26 use histograms to compare results of the LEAF 1313 and LEAF 1316 leach test methods. The position of the distribution indicates LEAF test bias. A distribution centered within the vertical dashed lines with a similar sample count to either side indicates little bias, while a distribution that extends more to the left or more to the right of the dashed lines indicates that the leach test results were biased low or biased high, respectively.

E
PLOTS SHOWING NORMALIZED LEAF 1313 TO POREWATER RESULTS ACROSS THE RANGE OF pH LEVELS TESTED

Figures E-1 through E-26 show normalized LEAF 1313 test results, where the results were normalized by dividing by the median porewater concentration (because results are displayed as $\log_{10}$, a value of zero indicates exact agreement). The ability of the 1313 test to reproduce porewater concentrations was evaluated based on how many results at natural pH plotted within the dark-shaded ±25% range.

F

PLOTS SHOWING NORMALIZED LEAF 1316 TO POREWATER RESULTS ACROSS THE RANGE OF L/S VALUES TESTED

Figures F-1 through F-26 show normalized LEAF 1316 test results (and 1313 at natural pH) as a function of L/S ratio. The results were normalized by dividing by the median porewater concentration (because results are displayed as $\log_{10}$, a value of zero indicates exact agreement). The ability of the 1316 test to reproduce porewater concentrations at any given L/S was evaluated based on how many results plotted within the dark-shaded ±25% range.

Export Control Restrictions

Access to and use of this EPRI product is granted with the specific understanding and requirement that responsibility for ensuring full compliance with all applicable U.S. and foreign export laws and regulations is being undertaken by you and your company. This includes an obligation to ensure that any individual receiving access hereunder who is not a U.S. citizen or U.S. permanent resident is permitted access under applicable U.S. and foreign export laws and regulations.

In the event you are uncertain whether you or your company may lawfully obtain access to this EPRI product, you acknowledge that it is your obligation to consult with your company's legal counsel to determine whether this access is lawful. Although EPRI may make available on a case by case basis an informal assessment of the applicable U.S. export classification for specific EPRI products, you and your company acknowledge that this assessment is solely for informational purposes and not for reliance purposes.

Your obligations regarding U.S. export control requirements apply during and after you and your company's engagement with EPRI. To be clear, the obligations continue after your retirement or other departure from your company, and include any knowledge retained after gaining access to EPRI products.

You and your company understand and acknowledge your obligations to make a prompt report to EPRI and the appropriate authorities regarding any access to or use of this EPRI product hereunder that may be in violation of applicable U.S. or foreign export laws or regulations.

About EPRI

Founded in 1972, EPRI is the world's preeminent independent, nonprofit energy research and development organization, with offices around the world. EPRI's trusted experts collaborate with more than 450 companies in 45 countries, driving innovation to ensure the public has clean, safe, reliable, affordable, and equitable access to electricity across the globe. Together, we are shaping the future of energy.

Leaching, Geotechnical, and Hydrologic Characterization of Coal Combustion Products from an Active Coal Ash Management Unit: Plant 42197. EPRI, Palo Alto, CA: 2021. 3002018780.

Electronic Filing: Received, Clerk's Office 07/01/2024

ABSTRACT

The appropriate selection and use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is highly dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field.

This report presents the results of geotechnical, hydrologic, and leaching characterization of samples of coal ash collected from an active coal ash disposal unit where dry-handled coal ash is placed over a portion of a former sluiced (i.e., wet-handled) coal ash deposit. The hydraulic conductivity of intact cores from the saturated coal ash was measured in context of the distribution of particles in the coal ash samples and the overburden pressure associated with disposal at depth within the facility. The leaching test results for LEAF tests (i.e., EPA Methods 1313 and 1314) were compared to the results for traditional tests (i.e., ASTM, TCLP, SPLP). In addition, porewater estimates derived directly from leaching tests were compared to measured porewater concentrations, and measured porewater concentrations were compared to groundwater concentrations.

Deliverable Number: 3002018780

Product Type: Technical Report

Product Title: Leaching, Geotechnical, and Hydrologic Characterization of Coal Combustion Products from an Active Coal Ash Management Unit: Plant 42197

PRIMARY AUDIENCE: Electric utility environmental professionals responsible for landfill and impoundment management of CCPs

SECONDARY AUDIENCE: Researchers and regulators interested in CCP leaching and chemistry

KEY RESEARCH QUESTION

The appropriate use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is highly dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field. The objectives of this research were (i) to determine the most appropriate approach for estimating porewater concentrations at CCP disposal facilities, and (ii) to highlight the potential connection between the CCP leaching performance of a disposal facility, based on porewater measurements or leaching tests, and sentinel monitoring of groundwater exterior to the disposed material.

RESEARCH OVERVIEW

The Electric Power Research Institute (EPRI), Vanderbilt University (VU), and University of Virginia (UVA) performed a study to develop relationships between the geochemistry of the disposed CCPs and the measured concentrations for inorganic constituents in the porewater of CCP disposal units. In addition, this study investigates the potential relationship between porewater concentrations and concentration in groundwater measured at adjacent monitoring wells.

CCP materials were collected at four locations from an active CCP disposal unit where coal ash was initially sluiced (wet-handled), and is now dry-handled. During field activities, porewater access points and subsurface gas access points were established for eight monthly sampling events. Collected materials were characterized for leaching and geotechnical/hydrologic properties. The hydraulic conductivity of intact cores from the ash deposit was measured in context of the distribution of particle sizes in the CCP samples and the overburden pressure associated with disposal at depth within the unit. The leaching test results for the Leaching Environmental Assessment Framework (LEAF) (i.e., EPA Methods 1313 and 1314) were compared to those for traditional tests (i.e., ASTM, TCLP, and SPLP). In addition, porewater estimates derived directly from leaching tests were compared to measured porewater concentrations, and measured porewater concentrations were compared to groundwater concentrations.

KEY FINDINGS

- Despite differences in coal ash placement (dry-handled ash in the upper portion and wet-handled ash in the lower portion), there was little observed variability in vertical concentration profiles. This observation suggest that infiltration moving through the unsaturated dry-handled ash (e.g., from precipitation, liquid dumps, water spray for dust management) results in migration of readily dissolved constituents from the dry-handled material into the underlying wet-handled coal ash. Downward movement of soluble constituents results in the pH and porewater composition within the saturated material being similar to the low L/S extraction fractions of composited dry material.
- The ratio of the available content to the total content shows that only a small fraction of total content of most trace constituents is leachable over a broad pH range.
- Suboxic to anoxic conditions are established at relatively shallow depths (> 5 m) below the surface of the dry-handled material.
- The high pH within the porewater of deposited material prevents development of significant microbial activity at depths greater than 5 m below the surface.
- Hydraulic conductivity of the ashes typically was within the range of 10^{-5} to 10^{-6} cm/s. Hydraulic conductivity diminished as the effective stress increased, but only modestly.
- Some parameters in the porewater (e.g., pH, temp, B, Co, Ni, and Zn) exhibited temporal variability due to factors such as seasonal changes or impacts of damage and repair of porewater access points. Other constituents (e.g., Cd, Ca, Cu, Mo, and Se) remained relatively constant within each porewater access point throughout the 8-month monitoring period. Spatial variability was observed for some constituents between porewater access points; however, no consistent pattern was observed.
- The limited data collected from downgradient monitoring wells and porewater access points suggest that porewater concentration alone is an unreliable indicator that a constituent has had an impact on elevated groundwater concentrations or for prediction of downgradient concentrations at this site.
- Traditional leaching tests, such as TCLP, SPLP, and ASTM, are poorer indicators of measured porewater concentrations than LEAF tests. Low liquid-to-solid ratio (L/S) eluates from EPA Method 1314 are better indicators than the traditional tests and EPA Method 1313 for concentrations for available content-limited constituents (e.g., B, Cd, Cl^-, Mo, Se, and SO_4^{-2}) because of the strong L/S-dependence. The data presented here showed that the traditional tests, with an L/S greater than 20 L/kg-dry, and EPA 1313 at L/S=10 L/kg-dry often under-predicted field porewater concentrations by an order of magnitude or more. These results indicate that additional information (e.g., available content and porewater L/S) is needed to provide a reasonable approximation of porewater concentrations. For constituents with solubility-controlled liquid-solid partitioning (e.g., As, Sb, and Tl), EPA 1313 tests at L/S=1 L/kg-dry provide an estimate of porewater concentrations generally within a factor of 2. The combination of pH-dependent leaching data (EPA 1313) with percolation column test results (EPA 1314) provides valuable information for geochemical modeling.

- For field environments that are oxidizing to slightly reducing, leaching test data approximated field porewater concentrations of solubility-controlled constituents within an order of magnitude. Because of the oxic to suboxic subsurface conditions at this site, sampling, laboratory handing, and testing conditions did not appear to significantly influence the redox condition of the field material. This in contrast to impoundments with highly reducing subsurface conditions, where material handling in the presence of oxygen during sampling and laboratory testing can significantly impact test results. The only constituent not well defined by any of the LEAF tests was chromium, the result for which may have been influenced by oxidization of materials during collection from a suboxic environment and testing in an oxic laboratory. The leaching results for chromium indicate that laboratory testing results for redox-sensitive elements (e.g., As, Cr, Sb, Se, V) may not directly reflect the leaching anticipated in porewater when the field environment is reducing, in part due to oxidation incurred during sampling, handling, and testing.

WHY THIS MATTERS

This research provides a unique opportunity to compare a statistically valid field porewater sample set to laboratory leaching test results on samples collected from the same location and depth interval as the porewater sampling point and provides information to guide appropriate use of these tests. It also provides information on, and comparison of, the spatial and temporal/seasonal variability in both porewater quality and laboratory leachate quality at a CCP site. Data collected during this research will inform EPRI physical and geochemical modeling of leaching within coal ash landfills and impoundments.

HOW TO APPLY RESULTS

The results of this research are site-specific, yet when considered with known differences in L/S associated with different leaching tests, and geochemical differences between the field and laboratory environment, they provide information for generalizing the best uses of different leaching tests and porewater data. Companies interested in performing similar comparisons between leaching tests and porewater will be interested in the field and laboratory methodologies described in Sections 2 and 3. Companies and stakeholders interpreting leaching test and porewater results will be interested in the results summarized in Sections 6 and 7.

LEARNING AND ENGAGEMENT OPPORTUNITIES

- A framework using geochemical modeling and porewater data to predict long-term leaching at CCP sites is being developed under EPRI Program 242's hydrogeochemistry project. A series of reports published from 2018 through 2021 describe results of this research. These reports can be accessed by searching epri.com for "Hydrogeochemical Assessment of Long-Term Leaching Characteristics at Coal Combustion Product Sites."
- Stakeholders, including regulatory agencies, reviewing leaching test analyses may be interested in results of this research to understand the relationship between the different leaching tests, and the relationship between leaching tests and porewater within CCPs.

Groundwater/Porewater Sample Points

VC-1	porewater access point in the CDL landfill
VC-2	porewater access point in the CDL landfill
VC-3	porewater access point in the CDL landfill
VC-4	porewater access point in the CDL landfill
209	downgradient groundwater monitoring well

931	downgradient groundwater monitoring well

Leaching/Extraction Tests

ASTM	ASTM D3987: Practice for Shake Extraction of Solid Waste with Water
1313	EPA Method 1313: Liquid-Solid Partitioning as a Function of Eluate pH Using a Parallel Batch Procedure
1314	EPA Method 1314: Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using an Up-Flow Percolation Column Procedure
1313_L/S=1	EPA Method 1313 modified for L/S=1 mL/g-dry and abbreviated to 5 target endpoint pH values about the own pH of the material
SPLP	EPA Method 1312: Synthetic Precipitation Leaching Procedure
TCLP	EPA Method 1311: Toxicity Characteristic Leaching Procedure

Equation and Parameter Variables

AC	available content (mg/kg-dry)
$C_{1313(\max pH\ 2,9,13)}$	max concentration from EPA 1313 at pH 2, 9, or 13 (mg/kg-dry)
F	Faraday constant (23,061 cal/(V mol))
Eh	redox potential (mV)
L/S	liquid-to-solid ratio for fully saturated pores (L/kg-dry)
$(L/S)_{1313}$	liquid-to-solid ratio for EPA 1313 extractions
PW	mean porewater concentration from monthly PAP monitoring (mg/L)
R	1.987 (cal/(K mol))
s	global standard deviation of a profile parameter in all “known ash samples”
T	temperature (K)
WC	water content (%)
x	parameter measurement (e.g., pH, concentration) from the low L/S extraction test
$\bar{x}$	global mean of a profile parameter in all “known ash samples” for all boreholes
z	concentration of a constituent in a leaching test (mg/L)
%D	percentage difference between leaching and porewater concentrations
ρ_{dry}	dry unit density (kg-dry/m^3)
θ_s	saturated water content (m^3_{water}/m^3)

1 INTRODUCTION

The appropriate use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field. For example, traditional leaching tests, including EPA Method 1311: Toxicity Characteristic Leaching Procedures (TCLP), EPA Method 1312: Synthetic Precipitation Leaching Procedure (SPLP), and ASTM D3987: Shake Extraction of Solid Waste with Water (ASTM), provide only a snapshot of leaching performance under conditions that often deviate substantially from current or anticipated future field conditions.

In 2012, the United States Environmental Protection Agency (EPA) published four leaching methods from the Leaching Environmental Assessment Framework (LEAF) as draft methods available for use. The four methods have since been validated (Garrabrants et al., 2012a; 2012b) and incorporated as final methods into the Agency's compendium of laboratory methods for solid wastes (SW-846, 2019). The four LEAF methods are:

- EPA Method 1313: Liquid-Solid Partitioning as a Function of Eluate pH Using a Parallel Batch Procedure
- EPA Method 1314: Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using an Up-Flow Percolation Column Procedure
- EPA Method 1315: Mass Transport Rates of Constituents in Solid Materials Using a Tank Leaching Procedure
- EPA Method 1316: Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using a Parallel Batch Procedure

The LEAF approach differs from traditional leaching assessment methodologies in that the leaching tests are designed to provide a series of eluates characteristic of leaching behavior dependent on one or more controlling factors rather than a single eluate that is representative of field leachate from a designed scenario. The EPA has provided a guide for how LEAF tests may be incorporated into common leaching assessment practices (EPA, 2019; Garrabrants et al., 2020a; 2020b).

There remains uncertainty as to the selection of specific test methods and interpretation of testing results to represent (i) the range of pH and liquid-to-solid ratio (L/S) within a waste mass and (ii)

Electronic Filing: Received, Clerk's Office 07/01/2024

the current and long-term geochemical conditions of the porewater of CCP impoundments and landfills. Thus, leaching tests have been widely applied, but often without consideration of their inherent limitations for providing information suitable for evaluation of long-term leaching performance. In addition, little information is available that directly compares measured field porewater concentrations at CCP disposal sites to the results of various leaching test results.

The Electric Power Research Institute (EPRI), Vanderbilt University (VU), and University of Virginia (UVA) initiated a study to develop relationships between the geochemistry of the disposed CCPs and the measured and predicted concentrations for inorganic constituents in the porewater of CCP disposal units. In addition, this study investigates the potential relationship between porewater concentrations and the concentrations in groundwater measured at adjacent downgradient monitoring wells; although this evaluation was limited because there were no upgradient or background monitoring wells that could be used for comparison. This research was accomplished by collecting CCP materials from an active disposal unit where dry-handled coal ash overlies wet-handled ash. During field activities, subsurface materials were collected during borings, and porewater access and subsurface gas access points were installed and sampled for eight monthly monitoring events. Collected materials were characterized for leaching and geotechnical/hydrologic properties. A framework for integrating these data is being developed under a separate EPRI project. This report provides the methodology for sampling and characterization of disposed CCPs collected from an ash management unit at Plant 42197, also referred to as "CDL." The report summarizes the results of characterization CCP samples, including leaching tests and geotechnical/hydrologic data, and monitoring data with respect to groundwater and coal ash porewater collected at the facility as well as vadose-zone subsurface gas concentrations monitored within the coal ash deposit.

Project Goals and Objectives

The goals of this research are (i) to determine the most appropriate approach for estimating porewater concentrations at CCP disposal facilities, and (ii) to highlight the potential connection between the CCP leaching performance of a disposal facility and monitoring of groundwater exterior to the disposed material, based on porewater measurements and leaching tests.

The specific objectives of this project include:

- Collecting field materials to qualify the spatial variability of materials disposed in the management unit and measurements of spatial and temporal variability of porewater and pore gas composition, and to allow for characterization of leaching and geotechnical/hydrologic properties;
- Characterizing the hydraulic properties of coal ash for use in hydrologic/reactive transport modeling of CCP impoundments and landfills;
- Establishing the relationships between the characterization of leaching from bulk samples using traditional leaching tests (i.e., TCLP, SPLP, and ASTM) and LEAF pH- or L/S-dependence leaching tests with measured porewater concentrations monitored at the site;
- Assessing the ability of leaching tests (traditional or LEAF tests) to directly estimate coal ash porewater concentrations; and

- Identifying the relationship, if any, between porewater concentrations within the saturated zone of the management unit and downgradient groundwater concentrations.

Site Description

The active landfill at Plant 42197 covers a 110-acre area that was part of a larger 300-acre CCP management unit constructed around 1970 and used to collect storm water and process water from the plant. Starting in the mid-1990s, the unit was divided into sections for sluicing/consolidation of bottom ash, storage of gypsum, and landfilling of dry-handled fly and bottom ash. A 5-ft layer of bottom ash with a permeable geomembrane was laid as a capillary break over the lower wet-handled coal ash deposit to separate this older material from the landfill. Fly ash is collected in a dry state and conditioned with moisture prior to spreading and compacting the ash on the landfill. Bottom ash from the bottom ash settling area is deposited and compacted into the unit primarily to provide surface stability for transport and construction equipment. Starting in October 2019, approximately one-quarter of the surface area of the landfill was covered with 1-2 feet of topsoil and seeded for final cover.

Sampling and Testing Approach

Fieldwork for this project included: (i) advancement of boreholes into the coal ash deposit to improve the understanding of the ash stratigraphy and to obtain samples of the unsaturated and saturated ash layers; (ii) installation of porewater access points (PAPs) within the saturated ash layer and subsurface gas access points (GAPs) within the unsaturated ash; and (iii) sampling of groundwater and porewater and subsurface gas on a monthly basis.

Figure 1-1 shows the relative locations of four boreholes (VC-1, VC-2, VC-3, and VC-4) drilled into the coal ash for material sampling at the site and for installation of PAPs. Additionally, the figure indicates the locations of two groundwater monitoring wells (209 and 931) that allow for sampling of downgradient groundwater in the alluvium that extends beneath the management unit. No upgradient groundwater monitoring well was identified that would provide data on the condition of groundwater prior to reaching the disposal facility. At each of the four borehole locations, bulk ash samples were collected at approximately 10-foot intervals by split spoon sampling. This material was tested in the field and in the laboratory to evaluate the homogeneity of material in the disposal facility and to characterize the leaching properties of the collected ash. In parallel, intact ash cores were collected by tube sampling to determine geotechnical characteristics and hydraulic conductivity of the disposed ash. On a monthly basis for eight months following the completion of the initial fieldwork, samples were collected from each PAP and from the two downgradient groundwater monitoring wells to provide points of comparison to PAP porewater samples. During monthly sampling, the composition of subsurface gas was monitored.

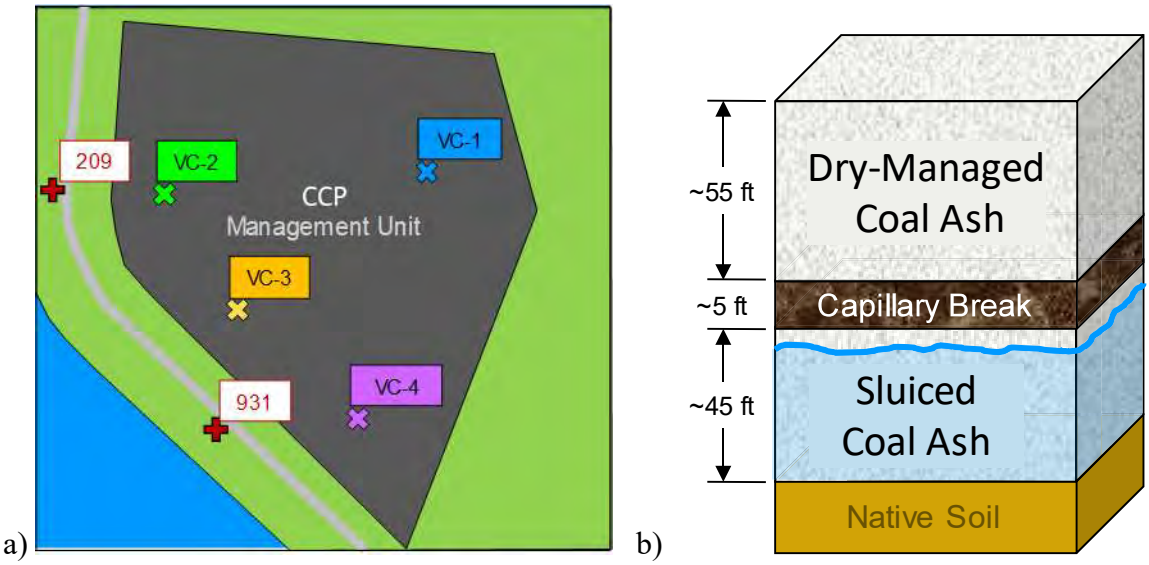

Figure 1-1
Schematic representations of the CDL management unit: a) plan view showing boreholes (VC-1 through VC-4) and groundwater monitoring wells; b) cross-section of disposal unit with approximate layer depths

Bulk samples of collected ash were shipped to the Department of Civil and Environmental Engineering at VU for characterization of leaching properties using the following tests:

- EPA Method 1313 to determine leaching behavior as a function of eluate pH at L/S values of 10 and 1 mL/g-dry,
- EPA Method 1314 to evaluate L/S-dependent leaching from a percolation column, and
- A trio of single-batch extraction tests (i.e., TCLP, SPLP, and ASTM) commonly used to estimate leaching concentrations.

The eluate pH for all leaching tests was measured and recorded so that comparisons could be made between leaching evaluations. The reported constituents include most of those found in the Code of Federal Regulations, Title 40, Section 257 (40 CFR 257), Appendix III for detection monitoring and Appendix IV for assessment monitoring, as well as several additional constituents. Although listed in 40 CFR 257 App III and IV, radium and total dissolved solids were not analyzed. Approximately 40 constituents were quantified in leachates and porewater/groundwater samples to provide a comprehensive basis for geochemical modeling of leaching test results.

The geotechnical and hydrologic properties of intact core samples were determined at the School of Engineering at UVA. Hydraulic conductivity of intact samples was measured using flexible-wall permeameters following the methods in ASTM D5084. Tests were conducted over a range of effective stresses to evaluate how hydraulic conductivity varies with packing configuration and overburden found at depth. Particle size analysis was conducted on each sample using the methods in ASTM D6913 to understand how the hydraulic conductivity varies with the composition of the ash.

2
COLLECTION OF FIELD MATERIALS

The locations of the four boreholes (VC-1, VC-2, VC-3, and VC-4) shown in Figure 1-1 were selected to be within the footprint of the saturated ash deposits, but out of the way of active ash placement. Thus, materials obtained from these boreholes were considered to capture the vertical and horizontal heterogeneity of ash materials above and below the water table. Prior to the 1990s, coal ash was sluiced from the main plant using process water to an outfall near the location of VC-1. Records indicate that the wet-handled ash is approximately 45-feet deep, covered by a 5-foot thick bottom ash capillary break, and, at the time of field sampling, approximately 55 feet of unsaturated dry-handled material consisting of fly ash mixed with bottom ash. The description of historical ash placement in this unit, and the lack of any significant known spatial variations in material types within the unit, indicated that the four locations would be representative of materials across the 110-acre disposal facility.

Initial Site Sampling

Field sampling included collection and testing of bulk ash samples from two to three consecutive split spoons interspersed with thin-wall tube sampling to obtain samples of undisturbed ash. This sequence was repeated at 10-foot intervals starting at five feet below ground surface (BGS). All drilling operations were conducted by a contracted drilling/engineering company. Boreholes were advanced using an 8.25-inch internal diameter (ID) hollow-stem auger (HSA) drilling a 13-inch diameter hole. Collected samples included small samples used in field-testing, bulk material preserved for leaching characterization at VU, and core samples for hydraulic property testing at UVA. Figure 2-1 shows a schematic of the samples collected at depth along with a summary of the number and type of samples collected at each borehole. In this figure, the depths BGS for each sample recorded during collection have been converted to elevations in feet above mean sea level (AMSL) after surveying of the PAP casings and ground elevations. An inventory of the collected samples is provided in Appendix A.

When the borehole depth reached a target level below the water table, prepacked PVC well screen was set in a sand layer for porewater recovery, and the borehole was sealed with bentonite pellets and then backfilled with bentonite chips to the target level for GAP placement. GAPs were set within a 1-foot interval of round river stone and sealed with a wetted and expanded bentonite cap (bentonite pellets) above and below the GAP layer. After the completion of initial site sampling (i.e., advancing borings and installation of monitoring points), the PAP wells were developed and readied for sampling. The finalized bore logs are maintained as electronic files available upon request.

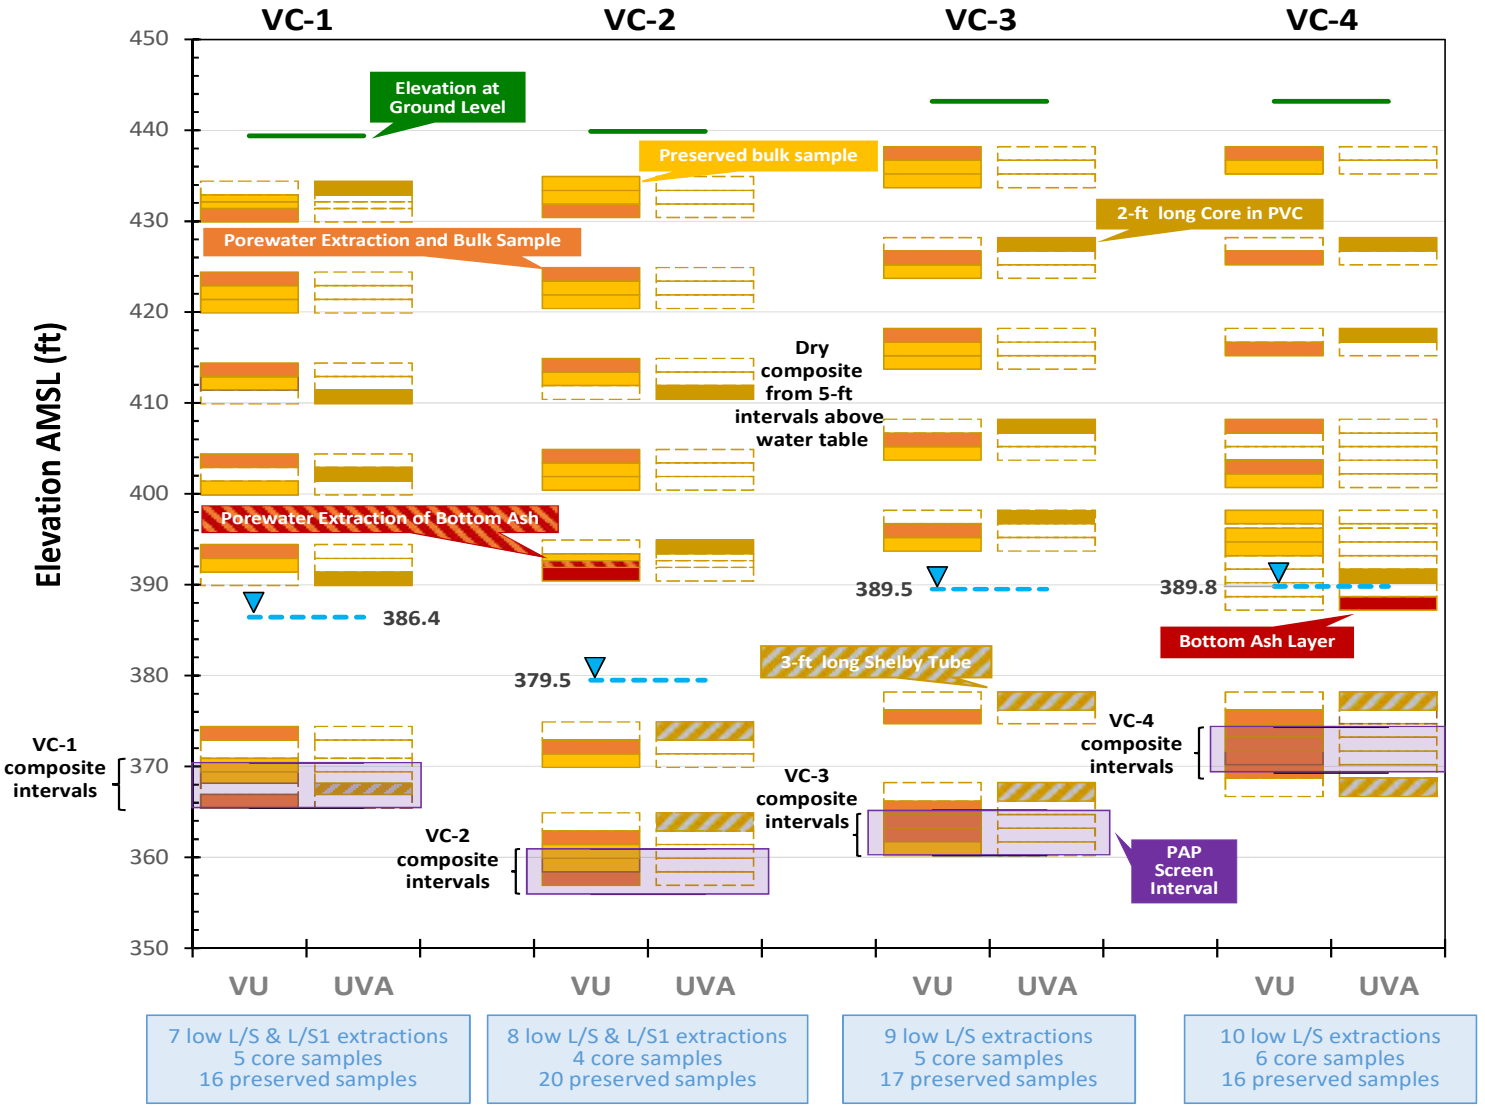

Figure 2-1
Ash sample collection and field testing for VC-1, VC-2, VC-3, and VC-4 boreholes

Bulk Material (Split Spoon Samples)

At each borehole location, 3-inch OD x 24-inch long split spoon samplers were advanced into the coal ash starting at 5 feet BGS (Figure 2-1). Upon retrieval by the drilling contractor, each split spoon sample was opened, recorded, and examined by a licensed geologist prior to release to VU for sample packaging, distribution, and laboratory analysis. VU field activities included preparation of samples for the following:

- Low L/S Field Extractions: Approximately 120 grams of ash from a split spoon was moderately packed into a 3.8-cm ID x 11-cm long acrylic cylinder equipped with a filtration stage and a 0.45-m polypropylene filtration membrane (Figure 2-2a). To ensure extractable moisture in visually dry samples, 10 to 20 mL of de-oxygenated, deionized water (DIW) was added to the cylinder prior to capping, sealing, and storage under an argon blanket (Figure 2-2b). In the laboratory, these samples were centrifuged at 1,000 revolutions-per-minute (rpm) for 5 minutes to extract the pore solution for analysis. During field operations, the porewater extraction tubes were stored in a pressure vessel that was purged with argon gas immediately after each sampling session. This unique field sampling and extraction technique was specifically designed for this project to optimize control of L/S ratio and maintenance of field reduction-oxidization (redox) conditions based on previous field sampling experience (EPRI, 2020).

a)  b) 

Figure 2-2
Low L/S Field Extraction: a) capped apparatus with sample and b) collected samples stored in pressure vessel prior to purging with argon

- Moisture Content Samples: In parallel to porewater testing, a known mass of ash (~20 g) was collected in a certified, pre-tared 125-mL high-density polyethylene (HDPE) bottle (Nalgene I-Chem #N311-0125) for moisture content analysis at VU.
- L/S≈1 Extractions: A known mass of ash (~150 g) from VC-1 and VC-2 split spoons was placed into a certified, pre-tared 50-mL HDPE DigiTube (SCP Science #010-500-253). The bottle was filled with de-oxygenated DIW and weighed to record the mass of added water. In the laboratory, these tubes were tumbled for 24 hours followed by filtration through 0.45-µm HDPE membrane and analysis of extracted fluid.

- Bulk Ash Collection: Remaining ash from each split spoon was vacuum-sealed in plastic bags (Figure 2-3) with oxygen scavenger packets (zero-valent iron) to preserve the redox conditions of the material. The preserved bulk material was maintained in its original cylindrical shape with the top and bottom of the core marked on the vacuum bag. Bulk samples were stored in coolers for shipment to VU.

Labels used for samples included "CDL" as a site identifier, the borehole number (VC-1, VC-2, VC-3, or VB-4), and the depth BGS from which the samples were taken. For example, the sample labeled "CDL_VC-3_16.5-18" in Figure 2-3 was collected from the split spoon at 16.5 to 18 feet BGS at borehole VC-3. For split spoons that penetrated an interface (e.g., between ash with visually different properties), the separate materials were collected as separate bulk samples in two vacuum-sealed bags. The upper portion was labeled with an "A" extension, while the lower portion was labeled with "B" at the same split spoon interval. All samples were stored at <5 °C and transported to the VU lab within 48 hours of collection, where they were stored in an environmentally controlled room at 5 °C prior to processing for leaching tests.

a) 

b) 

Figure 2-3
Examples of split spoon cores: a) as recovered and photo-documented in the field and b) as a vacuum-sealed bulk sample from borehole VC-3 (CDL_VC-3_16.5'-18') preserved for testing

Intact Cores (Tube Samples)

Thin-walled tube sampling of unsaturated ash was attempted, but the tubes would not penetrate the compacted unsaturated material without crumpling. Therefore, split spoon samples of unsaturated ash were extruded into 2-inch OD diameter x 24-inch long PVC tubes, maintaining the sample orientation, so that materials could be consolidated at UVA for testing. Oxygen scavenger packets were included within the tubes, and PVC endcaps were sealed to the tube with duct tape.

Below the water table, in the wet-handled ash, 3-inch OD by 36-inch long thin-wall tube samplers were pushed into the ash layer to obtain intact cores at locations targeted to collect samples near the PAP elevations. Each recovered thin-walled tube was sealed at both ends using plastic expanding inserts, capped with plastic endcaps, and sealed with duct tape. Oxygen scavenger packets were included in each thin-walled tube before sealing. Sample identification was based on the interval BGS from which the samples were recovered (e.g., the tube sampler recovered from the interval from 65 to 67 feet BGS at borehole VC-2 was labeled "CDL_VC-2_65-67").

Porewater Access Points

Once the 8.25-inch ID HSA was advanced to the target depth for placement of a PAP, a 2-inch OD Schedule 40 PVC pipe was installed through the HSA. At each well location, the contractor installed pre-packed, 5-foot screened section in agreement of the field team leads for VU, EPRI, and CDL. Each 13-inch diameter borehole was backfilled with 1 foot of clean sand before the well screen was set, and after setting the screen, was backfilled with sand to 2 feet above the top of the well screen. The sand pack was sealed with bentonite clay pellets, and bentonite chips were used to backfill the borehole to within ½ foot of the GAP depth.

Subsurface Gas Access Points

GAPs were established for monthly monitoring of subsurface gas at nominally 5-, 15-, and 50-feet BGS (50-foot deep GAPs were established at VC-1 and VC-3 only). Each GAP consisted of a ¼-inch diameter stainless steel tube set at depth within a 1-foot thick layer of round river rock and sealed from above and below with a 1-foot thick layer of expanded bentonite clay. The lower end of the GAP tubing was protected from rock, ash, and clay debris with an inverted steel cup. The stainless steel tubing was zip-tied to the PVC well and finished with a 2-way shut-off valve. The bed of river rock, nominal size of between ¾ inch and ¼ inch, ensures sufficient subsurface gas volume for measurement. A detail of the conceptual design of an installed GAP is illustrated in Figure 2-4.

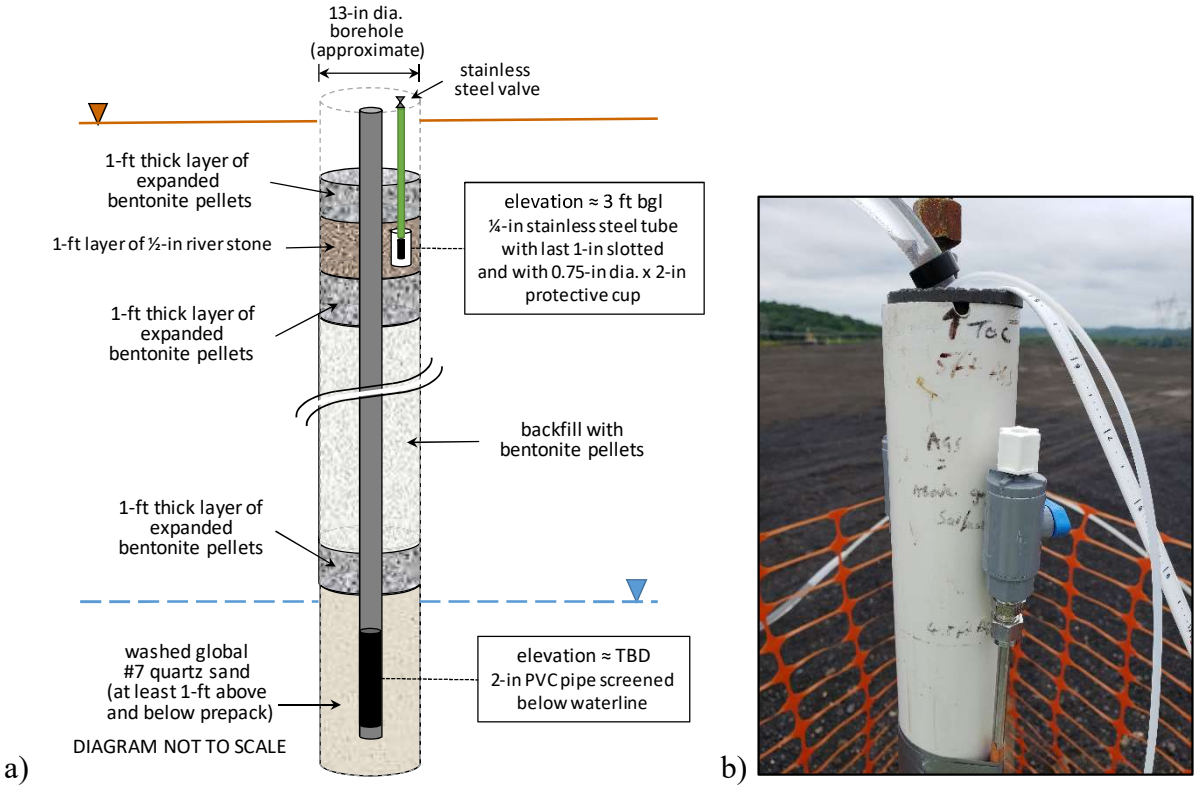

Figure 2-4
Porewater and gas access points: a) conceptual design of PAP and GAP installation and b) picture of installed PAP and GAP

Summary of Borehole and PAP/GAP Elevations

Within two weeks of field sampling, the drilling contractor installed dedicated pumps, developed the wells, and protected the borehole locations with a construction mesh. The horizontal location of the PAP and the elevations of the PVC tubing and ground surface level were surveyed by a professional land surveyor. A summary of the elevation survey results and elevation of pertinent sampling locations for the VC-1, VC-2, VC-3, and VC-4 boreholes is tabulated in Table 2-1. Figure 2-5 graphically shows the elevation relationships between the boreholes and the two downgradient monitoring wells (209 and 931), as well as porewater and groundwater elevations measured during the field study.

Table 2-1
Elevations Above Mean Sea Level (AMSL) for CDL Boreholes

	Elevations AMSL (ft)			
	VC-1	**VC-2**	**VC-3**	**VC-4**
Top of Well Casing	444.46	445.06	448.92	447.63
Ground Surface	439.4	439.9	443.2	443.2
GAP #1 (green)	434.4	435.0	438.4	438.1
GAP #2 (red)	424.4	425.0	427.7	428.3
GAP #3 (blue)	391.0	-	393.5	-
Water Level *	386.4	379.5	389.5	389.8
Top of PAP Well Screen	370.4	360.9	365.2	374.3
Bottom of PAP Well Screen	365.4	355.9	360.2	369.3

Note: (-) indicates that no GAP was placed adjacent to the water table at VC-2 or VC-4.

* water level measured on the date of well construction. Monthly water table elevations are provided in Figure 7-1.

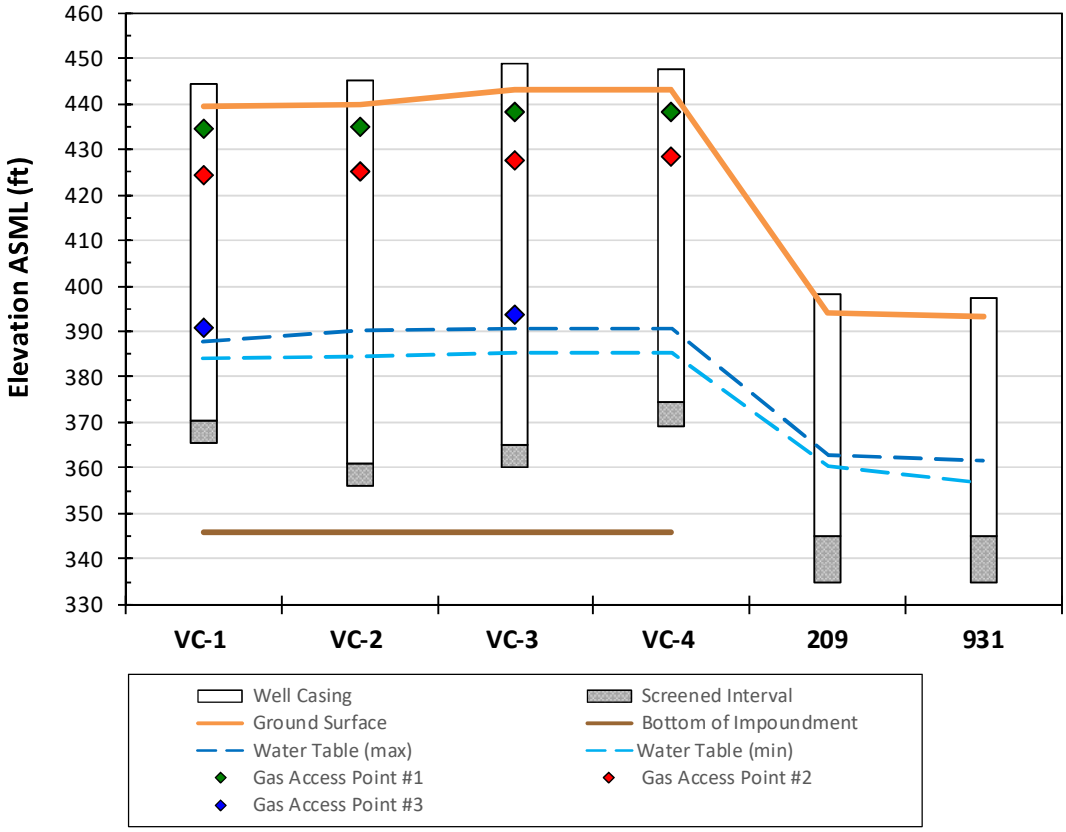

Figure 2-5
Summary of borehole and monitoring well elevations including screened intervals and GAPs. Maximum and minimum water table measurements from monthly measurements (Figure 7-1) are also shown. Figure does not depict horizontal monitoring point placement.

Monthly Field Monitoring

Porewater and subsurface gases were monitored monthly at each borehole location over eight months from June 2019 through January 2020. In addition, groundwater samples from monitoring wells 209 and 931 downgradient of the CCP landfill were collected.

Collection of Groundwater and Porewater

The relative locations of the four installed PAPs (VC-1, VC-2, VC-3, and VC-4) and the two existing groundwater sampling wells were shown previously in Figure 1-1. CDL field personnel accessed each well, stabilized the well using low-flow sampling techniques according to company standard operating procedures, and allowed VU field team access to the effluent line for collection of groundwater and porewater samples. At no time did the site owners' personnel retain custody of any samples used for this analysis.

The sampling flow rates for porewater and groundwater wells were approximately 150 mL/min and 50 mL/min, respectively. At 5-minute intervals, the pH, dissolved oxygen (DO), electrical conductivity (EC), oxidation-reduction potential (ORP), temperature, and turbidity of the sampled water were monitored using a flow-through multi-parameter sonde and separate

Electronic Filing: Received, Clerk's Office 07/01/2024

turbidity meter while water level was measured with a portable electronic water level meter. The criteria used to determine well stability were (i) turbidity less than 10 NTUs and (ii) pH stable within 0.1 standard unit over three consecutive 5-minute readings.

Groundwater and porewater samples were collected in 50-mL Digitubes including duplicate samples collected for anion analysis via ion chromatograph (IC) and duplicate samples collected for metals and other cation analysis via inductively coupled plasma (ICP) techniques (see *Chemical Analysis of Eluates, Groundwater, and Porewater* in Section 3 for details). Samples for ICP analysis were preserved in the field by addition of 1.5 mL of Tracemetal® grade nitric acid (3% total acid addition) using a 100-1000 µL Oxford Benchmate manual pipette and disposable tips. A set of four samples was collected unfiltered followed by a set of samples passed through a QuickFilter 609 cm^2, 0.45-mm inline filter. In total, eight 50-mL Digitubes were collected at each sampling location. All liquid samples were stored in a cooler of ice with an Elitech RC-5 USB temperature data logger to record the temperature within the cooler. Samples were transported by the field team to VU for immediate storage at 5 ºC prior to analysis. Analysis of the sample results showed negligible differences between the filtered and unfiltered samples, and the results from the unfiltered samples are used in the following analysis.

Subsurface Gas Monitoring

A description of the monitoring process for subsurface gas and a picture of gas monitoring apparatus are provided in Section 3.

Electronic Filing: Received, Clerk's Office 07/01/2024

3
MATERIALS AND METHODS

The following sections include brief descriptions of the test methods and analytical methods used in this study. Also described are the quality assurance/quality control (QA/QC) samples and criteria for each analytical method.

Collected Materials

Materials recovered during initial sample collection included bulk samples from split spoons and intact cores contained in PVC tubes or thin-wall stainless steel tubes. Laboratory processing of bulk material for leaching tests included (i) homogenization within each split spoon sample, (ii) compositing saturated ash samples from each borehole from materials collected near the screening level, and (iii) compositing unsaturated ash into one sample across the disposal facility.

Homogenization of Bulk Samples

Each recovered split spoon sample was crushed with a rolling pin and homogenized by hand through the plastic bag until the contents were well mixed. From this homogenized split spoon material, composite samples were created.

Material Composites

For each of four boreholes (VC-1, VC-2, VC-3, and VC-4), saturated ash homogenized from split spoons collected at the PAP screen elevation was used to develop a composite test material representative of the bulk ash deposited at the PAP. Table 3-1 shows the specific homogenized split spoon materials used to create each composite sample for the four boreholes. In addition, a fifth composite material of unsaturated ash was created by blending homogenized material above the water table from all boreholes collected; however, the intervals used in this composite, hereafter referred to as "Dry," varied with the intervals of unsaturated ash at each borehole.[1]

The composite material was created by mixing equal dry mass equivalents (i.e., the mass of "as received" material that equates to a prescribed mass of dry material) from each homogenized split spoon in a plastic bag under a N_2-purged environment in a Coy chamber (an anoxic glove box) to minimize air exposure. The composite material was homogenized by hand through the plastic bag until well mixed. This composited sample was used for total content analysis and characterization using LEAF leaching tests and traditional leaching tests (i.e., ASTM, TCLP, and SPLP).

[1] In other words, five composites are discussed in Section 4 – composites VC-1, VC-2, VC-3, and VC-4, which represent the lower wet-handled coal ash deposit and have corresponding PAP porewater samples, and the composite referred to as Dry, which represents the upper dry-managed coal ash deposit and does not have corresponding porewater samples.

Table 3-1
Below Ground Surface (BGS) and Top Elevations Above Mean Sea Level (AMSL) of Homogenized Split Spoon Intervals Used to Create Borehole Composites (VC-1, VC-2, VC-3, and VC-4)

Notes: PAP Screen elevation to middle of 5-ft screen.
All elevations shown at the top of the 2-ft split spoon sample.

Material Properties

Total Content by EPA Method 3052

The total elemental content of composite samples was determined by acid digestion following EPA Method 3052, with subsequent analysis of the digestate by Eurofins TestAmerica (Knoxville, TN). According to the Method 3052, a solid sample of up to 0.5 g (wet) is digested in 9 mL of nitric acid and 3 mL of hydrofluoric acid for 15 minutes in a microwave to accelerate the digestion reactions. Additional acid and reagent combinations, including hydrochloric acid and hydrogen peroxide, are added to ensure that the solid is dissolved. The microwave temperature profile includes reaching 180±5 ºC in approximately less than 5.5 minutes and remaining at 180±5 ºC for 9.5 minutes for the completion of specific reactions. After cooling, the vessel contents were centrifuged and decanted. The small volume of remaining digestate was diluted to a volume of 100 mL and chemically analyzed. Inductively coupled plasma–optical emission spectrometry (ICP-OES) following EPA Method 6010A was used to determine digestate concentrations for 26 constituents (i.e., Al, Sb, As, Ba, Be, Cd, Ca, Cr, Co, Cu, Fe, Pb, Li, Mg, Mn, Hg, Mo, Ni, K, Se, Ag, Na, Sr, Tl, V, and Zn). Boron was not included in this total content analysis because metaborate is added to the digestion process for Method 3052. Mercury concentrations in the digestate were measured by using cold vapor atomic absorption following EPA Method 7470A. The total content (mg/kg) is calculated by multiplying the concentration measured in the digestate (mg/L) by the L/S of the extraction procedure (L/kg). For this study, the resultant total content is effectively on a dry mass basis (mg/kg-dry) because the material submitted to the laboratory for testing was oven-dried prior to submission to the laboratory.

X-Ray Fluorescence Analysis

The elemental composition of coal ash samples was determined at UVA using x-ray fluorescence (XRF) quantitative analysis on an Epsilon 3X energy-dispersive XRF spectrometer (PANalytical, Malvern, UK) with a silver anode X-ray tube and 50-micron beryllium window.

Five-gram subsamples of coal ash were taken from the undisturbed core samples, air-dried for 24 hours at room temperature, and ground by hand to less than 0.075 mm using an agate mortar and pestle. For analysis, ground samples were packed into an 18-mL sample cup (28 mm ID x 30 mm). Each subsample was analyzed in duplicate following ASTM D8064 (2016) for the XRF analytical method of silicate rocks.

Loss on Ignition

Loss on ignition (LOI) was measured at UVA for subsamples of undisturbed coal ash material to quantify total organic matter content. LOI was conducted in accordance with ASTM D2974-14 by heating a pre-weighed sample at 550 °C using a Lindberg/Blue M 1200 °C Box Furnace (ThermoFisher Scientific, Waltham, MA).

Moisture Content

As part of the leaching test characterization using the LEAF methods, the moisture content of each study material was determined following the ASTM D2216 (2010). Moisture content on a dry mass basis was calculated as the difference in the mass of a "wet" subsample compared to the sample after oven drying to constant mass at 105±5 °C. The solids content is defined as the mass of solid material in an "as-tested" or "wet" subsample, measured on a "wet" basis. The determination of moisture content and solids content provides uniform bases for reporting of total content and leaching behavior results, allowing for comparison between moist and dry materials.

Porosity or Saturated Volumetric Water Content

Dry density and porosity of each material were determined at UVA using weight-volume computations, following the procedure in ASTM D7263 (2018). Under saturated conditions (i.e., when all voids are filled with water), the saturated volumetric water content equals the porosity.

Particle Size Distribution

Particle size distribution (PSD) of each CCP sample was determined at UVA by a combination of mechanical analysis following ASTM D6913-17 and sedimentation analysis following ASTM D7928-17. For mechanical analysis, a 100-g sample was oven-dried at 110±5 °C and passed through a series of US standard sieves: No. 10 (2 mm), No. 20 (0.85 mm), No. 60 (0.25 mm), No. 100 (0.15 mm), and No. 200 (0.075 mm). The fraction of the 100-g mass retained on each sieve was measured gravimetrically. Particle size distribution of the fraction coarser than the No. 200 sieve (0.075 mm) was calculated as the weight of solid retained on each sieve.

For sedimentation analysis, 50 g of dry solid that had passed the No. 200 (0.075 mm) sieve was soaked in 4% sodium metaphosphate, $(NaPO_3)_6$, solution for 12 hours and then transferred to a 1-L graduated cylinder. The graduated cylinder was capped, then agitated end-over-end for 60 seconds, and then settling of particles was monitored using a hydrometer. Stokes law was used to compute the PSD from the hydrometer data for the fraction of particles finer than the No. 200 sieve.

Saturated Hydraulic Conductivity

Hydraulic conductivity tests were conducted in flexible-wall permeameters following the methods in ASTM D5084-16. Sections of undisturbed coal ash were extruded from thin-wall sampling tubes (Figure 3-1) and cut into 76-mm long specimens. Non-woven geotextile disks and porous stones were placed on both ends of each coal ash specimen (Figure 3-2a) to ensure uniform flow distribution and to retain particles. Specimens were wrapped in a latex membrane and placed into a flexible-wall permeameter (Figure 3-2b).

In lieu of the more traditional tap water or 0.01 M $CaCl_2$ solution suggested in ASTM D5084, DIW was used as the permeant solution to ensure that the water entering the specimen had no ionic species that might alter the hydraulic conductivity or the leachable constituents in the coal ash. Effluent from the permeameter was collected following the procedure in ASTM D7100-11. Effluent samples were collected from the tests, stored in Teflon® sample bottles with minimal headspace, and shipped under chain of custody to VU for chemical analysis.

The falling headwater-constant tailwater method was used with an average hydraulic gradient of 15. No backpressure was applied to simulate field conditions and to minimize alterations in geochemistry. All tests were conducted at an initial effective stress of 20 kPa and continued until the hydraulic conductivity reached hydraulic equilibrium as defined in ASTM D5084 (steady hydraulic conductivity, incremental outflow divided by steady inflow within 1.0±0.25). At the conclusion of the test, weight-volume calculations were conducted to confirm that all specimens were saturated during testing.

After testing at 20 kPa was complete, three specimens, representing higher, lower, and intermediate hydraulic conductivity, were consolidated to an effective stress of 100 kPa and permeated again until hydraulic equilibrium was established (steady hydraulic conductivity, steady flow ratio 1.0±0.25). This procedure was repeated at effective stresses of 250, 400, and 500 kPa. The initial stress (20 kPa) was selected to replicate the stress condition of shallow coal ash in the basin. The higher stresses represent conditions at greater depths. Effluent samples from the higher-stress tests were not collected for chemical analysis.

Traditional Extraction Tests

EPA Method 1311 – Toxicity Characteristic Leaching Procedure

EPA Method 1311, or TCLP, is a single-point batch leaching test used to determine the toxicity characteristic of a material and the disposal options for a material under the Resource

Conservation and Recovery Act of 1986 (RCRA). TCLP was designed to simulate eluate concentrations for a plausible mismanagement scenario where hazardous waste is disposed in a municipal solid waste landfill. Thus, a solution of acetic acid in DIW is the extraction fluid to represent the primary acidity in municipal solid waste landfill leachate. Based on a pretest of the buffering capacity of test sample for acetic acid, either Extraction Fluid #1 (dilute acetic acid with a NaOH buffer at a pH of 4.93±0.05) or Extraction Fluid #2 (dilute acetic acid at a pH of 2.88±0.05) is selected for the test. Since the method allows for analysis of samples with filterable water (e.g., slurries), the specified L/S of 20 mL/g is based on the mass of moist sample recovered from pressure filtration at 15 lb/in^2 (103 kPa). The filtrate from pressure filtration was preserved and chemically analyzed in parallel to TCLP extracts. Therefore, the final dry-basis extraction L/S is typically greater than 20 mL/g-dry when filterable water is considered.

For TCLP analysis, 100 g of solid was pressure-filtered and the moist solid was mixed with Extraction Fluid #1 at an L/S of 20 mL/g-dry. The mixture was tumbled at 28±2 rpm for 18±2 hours. Although not specified in the method, the pH of the final eluate was measured and recorded so that test results could be compared to other leaching methods. The eluate from the extraction was pressure-filtered through a 0.22-µm borosilicate glass fiber filter and preserved for analysis. Filtrate from pressure filtration and the extraction eluate were analyzed separately, and an "effective" extraction concentration was calculated for each constituent as a volume-weighted average concentration of the two liquids. For QA/QC purposes, a method blank, with the filter paper and extraction fluid only, and duplicate samples for the composite at VC-3 were conducted in parallel using the same reagents.

EPA Method 1312 – Synthetic Precipitation Leaching Procedure

EPA Method 1312, or SPLP, is a single-batch leaching test used to evaluate the leaching behavior of a waste material in contact with acidic rain. The test is performed in the same manner as the TCLP, but with extraction fluids of 60/40 weight percent (wt%) sulfuric acid (H_2SO_4) and nitric acid (HNO_3) in DIW (Extraction Fluids #1 and #2) or DIW (Extraction Fluid #3). The selection of extraction fluid depends on the location of the site under investigation and the constituents being tested. Extraction Fluid #1 is used for sites east of the Mississippi River, Extraction Fluid #2 is used for sites west of the Mississippi River, and Extraction Fluid #3 is used only when cyanides or volatiles are to be analyzed.

Approximately 100 g of ash was pressure-filtered and the moist solid was mixed with Extraction Fluid #1 at an L/S of 20 mL/g. The mixture was tumbled at 28±2 rpm for 18±2 hours. Although not specified in the method, the pH of the final eluate was measured and recorded so that test results could be compared to other leaching methods. The eluate from the extraction was pressure-filtered through a 0.22-µm borosilicate glass fiber filter and preserved for analysis. Filtrate from pressure filtration and the extraction eluate were analyzed separately and an "effective" extraction concentration for each constituent was calculated as a volume-weighted average of the two liquids. A method blank, extraction fluid with no solid carried through test process, and duplicate samples for the composite at VC-4 were analyzed.

ASTM D3987 – Shake Extraction of Solid Waste with Water

ASTM D3987, or ASTM, is a single-point extraction test that is used to estimate leaching concentrations when no acid or base is added to the extraction. Since the method is patterned

after TCLP, the procedure is similar to the EPA method; however, DIW is used as the extraction fluid. A subsample of ash (70±0.1 g) was tumbled at 28±0.2 rpm with DIW at an L/S of 20 mL/g for 18±0.25 hours. After tumbling, the extract was separated from the solid by vacuum filtration through a 0.45-µm polypropylene membrane and the pH of the final eluate was measured and recorded. Reagent blanks, method blanks, and duplicate samples for the composite at VC-2 were analyzed.

Leaching Environmental Assessment Framework (LEAF) Methods

EPA Method 1313 – Liquid-Solid Partitioning as a Function of Eluate pH Using a Batch Extraction Procedure

EPA 1313 (SW-846, 2019) is a standardized, parallel batch extraction method used to evaluate the liquid-solid partitioning (LSP) of inorganic constituents as a function of eluate pH. The general procedure consists of nine batch extractions of a particle-size reduced subsample material contacted with leaching solution at an L/S of 10 mL/g-dry material and tumbled end-over-end over a specified contact interval. The leaching solution is DIW with additions of HNO_3 or potassium hydroxide (KOH) to adjust the final pH of the eluate to a target of nine specific pH values (i.e., pH values of 2, 4, 5.5, 7, 8, 9, 10.5, 12, and 13). An additional extraction without addition of acid or base was carried out to measure constituent leaching at the natural pH of the material.[2] After 24 hours of tumbling, the contact time associated with a sample particle size of 85 wt% less than 300 µm, the solid and liquid phases were separated by settling or centrifugation, and the pH, EC, and ORP of the clarified eluate were measured. The remaining slurry was vacuum-filtered through 0.45-µm pore size membranes prior to chemical analysis by ICP-OES, IC, and carbon analysis.

EPA 1313 provides (i) a titration curve of the pH response to additions of acid or base, (ii) the available content of constituents in the solid material, and (iii) the LSP curve for constituents over the tested pH range. Furthermore, the results of EPA Method 1313 are suitable for use in geochemical speciation modeling for the estimation of the solid-phase mineralogy and surface chemistry that controls constituent release.

Variants of EPA 1313 Methods

In this program, the full EPA 1313 method and variants of EPA 1313 were carried out on ash materials for different purposes:

- Full EPA 1313 was conducted on all composite samples (i.e., saturated ash composite from each borehole plus the site-wide unsaturated composite). The procedure was modified slightly to include an extra extraction filling the gap in pH between pH < 2.0 and pH = 4.
- For all composite materials, a variant of EPA 1313 was carried out using an L/S of 1 mL/g-dry and abbreviated to the natural pH and four other pH target values distributed over the range of pH 6 to 13 (i.e., five pH values in total). This modified 1313 test, referred to as

[2] The "natural pH," sometimes referred to as "own pH," is defined as the eluate pH in response to extraction in deionized water (i.e., no acid or base added) at an L/S of 10 mL/g-dry. To distinguish the natural pH at L/S=10 mL/g-dry (Method 1313 or 1313_3pt) from the pH response to DIW at L/S of 1 mL/g-dry measured using 1313_L/S=1, the former will continue to be called with "natural pH," while latter will be referred to as "own pH."

1313_L/S=1, was used to evaluate how changes in L/S may influence LSP concentrations and to provide verification data for development of geochemical speciation models.

EPA Method 1314 – Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio using a Percolation Column Procedure

EPA 1314 (SW-846, 2019) is a standardized, up-flow column procedure used to evaluate release of inorganic constituents from percolating solid materials as a function of cumulative L/S (i.e., the volume of liquid that passes through the column relative to the dry mass of material in the column). In this study, EPA 1314 was used to characterize the L/S-dependent leaching of constituents in 250-400 g-dry composited ash samples (e.g., VC-1, VC-2, VC-3, VC-4, and Dry). A 5-cm diameter by 30-cm glass column was packed with coal ash in a series of five lifts with moderate tamping between lifts. DIW was used as the eluent solution since the coal ash had relatively low organic carbon and clay contents compared to soils. The eluent was pumped at a flowrate of 0.75±0.25 L/S per day through the material in an up-flow direction to minimize air entrapment and flow channeling. Eluates were collected at predetermined cumulative L/S values (i.e., 0.2, 0.5, 1.0, 1.5, 2.0, 4.5, 5.0, 9.5, and 10 mL/g-dry). For each eluate fraction, the pH and conductivity were recorded prior to filtration and preservation for chemical analysis. To present the results, the eluate pH, and concentrations of constituents in the eluates (mg/L), and the cumulative release through the end of each eluate fraction (mg/kg-dry) were plotted as functions of L/S in separate graphs.

Comparison of Leaching Test Parameters and Conditions

All leaching tests conducted for this program are designed to measure the LSP of constituent release from a material under the specified test conditions shown in Table 3-2. TCLP, SPLP, and ASTM are single-batch leaching tests that yield only one result; thus, test duplicates were conducted as shown in the table to ensure the quality of test results. The EPA 1313 test and its variants are batch procedures, but with parallel extractions to provide data over a range of test conditions. These batch tests, however, differ in the chemical makeup of extraction fluid as well as in the specified L/S. Moving from left to right in Table 3-2, the leaching test conditions are presented in order of increasing L/S. In the last column are the test conditions for EPA 1314, designed to measure LSP as a function of cumulative L/S.

Table 3-2
Leaching Test Parameters and Test Conditions

Parameter	TCLP	SPLP	ASTM	1313	1313_L/S=1	1314
Method Type	Single-batch	Single-batch	Single-batch	Parallel batch	Parallel batch	Column
Number of Eluates	1	1	1	11**	5	9
Extraction Fluid	Acetic acid in DIW	H_2SO_4/HNO_3 in DIW	DIW	HNO_3 or KOH in DIW	HNO_3 or KOH in DIW	DIW
Extraction Fluid pH	#1: 4.93±0.05* #2: 2.88±0.05	#1: 4.20±0.05* #2: 5.00±0.05 #3: DIW	-	-	-	-
L/S	20 mL/g-filtered	20 mL/g-filtered	20 mL/g-wet	10 mL/g-dry	1 mL/g-dry	0.2-10 mL/g-dry (cumulative)
Eluate pH	-	-	-	<2, 3**, 4, 5.5, 7, 8, 9, 10.5, 12, 13, natural pH	5.5, 7, 8, 9, own pH	based on solid buffering capacity
Eluate Filtration	0.22-µm via pressure	0.22-µm via pressure	0.45-µm via vacuum	0.45-µm via vacuum	0.45-µm via vacuum	0.45-µm via vacuum
Eluate Measurements	pH, EC	pH, EC	pH, EC	pH, EC	pH, EC	pH, EC
Reagent Blank	No	No	Yes	No	No	Yes
Method Blank	Yes	Yes	Yes	Yes	Yes	No
Duplicate Test	VC-3	VC-4	VC-2	None	None	None
Chemical Analysis	ICP-OES/MS DIC/DOC IC	ICP-OES/MS DIC/DOC IC	ICP-OES/MS DIC/DOC IC	ICP-OES/MS DIC/DOC IC	ICP-OES/MS DIC/DOC IC	ICP-OES/MS DIC/DOC IC
Samples Tested	VC-1, VC-2, VC-3, VC-4, Dry composites	VC-1, VC-2, VC-3, VC-4, Dry composites	VC-1, VC-2, VC-3, VC-4, Dry composites	VC-1, VC-2, VC-3, VC-4, Dry composites	VC-1, VC-2, VC-3, VC-4, Dry composites	VC-1, VC-2, VC-3, VC-4, Dry composites

Note: * indicates the TCLP and SPLP extraction fluids used for these tests.
** the 1313 procedure calls for 9 pH extractions + natural pH. An additional extraction at pH 3 was performed for this testing.

Chemical Analysis of Eluates, Groundwater, and Porewater

For each eluate from a leaching test, the following parameters were measured.

Eluate pH

Eluate pH was measured on all aqueous extracts following EPA 9040C (SW-846, 2019) using an Accumet XL20 meter and a combined pH electrode on approximately 5 mL of eluate. Prior to testing, the electrode was calibrated with two National Institute of Standards and Technology (NIST) traceable pH buffer solutions that bounded the anticipated range of pH to be measured. A third mid-range NIST buffer was used to verify the calibration.

Specific Conductance

Specific conductance, or EC, is a measure of the ability of an aqueous solution to carry an electrical current. The property is dependent on (i) the presence of ions; (ii) total concentration, mobility, and variance of ions in solutions; and (iii) the temperature of the measurement. Conductivity of all leaching test eluates was determined following EPA Method 9050A (SW-846, 2019) using a standard conductivity probe calibrated to an appropriate standard conductivity solution for the conductivity range of concern.

Oxidation-Reduction Potential

ORP is a voltage differential related to the redox state of a solid-liquid solution and its effect on chemical composition (e.g., reduced/oxidized iron, dissolved oxygen, biological activity). ORP voltage of all eluate solutions was measured with a probe, consisting of a platinum electrode and a reference electrode, placed in contact with the soil solution. In laboratory tests, the ORP voltage reading was converted to redox potential (Eh) by addition of a probe-specific correction factor of 228 mV at 25 °C. In field measurements, however, the probe correction factor was automatically compensated for by the instrument to produce output as Eh values.

Since redox reactions vary with pH and the mineral species present, redox is parameterized in geochemical modeling as the pH+pE, where pE is the negative logarithm of the free electron concentration, or –log([e^-]). The corrected Eh values of leachates and eluates were converted to a pE value using the following equation:

$$pE = \frac{F}{2.303RT}(Eh/1000)$$

where F is the Faraday constant (23,061 cal/(V mol)),
Eh is the redox potential of the solution (mV),
2.303 is a conversion (ln[e^-]/2.303 log[e^-]),
R is the gas constant (1.987 cal/(K mol)),
T is the temperature (K), and
1000 is a units conversion (1,000 mV = 1 V).

Inductively Coupled Plasma Spectrometry

The eluate concentrations of trace elements and material major species (e.g., Al, Ca, Si) were determined using a combination of ICP-OES and inductively coupled plasma–mass spectrometry (ICP-MS). The choice of instrumentation was determined based on detection limits, expected concentrations, and environmental threshold values. Table 3-3 provides the method detection limits (MDLs) and lower limits of quantitation (LLOQs) used in this project.

Major species and trace elements present at higher concentrations were determined using a Varian Model 720-ES ICP-OES (Agilent Technologies, Santa Clara, CA) following EPA Method 6010D (SW-846, 2019). The ICP-OES was calibrated to a 5-point standard curve with an analytical range of 25 to 25,000 µg/L. For some high-concentration trace elements, the standard curve was extended up to 500,000 µg/L using a 7-point standard curve. For low-level trace analysis, concentrations were determined by ICP-MS using a Perkin Elmer Elan DRC II (Perkin Elmer, Waltham, MA) following EPA Method 6020A (SW-846, 2019). The ICP-MS was calibrated to a 5-point standard curve with range between approximately 1 and 250 µg/L and extended with a 7-point calibration curve to 1,000 µg/L for some constituents.

Analytical QA/QC included initial and continuing calibration checks and blanks, matrix spikes, and method blanks. Calibration check standards and matrix blanks were evaluated every 10 to 20 samples with the requirements that check standards were within 15% of the specified value and blanks were below LLOQs. Matrix spikes were required to have recoveries within 20% of the calculated concentration considering the spiked mass. Initial and continuing calibration check standards for ICP-OES and ICP-MS were 0.5 mg/L and 0.050 mg/L, respectively. Analyte concentrations measured at less than the MDL were reported as <MDL and graphed at one-half the MDL values to indicate that the measurement was conducted. Analytical results measured at less than the LLOQ but greater than the MDL are estimated values.

Table 3-3
Methods, MDLs, and LLOQs for Analysis of Eluates by ICP-OES and ICP-MS

Analyte	Symbol	Method	MDL (mg/L)	LLOQ (mg/L)
Aluminum	Al	ICP-OES	0.0034	0.025
Antimony	Sb	ICP-MS	0.000013	0.001
Arsenic	As	ICP-MS	0.000036	0.001
Barium	Ba	ICP-OES	0.0016	0.025
Beryllium	Be	ICP-MS	0.000035	0.001
Boron	B	ICP-OES	0.0023	0.025
Cadmium	Cd	ICP-MS	0.00018	0.001

Zinc	Zn	ICP-MS	0.000091	0.001

Ion Chromatography

The concentrations of anions in leaching test eluates were determined by IC using a Metrohm 881 Compact IC Pro (Metrohm USA, Riverview, FL) with a Metrosep A Supp 5 column and a conductivity detector following EPA Method 9056A (SW-846, 2019). A seven-anion calibration standard was diluted to form a 5-point calibration curve with the MDLs and LLOQs shown in Table 3-4. Since the calibration standards are diluted from a bulk multi-analyte standard, the calibration range differs for each analyte (e.g., 0.050-50 mg/L for Cl^- and 0.150-150 mg/L for SO_4^{-2}). Calibration check standards were required to be within 15% of the specified value, while acceptable analytical blanks were measured below the quantitation limits.

Table 3-4
MDLs and LLOQs for Analysis of Eluates by IC

Analyte	Symbol	MDL (mg/L)	LLOQ (mg/L)
Bromide	Br^-	0.0064	0.025
Chloride	Cl^-	0.0101	0.05
Fluoride	F^-	0.0063	0.02
Nitrate	NO_3^-	0.0112	0.1
Nitrite	NO_2^-	0.0108	0.05
Phosphate	PO_4^{-3}	0.0247	0.15
Sulfate	SO_4^{-2}	0.0254	0.15

Carbon Analysis

Carbon analysis for eluate samples included analyses for dissolved inorganic carbon (DIC) and dissolved organic carbon (DOC). Carbon analysis was conducted using a Shimadzu TOC-V CPH/CPN (Shimadzu Scientific Instruments, Inc., Columbia, MD) by catalytic oxidation/non-dispersive infrared detection (NDIR) following EPA Method 9060A. Total carbon (TC) in the eluate is converted to carbon dioxide via oxidation or decomposition, carried by a zero-CO_2 air stream into the NDIR. For analysis of DIC, liquid samples are acidified with 2-molar hydrochloric acid to liberate carbonates and other forms of inorganic carbon from solution as carbon dioxide, which is sparged from the liquid sample into the NDIR by the zero-CO_2 carrier gas. DOC is determined by measuring the TC of a sample after purging of inorganic carbon. The instrument was calibrated using sodium hydrogen carbonate and potassium hydrogen phthalate over a 5-point calibration curve for DIC and DOC, respectively. The resultant analytical range was between 0.1 and 100 mg/L, with MDL and LLOQ values shown in Table 3-5. Checks on QA/QC at a frequency of every 10 analytical samples included calibration checks with a required recovery within 15% of the specific value, and method blanks with a requirement that the concentration was less than quantifiable limits.

Table 3-5
MDLs and LLOQs for Eluate Analysis for Carbon

Analyte	Symbol	MDL (mg/L)	LLOQ (mg/L)
Inorganic carbon	DIC	0.15	0.5
Organic carbon	DOC	0.18	0.5

Subsurface Gas Analysis

The composition of subsurface gas was monitored monthly from June 2019 through January 2020. Subsurface gas was monitored for oxygen (O_2), carbon dioxide (CO_2), methane (CH_4), ammonia (NH_3), and hydrogen sulfide (H_2S) using a Ventis Pro 5 meter (Figure 3-3a) rented monthly from Industrial Scientific, Pittsburgh, PA. Table 3-6 shows the measurement units and calibration ranges for the five gases. To avoid any moisture from subsurface gas fouling the vacuum pump, the subsurface gas was drawn through a 250-mL syringe filled with desiccant (Figure 3-3b).

b) 

Figure 3-3
Subsurface gas monitoring apparatus: a) Ventis Pro 5 meter and b) connected tubing and desiccant syringe

Table 3-6
Calibration Ranges for Subsurface Gas Monitoring

Analyte	Symbol	Units	Calibration Range	
Ammonia	NH_3	ppm	0	500
Hydrogen sulfide	H_2S	ppm	0	500
Carbon dioxide	CO_2	%	0	5
Methane	CH_4	%	0	5
Oxygen	O_2	%	0	30

Data Management with LeachXS™

Laboratory and analytical information for leaching tests was recorded by the laboratory technician in Microsoft Excel® spreadsheets specifically designed for each test for use as templates for data collection and archiving. Analytical data documenting concentrations of constituents from each leaching test were entered into the same spreadsheets. These data templates were used as the interface for loading laboratory and analytical data into LeachXS™ (VU, 2019), a database-driven data management and reporting software program. LeachXS was used to (i) archive the laboratory and analytical data from leaching tests; (ii) compare test results between composite materials (e.g., VC-1, VC-2, VC-3, or VC-4) and between test types (e.g., TCLP, SPLP, ASTM, and LEAF); and (iii) generate the Excel plots used for this report. These data have also been added to EPRI's CPInfo database.

4
PHYSICAL AND HYDRAULIC PROPERTIES

Physical properties of the fly ash samples used for measurement of hydraulic properties are summarized in Table 4-1, composition of the solids is summarized in Table 4-2, and the hydraulic conductivities are summarized in Table 4-3.

Particle size distributions of the coal ash samples are shown in Figure 4-1. All of the ashes contained a broad range of particle sizes ranging from coarse-to-fine sand, silt, and clay-size (<2 μm) particles. Fines is the predominant fraction for all of the samples. Each has a broadly graded particle size distribution. The fines content (i.e., particles finer than 75 μm) ranges from 61.5% to 96.8%, and the clay-size (i.e., finer than 2 μm) ranges from 7.0% to 19.4%. No particles coarser than sand-size were observed.

Table 4-1
Physical Properties of Coal Ash Samples Used for Hydraulic Conductivity Testing

Sample ID	Sample Elevation at Top (ft AMSL)	Sample Elevation at Bottom (ft AMSL)	Water Content (%)	Dry Unit Weight (kg/m^3)	Pore L/S of Intact Cores (L/kg-dry)	Particle Size Fractions			
						% Gravel	% Sand	% Fines	% Clay
CDL-VC2-65	374.9	371.9	39.5	1,090	0.36	0	12.1	87.9	13.1
CDL-VC2-75	364.9	361.9	35.4	1,110	0.32	0	38.5	61.5	7.3
CDL-VC3-65	378.2	375.2	35.7	1,390	0.26	0	3.2	96.8	14.3
CDL-VC3-75	368.2	365.2	41.5	1,150	0.36	0	7.8	92.2	7.0
CDL-VC4-65	378.2	375.2	39.8	1,150	0.35	0	23.3	76.7	19.4
CDL-VC4-75	368.2	365.2	36.6	1,290	0.28	0	6.2	93.8	11.6

An estimate of the pore L/S ratio of intact cores was made from the water content and the dry unit density assuming a fully saturated 1 m^3 volume of ash:

$$L/S = \frac{WC/100}{\rho_{dry}} \times 1000$$

where L/S is the liquid-to-solid ratio for fully saturated pores (L/kg-dry);
WC is the water content (%) from Table 4-1;
ρ_{dry} is the dry unit density (kg-dry/m^3) from Table 4-1; and,
1000 is a unit conversion factor for volume (1000 L = 1 m^3).

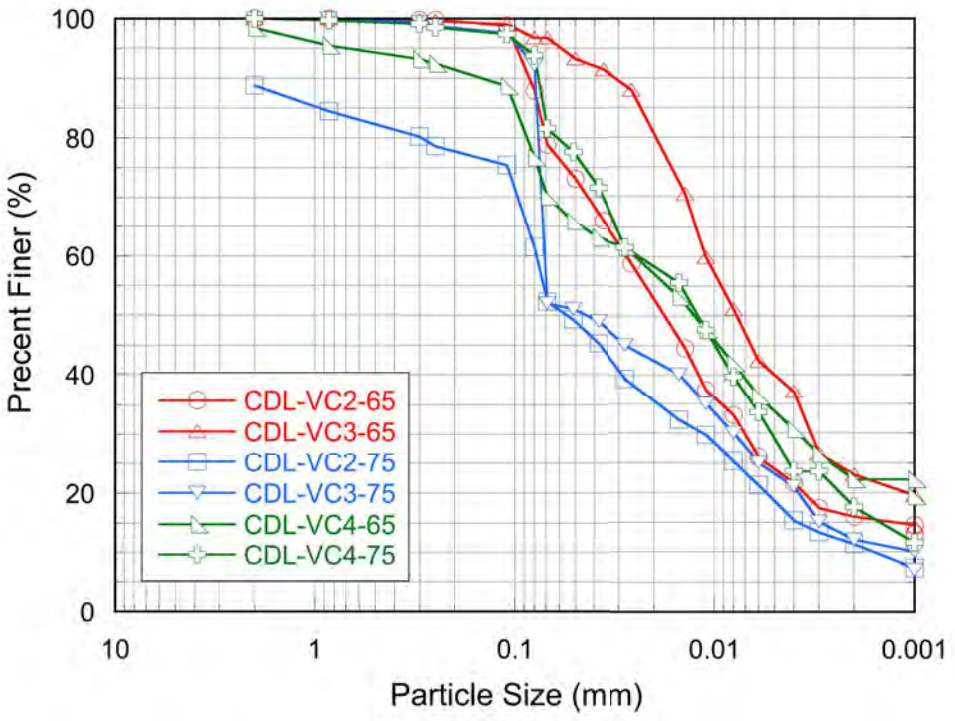

Figure 4-1
Particle size distribution of coal ash samples on which hydraulic conductivity tests were conducted

Table 4-2 indicates that all of the ash samples are predominantly composed of Al, Fe, and Si oxides, which reflects the predominant alumino-silicate mineral structure of the particulate. All samples contain modest amounts of Ca, K, and Ti. The LOI varies considerably, from 1.9% to 13.1%, with all but one sample having an LOI > 3.3%. The variability in composition of major elements appears to reflect the nature of the deposited ash as layers of fly ash and bottom ash.

Table 4-2
Composition of Solids (%) from LOI and XRF of Coal Ash Samples Used for Hydraulic Conductivity Assessment (elements exceeding 1.0%). Measurements were not conducted for CDL-VC3-65.

Composition	VC-2		VC-3		VC-4	
	65	75	65	75	65	75
LOI	2.0	2.7	-	1.9	13.1	3.3
Al_2O_3	15.8	16.1	-	17.2	15.6	17.5
CaO	7.9	8.9	-	6.6	8.4	5.3
Fe_2O_3	32.6	29.0	-	27.5	32.6	31.0
K_2O	3.7	4.2	-	4.5	3.7	4.0
SiO_2	35.2	36.4	-	39.2	34.6	37.3
TiO_2	1.3	1.3	-	1.4	1.2	1.4

The hydraulic conductivities fall into two groups (Table 4-3): more permeable samples (CDL-VC2-65, CDL-VC2-75, and CDL-VC3-75) and less permeable samples (CDL-VC3-65, CDL-VC4-65, and CDL-VC4-75). The more permeable ashes have hydraulic conductivities in the range of 10^{-5} cm/s, whereas the less permeable ashes have hydraulic conductivities in the range

of 10^{-6} cm/s. The differences in hydraulic conductivity between these groups cannot be attributed to particle size characteristics such as fines content or 2 -μm clay content (Figure 4-2). However, the less permeable ashes have higher dry density, and therefore lower void ratio (Figure 4-3).

Table 4-3
Hydraulic Conductivity of Coal Ash Samples

Sample ID	Effective Stress (kPa)	Hydraulic Conductivity (cm/s)
CDL-VC2-65	20	4.18×10^{-5}
	100	2.40×10^{-5}
	250	2.02×10^{-5}
	400	1.82×10^{-5}
	500	1.81×10^{-5}
CDL-VC2-75	20	2.43×10^{-5}
	100	1.90×10^{-5}
CDL-VC3-65	20	8.28×10^{-6}
	100	6.22×10^{-6}
	250	4.83×10^{-6}
	400	4.32×10^{-6}
	500	3.75×10^{-6}
CDL-VC3-75	20	1.54×10^{-5}
	100	1.26×10^{-5}
	250	1.09×10^{-5}
	400	8.15×10^{-6}
CDL-VC4-65	20	4.98×10^{-6}
	100	4.47×10^{-6}
CDL-VC4-75	20	2.07×10^{-6}
	100	1.96×10^{-6}

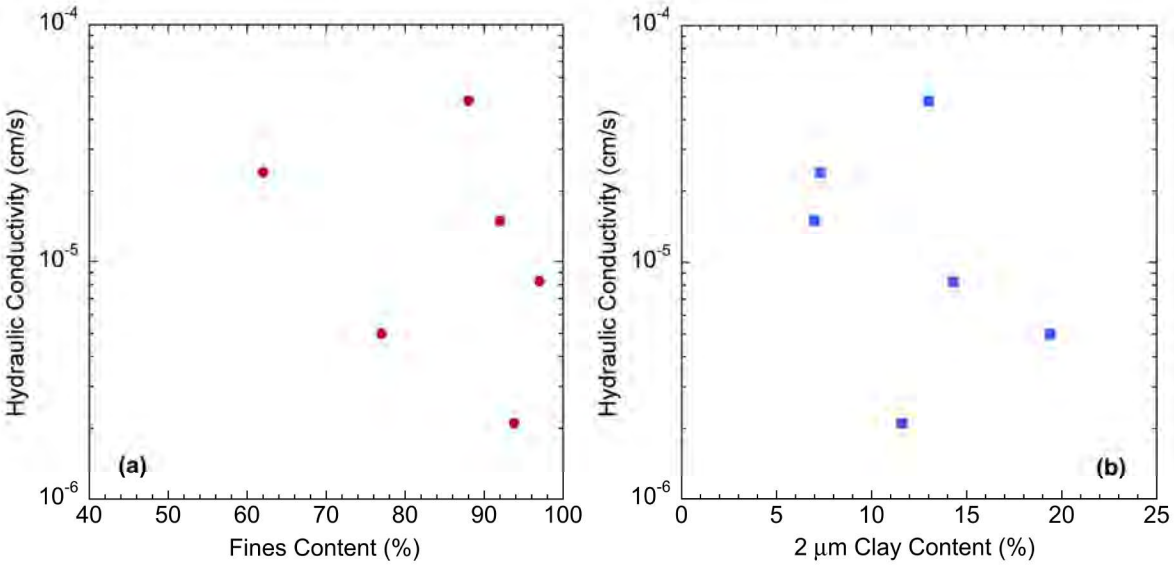

Figure 4-2
Hydraulic conductivity of coal ashes at 20 kPa effective stress as a function of (a) fines content and (b) 2-μm clay content

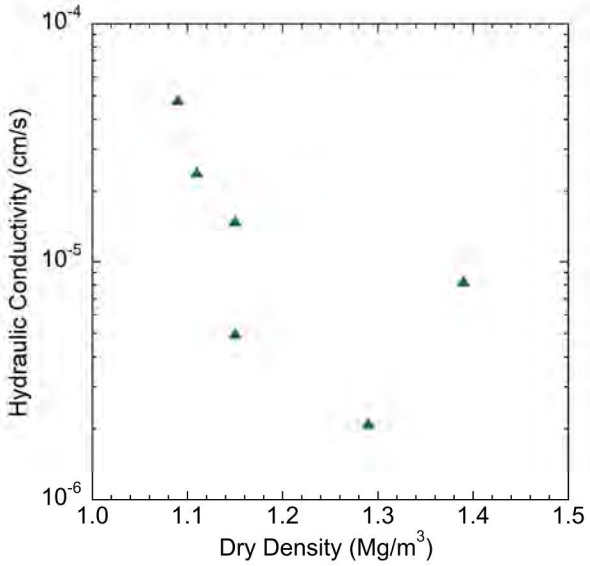

Figure 4-3
Hydraulic conductivity of coal ashes as a function of dry unit weight

Hydraulic conductivity of the coal ash samples as a function of confining stress is shown in Figure 4-4. The hydraulic conductivity diminishes only modestly with increasing stress, decreasing approximately by a factor of 2 as the effective stress is increased from 20 to 500 kPa. The insensitivity to stress is most likely due to the ash being predominantly comprised of silt-size and sand-size particles.

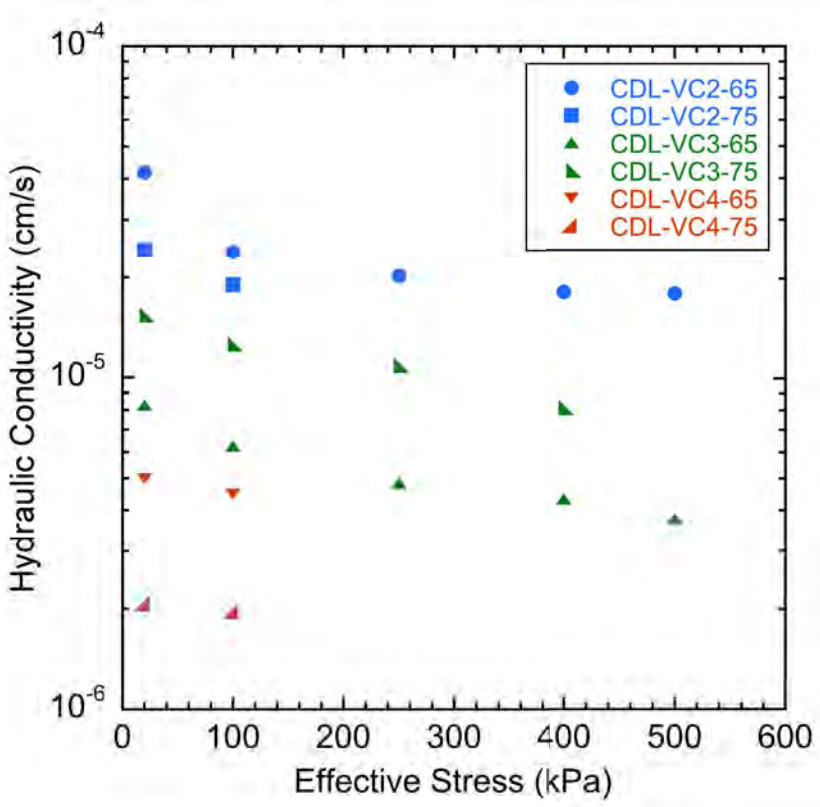

Figure 4-4
Hydraulic conductivity of coal ash samples as a function of effective stress

Electronic Filing: Received, Clerk's Office 07/01/2024

5
INDIVIDUAL SPLIT SPOON SAMPLE TESTING

Evaluation of Field Extractions (Low L/S and L/S ≈ 1)

During field sampling, grab samples of ash from each split spoon were extracted by centrifugation of the moisture content (i.e., Low L/S Field Extractions). Because the moisture content of the unsaturated split spoon material varied with depth and texture, a small amount of DIW was added to each extraction to ensure that a sufficient amount of liquid could be recovered and analyzed. The resultant L/S of Low L/S Field Extractions varied between 0.28 and 0.67 mL/g-dry, consistent with the L/S of porewater from intact core samples (Table 4-1).

Vertical Heterogeneity Within and Between Boreholes

Profile Plots of Field and Laboratory Extraction Data

After surveying of the borehole and PAP locations and elevations, depths BGS measured during sample recovery were converted to elevations ASML. The concentration from Low L/S Field Extractions of individual split spoon materials was plotted as a function of elevation to provide a visual indication of material heterogeneity with depth within a borehole. Examples of these borehole profile plots are presented in Figure 5-1 and Figure 5-2.

Each figure represents the concentration profiles for a measured constituent in the Low L/S Field Extractions for VC-1 (blue), VC-2 (green), VC-3 (orange), and VC-4 (purple). The constituent concentration is plotted along the x-axis, while the elevation for the center of the split spoon is plotted on the y-axis. The red horizontal line shows the surface elevation at the time of drilling. The 5-foot wide shaded area indicates the screening interval for the PAP in each borehole. The light-colored data points in each profile indicate the intervals from which material was taken to create the composite ash sample for each borehole used in detailed characterizations.

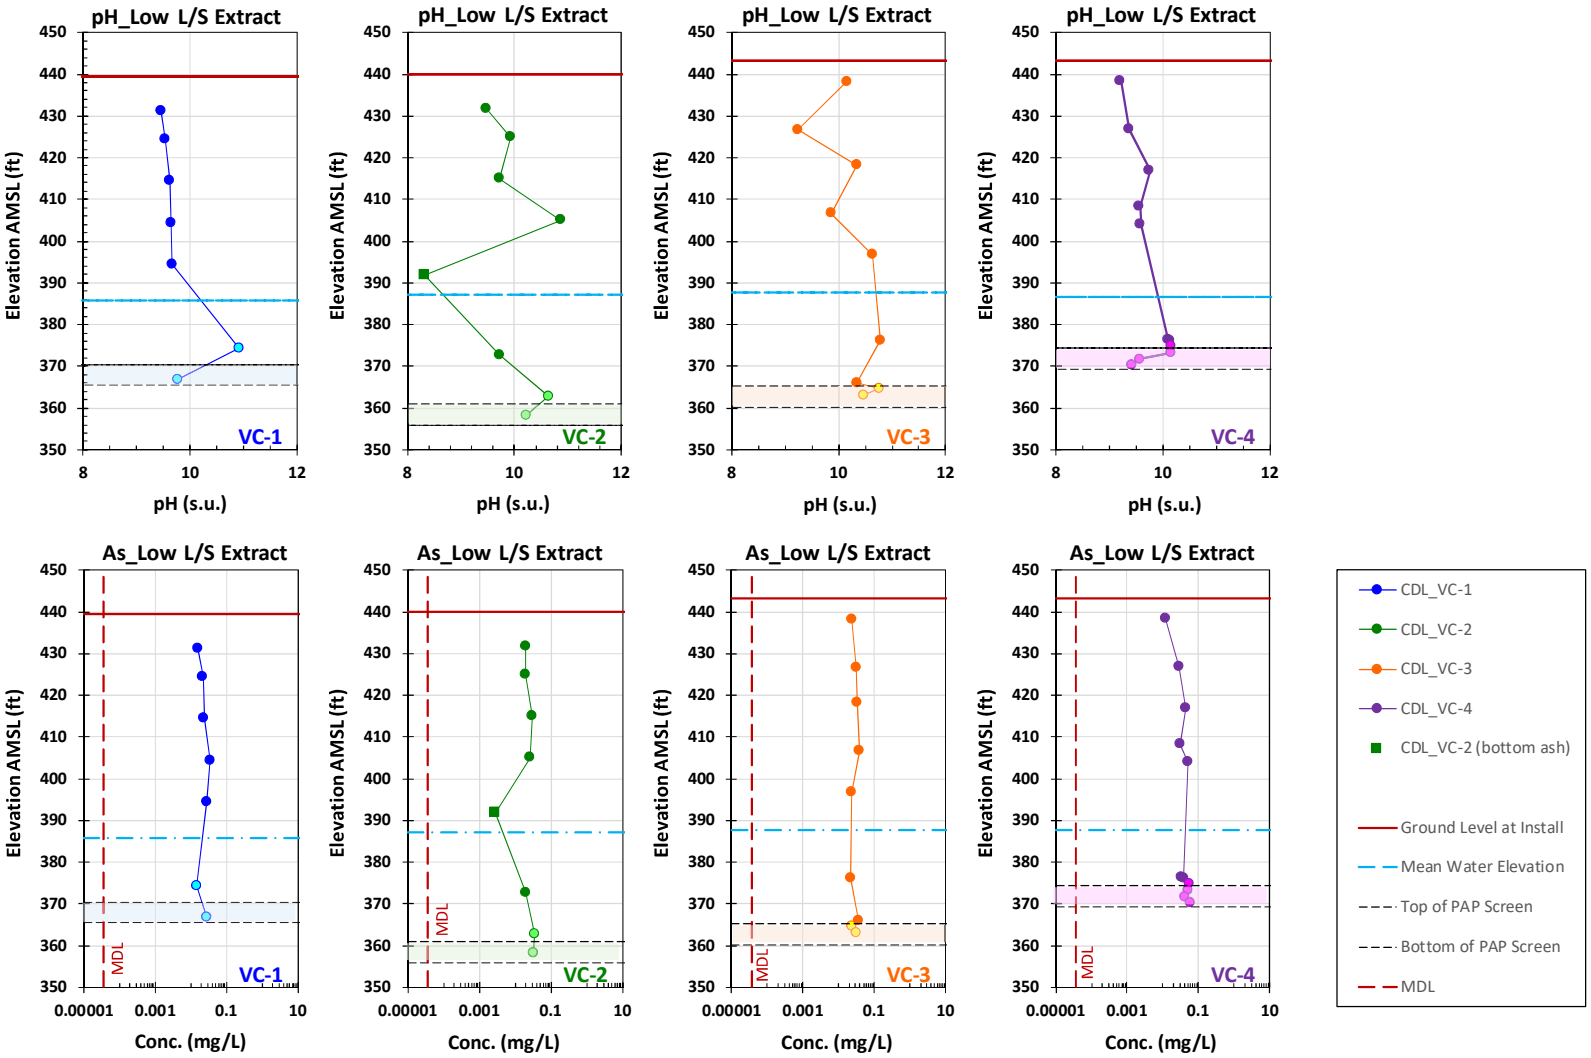

Figure 5-1
Low L/S Field Extraction concentration profiles within boreholes (VC-1, VC-2, VC-3, and VC-4): pH and arsenic; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL

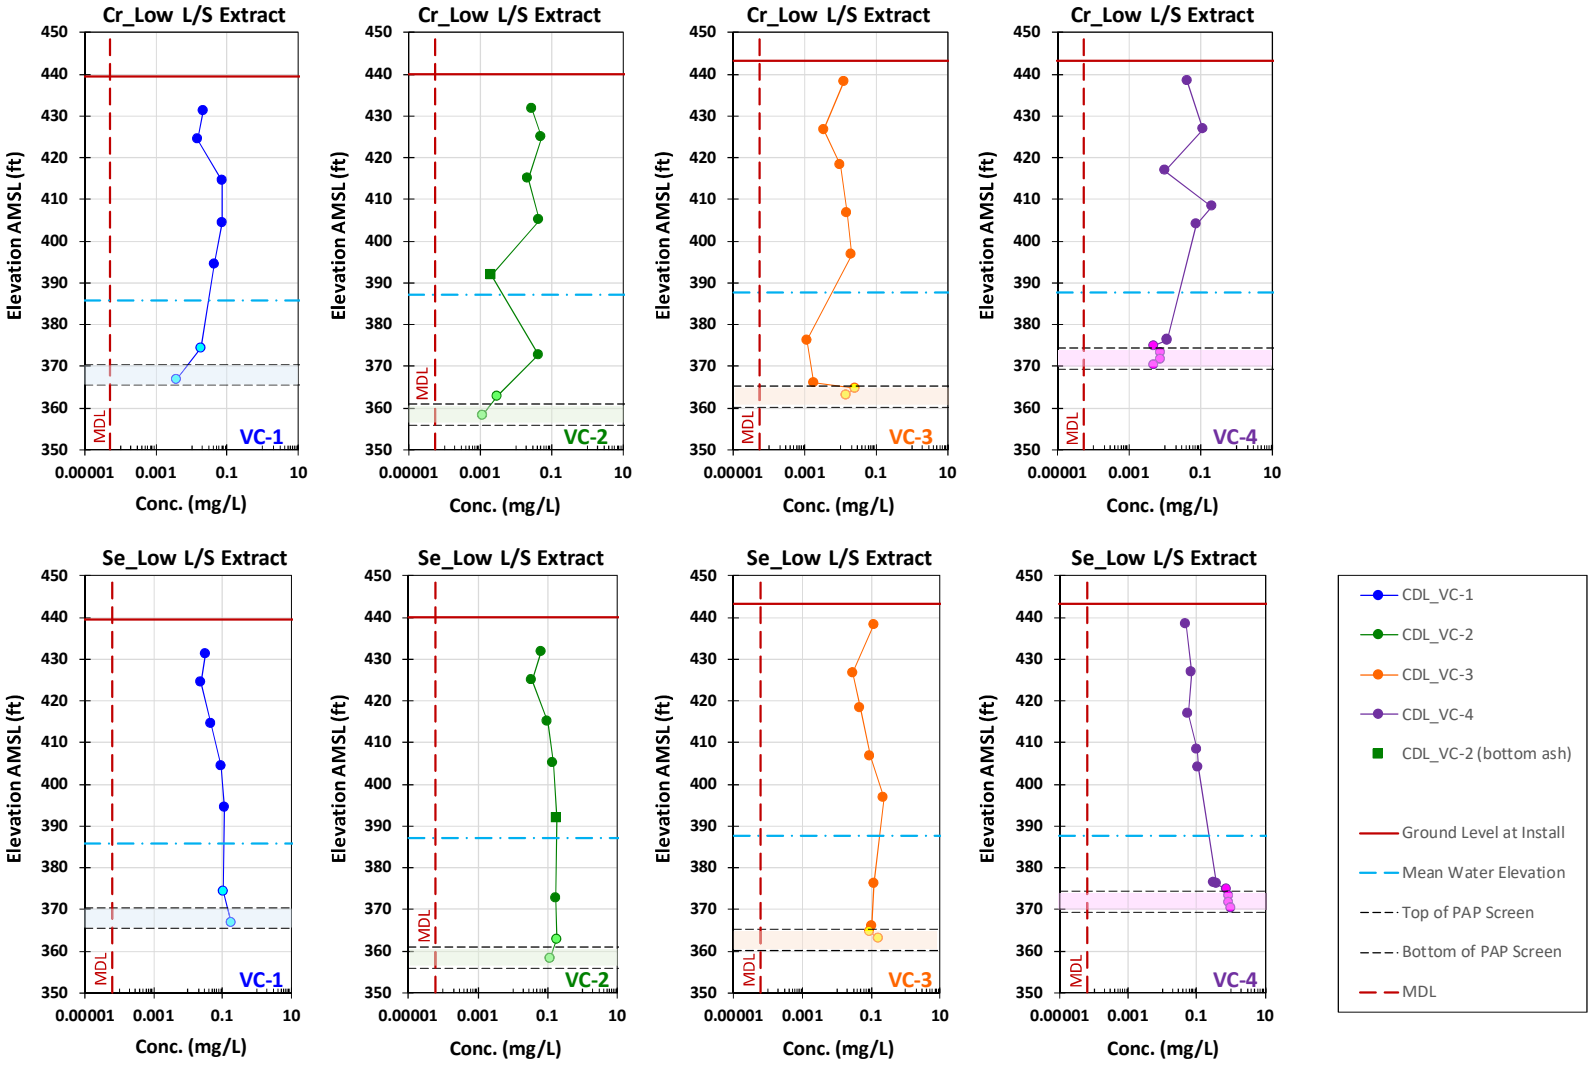

Figure 5-2
Low L/S Field Extraction concentration profiles within boreholes (VC-1, VC-2, VC-3, and VC-4): chromium and selenium; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL

Standardized Borehole Profiles of Low L/S Field Extractions

The concentration data for Low L/S Field Extractions were converted to standardized profile plots using the global mean and standard deviation for "known ash samples" in all boreholes as characterized by the geologist notes. The standardized concentration is calculated as:

$$\frac{x - \bar{x}}{s}$$

where x is the parameter (e.g., pH, concentration) from the extraction test,
$\bar{x}$ is the global mean of all "known ash samples" for all boreholes, and
s is the global standard deviation of all "known ash samples."

The global mean and standard deviation for all constituents are tabulated in Table 5-1. The standardized concentration provides a measure of the difference between the measured concentration and the mean as a number of standard deviations from the mean concentration. A homogenous material, for example, may have measurements within 2 standard deviations of the mean, while measurements greater than 4 standard deviations may have more than random variations such as influence from cover or underlying material. Justification for use of ash sample global statistics, rather than within-borehole statistics, was based on the results of t-test for pairwise comparisons assuming unequal variances, which showed no statistical difference in means between boreholes. In addition, the use of global statistics in standardized concentration profiles allows for comparison between boreholes on the same basis.

The standardized borehole profiles for the example constituents presented in Figure 5-1 and Figure 5-2 are presented in Figure 5-3 and Figure 5-4. The standardized profiles for all constituents are presented Appendix B-2. In general, the concentration profiles for most constituents are vertically consistent within the ash deposit and show no evidence of difference between the upper dry-handled coal ash and lower wet-handled coal ash.

Table 5-1
Global Mean and Standard Deviation of Laboratory Extractions (L/S=1) Concentrations

		Global "Ash" Statistics		
Analyte	**Units**	**Mean**	**Std. Dev**	**Coefficient of Variation**

Notes: ND = all or most of the L/S=1 concentrations were less than the MDL

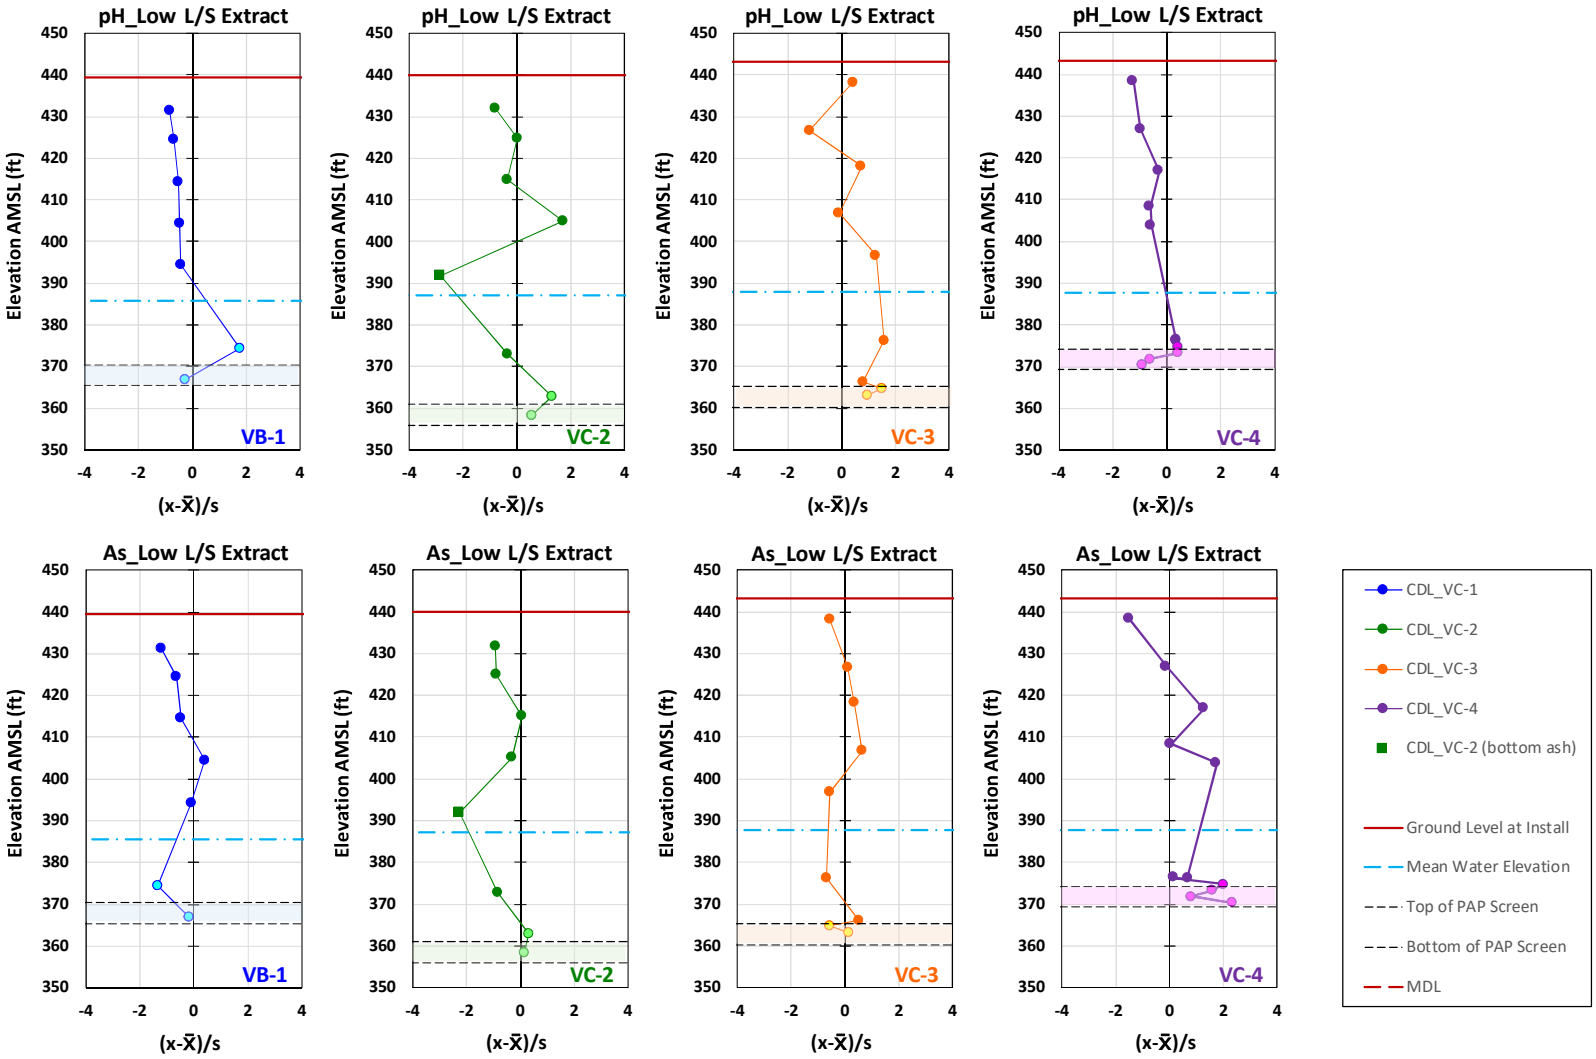

Figure 5-3
Standardized Low L/S Field Extraction profiles within boreholes (VC-1, VC-2, VC-3, and VC-4) standardized to the global mean (X̄) and standard deviation (s) of known ash samples: pH and arsenic; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL

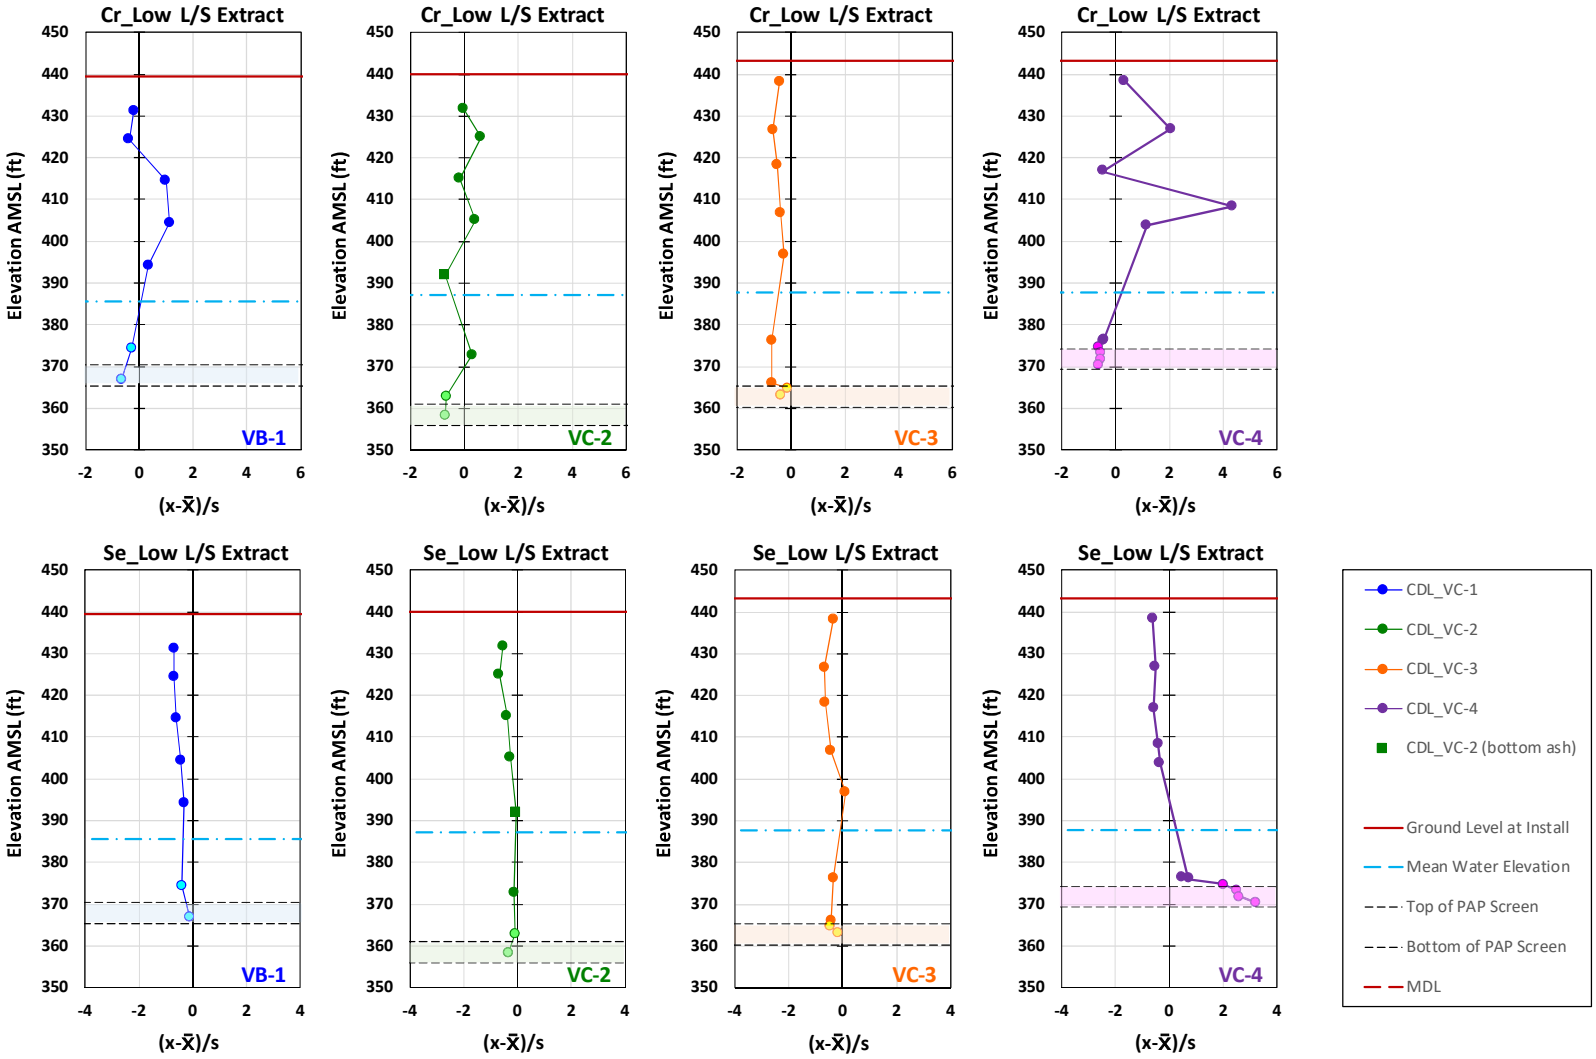

Figure 5-4
Standardized Low L/S Field Extraction profiles within boreholes (VC-1, VC-2, VC-3, and VC-4) standardized to the global mean (x̄) and standard deviation (s) of known ash samples: chromium and selenium; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL

Comparison of Standardized Borehole Profiles for Low L/S and L/S≈1 Field Extractions Based on Mass Release (mg/kg)

For boreholes VC-1 and VC-2, L/S≈1 Field Extractions were conducted as a comparator to the unique Low L/S Field Extractions. Example comparisons of standardized borehole variability graphs are presented in Figure 5-5 and Figure 5-6, while the complete results for all measured constituents are presented in Appendix B-3. In general, the variability between field extraction methods is negligible; however, the unique Low L/S Field Extraction technique provided data that are somewhat less variable than the L/S≈1 Field Extractions. The Low L/S extractions are considered to provide better control of redox conditions and L/S values that are more consistent with porewater values.

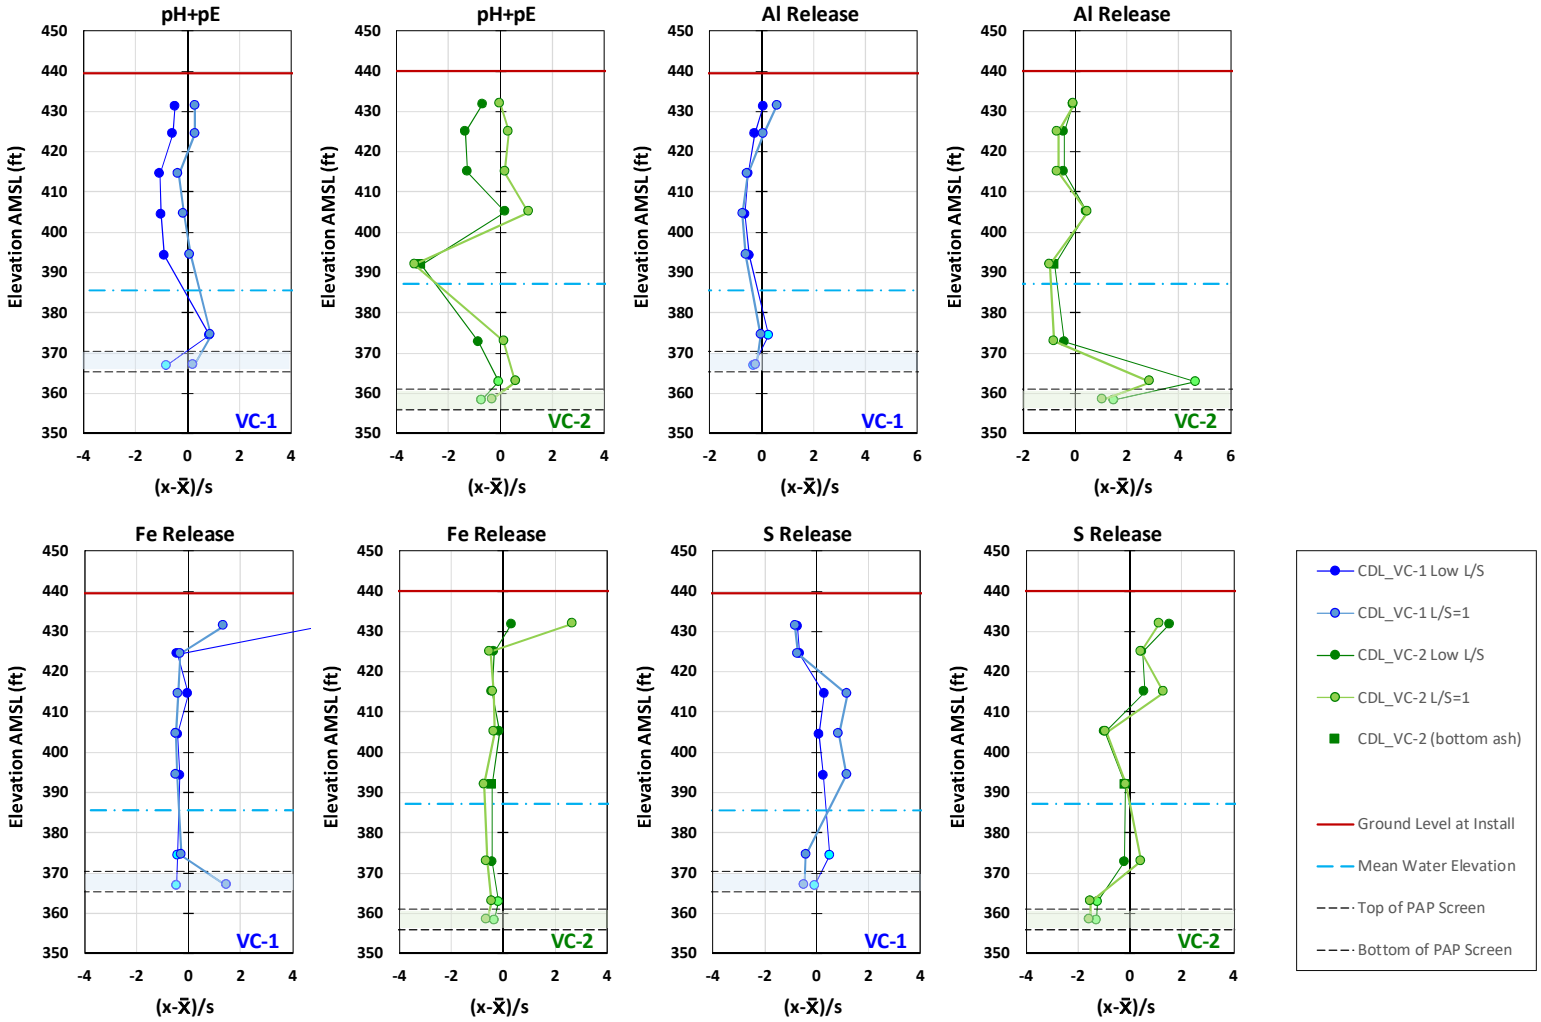

Figure 5-5
Comparison of standardized mass release profiles for Low L/S Field Extractions and L/S ≈ 1 Field Extractions of major constituents from VC-1 and VC-2: pH+pE, aluminum, iron, and sulfur; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL

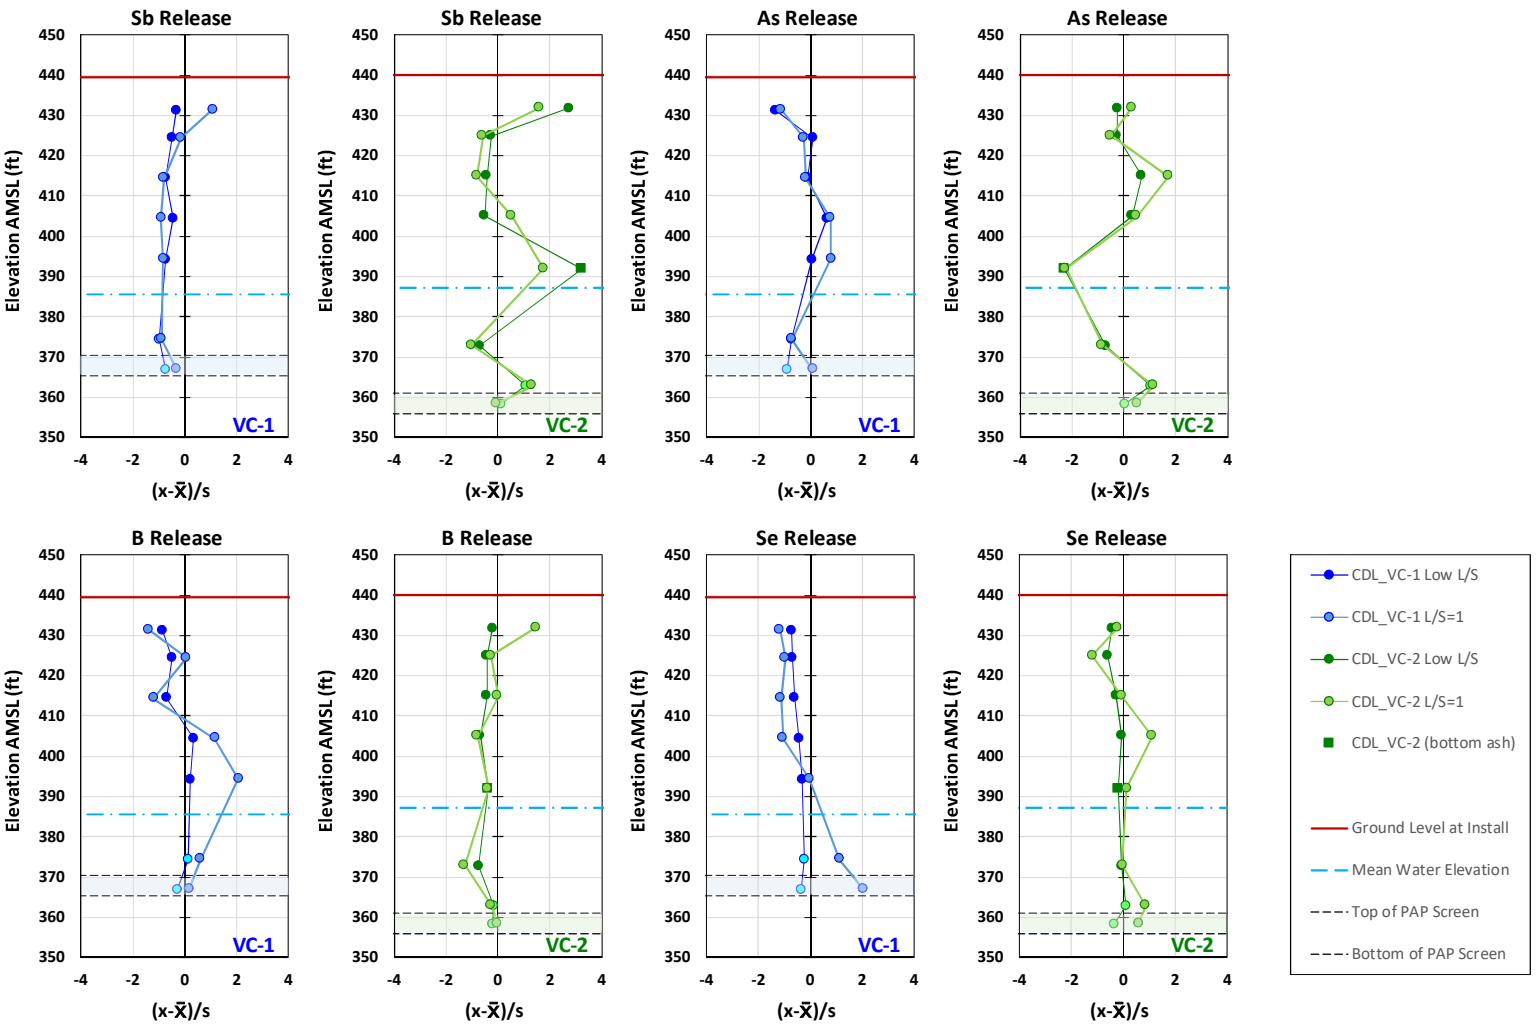

Figure 5-6
Comparison of standardized mass release profiles for Low L/S Field Extractions and L/S ≈ 1 Field Extractions of trace constituents from VC-1 and VC-2: antimony, arsenic, boron, and selenium; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL.

6
COMPOSITE ASH SAMPLE TEST RESULTS

Subsamples of bulk material collected from split spoon sampling were homogenized within each bulk storage packet. For borehole composites, the material in the storage packets around the PAP screening intervals was composited by equal dry mass from each packet as shown in Table 3-1. These composites of wet-handled ash were labeled for their respective borehole locations (i.e., VC-1 through VC-4). An additional site-wide composite of unsaturated material, labeled as "Dry," was created by equal mass from split spoon samples from dry-handled material in all boreholes collected above the water table. The five composites were subject to detailed investigation of total content, available content, and leaching characteristics as a function of pH and L/S.

Total Content

The total content analysis results for the five composite materials are shown in Table 6-1.[3] In preparation for EPA Method 3052, ash samples were dried under nitrogen and ground to pass a No. 100 (150 μm) sieve. Therefore, the total content results are reported on a dry-mass basis (mg/kg-dry), whereas typical EPA Method 3052 results would be based on "as received" solid sample (mg/kg), which can include the inherent moisture in the solid sample.

The coal ash composites are comprised mainly of Al, Ca, Fe, K, Na, and Si (not measured). Of the 26 constituents analyzed, Sb, Co, Mg, Mn, Hg, Ag, and Tl were reported for at least one of the five composites to have low total content relative to the commercial laboratory's reporting limit. Mercury was detected above reporting limit only in the "Dry" composite and, therefore, was not considered in the analysis of test leachates or the comparison to groundwater concentrations. The remaining low-concentration constituents were retained because preliminary testing indicated that leaching concentrations were low, but quantifiable in LEAF leaching tests.

For most elements analyzed (16 of 26), the dry-handled ash composite had a total content value within the range of values for the wet-handled composites. Only Pb, Hg, and Mo had a total content a factor of 1.5 or more higher than the highest wet-handled composite value within the range, while Cd, Li, Sr, and Zn had total contents slightly higher (within a factor of 1.0 to 1.5) than the highest wet-handled value. Total content values for Mn, K, and Na were slightly lower than the lowest wet-handled total content value.

[3] As noted in the test description in Section 3, boron was not analyzed for total content because metaborate is added to the digestion process for Method 3052.

Table 6-1
Total Contents for Composite Samples (VC-1, VC-2, VC-3, VC-4, and Dry) Based on EPA Method 3052

Analyte	Symbol	MDL (mg/kg)	VC-1 (mg/kg)	VC-2 (mg/kg)	VC-3 (mg/kg)	VC-4 (mg/kg)	Dry (mg/kg)
Aluminum	Al	2.9	21,000	17,000	27,000	18,000	27,000

Thallium	Tl	9.3	13 J	14 J	9.7 J	14 J	9.4 J
Vanadium	V	0.056	670	450	480	660	620
Zinc	Zn	4.6	410	430	410	420	460

Notes:
B the compound was found in the blank and sample.
F1 the matrix spike recovery is outside of acceptance limits
J the result is less than the reporting limit but greater than or equal to the MDL; estimated concentration.
ND the compound was not detected at a concentration above the MDL.

Leaching Test Results

For this project, leaching test results included LEAF test results (EPA 1313, 1313_L/S=1, EPA 1314) and traditional leaching tests (TCLP, SPLP, ASTM). All leaching data are presented in Appendix C for each composite sample as a function of pH and L/S. The graphs used in the following discussion of leaching test results were derived from the appendix figures either by combining data series (e.g., comparisons between composites) or by limiting axis domains. In

some cases, discussion graphs are presented as graphs of mass release (mg/kg-dry), which were derived from eluate concentrations (mg/L) multiplied by the associated L/S value (L/kg-dry). Mass release graphs are not presented in the appendix.

pH-Dependent Leaching Tests (EPA 1313, 1313_L/S=1)

Titration Curves

Titration curves from pH-dependent tests conducted on composite samples are presented in Figure 6-1. The titration curve indicates the amount of acid or base (shown as acid additions less than zero) required to provide a specific eluate pH, sometimes referred to as the acid/base neutralization capacity of the material. This data may be useful when leachates or materials from other processes or natural environments are introduced to a storage facility (e.g., pyritic tailings co-disposed with fly ash).

In LEAF nomenclature, the pH response when no acid or base is added to the extraction at an L/S of 10 mL/g-dry is referred to as the "natural pH" of the material. Because the natural pH is defined at an L/S of 10 mL/g, the term "own pH" will be used to differentiate the pH response at other L/S values (e.g., 1313_L/S=1) from the natural pH. The natural pH (EPA 1313) and own pH (1313_L/S=1) are tabulated for the five composite materials in Table 6-2 and represented in Figure 6-1 as large color-coded circles about a data point. The values for natural pH for the five composites are generally the same (average value of 10.41±0.18). The composite of the unsaturated ash (Dry) is the least alkaline (pH_{nat}=10.21), but not much more so than the composite of saturated ash at VC-2 (pH_{nat}=10.29). The most alkaline composite is the saturated ash composite at VB-3 (pH_{nat}=10.67). In comparison to natural pH, the own pH values are essentially the same as their associated natural pH values (within approximately 0.2 standard units).

Table 6-2
Natural pH (EPA 1313) and own pH (1313_L/S=1) of composite samples

	Method	L/S (mL/g-dry)	VC-1 pH (SU)	VC-2 pH (SU)	VC-3 pH (SU)	VC-4 pH (SU)	Dry pH (SU)
Natural pH	EPA 1313	10	10.44	10.29	10.67	10.43	10.21
Own pH	1313_L/S=1	1	10.66	10.64	10.71	10.29	10.01

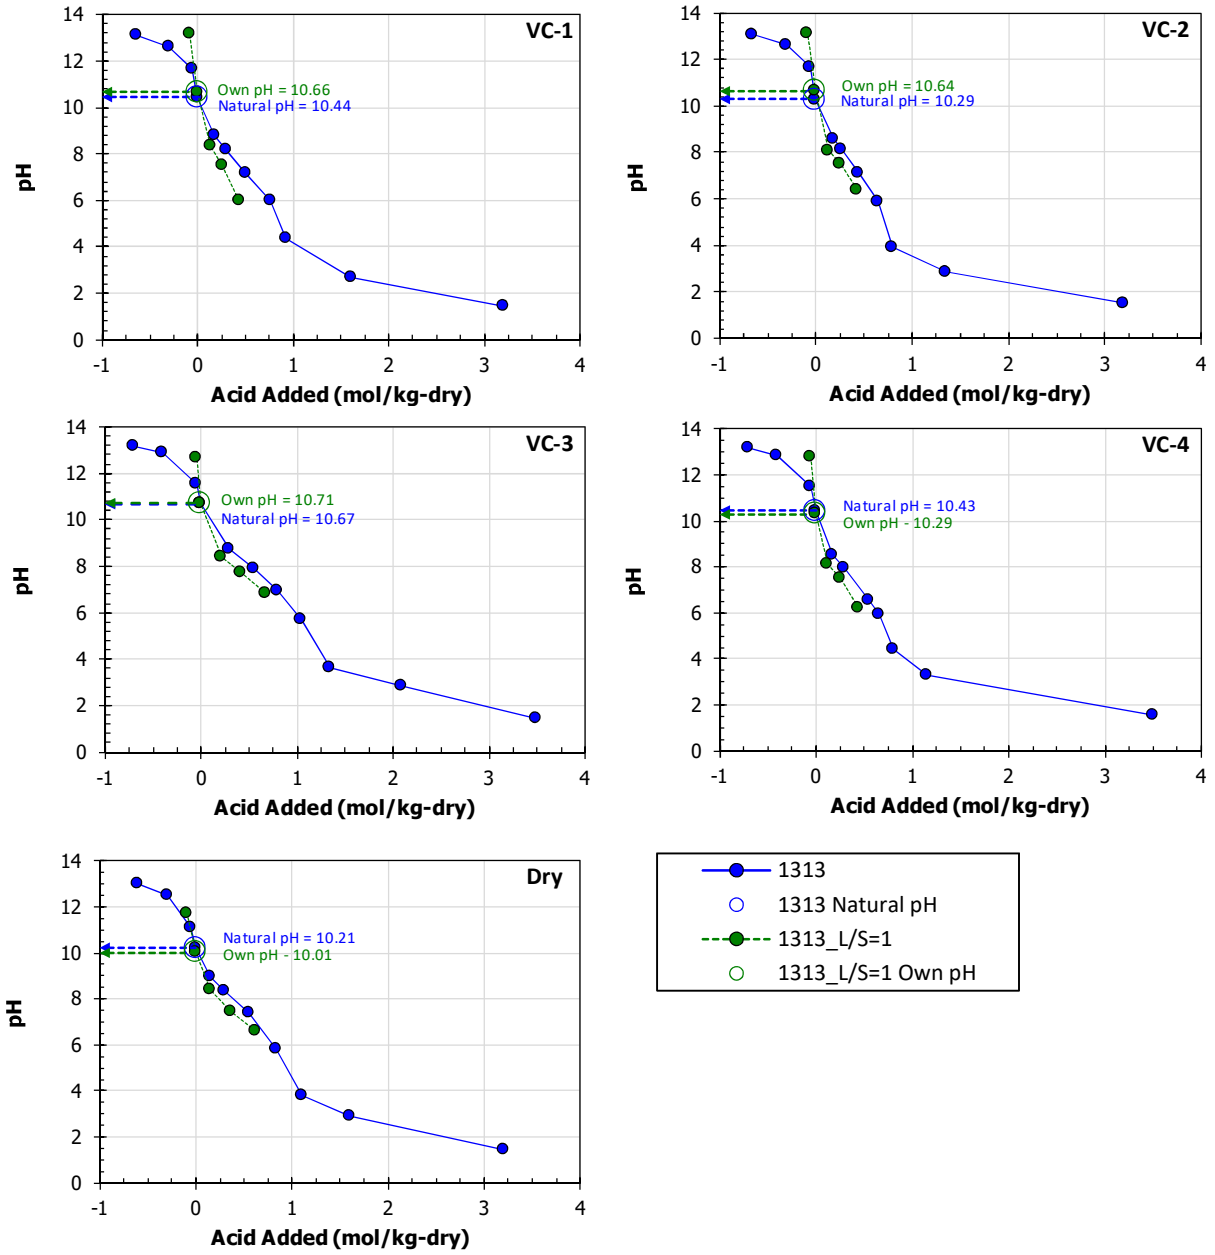

Figure 6-1
Titration curves from EPA 1313 test results from five composite samples (VC-1, VC-2, VC-3, VC-4, and Dry)

Constituent Concentrations

The concentration of a constituent in each eluate of a pH-dependent leaching test (i.e., EPA 1313 and 1313_L/S=1) is indicative of the speciation of the constituent and the LSP in equilibrium with the L/S, pH, EC, and ORP of the contacting fluid. Eluate concentrations are typically plotted as a function of eluate pH to indicate how LSP changes over a broad range of pH values. These data also can be used to parameterize controlling mineral sets in geochemical speciation models, for example, LeachXS™/ORCHESTRA (Meeussen, 2015), to create a source term for

fate and transport modeling. The pH-dependent leaching behavior of a constituent is useful when disposed materials may be contacted with water containing significant amounts of acid or base (e.g., pyrite-impacted groundwater or alkali process wastewaters).

However, for many field assessments, evaluation of LSP may be limited to an applicable pH domain. The applicable pH domain is typically centered about the natural pH of the material but should consider the potential for leachate pH values to shift with aging or external influences (EPA, 2019). For example, alkaline materials that may be exposed to the environment can carbonate, which neutralizes the pH toward the equilibrium pH of calcium carbonate (pH ~ 8.2). Therefore, an applicable pH domain that is inclusive of critical pH values and is based on target eluate pH values from EPA 1313 would be $8 \leq pH \leq 12$. Example test results from EPA 1313 are shown in Figure 6-2 with the applicable pH domain shaded. These examples show that LSP behavior can vary significantly between constituents (e.g., boron vs. lead) but that the behavior for a constituent is very consistent between composite samples. The concentrations within the applicable pH domain are often, but not always, considerably lower than the maximum concentration over the entire EPA 1313 test pH range.

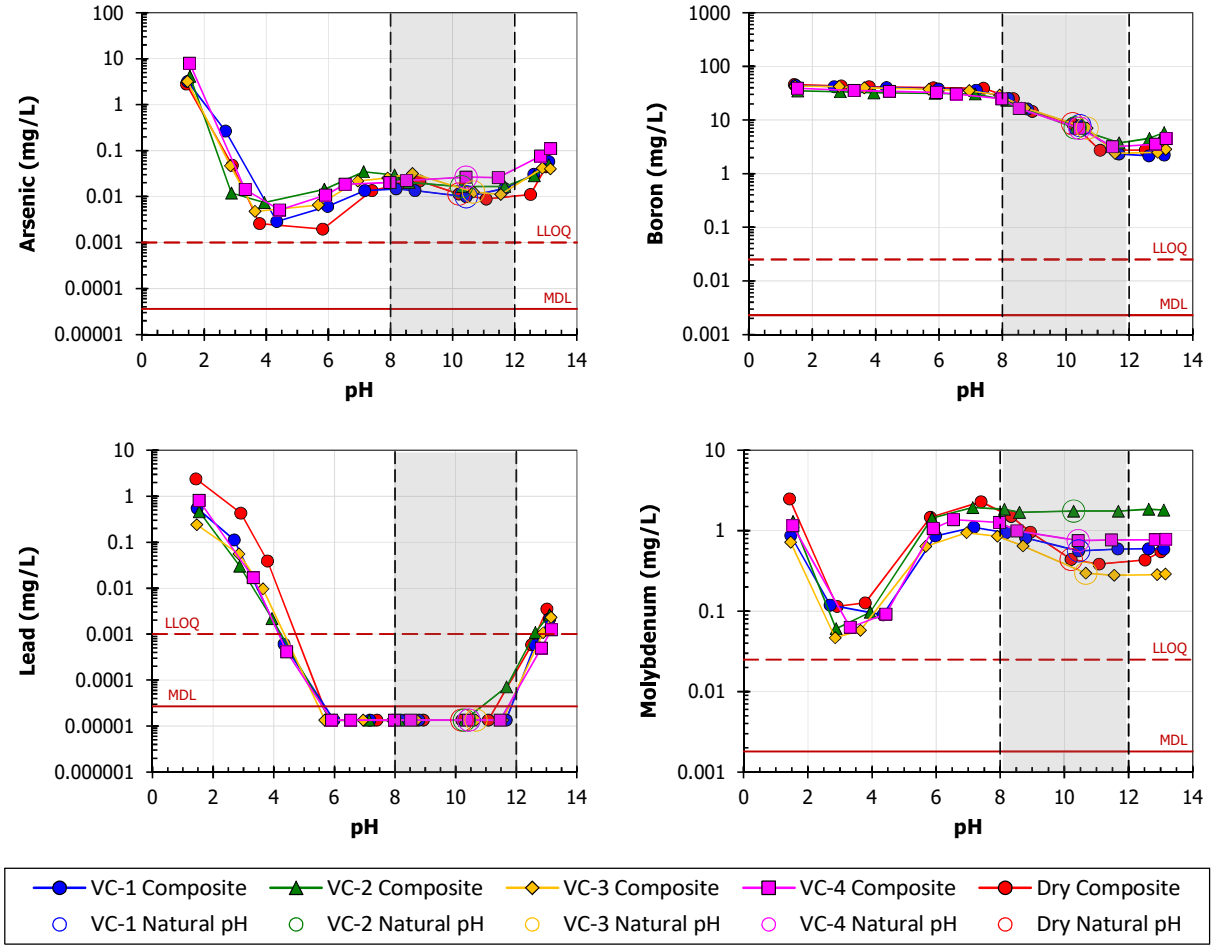

Figure 6-2
Example LSP behaviors from composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) showing applicable pH range ($8 \leq pH \leq 12$) for alkaline materials

Available Content Determination Using EPA 1313

The broad pH range of data provided by EPA 1313 data allows for evaluation of content of leachable constituent, known as the available content (EPA, 2019). The standard EPA methodology (EPA, 2019) for determination of available content is to identify the maximum leaching concentration (mg/L) from EPA 1313 test results at pH value of 2, 9, and 13 and calculate the mass release (mg/kg-dry) at the maximum LSP concentration:

$$AC = C_{1313(\max pH\ 2,9,13)} \cdot (L/S)_{1313}$$

where AC is the available content (mg/kg-dry);
$C_{1313(\max pH\ 2,9,13)}$ is the maximum concentration from EPA 1313 data at pH 2, 9, or 13 (mg/kg-dry); and,
$(L/S)_{1313}$ is the liquid-to-solid ratio for the EPA 1313 extractions of 10 mL/g-dry (10 L/kg-dry).

Values for the available content of constituents for the five composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) are reported in Table 6-3. The ratio of the available content to the total content (Table 6-4) indicates that for most constituents only a fraction (< 20%) is leachable over a broad pH range. In some cases, the available fraction is less than 1% of the total content. In Table 6-4, the high ratios (> 1) for Ca and Mg suggest either that digestion by EPA 3052 was not complete or that there is inherent error associated with multiplying a relatively small digestate concentration by a large effective L/S of 500 or more.

Table 6-3
Available Content for Composite Samples VC-1, VC-2, VC-3, VC-4, and Dry Based on the Maximum Concentration from EPA Method 1313

Analyte	Symbol	VC-1 (mg/kg-dry)	VC-2 (mg/kg-dry)	VC-3 (mg/kg-dry)	VC-4 (mg/kg-dry)	Dry (mg/kg-dry)

Vanadium	V	0.28	0.31	0.28	0.29	0.24
Zinc	Zn	0.024	0.019	0.031	0.022	0.041

Notes: B the compound was found in the blank and sample of the total content analysis extract.
F1 the matrix spike recovery for the total content analysis extract is outside of acceptance limits.
J the total content result is less than the LLOQ but greater than or equal to the MDL; estimated value.

Alternatively, the available content may be presented graphically as the maximum mass release from EPA 1313 data (Figure 6-3). These figures show that the maximum release for many constituents is often determined at pH $\leq$ 2, but that mass release may be similar at other pH values (see Mo). These figures also show that the absolute value determined for the available content may be dependent on the pH value used to determine the maximum concentration from EPA 1313. For example, the maximum mass release values for arsenic and boron are determined at a pH $\leq$ 2; however, the boron data plateaus in the acidic range, while the arsenic data is still on a steep increasing slope as pH decreases. Therefore, a minor change in the EPA 1313 eluate pH

will not significantly impact the available content determination for boron, while the same minor change may significantly alter the determined available content for arsenic.

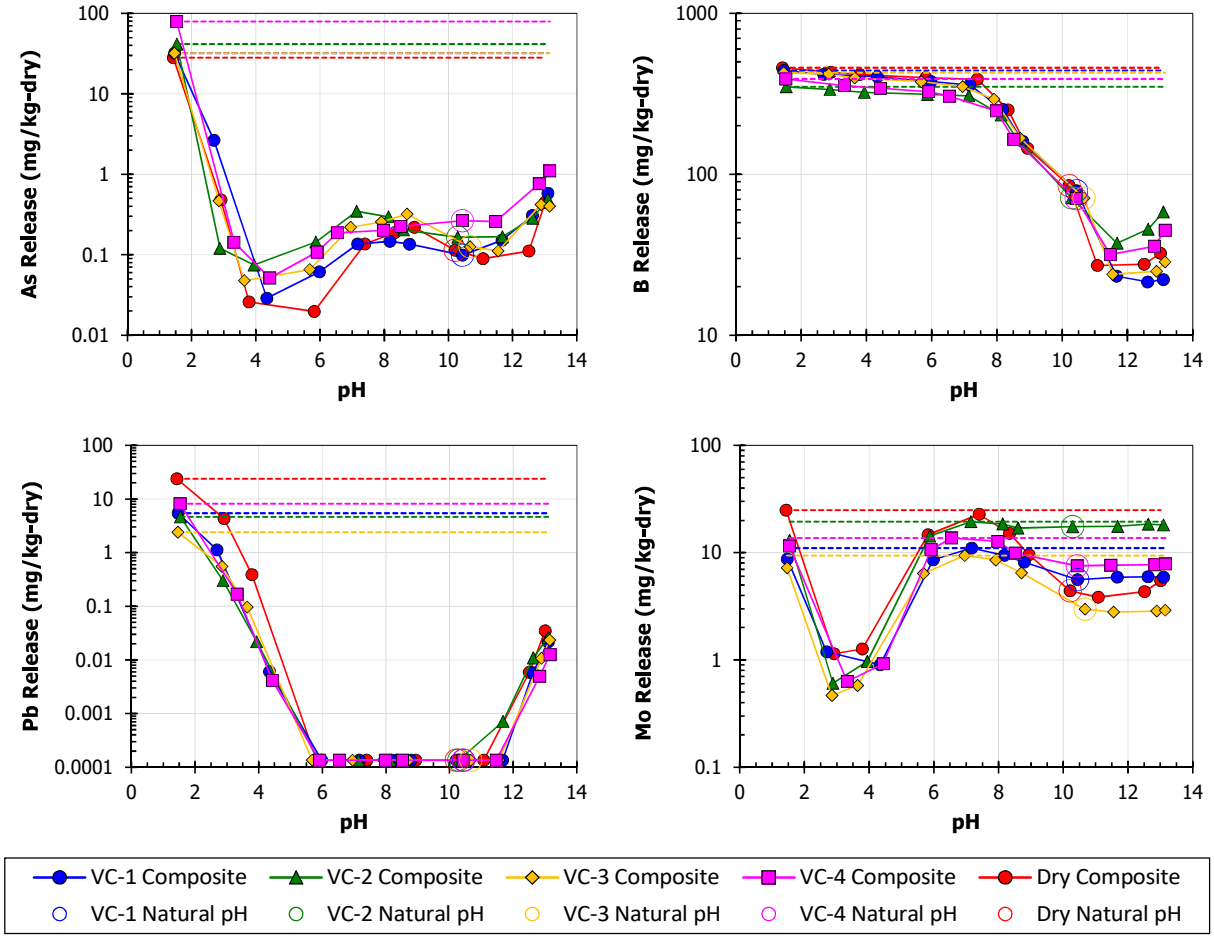

Figure 6-3
Example mass release from composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) showing available content (dashed horizontal lines)

L/S-Dependent Leaching Test Results (EPA 1314)

The results of EPA 1314 indicate how the LSP of constituents changes as the amount of water passing through a bed of material increases (i.e., the cumulative L/S, or ΣL/S). In general, soluble minerals are dissolved and removed from the column at low ΣL/S values; therefore, different minerals and processes (e.g., dissolution vs. desorption) may control the release of constituents at various points along the percolation column elution curve. As leaching progresses, the ionic strength of the porewater decreases, leading to changes in controlling minerals and, in some cases, the controlling LSP mechanisms (e.g., a constituent with an LSP limited by the available content at high concentration may show signs of solubility-controlled LSP at low concentration). In cases where the ΣL/S can be related to the rate of field infiltration, column test data can provide an estimate of leaching concentration as a function of time (Kosson et al., 2014; Garrabrants et al., 2020a, 2020b; EPA, 2019).

Electronic Filing: Received, Clerk's Office 07/01/2024

pH in Column Eluates

The measured pH values of eluates from the column test (EPA 1314) for the five composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) are presented in Figure 6-4. These graphs also indicate the natural pH (EPA 1313) and the own pH (EPA 1313_L/S=1) as dashed lines, and the range of pH values measured in the PAPs.

For the saturated composites (VC-1, VC-2, VC-3, and VC-4), the evolution of pH in the percolation column shows an initially increasing trend followed by a plateau at an approximate pH of 10, with the starting pH and the plateau varying slightly between composites. However, the evolution of pH for the Dry composite taken from samples above the water table shows a different trend, with an initially high pH that decreases by about 0.5 pH units to plateau at a pH of approximately 9.0. The increase in pH at low L/S for the saturated composites (VC-1 through VC-4) may be due to surficial oxidation or carbonation resulting from contact of moist, alkaline ash with air during sample handling.

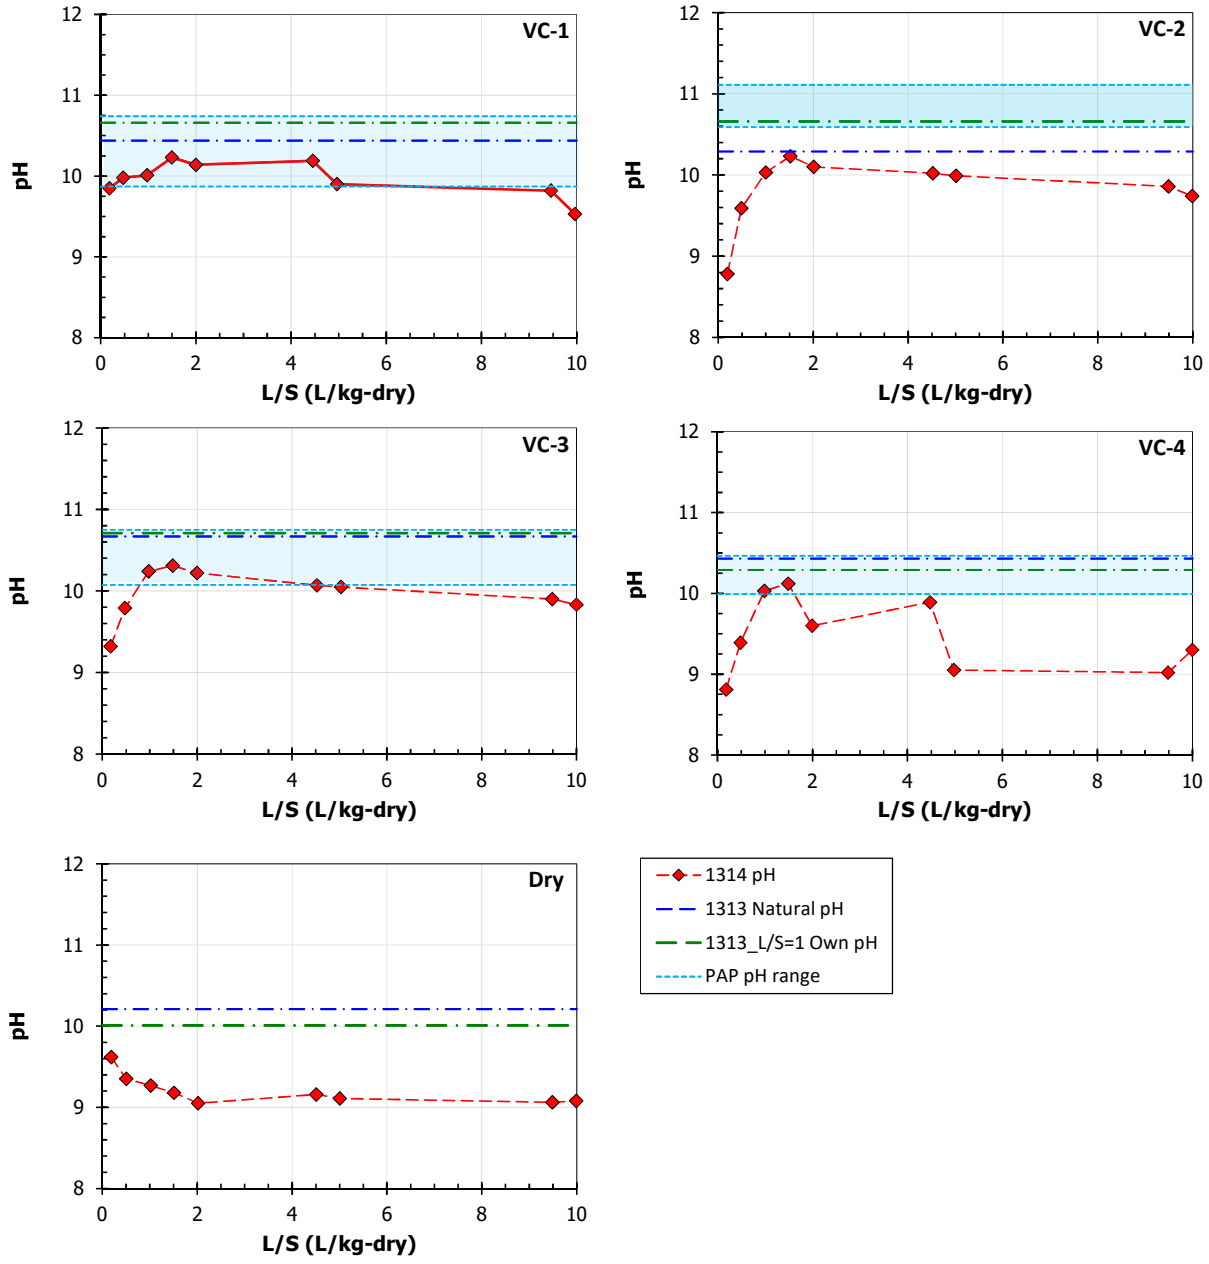

Figure 6-4
Evolution of pH in column eluates (EPA 1314) from five composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) compared to natural pH (EPA 1313), own pH (EPA 1313_L/S1), and range of porewater pH measurements

Table 6-5 compares the eluate pH values from the lowest L/S fraction of EPA 1314 to the range of pH values at higher L/S values, to the natural pH and own pH measured in batch leaching tests (EPA 1313 and 1313_L/S-1), and to the range of pH in porewater samples from the PAPs. In general, column test eluates at low L/S are approximately 1.5 pH units lower than measured in batch leaching tests. The difference may be explained predominantly by ionic strength changes with increasing L/S and interactions with dissolved constituents in equilibrium at the L/S values.

Table 6-5
Comparison of Eluate pH from Low L/S Column Fraction (EPA 1314) to the Natural pH (EPA 1313) and Own pH (1313_L/S=1) of Composite Samples

	Method	L/S (mL/g-dry)	VC-1 pH (SU)	VC-2 pH (SU)	VC-3 pH (SU)	VC-4 pH (SU)	Dry pH (SU)
1st Fraction	EPA 1314	0.2	9.85	8.78	9.32	8.81	9.62
Range	EPA 1314	2-10	9.5-10.1	9.7-10.1	9.8-10.2	9.0-9.9	9.0-9.2
Own pH	1313_L/S=1	1	10.66	10.64	10.71	10.29	10.01
Natural pH	EPA 1313	10	10.44	10.29	10.67	10.43	10.21
Porewater	-	0.35	9.9-10.7	10.6-11.1	10.1-10.8	10.0-10.5	-

Note: Porewater L/S estimated from porosity and density of intact cores collected at the elevation of the PAP.

Constituent Results

The concentration of a constituent's percolation column eluates (EPA 1314) indicates how the LSP changes as water passes through the material. Eluate concentrations and mass release are typically plotted as a function of the cumulative L/S (i.e., the cumulative amount of eluent passing through the column relative to the mass of material in the column).

Examples of typical L/S-dependent behavior from EPA 1314 conducted on the VC-1 composite are shown in Figure 6-5, presented as eluate concentration (mg/L) on the left and cumulative mass release (mg/kg-dry) on the right. In mass release graphs, the gray dashed line indicates the mass release proportional to the cumulative L/S expected if concentration is controlled by constant solubility. The following behaviors are shown in Figure 6-5:

- The eluate concentrations for Sb (top) are essentially constant as a function of L/S and, thus, the mass release is proportional to the cumulative L/S and the mass release curve follows the solubility indicator line. This L/S-dependent behavior is consistent with ***solubility-controlled LSP***.
- EPA Method 1314 data indicate that the constituent concentration of Co (middle) decreases rapidly up to an L/S of 2 L/kg-dry, indicating an ***available content-limited LSP***. Eluate concentrations that are a strong function of L/S may decrease to less than quantitation limits within the test cumulative L/S range, indicating depletion of the available content.
- The L/S-dependent leaching of Se (bottom) is a good example of rapid release of a soluble fraction of the available content without depletion. This differs from the example behavior of Co because, after an initial "wash off" of a highly soluble fraction, leaching concentrations remain detectable and relatively constant, suggesting the constituent exists in ***both content-limited (highly soluble mineral phase) and solubility-controlled (low-solubility mineral phase) LSP*** fractions.

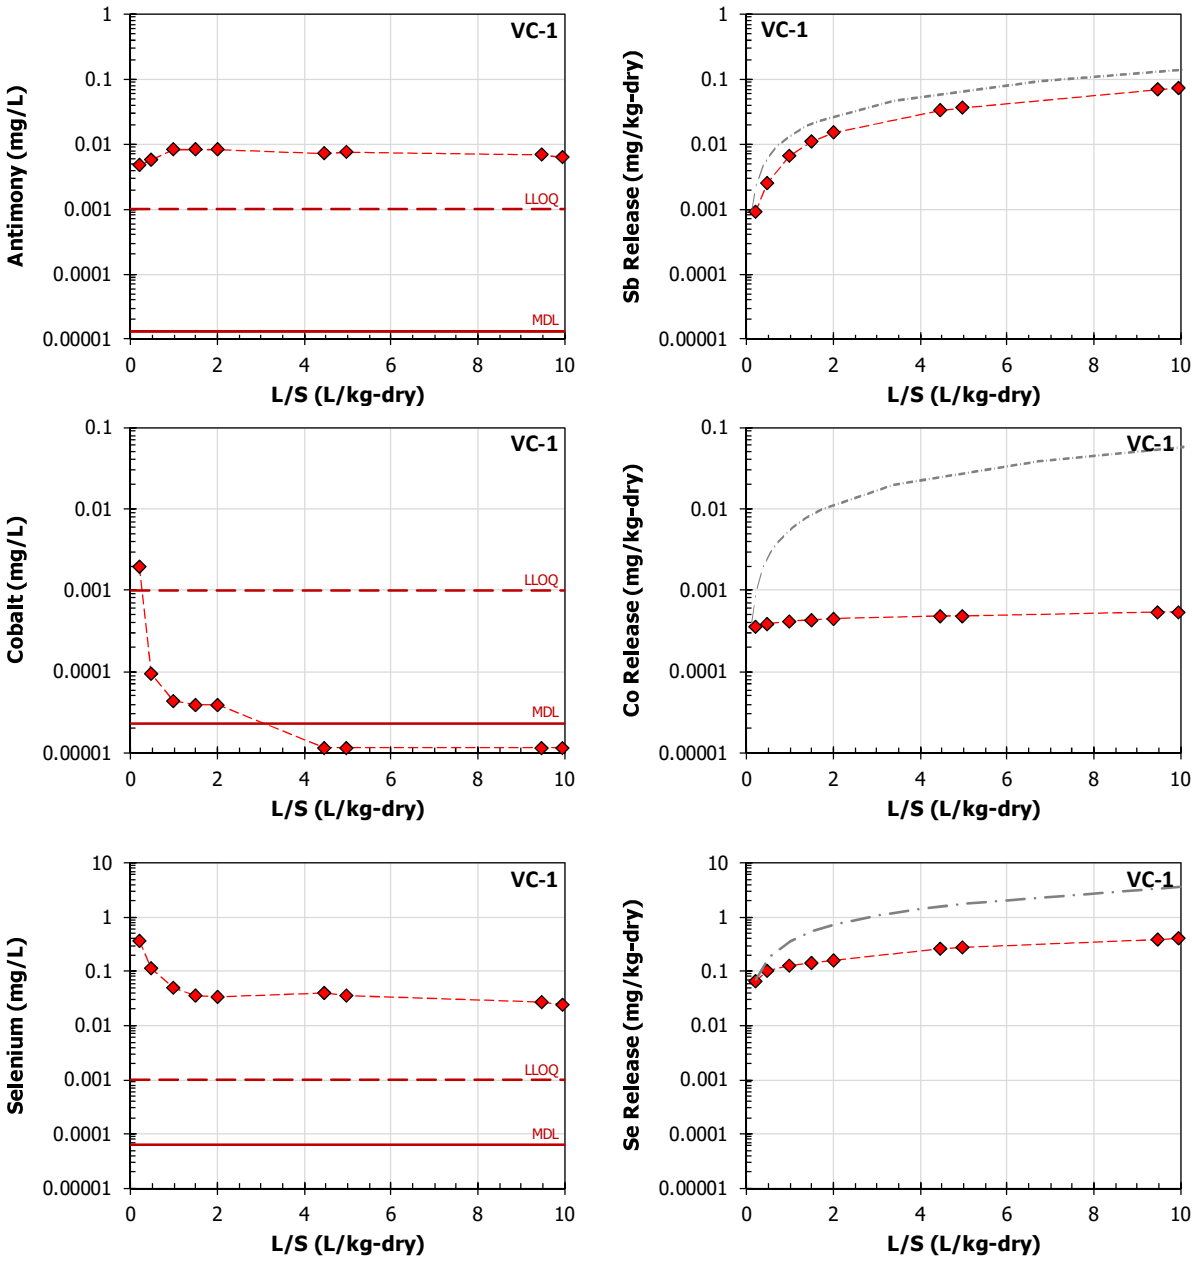

Figure 6-5
Example 1314 test results from VC-1 showing a solubility-controlled constituent (antimony) and depletion of the available content (cobalt) and wash-off of a soluble constituent fraction without depletion (selenium). The gray dot-dashed line indicates prototypical solubility-controlled release fitted to the first EPA 1314 data point.

Determining LSP Behavior

Solubility-Controlled LSP vs. Available Content-Limited LSP

Comparing the impacts of changing pH (e.g., within an EPA 1313 test) with the impact of changing L/S (e.g., within an EPA 1314 test) can be a helpful methodology for distinguishing

the LSP behavior of constituents. Often, the distinction of "solubility-controlled LSP" or "adsorption-controlled" behavior from those with "available content-limited LSP" is a useful classification for grouping large lists of constituents.

The following LSP leaching behaviors were observed from comparison of pH-dependent (EPA 1313) leaching data to L/S-dependent (EPA 1314) leaching data. The focus of the following classifications is limited to the applicable pH domain about the natural pH. Outside of those pH bounds, constituents that were classified as available content-limited may show solubility-controlled LSP or vice versa.

- Solubility-Controlled LSP – When the eluate concentrations are limited by mineral solubility, sorption to mineral phases, and precipitation/dissolution, eluate concentrations are considered ***solubility-controlled.*** Eluate concentrations are a strong function of pH and a weak function of L/S. The LSP for Sb (Figure 6-6) provide a good example of solubility-controlled LSP, as eluate concentrations change by orders-of-magnitude with pH (EPA 1313) but do not change with L/S over the range up to L/S=10 mL/g-dry (EPA 1314). However, the distinction between adsorption and solubility as a controlling mechanism within this classification may be unclear, as both mechanisms are strongly influenced by pH and the patterns for these mechanisms may look similar. Geochemical speciation modeling (not included in this scope) can be useful to discern specific pH-dependent mechanisms.
- Available Content-Limited LSP – When eluate concentrations are limited by the amount of leachable mass in the solid, the characteristic LSP behavior is considered ***available content-limited***. Eluate concentrations are a weak function of pH and a strong function of L/S. Over the applicable pH range ($8 \leq pH \leq 12$), the LSP behavior of Mo (Figure 6-6) presents a good example of available content-limited LSP, as the pH-dependent concentrations (EPA 1313) are relatively stable compared to the significant change in LSP (EPA 1314).
- Wash-Off with Depletion – When a percentage of a constituent is present in porewater or in an easily dissolvable form, there can be a significant initial flush of constituent from a column (i.e., orders-of-magnitude decrease through a $\Sigma L/S$ of 2 L/kg-dry). This behavior is typical for a ***wash-off release mechanism***. The pH-dependent leaching data alone may not indicate this behavior, and the L/S-dependent data become crucial. The endpoint of wash-off can result in depletion of the constituent from the material, evidenced by L/S-dependent concentrations below quantitation limits as presented for Mg in Figure 6-6.

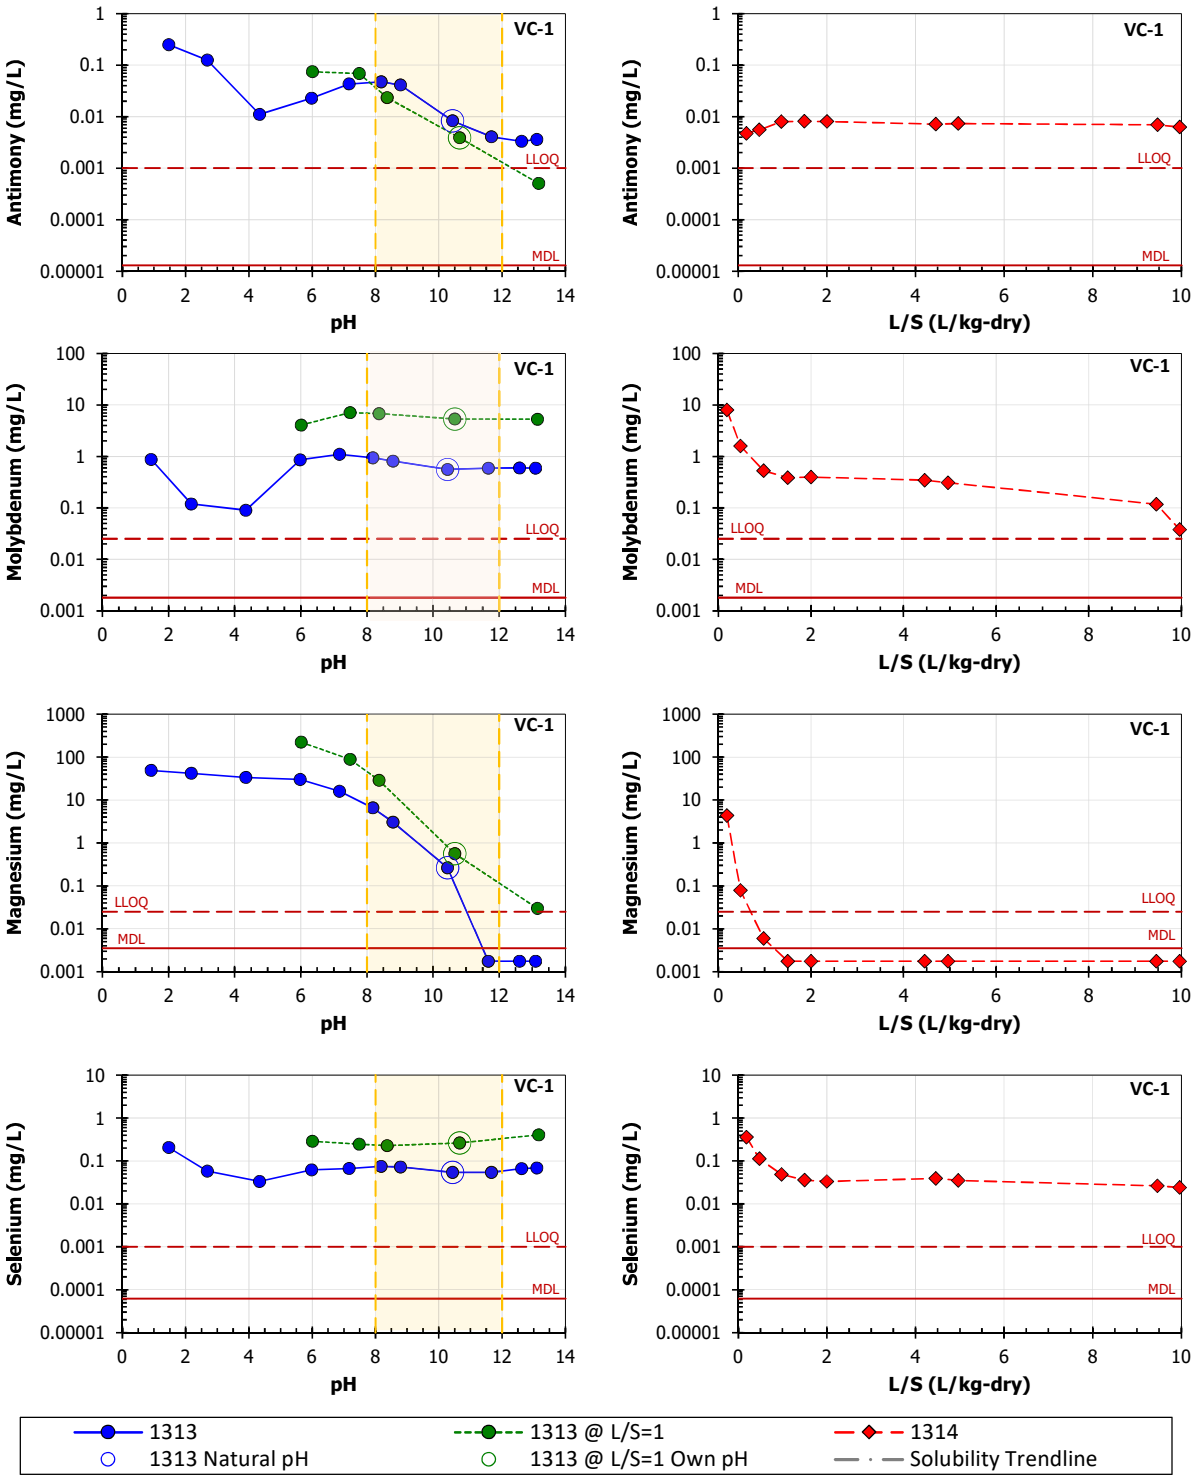

Figure 6-6
Examples of EPA 1313 and EPA 1314 data showing solubility-controlled LSP (antimony); available content-limited LSP (molybdenum); wash-off of soluble fraction leading to depletion (magnesium); and wash-off followed by solubility-controlled LSP (selenium)

- Wash-Off Followed by Solubility Control – In some cases, a secondary fraction of a constituent in the solid material may control eluate concentrations after the initial wash-off. This mechanism results in a relatively constant, detectable eluate concentration following wash-off. In Figure 6-6, Se LSP is a good example of this behavior.
- Non-Detected – For some constituents, eluate concentrations over the applicable pH domain ($8 \leq pH \leq 12$) are below the MDL of the analytical method. Therefore, LSP behavior cannot be determined.

The constituents that are included in each observed behavior are summarized in Table 6-6.

Table 6-6
LSP Behavior over Applicable pH Domain Based on Comparison of EPA 1313 and EPA 1314

LSP Behavior	Constituents
Available Content-Limited	Cl^-, Mo, K, Na
Wash-Off to Depletion	Mg, Mn, NO_3^-
Wash-Off Fraction/Solubility-Controlled	Ba, B, Cd, Cr, Cu, DOC, Li, Ni, Se, Si, Sr, SO_4^{-2}, V
Solubility-Controlled	Al, Sb, As, Ca, DIC, Tl
Non-Detect (values < MDL)	Be, Br^-, Co, F^-, Fe, Pb, PO_4^{-3}, Ag, Zn

The high number of constituents with wash-off followed by a low concentration of solubility-controlled LSP suggest a systematic controlling mechanism in the landfill. Figure 6-7 compares the L/S-dependent data between all composite samples. The data in this figure show that the eluate concentrations for the dry composite are often initially higher than the eluate concentrations of the saturated borehole composites (VC-1 through VC-4). In some cases (e.g., SO_4 in Figure 6-7), the LSP behavior in unsaturated ash is solubility-controlled whereas the LSP behavior in the saturated ash indicates a mobile constituent. These observations suggest that constituents leached from dry-handled ash penetrate into the saturated ash, providing the dissolved or easily solubilized fraction of a constituent in the observed wash-off behavior. Once the overburden constituents are released, the LSP behavior is controlled by the dissolution of more recalcitrant constituents in the saturated ash.

Electronic Filing: Received, Clerk's Office 07/01/2024

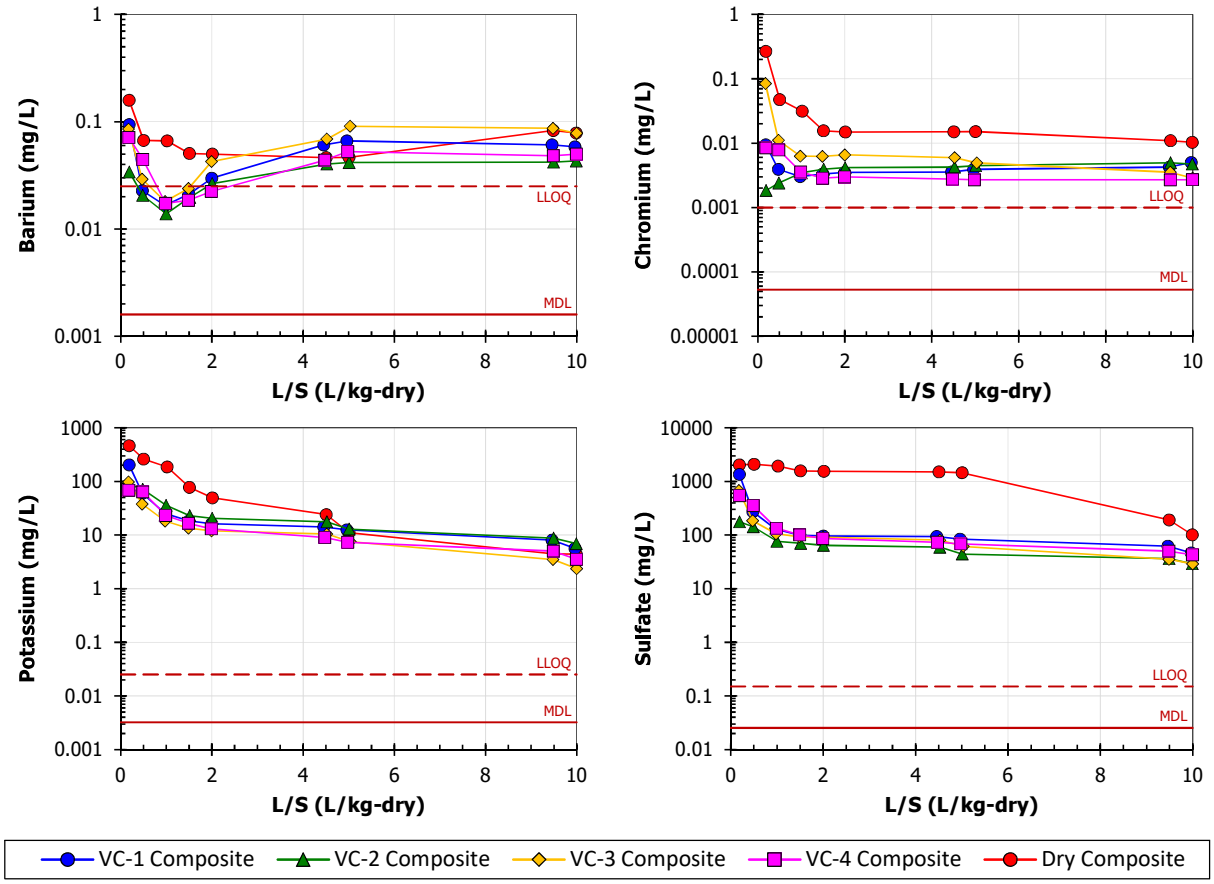

Figure 6-7
Comparison of L/S-dependent (EPA 1314) data showing influence of dry-handled ash (Dry composite) on eluate concentrations of wet-handled ash (VC-1, VC-2, VC-3, and VC-4)

Traditional Extraction Test Results

The L/S and measured pH from the extractions using the traditional leaching tests (TCLP, SPLP, and ASTM) are presented in Table 6-7.

Table 6-7
Liquid-to-Solid Ratio and Measured Extraction pH for Traditional Leaching Tests

Material	TCLP		SPLP		ASTM	
	L/S (mL/g-dry)	pH	L/S (mL/g-dry)	pH	L/S (mL/g-dry)	pH
VC-1	26.8	5.74	26.8	10.47	27.8	10.48
VC-2	28.8	5.39	28.8	10.40	30.0	10.51
VC-3	28.4	6.27	28.4	10.38	29.7	10.60
VC-4	26.9	5.47	26.9	10.32	28.1	10.51
Dry	24.8	5.78	24.8	10.04	24.8	10.20

The amount of extraction fluid for ASTM is determined as the mass of the "as received" test material in grams divided by the test-specific L/S of 20 mL/g. The resultant L/S on a dry basis is greater than 20 because of the water inherent in the pores of the "as received" material. The procedures for TCLP and SPLP require a pressure filtration preconditioning of the test sample to remove excess liquid, which is analyzed separately. The extraction fluid is based on the mass of the pressure-filtered solid material in grams divided by the same L/S of 20 mL/g. Therefore, the calculated L/S for TCLP and SPLP is lower than the L/S for the ASTM test that includes extra water. The measured pH for ASTM, which uses DIW as an extraction fluid, is consistent with the natural pH (1313) and own pH (1313_L/S=1) of the composites at VC-1, VC-2, VC-3, VC-4, and Dry reported in Table 6-2. For SPLP, the measured pH is slightly lower than the ASTM pH, consistent with the small amount of acid used in the extraction fluid. The stability of the measured pH for TCLP extracts across different composites reflects the buffering provided by the organic acetic acid.

The eluate constituent concentrations for TCLP, SPLP, and ASTM tests are presented in Table 6-8, Table 6-9, and Table 6-10, respectively. Since pH is an important factor for solubility-controlled LSP, these tables also include the final eluate pH. Recording of eluate pH allows for comparison of the results of these traditional tests to the pH- and L/S-dependent LEAF test results. In general, SPLP and ASTM concentrations were comparable to each other but were lower than TCLP concentrations, sometimes by orders-of-magnitude. In many cases, the increases in TCLP concentrations were caused by the lower pH of TCLP eluates. Exceptions for this site (which may not be generalizable) include As, Mo, and SO_4^{-2}, where similar concentrations were measure in all three procedures, and PO_4^{-2}, Se, and V, where SPLP and ASTM eluates had higher concentration than TCLP. All of these observations are consistent with the pH-dependent LSP curves discussed above.

Table 6-8

Comparison of Traditional and LEAF Test Results

When the pH and L/S of leaching tests are recorded, the test results from different leaching tests can be compared based on eluate pH or L/S. An example comparison is shown in Figure 6-8 for Mo leaching from the VC-2 composite. In Figure 6-8, the eluate concentrations (mg/L) are shown in the left column, and mass release values (mg/kg-dry) are shown in the right column. The upper row presents data as a function of pH, with L/S-dependence shown in the bottom row.

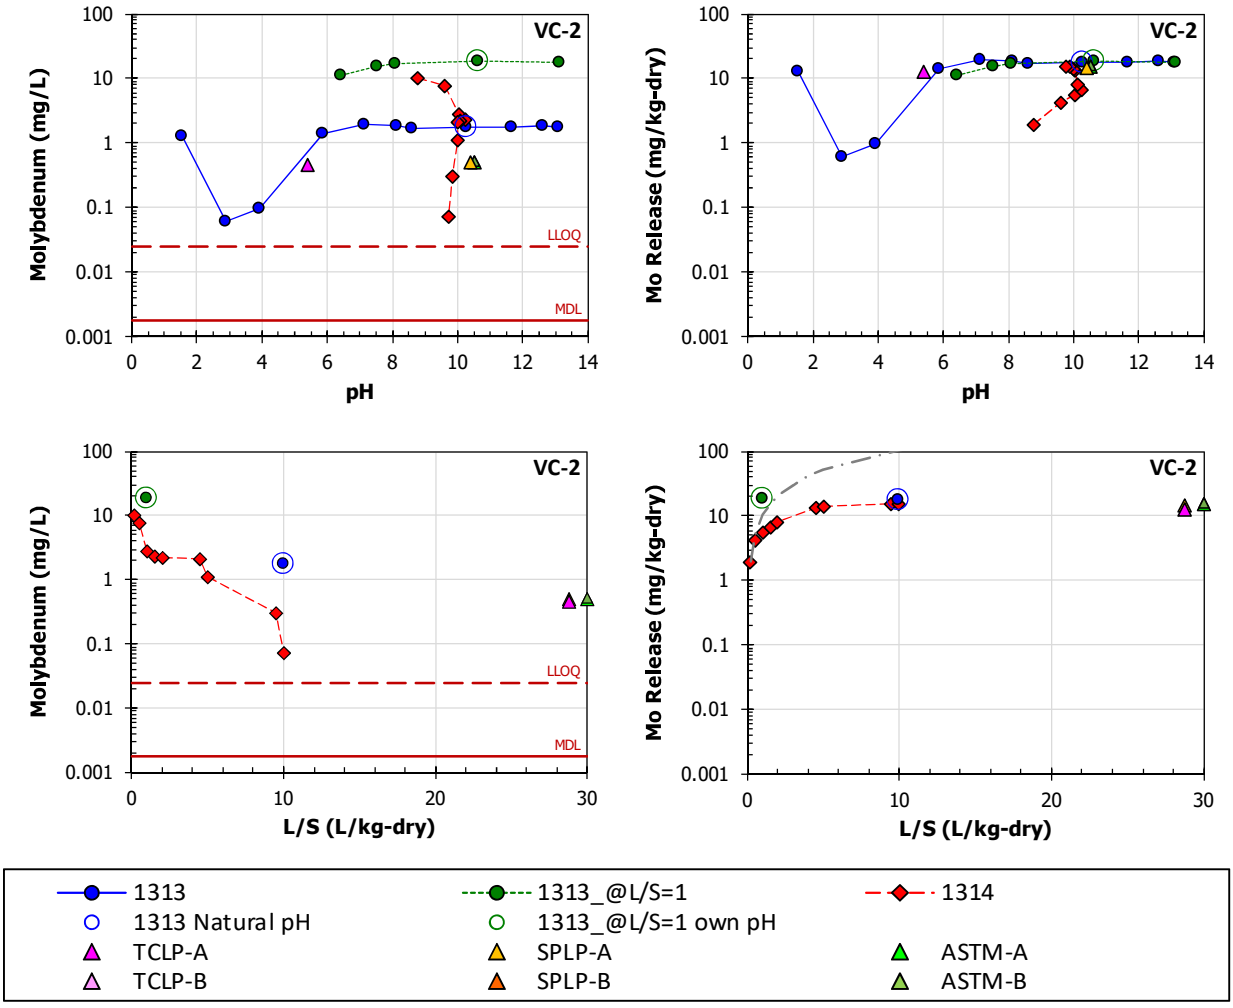

Figure 6-8
Comparison of molybdenum concentration (left) and mass release (right) using traditional (TCLP, SPLP, and ASTM) and LEAF tests (1313, 1313_L/S=1, and 1314); replicates indicated by "-A" and "-B"

For a constituent with available content-limited LSP, for example Mo, the concentrations obtained from the traditional leaching test data are slightly lower than those in EPA Method 1313 and consistent with the higher L/S for the traditional tests. The data for SPLP and ASTM are very close to the leaching response at natural pH measured in EPA Method 1313 due to the little to no acidity added. Conversely, the buffered solution of TCLP leads to a significant lower eluate pH. However, on a mass release basis (Figure 6-8 upper right) all of the results are consistent.

Electronic Filing: Received, Clerk's Office 07/01/2024

When data for a constituent with available content-limited LSP are compared as a function of L/S, the eluate concentrations of any single extraction at a fixed L/S are unlikely to match the column elution curve. The concentrations in the column test reflect a “progressive” leaching case where material is removed from the column, rather than a batch leaching case represented by single extractions. However, mass release as a function of L/S should be consistent between all tests because the basis of the data is the solid mass. Of course, the L/S of traditional tests are much higher than the L/S of either the LEAF tests or field conditions, so the data are not readily compared or applicable to leaching scenarios with low L/S values.

Electronic Filing: Received, Clerk's Office 07/01/2024

GROUNDWATER, POREWATER, AND SUBSURFACE GAS MONITORING

Measured field parameters for groundwater and porewater sampling as well as graphical presentation of groundwater and porewater concentrations from unfiltered samples are provided in Appendix D-1. These data represented the sampling period from June 2019 through January 2020. Monthly analysis of groundwater wells and PAPs focused on 17 constituents from 40 CFR 257 (As, B, Ba, Be, Ca, Cd, Cl^-, Co, Cr, F^-, Li, Mo, Pb, Sb, Se, SO_4^{-2}, and Tl) and 13 additional constituents (Ag, Br^-, Cu, DIC, DOC, Fe, K, Na, Ni, PO_4^{-3}, Sr, V, and Zn).

Groundwater and Porewater Parameters

Plots of field measurements are shown in Figure 7-1 and Figure 7-2. Within each bar chart, data for the porewater sampled at the four boreholes are presented in solid colors (i.e., blue for VC-1, green for VC-2, gold for VC-3, and purple for VC-4). The downgradient groundwater is presented as stripe-filled bars that are color-coded to their nearest PAP (i.e., the groundwater monitoring well at 209 is associated with VC-2 while the groundwater monitoring well at 931 is more directly opposite VC-4). Due to physical activity at the landfill during sampling (ongoing deposits and grading), not all PAPs were sampled each month.

The data in Figure 7-1 show that the water table elevation, pH, and electrical conductivity remain relatively constant over time at each sample point. The mean water table in the PAPs (386.8 ft AMSL) is approximately 27 feet higher in elevation than the mean water table of the downgradient wells (360.2 ft AMSL). The pH of the porewater in the PAPs is more alkaline ($pH_{ave\text{-}VCs}$=10.5±0.3) than in the downgradient monitoring wells (pH_{ave}=6.7±0.2).

Figure 7-2 presents measured values of water temperature, ORP, and DO, showing seasonal trends for all parameters. The ORP values of the PAP porewater appear to have significant variability, which may be indicative of the nature of the ORP measurement. The mean dissolved oxygen for the two downgradient monitoring wells (DO_{ave}=0.9±0.3 mg/L) is somewhat lower than in the PAPs ($DO_{ave\text{-}VCs}$=1.5±0.3 mg/L). The dissolved oxygen data for all of the porewater and groundwater measurements are notably less than the 9.1 mg/L for saturated surface water at 20 ºC (USGS, 1998) and, therefore, the porewater is considered to be suboxic.

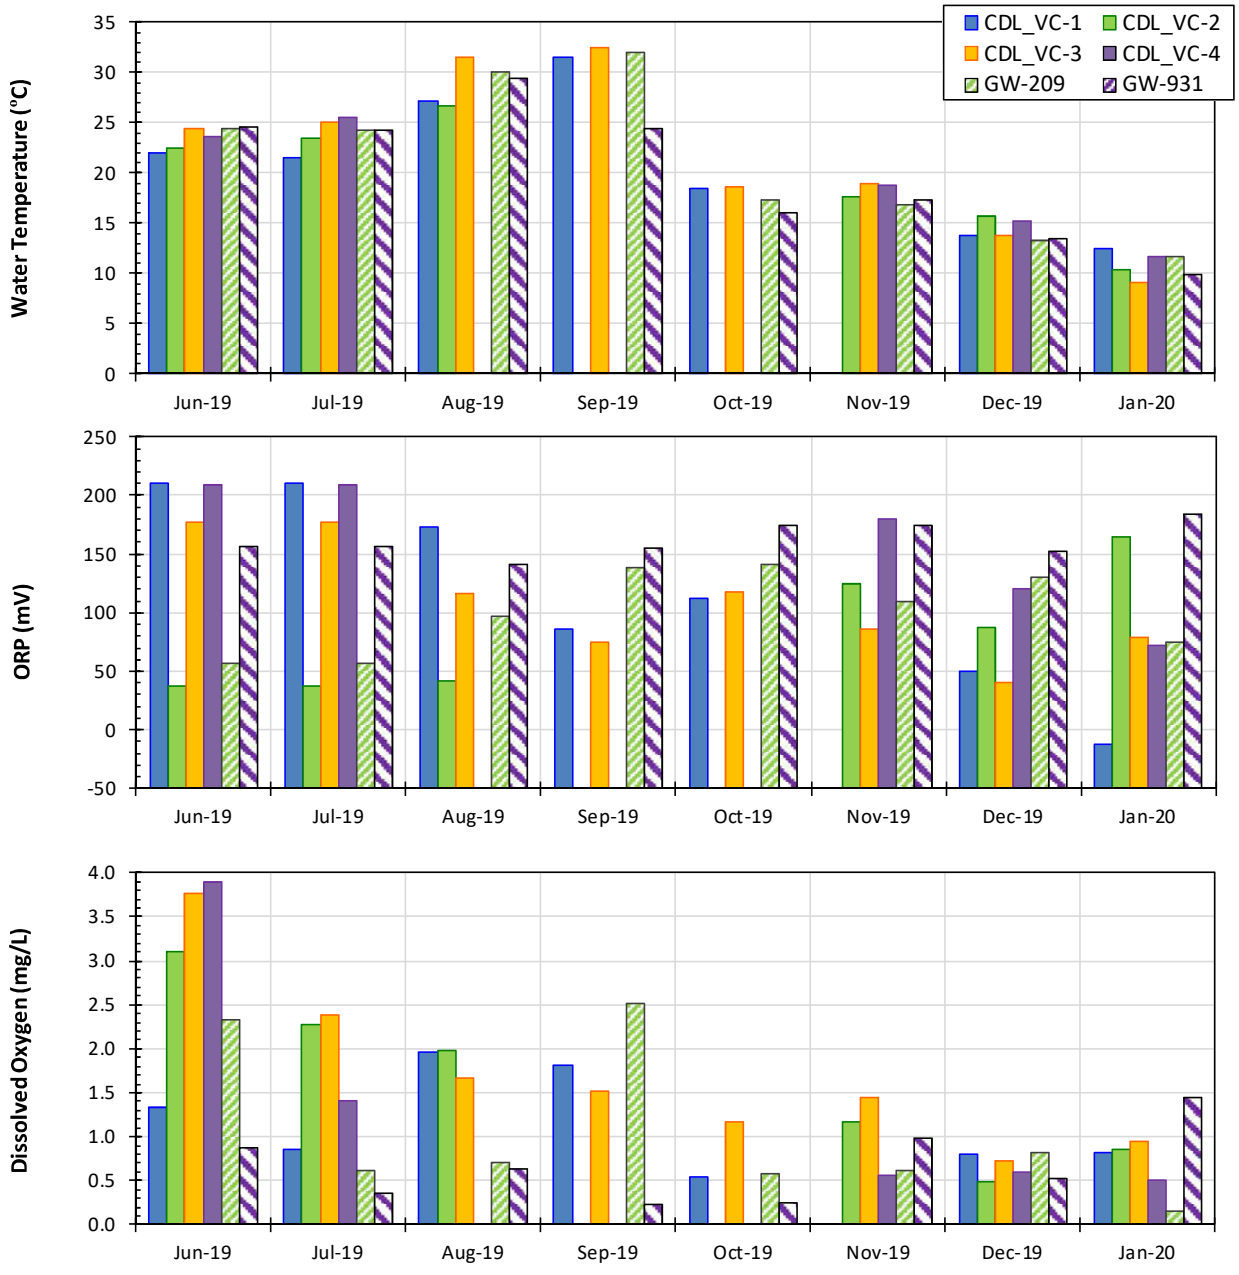

Figure 7-2
Groundwater and porewater field parameters from monthly sampling: water temperature, ORP, and DO

Concentrations in Groundwater and Porewater

Monthly analysis of groundwater wells and PAPs focused on 30 constituents, including 17 from 40 CFR 257 (As, B, Ba, Be, Ca, Cd, Cl^-, Co, Cr, F^-, Li, Mo, Pb, Sb, Se, SO_4^{-2}, and Tl). Thirteen additional constituents that were analyzed were Ag, Br^-, Cu, DIC, DOC, Fe, K, Na, Ni, PO_4^{-3}, Sr, V, and Zn. Examples of the results for selected constituents are presented in Figure 7-3 and Figure 7-4, while the graphical results for all 30 constituents are presented in Appendix D-1.

Given the geography and groundwater flow patterns at this site, there was not an upgradient monitoring well that could be used in a comparison to determine whether or not there were any impacts to groundwater from this CCP unit; therefore this analysis will not attempt to determine whether or not the groundwater quality represents releases from the coal ash. The discussion that follows allows for either possibility as the relationship between porewater and downgradient groundwater is explored.

An analysis of variance (ANOVA) was initially attempted to compare the groundwater and porewater datasets, but in most cases low p-values indicated that groundwater and porewater concentrations were not from the same statistical population. Instead, downgradient concentrations were directly compared to porewater concentrations using means and standard deviations. Table 7-1 summarizes the standard deviation analysis as follows:

- "GW >> PW" and "GW << PW" indicate that the mean groundwater concentration (GW) for a groundwater monitoring well was greater than or less than the mean porewater concentration (PW) at the associated PAP by a difference of three standard deviations or more;
- "GW > PW" and "GW < PW" indicate that the mean groundwater concentration at a groundwater monitoring well was greater than or less than the mean porewater concentration at the associated PAP by a difference of greater than one standard deviation, but less than three standard deviations; and,
- "GW ≈ PW" indicates that the mean groundwater concentration from a groundwater monitoring well was within one standard deviation of the mean porewater concentration of the associated PAP.

In Table 7-1, Ag, Be, Cr, F^-, and Pb are not included because the concentrations of these constituents were below the analytical MDL in both porewater and groundwater. The summary in the table assumes the potential for a connection between specific PAPs and specific groundwater monitoring wells (e.g., VC-2 and Well 209), based solely on geography and a general understanding of groundwater flow direction.

Table 7-1
Relationships between Groundwater and Porewater Based on PAP-Downgradient Groundwater Pairs (Well 209 and PAP at VC-2; Well 931 and PAP at VC-4)

	Monitoring Well 209 (GW) to PAP at VC-2 (PW)	Monitoring Well 931 (GW) to PAP at VC-4 (PW)
GW >> PW	B, Ca, Cl^-, Co, Fe, SO_4^{-2}	Co, Fe
GW > PW	-	Ni, Zn
GW ≈ PW	Ba	Ba, Cl^-,
GW < PW	As, Cu*, V	-
GW << PW	Cd*, Li, Mo, Ni, Sb*, Se, Tl*, Zn*	As, B, Ca, Cd*, Cu, Li, Mo, Sb*, Se, SO_4^{-2}, Tl*, V

Notes * Indicates that groundwater concentrations were all or mostly below the MDL

The following are observations from this summary.

- Co and Fe have higher concentrations in groundwater than in porewater for all comparisons, while Ba and Cl^- concentrations were similar or much higher in groundwater depending on the comparison. Higher groundwater concentrations suggest that porewater from the coal ash is not the primary source of the groundwater concentration and a limited relationship exists between recent porewater concentration and the downgradient groundwater concentrations at this site. Similar concentrations could be indicative of a release, especially if the constituent is environmentally conservative (e.g., B, Cl^-, and SO_4^{-2}); however, it is unlikely that there would be no dilution when leachate would be released to groundwater. The history and variety of residual storage at this site (e.g., underlying large area of sluiced ash, bottom ash collection ponds, gypsum storage stacks) confounds the ability to use boron as an indicator species for release from this landfill.
- Nine constituents (As, Cd, Cu, Li, Mo, Sb, Se, Tl, and V) have higher concentration in porewater than in both downgradient monitoring wells for all comparisons. Higher concentrations in coal ash porewater suggest that porewater has the potential to affect downgradient groundwater quality; however, porewater concentrations for several of these constituents (Cd, Li, Mo, Sb, Tl, and V) are 2 to 3 orders-of-magnitude higher in the coal ash deposit than in the downgradient wells, suggesting limited impact from porewater on downgradient monitoring well concentrations at this site.

Overall, these observations indicate that at this site, high porewater concentrations cannot be assumed to indicate impacts on downgradient groundwater concentrations.

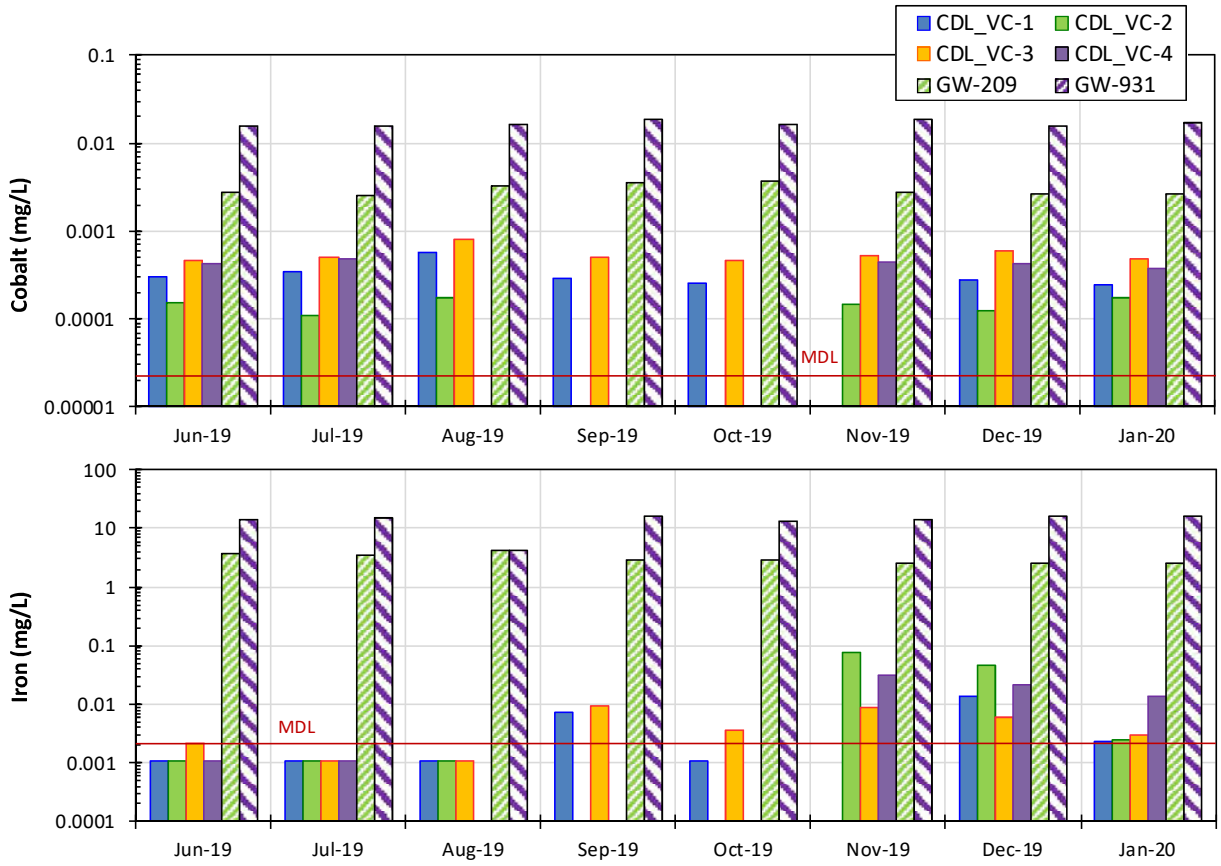

Figure 7-3
Groundwater and porewater monitoring from monthly sampling showing lower concentrations in coal ash porewater (VC-1, VC-2, VC-3, and VC-4) than in downgradient groundwater wells (209 and 931); concentrations plotted on a logarithmic axis

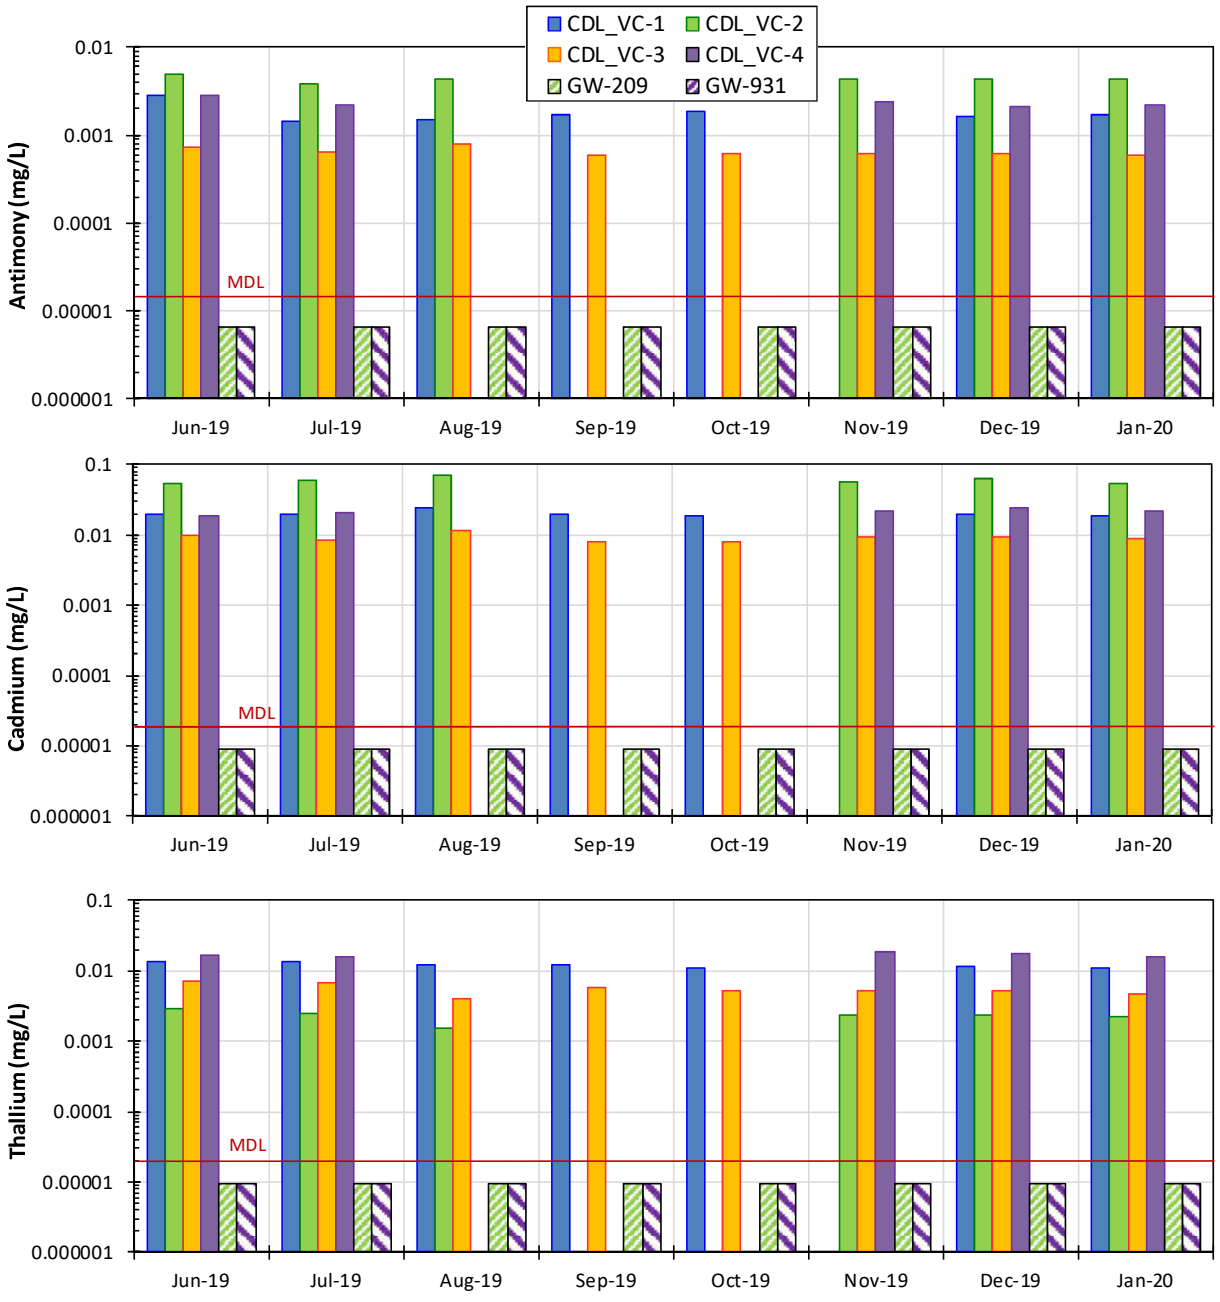

Figure 7-4
Groundwater and porewater monitoring from monthly sampling showing significantly higher concentrations in coal ash porewater (VC-1, VC-2, VB-3, and VC-4) than in groundwater from the downgradient wells (209 and 931); concentrations plotted on a logarithmic axis

Temporal and Spatial Variability in Porewater Parameters

Data reflecting the temporal variability of porewater parameters from monthly monitoring are presented as time-series plots as a function of date. The shapes of the time series distinguish porewater properties that are relatively constant over the sampling period from porewater properties that vary with time. Time-series plots are presented in Appendix D-2. Examples of time series plots for field parameters (Figure 7-5) indicate that variability over the sampling period may be primarily attributed to seasonal changes (e.g., temperature, redox conditions as seen by pH+pE). The trends in porewater constituent concentrations (Figure 7-6) show that many parameters remained relatively constant throughout the monitoring period. The trend lines for VC-2 (green) and VC-4 (pink) were interrupted due to activity on the landfill that caused damage to the PAP. The damage was repaired and the PAPs redeveloped prior to continuation of data collection.

The spatial variability between PAP concentrations was evaluated based on the differences between mean constituent concentrations. Concentrations of a constituent in a PAP were deemed systematically different if the mean concentration in that PAP was more than a factor of five higher or lower than the mean of other PAPs. Based on this analysis, the following observations were made:

- The mean concentrations of Ag, Be, Cr, F^-, and Pb were below the MDL for the analysis and, therefore, no spatial variability could be determined.
- The mean concentrations of Cl^-, Cu, Fe, SO_4^{2-}, Tl, and Zn in VC-2 and Cd and Sb in VC-3 were lower than the mean concentrations in the other PAPs; however, some of this variability may be explained by the damage to wells VC-2 and VC-4.
- The mean concentrations of Cl^- in VC-4, Li in VC-1, and Mo in VC-2 (Figure 7-6) were higher than the mean concentrations in the other PAPs.

Of the 23 constituents evaluated, only Cu and Zn had mean concentrations between PAPs that varied by more than an order-of-magnitude; however, no pattern in spatial variability was observed.

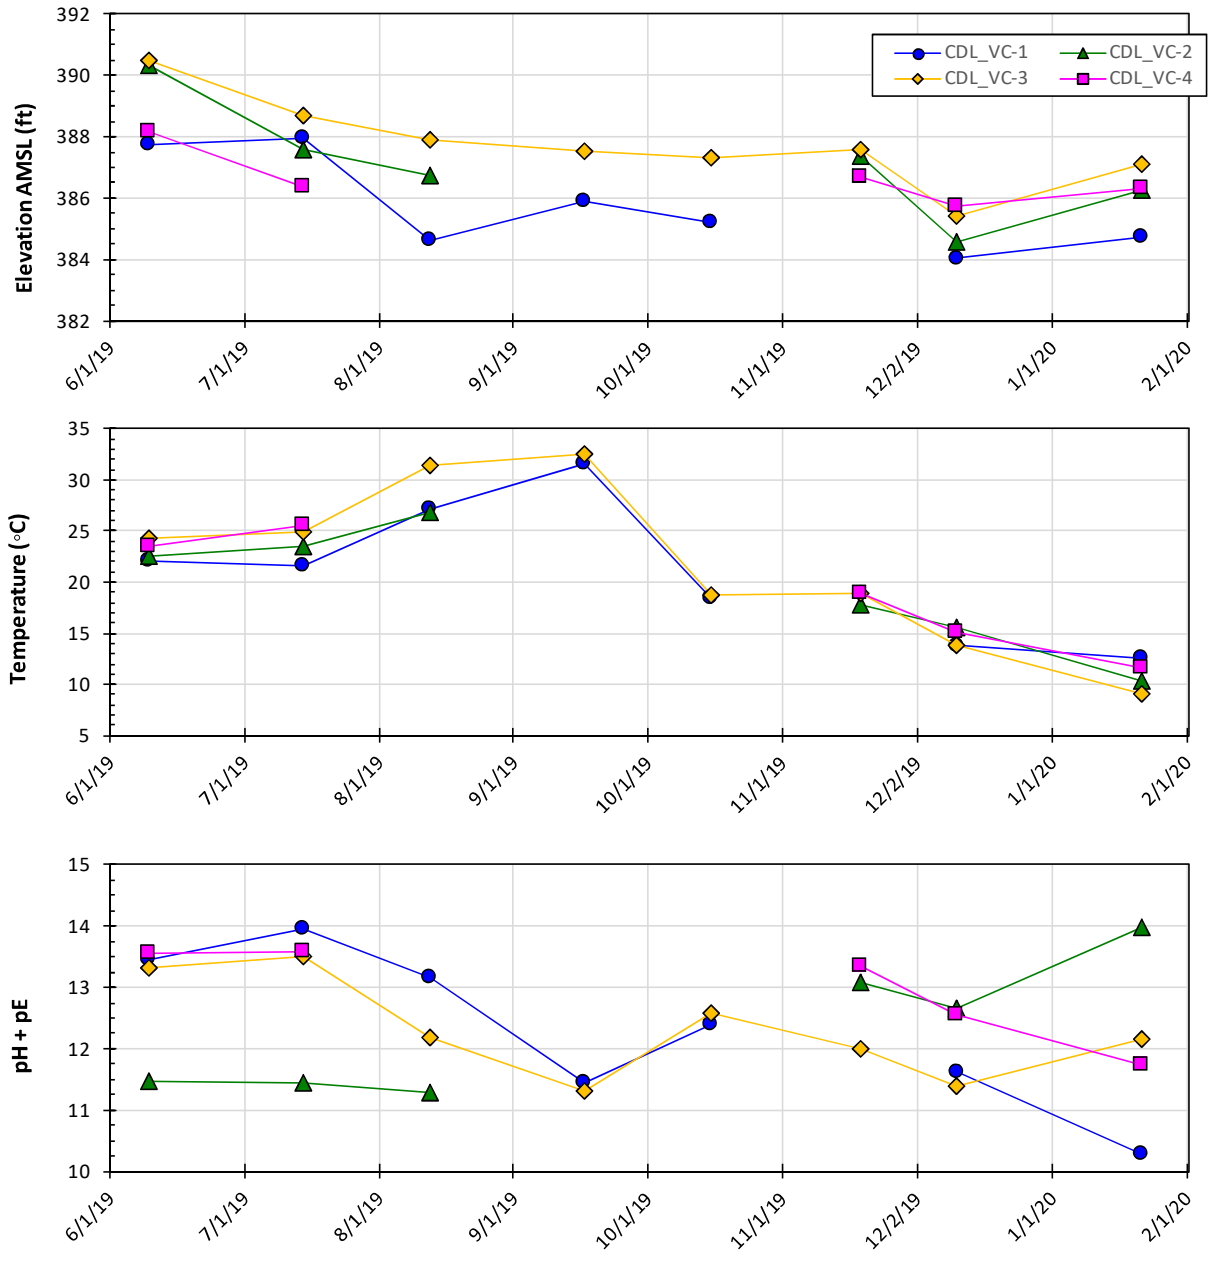

Figure 7-5

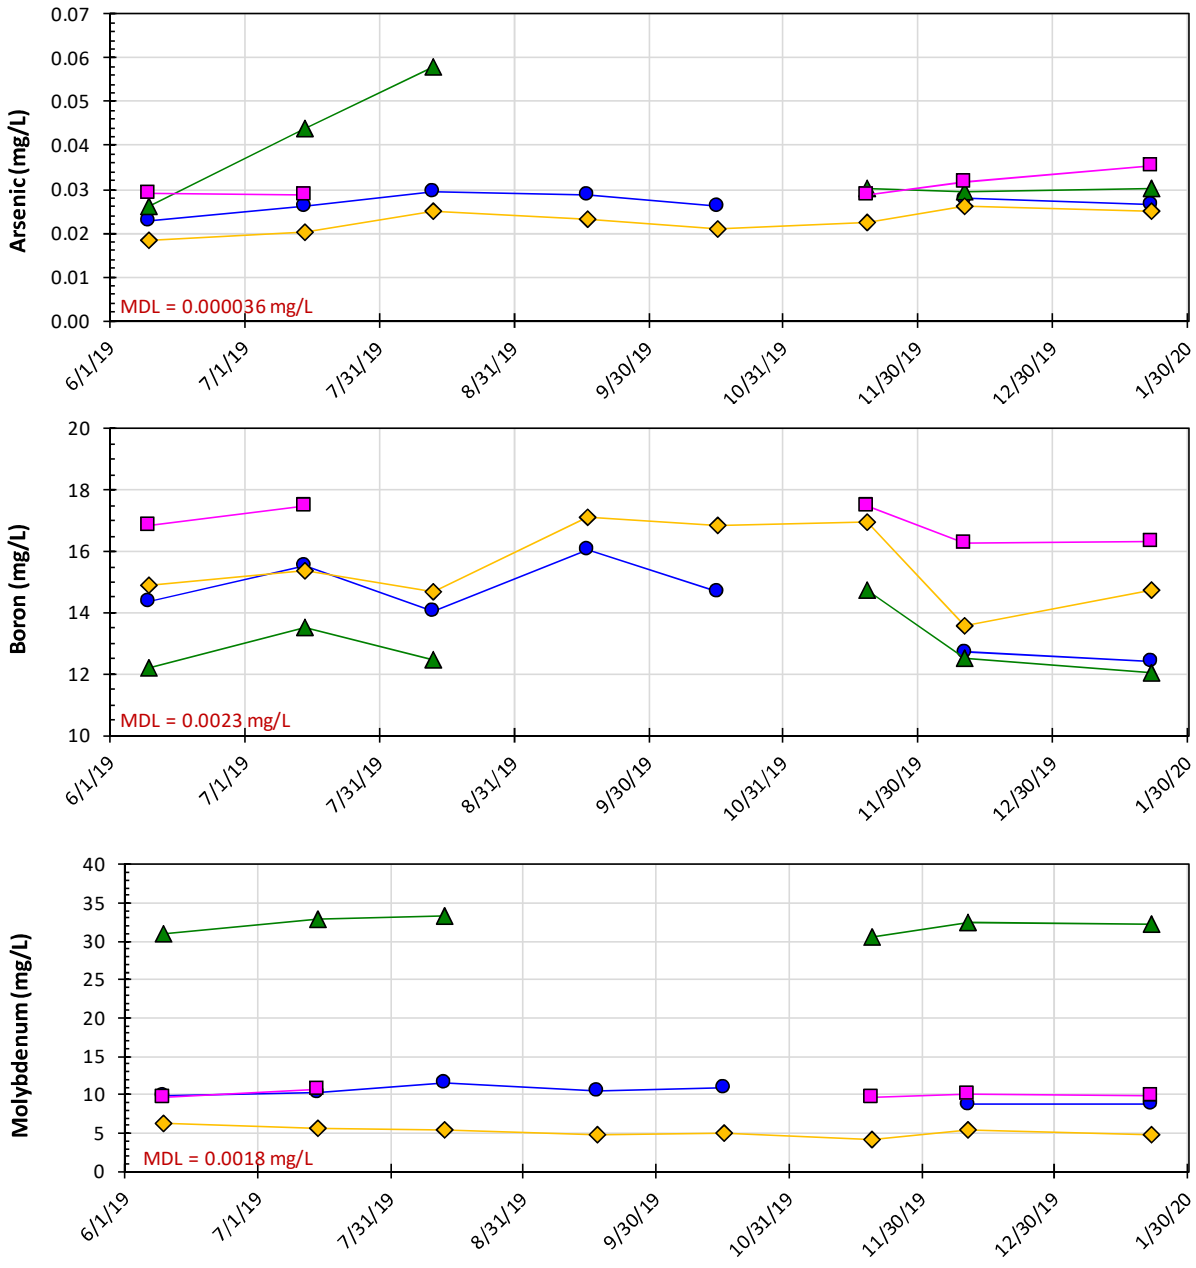

Figure 7-6
Example temporal porewater data showing relatively constant conditions: arsenic, boron, and molybdenum

Subsurface Gas Monitoring

Concentrations of O_2, CO_2, CH_4, NH_4, and H_2S were measured in the four boreholes using gas access points (GAPs). GAPs were installed at VC-1 and VC-3 at three depths (5, 15, and 50 feet BGS), while VC-2 and VC-4 had GAPs installed at 5 and 15 feet BGS. Full tabular data for subsurface monitoring are presented along with graphical comparisons in Appendix D-3.

Electronic Filing: Received, Clerk's Office 07/01/2024

The results of monthly gas monitoring varied to some degree by borehole:

- VC-1 consistently had higher subsurface O2 concentrations at a depth of 5 feet BGS than at 15 or 50 feet BGS (Figure 7-7). The data at this borehole suggest that oxygen is quickly depleted in the subsurface. At VC-3 and VC-4, there appears to be period of instability as initial O2 concentrations were significantly higher than after the first two months.
- CO2 levels were generally low and variable as a function of depth and time (Figure 7-8).
- CH4 concentration in subsurface gas was detected in VC-1 only at very low concentrations at depth (Figure 7-9). In this scenario, methane detection is likely indicative of localized decay of organic matter rather than a strongly reduced subsurface environment as noted in the closed impoundment discussed in EPRI (2020).
- Subsurface NH4 and H2S concentrations were negligible, detected very sporadically and at very low concentrations (Appendix D-3).

These data are indicative of a heterogeneous redox environment. At depth (> 5 feet BGS), O_2 concentrations, in particular, confirm the suboxic environment indicated by DO measurements in the porewater.

Comparison of Leaching Tests to Monthly Porewater Samples

The results of LEAF leaching tests and traditional tests (TCLP, SPLP, and ASTM) were plotted as a function of pH along with the porewater concentrations measured at the corresponding borehole (VC-1, VC-2, VC-3, or VC-4). Examples of these comparisons are shown in Figure 7-10 through Figure 7-12, while a full set of results is presented in Appendix E. In the pH-dependence graphs, monitored porewater data are presented both as data points representing monthly measured porewater concentrations and as dashed lines representing the mean pH and mean concentration of all measured values.

To the right of each pH-dependence graph, bar charts show the ratio of the leaching test concentration to the mean porewater concentration. The seven ratios are shown in increasing order of L/S, including:

- the 1st eluate from EPA 1314 at ΣL/S=0.2 mL/g-dry,
- the 2nd eluate from EPA 1314 at cumulative ΣL/S=0.5 mL/g-dry (displayed as L/S=0.3)[4],
- the 1313_L/S=1 concentration at own pH at L/S=1 mL/g-dry,
- the 1313 concentration at natural pH at L/S=10 mL/g-dry,
- TCLP conducted at an average L/S of 23 mL/g-dry,
- SPLP conducted at an average L/S of 22 mL/g-dry, and
- ASTM at an average L/S of 27 mL/g-dry.

The eluate-to-porewater-concentration ratios indicate how closely leaching test concentrations can predict measured field concentrations. For example, Figure 7-10 shows that B porewater concentrations are well predicted by low L/S batch leaching (1313_L/S=1) and, coincidently, by TCLP; however, the test-specific L/S of TCLP and resultant eluate pH are not representative of that in the coal ash porewater. For boron, all leaching test data estimate porewater concentrations within an order-of-magnitude. These observations are consistent with available content-limited LSP where eluate concentration is a strong function of L/S. Since the L/S of ASTM and SPLP is significantly greater than the L/S in the field, these traditional tests tend to underestimate the porewater concentrations for available content-limited LSP constituents by an order-of-magnitude or more.

[4] The first eluate is taken at L/S=0.2, the second is taken 0.3 pore volumes later, so the L/S is 0.3 and ΣL/S=0.5.

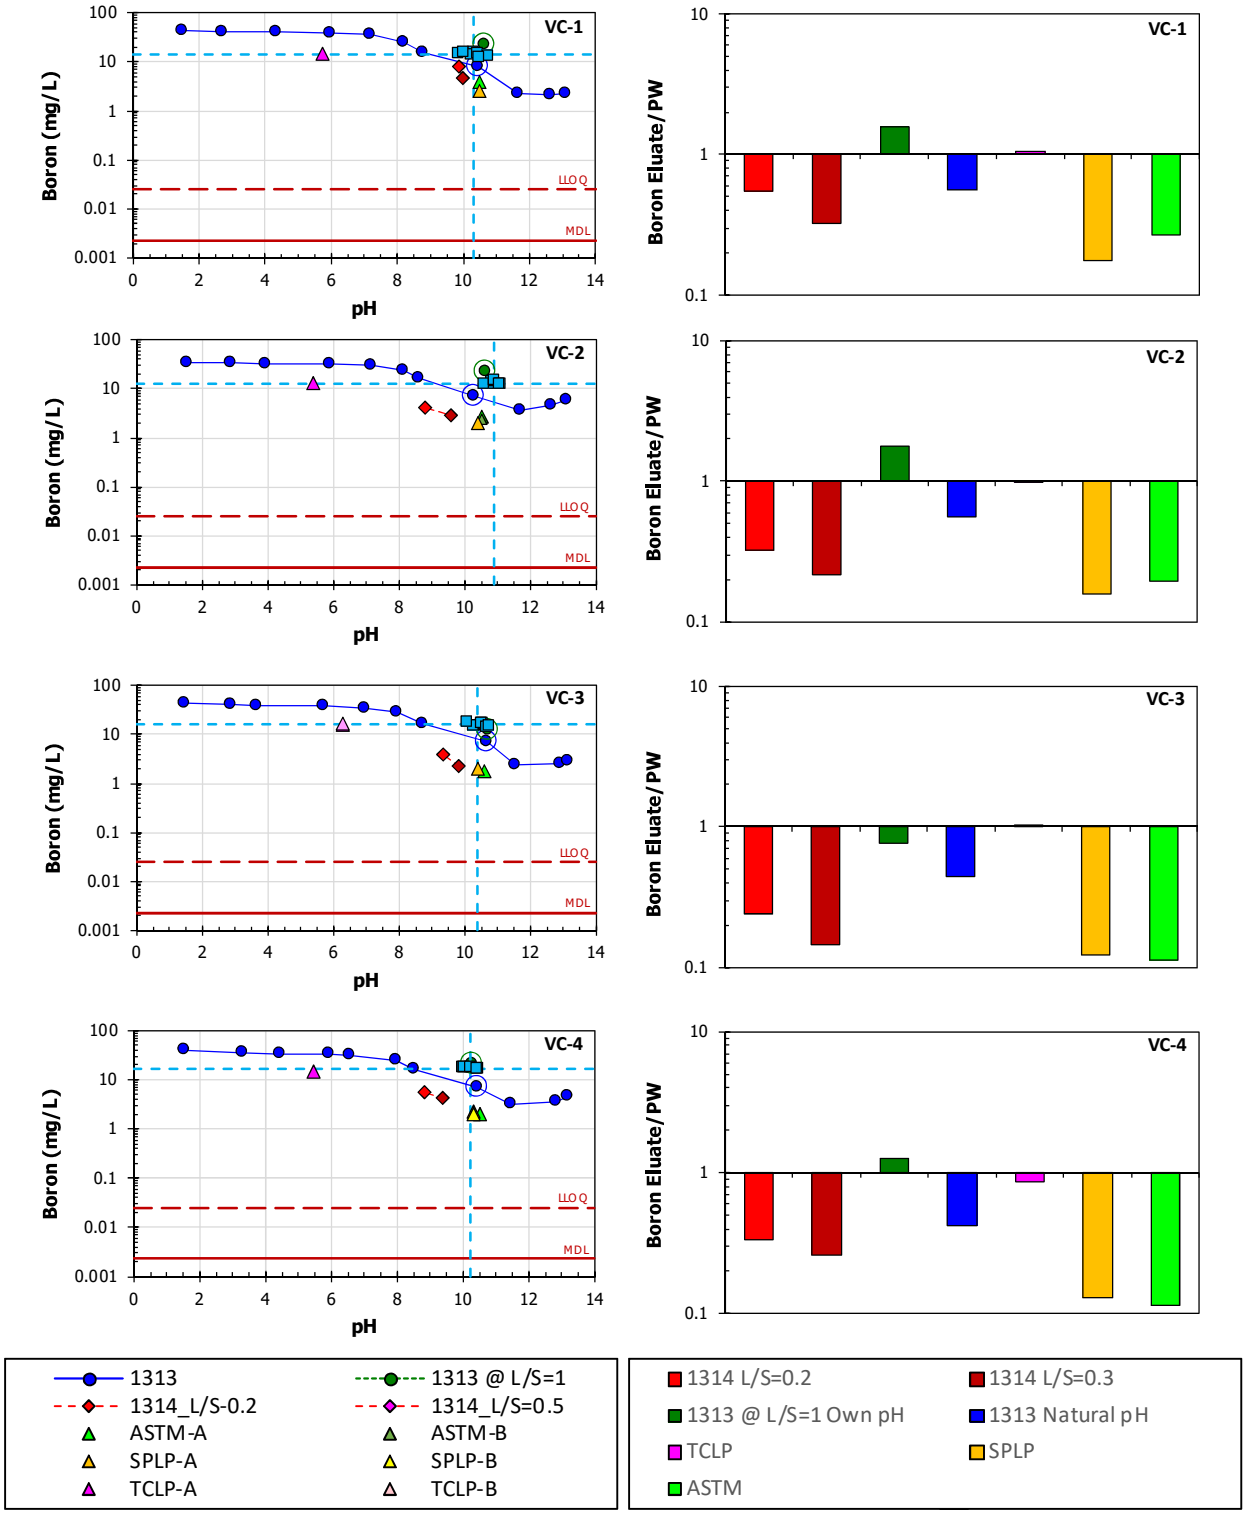

Figure 7-10
Boron concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right)

Of the 30 evaluated constituents, only chromium compared poorly to all of the leaching test concentrations. The porewater concentrations of Cr were less than the analytical MDL of 0.000053 mg/L in all four PAPs, while leaching tests returned concentrations between 0.001 and 0.1 mg/L (Figure 7-11). Subsurface gas measurements indicated a deficit of oxygen (Figure 7-7) without generation of carbon dioxide (Figure 7-8) or significant methane (Figure 7-9), which suggests suboxic conditions. Under these conditions, Cr is reduced to Cr(III), which would be insoluble at the porewater pH conditions. When samples are collected from the field, homogenized in the laboratory, and exposed to laboratory conditions during testing, the material oxidizes enough to convert a portion of Cr(III) to Cr(IV), leading to increased chromium concentrations in leaching test eluates. Conversely, arsenic, also a redox-sensitive constituent, is predicted within an order of magnitude in all leaching test approximations (Figure 7-12). The ability of leaching tests to approximate arsenic concentrations in the porewater is most likely due to the speciation of arsenic and the subsurface conditions. In literature, arsenic retained in fly ash as calcium-arsenate and arsenate hematite was less susceptible to changes due to redox conditions (Deonarine et al., 2016). In addition, the subsurface conditions here, while suboxic, are not sufficiently reducing to be affected by short-term exposures of the solid materials to oxygen in laboratory leaching tests.

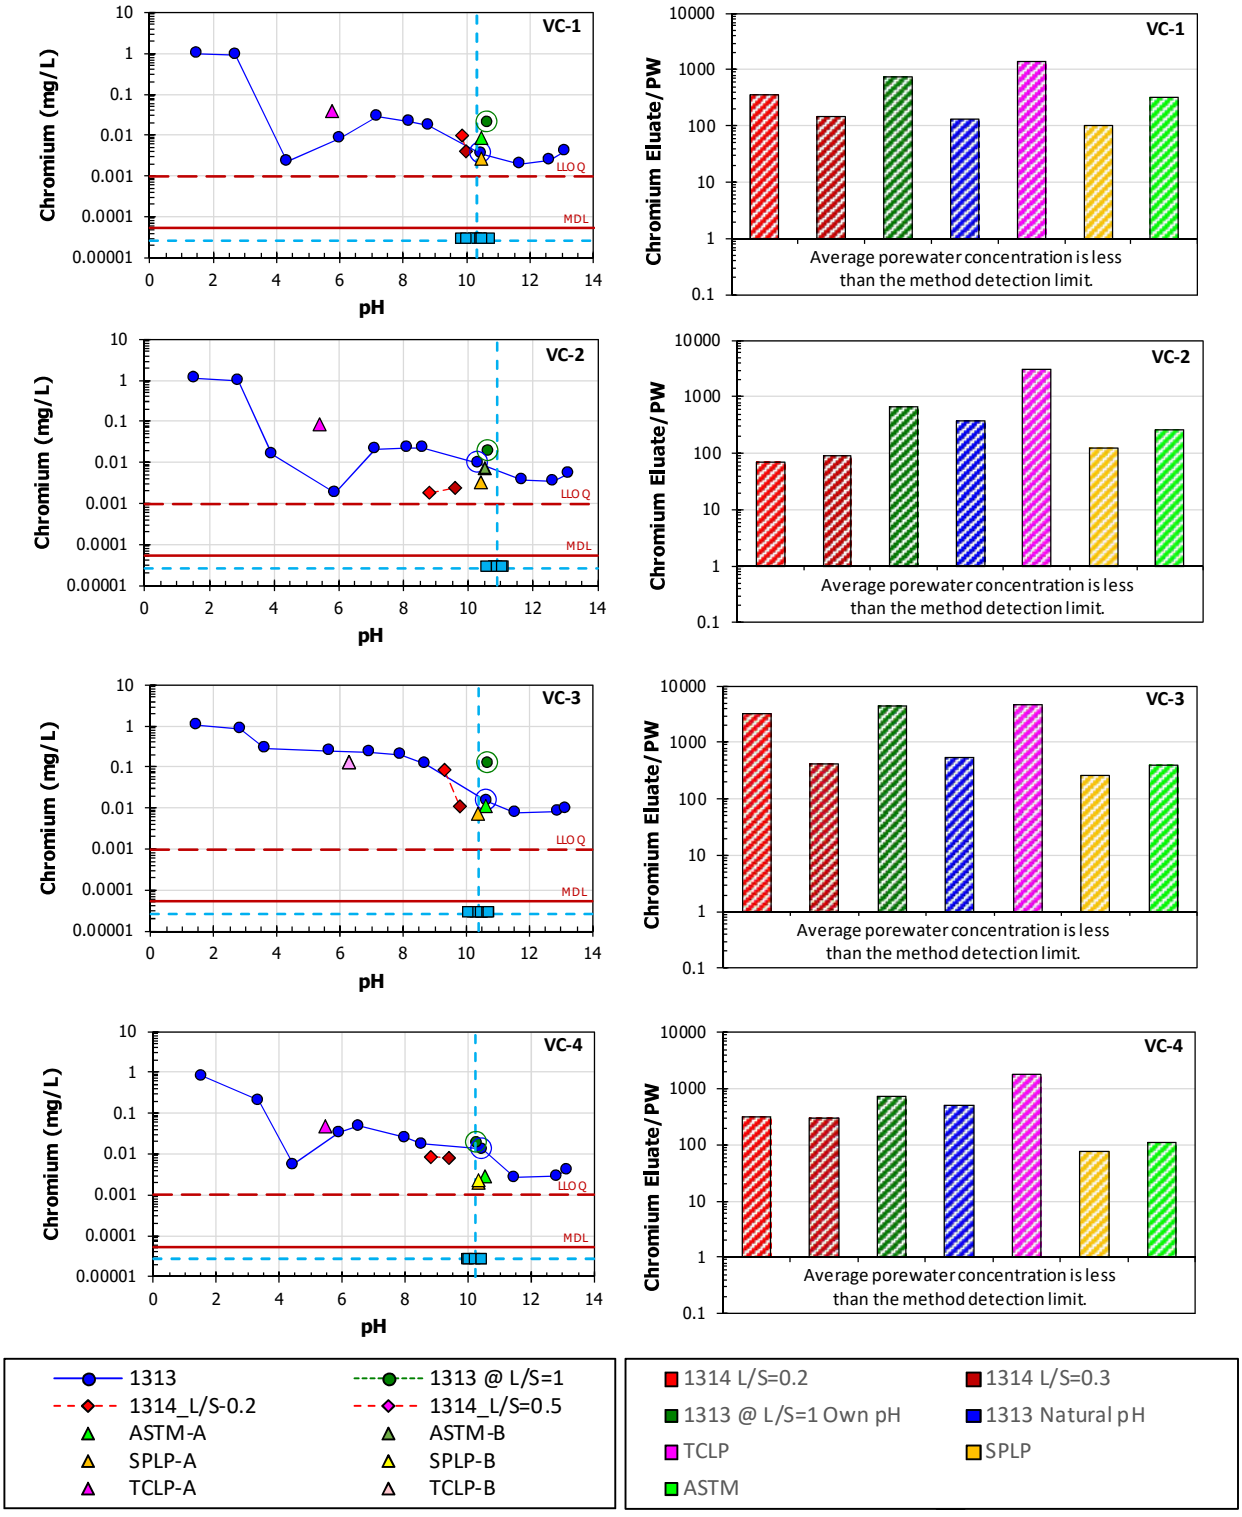

Figure 7-11

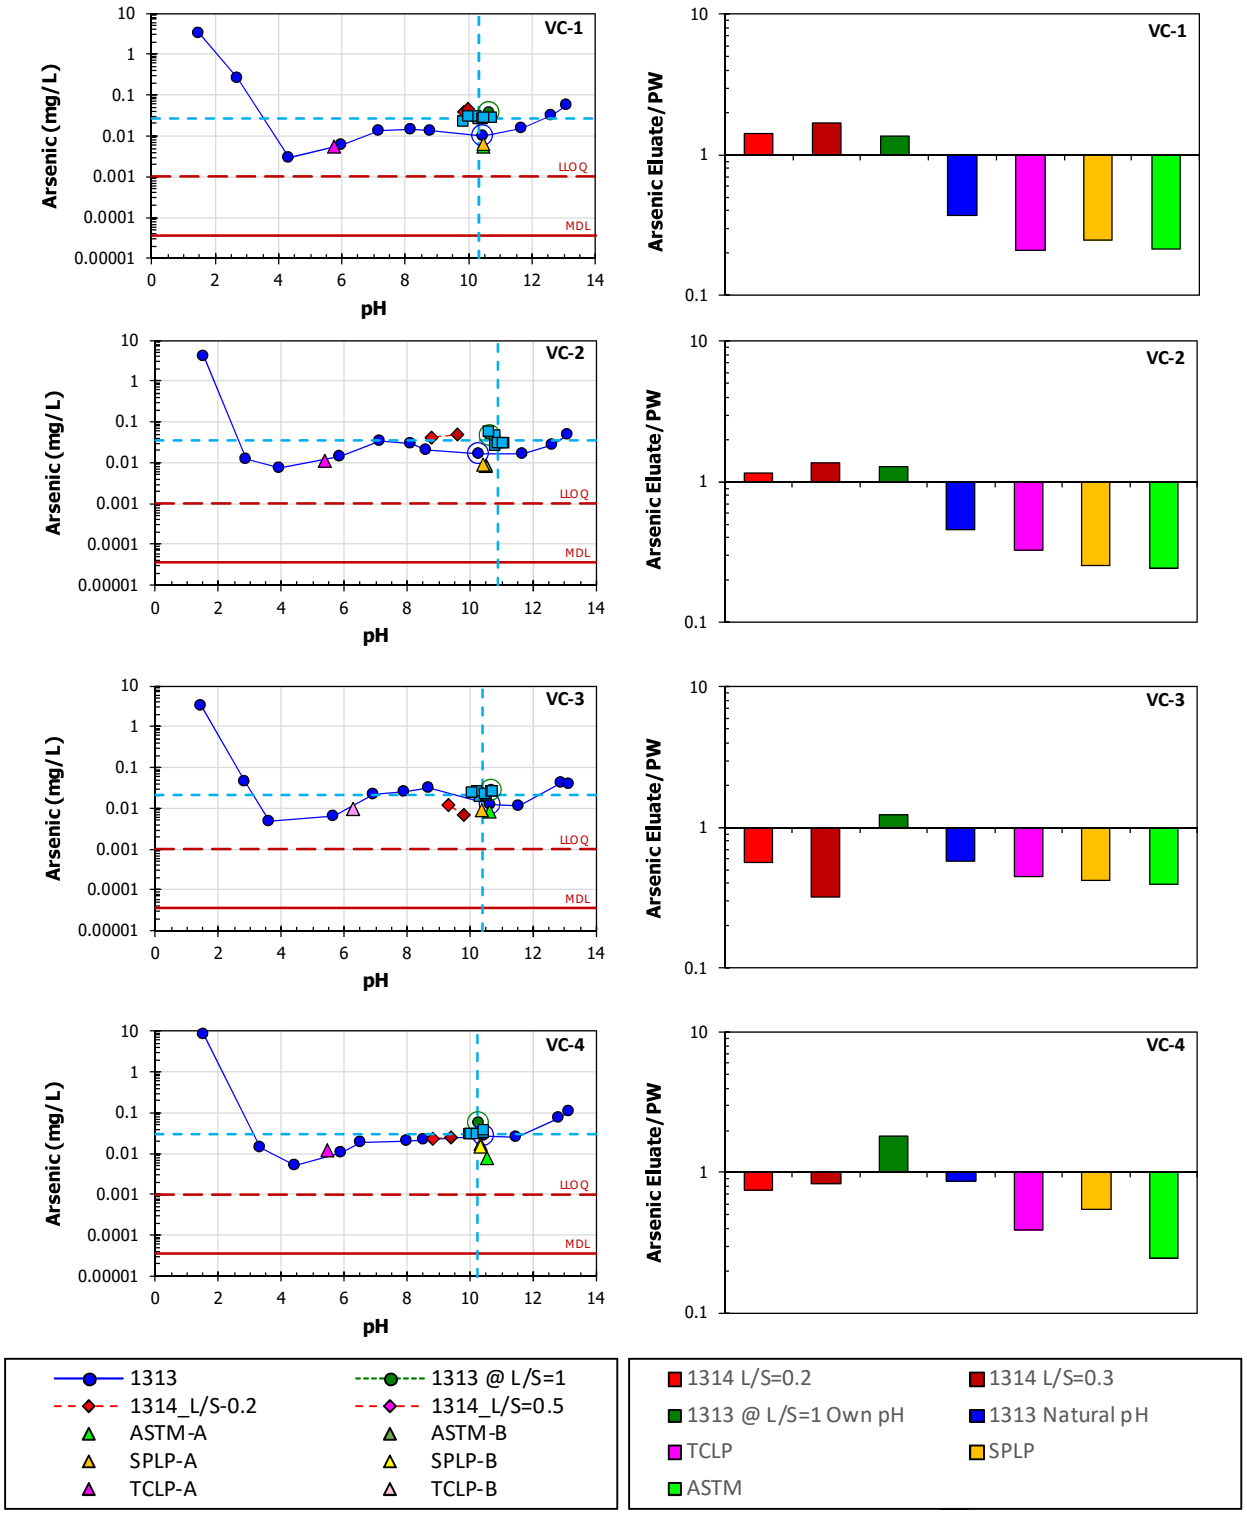

Figure 7-12
Arsenic concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right)

A qualitative summary of the ability of different leaching tests to estimate the measured porewater concentrations at each of the PAPs is shown in Table 7-2 for constituents with solubility-controlled LSP, Table 7-3 for constituents with wash-off followed by solubility control, Table 7-4 for constituents with available content-limited LSP, and Table 7-5 for constituents with non-detected data. In these tables, shading is used to indicate if the leaching test estimate is within 25% of the mean porewater concentration (green), within an order-of-magnitude of the mean porewater concentration (orange), or greater than an order-of-magnitude from the mean porewater concentration (red). These classifications are based on a percentage difference:

$$\%D = \frac{(z - PW)}{PW}$$

where %D is the percentage difference between leaching and porewater concentrations;
z is the leaching tests concentration (mg/L); and
PW is the mean porewater concentration from monthly PAP monitoring (mg/L).

When "GW <MDL" appears in the Notes column, the mean porewater concentration was less than the analytical MDL. Within the field of the table, an asterisk is used to indicate that the leaching test results were less than the MDL.

These tables provide an overview of the ability of leaching tests, conducted on materials collected from a suboxic environment and tests at mildly oxidizing conditions in a laboratory setting, to estimate porewater concentrations. This comparison indicated that the ability of leaching tests, conducted under specific test conditions, to predict porewater concentration varied by constituent and test. While no single leaching test consistently predicted concentrations within 25% of porewater concentrations for all constituents, the following observations were made:

- TCLP tends to over-predict porewater concentrations in alkaline ash (average pH_{nat}~10.4) by more than an order-of-magnitude for many constituents, in part, due to the pH (pH~5) imposed by the acetic acid leaching solution;
- EPA 1313, ASTM, and SPLP were usually within an order-of-magnitude for the solubility-controlled constituents where pH is the critical factor in LSP concentration and the leaching solution (i.e., deionized water for EPA 1313 at natural pH and ASTM, weak acid solution for SPLP) does not significantly alter eluate pH;
- EPA 1313 (L/S=10 L/kg-dry), ASTM (L/S~30 L/kg-dry), and SPLP (L/S~30 L/kg-dry) often under-predicted porewater concentrations by more than an order-of-magnitude for available content-controlled constituents because of the high L/S ratio relative to porewater L/S (0.35 L/kg-dry); and,
- EPA 1313_L/S=1 and low L/S 1314 column fractions usually yielded results within an order-of-magnitude of the porewater concentrations for both solubility-controlled and available content-controlled constituents.

When summarized by constituent, leaching test predictions *typically*:

- Over-predicted porewater concentrations for Sb and Cr;

- Under-predicted porewater concentrations for Ba, B, Cd, Ca, Cl^-, DOC, Li, Mo, Ni, K, Na, Sr, and SO_4^{-2};
- Over-predicted at L/S=0.2 and under-predicted at higher L/S for Co;
- Over-predicted at L/S<1.0 and under-predicted at higher L/S for P;
- Over-predicted at L/S<=1.0 and under-predicted at higher L/S for V; and,
- Did not consistently over- or under-predict porewater concentrations for As, Cu, DIC, Fe, Se, Tl, and Zn.

The above constituent evaluation does not include TCLP tests where leaching concentrations were primarily higher than porewater or those constituents where eluates and porewater concentrations were both usually less than MDL (i.e., Be, Br^-, F^-, Pb, and Ag).

The results of this qualitative summary should not be used without consideration of the redox conditions of the field and should always be shown along with the graphical data (e.g., Figure 7-10 through Figure 7-12) that indicate the pH result for the tests. For example, the table indicates that TCLP would provide a good estimate of porewater concentration for B; however, this is somewhat of a coincidence because the pH of TCLP is more than four pH units less than the natural pH of the ash.

SUMMARY OF OBSERVATIONS

The data presented in this report represent the results of geotechnical, hydrologic, and leaching characterization of samples of coal ash collected from an active CCP management unit at Plant 42197. The hydraulic conductivity of intact cores from the coal ash deposit was measured in context of the distribution of particles in the coal ash samples and the overburden pressure associated with disposal at depth within the coal ash deposit. The leaching test results for LEAF tests (i.e., EPA Methods 1313 and 1314) were compared to the results for traditional tests (i.e., ASTM, TCLP, and SPLP). In addition, porewater estimates derived from leaching tests were compared to measured porewater concentrations, and measured porewater concentrations were compared to groundwater concentrations.

Based on the presented data and analysis, the following general observations can be made:

- Despite differences in coal ash placement (dry-handled ash in the upper portion and wet-handled ash in the lower portion), ***there was little observed variability in vertical concentration profiles***. This observation, in combination with initial concentration from percolation column test results, suggest that infiltration moving through the unsaturated dry-handled ash (e.g., from precipitation, liquid dumps, water spray for dust management) results in migration of readily dissolved constituents from the dry-handled material into the underlying wet-handled coal ash. ***Downward movement of soluble constituents results in the pH and porewater composition within the saturated material similar to the low L/S extraction fractions of composited dry material***.
- The ratio of the available content to the total content shows that ***only a small fraction of total content of most trace constituents is leachable*** over a broad pH range.
- ***Suboxic to anoxic conditions are established at relatively shallow depths (> 5 m) below the ground surface of the dry-handled material***. Oxygen penetration from the surface is limited because of abiotic and biotic reactivity of the freshly deposited fly ash in conjunction with pore filling due to water additions to maintain dust control and compaction of additionally added materials (e.g., bottom ash) for structural workability (truck access).
- ***The high pH within the porewater of deposited material prevents development of significant microbial activity at depths greater than 5 m below the ground surface*** (or potentially even at shallower depths). This is in contrast to observations in some impoundments of only wet-handled material (EPRI, 2020), which showed nearly neutral porewater pH and indicators of robust microbial reduction of iron and sulfate along with methanogenesis.
- ***Hydraulic conductivity of the ashes typically was within the range of 10^{-5} to 10^{-6} cm/s***, with the lower hydraulic conductivities corresponding to higher dry unit weight. Fines content and 2-mm clay content had no consistent influence on hydraulic conductivity, in contrast to

previous experience (EPRI, 2020). Hydraulic conductivity diminished as the effective stress increased, but only modestly.

- ***Some parameters in the PAP porewater (e.g., pH, temp, B, Co, Ni, and Zn) exhibited temporal variability*** due to factors such as seasonal changes or impacts of damage and repair of porewater access points. Other constituents remained relatively constant within each porewater access point throughout the 8-month monitoring period. ***Spatial variability was observed for some constituents between PAPs; however, no consistent pattern was observed***. With the exception of Cu and Zn, concentrations between PAPs were within an order of magnitude.
- There were insufficient data from limited collection points to identify relationships between porewater and downgradient groundwater concentrations. For example, no upgradient groundwater well was identified to provide groundwater conditions in the flow path prior to the landfill. ***The limited data collected from downgradient monitoring wells and PAPs suggest that porewater concentration alone is an unreliable indicator that a constituent has had an impact on elevated groundwater concentrations or for prediction of downgradient concentrations at this site***.
- Traditional leaching tests, such as TCLP, SPLP, and ASTM, are poorer indicators of measured porewater concentrations than LEAF tests. ***Low liquid-to-solid ratio (L/S) eluates from EPA Method 1314 are better indicators than the traditional tests and EPA 1313 for concentrations for available content-limited constituents (e.g., B, Cd, Cl^-, Mo, Se, and SO_4^{-2}) because of the strong L/S-dependence.*** The data presented here showed that the traditional tests, with an L/S greater than 20 L/kg-dry, and EPA 1313 at L/S=10 L/kg-dry often under-predicted field porewater concentrations by an order of magnitude or more. These results indicate that additional information (e.g., available content and porewater L/S) is needed to provide a reasonable approximation of porewater concentrations. ***For constituents with solubility-controlled liquid-solid partitioning (e.g., As, Sb, and Tl), EPA 1313 tests at L/S=1 L/kg-dry provide an estimate of porewater concentrations generally within a factor of 2.*** The combination of pH-dependent leaching data (EPA 1313) with percolation column test results (EPA 1314) provides valuable information for geochemical modeling.
- For field environments that are oxidizing to slightly reducing, leaching test data usually approximated field porewater concentrations of solubility-controlled constituents within an order of magnitude. ***Because of the oxic to suboxic subsurface conditions at this site, sampling, laboratory handing, and testing conditions did not appear to significantly influence the redox condition of the field material.*** This is in contrast to impoundments with highly reducing subsurface conditions, where material handling in the presence of oxygen during sampling and laboratory testing can significantly impact test results. The only constituent not well defined by any of the LEAF tests was chromium, the result for which may have been influenced by oxidization of materials during collection from a suboxic environment and testing in an oxic laboratory. The leaching results for chromium indicate that laboratory testing results for redox-sensitive elements (e.g., As, Cr, Sb, Se, V) may not directly reflect the leaching anticipated in porewater when the field environment is highly reducing, in part due to oxidation incurred during sampling, handling, and testing.

ANALYTICAL QA/QC REPORTS

Analytical QA/QC reports are maintained as electronic files available upon request to EPRI.

Electronic Filing: Received, Clerk's Office 07/01/2024

Export Control Restrictions

Access to and use of this EPRI product is granted with the specific understanding and requirement that responsibility for ensuring full compliance with all applicable U.S. and foreign export laws and regulations is being undertaken by you and your company. This includes an obligation to ensure that any individual receiving access hereunder who is not a U.S. citizen or U.S. permanent resident is permitted access under applicable U.S. and foreign export laws and regulations.

In the event you are uncertain whether you or your company may lawfully obtain access to this EPRI product, you acknowledge that it is your obligation to consult with your company's legal counsel to determine whether this access is lawful. Although EPRI may make available on a case by case basis an informal assessment of the applicable U.S. export classification for specific EPRI products, you and your company acknowledge that this assessment is solely for informational purposes and not for reliance purposes.

Your obligations regarding U.S. export control requirements apply during and after you and your company's engagement with EPRI. To be clear, the obligations continue after your retirement or other departure from your company, and include any knowledge retained after gaining access to EPRI products.

You and your company understand and acknowledge your obligations to make a prompt report to EPRI and the appropriate authorities regarding any access to or use of this EPRI product hereunder that may be in violation of applicable U.S. or foreign export laws or regulations.

The Electric Power Research Institute, Inc. (EPRI, www.epri.com) conducts research and development relating to the generation, delivery and use of electricity for the benefit of the public. An independent, nonprofit organization, EPRI brings together its scientists and engineers as well as experts from academia and industry to help address challenges in electricity, including reliability, efficiency, affordability, health, safety and the environment. EPRI also provides technology, policy and economic analyses to drive long-range research and development planning, and supports research in emerging technologies. EPRI members represent 90% of the electricity generated and delivered in the United States with international participation extending to nearly 40 countries. EPRI's principal offices and laboratories are located in Palo Alto, Calif.; Charlotte, N.C.; Knoxville, Tenn.; Dallas, Texas; Lenox, Mass.; and Washington, D.C.

Leaching, Geotechnical, and Hydrologic Characterization of Coal Combustion Products from a Closed Coal Ash Impoundment: Capped Unit. EPRI, Palo Alto, CA: 2020. 3002017363.

Electronic Filing: Received, Clerk's Office 07/01/2024

ABSTRACT

The appropriate use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field.

This report presents the results of geotechnical, hydrologic, and leaching characterization of samples collected from a closed and capped coal ash impoundment. The hydraulic conductivity of intact cores from the pond was measured in context of the distribution of particles in the coal ash samples and the overburden pressure associated with disposal at depth within the pond. The leaching test results for LEAF tests (i.e., EPA Methods 1313 and 1314) were compared to those for traditional tests (i.e., ASTM, TCLP, SPLP). In addition, concentrations derived from leaching tests were compared to porewater concentrations determined from field samples, and field-sampled porewater concentrations were compared to groundwater concentrations, to evaluate similarities and dissimilarities between these results.

EXECUTIVE SUMMARY

Deliverable Number: 3002017363

Product Type: Technical Report

Product Title: Leaching, Geotechnical, and Hydrologic Characterization of Coal Combustion Products from a Closed Coal Ash Impoundment: Capped Unit

PRIMARY AUDIENCE: Electric utility environmental professionals responsible for landfill and impoundment management of CCPs.

SECONDARY AUDIENCE: Researchers and regulators interested in CCP leaching and chemistry.

KEY RESEARCH QUESTION

The appropriate use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field. The goals of this research were (i) to evaluate approaches for estimating porewater concentrations at CCP disposal facilities, and (ii) to explore potential connections between the CCP leaching performance of a disposal facility, based on porewater measurements or leaching tests, and monitoring of groundwater exterior to the facility.

RESEARCH OVERVIEW

Coal ash samples were collected at three locations from a closed and capped disposal impoundment. During field activities, porewater access and subsurface gas access points were established and monitored for 13 months. Collected solids were characterized for leaching and geotechnical/hydrologic properties. The hydraulic conductivity of intact cores was measured in context of the distribution of particle sizes in the coal ash samples and the overburden pressure associated with disposal at depth within the pond. The leaching test results for the Leaching Environmental Assessment Framework (LEAF) (i.e., EPA Methods 1313 and 1314) were compared to those for traditional tests (i.e., ASTM, TCLP, and SPLP). In addition, leaching test results were compared to porewater concentrations determined from field samples, and field-sampled porewater concentrations were compared to groundwater concentrations, to evaluate similarities and dissimilarities between these results.

KEY FINDINGS

- The hydraulic conductivity of intact ash samples is strongly dependent on the fraction of fines in the material. The measured hydraulic conductivity of finer, less permeable coal ash samples was lower (ranging from approximately $7x10^{-4}$ cm/s to $1x10^{-5}$ cm/s) than the hydraulic conductivity of coarser, more permeable samples (approximately $1x10^{-3}$ cm/s). In general, the measured hydraulic conductivity decreased with increasing effective stress, or overburden pressure; however, the hydraulic conductivity of coarser, more permeable coal ash samples decreased three times as much as that of finer, less permeable coal ash.

Electronic Filing: Received, Clerk's Office 07/01/2024

- The subsurface gas measurements and concentrations of redox-sensitive constituents in field porewater samples suggest that reduction-oxidation conditions of the closed disposal impoundment were more bio-chemically reduced than indicated by porewater analysis alone. Monitoring of subsurface gas concentrations shows the presence of hydrogen sulfide and methane, indicating strongly reducing conditions. Monthly data indicate that reducing conditions are spatially variable in extent and may be seasonally dependent. In addition, arsenic concentrations in the porewater are at the high end of previously reported ranges for coal ash. At intermediate reducing conditions, elevated concentrations of arsenic are likely due to loss of hydrous ferric oxides as ferric oxides are reduced and solubilized (conversion of insoluble Fe^{3+} to soluble Fe^{2+}). Under very low redox conditions, arsenic porewater concentrations decrease due to conversion of As(V) to As(III) and likely precipitation as sulfides. Conversely, the porewater concentrations of antimony and selenium in the reduced pond environment are suppressed due to formation of reduced species with lower solubility.
- Traditional leaching tests (i.e., TCLP, SPLP, and ASTM) are poor indicators of measured porewater concentrations. Low liquid-to-solid ratio (L/S) eluates from EPA Method 1314 were better indicators than the traditional tests for concentrations for available content-limited constituents (B, Ca, Cl, Mo, SO_4, Tl) because of the strong L/S-dependence. However, additional information (e.g., available content and porewater L/S) would be needed to provide a reasonable approximation of porewater concentrations. For constituents with solubility-controlled liquid-solid partitioning (Sb, As, Ba, Cr, F^-, Se, V, Zn), pH-dependence tests (e.g., EPA Method 1313) may provide valuable information for geochemical modeling, but, for this site, the natural or own pH responses did not reliably estimate field porewater concentrations, in part due to differences in redox as noted in the next bullet.
- When the field environment is highly reducing, laboratory leaching results for redox-sensitive elements (e.g., As, Cr, Sb, Se, and Fe) do not directly reflect the leaching anticipated in porewater. This is, in part, because reduced materials collected in the field are inevitably partially oxidized during sampling, handling, and testing.
- Porewater concentrations were not a reliable indicator for which constituents would have elevated concentrations, relative to background, in downgradient groundwater or for future prediction of downgradient concentrations at this site.

WHY THIS MATTERS

This research provides a unique opportunity to compare a field porewater sample set to laboratory leaching test results on samples collected from the same location and depth interval as the porewater sampling point and provides information to guide appropriate use of these tests. It also provides information on, and comparison of, the spatial and temporal/seasonal variability in both porewater quality and laboratory leachate quality at a CCP site. Data collected during this research will inform EPRI physical and geochemical modeling of leaching within coal ash landfills and impoundments.

HOW TO APPLY RESULTS

The results of this research are site-specific, yet when considered with known differences in L/S associated with different leaching tests, and geochemical differences between the field and laboratory environment, they provide information for generalizing the best uses of different leaching tests and porewater data. Companies interested in performing similar comparisons between leaching tests and porewater will be interested in the

Electronic Filing: Received, Clerk's Office 07/01/2024

field and laboratory methodologies described in Sections 2 and 3. Companies and stakeholders interpreting leaching test and porewater results will be interested in the results summarized in Sections 4 and 5, as well as the detail provided in Appendices C through G.

LEARNING AND ENGAGEMENT OPPORTUNITIES

- A framework using geochemical modeling and porewater data to predict long-term leaching at CCP sites is being developed under EPRI Program 49A's hydrogeochemistry project. A series of reports published from 2018 through 2020 describe results of this research. These reports can be accessed by searching epri.com for "Hydrogeochemical Assessment of Long-Term Leaching Characteristics at Coal Combustion Product Sites."
- Stakeholders, including regulatory agencies, reviewing leaching test analyses may be interested in results of this research to understand the relationship between the different leaching tests, and the relationship between leaching tests and porewater within CCPs.

1 INTRODUCTION

The appropriate use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is highly dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field. For example, traditional leaching tests, including EPA Method 1311: Toxicity Characteristic Leaching Procedures (TCLP), EPA Method 1312: Synthetic Precipitation Leaching Procedure (SPLP), and ASTM D3987: Shake Extraction of Solid Waste with Water (ASTM), provide only a snapshot of leaching performance under conditions that often deviate substantially from current conditions and anticipated future field conditions.

In 2012, the United States Environmental Protection Agency (EPA) published four leaching methods from the Leaching Environmental Assessment Framework (LEAF) as draft methods available for use. The four methods have since been validated (Garrabrants et al., 2012a; 2012b) and incorporated as final methods into the Agency's compendium of laboratory methods (SW-846). The four LEAF methods are:

- EPA Method 1313: Liquid-Solid Partitioning as a Function of Eluate pH Using a Parallel Batch Procedure
- EPA Method 1314: Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using an Up-Flow Percolation Column Procedure
- EPA Method 1315: Mass Transport Rates of Constituents in Solid Materials Using a Tank Leaching Procedure
- EPA Method 1316: Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using a Parallel Batch Procedure

The LEAF approach differs from traditional leaching assessment methodologies in that the leaching tests are designed to provide a series of eluates characteristic of leaching behavior dependent on one or more controlling factors rather than a single eluate that is representative of field leachate from a designed scenario. The EPA has provided a guide for how LEAF tests may be incorporated into common leaching assessment practices (EPA 2019, Garrabrants et al., 2019a, 2019b).

There remains uncertainty as to the selection of specific test methods to represent (i) the range of pH and liquid-to-solid ratio (L/S) within a waste mass and (ii) the current and long-term geochemical conditions of the porewater of CCP impoundments and landfills. Thus, leaching

tests have been widely applied, but often without consideration of their inherent limitations for providing information suitable for evaluation of long-term leaching performance. In addition, little information is available that directly compares measured field porewater concentrations at CCP disposal sites to the results of various leaching test results.

The Electric Power Research Institute (EPRI), Vanderbilt University (VU), and University of Virginia (UVA) collaborated on a study to evaluate relationships between the geochemistry of the disposed CCPs and the measured and predicted concentrations for inorganic constituents in the porewater of CCP disposal units. In addition, this study investigates the potential relationship between porewater concentrations and the concentrations in groundwater measured at adjacent monitoring wells. CCP materials were collected from two disposal sites. During field activities, porewater access and subsurface gas access points were established for eight to twelve months of monthly monitoring. Collected materials were characterized for leaching and geotechnical/hydrologic properties. A framework for integrating these data is being developed under a separate EPRI project. This report provides the methodology for sampling and characterization of disposed CCPs collected from a closed ash impoundment at Plant 42201, also referred to as "KSP." This report summarizes the results of leaching tests and monitoring data with respect to groundwater and impoundment porewater collected at the facility as well as vadose zone subsurface gas concentrations monitored within the impoundment.

Project Goals and Objectives

The goals of this research were (i) to evaluate approaches for estimating porewater concentrations at CCP disposal facilities, and (ii) to explore potential connections between the CCP leaching performance of a disposal facility, based on porewater measurements or leaching tests, and monitoring of groundwater exterior to the facility.

The specific objectives of this project include:

- Collecting field materials to qualify the spatial and temporal variability of materials disposed in the closed impoundment and to allow for characterization of leaching and geotechnical/hydrologic property determination.
- Correlating the characterization of leaching from bulk samples using traditional leaching tests (i.e., TCLP, SPLP, and ASTM) and LEAF pH- or L/S-dependence leaching tests with measured porewater concentrations monitored at the site.
- Assessing the ability of leaching tests (traditional or LEAF tests) to directly estimate porewater concentrations within the closed impoundment.
- Identifying the relationship, if any, between porewater concentrations within the closed impoundment and downgradient groundwater concentrations.

Site Description

The closed impoundment, represented in Figure 1-1a, is a triangular 25-acre area divided from a larger coal ash landfill constructed in the 1950s. The impoundment was used to collect storm water and process water from Plant 42201 before discharge into an adjacent river. Between 2012 and 2015, the impoundment received sluiced CCPs from the plant. In 2016, the inactive impoundment was closed, with the closure project completed approximately one month prior to

the field collection of field samples and establishment of groundwater sampling points. The closure project involved removal of free water from the impoundment, regrading of the coal ash to level the surface, and installation of a composite geosynthetic soil cover system as illustrated in Figure 1-1b. The cover is typically about 5 feet thick; however, the thickness of the cover system varies based on the ash layer elevations. At the time of the field investigation, phreatic porewater occurred approximately 6 feet below the surface of the ash layer. At the center of the impoundment, the ash layer is approximately 20 feet thick.

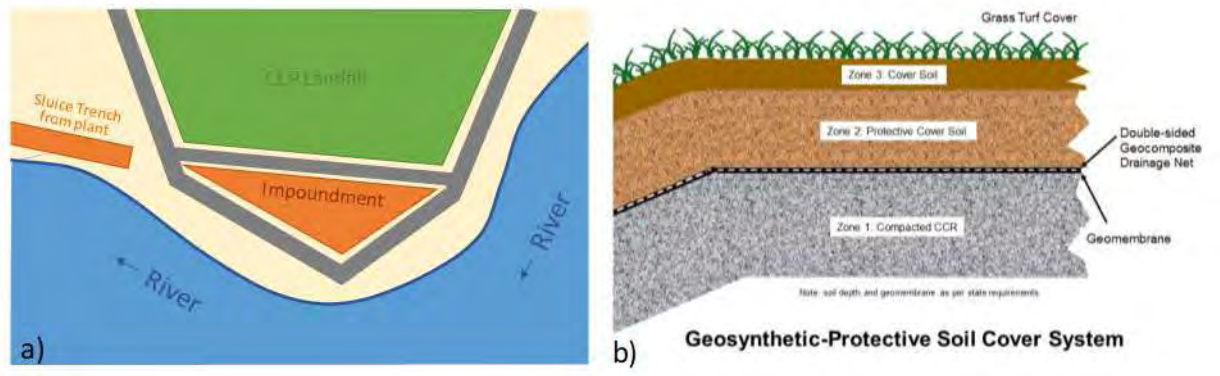

Figure 1-1
Schematic representations of the KSP closed impoundment: a) plan view of impoundment relative to the adjacent coal ash landfill and river; b) cross-section of typical geosynthetic soil cover

Sampling and Testing Approach

Fieldwork for this project included: (i) advancement of boreholes into the coal ash deposit to improve the understanding of stratigraphy and to sample contained solids (i.e., ash, cover fill, and native clay liner); (ii) installation of porewater access points (PAPs) and subsurface gas access points (GAPs) within boreholes in the ash deposit; and (iii) monthly sampling of groundwater and porewater and subsurface gas compositions. At each of three locations within the closed impoundment, bulk ash samples were collected from continuous split spoon sampling to evaluate the constituency of material in the ash deposit and leaching properties of the collected ash. In parallel, intact ash cores were collected to determine geotechnical characteristics and hydraulic conductivity of the disposed ash. At monthly intervals after the completion of initial field work, porewater was collected from each PAP along with groundwater collection at upgradient (background) and downgradient wells to provide points of comparison to porewater samples.

Characterization of leaching properties was carried out by personnel in the Department of Civil and Environmental Engineering at VU. Leaching characterization tests included EPA Method 1313 to determine leaching behavior as a function of eluate pH, EPA Method 1314 to evaluate L/S-dependent leaching from a percolation column, and a trio of single-batch extraction tests (i.e., TCLP, SPLP, and ASTM). For all leaching tests, the pH of all eluates was measured and recorded so that comparisons could be made between leaching evaluations. The reported constituents include most of those found in the Code of Federal Regulations, Title 40, Section 257 (40 CFR 257), Appendix III for detection monitoring and Appendix IV for assessment monitoring, as well as several additional constituents as listed in Table 3-3, Table 3-4, and Table

3-5 of this report. Relative to 40 CFR 257 App III and IV, a broader suite of approximately 40 constituents was quantified to provide a comprehensive basis for geochemical modeling of leaching test results. Although listed in 40 CFR 257 App III and IV, radium and total dissolved solids were not analyzed.

The geotechnical and hydrologic properties of intact core samples were determined at the School of Engineering at UVA. Hydraulic conductivity of intact samples was measured using flexible-wall permeameters following the methods in ASTM D5084. Tests were conducted over a range of effective stresses to evaluate how hydraulic conductivity varies with packing configuration and overburden found at depth. Particle size analysis was conducted on each sample using the methods in ASTM D6913 to understand how the hydraulic conductivity varies with the composition of the ash.

At UVA, a complementary series of tests to that of EPA Method 1314 was conducted on undisturbed samples collected in thin-wall sampling tubes for hydraulic conductivity testing in flexible-wall permeameters. Although the primary purpose of these tests was to measure the hydraulic conductivity of the coal ash samples, eluates collected from hydraulic conductivity testing served as a point of comparison to percolation leaching tests on composite samples according to EPA Method 1314. These tests on undisturbed samples in flexible-wall permeameters contrasted with conventional Method 1314 tests conducted on remolded (including partially oxidized) samples in rigid-wall columns, providing a direct assessment of the impacts of sample handling, column packing, and potential sidewall flow on percolation leaching. Additional discussion of these tests is included in the section on hydraulic conductivity test methods.

2
COLLECTION OF FIELD MATERIALS

Sample Locations

Ash, porewater, and gas samples were obtained at three boring locations (VB-1, VB-2, and VB-3). The approximate locations of these boreholes are shown in Figure 2-1 relative to the closed impoundment and the adjacent river. These locations were selected to be within the area of the closed impoundment and were considered to capture the vertical and horizontal heterogeneity of ash materials. When the impoundment was active, coal ash was sluiced from the main plant using process water into the impoundment near the location of VB-1. The water flowed toward VB-3 and onto the outfall to the river near location VB-2. Ash chemistry of the three locations is assumed representative of materials across the closed impoundment.

Figure 2-1
Schematic representation of the closed KSP ash impoundment, showing the approximate locations of three porewater access points (PAPs), VB-1, VB-2, and VB-3, and existing groundwater wells, 6AR and AD1 (out of frame).

Initial Site Sampling

The field sampling included continuous split spoon sampling to obtain bulk ash for leaching characterization and to provide an understanding of the ash deposit after closure, followed by discrete Osterberg sampling to obtain intact ash cores at approximate 5-ft intervals. All drilling

operations were conducted by a contracted drilling/engineering company. Prior to sampling, the top vegetation cover and geosynthetic cover in a 100-ft^2 area (10 ft by 10 ft) at each sampling location were removed by contractors. Bulk ash material was collected using 3-inch outside diameter (OD) x 24-inch long split spoons advanced through a 4.25-inch internal diameter (ID) hollow-stem auger (HSA) drilling a 9-inch diameter hole. Intact cores were collected at discrete depth intervals using thin-wall tube samplers pushed through an 8.25-inch ID HSA drilling a 13-inch hole. After the completion of the borings and installation of monitoring points, the geosynthetic cover was repaired and the cover fill replaced.

Bulk Material (Split Spoon Samples)

Split spoons were advanced from the upper cover-ash interface into the underlying native clay material (Table 2-1). Upon retrieval by the drilling contractor, each split spoon sample was opened and recorded by a licensed geologist and released to VU for documentation and collection. The borehole logs and an index with photographs of recovered split spoon material are provided in Appendix A and Appendix B, respectively. During field sampling, the activities included (i) preparation of ash extractions with de-oxygenated, deionized water (DIW) targeting an L/S of approximately 1 mL of water per estimated gram of dry ash and (ii) collection and preservation of bulk material for subsequent laboratory testing.

- L/S ≈ 1 Extractions: To protect the redox conditions of the sample and characterize the porewater composition for a screening analysis within each borehole, about 150-200 g of ash was placed into a certified, pre-tared 250-mL high-density polyethylene (HDPE) bottle (Nalgene I-Chem #N311-0250). The mass of the ash grab sample was measured and recorded. The bottle was filled with de-oxygenated DIW and weighed to quantify the mass of added water. The location of the ash grab sample within the split spoon was selected based on visual representativeness of ash.
- Bulk Ash Collection: Remaining ash from each split spoon was vacuum-sealed in plastic bags (Figure 2-2) and stored on ice for transport to the laboratory. To the extent possible, the bulk ash was maintained in its original split spoon shape and the top and bottom of the core were marked on the plastic bag.

Sample labels included “KSP” as a site identifier, the borehole number (VB-1, VB-2, or VB-3), and the depth below ground surface (BGS) from which the samples were taken. For example, the sample labeled “KSP_VB-3_15-17” in Figure 2-2 was collected from the split spoon at 15 to 17 feet BGS at borehole VB-3. For split spoons that penetrated an interface (e.g., between ash and the bottom native clay layer or between coal ash layers with visually different properties), the separate materials were collected as separate bulk samples in two vacuum-sealed bags. The upper portion was labeled with an “A” extension, while the lower portion was labeled with “B” at the same split spoon interval. All samples were preserved in coolers with ice and transported to the VU lab within 48 hours. During transport, the cooler temperature was monitored and recorded by an Elitech RC-5 USB temperature data logger. At the VU lab, all bulk materials were stored in an environmentally controlled room at 5 °C prior to processing for leaching tests.

a) 

b) 

Figure 2-2
Examples of split spoon cores: a) as recovered and photo-documented and b) vacuum-sealed bulk sample from borehole VB-3 (KSP_VB-3_15-17) preserved for testing

A schematic summary of the split spoon samples and the numbers of total samples preserved at each location are shown in Figure 2-3. In this figure, the depths BGS for each sample have been converted to elevations in feet above mean sea level (AMSL) after surveying of the PAP casings and ground elevations.

Intact Cores (Tube Samples)

Immediately following completion of the continuous split spoon borehole, the drilling rig was moved forward in its tracks 5 feet to advance an 8.25-inch HSA for push core sampling of ash. At each boring location, 3-inch OD by 36-inch long thin-wall tube samplers were pushed into the ash layer and obtained intact cores at intervals according to the observations from split spoon boring. The locations of the cores were targeted to collect samples across interfaces with the cover material and clay liner as well as major ash deposits within the ash column. Each recovered thin-walled tube was sealed at both ends using plastic expanding inserts, capped with plastic endcaps, and sealed with duct tape. The thin-walled tubes were vacuum-sealed in plastic bags and kept upright for transport. Sample identification was based on the interval BGS from which the samples were recovered. For example, the tube sampler recovered from the interval from 12 to 14.5 feet BGS at borehole VB-1 was labeled "VB-1_OST_12-14.5." The associated elevations for the three tube samples collected at each borehole are summarized in Table 2-1.

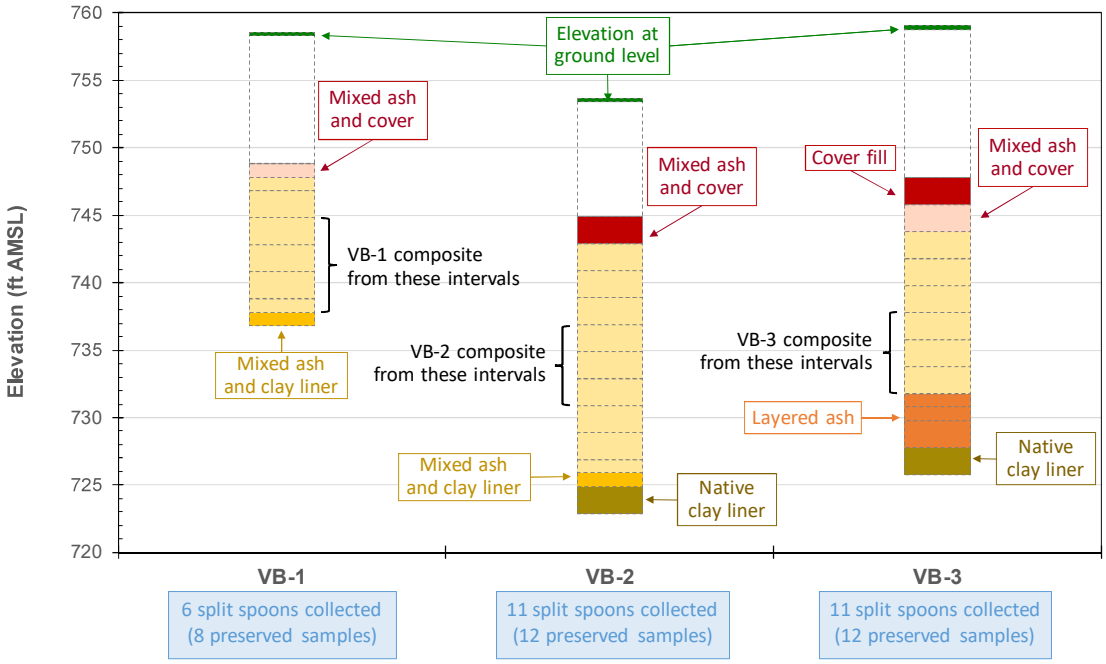

Figure 2-3
Collection of bulk material samples by split spoon, showing bulk samples composited around well screening levels

Porewater Access Points

Once the 8.25-inch ID HSA was advanced to the target depth for placement of the PAP, a 2-inch OD Schedule 40 PVC pipe was installed through the HSA. At each well location, the contractor installed a pre-packed, 2-foot screened section in agreement of the field team leads for VU, EPRI, and KSP after review of saturated zone observed for the continuous sampling borehole. Each 13-inch diameter borehole was backfilled with 1 foot of clean sand before the well screen was set, and after setting the screen, was backfilled with sand to 2 feet above the top of the well screen. The sand pack was sealed with bentonite clay pellets, and bentonite chips were used to backfill the borehole to within ½ foot of the GAP depth. Boring logs are presented in Appendix A.

Subsurface Gas Access Points

The composition of subsurface gas within the ash pond was sampled through GAPs set between 2 and 3 feet below the top of the ash deposit. Each GAP consisted of a ¼-inch diameter stainless steel tube set at depth within a 1-foot thick layer of round river rock and sealed from above and below with a 1-foot thick layer of expanded bentonite clay. The lower end of the GAP tubing was protected from rock, ash, and clay debris with an inverted steel cup. The stainless steel tubing was zip-tied to the PVC well and finished with a 2-way shutoff valve. The bed of river rock, nominal size of between ¾ inch and ¼ inch, ensures sufficient subsurface gas volume for measurement. A conceptual diagram and photograph are presented in Figure 2-4.

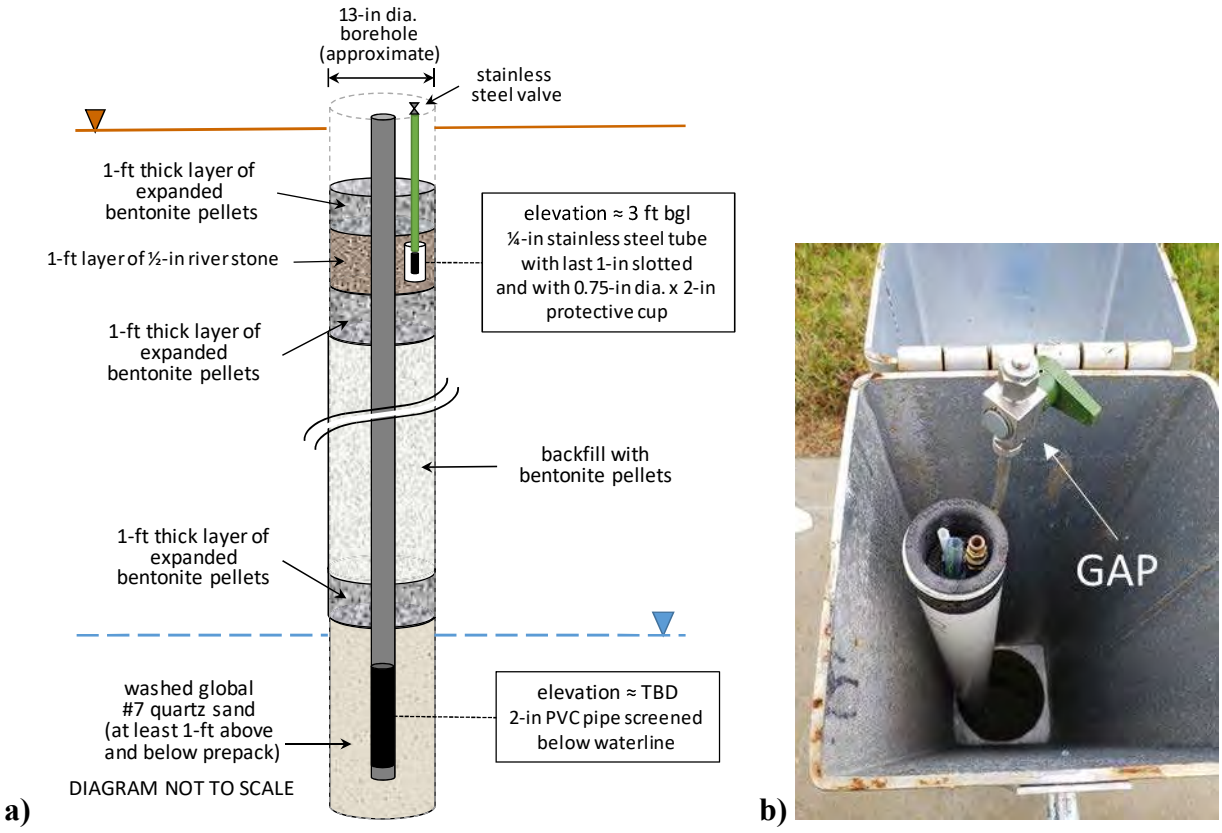

Figure 2-4
Porewater and gas access points: a) conceptual design of PAP and GAP installation and b) picture of installed PAP and GAP within a metal riser

Summary of Borehole Stratigraphy, Ash Collection, and PAP/GAP Installation

Within two weeks of field sampling, the drilling contractor installed dedicated pumps, developed the wells, and protected the borehole locations with a metal riser and concrete base. As part of this process, the horizontal location of the PVC riser, as well as the elevations of the well riser and ground level, were surveyed by a professional land surveyor. A summary of the elevation survey results and elevation of pertinent strata and sampling locations for the VB-1, VB-2, and VB-3 boreholes are tabulated in Table 2-1 and presented graphically in Figure 2-5 along with the stratigraphy for the upgradient background well (AD1) and downgradient compliance well (6AR).

Summary of the groundwater well and PAP elevations including pond stratigraphy and location of GAPs

Monthly Field Monitoring

Porewater and subsurface gases were monitored monthly at each PAP location over a 13-month period from September 2018 through September 2019. In addition, groundwater samples were analyzed from one upgradient (AD1) and one downgradient (6AR) monitoring well.

Collection of Groundwater and Porewater

Figure 2-1 shows the relative locations for the three installed PAPs (VB-1, VB-2, and VB-3) and the two existing groundwater sampling wells. Although the location of the upgradient well (AD1) is out-of-frame relative to this figure, the general direction of the well is indicated. KSP field personnel accessed each well, stabilized the well using low-flow sampling techniques according to company standard operating procedures, and allowed the VU field team access to the effluent line for collection of groundwater and porewater samples. At no time did the site owners' personnel retain custody of any samples used for this analysis.

The sampling flowrates for groundwater wells averaged approximately 150 mL/min and 300 mL/min for AD1 and 6AR, respectively. Porewater was sampled at approximately 50 mL/min to minimize drawdown of the water level in each PAP. At 5-minute intervals, the pH, dissolved oxygen (DO), electrical conductivity (EC), oxidation-reduction potential (ORP), temperature, and turbidity of the sampled water were measured through a multi-parameter sonde and separate turbidity meter, while water level was measured with a portable electronic water level meter. All measured parameters were recorded by KSP field personnel. The criteria used to determine well stability were (i) turbidity less than 10 NTUs and (ii) pH stable within 0.1 standard unit over three consecutive 5-minute readings.

Groundwater and porewater samples were collected in 50-mL SCP Science Digitubes including duplicate samples collected for anion analysis via ion chromatograph (IC) and duplicate samples collected for metals and other cation analysis via inductively coupled plasma (ICP) techniques (see *Chemical Analysis of Eluates, Groundwater, and Porewater* for details). Samples for ICP analysis were preserved in the field by addition of 1.5 mL of Tracemetal® grade nitric acid (3% total acid addition) using a 100-1000 µL Oxford Benchmate manual pipette and disposable tips. A set of four samples was collected unfiltered followed by a set of samples passed through a Quickfilter, 609 cm^2, 0.45-mm inline filter. In total, eight 50-mL Digitubes were collected at each sampling location. All liquid samples were stored in a cooler of ice with an Elitech RC-5 USB temperature data logger to record the temperature within the cooler. Samples were transported by the field team to VU for immediate storage at 5 ºC prior to analysis.

Subsurface Gas Monitoring

A description of the monitoring process for subsurface gas and a picture of gas monitoring apparatus are provided in Section 3.

3
LABORATORY MATERIALS AND METHODS

The follow sections include brief descriptions of the laboratory test methods and analytical methods used in this study. Also included are the quality assurance/quality control (QA/QC) samples and criteria for each analytical method.

Collected Materials

Materials recovered during initial sample collection from the ash deposit included bulk samples from split spoons and intact cores contained in thin-wall tubes. Processing of bulk material for leaching tests included (i) homogenization within each split spoon sample and (ii) compositing samples near the screening level.

Subsampling and Homogenization of Bulk Samples

Homogenized split spoon samples were used to evaluate the vertical and horizontal variability of ash deposits and provide materials for developing a representative composite for characterization of leaching parameters to be compared to monthly porewater monitoring. Each recovered split spoon sample was removed from its vacuum-sealed bag and bisected along the longitudinal axis as shown in Figure 3-1a. If the structure of split spoon material was not intact, the preserved sample was bisected vertically along the axis of the plastic bag Figure 3-1b. One-half of the material was immediately vacuum-sealed into a plastic bag and stored in the environmentally controlled room at 5 ºC for future use.

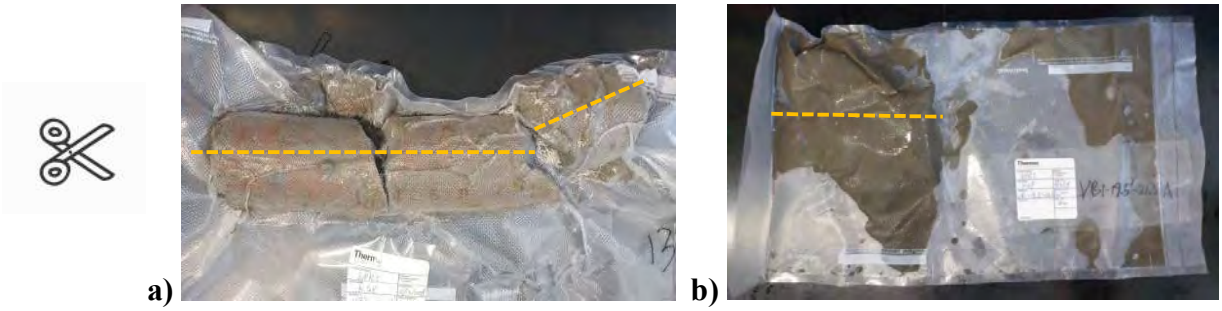

Figure 3-1
Schematic showing bisection of a) structurally sound split spoon material and b) bulk split spoon material

The remaining half of the split spoon material was placed in a plastic bag and sealed with lab tape to minimize exposure to air. This material was crushed with a rolling pin and homogenized by hand through the plastic bag until the contents were well mixed. This homogenized material was used as test material (i) in laboratory L/S=1 extractions for comparison to field L/S~1 extractions and (ii) for limited pH-dependence leaching methods to evaluate vertical heterogeneity within borehole samples.

Borehole Composite Materials

Homogenized split spoon material was used to develop a composite test material that would be representative of the bulk ash deposited near the screened interval of the PAP for each borehole. Table 3-1 shows the split spoon samples used to create each borehole composite sample. The selection of these intervals was based on the evaluation of laboratory L/S=1 extractions and considering the mass of composite that would be required to complete the testing program.

Table 3-1
Intervals (BGS) and Elevations (AMSL) of Split Spoon Samples Used in Borehole Composites

VB-1		VB-2		VB-3	
Interval (ft BGS)	**Elevation (ft AMSL)**	**Interval (ft BGS)**	**Elevation (ft AMSL)**	**Interval (ft BGS)**	**Elevation (ft AMSL)**
PAP Screen	740.8-738.8	PAP Screen	735.4-733.4	PAP Screen	735.8-733.8
13.5-15.5	744.8-742.8	16.5-18.5	736.9-734.9	21-23	737.8-735.8
15.5-17.5	742.8-740.8	18.5-20.5	734.9-732.9	23-25	735.8-733.8
17.5-19.5	740.8-738.8	20.5-22.5	732.9-730.9	25-27	733.8-731.8
19.5-21.5 (A)	738.8-737.3	-	-	-	-

The material was composited by mixing equal dry mass equivalents (i.e., the mass of "as received" material that equates to a prescribed mass of dry material) from each homogenized split spoon in a plastic bag. For VB-2 and VB-3 composites, each of three split spoons was used with 450 g-dry taken from each sample. However, for the VB-1 composite, there was not enough material in the three split spoons nearest the well screen, so a fourth split spoon was included with 250 g-dry taken from each homogenized split spoon sample. The plastic bag was sealed with lab tape to minimize air exposure and the composited material was homogenized by hand through the plastic bag until well mixed. This composited sample was used for total content analysis and characterization using LEAF leaching tests and traditional leaching tests (i.e., ASTM, TCLP, and SPLP).

Material Properties

Total Content by EPA Method 3052

The total elemental content of composite samples was determined by acid digestion following EPA Method 3052 with subsequent analysis of the digestate by Eurofins TestAmerica (Nashville, TN). According to the Method 3052, a solid sample of up to 0.5 g (wet) is digested in 9 mL of nitric acid and 3 mL of hydrofluoric acid for 15 minutes in a microwave to accelerate the digestion reactions. Addition acid and reagent combinations, including hydrochloric acid and hydrogen peroxide, are added to ensure that the solid is dissolved. The microwave temperature profile includes reaching 180 ± 5 ºC in approximately less than 5.5 minutes and remaining at 180 ± 5 ºC for 9.5 minutes for the completion of specific reactions. After cooling, the vessel contents were centrifuged and decanted. The small volume of remaining digestate was diluted to a volume of 100 mL and chemically analyzed. Inductively coupled plasma-optical emission

spectrometry (ICP-OES) following EPA Method 6010B was used to determine digestate concentrations for Ag, Al, As, Ba, Be, Ca, Cd, Cr, Co, Cu, Fe, K, Li, Mg, Mn, Mo, Na, Ni, Pb, Sb, Se, Sr, Ti, V, and Zn. Mercury in digestates was measured by using cold vapor atomic absorption following EPA Method 7470A. The total content (mg/kg) is calculated by multiplying the concentration measured in the digestate (mg/L) by the L/S of the extraction procedure (L/g). For this study, the resultant total content is effectively on a dry mass basis (mg/kg-dry) because the material submitted to the laboratory for testing was oven dried.

X-Ray Fluorescence Analysis

The elemental composition of coal ash samples was determined at UVA using x-ray fluorescence (XRF) quantitative analysis on an Epsilon 3X energy-dispersive XRF spectrometer (PANalytical, Malvern, UK) with a silver anode X-ray tube and 50-micron beryllium window. Five-gram subsamples of coal ash were taken from the undisturbed core samples, air-dried for 24 hours at room temperature, and ground by hand to less than 0.075 mm using an agate mortar and pestle. For analysis, ground samples were packed into an 18-mL sample cup (28 mm ID x 30 mm). Each subsample was analyzed in duplicate following ASTM 8064-16 for the XRF analytical method of silicate rocks.

Loss on Ignition

Loss on ignition (LOI) was measured at UVA for subsamples of undisturbed coal ash to quantify total organic matter content. LOI was conducted in accordance with ASTM D2974-14 by sintering a pre-weighed sample at 550 °C using a Lindberg/Blue M 1200 ºC box furnace (ThermoFisher Scientific, Waltham, MA). The mass lost during sintering was associated with the total organic matter.

Moisture Content

As part of the leaching test characterization using the LEAF methods, the moisture content of each study material was determined following ASTM D2216-19. Moisture content on a dry mass basis was calculated as the difference in the mass of a “wet” subsample compared to the sample after oven-drying to constant mass at 105 ± 5 ºC. The solids content is defined as the mass of solid material in an “as-tested” or “wet” subsample, measured on a “wet” basis. The determination of moisture content and solids content provides uniform bases for reporting of total content and leaching behavior results, allowing for comparison between moist and dry materials.

Porosity or Saturated Volumetric Water Content

Dry density (ρ_d) and porosity (n) of each material were determined at UVA using weight-volume computations, following the procedure in ASTM D7263-09. Under saturated conditions (i.e., when all voids are filled with water), the saturated volumetric water content (θ_s) equals the porosity.

Particle Size Distribution

Particle size distribution (PSD) of each coal ash sample was determined at UVA by a combination of mechanical analysis following ASTM D6913-17 and sedimentation analysis

following ASTM D7928-17. For mechanical analysis, a 100-g sample was oven-dried at 110±5 °C and passed through a series of US standard sieves: No. 10 (2 mm), No. 20 (0.85 mm), No. 60 (0.25 mm), No. 100 (0.15 mm), and No. 200 (0.075 mm). The fraction of the 100-g mass retained on each sieve was measured gravimetrically. Particle size distribution of the fraction coarser than the No. 200 sieve (0.075 mm) was calculated as the weight of solid retained on each sieve.

For sedimentation analysis, 50 g of dry solid that had passed the No. 200 (0.075 mm) sieve was soaked in 4% sodium metaphosphate, $(NaPO_3)_6$, solution for 12 hours and then transferred to a 1-L graduated cylinder. The graduated cylinder was capped, then agitated end-over-end for 60 seconds, and then settling of particles was monitored using a hydrometer. Stokes' law was used to compute the PSD from the hydrometer data for the fraction of particles finer than the No. 200 sieve.

Saturated Hydraulic Conductivity

Hydraulic conductivity tests were conducted in flexible-wall permeameters following the methods in ASTM D5084-16. Sections of undisturbed coal ash were extruded from the 73-mm ID, thin-wall sampling tubes (Figure 3-2) and cut into 76-mm long specimens. Non-woven geotextile disks and porous stones were placed on both ends of each coal ash specimen (Figure 3-3a) to ensure uniform flow distribution and to retain particles. Specimens were wrapped in a latex membrane and placed into a flexible-wall permeameter (Figure 3-3b).

In lieu of the more traditional tap water or 0.01 M $CaCl_2$ solution suggested in ASTM D5084, DIW was used as the permeant solution to ensure that the water entering the specimen had no ionic species that might alter the hydraulic conductivity or the leachable constituents in the coal ash. Effluent from the permeameter was collected following the procedure in ASTM D7100-11. Effluent samples were collected from the tests and stored in Teflon sample bottles with minimal headspace. Effluent samples were shipped under chain of custody to VU for chemical analysis.

The falling headwater-constant tailwater method was used with an average hydraulic gradient of 15. No backpressure was applied to simulate field conditions and to minimize alterations in geochemistry. All tests were conducted at an initial effective stress of 20 kPa and continued until the hydraulic conductivity reached hydraulic equilibrium as defined in ASTM D5084 (steady hydraulic conductivity, incremental outflow divided by inflow was constant within 1.0 ± 0.25). At the conclusion of the test, weight-volume calculations were used to determine that all specimens were fully saturated during testing.

After testing at 20 kPa was complete, three specimens, representing coarser, finer, and mid-range particle size distributions, were consolidated to 100 kPa and permeated again until hydraulic equilibrium was established (steady hydraulic conductivity, steady flow ratio 1.0 ± 0.25). The initial stress (20 kPa) was selected to replicate the stress condition of the coal ash with a burial depth of 1 m in the basin. The consolidation/permeation procedure was repeated at consolidation pressures of 250, 400, and 500 kPa to simulate stress at greater depths within the basin. The highest stress (500 kPa) corresponded to a depth of approximately 35 m. Effluent samples from these higher-stress experiments were not collected or chemically analyzed.

Traditional Extraction Tests

EPA Method 1311 – Toxicity Characteristic Leaching Procedure

EPA Method 1311, or TCLP, is a single-point batch leaching test used to determine the toxicity characteristic of a material and the disposal options for a material under the Resource Conservation and Recovery Act of 1986 (RCRA). At the time of test development, TCLP was designed to simulate eluate concentrations for a plausible mismanagement scenario where hazardous waste is disposed in a municipal solid waste landfill. Thus, a solution of acetic acid in DIW is the extraction fluid to represent the primary acidity in municipal solid waste landfill leachate. Selection of an extraction fluid is based on a pretest of the buffering capacity of a test sample for acetic acid. Extraction Fluid #1 is dilute acetic acid buffered at a pH of 4.93 ± 0.05 with sodium hydroxide, while Extraction Fluid #2 is dilute acetic acid at a pH of 2.88 ± 0.05 without added base. The test-specific L/S of 20 mL/g is based on a filtered sample after pressure filtration at 15 psi. Since the filtered solid may still contain moisture, the final dry-basis extraction L/S is typically greater than 20 mL/g-dry. The filtrate from pressure filtration was preserved and chemically analyzed in parallel to TCLP extracts.

For this study, 80 grams of filtered solid was mixed with 160 mL of Extraction Fluid #1 and tumbled at 28 ± 2 rpm for 18 ± 2 hours. Although not specified in the method, the pH of the final eluate was measured and recorded so that test results could be compared to other leaching methods. The eluate from the extraction was pressure-filtered through a 0.22-µm borosilicate glass fiber filter and preserved for analysis. Filtrate from pressure filtration and the extraction eluate were analyzed separately and an "effective" extraction concentration was calculated for each constituent as a volume-weighted average concentration of the two liquids. For QA/QC purposes, a method blank, with the filter paper and extraction fluid only, and a duplicate sample for VB-2 were conducted in parallel using the same reagents.

EPA Method 1312 – Synthetic Precipitation Leaching Procedure

EPA Method 1312, or SPLP, is a single-batch leaching test used to evaluate the leaching behavior of a waste material in contact with acidic rain. The test is performed in the same manner as in the TCLP, but with extraction fluids of 60/40 weight percent (wt%) sulfuric acid (H_2SO_4) and nitric acid (HNO_3) in DIW (Extraction Fluids #1 and #2) or DIW (Extraction Fluid #3). The selection of extraction fluid depends on the location of the site under investigation and the constituents being tested. Extraction Fluid #1 is used for sites east of the Mississippi River, Extraction Fluid #2 is used for sites west of the Mississippi River, and Extraction Fluid #3 is used only when cyanides or volatiles are to be analyzed.

For these tests, 100 grams of filtered solid was mixed with 160 mL of Extraction Fluid #1 and tumbled at 28±2 rpm for 18±2 hours. Although not specified in the method, the pH of the final eluate was measured and recorded so that test results could be compared to other leaching methods. The eluate from the extraction was pressure-filtered through a 0.22-µm borosilicate glass fiber filter and preserved for analysis. Filtrate from pressure filtration and the extraction eluate were analyzed separately and an "effective" extraction concentration for each constituent was calculated as a volume-weighted average of the two liquids. A method blank—extraction fluid with no solid carried through the test process—and a duplicate sample for VB-2 were analyzed.

ASTM D3987 – Shake Extraction of Solid Waste with Water

ASTM D3987-12, or ASTM, is a single-point extraction test that is used to estimate leaching concentrations when no acid or base is added to the extraction. Since the method is patterned after TCLP, the procedure is similar to the EPA method; however, DIW is used as the extraction fluid.

For these tests, a subsample of ash (70±0.1 g) was tumbled at 28±0.2 rpm with DIW at an L/S of 20 mL/g for 18±0.25 hours. After tumbling, the extract was separated from the solid by vacuum filtration through a 0.45-m polypropylene membrane and the pH of the final eluate was measured and recorded. Reagent and method blanks were analyzed, and a duplicate test was conducted on the VB-3 sample.

Leaching Environmental Assessment Framework (LEAF) Test Methods

EPA Method 1313 – Liquid-Solid Partitioning as a Function of Eluate pH Using a Batch Extraction Procedure

EPA Method 1313 is standardized, parallel batch extraction method used to evaluate the liquid-solid partitioning (LSP) of inorganic constituents as a function of eluate pH. The general procedure consists of nine batch extractions of a particle-size reduced subsample material that is contacted with leaching solution at an L/S of 10 mL/g-dry material and tumbled end-over-end over a specified contact interval. The leaching solution is DIW with additions of HNO_3 or potassium hydroxide (KOH) to adjust the final pH of the eluate to a target of nine specific pH values (i.e., pH values of 2, 4, 5.5, 7, 8, 9, 10.5, 12, and 13). An additional extraction without addition of acid or base was carried out to measure constituent leaching at the natural pH of the material.[1] After 24 hours of tumbling, the contact time associated with a sample particle size of 85 wt% less than 300 µm, the solid and liquid phases were separated by settling or centrifugation, and the pH, EC, and ORP of the clarified eluate were measured. The remaining slurry was vacuum-filtered through 0.45-µm pore size membranes prior to chemical analysis by ICP-OES, IC, and carbon analysis.

EPA Method 1313 provides (i) a titration curve of the pH response to additions of acid or base, (ii) the available content of constituents in the solid material, and (iii) the LSP curve for constituents over the tested pH range. Furthermore, the results of EPA Method 1313 are suitable for use in geochemical speciation modeling for the estimation of the solid phase mineralogy and surface chemistry that controls constituent release.

Variants of EPA 1313 Methods

In this program, the full EPA 1313 method and variants of EPA 1313 were carried out on ash materials for different purposes:

- An abbreviated, 3-point EPA 1313 (1313_3 pt) was conducted on two homogenized samples of individual split spoon samples from each borehole. Since the natural pH of the CCP

[1] The "natural pH," sometimes referred to as "own pH," is defined as the eluate pH in response to extraction in deionized water (i.e., no acid or base added) at an L/S of 10 mL/g-dry. To distinguish the natural pH at L/S=10 mL/g-dry (Method 1313 or 1313_3pt) from the pH response to DIW at L/S of 1 mL/g-dry measured using 1313_L/S=1, the former will continue to be called with "natural pH" while latter will be referred to as "own pH."

materials was expected to be near neutral, the pH targets selected included $1.5 \leq pH \leq 2$, the natural pH, and pH=9.0±0.5. The pH targets near pH 2.0 and 9.0 are useful for determining the available contents of cationic and oxyanionic constituents, respectively. The results of these 3-point pH-dependence tests on individual split spoon samples were compared to the full-range EPA 1313 of composite samples as an indicator of vertical heterogeneity within a borehole.

- EPA 1313 was carried out on composited ash samples from each borehole but using an L/S of 1 mL/g-dry and abbreviated to the natural pH and two pH targets on either side of the natural pH, for five pH values in total. This modified 1313 test, referred to as 1313_L/S=1, was used to evaluate how changes in L/S may influence LSP concentrations and to provide verification data for development of geochemical speciation models.

EPA Method 1314 – Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using a Percolation Column Procedure

EPA Method 1314 is a standardized, up-flow column procedure used to evaluate release of inorganic constituents from percolating solid materials as a function of cumulative L/S (i.e., the volume of liquid that passes through the column relative to the dry mass of material in the column). In this study, EPA 1314 was used to characterize the L/S-dependent leaching of constituents in 250-400 g-dry composited ash samples (e.g., VB-1, VB-2, and VB-3). A 5-cm diameter by 30-cm glass column was packed with coal ash in a series of five lifts with moderate tamping between lifts. DIW was used as the eluent solution since CCPs in general have relatively low organic carbon and clay contents compared to soils. The eluent was pumped at a flow rate of 0.75±0.25 L/S per day through the column in an up-flow direction to minimize air entrapment and flow channeling. Eluates were collected at predetermined cumulative L/S values (i.e., 0.2, 0.5, 1, 1.5, 2, 2.5, 4.5, 5, 9.5 and 10 mL/g-dry). For each eluate fraction, the pH and conductivity were recorded prior to filtration and preservation for chemical analysis. To present the results, the concentrations of constituents in the eluates (mg/L) as well as the cumulative release through the end of each eluate fraction (mg/kg-dry) were plotted as functions of L/S in separate graphs.

Comparison of Leaching Test Parameters and Conditions

All leaching tests conducted for this program are designed to measure the LSP of constituent release from a material under the specified test conditions shown in Table 3-2. TCLP, SPLP, and ASTM are single-batch leaching tests. Similarly, the EPA 1313 test and its variants are batch procedures, but with parallel extractions to provide data over a range of test conditions. These batch tests, however, differ in the chemical makeup of extraction fluid as well as in the specified L/S. Moving from left to right in Table 3-2, the leaching test conditions are presented in order of decreasing L/S from left to right. In the last column are the test conditions for EPA 1314, designed to measure LSP as a function of cumulative L/S.

Table 3-2
Leaching Test Parameters and Test Conditions

Parameter	TCLP	SPLP	ASTM	1313	1313_3-pt	1313_L/S=1	1314

Chemical Analysis of Eluates, Groundwater, and Porewater

Eluate pH

Eluate pH was measured on all aqueous extracts following EPA Method 9040C using an Accumet XL20 meter and a combined pH electrode on approximately 5 mL of eluate. Prior to testing, the electrode was calibrated with two National Institute of Standards and Technology (NIST) traceable pH buffer solutions that bounded the anticipated range of pH to be measured. A third mid-range NIST buffer was used to verify the calibration.

Specific Conductance

Specific conductance, or EC, is a measure of the ability of an aqueous solution to carry an electrical current. The property is dependent on (i) the presence of ions; (ii) total concentration, mobility, and variance of ions in solutions; and (iii) the temperature of the measurement. Conductivity of all leaching test eluates was determined following EPA Method 9050A using a standard conductivity probe calibrated to an appropriate standard conductivity solution for the conductivity range of concern.

Oxidation-Reduction Potential

ORP is a voltage differential related to the redox state of a solid-liquid solution and its effect on chemical composition (e.g., reduced/oxidized iron, dissolved oxygen, biological activity). ORP voltage of all eluate solutions was measured with a probe, consisting of a platinum electrode and a reference electrode, placed in contact with the soil solution. In laboratory tests, the ORP voltage reading was converted to redox potential (Eh) by addition of a probe-specific correction factor of 228 mV at 25 °C. In field measurements, however, the probe correction factor was automatically compensated for by the instrument and are output as Eh values.

Since, redox reactions vary with pH and the mineral species present, redox is parameterized in geochemical modeling as the pH+pE, where pE is the negative logarithm of the free electron concentration, or –log([e^-]). The corrected Eh values of leachates and eluates were converted to a pE value using the following equation:

$$pE = \frac{F}{2.303RT}(Eh/1000)$$

where F is the Faraday constant (23,061 cal/(V mol)),

Eh is the redox potential of the solution (mV),
2.303 is a conversion (ln[e^-]/2.303 log[e^-]),
R is the gas constant (1.987 cal/(K mol)),

T is the temperature (K), and

1000 is a unit conversion (1,000 mV = 1 V).

Inductively Coupled Plasma Spectrometry

The eluate concentrations of trace elements and material major species (e.g., Al, Ca, Si) were determined using a combination of ICP-OES and inductively coupled plasma – mass

spectrometry (ICP-MS). The choice of instrumentation was determined based on detection limits, expected concentrations, and environmental threshold values. Table 3-3 provides the method detection limits (MDLs) and lower limits of quantitation (LLOQs) used in this project along with the working ranges for each constituent.

Major species and trace elements present at higher concentrations were determined using a Varian Model 720-ES ICP-OES (Agilent Technologies, Santa Clara, CA) following EPA Method 6010D. The ICP-OES was calibrated to a 5-point standard curve with an analytical range of 25 to 25,000 µg/L. For some high-concentration trace elements, the standard curve was extended up to 500,000 µg/L using a 7-point standard curve. For low-level trace analysis, concentrations were determined by ICP-MS using a Perkin Elmer Elan DRC II (Perkin Elmer, Waltham, MA) following EPA Method 6020A. The ICP-MS was calibrated to a 5-point standard curve with range between approximately 1 and 250 µg/L and extended with a 7-point curve to 1,000 µg/L for some constituents.

Analytical QA/QC included initial and continuing calibration checks and blanks, matrix spikes, and method blanks. Calibration check standards and matrix blanks were evaluated every 10 to 20 samples with the requirements that check standards were within 15% of the specified value and blanks were below LLOQs. Matrix spikes were required to have recoveries within 20% of the calculated concentration considering the spiked mass. Initial and continuing calibration check standards for ICP-OES and ICP-MS were 0.5 mg/L and 0.050 mg/L, respectively. Analyte concentrations measured at less than the MDL were reported as <MDL and graphed at one-half the MDL values to indicate that the measurement was conducted. Analytical results measured at less than the LLOQ but greater than the MDL are estimated values.

Ion Chromatography

The concentrations of anions in leaching test eluates were determined by IC using a Metrohm 881 Compact IC Pro (Metrohm USA, Riverview, FL) with a Metrosep A Supp 5 column and a conductivity detector following EPA Method 9056A. A 7-anion calibration standard was diluted to form a 5-point calibration curve with the MDLs and LLOQs shown in Table 3-4. Since the calibration standards are diluted from a bulk multi-analyte standard, the calibration range differs for each analyte (e.g., 0.050-50 mg/L for Cl^- and 0.150-150 mg/L for SO_4^{-2}). Calibration check standards were required to be within 15% of the specified value, while acceptable analytical blanks were measured below the quantitation limits.

Table 3-4
MDLs and LLOQs for Analysis of Eluates by IC

Analyte	Symbol	MDL (mg/L)	LLOQ (mg/L)

Carbon Analysis

Carbon analysis for eluate samples included analyses for dissolved inorganic carbon (DIC) and dissolved organic carbon (DOC). Carbon analysis was conducted using a Shimadzu TOC-V CPH/CPN (Shimadzu Scientific Instruments, Inc., Columbia, MD) by catalytic oxidation/non-dispersive infrared detection (NDIR) following EPA Method 9060A. Total carbon (TC) in the eluate is converted to carbon dioxide via oxidation or decomposition, carried by a zero-CO_2 air stream into the NDIR. For analysis of DIC, liquid samples are acidified with 2-molar hydrochloric acid to liberate carbonates and other forms of inorganic carbon from solution as carbon dioxide, which is sparged from the liquid sample into the NDIR by the zero-CO_2 carrier gas. DOC is determined by measuring the TC of a sample after purging of IC. The instrument was calibrated using sodium hydrogen carbonate and potassium hydrogen phthalate over a 5-point calibration curve for DIC and DOC, respectively. The resultant analytical range was between 0.1 and 100 mg/L, with MDL and LLOQ values shown in Table 3-5. Checks on QA/QC at a frequency of every 10 analytical samples included calibration checks with a required recovery within 15% of the specific value, and method blanks with a requirement that the concentration was less than quantifiable limits.

Table 3-5
MDLs and LLOQs for Eluate Analysis for Carbon

Analyte	Symbol	MDL (mg/L)	LLOQ (mg/L)
Inorganic carbon	DIC	0.15	0.50
Organic carbon	DOC	0.18	0.50

Subsurface Gas Analysis

The composition of subsurface gas was monitored monthly from September 2018 through September 2019. Subsurface gas was monitored for oxygen (O_2), carbon dioxide (CO_2), methane (CH_4), ammonia (NH_3), and hydrogen sulfide (H_2S) using a hand-held field meter (Figure 3-4a). Table 3-6 shows the measurement units and calibration ranges for the five gases. To avoid any moisture from subsurface gas fouling the vacuum pump, the subsurface gas was drawn through a 250-mL syringe filled with desiccant (Figure 3-4b).

Figure 3-4
Subsurface gas monitoring apparatus: a) field meter and b) connected tubing and desiccant syringe

Table 3-6
Calibration Ranges for Subsurface Gas Monitoring

Analyte	Symbol	Units	Calibration Range	
Ammonia	NH_3	ppm	0	500
Hydrogen sulfide	H_2S	ppm	0	500
Carbon dioxide	CO_2	%	0	5
Methane	CH_4	%	0	5
Oxygen	O_2	%	0	30

Data Management with LeachXS™

Information on how leaching tests were conducted was recorded by the laboratory technician in Microsoft Excel® spreadsheets specifically designed for each test for use as templates for data collection and archiving. Analytical data documenting concentrations of constituents from each leaching test were entered into the same spreadsheets. These data templates were used as the interface for loading laboratory and analytical data into LeachXS™ (VU, 2019), a database-driven data management and reporting software program. LeachXS was used to (i) archive the laboratory and analytical data from leaching tests; (ii) compare test results between composite materials (e.g., VB-1, VB-2, or VB-3) or test results (e.g., TCLP, SPLP, ASTM, and LEAF); and (iii) generate the Excel plots used for this report.

4
TEST RESULTS AND DISCUSSION

A large volume of data was generated during this research. The discussion that follows presents representative example figures that illustrate observations based on all data. Graphs and data tables reflecting all data are provided in the appendices. In addition, key observations within subsections are denoted by underscored text.

Physical and Hydraulic Properties

Physical properties of the fly ash samples used for measurement of hydraulic properties are summarized in Table 4-1, composition of the solids is summarized in Table 4-2, and the hydraulic conductivities are summarized in Table 4-3.

Particle size distributions of the coal ash samples are shown in Figure 4-1. All samples contained a broad range of particle sizes ranging from those associated with coarse-to-fine sand, silt, and clay-size (<2 μm) particles. Each has a broadly graded distribution with relatively comparable fractions of all sizes and no gaps. The fines content (i.e., silt and clay-size particles finer than 75 μm) ranges from 36.6 to 92.2%, and the clay-size (i.e., finer than 2 μm) ranges from 5.2 to 19.8%. No particles coarser than sand-size were observed.

Table 4-1
Physical Properties of Coal Ash Samples Used for Hydraulic Conductivity Assessment

Sample ID	Sample Elevation at Bottom (ft AMSL)	Sample Elevation at Top (ft AMSL)	Water Content (%)	Dry Unit Weight (mg/m^3)	Particle Size Fractions			
VB-1_OST_12-14.5	743.8	746.3	41.5	1.14	0.0	15.5	84.5	15.1
VB-1_OST_17-19.5	738.8	741.3	52.0	1.00	0.0	25.2	74.8	10.0
VB-2_OST_13.5-15.5	737.9	739.9	37.5	1.11	0.0	64.4	36.6	5.2
VB-2_OST_18.5-21.5	731.9	734.9	28.7	1.35	0.0	23.1	76.9	12.6
VB-3_OST_17-20	738.8	741.8	36.3	1.28	0.0	34.5	65.5	14.0
VB-3_OST_24-27	731.8	734.8	27.9	1.26	0.0	7.8	92.2	19.8

Sample VB-2_OST_13.5-15.5 was notably coarser than the other samples and was classified as silty sand (SM) in ASTM D2487. This classification is characteristic of bottom ash mixed with fly ash. All other samples were classified as fine-grained “elastic silt” (ML) as defined in ASTM D2487, which is characteristic of fly ash.

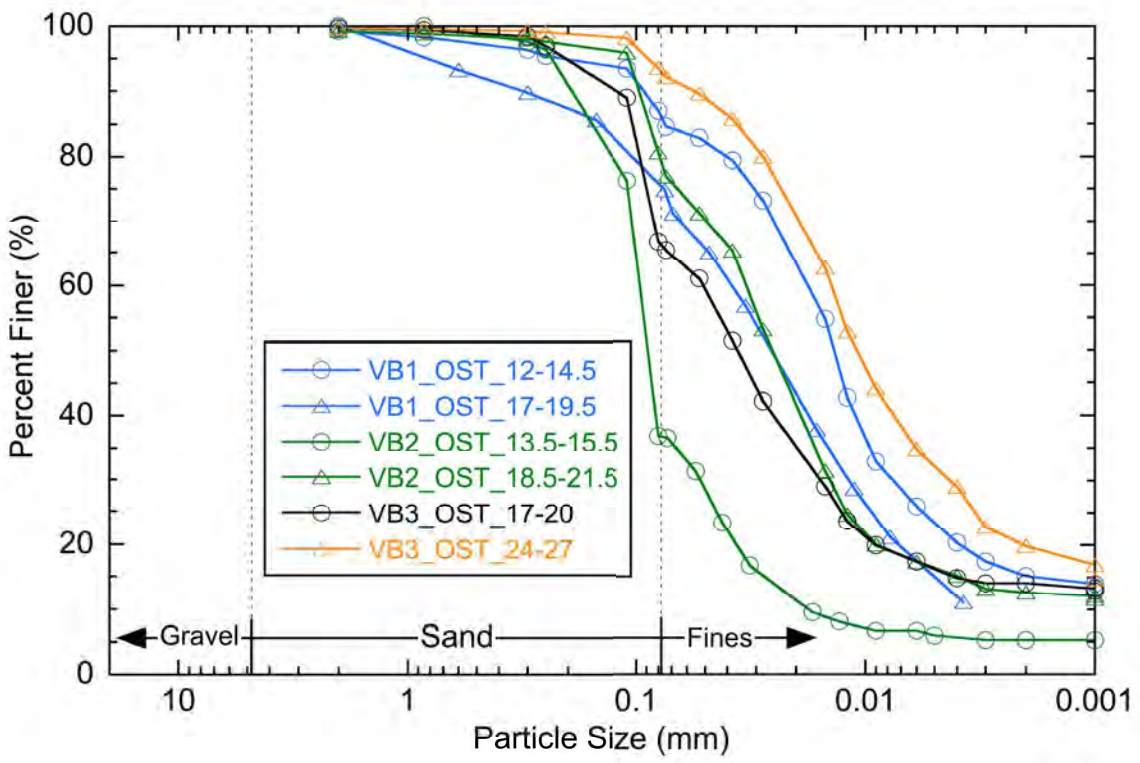

Figure 4-1
Particle size distribution of coal ash samples

Table 4-2 indicates that all of the ash samples are predominantly composed of Al and Si oxides, which reflects the predominant alumino-silicate mineral structure of the particulate. All samples contain modest amounts of Ca, K, Fe, and Ti. The VB-2 series samples are richer in iron than the other samples. The LOI varies considerably, from 0.50 to 11.83%.

Table 4-2
Composition of Solids (%) from LOI and XRF of Coal Ash Samples Used for Hydraulic Conductivity Assessment (elements exceeding 1.0%)

Composition	VB-1		VB-2		VB-3
	12-14.5	17-19.5	13.5-15.5	18.5-21.5	17-20
LOI	0.98	1.89	0.50	11.83	4.95
Al_2O_3	26.19	26.69	24.26	19.88	26.79
CaO	1.35	1.44	1.36	1.32	1.50
Fe_2O_3	16.14	11.34	22.99	19.45	12.61
K_2O	5.70	3.66	4.78	3.79	3.74
SiO_2	45.42	51.10	41.86	39.74	46.87
TiO_2	2.04	1.48	1.99	1.64	1.59

The hydraulic conductivities fall into two groups: the coarser, more permeable samples (VB-1_OST_17-19.5, VB-2_OST_13.5-15.5, and VB-3_OST_17-20) and the finer, less permeable samples (VB-1_OST_12-14.5, VB-2_OST_18.5-21.5, and VB-3_OST_24-27). The coarser samples have hydraulic conductivities in the range of 10^{-4} to 10^{-3} cm/s and fines content less than 75%, whereas the finer samples have hydraulic conductivities closer to 10^{-5} cm/s and fines content greater than 75%. There is a strong relationship between the hydraulic conductivity and fines content (Figure 4-2), with hydraulic conductivity diminishing as the fines content increases. The hydraulic conductivities also align well with hydraulic conductivities generally associated with the geotechnical classifications.

Table 4-3
Hydraulic Conductivity of Coal Ash Samples

Sample ID	Percent Fines (%)	Effective Stress (kPa)	Hydraulic Conductivity (cm/s)
VB-1_OST_12-14.5	84.5	20	2.0×10^{-5}
		100	2.0×10^{-5}
		250	1.4×10^{-5}
		400	1.3×10^{-5}
		500	1.3×10^{-5}
VB-1_OST_17-19.5	74.8	20	3.6×10^{-4}
VB-2_OST_13.5-15.5	36.6	20	1.3×10^{-3}
VB-2_OST_18.5-21.5	76.9	20	4.2×10^{-5}
		100	4.1×10^{-5}
		250	3.0×10^{-5}
		400	2.7×10^{-5}
		500	1.2×10^{-5}
VB-3_OST_17-20	65.5	20	6.3×10^{-4}
		100	6.9×10^{-4}
		250	2.5×10^{-4}
		400	2.3×10^{-4}
		500	9.7×10^{-5}
VB-3_OST_24-27	92.2	20	2.7×10^{-5}
		100	2.7×10^{-5}
		250	2.6×10^{-5}
		400	2.4×10^{-5}
		500	2.3×10^{-5}

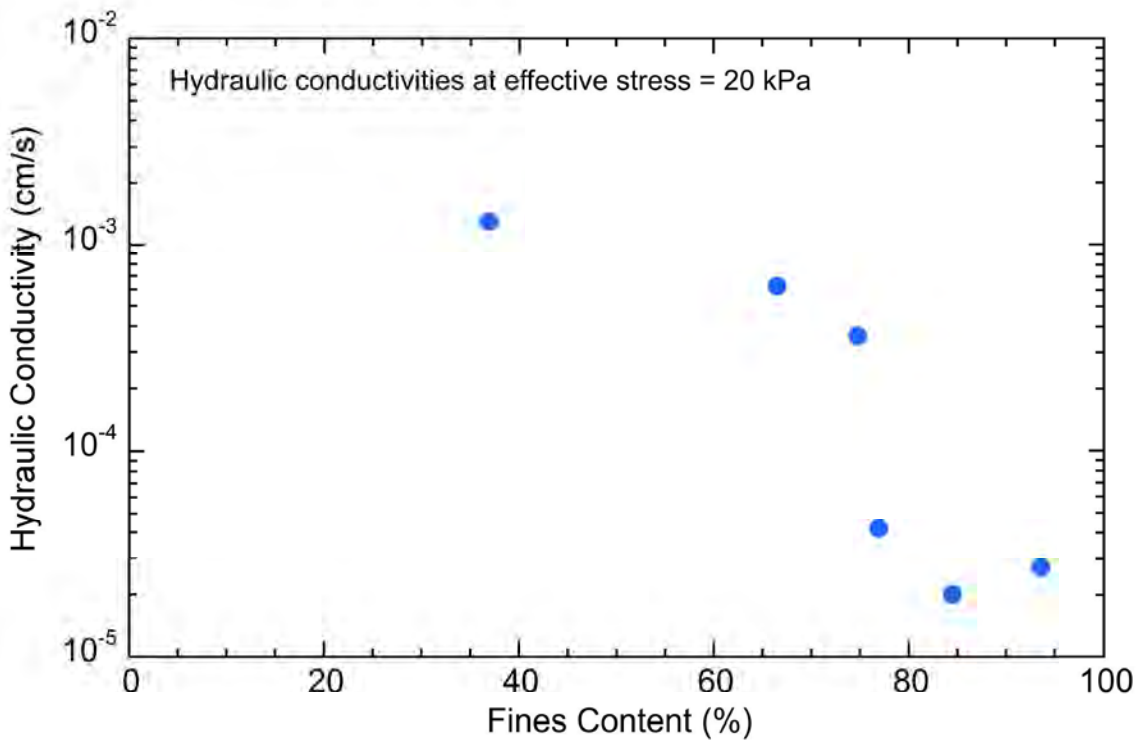

Figure 4-2
Hydraulic conductivity of coal ash at 20 kPa effective stress as a function of fines content

The hydraulic conductivity of the coal ash samples as a function of confining stress is shown in Figure 4-3. In general, the hydraulic conductivity decreases modestly with increasing effective stress. The hydraulic conductivity of the coarser, more permeable sample (VB-3_OST_17-20) is more sensitive to effective stress than the finer, less permeable samples. As the stress increased from 20 to 500 kPa, the hydraulic conductivity of the coarser sample decreased by a factor of 6.5. In contrast, the hydraulic conductivity of the finer, less permeable samples decreased by a factor of 2.1 on average over the same range of stresses. The greater sensitivity to stress for VB-3_OST_17-20 may reflect closure of larger pores between the sand-size particles, with the finer particles filling the remaining pores and resulting in lower hydraulic conductivity.

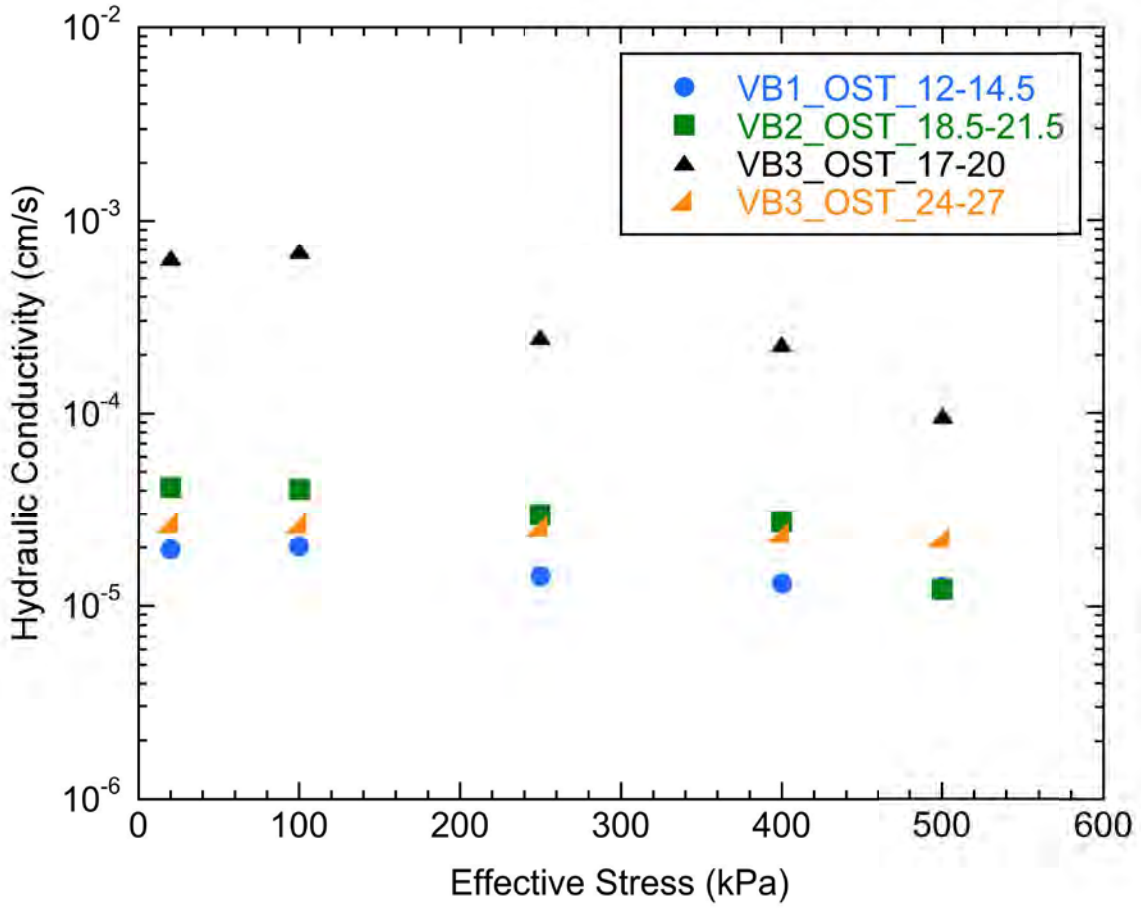

Figure 4-3
Hydraulic conductivity of coal ash samples as a function of effective stress

Individual Split Spoon Sample Testing

Evaluation of Field Extractions (L/S~1 vs. L/S=1)

During field sampling, extractions of split spoon materials were conducted using de-oxygenated water at an L/S~1. For each extract, approximately 150-g grab samples of recovered material from the center of the split spoon were contacted with approximately 150 mL of DI water that had been deoxygenated with nitrogen prior to field operations. If the split spoon indicated an interface between dissimilar materials (e.g., across the ash-cover or ash-liner interfaces or in layered ash), two extractions were conducted on grab samples of distinctive material types. Because the moisture content of the split spoon material varied with depth and texture, the resultant L/S of field extractions varied between 1.7 and 3.3 mL/g-dry.

The variation in L/S of field-extracted materials confounds the comparison of material within a borehole or between boreholes based on concentrations. Therefore, extractions at a constant L/S ratio were conducted in the laboratory. Collected bulk materials that had been vacuum-sealed to preserve the redox conditions of split spoon samples were homogenized within each split spoon. 100-g subsamples of homogenized material were extracted with DI water at an L/S=1 mL/g-dry. Figure 4-4 shows a comparison between field extractions (L/S~1) and laboratory extractions (L/S=1) as a function of pH and L/S. Comparisons of field and laboratory extraction data for all constituents are presented in Appendix C.1.

In these figures, the color of the data points indicates the borehole (e.g., VB-1 in blue, VB-2 in green, and VB-3 in orange), with lighter colors indicating field extractions and darker colors indicating laboratory extractions. The shape of the data point refers to the primary type of material used in the extraction (ash samples are shown as dots, cover material as squares, and liner material as diamonds). Solid data points are confirmed material types that fall within the material classification provided in the bore logs by the licensed geologist, while open data points indicate materials near interfaces that are likely to be a blend of two or more material types (e.g., open squares indicate blended samples of the ash and cover materials while open diamonds refer to blends of ash, layered ash, and liner material).

The data in Figure 4-4 show that the primary difference between laboratory tests is L/S ratio, which is most noticeable in the L/S-dependence plot. The pH range for the laboratory extractions is primarily the same as that of the field extractions.

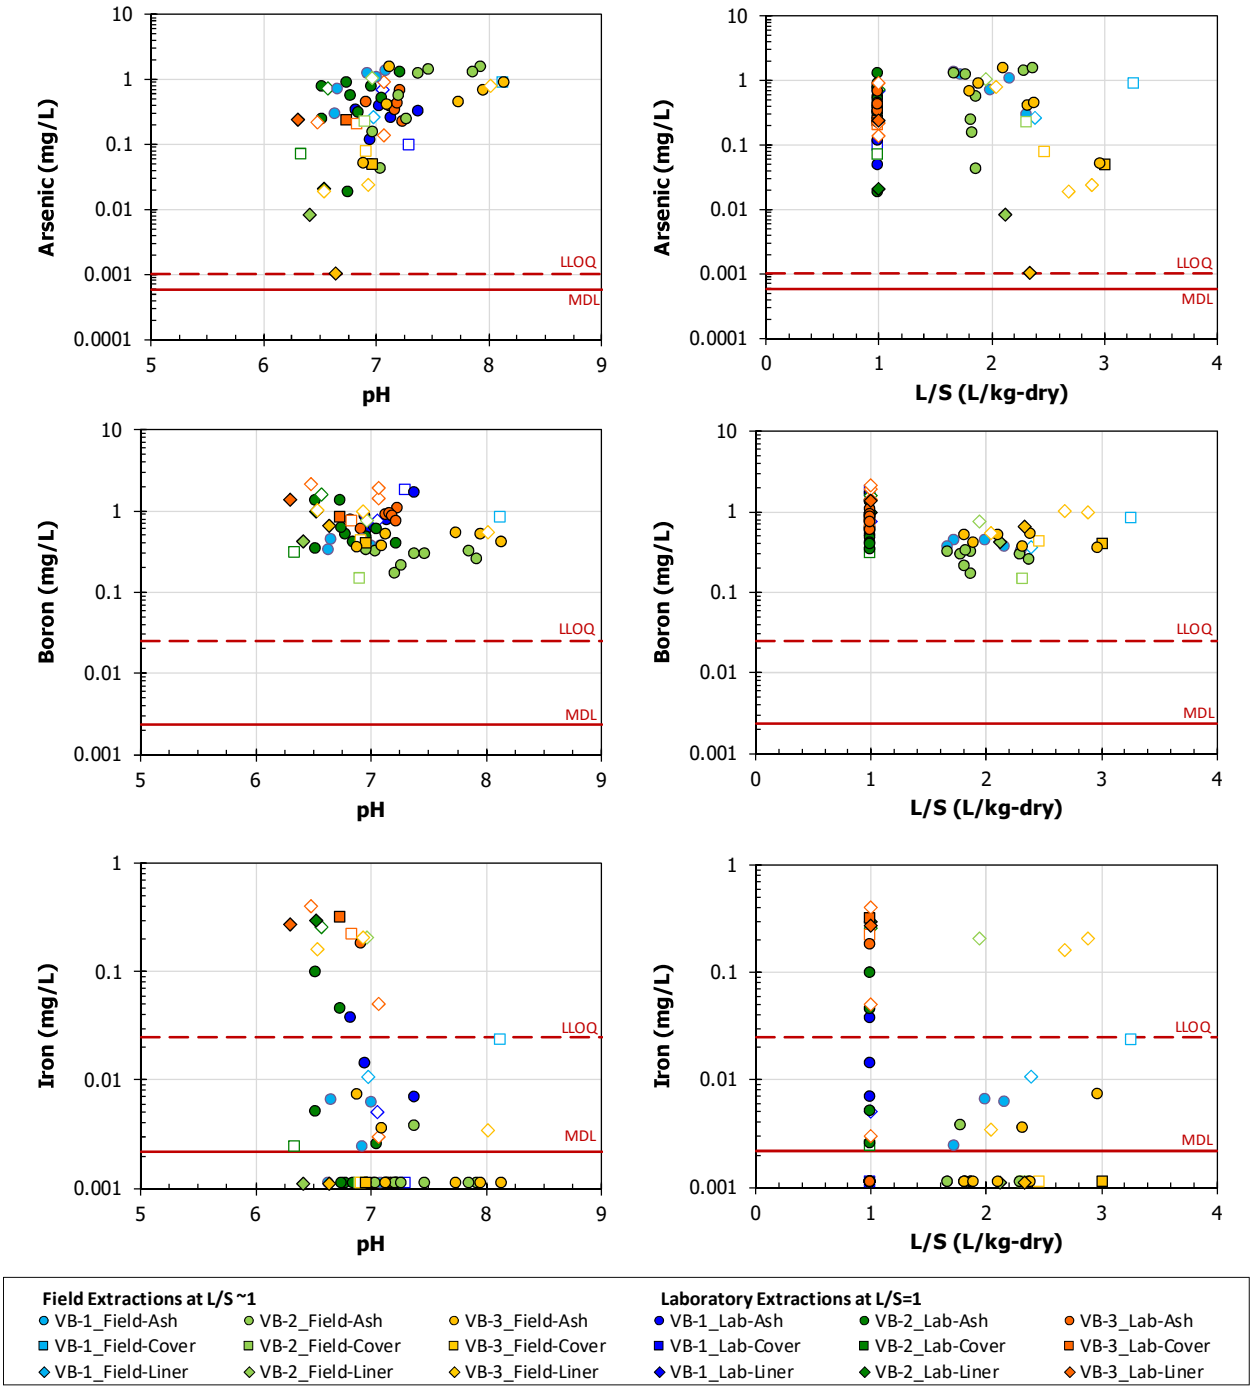

Figure 4-4
Comparison of field extractions at L/S~1 (lighter colors) to laboratory extractions at L/S=1 (darker colors) for individual split spoon materials shown as a function of pH (left) and L/S (right)

Vertical Heterogeneity Within and Between Boreholes

Profile Plots of Field and Laboratory Extraction Data

After surveying of the borehole and PAP locations and elevations, depths below grade that were monitored during sample recovery were converted to elevations ASML. The concentrations from field extractions (L/S~1) and laboratory extractions (L/S=1) of individual split spoon materials were plotted as a function of elevation to provide a visual metric of material heterogeneity with depth within a borehole. An example of these borehole profile plots is presented in Figure 4-5.

Each line of the figure represents the concentration profiles for a measured constituent in the laboratory extractions (L/S=1) for VB-1 in blue, VB-2 in green, and VB-3 in orange. The concentration is plotted along the x-axis, while the elevation for the center of the split spoon is plotted on the y-axis. The red horizontal line shows the elevation at the interface between cover material and the ash deposit, while the brown horizontal line indicates the elevation where the main ash deposit ended either at an interface with the underlying native clay liner material or in layers of different ash textures above the clay liner. The 2-foot wide shaded area indicates the screening interval for the PAP in each borehole. The 3 to 4 light-colored data points in each profile indicate the intervals from which material was taken to create the composite ash sample for each borehole used in detailed characterizations.

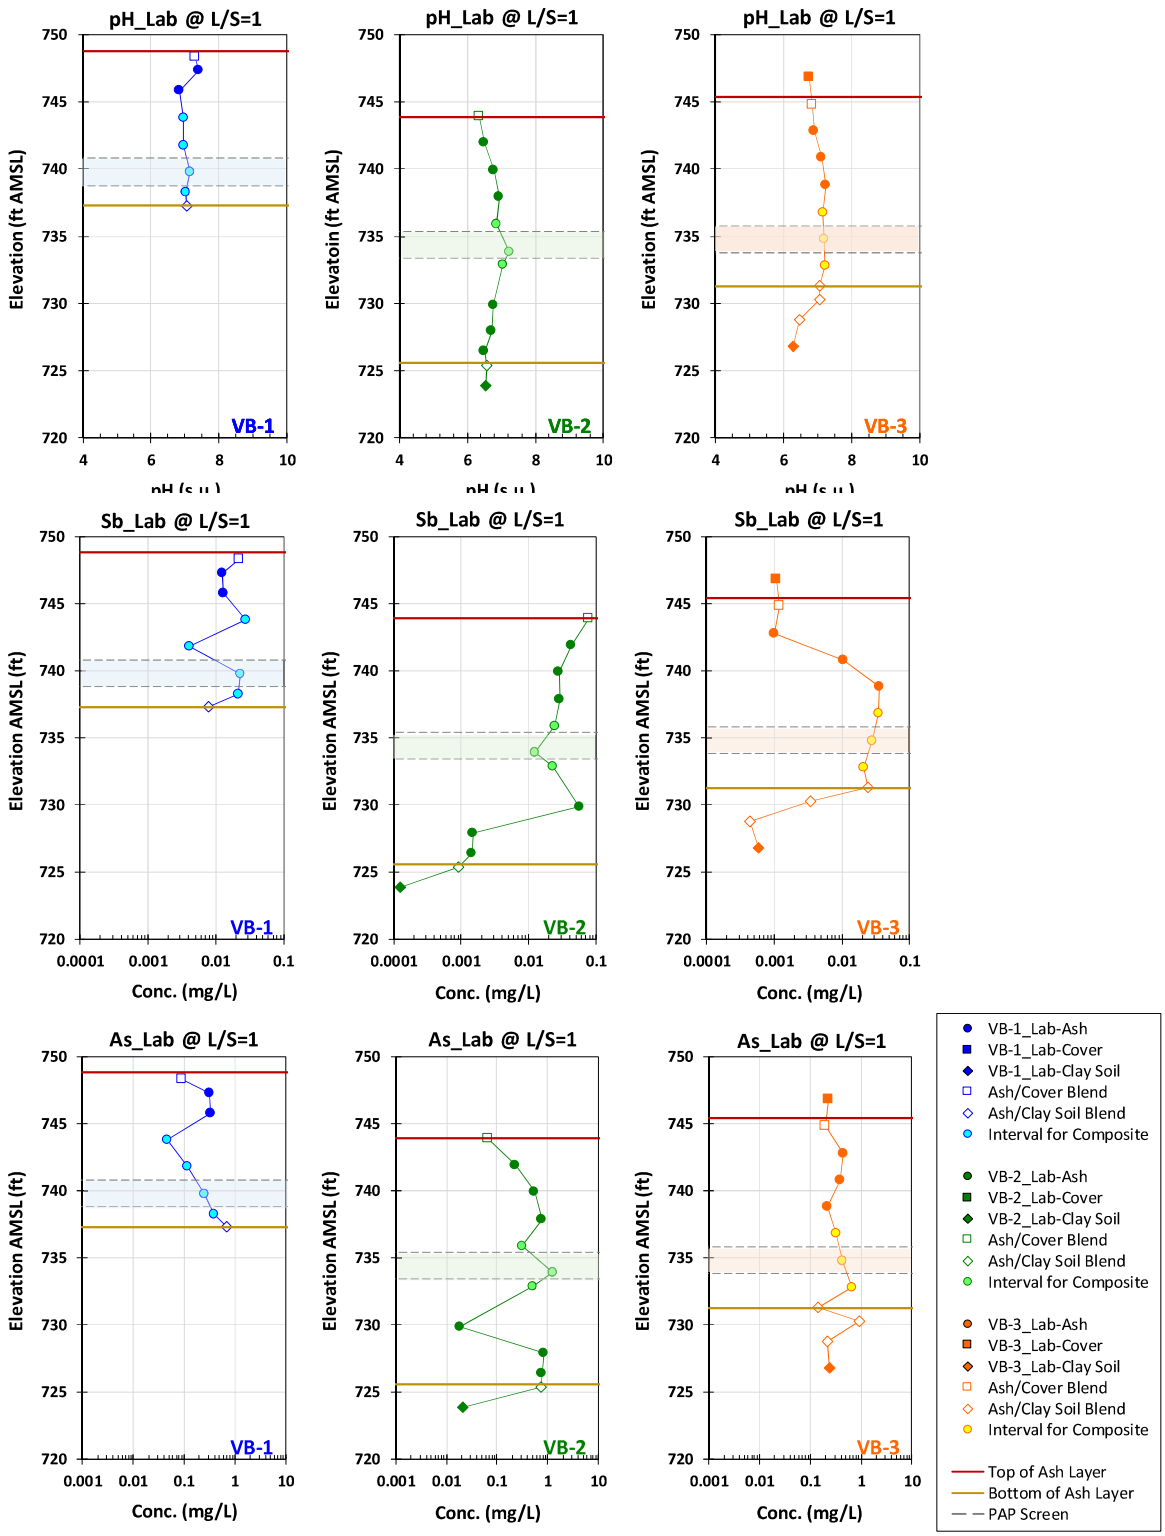

Figure 4-5
Laboratory extraction (L/S=1) concentration profiles within boreholes (VB-1, VB-2, VB-3) based on eluate concentration (SU or mg/L) for pH, antimony, and arsenic

Standardized Borehole Profiles of Laboratory Extraction (L/S=1) Concentrations

The concentration data for laboratory extractions of homogenized split spoon material were converted to standardized profile plots using the global mean and standard deviation for "known ash samples" in all boreholes based on geologist notes. The standardized concentration is calculated as:

$$\frac{x - \bar{x}}{s}$$

where x is the parameter (e.g., pH, concentration) from the extraction test,
$\bar{x}$ is the global mean of all "known ash samples" for all boreholes, and
s is the global standard deviation of all "known ash samples."

The standardized concentration provides a measure of the difference between the measured concentration and the mean as a number of standard deviations from the mean concentration. A homogenous material, for example, may have measurements within 2 standard deviations of the mean while measurements greater than 4 standard deviations may have more than random variations such as influence from cover or underlying material. Justification for use of ash sample global statistics, rather than within-borehole statistics, was based on the results of t-test results for pair-wise comparisons assuming unequal variances, which showed no statistical difference in means between boreholes. In addition, the use of global statistics in standardized concentration profiles allows for comparison between boreholes on the same basis.

Examples of the resulting standardized borehole profiles are shown in Figure 4-6 for major constituents and in Figure 4-7 for trace constituents. The standardized profiles for all constituents are presented Appendix C.2. The global mean and standard deviation for all constituents are tabulated in Table 4-4.

The process for collection of split spoon samples at boreholes VB-2 and VB-3 was designed to capture the interfaces at the cover and underlying materials, whereas the collection of split spoons at borehole VB-1 was centered on the ash material only. These sampling schemes are reflected in the results of the standardized profiles. Figure 4-6 shows that the concentration profiles for aluminum and iron from laboratory extractions (L/S=1) show very consistent response within the ash deposit, with clear influences from overlying and underlying materials. The profiles for antimony, arsenic, and boron in Figure 4-7 show more variation within the ash layers, with little to no influence from cover or underlying materials. Overall, the samples used in the composite materials for all boreholes were relatively consistent and are considered representative of the global mean of the stored ash.

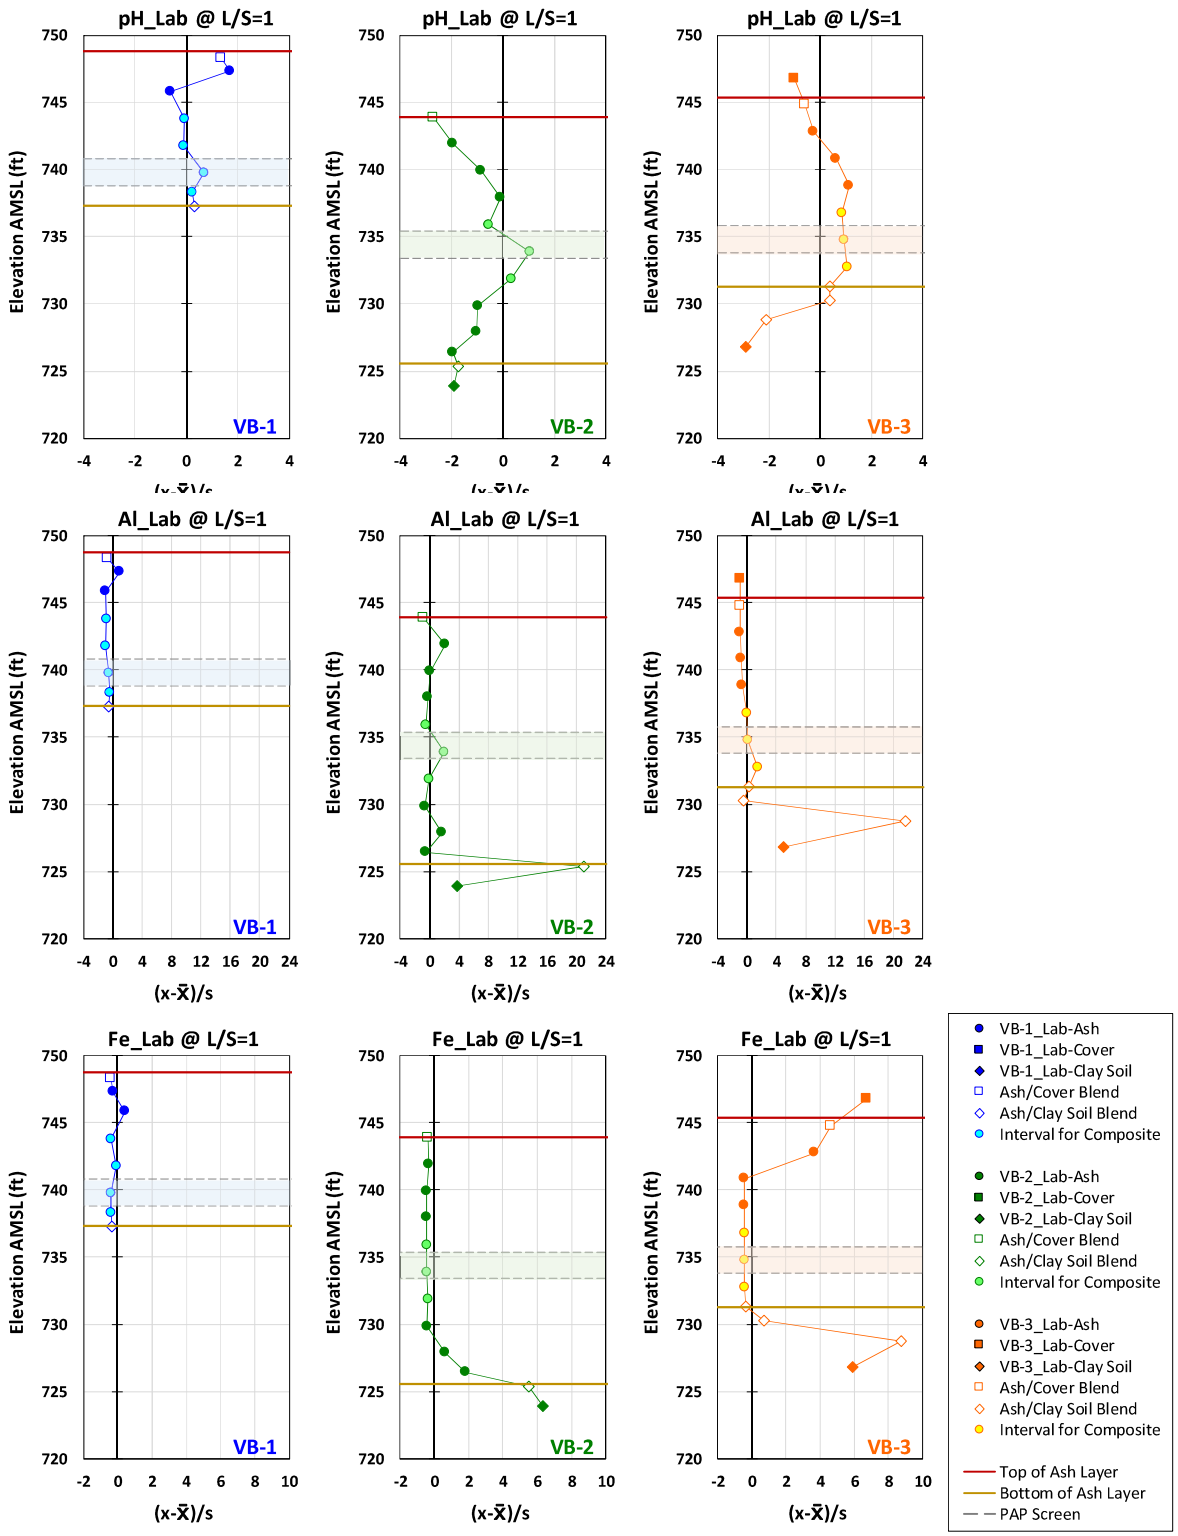

Figure 4-6
Laboratory extraction (L/S=1) concentration profiles within boreholes (VB-1, VB-2, and VB-3) standardized to the global mean (x̄) and standard deviation (s) of known ash samples for pH, aluminum, and iron

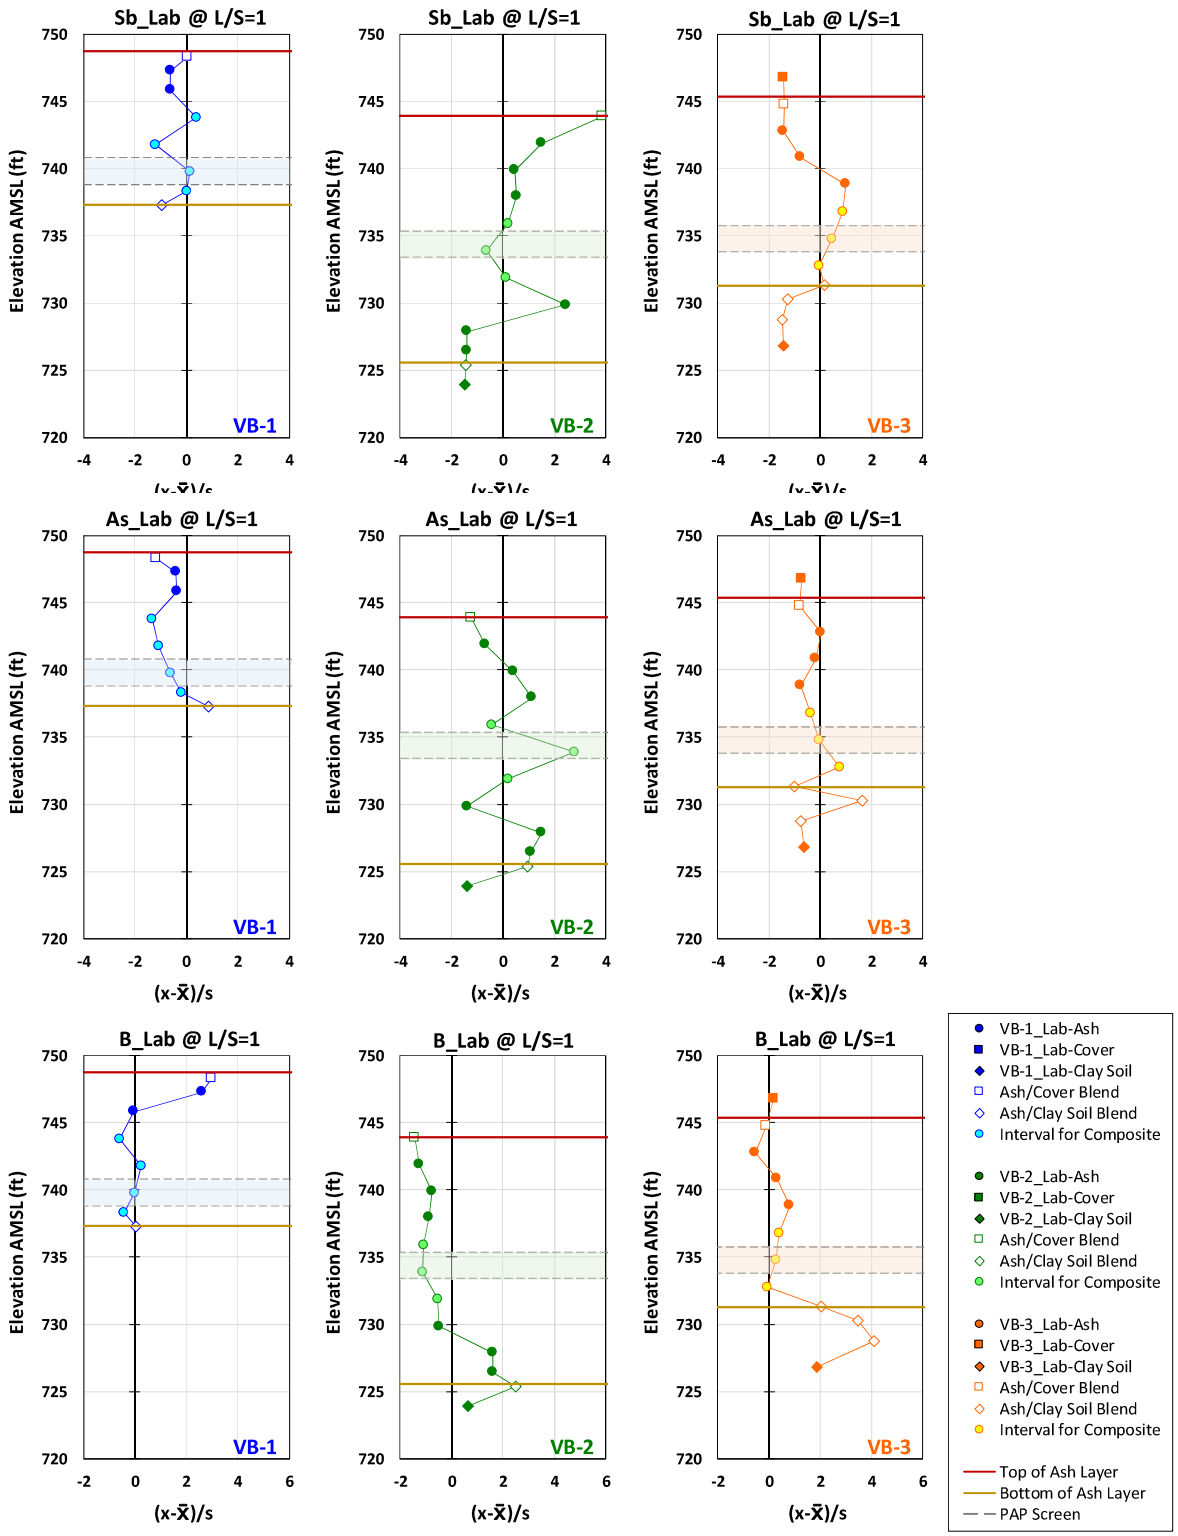

Figure 4-7
Laboratory extraction (L/S=1) concentration profiles within boreholes (VB-1, VB-2, and VB-3) standardized to the global mean (X̄) and standard deviation (s) of known ash samples for antimony, arsenic, and boron

Table 4-4
Global Mean and Standard Deviation of Laboratory Extractions (L/S=1) Concentrations

Analyte	Units	Global Statistics	
		Mean	Std. Dev.
EC	mS/cm	0.38	0.24

Notes: <MDL indicates all or most of the L/S=1 concentrations were less than the MDL

Comparison of Standardized Borehole Profiles for Field and Laboratory Extractions Based on Mass Release (mg/kg)

The standardized borehole variability graphs can be used to examine the differences between field extractions at L/S ~1 and laboratory extractions at L/S=1. Example comparisons for selected major and trace constituents are shown in Figure 4-8 and Figure 4-9, respectively, while the complete results for all measured constituents are presented in Appendix C.3.

In general, the variability of laboratory and field extraction are similar; however, the laboratory extractions are somewhat less variable than the field extractions. This observation is due to the homogenization within a split spoon sample that was conducted on the material used for laboratory extractions, especially for trace species where blending would matter most (see Figure 4-9). A secondary cause for lesser variability in the laboratory extraction data may be a result of redox changes between the laboratory and field extraction conditions.

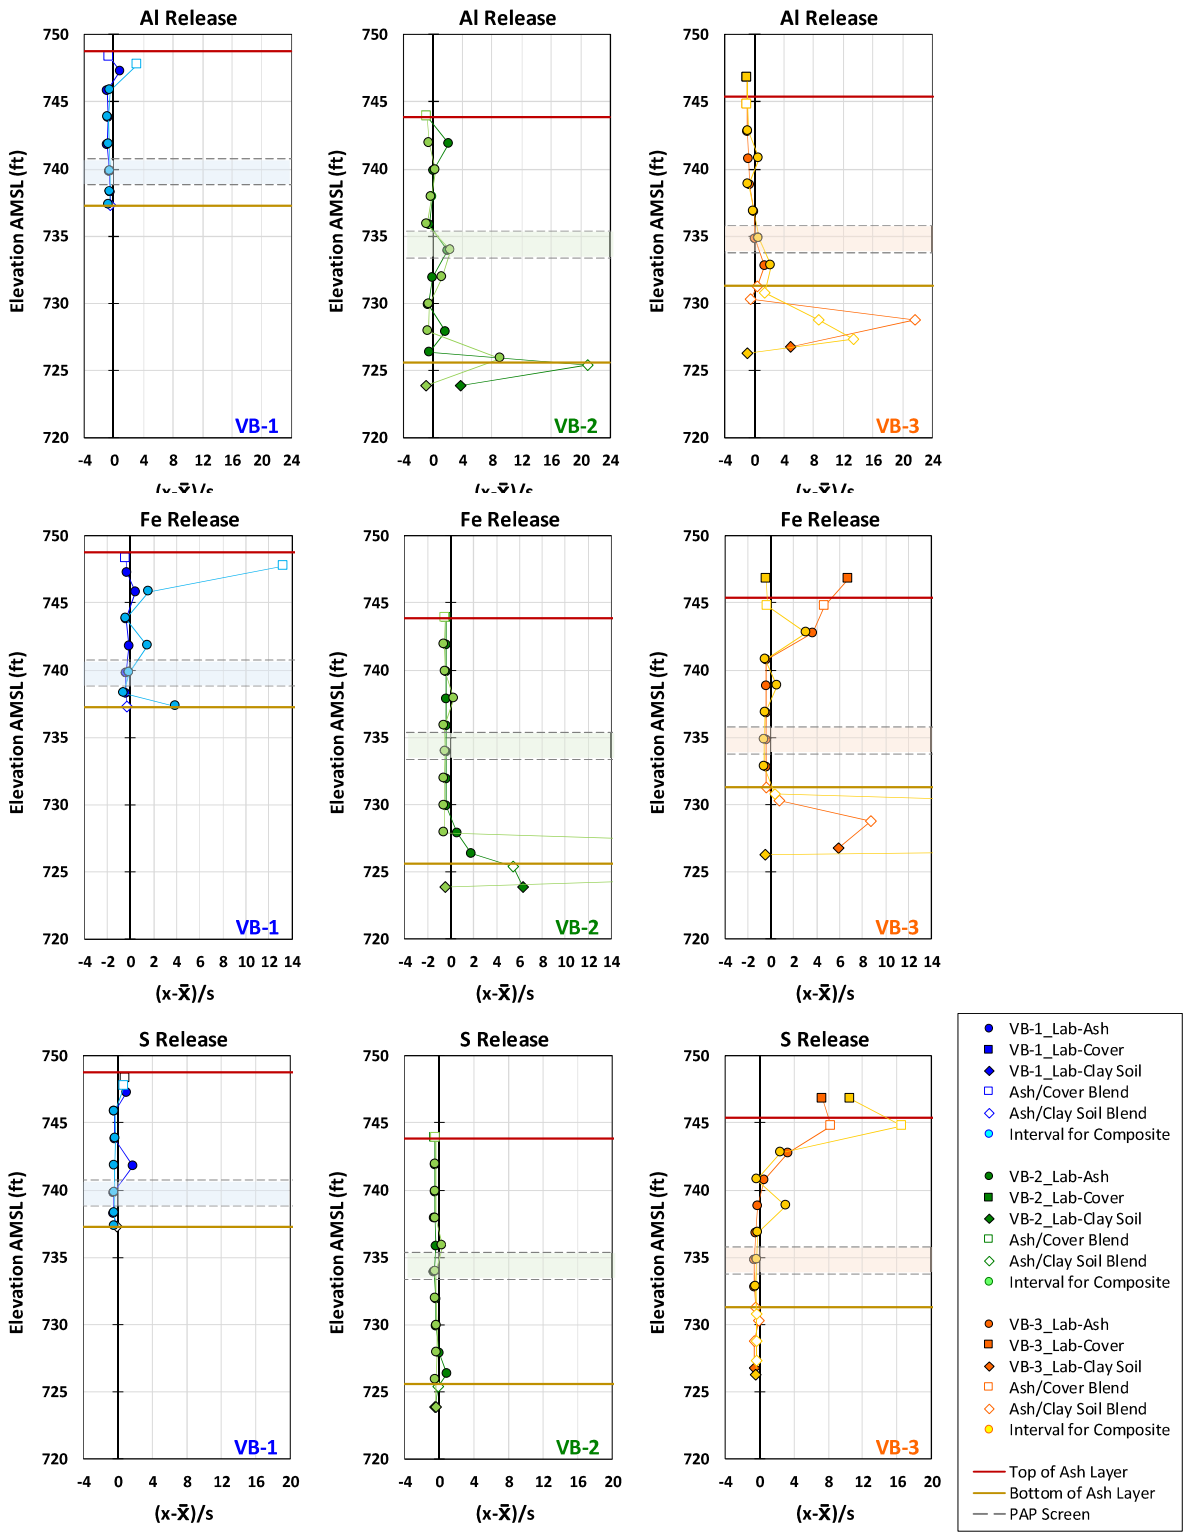

Figure 4-8
Comparison of standardized mass release profiles for field extractions (L/S~1) and laboratory extraction (L/S=1) of major constituents from VB-1, VB-2, and VB-3 for aluminum, iron, and sulfur

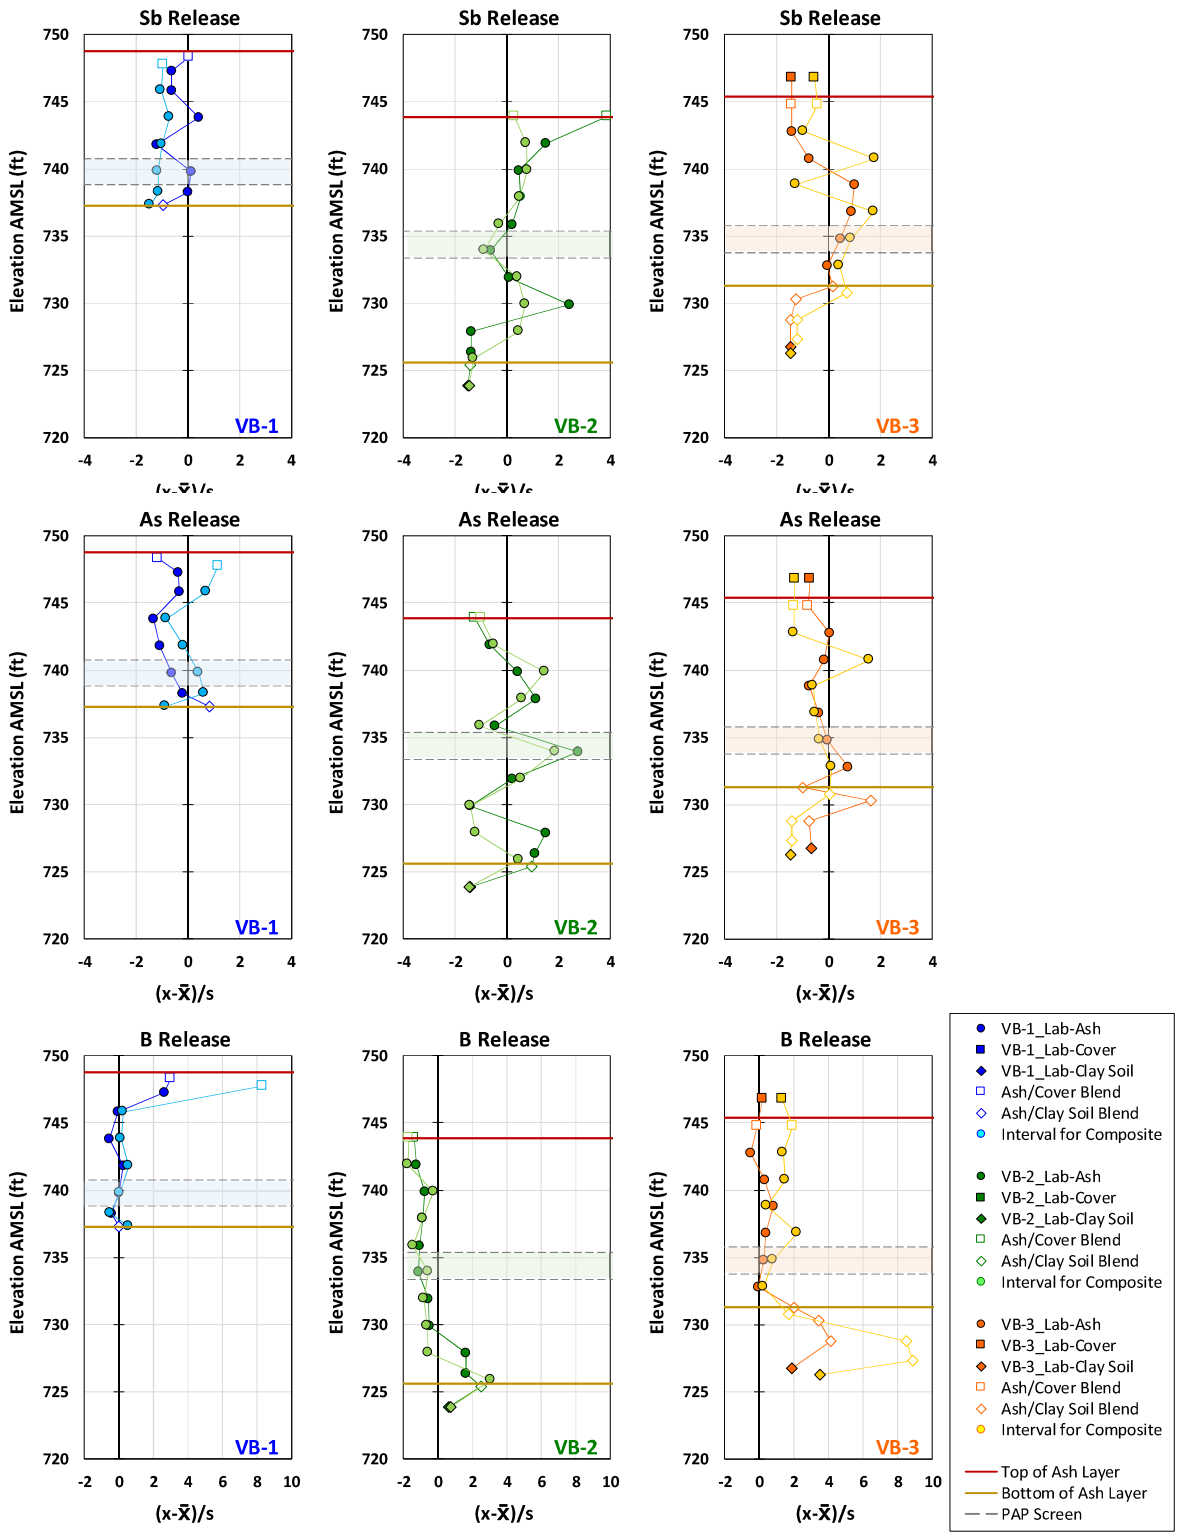

Figure 4-9
Comparison of standardized mass release profiles for field extractions (L/S~1) and laboratory extraction (L/S=1) of trace constituents from VB-1, VB-2, and VB-3 for antimony, arsenic, and boron

Composite Ash Sample Test Results

Subsamples of bulk material collected from split spoon sampling were homogenized within each bulk storage packet and then composited by equal mass over intervals around the PAP screening intervals. These composites were subject to detailed investigation of total and available content, leaching characteristics as a function of pH and L/S, and comparison between leaching tests and to porewater concentrations. The complete set of pH- and L/S-dependent results for all measured constituents is presented in Appendix D.1.

Total Content

In preparation for EPA Method 3052, ash samples were dried under nitrogen and ground to pass a No. 100 (150 μm) sieve. Therefore, although the EPA method is based on "as received" solid sample, which can include the inherent moisture within the material, the results presented on an "as received" mass (mg/kg) are, in this case, based on dry-mass (mg/kg-dry) like the LEAF tests. The total content reported for samples of the three composite materials is shown in Table 4-5. Of the 27 constituents analyzed, Sb, Mg, Hg, Se, Ag, and Tl were reported to have a total content less than the commercial laboratory's reporting limit shown in the table. Furthermore, the total content of thallium was not detected at a value greater than the shown MDL value. Based on the low total content and low eluate concentrations of initial leaching test results, Ag and Hg were not considered in the analysis of test leachates or the comparison to groundwater concentrations. The remaining constituents were retained because preliminary testing indicated that leaching concentrations were low, but quantifiable for most leaching tests.

Table 4-5
Total Content for Composite Samples VB-1, VB-2, and VB-3 Based on EPA Method 3052

Analyte	Symbol	MDL (mg/kg)	RL (mg/kg)	VB-1 (mg/kg)	VB-2 (mg/kg)	VB-3 (mg/kg)
Aluminum	Al	3.1	40	13,000	13,000	13,000
Antimony	Sb	2.0	6.0	3.5 J	3.3 J	4.5 J
Arsenic	As	1.4	10	92 B	110 B	110 B
Barium	Ba	0.24	1.0	370	360	400
Beryllium	Be	0.015	1.0	6.4	5.9	6.8
Cadmium	Cd	0.32	1.0	2.2	1.1	1.7
Calcium	Ca	11	500	930	980 F1	970
Chromium	Cr	0.14	1.5	140	140	150
Cobalt	Co	3.0	25	40	34	35
Copper	Cu	1.5	5.0	130	130	200

Lead	Pb	1.1	7.5	53	46	61
Lithium	Li	0.29	5.0	170	170	190

Table 4-5 (continued)
Total Content for Composite Samples VB-1, VB-2, and VB-3 Based on EPA Method 3052

Analyte	Symbol	MDL (mg/kg)	RL (mg/kg)	VB-1 (mg/kg)	VB-2 (mg/kg)	VB-3 (mg/kg)
Magnesium	Mg	3.7	500	110 J	110 J, F1	120 J
Manganese	Mn	0.11	1.5	250	210	170
Mercury	Hg	0.062	0.2	0.098 J	0.093 J	0.083 J
Molybdenum	Mo	0.16	4.0	8.2	4.5	5.0
Nickel	Ni	0.16	20	100	89	90
Potassium	K	100	1,000	12,000	15,000	15,000
Selenium	Se	1.7	7.5	6.1 J	4.4 J	5.3 J
Silver	Ag	0.11	3.0	1.8 J	1.7 J	1.9 J
Sodium	Na	260	500	1,400	1,700	1,800
Strontium	Sr	0.058	5.0	140	100 F1	120
Thallium	Tl	10	17	ND	ND	ND
Titanium	Ti	1.0	25	7,500	7,800	8,200
Vanadium	V	0.12	5.0	240	240	260
Zinc	Zn	2.0	12	120	110	120

Notes: B the compound was found in the blank and sample.

F1 the matrix spike recovery is outside of acceptance limits

J the result is less than the LLOQ but greater than or equal to the MDL; estimated concentration.

ND the compound was not detected at a concentration above the MDL.

pH-Dependent Leaching Tests

Titration curves from EPA 1313 and 1313_L/S=1 conducted on the VB-1, VB-2, and VB-3 composite samples are presented in Figure 4-10. The titration curve indicates the amount of acid or base (shown as acid additions less than zero) required to provide a specific eluate pH. This is sometimes referred to as the acid/base neutralization capacity of the material. Also shown in Figure 4-10 is the natural pH response for each composite material when no acid or base is added.

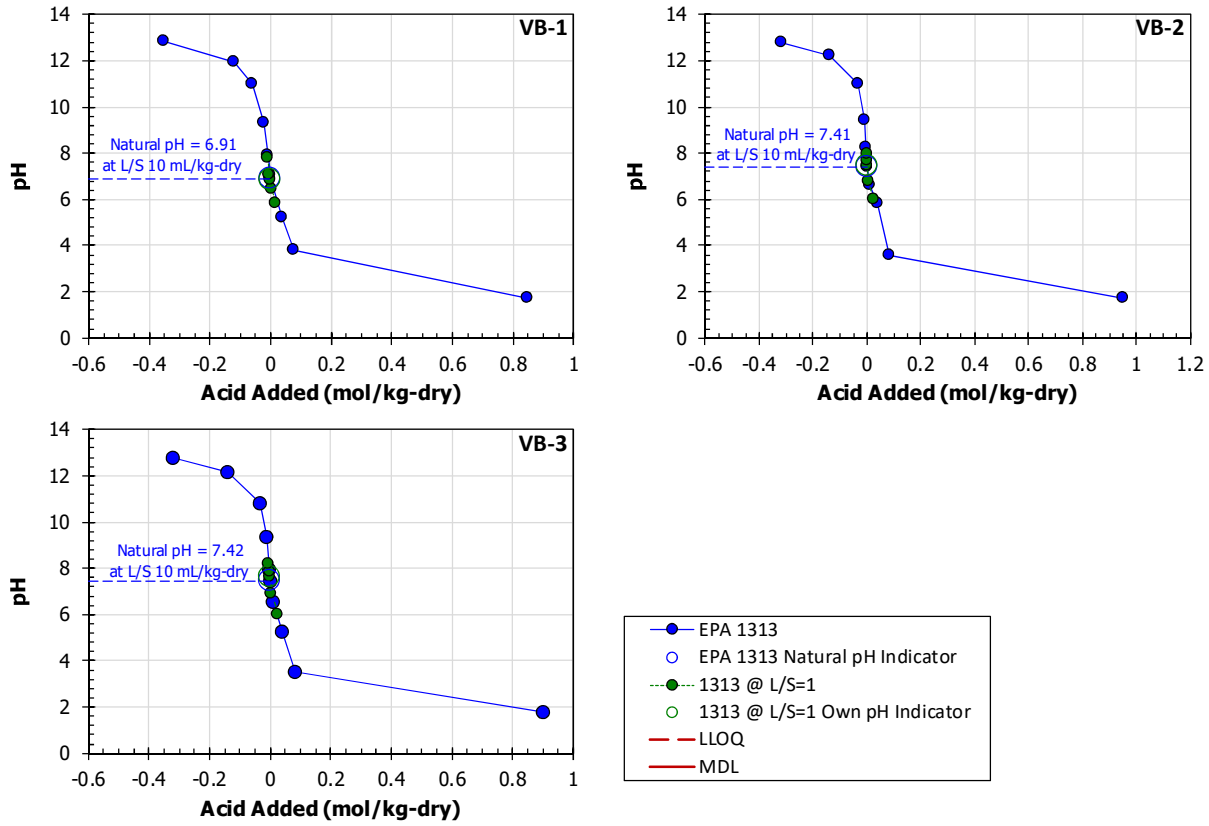

Figure 4-10
Titration curves from EPA 1313 test results from composite testing of VB-1, VB-2, and VB-3

The natural pH values for the three composites are presented in Table 4-6 along with the "own pH" values measured during 1313 testing at an L/S=1 mL/g-dry. Although the natural pH values for all composites are generally neutral, VB-1 is slightly more acidic (pH_{nat}=6.91) than the composites at VB-2 (pH_{nat}=7.41) or VB-3 (pH_{nat}=7.42). The different L/S ratios between natural pH and own pH had little effect on overall pH (less than 0.2 SU).

Table 4-6
Natural pH (EPA 1313) and Own pH (1313_L/S=1) of Composite Samples

	Method	L/S (mL/g-dry)	pH (SU) VB-1	pH (SU) VB-2	pH (SU) VB-3
Natural pH	EPA 1313	10	6.91	7.41	7.42
Own pH	1313_L/S=1	1	6.84	7.45	7.59

Constituent Concentrations

The concentration of a constituent in each eluate of a pH-dependent leaching test (i.e., EPA 1313 and 1313_L/S=1) is indicative of the LSP in equilibrium with the L/S, pH, EC, and ORP of the contacting fluid. Eluate concentrations are typically plotted as a function of eluate pH to indicate how LSP changes over a broad range of pH values. Example test results from EPA 1313 and

1313_L/S=1 are shown in Figure 4-11 through Figure 4-13 as pH-dependent eluate concentration (mg/L) and mass release (mg/kg-dry).

The pH-dependent leaching behavior of a constituent is useful when disposed materials may be contacted with water containing significant amounts of acid or base (e.g., pyrite-impacted groundwater or alkali process wastewaters). These data can be used to parameterize controlling mineral sets in geochemical speciation models, for example, LeachXS^{TM}/ORCHESTRA (Meeussen, 2015), to create a source term for fate and transport modeling.

Solubility-Controlled LSP vs. Available Content-Limited LSP

In addition, comparison of the effects of changing pH (e.g., within an EPA 1313 test) to the effects of changing L/S (e.g., between EPA 1313 and 1313_L/S=1 or EPA 1314) can be used to distinguish constituents with "solubility-controlled LSP" behavior from those with "available content-limited LSP." The following classifications are based on comparison of EPA 1313 test results to those of 1313_L/S=1 testing and, thus, the classifications are limited to a relatively narrow pH range about the natural pH. Outside of those bounds, constituents that were classified as available-content limited may show solubility-controlled LSP.

- Solubility-Controlled LSP – When the eluate concentrations are limited by mineral solubility and precipitation/dissolution, the LSP behavior is considered "solubility-controlled" and pH is a controlling factor for leaching. Eluate concentrations for these behaviors are often a strong function of pH. However, unless pH changes significantly when L/S is changed, eluate concentrations are a weak function of L/S. The pH-dependent results for Ba (Figure 4-11, top) as well as Cr, F^-, Sb, Se, V, and Zn (in Appendix D.1) are good examples of solubility-controlled LSP. For these constituents, eluate concentrations change by orders-of-magnitude as a function of pH but do not change when the L/S is reduced from L/S=10 mL/g-dry (EPA 1313) to L/S=1 mL/g-dry (1313_L/S=1).
- Similarly, adsorption/desorption processes can be highly pH-dependent and often can be classified along with solubility-controlled LSP. For example, the LSP behavior of arsenic (Figure 4-11, bottom) with regard to changes in pH and L/S has similar trends to the solubility-controlled LSP behavior of Ba; however, the primary mechanism for the pH-dependent LSP of arsenic is likely adsorption to hydrous ferric oxides (HFO) rather than solubility of arsenic species.

Electronic Filing: Received, Clerk's Office 07/01/2024

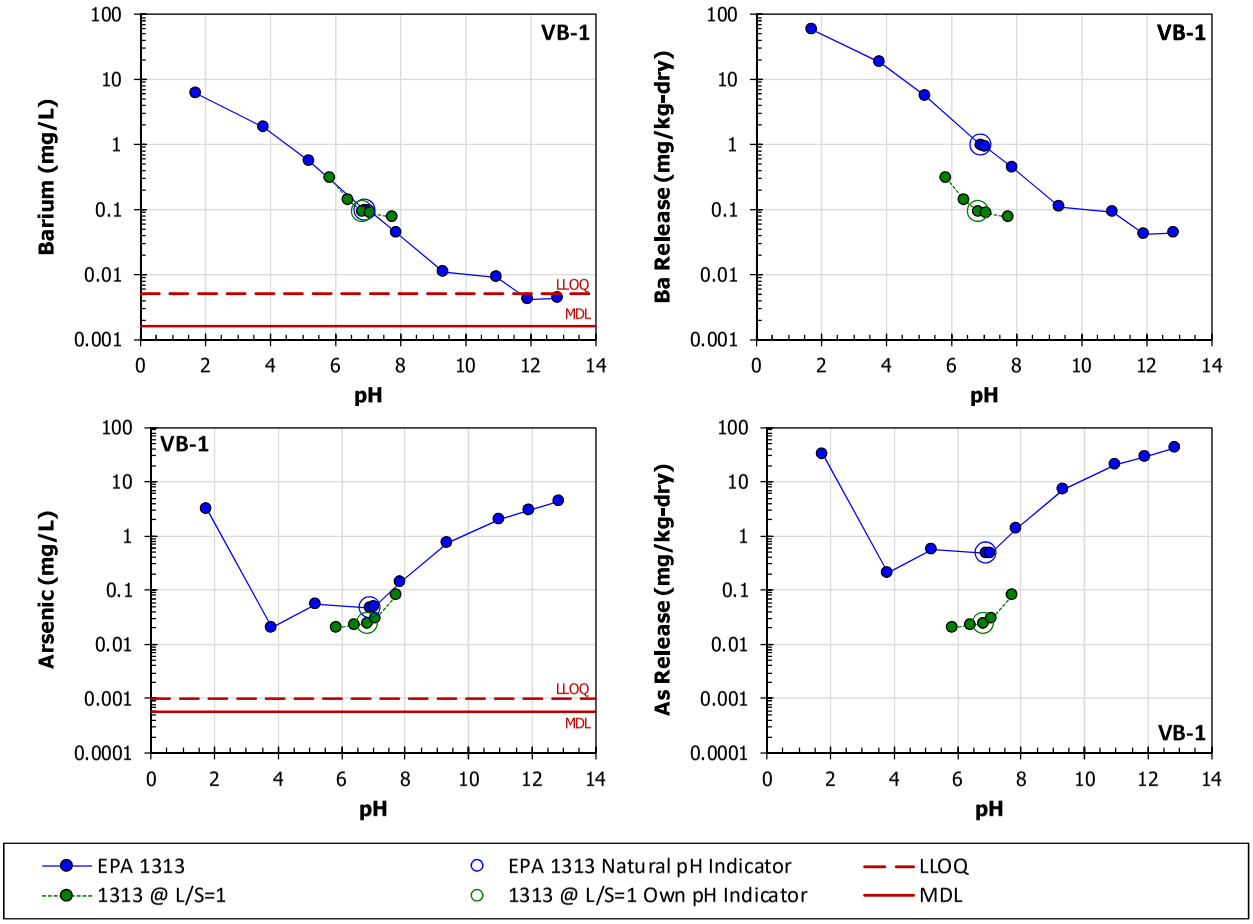

Figure 4-11
Example pH-dependent (EPA 1313) test results showing solubility-controlled LSP (barium) and adsorption-dominated LSP (arsenic)

- Available Content-Limited LSP – The concentration of some highly soluble constituents is not limited by the conditions of the eluate but by the amount of leachable mass in the solid. The characteristic pH-dependent behavior of these "available content-limited LSP" constituents is that eluate concentration curve is a weak function of pH but a strong function of L/S. Figure 4-12 presents examples of available content-limited LSP for B and SO_4^{-2} results from EPA 1313 and 1313_L/S=1. These figures show that pH-dependent concentrations within a test vary by approximately an order-of-magnitude across the entire pH range. However, when the L/S changes from L/S=10 mL/g-dry to L/S=1 mL/g-dry, the eluate concentration changes accordingly. Because the L/S effect is correlated to the magnitude of the L/S, the mass release (i.e., the eluate concentration multiplied by the L/S) is the same for both tests. Available content-limited LSP was observed for B, Ca, Cl^-, Mo, SO_4^{-2}, and Tl in VB-1, VB-2, and VB-3 composites (Appendix D.1).

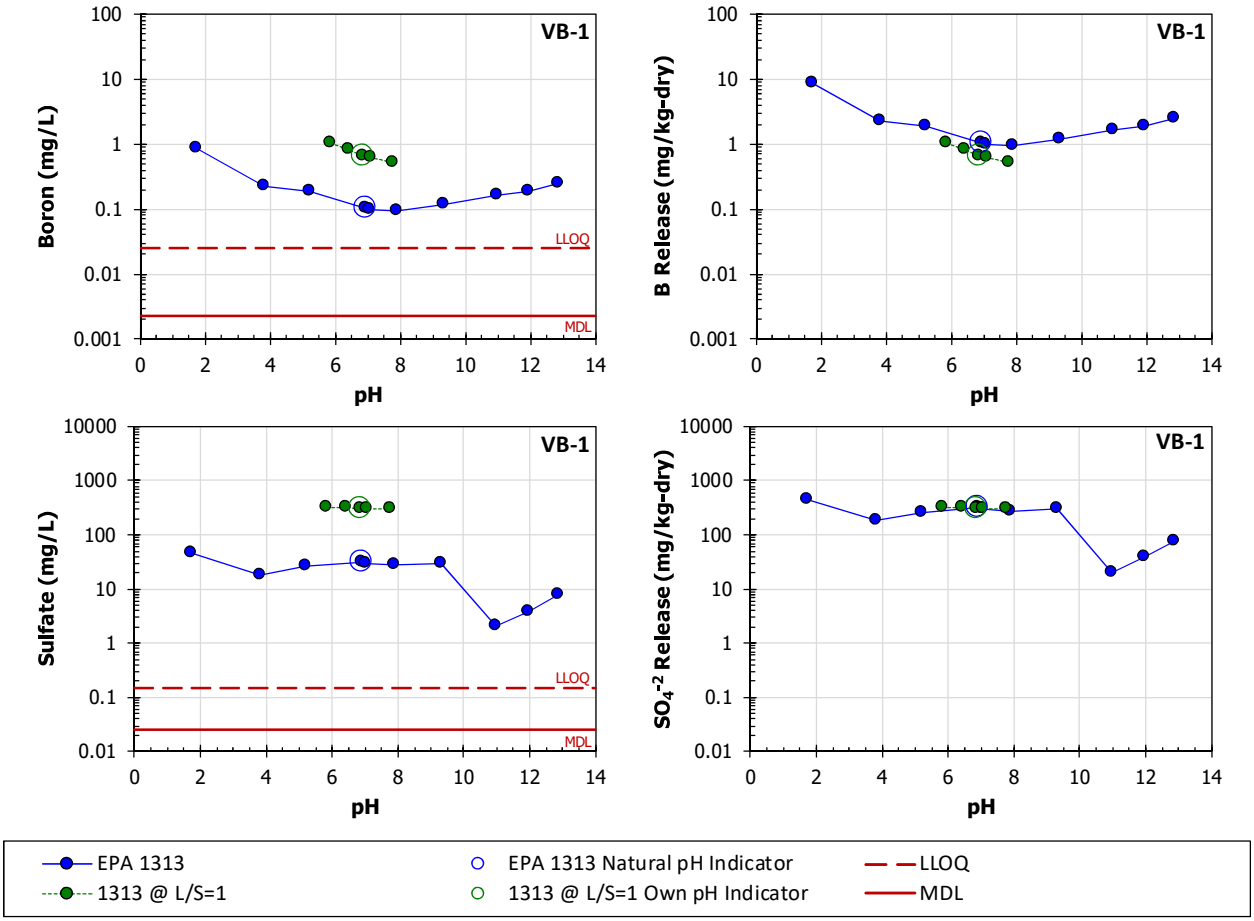

Figure 4-12
Example pH-dependent (EPA 1313) test results showing available content-limited LSP

For some constituents, the pH-dependent leaching data does not support the determination of LSP behavior, because eluate concentrations are less than the MDL for the analytical method. Figure 4-13 presents examples for Be and Li. Similar behavior was shown for Cd, Co, Cu, Fe, Ni, and Pb (Appendix D.1).

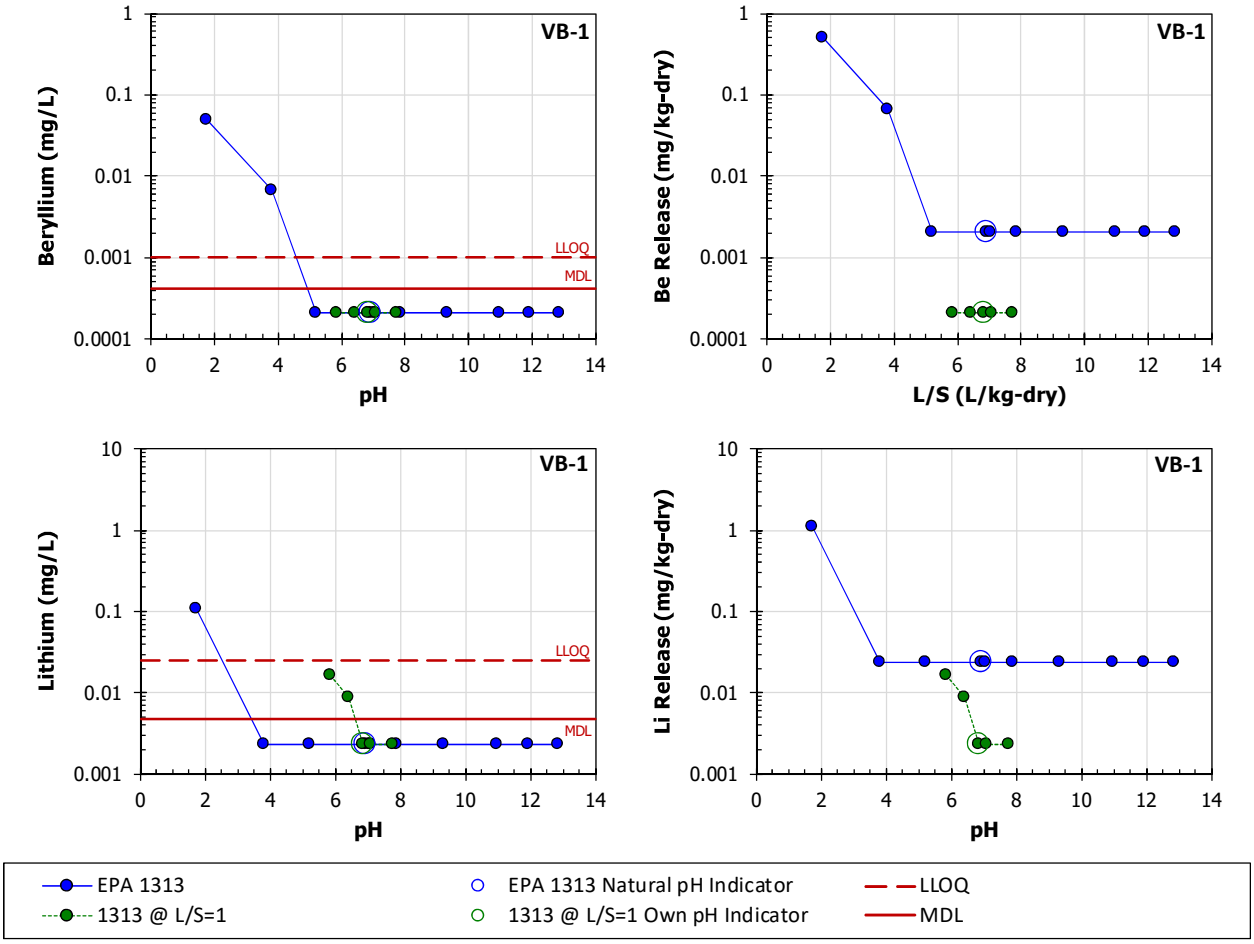

Figure 4-13
Example pH-dependent (EPA 1313) test results for constituents where LSP type could not be determined based on measured concentrations

Available Content Determination Using EPA 1313

The available content of the three borehole composites was determined from the maximum concentration over the pH range $2 \leq pH \leq 13$ from EPA 1313 testing. The available content values and pH locations for the maximum 1313 concentration are shown in Table 4-7. In Table 4-8, comparison of available content (mg/kg-dry) to the total content (mg/kg) shown in Table 4-5 indicates that only a small fraction of most constituents is leachable over a broad pH range. The high ratios of available Ca and Mg to their total content suggest either that digestion by EPA 3052 was not complete or that there is inherent error associated with multiplying a relatively small digestate concentration by a large effective L/S of 500 or more.

Table 4-7
Available Content for Composite Samples VB-1, VB-2, and VB-3 Based on the Maximum Concentration from EPA Method 1313

Notes:
- * total content data indicated an analytical anomaly (see error codes below).
- B the compound was found in the blank and sample of the total content analysis extract.
- F1 the matrix spike recovery for the total content analysis extract is outside of acceptance limits.
- J the total content result was less than the LLOQ but greater than or equal to the MDL; estimated value.

Comparison of pH-Dependent Leaching from Individual Split Spoon Samples to Composite Samples for Each Borehole

pH-dependent leaching data (EPA 1313) from composite samples was compared to laboratory extractions of individual split spoon materials to illustrate how the composite samples represented the strata of ash materials. Bulk materials collected by split spoon were homogenized within the vacuum-sealed bag prior to testing using a modified, 3-point version of EPA 1313. The 3-point version of EPA 1313 that was applied to individual split spoon samples included extractions at $1.5 \leq pH \leq 2$, the natural pH, and $pH = 9 \pm 0.5$, and the results were used as comparators to the full-range testing conducted on the composite samples. Example results are provided in Figure 4-14 and Figure 4-15 for major and trace constituents, respectively. The complete set of testing results are presented in Appendix D.2.

The data in these figures indicate the extent of agreement between individual split spoon data (individual points) and EPA 1313 testing of composites (continuous lines). The variability in leaching properties within a borehole (individual split spoons) is consistent with the laboratory and field extraction variability discussed above regarding variability of extraction tests within a borehole. The variability between composites and individual samples for trace constituents is dominated by the variability of composition for these constituents within the individual grab samples. When analyses approach quantitation limits (e.g., for trace constituents or LSP curves near the LLOQ), the variability is likely attributed to the measurement uncertainty.

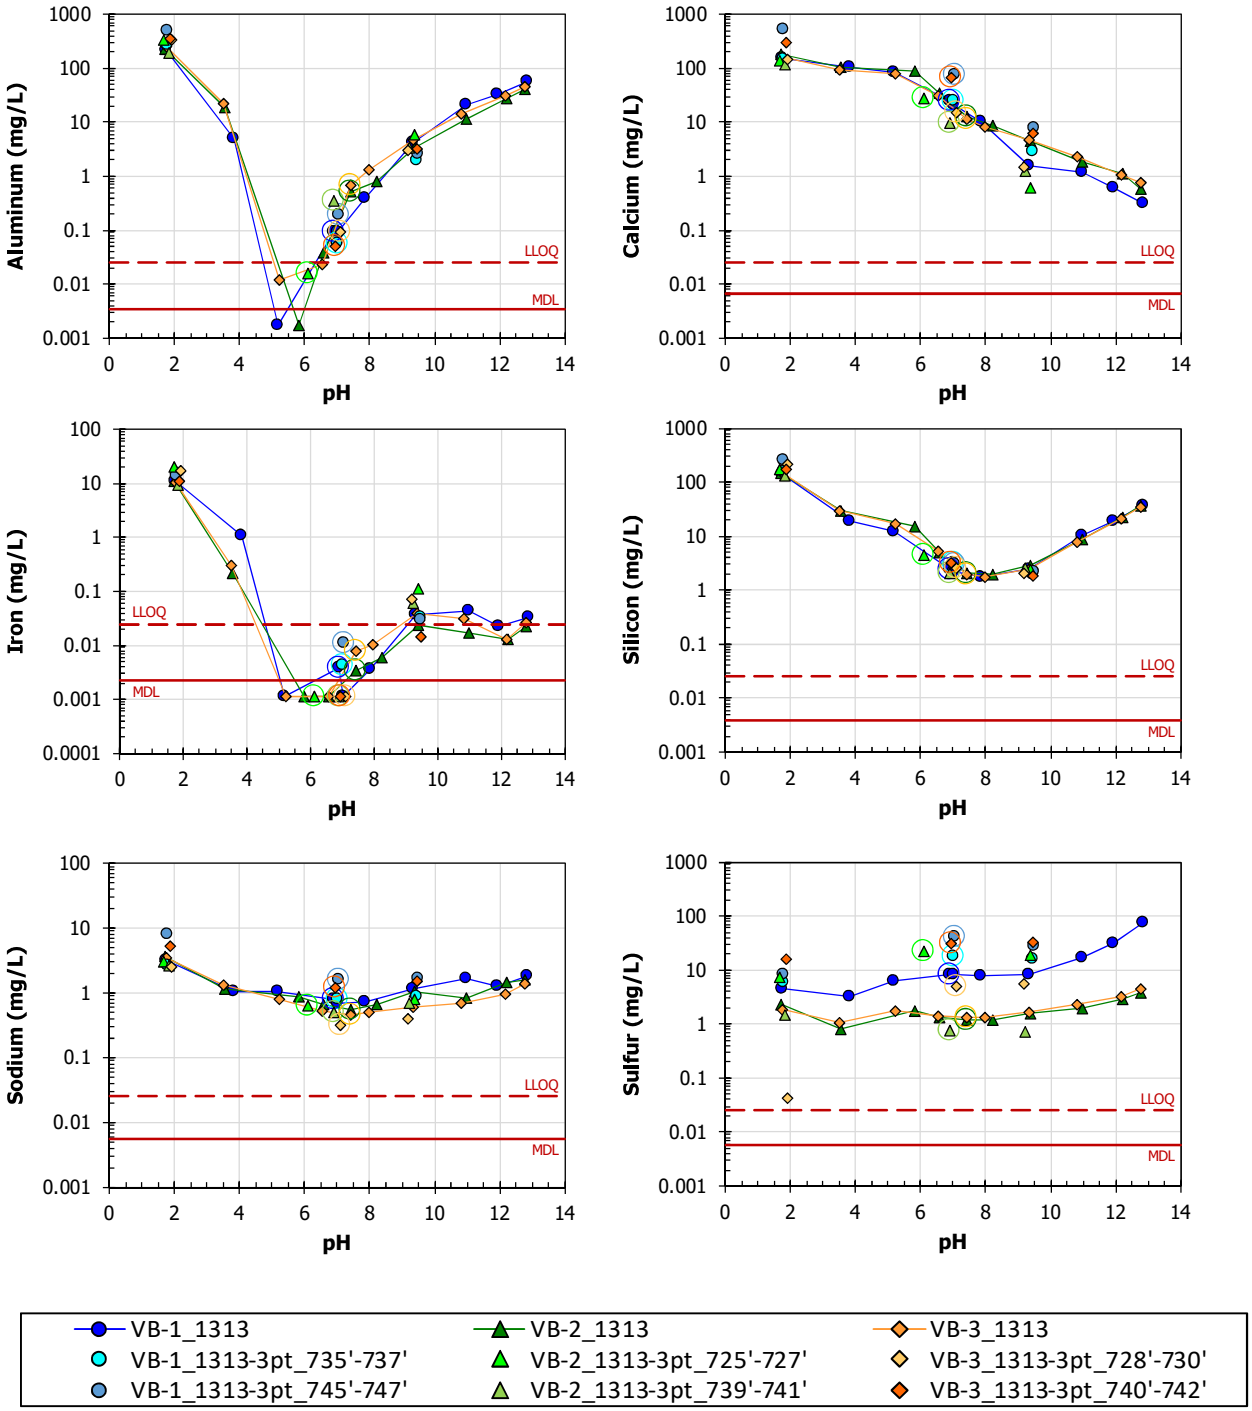

Figure 4-14
Comparison of pH-dependent leaching data for major constituents using individual split spoon samples (3-pt EPA 1313) and borehole composite materials (EPA 1313)

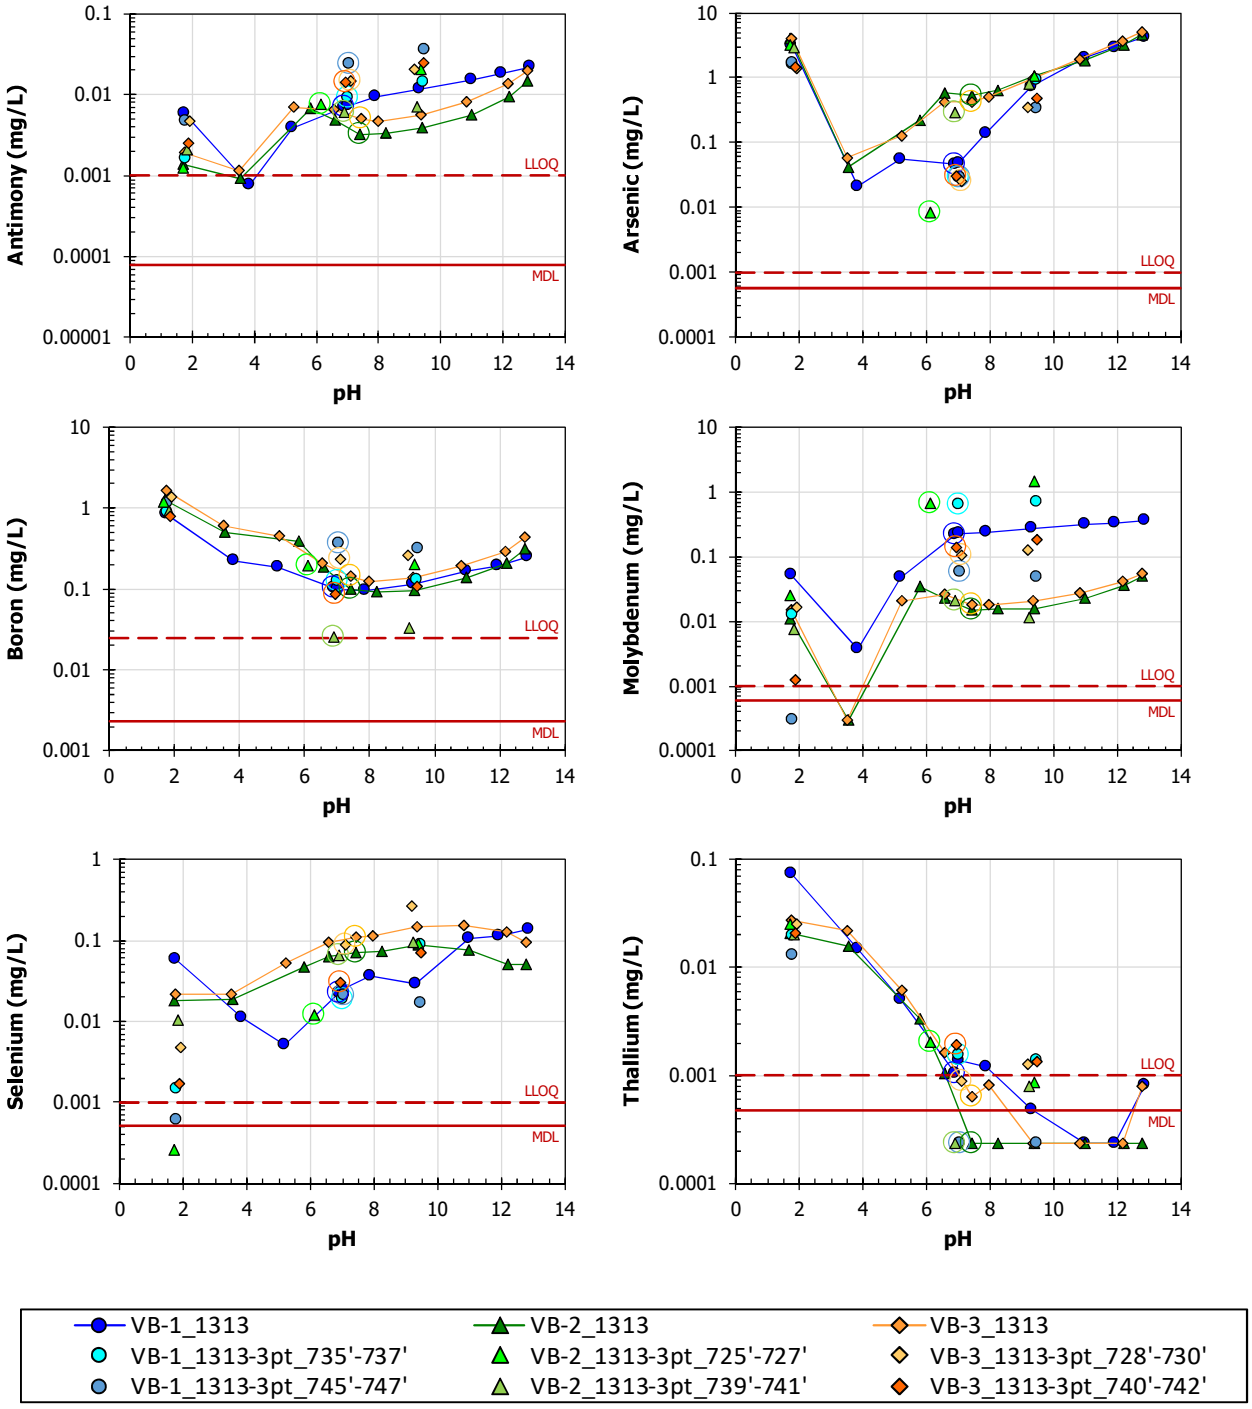

Figure 4-15
Comparison of pH-dependent leaching data for trace constituents using individual split spoon samples (3-pt EPA 1313) and borehole composite materials (EPA 1313)

L/S-Dependent Leaching Test Results

When conducted at low flow rate, the results of column tests (e.g., EPA 1314) indicate how the LSP of constituents changes as the cumulative L/S (i.e., the total amount of water passing through a column to the mass of solid in the column) increases. As soluble minerals dissolve and constituents are eluted from the material, different minerals control the release of constituents and the ionic strength of the eluate changes. In scenarios where L/S can be related to the rate of infiltration, column test data can provide an estimate of leaching concentration as a function of time (Garrabrants et al., 2019a; b).

Examples of typical L/S-dependent behavior from EPA 1314 conducted on the VB-1 composite are shown in Figure 4-16. In this figure, eluate concentration (mg/L) is presented in the left column while mass release (mg/kg-dry), determined by the accumulated interval mass released up through a cumulative L/S value, is shown in the right column. Interval mass release is calculated by multiplying the eluate concentration by the associated interval L/S value. In mass release graphs, the gray dashed line indicates the mass release proportional to the cumulative L/S expected if concentration is controlled by constant solubility.

- The eluate concentrations for Ba (Figure 4-16, top) are constant as a function of L/S and, thus, the mass release is proportional to the cumulative L/S and the mass release curve follows the solubility indicator line. This L/S-dependent behavior is consistent with a constituent that has solubility-controlled LSP. In the composites, As, F^-, Li, Sb, and V show the similar solubility-controlled LSP based on EPA 1314 data as Ba.
- For many constituents in the composite samples (Cd, Co, Cr, Ni, Se, Tl, and Zn), the L/S-dependent leaching data indicated that the constituent is quickly depleted from the matrix. For Tl (Figure 4-16, middle), the eluate concentration is a strong function of L/S but drops below the MDL when L/S increases beyond approximately L/S=3 L/kg-dry. This behavior is characteristic when the available content has been depleted.
- The L/S-dependent leaching of Cl^- (Figure 4-16, bottom) is an example of rapid release of a soluble fraction of the available content without depletion. This differs from the example behavior of Cd in that, after an initial "wash off" of a highly soluble fraction, leaching concentrations are detectable and relatively constant, suggesting a solubility-controlled fraction. Similar behavior was observed for B, Ca, Mo, and SO_4^{-2} in composite samples.
- Elements where EPA 1314 eluate concentrations were not detected include Be, Br^-, Cu, Fe, and Pb.

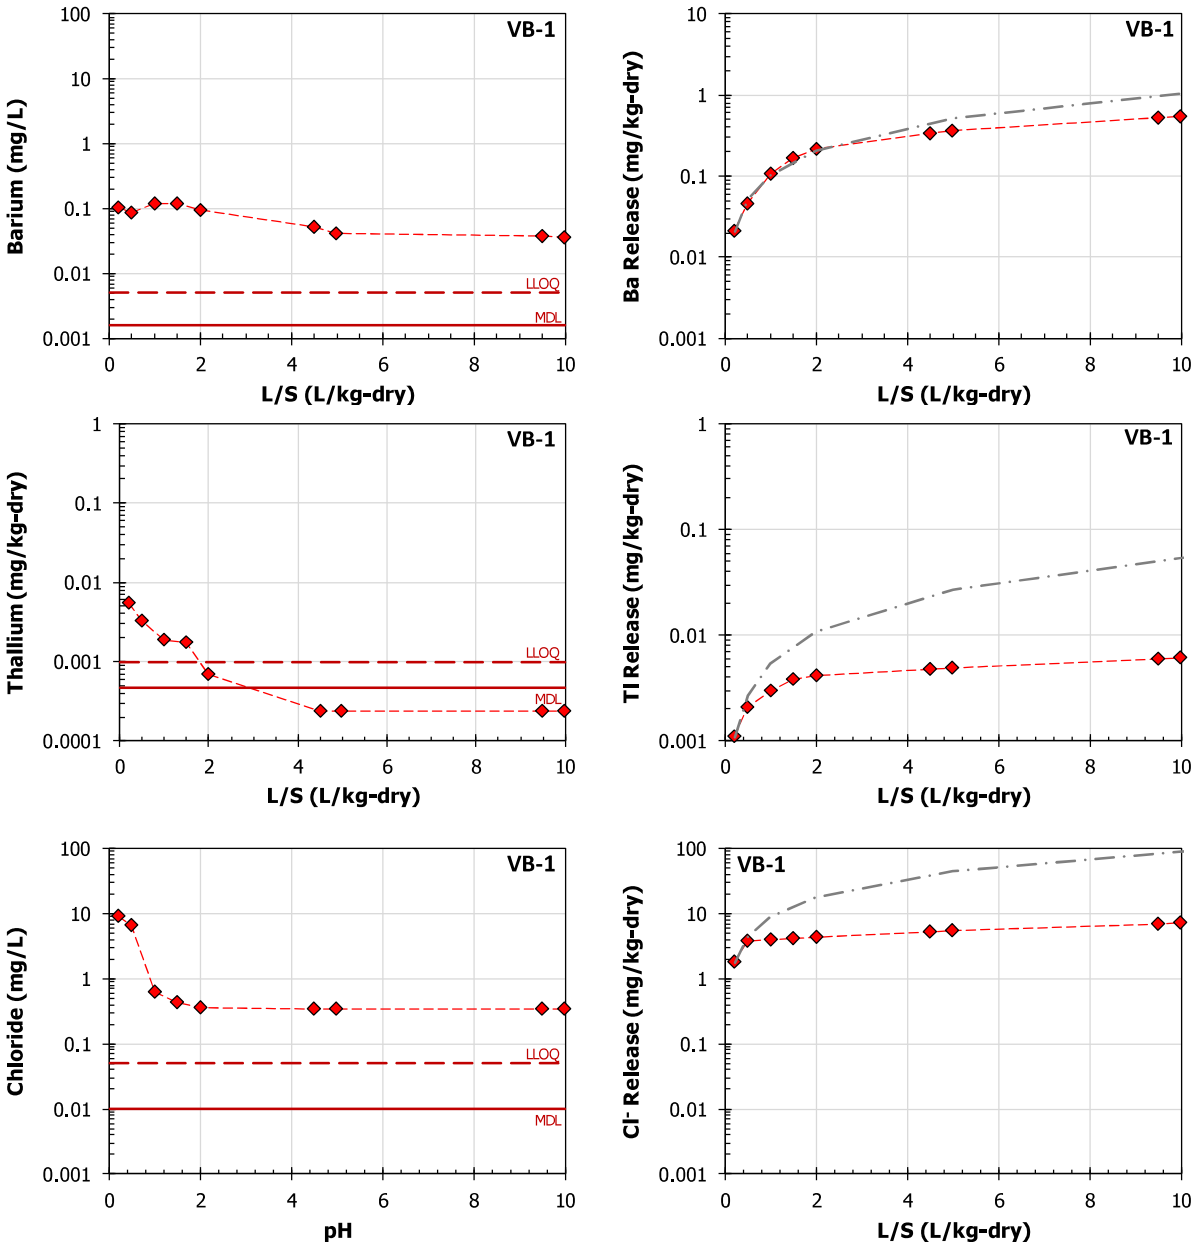

Figure 4-16
Example EPA 1314 test results from VB-1, showing a solubility-controlled constituent (barium), depletion of the available content (thallium), and wash-off of a soluble constituent fraction without depletion (chloride)

Traditional Extraction Test Results

The calculated L/S and measured pH from the extractions using the traditional leaching tests (TCLP, SPLP, and ASTM) are presented in Table 4-9.

Table 4-9
Liquid-to-Solid Ratio and Measured Extraction pH for Traditional Leaching Tests

Material	TCLP		SPLP		ASTM	
	L/S (mL/g-dry)	pH	L/S (mL/g-dry)	pH	L/S (mL/g-dry)	pH
VB-1	22.9	4.99	22.9	6.39	27.3	6.71
VB-2	22.1	5.00	22.1	6.89	28.1	7.27
VB-3	23.2	4.95	23.2	6.94	26.9	7.17

The amount of extraction fluid for ASTM is determined as the mass of the "as received" test material in grams divided by the test-specific L/S of 20 mL/g. The resultant L/S on a dry basis is greater than 20 because of the water inherent in the pores of the "as received" material. The procedures for TCLP and SPLP require a pressure filtration preconditioning of the test sample to remove excess liquid, which is analyzed separately. The extraction fluid is based on the mass of pressure-filtered solid material in grams divided by the same L/S of 20 mL/g. Therefore, the calculated L/S for TCLP and SPLP is lower than the L/S for the ASTM test that includes extra water.

The measured pH for ASTM, which uses DIW as an extraction fluid, is consistent with the natural pH (1313) and own pH (1313_L/S1) of the composites at VB-1, VB-2, and VB-3 reported in Table 4-6. The slight decrease in ASTM extraction pH compared to the natural pH (e.g., VB-1 pH_{ASTM}=6.71 versus pH_{Nat}= 6.91) may be attributed to the higher ASTM extraction L/S. For SPLP, the measured pH is slightly lower than the ASTM pH, consistent with the small amount of acid used in the extraction fluid. The stability of the measured pH for TCLP extracts across different composites reflects the buffering provided by the organic acetic acid.

The eluate constituent concentrations for TCLP, SPLP, and ASTM tests are presented in Table 4-10, Table 4-11, and Table 4-12, respectively. Since pH is an important factor for solubility-controlled LSP, these tables also include the final eluate pH. Recording of eluate pH allows for comparison of the results of these traditional tests to the pH- and L/S-dependent LEAF test results. In general, SPLP and ASTM concentrations were comparable to each other but were lower than TCLP concentrations due to the lower pH of TCLP eluates. Exceptions for this site (which may not be generalizable) include As, Mo, and SO_4^{-2}, where similar concentrations were measured in all three procedures, and PO_4^{-2}, Se, and V, where SPLP and ASTM eluates had higher concentration than TCLP eluates. All of these observations are consistent with the pH-dependent LSP curves discussed above.

Table 4-10
TCLP (EPA Method 1311) Eluate Concentrations

Comparison of Traditional and LEAF Test Results

When the pH and L/S of leaching tests are recorded, the test results from different leaching tests can be compared based on pH- or L/S-dependence. An example comparison is shown in Figure 4-17 for SO_4^{-2} leaching from the VB-1 composite. Similar comparisons for all constituents are presented in Appendix E.

Figure 4-17 presents data as a function of pH on the left and as a function of L/S on the right. For a constituent with available content-limited LSP, for example sulfate, the traditional leaching test data are consistent with LEAF test results considering the shift in pH (TCLP) and the higher L/S for the traditional tests.

Electronic Filing: Received, Clerk's Office 07/01/2024

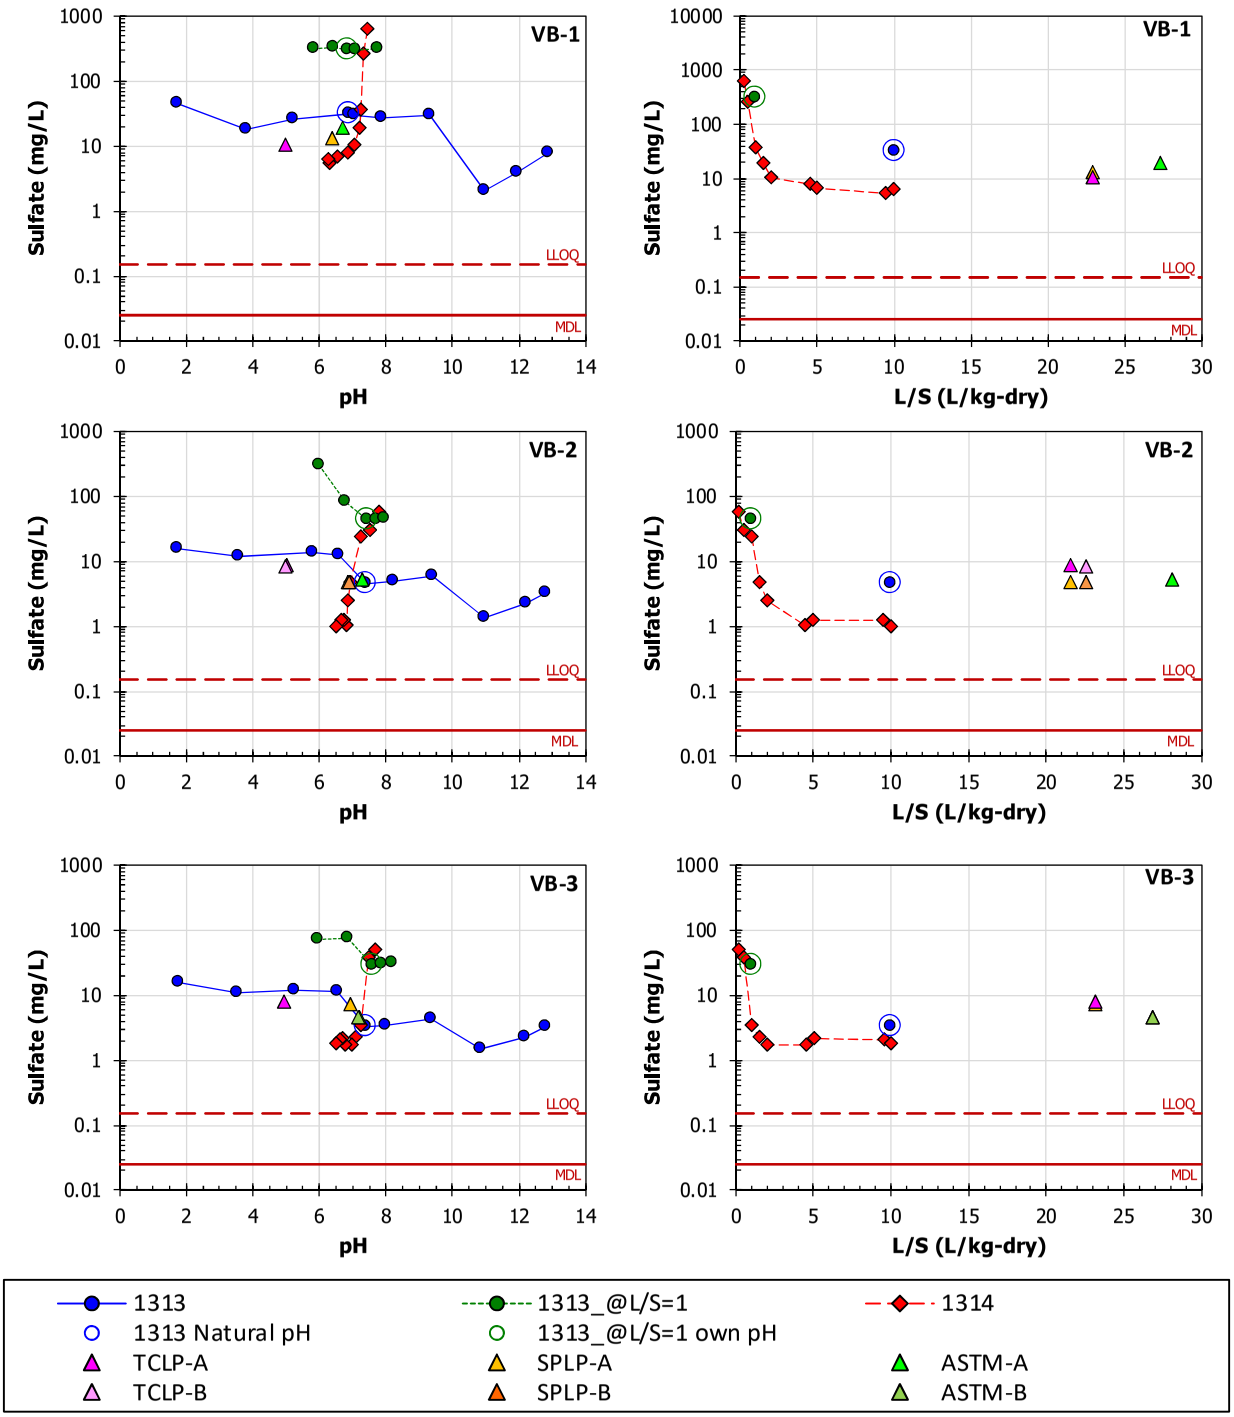

Figure 4-17
Comparison of sulfate concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

Groundwater, Porewater, and Subsurface Gas Monitoring

Measured field parameters for groundwater and porewater sampling as well as graphical presentation of groundwater and porewater concentrations are provided in Appendix F.1. These data represent the sampling period from September 2018 through September 2019.

Groundwater and Porewater Field Parameters

Plots of field measurements are shown in Figure 4-18 and Figure 4-19. Within each bar chart, data for groundwater sampled at the upgradient well (AD1) and downgradient well (6AR) are shown in light and dark gray, respectively, while data for porewater from the PAPs (VB-1, VB-2, and VB-3) are shown as blue, green, and gold bars, respectively.

The data in Figure 4-18 show that the water table elevation, pH, and electrical conductivity remain relatively constant over time at each sample point. No samples were collected in November due to a scheduling conflict. The mean water table at the upgradient well (773.4 ft AMSL) is approximately 30 feet higher in elevation than the mean water table of the three PAPs (741.6 ft AMSL) or the mean water table at the downgradient well (738.5 ft AMSL). The pH of the groundwater at the upgradient well is somewhat more alkaline ($pH_{ave\text{-}AD1}$=8.6±0.2) than the porewater in the PAPs ($pH_{ave\text{-}VB\text{-}1}$=8.1±0.1, $pH_{ave\text{-}VB\text{-}2}$=7.8±0.5, $pH_{ave\text{-}VB\text{-}3}$=7.7±0.4) and considerably more alkaline than in the downgradient well ($pH_{ave\text{-}6AR}$=4.8±0.1).

Figure 4-19 presents measured values of water temperature, ORP, and DO. Of these, water temperature and ORP show a seasonal trend. The decrease in ORP in the late summer and fall months may indicate an increase in biological activity. Although there is significant variability in the measured value, the mean dissolved oxygen in the downgradient well ($DO_{ave\text{-}6AR}$=1.0±0.5 mg/L) is somewhat lower than in the PAPs ($DO_{ave\text{-}VB\text{-}1}$=1.4±0.7 mg/L, $DO_{ave\text{-}VB\text{-}2}$=1.4±0.4 mg/L, $DO_{ave\text{-}VB\text{-}3}$=1.7±0.3 mg/L) and notably lower than in the upgradient well ($DO_{ave\text{-}AD1}$=2.6±0.5 mg/L). The expected value for dissolved oxygen at equilibrium with atmospheric oxygen at a temperature of 20 ºC is approximately 9.1 mg/L (USGS, 1998).

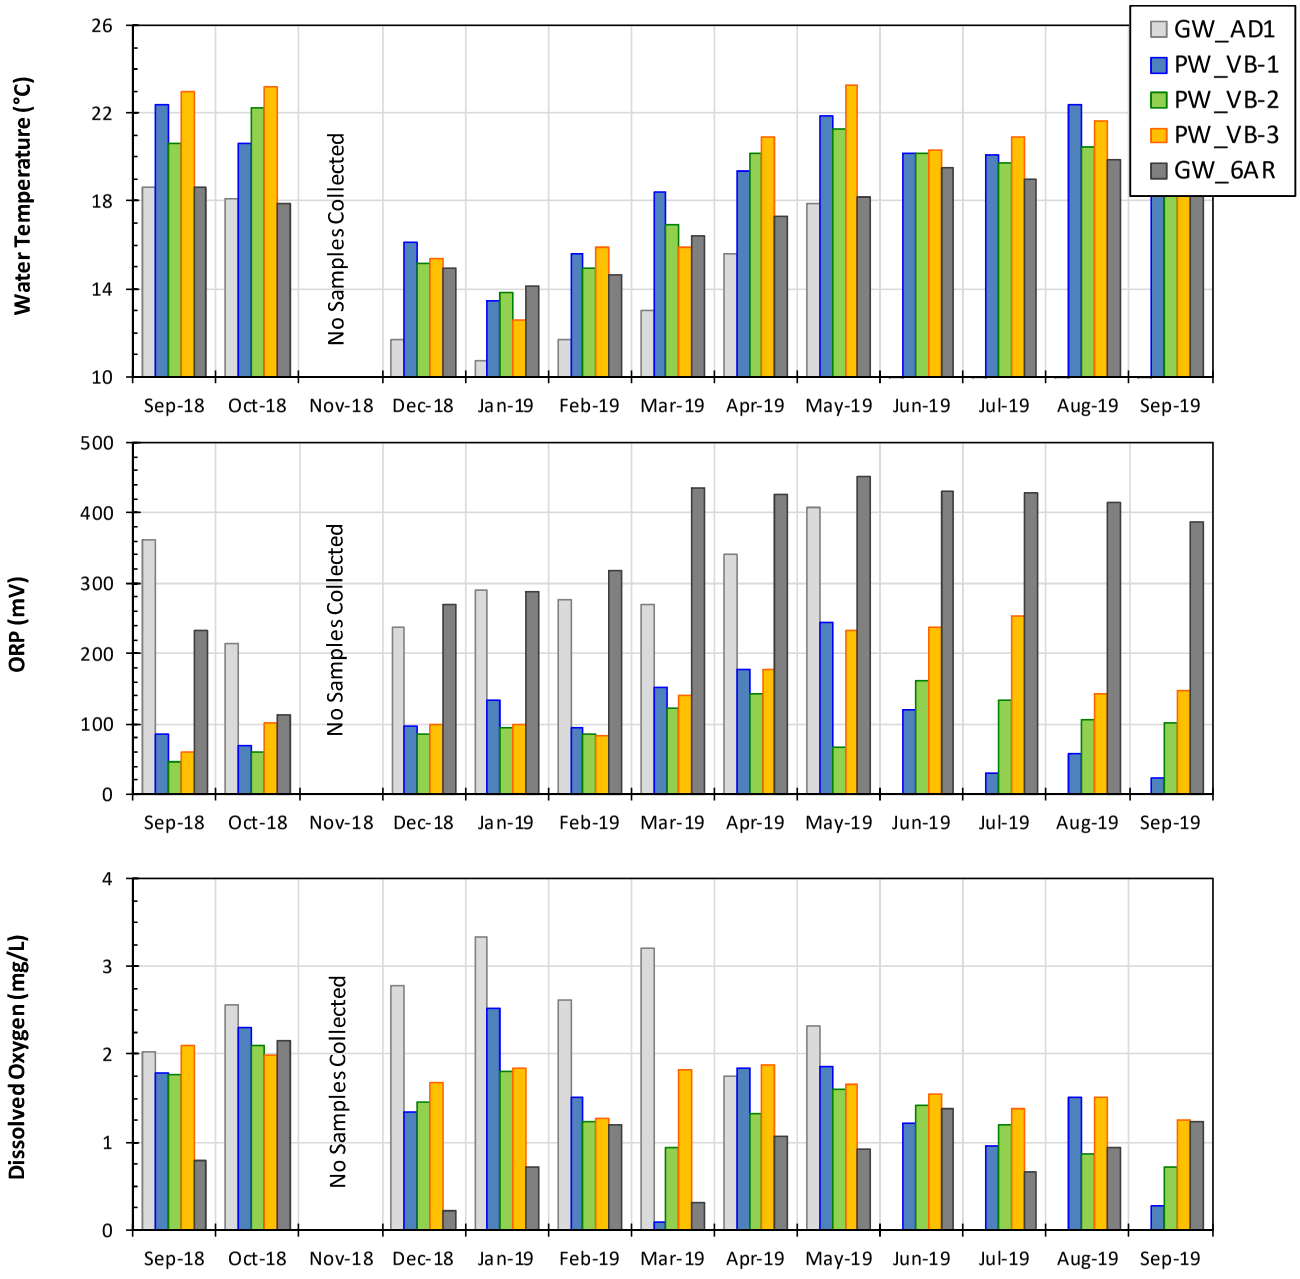

Figure 4-19
Groundwater and porewater field parameters from monthly sampling (temperature, ORP, and DO)

Concentrations in Groundwater and Porewater

Monthly analysis of groundwater wells and PAPs focused on 22 constituents, including 17 from 40 CFR 257 (As, B, Ba, Be, Ca, Cd, Cl^-, Co, Cr, F^-, Li, Mo, Pb, Sb, Se, SO_4^{-2} and Tl). Five additional constituents that were analyzed were Cu, Fe, Ni, V, and Zn. Examples of the results for selected constituents are presented in Figure 4-20 and Figure 4-21, while the graphical results for all 22 constituents are presented after the field parameter data tables in Appendix F.1.

Overall, concentrations in the downgradient groundwater well at 6AR are relatively low. A comprehensive review of impacts to groundwater based on one downgradient well (6AR) and one upgradient well (AD1) is not sufficiently robust to determine with confidence whether or not the groundwater quality at 6AR represents a release from the closed impoundment. Therefore, the discussion that follows allows for either possibility as the relationship between porewater and downgradient groundwater is explored. Table 4-13 groups the observed concentrations from monthly analysis to express the relationships between groundwater across the site (6AR vs. AD1) and porewater concentrations relative to downgradient groundwater (PAPs vs. 6AR). Of the 22 constituents analyzed, Pb, Sb, Tl, and V are not included in the table because the concentrations of these constituents were below the MDL in both porewater and groundwater.

Table 4-13
Relationships Between Upgradient Groundwater (AD1), Downgradient Groundwater (6AR), and Porewater at PAPs (VB-1, VB-2, and VB-3)

	Downgradient > Upgradient	**Downgradient ≤ Upgradient**
Porewater < Downgradient	Be**, Cd, Cr, Co, Fe,Ni, Se**, SO_4^{-2}, Zn	none
Porewater > Downgradient	B, Ca, Cl^-, Li	As*, Ba, Cu*, F^-, Mo*

Notes
* Indicates that groundwater concentrations mostly below the MDL
** Indicates that porewater concentrations all below the MDL

The following are observations from this review.

- Nine constituents (Be, Cd, Cr, Co, Fe, Ni, Se, SO_4^{-2}, and Zn) have higher concentrations in the downgradient monitoring well than in the upgradient background well, suggesting that there is a source for these constituents affecting the downgradient groundwater. However, these nine constituents also have higher concentrations in the downgradient well than in the porewater (e.g., Cd, Co, and Se in Figure 4-20), suggesting that porewater from the dewatered impoundment is not the primary source of the observed downgradient groundwater concentration. These observations suggest limited relationship between the recent porewater concentration and the downgradient groundwater concentrations at this site.
- Five constituents (As, Ba, Cu, F^-, and Mo) have higher concentration in porewater than in the downgradient monitoring well, suggesting that porewater has the potential to affect downgradient groundwater quality. However, the downgradient monitoring well has a concentration that is similar to or lower than concentrations in the upgradient monitoring well (e.g., As and F^- in Figure 4-21), indicating no change in groundwater quality for these constituents. Furthermore, porewater concentrations for As, F^-, and Mo are orders-of-magnitude higher than in the upgradient monitoring well, yet there is no increase in downgradient concentration relative to the upgradient well. These data suggest limited relationship between porewater and downgradient concentrations at this site.
- Four constituents (B, Ca, Cl^-, Li) have higher concentration in porewater than in downgradient groundwater, and higher concentrations in downgradient groundwater than in upgradient groundwater (e.g., B in Figure 4-21), suggesting a possible relationship between

the concentration in the ash deposit porewater and the concentration of groundwater in the downgradient well for these constituents. Furthermore, all four of these constituents may be considered indicators of coal ash leachate, but only B and Cl^- can be considered reasonably non-interacting with materials underlying the ash deposit.

The overall temporal means of porewater concentrations for B and Cl^- were calculated and compared to the difference in the temporal means of groundwater concentrations (i.e., temporal mean at 6AR minus temporal mean at AD1). If porewater concentrations can be used as an indicator of downgradient groundwater concentrations, this ratio should be similar between constituents. At VB-2, the closest PAP to the downgradient well at 6AR,[2] the ratios for B and Cl^- were both 2.8, indicating a potential relationship. In contrast, the same ratio for Ca was lower (1.4), while the ratio for Li was significantly higher (12). Increased Ca in the downgradient groundwater monitoring well relative to the upgradient well may be a consequence of the change in groundwater pH from ca. 8.5 to 4.5 and equilibrium with aquifer solids and/or influence from the ash porewater in conjunction with cation exchange and sorption within the aquifer. Similarly, increased Li concentrations may be a result of the change in groundwater pH or other influences, as well as uncertainty because the lithium concentrations in downgradient groundwater are near, and in some samples below, analytical method quantitation limits.

Overall, these observations indicate that porewater concentrations are unreliable as an indicator of whether or not a constituent will have an elevated downgradient concentration relative to upgradient groundwater. B and Cl^- are considered conservative ions, and the similar ratios suggest that these constituents can be tracers for evaluation of porewater migration into groundwater. However, porewater concentrations are not predictors of future groundwater concentrations because of the potential for rapid attenuation in proximity to the boundary of the disposal unit.

[2] These ratios do not vary significantly if all three PAPs are averaged.

Variability in Porewater Concentrations

The temporal variability data for porewater parameters from monthly monitoring are presented as time-series plots as a function of date. The shapes of the time series show which porewater properties are relatively constant over the 13 months of sampling and which samples vary with

time. Time-series graphs for porewater parameters and constituents are presented in Appendix F.2. Examples of parameters showing temporal variability are presented in Figure 4-22 and Figure 4-23. In these figures, variability may be preliminarily attributed to one or more of several factors including (i) seasonal changes (e.g., temperature, redox conditions as seen by pH+pE; Figure 4-22), (ii) groundwater level changes due to infiltration and river intrusion (e.g., porewater level, decrease in pH of VB-2 and VB-3 during late summer 2019; Figure 4-22), and (iii) changing conditions shortly after closure of the impoundment (e.g., variability in cobalt, copper, iron, nickel, and zinc in VB-3 porewater during the summer of 2018; Appendix F.2). In comparison, many parameters remain relatively constant throughout this brief monitoring period (e.g., As, B, and Mo; Figure 4-23).

Concentrations from a PAP were deemed higher than other PAPs if consistently higher by a factor of 3 to 5 or more during all sample events. Overall, there was no pattern to spatial variability that applied to all monitored constituents, and concentrations between PAPs were usually within a factor of 10. However, there were patterns that were evident by element as listed below:

- No variability, all non-detect: Sb, Be, Pb, Se, Tl, V
- Little variability between PAPs: Ba, B, Ca, Cl, Cr, Co, Cu, F^-
- VB-1 and VB-2 consistently higher than VB-3: As, Li
- VB-3 consistently higher than VB-1 and VB-2: Cd, Fe, Mo, Ni, Zn
- VB-2 and VB-3 consistently higher than VB-1: SO_4

Subsurface Gas Monitoring

The O_2, CO_2, CH_4, NH_4, and H_2S concentrations were measured in the three GAPs as presented in Figure 4-24 and Figure 4-25. Full tabular data for subsurface monitoring are presented along with graphical comparisons in Appendix F.3. Oxygen levels in the closed impoundment have been typically much less than in air, while CO_2 and CH_4 concentrations are often greater than the calibration limit of 5%. The concentrations of NH_4 and H_2S are sporadic but indicate elevated

concentrations up to 5 ppm for NH_4 and 30 ppm for H_2S. In general, these subsurface gas measurements imply a significant amount of biological activity that results in a stronger chemical reducing environment than indicated by the DO and ORP of the porewater samples.

Speciation of Arsenic, Iron, and Selenium Under Low Redox Conditions

At moderately low redox conditions, arsenic release can be associated with loss of HFO sorption sites as Fe(III) is reduced to Fe(II) at a pH+pE value of approximately 7 to 8. At these conditions, there would be a corresponding increase in the concentration of iron (Fe^{2+}) in solution. At lower values of pH+pE, sulfate is reduced to sulfide, and arsenic may be precipitated with sulfidic minerals. At these same redox conditions, biological activity would convert carbon dioxide to methane as observed for VB-2 and VB-3 (see top of Figure 4-25). These processes are consistent with the temporal dissolved arsenic and iron concentrations observed for VB-1, VB-2, and VB-3 (Figure 4-26), where increased dissolved iron in VB-3 was also accompanied with much lower dissolved arsenic concentration (ca. 3.5 vs. 1.0 mg/L) compared to VB-1 and VB-2. Considering the presence of methane, iron reduction appears to have been an intermediary step concurrent with sulfate reduction and methanogenesis, resulting in arsenic precipitation and lower solubility.

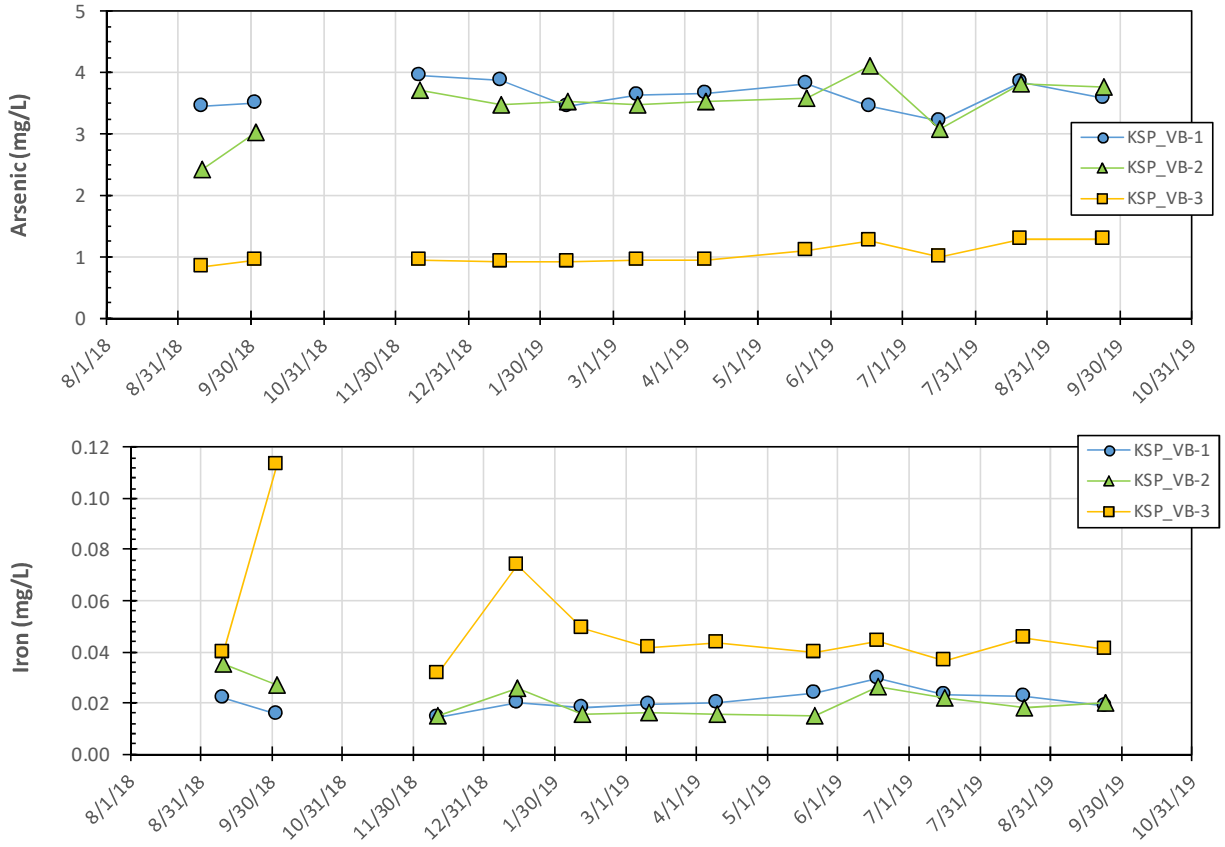

Figure 4-26
Temporal porewater data for arsenic and iron collected at boreholes VB-1, VB-2, and VB-3

Uncertainties in Redox Analysis and Impacts on Porewater Concentrations

Figure 4-27 presents a typical redox ladder for electron donors (e.g., O_2, $Fe(OH)_{3(am,\ s)}$, SO_4^{2-}, $CO_{2(g)}$) and products of biochemical reduction (e.g., CO_2, Fe^{2+}, HS^-, $CH_{4(g)}$).

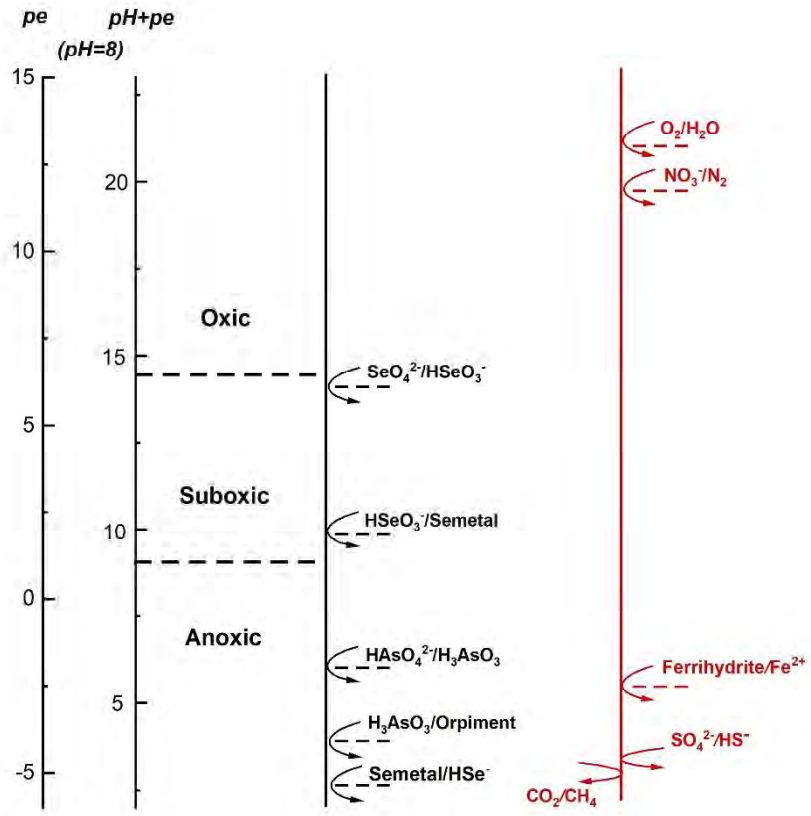

Figure 4-27
Redox ladder for relevant redox reactions (after Borch et al., 2010)

Porewater ORP measurements indicated suboxic to anoxic conditions, while subsurface gas measurements and porewater measurements of pH and dissolved constituents indicated mildly anoxic ($Fe(OH)_{3(am,\ s)}$ conversion to Fe^{2+}) to strongly anoxic and reducing (HS^- and robust CH_4 formation)[3] conditions in the ash deposit. Furthermore, porewater measured redox trended toward less reducing/more oxidizing conditions during warmer months, which is contrary to increased microbial activity, inducing more reducing conditions, at warmer temperatures. There is no clear explanation for the observed discrepancy between field-measured ORP and the redox state as deduced from gas measurements and porewater concentration data; however, the latter are generally considered more reliable indicators of redox conditions. There are several possible causes for the observed inconsistency:

- Integration Areas – Porewater reflects leaching in response to infiltration and possibly mixing with groundwater influx in response to changes in hydraulic heads (e.g., groundwater responses to changes in river elevation are evident in VB-3). In contrast, subsurface gas

[3] Hydrosulfide ion (HS^-) is a weak acid (pKa ≈6.9) resulting in a solution equilibrium with hydrogen sulfide (H_2S) gas, which was detected intermittently during subsurface gas analysis.

measurements integrate over a much larger area by diffusion and convection driven by barometric pressure changes. Gases released from the saturated zone in the coal ash can also be reflected in the gas monitoring. It is well established that the localized zones of microbially active/induced aerobic, suboxic, and highly reduced anoxic conditions can co-exist in close physical proximity (e.g., in biofilms).

- Sampling Effects – Porewater samples reflect integration over the zone of influence around the porewater access point during pumping for sampling.[4] Porewater sampling requires low-flow pumping of the porewater monitoring points, while the monitoring well remains uncapped and in exchange with the atmosphere. During initial monitoring point purging, porewater in the monitoring point can partially aerate and oxidize by oxygen exchange at the air-porewater interface within the monitoring point and the sand packing around the well screen if it is partially unsaturated.
- ORP Readings – Field monitoring instrumentation and the process of data documentation normally do not measure extremely low reducing conditions and, therefore, some negative instrument readings may have been misrepresented as positive readings. In order to examine this possibility, ORP based on sonde measurements (mV) at boreholes VB-1, VB-2, and VB-3 and resultant pH+pE values (Figure 4-28) are compared with the bounding case results if some sonde ORP measurements were actually negative values with the same absolute value (Figure 4-29). This figure indicates more reducing conditions during the warmer months and redox conditions (pH+pE) consistent with the subsurface gas measurements.

[4] For this project, porewater and groundwater sampling was conducted using low-flow sampling techniques that result in negligible drawdown.

Oxidization reduction potential and resultant pH+pE values if recorded ORP measurements were negative for boreholes VB-1, VB-2, and VB-3

Comparison of Leaching Tests to Monthly Porewater Samples

The results of LEAF leaching tests and traditional tests (TCLP, SPLP, and ASTM) were plotted as a function of pH along with the porewater concentrations measured at the corresponding borehole (VB-1, VB-2, or VB-3). Examples of these comparisons are shown in Figure 4-30 through Figure 4-32, while a full set of results is presented in Appendix G. In the pH-dependence graphs, monitored porewater data are presented both as data points representing monthly measured porewater concentrations and as dashed lines representing the mean pH and mean concentration of all measured values.

To the right of each pH-dependence graph, bar charts show the ratio of the leaching test concentration to the mean porewater concentration. The seven ratios are shown in increasing order of L/S, including:

- The 1st eluate from EPA 1314 at L/S=0.2 mL/g-dry,
- The 2nd eluate from 1314 at L/S=0.3 mL/g-dry (cumulative L/S=0.5 mL/g-dry),
- The 1313_L/S=1 concentration at own pH at L/S=1 mL/g-dry,
- The 1313 concentration at natural pH at L/S=10 mL/g-dry,
- TCLP conducted at an average L/S of 23 mL/g-dry,
- SPLP conducted at an average L/S of 22 mL/g-dry, and
- ASTM at an average L/S of 27 mL/g-dry.

The eluate-to-porewater-concentration ratios indicate how closely leaching test concentrations can predict measured field concentrations. For example, Figure 4-30 shows that B porewater concentrations are reasonably predicted by low L/S leaching test data (EPA 1314 and 1313_L/S=1) while being under-predicted by at least an order-of-magnitude at higher L/S ratios. This is consistent with available content-limited LSP where eluate concentration is a strong function of L/S. However, arsenic is under-predicted in all leaching test approximations at VB-1 and VB-2 (Figure 4-31), most likely because of oxidation of solid materials with experiments conducted under laboratory conditions. This observation is consistent with the reducing conditions observed through subsurface gas monitoring and explains why arsenic concentrations are different in the field than in laboratory samples, possibly due to the loss of HFO as adsorption sites and precipitation as arsenic sulfides. Due to the effects of oxidation of laboratory samples, the leaching tests tend to over-predict the porewater concentrations of other oxyanions including Sb (Figure 4-32), Se, and V.

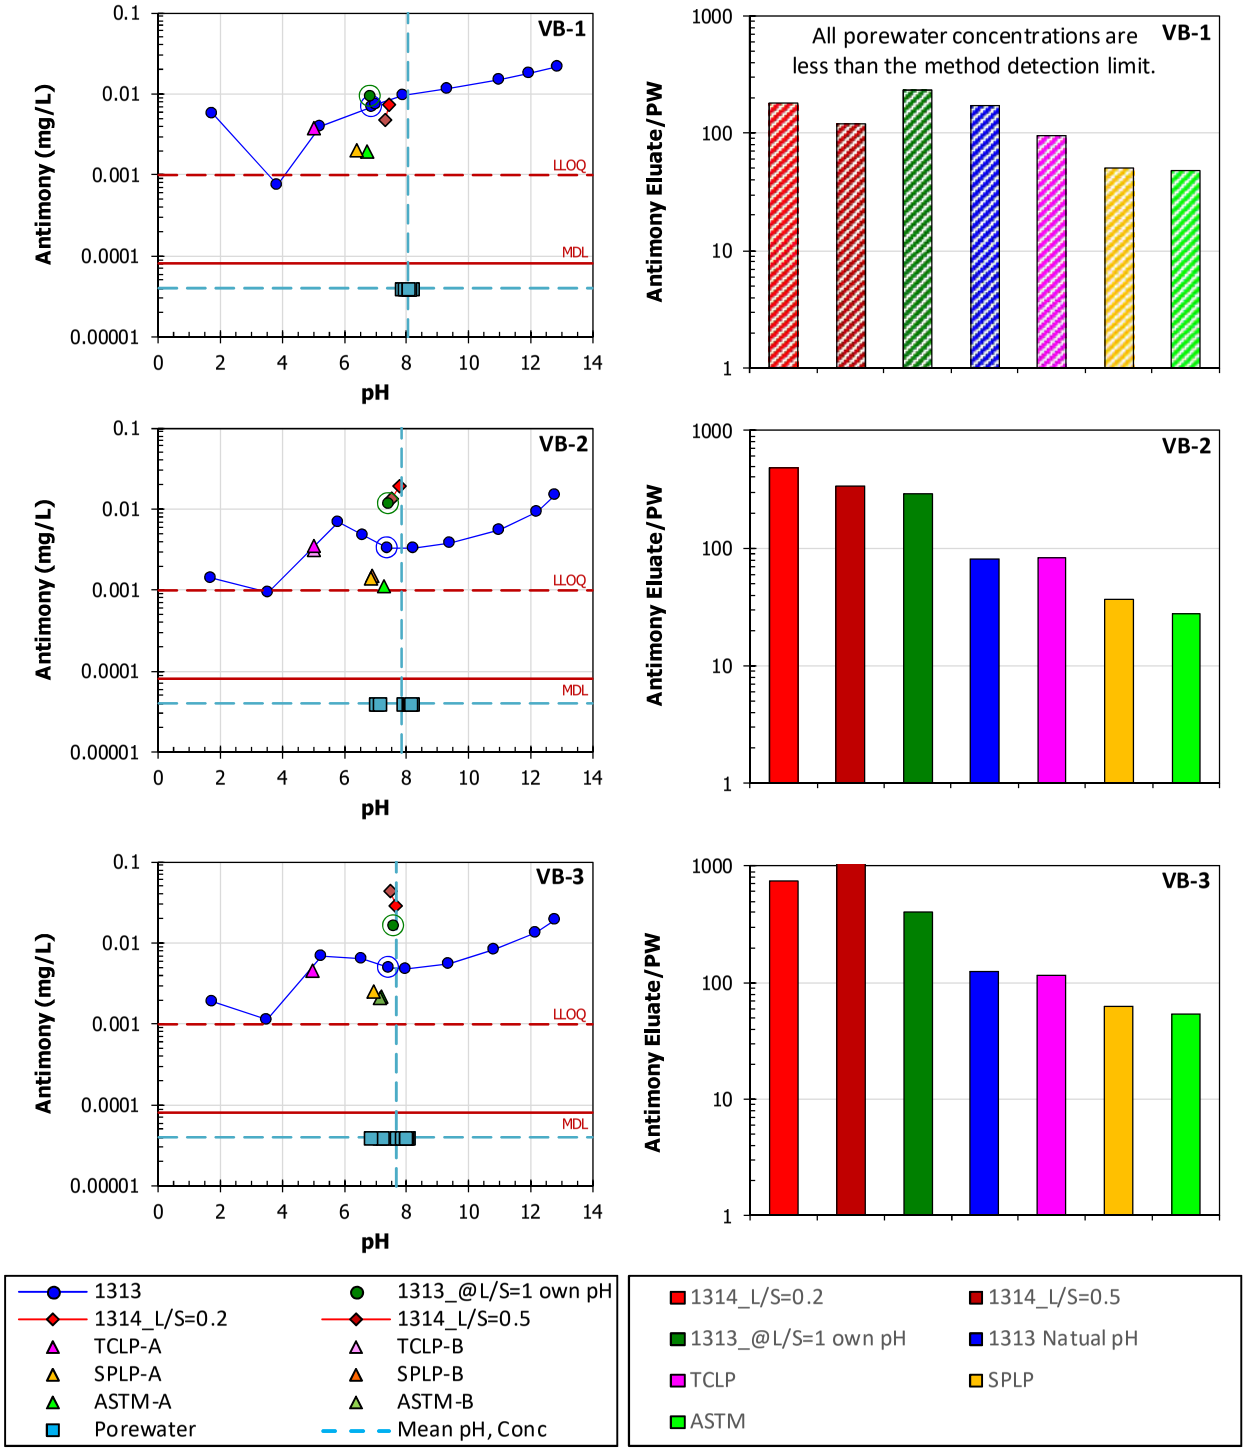

Figure 4-32
Antimony concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right); crosshatched ratio results indicate estimates based on at least one MDL value

A qualitative summary of the ability of different leaching tests to estimate the measured porewater concentrations at each of the PAPs is shown in Table 4-14 for constituents with solubility-controlled LSP, Table 4-15 for constituents with available content-limited LSP, and Table 4-16 for constituents where the LSP could not be determined. In those tables, shading is used to indicate if the leaching test estimate is within 25% of the mean groundwater concentration (green), within an order-of-magnitude of the mean porewater concentration (orange), or greater than an order-of-magnitude from the mean porewater concentration (red). When "GW <MDL" appears in the Notes column, the mean porewater concentration was less than the analytical MDL. Within the field of the table, an asterisk is used to indicate that the leaching test results were less than the MDL.

Table 4-14, Table 4-15, and Table 4-16 provide an overview of the ability of leaching tests, conducted on materials collected from a highly reducing environment and tests at mildly oxidizing conditions in a laboratory setting, to estimate porewater concentrations. The results of this qualitative summary should not be used without consideration of the redox conditions of the field and should always be shown along with the graphical data (e.g., Figure 4-30 through Figure 4-32) that preserve the pH result for the tests. For example, the table indicates that TCLP would provide a good estimate of porewater concentration for Ca; however, this is somewhat of a coincidence because the pH of TCLP is more than two pH units less than the natural pH of the ash.

[5] Although the liquid-solid partitioning (LSP) for arsenic appears to be solubility-controlled, arsenic LSP is likely a result of adsorption onto hydrous ferric oxides (HFO) and not solubility of arsenic-bearing minerals.

5
SUMMARY OF OBSERVATIONS

The data presented in this report represent the results of geotechnical, hydrologic, and leaching characterization of samples of coal ash collected from the closed and capped impoundment at Plant 42201. The hydraulic conductivity of intact cores from the ash deposit was measured in context of the distribution of particles in the coal ash samples and the overburden pressure associated with disposal at depth within the pond. The leaching test results for LEAF tests (i.e., EPA Methods 1313 and 1314) were compared to those for traditional tests (i.e., ASTM, TCLP, and SPLP). In addition, leaching test results were compared to porewater concentrations determined from field samples, and field-sampled porewater concentrations were compared to groundwater concentrations, to evaluate similarities and dissimilarities between these results.

Based on the presented data and analysis, the following general observations can be made:

- The hydraulic conductivity of intact ash samples is dependent on the fraction of fines in the material. The measured hydraulic conductivity of finer, less permeable coal ash was lower (ranging from approximately $7x10^{-4}$ cm/s to $1x10^{-5}$ cm/s) than the hydraulic conductivity of coarser, more permeable coal ash (approximately $1x10^{-3}$ cm/s). In general, the hydraulic conductivity decreases modestly with increasing effective stress.
- The subsurface within the closed impoundment was more bio-chemically reducing than indicated by porewater analysis. Monitoring of subsurface gas concentrations shows the presence of hydrogen sulfide and methane, indicating strongly reducing conditions. Monthly data indicate that the extent of reducing conditions is spatially variable and may be seasonally dependent. In addition, arsenic concentrations in the porewater are at the high end of previously reported ranges for coal ash (EPRI, 2019) in some areas. At intermediate reducing conditions (e.g., at VB-1), elevated concentrations of arsenic (ca. 3 mg/L) are likely due to loss of HFO when ferric oxides are reduced and solubilized (conversion of insoluble Fe^{3+} to soluble Fe^{2+}). Under very low redox conditions, as observed by subsurface gas monitoring at VB-2 and VB-3 by the presence of methane, arsenic porewater concentrations decrease due to conversion of As(V) to As(III) and likely precipitation as sulfides. Conversely, the porewater concentrations of Sb and Se in the reduced pond environment are suppressed due to formation of reduced species with lower solubility.
- Some constituents in the porewater samples exhibited temporal variability due to factors such as (1) seasonal changes in pH and redox, (2) changes that appeared to be related to seasonal groundwater elevation changes, and (3) changing conditions shortly after closure of the impoundment. However, some constituents such as, B, and Mo remained relatively constant within each porewater access point throughout the 13-month monitoring period.
- The data collected suggest that porewater concentration is an unreliable indicator for which constituents will have elevated groundwater concentrations or for prediction of downgradient concentrations at this site.

- Traditional leaching tests (TCLP, SPLP, and ASTM) are poor indicators of measured porewater concentrations. Low liquid-to-solid ratio (L/S) eluates from EPA Method 1314 are better indicators than the traditional tests for concentrations for available content-limited constituents (B, Ca, Cl, Mo, Tl) because of the strong L/S-dependence. However, additional information (e.g., available content and porewater L/S) is needed to provide a reasonable approximation of porewater concentrations. For constituents with apparent solubility-controlled liquid-solid partitioning (Sb, As, Ba, Cr, F^-, Se, SO_4, V, Zn), pH-dependence tests (e.g., EPA Method 1313) may provide valuable information for geochemical modeling, but, for this site, the natural or own pH responses did not reliably estimate field porewater concentrations, in part due to differences in redox as noted in the next bullet.
- When the field environment is highly reducing, laboratory leaching results for redox sensitive elements (e.g., As, Cr, Sb, Se, and Fe) do not directly reflect the leaching anticipated in porewater. This is, in part, because reduced materials collected in the field are inevitably partially oxidized during sampling, handling, and testing.

D
LEAF TEST RESULTS ON COMPOSITE SAMPLES

Table of Appendices

D.1 pH- and L/S-Dependent Test Results

The following graphs present the results of pH-dependent tests (i.e., EPA Method 1313 and the low L/S-modified 1313) and L/S-dependent test (i.e., EPA Method 1314) on composite samples from split spoon samples taken from three boreholes at the closed KSP impoundment. These figures show the following data for three composites of coal ash:

a) eluate concentration in mg/L as a function of pH (top, left),

b) eluate concentration in mg/L as a function of L/S (top, right),

c) mass release in mg/kg-dry as a function of pH (middle, left) including available content, derived from the maximum concentration in the 1313 LSP curve,

d) cumulative mass release in mg/kg-dry as a function of cumulative L/S (middle, right),

e) acid/base neutralization capacity (ANC/BNC) of the composite material as a function of pH, and

f) evolution of eluate pH from the percolation column test.

D.2 Comparison of Individual Split Spoon and Composite Sample Data

D.1 pH- and L/S-Dependent Test Results

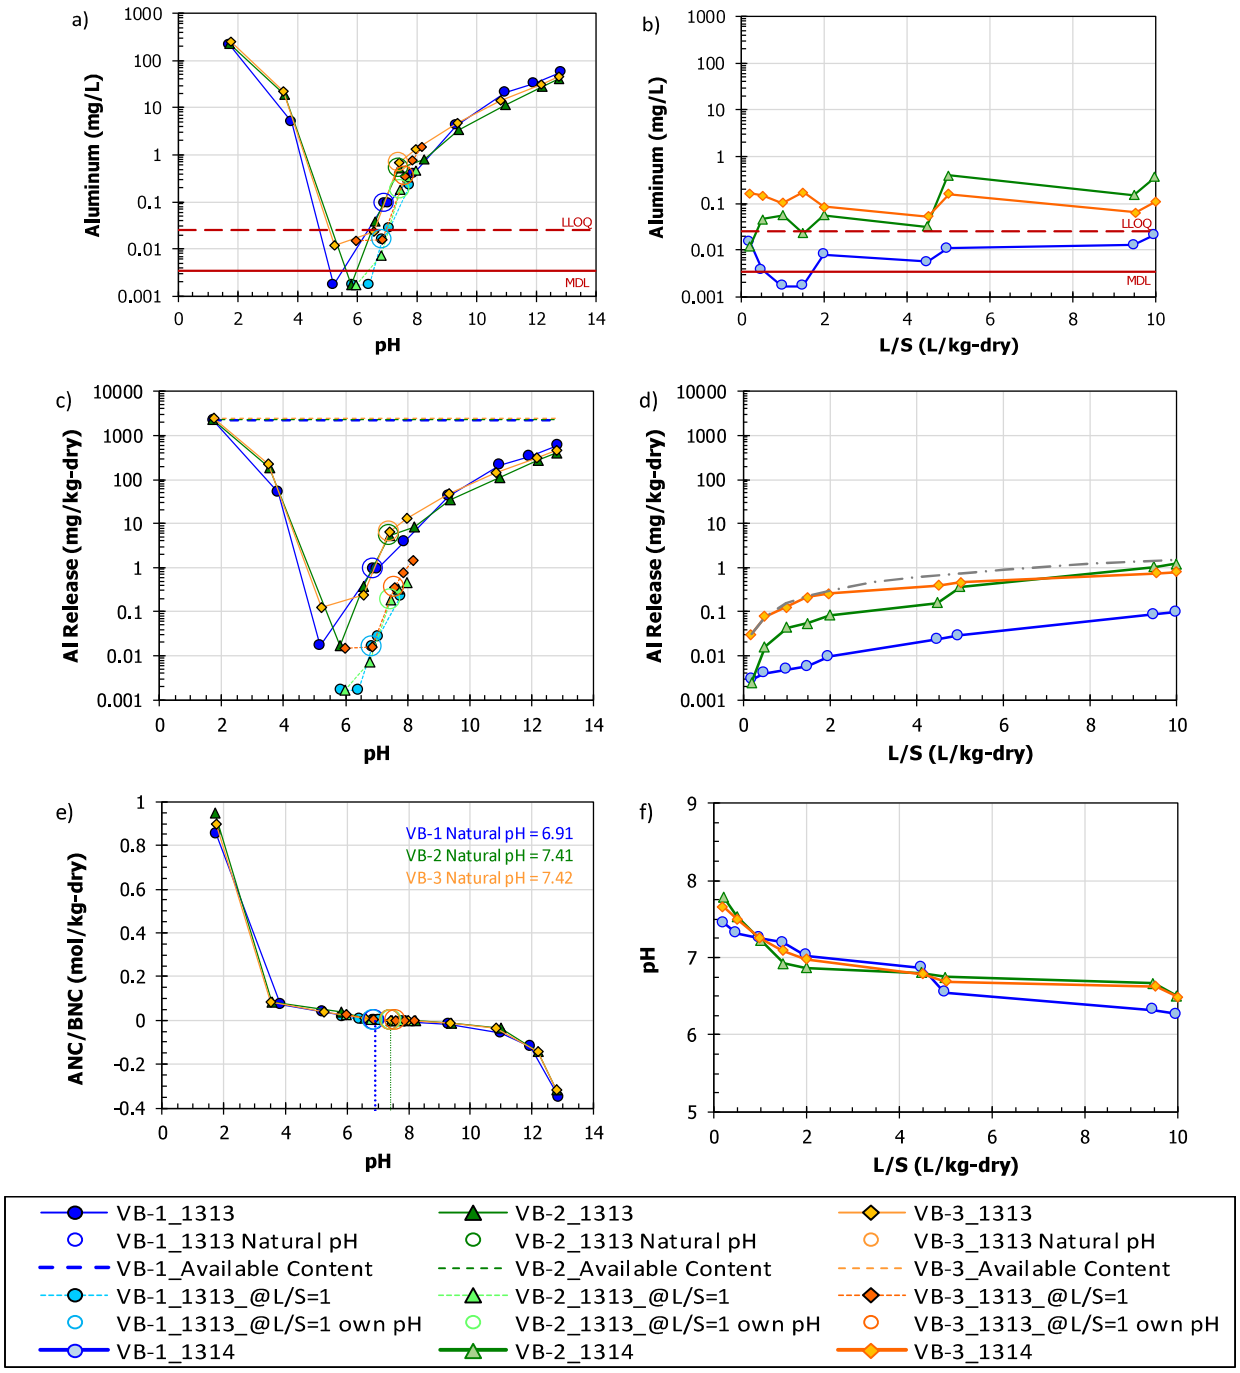

Figure D-1
Aluminum LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

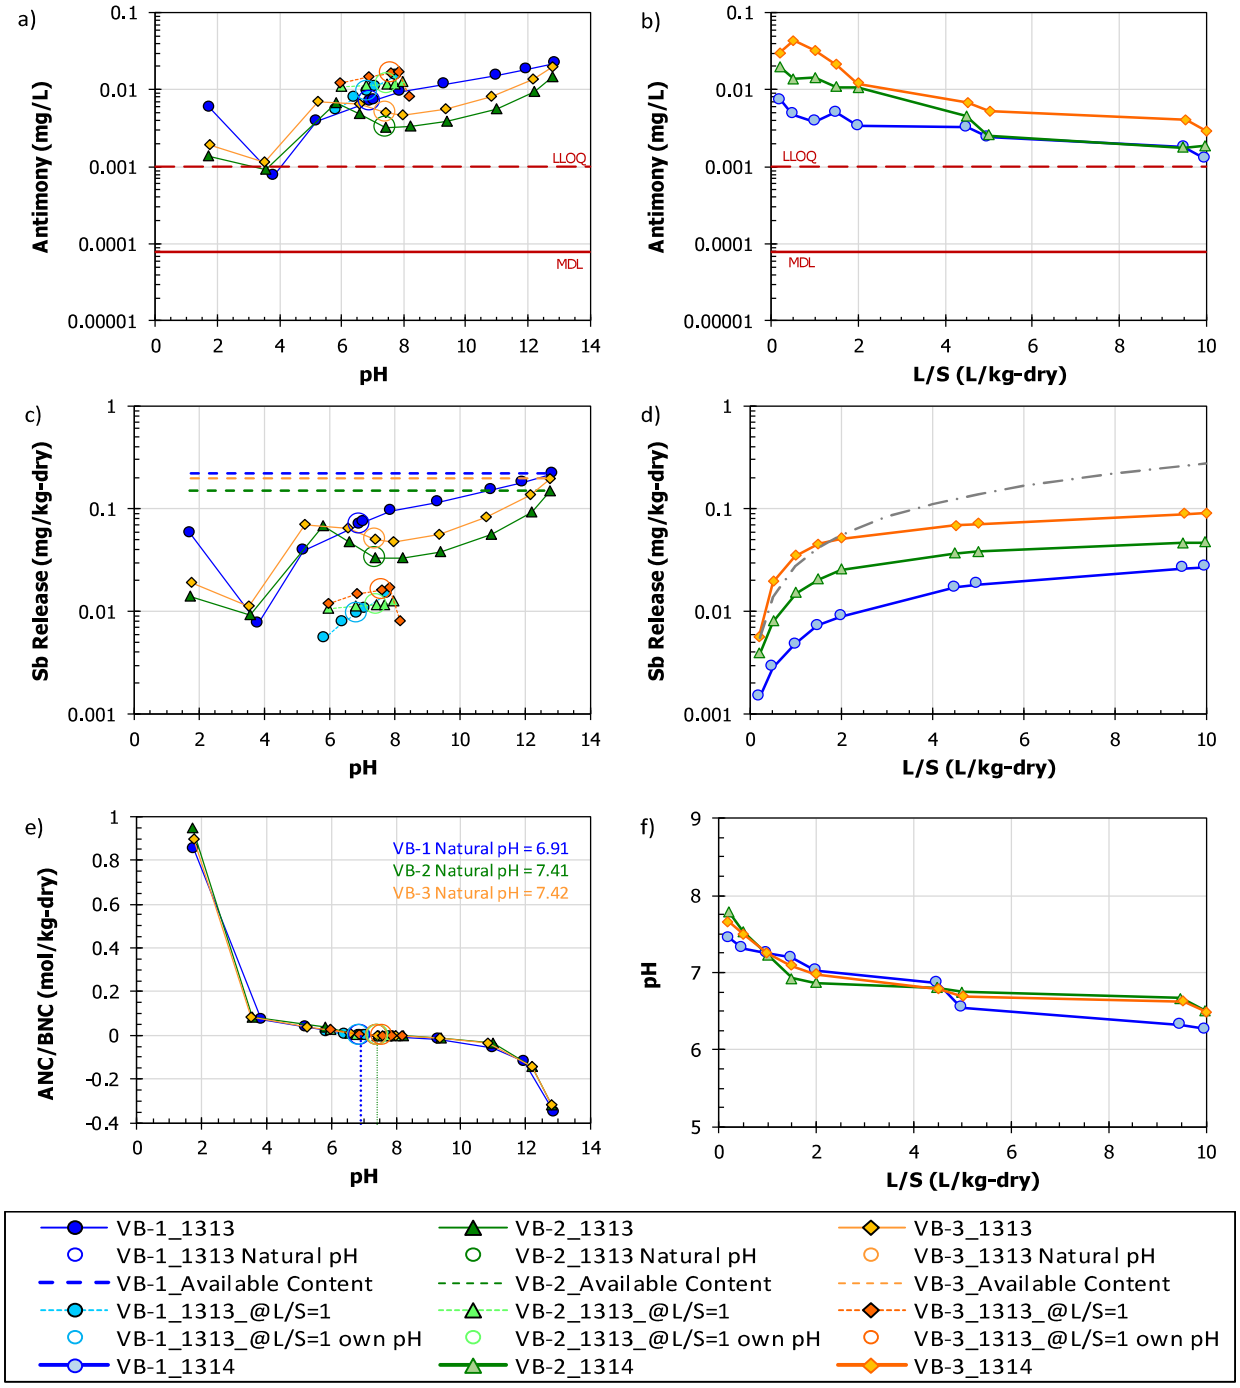

Figure D-2
Antimony LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

LEAF Test Results on Composite Samples

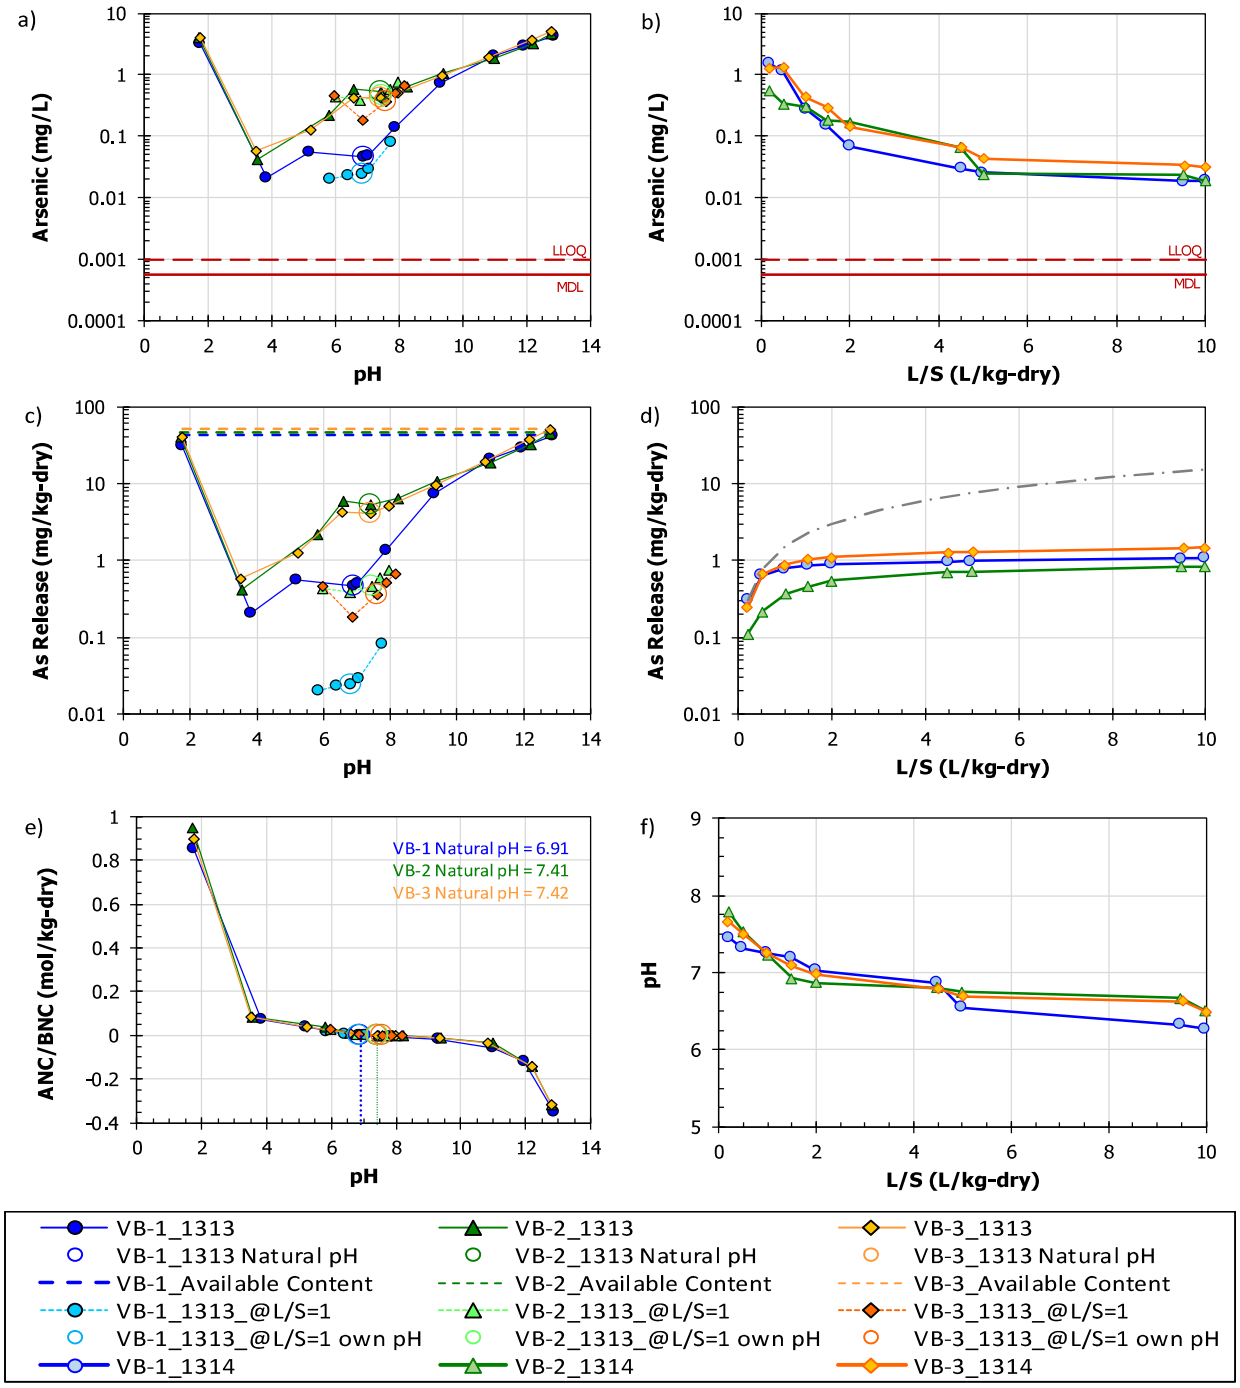

Figure D-3
Arsenic LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

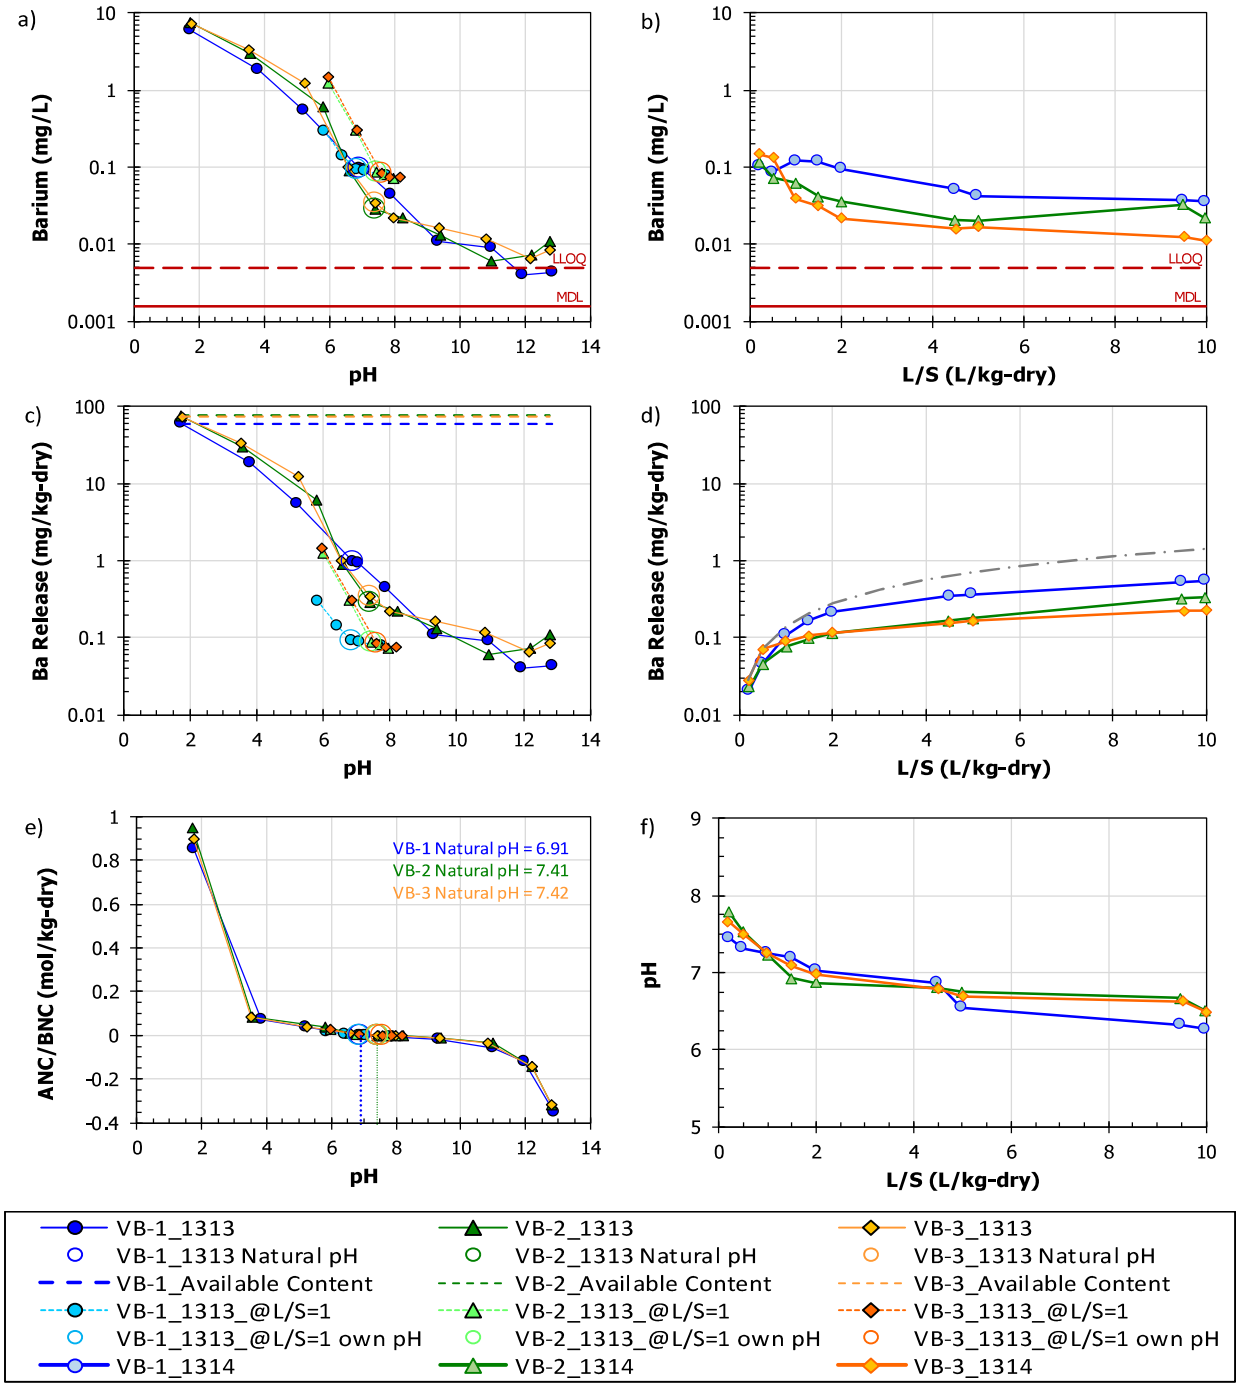

Figure D-4
Barium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

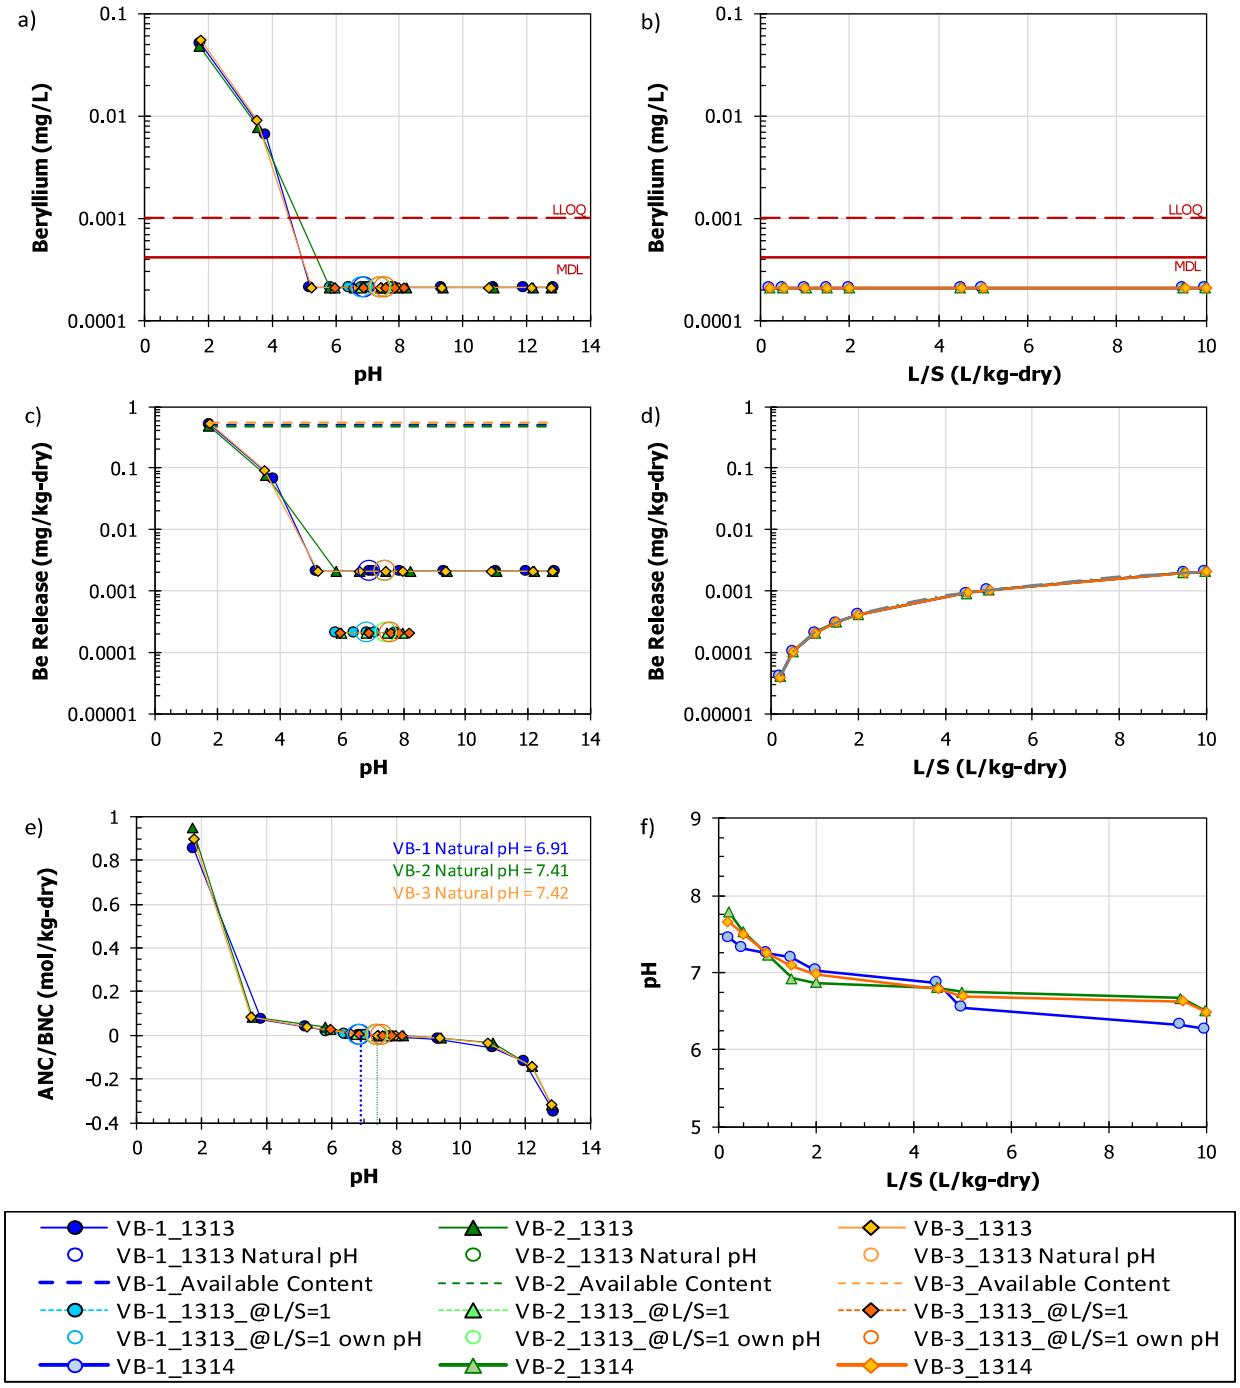

Figure D-5
Beryllium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

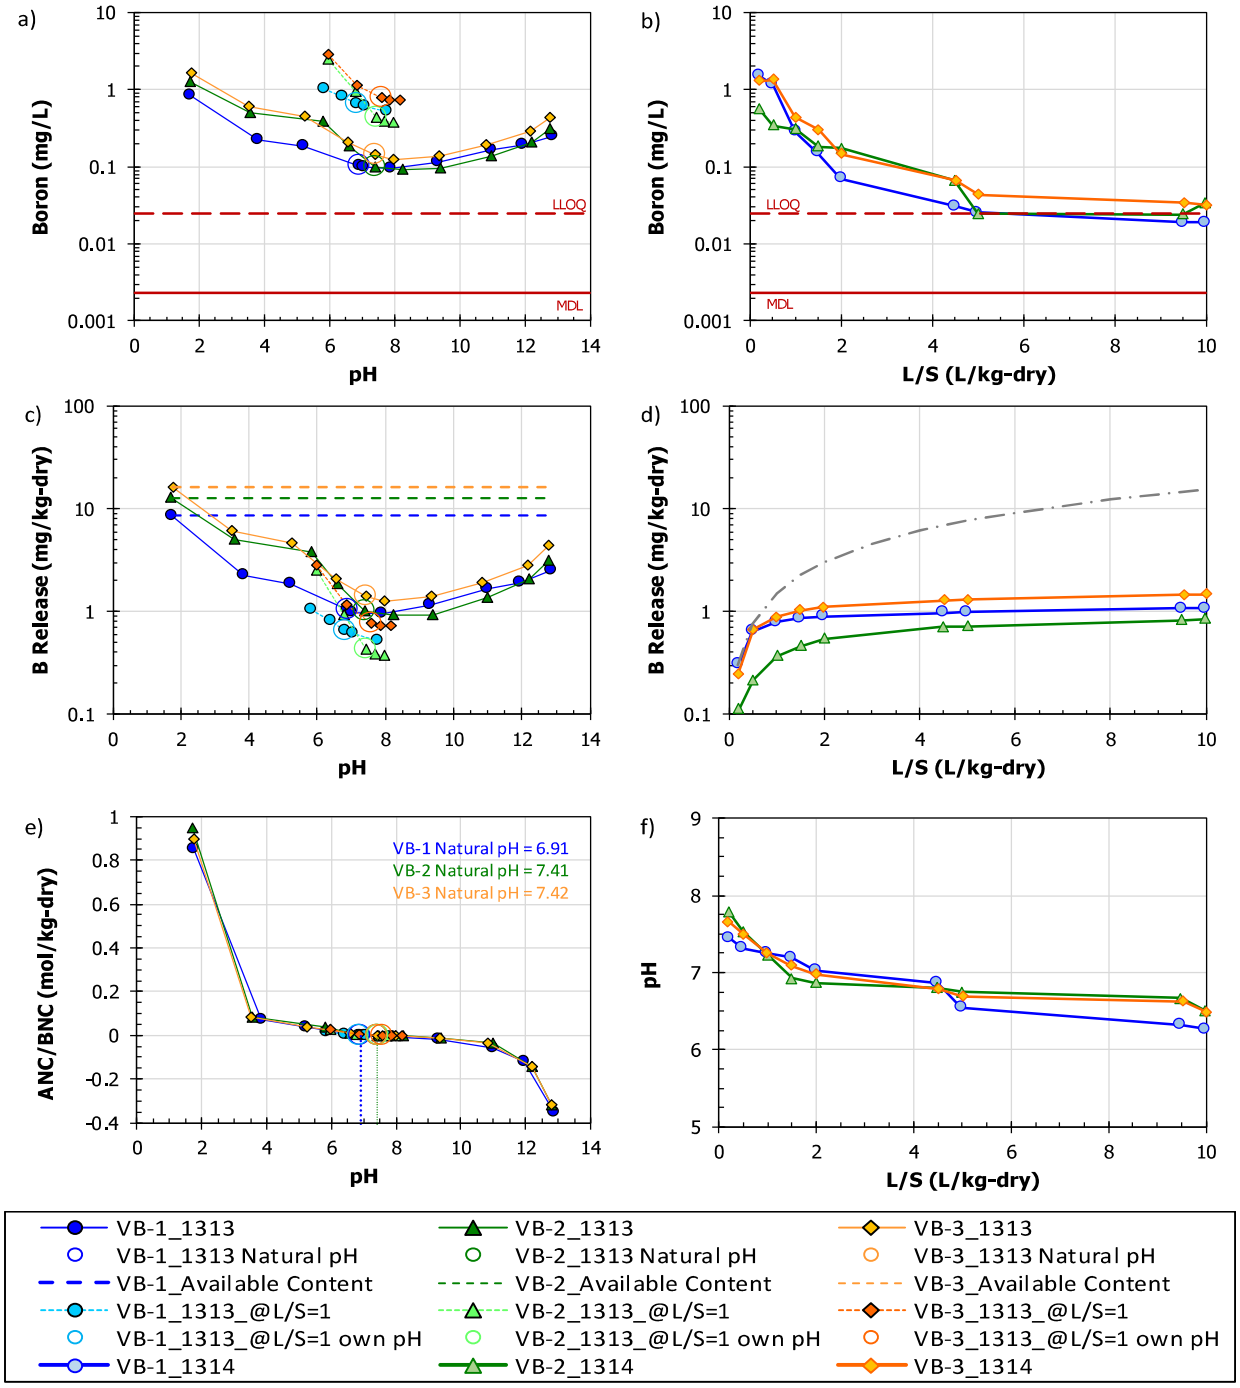

Figure D-6
Boron LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

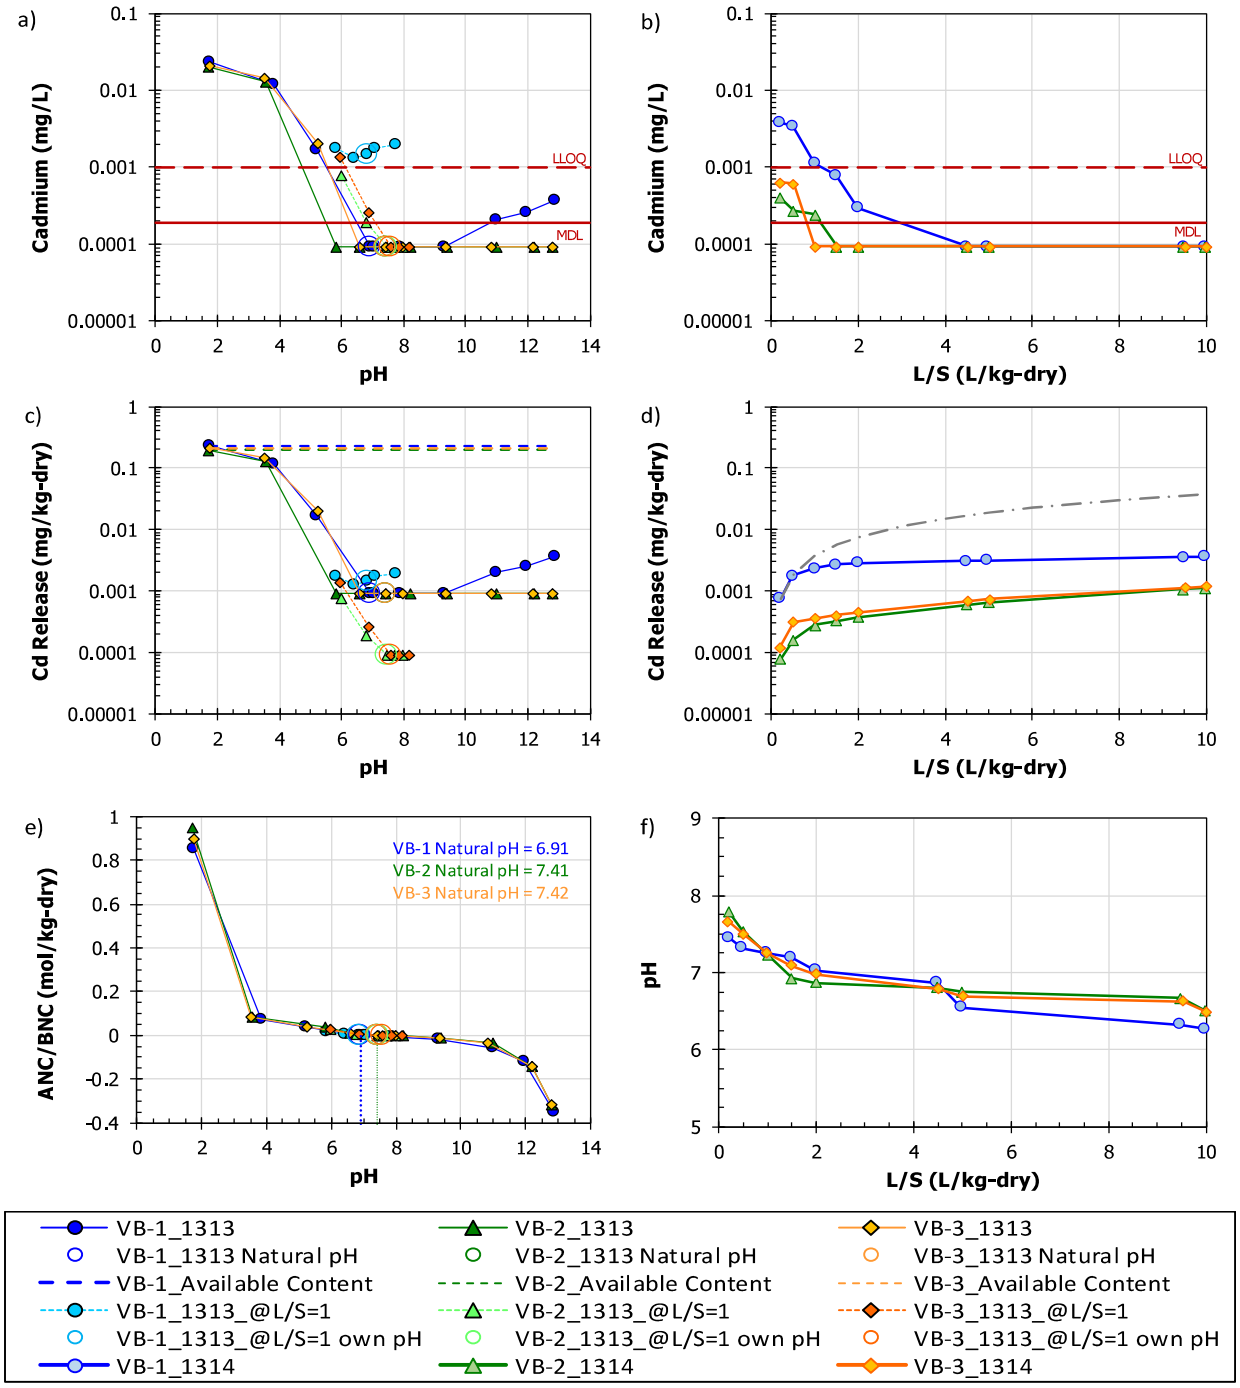

Figure D-7
Cadmium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

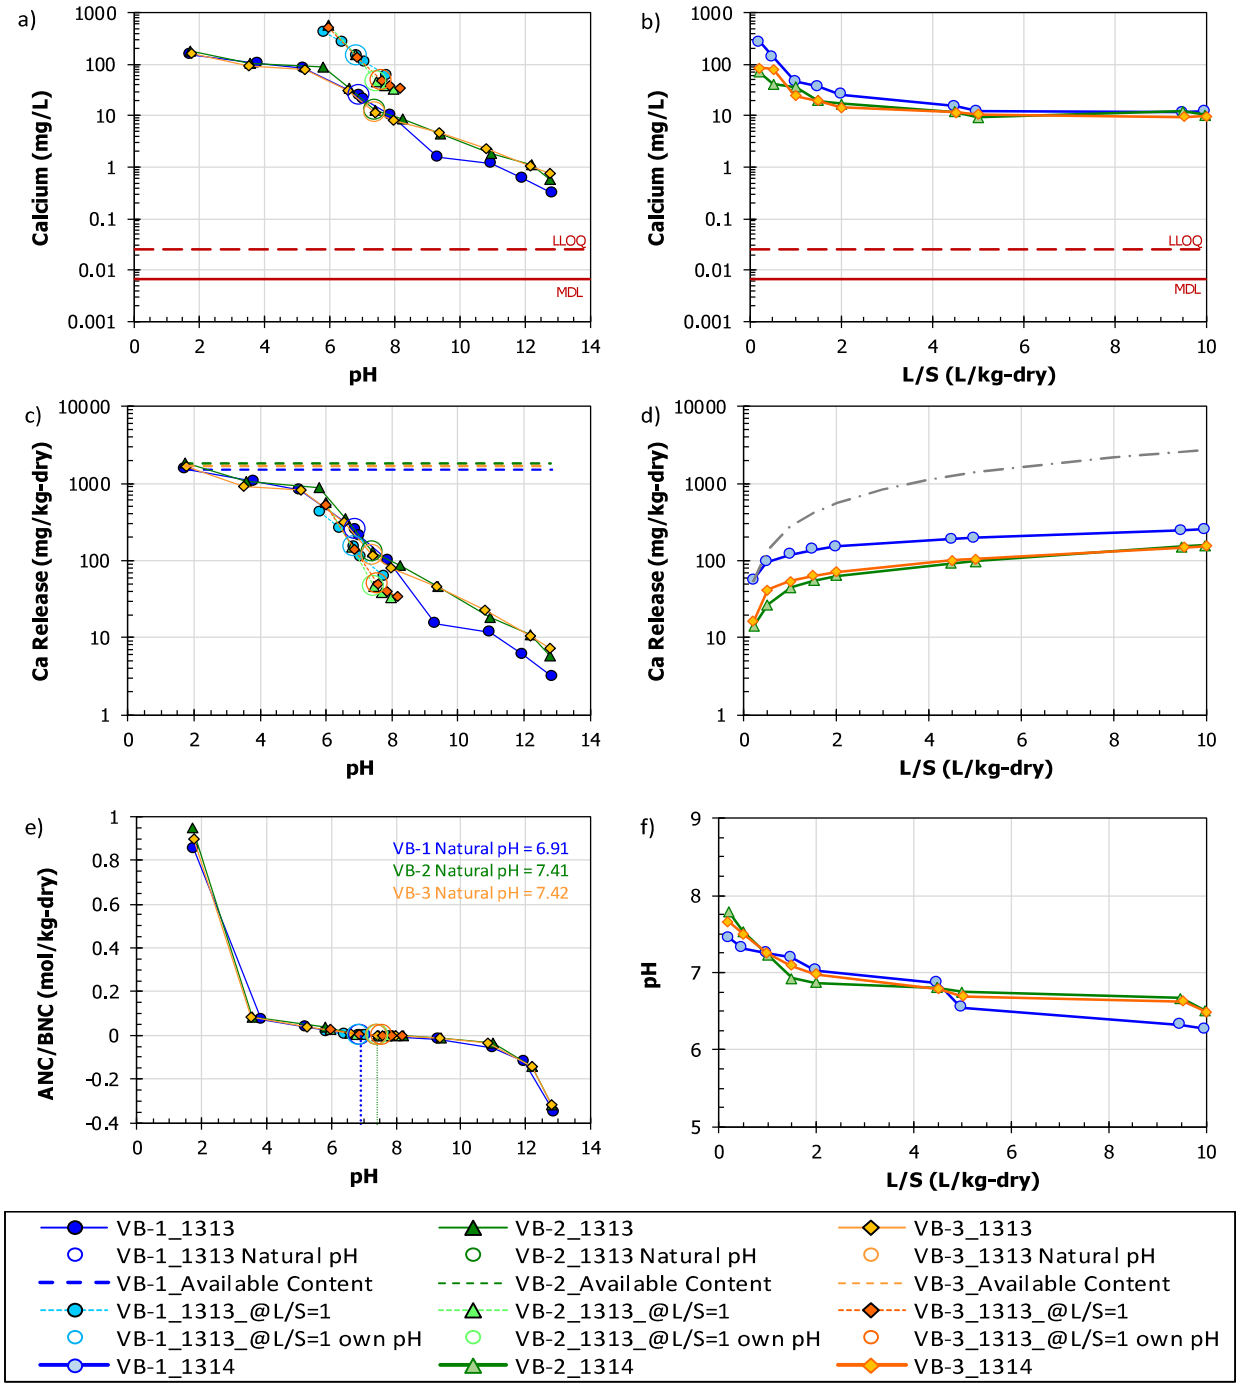

Figure D-8
Calcium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S.

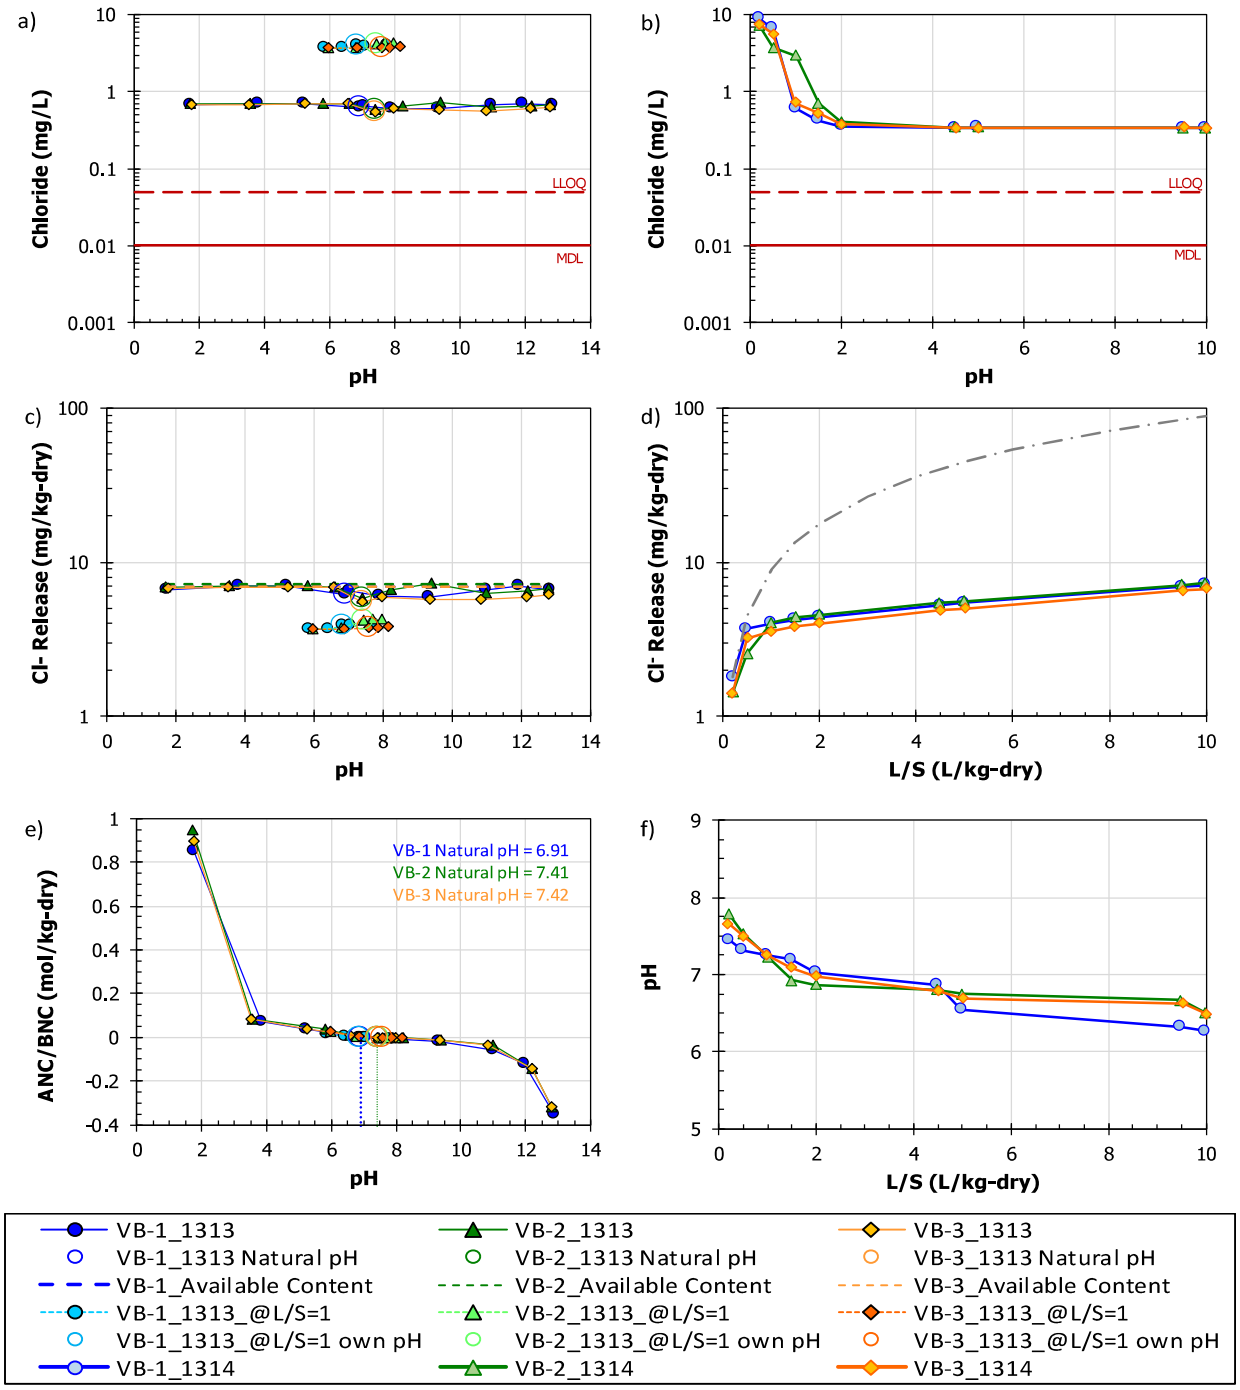

Figure D-9
Chloride LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S.

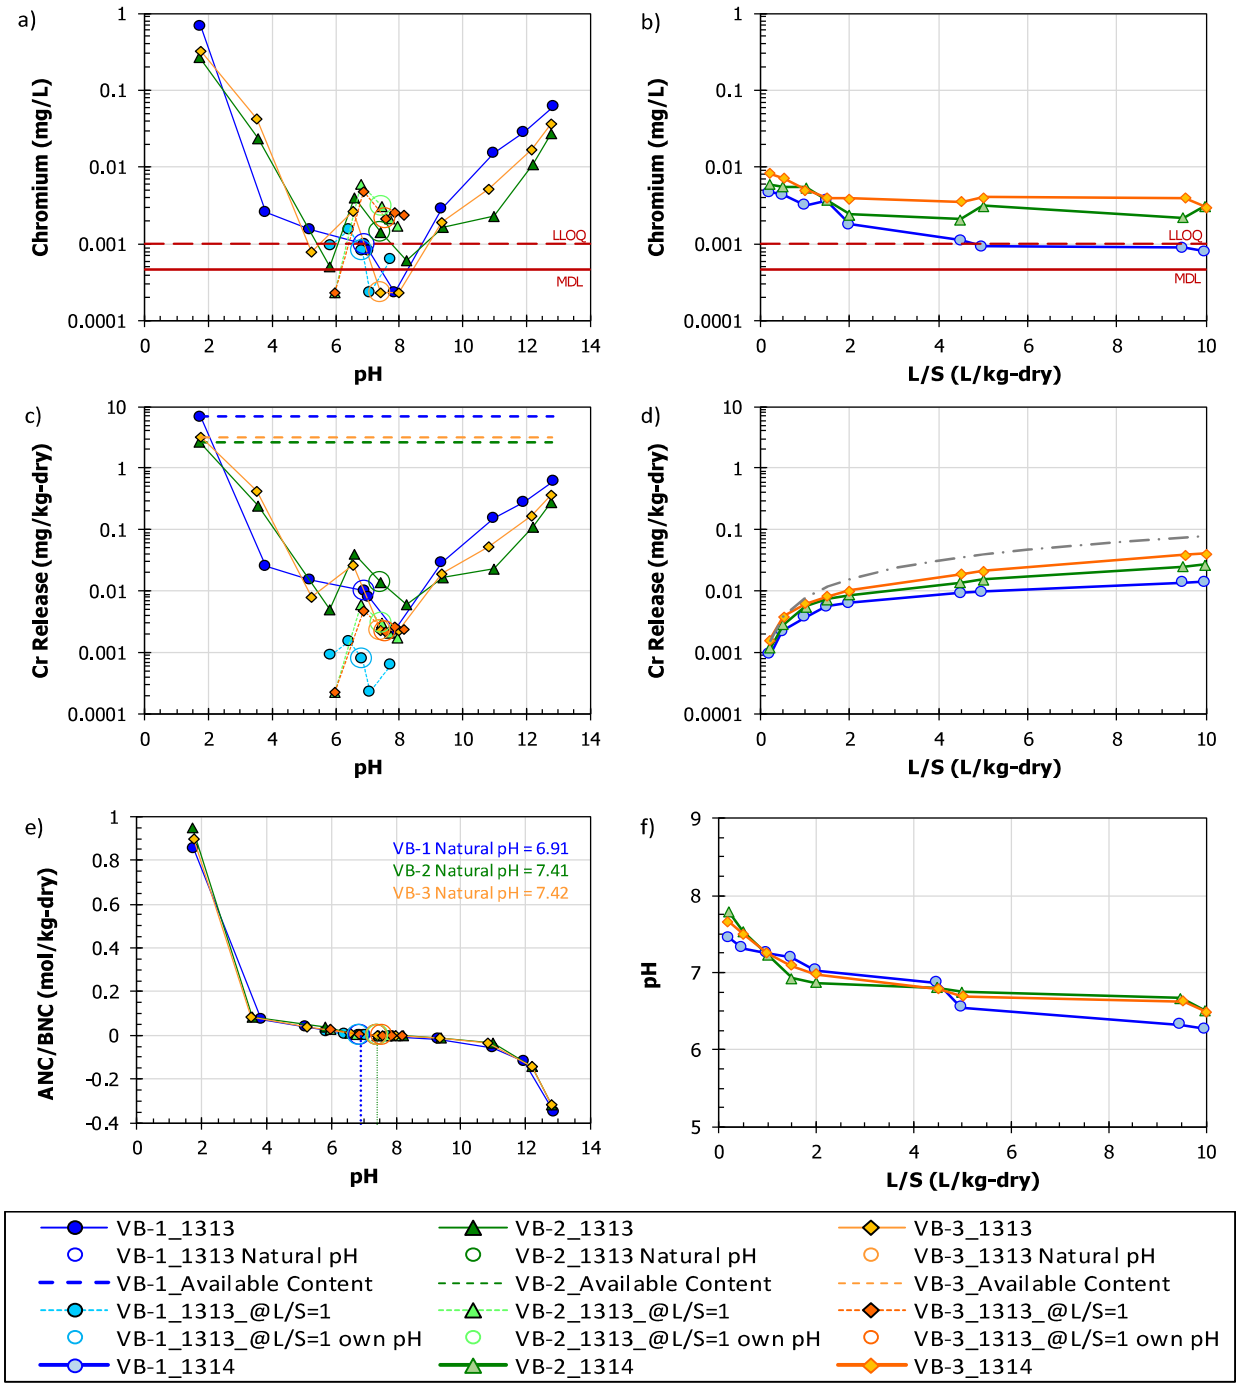

Figure D-10
Chromium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

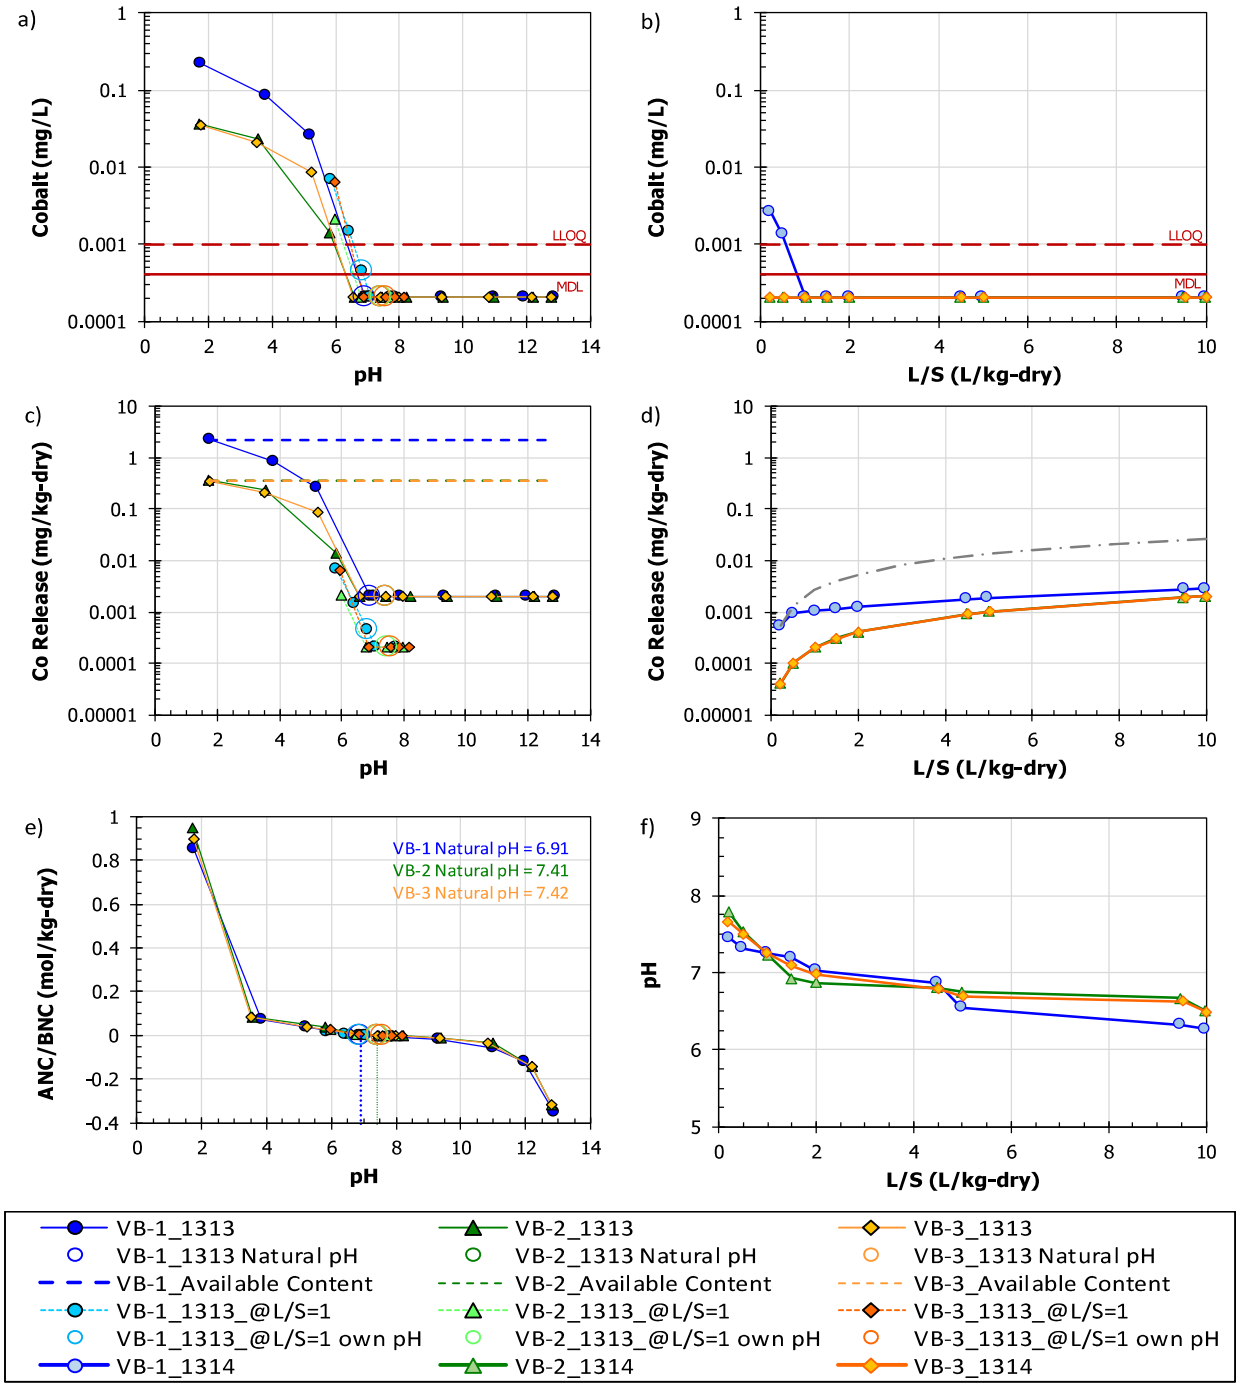

Figure D-11
Cobalt LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S.

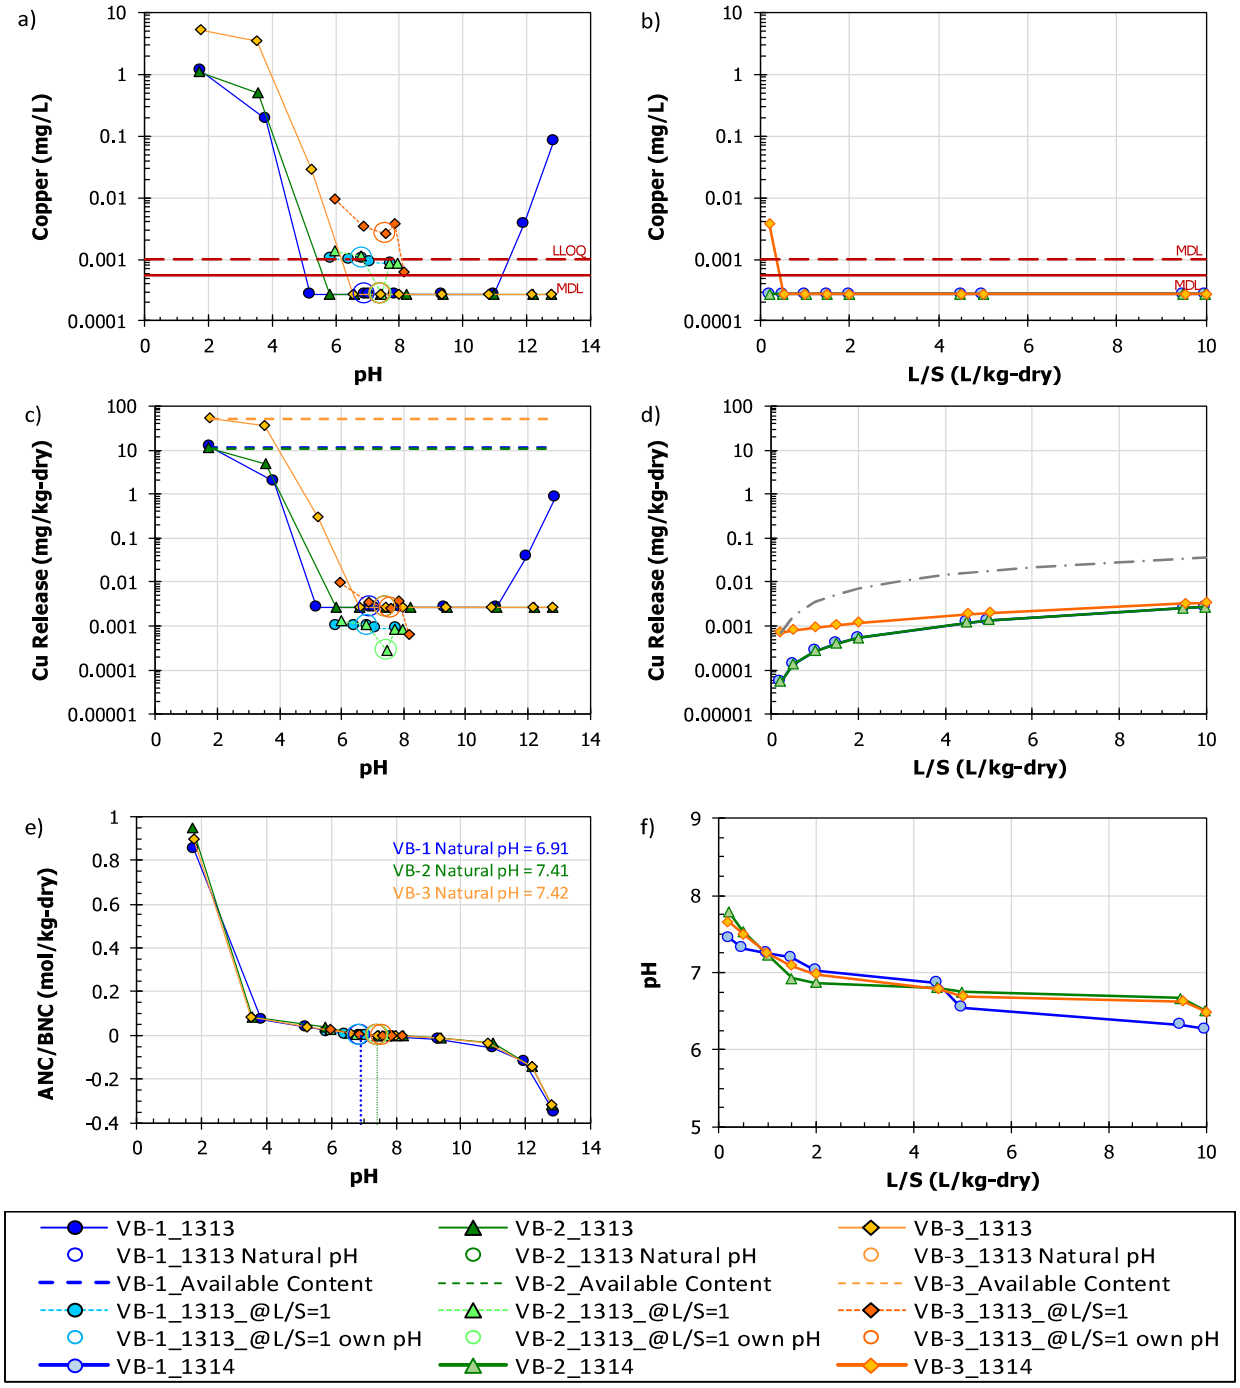

Figure D-12
Copper LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

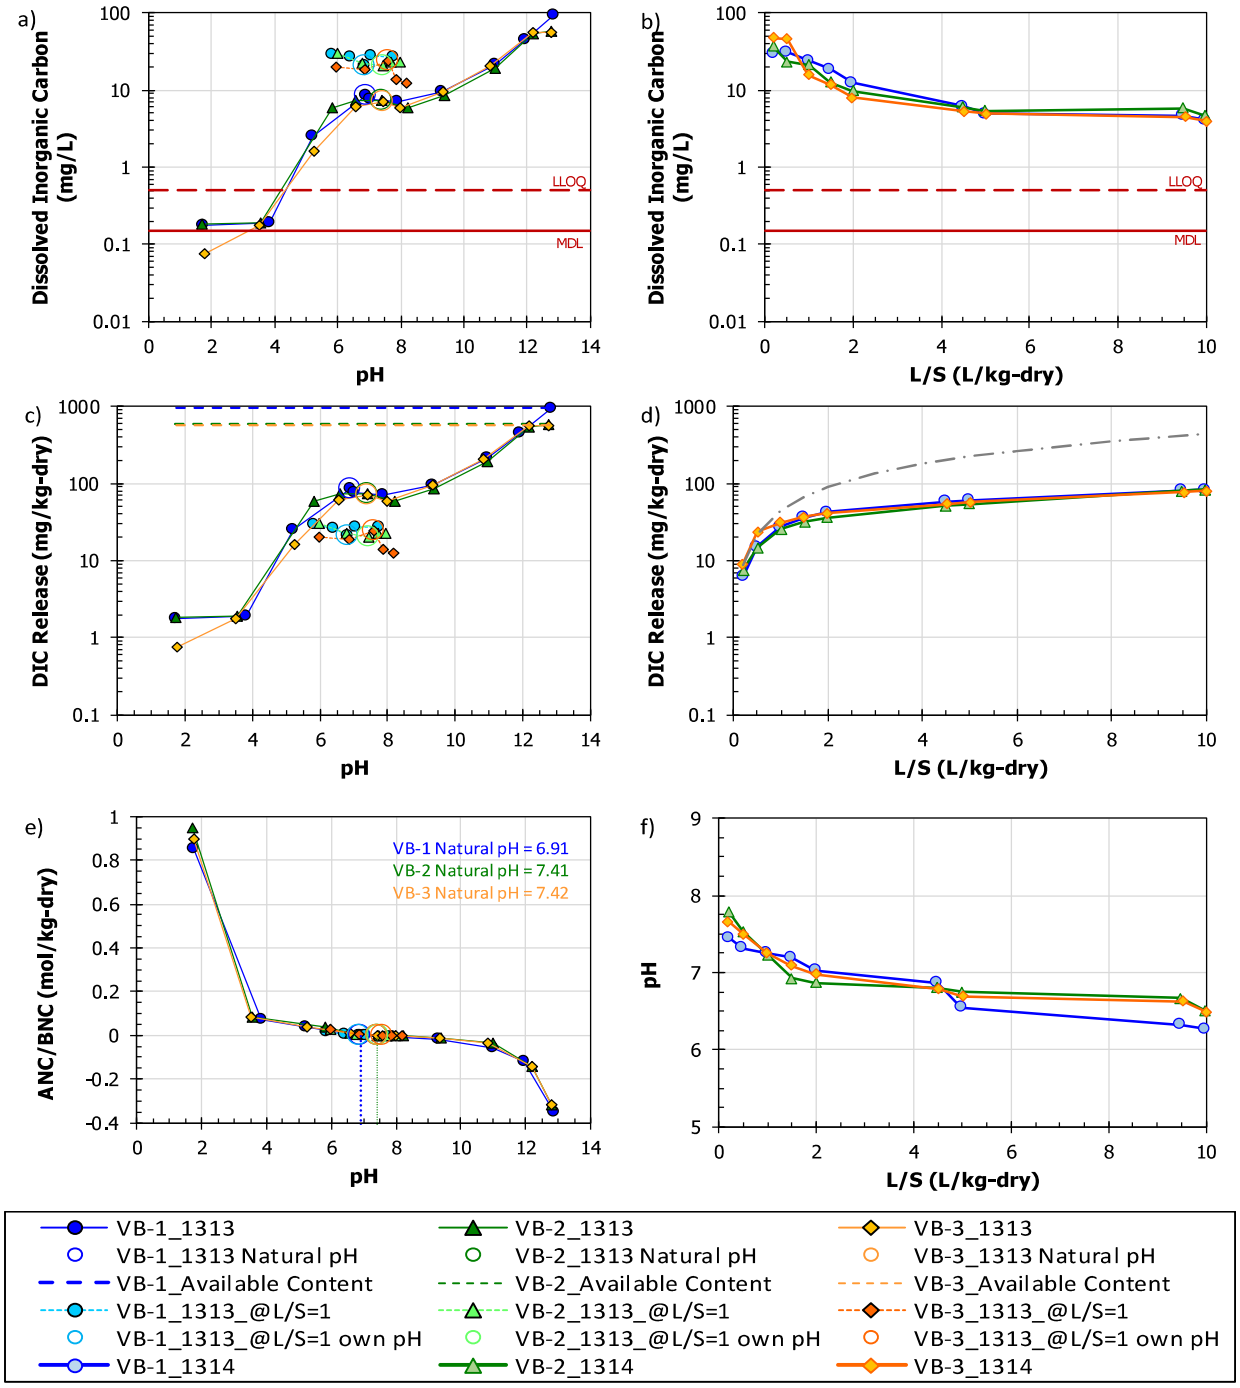

Figure D-13
Dissolved inorganic carbon LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

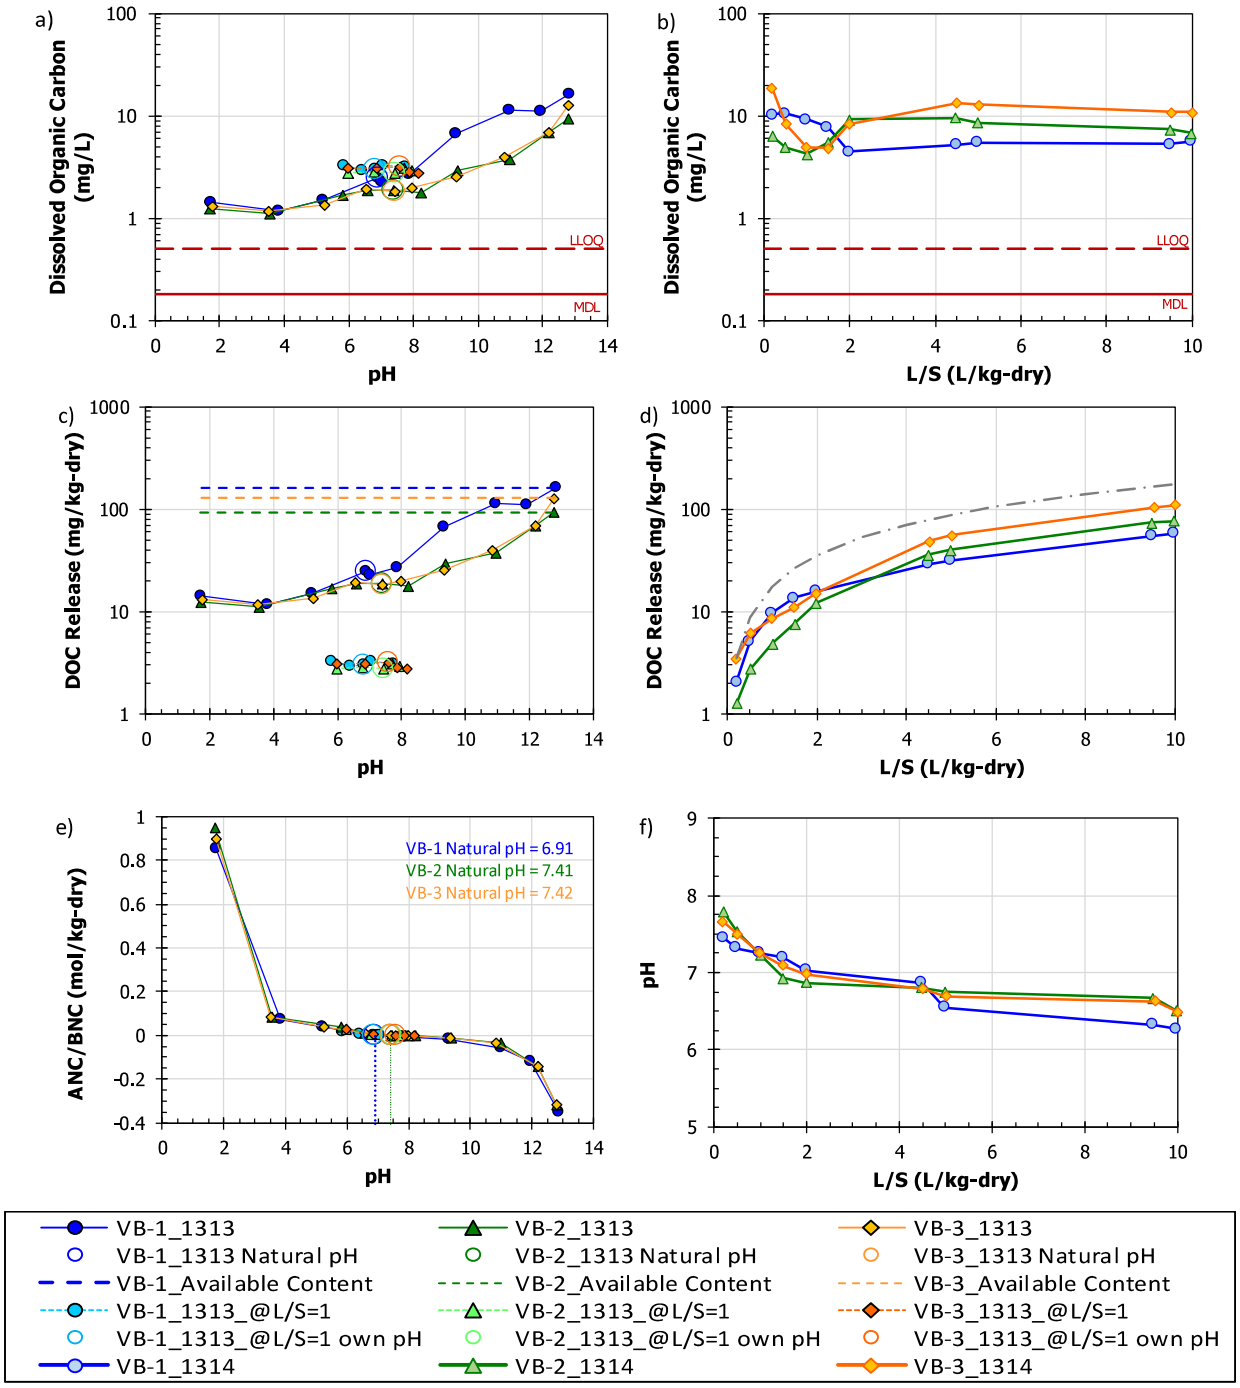

Figure D-14
Dissolved organic carbon LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

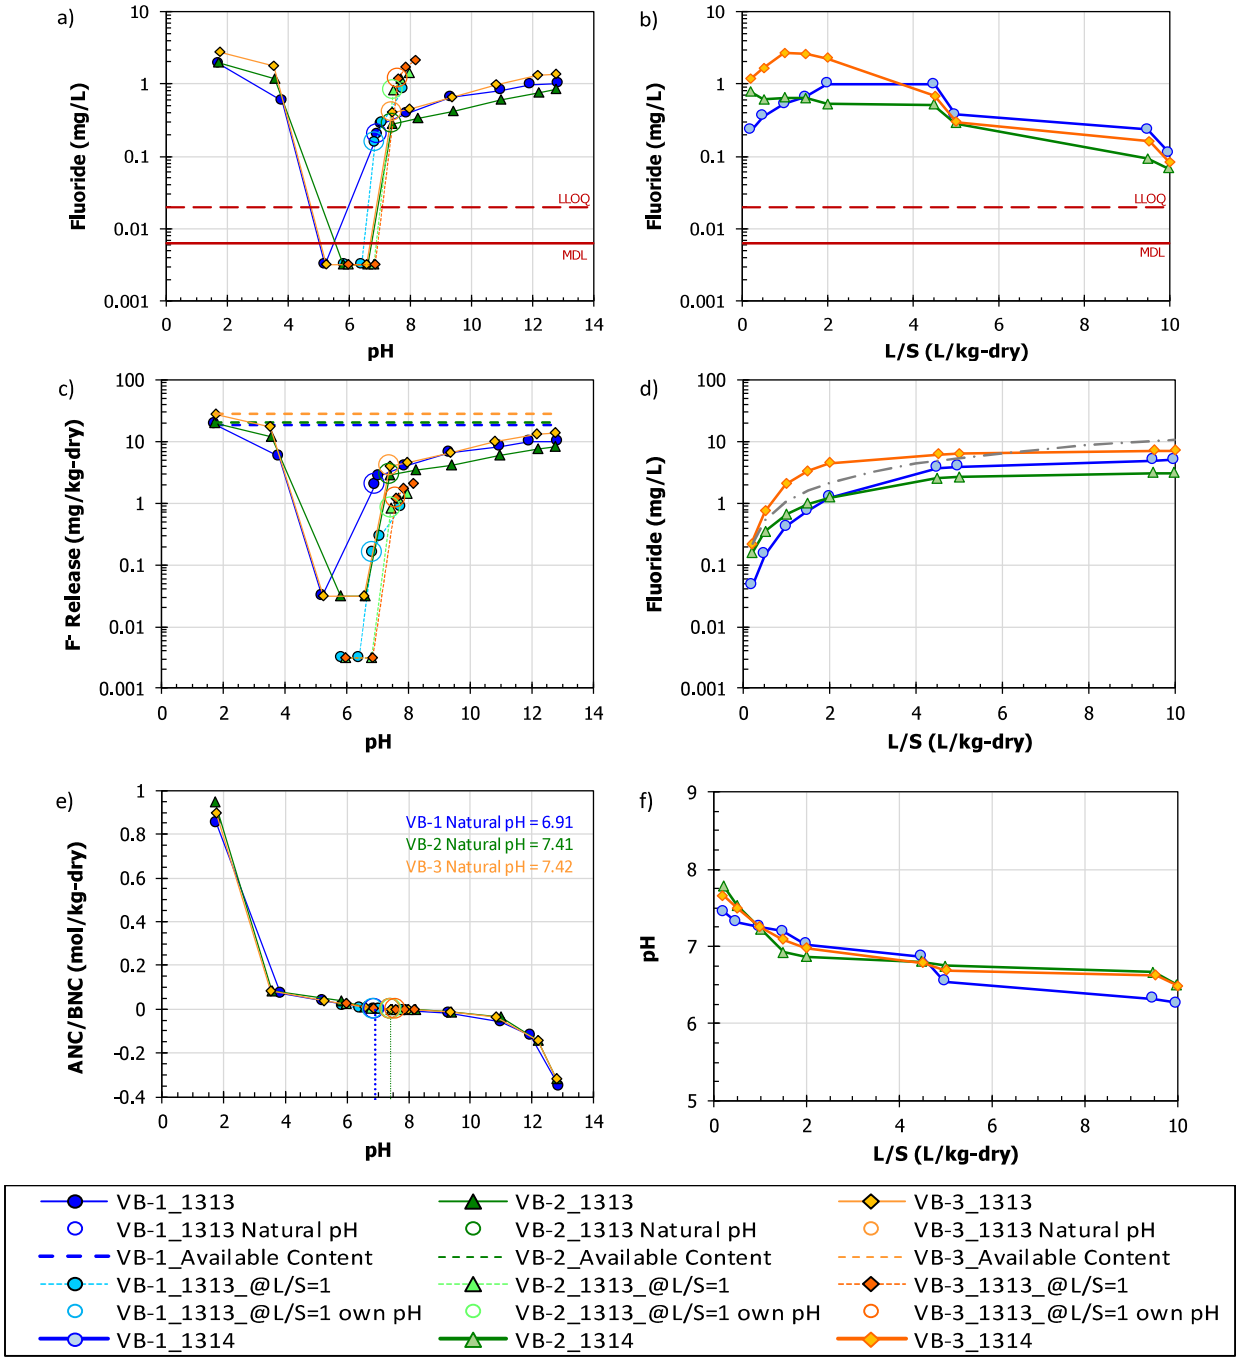

Figure D-15
Fluoride LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

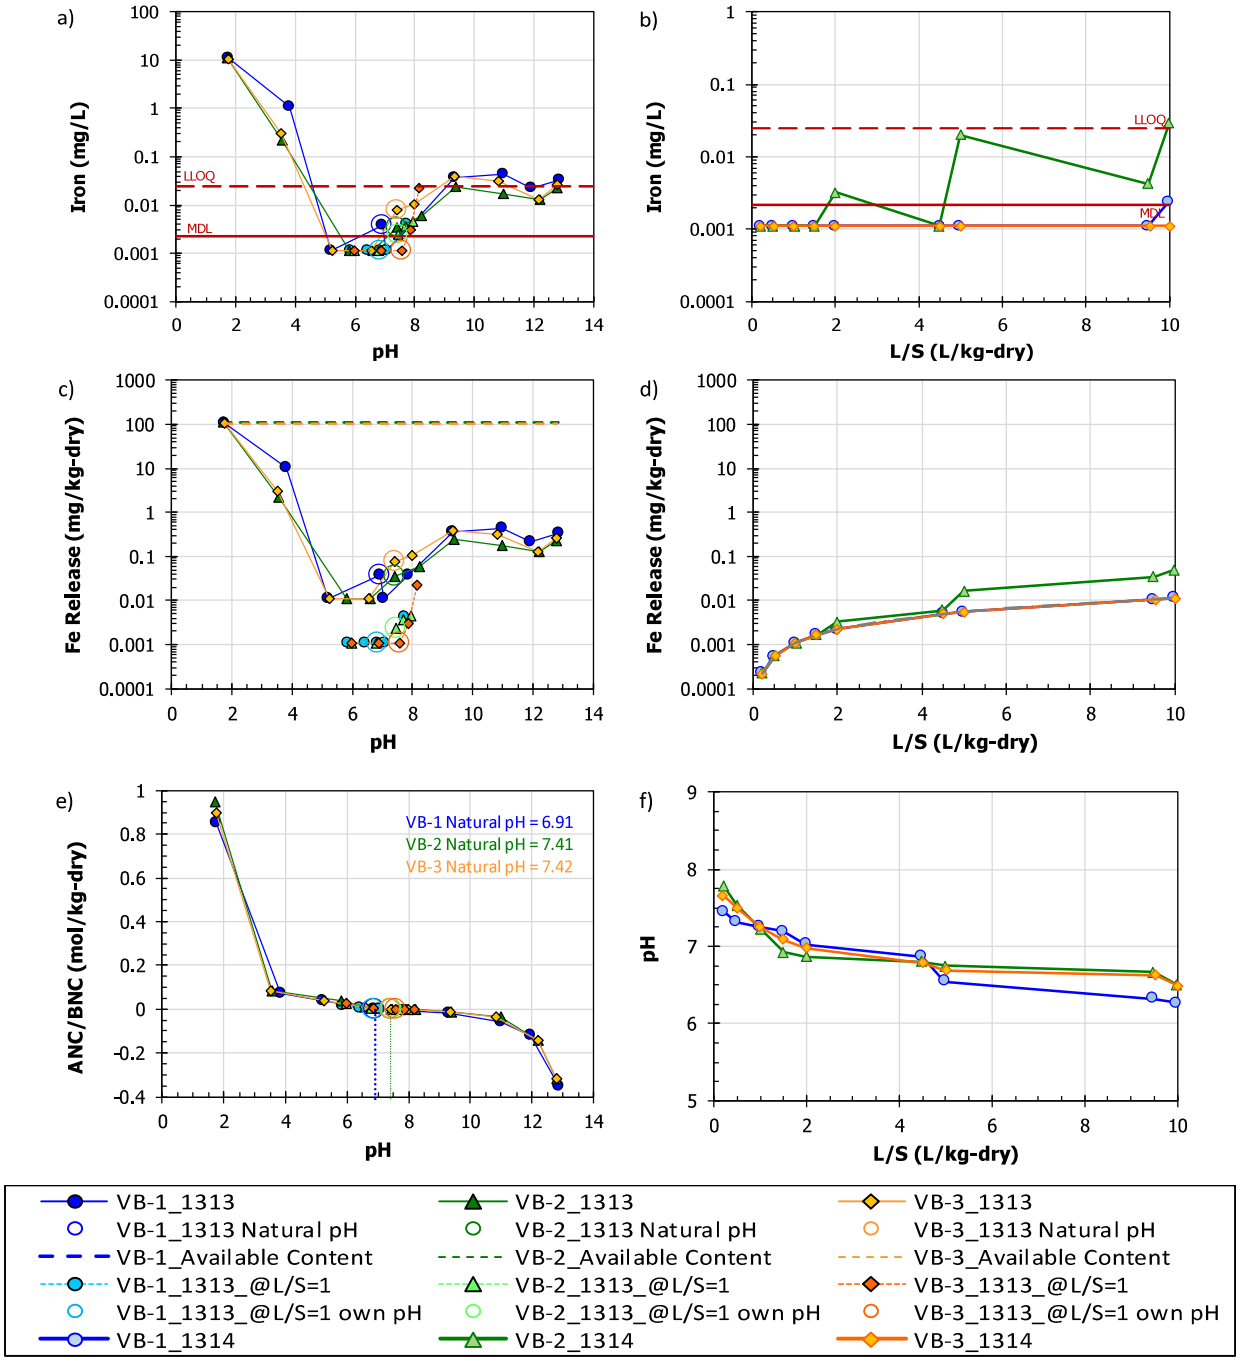

Figure D-16
Iron LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

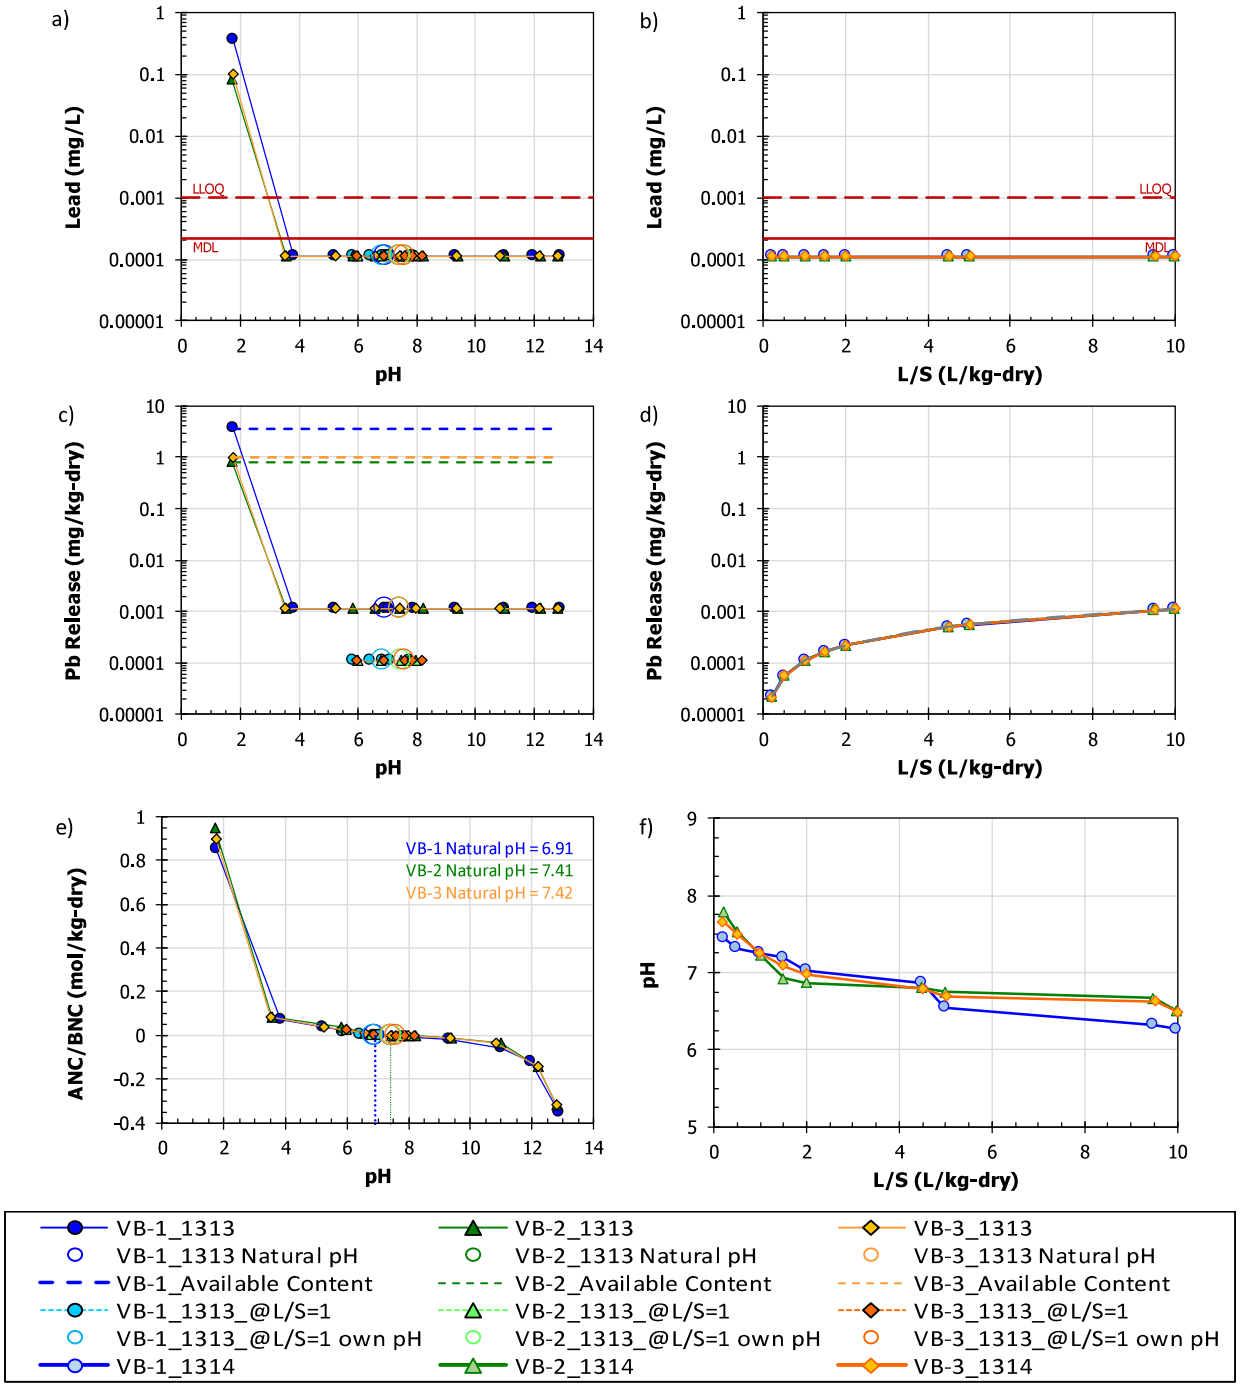

Figure D-17
Lead LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

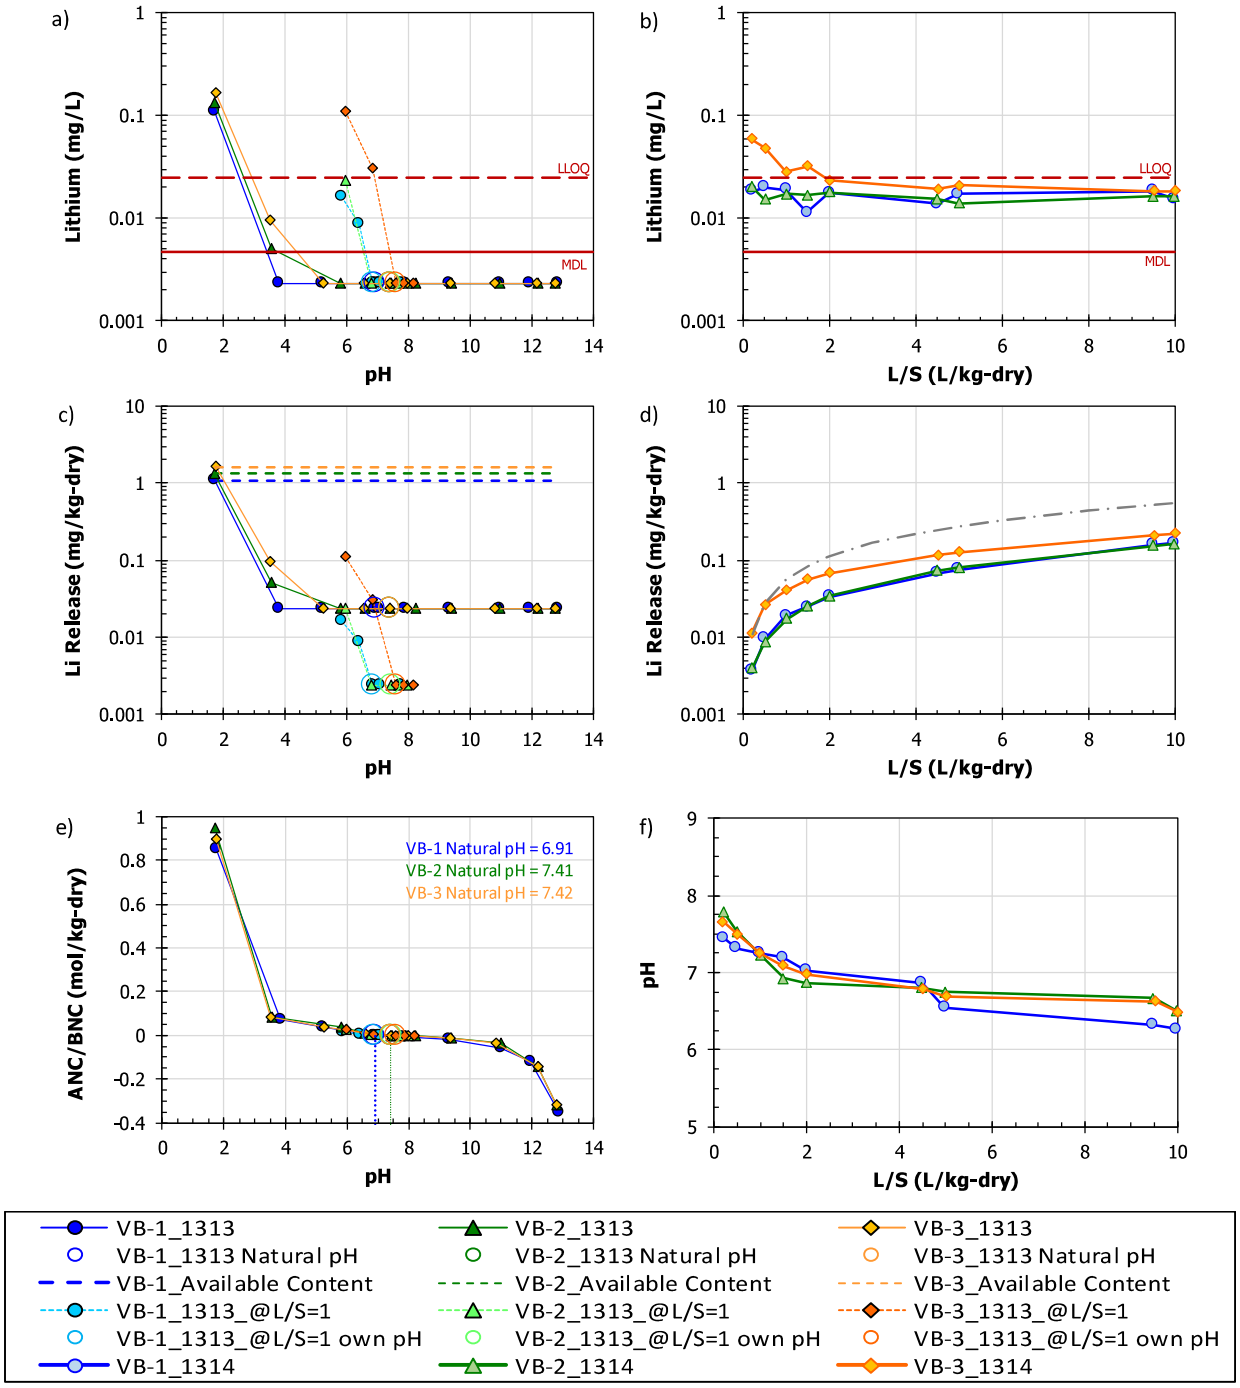

Figure D-18
Lithium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

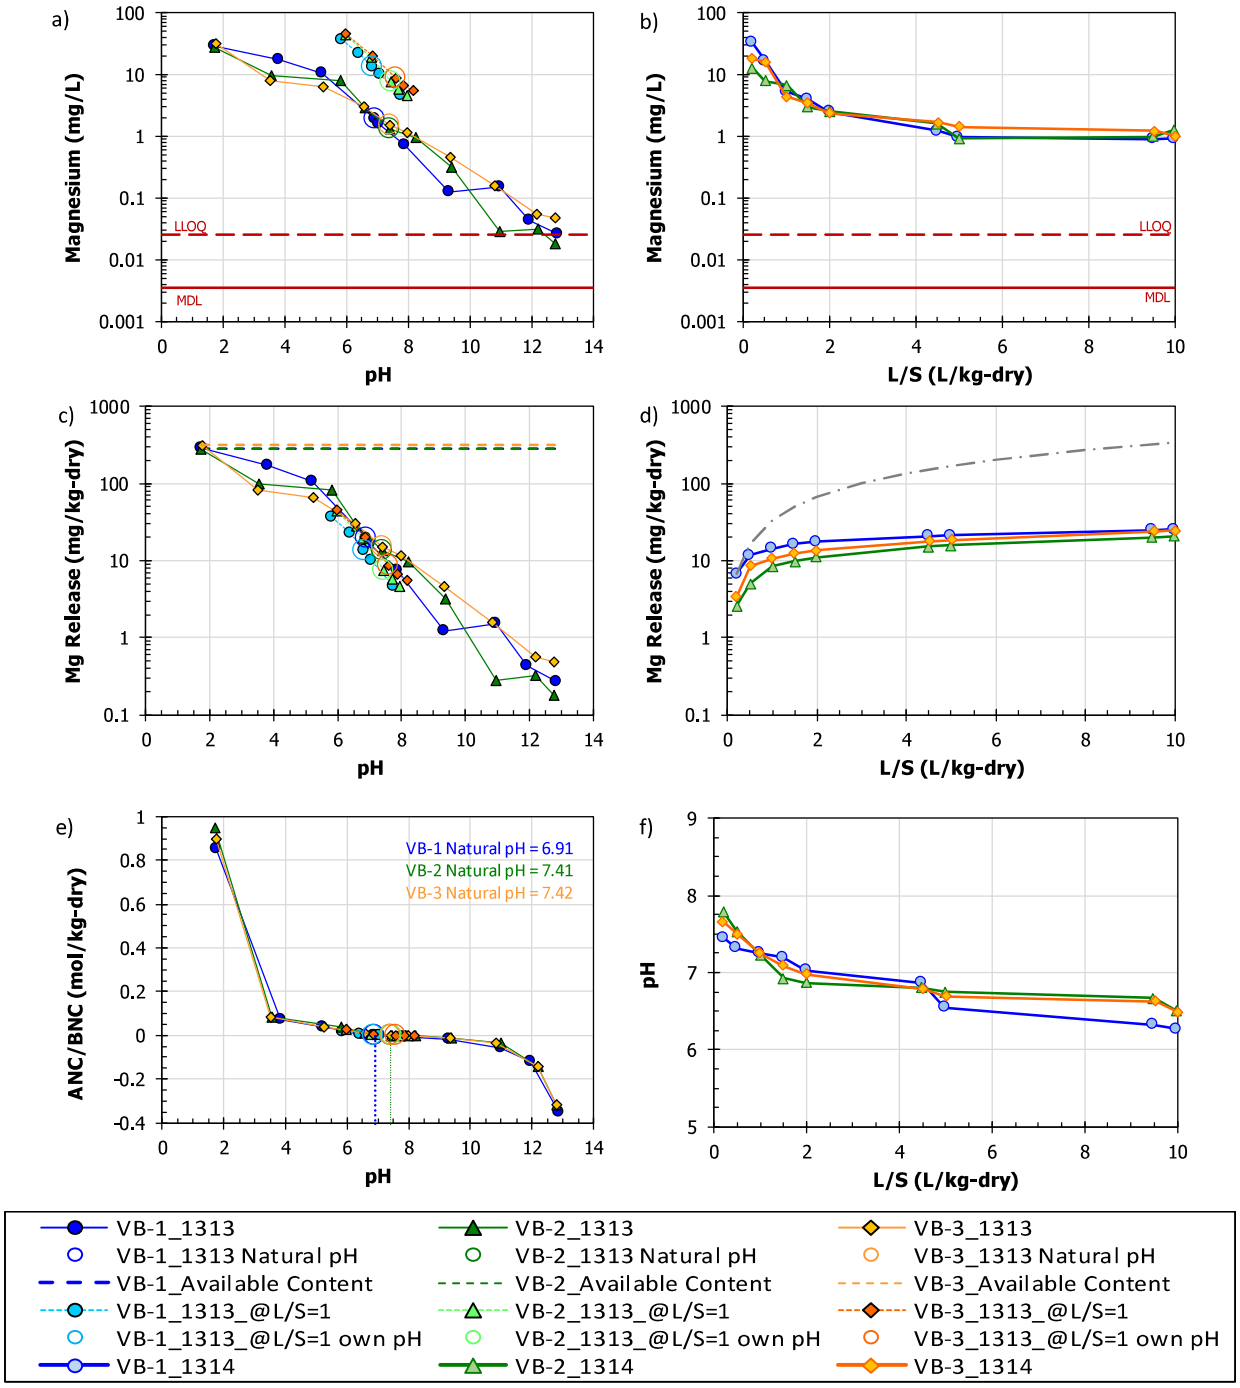

Figure D-19
Magnesium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

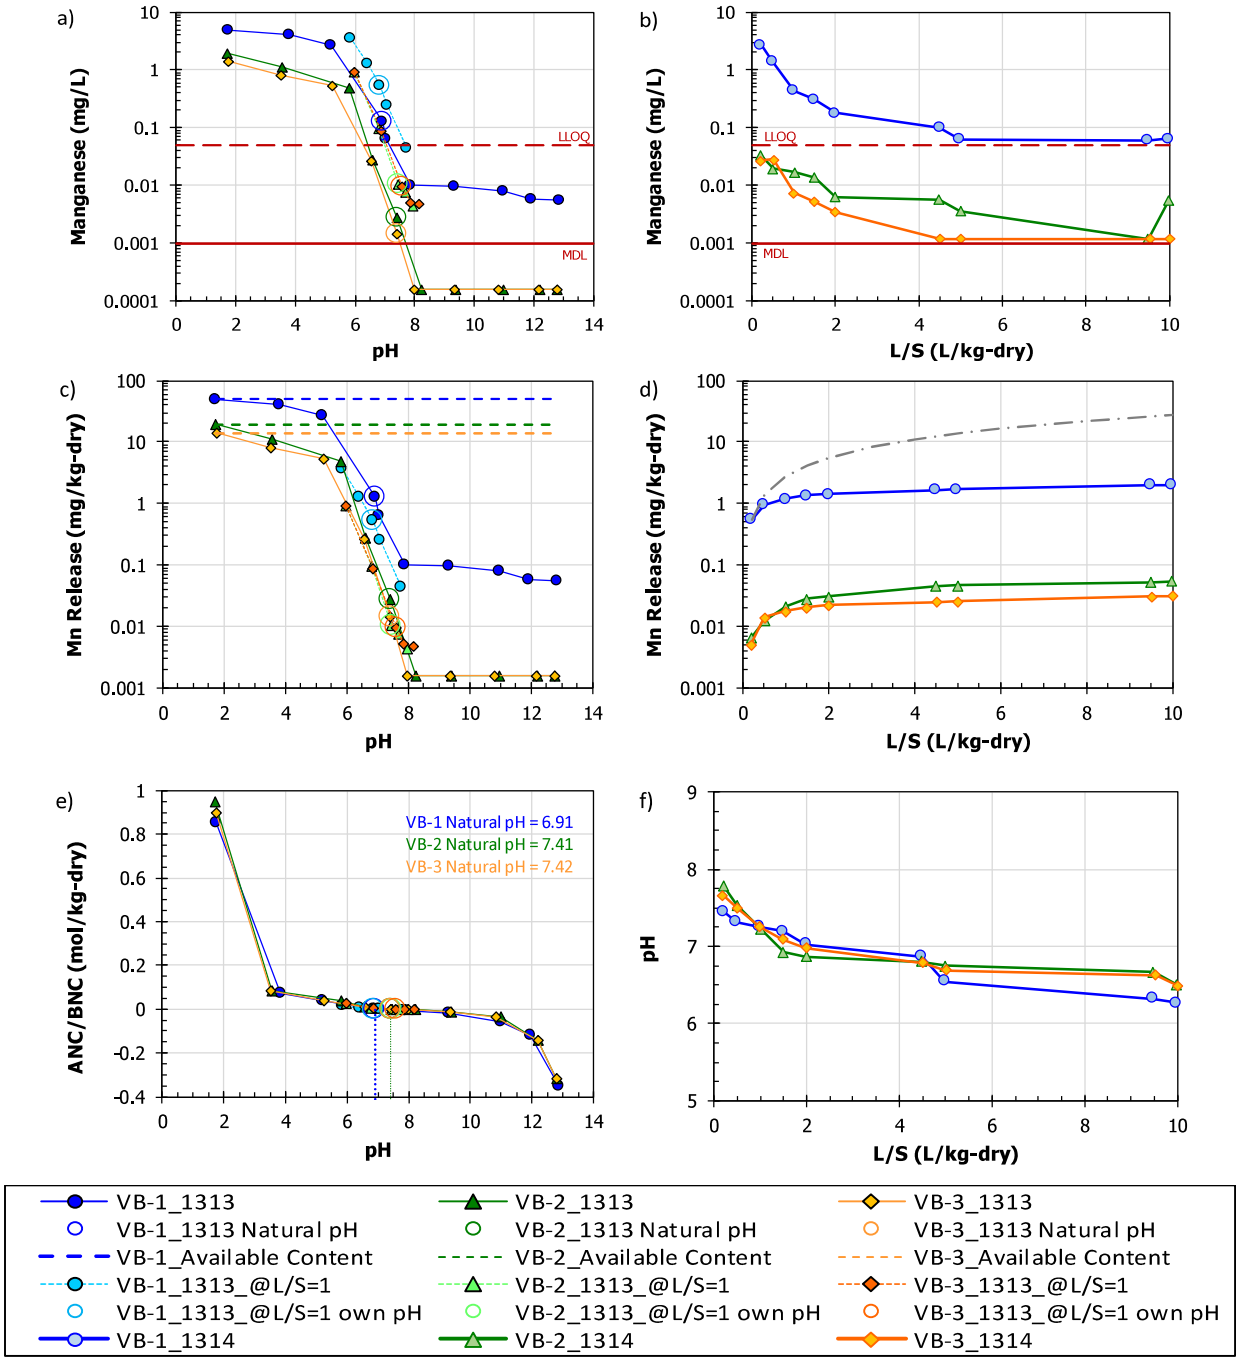

Figure D-20
Manganese LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

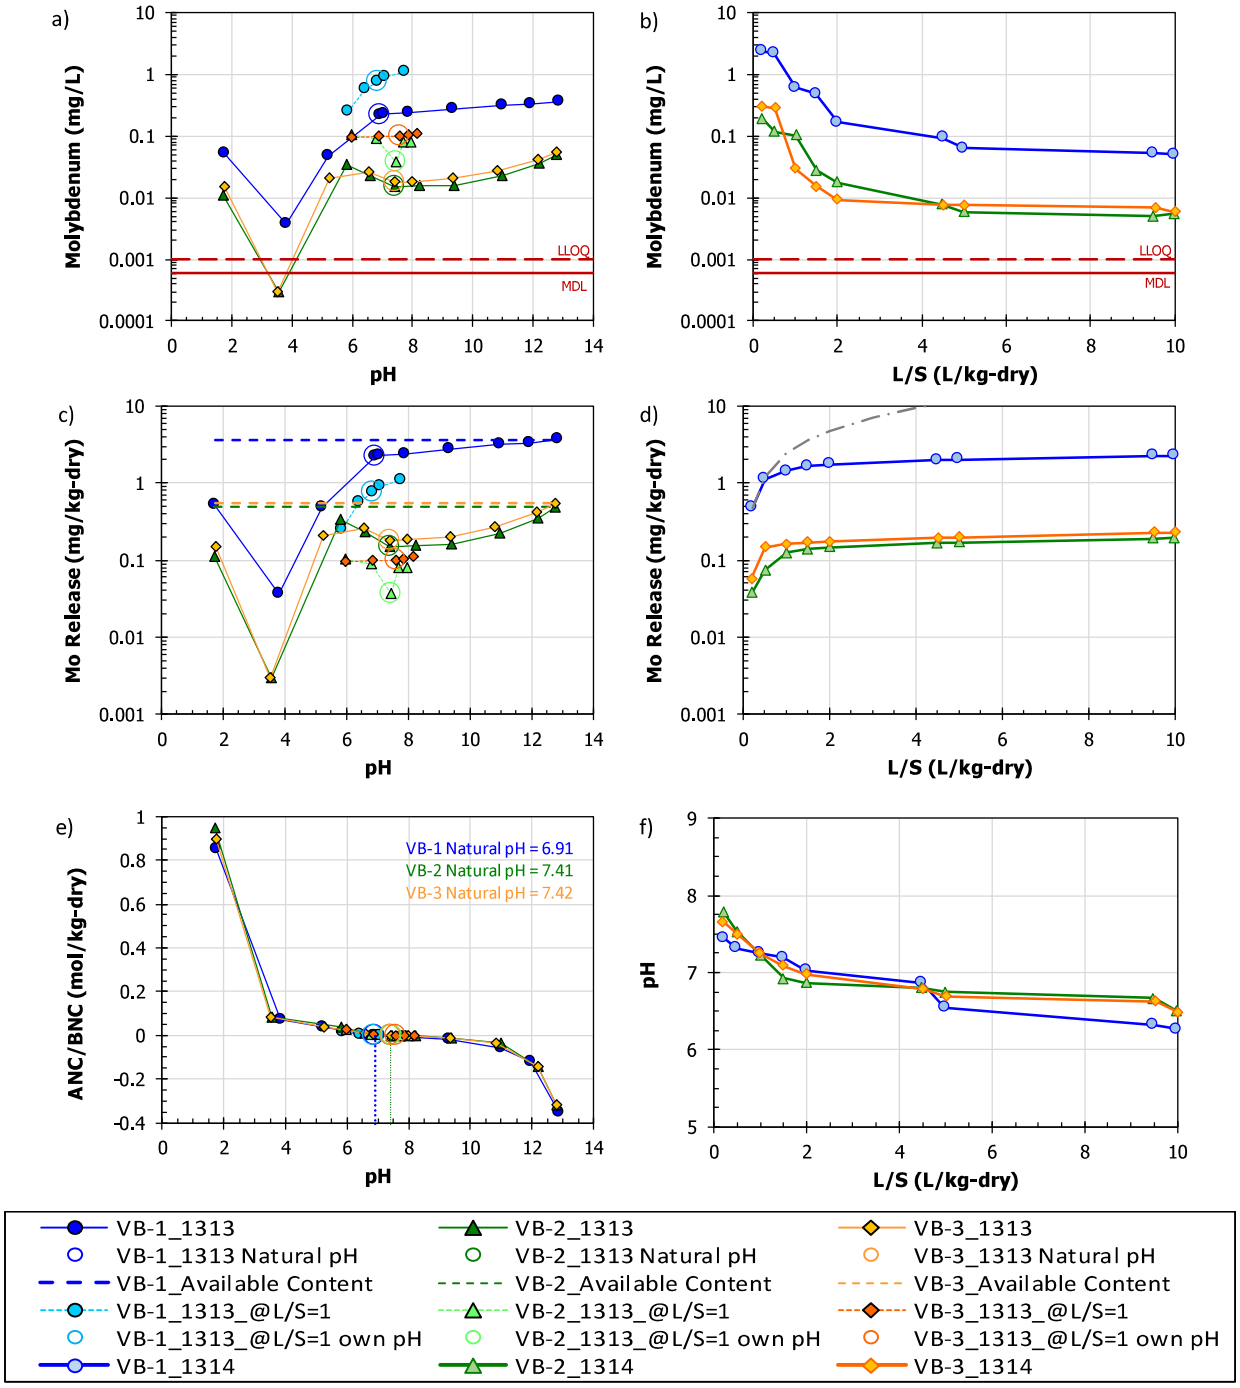

Figure D-21
Molybdenum LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

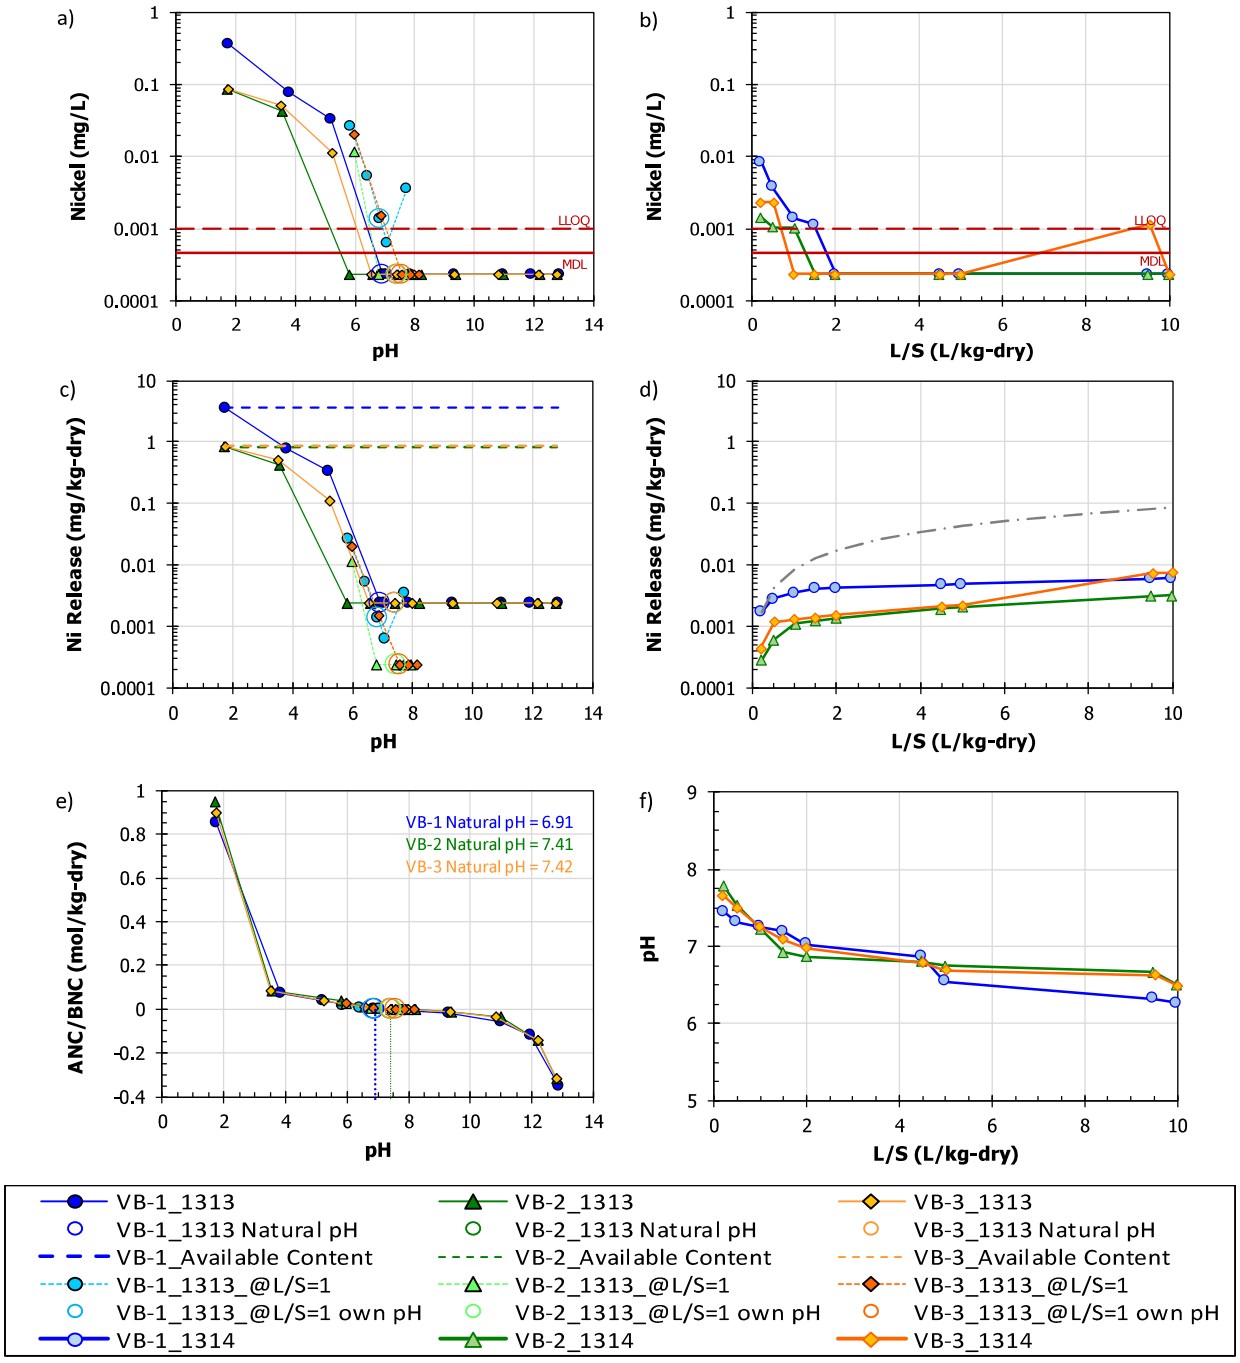

Figure D-22
Nickel LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

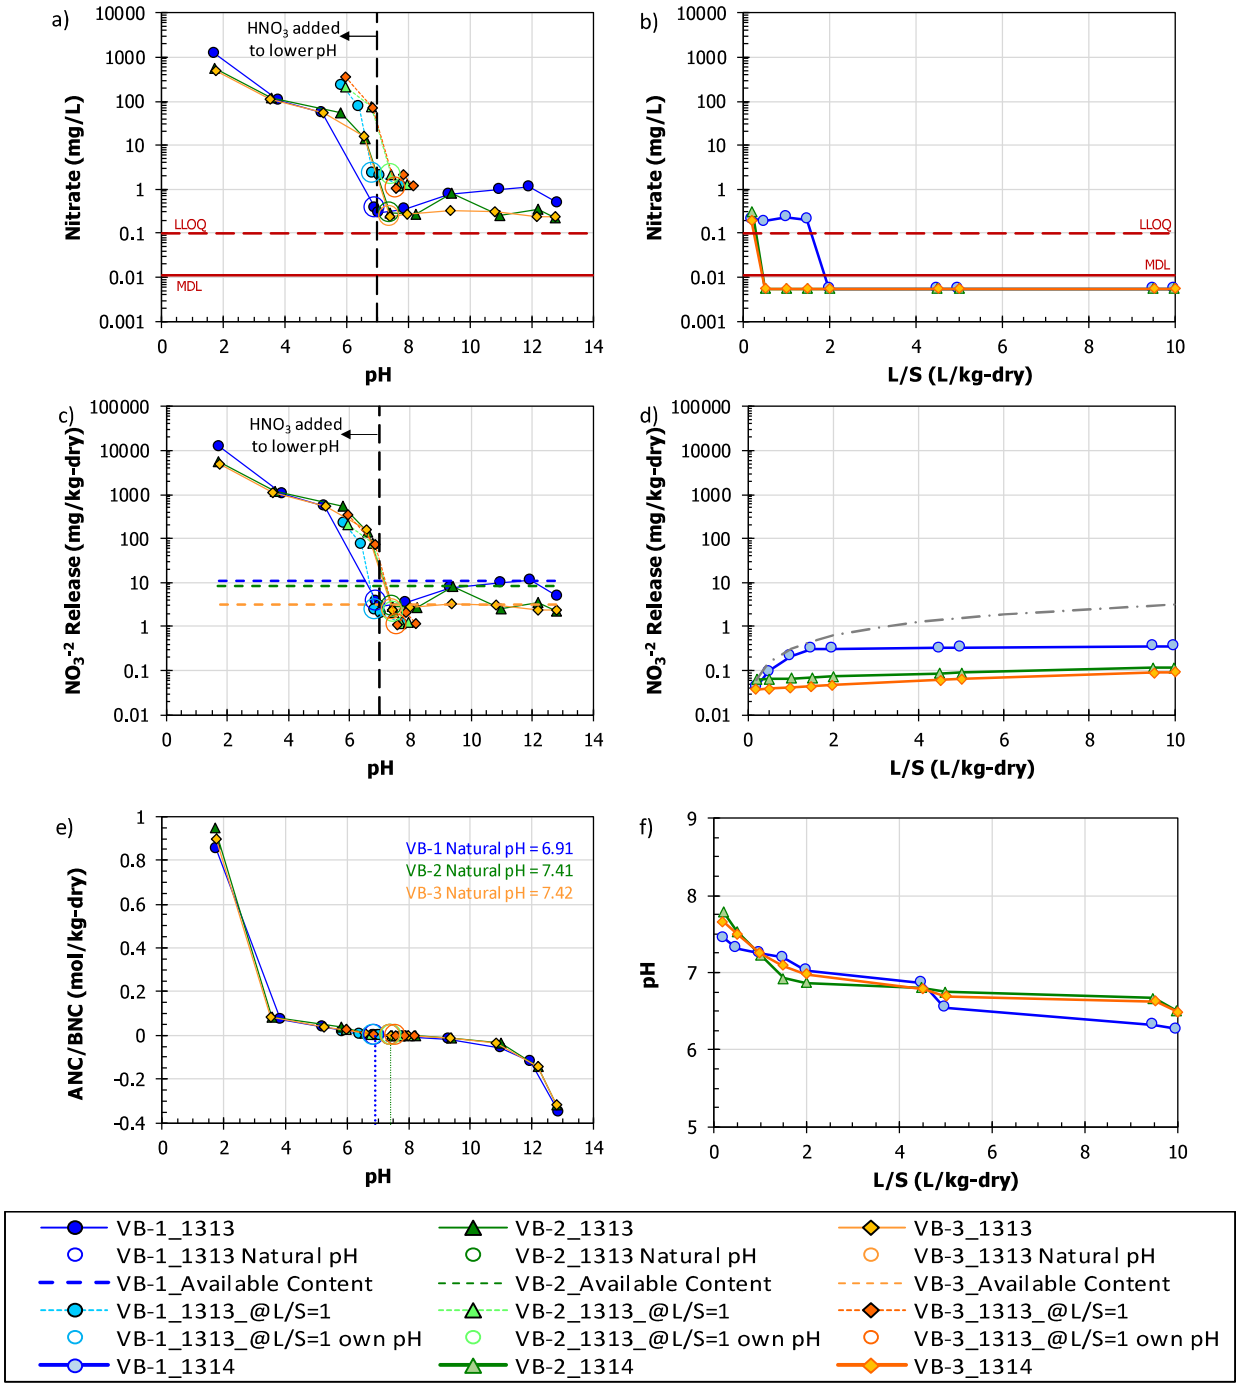

Figure D-23
Nitrate LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

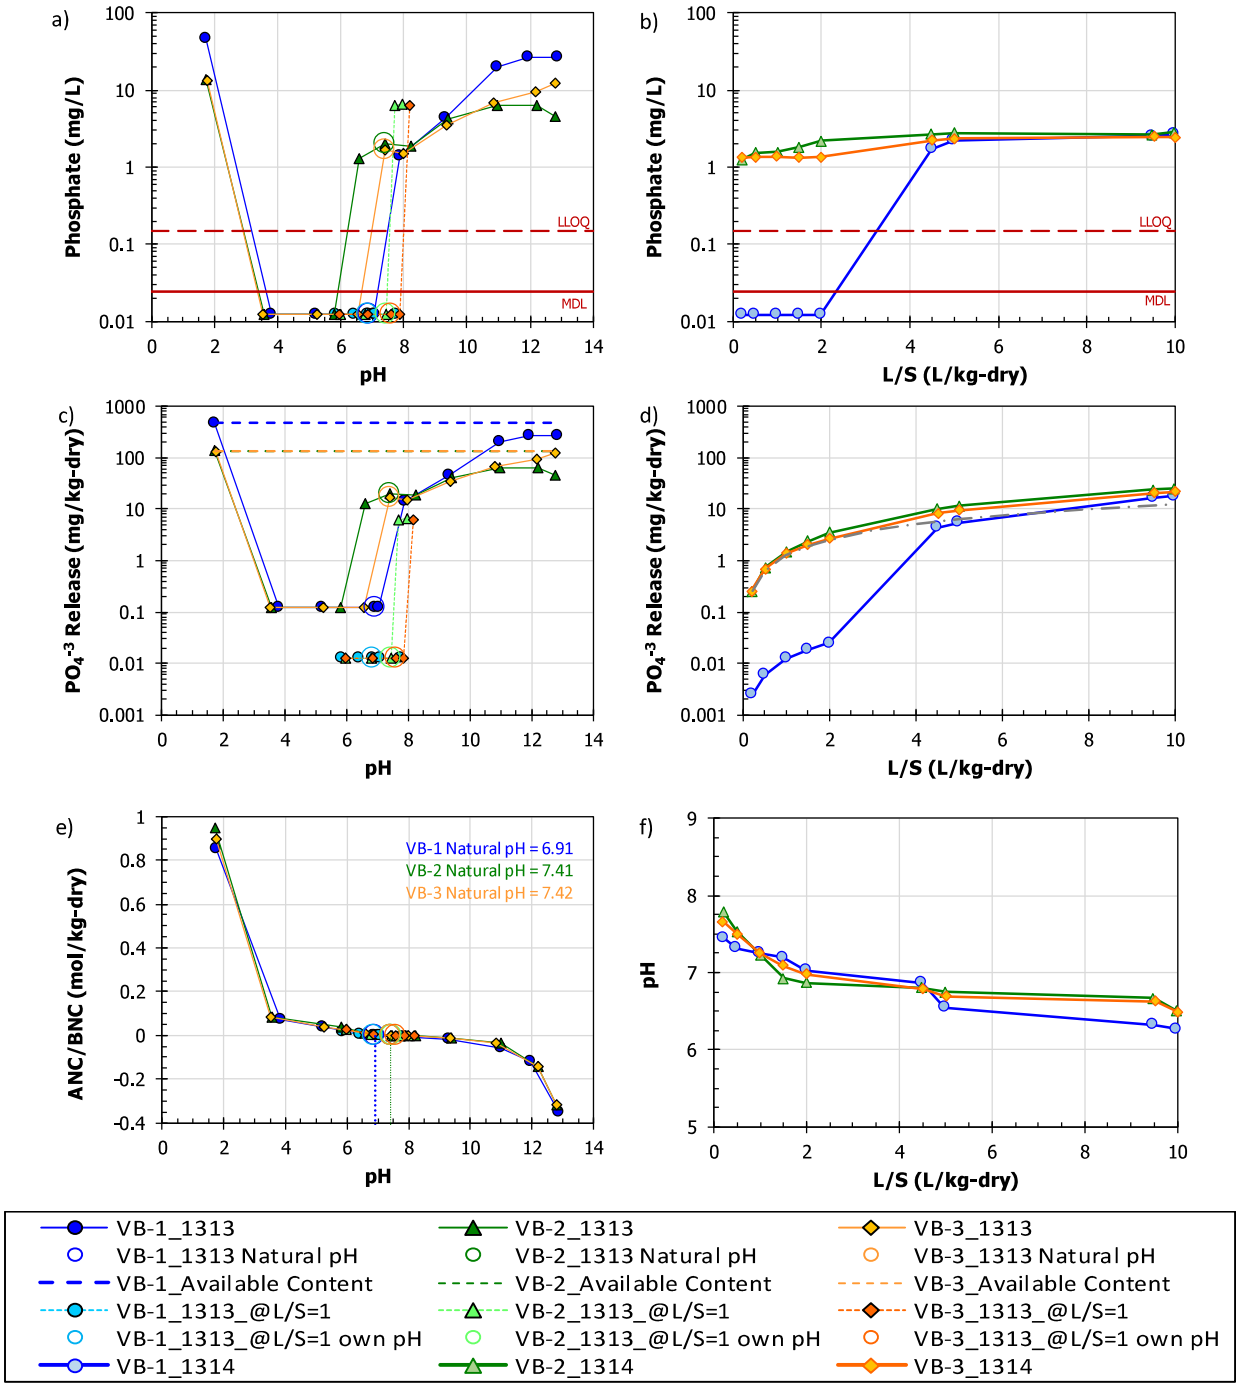

Figure D-24
Phosphate LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

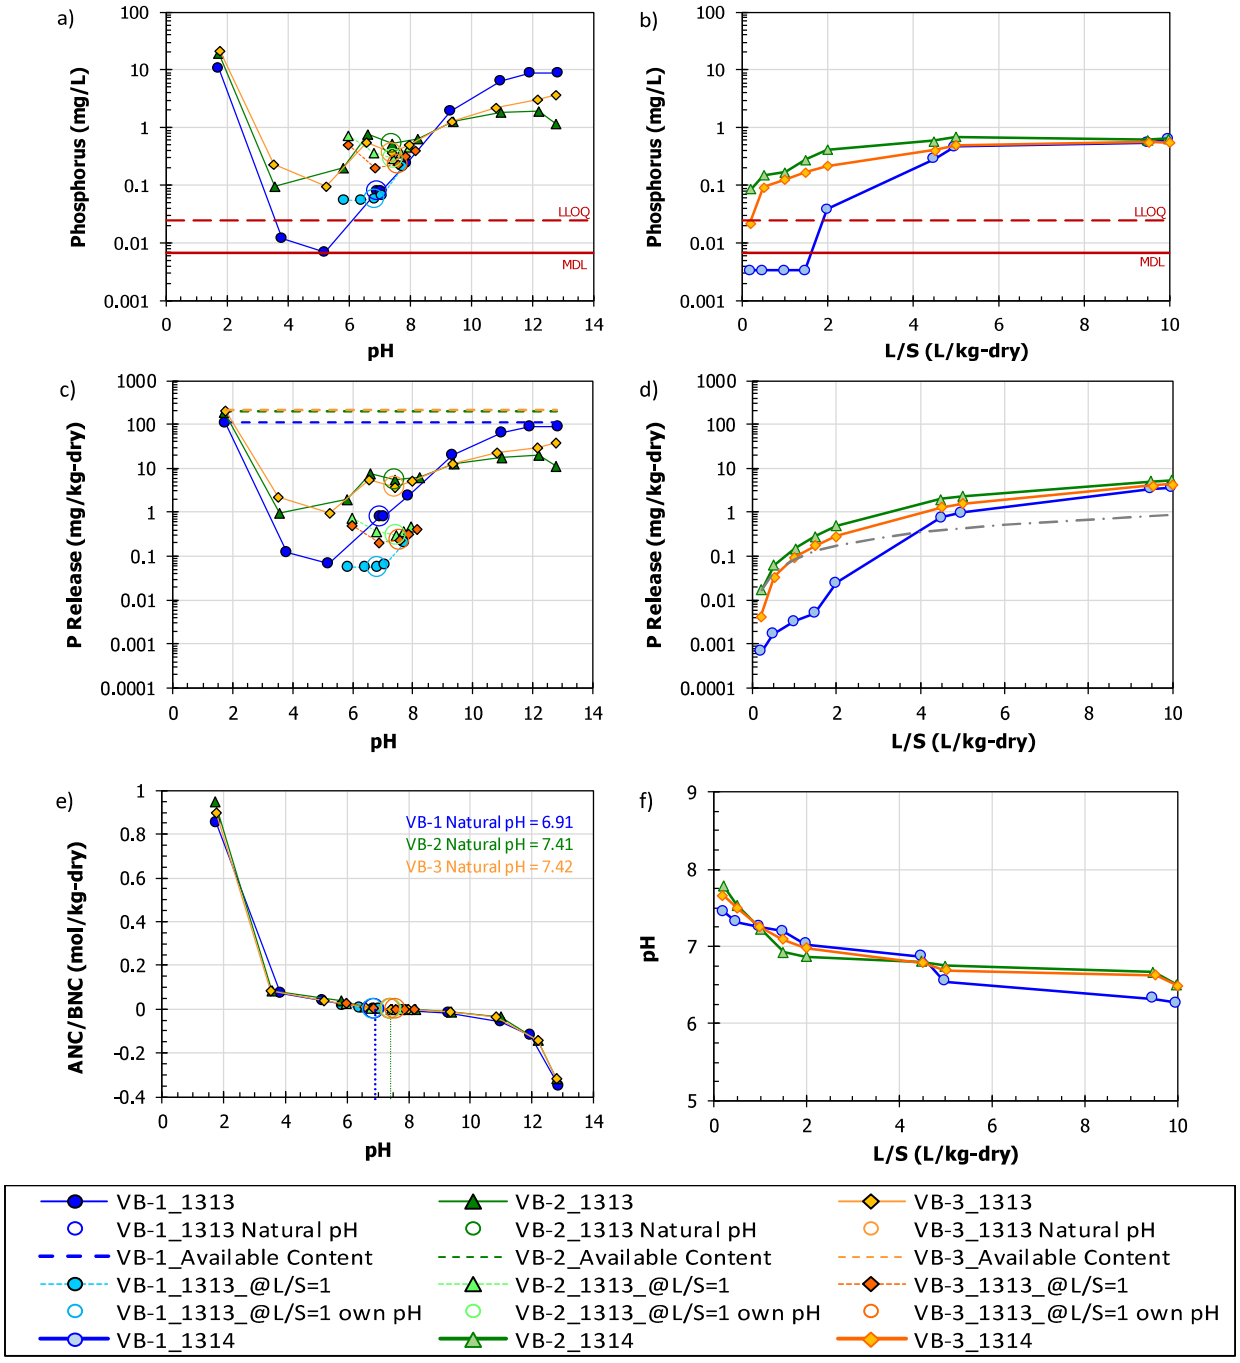

Figure D-25
Phosphorus LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

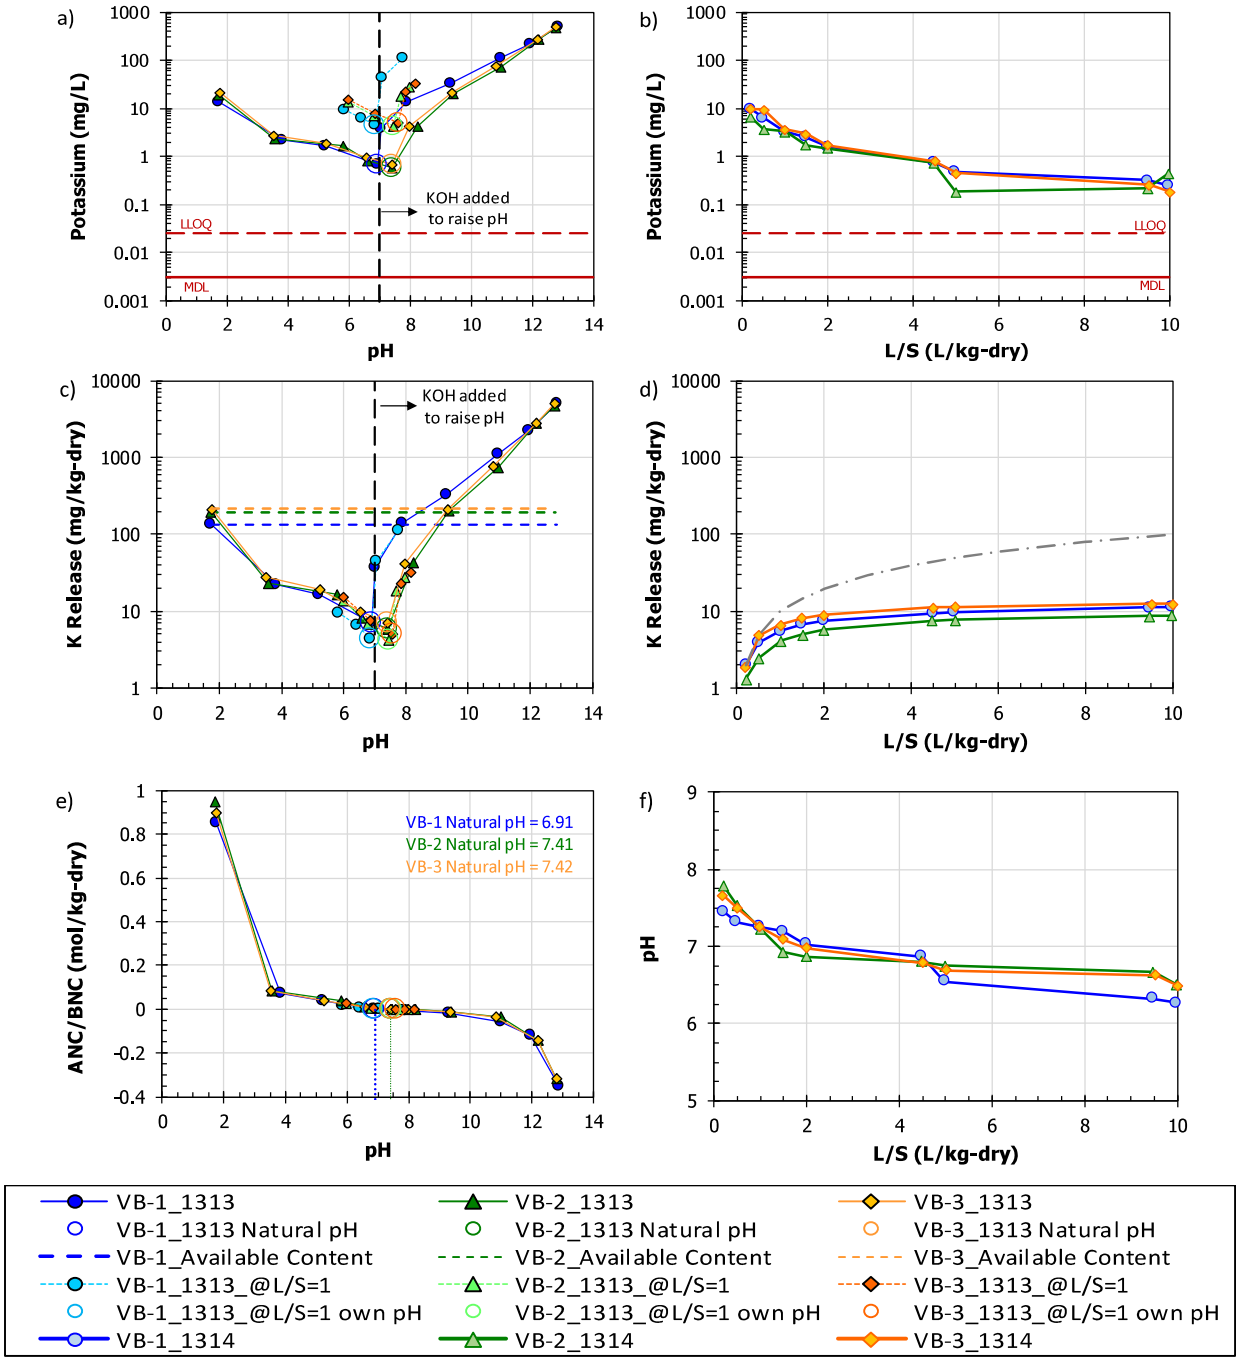

Figure D-26
Potassium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

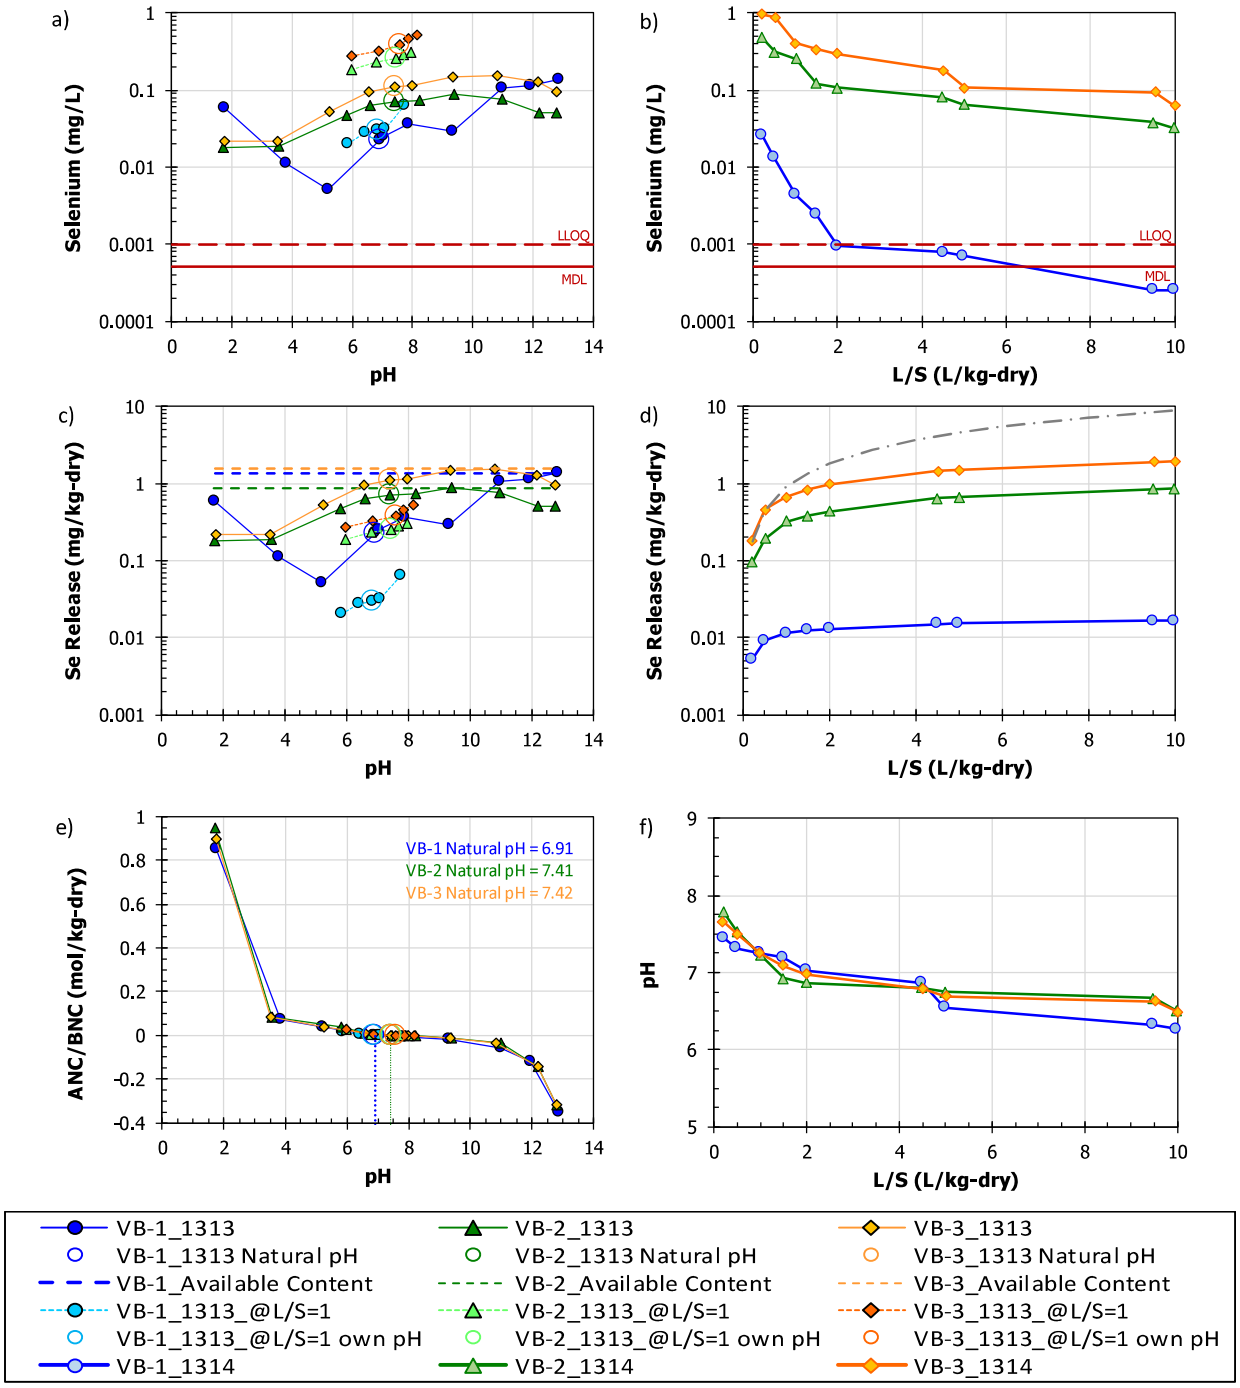

Figure D-27
Selenium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

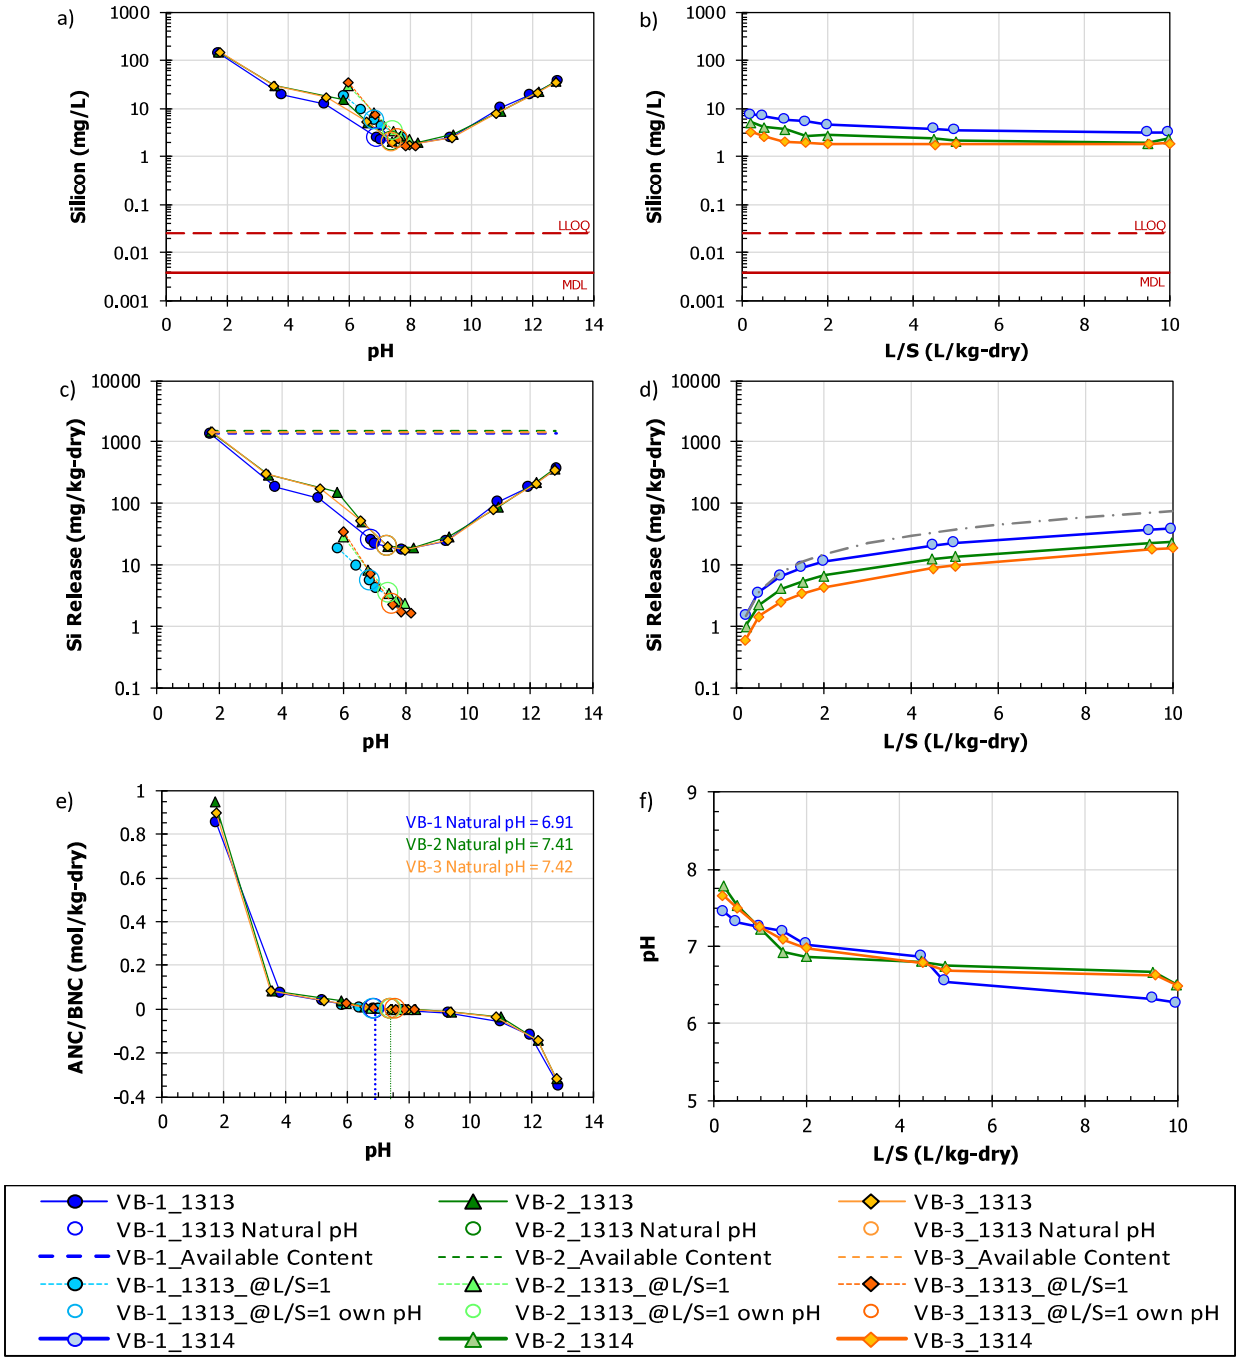

Figure D-28
Silicon LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

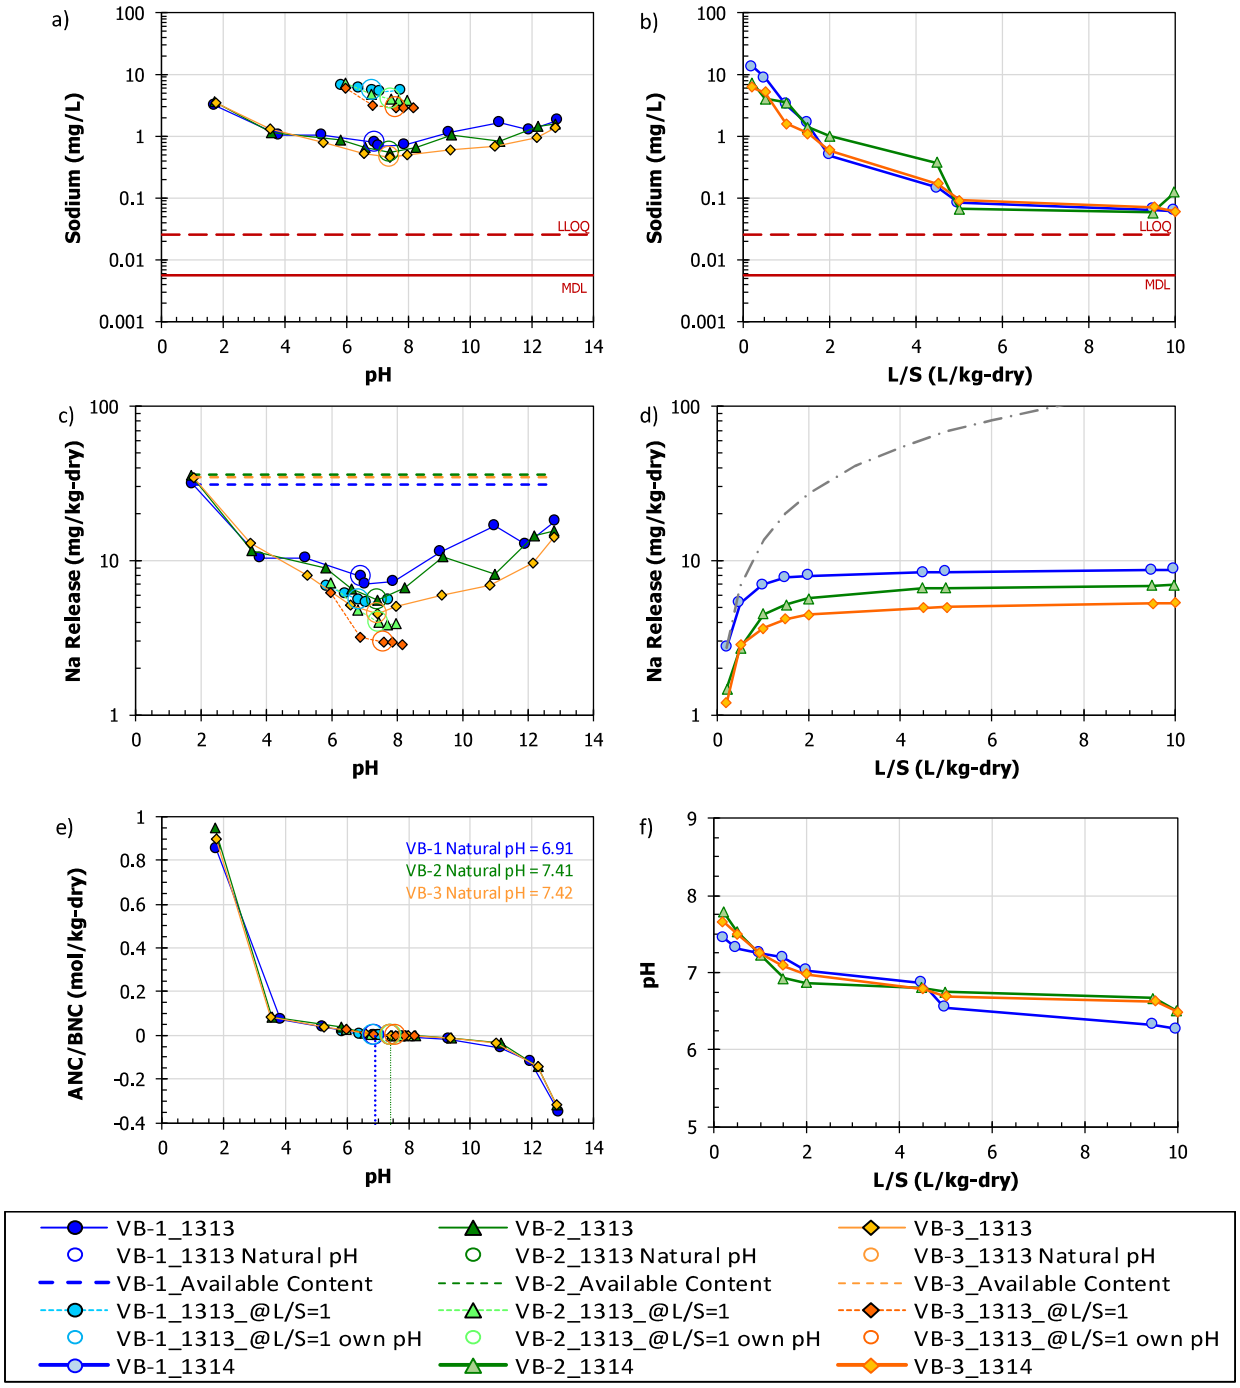

Figure D-29
Sodium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

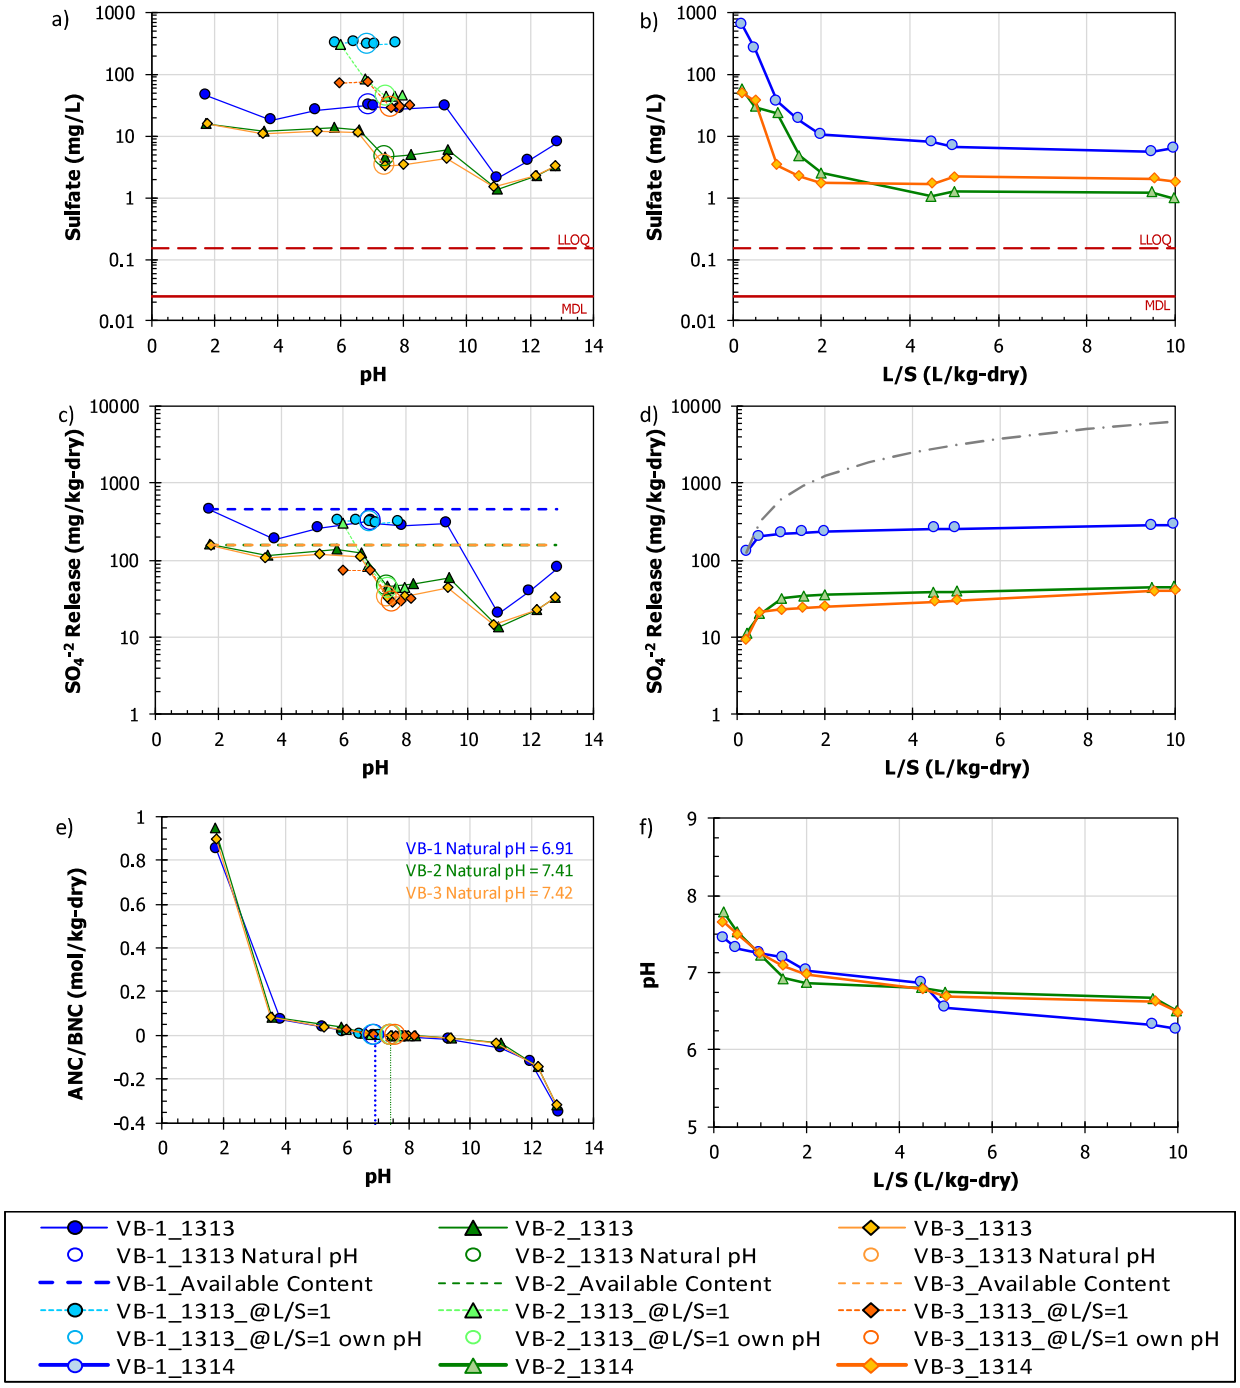

Figure D-30
Sulfate LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

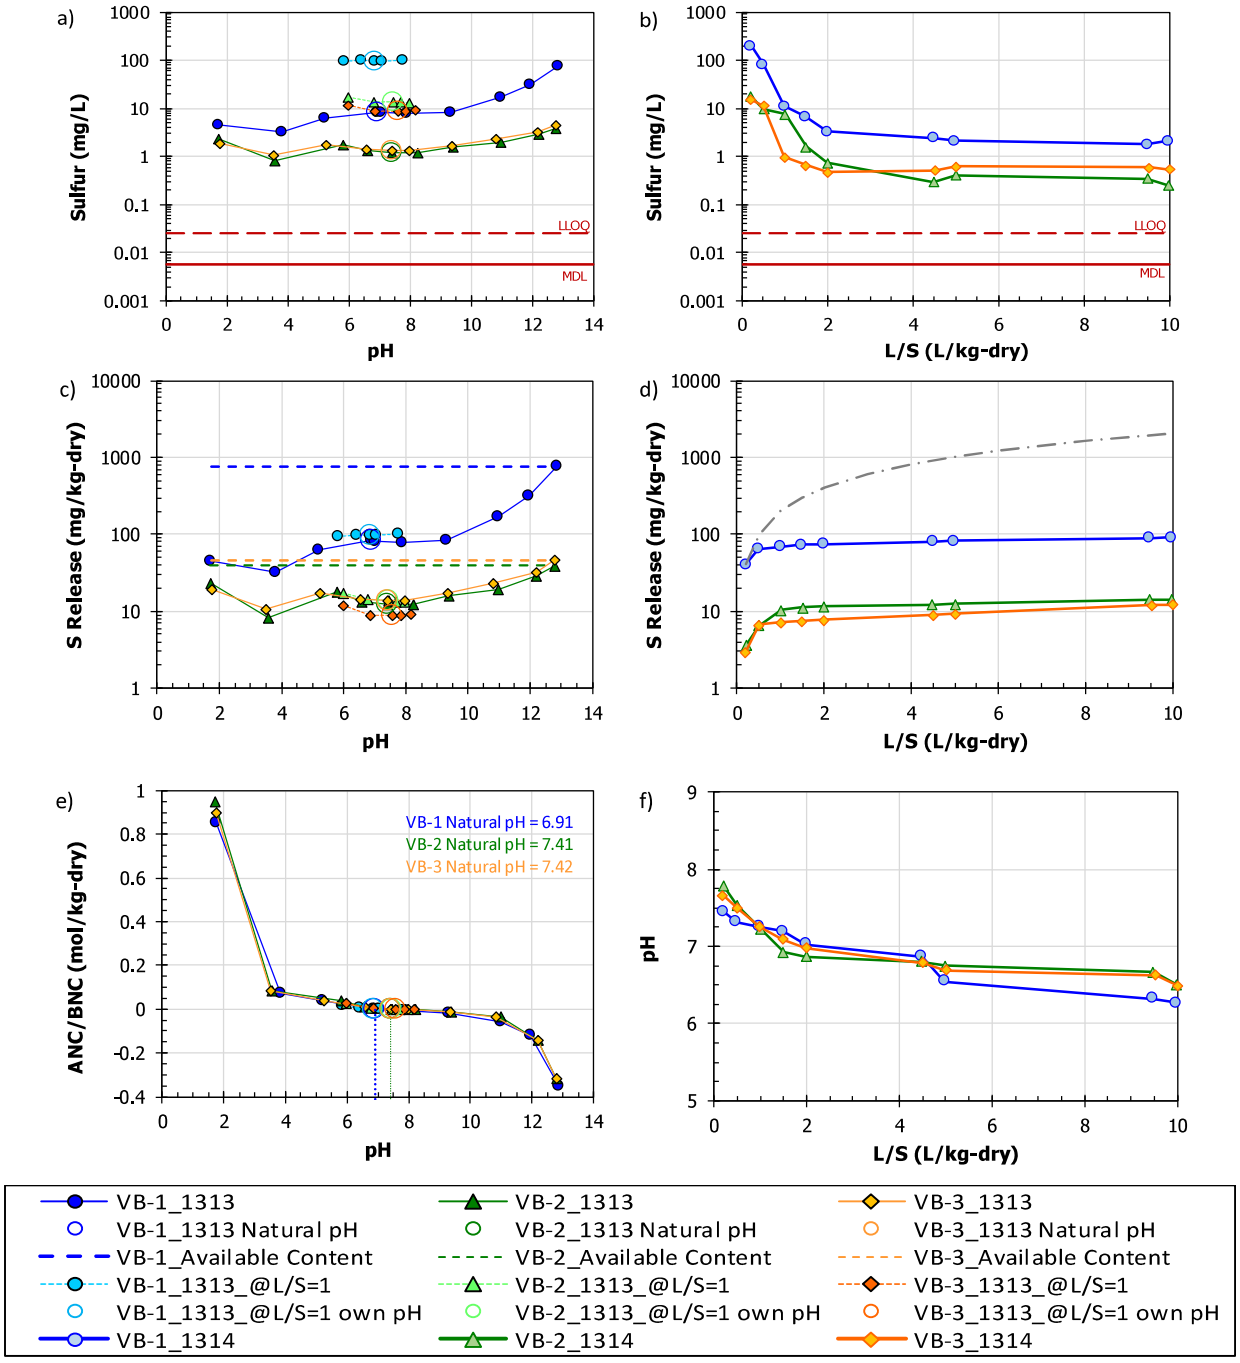

Figure D-31
Sulfur LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

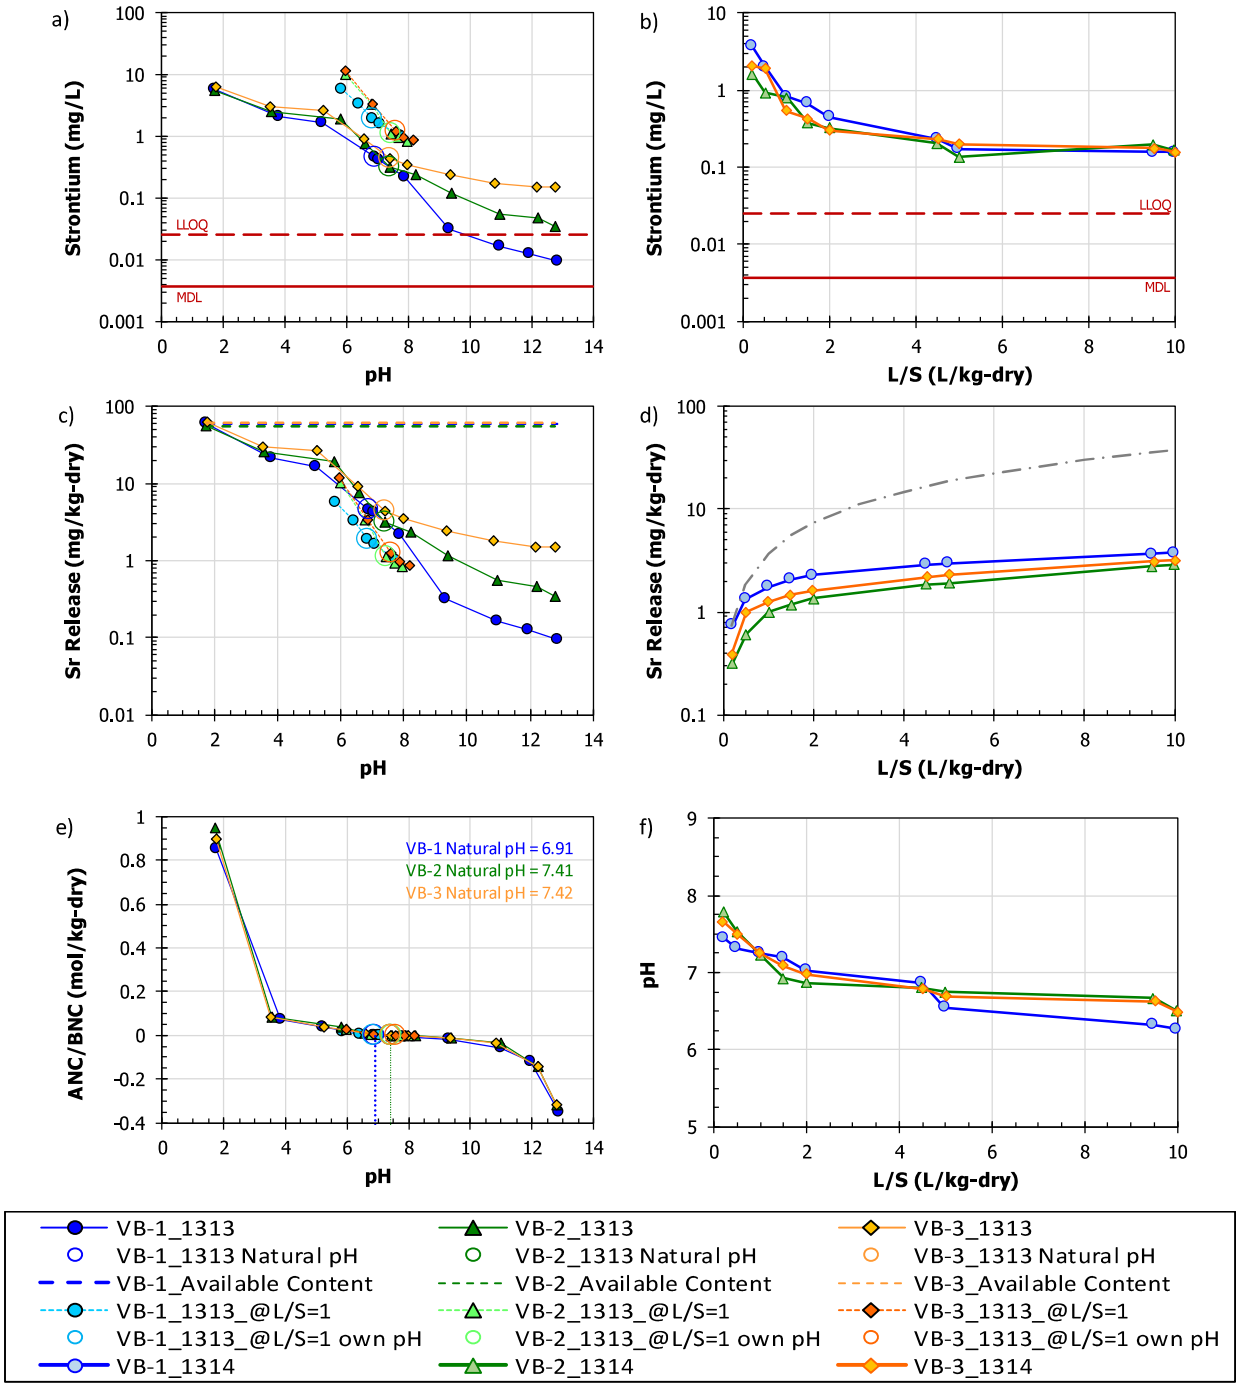

Figure D-32
Strontium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

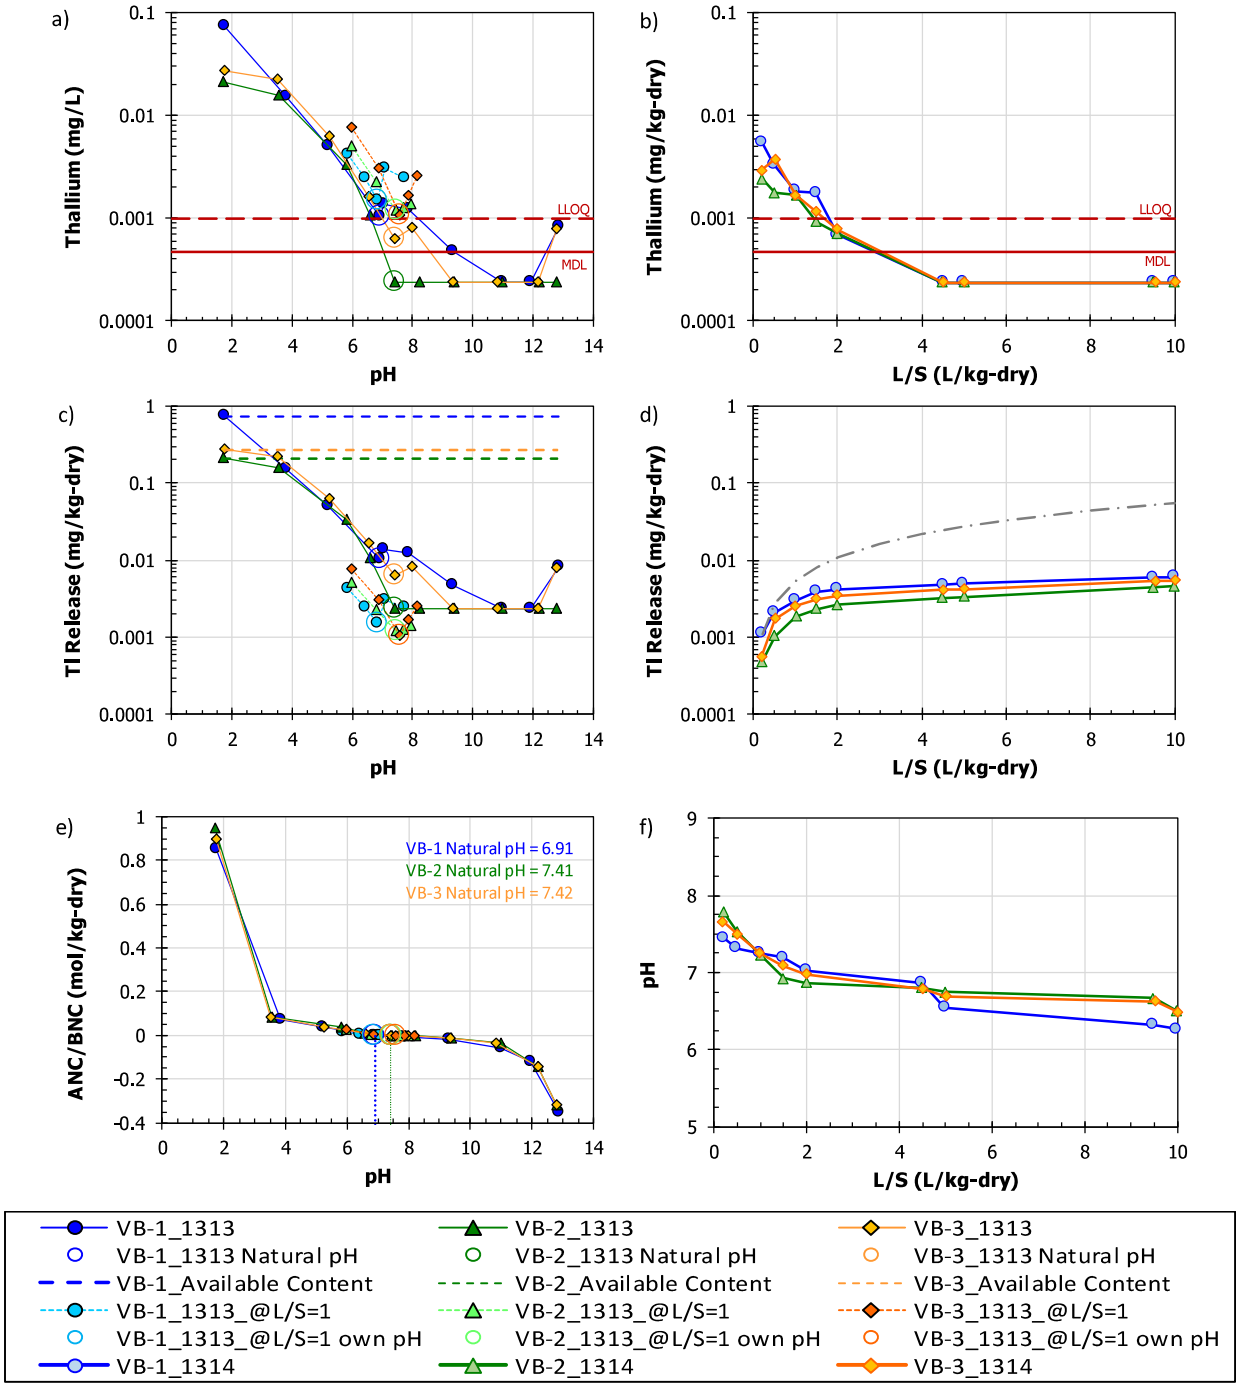

Figure D-33
Thallium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

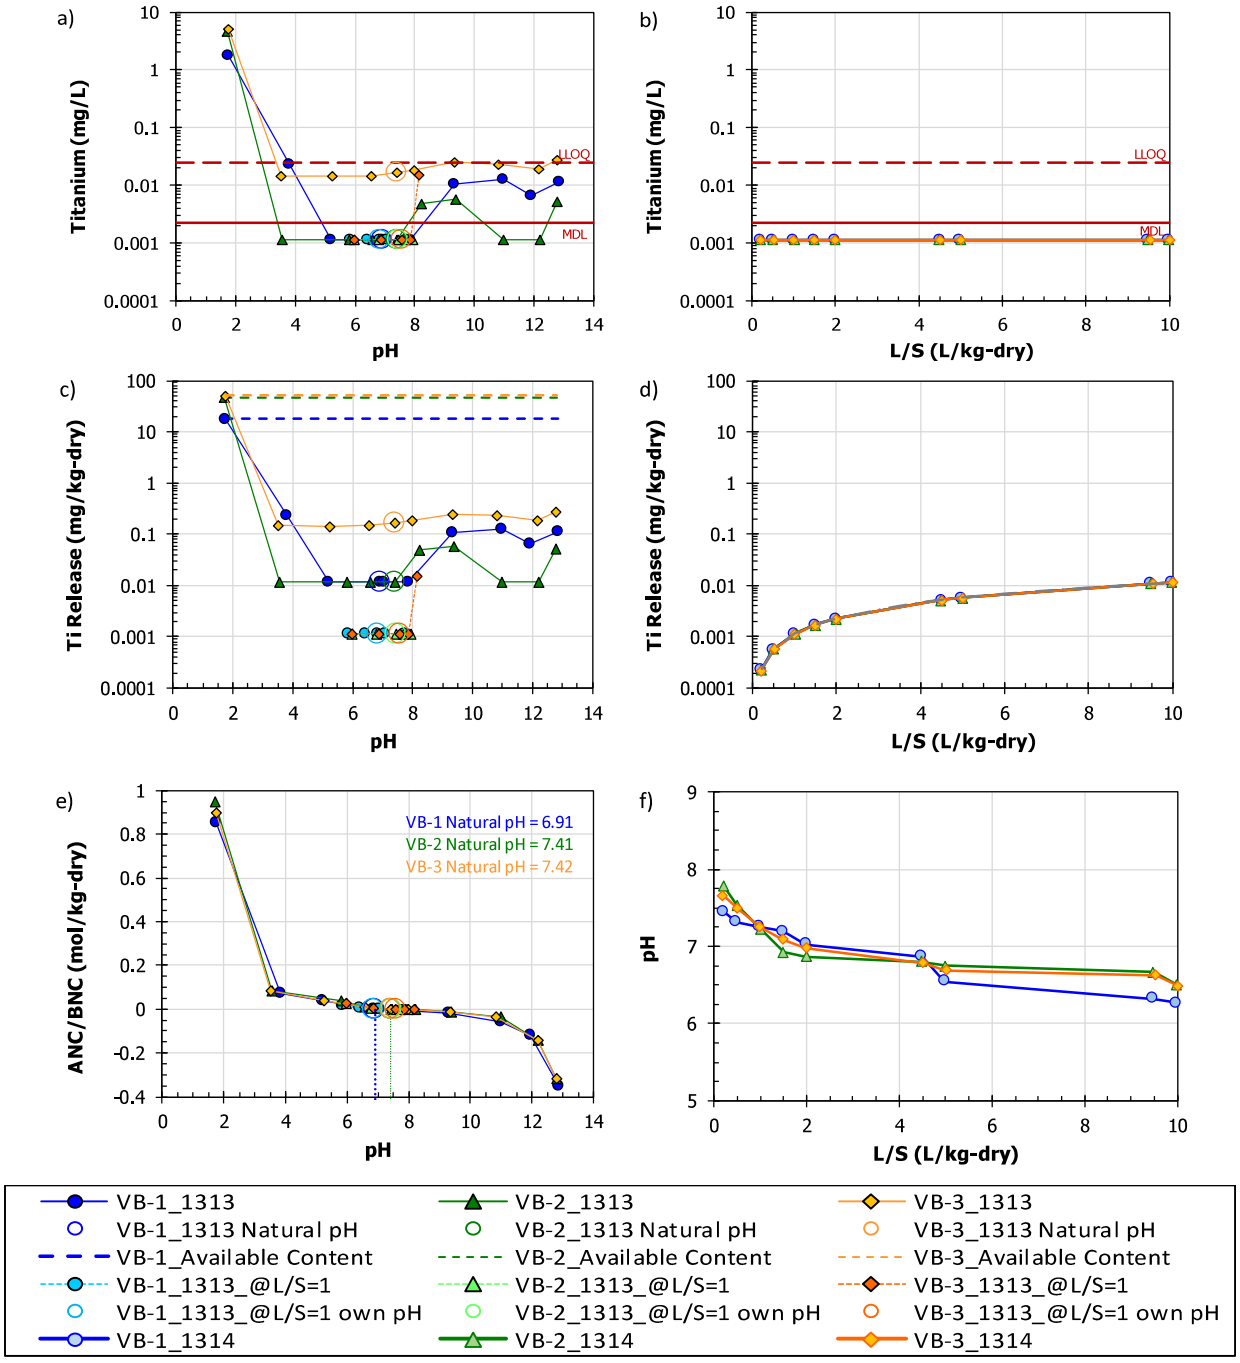

Figure D-34
Titanium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

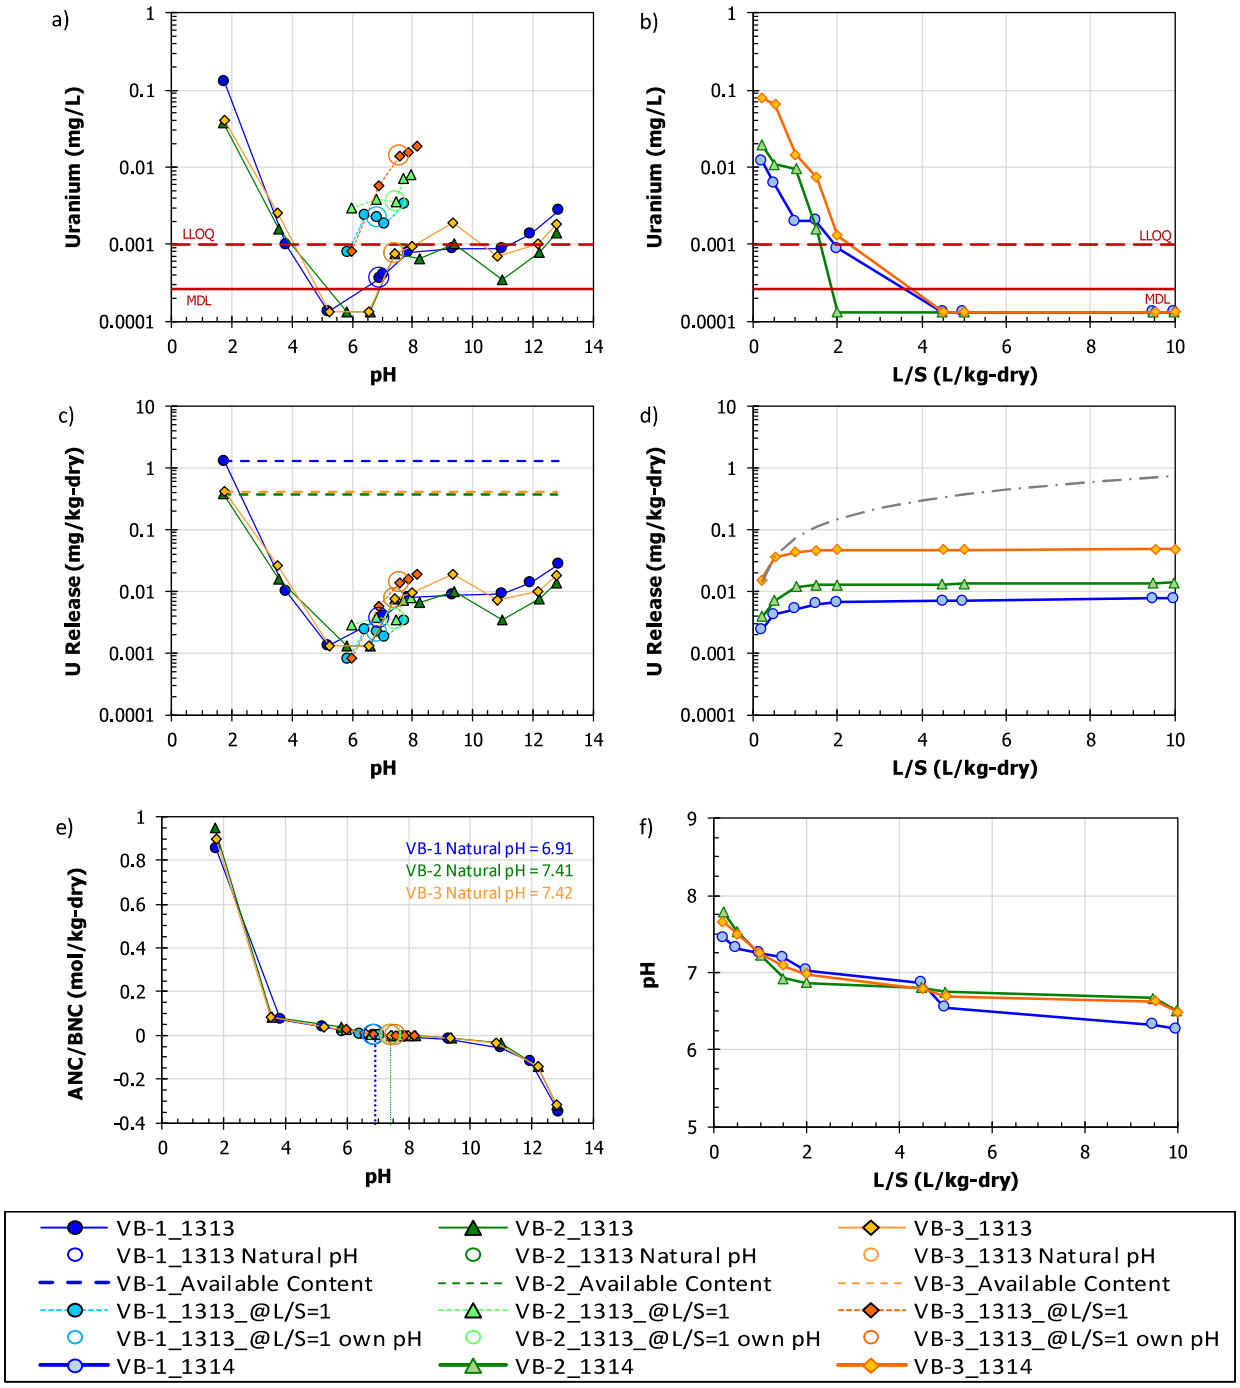

Figure D-35
Uranium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

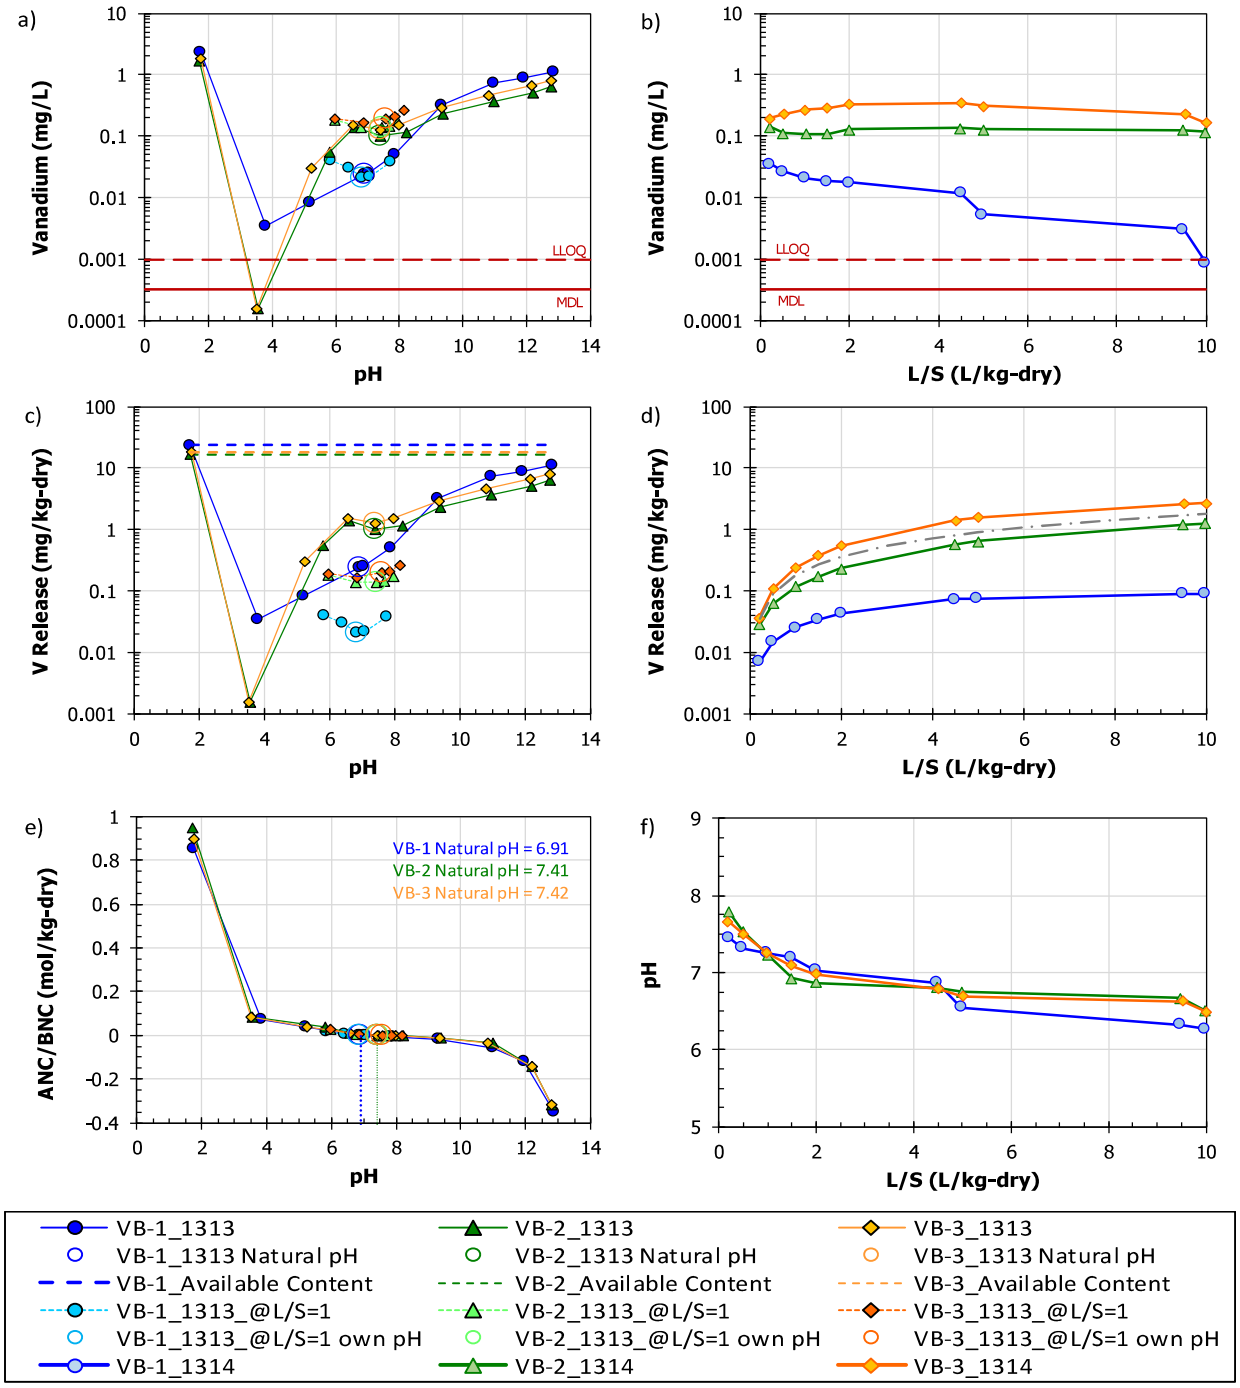

Figure D-36
Vanadium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

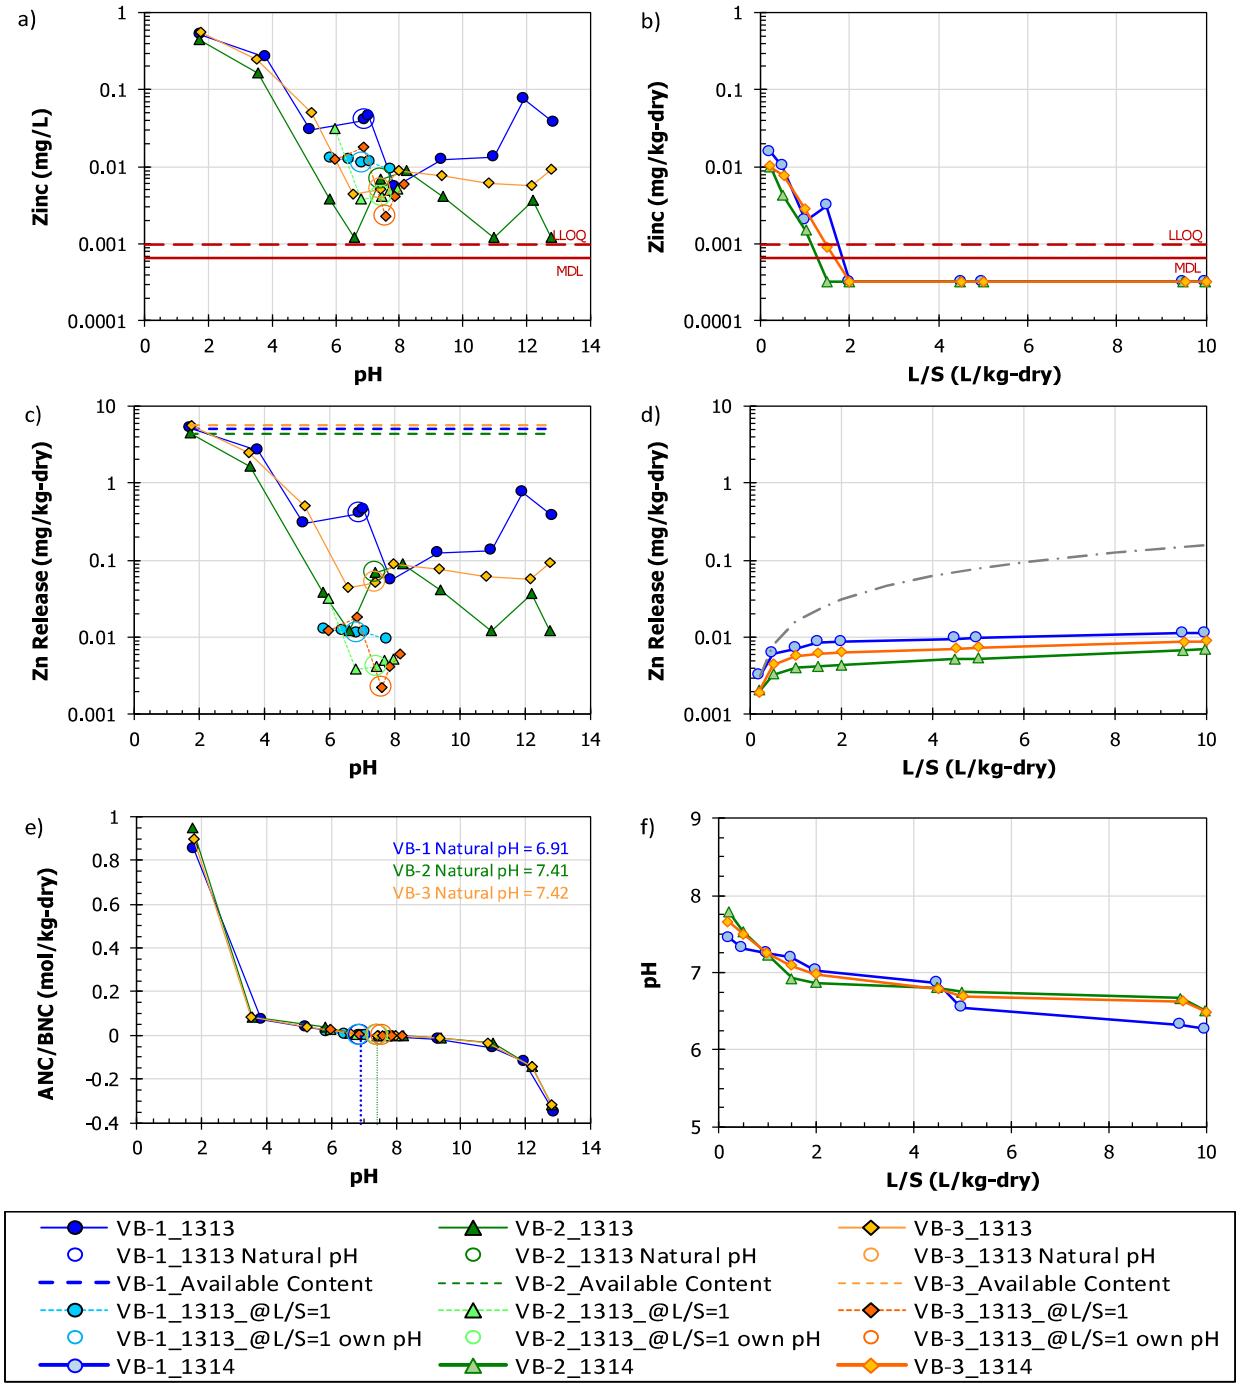

Figure D-37
Zinc LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

D.2 Comparison of Individual Split Spoon and Composite Sample Data

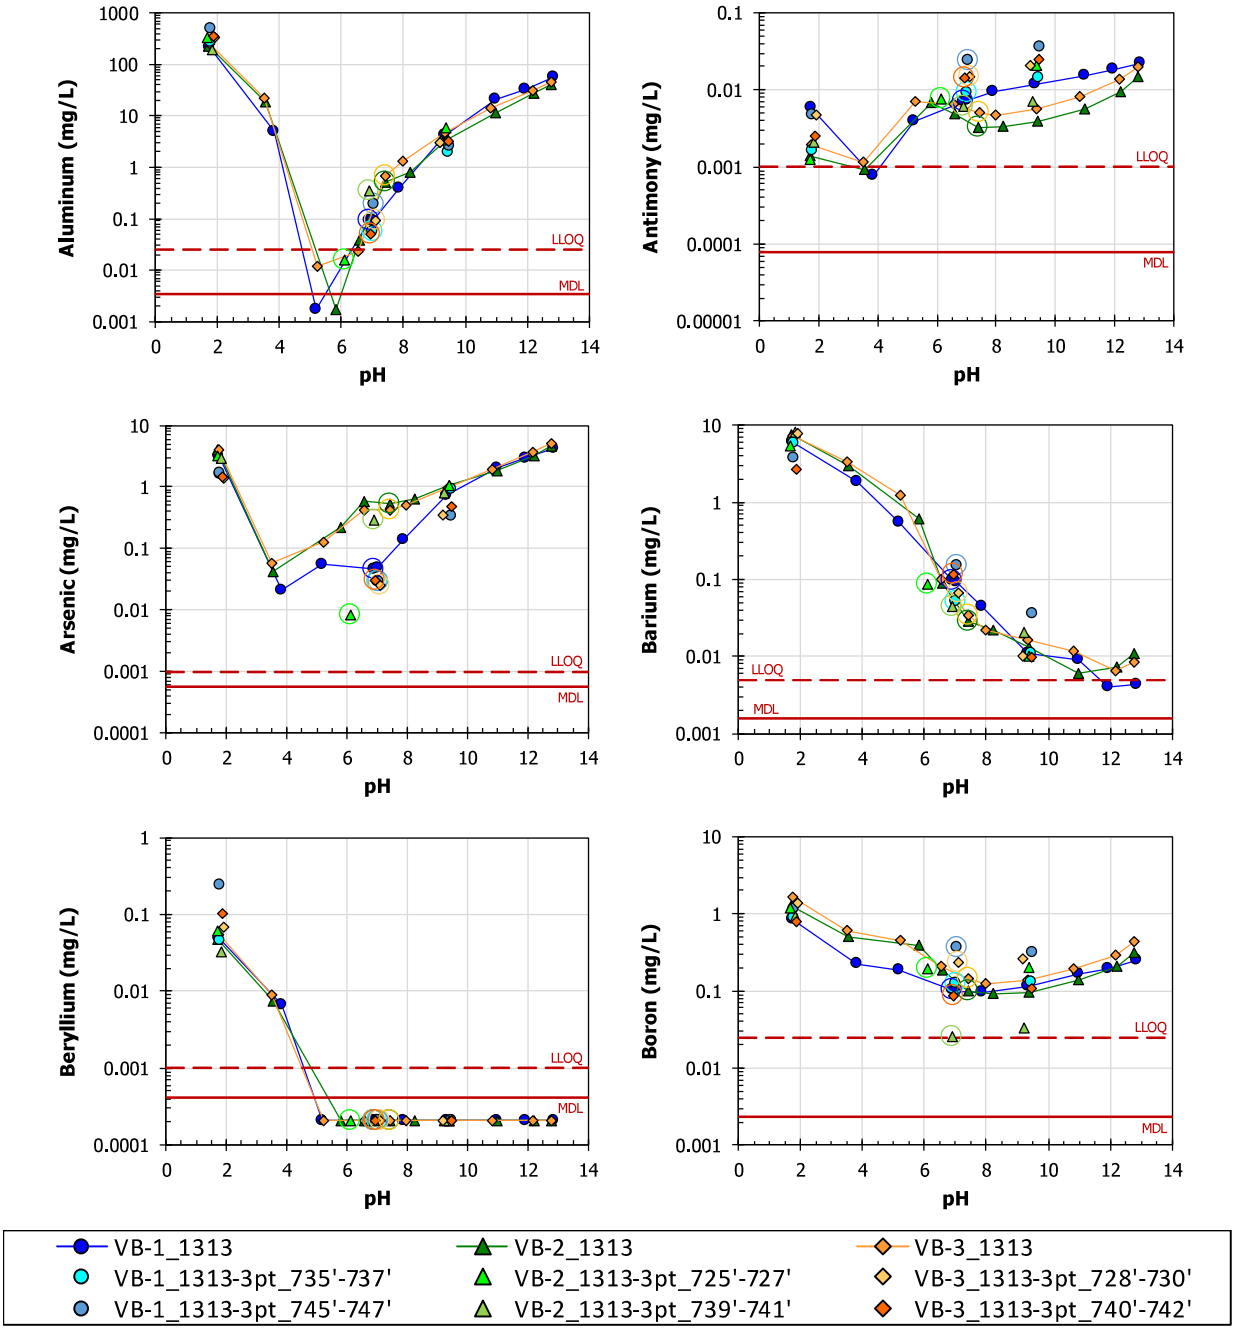

Figure D-38
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: aluminum, antimony, arsenic, barium, beryllium, and boron

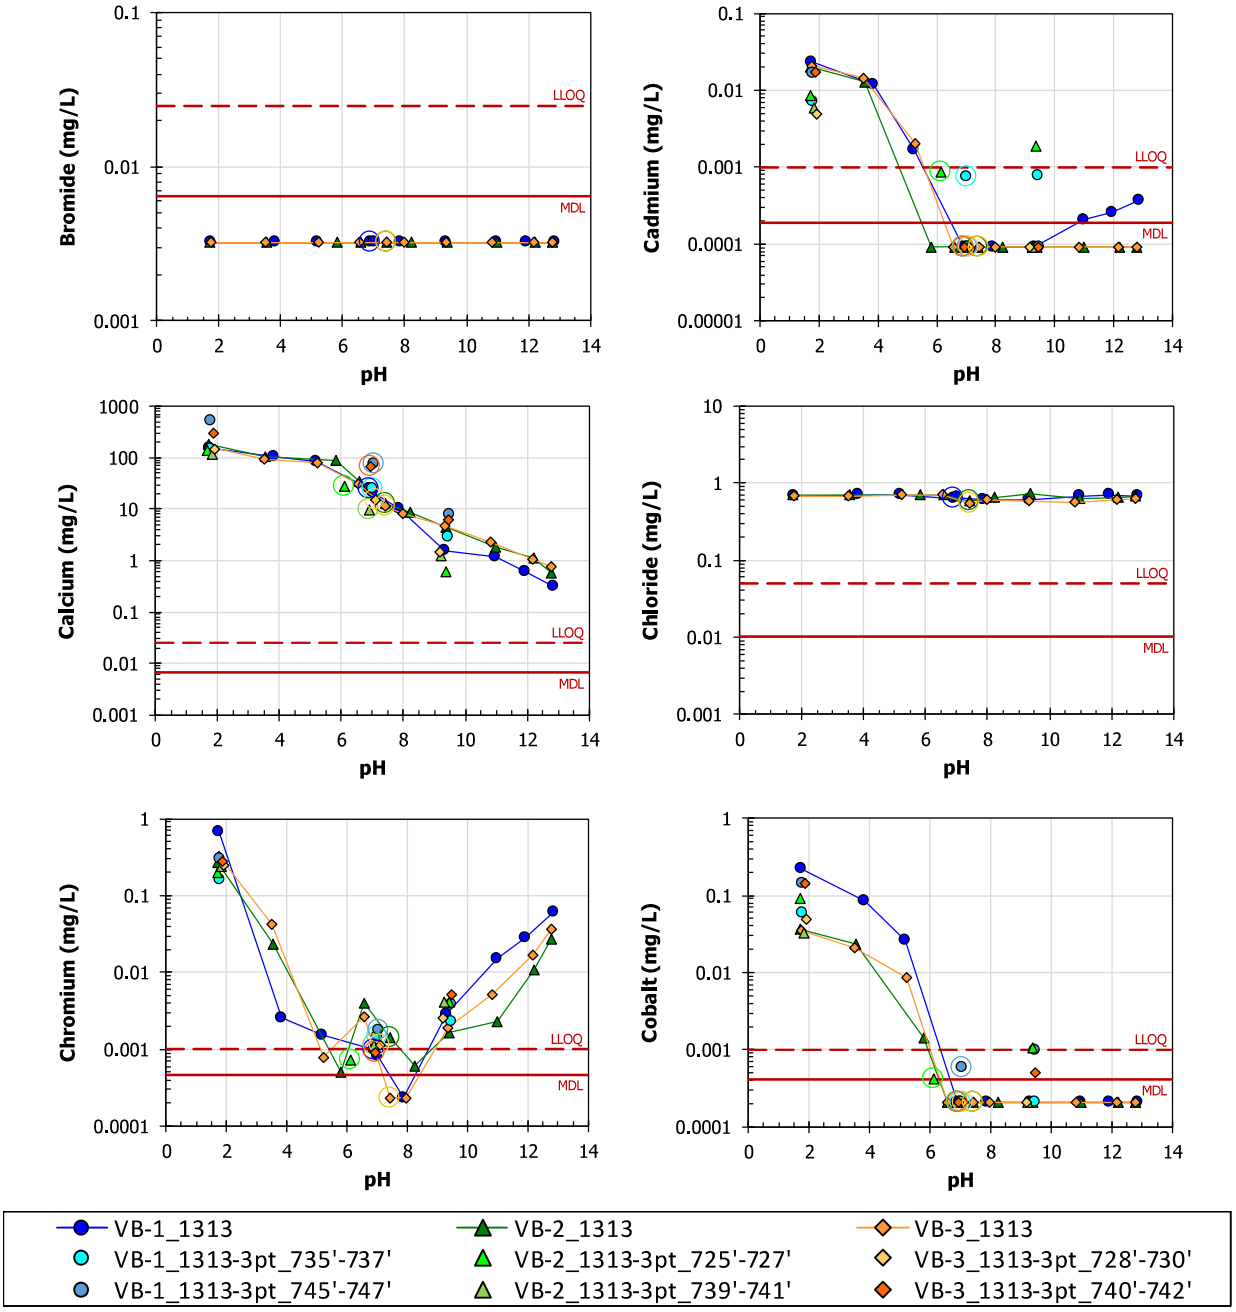

Figure D-39
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: bromide, cadmium, calcium, chloride, chromium, and cobalt

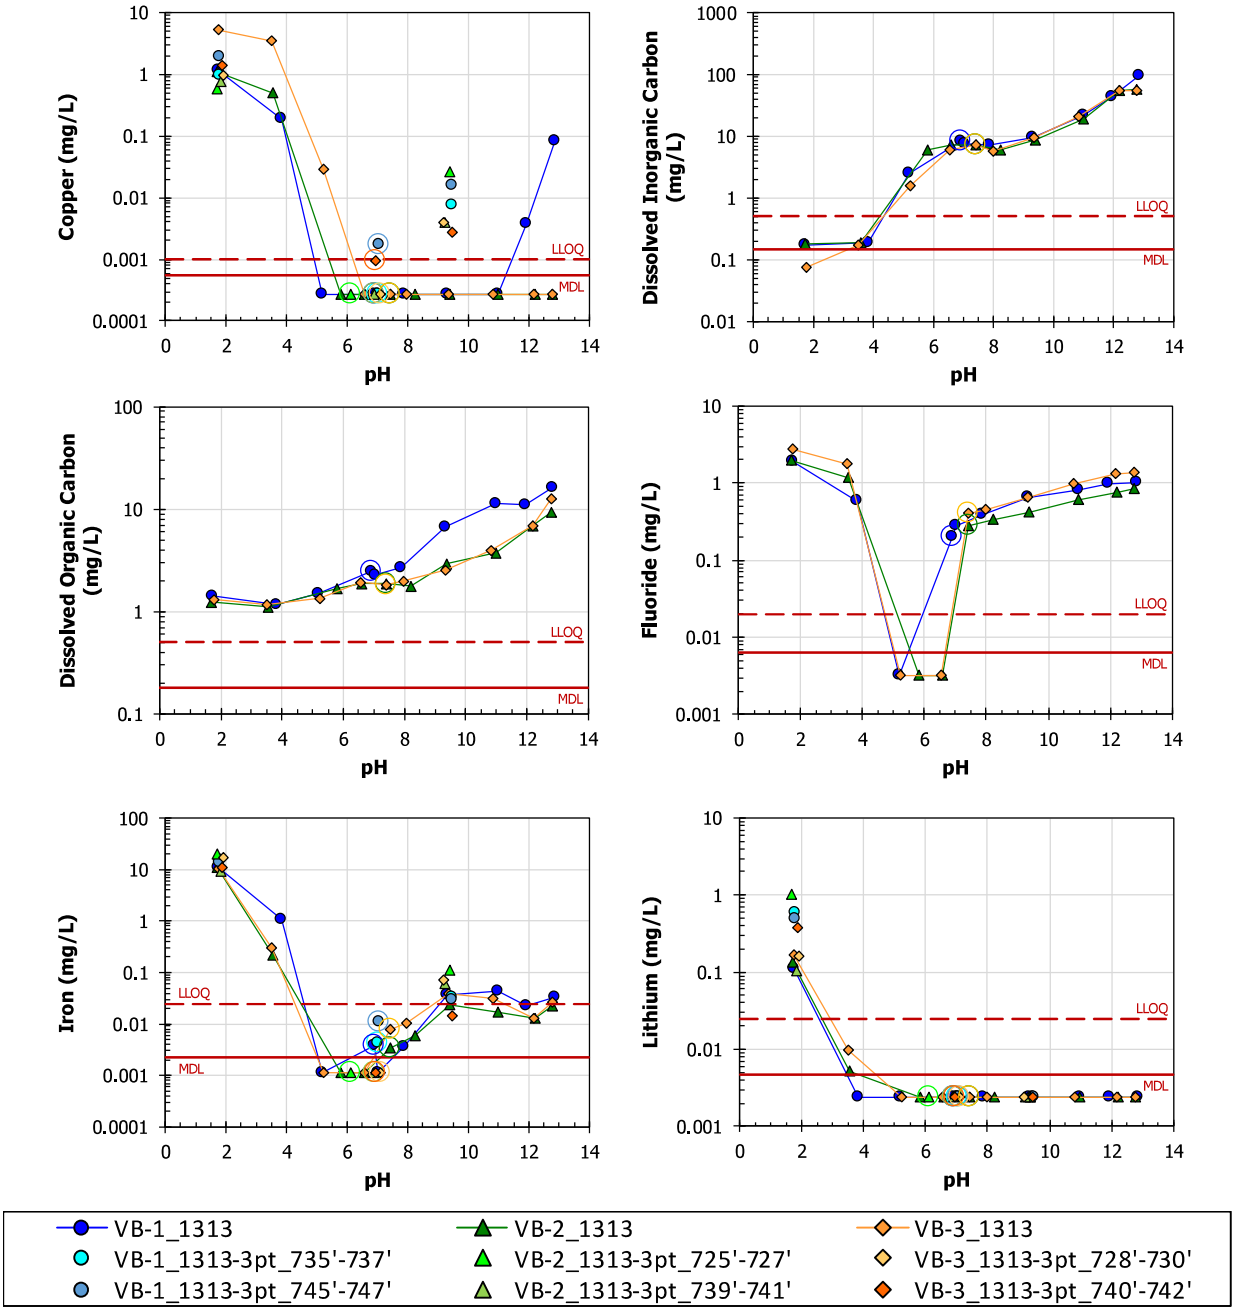

Figure D-40
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: copper, dissolved inorganic carbon, dissolved organic carbon, fluoride, iron, and lithium

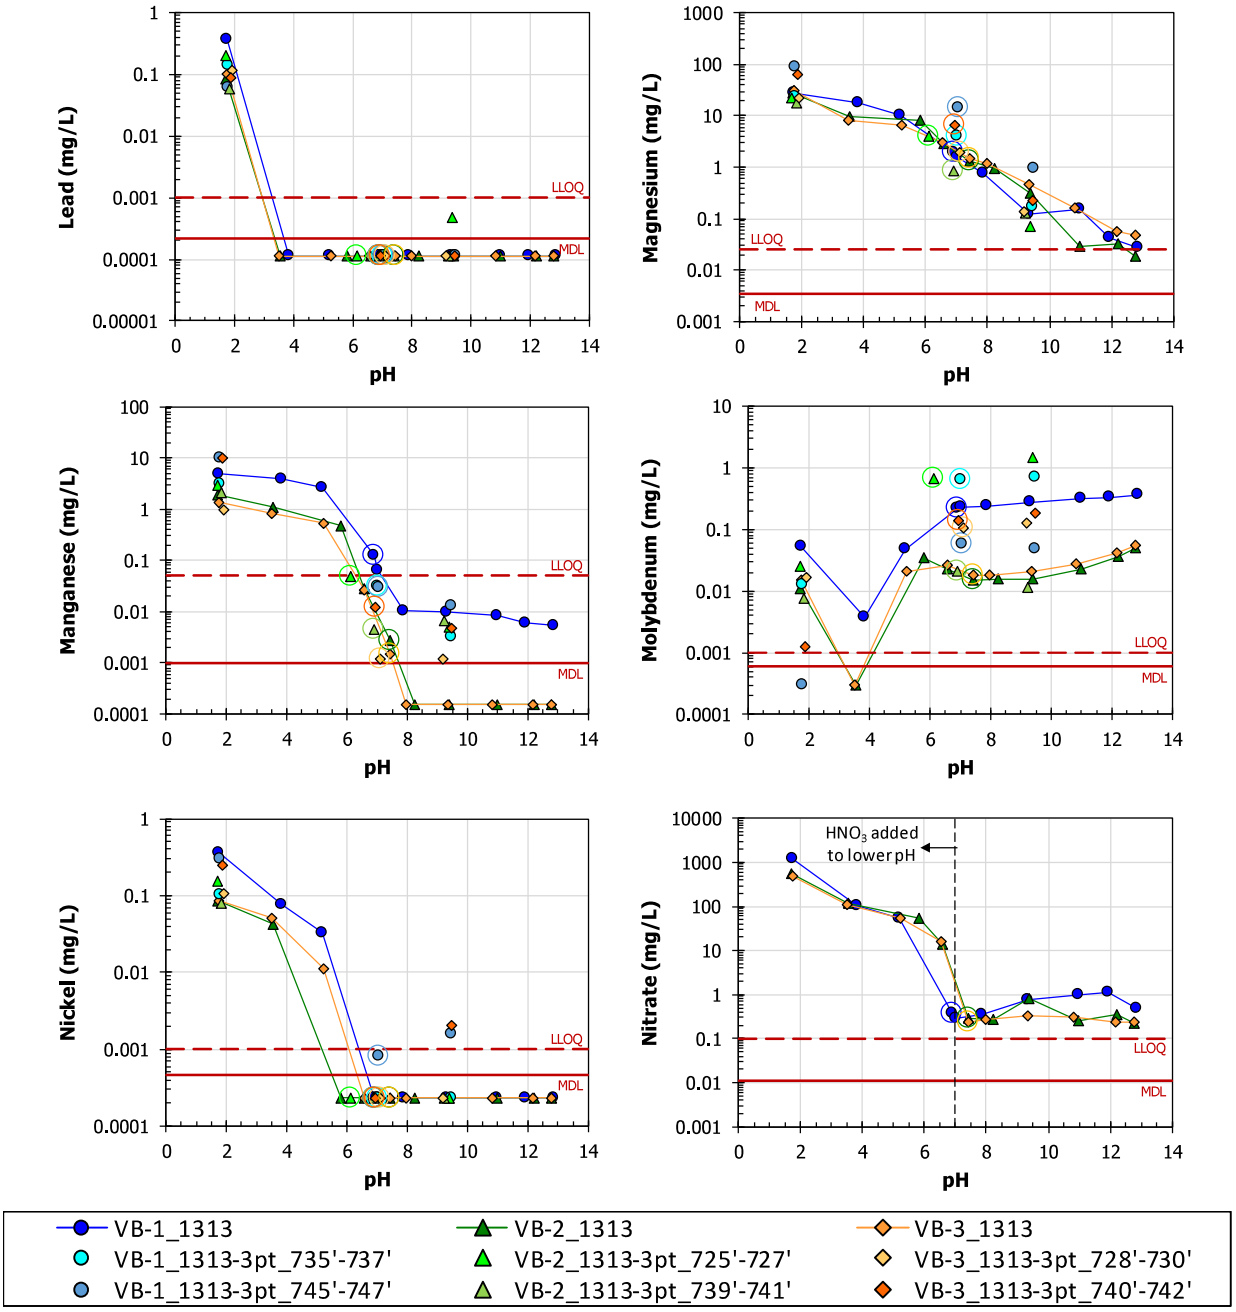

Figure D-41
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: lead, magnesium, manganese, molybdenum, nickel, and nitrate

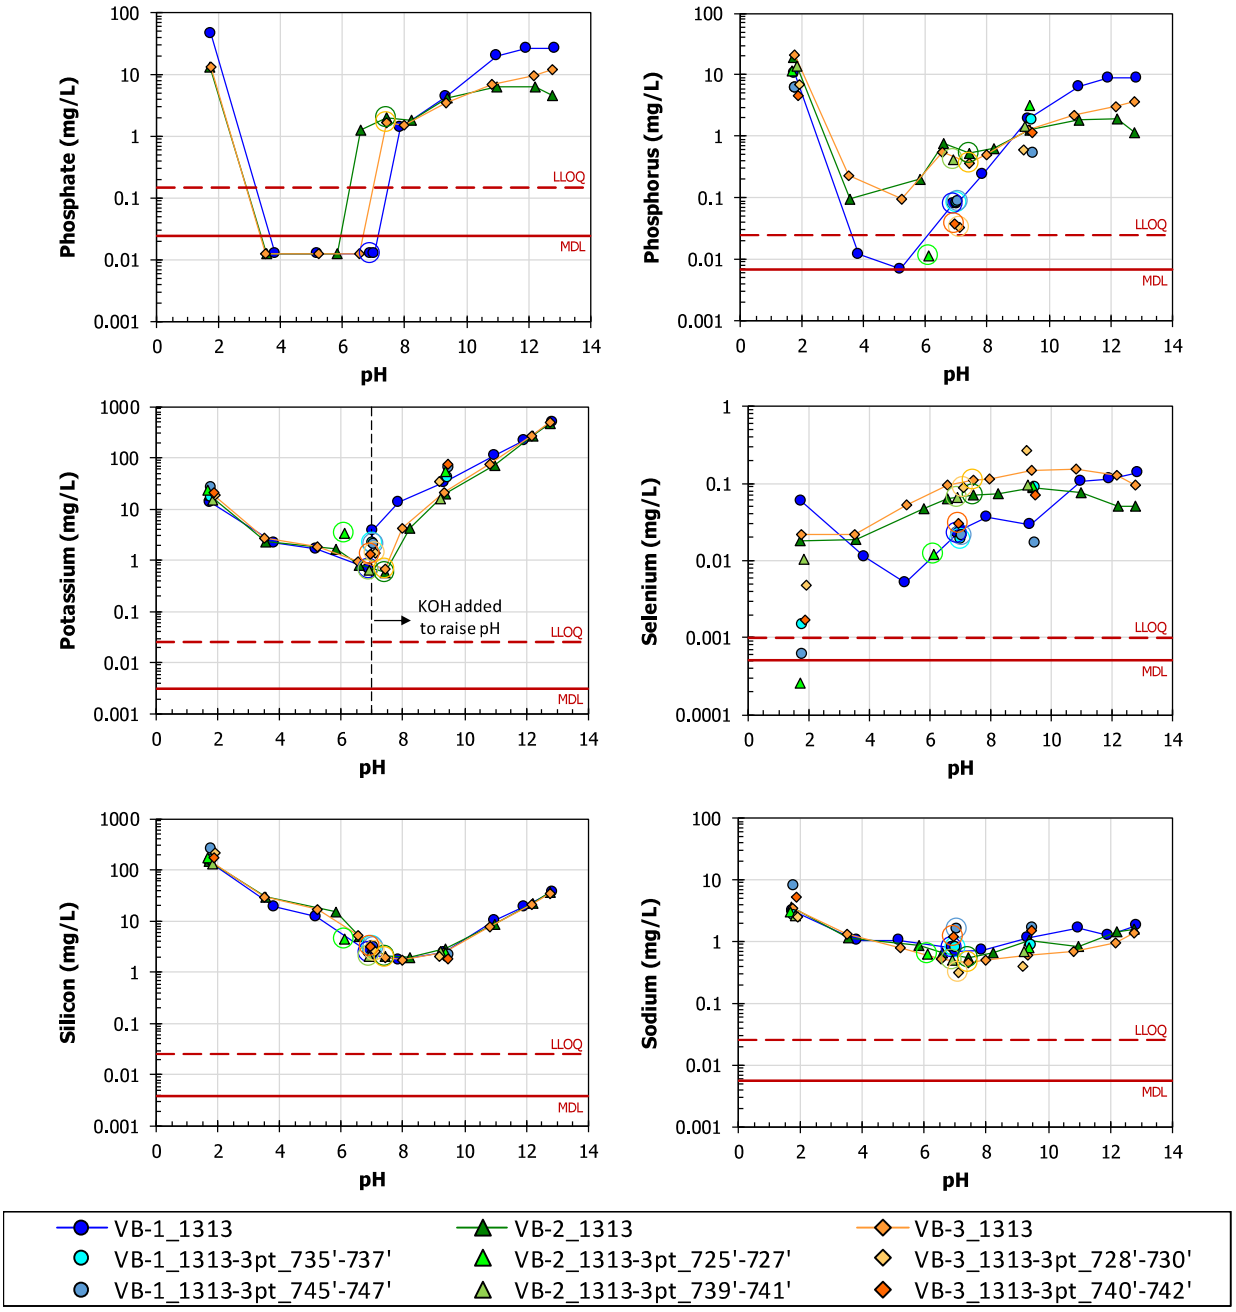

Figure D-42
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: phosphate, phosphorus, potassium, selenium, silicon, and sodium

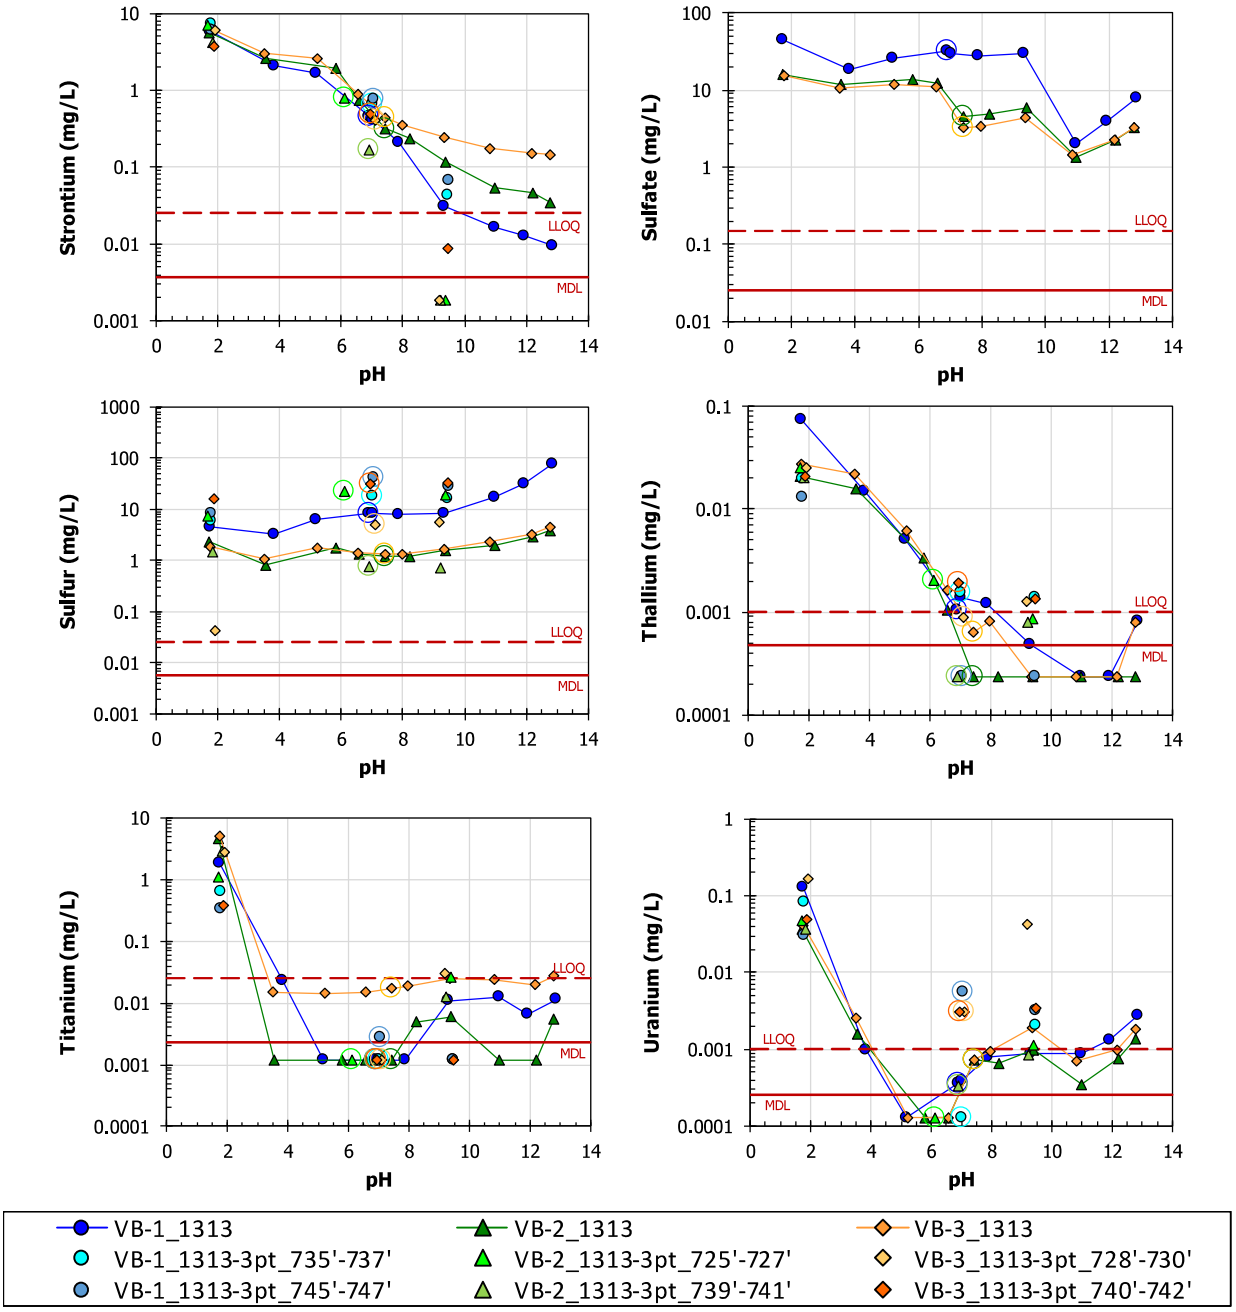

Figure D-43
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: strontium, sulfate, sulfur, thallium, titanium, and uranium

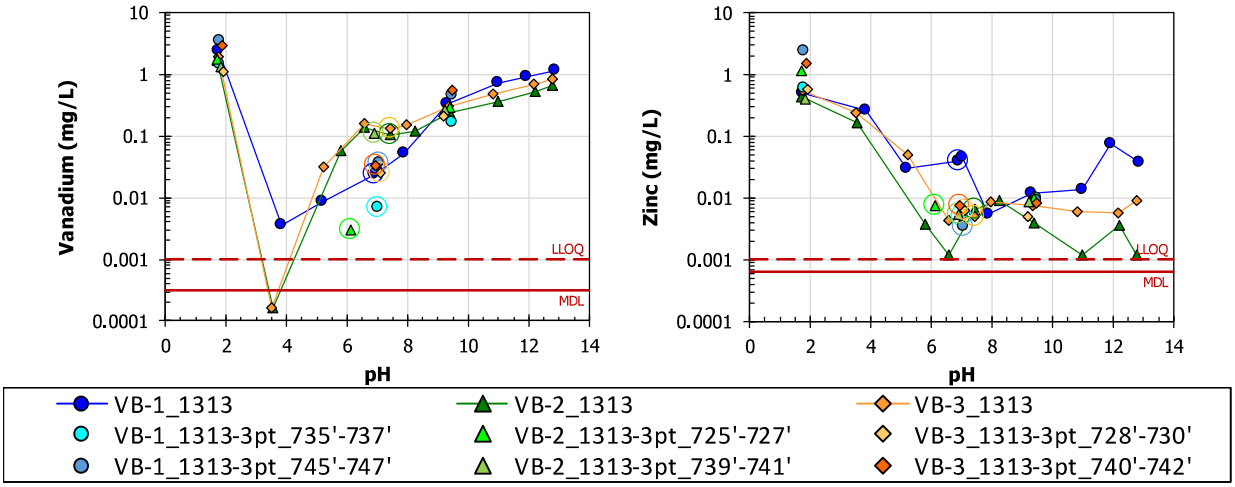

Figure D-44
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: vanadium and zinc

E
COMPARISON OF TEST METHOD RESULTS

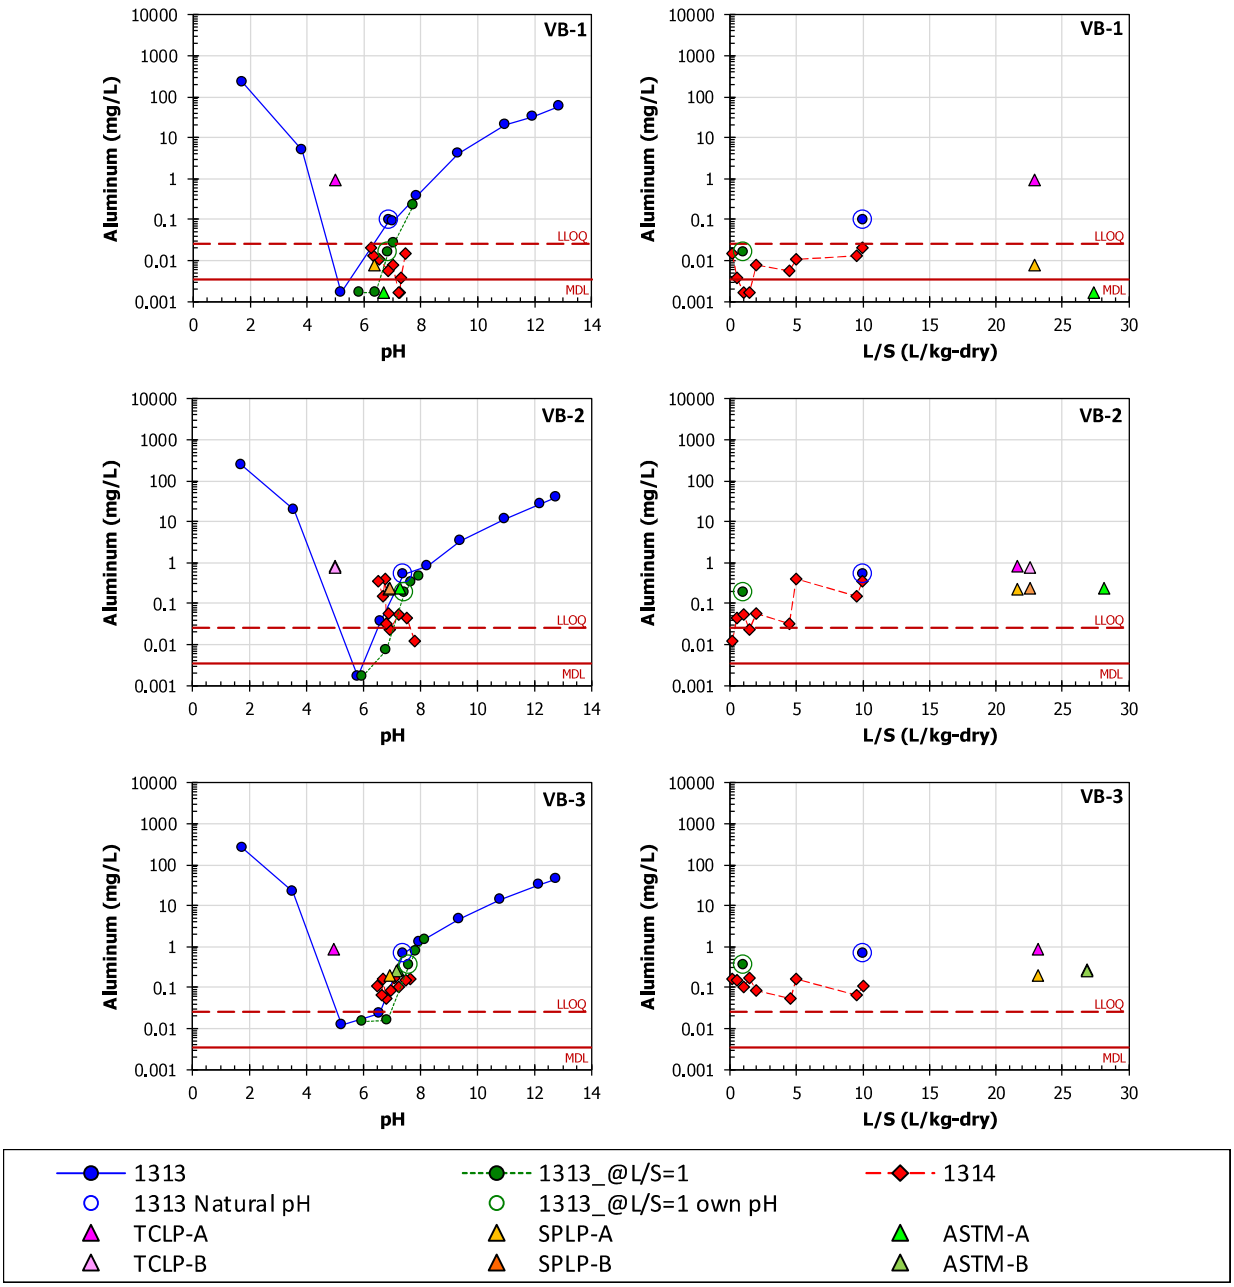

Figure E-1
Aluminum concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

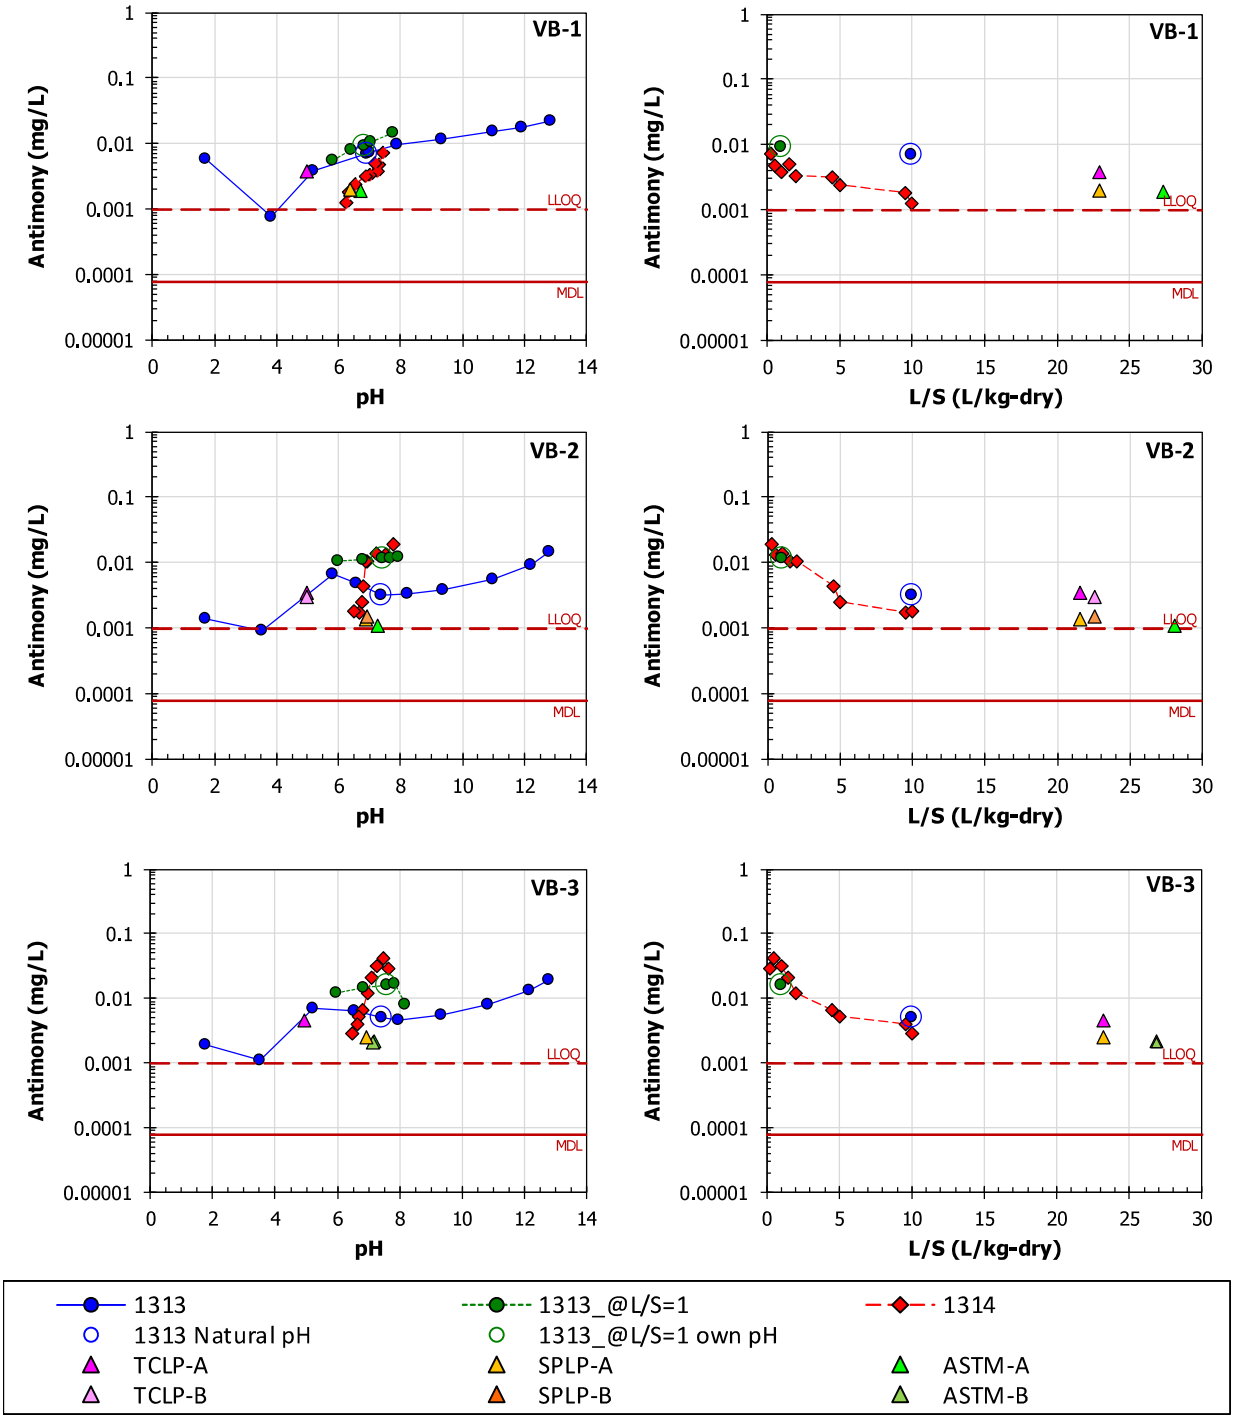

Figure E-2
Antimony concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

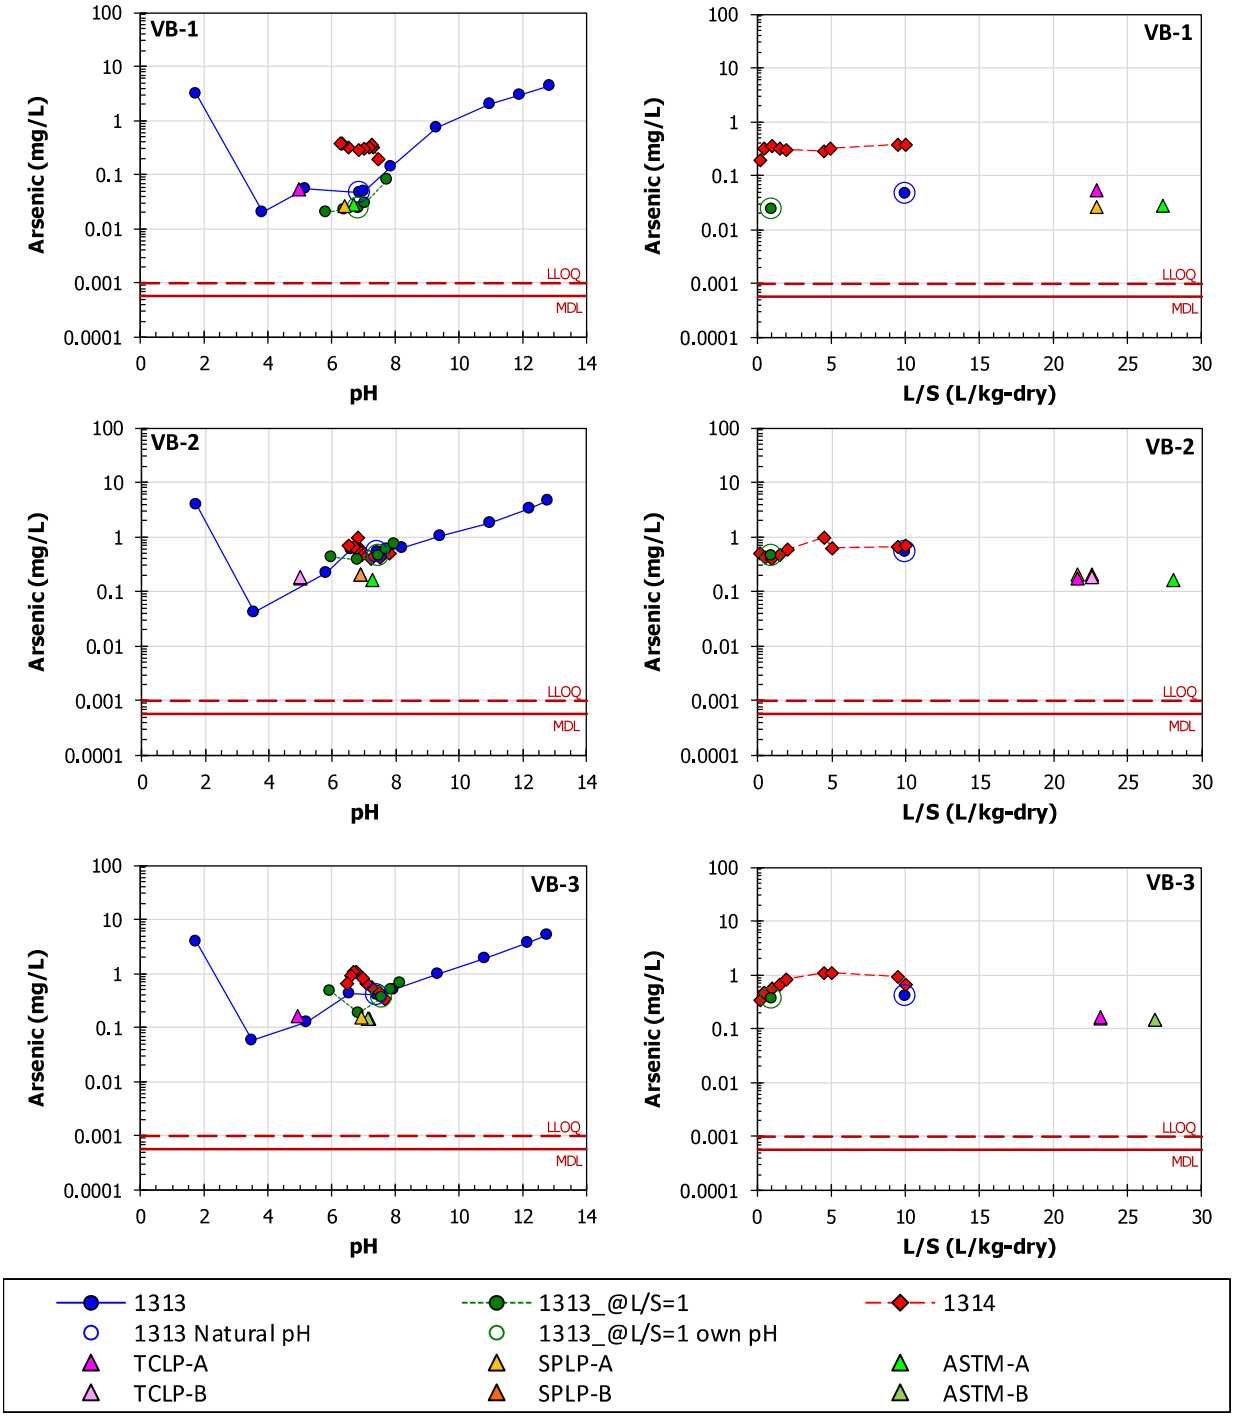

Figure E-3
Arsenic concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

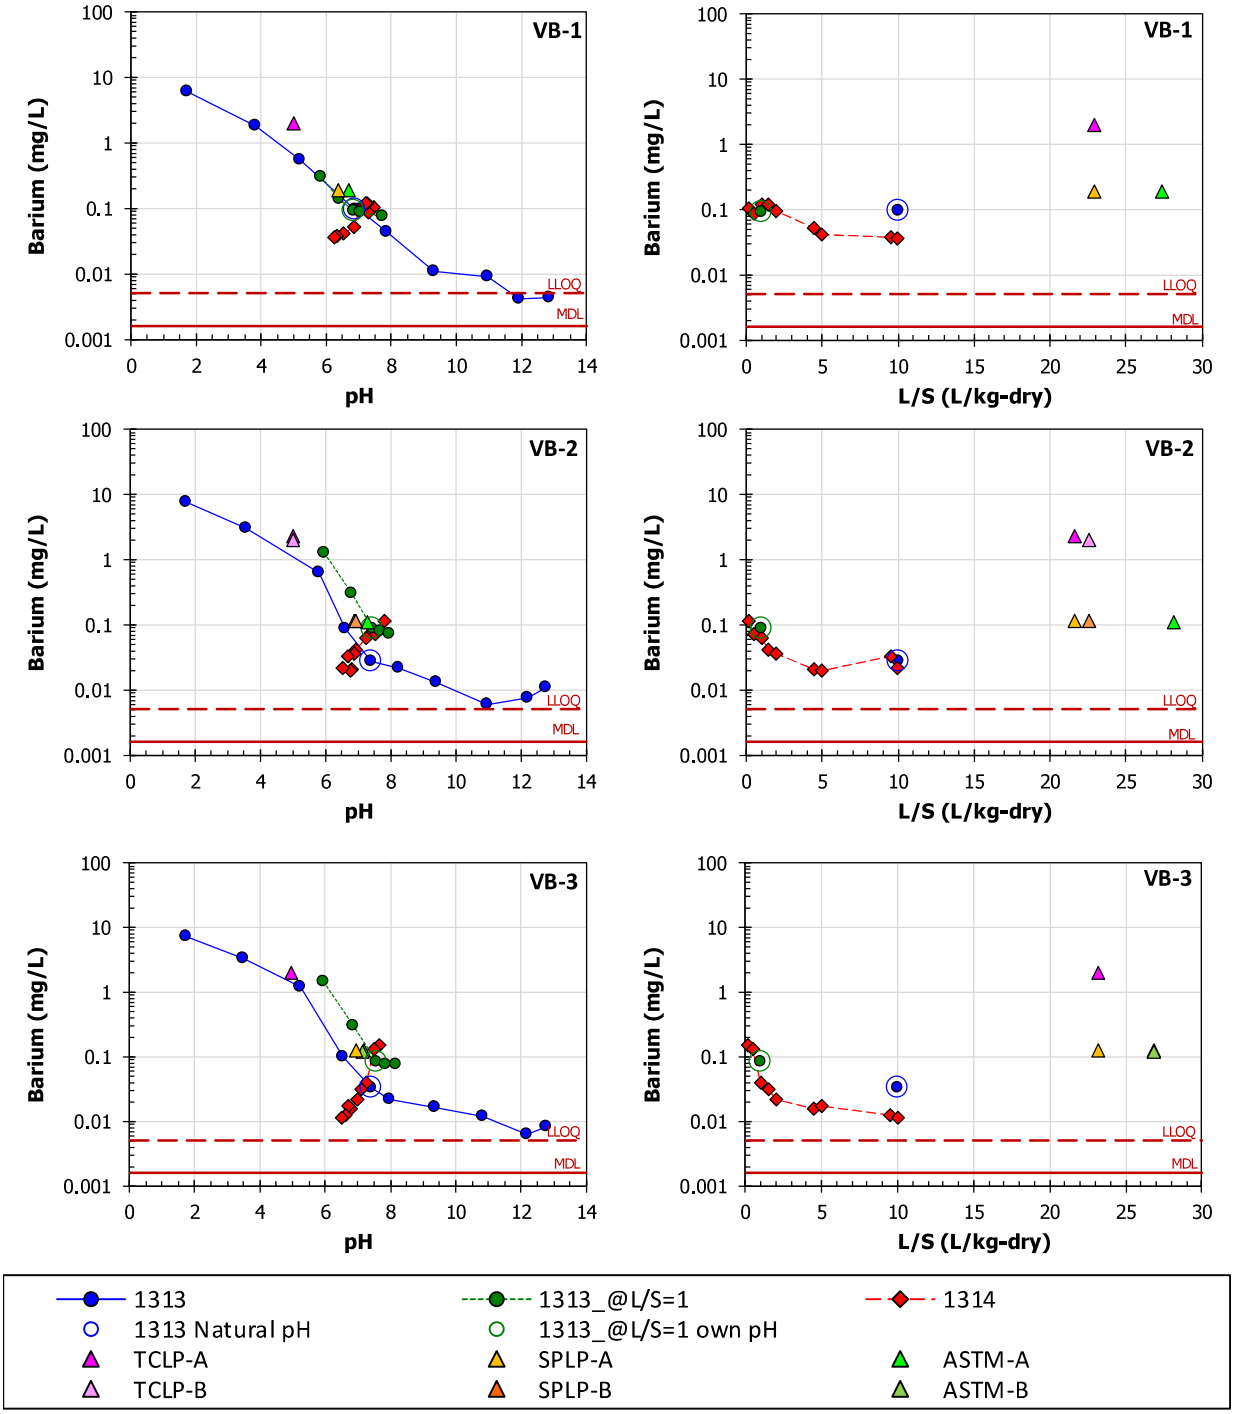

Figure E-4
Barium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

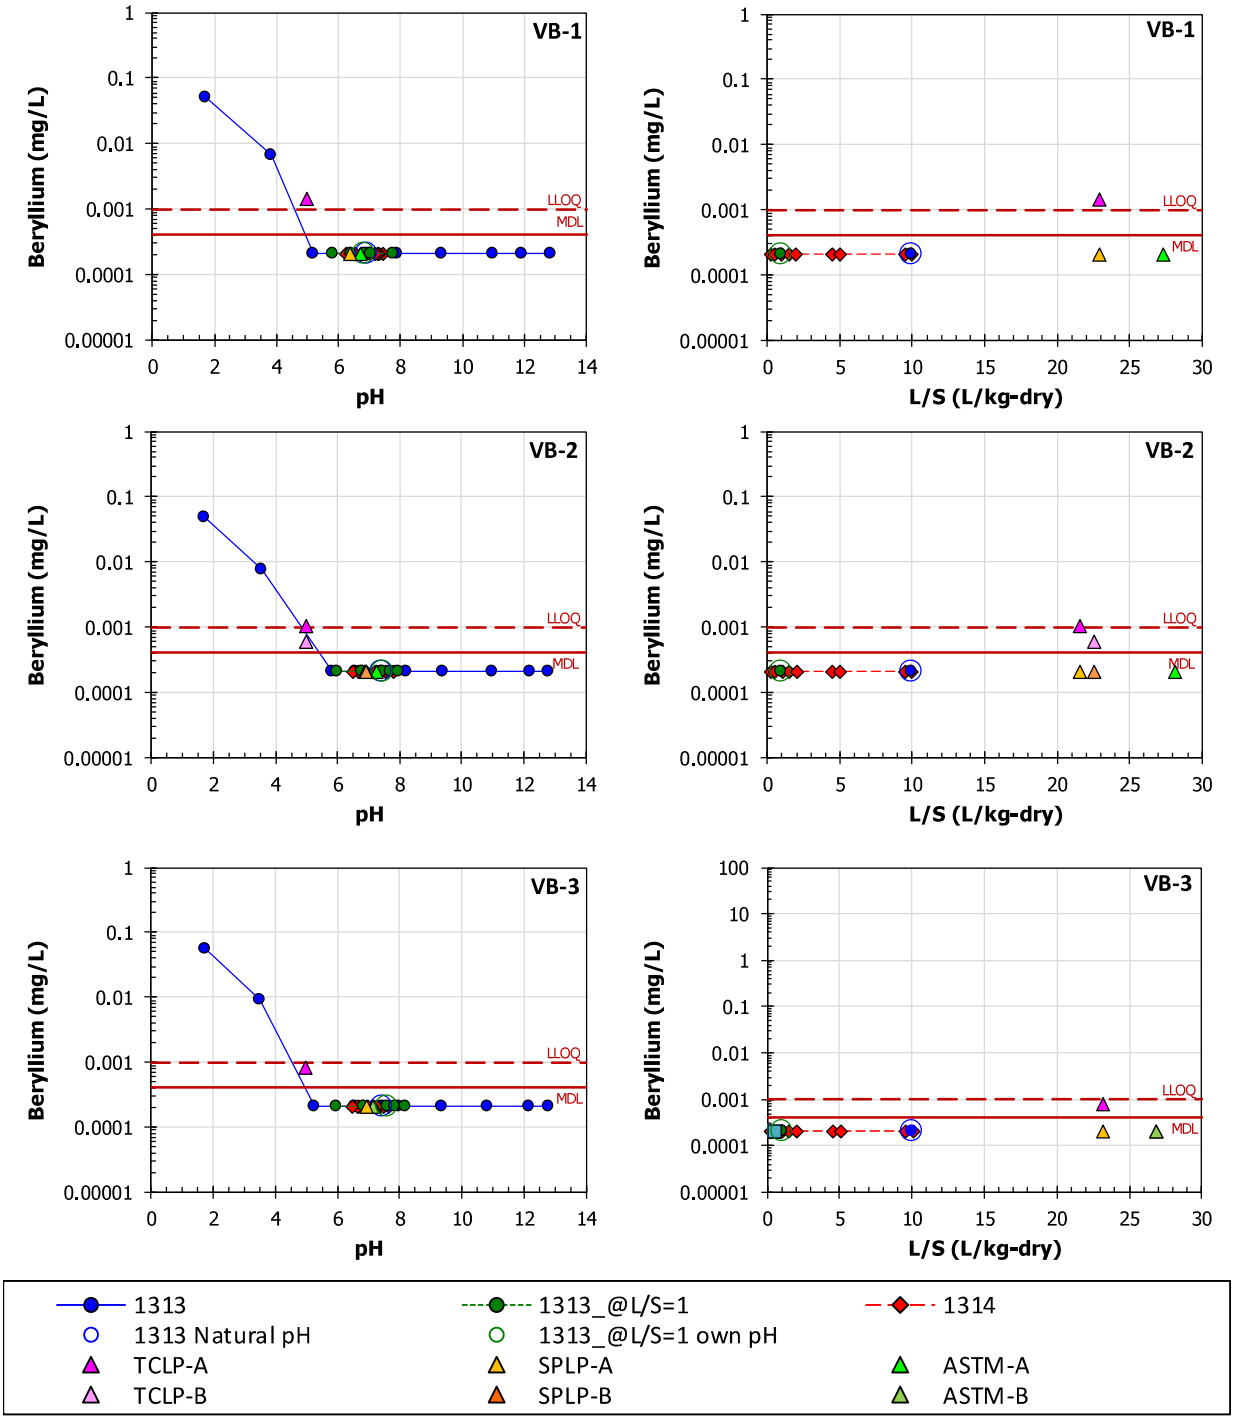

Figure E-5
Beryllium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

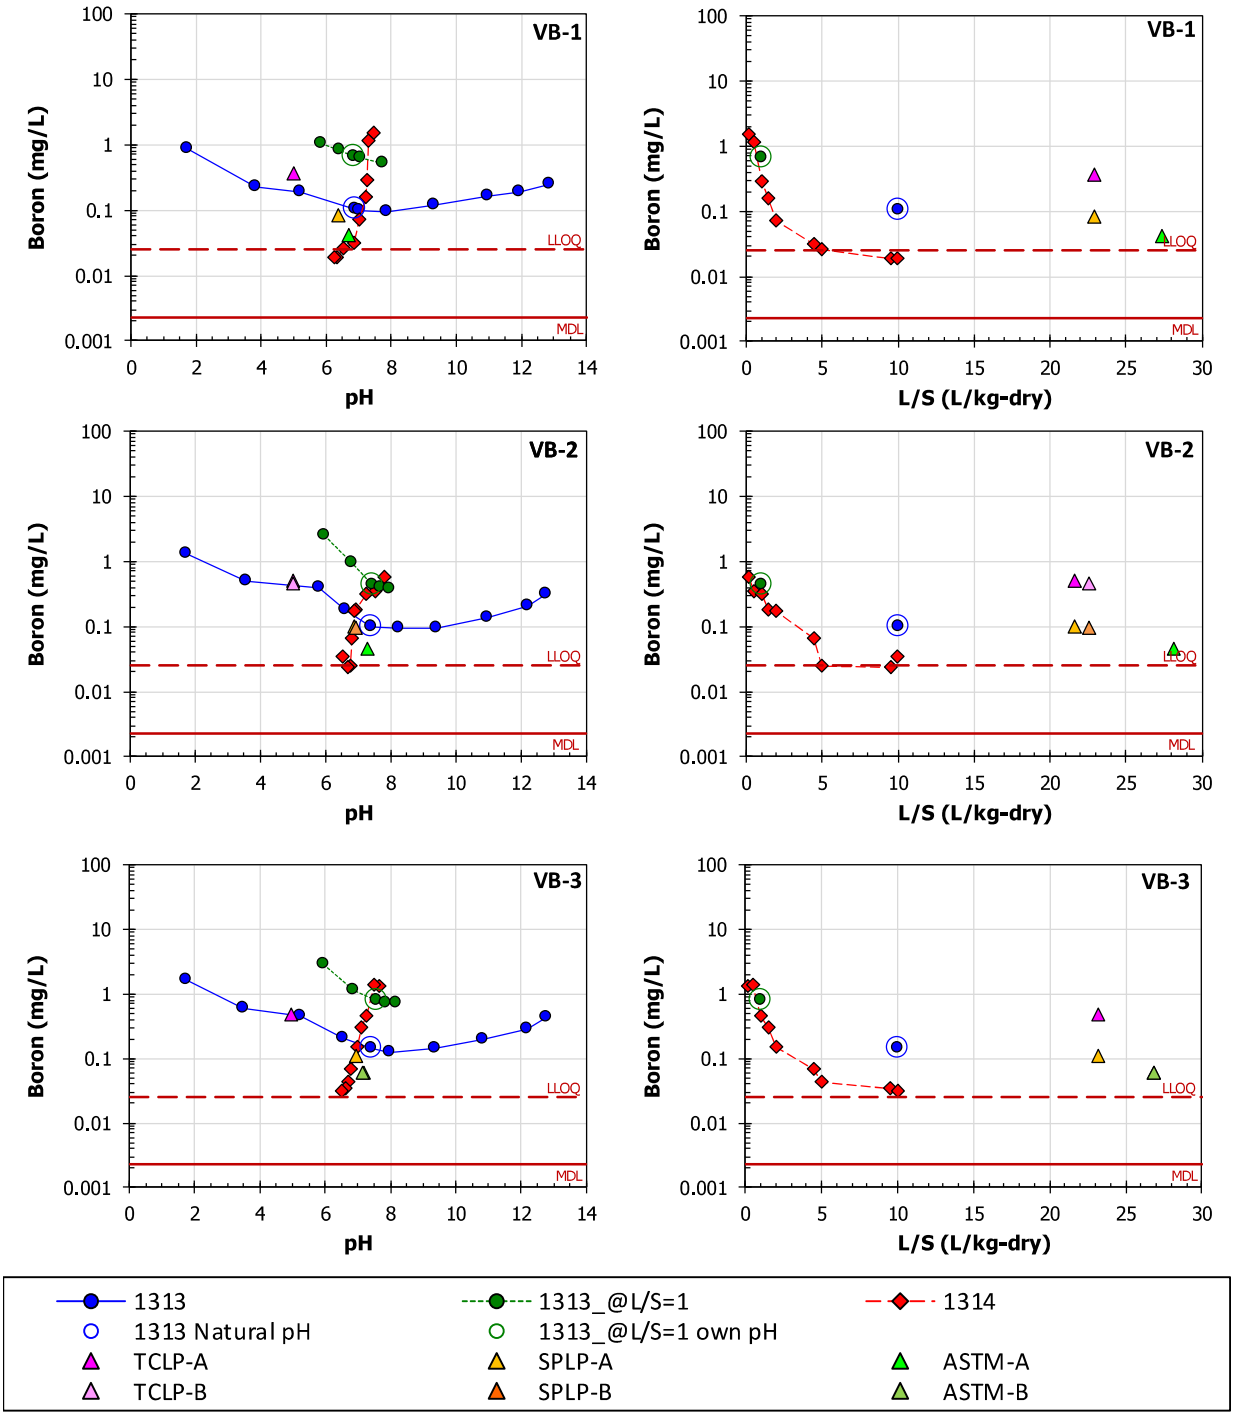

Figure E-6
Boron concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

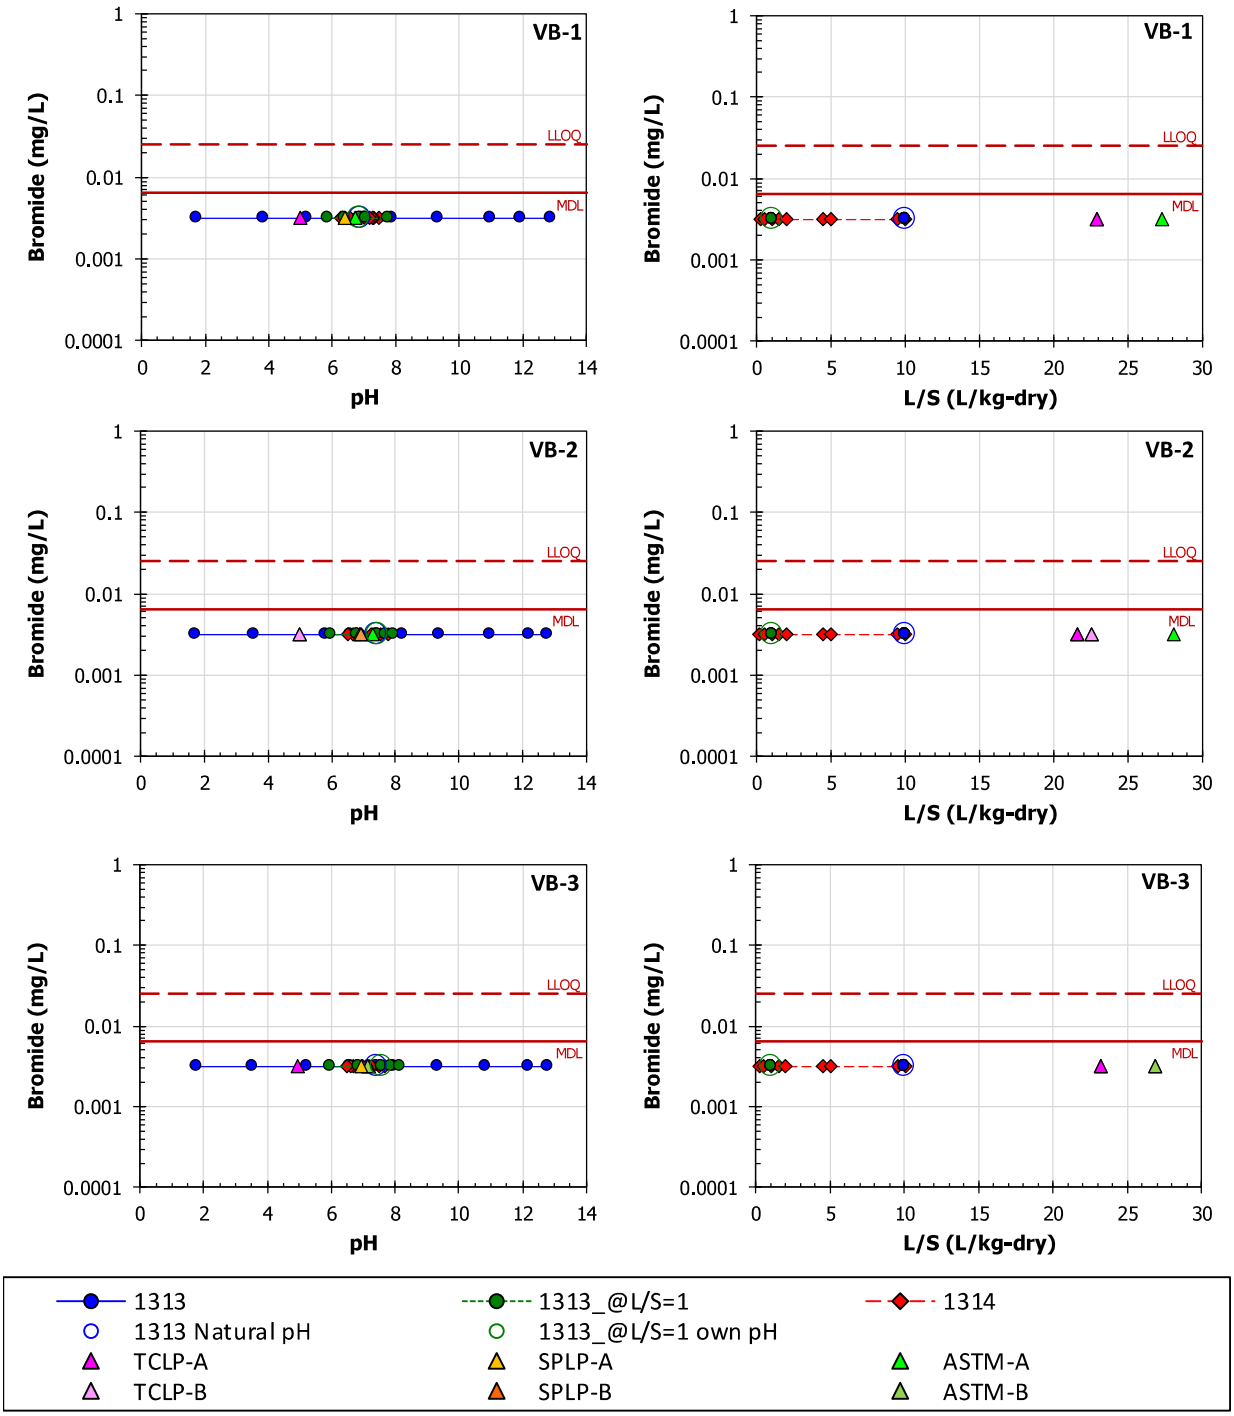

Figure E-7
Bromide concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

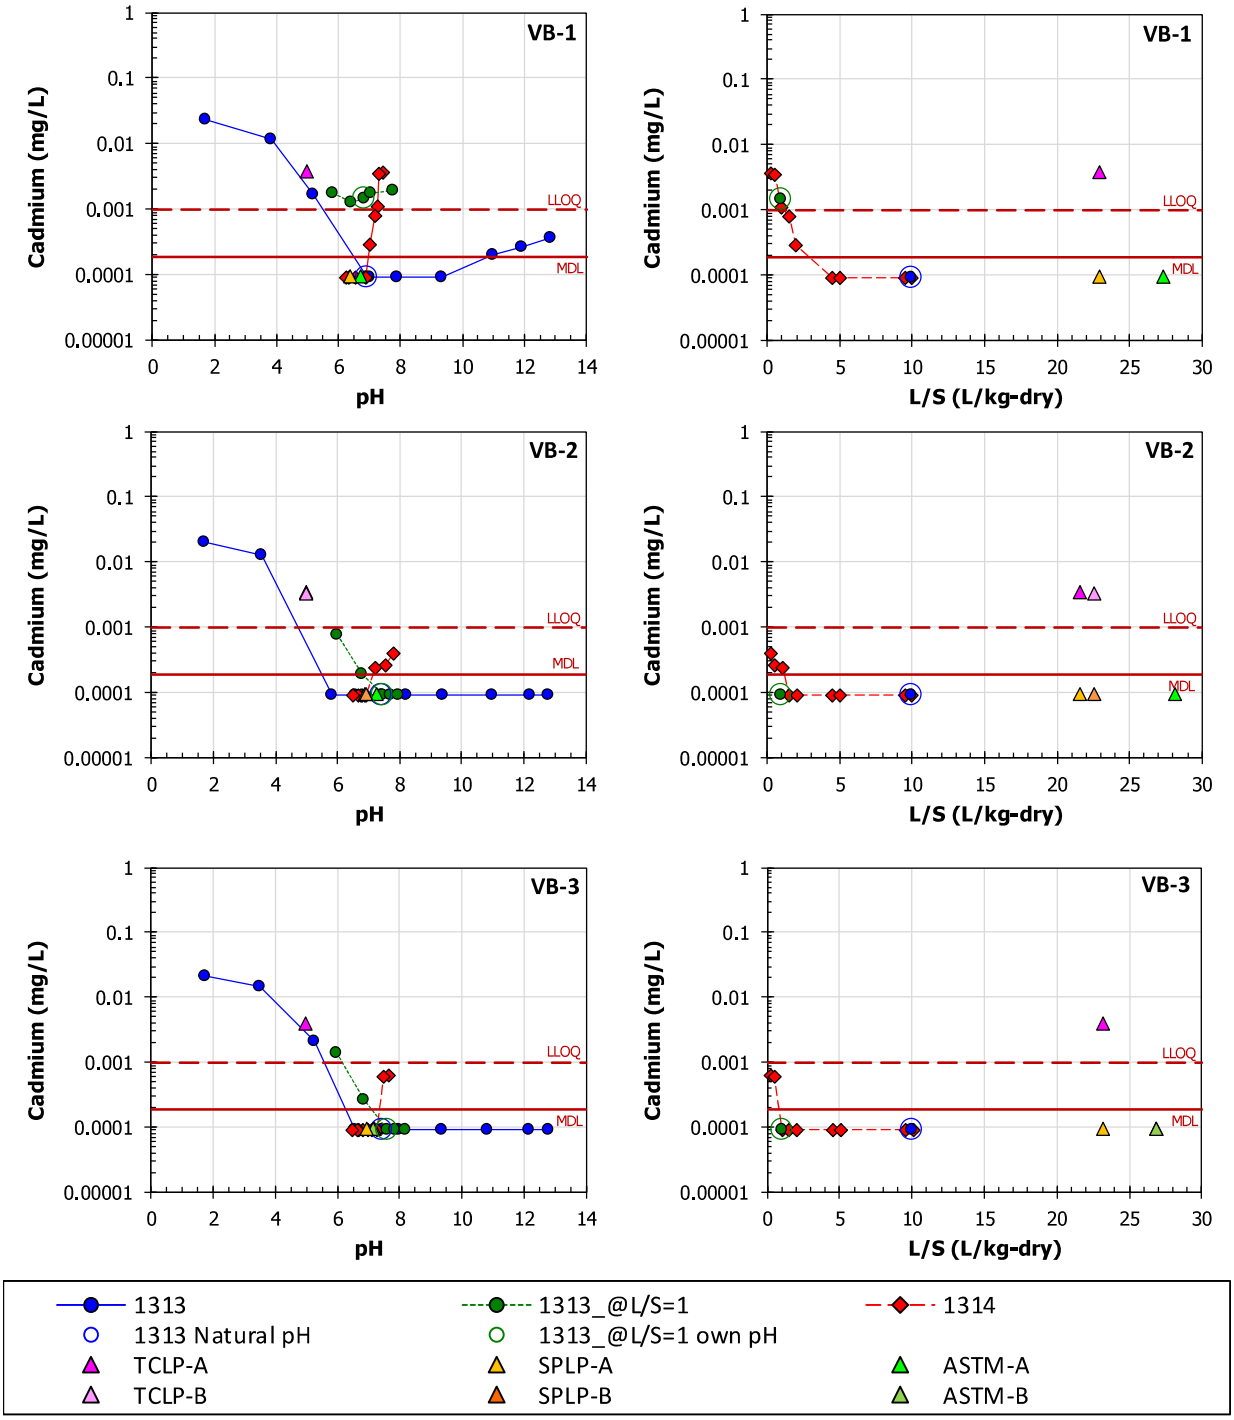

Figure E-8
Cadmium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

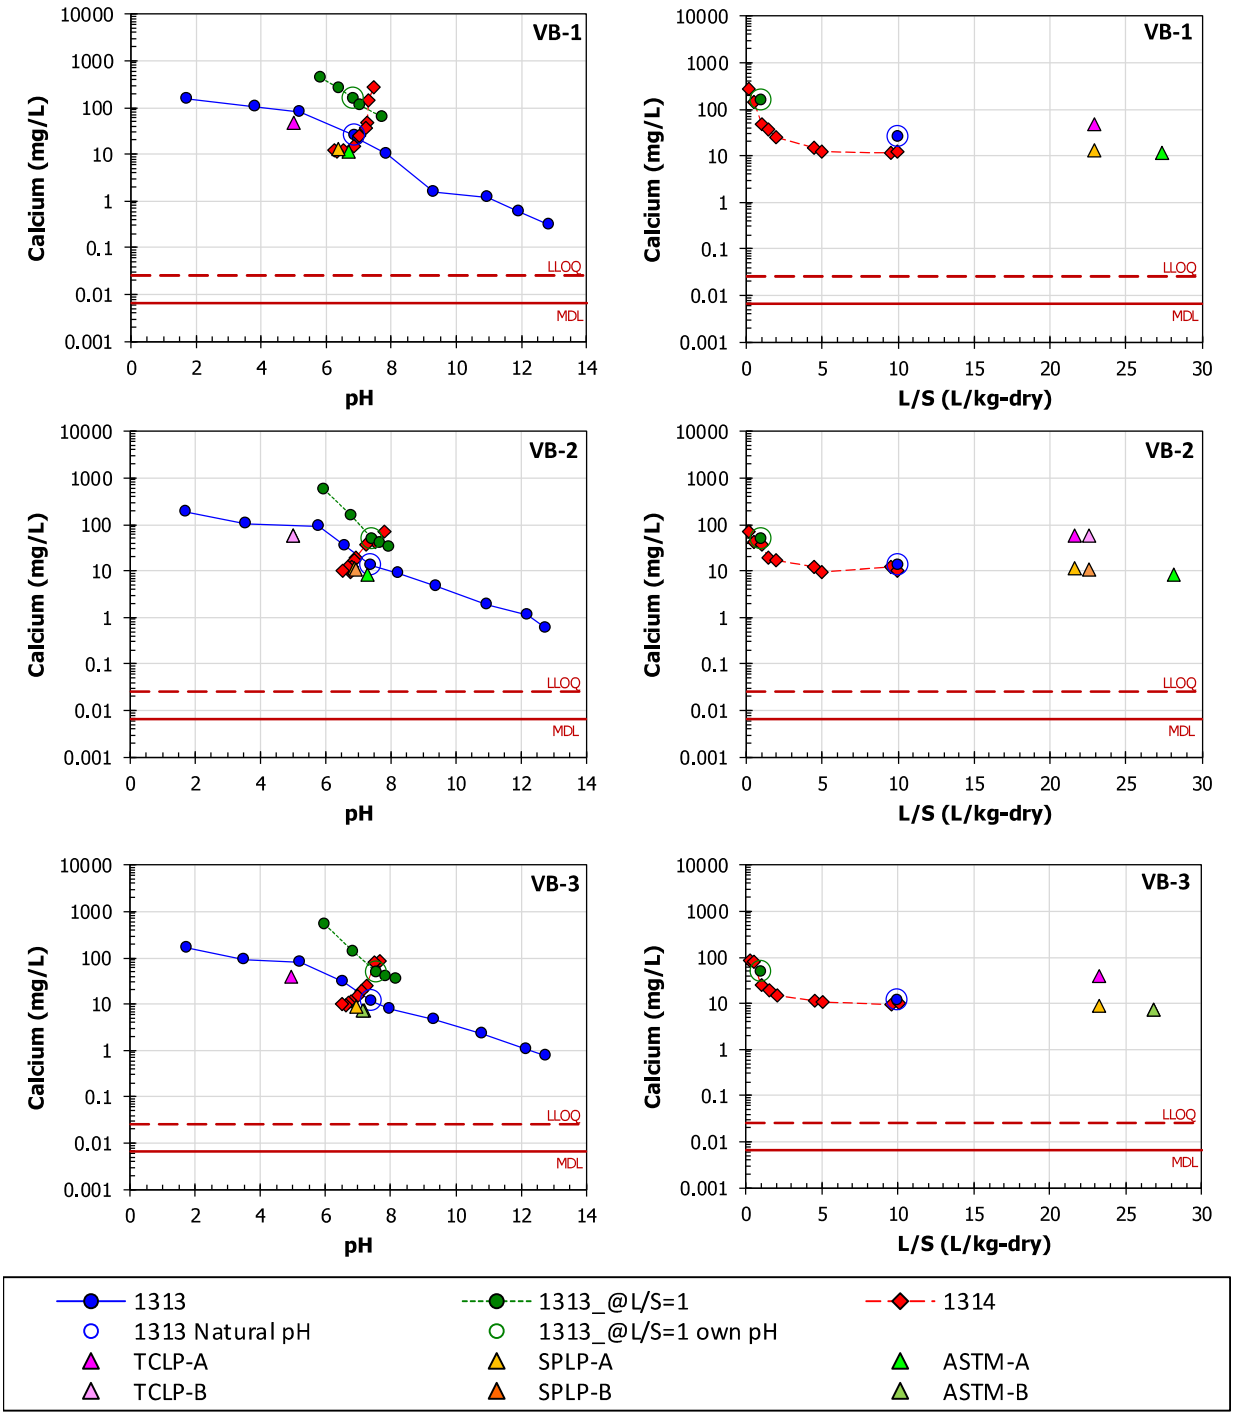

Figure E-9
Calcium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

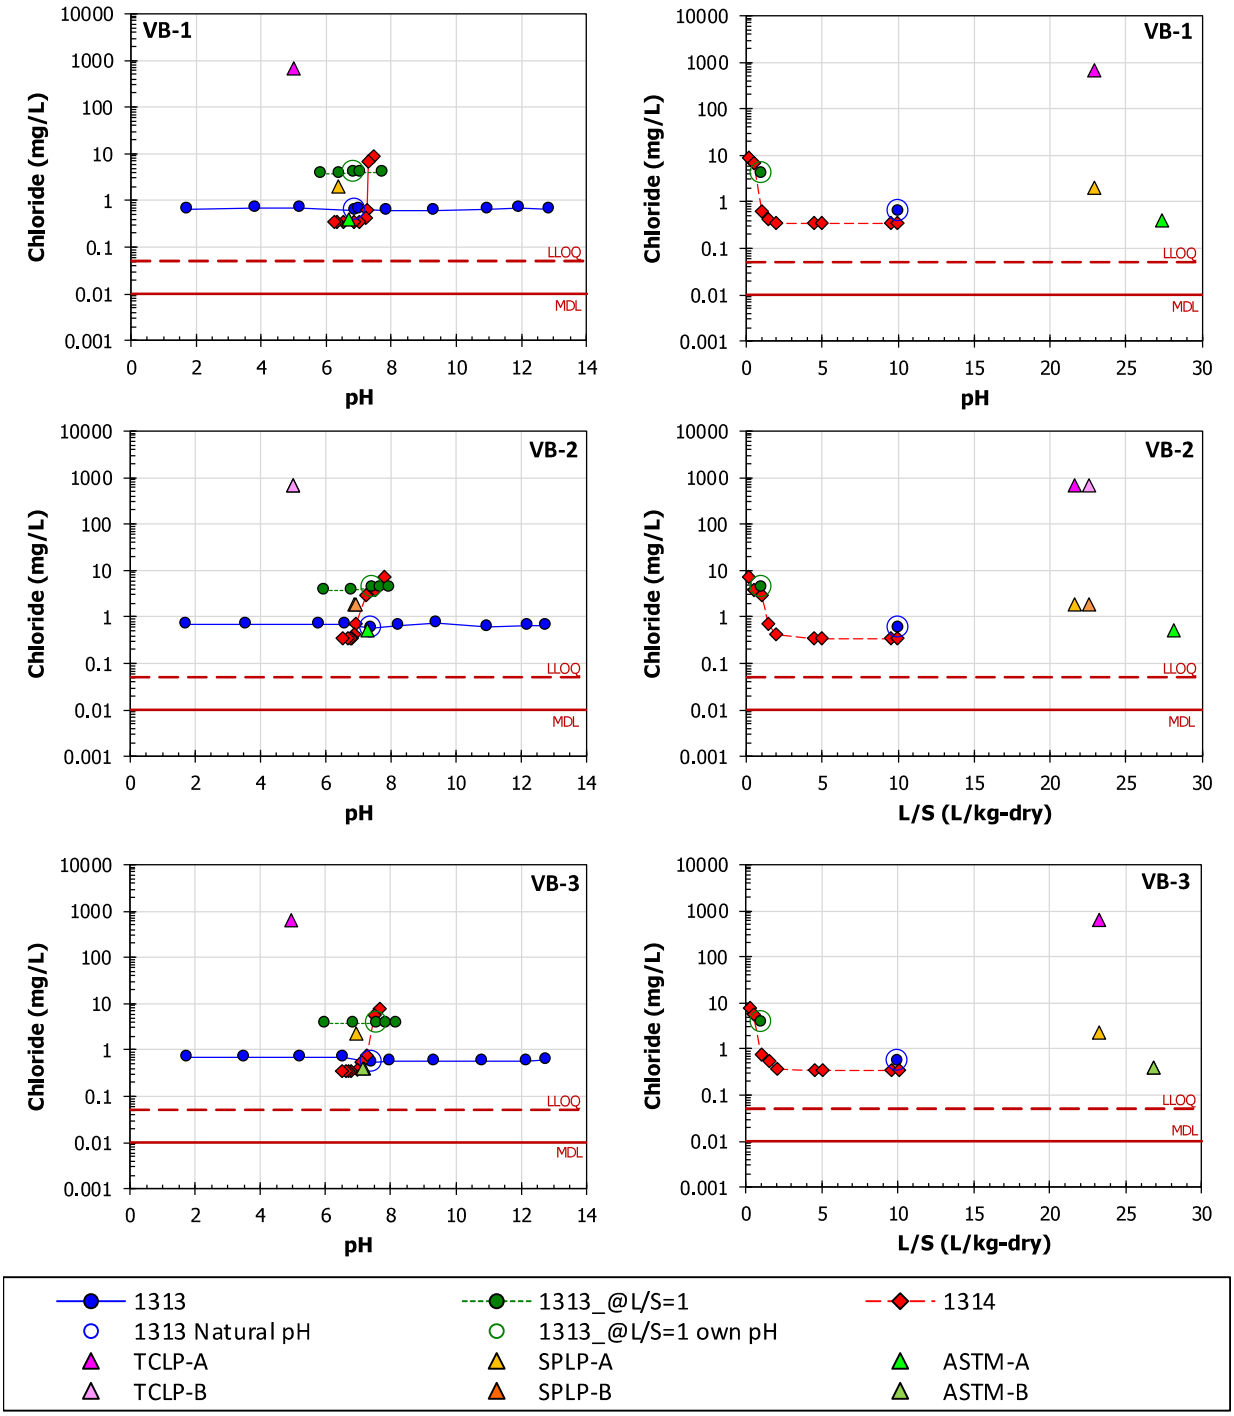

Figure E-10
Chloride concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

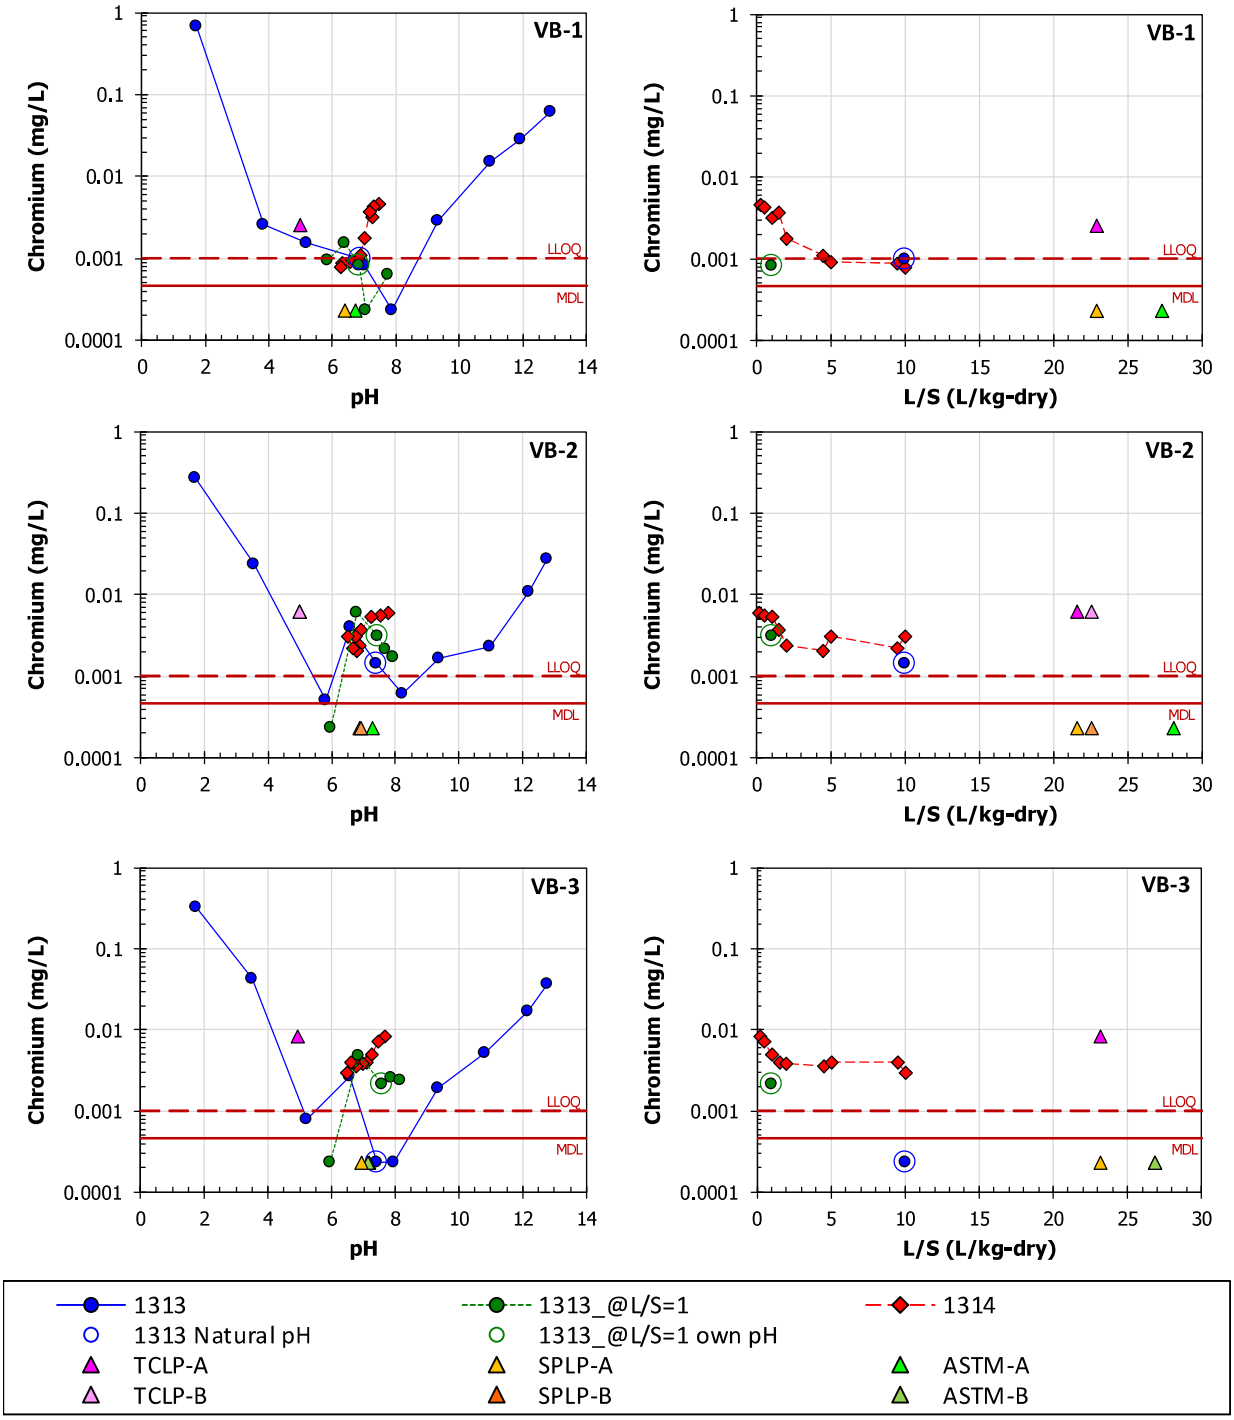

Figure E-11
Chromium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

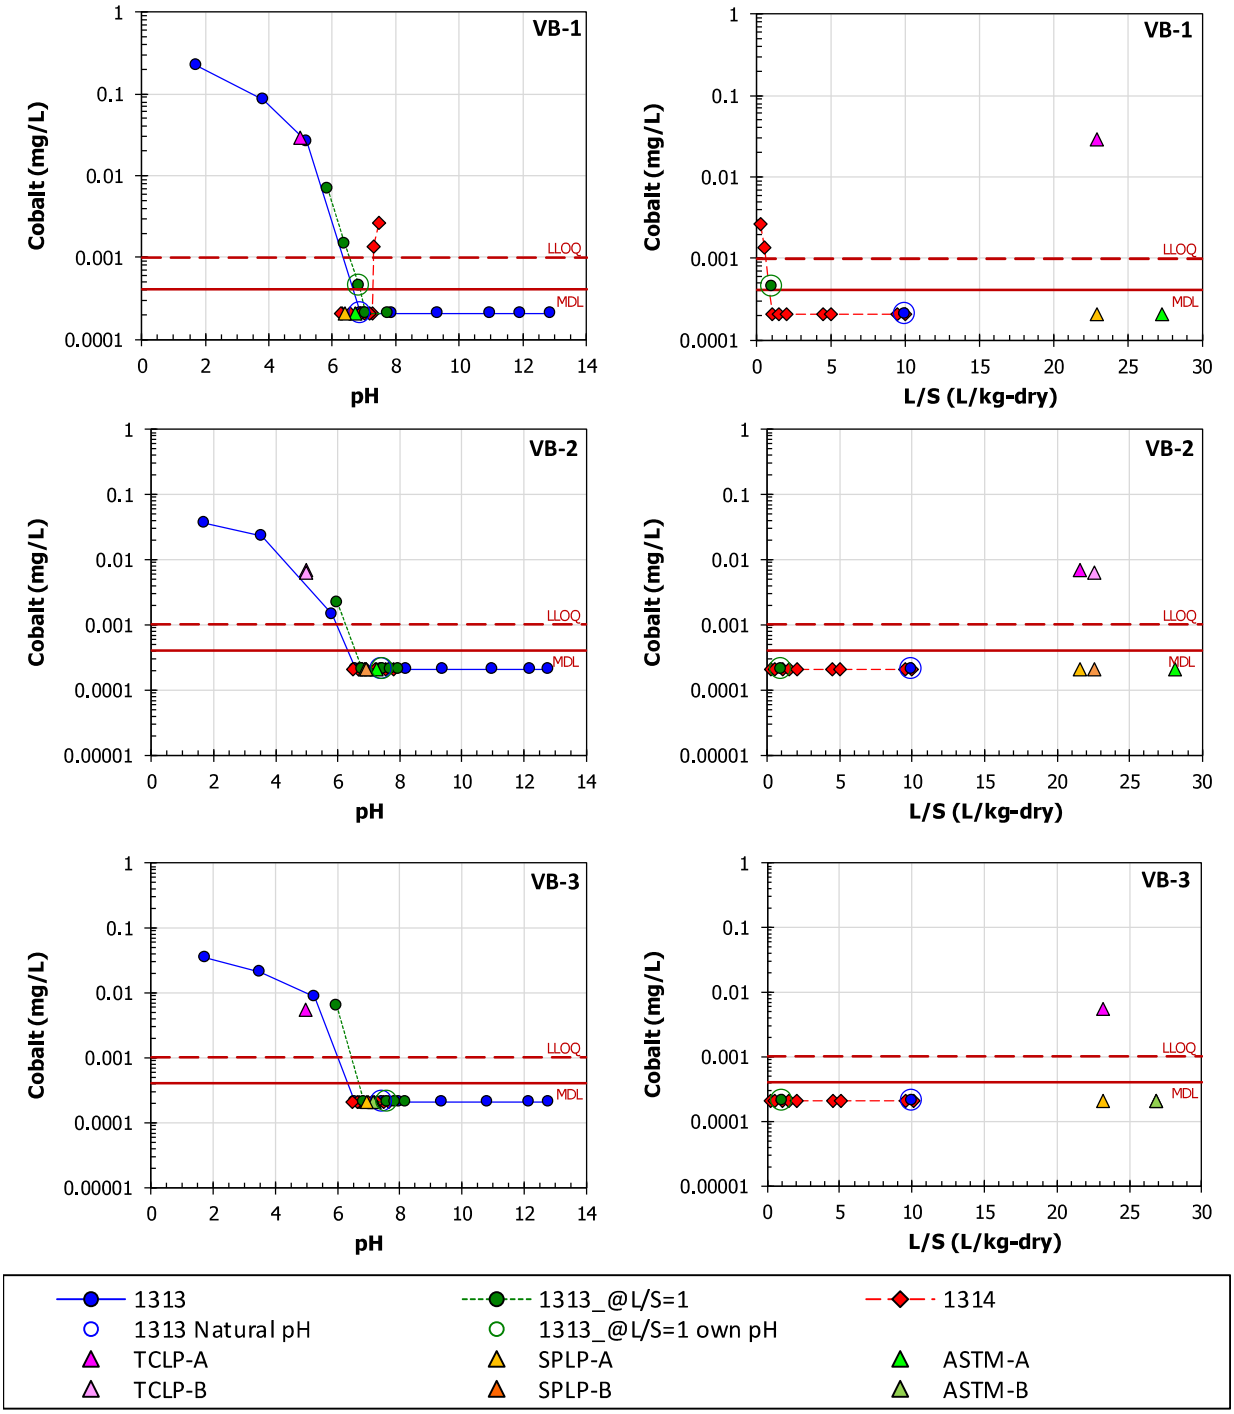

Figure E-12
Cobalt concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

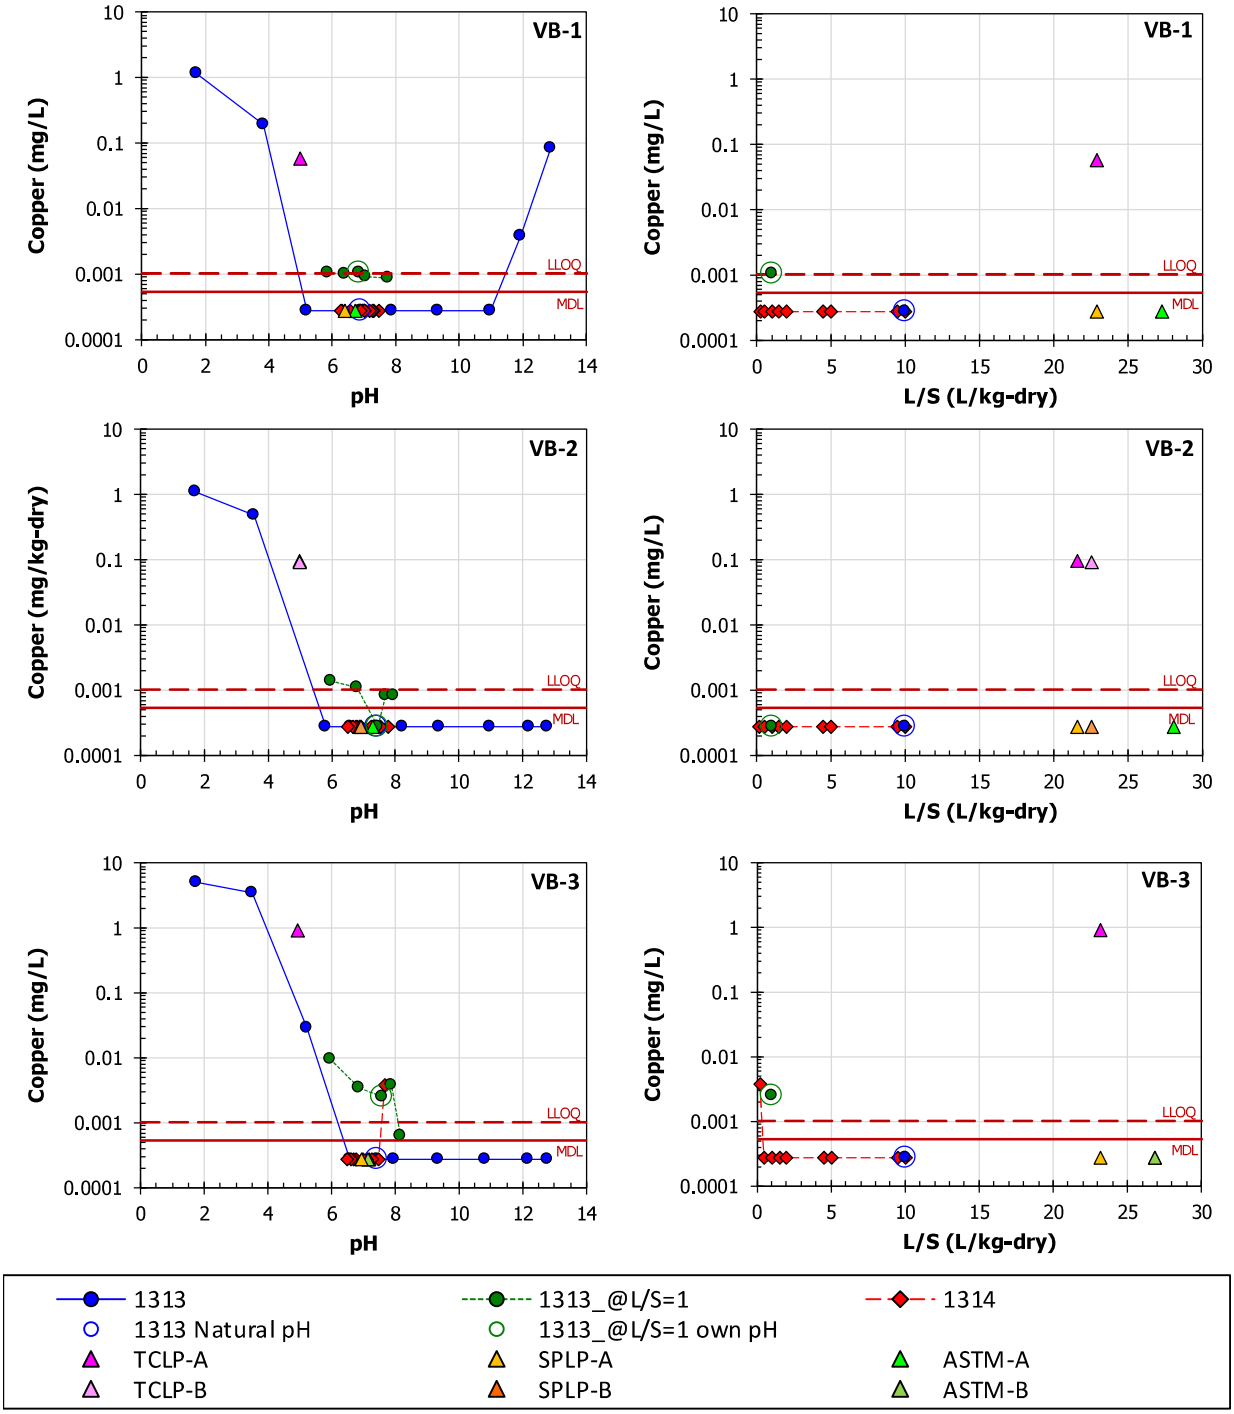

Figure E-13
Copper concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

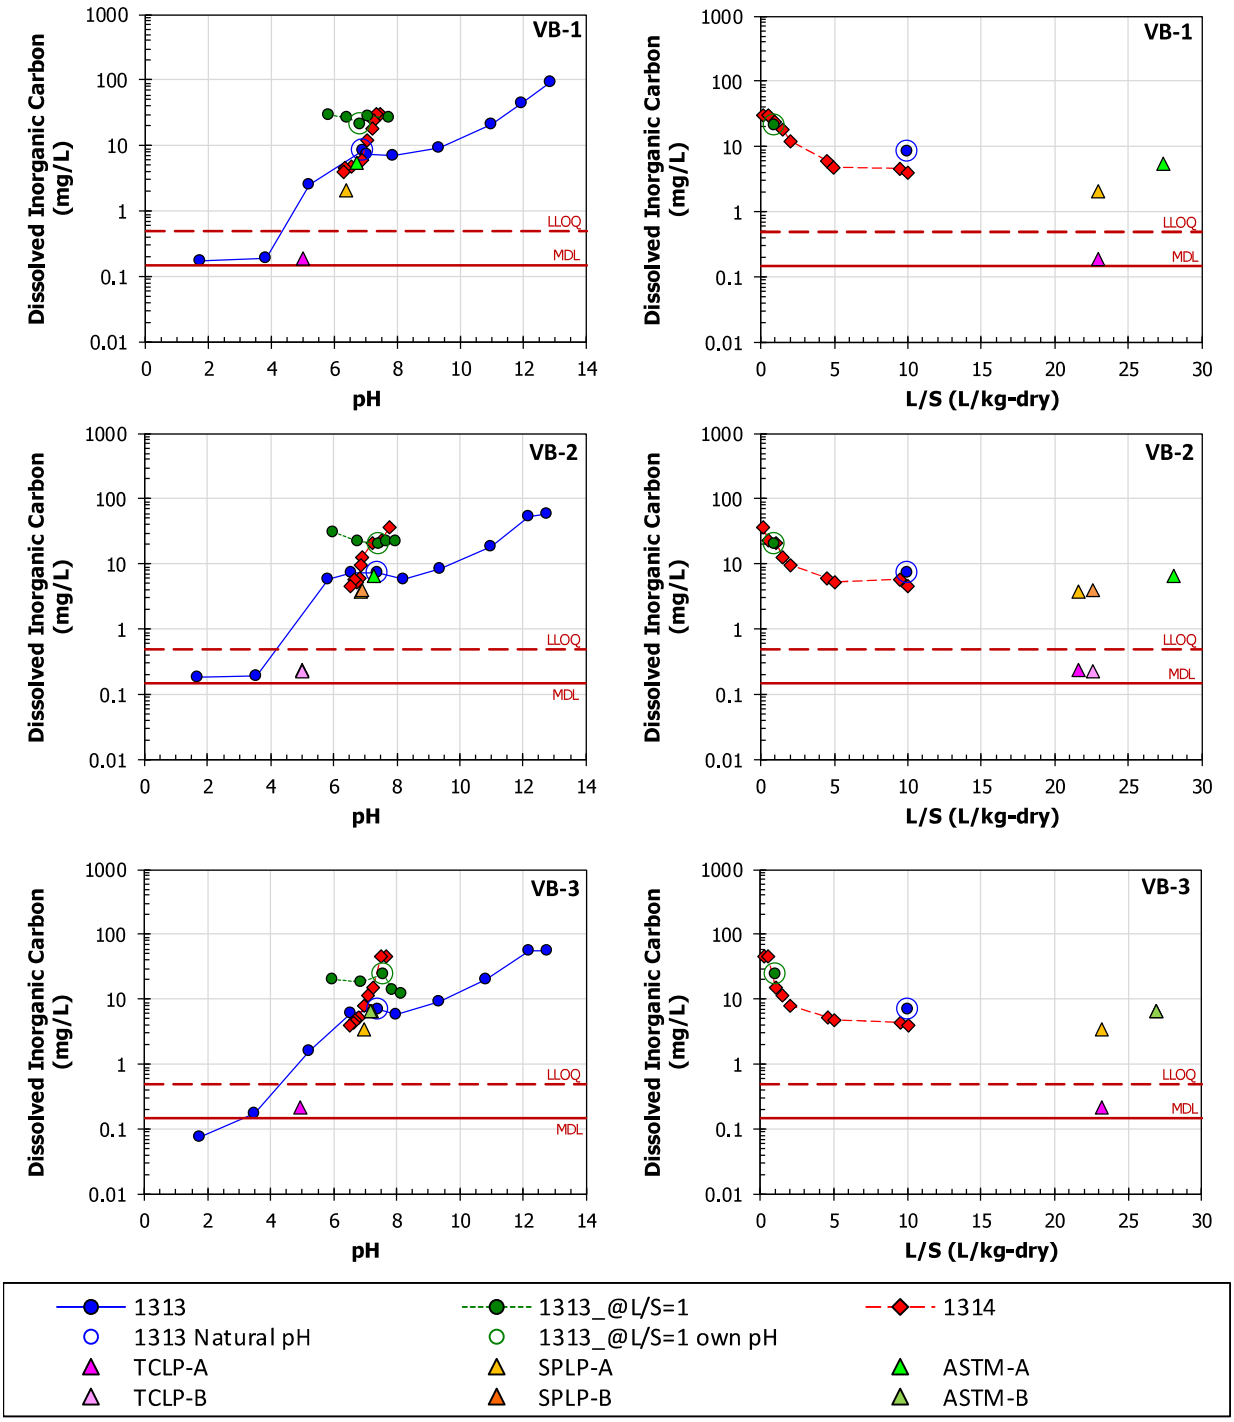

Figure E-14
Dissolved inorganic carbon concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

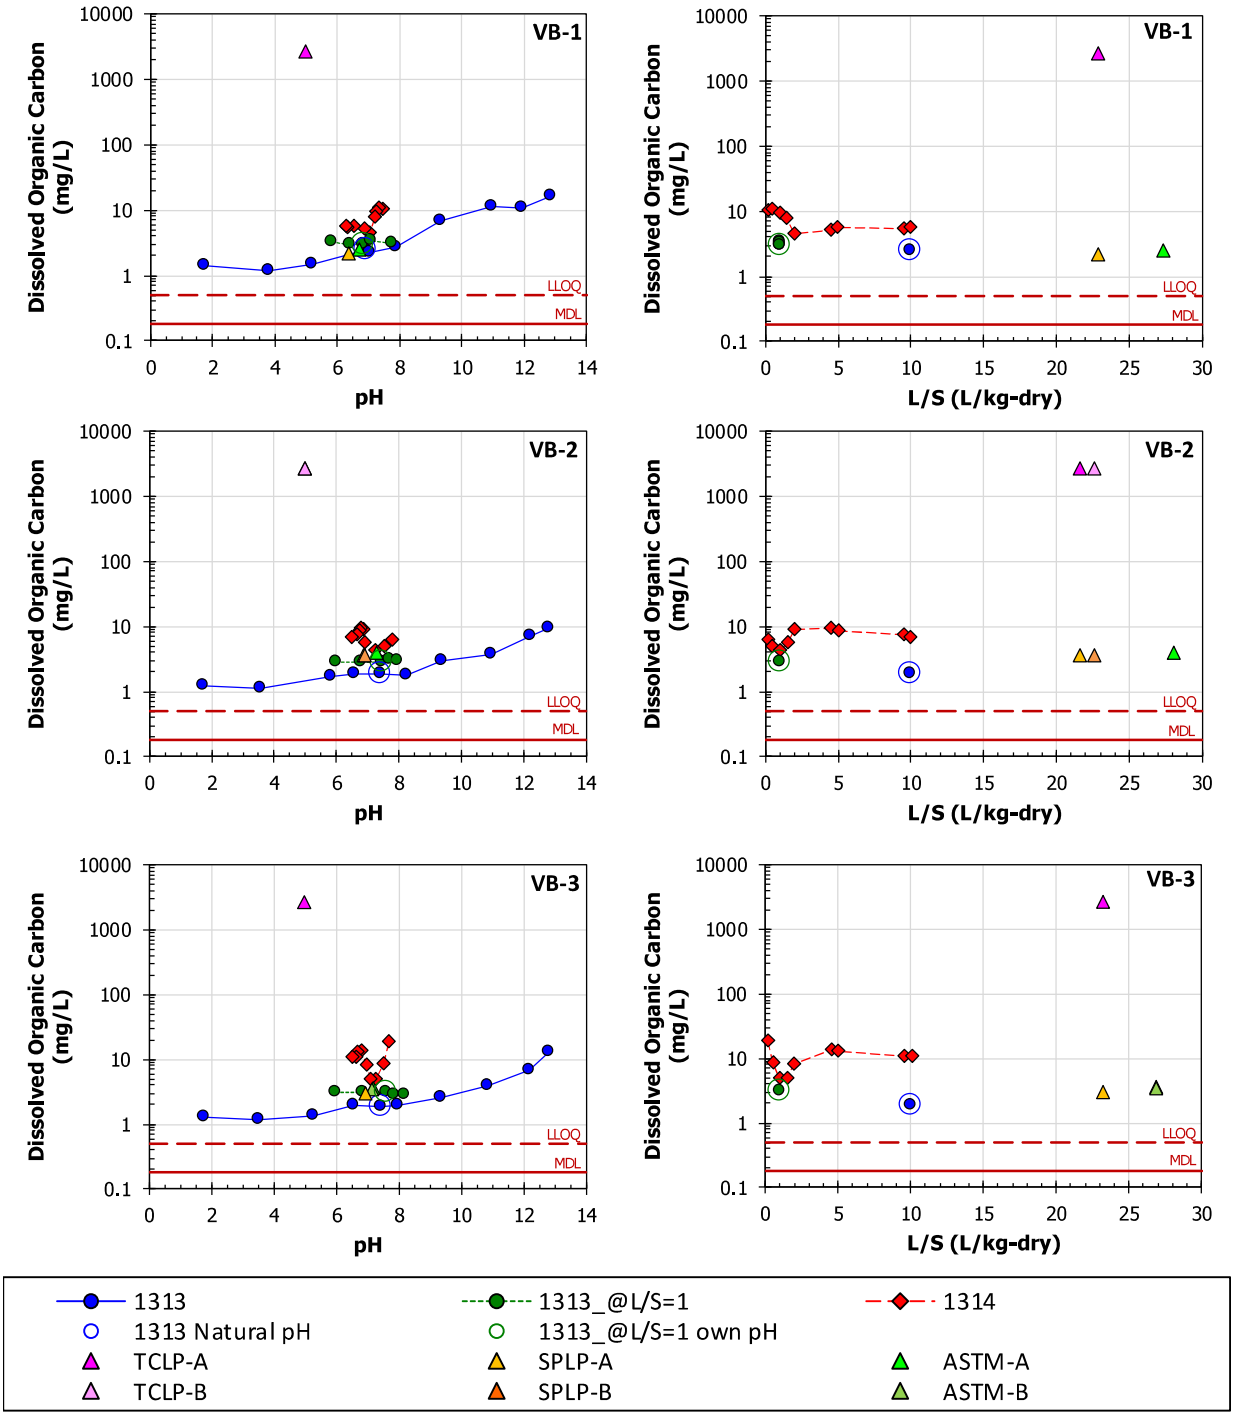

Figure E-15
Dissolved organic carbon concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

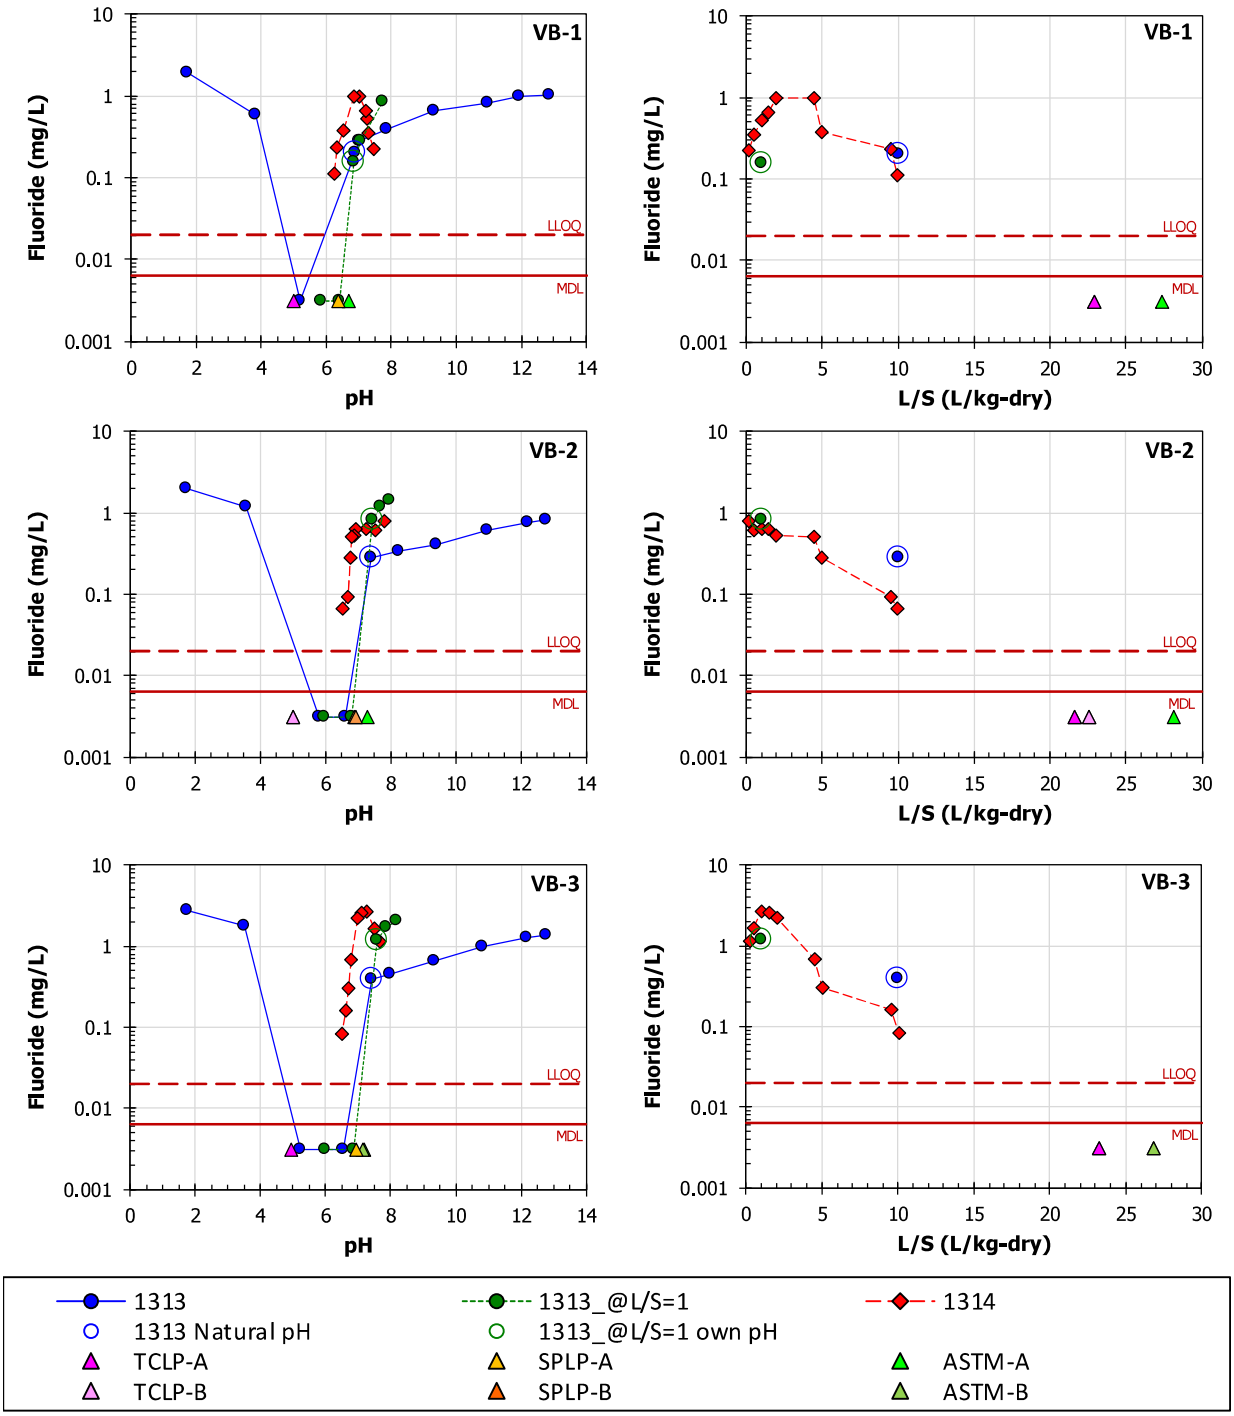

Figure E-16

ANALYTICAL QA/QC REPORTS

Analytical QA/QC reports are maintained as electronic files available upon request to EPRI.

Electronic Filing: Received, Clerk's Office 07/01/2024

Export Control Restrictions

Access to and use of this EPRI product is granted with the specific understanding and requirement that responsibility for ensuring full compliance with all applicable U.S. and foreign export laws and regulations is being undertaken by you and your company. This includes an obligation to ensure that any individual receiving access hereunder who is not a U.S. citizen or U.S. permanent resident is permitted access under applicable U.S. and foreign export laws and regulations.

In the event you are uncertain whether you or your company may lawfully obtain access to this EPRI product, you acknowledge that it is your obligation to consult with your company's legal counsel to determine whether this access is lawful. Although EPRI may make available on a case by case basis an informal assessment of the applicable U.S. export classification for specific EPRI products, you and your company acknowledge that this assessment is solely for informational purposes and not for reliance purposes.

Your obligations regarding U.S. export control requirements apply during and after you and your company's engagement with EPRI. To be clear, the obligations continue after your retirement or other departure from your company, and include any knowledge retained after gaining access to EPRI products.

You and your company understand and acknowledge your obligations to make a prompt report to EPRI and the appropriate authorities regarding any access to or use of this EPRI product hereunder that may be in violation of applicable U.S. or foreign export laws or regulations.

The Electric Power Research Institute, Inc. (EPRI, www.epri.com) conducts research and development relating to the generation, delivery and use of electricity for the benefit of the public. An independent, nonprofit organization, EPRI brings together its scientists and engineers as well as experts from academia and industry to help address challenges in electricity, including reliability, efficiency, affordability, health, safety and the environment. EPRI also provides technology, policy and economic analyses to drive long-range research and development planning, and supports research in emerging technologies. EPRI members represent 90% of the electricity generated and delivered in the United States with international participation extending to nearly 40 countries. EPRI's principal offices and laboratories are located in Palo Alto, Calif.; Charlotte, N.C.; Knoxville, Tenn.; Dallas, Texas; Lenox, Mass.; and Washington, D.C.

Guidelines for Development of Alternative Source Demonstrations at Coal Combustion Residual Sites. EPRI, Palo Alto, CA: 2017. 3002010920.

Electronic Filing: Received, Clerk's Office 07/01/2024

ABSTRACT

EPRI's guidance for alternative source demonstrations (ASDs) was developed to provide environmental managers at electric utilities with a list of alternative sources to check as well as a standardized, defensible approach for building and documenting an ASD when there are exceedances of one or more benchmarks established within a groundwater monitoring program. This guidance is designed for statistical benchmarks, in specific, statistically significant increases (SSIs) or statistically significant levels (SSLs) for groundwater monitoring under the federal Coal Combustion Residuals (CCR) rule and/or state regulations, but the guidance also applies to exceedances of other types of benchmarks such as groundwater quality standards.

The guidance provides information to help identify when a cause other than a release from the facility is the likely source of an SSI during detection monitoring or an SSL during assessment monitoring along with a checklist-based framework for developing a defensible ASD. The guidance covers ASDs developed in response to sampling causes, laboratory causes, statistical evaluation causes, natural variation, and alternative anthropogenic sources, with emphasis on development of an ASD when an SSI, SSL, or other exceedance is due to natural variation or an alternative anthropogenic source.

Product Type: Technical Report

Product Title: Guidelines for Development of Alternative Source Demonstrations at Coal Combustion Residual Sites

---

PRIMARY AUDIENCE: Electric utility environmental managers interpreting and responding to groundwater data collected under the Coal Combustion Residuals (CCR) rule and/or state rules

SECONDARY AUDIENCE: Consultants working for electric utilities with responsibility for responding to potential exceedances of benchmarks or criteria established for utility groundwater monitoring programs

KEY RESEARCH QUESTION

Groundwater monitoring programs developed for compliance with the federal CCR rule, and some state rules, use statistical analysis to determine whether or not individual results represent exceedances, which are often termed statistically significant increases (SSIs) over background in detection monitoring or statistically significant levels (SSLs) relative to a groundwater protection standard in assessment monitoring. However, the statistical methods are subject to false positive results, where a value that is not a true exceedance is flagged as such. Furthermore, there are literally dozens of causes related to sampling, laboratory analysis, natural variation, and other anthropogenic sources that can trigger an exceedance that is not due to a release from the monitored unit. When an exceedance is triggered due to a cause other than a release from the facility, federal and state regulations allow for an alternative source demonstration (ASD). At present, however, there are no criteria for how to develop and document an ASD.

RESEARCH OVERVIEW

This research provides guidance for identifying when an ASD is needed, evaluation techniques that can be used to support the demonstration, and a standardized checklist-driven approach for documenting a defensible ASD. The guidance is based on experience developing ASDs in states that have long used statistical analysis to determine compliance with groundwater quality benchmarks and is tailored for application in CCR monitoring programs.

KEY FINDINGS

- Potential sampling, laboratory, and statistical causes that can trigger an exceedance that is not due to a release from the CCR facility are described in Section 2. Checklist 1 outlines a methodology for demonstrating these causes.
- Natural variation can trigger an exceedance if there are changes in mineralogy along a groundwater flow path, changes in pH and/or redox over time or along a flow path, changes in groundwater elevation over time, and/or changes in groundwater flow direction over time (Section 4).
- Potential anthropogenic sources at a power plant that can trigger an exceedance at one or more monitoring locations include, but are not limited to, spills of petroleum or other materials, road salt, leakage of runoff from coal management areas, overspray of leachate used for dust control, accumulation of blowing dust near monitoring wells, leakage from leachate conveyance pipelines or tanks, and releases from other CCR units (Section 5).

Electronic Filing: Received, Clerk's Office 07/01/2024

- Potential off-site anthropogenic sources include, but are not limited to, agricultural activities, road salt, coal mining, brines associated with oil and gas production, leaking underground pipes, pumping-induced brackish water, septic systems, and industrial or municipal waste management (Section 5).
- An ASD due to natural variation or an off-site or on-site anthropogenic source will be strongest if multiple lines of evidence are developed. Key lines of evidence include a lack of exceedances and a lack of increasing trends for primary indicators of the CCR, leachate concentrations for the affected constituent that are lower than concentrations observed in groundwater, major ion chemistry in the affected monitoring well that does not represent mixing of leachate with background groundwater, tritium age-dating showing that the groundwater is older than the CCR unit, and isotopic data showing that the groundwater at the affected monitoring well is not a mixture of background groundwater and leachate (Section 6).

WHY THIS MATTERS

False identification of an SSI can trigger assessment monitoring, and false identification of an SSL can trigger corrective action, either of which can increase the cost and manpower resources needed for groundwater compliance at CCR sites. An ASD can be used to demonstrate that these incremental increases in resource allotment are not necessary if the statistical exceedance is not due to a release from the facility. ASDs may be reviewed by state regulators and the public, and this guidance provides a standardized, checklist-driven approach for documenting a strong ASD.

HOW TO APPLY RESULTS

Users of this guidance can begin by reviewing Sections 2, 4, and 5 to determine whether or not an ASD is appropriate, and if so, the potential alternative causes that may explain the ASD. Section 3 describes evaluation techniques that can be used to support the ASD. The user can then use the checklists described in Section 6 and provided at the end of the document in Appendix B to build the ASD.

LEARNING AND ENGAGEMENT OPPORTUNITIES

- Statistical analysis used in CCR groundwater monitoring programs is described in *Groundwater Monitoring Guidance for the Coal Combustion Residuals Rule*. EPRI, Palo Alto, CA: November 2015. 3002006287.
- Techniques for evaluating groundwater quality data are described in *Groundwater Quality Signatures for Assessing Potential Impacts from Coal Combustion Product Leachate*. EPRI, Palo Alto, CA: October 2012. 1017923.
- Methodologies for application and evaluation of isotopic analysis are provided in *Application of Isotopic Methods to Coal Combustion Residual Groundwater Quality Investigations*. EPRI, Palo Alto, CA: December 2017. 3002010911.

1
INTRODUCTION

Scope of Guidance

This guidance for alternative source demonstrations (ASDs) was developed to provide environmental managers at electric utilities with a list of alternative sources to check, and a standardized, defensible approach for building and documenting an ASD when there are exceedances of one or more benchmarks established within a groundwater monitoring program. The guidance is designed for statistical benchmarks, specifically statistically significant increases (SSIs) or statistically significant levels (SSLs) for groundwater monitoring under the Coal Combustion Residuals Rule (CCR Rule)[1] and/or state regulations, but the guidance is also applicable to exceedances of other types of benchmarks such as groundwater quality standards.[2]

The guidance provides information to help identify when a cause other than a release from the facility is the likely cause of an SSI during detection monitoring or an SSL during assessment monitoring, and a framework for developing a defensible ASD.

As provided for in the CCR Rule,[3] an alternative source demonstration can have a variety of causes:

- Sampling causes (ASD Type I)
- Laboratory causes (ASD Type II)
- Statistical evaluation causes (ASD Type III)
- Natural variation not accounted for in the basic detection monitoring or assessment monitoring statistics (ASD Type IV)
- Potential alternative sources (ASD Type V)
  - Anthropogenic impacts
  - Natural sources

Potential alternative sources, both anthropogenic and due to natural environmental influences, are the main focus of this report.

The scope of this document does not include guidance for performing a site investigation or establishing a groundwater monitoring system. Readers can refer to EPRI (2015) and a variety of other documents, many of which are listed in EPRI (2015), for such information.

[1] 40 CFR 257 Subpart D; published in 80 FR 21302-21501, April 17, 2015.

[2] The remainder of this document will primarily reference exceedances of SSIs or SSLs even though the methodology applies to exceedances of all types of benchmarks.

[3] 40 CFR 257.94(e)(2) for detection monitoring; 40 CFR 257.95(g)(3)(ii) for assessment monitoring.

2
TYPES OF ALTERNATIVE SOURCES

As stated in the CCR Rule at 40 CFR 257.94(e)(2), "The owner or operator may demonstrate that a source other than the CCR unit caused the statistically significant increase over background levels for a constituent or that the statistically significant increase resulted from error in sampling, analysis, statistical evaluation, or natural variation in groundwater quality. The owner or operator must complete the written demonstration within 90 days of detecting a statistically significant increase over background levels to include obtaining a certification from a qualified professional engineer verifying the accuracy of the information in the report." This section describes the five types of ASDs, provides example causes, and presents examples for how those causes might be identified.

Potential causes or investigation paths associated with each of the alternative source categories identified in the CCR Rule are listed in Table 2-1 and are discussed below. Anthropogenic sources are further discussed in Section 5, and natural variation is discussed in Section 4.

Table 2-1
ASD Types and Causes

Sampling Causes (ASD Type I)	Laboratory Causes (ASD Type II)	Statistical Evaluation Causes (ASD Type III)	Natural Variation (ASD Type IV)	Alternative Sources (ASD Type V - Natural and Anthropogenic)
• Sample mislabeling • Contamination • Change in technique • Excessive suspended solids or turbidity • Other sampling anomalies	• Analytical method • Calibration • Analytical technique • Contamination • Interference • Recording • Dilution errors • Digestion methods	• Lack of statistical independence • Outliers • Trends • Non-detect processing • False positives • New background data	• Geology • Precipitation • Seasonality • Water level • Changes in pH and/or ORP • Biological activity • Time of travel	• See Tables 2-2 and 2-3

Sampling Causes (ASD Type I)

- Sample mislabeling: One form of sample mislabeling is sample switching. Sample switching can be identified by sudden changes in concentration for the same constituent at two monitoring wells (Figure 2-1). Multiple constituents will be affected when this occurs, although it would only be evident for constituents with large differences in concentration

between the two monitoring wells. The multiple constituents will come from the same type of sample bottle (e.g., metals, IC analysis) if only one sample bottle is switched, and can come from multiple bottles if all bottles for two samples are switched. If analysis results suddenly differ from normal for a particular well, look for similar anomalies at other wells for patterns that could indicate swapped identification.

Another form of mislabeling can occur if the sample is taken from a different monitoring well than listed on the label (e.g., MW-01b instead of MW-01a), when the other monitoring well is not in the sampling program. In this case, only one monitoring well will show an anomaly for multiple constituents. This anomaly should affect all sampled constituents, although it will only be evident for constituents where concentration is different in the sampled well, relative to the well that should have been sampled. This case is more difficult to identify and demonstrate than the case of the switched sample. If all concentrations in a resample return to previous levels, then it is a possible explanation.

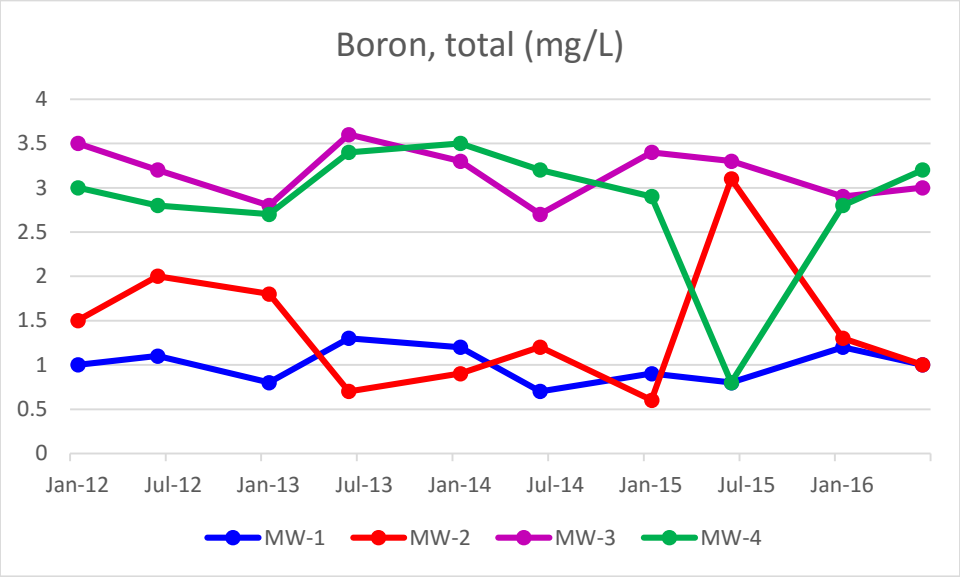

Figure 2-1
Time series plot showing potential sample mislabeling (switching)

- Contamination: If non-dedicated sampling devices are used to collect samples, contamination from the sampling equipment could potentially cause unrepresentative, elevated concentrations that could trigger an SSI/SSL. This type of sampling error is more likely to affect trace elements such as those found in Appendix IV of the CCR Rule than higher concentration elements such as those listed in Appendix III of the CCR Rule. An equipment blank (also called a rinsate blank) is a field quality control sample consisting of the rinsate from equipment used to collect the sample. Check the equipment blank analytical results to assess the potential for cross contamination, which will be evident by elevated concentration in the equipment blank. A field blank is a sample of deionized water from the laboratory that is opened in the field to assess the potential for field contamination. Field blanks are not always used for groundwater sampling at CCR sites. If field blank analytical results are available, check to assess the potential for field contamination unrelated to the sampling equipment.

Electronic Filing: Received, Clerk's Office 07/01/2024

- Sampling technique: A change in sampling technique, whether planned or due to an error, can have an influence on resulting concentrations if it affects the amount of sediment, as measured by turbidity, in the sample. See the next bullet for turbidity effects.
- Turbidity: Sudden increases in total dissolved solids and/or trace element concentrations can sometimes be associated with an increase in suspended solids/turbidity in a sample, relative to previous samples. Because the CCR Rule requires collection and analysis of unfiltered samples, elements comprising or attached to the particulate matter that causes turbidity are digested and analyzed along with the dissolved elements in the sample. Therefore, a turbid sample can yield higher concentrations for the elements that make up or are attached to the particulate matter. Evaluate the sampling technique used and the field analytical results, particularly the turbidity value if available, to assure that low-flow sampling procedures were properly followed. If the field analytical results do not indicate that stabilization of the field parameters (pH, temperature, specific conductance, dissolved oxygen, redox potential, and turbidity) was achieved, then sampling technique may be a defensible cause for an SSI/SSL. Some facilities establish sampling protocols that include collection of replicate filtered samples whenever a sample location has a turbidity greater than 10 to 20 NTU to allow comparison of analytical results between filtered and unfiltered samples. If filtered results are available, and are considerably lower than the unfiltered results, then turbidity resulting from differences in sampling technique, a screen failure in the monitoring well, or a need for redevelopment may be defensible alternative causes.
- Sampling anomalies: Review field documents (chain of custody form, calibration logs for field equipment, field notes, and field data) to see if any issues were encountered during the sampling event that could potentially affect the sample integrity. Potential anomalies may include improper bottles or preservation, inadequate calibration of field instruments, failure to achieve stabilized field parameters prior to sampling, use of non-dedicated or improperly cleaned equipment, improper labeling, etc.

Laboratory Causes (ASD Type II)

There are opportunities for potential contamination or errors associated with laboratory procedures, equipment decontamination and calibration, and sample handling and analysis. In addition to the analytical results, laboratory reports include documentation of methods and data qualifier flags to indicate potential issues that may affect the accuracy of results. The following are common data qualifiers for inorganic constituents sanctioned by USEPA:

- U = Reading was less than the method detection limit (MDL).
- J = Reading was less than the contract required quantitation limit but greater than or equal to the MDL.
- B = Analyte was found in the method blank as well as in the sample. Indicates possible/probable blank contamination.
- E = Reported value is estimated due to the presence of an interference. Look for comments.
- N = Spiked sample recovery not within control limits.
- * = Duplicate analysis not within control limits.
- D = The reported value is from a dilution.

The B, E, N, *, and D flags all indicate potential for laboratory errors that may have triggered an SSI/SSL, and warrant a closer look at the results to determine if the reported results may be invalid and if resampling and/or an ASD should be considered.

Potential errors associated with laboratory handling and analysis include:

- Calibration: Use of poorly or inadequately calibrated instruments may cause elevated analytical results that are not representative of the water quality at the sampling location. If results for a particular analyte in multiple samples, particularly if all were analyzed on the same day (laboratories typically recalibrate their instrumentation daily), are higher than the norm, then poor calibration of analytical equipment may be a potential cause. Consider reviewing instrument calibration records to see if poor calibration is a defensible alternative source for the SSI or SSL.
- Contamination: One or more samples may be contaminated by improperly cleaned and/or prepared sample bottles, analytical equipment, calibration standards, reagents, or preservatives. This type of error is more likely to be evident for trace elements such as those found in Appendix IV of the CCR Rule than for higher concentration constituents such as those listed in Appendix III of the CCR Rule. If sample contamination is suspected, evaluate the analytical results for trip blanks (if available) and method blanks. Trip blanks are sample bottles filled with laboratory-prepared deionized water that accompany the samples to and from the field, without being opened. If trip blank results show detection of analytes, it is possible that the sample bottles may not have been properly cleaned or the deionized water may have been contaminated. Method blanks are analyte-free laboratory quality control samples subjected to the entire analytical process used to demonstrate that the analytical system did not introduce contamination. The method blank results should be below the method reporting limits. If they are not, then the analytical process may have introduced contamination. Look for "B" data qualifiers to determine if the analytes were detected in the method blank.
- Digestion Methods: Use of more aggressive digestion methods using hydrofluoric acid for total digestion rather than concentrated nitric and/or hydrochloric acids for "total recoverable metals" may result in higher trace element concentration results compared to results using "total recoverable metals" methods. USEPA requires digestion consistent with "total recoverable metals" methods under the CCR Rule. If more aggressive digestion methods were used, reanalysis (if there is any remaining undigested sample) or resampling is warranted to determine if the SSI/SSL result persists when total recoverable digestion methods are used.
- Dilution Corrections: If dilutions were necessary to overcome matrix interferences, then review analytical results to ensure that the analytical results were properly corrected and that the resulting detection levels are low enough to detect increases over background levels. Look for the "D" data qualifiers to determine if dilutions were used. If a sample result is suddenly higher (especially if it is close to an order of magnitude higher) than the norm at a sample location and dilution was used, it is possible that the sample results were not corrected for the dilution ratio (Figure 2-2). Use of dilution ratios typically increases the MDL. If the sample results are non-detect but the MDL is higher than the norm, erroneous statistical identification of increasing trends may occur, depending on how non-detects are handled in the statistical analysis.

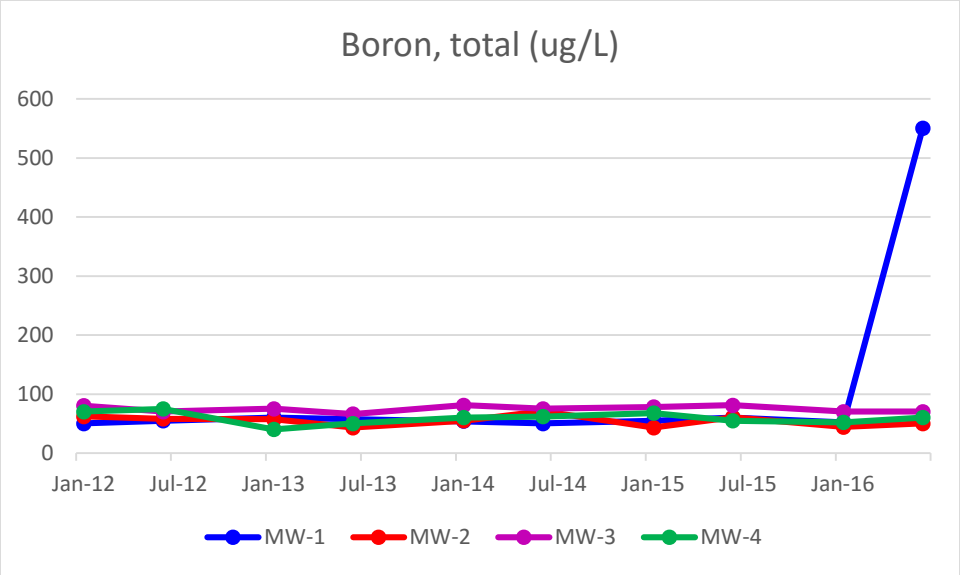

Figure 2-2
Time series plot showing potential dilution error

- Interference: Elevated analytical results may occur due to interference from other constituents present in the sample. If the laboratory identified interferences, the analytical report should include "E" data qualifiers. If interference was a problem, consider reanalyzing if there is sufficient remaining sample, and/or resampling and analyzing using methods that are less sensitive to interference from constituents of concern.
