- Vapor intrusion into the building via soil gas entry from vadose zones soils can be reduced by sealing foundational openings using products such as synthetic rubbers, acrylics, oil-based sealants, asphalt/bituminous products, swelling cement, silicon, epoxy or elastomeric polymers. EPA recommends screening the selected sealant(s) (e.g., checking the composition, relying upon manufacturer's data) to ensure they do not contain or emit vapor-forming chemicals that might pose a human health risk to building occupants. This interim mitigation approach is among the easiest and least expensive to implement; however, its effectiveness relies upon being able to identify and access openings for soil gas entry. EPA recommends appropriate monitoring of indoor air concentrations be conducted to ensure that sealing attains and sustains sufficient reduction in vapor intrusion. In some cases, however, sealing openings may not be capable of reducing indoor air concentrations to acceptable levels and/or some openings may not be visible and accessible. EPA recommends that this response option generally be supplemented by installing, operating, and maintaining an engineered exposure control (e.g., an active depressurization technology) that reduces or eliminates vapor entry into the building until remediation of subsurface vapor sources is complete and terminated.

- For commercial and industrial buildings where HVAC units blow air into the building and are well maintained, it may be advantageous to increase pressurization in the building to prevent or reduce vapor intrusion. In some cases (e.g., buildings with few doors and other openings), relatively small increases in building pressure may be sufficient, which may be accomplished by increasing the air flow rate and using specialized equipment to monitor and balance air flow rates. EPA recommends appropriate monitoring of pressure and other indicators (e.g., indoor air monitoring) be conducted to ensure that adequate pressurization is sustained throughout areas of the building that could be subject to vapor intrusion. In some climates and for some buildings, this response option may be impractical or prohibitively expensive.

- Vapor intrusion into the building via gas entry from sewer and drain lines can be reduced or eliminated by installing, repairing, and maintaining vapor traps.

- Increasing building ventilation (i.e., increasing the rate at which indoor air is replaced with outdoor air) can reduce the buildup of indoor air contaminants within a structure. Natural ventilation may be accomplished by opening windows, doors, and vents. Forced

or mechanical ventilation may be accomplished by using a fan to blow air into or out of the building. Increased ventilation is easiest and least costly to implement in locations where the air is not conditioned (heated or cooled). If indoor air is conditioned, increased ventilation can be a costly option because the conditioned air is ventilated to the outdoors. This drawback can be partly overcome by use of heat exchangers, but they are also costly. Another concern is that exhausting air from the building will generally contribute to under-pressurization of the building, relative to the subsurface, thereby potentially resulting in an increased rate of soil gas entry (i.e., vapor intrusion) unless ambient air entry into the building is increased equivalently. EPA recommends appropriate monitoring of indoor air concentrations be conducted to ensure that ventilation attains and sustains sufficient reduction in exposures to vapor-forming chemicals. In some cases, ventilation may not be capable of reducing indoor air concentrations to acceptable levels. In addition, building occupants may find it uncomfortable to increase the air exchange rate by more than a factor of three or four. EPA generally recommends that this response option be supplanted, when feasible, by installing, operating, and maintaining an engineered exposure control that reduces or eliminates vapor entry into the building until remediation of subsurface vapor sources is complete and terminated.

- Commercially available indoor air cleaners, which include both in-duct models and portable air cleaners, is another response option. These devices operate on various principles, including zeolite and carbon sorption and photocatalytic oxidation. Methods that rely on adsorption generate a waste that must be disposed of appropriately or regenerated and warrant periodic replacement of the adsorption medium. EPA recommends appropriate monitoring of indoor air concentrations be conducted to ensure that adequate treatment is sustained throughout the building. EPA generally recommends that this response option be supplanted, when feasible, by installing, operating, and maintaining an engineered exposure control that reduces or eliminates vapor entry into the building until remediation of subsurface vapor sources is complete and terminated.

- Temporary relocation may be implemented for buildings where conditions warranting prompt response action (see Section 7.5) and cannot be adequately addressed by other means.[218]

None of these options entails reducing the level of vapor-forming contamination in the subsurface medium (see Section 8.1). EPA generally recommends that these response options be supplanted, when feasible, by installing, operating, and maintaining an engineered exposure

[218] For response actions carried out under Sections 104(a) and 106(a) of CERCLA, OSWER Directive 9230.0-97 (*Superfund Response Actions: Temporary Relocations Implementation Guidance* (EPA 2002d)) states: "Temporary relocation should not be selected if health and safety risks or circumstances that pose an unreasonable inconvenience can be adequately addressed by other means without significantly increasing the overall cost or duration of the response action." Similarly, OSWER Directive 9355.0-71P (*Interim Policy on the Use of Permanent Relocations as Part of Superfund Remedial Actions* (EPA 1999f)) states: "EPA's preference is to address the risks posed by the contamination by using well-designed methods of cleanup which allow people to remain safely in their homes and business." OSWER Directive 9230.0-97 provides recommended procedures and other policies for temporarily relocating residents when this response action is selected and implemented under Sections 104(a) and 106(a) of CERCLA.

control that reduces or eliminates vapor entry into the building (see Section 8.2.2), until remediation of subsurface vapor sources is complete and terminated.

8.2.2 Active Depressurization Technologies for Existing Buildings

This section provides a brief overview of engineered systems that can be used to reduce or eliminate soil vapor intrusion in existing buildings, along with a summary of steps and considerations for selecting an appropriate technology for a given building. The focus is on active depressurization technologies most commonly employed for reducing soil vapor intrusion into buildings. This focus does not mean, however, that active depressurization technologies are always preferred over other mitigation methods or that they will be the best option for every site. More detailed information on vapor intrusion mitigation systems for existing buildings, including sub-membrane ventilation systems and passive technologies,[219] can be found in several EPA publications (e.g., EPA 2008c).

Active depressurization technologies (ADT) have been used successfully to mitigate the intrusion of radon into buildings and have also been successfully installed and operated in residential, commercial, and school buildings to control vapor intrusion from subsurface vapor-forming chemicals. ADT systems are widely considered the most practical vapor intrusion mitigation strategy for most existing buildings, including those with basement slabs or slab-on-grade foundations. ADT systems are generally recommended for consideration for vapor intrusion mitigation because of their demonstrated capability to achieve significant concentration reductions in a wide variety of buildings[220] and their moderate cost.

Sub-slab depressurization (SSD) systems, a common type of ADT system, function by creating a pressure difference across the building slab to prevent soil gas entry into the building (i.e., overcoming the building's natural under-pressurization, which is the 'driving force' for vapor intrusion; see Section 2.3). Creating this pressure difference is accomplished by extracting soil gas from beneath the slab and venting it to the atmosphere.[221] For the system to be effective by this mechanism,[222] this soil depressurization must be established and maintained at least near the primary openings for soil gas entry (EPA 1993a). Construction of SSD systems entails opening one or more holes in the existing slab, removing soil from beneath the slab to create a "suction pit" (6–18 inch radius), placing vertical suction pipes into the holes, and sealing the

[219] As noted in Section 3.3, engineered exposure controls that do not involve mechanical operations (e.g., creating a barrier between the soil and the building that blocks openings from soil gas entry into the building) are referred to as "passive."

[220] Folkes and Kurz (2002) describe a case study of a vapor intrusion mitigation program in Denver, Colorado. Sub-slab depressurization systems and/or sub-membrane depressurization systems were installed in 337 residential homes to control indoor air concentrations of 1,1-dichloroethylene (DCE) resulting from migration of vapors from groundwater with elevated 1,1-DCE concentrations. Over three years of monitoring data for 301 homes have shown that these systems are capable of achieving the very substantial reductions in concentrations in indoor air. Approximately one quarter of the systems warranted minor adjustment or upgrading after initial installation in order to achieve the state standards established for indoor air exposure.

[221] Depending, in part, upon location and prevailing statutes and regulations, governmental permits or authorizations may be required for venting systems that exhaust to the atmosphere.

[222] A second mechanism by which ADT systems can function is diluting the vapor concentrations beneath the slab and foundation (EPA 1993a, 2008c). Engineered controls designed and operated to use this mechanism predominately are often referred to as sub-slab ventilation systems.

openings around the pipes. These pipes are then connected together to a fan, which draws soil gas from the sub-slab area through the piping and vents it to the outdoors.[223] Sealing known and accessible openings in the slab and foundation can reduce the flow rate of conditioned indoor air that can be pulled into the sub-slab region by the suction wells and the sub-slab depressurization (EPA 2008).

SSD systems were first developed for radon reduction (EPA 1993a) and operate under similar design principles as radon mitigation methods. Figure 8-1 illustrates such an SSD system.

When sumps and associated drain tile systems are present, they may also be depressurized to prevent soil gas entry into the building (again, overcoming the building's natural under-pressurization). This variation on active depressurization is often referred to as drain-tile depressurization (DTD). Depressurization of drain tiles located near a foundation wall can help control soil gas entry at the joint between the foundation wall and slab. Figure 8-2 illustrates such a DTD system.

If the building has hollow block walls, the usual sub-slab suction point may not adequately mitigate the wall cavities, which may be particularly important if the outside surfaces are in contact with the soil. In these situations, the void network within the wall may be depressurized by drawing air from inside the wall and venting it to the outside. This method, called "block-wall depressurization" (BWD) is often used in combination with SSD. Because uniform depressurization of block walls can be difficult, BWD is generally recommended only when sub-slab or DTD prove inadequate to control vapor intrusion. Figure 8-3 illustrates such a BWD system.

In buildings with a crawl space foundation or a basement with a dirt floor, a flexible membrane may be installed over the floor to facilitate depressurization of the soil gas beneath the membrane, which prevents vapors from intruding into the crawl space or basement air. To maximize the effectiveness of a sub-membrane depressurization (SMD) system, EPA recommends the membrane cover the entire floor area and be sealed at all seams and penetrations. Figure 8-4 illustrates such an SMD system.

Extensive guidance is available for the design, sizing, installation, and testing of ADT systems for radon control in existing and new homes and large institutional (e.g., school) and commercial buildings. EPA recommends that ADT systems be designed and installed by qualified persons, typically environmental professionals and licensed radon contractors. EPA guidance for design of ADT systems can be found in several publications (e.g., EPA 1993a, 2008c). EPA recommends documenting each constructed ADT system via a system manual, as described further in Section 8.5.

The Vapor Intrusion Mitigation Quick Guide provided in Table 8-1 summarizes a list of steps for selecting and implementing a vapor intrusion mitigation system in existing buildings.

[223] A central issue that determines the design and effectiveness of ADT systems is the ease with which suction at one location can extend to other subsurface areas underneath the building. Where a good and uniform layer of aggregate (e.g., gravel or crushed rock) was placed underneath a slab foundation during construction, for example, such hydraulic control and communication can generally be expected to be good (EPA 1993a). Where the layer of aggregate under a slab is interrupted or uneven to a significant degree, additional suction pipes will generally be needed and their location will be increasingly important.

TABLE 8-1
VAPOR INTRUSION MITIGATION QUICK GUIDE FOR EXISTING BUILDINGS

Step 1: Consider Prompt Response Actions

It may be appropriate to implement certain interim measures before engineered controls are constructed and operated, as warranted and feasible. For example, building ventilation can be increased, cracks and other openings in the floor or foundation (that otherwise allow soil gas entry) can be sealed, or indoor air treatment can be conducted (refer to Section 8.2.1).

Step 2: Select a Building Mitigation System

The initial step in selecting the appropriate vapor intrusion mitigation technology is to conduct a visual inspection of an existing building. The selection of a vapor intrusion mitigation system primarily depends on building characteristics and contaminant concentrations. In the majority of cases, a type of active depressurization technology (ADT) can be an efficient, reliable, and cost-effective vapor intrusion mitigation technique. In some cases, however, other approaches may be preferable.

Factors that may prompt consideration of vapor intrusion mitigation approaches other than ADT include foundation conditions that prevent development and extension of a suction field below the building.

If there are no factors that would rule out an ADT technology, appropriate systems that can be considered include:

- Sub-slab depressurization (SSD) systems, particularly in houses having slabs (basements and slabs on grade) where drain tiles are not present.
- Drain-tile depressurization (sump/DTD or remote discharge/DTD) when drain tiles are present.
- Sub-membrane depressurization (SMD) in buildings with a crawlspace foundation or a basement with a dirt floor,
- Block-wall depressurization (BWD), usually used only as a supplement to SSD, DTD, or SMD to better mitigate vapors found to be migrating through the wall.

Step 3: Design Building Mitigation System

EPA recommends the final detailed design of the selected vapor intrusion mitigation technology specify the number and location of suction points, location and size of piping, suction fan, piping network and exhaust system, and sealing options to be used in conjunction with the ADT technology. Pre-mitigation diagnostic testing can provide information about the suction field underneath a building and pressure differences that will need to be overcome (EPA 1993a) if the ADT system is to be effective. Diagnostic testing during installation can also help verify the adequacy of the design.

Step 4: Install Building Mitigation System

EPA recommends that the vapor intrusion mitigation system be installed consistent with design specifications by equipment manufacturers, local permit conditions and regulations, and relevant industry standards.

Step 5: Confirm the Installed System is Operating Properly

EPA recommends a visual inspection of the installed system as a routine quality assurance step to confirm that all construction details have been completed. Post-construction monitoring is recommended (refer to Section 8.4) to demonstrate the ADT system is operating appropriately and effectively. Where a vapor intrusion mitigation system is not performing adequately, post-construction diagnostic tests can be helpful in trouble-shooting (EPA 1993a).

Step 6: Ensure Proper Operation and Maintenance of Vapor Intrusion Mitigation System (refer to Sections 8.3 and 8.4)

EPA recommends proper system maintenance and periodic inspections and monitoring to ensure the system is operating as designed and is effective at reducing indoor air concentrations to (or below) target levels. EPA recommends that site managers provide the building owner/occupant with information to help ensure proper operation and maintenance of the system.

EPA recommends that periodic inspections include periodic measurements to confirm that the building mitigation system is continuing to perform adequately.

The U.S. Navy has issued a concise fact sheet that contains useful technical information (DoN 2011b).

8.2.3 Approaches and Considerations for New Buildings

The ADT systems described above are generally available for new buildings also. However, a wider array of approaches and technical options is typically available to mitigate or avoid vapor intrusion for new buildings, compared to existing buildings. These options potentially include the choice of building location and opportunities to modify the building design and construction, which are not available for existing buildings. For example:

- At some sites, contaminated areas most likely to produce unacceptable vapor intrusion exposures can be avoided and designated for another purpose, such as recreational space or undeveloped landscape.

- Mitigation needs can also be considered in the selection of heating and cooling systems, which are normally selected based only on economics, aesthetics, preference, and custom. A system design that avoids creating under-pressurization inside the structure and maintains over-pressurization inside the structure may be effective in mitigating vapor intrusion.

- Passive barriers, such as a low-permeability membrane, can be more readily installed between the soil and the building during new building construction. Passive barriers are intended to reduce vapor intrusion by limiting openings for soil gas entry. However, passive barriers as stand-alone technologies may not adequately reduce vapor intrusion owing to difficulties in their installation and the potential for perforations of the barrier during or after installation. They are commonly combined with ADT systems or with sub-membrane ventilation systems to help improve their efficiency.

- Venting layers can be more readily installed between the soil and the building during new building construction.[224]

- New buildings may be designed to include a highly ventilated, low-occupancy area at ground level, such as an open parking garage.

Steps 2-6 of the Vapor Intrusion Mitigation Quick Guide provided in Table 8-1 are also pertinent to newly constructed buildings. EPA guidance for selecting, designing, and installing vapor intrusion mitigation systems for new buildings can be found in several publications (e.g., EPA 2008c). The U.S. Navy has issued a concise fact sheet that contains useful technical information (DoN 2011c).

[224] Constructed sub-slab ventilation systems typically consist of: a venting layer (e.g., filled with porous media such as sand or pea gravel; or suitably fabricated with continuous voids) below a floor slab to allow soil gas to move laterally to a collection piping system for discharge to the atmosphere; and a sub-slab liner that is installed on top of the venting layer to reduce entry points for vapor intrusion. These and other sub-slab ventilation systems function by drawing outside air into and through the sub-slab area, which dilutes and reduces concentrations of vapor-forming chemicals, and provides a route for soil gas to vent to the atmosphere or migrate outside the building footprint, rather than into a building.

8.2.4 Owner/Occupant Preferences and Building Access

Building owners and occupants can initially be notified in various ways that their home or building warrants construction and operation of a building mitigation system. Section 9.5 provides information regarding such notifications and other messages pertaining to building mitigation.

Whereas EPA managers and mitigation system designers may be primarily concerned with the performance, cost-effectiveness, and reliability of any mitigation system, the building owners and occupants may have additional perspectives and opinions that warrant consideration during technology selection, design, construction, and operation. For example, owners and tenants will often have strong opinions about where fans and piping are located, what level of fan noise is acceptable, and what quality of construction craftsmanship is satisfactory. When there are multiple mitigation options (for example, at a large commercial building), EPA recommends these options be presented fairly to the building owner and tenants, explaining the advantages and disadvantages associated with each and describing the rationale for the preferred alternative.

In some cases, obtaining and scheduling access to a building can be difficult, whether the structure is a commercial or institutional building or a private residence. Commercial building tenants may not want construction activities disrupting business operations. Some homeowners/tenants may resist granting access to their home. Other homeowners/tenants may prefer to schedule tests before or after their work-day. To address these practical and logistical concerns, EPA recommends that an access agreement(s) be executed between the property owner, any tenants, and the mitigating entity to ensure appropriate access as needed to operate, maintain, and monitor the engineered exposure controls in each impacted building.

8.3 Operation and Maintenance of Vapor Intrusion Mitigation Systems

For purposes of this Technical Guide, operation and maintenance (O&M) is used generically to refer to periodic inspections, component maintenance or replacements, repairs, and related activities that are generally necessary to ensure continued operation and effectiveness of engineered exposure controls to mitigate vapor intrusion. EPA generally recommends that such O&M activities be conducted routinely, be documented in an O&M plan (as described further in Section 8.5), and consider recommendations of equipment manufacturers, if any, and site-specific factors. Additional information about ensuring continued effectiveness of systems is available in EPA (2009b).

Design specifications for vapor migration systems may include (1) a maintenance frequency that varies over the operating period of the mitigation system and/or (2) a provision to evaluate and modify the frequency based on data or information obtained during monitoring and maintenance. For example, it may be acceptable to reduce inspection or maintenance frequency once efficient system operation has been demonstrated for at least an initial year, with triggers for additional, unscheduled inspections following alarms (from warning devices) and floods, earthquakes, and building modifications, if any.

Typical O&M activities for either passive or active systems may include, but are not limited to:

- Routine inspection of all visible components of the vapor intrusion mitigation system, including fans, piping, seals, membranes and collection points, to ensure there are no

signs of degradation or blockage. EPA recommends that the as-built drawing for the vapor intrusion mitigation system be examined to verify the system configuration has not been modified.

- Visual inspection of the building to evaluate whether any significant changes were made (such as remodeled basement, new furnace) that would affect the design of the vapor intrusion mitigation system or the general environment in which it is operated. A crawl space SMD membrane, for example, may warrant repair or replacement if its integrity is compromised.

- Visual inspection of the area of concern (including basement floor and wall seals, sumps, floor drains and utility penetrations) to ensure there are no significant changes in conditions that would warrant modification of the system design.

- Routine monitoring of vent risers for flow rates and pressures generated by the fan to confirm the system is working and moisture is draining correctly.

- Routine maintenance, calibration and testing of functioning components of the venting system consistent with the manufacturers' specifications.

    - Pressure readings for both active and passive depressurization systems as well as positive pressurization systems (e.g., periodic verification of measurable pressure differences across the slab).

    - Confirmation that the extraction fan is operating.

    - SSD system fans generally can function well for prolonged periods without maintenance; however, EPA recommends fans be replaced periodically throughout the operating life of the system (e.g., every 4 to 10 years) to avoid breakdowns and associated problems.

- Inspection of external electrical components to identify undesirable conditions, such as excessive noise, vibration, moisture, or corrosion, and to verify that the fan cut-off switch is operable.

    - Inspection of the fan(s) is important throughout the operating period but may be particularly important near the end of its expected lifespan. Noisy fans typically indicate problems with ball bearings and warrant replacement on that basis.

    - Confirmation of adequate operation of the warning device or indicator.

- Confirmation that building owner/occupants are knowledgeable about how to maintain system operation. Confirmation that a copy of the O&M manual is present in the building and has been updated as necessary.

EPA also recommends that the site team determine if there has been any change in ownership/occupant. If such a change has occurred, EPA recommends the site manager work with the new owner/occupant to ensure continued integrity and operation of the vapor intrusion mitigation system.

8.4 Monitoring of Vapor Intrusion Mitigation Systems

Regardless of the type of system selected for mitigating vapor intrusion in a given building, EPA recommends monitoring to demonstrate that performance standards are achieved at the time of installation and that those performance standards continue to be met throughout the operating period of the mitigation system. EPA recommends that any monitoring program developed for a building mitigation system be based upon site-specific considerations, including the degree of risk or hazard being mitigated, the building use, the technology used to mitigate vapor intrusion, whether the subsurface vapor source(s) is stable in extent and concentration, and coordination with site remediation efforts. For example:

- An older building with highly volatile chemicals at high concentrations may need a more intense level of monitoring than a new building with lower concentrations of less volatile chemicals.

- Passive systems are generally less predictable and less efficient at preventing vapor intrusion than active systems and, therefore, typically warrant more intensive monitoring, all else being equal.

- When contaminated groundwater plumes are migrating to new areas (i.e., expanding) or concentrations in shallow groundwater are increasing, increased frequency and intensity of mitigation monitoring may be warranted.

- During start-up, some remediation methods have the potential to alter soil gas conditions in ways and to a degree that may be difficult to predict. Increased frequency and intensity of mitigation monitoring may be warranted when such remediation methods are implemented near buildings undergoing mitigation.

Mitigation monitoring will generally entail two phases: (i) an initial post-construction phase, which is generally more intensive; and (ii) a subsequent phase, which may be comprised of fewer diagnostic tests to be conducted periodically. As with radon mitigation systems (EPA 1993a, Section 11.1.2), results of indoor air sampling during initial post-construction monitoring may be used to demonstrate that the occupant's exposure to vapor-forming subsurface contaminants has been reduced as anticipated. In addition, pressure field measurements in the subslab region can be used to demonstrate that the system has attained hydraulic control and communication (e.g., depressurization in the case of an ADT system) over the footprint of the building (or portion of a large building, as appropriate, considering the extent of subsurface contamination). Adjustments to the mitigation system and/or additional diagnostic testing (EPA 1993a, 1993c) may be warranted if the results of such testing do not clearly demonstrate that the system is achieving its intended performance and effectiveness. Once an adequate demonstration of effectiveness has been made for the vapor intrusion mitigation system, periodic monitoring is recommended to verify that this performance is sustained; for this purpose, monitoring may be comprised of fewer types of tests than during the immediate post-construction (i.e., start-up) phase at the discretion of EPA when the subsurface vapor source(s) is stable. Examples of various monitoring scenarios for these two phases are provided in Table 4 of CalEPA (2011), Table 6-2 of NJDEP (2012), and Table 3-1 of MADEP (2011). Additional information about ensuring continued effectiveness is available in the *Operational and Functional Determination and the Transfer of Fund-lead Vapor Intrusion Mitigation Systems to the State* (EPA 2009b).

When monitoring to assess the performance and effectiveness of building mitigation technologies, EPA recommends employing the methods, approaches described in Sections 5.4, 6.2, 6.4 and 7.0 of this Technical Guide. EPA also recommends that monitoring programs that assess the performance and effectiveness of remediation and mitigation systems be documented, preferably in work plans similar to those recommended herein for characterizing and assessing the vapor intrusion pathway (see Section 6.2). Such vapor intrusion monitoring plans may be incorporated as part of a comprehensive remedial design and operations manual or as a stand-alone document, depending upon site-specific circumstances. In addition, EPA recommends that data and other results obtained through such monitoring programs be documented (e.g., in the administrative record), as they become available.

The remainder of this section identifies and further discusses some elements commonly incorporated in monitoring programs for active depressurization technologies.

Pressure Measurements

Sub-slab probes can be used to monitor differential pressures for a direct indication of the hydraulic performance of ADT systems (i.e., the pressure difference across the slab prevents soil gas entry); see Section 2.3. For basements, the walls that are underground become part of the critical building envelope that must prevent soil gas entry. For subsurface depressurization systems, EPA recommends that the pressure gauge be monitored quarterly to verify the system is operating efficiently. A reduced monitoring frequency may be appropriate after one year of successful operation of the remedial system.

Tracer Testing

Openings within the building or leaks in the mitigation system can affect system performance. Tracers can be used either for leak detection through barriers, building materials or system components (piping, for example) or to measure the air exchange rate in the building.

Smoke testing is a qualitative form of tracer testing used to detect leaks (e.g., at seams and seals of membranes in SMD systems or at potential leakage points (openings) through floors above sealed crawl space systems or through conduits that facilitate preferential vapor migration), or to test airflow patterns. A limitation of smoke testing in existing structures is that non-noxious smokes can be expensive, and cheaper high-volume smoke sources can leave undesirable residues. The efficacy of smoke testing in some applications has been questioned on the grounds that many leaks are too small for visual detection using this method (Maupins and Hitchins 1998, Rydock 2001), and that leaks large enough to detect using smoke could be detected other ways. More quantitative methods have been recommended, such as tracer testing with instrumentation for quantitative results.

Air Sampling

Once an adequate demonstration of vapor intrusion mitigation system effectiveness has been made, indoor air quality generally will be acceptable as long as an adequate pressure difference is maintained throughout the footprint of the building. Periodic or intermittent sampling of indoor air, nevertheless, warrants consideration, since indoor air data can provide direct confirmation that the system is reducing exposure levels of vapor-forming chemicals and because depressurization technologies can be expected to alter the distribution of vapors in the vadose zone and available for soil gas entry, if any.

Weather-Related Considerations

EPA recommends that weather conditions be noted during monitoring activities (EPA 1993a). Weather conditions, such as temperature and precipitation, can affect the performance of a vapor intrusion mitigation system. For example, cold temperatures may increase the building depressurization created by the thermal stack effect and thus increase the driving force for soil gas entry, depending upon the height of the house and the temperature difference between indoors and outdoors (see Section 2.3). As a result, the ADT system may need to overcome more building depressurization than originally considered when designed. Precipitation may also increase moisture in the fill under the slab, which may affect the performance of the system, and is a factor to consider in developing a monitoring program.

Alarms

Alarms generally are used as part of a monitoring program to ensure that malfunctions of vapor intrusion mitigation systems are timely and readily detected and addressed. According to ASTM (2003), "All active radon mitigation systems shall include a mechanism to monitor system performance (air flow or pressure) and provide a visual or audible indication of system degradation and failure" (i.e., an 'alarm'). ASTM goes on to say, "The mechanism shall be simple to read or interpret and be located where it is easily seen or heard. The monitoring device shall be capable of having its calibration quickly verified on site." Such devices may indicate operational parameters (such as on/off or pressure indicators) or hazardous gas buildup (such as percent LEL indicators). EPA concurs with the cited advice from ASTM and recommends it be considered when monitoring and maintaining mitigation systems for vapor-forming chemicals and sites addressed by this Technical Guide.

In particular, EPA recommends that system failure alarms be installed on active depressurization systems, and appropriate responses to alarms be communicated by the building owner/occupants. EPA also recommends that alarms be placed in readily visible, frequently trafficked locations within the respective building and their proper operation be confirmed on installation and monitored periodically.

Placards

EPA also recommends that permanent placards be placed on the system to describe the system's purpose and operational requirements (e.g., power source) and instructions on what to do if the system does not operate as designed (for example, a phone number to call for corrective action). EPA recommends the placard provide information about how to read and interpret the monitoring instruments or warning devices provided. EPA also recommends that these placards be placed as close to the monitoring/alarm part of the system as possible, as well as close to the fan or other active parts of the system.

8.5 Documentation of Engineered Exposure Controls for Vapor Intrusion Mitigation

EPA recommends that documentation be provided to building owners and occupants and appropriate regulatory agencies[225] describing the vapor intrusion mitigation system (i.e., a 'system manual') and its associated O&M (i.e., an 'O&M plan'). The system manual provides a detailed record about the mitigation system, including as-built drawings, permits (if any), copies of agreements, and construction/layout plans, whereas the O&M manual describes the O&M activities to be conducted routinely and identifies which party is responsible for these O&M activities. Additional information about ensuring continued effectiveness is available in *Operational and Functional Determination and the Transfer of Fund-lead Vapor Intrusion Mitigation Systems to the State* (EPA 2009b).

O&M Plan

O&M plans generally are prepared on a site-specific basis, and they often are particularly useful at sites where:

- Monitoring is needed to verify remedial effectiveness.
- The remedial system warrants periodic adjustments and maintenance.
- Human health risk would result if the system fails or if site conditions change.
- Conditions that would trigger specific contingent response may occur sporadically or episodically.

Some site remedial systems may also warrant the use of a regulatory agency-approved contingency plan or similar corrective response document approved by the regulatory agency to identify conditions that may trigger the need for additional maintenance, collection of additional data, modifications of monitoring frequency, or other responses to ensure the remedy remains effective.

Communication with building owners and occupants about vapor intrusion and the O&M of a vapor intrusion mitigation system is critically important. For example, building owners may be concerned about some aspect of system operation and decide to turn it off. It is important to communicate that turning off the system may result in harmful indoor air concentrations inside the building.

System Manual

The specific contents of the system manual will depend on the type of system. EPA recommends, however, that the system manual generally include at least the following information or items:

- Cover/transmittal letter;

[225] For example, EPA recommends the potentially responsible party (PRP) provide a system manual and O&M plan to EPA at PRP-lead Superfund sites.

- Description and diagram of final as-built system layout with components labeled;
- Building permits for a vapor intrusion mitigation system;
- Pre- and post-mitigation air and gas sampling data;
- Pre- and post-mitigation diagnostic test data;
- Copies of contracts and warranties;
- Proper operating procedures of the system;
- Contact information of the contractor or installer;
- Copy of signed access agreement;
- Copy of vapor mitigation system O&M agreement;
- Copy of pre-mitigation sample result letter (see Section 9.4);
- Copy of post-construction sample result letter;
- Contact information in case of future questions; and
- Inspection and maintenance guidelines.

User's Guide

Documentation typically is also provided to the property owner and occupant in the form of a user's guide suitable to keep lay persons informed about the system and to provide a summary reference in case questions or issues arise pertaining to the system.

A user's guide is a brief summary of why a vapor intrusion mitigation system was installed at a property and how the system works, and may include the following: (1) a brief description of the system and its proper range of operation; (2) contact information for the party responsible for responding to malfunctions and ensuring the system performs properly; and (3) information about routine maintenance to be conducted by the owner/occupant, if any. EPA recommends that a user's guide be placed near the system for quick access and easy reference (e.g., into a clear protective sleeve and attached to the main extraction pipe of the ADT system). An easy-to-read user's guide may be especially helpful at rental properties because the guide informs each new tenant about what the system is and why it was installed.

8.6 Use of Institutional Controls

ICs may be used to restrict certain land uses, buildings, or activities that could otherwise pose an unacceptable human exposure via the vapor intrusion pathway.

Response actions for vapor intrusion may include ICs to restrict land use for protection of human health regardless of whether a vapor intrusion mitigation system provides interim measures to control (i.e., reduce, limit) human exposures. ICs can be used as either an interim

response until site cleanup goals are reached or as part of a long-term response where vapor-forming waste remains in place.

General EPA guidance on ICs is provided in *Institutional Controls: A Guide to Planning, Implementing, Maintaining, and Enforcing Institutional Controls at Contaminated Sites* ("PIME IC Guidance") (EPA 2012d). As discussed in the PIME IC Guidance, ICs are non-engineered instruments, such as administrative or legal controls, that help to minimize the potential for human exposure to contamination and protect the integrity of a response action. ICs typically operate by imposing land or resource use restrictions at a given site or by conveying notice to stakeholders regarding subsurface contamination or the possible need to refrain from certain actions that may result in human exposure to hazardous chemicals. For example, ICs may be used to restrict the development and use of properties for certain land uses (e.g., prohibiting residential housing, hospitals, schools, and day care facilities).

In some situations, ICs can be used to restrict access to a property, facilitate response activities conducted by a responsible party or EPA, such as the installation or maintenance of vapor intrusion mitigation systems, or help ensure the integrity of vapor mitigation systems. ICs may also be used to help inform the need for vapor intrusion mitigation for future construction where vapor-forming waste remains in place and may pose unacceptable human health risk due to vapor intrusion.

As described further in Section 2.2 of the PIME IC Guidance, ICs can be described in four general categories:

- Proprietary controls.
- Governmental controls.
- Enforcement and permit tools with IC components.
- Informational devices.

The first three categories (i.e., proprietary controls, governmental controls, and enforcement and permit tools with IC components) typically memorialize and prescribe substantive use restrictions concerning the land or resource use, while informational devices generally operate to provide notice of contamination and any remedial activities to parties. Depending on the nature of the site and the particular jurisdiction in which it is located, certain instruments may not be available or feasible for a particular site. Certain ICs may help facilitate how interim response actions and subsurface remediation are carried out, such as provisions addressing access, O&M of vapor intrusion mitigation systems, and design specifications for buildings (see Example #3 box below).

8.6.1 Evaluating ICs in the Overall Context of Response Selection

As a site moves through a program's response selection process (for example, a Superfund remedial investigation/feasibility study [RI/FS] or RCRA facility investigation/corrective measures study [RFI/CMS]), EPA recommends that site managers develop information about reasonably anticipated future land uses and infer reasonably expected exposure pathways related to land use. This information may be incorporated in the conceptual site model and often can be used to evaluate whether ICs will be needed to ensure protectiveness of current and

reasonably anticipated future land uses over time. EPA's land use guidance (EPA 1995a, 2010c) recommends that the site manager discuss reasonably anticipated future land uses of the site with local land use planning authorities, local officials, property owners, and the public, as appropriate, as early as possible during the scoping phase of the RI/FS, RFI/CMS, or equivalent phase under other cleanup programs.

EPA recommends that the Region's decisions to implement ICs be documented in proposed cleanup plans and in final cleanup decision documents. For example, for CERCLA cleanups, the proposed restriction, and need for ICs would normally be identified in the Proposed Plan for notice and opportunity to comment by potentially affected landowners and the public. Such use restrictions or notices typically are then selected and memorialized in the Record of Decision (ROD).

In some cases, unanticipated changes in land use may occur after the response action is implemented, which may impact the protectiveness of a completed response action and raise questions concerning the effectiveness of the ICs. As a result, vapor intrusion may be identified as a potential human exposure pathway in a subsequent periodic review. In this case, EPA recommends that site managers evaluate options for modifying the original response decision, including the need for new or additional ICs consistent with existing and reasonably anticipated future land uses and other response selection considerations.

8.6.2 Common Considerations and Scenarios Involving ICs

The evaluation of whether an IC is needed at a contaminated site, including one where the vapor intrusion pathway poses a current or potential threat to human health, is a site-specific determination. When evaluating whether an IC will be needed, EPA recommends that EPA Regional staff consider whether the site meets unlimited use and unrestricted exposure (UU/UE), among other factors. UU/UE is generally the level of cleanup at which all exposure pathways present an acceptable level of human health risk for all land uses, including reasonably anticipated future land use scenarios that are considered during response selection.

Common scenarios where ICs may be a useful instrument for fostering protectiveness at a site involving vapor intrusion threats include, but are not limited to, the following:

1. Existing buildings overlie soil or groundwater contamination, or a migrating groundwater plume that is moving toward existing buildings potentially poses a future vapor intrusion threat;

2. Future construction is planned or is reasonably anticipated on a site that overlies subsurface contamination with vapor-forming chemicals;

3. Changes to building construction/design (such as remodeling or ventilation changes) or building use (such as commercial building converted for residential use) potentially affect exposure to the vapor intrusion pathway;

4. Vapor intrusion mitigation systems are needed in buildings, or existing ventilation systems are being utilized for vapor intrusion mitigation, and continued access is sought to facilitate their O&M;

5. Response actions to reduce source contamination will not immediately meet response objectives; and

6. Response actions to reduce or eliminate source contamination will not be taken (for example, where it is technically impracticable to treat groundwater that is the source of vapor intrusion).

Informational ICs may also serve to provide notice to parties, including prospective purchasers, about what land or building uses are compatible with human health risk that may be posed by vapor intrusion at the site. For example, modifications to a building's ventilation or air conditioning system may affect building under-pressurization in a way that fosters a greater potential vapor intrusion threat. Various ICs can be tailored to address construction and design specifications of both existing and future buildings—a local ordinance, for example, may require parties to submit a building design to its building department that incorporates mitigation measures as determined appropriate by a Professional Engineer (P.E.) (see IC Example #1).

In addition to restricting land, building, or resource use, some types of ICs may provide an effective means for addressing O&M at vapor intrusion sites consistent with decision documents and enforcement documents. This could happen, for instance, when an IC specifies that mitigation systems be installed and maintained in future construction or if the use of an existing building changes (e.g., industrial building use changes to mixed commercial or residential uses). Provisions regarding access to and periodic maintenance and testing of the mitigation systems, and other site-specific obligations may be incorporated into the IC (see IC Example #2).

IC EXAMPLE 1:

City of Mandan, North Dakota Ordinance No. 1002 (City of Mandan 2006)

In 2006, the City of Mandan, North Dakota, enacted an ordinance that created an Environmental Institutional Control Zoning District to define an area of downtown Mandan impacted by petroleum contaminated soil and groundwater and to establish ICs for the protection of human health and the environment. Among other provisions, the ordinance requires any person proposing redevelopment, demolition, excavation, grading, or construction activities at properties within the District to submit to the city administrator or their appointee a contingency plan, approved by the North Dakota Department of Health, to evaluate and manage any petroleum contaminated soils or groundwater and any potential petroleum vapor impacts. The contingency plan must be prepared by a P.E. with experience in the environmental field, and the plan must consider and protect against, among other things, the vapor intrusion pathway. In addition, the ordinance also provides for restrictions on construction of new structures within the District. In pertinent part, the ordinance provides:

"Any person proposing to construct a new structure within the District shall submit a design for that structure that incorporates engineered controls to mitigate the effects of the potential presence of petroleum in the subsurface to the city administrator or their appointee. The design must be prepared by a P.E. and the design must be approved by the North Dakota Department of Health and must meet additional applicable codes and standards relative to the presence of petroleum. The design shall protect the public health and the environment by considering, at a minimum a) historic water/product intrusion; b) historic petroleum vapor/odor issues; c) potential future water/product intrusion; and d) potential future petroleum vapor/intrusion. The design shall incorporate vapor barriers, venting system, groundwater suppression/collection, and specialized HVAC as determined appropriate by a P.E."

IC EXAMPLE 2: State IC Legislation

Some states have enacted statutes that directly authorize proprietary controls for the purpose of preventing use in conflict with environmental contamination or remedies. These state statutes divide into ones modeled after the Uniform Environmental Covenants Act (UECA)[226] and other non-UECA statutes.[227] These UECA and non-UECA state statutes tend to provide advantages over traditional common law proprietary controls by reducing certain legal and management complications associated with their use. The Model UECA, for instance, contemplates that the grantee or "holder" of the "environmental covenant" may be given specific rights or obligations with respect to future implementation of the environmental covenant.[228] This ability to oblige parties to undertake affirmative actions at a site, such as long-term maintenance of a cap or O&M of a vapor intrusion mitigation system, through a UECA environmental covenant, is different from traditional common law proprietary controls.

Proprietary controls that bind current and subsequent landowners (that is, the proprietary control "runs with the land") to use restrictions at properties, as well as oblige them to undertake affirmative obligations, may have utility at vapor intrusion sites. For instance, at a contaminated site in Bucks County, Pennsylvania, an environmental covenant executed pursuant to the Pennsylvania Uniform Environmental Covenants Act contained provisions to address vapor intrusion threats. In addition to provisions for access, annual inspections, compliance reporting, and other specifications related to cleanup activities, parties to the environmental covenant agreed to construct slab-on-grade buildings without basements and install vapor barriers as an engineered control to mitigate the potential for vapor intrusion as part of the eventual development of the property. Further, the environmental covenant provided that engineering plans for the vapor barriers first be submitted to and approved by EPA prior to construction. For examples of environmental covenants executed pursuant to the Pennsylvania Uniform Environmental Covenants Act, Act No. 68 of 2007, 27 Pa. C.S. §§ 6501-6517: http://www.depweb.state.pa.us/portal/server.pt/community/land_recycling_program/20541/uniform_environmental_covenants_act/1034860

[226] UECA was developed by the National Conference of Commissioners on Uniform State Laws. See: www.uniformlaws.org.

[227] See, for example, Colo. Rev. Stat. § 25-15-320 (2011); Cal. Civ. Code § 1471 (2011).

[228] "Grantee" is a traditional property law term describing a person to whom property is conveyed. States that have passed legislation based on UECA have created different legal concepts specific to those jurisdictions. For example, UECA jurisdictions typically define "holder" and "environmental covenant" to reflect, respectively, the grantee and the servitude that imposes the land or resource use restrictions. The model UECA provides that "[h]older means the grantee of an environmental covenant…" See definition 6 in Section 2.0 of the model UECA.

8.6.3 Selecting the Right Instrument(s)

When evaluating potential IC instruments, EPA recommends that site managers and site attorneys balance the relative advantages and limitations of IC instruments under consideration—for example, consider legal implementation issues, jurisdictional questions, permanence and enforceability concerns—and select those that best achieve the response objectives. (IC Example #3 describes how these factors were considered at the Middlefield-Ellis-Whisman Study Area.)

EPA guidance on ICs provides detailed considerations regarding the selection of ICs and the relative strengths of the different categories of IC instruments.[229] Ultimately, the selection of ICs is a site-specific evaluation based on the characteristics of the site (for example, the nature and extent of the vapor intrusion threat) and the particular jurisdiction in which it is located. There are times when multiple IC instruments can be "layered" to best ensure protectiveness of the response action while meeting the response objectives outlined in the decision documents.[230]

Because many ICs are created pursuant to state and other non-federal laws, the authority to implement and otherwise oversee these ICs resides with government entities other than EPA. Units of local governments, for instance, typically have jurisdiction to implement, maintain, enforce, and terminate certain governmental controls, such as zoning ordinances and building permit conditions. Therefore, it is important to evaluate the capacity (financial, technical, etc.) and willingness of the entity ultimately responsible for taking over IC responsibilities prior to IC selection.[231] Site managers and site attorneys are encouraged to coordinate early with IC stakeholders so that adequate assurances may be acquired and then subsequently maintained as necessary over time.

Given the potential role of non-EPA entities, it may be appropriate for EPA to facilitate or recommend a process by which IC stakeholders provide similar assurances or otherwise reach a common understanding[232] regarding their respective IC responsibilities to ensure that selected ICs are effectively implemented, maintained, and enforced. At a vapor intrusion site, for example, a zoning ordinance may be effective in preventing or ensuring responsible future development of properties overlying a contaminated groundwater plume that presents a vapor intrusion pathway threat. Such zoning ordinances generally are designed and enacted by the local government. Once enacted, the ordinance must be followed and enforced for it to serve as an effective IC over its lifespan. One inherent limitation of governmental controls, however, is that their implementation, modification, and termination generally follow a legislative process

[229] See Site Manager's IC Guide and Section 3.2 of the PIME IC Guide for a framework to consider when deciding among available ICs.

[230] See Section 3.2 of the PIME IC Guide for more discussion on layering ICs.

[231] See Section 3.8 of the PIME IC Guide on IC stakeholder capacity considerations.

[232] Parties may be able to provide assurances or otherwise reach a common understanding regarding their respective IC roles and responsibilities through various mechanisms that may be available under state law (for example, a Memorandum of Understanding, Memorandum of Agreement, Administrative Order on Consent, contract, City Resolution, or enforceable agreement, etc.). For additional discussion about obtaining or memorializing IC assurances, see Sections 3.3, 3.8, and 4.3 of the PIME IC Guide.

IC EXAMPLE 3: Efforts to Address VI at the Middlefield-Ellis-Whisman Study Area

The Middlefield-Ellis-Whisman (MEW) Study Area is composed of four separate CERCLA sites—Raytheon Corp., Intel Corp. (Mountain View Plant), Fairchild Semiconductor Corp. (Mountain View Plant), and portions of the former Naval Air Station Moffett Field Superfund site—and many distinct parcels with land uses including residential, commercial, and light industrial. In 2009, EPA finalized a Supplemental FS for the MEW Study Area that presented an evaluation of a variety of remedial alternatives that could be used to mitigate potential vapor intrusion into current and future buildings overlying the shallow plume of contaminated groundwater. The FS provided an analysis of ICs using the NCP evaluation criteria: overall protection of human health and the environment; long-term protectiveness and permanence; compliance with applicable or relevant and appropriate requirements; reduction of toxicity, mobility, or volume through treatment; short-term effectiveness; implementability; and cost. The other two NCP evaluation criteria, state acceptance and community acceptance, were evaluated in the ROD Amendment for the vapor intrusion pathway remedy at the MEW Study Area.

In 2009, EPA published the Proposed Plan for the MEW Study Area that identified EPA's preferred alternatives for the vapor intrusion remedy. The Proposed Plan identified the adoption of a municipal ordinance as EPA's preferred IC, but the City of Mountain View and concerned property owners raised concerns that this was not necessary. Instead, EPA worked with the City of Mountain View, California, to have the City formalize its permitting procedures that apply to future construction. These permitting procedures oblige those proposing new building construction within the MEW Study Area to obtain EPA approval of construction plans to ensure that, where necessary, the appropriate vapor intrusion control system is integrated into building construction. In a 2010 ROD Amendment, EPA presented its selected remedy for the vapor intrusion pathway for the MEW Study Area. The ROD Amendment identified a combination of ICs for use at the site. In place of a municipal ordinance as called for in the Proposed Plan, the ROD Amendment selected reliance upon the internally modified permitting procedures by the City of Mountain View's Building, Planning, and Permitting Departments. The City will also implement remedy requirements for projects subject to the California Environmental Quality Act through that law's procedures. With regard to existing commercial buildings where an active remedy is necessary, EPA selected the use of recorded agreements that will help provide notice to current and future owners and occupants, notice to EPA and the MEW Companies when there is a change in building ownership or configuration, and the necessary access to install, maintain and operate the vapor intrusion remedy. These agreements will be binding on and enforceable against future property owners. Additionally, EPA selected the use of a tracking service to provide notice when changes are made to properties within the MEW Study Area. Additional controls that will be implemented by the City of Mountain View include creation of a mapping database to help ensure that parties interested in properties within the MEW Study Area are informed of the appropriate construction specifications when making inquiries with the City.

For more information on the MEW Study Area, see the *Final Supplemental Feasibility Study for the Vapor Intrusion Pathway* (June 2009), *Proposed Plan for the Vapor Intrusion Pathway* (July 2009), and *Record of Decision Amendment for the Vapor Intrusion Pathway* (August 2010), available at: www.epa.gov/region9/mew

outside the authority of EPA that may raise questions regarding the reliability and continued sustainability of the IC. Obtaining early and continued assurances from a local government specifying its commitment to the governmental control is recommended to help address this limitation prior to its selection as part of a final cleanup plan.

Certain IC instruments may not be available for use at a site, depending on federal, state, local, tribal, or other applicable laws. Therefore, after determining the universe of ICs available for use at a particular site, the practical and legal limitations can be evaluated. For example, large sites with widespread contamination pose unique IC challenges. These challenges could arise, for instance, where a contaminated groundwater plume underlies many distinct parcels with multiple property owners/occupants and vapor intrusion is the exposure pathway of concern. Negotiating and implementing proprietary controls with many property owners, some of whom may not be PRPs, may present legal, administrative, and other challenges.[233]

8.6.4 Long-term Stewardship

Long-term stewardship (LTS) activities are intended to help ensure that cleanups remain protective of human health and the environment over time and that reuse activities remain compatible with residual site contamination and associated human health risk potentially posed by the vapor intrusion pathway. LTS procedures vary widely, but they generally are intended to help assure compliance with the response actions at the site, including IC compliance, by providing relevant information in a timely manner to stakeholders who may use the property (e.g., owners, excavators, developers, prospective purchasers or tenants) or to parties who otherwise have IC responsibilities (i.e., an entity with enforcement authority). LTS procedures, for example, may entail provisions to monitor and then inform those responsible for the response actions of potential changes in land use, ownership, tenancy, or building construction at a site. Also, LTS procedures may facilitate monitoring IC(s) so that they remain effective and reliable over time. EPA guidance on ICs generally speaks to LTS procedures in terms of IC maintenance[234] and enforcement activities.[235]

Periodic Reviews

A key part of IC maintenance is a periodic process over the IC life cycle to critically review and evaluate the IC instrument(s). Site managers and other stakeholders can evaluate the status of IC implementation, maintenance and enforcement activities at a site and address any potential IC deficiencies during the periodic review. The CERCLA FYR process,[236] for example, allows site managers to evaluate overall protectiveness of the remedy, including ICs.[237]

---

[233] See Section 4.4 of the PIME IC Guide for strategies for implementing proprietary controls.

[234] The term "maintenance" generically refers to those activities, such as monitoring and reporting, that ensure ICs are implemented properly and functioning as intended.

[235] See Sections 8 and 9 of the PIME IC Guide discussing IC maintenance and enforcement activities.

[236] See CERCLA section 121(c).

[237] For general FYR guidance, see *Comprehensive Five-Year Review Guidance* (EPA 2001) at www.epa.gov/superfund/cleanup/postconstruction/5yr.htm. For a more detailed discussion on IC considerations during the CERCLA FYR process, see *Recommended Evaluation of Institutional Controls: Supplement to the "Comprehensive Five-Year Review Guidance,"* (EPA 2011c).

A list of possible IC-specific issues arising from any periodic review of a vapor intrusion site may include:

- ICs that are specified by the decision documents but are not yet in place;
- ICs that are in place but are not attaining compliance with the use restrictions specified by the decision documents (e.g., land use not compatible with IC-specified use restrictions);
- ICs are not identified in the decision documents but are necessary for the remedy to be protective of human health because of the vapor intrusion pathway; and
- Response selection assumptions change (e.g., toxicity values, potential exposure pathways, or land uses change) and warrant the need for new or different response actions, including additional IC(s).

IC Planning Documents

Responsibilities to monitor and report on IC compliance, among other obligations, may be documented in an Institutional Controls Implementation and Assurance Plan (ICIAP)[238] or other IC-related planning documents.[239] An ICIAP can serve to: (1) document the activities necessary to implement and ensure the long-term effectiveness and permanence of ICs (that is, the IC life cycle); and (2) identify the person(s) or organization(s) who, under state or local law, are responsible for conducting those activities. Some ICs generally fall within the jurisdiction of a particular category of stakeholders. Therefore, in addition to developing a comprehensive planning document, such as an ICIAP, it may be useful for parties who share IC responsibilities (e.g., a PRP and local government regarding the use of governmental controls, such as an ordinance or permitting system) to reach a common understanding and acknowledge various IC roles and responsibilities in a formalized manner. Where possible, EPA recommends that these types of arrangements among IC stakeholders be documented to describe commonly understood roles and responsibilities for proper and effective monitoring, reporting, and other IC maintenance and enforcement activities.

8.6.5 Community Involvement and ICs

EPA recommends that site managers and site attorneys provide adequate opportunities for public participation (including potentially affected landowners and communities) when considering appropriate use of ICs (EPA 2012e). Those opportunities may include providing appropriate notice and soliciting comments about cleanup plans. Community acceptance of the need for ICs to provide protection from residual contamination and public understanding of the legal and administrative steps for maintaining ICs often are important to the long-term effectiveness of ICs.

---

[238] For further guidance on developing ICIAPs, EPA developed *Institutional Controls: A Guide to Preparing Institutional Control Implementation and Assurance Plans at Contaminated Sites* (EPA 2012e).

[239] For example, other types of documents may address IC-related activities and responsibilities at a site, such as a ROD, O&M plan, and land use control and implementation plan for federal facility sites.

8.7 Termination/Exit Strategy

This sub-section focuses on the termination/exit strategy for vapor mitigation response actions. Termination for vapor mitigation activities implemented under CERCLA, RCRA, Brownfields, and federal facilities cleanups can occur when the objectives of these cleanup activities have been met. For purposes of this sub-section, termination refers to the cessation of all activities related to building mitigation, control of subsurface vapor source(s), ICs, and monitoring.

When mitigating vapor intrusion through subsurface source remediation, building mitigation, and ICs, it is important to develop termination criteria, including the rationale for their selection, early in the remedy planning (e.g., alternatives development) process. (Termination criteria generally refer to numeric cleanup levels for each site-specific contaminant and narrative cleanup objectives that are to be attained by the response actions.) EPA recommends that these termination criteria be recorded in decision documents, in any other planning reports, and in monitoring reports. EPA generally recommends also developing and documenting an exit strategy, which clarifies how it will be determined that the termination criteria have been attained (e.g., monitoring data and associated statistics that will be used to demonstrate attainment). This document could be developed in conjunction with the O&M plan and monitoring program so that all stakeholders are provided with a clear and comprehensive set of termination criteria for the remediation and mitigation systems and ICs. If site conditions (e.g., building usage, vapor flux) change during the cleanup activities, it may become necessary to modify the termination criteria and/or strategy.

When reviewing vapor intrusion activities, considerations for evaluating termination activities may include:

- Termination of subsurface remediation activities;
- Termination of engineered exposure controls (building mitigation);
- Termination of the associated ICs; and
- Termination of monitoring.

8.7.1 Termination of Subsurface Remediation Activities

Where feasible, the preferred response to address vapor intrusion is to eliminate or substantially reduce the level of volatile chemical contamination in the source media (e.g., groundwater and subsurface soil) to levels that eliminate the need to mitigate or monitor vapor intrusion, as noted in Section 8.1 of this Technical Guide. If subsurface remediation activities are being conducted at the site, termination of these activities will be contingent on demonstrating that the chemical-specific cleanup levels for the subsurface media have been attained. EPA recommends that the termination criteria and exit strategy for these remediation activities be documented to foster collection and evaluation of appropriate data to support eventual termination of these subsurface activities.

EPA recommends that site-specific monitoring data be evaluated to determine if the termination criteria have been met. Typically, monitoring will continue until the source(s) are remediated to cleanup levels that eliminate the need to mitigate vapor intrusion at the point of exposure. As appropriate, the exit strategy may provide criteria for phased remediation, resulting in a

termination evaluation as source cleanup levels are achieved in parts of the contaminated area. If the subsurface vapor source(s) is not remediated, it is generally anticipated that remediation (and monitoring and any building mitigation) will continue.

Monitoring, in part, could be based on data similar to those that were used in a multiple-lines-of-evidence approach for characterizing the pathway and human health risk or for supporting the decision to undertake preemptive mitigation/early action (e.g., soil gas sampling, sub-slab sampling, or vapor sampling within potentially affected structures). EPA recommends identifying and documenting target concentration(s) that would allow for remediation termination, along with recommended monitoring/sampling frequencies.

If evaluation of the site-specific data indicates an increase in subsurface vapor concentrations during the monitoring period, it may be appropriate to evaluate whether the subsurface remediation plan and the CSM are adequate and appropriate.

Typically, once it is preliminarily determined that the subsurface remediation system(s) may be terminated, EPA recommends a period of attainment monitoring. During the attainment period, EPA recommends that the remediation system (e.g., reagent delivery equipment, soil vapor extraction wells) not be operated for a sufficient period to allow subsurface vapors reach equilibrium and indicate post-remediation conditions. The type and frequency of data collected during attainment monitoring entails a site-specific determination. Additionally, EPA recommends that criteria be described and documented, as part of exit strategy development, to determine when ending the attainment monitoring period is appropriate. To develop an exit termination strategy, site-specific fate and transport data may be used to identify an appropriate time period to allow the vapor concentrations to equilibrate. In addition, the termination of the attainment monitoring period may involve an evaluation of the contaminant attenuation in the vadose zone.

8.7.2 Termination of Building Mitigation

For purposes of this Technical Guide, “termination of building mitigation” refers to ending the use of an engineered exposure control(s) that reduces or eliminates human exposure via the vapor intrusion pathway. Typically, vapor mitigation is implemented when it is determined that (1) unacceptable human health risk to inhabitants is identified, or (2) the system(s) was(were) installed as part of an early action strategy (see Sections 3.3 and 7.8 for a discussion of building mitigation as an early action).

As described in Section 8.2, vapor intrusion can be mitigated in specific buildings using either an active or passive vapor mitigation system (or a combination thereof).

Active Building Mitigation

Generally, building mitigation systems are implemented in conjunction with the investigation and remediation of subsurface vapor source(s). Typically, building mitigation systems will be operated until the source(s) are remediated to attain the cleanup levels (e.g., for the subsurface vapor source(s)) that eliminate the need to mitigate vapor intrusion at the point of exposure. If subsurface vapor source(s) are not remediated, it is generally anticipated that mitigation activities will continue indefinitely. As appropriate, the termination strategy may provide criteria for phased evaluation of system cessation as source cleanup levels are achieved in parts of the contaminated area.

Generally, once the subsurface vapor source(s) is remediated to levels that meet the remedial objectives and protect human health from the vapor intrusion pathway, EPA recommends that the site-specific monitoring data be evaluated to determine if the termination criteria for the building mitigation system have been met. These monitoring data, in part, could be based on data similar to those that were used for characterizing human health risk or for supporting the decision to undertake preemptive mitigation/early action during the vapor intrusion investigation (e.g., sub-slab soil gas sampling and/or indoor air sampling). EPA recommends identifying and documenting target concentration(s) that would allow for system termination, along with recommended monitoring/sampling frequencies. In addition, certain site-specific performance assessment data (e.g., standpipe vapor sampling) may also warrant consideration to make this determination.

Typically, once it is determined that the building mitigation system may be terminated, EPA recommends a period of attainment monitoring. During the attainment period, EPA recommends that the mitigation system (e.g., subslab suction wells or ventilation fans) be offline for a sufficient period to allow vapors beneath the structure reach equilibrium and indicate post-remediation conditions. The type and frequency of data collected during attainment monitoring entails a site-specific determination. Additionally, EPA recommends that criteria be established in the exit strategy to determine when ending the attainment monitoring period is appropriate. To develop an exit termination strategy, site-specific fate and transport data may be used to identify an appropriate time period to allow the vapor concentrations to equilibrate. In addition, the termination of the attainment monitoring period may involve an evaluation of the contaminant attenuation in the vadose zone.

If the attainment criteria evaluation indicates that cleanup levels and objectives are not being met, it may be necessary to continue or resume subsurface remediation and mitigation activities. Once it is determined that the cleanup levels and objectives have been met, the active components of the system may be removed from the building; on the other hand, the building owner may elect to continue to operate the mitigation system under their own discretion and for their own purposes (e.g., radon reduction and moisture control). Once the cleanup levels and objectives have been met, all O&M and monitoring of active mitigation systems specified by EPA can cease.

Passive Building Mitigation

The termination of passive vapor mitigation systems will typically be similar to the criteria established for the termination of active mitigation systems. In summary:

- Like active mitigation systems, passive mitigation systems are typically implemented in conjunction with the investigation and remediation of subsurface vapor source(s).

- Generally, once the subsurface vapor source(s) is remediated to levels that meet the cleanup levels and objectives that will protect human health from the vapor intrusion pathway, EPA recommends that the site-specific monitoring data be evaluated to determine if the termination criteria have been met.

If the site-specific criteria evaluation indicates that cleanup levels and objectives are not being met, it may be appropriate to evaluate the current system's effectiveness or the possible application of an active mitigation system. Once it is determined that contaminant cleanup levels and objectives have been met, all O&M and monitoring specified by EPA can cease. EPA

generally does not have a need to seek removal of barriers or seals that comprise a passive mitigation system as part of termination activities.

8.7.3 Termination of ICs

"Termination of ICs," as used in this Technical Guide, refers to discontinuing any and all ICs specified by EPA because restrictions on land or resource use and/or notices and other informational devices are no longer necessary to help ensure protectiveness of human health (i.e., human health risk from exposures to vapor intrusion, if any, are expected to be acceptable in the absence of all IC(s)). Generally, ICs are implemented in conjunction with the investigation and remediation of source(s). It is anticipated that ICs selected and implemented will be needed until (1) subsurface vapor source(s) are adequately remediated, or (2) restrictions on land, resource, or building use are no longer necessary based on current and reasonably anticipated future exposure scenarios. Therefore, when developing a termination strategy for ICs that have been selected as part of a response action, the strategy is typically based on data collected from the affected media.

EPA recommends that the exit strategy consider and identify cleanup levels for the subsurface vapor source(s). As long as the subsurface vapor source exceeds such cleanup levels, it is generally anticipated that the associated ICs will continue. As appropriate, the termination/exit strategy may provide criteria for a phased IC termination evaluation as source cleanup levels are achieved in parts of the contaminated area.

If the site-specific criteria evaluation indicates that terminating the ICs is appropriate, EPA may conclude that site conditions no longer warrant ICs being used as part of the response action for the vapor intrusion pathway. At this point, EPA could notify the appropriate entity(s), such as local or state government, tribe, affected landowner, or responsible parties, in writing that EPA's response objectives have been met and that the IC need not be maintained. As such, EPA's oversight of the IC(s) can cease.

8.7.4 Termination of Monitoring

For purposes of this Technical Guide, monitoring includes activities conducted to verify that the vapor intrusion pathway does not pose a health concern to building inhabitants while remediation and mitigation activities are underway and in the event that the remediation and mitigation activities are terminated. "Termination of monitoring," for purposes of this Technical Guide, refers to ending any monitoring that was needed to verify that no further response action, including IC-related activity, is necessary to protect human health from indoor air exposures posed by vapor intrusion. When developing termination criteria for monitoring, the decision is generally based on data collected from all the affected media.

As noted above, monitoring is generally implemented in conjunction with the remediation of subsurface vapor sources(s). EPA recommends that the exit strategy consider cleanup levels for all contaminated media. Typically, monitoring will continue until the source(s) are remediated to cleanup levels that eliminate the need to mitigate vapor intrusion at the point of exposure (i.e., allow building mitigation systems to be terminated). If the subsurface vapor source is not remediated, it is generally anticipated that any associated monitoring will continue. As appropriate, the exit strategy may provide criteria for phased monitoring, resulting in a termination evaluation as source cleanup levels are achieved in parts of the contaminated area.

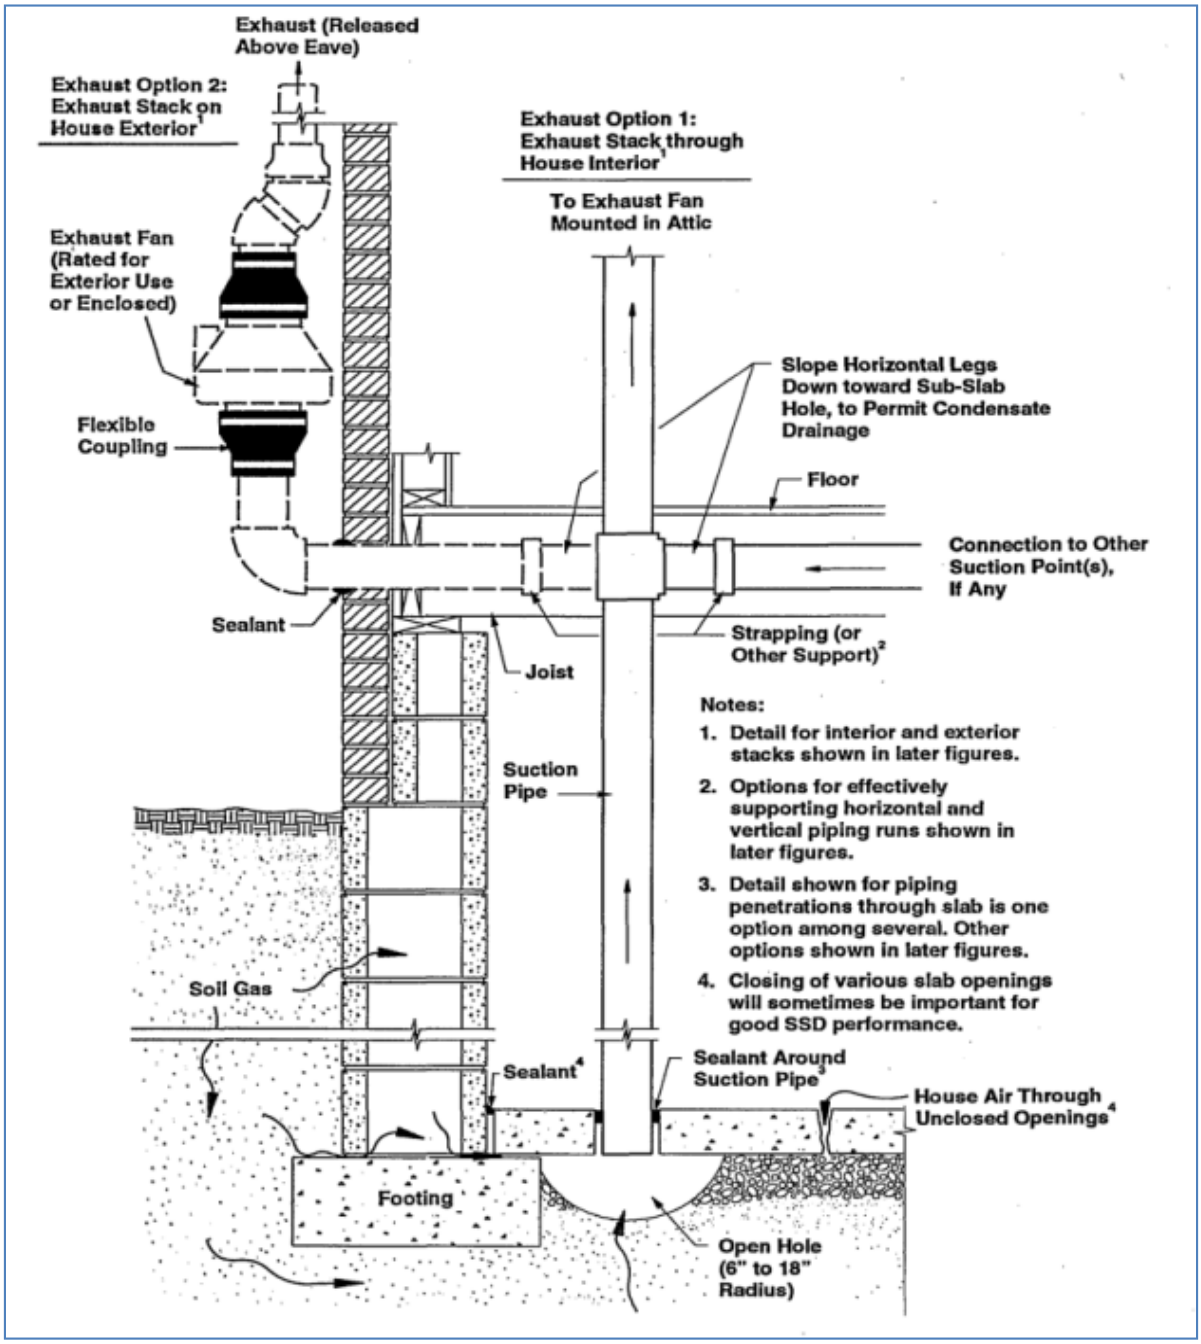

Figure 8-1 Illustration of Sub-slab Depressurization (SSD) System

Note: Shows one example of how a sub-slab depressurization system might be constructed. In this case, the example suction pipe has been inserted vertically downward through the slab from inside the house. Two options are indicated for location of the exhaust fan: one exterior to the building; and the other within an attic. In both of these cases, the exhaust gas stream is to be vented outside and above the building.

9.0 PLANNING FOR COMMUNITY INVOLVEMENT

Communicating information about environmental risk is one of the most important responsibilities of site managers and community decision-makers. Simply stated, risk communication, whether written, verbal, or visual statements concerning risk, is the process of informing people about potential and perceived hazards to their person, property, or community.

EPA recommends that human health risk be described in context, recognizing there are personal, cultural and societal dimensions of risk. EPA also recommends providing advice about risk-reduction behavior and encouraging a dialogue between the sender and receiver of the message. The best risk communication occurs in contexts in which the participants are informed about risks they are concerned about, the process is fair, and the participants are free and able to solve whatever communication difficulties arise. *Risk Communication in Action: The Risk Communication Workgroup* (EPA 2007) is one of several resources available that explain the elements of successful risk communication and describe communication tools and techniques.

Thus, community involvement is a key component of any site investigation or other EPA response action. Members of the public affected by environmental contamination can be made aware of what EPA is doing in their community and have a say in the decision-making process. Stakeholder and community involvement is particularly important for sites with vapor intrusion issues, in part because the exposure to toxic vapors may pose a significant human health risk that is unknown to inhabitants (in the absence of mitigation systems), as they potentially arise in homes, workplaces, schools, and places of commerce and gathering. Because of the potentially intrusive nature of assessment and mitigation for vapor intrusion, stakeholder involvement is important throughout the process.

EPA generally recommends that stakeholder and community involvement be conducted from the earliest stage of the site assessment and risk assessment process, with on-going education, two-way communication, and discussion throughout the entire process to create community trust and acceptance. For example, EPA recommends initiating community involvement activities as soon as possible after determining that vapor intrusion may exist at a particular site.

Informing the community about vapor intrusion concerns and plans to conduct an assessment, including sampling, can be resource intensive. Thus, EPA recommends evaluating each project, in coordination with appropriate state and tribal officials, to assess the level of stakeholder interest and need for community involvement during various stages of the decision-making process.

Public Participation and Risk Communication

A meaningful community involvement process is founded upon knowledge of effective public participation and risk communication practices. Public participation refers to the full range of activities that EPA uses to engage communities in the Agency's decision-making process. In 2003, EPA updated its Public Involvement Policy.[240] Its foundation includes seven basic steps to support effective public participation:

[240] EPA Public Involvement Policy (2003): http://www.epa.gov/publicinvolvement/policy2003/index.htm.

1) Plan and budget.

2) Identify those to involve.

3) Consider providing assistance.

4) Provide information.

5) Conduct involvement.

6) Review and use input and provide feedback to the public.

7) Evaluate involvement.

To help implement the steps, EPA developed a series of brochures[241] on effective public participation that outline how to budget for, plan, conduct, and evaluate public participation.

EPA Program-Specific Community Involvement Guidance and Recommendations

CERCLA and other EPA regulations[242] identify specific community involvement activities that are appropriate at certain points throughout the cleanup process. Specifically, in 2005, OSWER published the *Community Involvement Handbook*[243] (EPA 540-K-05-003). The handbook presents legal and policy motivations for Superfund community involvement and includes additional suggestions for involving the community in the Superfund process. In addition, EPA's *Proposed Guidelines for Brownfields Grants* encourages applicants to describe their plans for involving community-based organizations in site cleanup and reuse decisions.[244] The *Grant Funding Guidelines for State and Tribal Response Programs* for brownfields funding also encourage programs to establish, at a minimum, "mechanisms and resources to provide meaningful opportunities for public participation."[245] In addition, in 1995, EPA promulgated the *RCRA Expanded Public Participation* rule (60 FR 63417-34, December 11, 1995)[246] which created additional opportunities for public involvement in the permitting process and increased access to permitting information.[247]

[245] EPA Brownfields State and Tribal Response Program Grants website: http://www.epa.gov/brownfields/state_tribal/fund_guide.htm

[246] Section 7004(b) of the Resource Conservation and Recovery Act provides EPA broad authority to encourage and assist public participation in the development, revision, implementation, and enforcement of any regulation, guideline, or program under RCRA.

[247] EPA *RCRA Public Participation Manual*: http://www.epa.gov/osw/hazard/tsd/permit/pubpart/manual.htm

At sites with vapor intrusion issues, EPA recommends that the site planning team (i.e., the remedial project manager (RPM) or on-scene coordinator (OSC); community involvement coordinator (CIC); risk assessor; the enforcement case team; EPA contractor; state, tribal, or local agency staff; federal agency staff relevant to the site; or others) to consider the following:

- Develop a community involvement plan (CIP) or update the existing CIP.
- Learn about the site and the community to foster development of a CIP that highlights key community needs, concerns and expectations.
- Commit to ongoing, sustained communication activities throughout vapor mitigation and site cleanup efforts.
- Develop a communication strategy[248] and conduct outreach to inform stakeholders about the facts and findings pertaining to the site.
- Obtain written permission, if appropriate and necessary, for building/property access, and involve the property owner/occupant in identifying or removing potential indoor air contamination sources, including inspection of residence and completing an occupant survey.
- Fully communicate and interpret sampling results, and evaluate mitigation options, if any are warranted.
- Recognize preference of owners and occupants for confidentiality with regards to property-specific data.

When considering the most effective community involvement strategies, EPA recommends that its previous involvement be considered, as well as the existence of community or neighborhood groups and the phase of the regulatory process in which vapor intrusion is being addressed. Additional resources for planning and implementing effective community involvement activities are discussed in Section 9.2: Communication Strategies and Conducting Community Outreach.

9.1 Developing a Community Involvement or Public Participation Plan

A CIP is a site-specific strategy to enable meaningful community involvement throughout the cleanup process.[249] CIPs specify EPA-planned community involvement to address community needs, concerns, and expectations that are identified through community interviews and other means. A CIP will enable community members to understand the ways in which they can participate in decision-making throughout the cleanup process. That is, the CIP is a way for EPA to plan for informing and involving the community in the cleanup process and can be a powerful

[248] A communication strategy can be one component of a CIP, but it addresses a specific event, issue, or concern, such as an emergency response to a release, or communicating risk at a site. The CIP, on the other hand, describes an overall strategy for conveying information throughout the cleanup process at a site.

[249] Community involvement plans available at: http://www.epa.gov/superfund/community/pdfs/toolkit/ciplans.pdf

way to communicate EPA's commitment to listening and responding to community concerns, and provide timely information and opportunities for community involvement.

The CIP is intended to be a "living" document and is most effective when it is updated or revised as site conditions change. When developing the CIP document, EPA recommends that the site planning team consider the following steps:

Describe the Environmental Setting and Cleanup Process

Describe the release and affected areas (the site). This includes information about the site, its history, the key issues related to site contamination, and how vapor intrusion fits into EPA's overall cleanup effort at the site.

Describe and Learn about the Community

Describe the community. The community profile is a description of the affected community that summarizes demographic information and identifies significant subgroups in the population, languages spoken, and other important characteristics of the affected community, such as whether the site is located in an area with environmental justice concerns or includes sensitive populations. EPA recommends that the community profile also document information sources and describe how the profile was developed.

Learn about community needs, concerns and expectations: Issues of concern to residents and business owners can be identified through community interviews, informal discussions and interactions, local media reports, and other insights about the affected community. Questions may include:

- What are public perceptions and opinions of EPA and the cleanup process?
- How do people want to be kept informed (i.e., mechanisms to deliver information)?
- How do people want to be included in the decision-making process?
- What are the perceived barriers to effective public participation?
- Are there other sources of pollution that affect the community?
- Have there been past experiences of mistrust or any unique concerns?

This information can be used to recommend any special services to be provided, including technical assistance, formation of a Community Advisory Group, facilitation/conflict resolution, or translation services.

Write and Compile the CIP

Once the site planning team has learned about the community, it is time to put the information together in a way that will be useful to EPA and the community. In addition to the site description, community description, and community needs and concerns, the CIP also may include a reference listing of contacts (name, address, phone, email) useful for the

community or the site planning team. EPA recommends that the contact list generally include contact information for:

- The site planning team.
- Community groups and community leaders.
- Local elected officials.
- Local, state, tribal, and federal agency staff relevant to the site.
- Media contacts (including social media outlets and community journalists).
- Others, as appropriate.

To ensure that the CIP is indeed informed by the community, EPA recommends that a draft of the CIP be shared with the community, and their input and feedback be invited as it evolves. Again, the CIP is intended to be a "living" document and is most effective when it is updated or revised as site conditions change. In some cases, particularly when the CIP is updated or revised for a FYR or where community interest is minimal, a short CIP outlining EPA's plan for community involvement may be all that is needed. For most sites, EPA recommends that the CIP be written to address the community directly, and their active involvement be invited at each stage of the cleanup process.

9.2 Communication Strategies and Conducting Community Outreach

EPA recommends that community outreach activities be initiated as soon as possible after determining that vapor intrusion may exist at a particular site. Informing and educating the community includes distributing information and providing opportunities for EPA to listen to community concerns. EPA recommends community outreach activities be tailored to the community based on information gleaned from community interviews and other methods used in developing the CIP. Public health officials from state, tribal, or local agencies may be helpful in communicating risk information and answering questions from the community.

Communication Strategies

Communication strategies are plans for communicating information related to a specific issue, event, situation, or audience. They serve as the blueprints for communicating with the public, stakeholders, or even colleagues. EPA recommends that communication strategies:

- Outline the objective and goals of the communication.
- Identify stakeholders.
- Define key messages.
- Pinpoint potential communication methods and vehicles for communicating information and obtaining information from the community for a specific purpose.

When developing a communication strategy, the first step is to determine why the communication is necessary and define its desired objectives, and then to focus on defining the audiences and how to reach them. Keep in mind that the demographics, knowledge, and concerns of the audiences play an important role in defining the key messages. Once the key messages are defined, the outreach vehicle can be determined.

Conducting Community Outreach

The site planning team likely will use several different outreach techniques during the course of the cleanup process. When planning community outreach, EPA generally recommends that the site planning team collaborate with internal and external partners, such as local, state, and tribal officials and departments of health; faith-based organizations; and community groups. It is important to accommodate hearing-impaired or limited English proficiency (LEP)[250] persons in all outreach efforts by providing spoken or sign language interpreters at meetings and translating printed outreach materials. It also is important to ensure that the community understands the concept of vapor intrusion.

Examples of community outreach techniques to consider are described below.

Public Meetings/Gatherings

Public meetings are a useful opportunity to explain environmental conditions at the site, potential health impacts, intended indoor air sampling, and remediation strategies. It may be helpful to hold meetings prior to and following key sampling events to describe sampling strategies and consequent results, respectively. EPA recommends that the meeting include a period to address specific questions from the public regarding sampling results or any other specific concerns, as well as visual aids and maps and spoken or sign language interpreters to facilitate communication and discussion. The use of a CSM, for example, is useful in public meetings to graphically reinforce the messages. It may be helpful to follow up with meeting participants to inquire about the effectiveness of the meeting and whether it met their needs. Other meeting follow-up activities could include responding to requests for information, distributing meeting notes, and creating a mailing list.

Additional opportunities for the site planning team to communicate with the community in a group setting include public availability sessions and public forums or poster sessions at community group meetings or neighborhood board meetings. These options are a more informal way of interacting with community members and they allow a casual “question and answer” or discussion format as compared to the more formal presentation at a public meeting.

Mass Media

The media can be the best means of reaching a large audience quickly. Extending invitations to the media for important meetings, providing opportunities for media questions

[250] Executive Order 13166, *Improving Access to Services for Persons with Limited English Proficiency*, directs federal agencies to examine the services they provide, identify any need for services to those with LEP, and develop and implement a system to provide those services so LEP persons can have meaningful access to them.

to be addressed in a timely manner, and recognizing that the media control the content of their publications all are important considerations when working with the media. The site planning team can work with the Agency's regional site press officer to foster a relationship with the media by sharing the Agency's rationale for its plans and actions. It is appropriate to use the media to publicize a site-related decision, an upcoming meeting, changes in schedule, or changes in activities or expectations. Press releases can be used to inform the media of major site-related milestones.

Fact Sheets

Communities appreciate concise, easy-to-understand, and technically accurate fact sheets on the history of the contamination, chemicals of concern, human health risk, planned cleanup activities, and the vapor intrusion assessment and response actions. Be sure to include who to contact for more information.

Because sites involving vapor intrusion can be complex, it may be useful to include additional information in the fact sheets for home owners and renters, including information about household products that may be potential sources of indoor air contamination, as well as steps that can be taken to minimize these sources. EPA recommends preparing and distributing periodic status updates and fact sheets to concerned community members throughout the cleanup process.

Letters

Whenever there are plans to conduct indoor air sampling, EPA recommends sending a letter to each building owner and renter explaining plans to conduct indoor air sampling and requesting written permission for voluntary access to do so. In addition, a one-on-one meeting with the building owner or renter is generally recommended to discuss sampling efforts and access agreements in detail (see Section 9.3).

EPA also recommends that letters be sent to each building owner and renter to report sampling results in a timely manner (see Section 9.4). These letters and meetings often are part of a larger effort that also includes use of other communication strategies, such as community meetings and in-person visits.

In-person Visits

EPA recommends individual, one-on-one communication with each property owner and renter whenever possible.

- Try to schedule in-person visits with individual property owners and renters. These visits also may include owners and renters of properties located outside the planned investigation area. The initial visit can be used to explain sampling plans in more detail, answer questions, and obtain written permission to sample.

- During the visit, the property owner or renter can be briefed about any instructions to follow during sampling activities (for example, keep doors and windows closed during sampling). A general survey of the building could be conducted to determine likely sources of indoor air contaminants.

- EPA recommends the site planning team also describe to owners and renters the sampling devices that will be used, what they look like, where they will be located, and any restrictions or impediments to daily activities that may arise from the ongoing sampling activities.

Information Repository

An information repository can be established and maintained prior to, during, and following site activities, which is generally required for sites where remedial action or removal actions (where on-site action is expected to exceed 120 days) are undertaken pursuant to CERCLA. The information repository is intended to include the administrative record, fact sheets, question-and-answer sheets, and other site-related documents and be located reasonably near the site. However, given the tremendous change in information technology, it may also be appropriate to set up an Internet-based or digital repository (webpages) to share key information. This depends on the community's ability to access and utilize this technology. EPA recommends that community members be made aware of the information repository through the other public outreach mechanisms described above (e.g., local media, newsletters, and public meetings).

Electronic Notification

It also may be useful to establish a registration capability that allows interested community members to sign up for automatic alerts to updates posted on the site website or email listserv.

9.3 Addressing Building Access for Sampling and Mitigation

EPA recommends that all requests for access, as well as provision of access, be in writing in order to document EPA's due diligence to protect human health at the site. EPA recommends that the site planning team provide building owners and occupants with information about the sampling device(s)) being used, including what they look like, where they will be located and any restrictions or impediments to daily activities that may arise due to ongoing sampling.

In the case of an initial refusal to provide access, additional attempts for access are generally recommended, although regional practices may vary. EPA recommends documenting all attempts to gain access, for example using telephone conversation records, emails, or letters sent to home or building owners.

Gaining access to owner-occupied residences for vapor intrusion sampling and mitigation may be handled differently than for commercial buildings or rental properties.

Owner-Occupied Residences: Allowing EPA to sample or install mitigation systems in an owner-occupied residence is a voluntary action. EPA generally encourages owners to take advantage of an offer for an assessment and mitigation system, if necessary.

Rental Properties: Access may be voluntary or involuntary. Site planning teams often deal with both owners and renters when there is a need to sample on, in, or under a rental property. There are different legal and communication issues for owners and renters. For example, the owner is responsible for granting access for sampling and for installation of mitigation measures, if they are necessary; however, if the owner grants access, logistics normally are

arranged with the renter. EPA recommends apprising both the owner and the renter of human health risk that may be posed by vapor intrusion, which includes providing building-specific sampling results to both parties when available. If the owner of a rental property refuses access, EPA may, nevertheless, pursue access, in the interest of protecting the occupants, for determining the need for response, choosing a response action, taking a response action, or otherwise enforcing CERCLA or RCRA (EPA 1986, 1987, 2010a). Notifying the owner of a rental property of this statutory authority may help to avoid the need for legal action.

Nonresidential Buildings: Site managers also may need to sample on, in, or under nonresidential buildings, such as schools, libraries, hospitals, hotels, and stores. In these situations, broader outreach to the public may be appropriate in addition to maintaining direct contact with the property owner. Similar to rental properties, access for sampling and for implementation of mitigation methods, if they are necessary, may be voluntary or involuntary. If the owner of a nonresidential building refuses access, EPA may, nevertheless, pursue access, in the interest of protecting the occupants, for determining the need for response, choosing a response action, taking a response action, or otherwise enforcing CERCLA or RCRA (EPA 1986, 1987, 2010a).

Property Ownership Changes: For owners of homes or buildings who did not provide access for assessment sampling or installation of a mitigation system, EPA recommends that the site planning team make reasonable attempts to track ownership changes, although the appropriate state, tribal, or local agency or PRP may be in a better position to track this information. For example, reasonable attempts to make contact can be done by annually conducting drive-bys or inspections and noting homes or buildings for sale, periodically checking on-line real estate sales or title insurance listings, or using other mechanisms. Homes that were initially targeted but not sampled can be reconsidered during the review or if there are major changes to the toxicity values for the site contaminants of concern. Annually mailing notifications to buildings not previously sampled is a means to foster reconsideration of testing with a change in ownership. If ownership changes are noted, appropriate follow-up can be conducted with the new home owner or building owner.

Federal statutory authority to access private property to conduct investigations, studies and cleanups pursuant to CERCLA and RCRA is discussed in Section 1.2 of this Technical Guide.

9.4 Communication of Indoor Sampling Efforts and Results

The community involvement plan or public participation plan is intended to address community concerns and participation regarding indoor air and sub-slab sampling. In addition to the general community involvement activities occurring throughout the cleanup process (see Section 9.2), the site planning team may choose to hold a community meeting to discuss indoor sampling efforts and results. EPA recommends sending a letter to each home or building owner and renter explaining plans to conduct sampling or providing sampling results. EPA recommends that this letter be in addition to a one-on-one meeting with the building or home owner to discuss access agreements, sampling efforts, and sampling results. Prompt communication of sampling results to building or home owners is important as some people may choose to make precautionary decisions prior to regulatory decisions on remediation or mitigation measures.

EPA recommends the site planning team inquire about stakeholder preferences for confidentiality with regards to property-specific data. It may be appropriate to segregate data for private residential properties versus community properties (e.g., schools, daycare centers,

commercial buildings) or provide different types of property identifiers for these respective building types in reports and maps and tables displayed at public meetings or otherwise made available to the community.

Letters Transmitting Sampling Results[251]

EPA recommends that the site planning team provide validated sampling results and interpretations (e.g., chemicals of concern, associated risk assessment implications) in plain English (and translations, if necessary) to property owners and renters in a timely manner (e.g., within approximately 30 days of receiving the results). EPA also recommends the transmittal letter indicate what future actions (e.g., mitigation options), if any, are contemplated,[252] based on the sampling results, and contain additional site-specific and possibly building-specific information, including, but not limited to:

- Site and Home/Building Information.
  - Site name and location of contamination.
  - Date of sampling.
  - Address of sampled home or building.
  - Locations sampled (both indoor and outdoor).

- Sampling Results
  - Sampling results for site-related, vapor-forming chemical(s) and for any other chemicals, if detected, including an explanation of results believed to be attributable to background sources, if known.[253]
  - Risk-based screening levels (for example, VISLs described in Section 6.5) or other risk-based benchmarks used to explain and interpret the sampling results.
  - Explanation and interpretation of sampling results, if known, which may include a summary of the human health risk assessment, if available (see Section 7.4).[254]

[251] Within the community of risk professionals, the phrase 'risk communication' has come to mean communication that supplies lay people with the information they need to make informed independent judgments about human health risk or public safety (Morgan et al. 1992). In this case about vapor intrusion, the ultimate goal of risk communication is to assist stakeholders and the general public in understanding the investigation data and the rationale behind any risk-informed decision, so they may arrive at a balanced judgement that reflects the factual evidence in relation to their own interests and values.

[252] This section may include an explanation of mitigation process and responsibilities and a timeline for further contact regarding system installation and options. If a building mitigation system is recommended on the basis of a human health risk assessment, EPA recommends that the site planning team explain that the risk calculation reflects conservative, health-protective factors.

[253] With such information, EPA can help advise citizens about the environmental and public health threats they face that are within their control (e.g., from indoor sources). In cases where 'background' contamination may pose a human health risk, but its remediation is beyond the authority of the applicable statute, risk communication to the public may be most effective when coordinated with public health agencies (EPA 2002e). The public may also be advised about the scope and limits of EPA's statutory authorities.

[254] Assessment uncertainty is generally an important factor in deciding how to act (Frewer 2004); i.e., whether to reduce risk through response action or reduce uncertainty (e.g., through additional monitoring and data collection). Risk professionals, therefore, generally recommend that risk communication to stakeholders and the general public characterize the sources of uncertainty, as well as the magnitude of uncertainty associated with a particular hazard (see, for example, Frewer (2004) and Markon and Lemyre 92013)).

  - Simple tabulated and color-coded results (representing exceedances of human health risk levels or no exceedance).

- Diagrams/Illustrations
  - Diagrams and illustrations of sampling devices.
  - Diagrams and illustrations of sampling locations
  - Diagrams of specific mitigation systems (e.g., how a SSD system works and looks).

- Next Steps
  - Actions that property owners and occupants can take to reduce vapor intrusion exposure until mitigation systems are in place.

- Information Sources
  - Contact information for a person who can answer questions or supply further explanations.
  - The location of the site information repository or site website can be included as a resource for public access to more detailed information and site documents.

9.5 Transmitting Messages Regarding Mitigation Systems

The initial notification to residents or building owners about mitigating vapor intrusion can be delivered in various ways. A primary mechanism is a face-to-face meeting with the building owner or occupant to explain the sampling results and discuss next steps, including installation of a vapor intrusion mitigation system. EPA recommends that this meeting include a member of the site planning team (RPM or OSC and risk assessor, for example), a representative from the local health department or the Agency for Toxic Substances and Disease Registry (ATSDR), and the mitigation contractor scheduler. This meeting could discuss topics such as:

- Sampling Results: Describe where samples were taken and the chemicals of concern, and explain the results as related to site action levels. Any questions related to human health risk can be answered by the risk assessor or public health representative at this time. For questions or concerns regarding personal health, EPA recommends that residents and building owners contact their medical professional.

- Mitigation System Details: Describe the need for a mitigation contractor to visit the residence to identify potential locations for the mitigation system. The property owner will need to be present for the visit and will have input about where the system is installed, if they agree to install such a system. Photos of a mitigation system (piping, system fan, number of holes drilled in the slab, height of the vent on the outside of the residence, etc.) may be helpful. EPA recommends that plans and schedules for periodic inspection, maintenance, and monitoring also be described.

- Access: EPA recommends advance planning to ensure building access to install, monitor and maintain any mitigation system. Arrangements could be made at this meeting to sign an additional access agreement for these activities, if needed.

- Cost of the Mitigation System: Identify which party will pay for installation of the mitigation system and anticipated property-owner costs. For example, EPA or a PRP may pay for the

system installation, and the property owner or PRP may take responsibility to pay for the monthly costs associated with the mitigation system.

- Project Schedule and Next Steps: The meeting may be concluded by giving an overview of the overall project timeline, including the appointment for the mitigation contractor visit and system installation.

Notification also can be provided through the data transmittal letter. In many cases, however, the decision to install mitigation systems will not have been made prior to the transmittal of sampling results. In these situations, data transmittal letters can convey that EPA is reviewing all data results for the affected area and considering appropriate next steps. Once the decision document is signed, the site planning team can develop and mail a fact sheet to all community members in the affected area, followed by a community meeting.

In addition, if a vapor intrusion mitigation system is installed, EPA recommends that the property owner or renter be informed that the system normally is designed to protect the home or building only against vapor-forming chemicals coming from the subsurface. A vapor intrusion mitigation system generally will not protect the home against continuing indoor sources because vapor intrusion mitigation systems typically are not indoor air filtration systems.

EPA recommends that current owner-occupants be advised that if they decline or waive an offer to install a vapor mitigation system, they might be responsible for the costs of installing and maintaining their own system if they decide to do so at a later time. EPA also recommends documenting any declination or waiver.

9.6 Addressing Community Involvement at Legacy Sites

Ongoing site activities with assessment components, such as remedial investigations and monitoring, allow EPA to continually evaluate site conditions and adjust cleanup actions as warranted. During periodic reviews or conducting other site activities, such as the FYR pursuant to CERCLA, EPA has evaluated vapor intrusion where appropriate. In some instances, EPA has newly identified vapor intrusion as an exposure pathway. These mature or “legacy” sites present a unique challenge to site planning teams.

Conducting community involvement at legacy sites may be complicated by several factors including:

- A remedy for the control of exposure to volatile chemicals already has been installed, proposed, or is under construction as part of the cleanup plan.

- Ownership of properties previously exposed to VOCs has changed hands through resale, foreclosure, or assumption of the property by second-generation homeowners. These owners were not part of any original resolution of exposure issues and in many cases may not be aware that a remediation or treatment was put in place.

- Property owners and other community members who participated in prior cleanup efforts may be reluctant to fully engage with efforts to reopen lines of investigation at their properties.

In these and similar circumstances, the challenge for Agency representatives is to resume contact with communities who have put past difficulties behind them. In many cases, mailing lists are outdated, previous reliable contacts no longer are available, and elected officials may not have institutional memory of the events that prompted the remediation.

Strategies for Revitalizing Community Involvement at Legacy Sites

Every legacy re-entry will be a site-specific situation. Therefore, EPA recommends that events and activities be planned to acknowledge and accommodate the inevitable changes in the makeup of a community. In addition to the communication strategies and community involvement techniques described in Sections 9.1 through 9.5, additional suggestions to ease re-entry and revitalize community involvement at a legacy site include:

- Reassess the community and the site by revisiting the site and the surrounding areas and taking note of new construction.
- Reintroduce yourself and the Agency to current municipal staff and check previously used public venues for viability. Determine if new venues may be closer or more accessible to the community.
- If contacts within the community are still extant, reconnect; ask for updates on the growth and stability of the community. If no viable contacts exist, attempt to cultivate new ones.
- Revise and update mailing lists and fact sheets.

As with all sites affected by vapor intrusion issues, be prepared to meet with property owners door to door and to hold public meetings or forums to explain the current investigation and its importance to protecting human health.

9.7 Property Value Concerns for Current and Prospective Property Owners

EPA recognizes that vapor intrusion impacts may have implications for property values. In some instances, mitigation systems and other clean-up measures may help to restore property values.

Nevertheless, property value issues are outside the scope of Agency authority. In general, if asked, EPA recommends that regional staff suggest that prospective buyers and sellers contact real estate professionals and lenders from the local area with questions about property values. If a home owner or renter has questions about vapor intrusion mitigation systems, EPA regions can provide information that explains how vapor intrusion systems are designed to reduce exposure to chemicals found in indoor air and to avert human health-related problems.

9.8 Additional Community Involvement Resources

EPA's Superfund Community Involvement Program:

EPA's Superfund Community Involvement website contains many resources that may be helpful for planning community involvement activities for other cleanup programs. This resource includes a list of regional Superfund community involvement points of contact, a list of technical

assistance and training resources, and descriptions and links to community involvement policies, guidance and publications (see http://www.epa.gov/superfund/community/).

EPA's Superfund Community Involvement Toolkit (CI Toolkit):

While targeted to a Superfund Program audience, the CI toolkit may be helpful to a wide variety of users because it is a practical, easy-to-use aid for designing and enhancing community involvement activities and contains tips on how to avoid some of the pitfalls common to the community involvement process. The toolkit enables users to quickly review and adapt a variety of community involvement tools to engage the community during all stages of the cleanup process. Relevant tools include tips for conducting public availability and poster sessions and public meetings, developing fact sheets, working with the media, planning communication strategies, developing a Community Involvement Plan, and establishing an information repository (see http://www.epa.gov/superfund/community/toolkit.htm).

EPA's Community Engagement Initiative:

The OSWER CEI is designed to enhance OSWER and regional offices' engagement with local communities and stakeholders to help them participate meaningfully in government decisions on land cleanup, emergency preparedness and response, and the management of hazardous substances and waste (see http://www.epa.gov/oswer/engagementinitiative/).

10.0 GLOSSARY

The following definitions are provided for purposes of this Technical Guide:

accumulate ..... Increase gradually in amount as time passes. Note that there will be a finite maximum amount, which will be determined by site- and building-specific conditions and will reflect a balance among physical processes (e.g., soil gas entry, air exchange).

active ..... Involving mechanical operations; Compare with *passive*.

active depressurization technology..... Vapor intrusion mitigation method that creates a driving force for air flow from the building into the subsurface by lowering the pressure below the slab, thereby reducing vapor intrusion (soil gas entry into a building).

acute ..... Refers to repeated or single exposure for 24 hours duration or less. Compare with *short-term* and *subchronic*.

advection ..... As it pertains to soil gas, refers to bulk movement in the vadose zone induced by spatial differences in soil gas pressure. The direction of advective vapor transport is always toward the direction of lower air pressure.

aerobic ..... Describes a process or activity requiring oxygen. Compare with *anaerobic*.

air exchange rate ..... Rate of air infiltration into a building through windows, doorways, intakes and exhausts, 'adventitious openings' (e.g., cracks and seams that combine to form the building envelope), plus natural and mechanical ventilation.

ambient air ..... The outdoor air surrounding a building or site.

anaerobic ..... Describes a process or activity requiring the absence of oxygen. Compare with *aerobic*.

analyte..... A substance for which identification (of presence) and/or quantification (of amount, such as concentration) is/are sought by instrumental measurement.

attenuation ..... Decrease in vapor concentration in soil gas emanating from a subsurface vapor source along the migration route towards and into a building (indoor air)

attenuation factor..... The ratio of the indoor air concentration arising from vapor intrusion to the soil gas concentration at the source or a depth of interest in the vapor migration route.

background ..... Refers to a vapor-forming chemical(s) or location(s) that is(are) not influenced by the releases from a site, and is usually described (EPA 1989, 1995c, 2002e) as naturally occurring or anthropogenic: 1) *Anthropogenic* – natural

	and human-made substances present in the environment as a result of human activities and not specifically related to the site-related release in question; and, 2) *Naturally occurring* – substances present in the environment in forms that have not been influenced by human activity. Background may include a vapor-forming chemical(s) present in indoor air due to human activities that is(are) not related to vapor intrusion or site-related contamination.
background vapor concentration	This term may include the concentration of a vapor-forming chemical in indoor air that fits within the definition of "background" above. Information on background concentrations of vapor-forming chemicals in indoor air "is important to risk managers because generally EPA does not clean up to concentrations below natural or anthropogenic background levels" (EPA 2002e).[255]
background vapor source.....	The origin(s) and location(s) of a vapor-forming chemical(s), other than vapor intrusion, and not associated with or emanating from a site-related release(s) to the environment. Background vapor sources may include indoor or outdoor sources. See also *indoor vapor source, outdoor vapor source,* and *background vapor concentration;* compare to *subsurface vapor source*.
biodegradation.....	Decomposition or breakdown of a substance through the action of microorganisms (such as bacteria or fungi).
brownfield	A parcel of real estate that is abandoned or inactive or may not be operated at its fully beneficial use and on which expansion or redevelopment is contemplated or reasonably expected; distinguished from "greenfield" because expansion or redevelopment may be complicated by the presence of vapor-forming chemicals in the subsurface environment.
building.....	a structure that is intended for human occupancy and use. This would include, for instance, homes, offices, stores, commercial and industrial buildings, etc., but would not normally include sheds, carports, pump houses, or other structures that are not intended for human occupancy.
building survey.....	Refers generically to gathering -- by observation, interviews, reviewing documents and records or other means -- information about existing buildings, including,

[255] It should, however, be noted that some EPA regulations (e.g., indoor radon standards under 40 CFR 192.12) are inclusive of background.

	but not limited to, location, use, occupancy, basic construction (e.g., foundation type), heating ventilation and cooling systems, potential indoor sources of vapor-forming chemicals, and anticipated susceptibility to soil gas entry (e.g., presence of radon mitigation system).
capillary fringe	The porous material just above the ground water table which may hold water by capillarity (a property of surface tension that draws water upwards) in the smaller void spaces.
chlorinated hydrocarbon (CHC)	Compound comprised solely of the elements chlorine, hydrogen and carbon. Includes dry-cleaning solvents such as tetrachloroethylene (PCE) and degreasing solvents such as trichloroethylene (TCE) and 1,1,1-trichloroethane (TCA).
chronic	Refers to repeated exposure for more than approximately 10% of the life span (approximately seven years) in humans. Compare with *subchronic*.
concentration	Amount (mass) of a vapor-forming chemical contained in a unit quantity (e.g., volume) of a specific medium (e.g., air, soil gas).
conceptual site model (CSM)	Narrative description of the current understanding of the site-specific conditions, which, in the case of vapor intrusion, include the nature, location, and spatial extent of the source(s) of vapor-forming chemicals in the subsurface and the location, use, occupancy, and basic construction of existing buildings. A CSM represents an adaptation of a general *conceptual model* to account for and reflect site- and/or building-specific conditions. See also *model*.
crawl space	A type of basement in which one cannot stand up — the height may be as little as one foot, and the bottom surface is often bare soil.
complete (vapor intrusion) pathway	The vapor intrusion pathway is referred to as “complete” for a building or collection of buildings when five conditions are met under current conditions: (1) a subsurface source of vapor-forming chemicals is present underneath or near the building(s); (2) vapors form and have a route along which to migrate (be transported) toward the building(s); (3) the building(s) is (or are) susceptible to soil gas entry, which means openings exist for the vapors to enter the building(s) and driving forces exist to draw the vapors from the subsurface into the building(s); (4) one or more vapor-forming chemicals comprising the subsurface vapor source(s) is (or are) present in the indoor environment; and (5) the building(s)

	is (or are) occupied by one or more individuals when the vapor-forming chemical(s) is (or are) present indoors.
data objectivity	Refers to the accuracy, reliability, and absence of bias in the information; scientific information will generally attain this criterion when the original or supporting data are generated using sound research, investigatory, or statistical methods.
data quality objective (DQO)	Performance and acceptance criteria that clarify study objectives, define the appropriate type of data, and specify tolerable levels of potential decision errors that will be used as the basis for establishing the quality and quantity of data needed to support decisions.
data utility	Refers to the usefulness (e.g., relevance, importance) of the information to reaching a conclusion or judgment (e.g., is the vapor intrusion pathway complete or incomplete? Does the vapor-forming chemical in indoor air arise from background sources or vapor intrusion? Does vapor intrusion pose an unacceptable human health risk in a specific building?)
diffusion	Random motion that affects the distribution of molecules when there are spatial differences in chemical concentrations in the fluid (e.g., soil gas, indoor air, groundwater). The net direction of diffusive transport is toward the direction of lower concentrations.
driving force	refers to the combination of: (i) pressure differences between a building interior and the subsurface or ambient air, which foster vapor intrusion and infiltration, respectively, via advection; and (ii) concentration differences between a building interior and the subsurface or ambient air, which foster vapor transport via diffusion.
early action	Refers to a response action undertaken early in the cleanup process to achieve prompt risk reduction. Also see *response action* and *pre-emptive mitigation.*
evidence	A fact or other information (i.e., datum) ascertainable by direct observation, interviews, review of records and documents, instrumental analysis in a lab or field setting, research and testing, sampling of environmental media (e.g., indoor air, soil gas, groundwater), statistical analysis, or other means, which is useful for forming a conclusion or judgment; each distinguishable datum is referred to as a line of evidence, which may be categorized into scientific realms (e.g., geology, biology, physics) or investigatory objectives (e.g., characterization of subsurface vapor source, accounting for background sources)

exposure	Opportunity to come into contact with vapor-forming chemicals (via inhalation, in the case of vapor intrusion).
exposure assessment	Process of characterizing the magnitude, frequency, and duration of exposure to a vapor-forming chemical, along with the characteristics of the population exposed.
exposure control	Modification of a property or building intended to reduce or eliminate human exposure to hazardous vapors in buildings or explosive vapors in structures, which arise from the vapor intrusion; such controls may include engineered methods (e.g., active depressurization technologies, mechanical ventilation, indoor air treatment) or non-engineered methods (e.g., institutional controls, such as deed notices and land use restrictions)
exposure pathway	The physical course a vapor-forming chemical takes from its source (e.g., groundwater) to the individual (in a building in the case of vapor intrusion).
exposure route	The way in which a vapor-forming chemical enters a human body (i.e., inhalation in the case of vapor intrusion).
flux	The rate of movement of mass through a unit cross-sectional area per unit time in response to a concentration gradient or a driving force for advection.
gas	A fluid (as air) that has neither independent shape nor volume but tends to expand indefinitely; a state of matter in which the matter concerned occupies the whole of its container irrespective of its quantity.
grab sample	A sample of air collected over a short (practically instantaneous) duration. Compare with *time-integrated sample*.
hazard index (HI)	The sum of hazard quotients for substances that affect the same target organ or organ system. Because different pollutants can cause similar adverse health effects, it is often appropriate to combine hazard quotients associated with different substances.
hazard quotient (HQ)	The ratio of the potential exposure to the substance and the level at which no adverse effects are expected. If the HQ is calculated to be equal to or less than 1, then no adverse health effects are expected as a result of exposure. If the HQ is greater than 1, then adverse health effects are possible.
hazardous	Involving or exposing one to threat of adverse health effects (due to toxicity) or loss of loss of life or welfare (due to explosiveness).

Henry's Law Coefficient or Constant	Ratio of a chemical's vapor pressure in air to its solubility in water. Generally reported for standard reference temperature, such as 25 °C.
human exposure pathway	A way that people may come into contact with environmental contaminants while performing their day-to-day indoor activities.
human health risk assessment	The evaluation of scientific information on the hazardous properties of vapor-forming chemicals (hazard assessment and characterization), the dose-response relationship, and the extent of human exposure to those agents. The product of the risk assessment is a statement regarding the probability that populations or individuals so exposed will be harmed and to what degree and describing the principal technical uncertainties (i.e., risk characterization).
hydrocarbon	Compound comprised solely of the elements hydrogen and carbon. See also *chlorinated hydrocarbon* and *petroleum hydrocarbon*.
inclusion zone	Land area within which EPA recommends assessing the vapor intrusion pathway, which extends beyond the aggregate boundaries of the site-specific source(s) of vapor-forming chemicals.
indoor vapor source	Refers to a vapor-forming chemical(s) in indoor air which originates within a building. Indoor sources of vapor-forming chemicals may include, but are not limited to, use and storage of consumer or household products, use or storage of industrial materials or products, combustion processes, activities or operations within a building, and releases from interior building materials (e.g., off-gases from furniture or clothing); for example, operational use or storage of chemicals in an industrial building may represent an indoor vapor source separate from a site-related release. Also see *background vapor source;* compare to *subsurface vapor source*.
infiltration	Air leakage into a building through random cracks, interstices, and other unintentional openings in the building envelope.
institutional control (IC)	Non-engineering measures intended to affect human activities in such a way as to prevent or reduce exposure to hazardous substances. For example, ICs may be used to restrict certain land uses, buildings, or activities that could otherwise result in unacceptable exposure to the vapor intrusion pathway. Generally, four categories of ICs are recognized: governmental controls; proprietary controls; enforcement tools; and informational devices. They are almost always used in conjunction with, or as a

	supplement to, other cleanup measures such as treatment or containment.
interim action	Refers to a response action that is undertaken to protect human health, but is limited in scope and objective (e.g., does not accomplish complete or final remediation of subsurface vapor sources). Also see *response action.*
interzonal air flow	Movement or transport of air through doorways, ductwork, and service chaseways that interconnect rooms or zones within a building.
lines of evidence	Data collected and weighed together in supporting assessments of the vapor intrusion pathway, which are identified and described throughout Sections 2 through 7 inclusive. See also *evidence*.
lower explosive limit (LEL)	The lowest concentration at which a gas or vapor is flammable or explosive at ambient conditions.
mitigation	Interim actions taken to reduce or eliminate human exposure to vapor-forming chemicals in a specific building arising from the vapor intrusion pathway; compare with *remediation.*
model	Refers to a description of a system. In the case of vapor intrusion the 'system' will generally consist of a subsurface source of vapors, one or more buildings potentially subject to soil gas entry, and the soil underlying the building(s). *Conceptual models* (i.e., models that are conceptual) are comprised of narrative descriptions that identify the primary physical elements and processes of the system and the interactions between and relationships among them; for example, Section 2 of this document provides a general conceptual model of how vapor intrusion can arise and why it may be variable over time and in space. A *mathematical model* is an expression of a conceptual model, which uses mathematical symbols and language to identify key elements (e.g., variables) and processes. Generally, mathematical models are highly idealized or simplified descriptions, compared to the complex systems they represent. For example, Johnson and Ettinger (1991) formulated an idealized mathematical model of vapor intrusion. In the case of a *physical model,* the description is provided using physical objects, which may or may not have full functionality; for example, a physical model of a construction project might differ from a planned system in its scale, but would necessarily show significant elements in relationship to each other.

near-source	Refers to a soil gas sample collected within a practically short distance from subsurface vapor source
nonresidential building	Refers to a building other than a home; includes, but is not limited to, institutional buildings (e.g., schools, libraries, hospitals, community centers and other enclosed structures for gathering, gyms and other enclosed structures for recreation); commercial buildings (e.g., hotels, office buildings, many (but not all) day care centers, and retail establishments); and industrial buildings where vapor-forming chemicals may or may not be routinely used or stored. Compare with *residential building*; see also *building*.
outdoor vapor source	Refers to a vapor-forming chemical(s) present in outdoor (ambient) air. Sources of vapor-forming chemicals in outdoor air may include, but are not limited to, releases from industrial facilities, vehicle exhaust, yard maintenance equipment, fuel storage tanks, paint or pesticide applications, agricultural activities, and fires, as well as site-related contamination, activities, and operations (e.g., emissions from remediation equipment). Also see *background vapor source;* compare to *subsurface vapor source*.
passive	Not involving mechanical operations; Compare with *active*.
petroleum hydrocarbon (PHC)	Hydrocarbons derived from petroleum and present in various refined products of petroleum (such as automotive gasoline, diesel fuel, lubricating oils). See also *hydrocarbon*.
potentially complete (vapor intrusion pathway)	The vapor intrusion pathway is referred to as 'potentially complete' for a building when: a subsurface source of vapor-forming chemicals is present underneath or near an existing building or a building that is reasonably expected to be constructed in the future; vapors can form from this source(s) and have a route along which to migrate (be transported) toward the building; and three additional conditions are reasonably expected to all be met in the future, which may not all be met currently (i.e., the building is susceptible to soil gas entry, which means openings exist for the vapors to enter the building and driving forces exist to draw the vapors from the subsurface through the openings into the building; one or more vapor-forming chemicals comprising the subsurface vapor source(s) is (or will be) present in the indoor environment; and the building is or will be occupied by one or more individuals when the vapor-forming chemical(s) is (or are) present indoors.

preemptive mitigation (PEM)	Implementation of systems or control measures to mitigate the vapor intrusion pathway as an early action, even though all pertinent lines of evidence have not yet been completely developed to characterize the vapor intrusion pathway for the subject building(s). Also see *early action* and *response action.*
preferential migration route	Naturally occurring subsurface feature (e.g., gravel lens, fractured rock) or anthropogenic (human-made) subsurface conduit (e.g., utility corridor or vault, subsurface drain) that is expected to exhibit little resistance to vapor flow in the vadose zone (i.e., exhibits a relatively high gas permeability) or groundwater flow (i.e., effectively exhibits a relatively high hydraulic conductivity), depending upon its location and orientation relative to the water table and ground surface, thereby facilitating the migration of vapor-forming chemicals in the subsurface and towards or into buildings
pressure difference/differential pressure	Difference between the air pressure within a building and the subsurface environment or ambient air. Can promote advective flow of gas into or out of a building through pores, cracks, or openings in the building foundation or envelope.
radon	A radioactive gas formed during the radioactive decay of radium, which occurs naturally in many geologic settings.
reasonable maximum exposure (RME)	A semi-quantitative term, referring to the lower portion of the high end of the exposure distribution; conceptually, above the 90th percentile exposure but less than the 98th percentile exposure.
reasonable worst case	A semi-quantitative term, referring to the upper portion of the high end of the exposure distribution, but less than the absolute maximum exposure.
reference concentration (RfC)	An estimate of the continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime.
remediation	Refers to interim and final cleanups, whether conducted pursuant to RCRA corrective action, the CERCLA removal or remedial programs, or using EPA brownfield grant funds with oversight by state and tribal response programs. In addition to permanent remedies for subsurface vapor sources, site remediation may also entail implementation of institutional controls and construction and operation of engineered systems.

residential building	refers to a building used as or intended for use as a home; includes, but is not limited to, single-family detached homes with foundations, trailer homes, multi-unit apartments and condominiums. Compare with *non-residential building;* see also *building*.
response action	any action taken to reduce or eliminate human exposure to or risk posed by hazardous vapors in buildings and structures, which arise from the vapor intrusion pathway; these actions may include engineered exposure controls in a specific building(s), non-engineered exposure controls, remediation of subsurface vapor sources, and associated monitoring to assess effectiveness and protectiveness. Also see *remediation* and *mitigation.*
risk	Probability of an adverse human health effect (due to toxicity) or physical hazard (e.g., due to potential for explosion) caused under specific circumstances by a vapor-forming chemical.
risk communication	The process of exchanging information about health threats and levels or significance of human health risk.
risk management	The process of determining whether response action(s) is(are) warranted to protect human health and, if so, selecting response actions to implement.
screening	Process of comparing concentrations of vapor-forming chemicals in a specific medium (e.g., indoor air, soil gas, crawl space air, groundwater) to screening levels to identify sites, buildings, or chemicals unlikely to pose a health concern through the vapor intrusion pathway versus those warranting further investigation or analysis.
screening level	Risk-based concentrations derived from standardized equations combining exposure information and assumptions with toxicity values.
short-term	Refers to repeated exposure for more than 24 hours, up to 30 days. Compare with *acute* and *subchronic*.
significant opening	Refers to refer to an atypical form and amount of an opening in a building (e.g., a sump, an unlined crawl space, an earthen floor), which could facilitate greater amounts of soil gas entry, all else being equal. Forms of openings typically expected to be present in all buildings include cracks, seams, interstices, and gaps in basement floors and walls or foundations and perforations due to utility conduits.
site	The geographical area where investigation and evaluation of the presence of vapor-forming chemicals is desired; in many situations, it includes areas surrounding

	a facility where a release to the subsurface environment is known or suspected to have originated.
soil gas	The gas present underground in the pore spaces between soil particles.
soil gas concentration	Vapor concentration in a soil gas sample. Sub-slab soil gas is found immediately beneath a building. Near-source or exterior soil gas samples are collected at other depths and typically outside the building footprint.
source strength	Vapor concentration(s) of vapor-forming chemical(s) arising from a subsurface vapor source.
stakeholder	A person, group, community, or corporate entity with an interest in activities at a site with subsurface contamination.
subchronic	Refers to repeated exposure for more than 30 days, up to approximately 10% of the life span (approximately seven years) in humans. Compare with *short-term* and *chronic*.
subsurface remediation	Response action that eliminates or substantially reduces the level of vapor-forming chemicals in the subsurface vapor source via treatment or physical removal. Compare with *mitigation.*
subsurface vapor source	Refers to a vapor-forming chemical(s) present in the subsurface environment arising from a release(s) to the environment. A subsurface vapor source may occur as a non-aqueous-phase liquid (NAPL), adsorbed-phase contamination, or dissolved-phase contamination, which may be present in the vadose zone, in groundwater, or within sewers and other conduits. Information on subsurface vapor sources is important to risk managers because response actions are generally warranted when vapor intrusion is determined to pose unacceptable human health risks. Compare with *background vapor source* and *background vapor concentration*.
termination criteria	Refers to numeric cleanup levels for each site-specific contaminant and narrative cleanup objectives that are to be attained by the response actions.
time-integrated sample	Sample collected over an extended period of time to account for temporal variations in vapor concentrations. Compare with *grab sample*.
toxicity value	Refers to an inhalation unit risk (IUR) for potential cancer effects or an inhalation reference concentration (RfC) for potential non-cancer effects of a vapor-forming chemical.

vadose zone	The soil zone between land surface and the groundwater table within which the moisture content is less than saturation (except in the capillary fringe). Soil pore spaces not occupied by moisture contain (soil) gas. Also referred to as the "unsaturated zone."
vapor	A substance in the gaseous state as distinguished from the liquid or solid state.
vapor intrusion	The migration of potentially hazardous vapors from any subsurface contaminant source, such as contaminated soil or groundwater, through the vadose zone and into a building or structure.
vapor source	The place and form of origin of chemical vapors. Also see *background vapor source*, *indoor vapor source*, *outdoor vapor source*, and *subsurface vapor source*.
vapor-forming chemical	A volatile chemical that EPA recommends be routinely evaluated during a site-specific vapor intrusion assessment, when it is present as a subsurface contaminant.
volatile chemical	Chemical with a vapor pressure greater than 1 milliliter of mercury (mm Hg), or Henry's law constant greater than 10^{-5} atmosphere-meter cubed per mole.
volatility	The tendency of a substance to form vapors, which are molecules in a gaseous state, and escape from a liquid or solid source. This tendency is directly related to a substance's vapor pressure and Henry's law constant and is indirectly related to a substance's molecular weight (i.e., substances with lower molecular weights tend to volatilize more readily than substances with similar molecular structures that have higher molecular weights).
water table	The water surface in an unconfined aquifer at which the fluid pressure in the pore spaces is at soil gas pressure.
weight of evidence	Refers to a conceptual approach to data evaluation, in which each of several lines of evidence is critically appraised for its quality (e.g., utility, objectivity) and systematically assessed for its logical support for a particular conclusion, as well as alternative conclusions; the appraisals consider lines of evidence individually and in light of other lines of reliable evidence for purposes of determining whether a particular conclusion is supported by the preponderance of the evidence and is consistent with the conceptual site model; this 'weighing' concept does not entail a quantitative (*a priori*) scheme to score or rank the individual lines of evidence. See also *evidence*.

work plan	A site-specific document that includes a project description, project objective(s), historical information about the site.
worst case	A semi-quantitative term, referring to the absolute maximum plausible exposure (i.e., a bounding – high-impact – case).

APPENDIX A
RECOMMENDED SUBSURFACE-TO-INDOOR AIR ATTENUATION FACTORS

A.1 INTRODUCTION

This Technical Guide includes recommended medium-specific (groundwater, soil gas, and indoor air) Vapor Intrusion Screening Levels (VISLs) that are intended to help identify those sites unlikely to pose a health concern from vapor intrusion and identify areas or buildings that may warrant further investigation of the vapor intrusion pathway. These VISLs are recommended for use in evaluating the concentrations of vapor-forming chemicals measured in groundwater, "near-source" exterior soil gas, and sub-slab soil gas in residential and nonresidential settings where the potential for vapor intrusion is under investigation.

The subsurface VISLs are developed considering a generic conceptual model for vapor intrusion consisting of a groundwater or vadose zone source of vapor-forming chemicals that diffuse upwards through unsaturated soils towards the surface and enter buildings. The underlying assumption for this generic model is that subsurface characteristics will tend to reduce or attenuate soil gas concentrations as vapors migrate upward from the source and into structures. Section 6.5.2 describes this conceptual model further. In general, EPA recommends considering whether the assumptions underlying the generic conceptual model are attained at each site. The *Vapor Intrusion Screening Level (VISL) Calculator User's Guide* (EPA 2015a) provides additional information about the technical basis for deriving the VISLs.

Comparison of sampling results to medium-specific VISLs (see Section 6.5.4) comprises one line of evidence in the multiple-lines-of-evidence approach described in this Technical Guide (see, for example, Sections 7.1 and 7.2). The subsurface (groundwater and soil gas) VISLs (C_{VISL}) are calculated using risk-based, screening levels for indoor air ($C_{target,ia}$) and a medium-specific, subsurface-to-indoor air attenuation factor (α_{VI}), as follows:

$$C_{VISL} = \frac{C_{target,ia}}{\alpha_{VI}} \qquad \text{Equation A.1}$$

The risk-based, indoor air screening levels ($C_{target,ia}$) are calculated according to the guidance provided in *Risk Assessment Guidance for Superfund (RAGS) Part F* (EPA 2009) as implemented in EPA's Regional Screening Levels (RSLs) for Chemical Contaminants at Superfund Sites (http://www.epa.gov/reg3hwmd/risk/human/rb-concentration_table/). The medium-specific, attenuation factors (α_{VI}) recommended for calculating the subsurface VISLs are derived from information in *EPA's Vapor Intrusion Database: Evaluation and Characterization of Attenuation Factors for Chlorinated Volatile Organic Compounds and Residential Buildings* (EPA 2012a).

This appendix describes the technical basis for the selection of the subsurface-to-indoor air attenuation factors (α_{VI}) that are recommended for use in calculating the VISLs for groundwater, sub-slab soil gas, "near-source" exterior soil gas, and crawl space air, according to Equation A.1.

A.2 DEFINITION AND DESCRIPTION OF ATTENUATION FACTOR

Vapor attenuation refers to the reduction in concentration of vapor-forming chemicals that occurs during vapor migration in the subsurface, coupled with the dilution that can occur when the vapors enter a building and mix with indoor air (Johnson and Ettinger 1991). The aggregate effect of these physical and chemical attenuation mechanisms can be quantified through the use of a subsurface-to-indoor air vapor intrusion attenuation factor (α_{VI}), which is defined as the ratio of the indoor air concentration arising from vapor intrusion ($C_{IA\text{-}VI}$) to the subsurface vapor concentration (C_{sv}) at the source or a depth of interest in the vapor migration route (EPA 2012a):

$$\alpha_{VI} = \frac{C_{IA-VI}}{C_{SV}} \alpha_{VI} = \frac{C_{IA-VI}}{C_{SV}} \qquad \text{Equation A.2}$$

As defined here, the vapor attenuation factor is an inverse measurement of the overall dilution that occurs as vapors migrate from a point of measurement in the subsurface into a building; i.e., attenuation factor values decrease with increasing dilution of vapor concentration.

Subsurface vapor concentrations (C_{SV}) may be measured directly under a building (often called sub-slab soil gas or just sub-slab), measured exterior to a building at any depth in the unsaturated zone (often called exterior soil gas), or derived from groundwater concentrations by converting the dissolved concentration to a vapor concentration assuming equilibrium conditions (i.e., by multiplying the groundwater concentration by the chemical's dimensionless Henry's law constant for the groundwater temperature *in situ*) (EPA 2001); also see Appendix C of this Technical Guide.

Subfloor vapor concentrations may also be measured in building crawl spaces. Although crawl space samples are not strictly subsurface samples, they represent the vapor concentration underlying a building's living space. Thus, crawl space samples may be evaluated in a manner similar to subsurface vapor samples.

A.3 RECOMMENDED ATTENUATION FACTORS

This section summarizes the technical basis and rationale for EPA's recommended attenuation factors for groundwater, sub-slab soil gas, exterior soil gas, and crawl space air, as follows:

- Section A.3.1 summarizes EPA's database of empirical attenuation factor values and the results of analyzing that database.
- Section A.3.2 identifies the recommended empirically based attenuation factors for groundwater.
- Section A.3.3 identifies the recommended attenuation factor for sub-slab soil gas and presents a theoretical analysis that supports the selection of the recommended empirically based value.
- Section A.3.4 recommends a generic attenuation factor for exterior soil gas and discusses its basis, justification, and limited applications.

- Section A.3.5 identifies the recommended attenuation factor for crawlspace vapor.
- Section A.3.6 presents a reliability analysis of the recommended generic attenuation factors.

A.3.1 EPA'S VAPOR INTRUSION DATABASE (EPA 2012A)

The information in *EPA's Vapor Intrusion Database: Evaluation and Characterization of Attenuation Factors for Chlorinated Volatile Organic Compounds and Residential Buildings* (EPA 2012a) is used to derive recommended attenuation factor values for use in evaluating subsurface sample concentrations collected as part of vapor intrusion investigations. EPA's vapor intrusion database consists of numerous pairings of concentrations in indoor air and subsurface samples (groundwater, sub-slab soil gas, exterior soil gas, and crawlspace vapor) from actual sites. It represents the most comprehensive compilation of vapor intrusion data for chlorinated hydrocarbons (CHCs) available at this time.

EPA's vapor intrusion database was analyzed and screened to reduce the impacts of background sources to indoor air concentrations. The resulting data distributions are considered representative of vapor intrusion of CHCs from subsurface vapor sources into residential buildings for most conditions. These distributions serve as the basis for identifying the high-end (conservative) attenuation factors for those media.

Table A-1 and Figure A-1 (Table 19 and Figure 34, respectively, in EPA (2012a)) present and compare the distributions of the attenuation factors (groundwater, exterior soil gas, sub-slab soil gas, and crawl space) that remain after applying the respective source strength and indoor air screens considered most effective at reducing the influence of background contributions to indoor air concentrations. These data demonstrate that the attenuation factor distributions obtained for groundwater, sub-slab soil gas, and crawl spaces for multiple buildings and sites are consistent with the conceptual model for vapor intrusion, which predicts that greater attenuation is expected with greater depths to the vapor sources or vapor samples. As shown in Table A-1 and Figure A-1, the paired groundwater–indoor air data generally exhibit greater attenuation (lower attenuation factors) than the paired sub-slab soil gas–indoor air data, which in turn exhibit greater attenuation than the paired crawl space-indoor air data.

A.3.2 RECOMMENDED ATTENUATION FACTORS FOR GROUNDWATER

To account for the inherent temporal and spatial variability in indoor air and subsurface vapor concentrations, the 95th percentile value of the "source-screened" groundwater data subset in EPA 2012a is recommended as a reasonably conservative generic attenuation factor, after considering a range of values. **Thus, for groundwater, the recommended generic attenuation factor (α_{gw}) is 0.001.** This value is considered to apply for any soil type in the vadose zone (excepting where preferential vapor pathways are present; see Section 5.4) in cases where the groundwater is greater than five feet below the ground surface. If the depth to groundwater is less than five feet below the building foundation, investigation of the indoor space is recommended, as there is potential for contaminated groundwater to contact the building foundation, either because the capillary fringe intersects the building foundation or groundwater fluctuations results in groundwater wetting the foundation.

Table A-2 (Table 13 in EPA (2012a)) provides statistics and Figure A-2 (Figure 28 in EPA (2012a)) shows box-and-whisker plots for individual sites compared with the statistics for the combined set of screened groundwater attenuation factors. This table and figure show that the 95th percentile value of the combined groundwater-indoor air measurements is considered appropriate for estimating reasonable maximum indoor air concentrations that might be observed at a site due to vapor intrusion. The majority of sites and buildings would be expected to exhibit lower indoor air concentrations.

A factor that commonly results in greater attenuation (lower attenuation factors) is the presence of laterally extensive, unfractured fine-grained sediment in the vadose zone. Table A-3 (Table 14 in EPA (2012a)) provides selected statistics and Figure A-3 (Figure 29 in EPA (2012a)) shows the box-and-whisker plots for the groundwater attenuation factors for three soil types. Comparing each descriptive statistic (except for the 25th percentile values) indicates that the attenuation factor values for residences overlying soils classified as "very coarse" generally are larger than those for residences overlying soils classified as "coarse," which are larger than those for soils classified as "fine." This pattern is consistent with the conceptual model for vapor intrusion; smaller attenuation factors, which indicate greater reduction in vapor concentration, would be expected in vadose zones with finer-grained soils, when all other factors (e.g., depth to groundwater, biodegradability of the volatile chemicals) are the same. The 95th percentile value of the coarse-grained soil is equal to the generic value, as expected, since coarse-grained soil provide low resistance to vapor transport and thus would be expected to yield high-valued attenuation factors. Where fine-grained sediments underlay buildings, however, more attenuation is expected and observed in the database. **Thus, a semi-site-specific attenuation factor of 0.0005 may be used at sites where laterally extensive fine-grained sediment has been demonstrated through site-specific sampling to underlay buildings being investigated for vapor intrusion**.

A.3.3 RECOMMENDED GENERIC ATTENUATION FACTOR FOR SUB-SLAB SOIL GAS

To account for the inherent temporal and spatial variability in indoor air and subsurface vapor concentrations, the 95th percentile value of the "source-screened" sub-slab data subset in EPA (2012a) is recommended as a reasonably conservative generic attenuation factor, after considering a range of values. Thus, **for sub-slab soil gas, the recommended generic attenuation factor (α_{ss}) is 0.03.**

The selection of this value can be supported by theoretical analysis. Specifically, a simple mass balance analysis, assuming a well-mixed interior volume and steady-state conditions, indicates that the theoretical (true) sub-slab soil gas attenuation factor can be expressed as the ratio of the soil gas entry rate to the building ventilation rate (Song et al., 2011; EPA 2012a) for cases where there is no background contribution to the indoor air concentration. Using median values for residential building volume and air exchange rate (395 m^3 and 0.45 ACH, respectively) provided in the *Exposure Factors Handbook 2011 Edition* (EPA, 2011) and a mid-range value of 5 L/min for soil gas entry rate in sandy materials (EPA 2002, Appendix G), the central tendency value of the sub-slab soil gas attenuation factor (according to Equation 4a therein), is expected to be approximately 0.002. Using upper-end (10th percentile) values for residential building volume and air exchange rate (154 m^3 and 0.18 ACH, respectively (EPA 2011)) and soil gas entry rate (10 L/min), an upper-end value of 0.02 for the sub-slab soil gas attenuation factor is obtained. These values agree well with the 95th percentile and 50th percentile (median) values

(0.03 and 0.003, respectively) obtained from the source-screened data. These calculations buttress the conclusion that the sub-slab attenuation factor distributions summarized in EPA's vapor intrusion database report can be considered representative of vapor intrusion of CHCs into residential buildings for most conditions.

Table A-4 (Table 10 in EPA (2012a)) provides statistics and Figure A-4 (Figure 25 in EPA (2012a)) shows box-and-whisker plots for individual sites compared with the statistics for the combined set of screened sub-slab attenuation factors. This table and figure show that the 95th percentile value of the combined sub-slab-indoor air measurements is considered appropriate for estimating reasonable maximum indoor air concentrations that might be observed at a site due to vapor intrusion. The majority of sites and buildings would be expected to exhibit lower indoor air concentrations.

A.3.4 RECOMMENDED ATTENUATION FACTOR FOR "NEAR-SOURCE" EXTERIOR SOIL GAS

Based upon the conceptual model for vapor intrusion, the attenuation factors for exterior soil gas data would be expected to be less than those for sub-slab soil gas, because the former includes an additional contribution from attenuation through the vadose zone, and greater than those for groundwater vapors for a given building at a site where groundwater is the primary subsurface source of vapors. The distributions of exterior soil gas attenuation factors shown in Table A-1 and Figure A-1 do not exhibit this expected relationship. In addition, a comparison of exterior soil gas to sub-slab soil gas concentrations for buildings where both types of samples were collected, shown in Figure A-5 (see Figure 6 in EPA (2012a)), suggests that a substantial proportion of the exterior soil gas data in the database, particularly shallow soil gas data, may not be representative of soil gas concentrations directly underneath a building. On this basis, shallow exterior soil gas sampling data generally are not recommended for purposes of estimating indoor air concentrations and the exterior soil gas attenuation factors in Table A-1 are not recommended for use in deriving generic attenuation factors.

Based upon the data in Figure A-5, "deep" exterior soil gas data appear to more reliably reflect sub-slab concentrations beneath buildings. On this basis, "near-source" soil gas sampling data (i.e., collected in the vadose zone immediately above each vapor source) generally are allowed for purposes of assessing vapor concentrations that may be in contact with the building's sub-slab, as discussed further in Section 6.4.4. However, the same conservative attenuation factor value for sub-slab soil gas is recommended for use with "near-source" exterior soil gas data for this purpose. **Thus, for "near-source" exterior soil gas, the recommended generic attenuation factor is 0.03**.

A.3.5 RECOMMENDED ATTENUATION FACTOR FOR CRAWLSPACE VAPOR

The distribution of attenuation factors presented in Figure A-1 show that attenuation between building crawlspaces and living spaces is limited. To account for the inherent temporal and spatial variability in indoor air and crawlspace vapor concentrations, the 95th percentile value of the "indoor air-screened" crawlspace data subset in EPA (2012a) is recommended as a reasonably conservative generic attenuation factor, after considering a range of values. **Thus, for crawl space vapor the recommended generic attenuation factor is 1.0** (0.9 rounded up to 1.0).

A.3.6 RELIABILITY ANALYSIS OF THE RECOMMENDED SUBSURFACE-TO-INDOOR AIR GENERIC ATTENUATION FACTORS

An analysis was performed to determine the reliability of these recommended attenuation factors for screening in residences in EPA's vapor intrusion data base with measured indoor air concentrations exceeding target levels corresponding to a cancer risk of 10^{-6} and a hazard quotient of 1. The reliability analysis was performed separately for each medium by determining the number of correct assessments and the number of false negatives for a range of attenuation factors. The potential incidence of false negatives is a critical criterion, because the primary objective of risk-based screening is to identify sites or buildings unlikely to pose a health concern through the vapor intrusion pathway (see Section 6.5.1).

For the purposes of this analysis:

- A correct assessment is deemed to occur either: (1) when a chemical's measured indoor air concentration exceeds the target level and the measured subsurface vapor concentration also exceeds the appropriate medium-specific VISL calculated using the specified generic attenuation factor, or (2) when a chemical's measured indoor air concentration is below the target level and the measured subsurface vapor concentration also is below the appropriate medium-specific VISL calculated using the recommended generic attenuation factor. Correct assessments in this analysis represent a correct decision based on subsurface concentration data regarding the potential for vapor intrusion to pose indoor air concentrations that exceed target risk-based concentrations in affected buildings.

- A false negative is deemed to occur when a chemical's measured indoor air concentration exceeds the target level, but the measured subsurface vapor concentration does not exceed the appropriate medium-specific VISL calculated using the specified generic attenuation factor. False negatives in this analysis represent the potential for making an incorrect decision based on subsurface concentration data regarding the potential for vapor intrusion to pose indoor air concentrations that exceed target risk-based concentrations in affected buildings.

This assessment uses the Data Consistency Subset of the EPA's vapor intrusion database for residential buildings (i.e., before screening to minimize the impacts of background contributions to indoor air as described in EPA (2012a)). This subset was chosen to allow for the possibility that background indoor air contributions were incorrectly identified and removed from further analysis in the "source-screened" data subsets presented in EPA (2012a). Thus, false negatives may appear if indoor or ambient (outdoor) sources of VOCs are present and they exceed the

indoor air target level. This choice of datasets provides a conservative estimate of the frequency of false negatives identified by this reliability analysis. Even lower rates of false negatives would be obtained when considering the "source-screened" data subsets, described in EPA (2012a), in which the impacts of background contributions to indoor air are minimized.

The results of this assessment are shown in Figures A-6 through A-8 for sub-slab soil gas, groundwater, and exterior soil gas.[256] The essential results are as follows:

- The recommended generic attenuation factors yield low rates of false negatives (< 2%) for all three media when individual pairs of samples are evaluated together.

- The recommended generic attenuation factors for groundwater, exterior soil gas, and sub-slab soil gas provide generally high rates of correct assessments when individual pairs of samples are evaluated together: 78% for groundwater; 76% for exterior soil gas; and 87% for sub-slab soil gas. Higher rates of correct assessments are expected for sub-slab soil gas than for the other subsurface media, likely due to the closer spatial correspondence of building sub-slab soil gas and indoor air samples.

- The rates of correct assessments appear to level off in Figure A-6 through A-8 at about the point on the x-axis where the recommended generic attenuation factors occur.

- The rates of false positives using the Data Consistency Subset can be inferred from Figure A-6 through A-8. This analysis indicates that use of ground water data or exterior soil gas data is more likely to incorrectly identify a site or building as warranting further investigation than is use of sub-slab soil gas data.

Compared to the values estimated in Figures A-6 through A-8, significantly higher rates of a correct assessment (and, hence, lower rates of false negatives and false positives) are reasonably anticipated to be realized by following this Technical Guide. Specifically, collecting multiple samples to characterize spatial and temporal variability (see, for example, Section 6.4), collecting multiple lines of additional evidence (see, for example, Section 6.3 and 7.1), and weighing this information together (see, for example, Sections 6.3 and 7) are reasonably expected to significantly reduce the "error rates" estimated in this reliability analysis, which are based upon comparison of individual pairs of indoor air and subsurface sample concentrations.

As previously stated, this Technical Guide includes subsurface VISLs that are intended to help identify those sites with the potential to pose a vapor intrusion concern. The reliability analysis described above suggests the recommended attenuation factors, on which the recommended VISLs are based, can reasonably be expected to provide an acceptably small probability of 'screening out' sites that pose a vapor intrusion concern and a high probability of correctly identifying sites or buildings that may pose a vapor intrusion concern.

[256] The reliability assessment was not conducted for crawlspace data, because the distribution of attenuation factors presented in Figure A-1 show that attenuation between building crawlspaces and living spaces is limited.

A.4 CONSIDERATIONS FOR NONRESIDENTIAL BUILDINGS

The recommended attenuation factors (see Sections B.3.2 through B.3.5) are proposed for use for nonresidential buildings as well as residential buildings. The rationale is that, in many geographic locations, some commercial enterprises have been established in converted residential buildings. Although used for commercial purposes, such buildings can reasonably be expected to exhibit similar susceptibility to vapor intrusion and similar interior mixing and dilution (and, hence, similar attenuation factors) as residential buildings represented in EPA's vapor intrusion database. In addition, McDonald and Wertz (2007) found that sub-slab attenuation factors for commercial and institutional buildings in Endicott, New York, which were not "extraordinarily large", were not substantially different than those for residential buildings in the same area.

There are theoretical considerations to support expectations that larger nonresidential buildings that are constructed on thick slabs will have lower attenuation factors than residential buildings. These considerations include:

- Given that the size (e.g., interior height and footprint area) and air exchange rate tend to be larger for many nonresidential buildings (see, for example, Table A-5), it is expected that building ventilation rates for many nonresidential buildings would be higher than those for residential buildings. A higher ventilation rate is expected to result in greater overall vapor dilution as vapors migrate from a subsurface vapor source into a building. On this basis, many nonresidential buildings would be expected to have lower attenuation factors than those for residential buildings, all else being equal.

- Comparing buildings with slab-on-grade construction, nonresidential buildings tend to have thicker slabs than residential buildings. With thicker slabs, a given amount of differential settling would be expected to lead to less cracking in the slab and would be less likely to create cracks that extend across the entire slab thickness. Buildings with thicker slabs would, therefore, be expected to exhibit lower soil gas entry rates, all else being equal.

Where appropriate, EPA may consider appropriate building-specific data, information, and analysis when evaluating vapor intrusion into large nonresidential buildings.

APPENDIX B
DATA QUALITY ASSURANCE CONSIDERATIONS

B.1 INTRODUCTION

Site-specific investigations of the vapor intrusion pathway will generally entail the collection and evaluation of environmental data and possibly the use of modeling. As noted in Exhibit B-1, EPA generally recommends the use of a quality assurance project plan (QAPP) for the collection of primary (and existing or secondary) data. A QAPP is a tool for project managers and planners to document the type and quality of data needed to make environmental decisions and to describe the methods for collecting and assessing the quality and integrity of those data. A QAPP is a plan or roadmap intended to help a project team document how they plan, implement, and evaluate a project. It applies the systematic planning process and the graded approach for collecting environmental data for a specific intended use. EPA standards governing the collection of data are outlined in Exhibit B-1.

Exhibit B-1. EPA Data Standards

CIO 2105 (formerly EPA Order 5360; *Policy and Program Requirements for the Agency-wide Quality System*, May 2000) is intended to promote the organization collecting or using the data to (1) establish a Quality System and prepare and approve a QAPP for each project.

For clarity, CIO 2105 will be replaced by the following two standards:

- CIO 2106-S-01 is the *Quality Standard for Environmental Data Collection, Production, and Use by EPA Organizations*, also called "Internal Standard" (EPA 2013a); and
- CIO 2106-S-02 is the *Quality Standard for Environmental Data Collection, Production, and Use by Non-EPA (External) Organizations*, also called "External Standard" (EPA 2013b).

These standards conform to *EPA Quality Policy*, CIO 2106.0, "Quality Policy" (EPA 2008a), *Procedure for Quality Policy,* CIO 2106-P-01.0, "Quality Procedure" (EPA 2008b), and the American National Standards Institute (ANSI) consensus standard, *Quality Systems for Environmental Data and Technology Programs – Requirements with Guidance for Use* (ANSI/ASQ 2004).

Two guidance documents accompany these standards:

- *EPA Guidance on Quality Management Plans* (EPA 2012b, CIO 2106-G02-QMP), documents the quality system of the organization conducting environmental data collection or using the data for EPA.
- *EPA Guidance on Quality Assurance Project Plans* (EPA 2012a, CIO 2106-G-05) focuses on projects requiring the collection of new data, projects using existing data, and projects involving modeling.

EPA also encourages the use of the *Uniform Federal Policy for Quality Assurance Project Plans (UFP-QAPP)* (EPA/DoD 2005) as a collaborative approach to fulfill the purposes of a QAPP, especially for Federal Facilities. OSWER Directive 9272.0-17, *Implementation of the Uniform Federal Policy for Quality Assurance Project Plans (UFP-QAPP) at Federal Facility Hazardous Waste Sites* (EPA 2005a) and OSWER Directive 9272.0-20 (EPA 2005b) state that QAPPs prepared and approved under the UFP conform to EPA's quality standards and are consistent with EPA Standards CIO 2106-S-0 and CIO 2106-S-02, EPA's Quality Policy (EPA 2008a), and ANSI/ASQ 2004.

B.2 RECOMMENDATIONS

This appendix provides two recommendations concerning the key components of QAPP development. These recommendations are not exhaustive, but are included as a starting point as considerations before studying or applying EPA or UFP QAPP guidance.

Recommendation 1: Using the conceptual site model (CSM), develop the project plan and QAPP through a process that involves all key players and share these materials with interested parties in draft form so that potential study weaknesses can be addressed early. The CSM is developed to portray the current understanding of site conditions, the nature and extent of contamination, routes of contaminant transport, potential contaminant pathways, and potentially exposed human population. Developing the CSM is the first step in EPA's DQO process.

Recommendation 2: Use systematic planning in developing project documents, including the QAPP. Systematic planning is a science-based, common-sense approach designed to ensure that the level of documentation and rigor of effort in planning is commensurate with the intended use of the information and available resources. DQOs are a key component of systematic planning and play a central role in the systematic planning process. DQOs generally are addressed within the QAPP and typically are a critical element in the planning for environmental investigations. *Guidance on Systematic Planning Using the Data Quality Objectives Process (QA/G-4)* (EPA 2006) provides guidance addressing implementation of DQOs and application of systematic planning to generate performance and acceptance criteria for collecting environmental data.

Table B-1 summarizes the steps in the DQO process, the purpose of each step, and provides some examples of how plans could be structured.

TABLE B-1. EXAMPLE OF STEPS IN THE DQO PROCESS

DQO Step	Purpose of the DQO Step	Example Application for Vapor Intrusion
1. State the Problem	Summarize the problem (e.g., the monitoring hypothesis, the investigation objective(s)) for which new environmental data will be collected or modeling or analysis will be performed.	Indoor air in one or more buildings overlying a shallow plume of PCE-contaminated groundwater is (are) to be sampled to determine whether PCE is present. The original PCE release occurred at an industrial site approximately 1,000 feet away from the closest building.
2. Identify the Decision	Identify the decision that will be supported by the new data, modeling or analysis.	The data will be used to support decisions about whether additional indoor air sampling or preemptive vapor intrusion mitigation will be pursued in one or more buildings.
3. Identify the Inputs to the Decision	Identify the information needed to support the decision, including data gaps that warrant collection of new information.	Indoor air sampling data for one or more buildings, in conjunction with information about measured or interpolated concentrations in groundwater near or underneath the building(s).
4. Define the Boundaries of the Study	Specify the spatial and temporal aspects of the environmental media or endpoints that the data are to represent to support the decision.	The boundaries of this initial study area extend a prescribed distance outside the lateral extent of the plume. Eventually, the boundaries of a vapor intrusion impact zone will be defined by the extent to which indoor air contamination can be associated with site-related contamination.
5. Develop a Decision Rule	Develop a logical "if…then" statement that defines the conditions that will inform the decision-maker to choose among alternative decisions.	Buildings with detectable concentrations of PCE in indoor air samples will be considered for additional indoor air sampling or preemptive vapor intrusion mitigation.
6. Specify Tolerable Limits on Decision Errors	Specify acceptable limits on decision errors, which are used to establish performance goals for limiting uncertainty in the analysis.	EPA recommends analytical limits of detection be less than risk-based screening levels for PCE to ensure that a building's indoor air concentration is not misidentified.
7. Optimize the Design for Obtaining Data	Identify the most resource-effective sampling and analysis design for generating the information needed to satisfy the DQOs.	Time-integrated samples will be collected in basements and in the first above-ground level of each building. The sampling and analysis plan and approach will be documented in a QAPP.

APPENDIX C
CALCULATING VAPOR SOURCE CONCENTRATION FROM GROUNDWATER SAMPLING DATA

Correcting the Henry's Law Constant for Groundwater Temperature

In the case of groundwater as the vapor source, the subsurface source concentration (C_{sv}) is estimated assuming that the vapor and aqueous phases are in local equilibrium according to Henry's law such that:

$$C_{sv} = H'_{TS} \times C_w \qquad \text{Equation C.1}$$

where:

C_{sv} = vapor concentration at the source of contamination (g/cm^3-v),

H'_{TS} = Henry's law constant at the system (groundwater) temperature (dimensionless), and

C_w = concentration of volatile chemical in groundwater (g/cm^3-w).

The Henry's law constants generally are reported for a temperature of 25 degrees Celsius (^{o}C). **Table C-1** provides these values for the chlorinated hydrocarbons (CHCs) in the vapor intrusion database. Average groundwater temperatures, however, are typically less than 25^{o}C. In such cases, use of the Henry's law constant at 25^{o}C may over-predict the volatility of the contaminant in water.

As described in EPA's *Soil Screening Guidance* (EPA 1996), the dimensionless form of the Henry's law constant at the average groundwater temperature (H'_{gw}) may be estimated using the Clapeyron equation:

$$H'_{gw} = \frac{\exp\left[-\frac{\Delta H_{v,gw}}{R_c} \times \left(\frac{1}{T_{gw}} - \frac{1}{T_R}\right)\right] H_R}{R \times T_{gw}} \qquad \text{Equation C.2}$$

where:

$\Delta H_{v,gw}$ = enthalpy of vaporization of the specific chemical at the groundwater temperature (cal/mol),

T_{gw} = groundwater temperature (^{o}K = ^{o}C + 273.15),

T_R = reference temperature for the Henry's law constant (298.15^{o}K),

R_C = gas constant (= 1.9872 cal/mol-^{o}K),

H_R = Henry's law constant for the specific substance at the reference temperature (atm-m^3/mol), and

R = gas constant (= 8.205 E-05 atm-m^3/mol-^{o}K).

The enthalpy of vaporization at the groundwater temperature can be approximated from the enthalpy of vaporization at the normal boiling point, as follows:

$$\Delta H_{v,gw} = \Delta H_{v,b}\left[\frac{\left(1-T_{gw}/T_C\right)}{\left(1-T_B/T_C\right)}\right]^{\eta} \qquad \text{Equation C.3}$$

where:

$\Delta H_{v,gw}$ = enthalpy of vaporization at the groundwater temperature (cal/mol),

$\Delta H_{v,b}$ = enthalpy of vaporization at the normal boiling point (cal/mol),

T_C = critical temperature for specific chemical (^oK),

T_B = normal boiling point for specific chemical (^oK),

η = exponent (unitless), and

all other symbols are as defined previously. **Table C-1** provides the chemical-specific property values used for temperature corrections to the Henry's law constant. **Table C-2** provides the value of η as a function of the ratio T_B/T_C. If site-specific data are not readily available for the groundwater temperature, then Figure 1 of the EPA fact sheet, *Correcting the Henry's Law Constant for Soil Temperature* (EPA 2001) can be used to generate an estimate.

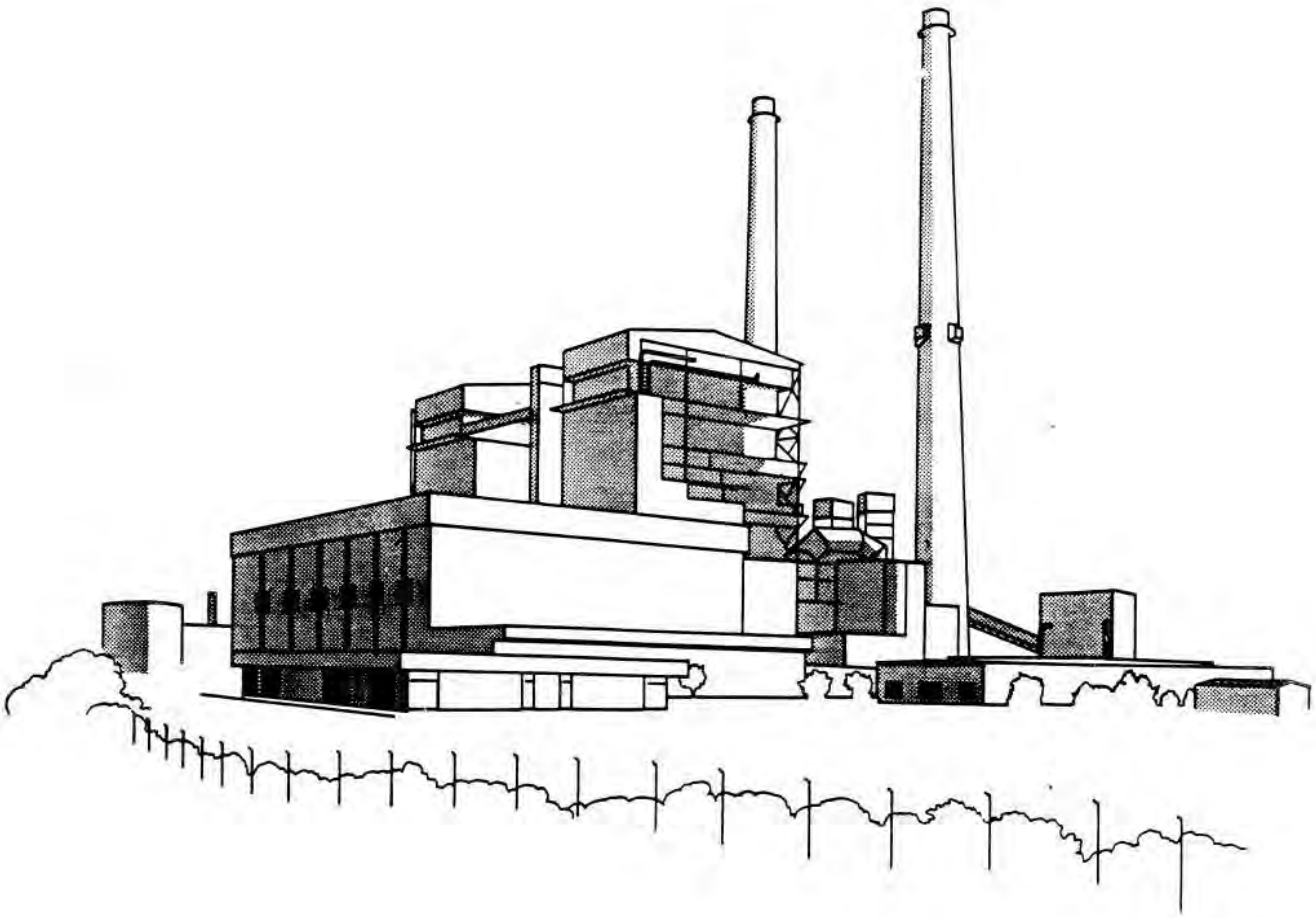
Report to Congress

Wastes from the Combustion of Coal by Electric Utility Power Plants



UNITED STATES ENVIRONMENTAL PROTECTION AGENCY
WASHINGTON, D.C 20460

MAR 8 1988

THE ADMINISTRATOR

Honorable George Bush
President of the Senate
Washington, D.C. 20510

Dear Mr. President:

I am pleased to transmit the Report to Congress on Wastes from the Combustion of Coal by Electric Utility Power Plants. The report presents the results of studies carried out pursuant to Section 8002(n) of the Resource Conservation and Recovery Act of 1976 as amended (42 U.S.C. Section 6982(n)).

The report provides a comprehensive assessment of the management of solid wastes generated by the combustion of coal from electric utility power plants. These wastes account for approximately 90 percent of all wastes generated from the combustion of fossil fuels. The principal waste categories covered include fly ash, bottom ash, boiler slag and flue gas emission control waste.

The report and appendices are transmitted in two separate volumes.

Sincerely,

Lee M. Thomas

Enclosure

THE ADMINISTRATOR

Honorable James C. Wright
Speaker of the House
of Representatives
Washington, D.C. 20515

Dear Mr. Speaker:

I am pleased to transmit the Report to Congress on Wastes from the Combustion of Coal by Electric Utility Power Plants. The report presents the results of studies carried out pursuant to Section 8002(n) of the Resource Conservation and Recovery Act of 1976 as amended (42 U.S.C. Section 6982(n)).

The report provides a comprehensive assessment of the management of solid wastes generated by the combustion of coal from electric utility power plants. These wastes account for approximately 90 percent of all wastes generated from the combustion of fossil fuels. The principal waste categories covered include fly ash, bottom ash, boiler slag and flue gas emission control waste.

The report and appendices are transmitted in two separate volumes.

Sincerely,

Lee M. Thomas

Enclosure

EXECUTIVE SUMMARY

The Environmental Protection Agency (EPA) has prepared this report on fossil fuel combustion wastes pursuant to the requirements of Section 8002(n) of the Resource Conservation and Recovery Act (RCRA), as amended in 1980. These amendments to the Act added Section 8002(n), which directed the Administrator of EPA to

> conduct a detailed and comprehensive study and submit a report on the adverse effects on human health and the environment, if any, of the disposal and utilization of fly ash waste, bottom ash waste, slag waste, flue gas emission control waste, and other by-product materials generated primarily from the combustion of coal or other fossil fuels.

Pending the completion of this study, fossil fuel combustion wastes were exempted from the hazardous waste requirements established under RCRA. Under Section 3001(b)(3)(A), EPA is prohibited from regulating these wastes until at least six months after this report is submitted to Congress.

If EPA determines that fossil fuel combustion wastes are hazardous under RCRA, and therefore subject to regulation under Subtitle C, EPA has some flexibility to promulgate regulations that take into account the unique characteristics of these wastes. Section 3004(x) states ...

> If ... fly ash waste, bottom ash waste, slag waste and flue gas emission control waste generated primarily from the combustion of coal or other fossil fuels ... is subject to regulation under this subtitle, the Administrator is authorized to modify the requirements of subsections (c), (d), (e), (f), (g), (o) and (u) and section 3005(j) ... to take into account the special characteristics of such wastes, the practical difficulties associated with implementation of such requirements, and site-specific characteristics ... so long as such modified requirements assure protection of human health and the environment.

This report examines only those wastes generated from the combustion of coal by the electric utility industry. These wastes account for approximately 90 percent of all wastes generated from the combustion of fossil fuels. EPA has deferred study of the disposal of wastes generated by the combustion of other fossil fuels and from coal combustion in industries other than the electric utility industry until a later date.

Coal-fired power plants produce substantial quantities of wastes. In 1984 about 69 million tons of ash and 16 million tons of flue gas desulfurization wastes were generated. Because of increasing reliance on coal for producing electricity, by the year 2000 the amount of ash waste is expected to increase by about 75 percent to about 120 million tons annually; production of FGD wastes is expected to triple to about 50 million tons annually.[1] In addition to the high-volume ash and flue gas desulfurization wastes, coal-fired power plants also generate several lower-volume waste streams as a result of equipment maintenance and cleaning activities.

About one-fifth of all waste generated at coal-fired electric utility power plants is currently reused; the remaining four-fifths are typically disposed in surface impoundments or landfills. The recycled wastes, usually fly ash, bottom ash, or boiler slag, have been used primarily as cement additives, high-volume road construction material, and blasting grit. There is some potential for increased use of these wastes in such applications. However, barring the

---

[1] It is possible that advances in coal combustion technology will alter the amount and types of coal-combustion wastes produced in the future. An analysis of these technological advances is beyond the scope of this report.

development of new utilization techniques, or major changes in combustion and environmental control technologies, the proportion of coal combustion wastes that are reused is unlikely to change significantly.

While utility waste management sites are currently exempt from RCRA hazardous waste requirements, they are subject to state and local level solid waste laws and regulations. There is substantial variation in the state-mandated disposal requirements.

Most utility waste management facilities were not designed to provide a high level of protection against leaching. Only about 25 percent of all facilities have liners to reduce off-site migration of leachate, although 40 percent of the generating units built since 1975 have liners. Additionally, only about 15 percent have leachate collection systems; about one-third of all facilities have ground-water monitoring systems to detect potential leachate problems. Both leachate collection and ground-water monitoring systems are more common at newer facilities.

The primary concern regarding the disposal of wastes from coal-fired power plants is the potential for waste leachate to cause ground-water contamination. Although most of the materials found in these wastes do not cause much concern (for example, over 95 percent of ash is composed of oxides of silicon, aluminum, iron, and calcium), small quantities of other constituents that could potentially damage human health and the environment may also be present. These constituents include arsenic, barium, cadmium, chromium, lead, mercury, and selenium. At certain concentrations, these elements have toxic effects.

To assess the potential threat to health and the environment posed by these wastes and to document any specific damage cases, EPA, other agencies, and various private organizations sponsored several studies. The main research efforts cited in this Report to Congress are a 1985 study by Arthur D. Little, Inc. for EPA, which characterized the environmental effects of waste disposal at several utility disposal sites, and a series of reports submitted to the Agency in 1982 by the Utility Solid Waste Activities Group, the Edison Electric Institute, and the National Rural Electric Cooperative Association.

The findings of these various research efforts indicate that most coal combustion wastes do not exhibit any of the four hazardous characteristics defined in RCRA Subpart C. The results of a substantial number of extraction procedure tests were examined; these tests indicated that metals do not generally leach out of coal combustion wastes at levels classified as hazardous under RCRA. The only metals which were found in any ash or sludge samples at "hazardous" levels were cadmium and arsenic. For boiler cleaning wastes, chromium and lead were sometimes found at levels classified as hazardous under RCRA. This waste stream was also found to be corrosive in a number of samples. Results of EP Tests performed on co-disposed high and low volume wastes indicate, however, that boiler cleaning wastes do not exhibit hazardous characteristics when co-disposed with ash.

While most of the laboratory results indicated that coal combustion wastes do not possess RCRA hazardous characteristics, in some instances, data on actual field observations indicate that migration of potentially hazardous constituents from utility waste disposal sites has occurred. For example, observed

concentrations of contaminants found in ground water downgradient from the sites exceed the Primary Drinking Water Standards about 5 percent of the time. Although the magnitude of the PDWS exceedances are typically not many times greater than the standard, a large number of disposal facilities report at least one PDWS exceedance at some time.

While a causal connection cannot always be made between the utility waste disposal site and the presence of contaminants at concentrations in excess of these standards, the available information indicates that some ground-water contamination from utility disposal sites is indeed occurring. The actual potential for exposure of human and ecological populations is likely to be limited, however, since ground water in the vicinity of utility waste disposal sites is not typically used for drinking water; the concentrations of contaminants in the ground water also tend to be diluted in nearby surface water bodies. These surface water bodies are typically used by electric utilities in the power plants for cooling and other purposes.

The electric utility industry currently spends about $800 million annually to dispose of its coal-fired combustion wastes. Under current practices, costs for waste management at most basic facilities range from as little as $2 per ton to as much as $31 per ton. Mitigative measures to control potential leaching include installation of liners, leachate collection systems, and ground-water monitoring systems and corrective action to clean up ground-water contamination. These mitigative measures, which are currently used at some utility waste disposal sites, may reduce the likelihood of ground-water contamination, but may also substantially increase disposal costs. For example,

the incremental cost of new waste disposal practices, excluding corrective action costs or higher recycling costs, could range up to $70 per ton, or $3.7 billion annually if all wastes were listed as hazardous. While substantial on a total cost basis, these increases would be unlikely to significantly affect the rate at which existing power plants consume coal. Due to the competitiveness of alternative fuels for electricity generation at future power plants, however, any increase in disposal costs could potentially slow the growth in electric utility coal consumption in future years. Moreover, if new disposal standards require corrective action measures as set forth in 40 CFR 264.100, the costs to utilities could be extremely high and could have a substantial effect on the utility industry.

Based on the findings from this Report to Congress, the Agency presents three preliminary recommendations for those wastes included in the scope of this study. The recommendations are subject to change based on continuing consultations with other government agencies and new information submitted through the public hearings and comments on this report. Pursuant to the process outlined in RCRA 3001(b)(3)(C), EPA will announce its regulatory determination within six months after submitting this report to Congress.

First, EPA has concluded that coal combustion waste streams generally do not exhibit hazardous characteristics under current RCRA regulations. EPA does not intend to regulate under Subtitle C fly ash, bottom ash, boiler slag, and flue gas desulfurization wastes. EPA's tentative conclusion is that current waste management practices appear to be adequate for protecting human health and the environment. The Agency prefers that these wastes remain under Subtitle D

authority. EPA will use section 7003 of RCRA and sections 104 and 106 of CERCLA to seek relief in any cases where wastes from coal combustion waste disposal sites pose substantial threats or imminent hazards to human health and the environment. Coal combustion waste problems can also be addressed under RCRA Section 7002, which authorizes citizen lawsuits for violations of Subtitle D requirements in 40 CFR Part 257.

Second, EPA is concerned that several other wastes from coal-fired utilities may exhibit the hazardous characteristics of corrosivity or EP toxicity and merit regulation under Subtitle C. EPA intends to consider whether these waste streams should be regulated under Subtitle C of RCRA based on further study and information obtained during the public comment period. The waste streams of most concern appear to be those produced during equipment maintenance and water purification, such as metal and boiler cleaning wastes. The information available to the Agency at this time does not allow EPA to determine the exact quantity of coal combustion wastes that may exhibit RCRA Subtitle C characteristics. However, sufficient information does exist to indicate that some equipment maintenance and water purification wastes do occasionally exhibit RCRA hazardous characteristics, and therefore, may pose a danger to human health and the environment. These wastes are similar to wastes produced by other industries that are subject to Subtitle C regulation, and waste management practices for coal combustion wastes are often similar to waste management practices employed by other industries. EPA is considering removing the exemption for all coal-fired utility wastes other than those identified in the first recommendation. The effect would be to apply Subtitle C regulation to any of those wastes that are hazardous by the RCRA characteristic tests. EPA

believes there are various treatment options available for these wastes that would render them nonhazardous without major costs or disruptions to the utilities.

Third, EPA encourages the utilization of coal combustion wastes as one method for reducing the amount of these wastes that need to be disposed to the extent such utilization can be done in an environmentally safe manner. From the information available to the Agency at this time, current waste utilization practices appear to be done in an environmentally safe manner. The Agency supports voluntary efforts by industry to investigate additional possibilities for utilizing coal combustion wastes.

Through its own analysis, evaluation of public comments, and consultation with other agencies, the Agency will reach a regulatory determination within six months of submission of this Report to Congress. In so doing, it will consider and evaluate a broad range of management control options consistent with protecting human health and the environment. Moreover, if the Agency determines that Subtitle C regulation is warranted, in accordance with Section 3004(x) EPA will take into account the "special characteristics of such waste, the practical difficulties associated with implementation of such requirements, and site-specific characteristics . . .," and will comply with the requirements of Executive Orders 12291 and 12498 and the Regulatory Flexibility Act.

CHAPTER ONE

INTRODUCTION

This is the Environmental Protection Agency's Report to Congress on wastes from fossil fuel combustion, as required by section 8002(n) of the Resource Conservation and Recovery Act. It describes sources and quantities of utility waste, current utilization and disposal practices and alternatives to these practices, potential dangers to human health and the environment, and the costs of current and alternative waste management practices. This report is based on numerous literature reviews and contractor studies; EPA's RCRA Docket contains copies of the source materials that the Agency used in preparing this report.

1.1 Legislative History

Because Congress has amended the Resource Conservation and Recovery Act several times and EPA's regulatory program continues to evolve in response to these Congressional mandates and other additional information, a brief legislative and regulatory history is provided below.

The Resource Conservation and Recovery Act (RCRA, or the Act) of 1976 (Public Law 94-580) substantially amended the Solid Waste Disposal Act of 1965 and authorized the U.S. Environmental Protection Agency (EPA) to establish and enforce regulations concerning the identification, generation, transportation, and management of hazardous waste. These regulations would accomplish the Act's objectives of "...promote[ing] the protection of health and the environment ... and conserve[ing] valuable material and energy resources...."[1] RCRA comprises several subtitles, including Subtitle C-- Hazardous Waste

Management, and Subtitle D-- State or Regional Solid Waste Plans. The intent of the regulations promulgated under Subtitle C of the Act is that wastes identified as hazardous be properly managed from "cradle to grave," that is, from the time they are generated, during transport, throughout their use in various applications, and during disposal. As provided under RCRA Subtitle D, other wastes not considered hazardous as defined under Subtitle C are subject to State regulations.

On December 18, 1978, EPA proposed the first regulations to implement Subtitle C. In the course of preparing these regulations, EPA recognized that certain very large-volume wastes (e.g., wastes generated by utility power plants) could require special treatment:

> ... The Agency has very little information on the composition, characteristics, and the degree of hazard posed by these wastes, nor does the Agency yet have data on the effectiveness of current or potential waste management technologies or the technical or economic practicability of imposing the Subpart D standards [current RCRA section 3004--Standards applicable to owners and operators of hazardous waste treatment, storage, and disposal facilities] on facilities managing such waste.
>
> The limited information the Agency does have indicates that such waste occurs in very large volumes, that the potential hazards posed by the waste are relatively low, and that the waste generally is not amenable to the control techniques developed in Subpart D.[2]

Thus, the Agency proposed a limited set of regulations for managing large-volume wastes, pending an additional rulemaking. Until that rulemaking was completed, EPA proposed exempting utility wastes from storage and disposal regulations.

On May 19, 1980, EPA promulgated the first regulations implementing Subtitle C of RCRA. By then, Congress was debating RCRA reauthorization, and both Houses had passed bills restricting EPA's ability to regulate utility wastes. Anticipating the enactment of legislation amending RCRA Section 3001, EPA excluded utility wastes from the promulgated regulations, writing in the preamble:

> The United States Senate and House of Representatives have each recently passed a bill to reauthorize and amend RCRA (S.1156 and H.R.3994). Both bills contain amendments to Section 3001 which, if enacted, would repeal or temporarily suspend EPA's authority to regulate certain utility and energy development wastes as hazardous wastes under Subtitle C. These bills are now awaiting action by a conference committee. Because it appears likely that Congress will act before November 19, 1980 [the end of the six month comment period on the promulgated interim final regulations and the date on which they would take effect] to exempt these wastes, EPA has temporarily excluded them from this regulation (see section 261.4(b)). This exclusion will be revised, if necessary, to conform to the legislation which is ultimately enacted.[3]

In fact, Congress did act before November 19, 1980; the Solid Waste Disposal Act Amendments (Public Law 96-482) were passed in October 1980.

As anticipated, the amendments temporarily exempted from regulation fly ash waste, bottom ash waste, boiler slag waste, and flue gas emission control waste generated primarily from the combustion of coal or other fossil fuels. In section 8002(n), Congress directed EPA to produce a report on the kinds of waste generated by the combustion of coal and other fossil fuels, which would include an analysis of eight topics:

1. the source and volumes of such material generated per year;

2. present disposal and utilization practices;

3. potential danger, if any, to human health and the environment from the disposal and reuse of such material;

4. documented cases in which danger to human health or the environment from surface runoff or leachate has been proved;

5. alternatives to current disposal methods;

6. the costs of such alternatives;

7. the impact of those alternatives on the use of coal and other natural resources; and

8. the current and potential utilization of such materials.[4]

Finally, in section 3001(b)(3)(C), Congress directed that within six months after submitting this report, EPA must conduct public hearings and decide whether regulating the management of coal combustion wastes under Subtitle C is warranted. Once the decision is made, the Administrator must publish the Agency's regulatory determination in the Federal Register.

In a January 1981 letter,[5] Gary Dietrich, then Associate Deputy Assistant Administrator for Solid Waste, provided an interpretation of RCRA regulations concerning the exemption from regulation of fossil fuel combustion waste.[6] (This letter, as well as a February 18, 1981 memorandum that enclosed it as part of a mailing to EPA Regional Directors, is included as Appendix A.) The letter noted that the beneficial use of hazardous waste as a fuel was not subject to regulation, though it might well be subject to regulation in the future. This meant that utilities could burn as fuel a combination of

hazardous waste and coal, as long as more than 50 percent of the mixture was comprised of coal. The letter also addressed disposal, noting that wastes produced in conjunction with the burning of fossil fuels (e.g., cleaning and other maintenance-related wastes) may be exempt from Subtitle C regulations provided they are mixed and co-disposed or co-treated with fossil fuel wastes and provided "there is no evidence of any substantial environmental danger from these mixtures."[7] The letter concluded:

> ...Pending the completion of [further study on the hazards posed by waste from coal-fired utility plants and the collection of relevant data from the utility industry], EPA will interpret 40 CFR 261.4(b)(4) to mean that the following solid wastes are not hazardous wastes:
>
> (a) Fly ash, bottom ash, boiler slag, and flue gas emission control wastes resulting from (1) the combustion solely of coal, oil, or natural gas, (2) the combustion of any mixture of these fossil fuels, or (3) the combustion of any mixture of coal and other fuels, where coal makes up more than 50 percent of the mixture.
>
> (b) Wastes produced in conjunction with the combustion of fossil fuels, which are necessarily associated with the production of energy, and which traditionally have been, and which actually are, mixed with and co-disposed or co-treated with fly ash, bottom ash, boiler slag, or flue gas emission control wastes from coal combustion.

This provision includes, but is not limited to, boiler cleaning solutions, boiler blowdown, demineralizer reagent, pyrites, and cooling tower blowdown.

In November 1984, Congress reauthorized RCRA by passing the Hazardous and Solid Waste Amendments (HSWA). These amendments restricted the land disposal

of certain hazardous wastes without treatment, established minimum technology requirements for landfills and surface impoundments, issued corrective action requirements for continuing releases at permitted facilities, and established interim status requirements for surface impoundments. Under this new legislation, EPA was granted some flexibility to promulgate regulations that take into consideration the unique characteristics of several types of large-volume wastes, including wastes generated by utility power plants. Specifically, if EPA determined that some or all of the wastes from fossil fuel combustion were subject to regulation under Subtitle C, EPA was empowered to modify the standards imposed by HSWA "...to take into account the special characteristics of such wastes, the practical difficulties associated with implementation of such requirements, and site-specific characteristics ... so long as such modified requirements assure protection of human health and the environment."[8]

The HSWA Conference Report accompanying H.R. 2867 (which in its final amended form was passed by both Houses of Congress as Public Law 98-616) provides clarification:

> This Amendment recognizes that even if some of the special study wastes [which include utility wastes as specified in Section 8002(n)] are determined to be hazardous it may not be necessary or appropriate because of their special characteristics and other factors, to subject such waste to the same requirements that are applicable to other hazardous wastes, and that protection of human health and the environment does not necessarily imply the uniform application of requirements developed for disposal of other hazardous wastes. The authority delegated to the Administrator under this section is both waste-specific and requirement-specific. The Administrator could also exercise the authority to modify requirements for different classes of wastes. Should these wastes become subject to the requirements of Section 3005(j), relating to the retrofit of surface impoundments, the Administrator could

> modify such requirements so that they are not identical to the requirements that are applied to new surface impoundments containing such wastes. It is expected that before any of these wastes become subject to regulation under Subtitle C, the Administrator will determine whether the requirements of Section 3004(c), (d), (e), (f), (g), (o), and (u), and Section 3005(j) should be modified.[9]

1.2. Scope and Sources

This report addresses only the wastes generated by coal-fired electric utility power plants. Because this industry generates the vast majority of all fossil fuel combustion waste (nearly 90 percent),[10] EPA decided to focus its study in this area. This study does not address oil- and gas-fired electric utility power plants or coal, oil and gas-fired industrial boilers.

A number of research projects were undertaken to provide data for this report. EPA sponsored a major study of current coal ash and flue gas desulfurization waste management practices at coal-fired electric utility power plants.[11] In this study comprehensive environmental monitoring was conducted, which included characterizing the wastes, soils, ground water, and surface water at six disposal sites. The contractor (Arthur D. Little, Inc.) evaluated the environmental effects of the disposal practices used at these six sites and, by inference, what effects may be present at other utility waste disposal sites. They also performed extensive engineering and cost evaluations of disposal practices at the six sites.

EPA also sponsored a separate study effort to develop information on the incidences of ground water contamination resulting from utility waste management practices.[12] In this study, contamination was defined as the presence of hazardous constituents at levels above primary drinking water

standards. The main source of information for this phase of the research was a review of case files at the state offices having responsibility for such matters.

In addition, the Agency also reviewed reports submitted by the Utility Solid Waste Activities Group (USWAG), the Edison Electric Institute (EEI), and the National Rural Electric Cooperative Association (NRECA).[13] The reports present information on the sources, volumes, and physical and chemical characteristics of waste streams; ground-water monitoring results assembled from various utility plants; damage case information from various sources; costs of complying with hazardous waste regulations; and resource recovery opportunities using utility wastes.

EPA also has incorporated findings from several documents prepared by the Department of Energy (DOE) and the Electric Power Research Institute (EPRI).[14] These reports examined the chemical composition of utility wastes, technologies for disposal and the costs associated with disposal, as well as results of leaching tests performed on utility wastes.

Finally, EPA gathered information from the Utility Data Institute's Power Statistics Database.[15] This database contains information concerning the size of utility power plants, location of power plants, the types of disposal technologies employed by each power plant, and the amount of waste produced by site and by region. The information on location of power plants was combined with hydrogeologic, population, and ecological profiles of these locations to analyze the potential for exposure to coal combustion wastes.

1.3 Organization

The following chapters of this report address the eight issues (enumerated earlier in this chapter) as required by Section 8002(n) as they apply to coal-fired combustion wastes generated by electric utilities. Chapter Two of this report provides an overview of the U.S. electric utility industry. Chapter Three examines the amount and types of wastes that are generated. Chapter Four discusses current waste management and disposal practices used by the electric utility industry, as well as alternatives to these practices; a review of applicable State regulations is included in this chapter. Chapter Five reviews the potential and documented impact of these wastes on human health and the environment, and Chapter Six evaluates costs associated with current waste disposal practices and additional costs that could be incurred under a variety of alternative waste management practices. Finally, Chapter Seven summarizes the conclusions contained in the previous chapters and presents recommendations.

[10] Most fossil fuel combustion wastes are generated from coal. For example, as indicated in Physical-Chemical Characteristics of Utility Solid Wastes (by Tetratech, Inc. for EPRI, September 1983), only about one percent of utility wastes are generated from oil; the remaining 99 percent is largely attributable to coal-fired electricity production. Of the coal consumed in the U.S., electric utilities burn nearly 90 percent (excluding metallurgical coal, which is not burned but is instead converted into coke primarily for making steel).

More sources are included in the Bibliography.

[15] Utility Data Institute's Power Statistics Database was developed under the auspices of the Edison Electric Institute to assist in their analysis of issues affecting the electric utility industry.

CHAPTER TWO

OVERVIEW OF THE ELECTRIC UTILITY INDUSTRY

This chapter provides a general overview of the U.S. electric utility industry. Section 2.1 summarizes electricity demand and discusses the overall structure of the electric utility industry. Section 2.2 focuses the discussion on the role that coal plays in generating electricity. Section 2.3 provides details of coal-fired electric generating technologies and the regional characteristics of coal-fired plants. The chapter concludes with a discussion in Section 2.4 of the waste streams that are produced during coal combustion.

2.1 THE DEMAND FOR ELECTRICITY

The generation, transmission, and distribution of electricity is one of our nation's largest industries. With annual revenues in excess of $140 billion and assets of about $500 billion, the electric utility industry provides vital services to nearly every person in the U.S.[1]

Total demand for electricity in the U.S. has increased substantially in recent decades and will likely continue to grow in coming years (see Exhibit 2-1). From the 1940's through the early 1970's, electricity demand grew at about 7 percent per year, doubling approximately every ten years. This growth slowed beginning with the 1973 OPEC oil embargo and subsequent changes in the energy markets such as fuel price increases, shifts in the economy to markets that require less electricity to meet their power needs, and energy conservation measures. Since 1973, growth in electricity demand has averaged

EXHIBIT 2-1

GROWTH IN ELECTRICITY DEMAND - 1975-2000

about three percent per year. Expectations are that electricity demand will continue to grow at an average rate of about 2 to 3 percent per year over the next several years.[2]

Every major segment of the U.S. economy relies on electricity to meet a portion of its energy needs. As shown in Exhibit 2-2, the demand for electricity is divided almost evenly between the industrial, commercial, and residential sectors. This demand for electricity has continued to increase over the last decade with total sales increasing from 1.7 million gigawatt-hours (Gwh) in 1975 to 2.3 million Gwh in 1985.[3] As demand has increased, electricity sales patterns have remained relatively consistent. Industry continues to be the largest consuming sector, although industry's fraction of total sales has decreased by about 2.7 percent from 1975 to 1985, primarily due to an increased market share for the commercial sector (i.e., stores, office buildings, restaurants, etc.). Residential customers consume about one-third of all electricity for basic necessities such as lighting, heating, and electrical appliances.

Virtually every geographic area in the U.S. relies on electricity supplied by the electric utility industry. As shown in Exhibit 2-3, electricity demand is highest in the eastern half of the U.S., particularly in EPA Regions 3-6 (see Exhibit 2-4 for a map of these EPA Regions). This level of demand is not surprising considering that these areas are the most heavily industrialized and densely populated areas of the country.

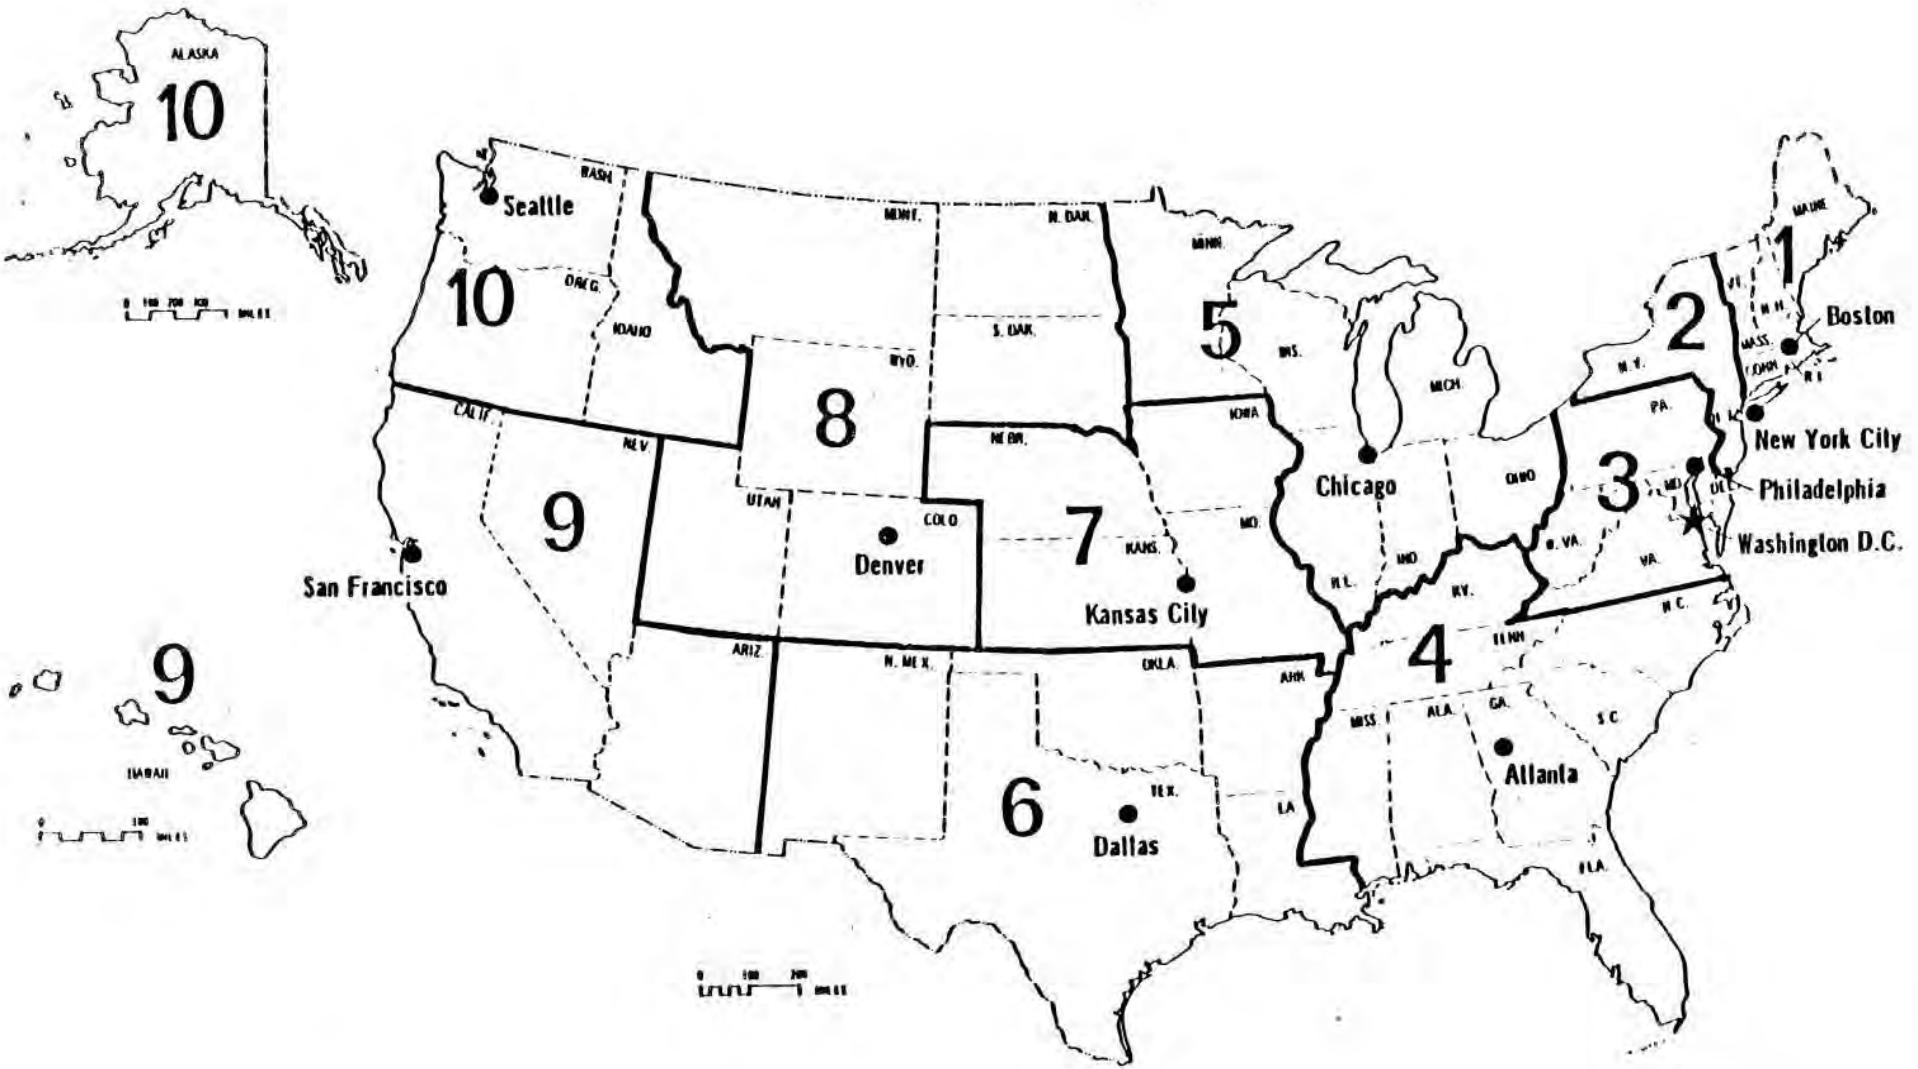
EXHIBIT 2-4

EPA FEDERAL REGIONS



2.1.1 Structure of the U.S. Electric Utility Industry

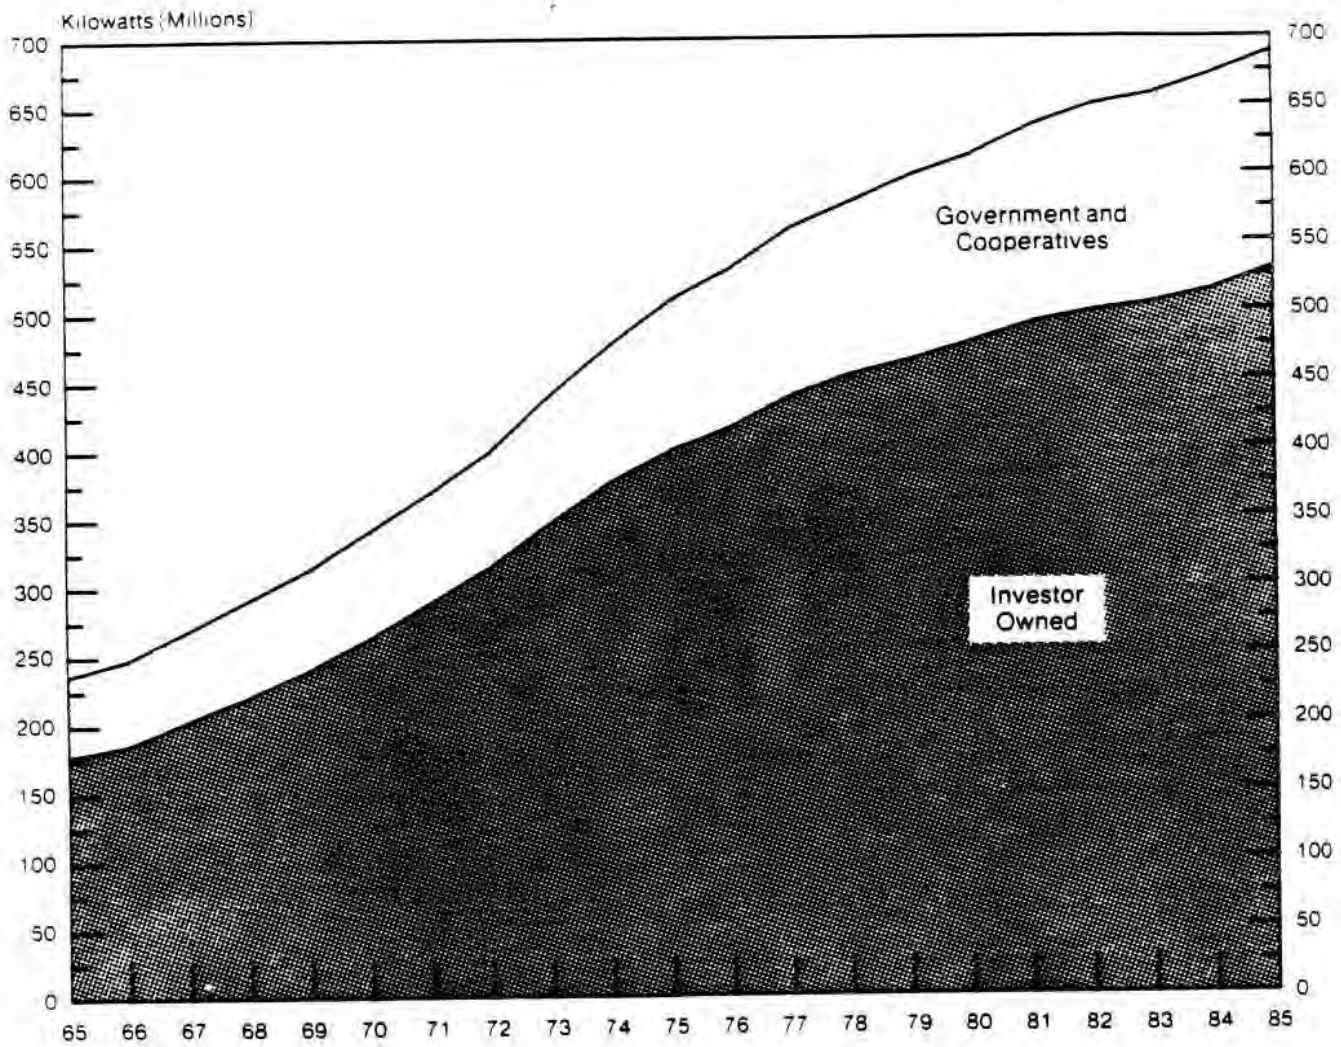
The U.S. electric power industry is a combination of private, Federal, and public nonprofit organizations. The distribution of capacity, generation, revenue, and sales differs widely among these ownership groups since each group has different objectives, organizational characteristics, and financing methods. Private investor-owned utilities dominate the U.S. electric utility industry as shown in Exhibit 2-5. Investor-owned utilities have historically served large consolidated markets to take advantage of economies of scale. Federal, municipal, cooperative, and other publicly-owned utilities have generally served smaller markets where local governments or nonprofit organizations have had access to limited supplies of less expensive Federal power or to government-supplied capital for power plant construction. These circumstances have allowed municipal, cooperative, or other publicly-owned utilities to predominate in areas not traditionally served by investor-owned utilities.[4] A brief discussion of each type of organization is provided below.

2.1.1.1 Investor-Owned Utilities

Investor-owned utilities account for about three-quarters of all U.S. electric utility generating capacity, generation, sales, and revenue. Investor-owned utilities are privately owned, profit-oriented businesses granted service monopolies in certain geographic areas. As franchised monopolies, they are obligated to provide service to all customers within their geographic area. In providing this service, investor-owned utilities are required to charge reasonable prices, to charge similar prices to similar

EXHIBIT 2-5

GENERATING CAPACITY IN THE UNITED STATES



Source: Edison Electric Institute, Statistical Yearbook for the Electric Utility Industry/1985, December 1986.

customers, and to give customers access to services under similar conditions.[5] Investor-owned utilities operate in all states except Nebraska (which depends primarily on public power districts and rural electric cooperatives for electricity). In 1984, consumers paid an average of 6.5 cents per kilowatt-hour (kwh) for privately-produced power compared to the industry average from all ownership groups of 6.3 cents per kilowatt-hour (an average customer consumed 23,150 kwh in 1984).[6]

2.1.1.2 Federal Power

The U.S. Government is the second largest producer of electricity in the United States with roughly 10 percent of total U.S. generation and generating capacity. Consumers of Federal power paid the lowest rate among the different ownership groups -- only 3.5 cents per kwh on average in 1984, (compared to an industry average of 6.3 cents per kwh).[7] Federal power production is designed to provide power at the lowest possible rate, with preference in the sale of electricity given to public entities and cooperatives.[8] In this role the Federal Government is primarily a generator and wholesaler of electricity to other organizations, rather than a direct distributor to electricity consumers.[9]

2.1.1.3 Municipal Utilities

Municipal utilities are nonprofit local government agencies designed to serve their customers at the lowest possible cost. Most municipal utilities simply distribute power obtained from one of the other ownership groups (e.g., Federal facilities), although some larger ones also generate and transmit

power. Municipally-owned electric utilities rank third in the amount of installed capacity (5.5 percent of total generating capacity), but comprise the single most numerous ownership group (1,811 utilities in 1984).[10] Average revenue per kwh sold in 1984 was 5.69 cents compared to an industry average of 6.3 cents per kwh. Municipal utilities are exempt from local, state, and Federal taxes and have access to less expensive capital via public financing and less expensive Federal power. As a result, municipal utilities can generally afford to charge less than investor-owned utilities for the power they produce.[11]

2.1.1.4 Cooperatives

Rural electric cooperatives are owned by and provide electricity to their members and currently operate in 46 states. They have the lowest amount of installed capacity among all ownership categories (24.7 gigawatts in 1984 or less than 4 percent of all capacity).[12]

In 1984, average revenue for cooperatives from sales to consumers was 6.7 cents per kwh, the highest of all ownership types (the industry average was 6.3 cents per kwh). Large construction programs in the 1970's usually account for the high rates.[13]

2.1.1.5 Other Public Entities

There are a variety of other public organizations that provide electric power, including public power districts, state authorities, irrigation districts, and various other State organizations. These other public entities

operated a combined total of 32.8 gigawatts in 1984, or about 5 percent of all generating capacity in the U.S.[14] The public power districts are concentrated in five states -- Nebraska, Washington, Oregon, Arizona, and California. The average price paid for electricity from all of these entities was 4.37 cents per kwh in 1984, compared to an industry average of 6.3 cents per kwh.[15]

2.1.2 Economic and Environmental Regulation of the Electric Utility Industry[16]

The electric utility industry is regulated by several different regulatory bodies at both the Federal and State levels. According to the U.S. Department of Energy: "The basic purpose of public utility regulation is to assure adequate service to all public utility patrons, without discrimination and at the lowest reasonable rates consistent with the interests both of the public and the electric utilities."[17] This regulation involves both economic and environmental objectives. As natural monopolies, electric utilities are regulated to ensure that adequate, reliable supplies of electric power are available to the public at a reasonable cost. Additionally, since the operations of electric utilities can affect environmental quality, they are regulated to ensure the protection of the nation's air and water resources. This section briefly reviews the main regulatory bodies that affect the electric utility industry.

2.1.2.1 Federal Regulation

There are five major organizations at the Federal level that regulate some aspect of the electric utility industry -- the Federal Energy Regulatory Commission (FERC), the Economic Regulatory Administration (ERA), the

Securities and Exchange Commission (SEC), the Nuclear Regulatory Commission (NRC), and the Environmental Protection Agency (EPA).

- The Federal Energy Regulatory Commission (FERC) oversees various aspects of the electric utility, natural gas, hydroelectric, and oil pipeline industries. FERC approves the rates and standards for wholesale interstate electricity sales between investor-owned utilities and other investor-owned utilities, municipals, or cooperatives (these sales are about 15 percent of total U.S. electricity sales).[18] It determines whether these rates are reasonable and non-discriminatory. FERC also oversees utility mergers and the issuance of certain stock and debt securities, approves the rates of Federal Power Marketing Administrations, and administers agreements between utilities concerning electricity transmission.

- The Economic Regulatory Administration (ERA) has several responsibilities, including administering a program to ensure that all future power plants have the potential to burn coal, regulating international electricity transmission connections, and licensing exports of power.

- The Securities and Exchange Commission (SEC) is an independent regulatory agency established to regulate interstate transactions in corporate securities and stock exchanges. With respect to the electric utility industry, the SEC regulates the purchase and sale of securities, utility properties, and other assets.

- The Nuclear Regulatory Commission (NRC) is involved only in the regulation of nuclear facilities owned and operated by the utility industry. Its main responsibilities include licensing the construction and operation of nuclear facilities, licensing the possession, use, transportation, handling, and disposal of nuclear materials, licensing the export of nuclear reactors and the import and export of uranium and plutonium, and regulating activities affecting the protection of nuclear facilities and materials.

In addition to these regulatory bodies, the Environmental Protection Agency (EPA) is the main Federal regulatory authority for protecting the nation's air and water quality. As part of its overall authority, EPA sets limits on the level of air pollutants emitted from electric power plants and develops regulations to control discharges of specific water pollutants.

Throughout this Report to Congress key regulations that affect the electric utility industry are discussed. While EPA often takes the Federal lead when these regulations are developed, the Agency also works closely with the States since they often retain primary authority for implementing and enforcing standards (for example, see Section 4.1 on state regulation of coal combustion wastes).

2.1.2.2 State Regulation

States are also involved in the environmental and economic regulation of the electric utility industry. As mentioned above, the States often share regulatory authority with the various Federal organizations. For environmental regulation the States often have their own environmental protection agencies to implement and enforce State and Federal environmental regulations. For example, they are responsible for drafting State Implementation Plans (SIP) that must be approved by the U.S. EPA to attain National Ambient Air Quality Standards (NAAQS). Similarly, as will be discussed in greater detail in Chapter Four, the States have authority for implementing and enforcing regulations concerning the disposal of solid wastes under Subtitle D of RCRA. Environmental regulations for which the States exercise regulatory authority are discussed throughout this Report to Congress.

States are also very involved in the economic regulation of the electric utility industry. The primary goals of state economic regulation is usually to provide adequate nondiscriminatory service to electricity consumers at reasonable prices.[19] This is usually accomplished by state regulatory

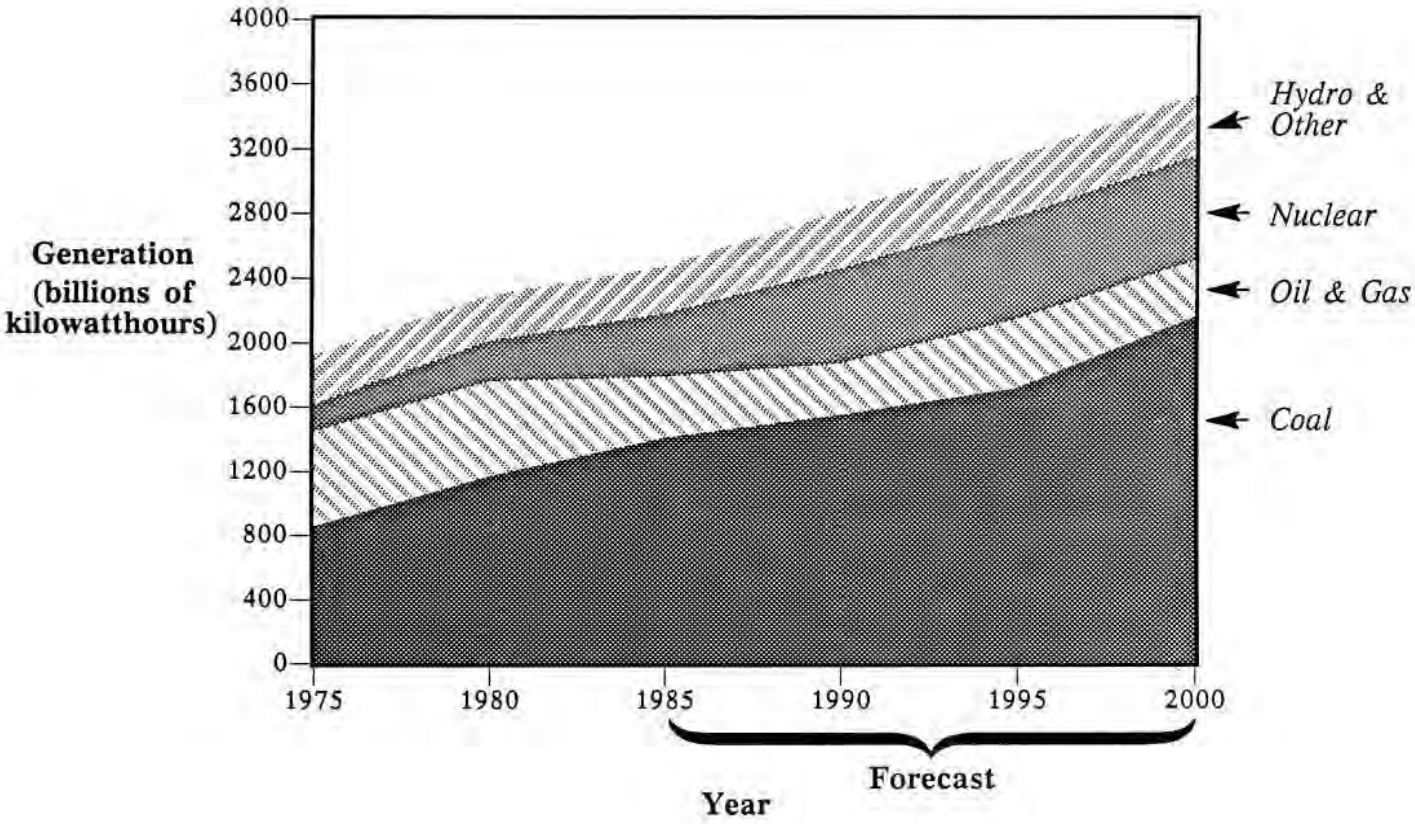
agencies such as public utility commissions. The amount of authority these state regulatory agencies have can differ widely from state to state. However, these agencies usually have the authority to approve electricity price levels and the rates of return allowed for utility stockholders. State regulators also approve the franchise under which the utility operates. Licensing for construction and operation and approval of the sites at which power plants will be built are also important functions of some state regulatory commissions. Other areas into which some commissions have entered to ensure that utility activities protect the public interest include setting rules about when competitive bids are required, promulgating company performance standards, deriving methods for allocating power during shortages, establishing billing and safety rules, and promoting conservation.[20]

2.2 IMPORTANCE OF COAL TO ELECTRIC UTILITIES

Electric utilities use many different technologies and energy sources to generate electricity. At present, as shown in Exhibit 2-6, over 70 percent of electricity in the U.S. is generated by the combustion of fossil fuels (coal, oil and natural gas); most of the remaining 30 percent is generated by hydroelectric plants and nuclear power plants. A small portion of electricity demand is satisfied by alternative sources such as geothermal energy, renewable resource technologies (e.g., wood, solar energy, wind), purchased power from industrial and commercial cogeneration (cogeneration is the simultaneous production of electricity and process steam; the electricity is typically used by the cogenerator or sold to another industry while the steam is used for various production processes), and power imports (primarily from Canada).

EXHIBIT 2-6

ELECTRICITY GENERATION BY PRIMARY ENERGY SOURCE
1975-2000



Source: 1975-1985: Energy Information Administration, Electric Power Monthly DOE/EIA-0226 (85/12), December 1985, p. 10.

1985-2000: ICF Incorporated, Analysis of 6 and 8 million Ton and 30 Year/NSPS and 30 Year/1.2 lb. Sulfur Dioxide Emission Reduction Cases, Prepared for Environmental Protection Agency, February 1986.

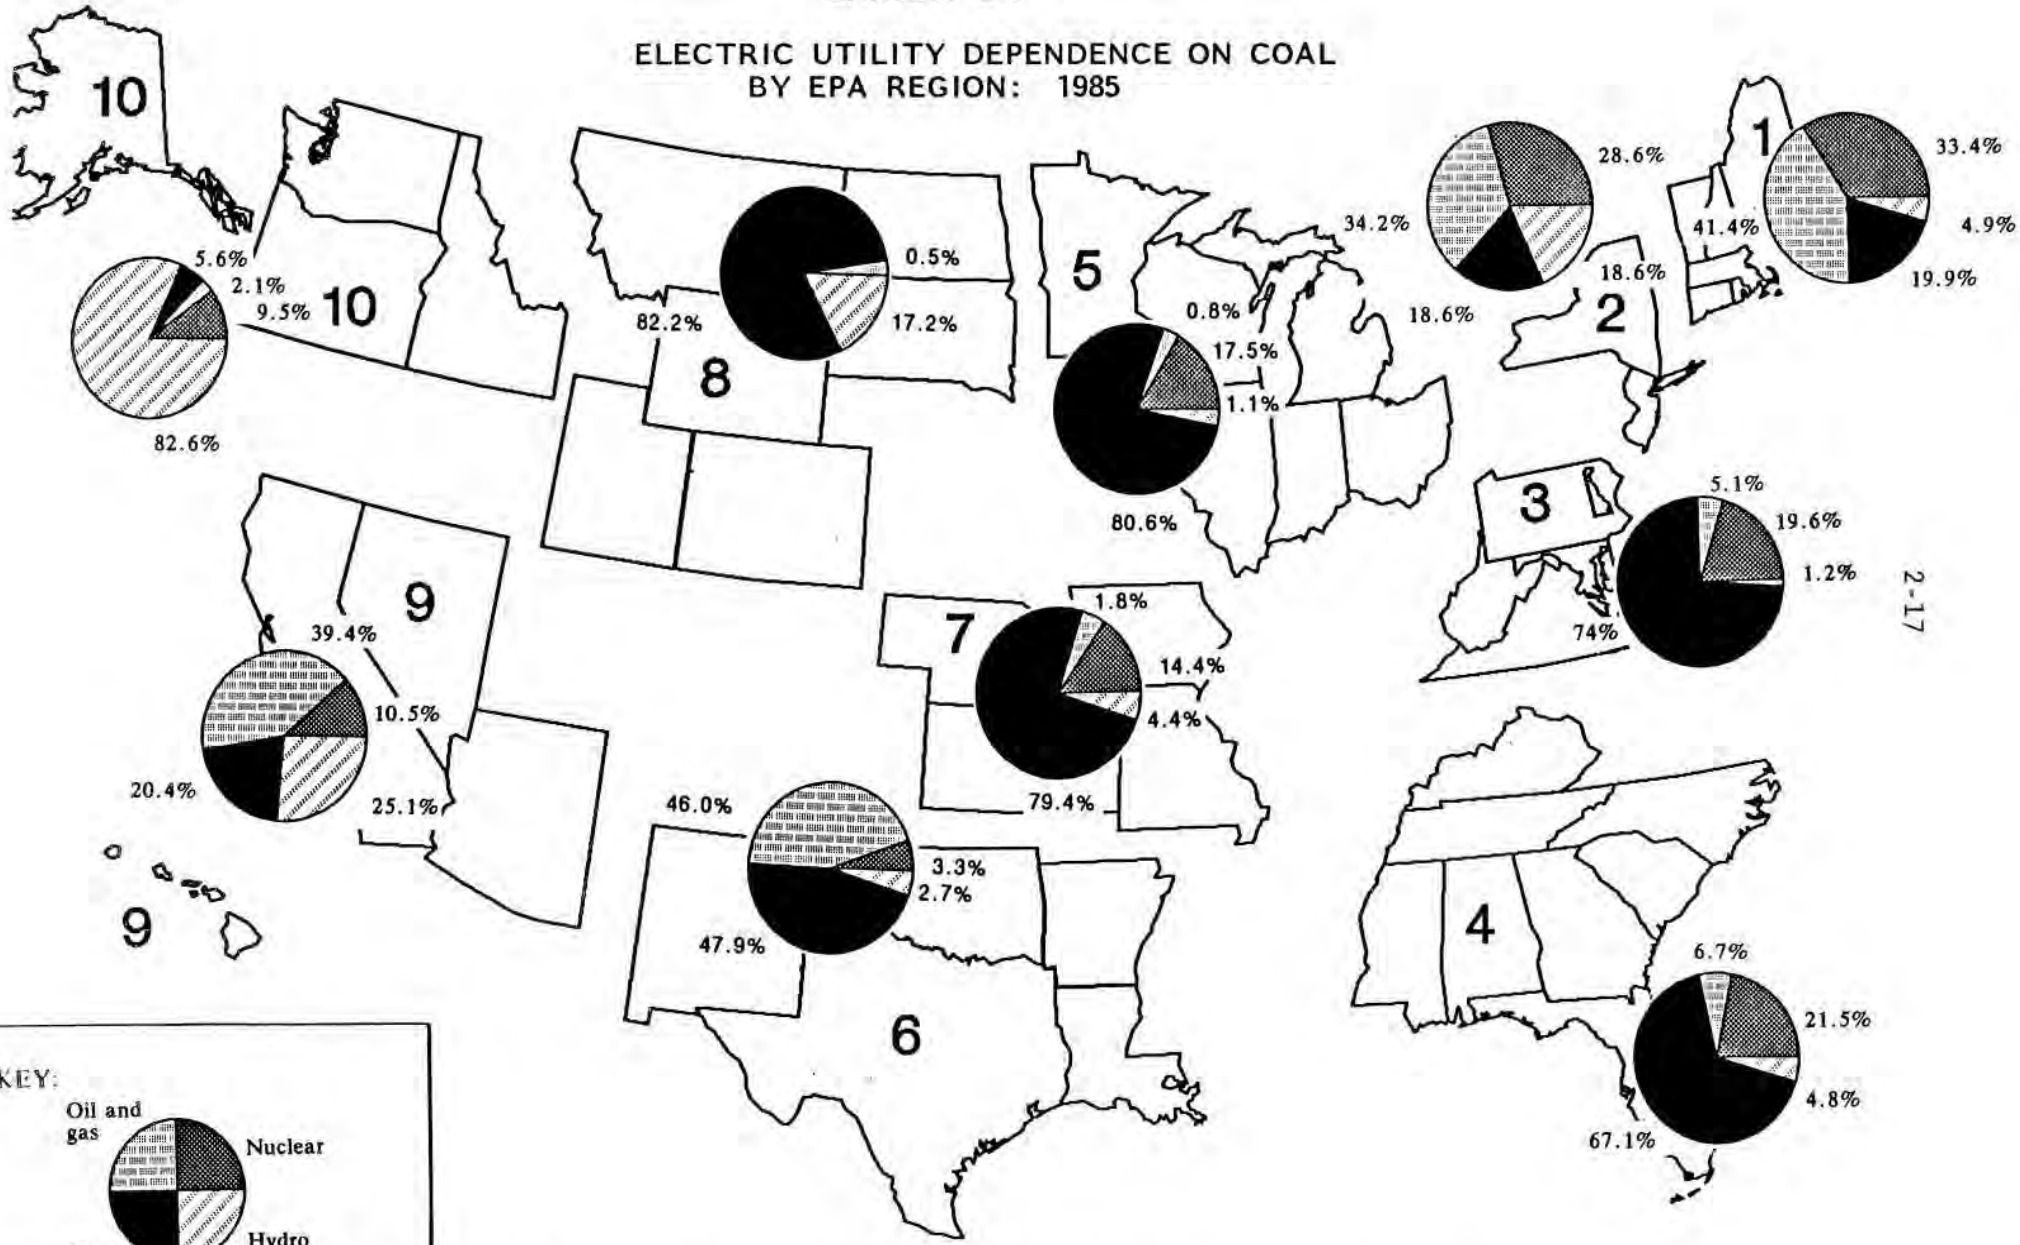
In 1984, coal accounted for more than half of all the electricity generated in the U.S.[21] The portion of electricity generated from coal is expected to remain at about this level throughout the rest of the century since coal-fired generation is expected to remain economically attractive. The relative contribution to total generation made by other fossil fuels and by hydroelectric power will likely continue to decline, while the contribution made by nuclear power plants will likely increase for the next few years as several new units come on-line. However, the addition of nuclear plants beyond those now under construction will be minimal, leading to an eventual decline in nuclear's relative contribution. Cogeneration, power imports, and emerging technologies are expected to continue to grow, but their share of total generation will remain small. As a result, coal will continue to be the major fuel source for electricity generation.

The extent of the electric utility industry's dependence on coal varies geographically. Exhibit 2-7 shows that coal accounts for over three-quarters of electricity generation in some regions, but less than half in others. For example, in the far West and southern Plains states, the local availability of oil, gas, and hydroelectric power has limited regional dependence on coal. In many of the eastern regions, where coal is relatively more accessible and less costly than oil or gas, coal is significantly more dominant. Despite these regional variations, however, coal-fired electricity generation is an important source of electricity in most regions of the United States.

The use of coal by electric utilities has also made the coal and electric utility industries highly interdependent; not only does coal-fired electricity generation account for over half of the electricity produced in the U.S., but

EXHIBIT 2-7

ELECTRIC UTILITY DEPENDENCE ON COAL
BY EPA REGION: 1985



KEY:

the electric utility industry is the largest customer of the coal industry, purchasing approximately three-quarters of all coal mined, as shown in Exhibit 2-8. This interdependence has increased as electric utility coal consumption has grown from 406 million tons in 1975 to over 600 million tons in 1985.[22] Moreover, electric utility coal consumption is expected to continue to increase to about 1 billion tons by the year 2000.

2.3 OVERVIEW OF COAL-FIRED POWER PLANTS

Coal-fired power plants can vary greatly in terms of their generating capacity and the type of boiler technology they employ which, in turn, can affect the amount and type of combustion wastes produced. This section discusses the geographic differences in the size of plants and generating units and describes the three main boiler types along with the regional importance of each.

2.3.1 Regional Characteristics of Coal-Fired Electric Generating Plants

Coal-fired power plants can range in size from less than 50 MW to larger than 3000 MW. In many cases, particularly at the larger power plants, one power plant site may be the location for more than one generating unit (a generating unit is usually one combination of a boiler, turbine, and generator for producing electricity). Exhibit 2-9 shows the number of coal-fired power plants and number of units in each EPA region and their average size in megawatts. On average, each power plant site is comprised of about three generating units. The average generating capacity of coal-fired power plants in the U.S. is approximately 584 MW, with an average unit size of 257 MW.

a/ The total amount of generating capacity indicated by multiplying the number of units by their average size (e.g., 1378 units X 257 Mw = 354,146 Mw) is greater than the amount indicated by multiplying the number of power plants by their average (e.g., 514 plants X 584 Mw = 300,176 Mw) because the information in the UDI Power Statistics Database by generating units includes units planned, currently under construction, etc. while the information by power plants refers only to power plants currently operating.

Regional averages for power plant size range from 297 MW in Region 2 to 852 MW in Region 6. Unit sizes range from an average of 138 Mw in Region 2 to 580 Mw in Region 6. Individual power plants and units can be larger or smaller than these averages indicate.

The majority of coal-fired plants (60%) are smaller than 500 MW, while only about 4 percent of U.S. coal-fired power plants have a generating capacity exceeding 2000 MW. Exhibit 2-10 shows the distribution of coal-fired plant sizes across EPA regions.

2.3.2 Electricity Generating Technologies

The basic process by which electricity is produced with coal is shown in Exhibit 2-11. When coal is burned to produce electricity, there are three key components that are critical to the operation of the power plant: the boiler, turbine, and generator. As coal is fed into the boiler, it is burned in the boiler's furnace. In the boiler there are a series of water-filled pipes. As heat is released during combustion, the water is converted to steam until it reaches temperatures that can exceed 1000°F and pressures that approach 4000 pounds per square inch. This high pressure, high temperature steam is then injected into a turbine, causing the turbine blades to rotate. The turbine, in turn, is connected to a generator, so the mechanical energy available from the rotating turbine blades is transformed into electrical energy. The electricity produced by this process is distributed via transmission lines to residential, commercial, and industrial end-users who rely on the power to meet their electrical requirements. Although each step of this process is critical to the production of electricity, this study focuses on boilers only

since it is in the boiler where the combustion wastes are produced as the coal is burned.

There are three main types of boilers: (1) pulverizers, (2) cyclones, and (3) stokers. As discussed below in greater detail, the key differences between these boiler types are operating size and the procedures used for handling and burning the coal. Pulverized coal boilers are so-named because the coal is finely pulverized prior to combustion; most utility boilers are this type. Cyclones have been used in past utility applications, but have not been built recently. They are called cyclones because of the cyclone-like vortex created by the coal particles in the furnace during combustion. Stoker boilers are usually used when smaller capacities are required (e.g., 20-30 MW) and burn coal in a variety of sizes.

A brief description of each of these coal combustion technologies follows.[23]

2.3.2.1 Pulverized-Coal Boiler

Exhibit 2-12 shows a typical pulverized-coal boiler setup. In a pulverized coal boiler, coal is ground to a fine size (about 200 mesh, which is powder-like) in a pulverizer or mill. The pulverized fuel is then carried to the burners by forced air injection and blown into the furnace, where it is burned in suspension. Much of the ash remaining after combustion remains airborne and is carried from the furnace by the flue gas stream (i.e., it becomes fly ash; see Chapter Three for a more detailed discussion of types of waste and how they are produced). Some ash is deposited on the furnace walls,

EXHIBIT 2-12

DIAGRAM OF A PULVERIZED COAL BOILER

Source: Babcock and Wilcox Co., Steam: Its Generation and Use, New York, NY 1978.

where it agglomerates and may sinter or fuse. Ash that falls to the bottom of the furnace is removed via an ash hopper. Ash deposits and slagging are more of a problem in pulverized coal boilers than in stoker boilers.

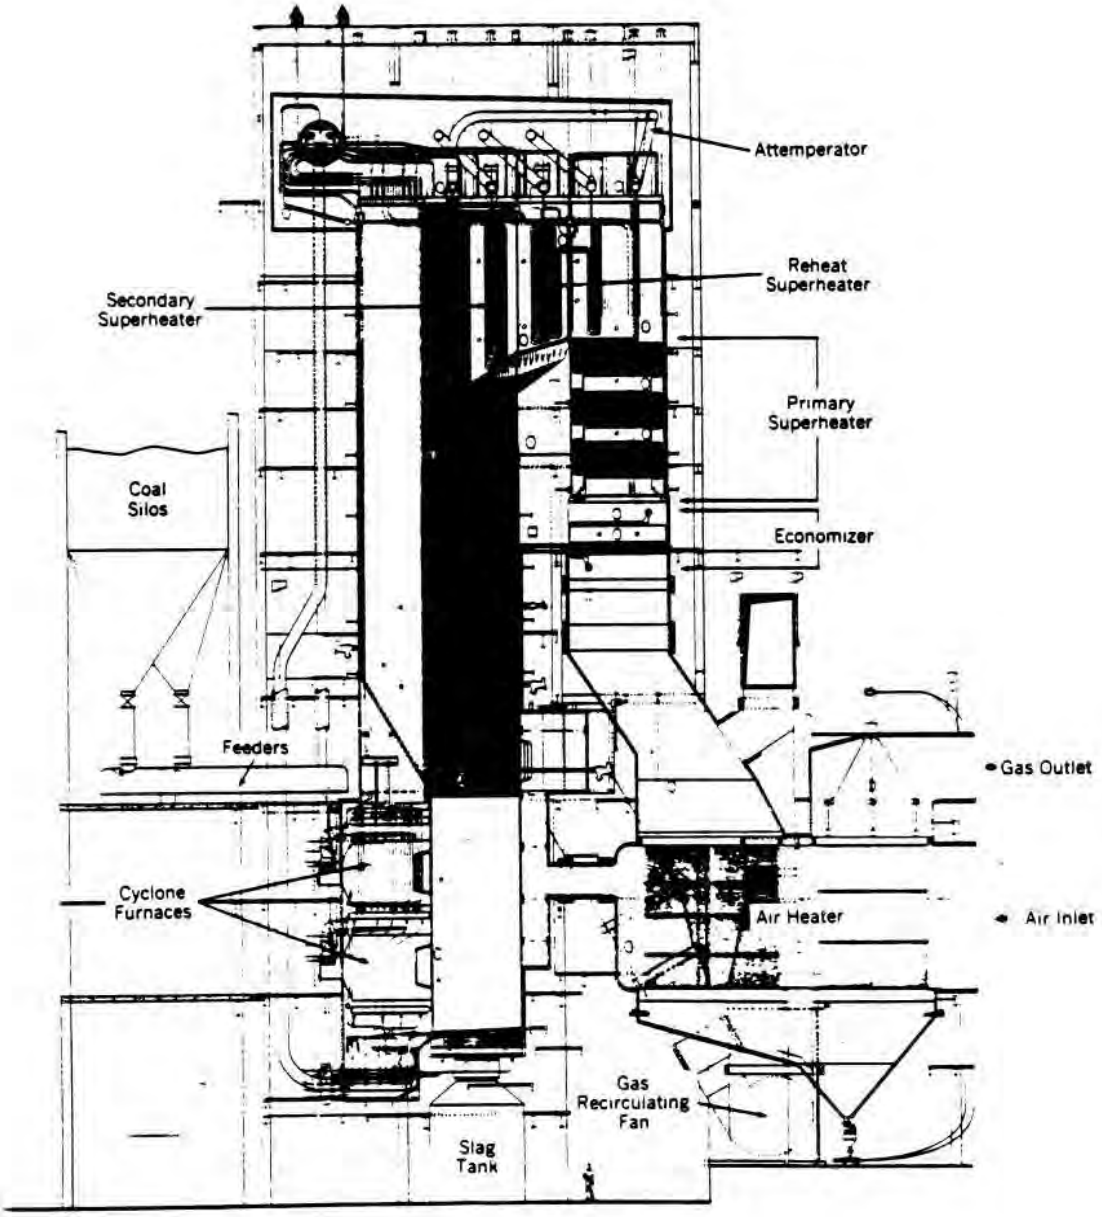
Most modern pulverized-coal boilers have dry-bottom furnaces; that is, the ash is intended to be removed as a dry solid before complete melting occurs. As a result, for dry-bottom boilers, the ash-fusion temperature (the melting point) of the coal must be high enough to prevent the ash from becoming a running slag (i.e., a liquid form). Wet-bottom, or slag-tap, pulverized-coal boilers are designed to remove the ash as a flowing slag. These boilers depend on lower ash-fusion temperature coals so that the ash will melt to form slag for easier removal.

2.3.2.2 Cyclones

The cyclone furnace consists of a water-cooled horizontal furnace in which crushed coal is fired and heat is released at high rates, as shown in Exhibit 2-13. The temperature inside the furnace may reach 3000°F, which is sufficient to melt the ash into a liquid slag that forms on the walls of the furnace. Air circulation within the furnace typically creates a cyclone-like vortex that not only helps the coal to burn in suspension but also causes many coal particles to impinge upon the slag-covered walls of the furnace. This tendency for coal particles to adhere to the walls of the cyclone boiler aids the combustion process because the coal particles will burn more thoroughly before reaching the bottom of the boiler. Most of the ash is retained in the slag layer, thus minimizing the amount of fly ash that is carried out of the boiler. The slag,

EXHIBIT 2-13

DIAGRAM OF A CYCLONE BOILER



Source: Babcock and Wilcox Co., Steam: Its Generation and Use, New York, NY, 1978.

or melted ash particles, is typically removed at the bottom of the furnace.

The cyclone offers the advantage of being able to burn low ash-fusion coals that create problems when burned in most conventional pulverized-coal burners. The cyclone design also helps to minimize erosion and fouling problems in the boiler. The smaller amounts of fly ash created compared to other boiler types reduces the costs associated with particulate collection.

2.3.2.3 Stokers

Stokers are designed to mechanically feed coal uniformly onto a grate within a furnace. Because most of the combustion takes place in the fuel bed, not in suspension within the furnace, the heat release rate of this type of boiler is lower than it is for pulverizers or cyclones. As a result, stokers are generally designed for smaller-sized applications. In fact, this boiler type is used by many manufacturing industries, but has seen only limited use by electric utilities.

Stokers are classified by the method of feeding fuel to the furnace and by the type of grate. The three most important stoker types include:

1) the spreader stoker, the most popular type of overfeed stoker,

2) other overfeed stokers, such as the chain-grate, travelling-grate stoker, or the vibrating-grate stoker, and

3) the underfeed stoker.

The major features of each are summarized in Exhibit 2-14. An illustration of a spreader stoker is provided in Exhibit 2-15.

Use of the different boiler types varies by geographic region. As shown in Exhibit 2-16, about three-fourths of all boiler capacity in the U.S. uses pulverizers, with most of these dry-bottom pulverizers. Cyclones are the next most prevalent boiler type, representing only about 8 percent of all boilers. Stokers represent less than one-half of one percent of the total; due to their size limitations stokers are used primarily in other industrial applications for the production of steam.

Exhibit 2-17 shows the distribution of average capacity for each boiler type by EPA region. The range in average sizes is most pronounced in dry bottom boilers (127.8-610.0 MW), which reflects their substantial flexibility in terms of size and dominance in electric utility applications. Stokers tend to have the smallest capacities (an average of 14 MW nationwide), limiting their usefulness in utility applications compared to all of the other boiler types.

2.4 COAL CONSTITUENTS AND BY-PRODUCTS

Despite its attractiveness as a power plant fuel, coal has its drawbacks. As a solid fuel, coal is often more difficult and more costly to transport, store, and burn than oil or gas. Also, coal's many impurities require environmental control at various stages of the fuel cycle.

EXHIBIT 2-14

CHARACTERISTICS OF VARIOUS TYPES OF STOKERS

Stoker Type & Subclass	Typical Maximum Capacity Range (pph steam) a/	Burning Rate (Btu/hr/ft^2) b/	Characteristics
1. Spreader			Capable of burning a wide range of coals, best ability to follow fluctuating loads, high fly ash carry over, low load smoke.
- Stationary and dumping grate	20,000-80,000	450,000	
- Travelling grate	100,000-400,000	750,000	
- Vibrating grate	20,000-100,000	400,000	
2. Overfeed			Characteristics similar to vibrating-grate stokers except these stokers experience difficulty in burning strongly caking coals
- Chain grate and travelling grate	20,000-100,000	600,000	
- Vibrating grate	30,000-150,000	400,000	Low maintenance, low fly ash carry over, capable of burning wide variety of weakly caking coals, smokeless operation over entire range.
3. Underfeed			Capable of burning caking coals and a wide range of coals (including anthracite), high maintenance, low fly ash carry over, suitable for continuous-load operation.
- Single or double retort	20,000-30,000	400,000	
- Multiple retort			

a/ pph = pounds steam/hr; 1 pph = 1000 Btu/hr.

b/ Maximum amount of Btus consumed per hour for each square foot of grate in the stoker.

These impurities are typically referred to as "ash", whether the reference is to some of the constituents that compose the coal itself prior to combustion or the waste products that result from its combustion. Some coal ash is inherent to the coal seam, while other ash comes from non-coal strata near the coal seam which are intermixed during mining. The coal consumed by electric utilities is generally over 10 percent ash.[24] At current rates of coal consumption, about 70 million tons of ash pass through coal-fired power plants each year.[25]

The ash generated at utility power plants is produced inside the boiler furnace from the inorganic components as the organic components of the coal combust. The types of ash produced can vary -- some ash is swept through the furnace with the hot flue gases to form fly ash, while some settles to the bottom of the boiler as bottom ash or slag. The amount of each type of ash produced depends upon the boiler configuration as described in Section 2.3 and the characteristics of the coal (see Chapter Three for further discussion of ash types).

Air quality regulations have long restricted the amount of fly ash that may be released through a power plant's stacks. Primarily through the use of electrostatic precipitators or bag houses, power plants collect fly ash particles, leaving the flue gases nearly particulate-free as they are emitted from the stack. As a result, the fly ash, bottom ash, and slag that is collected during and after combustion is approximately equal to the amount of ash in the coal prior to combustion.

For many power plants constructed since the 1970's, additional environmental controls also require that a portion of the sulfur oxides be removed from the flue gases. The dominant technology for removing sulfur oxides is known as flue gas desulfurization (FGD), in which alkaline agents, usually in liquid slurry form, are mixed with the flue gases to convert the sulfur into non-gaseous compounds. The resulting waste product is generally referred to as FGD sludge and can amount to 25 percent or more of the volume of coal consumed at a given plant.[26] In total, U.S. coal-fired power plants produce about 85 million tons of ash and FGD sludge per year. By the end of the century, this volume is expected to approximately double.

Exhibit 2-18 shows the number of coal-fired utility power plants and units that produce FGD wastes in each EPA region as of 1985. Regions 6, 8, and 9 have the highest proportion of both plants and units producing FGD wastes. For example, more than half of the coal-fired units in region 9 produce FGD wastes. The high proportion of FGD-producing plants in these regions is in part attributable to the fact that many of the coal-fired plants in these regions are relatively new and were required to incorporate scrubbers to meet air emission regulations.

Plants and units producing FGD waste represent a smaller percentage in other regions, primarily because these regions relied on coal-fired capacity for a major portion of their generation before units with FGD technology were installed. For example, the absolute number of both plants and units producing FGD waste is greatest in Region 4, reflecting this area's reliance on coal for generating electricity.

EXHIBIT 2-18

ELECTRIC UTILITY PRODUCTION OF FGD WASTES: 1985

Regions 1 and 10, at the other extreme, have no plants or units producing FGD wastes. These regions (New England and the Pacific Northwest) are not highly dependent upon coal and consequently, have relatively few coal-fired plants.

Numerous other types of wastes are produced during normal operation and maintenance at coal-fired power plants. These include, among others, boiler blowdown, coal pile runoff, cooling tower blowdown, demineralizer regenerants and rinses, metal and boiler cleaning wastes, pyrites, and sump effluents. These wastes are usually small in volume relative to ash and FGD sludge, but because they may have higher concentrations of certain constituents that may cause environmental concern, they also require care in handling and disposal. All of these wastes are discussed in greater detail in Chapter Three.

[26] For example, a coal with 2 percent sulfur would produce approximately 80 pounds sulfur dioxide per ton of coal consumed. A limestone scrubber capturing 90 percent of the sulfur dioxide, assuming a stoichiometric ratio of 1.4 and a sludge moisture content of 50 percent, would product almost 500 pounds of FGD sludge per ton of coal consumed. See Appendix B for a detailed discussion of the methodologies used to determine this calculation.

CHAPTER THREE

WASTES GENERATED FROM COAL-FIRED ELECTRIC UTILITY POWER PLANTS

As part of EPA's responsibility under Section 8002(n) of RCRA, Congress directed that the study of wastes from the combustion of fossil fuels should include an analysis of "the source and volumes of such material generated per year." In response to this directive, this chapter examines the physical and chemical characteristics of the types and quantities of wastes that are generated currently and likely to be generated in the future.

3.1 OVERVIEW OF ELECTRIC UTILITY WASTES

As discussed initially in Chapter Two, the noncombustible material that remains after coal is burned is called ash. The proportion of noncombustible material in coal is referred to as the ash content. There are four basic types of wastes that can be produced directly from coal combustion: fly ash, bottom ash, boiler slag, and flue gas desulfurization (FGD) sludge. The smaller ash particles entrained by the flue (exhaust) gas are referred to as fly ash and are produced in varying degrees by all plants. Larger ash particles that settle on the bottom of the boiler will form either bottom ash (if the particles have never completely melted) or boiler slag (if the ash particles have melted), depending on the furnace design. Another waste product, called FGD sludge, is generated when some of the sulfur dioxide (formed when the sulfur present in the coal combines with oxygen during combustion) is removed from other flue gases. This removal process is required by the Clean Air Act Amendments of 1979, which revised the New Source

Performance Standards for any electric utility boiler constructed after September 1978. These plants are required to remove 90 percent of the sulfur dioxide, which is usually accomplished with a flue gas desulfurization (FGD, or scrubber) system. Because they are generated in very large quantities, these four waste materials -- fly ash, bottom ash, boiler slag, and FGD sludge -- are referred to by the industry as high-volume wastes. This term will be used throughout this study to be consistent with the terminology that is commonly used for these wastes.

Electric utility power plants also generate waste streams that the industry typically calls low-volume wastes, which are formed during equipment maintenance and water purification processes. Types of low-volume wastes generated by coal-fired power plants include boiler blowdown, coal pile runoff, cooling tower blowdown, demineralizer regenerants and rinses, metal and boiler cleaning wastes, pyrites, and sump effluents. Because it is common industry terminology, the term "low-volume wastes" will be used throughout this report; however, some of these wastes (such as cooling tower blowdown) can be generated in substantial quantities, although generally in smaller quantities than high-volume wastes.

The remainder of this chapter describes each type of high-volume and low-volume waste stream, the various methods of collection used for each, the volumes produced, and the physical and chemical characteristics that determine the waste's behavior during disposal and its potential to leach.

3.2 HIGH-VOLUME WASTES

High-volume coal combustion utility wastes are those waste streams generated in the boiler furnace -- fly ash, bottom ash, and boiler slag -- and in the cleaning of coal combustion flue gas. The following sections describe the volumes and the physical and chemical characteristics of these high-volume waste streams.

3.2.1 Ash

The noncombustible waste material that remains after coal is burned is referred to as ash. Some noncombustible materials are characteristic of the coal itself, originating from the chemical elements in the plants from which the coal was formed. These materials generally account for no more than two percent of the ash content of the coal. Other noncombustible materials extraneous to the coal, such as minerals lodged in the coal seam during or after its geologic formation and rocks near the coal seam that are carried away with the coal during mining, are burned during the fuel combustion process along with the coal itself. These materials account for most of the ash content.

3.2.1.1 How Ash is Generated

The type of ash produced from a boiler is determined by the type of coal that is burned and the design of the boiler furnace. As discussed in Chapter Two, the major types of boilers used by electric utilities are wet-bottom pulverizers, dry-bottom pulverizers, cyclone-fired boilers, and stokers.

Pulverizers are the most widely used boilers in the electric utility industry because they can burn many different types of coal. Due to the very fine consistency of the coal after it is pulverized, the ash particles are easily carried out of the boiler along with the flue gases, resulting in a relatively large proportion of fly ash.

The amount of fly ash that accumulates in a pulverizer depends on whether it is dry-bottom or wet-bottom.[1] In dry-bottom pulverizers, which constitute the majority of electric utility boilers, ash particles in the coal generally do not melt during the combustion process because the ash fusion temperature (i.e., the melting point) is higher than the operating temperature in the boiler. In dry-bottom pulverizers, therefore, about 80 percent of the fine ash remains in the flue gas as fly ash. The remaining ash settles to the bottom of the boiler (hence the term bottom ash) where it is collected at a later time. In wet-bottom pulverizers, about 50 percent of the ash exits the boiler as fly ash, while the other 50 percent remains in the furnace. However, ash particles that remain in wet-bottom pulverizers become molten; this boiler slag remains in a molten state until it is drained from the boiler bottom.

Cyclone-fired boilers burn larger-sized coal particles than do pulverizers, since partial crushing is the only preparation required prior to injection into the furnace. The amount of fly ash that is generated in a cyclone boiler is less than that generated in a pulverizer because of the larger-sized coal particles and the design of the cyclone boiler. Because the air circulation within the boiler furnace is designed to create a cyclone-like

vortex, the coal particles have a tendency to contact the boiler walls. The operating temperature is high enough to melt the ash so that it adheres to the furnace walls as liquid slag. Excess slag continually drains to the bottom of the furnace, where it is removed for disposal. Only 20 to 30 percent of the ash formed in a cyclone boiler leaves the boiler as fly ash.

A few older and smaller power plants have stoker-type boilers, in which coal is burned on or immediately over a grate in the furnace. Stokers are designed to burn coals that do not contain too many small particles (fines), which can tend to smother the fire. Because there are fewer small particles, the amount of fly ash is reduced. For example, in a spreader stoker, the most common type of stoker boiler, the coal is uniformly fed over the fire in a manner that enables suspension burning of the finer pieces, while heavier pieces of coal fall onto the grate for further combustion. The large amount of coal that is burned on the grate reduces the amount of fly ash; the ash produced in a spreader stoker is generally about 50 percent fly ash and 50 percent bottom ash.

3.2.1.2 Methods of Ash Collection

As the flue gas leaves the boiler, it is passed through a mechanical ash collector to remove some of the fly ash particles. A mechanical ash collector operates by exerting centrifugal force on the fly ash particles, throwing them to the outside wall of the collector where they can be removed. These collectors are effective mainly for capturing the larger fly ash particles. To remove the smaller particles, the flue gas must then pass through some

other type of particulate control device, such as an electrostatic precipitator, a baghouse, or a wet scrubber.

The electrostatic precipitator (ESP) is the most common device for fine ash collection. ESPs operate by applying an electrical charge to the fly ash particles. In the presence of an intense electrical field, the charged particles are attracted to a grounded collection electrode. The collected dust is then discharged to a storage hopper by a process called rapping that dislodges the collected particles. ESPs are most efficient when coal with high sulfur content is used because the sulfur dioxide in the flue gas helps retain the electrical charge. When properly designed and maintained, an ESP is capable of collecting over 99 percent of the ash present in the flue gas.[2]

When coal with lower sulfur content is burned, baghouses (also called fabric filters) are often more appropriate to use as fly ash collection devices. If operated efficiently, they also can remove over 99 percent of the ash from the flue gas.[3] In this system, the flue gas passes through a filter that traps the ash particles. The ash builds up on the filter, forming a filter cake. As this process continues, the ash collection efficiency tends to increase as it becomes more difficult for particles to pass through the filter material. Periodically, the cake is dislodged from the filters, which reduces efficiency until buildup occurs again.

Some power plants remove fly ash by the wet scrubbing method, in which liquids are used to collect the ash. In one method, the ash particles are removed from the flue gas stream by contacting them with a scrubbing liquid in a spray tower. This process forms an ash slurry, which is then discharged.

Alternatively, fly ash particles may be dislodged from the walls of the scrubber by a liquid flushing of the scrubber. Because the operation of a scrubber is very plant-specific, the collection efficiency of wet scrubbers varies, though wet scrubbers are generally not as efficient as ESPs and baghouses. The advantage of wet scrubbers, however, is that they can also be used simultaneously to collect sulfur oxides from the flue gas system.

Ash particles that do not escape as fly ash become bottom ash or boiler slag. In dry-bottom pulverizers and stokers, the temperatures are low enough to allow the molten ash to cool and reform into dry, solid ash particles, or bottom ash. In smaller boilers of this type, the ash falls onto a grate, which then is opened, allowing the ash to drop into a flat-bottom hopper. The large quantities of bottom ash produced in larger boilers often require hoppers with sloped sides for self-feeding. Some hoppers may contain water to quench the ash and to facilitate disposal.

In cyclone-fired boilers and wet-bottom pulverizers, the liquified ash particles that fall to the bottom of the boiler during combustion remain in a molten state and coalesce into large masses (called slag), which then drop onto the boiler floor. The slag is tapped into a water-filled hopper, or slag tank, which is periodically emptied and the slag disposed. Slag tanks for cyclone-fired boilers are similar to those used for pulverizers but have a higher relative capacity because a greater percentage of the ash in cyclones becomes boiler slag.

3.2.1.3 Quantities of Ash Generated

Nearly all of the noncombustible material in coal ends up as fly ash, bottom ash, or boiler slag. As mentioned earlier, the coal industry and the electric utility industry refer to this material as a coal's ash content. As a result, the volume of ash generated is directly related to the amount of coal consumed and the ash content of the coal. The ash content of coal will vary according to several factors, including coal-producing region, coal rank (i.e., bituminous, subbituminous, anthracite, or lignite), mine, seam, and production method. Although the proportion of ash in coal may range from 3 to 30 percent, the industry-wide average for electric utility power plants is 10.1 percent.[4] Exhibit 3-1 shows the average ash content of coal that was delivered to coal-fired power plants in 1985 for some of the major coal-producing regions.

In 1984, electric utilities generated about 69 million tons of coal ash. Ash generation is expected to increase considerably, to about 120 million tons in the year 2000, an increase of about 72 percent over 1984 levels. This increase can primarily be attributed to the increase in the demand for coal by electric utilities. While there is some uncertainty over the amount of coal that will be consumed by electric utility power plants, coal-fired electricity generation is likely to increase significantly. For example, one estimate indicates that by the year 2000 electric utility power plants will burn over one billion tons of coal to meet 61 percent of total electricity demand,[5] an increase of 70 percent over the 664 million tons consumed in 1984.[6] Exhibit 3-2 shows historical and forecasted future ash generation by coal-fired electric power plants.

EXHIBIT 3-1

REPRESENTATIVE ASH CONTENTS BY PRODUCING REGION AND COAL RANK: 1985

Coal Rank and Region	Percent Ash
Anthracite	
Northeastern Pennsylvania	29.4
Bituminous	
Western Pennsylvania	10.9
Northern West Virginia	10.4
Ohio	11.3
Eastern Kentucky	9.9
Alabama	12.2
Illinois	9.7
Colorado	6.2
Utah	9.4
Arizona	8.9
Subbituminous	
Wyoming	5.9
New Mexico	18.8

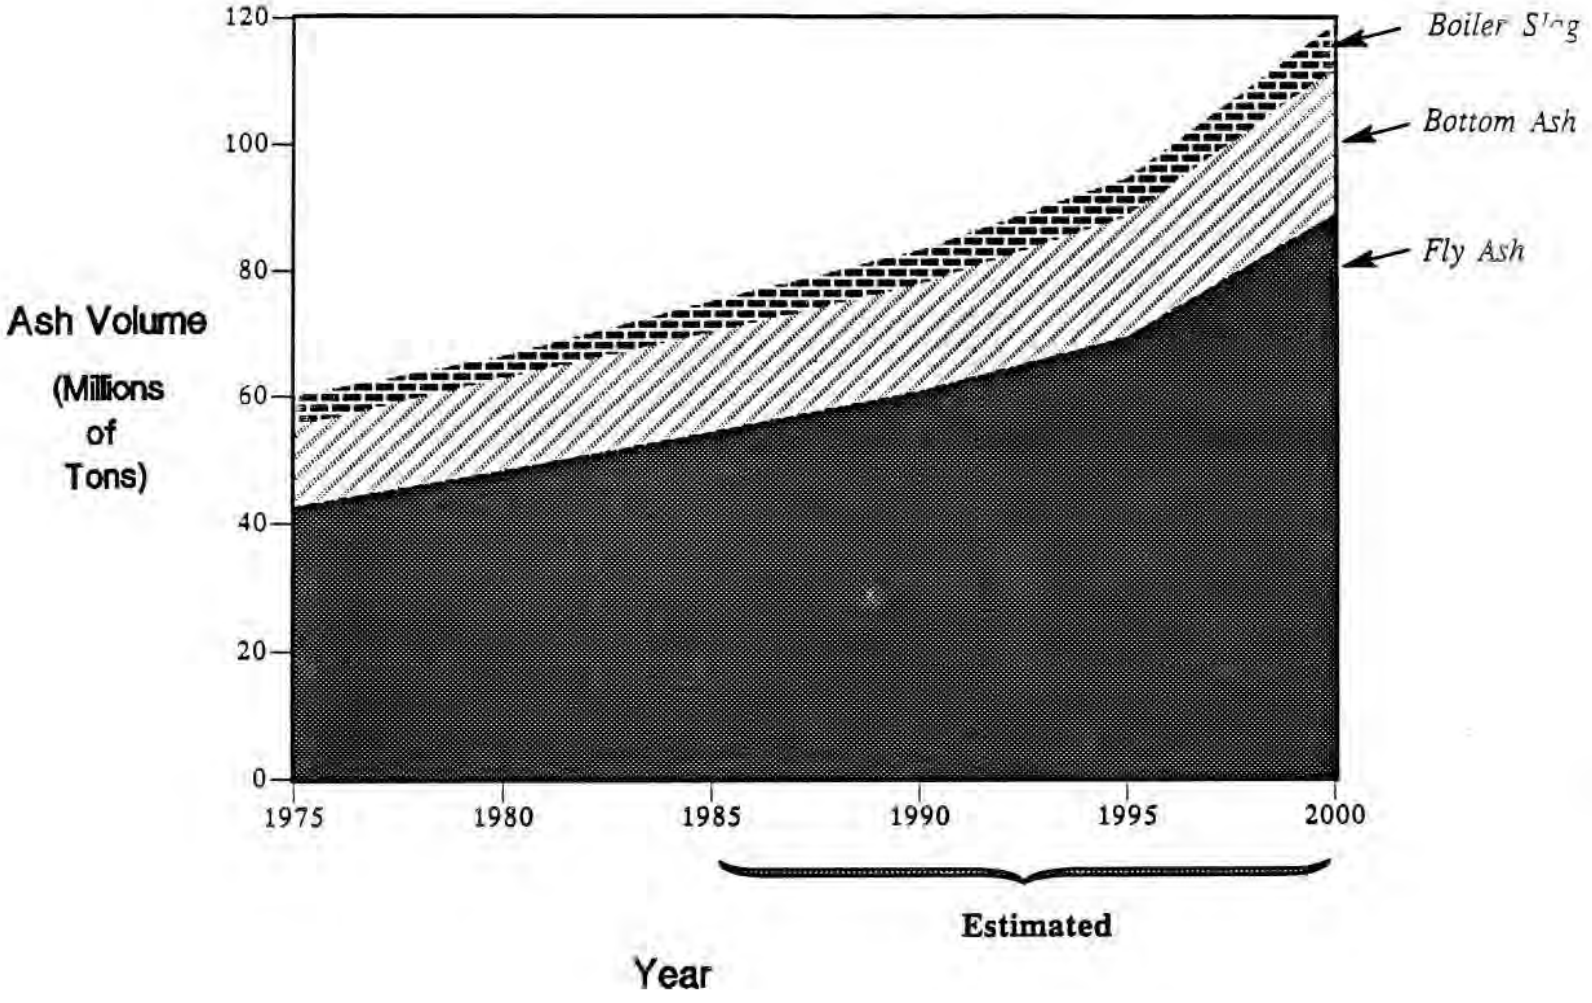
ELECTRIC UTILITY POWER PLANTS
1975 - 2000



Sources: 1975-1984: American Coal Ash Association.
1985-2000: ICF Incorporated. See Appendix B for in-depth discussion of the methodologies used to develop these estimates.

The average ash content of coal burned by electric utilities has declined from about 14 percent to slightly more than 10 percent over the past decade (see Exhibit 3-3). To meet particulate emission standards and to lower certain operating and maintenance costs, more electric utilities are now choosing to burn coal with lower ash contents. Although some coals are naturally low in ash, producers and/or utilities can also reduce ash content by cleaning the coal.[7] In some cases, cleaning can reduce ash content by as much as 50 to 70 percent. At present, utilities clean about 35 percent of all the coal they consume; most of the coal that is cleaned comes from eastern and midwestern underground bituminous coal-mining operations. Another reason for the increased use of coal with lower average ash content is the growth in Western coal production, particularly in the Powder River Basin area of Montana and Wyoming. These coals are naturally low in ash content, and little ash is extracted during the mining process.

The quantity of fly ash and bottom ash produced is likely to increase faster over time than the quantity of boiler slag because most new coal-fired plants will employ dry-bottom pulverizer boilers, which generate fly ash and bottom ash rather than boiler slag. Because dry-bottom pulverizers are capable of burning coal with a wide range of ash fusion temperatures,[8] they are able to burn a greater variety of coals compared with cyclone boilers and wet-bottom pulverizers. Another advantage of dry-bottom pulverizers is that they produce less nitrogen oxide emissions than do other boiler types, which enables electric utilities to meet requirements for nitrogen oxide emissions control more easily.

3.2.1.4 Physical Characteristics of Ash

The physical characteristics of coal combustion ash of interest are particle size and distribution, compaction behavior, permeability, and shear strength. Exhibit 3-4 provides representative ranges of values for these characteristics of fly ash, bottom ash, and boiler slag.

The greater the assortment of particle sizes in the material, the more it can be compacted to achieve greater density and shear strength and lower permeability. Generally, fly ash is similar in size to silt. Most fly ash particles are between 5 and 100 microns in diameter; within a single sample, the largest particles may be 200 times larger than the smallest particles.[9] The size of bottom ash and boiler slag particles can range from that of fine sand to fine gravel, or about 0.1 to 10 millimeters.[10]

Compaction behavior refers to the amount of settling that takes place after disposal and the rate at which such settling occurs. Compressibility, density, and moisture content are factors affecting compaction behavior.[11] When compacted and dry, most fly ash and bottom ash behave very similarly to cohesive soil.

Permeability reflects the rate at which water will seep through the waste material in a given period of time and provides a good first estimate of the rate and quantity of leachate migration. A number of factors can influence the degree of permeability, such as the size and shape of the waste particles, the degree of compaction, and the viscosity of the water. Properly compacted fly ash often has low permeability, similar to that of clay, while the

EXHIBIT 3-4

REPRESENTATIVE RANGES OF VALUES FOR THE PHYSICAL CHARACTERISTICS OF FLY ASH, BOTTOM ASH, AND BOILER SLAG

	Fly Ash	Bottom Ash/ Boiler Slag
Particle Size (mm)	0.001-0.1	0.1-10
Compaction Behavior:		
Compressibility (%)	1.8	1.4
Dry Density (lbs/ft^3)	80-90	80-90
Permeability (cm/sec)	10^{-6}-10^{-4}	10^{-3}-10^{-1}
Shear Strength		
Cohesion (psi)	0-170	0
Angle of Internal Friction (^{o})	25-45	25-45

permeability of bottom ash is usually slightly higher. Boiler slag is higher still, having a permeability comparable to that of fine gravel.

Shear strength is an important determinant of the shape and structural stability of wastes disposed in landfills; a strong material (i.e., one with high shear strength) can form steep slopes and support heavy loads from above. Two indicators of shear strength are cohesion, a measure of the attraction between particles due to electrostatic forces, and the angle of internal friction, an indicator of the friction between particles. Dry, nonalkaline ash has no cohesion. Dry ash that is alkaline demonstrates some cohesion and, when compacted, increases in strength over time. The angle of internal friction associated with ash varies with the degree of compaction, although it is similar to that for clean, graded sand.

3.2.1.5 Chemical Characteristics of Ash

The chemical composition of ash is a function of the type of coal that is burned, the extent to which the coal is prepared before it is burned, and the operating conditions of the boiler. These factors are very plant- and coal-specific.

In general, over 95 percent of ash is made up of silicon, aluminum, iron, and calcium in their oxide forms. Magnesium, potassium, sodium, and titanium are also present to a lesser degree. Exhibit 3-5 shows the concentration of these major elements typically found in fly ash, bottom ash, and boiler slag.

Ash also contains many other elements in much smaller quantities. The types and proportions of these trace elements are highly variable and not

readily categorized. Concentrations for various trace elements in coal ash are shown in Exhibit 3-6, which indicates the potential range of values and median concentration for such trace elements for coals from different regions of the U.S. A summary of how the concentration of elements in ash varies according to coal source is shown in Exhibit 3-7. For example, Eastern and Midwestern coal ashes usually contain greater amounts of arsenic, selenium, chromium, and vanadium than do Western coal ashes, while Western coals have larger proportions of barium and strontium. Coal mining and cleaning techniques can reduce the amount of trace elements that are ultimately found in the ash after combustion. For example, in some cases, coal cleaning can remove more than half of the sulfur, arsenic, lead, manganese, mercury, and selenium that is contained in the coal prior to combustion.

The proportions of elements contained in fly ash, bottom ash, and boiler slag can vary. Exhibit 3-8 provides ranges and median values for element concentrations in different types of ash -- bottom ash and/or boiler slag, and fly ash. The concentrations of elements formed in fly ash are shown for two types -- the larger particles removed from the flue gas by mechanical collection and the smaller particles removed with an electrostatic precipitator or a baghouse (see Section 3.2.1.2 for more detail on methods of ash collection). For example, much higher quantities of arsenic, copper, and selenium are found in fly ash than are found in bottom ash or boiler slag. The distribution of elements among the different types of ash is largely determined by the firing temperature of the boiler relative to the coal's ash fusion temperature, which in turn affects the proportions of volatile elements that end up in fly ash and bottom ash. Some elements, such as sulfur, mercury, and chlorine, are almost completely volatilized and leave the boiler

in the flue gas rather than remaining in the bottom ash or boiler slag. Some of these more volatile elements may condense on the surface of the fly ash particles as the flue gas cools.

3.2.2 FGD Sludge

Another waste stream often generated in large volumes by coal-fired utility power plants is FGD sludge, which is created when utilities remove sulfur oxides from the flue gases. Emissions of sulfur oxides in the flue gases are due to the oxidation of sulfur during coal combustion. State and Federal regulations require power plants to control the amount of sulfur oxides released through the stack. To meet the applicable requirements most power plants use coals whose inherent sulfur content is low. If the sulfur content is so low that additional sulfur dioxide removal is not needed, then FGD sludge is not produced.

Present requirements for all new coal-fired plants, however, not only limit the amount of sulfur oxides that can be emitted, but also mandate a percentage reduction in the amount of sulfur dioxide emissions.[12] This requirement will substantially increase the number of sulfur dioxide control systems in use. The primary method of sulfur dioxide control currently available is a flue gas desulfurization (FGD) system through which the flue gases pass before being emitted from the stack. The wastes produced by this system are called FGD (scrubber) sludge. Other methods of control include newer technologies such as fluidized bed combustion (FBC) and limestone injection multistage burners (LIMB).[13] The technical and economic feasibility of the latter two technologies are currently under evaluation by private industry and the U.S.

Department of Energy. If these technologies do become more widely available, they also will produce substantial volumes of wastes.

3.2.2.1 Methods of FGD Sludge Collection

There are two major types of FGD (scrubber) systems. Non-recovery systems produce a waste material for disposal. Recovery systems produce recyclable by-products. Exhibit 3-9 illustrates the different types of FGD systems currently in use. Non-recovery systems, which account for 95 percent of the scrubber systems now in use by electric utilities, are further classified as wet or dry systems. In wet non-recovery scrubber systems, the flue gas contacts an aqueous solution of absorbents, thereby producing waste in a slurry form. The wastes generated by dry non-recovery systems contain no liquids.

Direct lime and limestone FGD systems are the most common wet non-recovery processes. With these systems, flue gases pass through a fly ash collection device and into a contact chamber where they react with a solution of lime or crushed limestone in the form of a slurry. The slurry circulates between the contact chamber and a separate reaction tank, where the reagents are added. From the reaction tank, the slurry is fed to a thickening and dewatering device to be prepared for disposal. After dewatering, the resulting liquid is recycled back to the reaction tank and the sludge solids are removed for disposal. Under certain conditions, direct lime and limestone scrubbers have been able to remove over 95 percent of the sulfur dioxide in the flue gas.[14]

EXHIBIT 3-9

MAJOR TYPES OF FLUE GAS DESULFURIZATION SYSTEMS

Non-Recovery		Recovery	
Wet	Dry	Wet	Dry
Direct Lime	Spray Drying	Wellman-Lord	Alumina/Copper* Sorbent
Direct Limestone	Dry Sorbent Injection*	Magnesium Oxide	Activated Carbon* Sorbent
Alkaline Fly Ash			
Dual-Alkali			

*Systems are currently in development and testing phases, and are not as yet being used commercially.

Source: Tetra Tech Inc., Physical-Chemical Characteristics of Utility Solid Wastes, Prepared for Electric Power Research Institute, EPRI EA-3236, September 1983, pp. 4-1 - 4-4.

A variation on the direct lime and limestone systems is the alkaline fly ash scrubber. Several western power plants that burn coal containing high-alkaline ash use these systems, which can improve sulfur dioxide removal. Rather than being collected by a separate upstream device (such as an ESP or baghouse), fly ash particles remain in the gas stream as it passes through the scrubber. In the scrubber, the alkaline fly ash, augmented with an alkaline lime/limestone slurry, acts to remove sulfur oxides. Alkaline fly ash scrubbers are not as efficient as direct lime and limestone systems, removing on average only about 40 percent of the sulfur dioxide.[15]

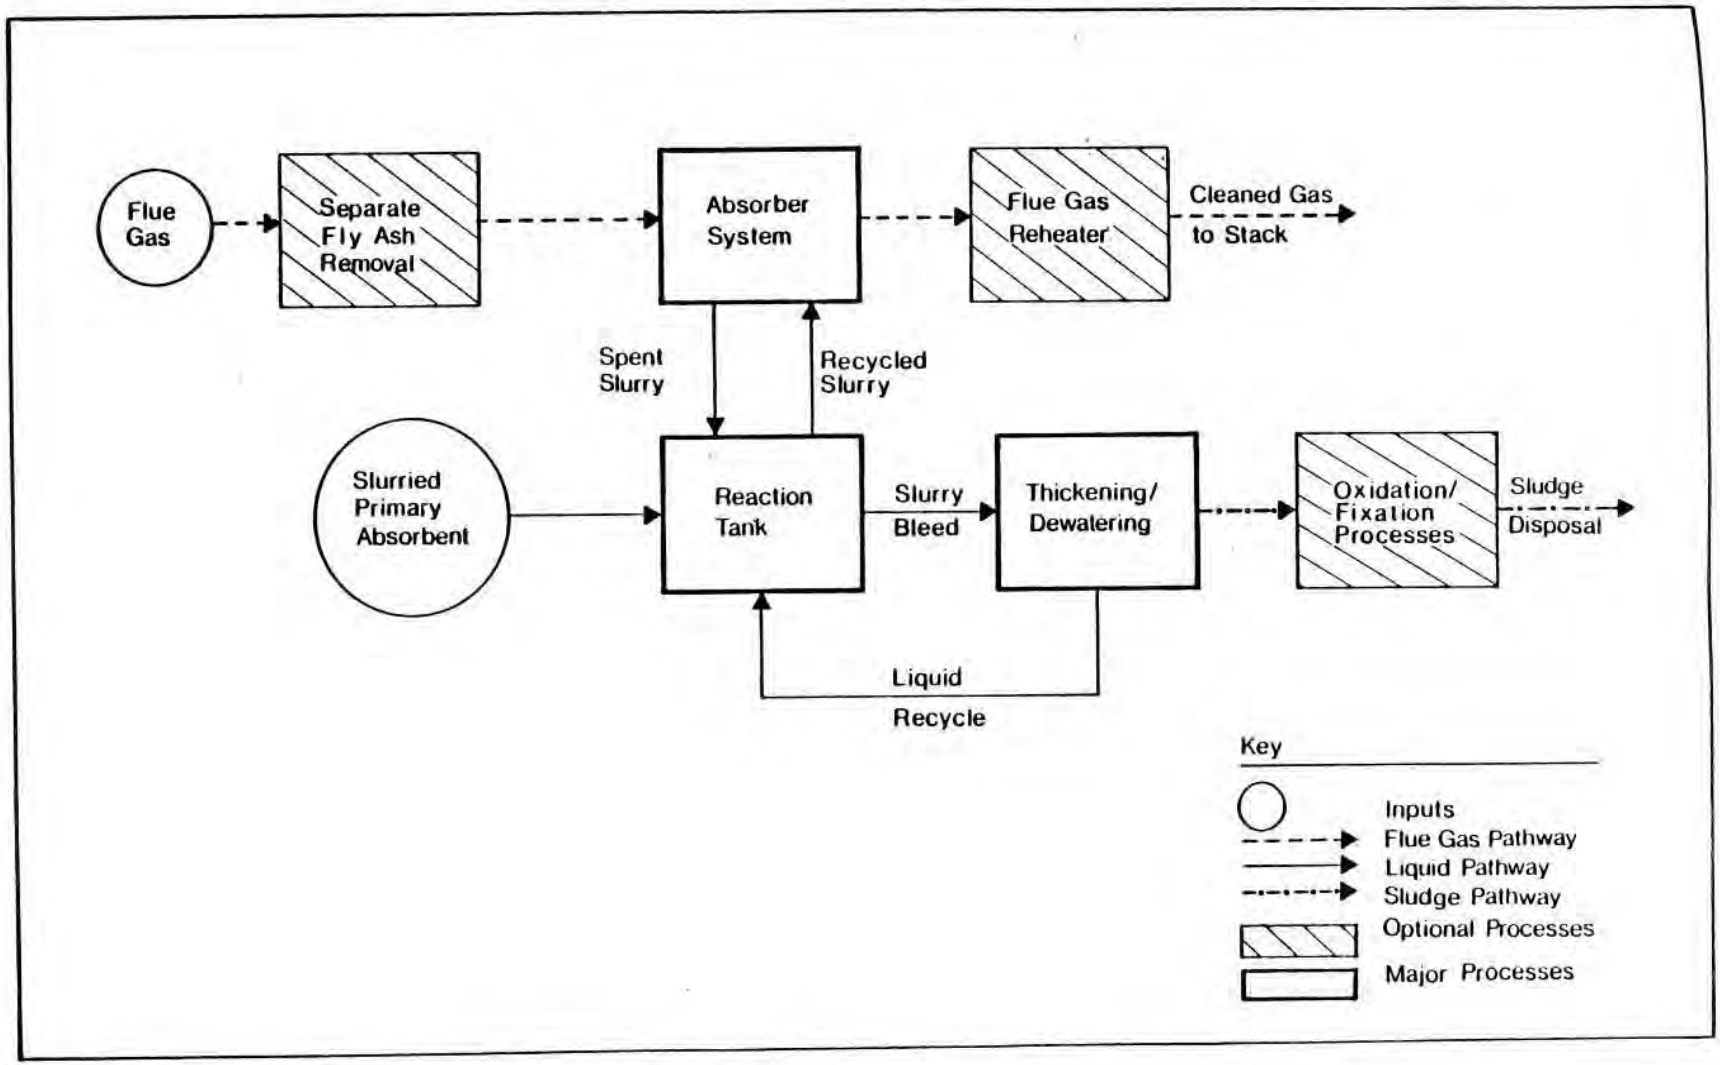
Another wet non-recovery system is the dual-alkali process. These scrubbers operate in much the same manner as the direct lime and limestone scrubbers. However, dual-alkali systems use a solution of sodium salts as the primary reagent to which lime is added for additional absorption. The soluble sodium salts are then recycled to the scrubber system and the insoluble portion of the slurry is left to settle so that it can be collected and disposed. Like direct lime and limestone systems, dual-alkali scrubbers remove up to 95 percent of the sulfur dioxide.[16]

Exhibit 3-10 presents a diagram of the operations of a wet FGD system. The flows shown for the flue gas, absorbent, slurry, and sludge are essentially the same for direct lime, direct limestone, alkaline fly ash, and dual-alkali systems.

At present, the two most popular methods of dry scrubbing under investigation are spray-drying and dry sorbent injection, although only the spray-drying process is now in commercial use at electric utility power plants.

EXHIBIT 3-10

FLOW DIAGRAM OF WET FLUE GAS DESULFURIZATION SYSTEM



Source: Tetra Tech Inc., Physical-Chemical Characteristics of Utility Solid Wastes, Prepared for Electric Power Research Institute, September 1983, p. 4-3.

A flow diagram of a spray-drying system is presented in Exhibit 3-11. With this system, a fine spray of an alkaline solution is injected into the flue gas as it passes through a contact chamber, where the reaction with the sulfur oxides occurs. The heat of the flue gas evaporates the water from the absorbent solution, leaving a dry powder. This powder is then collected downstream of the contact chamber by a particulate collector, usually a baghouse. Spray-drying typically removes about 70 percent of the sulfur dioxide from the flue gas.[17] Because of the relatively low percentage reduction in sulfur dioxide achieved by spray-drying scrubbers compared with other scrubber technologies, this dry-scrubbing method is most commonly used for furnaces that burn lower sulfur coals.

Dry sorbent injection, illustrated schematically in Exhibit 3-12, is not yet used commercially by electric utilities, although one utility is designing a generating unit that will use this type of scrubber and which is due to begin operation by 1990.[18] This system involves the injection of a powdered sorbent, either nacholite or trona, into the flue gas upstream of a baghouse. Sulfur dioxide reacts with the reagent in the flue gas and on the surface of the filter in the baghouse. The dry wastes, which form a filter cake, are then removed during normal filter cleaning.

Dry injection offers several advantages over traditional wet scrubbing and spray-drying techniques: the required equipment is smaller and less expensive, no water is needed, flue gas reheating is not necessary, and sulfur dioxide and fly ash are removed simultaneously. Potential drawbacks of this process are the limited geographic availability of the sorbents and problems associated with waste disposal. For example, the waste tends to be very water soluble,

EXHIBIT 3-11

and could potentially affect ground-water quality. Also, dry injection is most effective when used for low-sulfur coals, achieving only 70 to 80 percent sulfur dioxide removal in most cases, compared with up to 95 percent removal by wet scrubbing systems.[19]

Recovery systems are designed to produce a salable by-product such as sulfur, sulfuric acid, or liquid sulfur dioxide; however, small amounts of waste are still produced. A prescrubber is usually required upstream of the main scrubber to filter out such contaminants as fly ash and chlorides. Secondary waste streams formed by the oxidation of the absorbent are sometimes present and, along with the prescrubber by-products, are the materials that need to be disposed. Two recovery FGD systems presently used commercially, the Wellman-Lord and Magnesium Oxide processes, are both based on wet scrubbing. Diagrams of these systems are shown in Exhibit 3-13. Other recovery systems, both wet and dry, have been developed, but are still in the testing phase.

3.2.2.2 Quantities of FGD Sludge Generated

There has been a large increase in the quantity of FGD sludge generated over the past decade, as shown in Exhibit 3-14. This increase is due to the more widespread use of scrubbers brought about by tightened state limits on sulfur dioxide emissions, the Federal New Source Performance Standards (NSPS) of the Clean Air Act of 1971, and the revisions to the NSPS in 1979. This trend will continue as new power plants are equipped with scrubbers as required under the NSPS. By the year 2000, scrubber capacity is likely to be several times greater than at present.

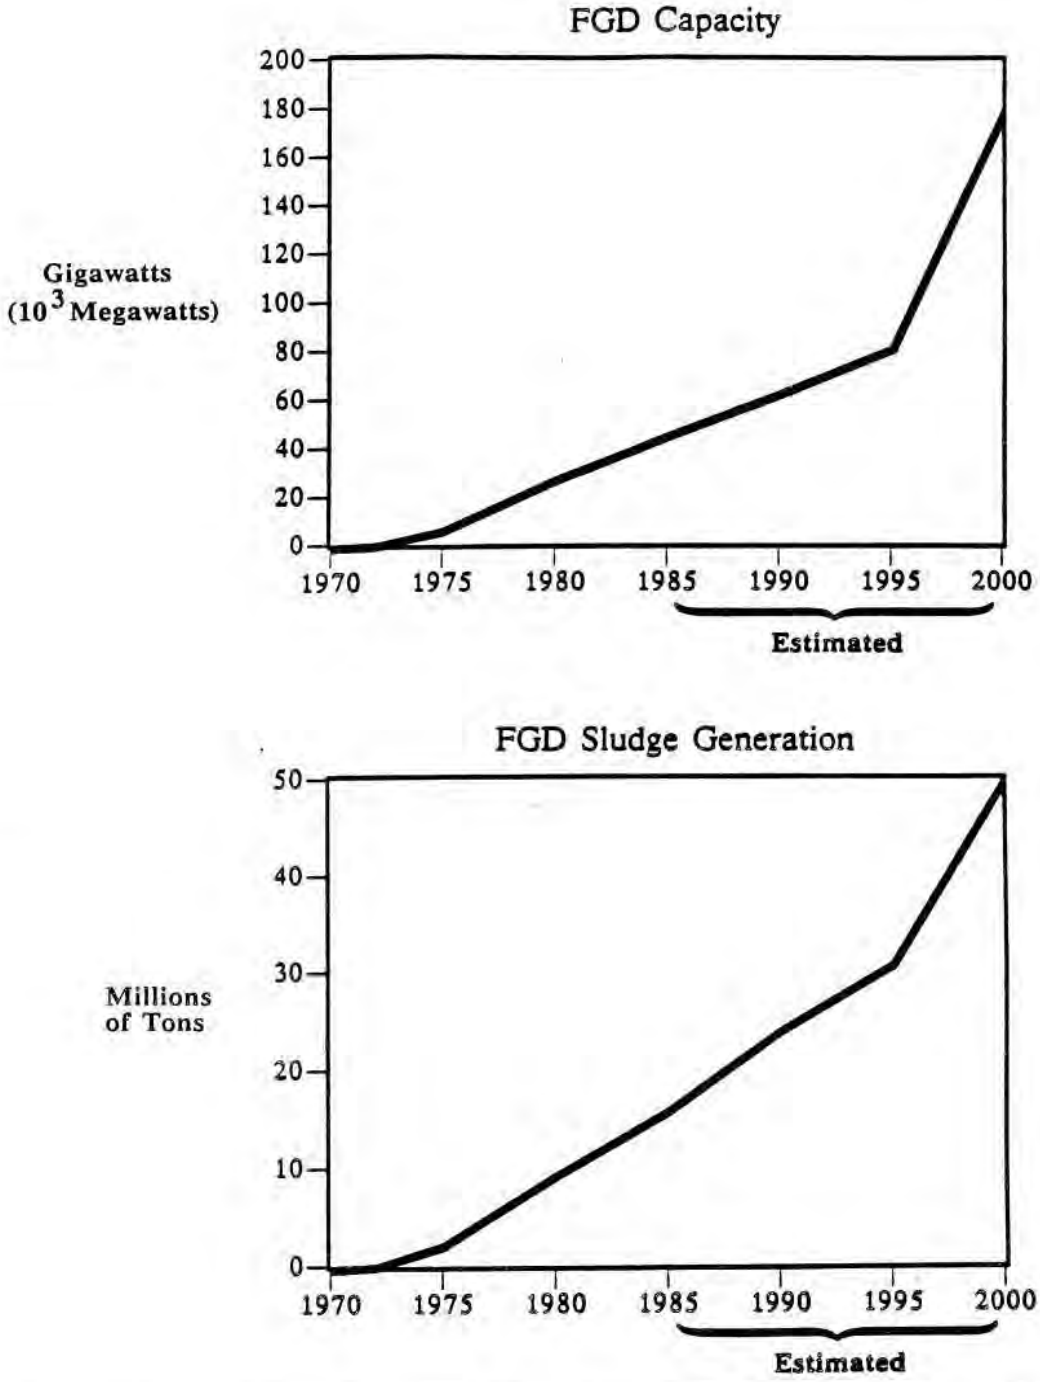
FGD CAPACITY AND FGD SLUDGE GENERATION
1970-2000



Source: 1970-1984: Energy Information Administration, Cost and Quality of Fuels for Electric Utility Plants, and Arthur D. Little, Inc., Full Scale Field Evaluation of Waste Disposal from Coal-Fired Electric Generating Plants, Vol. 1, June 1985.

1985-2000: ICF Incorporated. See Appendix B for in-depth discussion of the methodologies used to develop these estimates.

The dramatic increase in scrubber capacity has a direct effect on the amount of scrubber sludge produced. In 1984, about 16 million tons of scrubber sludge were generated. By 2000, the annual amount of sludge produced is estimated to be about 50 million tons, over three times the sludge generated at present.[20]

All FGD sludge is comprised of spent reagent, which is made up of the chemicals that result from the reaction of the absorbent with the sulfur oxides in the flue gas, plus any unreacted portion of the absorbent. The sludge may also contain water and fly ash. Several factors determine how much spent reagent, water, and ash are present in the FGD sludge. These factors include the type of scrubber system used, the characteristics of the coal, and the sulfur dioxide emission limit that the power plant is required to meet by state or Federal law.

The type of FGD system is an important determinant of the amount of spent reagent, amount of water, and amount of ash present in the sludge. Reagents used in different systems vary as to their absorbent utilization, or "stoichiometry," which is the percentage of the reagent that reacts with the sulfur oxides. A lower percentage implies more reagent is needed to remove a given percentage of sulfur dioxide. Direct limestone systems have an average absorbent utilization of 80 percent, while the direct lime and dual-alkali processes both achieve higher utilization of 90 and 95 percent, respectively. This results in the generation of about six percent more sludge by direct limestone scrubbers compared to direct lime and dual-alkali processes.[21]

Wet systems, both non-recovery and recovery, employ aqueous solutions to remove the sulfur oxides from the flue gas. Dry FGD systems use no water for sulfur oxide removal, although dry FGD wastes may be mixed with water prior to disposal, which increases the volume of sludge. Because of their dependency on water, wet FGD systems generally produce larger volumes of wastes than do dry systems.

Wet FGD systems can also be used as fly ash removal devices. The amount of ash in the sludge depends on how much fly ash is generated by the boiler and whether any other particulate control device is upstream of the scrubber. In particular, alkaline fly ash scrubbers rely on the entrapment of ash to act as their primary absorbent, and therefore their sludge contains large amounts of ash. The collection of fly ash and wastes in a spray-drying system occurs simultaneously by a baghouse; therefore, the wastes from these systems also contain large proportions of ash. Recovery FGD systems often require prescrubbers to remove fly ash. Although recovery systems produce only about half the wastes of non-recovery systems, these wastes are predominantly made up of ash.

Specific characteristics of the coal can have a large effect on the quantity of sludge generated. For example, the higher the sulfur content, the more reagent that must be used to achieve a certain level of sulfur dioxide removal and, consequently, the more spent reagent in the sludge. The ash content of the coal affects the amount of ash caught up in the sludge. Just as using low-sulfur coal will reduce the amount of spent reagent, reducing the ash content prior to combustion will greatly reduce the amount of fly ash that is absorbed by wet scrubbers and thus the amount of sludge that must be disposed.

The amount by which a power plant must reduce sulfur dioxide emissions also affects the volume of sludge produced. To achieve a higher reduction, the amount of reagent used in the scrubber needs to be increased, which will, in turn, produce greater quantities of sludge.

3.2.2.3 Physical Characteristics of FGD Sludge

In general, the same physical properties important in determining the disposal behavior of ash are also important determinants of the disposal characteristics of FGD sludge. These physical characteristics -- particle size, compaction behavior, permeability, and shear strength -- vary considerably depending on the type of scrubber system and what (if any) preparation is done prior to disposal. Exhibit 3-15 presents representative ranges of values for these characteristics of FGD sludge.

Depending on the type of FGD system used, the particle size distribution of FGD sludge can vary substantially. For example, sludge from wet scrubbers tends to have a narrow range of particle sizes. The particles produced by dual-alkali systems are finer than those produced by direct lime or limestone scrubbers, while dry scrubbers generally produce sludge containing larger particles.

The density of FGD sludge depends directly on the method of handling. Wet sludge mixed with ash will have a higher density than untreated sludge, while chemical fixation increases the density even more.[22] The density of the particles in dry sludge varies widely.

Permeability (cm/sec)	10^{-6}-10^{-4}	10^{-7}-10^{-6}
Unconfined Compressive Strength (psi)	0-1600	41-2250

Source: Tetra Tech Inc., Physical-Chemical Characteristics of Utility Solid Wastes, prepared for Electric Power Research Institute, EPRI EA-3236, September 1983, pp. 4-8 - 4-15.

The solids content of scrubber sludge is a function of many things, including whether the sludge is treated prior to disposal, the size of the particles in the sludge, the sulfur content of the coal, the amount of ash present in the sludge, and the desulfurization process used. The percentage of solids in untreated sludges usually ranges from 20 to 40 percent, although it can be as high as 60 percent.[23] Depending on the method of treatment used before disposal (if any), the percentage of solids could be much higher. In fact, some chemical fixation processes are designed to transform the sludge into a cement-like product.

The permeabilities of untreated FGD sludges from wet scrubber systems generally are very similar. Mixing the sludge with fly ash does not necessarily change the degree of permeability, although if fly ash acts as a fixative when added to the sludge, the mixed waste product will have a reduced permeability. Chemical fixation also can decrease permeability. Sludge from dry scrubber systems has low permeability relative to sludge from wet systems.

The shear strength of FGD sludge is referred to as "unconfined compressive strength," which reflects the load-bearing capacity of the sludge. The unconfined compressive strength of sludge is sensitive to the moisture content and age of the sludge. Untreated wet sludge has no compressive strength and is similar to toothpaste in this respect. Mixing with ash or lime increases compressive strength, as does chemical fixation. Also, as the treated sludge ages, its compressive strength becomes greater.

3.2.2.4 Chemical Characteristics of FGD Sludge

The major constituents found in wet FGD sludge are determined by the absorbent reagent used, the quantity of fly ash present, the sulfur content of the coal, and whether or not forced oxidation is used.

Most wet FGD systems operate by causing the sulfur dioxide in the flue gas to react with an absorbent reagent, such as lime or limestone, to form a calcium compound, such as calcium sulfite (CaSO3), calcium sulfate or gypsum (CaSO4), or calcium sulfite-sulfate (CaSO3·CaSO4), which can then be removed from the system in the sludge. The ratio of calcium sulfate to calcium sulfite is generally greater in sludge generated by direct limestone scrubber systems than in that produced by direct lime systems.

Dual-alkali scrubber systems differ slightly in that they use absorbent solutions containing sodium hydroxide (NaOH) or sodium sulfite (Na2SO3) as well as lime; sludges from these processes tend to have high levels of calcium sulfite and sodium salts. Because these compounds are highly soluble and apt to leach, they may pose problems as major components in a landfilled sludge.[24]

Spray-drying scrubber systems produce particulates containing either sodium sulfate (Na2SO4) and sodium sulfite (Na2SO3) or calcium sulfate (CaSO4) and calcium sulfite (CaSO3), depending on whether the reagents are sodium- or calcium-based.

Exhibits 3-16 and 3-17 show the major chemical constituents found in sludge solids and sludge liquors. Oxides of calcium, silicon, magnesium, aluminum, iron, sodium, and potassium can be found in most FGD sludge. The presence of

these compounds results from the presence of fly ash in the sludge, and they are unreactive in FGD systems. In wet scrubbers that also serve as fly ash collection devices, more than 50 percent of the sludge solids may be ash. However, when an ESP or baghouse precedes the scrubber, ash may make up less than 10 percent of the sludge solids.[25]

The calcium sulfate/calcium sulfite ratio of the sludge solids is important because sludge containing a greater proportion of sulfates has better disposal properties due to its lower solubility. This ratio is usually higher in systems scrubbing lower sulfur coals and in direct limestone systems. Many scrubber systems add a forced oxidation step to lower the calcium sulfite content of the sludge, thereby lowering its solubility.

The concentration of trace elements in FGD sludge reflects the levels of trace elements in the ash, the efficiency of the scrubber in capturing trace elements in the flue gas, and the trace elements present in the reagent and in the process makeup waters. Fly ash is the primary source of most of the trace elements found in scrubber sludge. Some elements, such as mercury and selenium, may be scrubbed directly from the flue gases and then captured in the scrubber sludge. Exhibit 3-18 illustrates the concentrations at which major trace elements are found in sludge from wet scrubber systems.

3.3 LOW-VOLUME WASTES

Low-volume utility wastes are those waste streams generated in the routine cleaning of plant equipment and in purifying of water used in the combustion process. The types and volumes of low-volume wastes vary among different power

plants, depending on plant-specific factors such as the size of the plant, the type of equipment, and the age of the equipment. Some low-volume wastes commonly produced are:

- boiler blowdown,
- coal pile runoff,
- cooling tower blowdown,
- demineralizer regenerants and rinses,
- metal and boiler cleaning wastes,
- pyrites, and
- sump effluents.

Estimates of the total amount of low-volume wastes generated each year by coal-fired power plants are not available. The frequency of generation and the quantities generated vary widely from power plant to power plant, depending on the maintenance requirements of the plant and operating conditions. Variations also occur within the same power plant, according to its maintenance schedule and operations. Exhibit 3-19 gives representative annual production figures for low-volume wastes generated by a typical power plant.

This section presents for each type of low-volume waste a brief description of how the waste is generated, typical quantities produced, and the physical and chemical composition of the waste.

3.3.1 Boiler Blowdown

Boiler systems can be either a once-through (supercritical) type or a

drum-type. In drum-type boiler systems, after steam passes through the turbines, it is converted back to water in the condenser and is recirculated through the boiler to produce steam again. In this process, impurities that become concentrated in the feedwater periodically must be purged from the system. This waste stream is known as boiler blowdown. A once-through system, however, maintains pressurized steam throughout the cycle, and thus does not require the recirculation of water. These boiler types, therefore, do not generate boiler blowdown.

Boiler blowdown is produced either in a continuous stream or intermittently during the day. The flow is adjusted in order to maintain the desired water quality in the boiler and is dependent on the quality of the feedwater and the size and condition of the boiler. The average blowdown rate for a 500 megawatt unit can range from 20 to 60 gallons per minute, or about 2 to 7 gallons per megawatt-hour.[26]

Boiler blowdown is generally fairly alkaline with a low level of total dissolved solids. The waste stream usually contains certain chemical additives used to control scale and corrosion. Trace elements commonly found in boiler blowdown are copper, iron, and nickel. The components and characteristics of boiler blowdown are presented in Exhibit 3-20.

3.3.2 Coal Pile Runoff

Power plants typically maintain two types of coal storage piles in their coal yards: an active pile to supply their immediate needs and an inactive or long-term pile, which generally stores a 60- to 90-day supply of coal. Coal

piles are usually 25-40 feet high and can cover an area of up to 75 acres, depending on the size and demands of the power plant.[27] Inactive coal piles are generally sealed with a tar spray to protect the coal against the weather; active piles are usually open and exposed. Coal pile runoff is formed when water comes into contact with the piles, whether from rainfall or snowfall, during spraying for dust control, or from underground streams that surface under the piles.

The quantity of coal pile runoff depends primarily on rainfall and, to a lesser extent, the permeability of the soil. It has been estimated that, on average, 73 percent of the total rainfall on coal piles becomes coal pile runoff.[28]

The composition of coal pile runoff is influenced by the composition of the coal, the drainage patterns of the coal pile, and the amount of water that has seeped through. Bituminous coals generate runoff that is usually acidic, with the level of acidity depending on the availability of neutralizing materials in the coal, while subbituminous coals tend to produce neutral to alkaline runoff. Elements commonly found in high concentrations in coal pile runoff are copper, zinc, magnesium, aluminum, chloride, iron, sodium, and sulfate. Exhibit 3-21 displays ranges of concentrations for these and other characteristics.

3.3.3 Cooling Tower Blowdown

Power plants need cooling systems to dissipate the heat energy that remains after the production of electricity.[29] The two major types of cooling systems are once-through and recirculating. Cooling tower blowdown generally refers to

the water withdrawn from a recirculating cooling system to control the concentration of impurities in the cooling water; although once-through systems also discharge water from the cooling system, this discharge is not typically referred to as cooling tower blowdown. At present, about two-thirds of electric utility power plants use a once-through cooling system. This percentage may decrease, however, due to concern over water availability and potential environmental concern over thermal discharges; consequently, future plants may be built with recirculating systems that use cooling towers or cooling ponds.[30]

Once-through cooling systems are primarily used by power plants located next to large bodies of water. After passing through the condenser, the cooling water is discharged, usually into a river, lake, or pond. The quantity discharged ranges from 26,000 to 93,000 gallons per megawatt-hour. For a 500 megawatt plant, this roughly equals 70-300 billion gallons per year.[31] In most instances, the chemical composition of the water remains the same after passing through the condenser, but some changes may occur as the result of the formation of corrosion products or the addition of biocides.

Recirculating cooling systems can use either cooling ponds or cooling towers. In a cooling pond system, water is drawn from a large body of water, such as a pond or canal. After it passes through the condenser to absorb waste heat, the water is recycled back into the pond or canal. Cooling tower systems operate by spraying the water through a cooling tower. About 80 percent of the waste heat contained in the water is then released through evaporation. The remainder of the water is recycled back through the cooling tower system. Cooling tower blowdown is a waste stream bled off to control the concentrations

of impurities and contaminants in the cooling system that could lead to scale formation in the condenser.[32]

The cooling tower blowdown rate is adjusted to maintain water quality in the recirculating cooling system in order to prevent scale formation in the condenser. The quantity of blowdown generated is a function of the quality of the makeup water (the water added to the system to replace that which is lost by evaporation and blowdown), the condition of the cooling system, and the amount of water evaporated by the cooling tower. For a representative 500 megawatt unit, the blowdown rate varies between 2 and 30 cubic feet (15 to 225 gallons) per second.[33]

The composition and quantity of cooling tower blowdown varies greatly from plant to plant. It generally reflects the characteristics of the makeup waters (e.g., fresh water versus brackish or saline water) and the chemicals added to prevent the growth of fungi, algae, and bacteria in the cooling towers and to prevent corrosion in the condensers. Some of these chemical additives are chlorine, chromate, zinc, phosphate, and silicate. Ranges of concentration for some of the characteristics and components of cooling tower blowdown are shown in Exhibit 3-22.

3.3.4 Demineralizer Regenerant and Rinses

A power plant must treat water prior to its use as makeup water. The use of demineralizers is the most common method of purification. During the demineralization process, which may entail several rinses, high-purity process water is provided for the boiler through an ion exchange process. The wastes

produced in this process can be either acidic or alkaline. When sulfuric acid is employed as the regenerant, calcium sulfate is precipitated in the waste stream. Exhibit 3-23 presents ranges for the components of demineralizer regenerants and rinses.

Regeneration of boiler makeup water by demineralizers is done on a batch basis. The frequency with which the process occurs depends on the quality of the incoming water, although for a 500 megawatt unit, regeneration usually occurs every one to four days. A single regeneration requires approximately 30,000 gallons of water, which amounts to about 3-10 million gallons per year.[34]

3.3.5 Metal and Boiler Cleaning Wastes

This category of low-volume waste streams can be divided into two basic types: gas-side cleaning wastes and water-side cleaning wastes. Gas-side wastes are produced during maintenance of the gas-side of the boiler, which includes the air preheater, economizer, superheater, stack, and ancillary equipment. Residues from coal combustion (such as soot and fly ash), which build up on these surfaces, must be removed periodically -- usually with plain water containing no chemical additives.

Water-side wastes are produced during cleaning of the boiler tubes, the superheater, and the condenser, which are located on the water-side or steam-side of the boiler. The scale and corrosion products that build up on these boiler parts must be removed with cleaning solutions containing chemical additives.

The boiler and auxiliary equipment are cleaned intermittently, creating large quantities of wastes in a short time. Gas-side boiler cleaning is done approximately twice a year. The volume of the waste stream produced depends on the size of the boiler and the number of rinses. For a typical plant, gas-side cleanings can produce between 24,000 and 700,000 gallons of wastes. Water-side equipment is cleaned less frequently, approximately once every three years. As is true of gas-side cleaning, the volume of waste produced varies with the number of rinses. A representative 500 megawatt unit generates about 120,000-240,000 gallons of wastewater per treatment.[35]

Because no chemicals are used, the composition of the waste streams associated with gas-side cleaning directly reflects the composition of the soot and fly ash residues and, therefore, of the coal that is burned. Exhibit 3-24 shows two reported values for components and characteristics of gas-side cleaning waste streams.

The particular solution used for the cleaning of the water-side of the boiler varies depending on the equipment being cleaned and the type of scale that needs to be removed. When the scale contains high levels of metallic copper, an alkaline solution that contains ammonium salts, an oxidizing agent such as potassium or sodium bromate or chlorate, and nitrates or nitrites is used. Exhibit 3-25 presents some of the major characteristics associated with these types of solutions and representative ranges of concentrations in which they are found.

For the removal of scale caused by water hardness, iron oxides, and copper oxide, an acid cleaning solution is needed. Usually hydrochloric acid acts as

the solvent in these solutions, although sulfuric, phosphoric, and nitric acids can also be used. Organic acids have been used increasingly as substitutes for hydrochloric acid because of their lower toxicity. For the removal of silica deposits, hydrofluoric acid or fluoride salts are added to the cleaning solution. Exhibit 3-26 presents the various characteristics of acid boiler cleaning solutions.

Alkaline chelating rinses and alkaline passivating rinses are often used to remove iron and copper compounds and silica and to neutralize any residual acidity left over from acid cleaning. These solutions may contain phosphates, chromates, nitrates, nitrites, ammonia, EDTA, citrates, gluconates, caustic soda, or soda ash. Exhibit 3-27 gives representative ranges for these components and others present in these rinses.

3.3.6 Pyrites

Pyrites are the solid mineral compounds, such as iron sulfides or other rock-like substances, present in raw coal. Most pyrites are generally separated out before coal is burned, usually at a preparation plant prior to shipment to the power plant. Smaller quantities of pyrites are often removed at the power plant just before the coal is pulverized. The size of the deposits depends on the method by which they are separated from the coal.

The volume of pyrites collected at a power plant depends on the amount and quality of the coal that is burned, which is determined by the source of the coal and the preparation process, as well as by the coal pulverization process.

The amount of pyrites to be disposed at a power plant can vary considerably, although coal typically contains up to 5 percent pyrites.[36] A 500 megawatt plant, depending on how often it operates and the quality of its coal, will generate, on average, between 30,000 and 100,000 tons of pyrites per year. The characteristics of pyrites and pyrite slurry transport water are shown in Exhibit 3-28.

3.3.7 Sump Effluents

Floor and yard drains collect waste streams from a variety of sources at power plants, such as rainfall, seepage from ground-water sources, leakage, small equipment cleaning operations, and process spills and leaks. As a result, the composition of drain effluents is highly variable. Depending on the particular circumstances at the power plant, these waste streams may contain coal dust, fly ash, oil, and detergents.

The frequency of sump effluent generation and quantities generated are very plant-specific. The more efficient a plant's operating procedures, the smaller this waste stream will be. Also, power plants located in dry areas of the country will have relatively small amounts of wastes collected in yard drains.

3.4 SUMMARY

In the process of generating electricity, coal-fired utility power plants produce a number of waste products. These wastes are produced in large quantities and have widely varying physical and chemical characteristics.

- Coal-fired electric utility power plants produce three major forms of wastes:

  1) Ash, formed from the noncombustible material present in coal. There are three types of ash -- fly ash, bottom ash, and boiler slag;

  2) FGD sludge, produced by flue gas desulfurization systems designed to remove sulfur oxides from flue gas; and

  3) Low-volume wastes, generated primarily from equipment maintenance and cleaning operations.

- In 1984, about 69 million tons of ash and about 16 million tons of FGD sludge were produced by coal-fired electric utilities. By the year 2000, these wastes are expected to increase to about 120 million and 50 million tons, respectively.

- Several physical characteristics of utility waste determine the waste's behavior during disposal and the potential for leachate problems. These characteristics vary a great deal among the different types of ash and FGD sludge.

- The chemical constituents of ash and FGD sludge largely depend on the chemical components in the coal. Other chemical compounds present in FGD sludge, primarily calcium and sodium salts, are the result of the reactions between the absorbent reagent used and the sulfur oxides in the flue gas.

- Compared with ash and FGD sludge, low-volume wastes are generally produced in much smaller quantities. Many of these wastes contain various chemicals from the cleaning solutions used for power plant operations and maintenance; potentially-hazardous elements in these chemicals may be found at high concentrations in the low-volume waste.

CHAPTER THREE

NOTES

[5] ICF Incorporated, Analysis of 6 and 8 Million Ton and 30 Year/NSPS and 30 Year/1.2 Pound Sulfur Dioxide Emission Reduction Cases, prepared for EPA, February 1986. There are many factors that can affect the amount of coal consumed, including electricity growth rates, oil and gas prices, types of technology available, etc. Nevertheless, utilities will continue to burn substantial amounts of coal in the foreseeable future.

[6] Energy Information Administration, Electric Power Annual 1984, DOE/EIA-0348(84), p. 45.

[7] There are presently over 500 coal cleaning plants in the U.S., the majority of which are operated by coal companies and located at the mouth of the mine. The type of cleaning method employed depends upon the size of the coal pieces to be cleaned, a factor that can be controlled at the cleaning plant.

The most widely used methods of coal cleaning are those that use specific gravity, relying on the principle that heavier particles (i.e., impurities) separate from lighter ones (i.e., coal) when settling in fluid. A common method of cleaning coarse coal pieces is to pulse currents of water through a bed of coal in a jig; impurities, such as shale and pyrite, sink, while the coal floats on top. The heavy, or dense, media process is used for cleaning coarse and intermediate-sized pieces. A mixture of water and ground magnetite, having a specific gravity between that of coal and its impurities, acts as a separating fluid. An inclined vibrating platform with diagonal grooves, known as a concentrating table, also is used to clean intermediate-sized coal pieces. Raw coal slurry is fed onto the high end of the table. As the slurry flows down, the vibrations separate the coal from the refuse, allowing the lighter coal to be carried along in the water, while the heavier impurities are trapped in the grooves.

Because of their small size, fine coal particles are very difficult to clean. Their recovery is important, however, because these particles can provide up to 25 percent of the energy derived from raw coal. A popular method of fine coal cleaning is froth flotation. The coal pieces are coated with oil and then agitated in a controlled mixture of water, air, and reagents until froth is formed on the surface. Bubbles tend to attach to the coal pieces, keeping them buoyant, while heavier particles such as pyrite, shale, and slate remain dispersed in the water. The coal can then be removed from the

surface. For more information, see Coal Preparation, 4th edition, Joseph Leonard, editor, American Institute of Mining, Metallurgical, and Petroleum Engineers, Inc., 1979.

[8] Ash melts when heated to a sufficiently high temperature. The temperatures at which the ash changes forms -- e.g., melting from a cone shape to a spherical shape to a hemispherical shape to a flat layer -- are referred to as ash fusion temperatures.

[10] Ibid.

[11] The compressibility of a material is measured as the ratio of its height at 50 psi to its original height at atmospheric pressure. The dry density, the ratio of weight to unit volume of the material containing no water, affects permeability and strength, which in turn determine the structural stability of a landfill and the extent of leachate mobility. The optimum moisture content is the moisture content, in percentage terms, at which the material attains its maximum density.

[12] In 1979 the New Source Performance Standards, part of the Clean Air Act of 1971, were revised. The new regulations required that all coal-fired electric utility units with capacity greater than 73 megawatts, whose construction commenced after September 18, 1978, would not only have to meet a 1.2 pound sulfur dioxide per million Btu emission limit, but would have to do so by a continuous system of emissions reduction. New power plants must reduce sulfur dioxide emissions between 70 and 90 percent, depending on the type of coal burned.

[13] During fluidized bed combustion the sulfur oxides react with limestone or dolomite to form calcium sulfate. In LIMB technology, limestone is injected into the boiler, also forming calcium compounds.

[36] Ibid., p. 28. The term "pyrites" is used to refer to a variety of rock-like substances that may be found in raw coal; it does not just refer to pyritic sulfur that is found in all raw coal, although pyritic sulfur is typically part of the pyrites generated at a power plant.

CHAPTER FOUR

COAL COMBUSTION WASTE MANAGEMENT PRACTICES

Under Section 8002(n) of RCRA, EPA is to analyze "present disposal and utilization practices" and "alternatives to current disposal methods." This chapter addresses these issues by first examining the various state regulations that affect coal combustion disposal since these regulations set the context for current practices. The following section describes coal combustion waste management practices. First, three commonly employed types of land management practices are described in detail. Next, this chapter describes additional measures currently employed by some utilities; more widespread use of these technologies could be employed as an alternative to current practices. Ocean disposal, an alternative that is in the research and development stage, is also addressed in this chapter. Finally, the extent of coal combustion waste recycling as an alternative to disposal is described.

4.1 STATE REGULATION OF COAL COMBUSTION WASTE DISPOSAL

Since coal combustion wastes are currently exempt from Federal hazardous waste regulation under RCRA, their regulation is primarily carried out under the authority of state hazardous and solid waste laws. State solid waste laws establish programs to provide for the safe management of non-hazardous solid wastes. If solid wastes are considered hazardous, state hazardous waste laws establish programs to provide for their safe management. To implement these laws, state health or environmental protection agencies promulgate solid and hazardous waste regulations. A 1983 report for the Utility Solid Waste Activities Group (USWAG) surveyed these regulations; the USWAG report provided

summaries of state regulations based on applicable state laws, regulations, and interviews with state environmental officials.[1] EPA updated the information provided in the USWAG summaries for the purposes of this report.

Exhibit 4-1 lists the disposal requirements promulgated under each state's solid waste (non-hazardous) regulations. (As will be discussed below, it is very rare for coal combustion wastes to be regulated as hazardous under state regulations.) The list of states is arranged in descending order according to each state's share of national coal-fired generating capacity (Column 1 of Exhibit 4-1). The information shown in the Exhibit is discussed in detail in Sections 4.1.1 and 4.1.2.

4.1.1 State Classification of Coal Combustion Wastes

Forty-three states have exempted coal combustion wastes from hazardous waste regulation.[2] As a result, in these states the state solid waste laws, which apply to non-hazardous wastes, regulate the disposal of these coal combustion wastes. Column 2 of Exhibit 4-1 shows that: (1) in seven states, coal combustion wastes are not exempt from hazardous waste regulation (indicated by an entry of CH), which means that they are tested to determine whether they will be regulated as solid or hazardous wastes; (2) in all but one of the remaining states wastes are regulated by solid waste regulations (indicated by an entry of SW); and (3) in the one remaining state, wastes are exempt from both the hazardous waste and solid waste regulations (indicated by an entry of EX).

NOTES

Column (1) Percent national coal-fired capacity: i.e., each state's share of total U.S. coal-fired generating capacity.

Column (2) Classification: SW - coal combustion waste is exempted from hazardous waste regulation and regulated as a solid waste.

CH - coal combustion waste is not exempted from hazardous waste regulation and is tested for hazardous characteristics (In practice, coal combustion wastes are rarely considered hazardous, therefore columns 3-8 reflect solid, not hazardous, waste regulations).

EX - coal combustion waste is exempted from both solid and hazardous waste regulation.

Column (3) Permits: Permits are required for off-site facilities only, or for both on-site and off-site facilities.

Columns (4), (5), (6), (7), (8), (9): YES - the disposal standard is imposed by state regulations.

NO - the disposal standard is not imposed by state regulations.

MAY - the regulation states that a case-by-case investigation will determine whether the disposal standard will be imposed.

Source: Wald, Harkrader & Ross, Survey of State Laws and Regulations Governing Disposal of Utility Coal-Combustion Byproducts, prepared for the Utility Solid Waste Activities Group, September, 1983.

Of the seven states that do not exempt coal combustion wastes from hazardous waste regulation (indicated by a CH classification in Exhibit 4-1), California burns little coal to produce electricity. The hazardous waste regulations of the six remaining states -- Kentucky, Tennessee, New Jersey, Oklahoma, Maine, and Washington -- regard coal combustion wastes as "characteristic" waste; that is, the wastes are tested for Extraction Procedure (EP) toxicity (see Chapter Five for further discussion), and if the waste proves to be toxic, some or all sections of state hazardous waste regulations apply. In Kentucky, for example, hazardous waste standards concerning lining and leachate control are enforced for coal combustion wastes that are found to be toxic, but utilities are not required to participate in the hazardous waste management fund established to ensure the long-term viability of disposal facilities. Similarly, according to the hazardous waste regulations of Tennessee and Oklahoma, if a waste is determined to be toxic, strict analysis and monitoring requirements must be followed, but compliance with state hazardous waste design and operating standards is not required. Officials from these five states have indicated that it is very rare for a coal-burning utility's waste to be classified as hazardous.[3] Therefore, state solid waste regulations, with only isolated exceptions, establish the standards applicable to most coal combustion waste disposal activities.

Although solid waste regulations in most states do not differentiate between coal combustion wastes and other solid wastes, solid waste regulations in three states make specific reference to coal combustion waste disposal:

- Ohio's solid waste regulations list "non-toxic fly ash ... and slag ... that are not harmful or inimical to public health" as wastes that are exempt from solid waste regulation. Ash is typically determined to be non-toxic, according to the USWAG report.

- Maine's solid waste regulations provide a separate, more stringent set of design and operating requirements for the disposal of coal combustion wastes. The requirements call for lining, leachate control, and ground-water monitoring at coal combustion waste sites. These standards do not apply to other solid waste disposal facilities.[4]

- Pennsylvania has established industry-specific waste disposal standards. Pennsylvania's regulations for coal combustion waste disposal exclude the leachate control systems and liner requirements that apply to general solid waste disposal facilities.

4.1.2 Requirements for Coal Combustion Waste Disposal

The solid waste regulations of every state require that off-site solid waste disposal facilities be permitted or have some form of official approval. In order to obtain a permit, the operator of a facility must meet the requirements that are outlined in the regulations. These regulations are listed in Exhibit 4-1 and described below:

- The regulations in 41 states require permits for both on-site and off-site facilities. Eight states' regulations explicitly exempt on-site disposal from the permit requirement (Ohio, which exempts coal combustion wastes from solid waste regulation, is not included among the eight states). Column 3 of Exhibit 4-1 shows whether a permit is required for the operation of on-site and off-site solid waste disposal facilities.[5]

- Site restrictions are included in the solid waste regulations of 30 states. Examples of site restrictions are prohibiting solid waste disposal facilities from violating local zoning laws, banning placement of a new facility in a 100-year floodplain, and prohibiting waste placement unless there is a minimum depth to ground water. Column 4, "site restrictions," shows whether a state's regulations include restrictions on a disposal facility's location.

- Five states' regulations (Florida, Louisiana, Colorado, Washington, and Maine) call for all solid waste facilities to have a clay or synthetic liner. In addition, six states' regulations (Kentucky, Alabama, Tennessee, Wisconsin, New York, and Mississippi) call for the state permitting authority to determine, on a case-by-case basis, whether a liner is required. Column 5, "liners," shows whether the state's regulations include a requirement for liners at solid waste disposal facilities.

- Leachate control systems are collection devices placed under wastes in landfills or impoundments to collect waste leachate. Regulations in 12 states call for leachate control systems in all solid waste disposal facilities; the regulations of an additional 8 states allow leachate control systems to be required on a case-by-case basis. Column 6, "leachate control systems," shows whether a state's regulations include a requirement for leachate control systems at solid waste disposal facilities.

- The solid waste regulations of 17 states call for ground-water monitoring systems at all solid waste disposal facilities. The regulations of an additional 11 states specify that ground-water monitoring may be required on a case-by-case basis. Column 7, "ground-water monitoring," shows whether a state's regulations include requirements for ground-water monitoring wells at solid waste disposal facilities.

- Twenty-six states have solid waste regulations that call for closure and post-closure care. Column 8, "closure conditions," shows whether a state's regulations include requirements for closure and post-closure care for disposal facilities that have ceased operating.

- Thirteen states have solid waste regulations that include a financial assurance requirement. Column 9, "financial assurance," shows whether a state's regulations include a requirement that a solid waste facility operator post a bond or participate in a waste management fund to ensure the long-term viability of safe disposal facilities.

The management of waste in surface impoundments, a common practice for coal-burning utility plants, is often only indirectly addressed by state solid waste regulations. Only six states -- Louisiana, Colorado, New York, Washington, Oregon, and New Hampshire -- have solid waste regulations that include requirements exclusively for surface impoundments. The solid waste regulations of Indiana, Tennessee, Kentucky, North Carolina, Georgia, and Missouri exclude surface impoundments and defer to state water laws for regulatory authority. The water regulations in these states do not include any design and operating requirements for surface impoundments. However, according to the USWAG report, the water agencies in Missouri do regulate the design and operation of impoundments -- requiring lining and ground-water monitoring. According to the same report, state water agencies in Pennsylvania also regulate the design and operation of surface impoundments.

The regulatory requirements discussed above refer to regulations explicitly promulgated by the states for waste disposal facilities. However, state solid and hazardous waste regulations generally allow state authorities a large degree of discretion in designing site-by-site disposal standards that are more strict than those specified in the solid waste regulations. Many states' regulations allow local governments to design their own waste disposal regulations, provided that the standards set forth in the state solid waste regulations are enforced. Interviews with several state environmental

officials and the summaries in the USWAG report indicate that in some states coal combustion utility wastes are regulated more stringently than what is required by the solid waste regulations. For example, the solid waste regulations in Texas have few design and operating requirements and exempt on-site disposal from the permit requirement. It is, however, the policy of the state environmental agency to provide guidelines for on-site facilities as well as off-site facilities, and to require ground-water monitoring. (For more information on individual state regulations, see Appendix C.)

4.1.3 Summary

The regulation of coal combustion waste is generally carried out under state solid, not hazardous, waste regulations. These solid waste regulations vary from state to state. Based on the requirements included under each state's solid waste regulations (as shown in Exhibit 4-1), it is difficult to generalize about the extent of state regulation of coal combustion wastes; some states have very stringent regulations and/or policies, such as those that impose design and operating standards and on-site and off-site permit requirements, whereas other states have few requirements or exempt on-site disposal from regulation. For a number of states, requirements are determined on a case-by-case basis. This allows the states to take climatic, geologic, and other site-specific characteristics into account for each waste management facility.

4.2 AVAILABLE WASTE MANAGEMENT METHODS AND CURRENT PRACTICES

There are a variety of methods available for managing coal combustion wastes. Wastes may be land managed in impoundments, landfills, mines, and quarries or may be reused for various purposes. This section describes types of land management of coal combustion wastes and their prevalence within the ten EPA-designated regions of the United States. The second part of the section reviews available waste management technology alternatives (such as lining, leachate collection, and pre-disposal treatment), and explores how these different technologies are currently used in different parts of the U.S. and how these technologies have changed over time. The third part of this section describes the potential for ocean disposal to be used to manage coal combustion wastes. The final section describes coal combustion waste recycling. The waste management methods discussed in this section apply to high-volume and low-volume utility waste streams since these wastes are often co-disposed in the same facility.[6]

4.2.1 Land Management of Coal Combustion Wastes

80 percent of coal combustion waste is treated, stored, and/or disposed by means of land management, with the remaining 20 percent recycled (see Section 4.2.4). This section describes three common methods of land management currently used for coal combustion wastes. It also presents data on use of these management methods geographically and how land management practices have changed over time.

4.2.1.1 Types of Coal Combustion Waste Land Management

Three types of utility waste land management facilities are commonly used today:[7]

- **Surface Impoundments** -- often called wet ponds, in which coal combustion wastes are disposed as a slurry or sludge, allowing solids to settle and accumulate at the bottom of the pond.
- **Landfills** -- facilities used for disposing of dry or dewatered coal combustion wastes; landfills are typically managed like an earth-moving operation in which the wastes are disposed in the excavated area.
- **Mines and Quarries** -- abandoned pits in which wet or dry wastes are disposed.

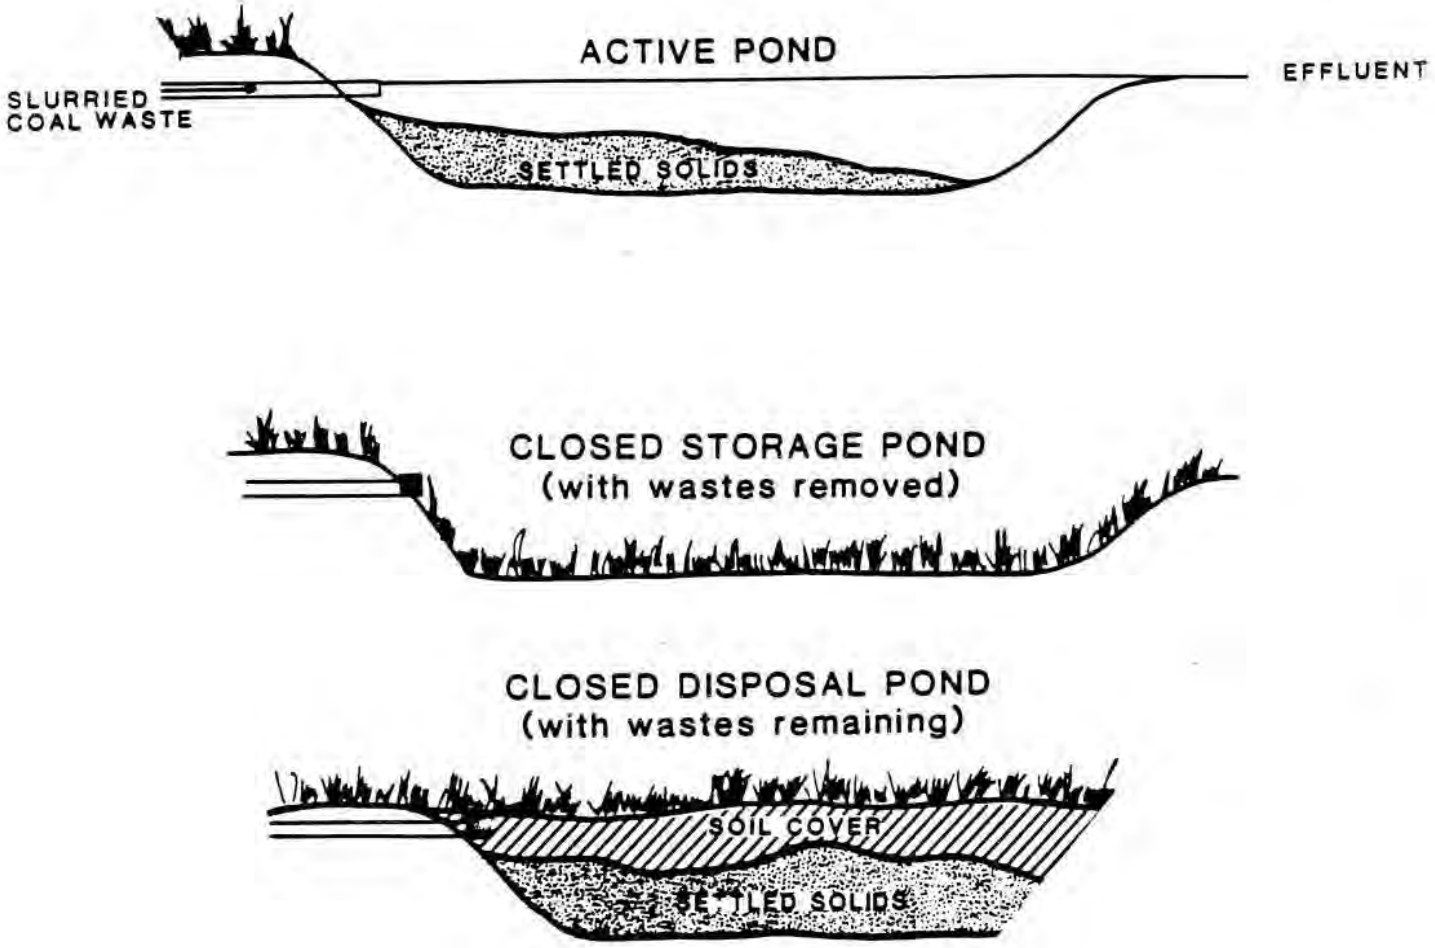
Surface Impoundments

Surface impoundments are used to treat, store, and dispose of coal combustion wastes. Slurried coal ash and other wastes are introduced into the impoundment; the solids settle out and gradually accumulate at the bottom of the pond, leaving relatively clear water at the surface, which is often discharged to surface water. By using this method, certain types of waste treatment, such as neutralization of acids, can be accomplished concurrently with disposal. Exhibit 4-2 illustrates the different stages in the life of a typical impoundment.

Historically, wet ponding has been one of the most widely used disposal methods for coal ash and FGD wastes because it is simple and easily implemented. In 1983, about 80 percent of the waste management facilities used

EXHIBIT 4-2

TYPICAL SURFACE IMPOUNDMENT (POND) STAGES



by utilities employed some type of sedimentation treatment pond; most of these treatment ponds were used directly as final disposal impoundments (about 45 percent of all facilities; see section 4.2.1.2). The remainder of the impoundments were used only for treatment and temporary storage of waste, in part to comply with the National Pollutant Discharge Elimination System established in Section 402 of the Clean Water Act.[8] In recent years, some state and local regulations concerning wet ponds have become more restrictive, requiring liners and ground-water monitoring at these facilities. These types of restrictions will tend to increase wet ponding costs, making it less attractive as a disposal option.[9]

Utilities may use a single pond or a series of ponds to facilitate the settling of solids. Chemicals or different wastes can be added at different points in the ponding system to produce desired chemical reactions, such as metals precipitation or neutralization. Fly ash, bottom ash, and FGD wastes are usually sluiced with water to the impoundments. The ash solids may be allowed to accumulate in a pond until it is full, or the pond may be drained and the solids dredged periodically and taken to an alternative disposal site, such as a landfill.

Pond designs vary widely depending upon local site conditions, the regulations that govern design of the impoundment, and whether bottom ash, fly ash, FGD wastes, or a combination of wastes are to be disposed and/or treated in the ponds. Because utility wastes are generated in large volumes, a pond's total surface area may cover up to several hundred acres, and the initial depth of a pond may be anywhere between 10 and 100 feet.[10] The total

volume of an impoundment system depends on several factors, including the total quantity of ash to be disposed (both dry and slurried volumes), the liquid and solid retention times, the type and degree of treatment performed, and the desired quality of the discharge or effluent. The number of ponds in a system and the specific uses to which each is put can also influence the total volume required for wet ponding.

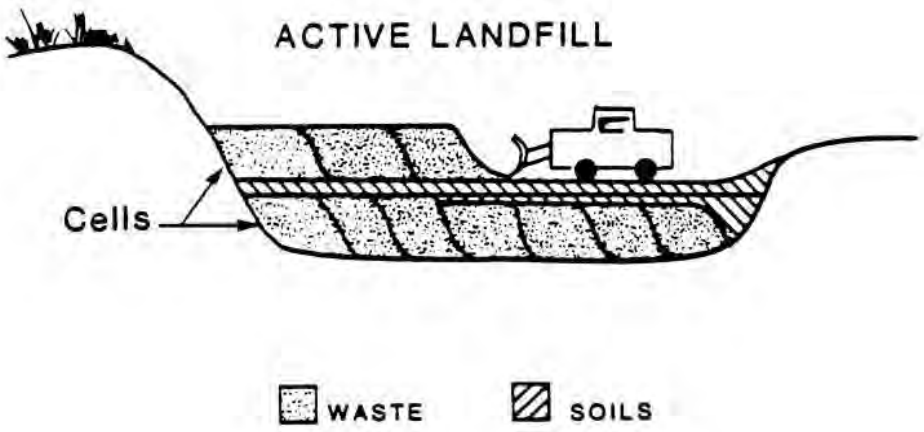
Landfills

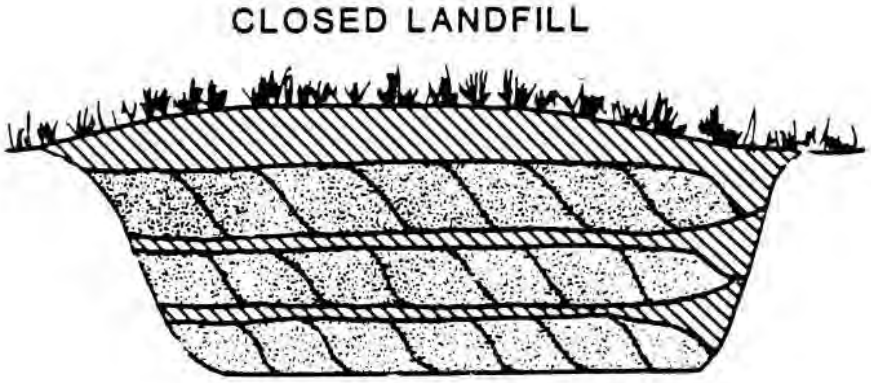
Landfills are used to dispose of coal combustion wastes such as fly ash, bottom ash, and FGD sludges when they are produced or after they are dredged from surface impoundments that are used as interim treatment facilities. The typical design of a landfill during its active stage and after closure is depicted in Exhibit 4-3.

Landfills are constructed in a somewhat similar fashion to surface impoundments. Excavation is required in both cases, but may be ongoing throughout a landfill's active life because most large landfills are divided into sections, or cells, of which only one or two may be active at any given time. A landfill cell is defined as the area (up to several hundred square feet) over which waste is placed to a depth ranging from one to ten feet (industry practice refers to each layer of cells as a lift). Several lifts may be stacked atop one another in the landfill. A cell may be open for periods ranging from a day to a few weeks, after which it is usually covered with six inches to several feet of soil. The waste and soils are often sprinkled with water throughout the fill operation to mitigate potential dust problems.

EXHIBIT 4-3

DIAGRAMS OF ACTIVE AND CLOSED LANDFILLS





Excavation may be initiated in phases; for example, as one cell is filled, another is prepared for waste placement, while yet another is being excavated. Roads are built in to provide access for waste-hauling equipment as well as for the earth-moving and earth-compacting equipment that prepares the waste after it has been placed in the landfill cell. After a cell is filled, the access road frequently becomes part of the containment system as a wall separating one cell from the next.

Landfilling of coal ash and FGD sludges has increased over the past few years as the costs of wet ponding have increased (see section 4.2.1.2). Most electric utilities that use landfills currently dispose their high-volume wastes in Subtitle D (non-hazardous waste) landfills. Landfills in compliance with RCRA Subtitle C standards may be used occasionally for disposal of small quantities of hazardous waste.[11]

Mine and Quarry Disposal

Some utilities use abandoned mines or quarries as ash and FGD sludge disposal sites. Abandoned mine disposal includes the use of mine shafts as well as strip-mined areas. Wastes disposed to abandoned mine shafts can be dumped into the shaft or carefully placed within the mine to fill the areas remaining after the coal or other material has been removed. Strip-mined areas may be filled like a landfill. Regulatory agencies may consider wastes disposed in this manner to pose less of a threat than the runoff and potential contamination from the abandoned mine itself.[12] In some cases, a chemical reaction between the waste and the mine runoff and leachate might actually

reduce the toxicity of the runoff (for example, an alkaline sludge could neutralize acid mine drainage). However, the likelihood of such a mitigative effect is very site-specific and would not necessarily occur uniformly throughout any given mine disposal site.

In a few cases, utility wastes, particularly acidic wastes, have been disposed in quarries. Limestone quarries are considered the best setting for this type of disposal because they provide a natural acid buffering capacity and the capacity for the metals present in the waste to be attenuated by chemically combining with materials in the quarry.[13] Quarry disposal of wastes works well for lime or limestone slurry wastes, which harden to form a concrete-type floor at the bottom of the quarry, thereby plugging any potential leakage paths. The probability of achieving success with this method must be evaluated on a case-by-case basis prior to its use.

4.2.1.2 Prevalence of Various Land Management Methods

Use of the waste management methods described above can vary from plant to plant and, in some cases, among individual generating units at a single power plant. This section presents information on how these utility waste management methods are employed nationwide and within EPA regions. It also discusses how these utility waste management methods have changed over time. The emphasis is on surface impoundments and landfills because these two waste management methods are the most commonly-used utility waste management practices in the United States.

The information presented in this section was derived from the Edison Electric Institute Power Statistics Database, currently maintained by the Utility Data Institute. This database contains information on power plant characteristics for all electric utility generating plants in the U.S. These data include number of power plants, number of generating units at each power plant site, type of fuel, plant capacity, as well as other information. It also contains information on the type of waste management methods currently used by power plants throughout the country, including type of disposal facility and whether the wastes were disposed at the power plant or in off-site facilities. Because each generating unit at a power plant may have its own waste management practice, the database gives waste disposal information for all generating units.

Data were not available for all generating units in the database. When information is not available, the extent of data coverage is indicated. In some instances the number of generating units on which no information was available was quite high. Although EPA recognizes the possibility of some statistical bias due to lack of data on some generating units, this database is the most comprehensive source available on utility waste management practices. EPA has no reason to believe that such bias is serious enough to call into question conclusions drawn in this analysis.

Exhibit 4-4 displays, for each of the ten EPA regions of the U.S. (see Exhibit 2-4 for a map of these regions), the number of generating units whose waste is managed in surface impoundments, in landfills, or mines. The most

a/ The data are provided by generating unit because each generating unit at a power plant may have its own management facility. A generating unit typically refers to a single boiler, turbine, and generator set at a power plant. A power plant may have more than one generating unit at the site. For the database used here, data were available for 1,378 generating units located at 514 power plants.

common types of facilities used by the electric utility industry are surface impoundments and landfills:

- Landfills are the most common type of disposal facility used. Of the 1,094 generating units for which data were available (for 284 units, type of waste disposal method was unknown), 578 units (about 53 percent) used landfills for waste disposal. Landfills are used throughout the United States, with the largest number (over one-half of all landfills) located in the high coal-consuming, industrialized areas of the East and Midwest (Regions 3 and 5).

- Surface impoundments are also commonly used; approximately 44 percent of the generating units (483 out of 1,094) used this type of management facility. Of the 483 generating units that place wastes in surface impoundments, nearly 75 percent are located in Regions 4 and 5. (In the past, access to abundant, inexpensive supplies of water in these Regions often made it economical to use this management option.)

- Mine disposal is used for about three percent of all generating units (33 units out of 1,094). This disposal technique is used most frequently in the western U.S., particularly Region 8. Power plants in this area are often located at or near the coal mine that is supplying the plant. Since the coal mine is located nearby, disposal of waste in the mine is often economic.

When managing coal combustion wastes, electric utilities may treat, store, or dispose of the wastes at the power plant or at facilities located off-site. EPA could not determine from the data available how far the wastes are transported when managed off-site, although the cost of transporting the wastes would tend to encourage disposal near the power plant. A summary of industry practices is provided in Exhibit 4-5, which shows for each EPA region, by type of facility, whether the wastes are managed on-site or off-site.

* The data are provided by generating unit because each generating unit at a power plant may have its own management facility. A generating unit typically refers to a single boiler, turbine, and generator set at a power plant. A power plant may have more than one generating unit at the site. For the database used here, data were available for 1,378 generating units located at 514 power plants.

- Nearly 70 percent of all generating units in the U.S. manage their coal combustion wastes on-site (based on information for 984 units, 674 units dispose on-site). About two-thirds of the on-site facilities are surface impoundments; most of the other on-site facilities are landfills.

- Landfills are used for about 95 percent of all off-site disposal in the U.S. This is not surprising considering that surface impoundments are typically used when wastes are transported as a wet slurry; the cost of disposal could become prohibitive if a utility transported the slurry off-site.

- Coal combustion waste management practices also differ by region:

  -- In the Northeast (Regions 1 and 2), where few coal-fired generating units are located, management tends to occur off-site in landfills.

  -- The highest percentage of on-site management is found in the South (Region 4), where about 95 percent of all units manage their waste on-site (212 units, based on information from 224 units). On-site management is common because utilities in this region often use surface impoundments, which are typically located at the power plant.

  -- In the Rockies and northern Great Plains area (Region 8), most of the off-site disposal (23 of 36 units) occurs in mines that are generally adjacent to the power plant.

These trends in utility waste management methods have been changing in recent years, with a shift towards greater use of disposal in landfills located on-site. For example, for generating units built since 1975, nearly 65 percent currently dispose of coal combustion wastes in landfills, compared with just over 50 percent for units constructed before 1975. Similarly, over 80 percent of all units built since 1975 use

on-site management facilities, compared with just under 65 percent of all units built before 1975 that manage wastes on-site.

4.2.2 Alternative Waste Management Technologies

Section 4.2.1 described the types of land management facilities used by utilities and patterns of use. This section describes the additional technologies that utilities may employ at the facilities described above in order to reduce potential environmental risk associated with waste management. For example, some utilities use liner systems for impoundments and landfills, leachate collection systems, and ground-water monitoring systems to control and monitor waste constituent migration. Pre-treatment technologies, by altering physical and chemical properties, can also render wastes more amenable for certain disposal methods. This section also presents data on the prevalence of these various technologies. The alternative technologies discussed in this section, although not necessarily the same as technologies required for RCRA Subtitle C facilities, may be required by current state regulations (described in Section 4.1) and could be more widely used in the future to further mitigate potential environmental impacts at utility waste disposal sites not currently employing these technologies.

4.2.2.1 Installation of Liners

Until recently, most surface impoundments and landfills used for utility waste management have been simple, unlined systems. Lining is

becoming a more common practice, however, as concern over potential ground-water contamination from "leaky ponds" and, to a lesser extent, from landfills has increased. Some waste management facilities use one or more impermeable synthetic liners; some are lined with one or more layers of low-permeable clay[14]; and some use a combination of clay and synthetic liners.

Synthetic Liners

Several dozen manufacturers and distributors supply impermeable synthetic liners. The most common materials of construction for these liners include polyvinyl chloride (PVC) and high-density polyethylene (HDPE), although several other impermeable synthetics have also been used. Liners may be reinforced with fibers to increase strength and decrease the likelihood of punctures. The liners can be purchased in standard thicknesses that range from 10 mils to 100 mils,[15] or can be made to order. Most liner installations will include protective geotextile fabric above and/or below the impermeable synthetic liner to minimize further the potential for puncture.

Preparation of the site prior to installation of a synthetic liner is similar to that which occurs before clay liner construction. However, more care must be taken to smooth out the surfaces to eliminate any peaks and cavities on the disposal facility floor that could cause a puncture of the liner material. Consequently, surface preparation costs are greater than those for clay liners. Excavation costs are usually less, however,

because the thinner synthetic liners allow shallower excavation (i.e., the additional excavation required to install a clay liner that is several feet thick can be avoided if a much thinner synthetic liner is installed).

The liner itself, which comes rolled or folded in large pieces, is laid in the field and sealed along the seams by heat or solvent fusion techniques; the seams may be field tested at spot checkpoints. The liner is usually covered with a foot or more of soil to protect it from puncture and to keep it in place during construction of the disposal facility. The edges of the liner at the tops of the dikes or landfill cell walls must be well secured to prevent the liner from pulling out and shifting due to the mass of the wastes placed in the impoundment or landfill. Some facilities are double lined and often contain a leachate collection system located in a soil or sand layer between the two liners.

Among the limitations to the use of synthetic liners is their susceptibility to tear and puncture. This is of particular concern in a single-lined impoundment because of the opportunity for liquids to seep through a single tear. Synthetic liners are also susceptible to degradation by certain waste materials. Acidic wastes, for example, can degrade some synthetic liner materials. As with clay liners, waste/liner compatibility testing should be performed to ensure that the disposed wastes will not weaken or permeate the liner. Additionally, because the seams of a synthetic liner are frequently weaker than the liner itself, they may pull apart under stress (e.g., large mass loadings or wave

action). Finally, dredging of synthetically-lined impoundments must be done cautiously, sometimes at very significant expense.

Synthetic liners, unlike clay liners (described below), are impermeable. Another advantage is the ease of repairing an exposed, damaged impoundment liner. A tear or puncture can be patched and seamed, and an impoundment put back into service, relatively quickly. (To repair subsurface damage, however, the impoundment must be wholly or partially drained.) Another advantage to using synthetic liners is that because of manufacturer quality control, a facility owner can be fairly certain that each liner sheet is as impermeable as the next. Clay is expensive to transport and in areas of the country where clay soils are scarce, a synthetic liner system may prove to be the less expensive option.

Clay Liners

The installation of a clay liner in a surface impoundment or landfill entails several steps. First, the site must be excavated or graded to a level below the design elevation of the facility floor. Many facilities take advantage of natural low areas or abandoned ponds to minimize excavation costs. The excavated earth can be used to build up the dike walls for the impoundment or to build containing berms within the landfill. Occasionally, soil must be brought to the construction site to raise the dikes to the design height.

Once the floor and dikes or berms have been prepared, the clay liner is laid in 6- to 9-inch lifts; its final thickness will be between 1 foot and 8 feet. Each lift is individually compacted before the next one is laid, thereby providing effective compaction and minimizing leakage potential. Field testing of the clay for permeability and other pertinent characteristics is sometimes performed during construction to provide quality assurance. Before the impoundment or landfill can be used, the liner is visually inspected for flaws; non-contaminated water may also be piped to the pond to assure that the liner is sufficiently impermeable.

One of the primary concerns about the use of clay liners is whether the entire clay liner meets thickness and permeability requirements. If weather conditions during liner construction are arid and hot, the liner may dry out and crack, causing localized areas of leakage. If conditions are wet or the clay is too moist, clay compaction may never be sufficient to achieve the necessary low permeability. The clays used as liner materials vary in the degree to which they are compatible with the wastes placed in the facility. Laboratory tests, in which the proposed liner material is exposed to the wastes intended for management, should be conducted for each facility to ensure that components of the waste material will not unduly alter the permeability of the clay used as liner material. If the chemical characteristics of the generated waste were to change over time, then the tests would need to be repeated to determine what effect the altered waste stream would have on the clay liner.

An advantage of clay liners is their potential for chemical, particularly cation, attenuation. The chemical structure of clay allows its use as an exchange site for metallic cations and other ions that might gradually seep out of the facility. Such exchange further reduces the opportunities for migration of waste constituents to the ground water. For facilities with fairly ready access to clays, the capital and construction costs associated with the use of a clay liner, even one that is several feet thick, may be substantially lower than those associated with the use of a synthetic liner.

Composite Liners

Many waste management facilities in industries currently subject to RCRA Subtitle C requirements are installing liner systems that combine both clay liner and synthetic liner technologies. Most commonly, an impoundment or landfill will be lined with 2-4 feet of impermeable clay, which is then prepared for placement of a synthetic liner. The synthetic liner may be covered with 1-2 feet of sand to serve as drainage for a leak detection system. Some facilities may then add another 1- to 2-foot layer of clay, which is again prepared for placement of the upper synthetic liner. In landfills, another leachate collection system is usually placed above this upper liner.

The composite synthetic/clay liner system offers a combination of advantages over single-material liners. A composite liner has some of the advantages provided by synthetic liners, such as factory quality control

and ease of repair (for the upper liner), as well as the advantage of clay's propensity for attenuating escaped ions. Furthermore, use of multiple-liner materials reduces the likelihood that waste material will leak into the ground water because of chemical incompatibility between a waste and a single liner material. In general, the more layers of impermeable liner material that are used, the more efficient containment of liquids will be, thus reducing the likelihood of a release of waste material.

The biggest drawback of the composite synthetic/clay liner system is the cost of installation. Utility waste landfills are very large (up to 100 acres or more), and a liner large enough to cover such a area could be very expensive. In areas where labor costs are high and clay is unavailable locally and must be transported long distances, these costs would be magnified.

Frequency of Liner Use

Some electric utilities have installed liners to retard the flow of leachate from the waste disposal facility to the surrounding area. Exhibit 4-6 shows the extent to which electric utilities are currently using this technology.

- About 25 percent of all generating units in the U.S. for which data were available (139 of 580 units) have installed some type of liner. There are no available data on the material used to construct these liners or if more than one liner has been installed at the disposal facility.

* The data are provided by generating unit because each generating unit at a power plant may have its own waste management facility. A generating unit typically refers to a single boiler, turbine, and generator set at a power plant. A power plant may have more than one generating unit at the site. For the database used here, data were available for 1378 generating units located at 514 power plants.

- Based on the information available, landfills are more likely to be lined than surface impoundments. Of the 222 generating units that use landfills and that indicated whether the disposal facility was lined or not, about 40 percent (90 units) have lined disposal facilities. Only 13 percent of surface impoundments have liners installed (based on information from 348 of the 483 units).

The information in Exhibit 4-6 should be interpreted cautiously since data were available for only 42 percent of the population (580 units of 1,378 units). One of the reasons this information is unavailable is due to the number of electric utilities that dispose of coal combustion wastes off-site. In many of these cases, the utility does not know whether the off-site disposal facility is lined or not since the utility does not run the disposal operation.

Liner use has been increasing in recent years. Before 1975, less than 20 percent of all generating units managed their coal combustion wastes in lined facilities. For units constructed since 1975, however, this percentage has increased to over 40 percent. The proportion of lined management facilities is particularly high at generating units that produce FGD sludge; since 1975 about 60 percent of management facilities containing these wastes have been lined.

4.2.2.2 Leachate Collection and Ground-Water Monitoring

Any lined management facility may have a leachate collection system and any facility (lined or unlined) may be equipped with a ground-water monitoring system. Leachate collection systems are used to prevent the

migration of contamination from a landfill or impoundment. Both systems can be used to monitor the rate and extent of contaminant migration. The design and placement of ground-water monitoring and leachate collection systems should take into account the manner in which a landfill or impoundment might potentially interfere with natural ground-water flow and usage patterns.

In surface impoundments, the leachate collection system(s) can be placed below the entire liner system or it can be placed between any two liners. Leachate collection systems typically consist of a drainage media (coarse sand and/or gravel) and perforated pipes (called riser pipes) that slope toward a collection sump. The collected leachate is pumped out via these riser pipes to the surface for treatment and/or disposal. If the riser pipes through which the leachate is pumped perforate the synthetic or clay liner, tight seals are necessary to ensure that the leachate does not escape through the perforation.

In landfills, leachate control systems can be installed below all liners (this is usually called a pressure relief system), between liners (the inter-liner leachate control system), and/or above the upper liner. The floors of a landfill cell are designed to slope to the leachate collection sumps and are usually covered with a drainage media such as sand or gravel. Each leachate control system has its own collection sump, which is emptied through riser pipes so that the leachate can be treated or disposed appropriately. As with impoundment liner systems, riser pipes, if they pierce the liners, must be sealed to prevent leakage.

Ground-water monitoring wells are placed at strategic locations to facilitate early detection of any contaminants that escape the facility and migrate to the ground water. The design and placement of the monitoring wells is based on site-specific hydrogeological assessments, soil chemistry, specific regulatory directives, and other physical and chemical factors. Downgradient wells typically are used to monitor the extent of contamination arising from a facility, and upgradient "background" wells are installed to serve as controls.

Most newer utility waste management facilities have ground-water monitoring systems, and many also have leachate collection systems. In other industries, permitted facilities subject to Subtitle C regulations are required by law to have both ground-water monitoring and leachate collection systems.[16] For utility waste disposal sites, it is estimated that about 15 percent of all facilities have leachate collection systems and about 35 percent have ground-water monitoring systems.[17]

4.2.2.3 Pre-disposal Treatment

Facilities employ a variety of waste treatment processes to alter the physical or chemical characteristics of wastes so that they will be compatible with the disposal method used. Treatment methods may also be employed to comply with the effluent limitations established under the Clean Water Act.

Sludge Dewatering

The most commonly used pre-disposal treatment process is sludge dewatering. This process is often necessary so that the sludge can be more easily handled and of a consistency suitable for landfill disposal. This procedure can also be used for any wet coal ash or combined coal ash/FGD sludge wastes. Most frequently, sludge dewatering is accomplished by sedimentation of the suspended solids in surface impoundments or, in some cases, in clarification tanks. This type of dewatering is carried out at 80 percent of the utilities.[18]

After the waste solids have had sufficient time to settle, the water layer is drawn off the tank or impoundment and is either discharged subject to National Pollutant Discharge Elimination System (NPDES) permits or recycled back to the plant as sluice or cooling water. The sludge layer containing the solid ash and other particles is allowed to accumulate for several months (or longer), and is finally dredged after the pond is drained. With this process, the solids content (initially between 5 and 15 percent by weight) can be increased to between 30 and 60 percent. The final solids content in the sludge is affected by the sedimentation impoundment or tank design, the initial solids content, the liquid and solids retention times, and the physical and chemical characteristics of the solid particles.

Even after dewatering, the settled sludges often have a mud-like consistency and still contain so much free liquid that they are

inappropriate for landfill disposal. In this case, the sludge may be further dewatered by natural or mechanical processes. In arid and semi-arid areas, the sludges may be retained in the impoundments until natural evaporation removes still more water. Sludges may also be placed on drying beds made of screens, sand, or other drainage media designed to allow water to percolate out by gravity, while the solids are retained. In mechanical sludge dewatering, belt or vacuum filters, filter presses, thermal dryers, or other processes are used. Ten percent of the utilities use some sort of filtration to dewater sludges.[19] For high-volume sludges, however, mechanical dewatering equipment may be expensive and inconvenient to operate.

Reagent Addition

Most FGD sludges and some other wet sludges can be rendered less chemically reactive and/or more structurally stable by adding solidification, stabilization, or fixation reagents. This practice is not widespread; less than 10 percent of the utilities report using these processes.[20] Solidification agents, such as sawdust or soil, absorb the liquid in a sludge but do not chemically react with the sludge. Stabilization and fixation reagents chemically react with some portion of the sludge -- either the water, the dissolved solids, the particulate solids, or some combination of the three-- and, in some cases, may render potentially hazardous material non-hazardous as a result. All of these processes result in an increased volume of waste that contains less free water and is easier to handle than the original waste stream. An

additional benefit is an increase in the structural integrity (shear stress and load-bearing potential; see Chapter Three for discussion of these characteristics) of the waste material so that it may be placed in deeper disposal facilities and covered with more material.

Low-volume Waste Treatment

The major methods available for low-volume waste management and treatment include:

- co-disposal;
- contract disposal;
- evaporation;
- incineration;
- neutralization;
- physical/chemical treatment; and
- recycle/reuse.

The type of waste management method used most often depends on the type of low-volume waste stream. Exhibit 4-7 shows the treatment process commonly used for each low volume waste stream. Each of these treatment processes is discussed briefly below.

EXHIBIT 4-7

SUMMARY OF CURRENT HANDLING, TREATMENT AND DISPOSAL OF LOW VOLUME WASTES

Low Volume Waste	Treatment	Predominant Disposal Method
Waterside Cleaning Waste	If organic chelating agents are used, this stream can be incinerated. If acids are used, the stream is often neutralized and precipitated with lime and flocculants.	1. Co-disposal with high volume wastes in pond or landfill following treatment. 2. Disposal by paid contractor.
Fireside Cleaning Waste	Sometimes neutralized and precipitated. For coal-fired plants most often diverted to ash ponds without treatment. If metals content is high, chemical coagulation and settling is used.	1. Co-disposal with high volume wastes in pond without treatment. 2. Ponding following treatment.
Air Preheater Cleaning Waste	Settling in ash pond; neutralized and coagulated if combined with other streams before treatment.	1. Co-disposal in pond without treatment. 2. Ponding with treatment.
Coal Pile Runoff	Neutralized by diverting to alkaline ash pond. Fine coal material caught in perimeter ditch is often diverted back to coal pile.	1. Co-disposal of sludge in landfill after treatment. 2. Co-disposal in ash pond.
Wastewater Treatment	Usually ponded with ash or as a separate waste. Sometimes solids co-disposed with bottom ash.	1. Ponding 2. Landfilling
Make-up Water Treatment	usually co-disposed in ash pond.	1. Co-disposal in pond.
Cooling Tower Basin Sludge	Very little survey or literature information; infrequent stream. Sludge comingled with wastewater treatment sludge.	1. Landfilling

SUMMARY OF CURRENT HANDLING, TREATMENT AND DISPOSAL OF LOW VOLUME WASTES

Low Volume Waste	Treatment	Predominant Disposal Method
Demineralizer Regenerants	Equalized in tanks, then comingled into ash ponds.	1. Ponding
Pyrite Wastes	Disposed in landfills with bottom ash or diverted to ash pond	1. Ponding 2. Landfilling

Source: EPRI, Characterization of Utility Low-Volume Wastes, prepared by Radian Corporation, Austin, Texas, May 1985.

-- Co-Disposal

Co-disposal of low-volume wastes with high-volume wastes into landfills and surface impoundments is commonly used in the utility industry. A January 1981 EPA letter (the Dietrich memorandum) currently allows co-disposal of low-volume wastes with high-volume wastes in landfills and surface impoundments.[21] In a 1985 EPRI study on low-volume waste management, about three-fourths of the power plants interviewed co-disposed some low-volume wastes in a surface impoundment or landfill.[22] The amount of treatment necessary before co-disposal varies with the waste stream. Solid wastes are typically disposed directly into the waste management facility. Liquid wastes are often routed to an interim treatment surface impoundment. Once in the surface impoundment, evaporation occurs and the remaining sludge is landfilled. If the liquid waste is chemically treated before ponding, heavy metals are often removed in a treatment facility; the treated liquid may then be reused or diverted to a surface impoundment while the residue from the treatment process is disposed in a landfill.

-- Contract Disposal

Many utilities hire outside contractors to treat and dispose of low-volume wastes. Contract disposal is most common for low-volume waste streams produced intermittently that are difficult to treat on-site. For example, hydrochloric acid boiler cleaning waste typically requires neutralization with high dosages of a caustic material. Construction of an on-site treatment system for this waste stream requires a large capital investment, although boiler cleaning wastes are produced only over a few hours once every two to five years. As a result, some

utilities (7 of 22 power plants surveyed in EPRI's 1985 study) employ outside contractors when boiler cleaning is required.[23] The treated boiler cleaning waste is then co-disposed on-site or disposed of off-site.

Contract disposal is also a common waste management practice for spent ion exchange resin. In EPRI's 1985 study, of five power plants responding, four plants hauled these wastes off-site while one power plant co-disposed the waste on-site.[24]

-- Evaporation

Evaporation ponds are used to dispose of high concentration, low-volume liquid wastes. Prior to final disposal, liquid wastes are diverted to an evaporation pond, generally shallow ponds with a large surface area. The sludge remaining after most of the water evaporates is then dredged and disposed of in a landfill.

-- Incineration

Incineration of low-volume wastes includes injection into the boiler or mechanical evaporation. This method of disposal is most common with organic cleaning wastes (Ethylenediamide tetracedic acid (EDTA) or citrate waste). A 1987 EPRI study[25] examined the effect of incinerating EDTA and citrate wastes in a utility boiler. The findings showed that the additional metals contributed were minimal compared to the amount contributed by the coal.

Two of the twenty-two power plants interviewed in EPRI's 1985 study use this method of waste disposal.[26]

-- Neutralization

Acidic or alkaline wastes can be treated with either strong bases or acids, respectively, to produce a near neutral stream. For example, wastewaters, demineralizer regenerant, and coal pile runoff must typically be within a pH range of 6.0 to 9.0 to meet Clean Water Act (CWA) and National Pollutant Discharge Elimination System (NPDES) limits. Neutralization can be used to achieve these levels. Similarly, hydrochloric acid boiler cleaning waste, which may have a ph below 2.0, can undergo neutralization to raise the ph above RCRA corrosivity guidelines (ph values between 2.0 and 12.5 are not considered corrosive under RCRA).[27]

-- Other Physical/Chemical Treatment

Physical and/or chemical treatment systems can be used for reducing and removing dissolved and suspended contaminants from aqueous streams. The most prevalent treatments incorporate pH adjustment (i.e., addition of basic or acidic materials), precipitation (i.e., separating solids from solution or suspension), flocculation (i.e., aggregation of fine suspended particles), clarification (i.e., separating liquid and suspended solids) and filtration (i.e., trapping suspended solids). The continuous waste streams are treated to allowable levels. Boiler chemical cleaning and fireside cleaning wastes require higher reagent doses and occasionally additional

processing to meet Clean Water Act (CWA) and National Pollutant Discharge Elimination System (NPDES) discharge limits for metals. Ten of the 15 power plants questioned in EPRI's 1985 study route boiler cleaning wastes through physical and/or chemical treatment systems prior to discharge.[28]

-- Reuse

Reuse is a common practice for many water-based low volume wastes, especially in water-limited regions of the country. For example, less contaminated streams (boiler blowdown, yard drains) can be used without treatment in cooling towers, ash handling systems, and flue gas desulfurization systems. Other wastes, such as boiler cleaning wastes and coal pile runoff, cannot easily be reused because they require extensive treatment prior to reuse. If a power plant does decide to treat these waste streams, the liquid portion of treated waste may be reused while the sludges produced during treatment are typically landfilled.

4.2.3 Ocean Disposal

Many different types of wastes, including industrial and municipal wastes, have been disposed at sea in the past, although the use of this method for disposing coal combustion wastes is only in the research and development phase. Typically, industrial and municipal wastes are shipped out to sea and disposed at any of several regulated dump sites, which are located anywhere from 20 miles to over 100 miles off the shore line. Another method of ocean disposal (seldom used, however) involves pumping or

gravity feeding wastes through a pipeline that feeds directly from the land-based waste generating site or dump site into the ocean. When the wastes reach the final oceanic disposal site, they either dissolve and disperse or form a manmade reef.

The 1972 Marine Protection Research and Sanctuaries Act (MPRSA), EPA regulations regarding ocean disposal,[29] and the London Dumping Convention currently regulate ocean dumping with respect to the solids content, metals content, and toxicity of wastes considered for this method of disposal.

4.2.4 Waste Utilization and Recovery of Various Waste By-Products

Although the majority of the waste generated by coal-fired electric utilities is land disposed, a substantial percentage is recovered and reused. From 1970 to 1980, an average of 18 percent of all coal ash generated annually was utilized;[30] from 1980 to 1985, the average coal ash utilization rate exceeded 22 percent, with utilization in 1985 over 27 percent of all coal ash produced.[31] The amount of FGD sludge waste utilized is less than one percent of the total volume of FGD waste generated, although more efficient FGD sludge recovery and utilization processes currently being developed by the utility industry may increase this use. The combined utilization rate for all high-volume coal combustion wastes, i.e., fly ash, bottom ash, boiler slag, and FGD sludge, was about 21 percent in 1985.

The recovery processes are usually performed at the power plant. Use of the recycled waste may occur on-site or the recycled product may be sold for off-site use. Like any industrial product, the wastes to be recycled may be accumulated on-site prior to sale and delivery.

The recovery processes and the uses for waste by-products are numerous and quite varied:

- Bottom ash currently has the highest rate of utilization at 33 percent. It is used as blasting grit, road and construction fill material, for roofing granules, and has other miscellaneous uses.[32]

- Fly ash utilization is substantial. About 17 percent of fly ash production is used for concrete admixture, cement additives, grouting, road and construction fill material, and for miscellaneous other uses.[33]

- FGD wastes are not heavily utilized in the industry (less than 1 percent), but some utilities have the capacity to recover sulfur, sulfuric acid, or other sulfur products from the waste.[34]

- Some low-volume wastes (particularly solvents) that are segregated from the high-volume waste streams are potentially recoverable or available for other uses.

- Numerous other recovery processes and utilization techniques are currently in the research and development phase. At this time, however, the Agency is unaware of any advances in recovery processes that will significantly change the proportion of coal combustion wastes that are disposed.

Coal Ash

There are a variety of different options currently available for the utilization of fly ash, bottom ash, and boiler slag from coal-fired electric

utilities. All types of coal ash are appropriate for use as construction materials, as cement additives, and for several other uses. Coal ash utilization is primarily centered in the southeast and north central United States.[35]

Most fly ash and some bottom ash exhibit pozzolanic (bonding) properties -- that is, the dried materials are cohesive and exhibit high shear strength and compressive load-bearing characteristics. These properties make ash an appropriate substitute for portland cement for many applications, including concrete production, standard cement production, and for special uses such as for the production of road base cement or even grouting.

Cement made with fly ash may be preferable to regular portland cement for some applications. One of the key benefits is the absence of heat release while the concrete or cement mixture cures; this absence of heat generation means that the design structural strength is more likely to be achieved. However, the use of fly ash and bottom ash as cement substitutes is limited because of the wide variability in ash composition, even in ash originating from the same coal supply or utility. The presence of metals in the ash can reduce the structural integrity of the final concrete by preventing the necessary chemical bonding. The presence of large quantities of sulfates or nitrates will also interfere with the pozzolanic properties. Because of this bonding interference, fly ash and bottom ash are thought to be able to replace no more than 20 percent of the cement used (or about 15 million tons of ash annually).[36] Improvements in utilization techniques may reduce the bonding interference and increase the reutilization potential of

fly ash; however, the Agency is unaware of technical advances at this time that will allow substantially greater utilization in cement applications.

Fly ash and bottom ash are also commonly used as high-volume fill for various construction materials. The pozzolanic properties of these materials facilitate soil stabilization, making them desirable as fill additives. Coal ash has been used as fill in asphalt, road bases, parking lots, housing developments, embankments, and to line on-site disposal facilities at the utilities. In the future, numerous other construction applications may use coal ash as fill, particularly if the ash is available at lower cost than standard fill materials. However, the use of ash as fill is limited somewhat because of the variability of the ash composition.

Bottom ash and boiler slag have been used as substitutes for sand in sand-blasting operations and road de-icing. Ash and slag particles are similar in size and density to sand particles. In areas where sand is costly to transport, these wastes can be economical substitutes. Ash is less corrosive than salt and could therefore be a preferable de-icing material, although in some municipalities the use of ash for de-icing has been prohibited due to public concern over aesthetics (e.g., ash residue on cars).

A variety of minor uses for fly ash and bottom ash have been considered, some of which have already been implemented at a small number of utilities. For example, bottom ash has been used for granular roofing material. Fly ash has been used by some facilities as a stabilization reagent for acidic

aqueous or semi-solid hazardous wastes: the high-pH fly ash reacts with other, low-pH waste to generate a neutral solution and to simultaneously precipitate dissolved metals as oxides and hydroxides. Because the fly ash exhibits pozzolanic properties, the ultimate waste product, when dried, often resembles concrete. The metals from the original waste stream are usually so strongly bound within the chemical structure of the final waste product that they will not leach out, even under acidic conditions.

Because fly ash has some of the same physical characteristics as a silty clay, fly ash may be used as an additive to clay liners for waste management facilities, particularly for impoundments. Fly ash is cohesive and fairly impermeable when properly compacted, and mixes well with some of the clays used in impoundment liners. However, because chemical composition of fly ash is variable, its utilization as liner material may be limited. If methods are improved to be sure that minimum permeability and shear strength requirements could be maintained over time, then the use of fly ash as an impoundment liner material may increase.

Fly ash has been used occasionally as a soil conditioner to increase the pH of acidic soils, thereby enhancing crop growth. Fly ash can also contribute minerals to the soil. However, soil conditioners in common use today, mostly agricultural limestones, are so inexpensive and easy to obtain that it would be difficult to penetrate this market with a fly ash product.

There are few processes currently available for recovery of materials from coal ash. One facility has had some commercial success at producing

magnetite from fly ash.[37] Magnetite recovered from fly ash actually contains a higher percentage of magnetics than does natural magnetite, making it a more efficient coal cleaning agent. This particular technology shows some promise of expanding; other processes, mostly for metals recovery, are in the development stage. Recovery processes for alumina and titanium are at an advanced stage of development. However, while both these technologies have been proven feasible, neither is currently economically competitive with ore-processing technologies. Another potential metal recovery process, dubbed the DAL process and still in the research stage, involves a series of relatively simple operations that can be performed with commercially available process equipment to recover various metals from fly ash. Theoretically, this process could show a substantial return on investment soon after the recovery facility began operating.[38]

There is little information available to the Agency on the environmental effects of utilization of coal combustion wastes. For many applications, such as the use of coal ash in cement and concrete products, it would appear that any adverse environmental impacts would be minimal. To the extent that coal combustion wastes can be recycled in an environmentally acceptable manner, utilization would help to reduce the amount of waste disposed. The Agency is very interested in reducing the amount of waste that needs to be disposed by the utility industry; however, barring major breakthroughs in recycling techniques, it appears the potential for significantly increasing the amount of waste utilization may be limited.[39] Given current utilization techniques, the Agency expects that the major portion of coal combustion wastes will continue to be land disposed.

FGD Wastes

The prospects for utilization of FGD sludge are less promising than those for ash utilization. FGD sludge is not structurally stable or strong enough to serve as a construction material, nor does it show the pozzolanic properties required for a cement substitute. Current research in the field of FGD sludge utilization is focusing on a dry scrubber method in which reagents will be used to precipitate the FGD waste streams as dry gypsum powder. Gypsum is sold for use in wallboard; however, there is currently a glut on the market, and in any case, other sources of gypsum may be preferred because the gypsum produced from FGD is often of lesser quality. Some researchers are making an effort to find a reagent that will precipitate a dry powder which, when mixed with water, will exhibit pozzolanic properties and will harden to a concrete-like material. No testing has been done, however, as the research is still in the conceptual stage.

Although by-product utilization of FGD sludges comprises less than one percent of total sludge production, a much greater percentage of FGD by-products may be recoverable in the very near future since two full-scale recovery processes and one test-scale recovery process for FGD by-products are currently under development. Of the two full-scale processes, the Wellman-Lord process recovers both sulfuric acid and elemental sulfur from the waste stream, while the magnesium oxide scrubber process recovers only sulfuric acid.[40] The citrate scrubbing process, currently in the testing phase, recovers elemental sulfur. FGD recovery processes currently in the

research stage will be used to recover elemental sulfur, sulfuric acid, and gypsum from the FGD process, and should be available for full-scale use within the next decade.[41] All recovery processes for FGD wastes generate both a by-product stream and a waste stream that must be disposed.

Low-Volume Utility Wastes

EPA currently assumes that most low-volume utility wastes are co-disposed with the high-volume wastes or, in some instances, burned in the boiler at the power plant, although little data exist that accurately describe industry-wide practices on low-volume waste disposal.[42] Since co-disposal is a common industry practice, low-volume wastes do not have specific processes associated with their recovery or utilization. Although this practice of co-disposal (or burning) may continue into the future, certain waste streams, such as spent cleaning solvents, might be recovered by distilling and collecting the solvents at high temperature, which would leave a low-volume residue to be disposed. The recovered solvent could then be reused on-site as a cleaning solvent or sold to another facility. If an organic solvent were contaminated in such a way that contaminant removal were difficult or impossible, the contaminated solvent could be burned. For low-volume waste streams burned in the boiler, these wastes could be transported to an off-site facility that would burn them as fuel. If low-volume wastes were considered hazardous, regulations might restrict the burning of these wastes, potentially making this option infeasible.[43]

Other recovery schemes for individual low-volume waste streams may be developed if these streams are segregated from the high-volume wastes. At this time, however, few recovery processes and utilization techniques have been considered separately for low-volume utility wastes.

Recycled Effluent

Approximately 25 percent of the utilities that utilize surface impoundments recycle some of their pond effluent back to the plant.[44] If the recycled effluent is used as sluice water, the system pH may increase to values well above 10. The recycled effluent may also be used as cooling water prior to ultimate discharge. Although effluent recycling is not a waste recovery or utilization technique, it can affect the chemical characteristics of the solid wastes that may come into contact with the recycled water.

4.3 SUMMARY

Coal combustion waste management practices by electric utilities vary widely across the industry. State regulation, regional factors such as land availability and water availability, and age of the power plant all have an effect on the type of waste management practices that are employed. Alternative practices, such as ground-water monitoring and leachate collection, are used by some utilities, and in some states are mandated by regulation. A significant portion of coal combustion by-products are recovered and utilized for various purposes.

- All but one state regulates the disposal of coal combustion wastes under their hazardous or solid waste disposal regulations. One state exempts these wastes from regulation.

- State solid waste regulations applicable to coal combustion wastes vary widely across the country. Generally, solid waste regulations require that disposal facilities have permits; location restrictions and standards related to liners, leachate control, and ground-water monitoring are applied on a case-by-case basis.

- Currently, about 80 percent of all coal-fired power plant wastes are land managed; the remaining 20 percent are recycled or recovered. The most common types of disposal facilities used by utilities generating coal-fired wastes are surface impoundments, landfills, and abandoned mines.

- Currently, about 25 percent of utility treatment, storage, and disposal facilities that receive combustion waste are lined. About 15 percent of all facilities have leachate collection systems, and 35 percent have ground-water monitoring.

- Newer facilities are more likely to be lined, have leachate collection systems, and ground-water monitoring systems. More than 40 percent of all generating units constructed since 1975 use lined disposal facilities.

- About 20 percent of all high-volume combustion wastes, particularly fly ash and bottom ash, are recycled, primarily as cement additives, high-volume road construction material, or blasting grit.

- About 99 percent of FGD wastes are currently disposed; however, recovery of sulfur and sulfur products from FGD wastes is a developing and promising technology.

CHAPTER 4

NOTES

[1] Wald, Harkrader & Ross, Survey of State Laws and Regulations Governing Disposal of Utility Coal-Combustion Byproducts, for the Utility Solid Waste Activities Group (USWAG), 1983.

[2] States have probably followed U.S. EPA's lead in exempting coal combusting wastes. Many states' regulations explicitly refer to 40 CFR 261.4, or use the clause's exact wording.

[3] The following State officials were interviewed: Brett Bettes, Solid Waste Division, Washington Department of Ecology, January 6, 1987; Ken Raymond, Industrial and Solid Waste Division, Oklahoma Department of Health, December 31, 1986; Dwight Hinch, Division of Waste Management, Tennessee Department of Health, December 31, 1986; Shelby Jett, Division of Waste Management, Kentucky Department of Environmental Protection, January 6, 1987; Vincent Nikle, Assistant Liaison's Office, New Jersey Department of Environmental Protection, December 17, 1986.

[4] According to Maine's Solid Waste Management Regulations: "More Stringent Criteria for Large-Scale Disposal of Oil, Coal and Incinerator Ash: Because of the concentration of heavy metals in residues from the combustion of municipal solid waste or the combustion of oil or coal, including bottom ash and fly ash, disposal of such ashes when they occur in amounts that exceed a total accumulation of 20 cubic yards of coal ash ... per week over any one-month period shall be confined to a secure landfill. For the purposes of these rules, a secure landfill shall mean a landfill with a liner and a leachate management system." (Maine's Solid Waste Management Regulations, Chapter 401.2.3.).

[5] The exhibit assumes that both on-site and off-site permits are required unless the regulations explicitly state otherwise.

[6] See Chapter One for discussion of the regulation of low-volume utility waste streams.

[7] Waste piling, a method occasionally employed by utilities, is not discussed in this report. Waste piles are mounds of ash placed on the ground and covered with soil.

GLOSSARY

acidity - the amount of free carbon dioxide, mineral acids and salts (especially sulfates or iron and aluminum) which hydrolyze to give hydrogen ions in water and is reported as milli-equivalents per liter of acid, or ppm acidity as calcium carbonate, or pH the measure of hydrogen ions concentration. Indicated by a pH of less than 7.

administrator - the Administrator of the United States Environmental Protection Agency, or his/her designee.

alkaline cleaning solution wastes - water-side cleaning waste resulting from the removal of high copper content scale from the utility boiler.

alkaline passivating waste - water-side cleaning waste resulting from the removal of iron and copper compounds and silica to neutralize acidity after acid cleaning.

alkalinity - the amount of carbonates, bicarbonates, hydroxides and silicates or phosphates in the water and is reported as grains per gallon, pH, or ppm of carbonate. Indicated by a pH of greater than 7.

alkaline fly ash scrubber - a flue gas desulfurization system in which flue gas reacts with alkaline fly ash that is augmented with a lime/limestone slurry.

anthracite - a high ASTM ranked coal with dry fixed carbon 92% or more and less than 98%; and dry volatile matter 8% or less and more than 2% on a mineral-matter-free basis.

aquifer - a water-bearing bed or structure of permeable rock, sand, or gravel capable of yielding quantities of water to wells or springs.

ash - the incombustible solid matter in fuel.

ash fusion - the temperatures at which a cone of coal or coke ash exhibits certain melting characteristics.

attenuation - a process that slows the migration of constituents through the ground.

baghouse - an air pollution abatement device used to trap particulates by filtering gas streams through large fabric bags usually made of glass fibers.

base load - base load is the term applied to that portion of a station or boiler load that is practically constant for long periods.

batch test - a laboratory leachate test in which the waste sample is placed in, rather than washed with, leachate solution.

bituminous coal - ASTM coal classification by rank on a mineral/matter-free basis and with bed moisture only.

> low volatile: dry fixed carbon 78% or more and less than 86%; and dry volatile matter 22% or more and less than 14%.
> medium volatile: dry fixed carbon 69% or more and less than 78%; and dry volatile matter 22% or more and less than 31%.
> high volatile (A): dry fixed carbon less than 69% and dry volatile matter more than 31% - Btu value equal to or greater than 14,000 moist, mineral-matter-free basis.
> high volatile (B): Btu value 13,000 or more and less than 14,000 moist, mineral-matter-free basis.
> high volatile (C): Btu value 11,000 or more and less than 13,000 moist, mineral-matter-free basis commonly agglomerating, or 8,300 to 11,500 Btu agglomerating.

blower - the fan used to force air through a pulverizer or to force primary air through an oil or gas burner register.

boiler - a closed vessel in which water is heated, steam is generated, steam is superheated, or any combination thereof, under pressure or vacuum by the application of heat.

boiler blowdown - removal of a portion of boiler water for the purpose of reducing solid concentration or discharging sludge.

boiler cleaning waste - waste resulting from the cleaning of coal combustion utility boilers. Boiler cleaning wastes are either water/side or gas-side cleaning wastes.

boiler slag - melted and fused particles of ash that collect on the bottom of the boiler.

boiler water - a term used to define a representative sample of the boiler circulating water. The sample is obtained after the generated steam has been separated and before the incoming feedwater or added chemical becomes mixed with it so that its composition is affected.

bottom ash - large ash particles that settle on the bottom of the boiler.

British Thermal Unit (Btu) - the mean British Thermal Unit is 1/180 of the heat required to raise the temperature of 1 pound of water from 32°F to 212°F at a constant atmospheric pressure. It is about equal to the quantity of heat required to raise 1 pound of water 1 degree F.

capacity factor - the total output over a period of time divided by the product of the boiler capacity and the time period.

CERCLA - The Comprehensive Environmental Response, Compensation, and Liability Act, commonly referred to as Superfund.

cell - a section of a landfill, or the size of that section. Usually only a few cells of a landfill are open to accept waste at a time.

chain grate stoker - a stoker which has a moving endless chain as a grate surface, onto which coal is fed directly from a hopper.

coal pile runoff - surface runoff from a plant's coal pile.

cogeneration - the production of steam (or hot water) and electricity for use by multiple users generated from a single source.

column test - a leachate extraction procedure that involves passing a solution through the waste material to remove soluble constituents.

contingency plan - a document setting out an organized, planned, and coordinated course of action to be followed in case of a fire or explosion or a release of hazardous waste constituents into the environment.

cooling tower blowdown - water withdrawn from the cooling system in order to control the concentration of impurities in the cooling water.

cyclone furnace - specialty furnace for high intensity heat release. So named because of its swirling gas and fuel flows.

demineralizer regeneration and rinses waste - a low volume wastewater generated from the treatment of water to be used at the plant.

direct lime flue gas desulfurization - see lime/limestone FGD process.

direct limestone flue gas desulfurization - see lime/limestone FGD process.

disposal - the discharge, deposit, injection, dumping, spilling, leaking, or placing of any solid waste or hazardous waste into or on any land or water such that any constituent thereof may enter the environment or be emitted into the air or discharged into any waters, including ground waters.

dry-bottom furnace - a pulverized-fuel furnace in which ash particles are deposited on the furnace bottom in a dry, non-adherent condition.

dry scrubber - an FGD system for which sulfur dioxide is collected by a solid medium; the final product is totally dry, typically a fine powder.

dry sorbent injection - an FGD system in the research and development stage for which a powdered sorbent is injected into the flue gas before it enters the baghouse. Sulfur dioxide reacts with the reagent in the flue gas and on the surface of the filter in the baghouse.

dual alkali fly ash scrubber - a flue gas desulfurization system similar to the lime/limestone process, except that the primary reagent is a solution of sodium salts and lime.

effluent - a waste liquid in its natural state or partially or completely treated that discharges in to the environment from a manufacturing or treatment process.

electrostatic precipitator - an air pollution control device that imparts an electrical charge to particles in a gas stream causing them to collect on an electrode.

evapotranspiration - the combined process of evaporation and transpiration.

fabric filter - a cloth device that catches dust and particles from industrial or utility emissions.

flash point - the lowest temperature at which vapors above a volatile combustible substance ignite in air when exposed to flame.

flue gas - the gaseous products of combustion in the flue to the stack.

flue gas desulfurization (FGD) sludge - waste that is generated by the removal of some of the sulfur compounds from the flue gas after combustion.

fly ash - suspended ash particles carried in the flue gas.

furnace - the combustion chamber of a boiler.

gas-side cleaning waste - waste produced during the removal of residues (usually fly ash and soot) from the gas-side of the boiler (air preheater, economizer, superheater, stack, and ancillary equipment).

ground water - water found underground in porous rock strata and soils.

ground water monitoring well - a well used to obtain ground-water samples for water-quality analysis.

hazardous waste - a solid waste, or combination of solid wastes, which, because of its quantity, concentration, or physical, chemical, or infectious characteristics, may (1) cause, or significantly contribute to, an increase in serious irreversible, or incapacitating reversible illness; or (2) pose a substantial present or potential hazard to human health or the environment when improperly treated, stored, transported, disposed of, or otherwise managed.

hard water - Water that contains sufficient dissolved calcium and magnesium to cause a carbonate scale to form when the water is boiled or to prevent the sudsing of soap in the water.

high volume waste - fly ash, bottom ash, boiler slag, and flue gas desulfurization sludge.

hydraulic conductivity - the quantity of water that will flow through a unit cross-sectional area of a porous material per unit of time.

hydrochloric acid cleaning waste - wastes from the cleaning of scale caused by water hardness, iron oxides, and copper.

land disposal - the placement of wastes in a landfill, surface impoundment, waste pile, injection well, land treatment facility, salt dome formation, salt bed formation, or underground mine or cave.

landfill - a disposal facility or part of a facility where hazardous waste is placed in or on land and which is not a land treatment facility, a surface impoundment or injection well.

leachate - the liquid resulting from water percolating through, and dissolving materials in, waste.

leachate extraction test - a laboratory procedure used to predict the type and concentration of constituents that will leach out of waste material.

leachate collection, removal, and treatment systems - mitigative measures used to prevent the leachate from building up above the liner.

lift - the depth of a cell in a landfill.

lignite - a coal of lowest ASTM ranking with calorific value limits on a moist, mineral-matter-free basis less than 8,300 Btu.

lime - calcium oxide (CaCO3), a chemical used in some FGD systems.

limestone - calcium carbonate (CaOH2), a chemical used in some FGD systems.

lime/limestone FGD process - form of wet non-recovery flue gas desulfurization system in which flue gases pass through a fly ash collection device and into a contact chamber where they react with a solution of lime or crushed limestone to form a slurry which is dewatered and disposed.

liner - a mitigative measure used to prevent ground-water contamination in which synthetic, natural clay, or bentonite materials that are compatible with the wastes are used to seal the bottom or surface impoundments and landfills.

low volume waste - wastes generated during equipment maintenance and water purification processes. Low volume wastes include boiler cleaning solutions, boiler blowdown, demineralizer regenerant, pyrites, cooling tower blowdown.

mechanical stoker - a device consisting of mechanically operated fuel feeding mechanism and a grate, and is used for the propose of feeding solid fuel into a furnace, and to distribute it over a grate, admitting air to the fuel for the purpose of combustion, and providing a means for removal or discharge of refuse.

net recharge - the amount of precipitation absorbed annually into the soil.

off-site - geographically noncontiguous property, or contiguous property that is not owned by the same person. The opposite of on-site.

on-site - the same or geographically contiguous property which may be divided by public or private right(s)-of-ways, provided the entrance and exit between the properties is at across-roads, intersection, and access is by crossing as opposed to going along the right(s)-of-way. Noncontiguous properties owned by the same person but connected by a right-of-way which the person controls and to which the public does not have access, is also considered on-site property.

Part A - the first part of the two part application that must be submitted by a TSD facility to receive a permit. It contains general facility information.

Part B - the second part of the two part application that includes detailed and highly technical information concerning the TSD in question. There is no standard form for the Part B, instead the facility must submit information based on the regulatory requirements.

particulates - fine liquid or solid particles such as dust, smoke, mist, fumes, or smog, found in the air or emissions.

permeability (1) - the ability of a geologic formation to transmit ground water or other fluids through pores and cracks.

permeability (2) - the rate at which water will seep through waste material.

petroleum coke - solid carbaceous residue remaining in oil refining stills after distillation process.

pH - a measure of the acidity or alkalinity of a material, liquid or solid. pH is represented on a scales of 0 to 14 with 7 being neutral state, 0 most acidic and 14 most alkaline.

plume - a body of ground water originating from a specific source and influenced by such factors as the local ground-water flow pattern and character of the aquifer.

pond liquors - waste fluid extracted from a surface impoundment or landfill.

pozzolanic - forming strong, slow-hardening cement-like substance when mixed with lime or other hardening material.

PDWS - Primary Drinking Water Standards established by the Safe Drinking Water Act.

pulverizer - a machine which reduces a solid fuel to a fineness suitable for burning in suspension.

pyrites - solid mineral deposits of raw coal that are separated from the coal before burning.

reagent - a substance that takes part in one or more chemical reactions or biological processes and is used to detect other substances.

recharge - the replenishment of ground water by infiltration of precipitation through the soil.

RCRA - Resource Conservation and Recovery Act, as amended (Pub. L. 94-580). The legislation under which EPA regulates solid and hazardous waste.

RCRA Subtitle C Characteristics - criteria used to determine if an unlisted waste is a hazardous waste under Subtitle C of RCRA.

- corrosivity - a solid waste is considered corrosive if it is aqueous and has a pH less than or equal to 2 or greater than or equal to 12.5 or if it is a liquid and corrodes steel at a rate greater than 6.35 mm per year at a test temperature of 55°C.

- EP toxicity - a solid waste exhibits the characteristic of EP (extraction procedure) toxicity if, after extraction by a prescribed EPA method, it yields a metal concen- tration 100 times the acceptable concentration limits set forth in EPA's primary drinking water standards.

- ignitability - a solid waste exhibits the characteristic of ignitability if it is a liquid with a flashpoint below 60°C or a non-liquid capable or causing fires at standard temperature and pressure.

- reactivity - a waste is considered reactive if it reacts violently, forms potentially explosive mixtures, or generates toxic fumes when mixed with water, or if it is normally unstable and undergoes violent change without deteriorating.

SDWS - Secondary Drinking Water Standards established by the Safe Drinking Water Act.

settling lagoon - surface impoundment.

shear strength - the resistance offered by a material subjected to a compressive stress created when two contiguous parts of the material are forced in opposite parallel directions.

slag - molten or fused solid matter.

sludge - a soft water-formed sedimentary deposit that is mud-like in its consistency.

slurry - a mixture of insoluble mater in a fluid.

solid waste - As defined by RCRA, the term "solid waste" means any garbage, refuse, sludge from a waste treatment plant, water supply treatment plant, or air pollution control facility and other discarded material, including solid, liquid, semisolid, or contained gaseous material resulting from industrial, commercial, mining, and agricultural operations, and from community activities,

but does not include solid or dissolved material in domestic sewage, or solid or dissolved materials in irrigation return flows or industrial discharges which are point sources subject to permits under the Clean Water Act, or special nuclear or byproduct material as defined by the Atomic Energy Act of 1954.

spray drying process - a flue gas desulfurization system in which a fine spray of alkaline solution is injected into the flue gas as it passes through a contact chamber, where the reaction with the sulfur oxides occurs. The heat of the flue gas evaporates the water in the solution, leaving a dry powder, which is collected by a particulate collector.

stabilization - making resistant to physical or chemical changes by treatment.

steady state - an adjective that implies that a system is in a stable dynamic state in which inputs balance outputs.

stoker - see mechanical stoker.

storage - the holding of waste for a temporary period, at the end of which the hazardous waste is treated, disposed of, or stored elsewhere.

subbituminous coal - An intermediate rank coal between lignite and bituminous with more carbon and less moisture than lignite.

sump effluent - waste from sumps that collect floor and equipment drains.

surface impoundment - a facility which is a natural topographic depression, artificial excavation, or diked area formed primarily of earthen materials (although it may be lined with artificial materials), which is designed to hold an accumulation of liquid wastes or wastes containing free liquids.

surface water - water that rests on the surface of the rocky crust of the earth.

traveling grate stoker - a stoker similar to a chain grate stoker except that the grate is separate from but is supported on and driven by chains.

trace element - An element that appears in a naturally-occurring concentration of less than 1 percent.

treatment - any method, technique, or process, including neutralization, designed to change the physical, chemical, or biological character or composition of a waste so as to neutralize it, recover it, make it safer to transport, store or dispose of, or amenable for recovery, storage, or volume reduction.

TSD facility - waste treatment, storage, or disposal facility.

utility boiler - a boiler which produces steam primarily for the production of electricity in the utility industry.

volatile - A volatile substance is one which tends to vaporize at a relatively low temperature.

water-side cleaning waste - waste produced during the removal of scale and corrosion products from the water side of the boiler (i.e., the piping systems containing the steam or hot water).

wet bottom furnace - a pulverized fuel fired furnace in which the ash particles are deposited and retained on the floor thereof and molten ash is removed by tapping either continuously or intermittently. (also called a slag tap furnace)

wet scrubber - a device utilizing a liquid, designed to separate particulate matter or gaseous contaminants from a gas stream by one or more mechanisms such as absorption, condensation, diffusion, inertial impaction.

CHAPTER FIVE

POTENTIAL DANGERS TO HUMAN HEALTH AND THE ENVIRONMENT

Under Section 8002(n) of RCRA, EPA is to analyze the "potential danger, if any, to human health and the environment from the disposal and reuse" of coal combustion wastes and "documented cases in which danger to human health or the environment from surface runoff or leachate has been proved." This chapter examines potential and documented dangers to human health and the environment caused by wastes generated from the combustion of coal at electric utility power plants.

As described in Chapter One, special large volume wastes, including coal combustion wastes, are to be treated differently under RCRA than other industrial wastes. Due to the extremely large volume of coal combustion waste and the expectation of relatively low risk from its disposal, Congress directed EPA to evaluate all the factors in 8002(n) of RCRA in determining whether Subtitle C regulation is warranted. The danger from coal combustion waste management is only one of the factors EPA must consider. In order to provide a starting point for evaluating the potential danger from coal combustion waste management, this chapter begins by providing the reader with background information on the characteristics that an industrial solid waste must exhibit to be considered hazardous under RCRA, and then looks at which of these characteristics apply to coal combustion wastes. The next section analyzes several studies that monitored ground-water and surface-water concentrations in and around coal combustion waste disposal sites and documented the number of times that drinking water standards were exceeded. The third section of this

chapter reviews studies that compiled and evaluated reported incidences of contamination to ground water and surface water due to the disposal of coal combustion wastes. Finally, the fourth section analyzes the factors affecting the exposure of humans, animals, and plants to contaminants from coal combustion waste by examining environmental setting and population data for a random sample of 100 coal-fired utility power plants.

5.1 RCRA SUBTITLE C HAZARDOUS WASTE CHARACTERISTICS AND LISTING CRITERIA

Under RCRA, solid wastes are classified as hazardous if they exhibit characteristics of ignitibility, corrosivity, reactivity, and/or EP toxicity as defined by RCRA or if they are listed as hazardous by the Administrator.

- Ignitibility refers to the tendency of a substance to catch fire. A liquid waste is ignitable if it has a flash point less than 60°C, as determined by EPA-specified test protocols. A non-liquid waste is ignitable if, under standard temperature and pressure, it is capable of causing a persistent, hazardous fire through friction, absorption of moisture, or spontaneous chemical change.[1]

- Corrosivity of waste is determined by measuring the waste's pH, the value used to express relative acidity or alkalinity. A pH value of 7.0 is neutral; substances with a pH less than 7.0 are acidic, while those with a pH greater than 7.0 are alkaline. A waste is corrosive, and therefore hazardous, if it is aqueous and has a pH less than or equal to 2.0 or greater than or equal to 12.5.[2] A waste is also corrosive if it is liquid and corrodes steel at a rate greater than 6.35 mm per year. The pH measurements and the corrosion rate must be determined using EPA-approved methods.[3]

- Reactivity refers to the stability of a substance. Wastes that are highly reactive and extremely unstable tend to react violently or explode. A waste is reactive if it undergoes violent physical change without detonating, if it reacts violently with water, if it forms a potentially explosive or toxic mixture with

water, or if it is capable of detonating or exploding at standard temperature and pressure.[4]

- Extraction Procedure (EP) Toxicity is determined from a laboratory procedure designed to simulate leaching from a disposal site under actual disposal conditions.[5] Concentrations in the effluent from this test are compared with the Primary Drinking Water Standards (PDWS) of eight constituent metals to determine whether a waste is hazardous. A waste is EP toxic if it produces a leachate using an EPA-approved procedure that has concentrations of contaminants that are 100 times the PDWS.[6]

Wastes are also regulated as hazardous wastes under Subtitle C if the Administrator lists them in 40 CFR 261.31-261.33. The Administrator may list wastes using several criteria:

- if they are ignitable, corrosive, reactive, or EP toxic as described above.
- if they have been found to be fatal to humans in low doses, or, in the absence of data on human toxicity, fatal to animals in laboratory tests (these wastes are designated Acute Hazardous Wastes).[7]
- if they contain any of the toxic constituents listed in Appendix VIII of 40 CFR 261, unless the Administrator, after considering the factors contained in 40 CFR 261.11(a)(3), concludes that "the waste is not capable of posing a substantial present or potential hazard to human health or the environment when improperly treated, stored, transported or disposed of, or otherwise managed." The factors that the Administrator may consider include the toxicity of the constituent, the concentration of the constituent in the waste, the potential for degradation, the degree of bioaccumulation to be expected from the constituent, and the quantities of the waste generated. These wastes are designated Toxic Wastes.[8]

Determining whether coal combustion wastes show any of the hazardous characteristics is important in analyzing potential danger to human health and the environment. In general, most coal combustion wastes, such as ash and FGD sludge, are not ignitable. Reactivity is also generally not a characteristic

of concern for coal combustion wastes. The chemical and physical characteristics of most coal combustion wastes identified in Chapter Three indicate that these wastes are very stable and will likely not react with other substances in their disposal area. The remainder of this section will analyze data on coal combustion wastes to see if these wastes exhibit the characteristics of corrosivity and/or EP toxicity.

5.1.1 Corrosivity of Coal Combustion Wastes

Under current RCRA regulations, only liquid wastes can be considered corrosive. Coal combustion ash, therefore, could not by itself be considered corrosive, even if it generates a corrosive leachate.

For wastes that are aqueous, a waste is corrosive if its pH is less than or equal to 2.0 or greater than or equal to 12.5. Available data indicate that the pH values of most waste streams of coal-fired power plants do not fall within these ranges; in fact, the only wastes that may be classified as corrosive according to the above definition are water-side, hydrochloric acid-based cleaning wastes, which have had measured pH as low as 0.5 (see Exhibit 3-26). In an EPRI report on low volume wastes (see section 5.1.2) three samples of hydrochloric acid-based boiler cleaning waste all had pH levels less than 2. However, these wastes are often neutralized before disposal. Several other waste streams have pH levels which fall very near the corrosive ranges. Most of these are also low volume wastes. Boiler blowdown has measured pH as high as 12, with a range of 8.3-12 (see Exhibit 3-20), and coal pile runoff has measured pH as low as 2.1, with a range of 2.1-6.6 (see Exhibit 3-21). Sludge from dual-alkali FGD processes using eastern coal is a high volume waste with

measured pH of approximately 12.1 (see Exhibit 3-17). Chapter Three contains a complete description of these wastes.

Several studies of coal combustion waste streams surveyed in this chapter indicate that the alkalinity or acidity of coal combustion wastes, while not necessarily falling in the RCRA corrosive ranges, may occasionally reach levels of potential concern. For example, pH readings of waste fluids taken during a study by Arthur D. Little were as high as 11.4 (see Section 5.2.1). Three case studies described in Appendix D (a study of 12 Tennessee Valley Authority power plants, an individual study at the Bull Run Power Plant, and a study of the Savannah River Project) showed pH readings of waste fluids at 2.0, 3.5, and 2.9, respectively. Section 5.3.1 describes a documented case in which highly alkaline coal combustion waste (pH 12.0) caused substantial harm to aquatic life after it accidentally spilled into Virginia's Clinch River in 1967.

5.1.2 Extraction Procedure (EP) Toxicity of Coal Combustion Wastes

Current RCRA regulations (40 CFR 261.24) specify that if a leachate extracted using an EPA-approved extraction procedure contains any of the metals shown in Exhibit 5-1 at concentrations equal to or greater than the given limit, the waste is classified as EP toxic and, unless otherwise exempted, will be subject to Subtitle C regulation.[9] The concentrations shown in Exhibit 5-1 are 100 times the current Primary Drinking Water Standards (PDWS) established by the Safe Drinking Water Act for those constituents.

Waste extraction tests are used to predict the type and concentration of constituents that may leach from a waste disposal site under field conditions.

EXHIBIT 5-1

MAXIMUM CONCENTRATION OF CONTAMINANTS FOR CHARACTERISTIC OF EP TOXICITY

Contaminant	Level	
Arsenic	5.0	mg/l
Barium	100.0	mg/l
Cadmium	1.0	mg/l
Chromium	5.0	mg/l
Lead	5.0	mg/l
Mercury	0.2	mg/l
Selenium	1.0	mg/l
Silver	5.0	mg/l

Source: 40 CFR 261.24, January 16, 1987.

Most extraction tests are conducted by mixing or washing a waste sample with a water-based solution of a specified composition for a specified length of time. The resulting leachate solution is then separated from the solids and tested for constituent concentrations.

5.1.2.1 Types of Extraction Procedures

Several different types of waste extraction procedures are described in detail below. Although under current regulations only the Extraction Procedure (EP) toxicity test is used to determine whether a waste is EP toxic, EPA has recently proposed a new procedure, the Toxic Characteristic Leaching Procedure (TCLP), to replace the EP test (see Federal Register, Volume 51. No. 114, June 13, 1986, p. 21648). Furthermore, in the period since EPA has promulgated the Extraction Procedure (EP) toxicity test, many people have alleged that the EP provides an inappropriate measure of leaching under field conditions. For these reasons, EPA has reviewed the results of other extraction procedure tests as well as the EP. To the extent that the results of these other procedures on coal combustion wastes are generally consistent with the EP results, the debate over whether the EP test is appropriate or not is moot. Three of the extraction tests described below (EP, TCLP, and ASTM) are batch leaching tests. Batch tests are conducted by placing a waste sample in a water-based solution for a specified period of time. The fourth procedure, the column test, passes a solution through the waste.

- The procedure for the standard EPA extraction test, the Extraction Procedure (EP) toxicity test,[10] requires obtaining a waste sample of at least 100 grams and then separating the liquids from the solids. The solid portion is placed in a container along with 16 times its weight in deionized water, and continually agitated at 20-40°C. Throughout the test, the pH of the batch

mixture is monitored. If the solution remains above pH 5.0, acetic acid is added to maintain a pH of 5.0. If the solution is less than pH 5.0, no acetic acid is added. If the pH of the batch solution is not below 5.2 after the initial 24-hour agitation period, the pH is adjusted to 5.0 $\pm$ 0.2 at the beginning of each hour during an additional 4 hour agitation period. After agitation, the leachate solution is then separated from the solid portion, and the liquid extracted from the original waste sample is added to the leachate solution. These combined liquids are then tested for constituent concentrations.

- Toxic Characteristic Leaching Procedure (TCLP), which EPA has proposed as a replacement for the EP,[11] uses a different leaching solution depending on the nature of the waste being tested. For wastes of low alkalinity, a pH 5.0 acetic acid/sodium acetate buffer is used for extraction. If the waste is more alkaline, a normal acetic acid solution is used. Unlike the EP toxicity test, the TCLP can be used for volatile waste constituents.

- The American Society for Testing and Materials (ASTM) developed the ASTM A procedure, which requires 48-hour agitation of a 1:4 mixture of waste to distilled deionized water. Another test, ASTM B, involves the extraction of waste constituents in a buffered acetic acid solution of pH 4.5.[12] ASTM D, similar to ASTM A, involves the 48-hour agitation of a 350-gram sample with 1400 milliliters of deionized distilled water, and the filtering of the aqueous phase, after agitation, with a 0.45 micron filter.

- Unlike the batch testing methods described above, the column test is conducted by passing a solution through the waste. This test process simulates the migration of leachate and ground water through waste, but still cannot duplicate field conditions perfectly. Because there is no standard column test procedure, column tests are described individually in the studies reviewed in the next section of this chapter.

The results of various studies (conducted with the above-mentioned extraction tests) on the leaching of constituents from coal combustion wastes are discussed below.

5.1.2.2 Results of Extraction Tests

Tetra Tech Study

In 1983 Tetra Tech conducted a literature review for the Electric Power Research Institute (EPRI) and reported results from a number of leachate extraction studies.[13] An examination of the results of various leaching tests (EP toxicity test, ASTM A, and ASTM B) on coal ash and flue gas desulfurization (FGD) sludge revealed that results differed by waste type and were ultimately dependent upon the source of the fuel (see Exhibit 5-2) and the mechanics of combustion. The study results were presented separately for ash and FGD sludge.

Results of the batch leaching tests (EP, ASTM A, and ASTM B) reported in the studies reviewed by Tetra Tech were presented as averages of the element concentrations found in numerous runs of one type of extraction test. Ranges of the concentrations were sometimes presented as well. Depending on the laboratory that ran the test, EP, ASTM A, and ASTM B batch leaching tests were run on as few as 3 and as many as 62 samples.

Tetra Tech reviewed 457 EP tests on various types of ash. Results from these EP tests show a geometric mean concentration for selenium equal to its PDWS. Geometric mean concentrations for the other 7 metals were below their respective PDWS. The maximum concentrations were 4 times the PDWS for silver, 29 times for arsenic, 8 times for barium, 140 times for cadmium, 14 times for chromium, 4 times for mercury, 5 times for lead, and 17 times for selenium.

Tetra Tech also reported results from 202 ASTM A tests on ash. Selenium was

EXHIBIT 5-2

EFFECT OF GEOGRAPHIC COAL SOURCE ON ELEMENT CONCENTRATION IN ASH

Element	Geographic Variation
Arsenic	low in western coal ash; difference in concentration between eastern coal and midwestern coal ashes indistinguishable
Barium	highest in western coal ash
Cadmium	most concentrated in midwestern coal ash
Chromium	low in western coal ash; difference in concentration between eastern and midwestern coal ashes indistinguishable
Mercury	highest in eastern coal ash; all distributions highly skewed toward high concentrations
Lead	highest in midwestern coal ash
Selenium	similar in eastern and midwestern coal ash; lower in western coal ash
Strontium	highest in western ash; lowest in midwestern ash
Vanadium	similar in eastern and midwestern coal ash; lower in western coal ash
Zinc	highest in midwestern ash; lowest in western ash

the only constituent with a geometric mean concentration greater than the PDWS, at a level approximately 2 times the PDWS. The maximum concentrations were less than the PDWS for silver and mercury. For the other elements, the maximum concentrations from the ASTM-A procedure were 7 times PDWS for arsenic, 4 times for barium, 1.3 times for cadmium, 10 times for chromium, 5 times for lead, and 48 times for selenium.

Cadmium was the only constituent in fly ash leachate extracted using the EP for which there was a maximum concentration over 100 times the PDWS (and therefore above the EP toxicity level). The EP produced a leachate that had a maximum cadmium concentration 140 times the PDWS. However, the average cadmium concentration for the 62 EP samples was only half the PDWS. Tetra Tech did not report the percentage of samples whose cadmium concentration exceeded 100 times the PDWS. In general, the more acidic or alkaline the leaching solution, the higher the concentrations of leached constituents. Tetra Tech concluded that the geometric mean concentrations from the EP and ASTM-A tests were similar. The results of the EP and ASTM-A tests are presented in Exhibit 5-3.

Tetra Tech also reviewed data from a number of column tests on coal ash. The test results did not show any concentrations greater than 100 times the PDWS for any element tested. One test was conducted during a two-year period using a continuous-flow method to produce leachate from fly ash. In another test, fly ash and bottom ash were packed separately in glass columns, each of which was leached for 27 days with 200 milliliters per day of either distilled water, dilute base, or dilute acid. For a third test, fly ash and bottom ash were packed in water-saturated glass columns. At one-week intervals, the columns were flushed from below at a moderate rate for two hours. This test was

intended to simulate the intermittent wetting to which some ash disposal sites are subject.

Partly because flue gas desulfurization (FGD) technologies have only achieved widespread commercial usage in recent years, FGD sludge has not been as thoroughly characterized as coal ash. However, the Tetra Tech study reported the results of tests performed on sludges from a number of scrubber processes, including the lime/limestone/alkaline fly ash process, the dual alkali/sodium carbonate process (both these processes produce "lime sludge" and are the main technologies currently in use), and the spray drying process (this process produces calcium-based dry scrubber sludge and may be used more extensively in the future).

Results from EP tests on calcium-based dry scrubber sludge showed a maximum concentration of cadmium that was 150 times the PDWS, above the EP toxic level. Arsenic and selenium were also analyzed using the EP test; the maximum arsenic concentration was 32 times the PDWS and the maximum for selenium was 1.8 times the PDWS. No other constituents were tested for this waste stream. (Results from the EP studies on calcium-based dry scrubber sludge were not averaged but reported as ranges - the number of tests performed was not given).

Tetra Tech also presented results of EP tests on lime sludge. These tests measured concentrations of all EP toxicity constituents, and none were found to be at EP toxic levels.

Tetra Tech also reported on column tests performed on FGD sludge. In one column test, calcium-based dry scrubber sludge was leached with deionized water

for 11 months. In another, various proportions of fly ash, wet calcium sulfate (i.e., gypsum), calcium sulfite precipitate, and calcium oxide (lime) were mixed, cured for 500 days, and leached with deionized water that was forced through the waste columns. The leaching test results (reported in a manner similar to that for reporting results of coal ash leaching studies) indicated, on the basis of an unreported number of tests, that PDWS constituents in lime sludge and calcium-based dry scrubber sludge leached at concentrations that exceeded their PDWS by multiples of less than 5 for silver, 32 for arsenic, 2 for barium, 30 for chromium, 10 for lead, and 15 for selenium; the concentration of mercury found in sludge leachate matched its PDWS. No constituents were at concentrations above 100 times the PDWS.

In summary, none of the coal ash or FGD sludge leaching studies reviewed by Tetra Tech showed constituent concentrations greater than 100 times the PDWS, with the exception of cadmium from calcium-based dry scrubber FGD sludge and from coal ash. Both results were from EP toxicity procedure tests. The behavior of these wastes primarily depended on the source of the fuel and the mechanics of combustion. Tetra Tech concluded that there were gaps in the characterization of these wastes that made definitive conclusions difficult to reach.

Department of Energy Study

The Department of Energy (DOE) conducted a compilation study of leaching test results, Analytical Aspects of the Fossil Energy Waste Sampling and Characterization Project,[14] for the purpose of generating a data base on the

leaching characteristics of coals and their combustion wastes. The EP test was compared to a water leach test developed by ASTM (this test later became ASTM D) and evaluated to determine the precision of the EP toxicity method when applied to coal wastes. In their summary of the collected data, DOE reported that for six of the analyzed constituents there were no significant differences between the testing results derived from the two methods. The results of 2492 separate extraction tests for the eight PDWS constituent metals (arsenic, barium, cadmium, chromium, lead, mercury, selenium and silver) indicated that none of the metals leached at concentrations that exceeded the PDWS by 50 times, and most leached at concentrations less than 10 times the PDWS. This was true for both the EP test and the ASTM test.

Arthur D. Little Study

EPA sponsored a study by Arthur D. Little, Inc. (see Section 5.2.1) which included EP Toxicity tests on 20 fly ash samples from 16 power plants and 3 FGD waste samples from 3 power plants.[15] The names of the plants from which the samples were taken were not revealed because Arthur D. Little did not consider the single "grab" samples obtained for testing to be representative. The EP test results showed no EP toxic levels in the extracted leachates of any samples. Silver and mercury concentrations were below the reported detection limits of .001 mg/l and .002 mg/l, respectively, for all samples. Lead was detected in only three out of seventeen samples. Other PDWS constituents (arsenic, cadmium, chromium, selenium, and barium) were detected, but all were found at concentrations less than 100 times the PDWS. In contrast to the Tetra Tech study reported above, leachates extracted from FGD samples had concentrations of PDWS constituents that tended to be lower than the

concentrations in leachates extracted from fly ash samples, whereas the Tetra Tech report indicated that, in general, higher concentrations of PDWS constituents were leached from FGD sludges than from coal ash. This discrepancy may be due to variations in the wastes themselves, which, in turn, are due to differences among coals derived from different sources. Results of the Arthur D. Little study are presented in Exhibit 5-4.

Battelle Pacific Northwest Study

In another study for the Electric Power Research Institute (EPRI), Battelle Pacific Northwest reviewed data developed during a round-robin study that compared results from three laboratories performing both the EP and TCLP tests.[16] Battelle Northwest compared the two extraction procedures by looking at the ratio of the mean TCLP concentrations to the mean EP concentrations for each element. These ratios fell within the range of 0.8 to 1.2 about 60 percent of the time. Only 15 percent of the ratios exceeded 2.0. In 83 percent of the comparisons, the TCLP test leachate contained greater concentrations of the PDWS constituents than the EP test leachate.[17]

Battelle compared the maximum mean concentration of each compound (taken from the pool of averaged results for each constituent from both EP and TCLP testing of all the waste samples) with the corresponding PDWS. This comparison indicated that for both the EP and the TCLP procedures, concentrations of silver, barium, and mercury were less than the established PDWS for those metals, whereas the concentration of arsenic was 21 times the PDWS; cadmium, 25 times; chromium, 13 times; lead, 4 times; and selenium, 14 times.

University of Alberta Study

The University of Alberta conducted a study for EPRI that involved passing a water-based solution through a series of columns with increasing ash concentrations.[18] The study results indicate that while some constituent metals were initially released or mobilized from the wastes using this method, these same constituents were attenuated in columns further along in the series. Boron, selenium, and arsenic were initially mobilized, but only boron remained mobilized to a significant extent. Arsenic and selenium interacted in successive columns such that the movement of arsenic and selenium through the system was retarded.

In addition to studying the test leachates, the University of Alberta researchers studied the fly ash itself to determine the processes that affect the migration of metal constituents. The study results indicated that some constituents are not uniformly distributed within the fly ash particles. The fly ash particles typically consist of an interior "glass" matrix covered by a relatively reactive and soluble exterior coating. The study found that arsenic and selenium were concentrated almost exclusively in the coating of the fly ash particles and thus were readily leached; the barium concentration was split evenly between the interior and exterior of the particles; about 75 percent of the cadmium and chromium were concentrated in the interior glass matrix; and almost all the lead was concentrated in the interior glass matrix and was, therefore, not readily mobilized.

The study attributed the uneven concentration of constituents in the fly ash particles to the vaporization of relatively volatile constituents during

combustion, followed by the condensation of these constituents on the exterior of fly ash particles entrained in the flue gas. However, this study reported that lead was contained within the interior glass matrix of the fly ash particles, while the Tetra Tech study discussed earlier reported that lead was volatile and thus likely to be found on the surface of fly ash particles. Both studies reported that arsenic and selenium were found on the surface of the fly ash particles. The University of Alberta concluded that the physical and chemical characteristics of the fly ash were determined by both the chemical composition of the coal from which it came and the mechanics of fly ash formation during combustion.

The difference between the University of Alberta study and the standard leaching test studies is that the mobility of constituents was observed under a variety of conditions. A number of waste concentrations could be tested in the columns to imitate specific field conditions. (Single column extractions also possess such flexibility, but to a lesser degree.) The University of Alberta study simulated landfill conditions by allowing the laboratory leachate solution to continually change as it migrated through multiple waste columns, whereas in batch extraction tests the laboratory leachate solution is allowed to come into contact with only one ash sample.

Battelle Chemical Characterization Study

Battelle Pacific Northwest Laboratories recently completed a study for EPRI on chemical characteristics of fly ash, bottom ash, and FGD sludge.[19] As part of this study, Battelle performed a comparison of the EP Toxicity Test and the TCLP test. While most of the results of the two procedures were consistent,

differences were observed with acidic samples. One acidic fly ash EP sample had both arsenic and chromium above RCRA limits. Another acidic fly ash sample also exhibited elevated levels of arsenic and chromium, but not at levels exceeding RCRA limits. The study found, however, that the two samples showed considerably less leachability for arsenic and chromium with the TCLP, while other elements tested showed similar results from the two testing procedures. The study concluded that the difference between the two types of tests resulted from the acidic character of the samples.

Radian Corporation Study

The Radian Corporation conducted two studies for EPRI that involved testing various low-volume waste streams. In the first of these studies (published in May 1985),[20] Radian Corporation collected thirty-two samples on eight types of low volume wastes. These samples were tested using the EP toxicity test as well as some other testing procedures. The results of the EP toxicity test showed that the only waste stream Radian tested that exceeded the EP toxicity limits in the 1985 Radian study was untreated boiler chemical cleaning waste. Exhibit 5-5 presents the results for three samples of untreated boiler cleaning wastes. All three samples had elevated levels of chromium and cadmium, including exceedances of EP toxicity limits, and two samples of boiler cleaning wastes had elevated concentrations of lead, including an exceedance of EP limits. This study also performed EP tests on boiler cleaning wastes after neutralization in a plant treatment system. As shown in Exhibit 5-5, the two samples of treated boiler cleaning waste did not exceed EP toxicity limits for any metals.

Source: Electric Power Research Institute, Characterization of Utility Low-Volume Wastes, Radian Corporation, May 1985.

In Radian Corporation's second study of low-volume wastes (published in July 1987),[21] they collected additional data on certain low-volume waste streams that the first study indicated might have high concentrations of metals. As shown in Exhibit 5-6, eight of twenty-one samples of low-volume liquid wastes from coal-fired plants were found to exceed EP toxicity limits. For boiler chemical cleaning wastes, 7 of 10 samples exceeded EP toxicity limits for at least one constituent. Six of the boiler chemical cleaning waste exceedances were for chromium and the remaining exceedance was for lead. One wastewater brine sample out of five tested samples exceeded the EP limits for selenium. There were no reported EP exceedances for waterside rinses or coal pile runoff.

Radian Corporation also conducted EP Toxicity tests on low-volume waste sludges. None of the three samples from coal-fired power plants were considered EP Toxic, including a boiler chemical cleaning waste sludge. For the two wastewater pond sludges, the study compared the EP and TCLP testing procedures. Results of the EP and TCLP tests are shown in Exhibit 5-7. The two extraction procedures produced nearly identical concentrations of metals in their extracts.

As in their first study, the Radian Corporation also sampled low-volume wastes that had been treated. This study found significant reductions in concentrations of chromium, copper, iron, nickel and zinc after hydrochloric acid boiler cleaning waste was neutralized.

The study also examined the treatment effectiveness of co-disposal of low-volume wastes with high-volume wastes. Results of EP toxicity tests on co-disposal mixtures found that co-disposal significantly reduced concentrations of contaminants in the co-disposed mixture. Results of the EP tests are

presented in Exhibit 5-8 for co-disposal with fly ash from three geographic areas.

5.1.2.3 Summary of Extraction Test Results

In conclusion, the results of these studies indicate that coal combustion utility wastes may leach several elements, including PDWS constituents. While a variety of extraction procedures were used in these studies, and questions have been raised about the applicability of certain testing methods to coal combustion wastes (which are generally disposed on-site in monofills), all of the extraction procedures used in the studies (EP, TCLP, ASTM, and column) produced average concentrations of constituents that were below the EP toxic level for all waste streams except untreated boiler cleaning waste. In the 1987 Radian Corporation study, untreated boiler cleaning wastes had a mean concentration 169 times the PDWS for chromium using the EP Toxicity test.

For the high-volume waste streams, cadmium, arsenic, and chromium were the only elements for which a maximum concentration was found that was over 100 times the PDWS. Arsenic and chromium were above EP toxicity limits based on EP tests for one acidic fly ash sample in the Battelle chemical characterization study. These were the only exceedances based on 23 samples. Cadmium was found at a concentration 150 times the PDWS in calcium-based dry scrubber sludge leachate and at a concentration 140 times the PDWS in some coal ash leachate as reported in the Tetra Tech study; these leachates were extracted using the EP test method. For both types of waste, however, the exceedances represented the maximum concentrations; all averages of cadmium concentration levels were below 100 times the PDWS. In fact, the geometric mean of cadmium in coal ash

leachates in the Tetra Tech study was just under 0.5 of the PDWS.

For the low-volume waste streams, the only exceedance of EP toxicity limits for wastes other than boiler cleaning waste was one wastewater brine sample that had selenium at 150 times the PDWS. The mean concentration of selenium in the wastewater brine samples was below EP toxicity limits. While untreated boiler cleaning wastes had exceedances of EP toxicity limits for chromium and lead, as noted above, EP toxicity tests on neutralized boiler cleaning wastes and on boiler cleaning wastes co-disposed with fly ash showed no exceedances of EP limits.

5.2 EFFECTIVENESS OF WASTE CONTAINMENT AT UTILITY DISPOSAL SITES

Coal combustion wastes contain trace elements that at certain levels could pose a potential danger to human health and the environment if they migrate from the disposal area. The extraction procedure tests described in Section 5.1.2 indicate that these trace elements may leach out of disposed wastes, although rarely at concentrations greater than 100 times the PDWS. This section of the report analyzes studies of ground-water and surface-water quality at and around utility disposal sites to ascertain whether potentially hazardous constituents that leach out of the waste migrate into surrounding ground water or surface water. The studies discussed in this section use as a measure of water quality the concentration of Primary Drinking Water Standards (PDWS) and Secondary Drinking Water Standards (SDWS) constituents in the water around utility waste disposal sites. Primary and Secondary Drinking Water Standards were established in the Safe Drinking Water Act. Primary Drinking Water Standards establish concentration limits for toxic constituents. Secondary Drinking Water Standards

are based on aesthetic characteristics such as taste, color, and odor. Exhibit 5-9 shows the current PDWS and SDWS. If ground water and surface water downgradient from waste disposal sites have concentrations of constituents in excess of PDWS or SDWS, and upgradient concentrations are below the standards or are lower than the downgradient concentrations, the coal combustion waste could be one of the sources contributing to ground water or surface water contamination.

EPA has conducted a number of studies on the quality of ground water in the immediate vicinity of utility disposal sites. Arthur D. Little performed extensive ground-water monitoring at six utility disposal sites. In a second study, Franklin Associates compiled data from state records on ground-water quality in the vicinity of 66 utility disposal sites. This section also reviews and evaluates a study conducted by Envirosphere for USWAG on available data on ground-water quality at 23 electric utility sites to evaluate whether and to what extent occurrences of ground-water contamination have resulted from the disposal of coal combustion wastes.

5.2.1 ADL Study of Waste Disposal at Coal-Fired Power Plants

Arthur D. Little, Inc. (ADL), conducted a three-year study for EPA's Office of Research and Development to assess the environmental effects and engineering costs associated with coal ash and flue gas desulfurization waste disposal practices at six coal-fired power plants.[22] Appendix E contains a detailed discussion of the study, including how the six sampled sites were selected, the study approach, and results for each site. A summary of the six sites is presented below:

EXHIBIT 5-9

PRIMARY DRINKING WATER STANDARDS

Contaminant	Concentration (mg/l)
Arsenic	0.05
Barium	1.0
Cadmium	0.01
Chromium	0.05
Fluoride	4.0
Lead	0.05
Mercury	0.002
Nitrate (as N)	10.0

Silver	0.05

SECONDARY DRINKING WATER STANDARDS

Contaminant	Level
Chloride	250 mg/1
Color	15 color units
Copper	1.0 mg/1
Corrosivity	Noncorrosive
Foaming Agents	0.5 mg/1
Iron	0.3 mg/1
Manganese	0.05 mg/1
Odor	3 Threshold odor number
pH	6.5 - 8.5
Sulfate	250 mg/1
Total Dissolved Solids	500 mg/1
Zinc	5.0 mg/1

Source: 40 CFR 141 and 143, September 1, 1986.

- The Allen Plant in North Carolina disposed of a mixture of fly ash and bottom ash in two unlined disposal ponds, one closed and one in active use. Intermittent waste streams, such as boiler wastes and coal pile runoff, were also disposed in the ponds. While concentrations of trace elements in downgradient ground water were higher than upgradient concentrations, exceedances of the Primary Drinking Water Standards were not found. Elevated concentrations of arsenic (up to 31 times the PDWS) were found in fluids within the active ash pond. Attenuation tests indicated that the arsenic concentrations would be chemically attenuated by iron and manganese in the soils beneath and surrounding the site. Ground-water contamination, particularly from arsenic, could have resulted if these attenuative soils had not been present. Secondary Drinking Water Standards were exceeded in both the upgradient and downgradient ground water for manganese and in the downgradient ground water for iron. This was attributed to high concentrations of these elements present in the soils of the site. Steady-state conditions have probably not been achieved at the Allen site; increases in downgradient ground-water concentrations of non-attenuated contaminants may be expected in the future.

- The Elrama Plant in western Pennsylvania disposed a fixated FGD sludge-fly ash mixture, along with small volumes of bottom ash and sludge from coal pile runoff treatment ponds, in an abandoned coal-mining area 12 miles from the plant. Part of the landfill is underlain by acid-producing spoils from the strip mining of coal. Cadmium was found in concentrations exceeding the Primary Drinking Water Standard by as much as 20 times in downgradient ground water; the highest concentration was found in the well closest to the landfill. There were no upgradient exceedances for cadmium. Steady-state conditions did not appear to have been achieved at the site, so that effects of leachate from the landfill may be expected to increase with time. Secondary Drinking Water Standards (for pH, manganese, sulfate, and iron) were exceeded at the site in both upgradient and downgradient ground water. These exceedances probably occurred because of characteristics of the disposal area and because ground water was already contaminated from acid mine drainage. Test results indicated that any constituent migration from the landfill did not measurably affect the water quality of the nearby Youghiogheny River.

  Arsenic was repeatedly detected at levels three to five times the Primary Drinking Water Standard in pond liquors, but appeared to be attenuated by soils at the site. This suggests the possibility that similar wastes

at other sites could leach arsenic at higher levels if arsenic were not attenuated by surrounding soils or diluted before reaching drinking water.

The results discussed above indicate that the fixated FGD/fly ash wastes have been, and will continue to be, a source of contamination at the site. Because exceedances for many contaminants were probably due to concurrent contamination from acid mine drainage, leachate from coal combustion waste may have only a small incremental impact on water quality.

- The Dave Johnston plant in Wyoming is located in an arid region with little ground-water recharge. The plant is the oldest of the six sites, and burns low-sulfur western coal. There are a number of disposal areas at the site; the ADL study investigated two unlined fly ash landfills, one active and one closed. Exceedances of the Primary Drinking Water Standards for cadmium (up to 3 times the PDWS) were found in ground water upgradient and downgradient of the site. Cadmium was found at elevated concentrations in pond liquors and ground water beneath the wastes. Exceedances of Secondary Drinking Water Standards for manganese and sulfate were also observed in downgradient and upgradient ground water. These two contaminants and boron were found in elevated concentrations in ground water beneath the waste and in pond liquors. No samples were analyzed for the presence of arsenic in the pond liquors. Chemical attenuation by soils at the site was found to be low for trace metals such as arsenic.Interpretations of the sampling results were difficult to make because other potential contamination sources exist, such as other waste disposal areas at the site (the location and ages of which are uncertain) and contaminants naturally occurring in the soil, which is highly mineralized around the Johnston site; and uncertainties with regard to what degree leachate from the two landfills had reached the downgradient wells. Contamination from the site could possibly increase until steady-state concentrations are reached.

- The Sherburne County Plant in central Minnesota disposed of fly ash and FGD waste in one clay-lined pond and bottom ash in an adjacent clay-lined pond. Exceedances of the Primary Drinking Water Standards were observed in both upgradient and downgradient ground water for cadmium (up to 2 times the PDWS for both) and for nitrate, and in downgradient ground water for chromium (up to 1.2 times the PDWS). Pond liquors were found to exhibit high concentrations of several constituents, including cadmium (up to 30 times the PDWS), chromium (up to 16 times the PDWS), fluoride, nitrate, lead (up to 28 times the PDWS), and selenium (up to 25 times the PDWS). While the pond

liquors exhibited high concentrations of contaminants, leachate from these wastes did not appear to have migrated into and mixed with ground water to a great extent. Ground-water samples collected at the site seemed to indicate that a few constituents (sulfate and boron) had migrated from the wastes, but not at levels exceeding SDWS. The clay liner appeared to have significantly reduced the rate of release of leachate from the disposal ponds, precluding the development of elevated trace metal concentrations at downgradient wells. Over time, downgradient wells will likely show increased levels of contamination, since steady-state conditions had not been achieved between leachate from the landfill and the ground water. Without the clay liner, the leachate seepage rate would probably have been much greater. Since the surrounding soils may not chemically attenuate selenium, this contaminant might cause PDWS exceedances once steady-state concentrations in ground water are reached.

- The Powerton Plant disposed fly ash, bottom ash, and slag in an older landfill approximately one mile south of the site. In a newer portion of the landfill, disposal operations consisted of disposing intermixed fly ash and slag. The newer landfill and part of the older one are underlain by a liner consisting of ash and lime. The downgradient ground-water wells exhibited levels of cadmium up to three times the Primary Drinking Water Standard and, in one sample, lead at four times the PDWS. An upgradient well, located on the border of the landfill wastes, exhibited a concentration of cadmium at the level of the Primary Drinking Water Standard. Secondary Drinking Water Standards for iron, manganese, and sulfate were exceeded in downgradient wells, and for manganese in an upgradient well (but at a level of exceedance lower than the downgradient measurements). These results indicate that leaching and migration of ash wastes had occurred at the site, but it was difficult to determine the effect the leachate had, or will have, on ground-water quality. Dilution and chemical attenuation may have prevented the buildup at downgradient locations of significant concentrations of trace metals such as arsenic and selenium. The degree to which Lost Creek, a nearby downgradient stream, was diluting waste constituents that reach it may be significant.

- The Lansing Smith plant in southern Florida disposed a mixture of fly ash and bottom ash in an unlined disposal pond located in a coastal area. Concentrations greater than the Primary Drinking Water Standards were observed for cadmium (up to five times the PDWS), chromium (up to four times the PDWS), and fluoride in the downgradient ground water at the site and, with the possible exception

of fluoride, appeared to be due largely to the leaching of the ponded ash wastes. Exceedances of Secondary Drinking Water Standards for sulfate, chloride, manganese, and iron were also observed in downgradient ground water. However, most of these contaminants are seawater-related and their reported concentrations appeared to be influenced by the use of seawater in plant operations and infiltration of estuarine (saline) water at the site. The leachate generated migrates to a shallow, unused, tidal aquifer. These results indicate that ash disposal at this site appears to have had a measurable impact on ground-water quality. Health risks at this particular site, however, were probably minimal since the ground water and surface water were not used as a source of drinking water.

5.2.1.1 Ground-water Sampling

Exhibits 5-10 and 5-11 summarize the results of the ADL ground-water quality data at the six disposal sites for constituents with established Primary and Secondary Drinking Water Standards, respectively. As can be seen from Exhibit 5-10:

- One site had no exceedances of PDWS constituents, either upgradient or downgradient.
- One site had PDWS exceedances for cadmium only, with the same maximum PDWS exceedance upgradient and downgradient.
- One site had downgradient PDWS exceedances for cadmium, chromium, and nitrate, but for cadmium and nitrate the upgradient exceedances were at least as large as the downgradient exceedances. There were no upgradient exceedances of chromium; the one downgradient exceedance was 1.2 times PDWS.
- The three remaining sites had downgradient PDWS exceedances for cadmium that were more frequent and larger than upgradient exceedances. The largest downgradient exceedance for cadmium at any of the six sites was 20 times the PDWS.
- There were no upgradient chromium exceedances and only three exceedances out of 94 downgradient observations. Two of the downgradient exceedances were 1.2 times the PDWS and one was 4 times the PDWS. These three exceedances were at three different sites.

5/ As indicated in footnote 15, the Max. Exceed column for the reported pH measurements is a tabulation of the actual measurements, not the maximum exceedance divided by the drinking water standard.

- One site had downgradient PDWS exceedances for fluoride in 5 of 14 samples. The maximum exceedance was 13.5 times the PDWS. There were no upgradient PDWS exceedances for fluoride at any of the six sites.

- There were no lead exceedances upgradient and only one PDWS exceedance out of 94 downgradient observations at 4 times the PDWS.

- The contaminants of most concern at the six sites appear to be cadmium and, to a lesser extent, chromium. For both of these contaminants, three sites had exceedances of the PDWS in downgradient ground water at levels higher than were found in upgradient ground water.

For constituents for which there are Secondary Drinking Water Standards, exceedances in downgradient ground water generally were higher than levels observed in upgradient wells. Results are shown in Exhibit 5-11.

5.2.1.2 Surface Water Sampling

Exhibit 5-12 summarizes the results of surface-water quality data obtained by ADL at background, peripheral, and downstream locations at three of the study sites -- Elrama, Powerton, and Lansing Smith -- for constituents with established Primary and Secondary Drinking Water Standards. Examination of these results for PDWS constituents indicates that:

- At the Lansing Smith site, downgradient and peripheral surface water samples showed cadmium concentrations up to 5 times the PDWS, chromium concentrations up to 1.2 times the PDWS, and fluoride concentrations up to 20 times the PDWS. No upgradient samples were collected at the Lansing Smith site.

- Exceedances were found for cadmium (up to 2 times the PDWS) and nitrate (up to 1.2 times the PDWS) in both upgradient and downgradient surface water at the Powerton site. The exceedances were similar in upgradient and downgradient samples both in terms of the proportion of samples in which exceedances were found and the magnitude of the exceedances.

4/ Max. Exceed. is the concentration of the greatest reported exceedance divided by the drinking water standard for that particular contaminant. The only exception is for pH, where Max. Exceed. is the actual measurement.

5/ As indicated in footnote 10, the Max. Exceed. column for reported pH measurements is a tabulation of the actual measurements, not the maximum exceedance divided by the drinking water standard.

- No exceedances of PDWS were found upgradient or downgradient at the Elrama site, although there had been downgradient exceedances at Elrama in ground water for cadmium and chromium.

5.2.1.3 Waste Fluid Sampling

In addition to ground-water monitoring, waste fluid samples were collected from the waste ponds at the Allen, Sherburne County, and Lansing Smith sites, and from dry fly ash landfills at the Dave Johnston site. Water from within and beneath FGD sludge and fly ash waste mixtures were collected from the Elrama landfill. No waste fluid samples were obtained at the Powerton site. Key observations are presented below.

- Arsenic was present in the waste fluids at elevated concentrations (up to 31 times the Primary Drinking Water Standard) at two of the five sites sampled. At these sites (Allen and Elrama), arsenic may be attenuated by soils at the site; attenuation tests indicate the soils had a moderate to high attenuation capacity, and no exceedances for arsenic were observed in ground water at the sites. The Dave Johnston site was the only disposal area where soils were found to have low attenuation capacities for arsenic; however, there are no data pertaining to waste fluids at this site, and exceedances for arsenic in the ground water were not observed. These results indicate that, depending on the coal source, arsenic may occur at elevated concentrations in waste fluids, but can be attenuated by soils within and surrounding a coal combustion waste disposal site. If the soils at a disposal site have low attenuation capacities for arsenic, this element may be of concern with regard to ground water and surface water contamination.

- Cadmium is present at elevated concentrations (up to 30 times the Primary Drinking Water Standard) in the waste fluids at all five sites. At Powerton, although no waste fluid samples were taken, ground-water samples obtained from directly beneath the wastes also exhibited elevated concentrations of cadmium. These results support the conclusion that elevated concentrations of cadmium observed in downgradient ground water may be attributable to coal combustion wastes.

- Chromium is present at elevated concentrations (up to 21 times the Primary Drinking Water Standard) in the waste fluids at two of the five sites. At these sites, higher chromium concentrations were found in downgradient ground water than were found in upgradient ground water. These observations suggest that ground-water contamination by chromium at these two study sites may be attributable to the coal combustion wastes. At a third site at which downgradient exceedances of chromium in ground water were observed, waste fluid samples were mixed with ground water occurring beneath the wastes during collection, which may account for lower waste fluid concentrations at this site.

- Other constituents that were found at elevated concentrations within the waste fluids include fluoride at all five sites (up to 10 times the PDWS); lead at one of five sites (up to 28 times the PDWS); nitrate at one of five sites (up to 7 times the PDWS); and selenium at one of four sites (up to 25 times the PDWS).

- Constituents for which Secondary Drinking Water Standards are established were found at the following elevated concentrations: chloride at three of five sites (up to 61 times the SDWS); iron at two of five sites (up to 221 times the SDWS); manganese at four of five sites (up to 466 times the SDWS); and sulfate at four of five sites (up to 42 times the SDWS). Exceedances of pH standards were found in the waste fluids at two of three sites tested. At these two sites, both acidic (as low as pH 5.9) and alkaline (as high as pH 11) conditions were found to exist. Average pH values measured in these waste fluids indicated that they were generally alkaline.

- Results of waste fluid sampling at the Sherburne County site showed exceedances of Primary Drinking Water Standards for cadmium (up to 30 times PDWS); chromium (up to 16 times the PDWS); fluoride (up to 13 times the PDWS); lead (up to 28 times the PDWS); nitrates (up to 6.9 times the PDWS); and selenium (up to 25 times the PDWS). Measurements also showed maximum exceedances of Secondary Drinking Water Standards for chloride (up to 1.9 times the SDWS); iron (up to 6.1 times the SDWS); manganese (up to 316 times the SDWS); and sulfate (up to 42 times the SDWS). This was the only site where disposal areas or ponds were completely lined. The clay liner appeared to have reduced the release of leachate, thereby concentrating waste constituents.

Results from waste fluid studies conducted by other organizations are described in Appendix D.

5.2.1.4 Summary

Results from the Arthur D. Little study suggest that under the waste management procedures used by the facilities studied, some coal combustion waste leachate was migrating into ground water beneath and downgradient from disposal sites. Five sites had concentrations of cadmium in downgradient ground water that exceeded the PDWS. Two of these five had maximum upgradient exceedances at the same level as the maximum downgradient exceedance, and two of the sites had upgradient concentrations that were equal to or above the PDWS, although the maximum concentration was less than the downgradient concentrations. One of the five sites had upgradient measurements of cadmium that were below the PDWS. Exceedances of chromium were detected in a few ground-water samples downgradient of three sites; there were no chromium concentrations above the PDWS in the upgradient ground water of any site. There were no detected exceedances of arsenic, barium, mercury, selenium, or silver in the ground water or surface water at any of the six sites. In total, approximately 5 percent of the downgradient observations exceeded the PDWS.

5.2.2 Franklin Associates Survey of State Ground-Water Data

EPA commissioned Franklin Associates to gather data from state regulatory agencies on the quality of ground water at or near coal-fired electric utility fly ash disposal sites.[23] The objective of this survey was to determine the level of ground-water contamination in the vicinity of disposal sites. However,

according to the Franklin Associates report: "No attempt was made to determine what monitoring wells might be up gradient, or what wells might be down gradient, or even as to whether specific ash disposal sites were in fact contributing specific pollutants."

Franklin Associates contacted 44 states in which coal-fired facilities were located; of these 44 states, 13 provided data. The data base that was developed included data from more than 4700 well samples taken from 66 sites.

Analysis of these samples revealed 1129 exceedances of the PDWS out of more than 15,000 observations, as shown in Exhibit 5-13. Ninety-two percent of the exceedances were less than ten times the PDWS; eight of the exceedances were 100 times greater than the PDWS.

There were 5952 exceedances of the SDWS out of nearly 20,000 observations as shown in Exhibit 5-14. These secondary standards were exceeded more frequently than the primary standards, and exceedances were usually greater. For example, about 77 percent of the SDWS exceedances were less than 10 times the standard (compared with 92 percent for PDWS exceedances), whereas 4 percent of the exceedances were greater than 100 times the SDWS (compared with less than one percent for PDWS exceedances).

Since this study did not compare upgradient and downgradient concentrations, it is not possible to determine whether occurrences of contamination at particular sites are the result of utility waste disposal practices or background levels of contaminants.

5.2.3 Envirosphere Ground-Water Survey

In response to the temporary exemption of utility wastes from regulation under Subtitle C of RCRA, the Utility Solid Waste Activities Group (USWAG) commissioned Envirosphere, Inc., to review information available from electric utilities on the quality of ground water at utility waste disposal sites.[24] Envirosphere solicited information from 98 utilities on the number and type of constituents they monitored, the frequency with which measurements were taken, and the period of time for which they had collected ground-water monitoring data. Ninety-six of the contacted utilities responded to the request for information. From these 96 utilities, Envirosphere selected for further study those that appeared to have adequate data on ground-water quality. These utilities were contacted and asked to provide their available data for use in Envirosphere's study. The participating utilities (the exact number of utilities was not provided) forwarded the requested information to Envirosphere on the 28 disposal facilities they operated. The utilities chose to withdraw three of the 28 disposal sites from the study subsequent to the analysis of the data, leaving 25 disposal sites in the data pool.

In order to analyze the data, Envirosphere paired the measurements taken at upgradient and downgradient wells at approximately the same time and in the same aquifer.[25] These data were then compared to the applicable drinking water standards to determine whether the standards had been exceeded. Two disposal sites were then eliminated from further consideration because no upgradient wells could be identified. The remaining 23 disposal sites produced a total of 9,528 paired measurements of upgradient and downgradient ground-water concentrations.

Exhibit 5-15 summarizes the information from the Envirosphere data base for those cases where the Primary Drinking Water Standards (PDWS) were exceeded by the downgradient measurement. The most obvious indication that a waste facility is contributing to a PDWS exceedance is a measurement indicating downgradient values higher than the PDWS and upgradient values lower than the PDWS. According to Envirosphere's report, about 1.7 percent of the data fell into this category.[26] For those cases in which both the upgradient and downgradient values were exceeded, Envirosphere argued that it was difficult to attribute the exceedances to the disposal facility without further site-specific analysis. About 5 percent of the measurements fell into this category, with 60 percent of these indicating upgradient values equal to or greater than the downgradient values.

Maximum concentrations of several substances significantly exceeded the PDWS in downgradient wells: arsenic, 560 times the PDWS; lead, 480 times the PDWS; mercury, 235 times the PDWS, and selenium, 100 times the PDWS. These values must be compared to the maximum upgradient reading since some of the contamination may be unrelated to the disposal facility. As shown in Exhibit 5-15, the downgradient concentration was sometimes higher than the upgradient value even when the upgradient value exceeded the PDWS. However, exceedances of the magnitudes shown in Exhibit 5-15 comprised a small fraction of the total measurements in the Envirosphere data base.

The Envirosphere data also included information regarding exceedances of the Secondary Drinking Water Standards (SDWS). A summary of these data is shown in Exhibit 5-16. The data indicate that in 8.2 percent of the cases the

SUMMARY OF PDWS EXCEEDANCES IN ENVIROSPHERE'S GROUND-WATER DATA

Constituent	Total Observations	Downgradient Observations a/ Exceeding PDWS When: Upgradient Does Not Exceed — Number	%	Upgradient Exceeds — Number	%	Maximum Downgradient Observation (X PDWS) b	
Arsenic	588	7	1	0	0	560	(192)
Barium	298	0	0	0	0	1	(3)
Cadmium	571	59	10	9	2	6	(1)
Chromium	658	20	3	10	2	20	(76)
Lead	639	29	5	67	10	480	(220)
Mercury	575	8	1	2	c/	235	(9)
Selenium	489	5	1	34	7	100	(100)
Silver	261	0	0	0	0	1	(0.2)
TOTAL	4079	128	3 d/	122	3 d/		

a/ Envirosphere classified measurements by comparing downgradient values with upgradient values. When the downgradient value exceeded the PDWS, classification depended on whether the upgradient value also exceeded the PDWS. Both categories of measurements are shown here, although Envirosphere focused primarily on pairs of measurements in which the downgradient value exceeded the PDWS but the upgradient value did not.

b/ Maximum downgradient value observed in the Envirosphere data base. The corresponding paired upgradient concentrations are not available. The maximum upgradient value of all measurements at the same facility is shown in parentheses.

c/ Less than 0.5 percent.

d/ These percentages apply to the total number of observations. Envirosphere "normalized" the data to correct for sites that had a high proportion of data points so that one site would not be overly represented; these normalized values are noted in the text of the report.

downgradient value exceeded the SDWS while the upgradient value did not. In some cases the exceedances were substantially greater than the SDWS; e.g., the maximum observation for iron was 3458 times greater than the SDWS and manganese was 474 times greater.

In summary, the Envirosphere ground-water data show that Primary and Secondary Drinking Water Standards were exceeded in ground water downgradient from utility waste disposal facilities. However, the percentage of cases in which constituent concentrations in downgradient wells exceeded the standards when those in upgradient wells did not was small. There are limitations in the data, due in part to the way in which they were collected (e.g., only data from those utilities that voluntarily submitted data are included in the report). There is also a limited amount of information regarding the extent to which site-specific factors, such as environmental setting characteristics or other possible sources of contamination, could have had an effect on ground-water contamination.

5.2.4 Summary

The studies described in this section demonstrate that downgradient ground-water and surface-water concentrations exceeded the PDWS and SDWS for a few constituents. In some of these downgradient exceedances, corresponding upgradient exceedances also occurred, suggesting that the contamination was not necessarily caused by the waste disposal sites. For cases in which the downgradient ground water had constituent concentrations higher than the corresponding upgradient concentrations, the PDWS exceeded most often were those for cadmium, chromium, lead, and to a lesser extent, arsenic.

Some PDWS exceedances were quite high, e.g., up to 560 times for arsenic and 480 times for lead (see Exhibit 5-15). However, the frequency of PDWS exceedances for downgradient ground water and surface water is rather low. For example, 3.7 percent of the Envirosphere data had downgradient ground-water concentrations of PDWS higher than those measured in upgradient wells. Three of the six Arthur D. Little sites had downgradient ground water with concentrations of constituents that were both above the PDWS and above corresponding upgradient concentrations. Although the Arthur D. Little pond liquor data show high concentrations of PDWS and SDWS constituents, in most cases the constituents appeared to be contained within the disposal area or attenuated in the surrounding soils. This is particularly true for the case of arsenic, which was detected in the waste fluids at a level 31 times the PDWS, but was not found at elevated levels in ground water or surface water. There were no exceedances of arsenic, barium, mercury, selenium, or silver in downgradient ground water at any of the six Arthur D. Little sites. The Envirosphere study detected no exceedances of barium or silver.

5.3 EVIDENCE OF DAMAGE

This section examines documented cases in which danger to human health or the environment from surface runoff or leachate from the disposal of coal combustion wastes has been proved. The first part of this section reviews two major studies conducted for the Utility Solid Waste Activities Group (USWAG): a 1979 Envirosphere, Inc., study and a 1982 Dames and Moore study. To supplement these two major studies, in 1987 EPA conducted a literature review of all readily-available sources, which revealed only two additional case studies on proven damages occurring in 1980 and 1981. The Agency has not identified any

proven damage cases in the last seven years; however, no attempt was made to compile a complete census of current damage cases by conducting extensive field studies.

As with all damage cases, it is not always clear whether damages could occur under current management practices or whether they are attributable to practices no longer used. As described in Chapter Four, there has been an increased tendency in recent years for utilities to utilize mitigative technologies, including a shift to greater use of landfills rather than surface impoundments and an increased use of liners.

5.3.1 Envirosphere Case Study Analysis

The Utility Solid Waste Activities Group (USWAG) and the Edison Electric Institute (EEI) commissioned the Envirosphere Company in 1979 to investigate and document available information on the nature and extent of the impact of utility solid waste disposal on public health, welfare, and the environment.[27] To conduct this analysis, Envirosphere reviewed various reports, including EPA's damage incident files, environmental monitoring studies at utility disposal sites, and other research and studies as available; they contacted state regulatory agencies to determine what information was available in state files.

From its review of the available data, Envirosphere found few documented cases where utility solid waste disposal had potentially adverse environmental effects. They identified nine cases from EPA's damage incident files that appeared to show damage to the environment. Envirosphere reviewed data from environmental monitoring studies at the utility disposal sites and other

available research, and noted that the information available on the potential impacts of utility waste disposal was inconclusive. Some data indicated "... that elevated levels of some chemical parameters have occurred at locations downgradient of some utility solid waste disposal sites." Envirosphere concluded, however, that it was not clear to what extent these impacts could be attributed to utility solid waste disposal practices.

Some of the specific cases from Envirosphere's sources are summarized below:

- Texas, 1977. A clay liner was improperly installed in a 14.3 acre disposal pond for metal cleaning solutions. The liner dried and cracked before wastes were introduced into the facility. After the pond was put in service, ground-water monitoring wells detected contaminant migration. Levels of selenium and chromium occasionally exceeded the PDWS for these elements, and several SDWS were exceeded. The pond was taken out of service, the liner was saturated with water, and the pond was put back into operation.

- Indiana, 1977. Envirosphere found that leaching from two large, unlined ash disposal ponds was contributing to ground-water contamination. Arsenic and lead were found in downgradient ground water at concentrations about two times the PDWS, while concentrations of selenium were about four times the PDWS.

- Pennsylvania, 1975. A private waste handler illegally disposed fly ash in a marsh located in a tidal wetland area. Visual inspections by the state indicated marsh contamination due to fly ash leachate. When ordered to stop the dumping and clean up the site, the handler declared bankruptcy, and the ash remained in the marsh. Detailed analysis of any potential impacts has not been conducted.

- Connecticut, 1971. A municipal landfill, which was located in a marsh, accepted many substances, including large quantities of fly ash. Surveys revealed numerous SDWS contaminants, some of which appeared to be related to the ash. The site, considered unsuitable for disposal of solid waste, was closed and turned into a state park.

- Virginia, 1967. A dike surrounding a fly ash settling lagoon collapsed, and 130 million gallons of caustic solution (pH 12.0) were released into the Clinch River.

> Large numbers of fish were killed over a distance extending 90 miles from the spill site. Surveys conducted 10 days after the spill showed dramatic reductions in bottom dwelling fish food organisms for 77 miles below the release site. Virtually all such organisms were eliminated for a distance of 3 to 4 miles. The waste was eventually diluted, dispersed, and neutralized by natural physical/chemical processes. Two years after the spill, however, the river had not fully recovered.

5.3.2 Dames & Moore Study of Environmental Impacts

Dames & Moore, in a study for USWAG, conducted a survey of existing data and literature to document instances in which danger to human health and the environment was found to have occurred because of the disposal of coal combustion wastes.[28] Dames & Moore established criteria by which to evaluate whether a given record of a contamination incident could be considered "documented" evidence proving danger to health or the environment: 1) the report must exist in the public record; 2) the case must involve high-volume (utility) wastes; 3) information must exist to permit determination of possible health or environmental risks; and 4) the possible risks may have been caused by leachate migration or runoff from utility disposal sites.

The danger to health and the environment was examined by accounting for the types, concentrations, and locations of constituents shown to be present that could have harmful effects. In addition, Dames & Moore considered both the potential for public access to utility waste constituents and any observed effects on the population or environment. The three major data sources providing information reviewed in this study were computer data bases used to search for publicly available references; Federal Government agencies such as

EPA, U.S. Geological Survey, and the Tennessee Valley Authority; and 12 state environmental, natural resource, health or geological agencies.

Using information from these sources, Dames & Moore identified seven cases that presented a potential danger to human health and the environment. Six of the seven cases involved potential impacts from ground water and one case involved surface water. Dames & Moore concluded that none of these cases represented a "documented" case of such danger. However, Dames & Moore eliminated several sites from the documented category because they believed sufficient data from the sites were unavailable or did not meet the selection criteria described above. Dames & Moore evaluated in detail the seven sites at which there existed a potential for adverse environmental and health effects. Their findings are summarized below.

- Chisman Creek Disposal Site, York County, Virginia. The Chisman Creek disposal area was an inactive site with four separate fly ash disposal pits on both sides of Chisman Creek. An electric utility hired a private contractor to transport and dispose of fly ash and bottom ash from petroleum coke (a residual product of the oil distillation process) and coal combustion. The site was active from the late 1950's to 1974. In 1980, nearby residential drinking water wells became green from contamination of vanadium and selenium and could no longer be used. The site is currently on the CERCLA (Superfund) National Priorities List. A minimum of 38 domestic wells and 7 monitoring wells near the four disposal sites were sampled over time. Two off-site domestic wells located 200 feet from the disposal area had elevated concentrations of vanadium, selenium, and sulfate. One of these two wells was sampled four times. Three of the four measurements exceeded the PDWS for selenium up to 2 times. Another domestic well contained 0.11 mg/l of vanadium. (EPA has not established concentration limits for vanadium.) At both wells, sulfate concentrations exceeded the SDWS. In addition, samples from six of the seven monitoring wells exhibited increased concentrations of sulfates. The highest concentrations of selenium and vanadium that were observed in monitoring well samples were 0.03 (3 times

the PDWS) and 30 mg/l, respectively. The high concentrations of selenium and vanadium were noticed in monitoring wells that were drilled directly through the disposal pits.

The Virginia State Water Control Board (SWCB) conducted the initial study at this site. The SWCB concluded that the quality of ground water immediately beneath and down-gradient from the site had been affected. Moreover, the SWCB stated that the water in the two domestic wells had elevated concentrations of selenium and vanadium because of the disposal of the fly ash. Dames & Moore was critical of the conclusions reached by the SWCB because of what they termed "significant data gaps." Dames & Moore cited a lack of background water quality information and a general lack of information on the well installation, sample collection procedures, and other possible sources of contamination, such as the York County landfill which is adjacent to one of the ash disposal areas. The two contaminated off-site domestic wells identified by the SWCB, however, were over 2,000 feet from the county landfill but within a couple of hundred feet from the ash disposal areas. Additionally, monitoring wells located between the landfill and the affected domestic wells did not register the same elevated concentrations of selenium. Residents in the area no longer rely on ground water for their drinking water.

- Pierce Site, Wallingford, Connecticut. Coal fly ash had been deposited at the Pierce Site since 1953. In 1978, the United States Geological Survey (U.S.G.S.) collected ground-water quality data from three on-site wells - one upgradient and two downgradient. The U.S.G.S. took samples from the wells on three days over a period of two months. One sample from one downgradient well showed a concentration of chromium that exceeded the PDWS by a multiple of 1.6. Concentrations of cadmium, manganese, zinc, and sulfate were higher in the downgradient wells than in the upgradient well.

  According to Dames & Moore, there were not enough data at this site to state conclusively whether or not the ground water had been adversely affected by the fly ash pit. To determine potential damage to ground water quality, Dames & Moore stated that EPA recommends a minimum of three downgradient wells and one upgradient well. In this case, there were only two downgradient wells. Three samples over a period of two months were not considered sufficient because naturally occurring temporal changes in the area were believed to render comparisons invalid.

  The Pierce disposal site is situated on a deposit of thick, stratified sediments composed of particles that

range in size from clay to coarse sand. The disposal site is located within a few hundred feet of the Quinnipiac River, and the ground water flows from the site to the river, which diluted contaminants in the ground water. Although there are residences within a few blocks of the power plant, they do not use local ground water for drinking supplies.

- Michigan City Site, Michigan City, Indiana. The Michigan City site, situated on the shore of Lake Michigan, contained two fly ash disposal ponds. Ground-water flow at the site was towards Lake Michigan, facilitated by the porous sand that underlies the site. Twenty-one monitoring wells were installed at this site. Two of these were placed upgradient from the site outside the site boundaries; the remaining 19 wells were established within the boundaries of the facility and downgradient from the disposal areas.

  Monitoring of the wells (which took place periodically over a one-year period) indicated that trace metals migrated from the disposal sites and that certain constituents had elevated ground-water concentrations. Arsenic and lead were observed in concentrations that exceeded their PDWS. Seven samples collected from three downgradient monitoring wells had arsenic concentrations that exceeded the standard -- up to 100 times the PDWS. All of the samples taken from the upgradient off-site monitoring wells contained arsenic at concentrations below the PDWS. Five of the downgradient monitoring wells contained lead concentrations which exceeded the PDWS, with the highest exceedance 7 times the PDWS. Three samples from the two upgradient monitoring wells also had lead concentrations in excess of the standard, with the highest exceedance 3 times the PDWS.

  Dames & Moore concluded that effects on ground water appeared to be limited to areas within the facility boundaries because of attenuation mechanisms operative at the site -- absorption, dilution, precipitation, and a steel slurry wall installed between the disposal site and Lake Michigan. However, no downgradient monitoring wells were situated off-site. Based on the locations of the waste disposal sites and the monitoring wells, it appears that the ash ponds are responsible for arsenic concentration above the PDWS in the ground water within the site boundaries. Because high lead concentrations were observed in some of the upgradient background wells, it is impossible to state with certainty that the high lead concentrations in the ground water are attributable to the disposal sites. Dames and Moore noted that nearby residents do not use the ground water for their water supply.

- Bailly Site, Dune Acres, Indiana. The Bailly site is located near the Indiana National Lakeshore on Lake Michigan in a highly industrialized area. Fly ash at this site has been slurried to interim settling ponds, which are periodically drained. The drained ash is then disposed in an on-site pit. Two aquifer units, designated Unit 1 and Unit 3, underlie the site. Unit 1 contains fine-to-medium sand and some gravel, while Unit 3 is composed of sand with overlying layers of varying amounts of sand, clay and gravel.

  Ground-water samples from Unit 1 were collected from an upgradient well and from several wells downgradient from the ash settling ponds. Samples from Unit 3 were collected upgradient and from one well downgradient from the ash ponds. These wells were sampled at five-week intervals between September 1976 and May 1978.

  In samples from Unit 1, arsenic, cadmium, fluoride, and lead occasionally exceeded the PDWS. Upgradient concentrations of arsenic never exceeded the PDWS, whereas the maximum downgradient concentration for arsenic was 4.6 times the PDWS. Downgradient on-site concentrations of cadmium exceeded the PDWS at one well by 25 times, while the maximum upgradient concentration of cadmium exceeded the PDWS by 22 times. One downgradient well measurement indicated lead concentrations that exceeded PDWS by 1.26 times.

  All of the above-mentioned exceedances were observed in Unit 1. None of the samples from Unit 3 contained constituents at concentrations that exceeded the PDWS.

  Aluminum, boron, iron, manganese, molybdenum, nickel, strontium, and zinc all increased in concentration downgradient from the disposal areas, though not in levels exceeding the SDWS.

  Leachate from the ash disposal ponds is the most probable contributor to the increased concentrations of arsenic and lead observed in the aquifer samples taken from the on-site wells. Cadmium was the only constituent whose downgradient off-site concentration was observed to exceed the PDWS. However, because elevated cadmium concentrations were also found in samples taken from the background well, the elevated concentrations of cadmium may not have been caused by the leachate from the coal ash. Dames and Moore noted that ground water at this site flows away from the nearest residential area.

- Zullinger Quarry Fly Ash Disposal Site, Franklin County, Pennsylvania. The Zullinger quarry was situated in a limestone formation in south-central Pennsylvania. The

quarry was excavated to 40 feet below the water table. Fly ash was deposited in the quarry from 1973 to 1980 with no attempt to dewater the quarry prior to placement of the fly ash.

The site operator, consultants, and the Pennsylvania Department of Environmental Resources (DER) have been independently involved in water quality investigations at the site. Initially, six monitoring wells were established onsite. Later, several existing off-site domestic wells were added to the sampling program. Two of the monitoring wells were installed upgradient to provide background constituent concentrations. The other monitoring wells, and the domestic wells in the sampling program, were downgradient from the fly ash deposited in the quarry.

Lead was found to exceed its PDWS by up to eight times in eight out of over 100 samples. Six of these eight exceedances occurred in two on-site monitoring wells, while the seventh (2.6 times PDWS) was found in an off-site domestic well. Another exceedance (1.5 times PDWS) was found in the background well.

Several constituents for which there are secondary drinking water standards were found in elevated concentrations downgradient from the ash disposal site. Sulfate concentrations increased dramatically during the first few years of quarry filling, then began to sharply decline in 1976 when the fly ash had filled the quarry. From 1976 until deactivation of the disposal site in 1980, the fly ash was deposited above the water table. Zinc and iron were also found in elevated concentrations. Elevated levels of sulfate, zinc, and iron are probably attributable to leachate from the fly ash, as are the lead levels in excess of the PDWS. Most of the trace metals appear to be attenuated onsite by the limestone formation.

- Conesville Site, Conesville, Ohio. Various types of coal combustion waste had been deposited at the Conesville site in central Ohio. The monitoring program at the Conesville site was established to determine the ability of an FGD sludge fixation process (Poz-O-Tec, a solid material produced by mixing FGD sludge with fly ash and lime) to stabilize and thus immobilize potential contaminants. The stabilized FGD sludge has been deposited next to a fly ash pond. Permeable sand and gravel underlie the Muskingum River flood plain on which the Conesville site is located.

  A total of 34 monitoring wells were installed at the Conesville site. Two of the wells were situated upgradient from the disposal area to provide the

necessary background water quality data. Two sets of water quality data were taken, the first between February 27 and April 12, 1979, and the second between December 4, 1979, and July 10, 1980.

Some samples from the first set of data contained constituents at concentrations that exceeded the PDWS. Lead concentrations exceeded the PDWS in two on-site wells by up to 3 times and three off-site wells by up to 2 times. The concentration of mercury found in one sample from an on-site well exceeded the PDWS by 1.4 times; however, this exceedance could not be attributed to the fly ash. One of the fourteen background measurements had the highest observed concentration of selenium, 6 times the PDWS. Thus, selenium appears to be leaching from indigenous sediments rather than from the FGD waste and fly ash deposited at the site. The first set of data also showed the SDWS constituents of calcium, magnesium, total dissolved solids, sulfate, and iron, had increased in those wells located on the site property and just across the property boundaries.

Measurements taken between December 1979 and July 1980 showed increases in calcium, magnesium, total dissolved solids, and sulfate relative to those measurements taken in the first data collection period. Concentrations in excess of the PDWS were found for selenium (several wells), arsenic (one sample), cadmium (four samples), and chromium (five samples). Two of the chromium exceedances were found in on-site wells, while three occurred in off-site wells, with concentrations ranging up to 16 times the PDWS on-site and 2 times the PDWS off-site. Background wells also had elevated levels of selenium. The single arsenic exceedance (2.4 times the PDWS) and all of the cadmium exceedances (up to 12 times the PDWS) were detected in on-site wells. In contrast to the first round of sampling, lead was not detected in concentrations greater than the PDWS. The only constituents that appear to be migrating offsite are lead and chromium. Based on the data collected, it appears there may be a temporal variation in the water quality at this site. Dames and Moore noted that the town of Conesville is downgradient from the site but on the other side of the river, which would tend to mitigate potential adverse impacts.

- Hunts Brook Watershed, Montville-Waterford, Connecticut
  The electric utility hired a private contractor to transport and dispose of fly ash in three separate sites (Chesterfield-Oakdale, Moxley Hill, and Linda Sites) along three different tributaries to Hunts Brook. Disposal of fly ash in this area began in the mid 1960's and ended in 1969. The surface-water quality studies that took place in this area focused on pH, iron,

sulfate, and total dissolved solids (TDS). No analyses were performed for any of the PDWS constituents. Upstream surface water samples were compared to downstream samples to determine if the surface water quality had been degraded at any of the sites.

At the Chesterfield-Oakdale site, concentrations of iron in the surface water increased from less than the SDWS to more than 100 times the SDWS between the upstream and downstream sampling points. Sulfate concentrations increased by over an order of magnitude, from 20 to 299 mg/l, (at 299 mg/l, still only 1.2 times the SDWS) between the upstream and downstream sampling positions, while TDS increased from less than the SDWS to 44 times the SDWS. At another sampling point approximately 1.2 miles downstream from the site, the measured parameters had all returned to levels close to the upstream values.

At the Moxley Hill Site, the pH and iron concentrations remained relatively constant between the upstream and downstream sampling points; median sulfate values increased, although not to levels exceeding the SDWS. The elevated concentrations of sulfate and TDS had been significantly attenuated at another point three-quarters of a mile downstream.

At the Linda Site, no upstream data were collected. It is therefore impossible to quantify the potential effects of fly ash deposition on the water quality.

5.3.3 Other Case Studies of the Environmental Impact of Coal Combustion By-Product Waste Disposal

This section presents a review of two independent case studies of ground-water contamination at utility disposal sites.

Cedarsauk Site, Southeastern Wisconsin

The Cedarsauk site is a fly ash landfill in southeastern Wisconsin. At the time of this study,[29] fly ash had been deposited at the site into an abandoned sand and gravel pit over a period of eight years. Part of the pit is in direct contact with an aquifer composed mainly of sand and gravel with some clay. This upper aquifer is approximately 15 to 20 meters thick with a permeability of 10^{-3}

to 10^{-2} cm/sec. Soluble carbon aqueous material comprises about 35 percent of the aquifer. The upper sandy aquifer overlies another aquifer consisting of fractured dolomite-bedrock.

A water quality study of the area was undertaken in 1975. This study eventually included 35 monitoring wells and seven surface-water sampling sites. Twenty of the wells were placed upgradient of the site to provide background water quality information, while the remaining wells were positioned downgradient. Sampling was performed on a monthly basis. Most of the ground-water flow beneath the site surfaced in a marsh directly east of the ash disposal area.

The monitoring results showed that downgradient ground water had SDWS exceedances. Background levels of total dissolved solids (TDS) were below 500 mg/l, while the levels in the ground water downgradient from the disposal site exceeded 800 mg/l, or 1.6 times the SDWS. After eight years of disposal, the contaminant plume appeared to stabilize approximately 200 meters downgradient from the ash disposal site. The stabilization of the constituent plume appeared to be due to dilution and the ability of the materials in the aquifer to attenuate contaminants. Only iron, manganese, and zinc were found in detectable quantities in the downgradient off-site wells.

The maximum detected iron concentration was more than 33 times the SDWS, while the maximum manganese concentration reached 30 times the SDWS. Neither iron nor zinc could be detected 200 meters downgradient from the disposal site. Another contributor to ground-water contamination at this site was sulfate. Background concentrations of sulfate varied between 20 and 30 mg/l (well below

the SDWS), while the concentrations of sulfate in the contaminant plume achieved levels approximately 3.4 times the SDWS. Other trace metals for which analyses were performed, such as copper, molybdenum, nickel, lead, and titanium, were not detected.

As the leachate contacted the sediments in the aquifer, it was neutralized from an initial pH value of 4.5 to around neutral pH levels (i.e., about 7.0). This change in pH probably caused the precipitation of many of the trace metals and other constituents in the leachate. In addition, adsorption reactions between the clay in the sediments and the constituents probably attenuated the leachate concentrations of many of the potential contaminants observed in the leachate.

Center Mine, Center, North Dakota

Fly ash at this site had been deposited in a mine pit and between mine ash piles. A study was conducted to determine the potential effects of FGD and fly ash disposal on ground water quality at the surface mining site.[30] This investigation used field monitoring and laboratory column leaching experiments in conjunction with geochemical computations. By collecting both field and laboratory data, the investigators hoped to test the applicability of laboratory column experiments to field situations. Roughly 150 wells were placed both in the vicinity of the waste disposal sites and in unaffected areas.

Ground-water concentrations were generally within drinking water standards in the background wells. However, selected constituents were higher than the drinking water standards. For instance, sulfate concentrations tended to exceed

the SDWS by a factor of 2 to 4. The maximum iron concentration was 4.3 times the SDWS. Manganese concentrations were all above the SDWS, varying from 0.06 to 2.75 mg/l, or 1.2 to 55 times the SDWS.

Samples collected from wells located adjacent to the FGD waste site indicated that none of the PDWS constituents exceeded the standards. For the SDWS constituents, molybdenum concentrations fluctuated between 0.070 and 4.850 mg/l, and sulfate concentrations reached a high of 9,521 mg/l, or 38 times the SDWS. (EPA has not established maximum concentration levels for molybdenum.)

Ground water in areas that appear to be affected by leachate from the fly ash disposal sites had sulfate concentrations ranging from 21.7 to 211 times the SDWS. Higher values were obtained immediately below recent deposits of fly ash, while lower values were observed at older sites or at greater distances from the disposal area. Arsenic and selenium concentrations in the ground water were as high as 0.613 mg/l (12 times the PDWS) and 0.8 mg/l (80 times the PDWS), respectively. The highest arsenic and selenium concentrations were associated with higher pH values. Ground-water pH values for samples in the area of the fly ash ranged from 6.95 to 12.1. (The Secondary Drinking Water Standard for pH is 6.5 to 8.5). Iron and manganese concentrations were also high in samples taken from around the fly ash disposal site. The maximum concentration of iron was 8.6 times the SDWS; the maximum concentration of manganese was 130 times the SDWS.

Leachates from the fly ash of western coals are often characterized by a high pH that tends to cause many potentially harmful constituents to be released. The pH-dependent solubility of many trace elements, as apparently

observed at this site, demonstrates the importance of neutral pH values that are conducive to contaminant attenuation.

5.3.4 Summary

The studies reviewed in this section indicate that constituents from coal-combustion waste disposal sites have been detected in both on-site and off-site ground and surface water. However, those constituents that did exceed the drinking water standards seldom exceeded these standards by more than ten times. Moreover, the total number of exceedances is quite small compared to the total number of monitoring wells and samples gathered. The contaminant exceedances that do occur appear to be correlated to some extent with acidic or alkaline pH levels. At fly ash disposal sites, pH values between 2 and 12 have been measured. High and low pH values can contribute to metal solubility in ground water.

There are two documented cases of coal combustion waste disposal sites causing significant harm to the environment. Drinking water wells around the Chisman Creek fly ash disposal site in Virginia (which was closed in 1974) were contaminated with high concentrations of vanadium and selenium. Concentrations of these elements at this site were also due to petroleum coke waste (a product of oil combustion, not coal combustion). The site has been placed on the CERCLA National Priority List. In 1967, a dike failed at a utility waste disposal site on the banks of the Clinch River in Virginia, causing waste to spill into the river. This accident caused substantial damage to the biotic life in the river.

5.4. FACTORS AFFECTING EXPOSURE AND RISK AT COAL COMBUSTION WASTE SITES

The previous sections analyzed the constituents of coal combustion waste leachates and the quality of the ground water and surface water surrounding disposal sites. However, this is only part of determining the potential dangers that the wastes pose to human health and the environment. Exposure potential, the degree to which populations could be expected to be exposed to potentially harmful constituents, must also be analyzed. Exposure potential is determined by a variety of factors. Hydrogeologic characteristics of a site will affect the migration potential of waste constituents. Proximity of sites to drinking water sources and to surface-water bodies will determine potential for exposure to populations using the water sources.

In order to address this issue of exposure, EPA collected a wide variety of data on a random sample of 100 coal-fired utility plants around the country. The sample was taken from the Utility Data Institute Power Statistics Database, which contains information on every coal-fired electric utility plant in the country. Most plants dispose of their waste on-site, and in these cases information was collected on the plant location given by the data base. If the plant disposed off-site, data were collected on that off-site location. EPA assumed that off-site disposal took place at the nearest municipal landfill, unless additional information indicated otherwise. Characteristics such as depth to ground water, hydraulic conductivity, distance to surface water, location of private and public drinking water systems, type of surrounding natural ecosystems, and location of human population were obtained from a wide variety of sources. This simple aggregation of the individual factors affecting exposure at coal combustion waste sites provides a qualitative perspective on

the potential risk that coal combustion waste sites pose, and is presented in Sections 5.4.1-5.4.3. Appendix F displays the data for each coal combustion waste site in the random sample.

5.4.1 Environmental Characteristics of Coal Combustion Waste Sites

Environmental characteristics of coal combustion utility waste sites will have a significant effect on the potential for the waste constituents to travel and reach receptor populations. Key environmental characteristics are:

- Distance to surface water - The distance between a coal combustion waste disposal site and the nearest surface water body. Proximity to surface water would decrease the possible health effects of ground-water contamination due to the fact that there would be fewer opportunities for drinking water intakes before the ground water reached the surface water body; once the plume reached the surface water, contamination would be diluted. However, proximity to surface water would possibly increase danger to aquatic life because less dilution of the contaminant plume would occur before the plume reached the surface water body.

- Flow of surface water - A high surface water flow will increase the dilution rate of coal combustion constituents that may enter the surface water, thereby reducing concentrations in the surface water.

- Depth to ground water - The distance from ground level to the water table. A larger depth to ground water will increase the time it takes for waste leachates to reach the aquifer; it also allows more dispersion of the leachate before it reaches the aquifer so that once the leachate reached the aquifer, concentrations of metals would be decreased.

- Hydraulic conductivity - This factor is an indication of the rate at which water travels through the aquifer. A high hydraulic conductivity indicates that constituents will travel quickly through the ground water and possibly more readily reach drinking water wells, although high conductivity also indicates a more rapid dilution of constituent concentration.

- Net recharge - This factor is a measure of net precipitation of a site after evapotranspiration and estimated runoff is subtracted. Recharge is calculated in order to determine the amount of rainfall annually absorbed by the soil. A high net recharge indicates a short period of time for contaminants to travel through the ground to the aquifer, but will also indicate a higher potential for dilution.

- Ground-water hardness - This factor is a measure of the parts per million (ppm) of calcium carbonate (CaCO3) in the aquifer. Ground water with over 240 ppm of CaCO3 is typically treated when used as a public drinking water supply. This treatment of the hard ground water has an indirect mitigative effect on exposure because treatment of the ground water will tend to remove contamination from other sources.

To conduct this exposure analysis, environmental data on the 100 randomly selected coal combustion waste sites were gathered using a number of sources. These data were then aggregated in order to present an overview of the environmental characteristics that contribute to exposure. The data collected on the sample of coal combustion waste sites were compared to information presented in a study by Envirosphere for the Electric Power Research Institute.[31] The Envirosphere report gave detailed information on the hydrogeologic settings of 450 operating utility plants. The information provided by the exposure analysis on the sample of 100 plants corresponded fairly closely with the settings described in the Envirosphere report.

The following sections summarize the data that were collected and the relationship of the various characteristics to potential exposure.

5.4.1.1 Distance to Surface Water and Surface-Water Flow

The proximity of a waste site to surface water affects exposure potential in several ways. If the site is very near a surface-water body, there is less

opportunity for humans to use contaminated ground water as a source of drinking water. However, sites that are close to surface water can more easily contaminate the surface-water body, although waste constituents will be more quickly diluted if the flow of the surface water is high.

Distance to the nearest surface-water body, e.g., creek, river, lake, or swamp, was determined from measurements obtained using United States Geologic Survey (U.S.G.S.) maps. The sample of coal combustion waste sites was located on 7-1/2 or 15 minute maps, and the distance between the site and nearest surface water body was calculated.

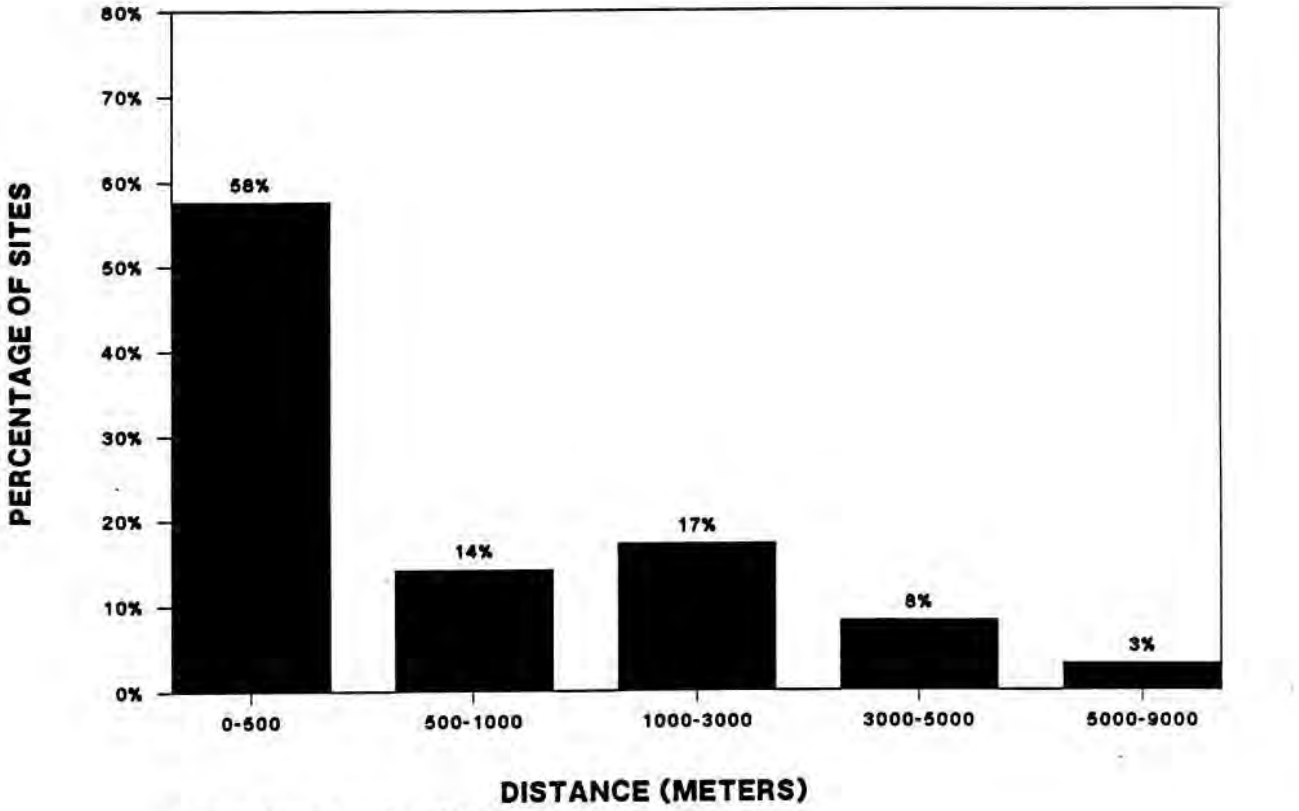
When the boundaries of the plant or waste site were marked on the maps, the reference point was the downgradient boundary of the site. If the boundaries were not marked, the latitude and longitude points for the sites provided by the Utility Data Institute Power Statistics Database were used.

The average distance from the sample of coal-burning waste sites to surface-water body is 1279 meters. Distances range from 10 to 18,000 meters. Over 50 percent of the disposal sites are within 500 meters of surface water; more than 70 percent are within 1,000 meters of surface water. Exhibit 5-17 provides the number and percentage of sites within specified distances of surface water.

Since most sites are located somewhat near surface-water bodies, the potential for human exposure to contaminated ground water seems to be low. The proximity of the sites to surface water could, however, pose a threat to aquatic life and to humans using the surface water if contaminants are entering

EXHIBIT 5-17

DISTANCE OF COAL COMBUSTION WASTE SITES TO SURFACE WATER



SOURCE: ICF Inc, based on USGS data

the surface water. The concentration in surface water will be less, however, if the surface-water body close to the site has a high flow.

Flow data on surface-water bodies near the sample of 100 sites were obtained from U.S.G.S. data. Flow is expressed in terms of cubic feet per second (cfs), and given for minimum and maximum average flow for one-month periods. In order to obtain a conservative estimate of exposure (i.e., one that does not understate exposure) this report used estimates for the month with the minimum monthly flow. The results are presented in Exhibit 5-18.

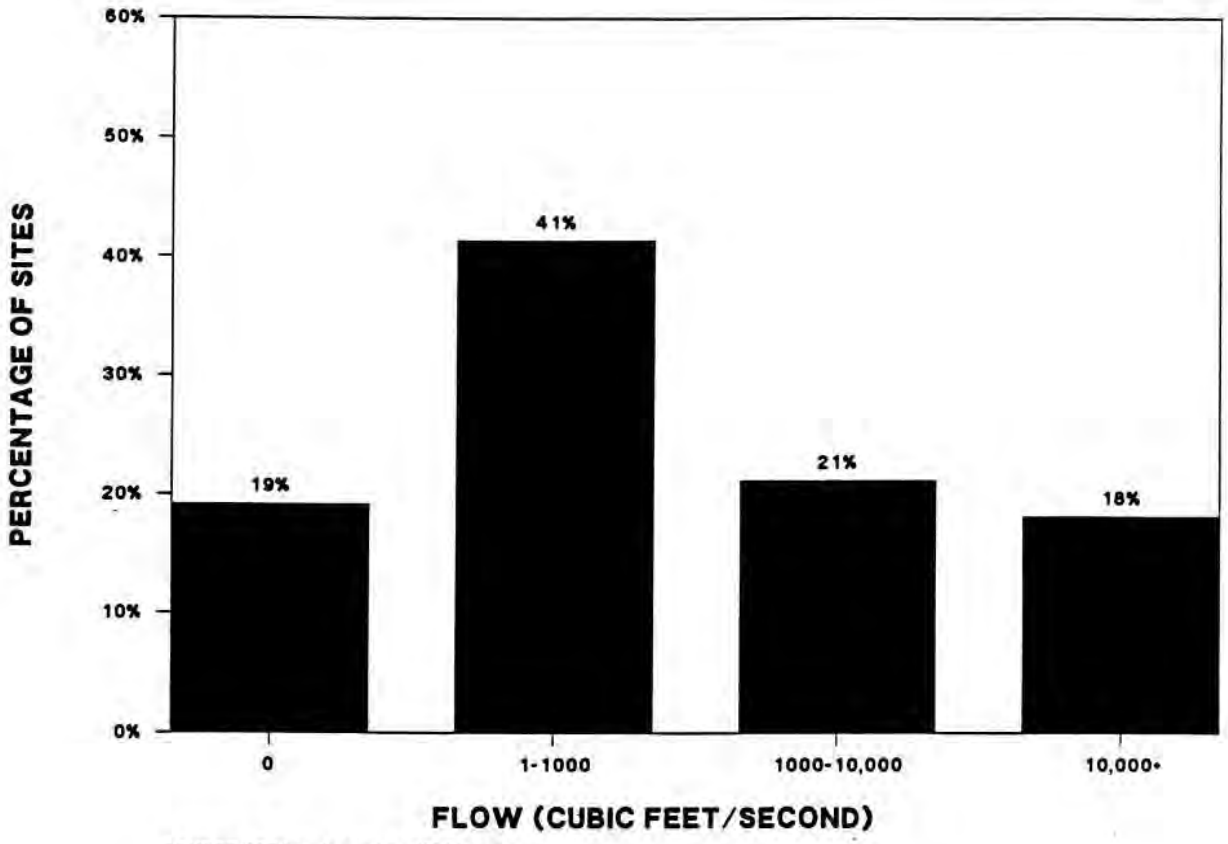
Exhibit 5-18 shows that 19 percent of the sites have a flow of zero. A zero flow generally indicates that the body of water is a lake, swamp, or marsh that does not have any continual flow of water, although this category could include a seasonal stream. For surface-water bodies with zero flow, dilution of potential contamination would occur because of the volume of water in the surface-water body, but there would not be any additional dilution as water flowed away from the source of contamination. Forty-one percent of the surface-water bodies have a flow of 1-1000 cubic feet per second, 21 percent have a flow of 1,000-10,000 cfs, and 18 percent have a flow of over 10,000 cfs.

5.4.1.2 Hydrogeologic Measurements

The hydrogeologic measurements of depth to ground water, hydraulic conductivity, and net recharge were determined through the use of information provided by the DRASTIC system. The DRASTIC system, developed by the National Well Water Association, categorizes aquifers on the basis of geographic region and subregion. Each site was located on a 7 1/2 or 15 minute U.S.G.S. map that

EXHIBIT 5-18

FLOW OF NEAREST SURFACE-WATER BODY



SOURCE: ICF Inc, based on USGS data

was then compared with a map on which the 11 major DRASTIC regions had been outlined. The topography and geology of the sites, which were determined from looking at the U.S.G.S. maps, were assessed in order to further classify thesites into DRASTIC subregions. Subregions are defined by hydrogeologic characteristics and vary in size from a few acres to hundreds of square miles. Measurements for depth to ground water, hydraulic conductivity, and net recharge of the sites were taken largely from A Standardized System for Evaluating Ground-water Pollution Potential Using Hydrogeologic Settings, by the National Well Water Association, which presents a range of values for each of these hydrogeologic properties for each subregion.[32] The ranges were compared with characteristics that could be observed by studying U.S.G.S. maps, and, when necessary, they were modified accordingly.

Depth to Ground Water

A small depth to ground water indicates a higher potential for waste constituents to reach the ground water at harmful concentrations than if the distance to ground water were greater, thereby increasing the chance of ground-water contamination. Depth to ground water was generally based on DRASTIC region and subregion, but was modified when the topography or site characteristics indicated a depth different from that provided by the DRASTIC system. For example, if the DRASTIC subregion indicated that there was a high depth to ground water range, but a particular site was located very near a surface-water body, the Agency used a smaller depth to ground water than the DRASTIC range indicated.

Exhibit 5-19 provides the number and percentage of sites within each range of depth to ground water. Depth to ground water is calculated in feet and based on 10 ranges. In over 80 percent of the sites depth to ground water is less than 30 feet, indicating a reasonably high potential that leachate from the disposal site would reach the ground water.

Hydraulic Conductivity

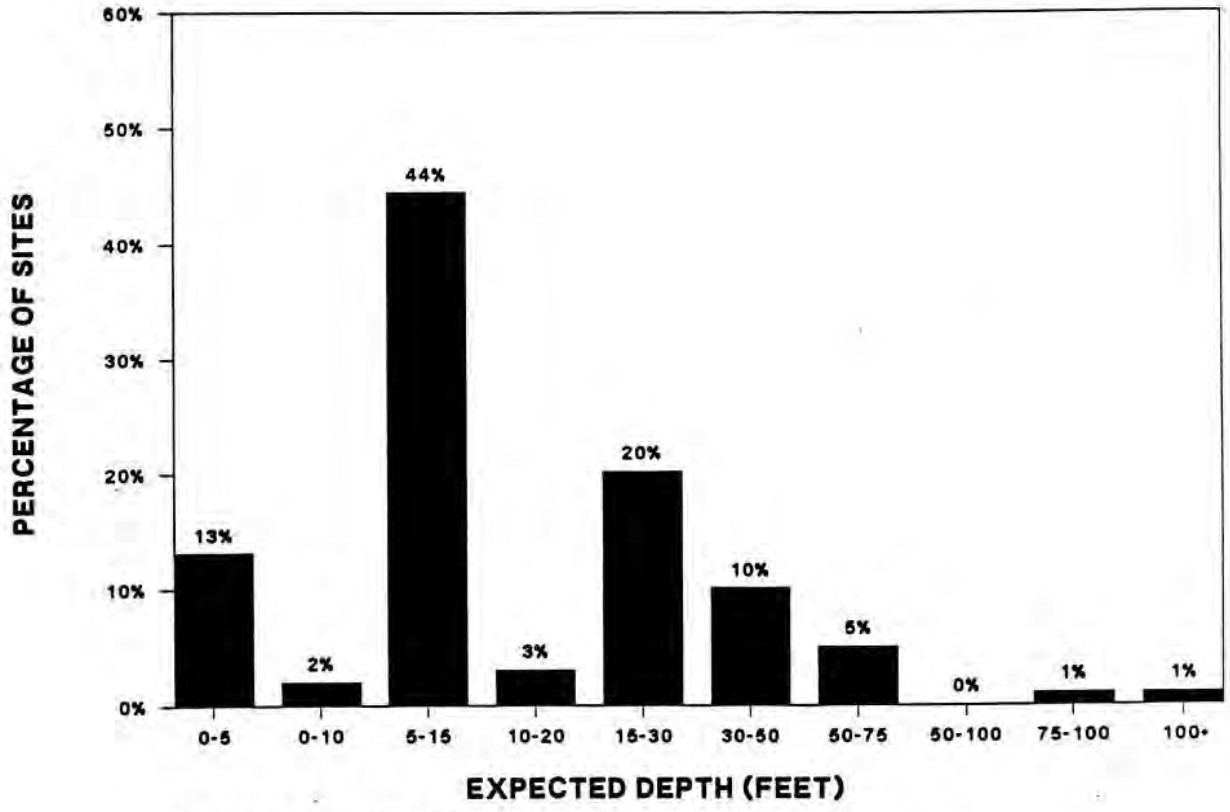
Hydraulic conductivity is an indication of the ease with which a constituent may be transported through the ground water. Conductivity is also based on the site's DRASTIC region and subregion, and is measured in gallons per day per square foot and grouped into six ranges.

Hydraulic conductivity is one of the factors used to calculate ground-water velocity, or volumetric flow of the water table. Velocity has a direct bearing on the degree to which leachate constituents are diluted once they reach the ground water and travel to a point of exposure (i.e., human drinking water source). High ground-water conductivity signifies high velocity and therefore a high dilution potential.

Exhibit 5-20 provides the number and percentage of sites falling into each hydraulic conductivity range. Thirty-three percent of the sites show a hydraulic conductivity of 700-1,000 gallons per day per square foot; 27 percent have a conductivity of 1,000-2,000 gallons per day per square foot. There is a wide spread of conductivity values -- indicating hydrogeologic diversity among sites.

EXHIBIT 5-19

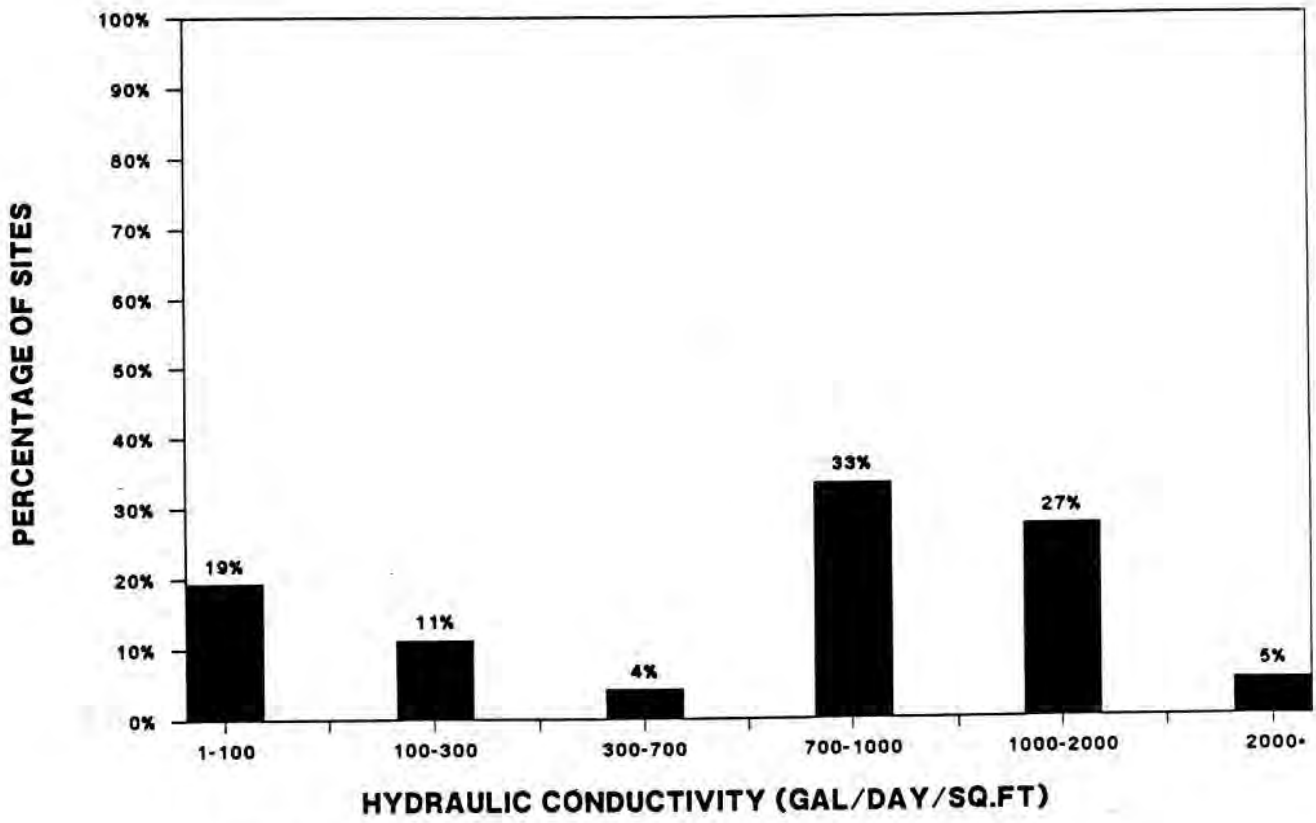
DEPTH TO GROUND WATER
AT COAL COMBUSTION WASTE SITES



SOURCE: ICF Inc, based on DRASTIC

EXHIBIT 5-20

HYDRAULIC CONDUCTIVITY
AT COAL COMBUSTION WASTE SITES



SOURCE: ICF Inc, based on DRASTIC data

While ground-water velocity gives an indication of how fast contamination may travel in the ground water, contaminants do not move at the same velocity as the ground water. This is because of basic interactions between contaminants and soil that retard the movement of the contaminants. There are three different mechanisms that affect the retardation of contaminant movement -- exchange on soil particle sites (ion exchange), adsorption onto soil particle surfaces, and precipitation. The exchange and adsorption mechanisms will retard the movement of contaminants but will not eliminate the movement of all contaminants due to limited soil attenuation capacity.

As with the diversity among sites in terms of hydraulic conductivity and ground-water velocity, the various attenuation mechanisms differ among sites. To determine the attenuation potential at a site requires detailed data inputs on water chemistry on a site-specific basis.

Net Recharge

Net recharge indicates how much water is annually absorbed into the ground. It is measured by subtracting evapotranspiration (the amount of rainfall that evaporates and transpires from plant surfaces) and estimated runoff from total precipitation at a site. It affects exposure potential in a number of ways. Low recharge will result in smaller volumes of more concentrated leachate, but if the aquifer is deep and/or has a high velocity, it will quickly dilute the leachate. High recharge produces more leachate, but may also indicate that the area has higher ground-water flow.

Exhibit 5-21 shows the number and percentage of sites that fall into each range. Recharge is measured in inches and is grouped into five ranges. Although a wide variety of net recharge ranges is represented by the sample, the recharge of sites generally falls into the higher ranges of 4-7 inches, 7-10 inches, and over 10 inches. For example, more than 80 percent of the sites have a net recharge of over 4 inches and over 50 percent have a recharge of over 7 inches. This implies that leachate constituents will be more quickly carried to the water table but the higher recharge rate will also result in greater dilution of the leachate.

Ground-water Hardness

The hardness of the ground water near coal combustion waste sites will have an effect on potential exposure through drinking water since excessive hardness is typically treated in a public drinking water system. Treatment would lessen the exposure potential to humans from contaminants in the ground water from other sources (such as coal combustion wastes). Measurements for ground-water hardness were obtained by locating the sites on maps provided in Ground-water Contamination in the United States (Pye, Patrick, and Quarles).[33]

As shown in Exhibit 5-22, ground-water hardness is measured in parts per million (ppm) of calcium carbonate (CaCO3) and grouped into five ranges. Ground water with a hardness of over 240 ppm of calcium carbonate is typically treated if used in a public drinking water system. In this sample, 45 percent of the sites show ground-water hardness in this range. Ground water with a hardness of 180-240 ppm of calcium carbonate may also be treated, although

EXHIBIT 5-21

NET RECHARGE
AT COAL COMBUSTION WASTE SITES

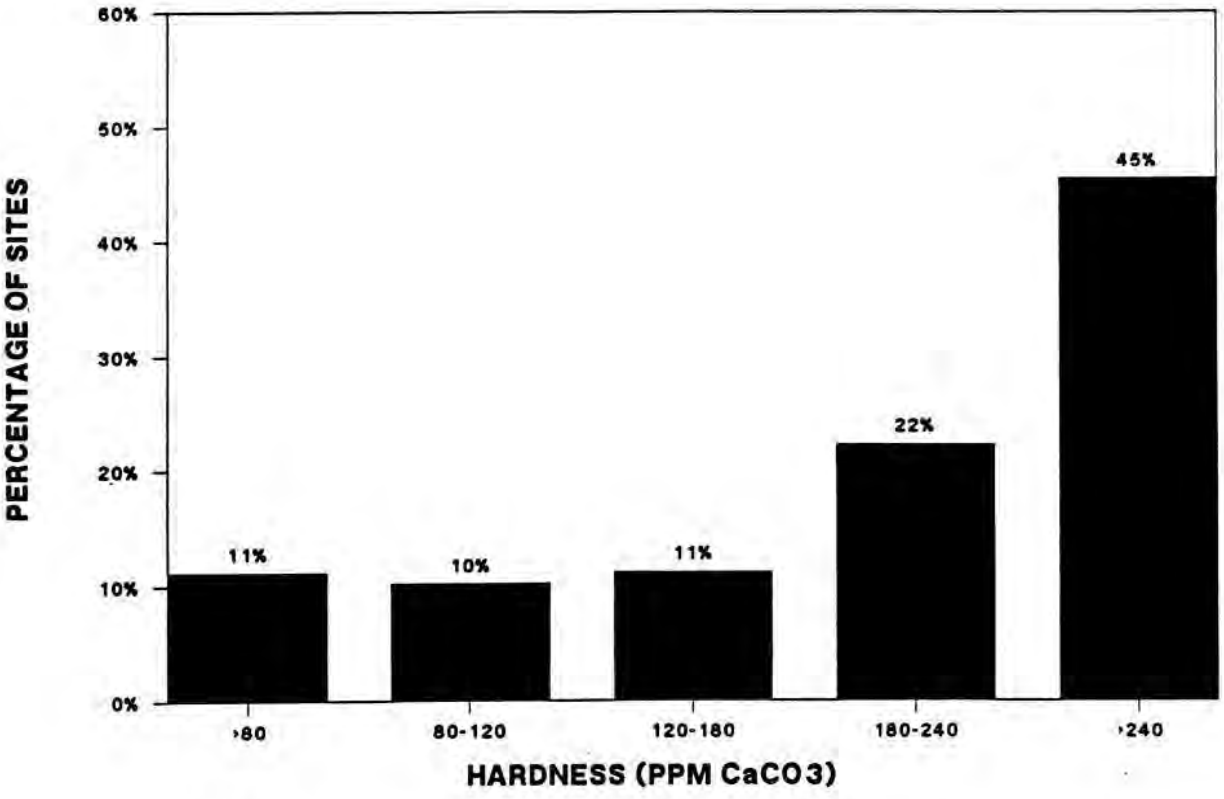
EXHIBIT 5-22

GROUND-WATER HARDNESS
AT COAL COMBUSTION WASTE SITES



SOURCE: ICF Inc, based on Pye, et al, Groundwater Contamination in U.S.

treatment is much less likely. An additional 22 percent fall in the 180-240 ppm range.

The high levels of calcium carbonate found in the ground water near coal combustion waste disposal sites suggest that if a drinking water supply is in the vicinity, the water would often require treatment before being used. Therefore, contamination that might exist in the drinking water from other sources would be mitigated due to the treatment process since trace constituents tend to be removed during the treatment process.

5.4.2 Population Characteristics of Coal Combustion Waste Sites

Environmental characteristics, such as distance and flow of surface water and hydrogeologic measurements, are only one part of the analysis of exposure potential. Opportunities for human exposure to coal combustion waste constituents depend in part on the proximity of coal combustion waste disposal sites to human populations and to human drinking water supplies. Census data (1980) provide information about the number of people living within specified distances from the coal combustion waste sites. This information is obtained through the CENBAT program, part of the Graphic Exposure Modeling System developed by EPA's Office of Solid Waste. The Federal Reporting Data System (FRDS) data base, developed by EPA's Office of Drinking Water, provides estimates of the number of public water supply systems and the size of the populations using them.

5.4.2.1 Proximity of Sites to Human Populations

CENBAT provides information on the number of people living within specified distances around designated locations. The sites were defined by latitude and longitude coordinates. Populations were analyzed for areas within 1-, 2-, 3-, 4-, and 5-kilometer radii of the waste disposal sites.

Exhibit 5-23 shows the distribution of population within one kilometer of the waste disposal sites. The CENBAT results show that most sites, 71 percent, do not have any population within a one-kilometer radius. Overall, the population range within a one-kilometer radius is 0 - 3708 people, with an average of 359 people.

Exhibit 5-24 shows the population characteristics for the sample of coal combustion waste sites at a three-kilometer radius. When the search distance is increased to three kilometers, the percentage of sites that have no people within a three-kilometer radius decreases to 32 percent. Average population within three kilometers is 3,737, and the range is 0 - 35,633 people. There is a large degree of diversity of populations at this distance. For example, while 32 percent of the sites have zero population, the same percentage has populations over 2,000.

Exhibit 5-25 shows the distribution of populations within a five-kilometer radius. Only 10 percent of the sites do not have any population living within this distance. The average population is 12,128 people, with a range from 0 to 123,160. The diversity among coal combustion waste disposal sites is even more apparent at this distance. While 20 percent of the sites have populations

EXHIBIT 5-23

POPULATIONS WITHIN ONE KILOMETER OF WASTE SITES

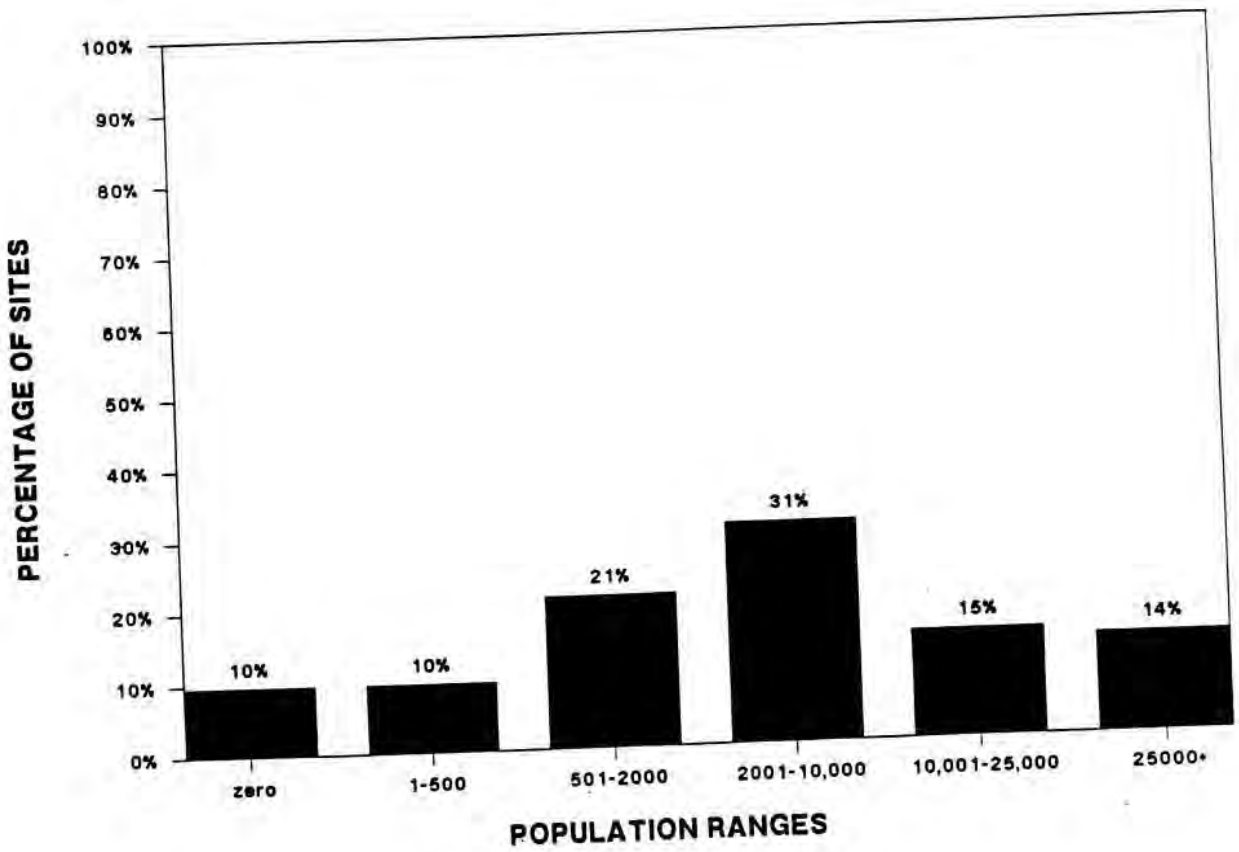
EXHIBIT 5-25

POPULATIONS WITHIN FIVE KILOMETERS OF WASTE SITES



SOURCE: ICF Inc., based on CENBAT

within a five-kilometer radius of fewer than 500 persons, 29 percent have populations over 10,000.

The CENBAT results indicate that density increases on average with distance from the disposal site. Many waste sites appear to be located on the outskirts of populated areas, with fairly low population immediately adjacent to the site, but with significant populations within a five-kilometer radius.

5.4.2.2 Proximity of Sites to Public Drinking Water Systems

If coal combustion waste sites are close to public drinking water systems, there may be potential for human exposure through drinking water supplies. The location of public water supplies was determined through the use of the Federal Reporting Data System (FRDS), developed by EPA's Office of Drinking Water.

The FRDS data base provides the number of public water supply systems located within specified distances from a site and the populations using the systems. It should be noted that the FRDS data base locates water systems based on the centroid of the zip code of the mailing address of each utility and that the actual location of the intake or well may be different. This can cause some inaccuracy in the calculation of the distance and location of public drinking water supplies in relation to the waste site. In order to remedy potential inaccuracies and omissions, the locations of public water systems that appeared on topographical maps but were not reported by FRDS are also recorded.

Exhibit 5-26 shows the population served by public water systems located in the downgradient plume from the sites and within a five-kilometer radius. The exhibit also shows how many sites have no public water systems within a five-kilometer radius. Sixty-six percent of the sites have no public water systems within a five-kilometer radius. Fifteen percent of coal combustion sites have public water systems located within a five-kilometer distance and had systems which served over 5,000 people, and 19 percent have public water systems that serve fewer than 5,000 people.

The population data indicate that while there are often quite large populations in the vicinity of coal combustion waste sites, only 34 percent of the sites have public drinking water systems downgradient from the site.

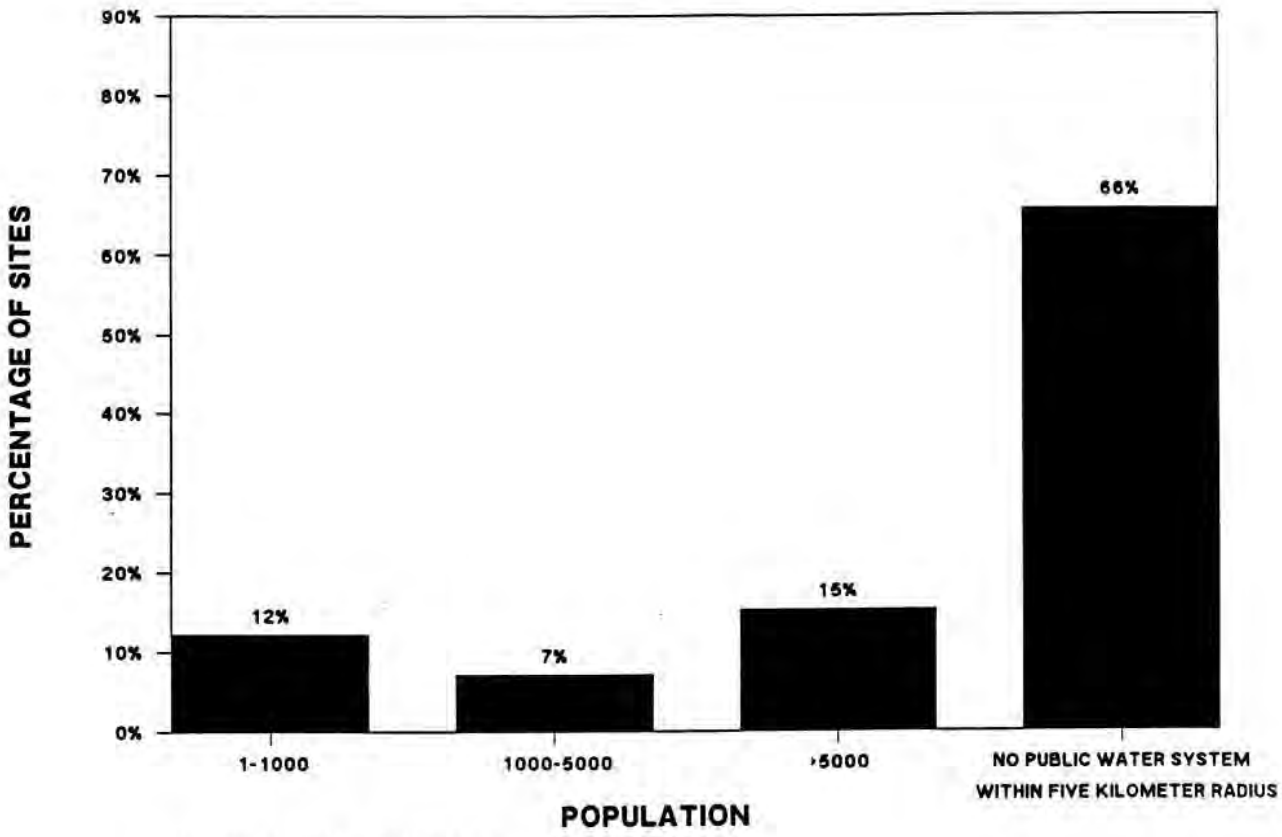
5.4.3 Ecologic Characteristics of Coal Combustion Waste Sites

Ecological data on endangered, threatened, or unique plants and animals is available through state Heritage Programs. The Nature Conservancy established the Heritage Programs, which now usually function as offices of state governments. The Heritage Programs develop and maintain data bases that describe jeopardized species and rare ecosystems within each state. It should be noted that there can be substantial variation in the completeness of data available from different states; some state Heritage Programs are fairly new, and basic data collection is still in its preliminary stages.

While it may not currently be possible to quantitatively model risk to ecosystems from coal combustion waste, the information provided by the Heritage Programs can indicate whether there are any jeopardized species near a specific

EXHIBIT 5-26

POPULATIONS SERVED BY PUBLIC WATER SYSTEMS NEAR WASTE SITES



SOURCE: ICF, based on FRDS data

waste site. If potentially hazardous constituents of coal combustion waste do migrate and produce environmental contamination, it could affect species and natural communities that are particularly vulnerable, thereby lessening ecosystem diversity.

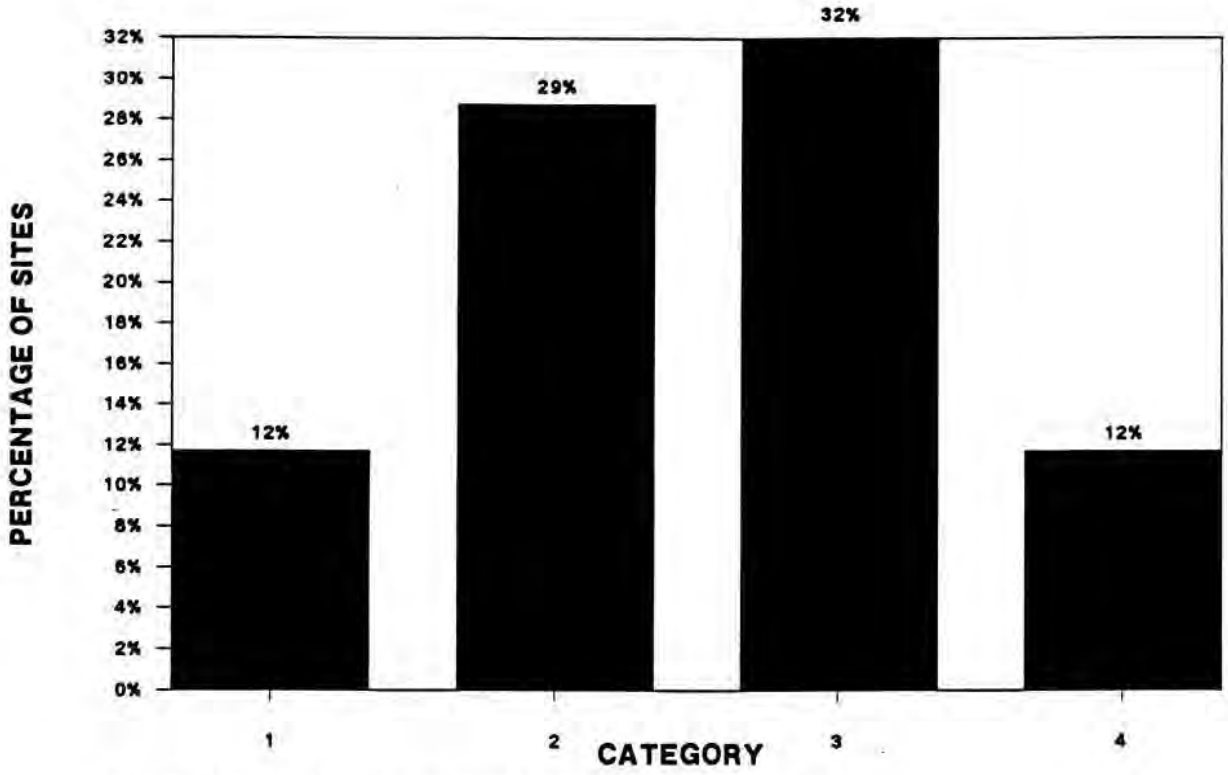
EPA provided Heritage Program staff with latitudes and longitudes for the sampled sites in states that had such programs. Using these coordinates, the Heritage Program staff performed a search of their data bases for rare or endangered species within a five-kilometer radius from the site.

The sample sites were grouped into four categories based on the results obtained from the Heritage Program. Category 1 includes sites having Federally designated threatened or endangered species within the five-kilometer radius. Category 2 includes sites that have no Federally designated threatened or endangered species within the five-kilometer distance, but which do contain species or natural communities designated by state Heritage Offices as critically endangered in that state. Category 3 contains sites for which there are species or natural communities of concern in the area. For sites in Category 4, there is no record of the existence of species of concern in the five-kilometer area.

Information was available on 85 of the 100 coal combustion waste sites in the sample. Exhibit 5-27 presents the breakdown of sites according to the categories described above. Twelve percent of the sites fall into Category 1, 29 percent in Category 2; 32 percent in Category 3; and 12 percent in Category 4 (no information was available for 15 percent).

EXHIBIT 5-27

ECOLOGICAL STATUS OF WASTE SITES



Category 1 : Federally designated plants or animals within a five km. radius
Category 2: Species of priority state concern within five km. radius
Category 3: species of concern to state environmental offices
Category 4: no data on ecosystem surrounding the site

SOURCE: ICF Inc., based on State Heritage Data

Given the high percentage of sites that have rare plant and animal communities within a five-kilometer radius supplies, and the proximity discussed earlier of waste disposal sites to surface-water bodies (which provide animals with drinking water), there could be a high potential for species exposure to coal combustion constituents.

5.4.4 Multivariate Analysis

The previous sections of this exposure analysis presented independent analyses of the population, environmental, and ecological characteristics of coal combustion waste sites. This section examines a number of these factors simultaneously in order to determine interactions that affect the overall potential for exposure from coal combustion waste sites.

As mentioned previously, only 34 percent of coal combustion waste sites (based on a random sample of 100 sites) have public drinking water systems in the downgradient plume within 5 kilometers of the waste site. Some of these public drinking water systems may use ground water that is currently treated before it is used as drinking water, indicating that human populations are unlikely to be directly exposed to any water that may be contaminated from coal combustion waste constituents. As discussed earlier, one reason for treating the water is ground-water hardness. Ground water that has a hardness greater than 240 ppm CaCO3 is likely to be treated if it is used as a drinking water source. Of the 34 percent of the sites in the sample that have public water systems in the downgradient plume within 5 kilometers of the waste site, just under one-half of these sites have ground water with a hardness over 240 ppm CaCO3. These results show that the potential for human exposure through

drinking water is likely to be less than the proximity to public drinking water systems (FRDS data) indicates. Of all the sites sampled, only 18 percent have public drinking water systems within 5 kilometers and ground water under 240 ppm $CaCO_3$.[34]

The potential for human exposure through drinking water can be further evaluated by comparing the FRDS and ground-water quality characteristics with the hydrogeologic factors of net recharge and depth to ground water. Sites with a net recharge greater than 7 inches and a depth to ground water of fifteen feet or less are more likely to develop ground-water contamination due to waste leaching since water has a greater likelihood of contacting the coal combustion wastes. Of the 18 percent of the sites that have public water supplies and ground-water hardness below 240 ppm $CaCO_3$, two-thirds have a net recharge greater than 7 inches as well as a depth to ground water of 15 feet or less. Therefore, only 12 percent of the sites in the sample (18 percent x 2/3) have ground water that is likely to be used without treatment and hydrogeologic characteristics that indicate high potential for leachate migration.

This multivariate analysis of the factors affecting exposure at coal combustion waste sites illustrates the limited potential for human health risk through drinking water. Only 34 percent of the sites have public water systems within five kilometers and many of these public water systems are likely to treat the ground water due to hardness.

5.5 SUMMARY

This chapter has reviewed available information on the potential for coal-fired combustion wastes from electric utility power plants to affect human health and the environment. First, data on the potential corrosivity and EP toxicity of utility wastes was reviewed. After determining that coal combustion leachate sometimes contains hazardous constituents at levels above drinking water standards, the potential for this leachate to migrate from waste disposal sites was examined. Results of ground-water monitoring in several studies were interpreted and a number of compilations of "documented" damage cases were evaluated. After describing instances in which trace elements in coal combustion leachate have migrated from waste disposal sites, the potential effect of these migrations was examined. A sample of 100 utility waste disposal sites was selected, and these sites were evaluated in terms of population, environmental, and ecological characteristics to assess the potential for leachate migration and exposure of human and ecological populations.

Based on these data and analyses, several observations relating to potential dangers to human health and the environment can be made:

- If the current exemption from Subtitle C regulation were lifted for coal combustion wastes and these wastes were required to be tested for corrosivity or EP toxicity, most current waste volumes and waste streams would not be subject to hazardous waste regulation. The only waste stream which has had corrosive results is boiler cleaning waste. (Since coal ash is not aqueous, it cannot be corrosive.) For the other waste streams, available data indicate that while some of these waste streams could have high or low pH levels, they are not likely to fall under the RCRA definition of corrosive waste.

Similarly, while a few high-volume waste samples did exceed the EP toxicity limits for cadmium, chromium, and arsenic, this was limited to a few waste streams and represented only a small fraction of the samples for these waste streams (the chromium and arsenic exceedances were from only one fly ash sample). Available data on low-volume wastes showed that the only waste stream with significant RCRA exceedances was boiler cleaning waste, which had exceedances for chromium and lead. Wastewater brines were shown to exceed the RCRA standard for selenium in one sample. Results of EP tests on co-disposed wastes indicate that boiler cleaning wastes may not possess hazardous characteristics when co-disposed with ash. Results for all other waste streams and all other constituents were below EP toxicity limits.

- Results available from ground-water monitoring studies and documented cases of ground-water or surface-water contamination show some migration of PDWS constituents from utility waste disposal sites. In the most comprehensive and systematic of these studies, the Arthur D. Little survey of six utility sites, evidence of constituent migration downstream from the waste sites was conclusive only for cadmium. The Envirosphere ground-water study showed that only 3.7 percent of the samples showed downgradient concentrations of PDWS constituents that were higher than the concentrations of upgradient constituents (indicating that some contaminants are migrating from the site). This tends to support the results of the waste extraction tests. For the one utility disposal site on the National Priorities List, a site currently inactive since it was closed in 1974, the major ground-water contaminants were vanadium and selenium. However, this site differs from some other sites for which ground-water quality data are available in that wastes are from both coal and petroleum coke combustion.

- Although coal combustion waste leachate has the potential to migrate from the disposal area, the actual potential for exposure of human and ecological populations is likely to be limited. Because utility plants need a source of water to operate, most of the disposal sites are located quite close to surface water. Fifty eight percent of the 100 sample sites were within 500 meters of surface water. It is not common for drinking water wells to be located between the disposal site and the nearest downgradient surface water body. The effect of this proximity to surface water is that only 34 percent of the sampled sites had drinking

water intakes within five kilometers. Furthermore, the flow of the surface water will tend to dilute the concentrations of trace metals to levels that satisfy drinking water standards.

- Simultaneously examining the environmental and population characteristics of coal combustion waste sites shows even less potential for exposure to human populations. 12 percent of the sites in the sample have public water systems within five kilometers of the site where the ground water may not be treated (i.e., ground-water hardness below 240 ppm $CaCO_3$) and hydrogeologic characteristics that indicate high potential for leachate migration.

CHAPTER 5

NOTES

1 See 40 CFR 261.21.

2 See 40 CFR 261.22. In using pH to determine corrosivity, EPA explained that "wastes exhibiting low or high pH can cause harm to human tissue, promote the migration of toxic contaminants from other wastes, and harm aquatic life."

3 These methods are set forth in 40 CFR 260.21 and 260.22.

4 See 40 CFR 261.23.

5 See 40 CFR 261.24.

6 See 40 CFR Part 261, Appendix II. These procedures for testing and the limits allowed for determining whether a waste is hazardous or not are currently under review.

7 A waste would be considered hazardous if it has been shown to have an oral LD 50 toxicity to rats of less than 50 mg/kg, an inhalation LC toxicity to rats of less than 2 mg/1, or a dermal LD 50 toxicity to rabbits of less than 2000 mg/kg.

8 See 40 CFR 261.11.

9 See CFR 40 Section 261.24. RCRA also establishes EP toxicity limits for six pesticides.

10 See CFR 40 Section 261, Appendix II.

11 Federal Register, Volume 51, No. 114, Friday, June 13, 1986, p. 21648.

12 Since the completion of the ASTM B tests discussed in this section, ASTM has dropped this extraction test (EPRI 1983).

25 It is not necessarily true that measurements taken from upgradient and downgradient wells at approximately the same time yield comparable measurements. In fact, due to migration time, there will be a lag between the time of comparable upgradient and downgradient measurements.

26 Envirosphere Company, Op. cit., p. 38. These percentage numbers do not correspond precisely to the data in Exhibit 5-11 because Envirosphere normalized the data it received from the utilities so that each facility would be weighted evenly (i.e.,, a facility with many more measurements would not be weighted excessively). Envirosphere reports that 1.7 percent of the normalized data had upgradient measurements lower than the PDWS and the downgradient higher than the PDWS; 5 percent of the data indicated that both values exceeded the standard.

34 Ground water over 180 ppm CaCO3 may also be treated. Of the 34 percent of the sites in the sample that have public water systems in the plume downgradient from the site within 5 kilometers, 73 percent have ground water with a hardness over 180 ppm CaCO3. Therefore, only 9 percent of the sites in the sample have both public water systems within 5 kilometers and ground water under 180 ppm CaCO3. Since many public water systems may not treat water in the range of 180-240 ppm CaCO3, the discussion in the report focuses only on ground water in excess of 240 ppm CaCO3. This is a conservative assumption since the water may be treated, either by the public authority or the private homeowner. In all cases, the extent of exposure through private wells would have to be evaluated on a site-by-site basis.

CHAPTER SIX

ECONOMIC COSTS AND IMPACTS

Section 8002(n) of RCRA requires that EPA's study of coal combustion wastes examine "alternatives to current disposal methods," "the costs of such alternatives," "the impact of those alternatives on the use of coal and other natural resources" and "the current and potential utilization of such materials." In response to these directives this chapter examines the potential costs to electric utilities if coal-fired combustion waste disposal practices are regulated differently than they are currently.

The first section of this chapter (Section 6.1) examines the costs incurred by electric utilities using current disposal methods for coal combustion wastes.[1] Section 6.2 follows with a discussion of the costs that could be incurred if coal combustion wastes were regulated differently than they are today. These costs include the costs of implementing alternative waste management practices and the costs of additional administrative responsibilities that would be incurred. Section 6.3 examines how new regulations might affect the cost of utilizing coal combustion wastes in various by-product applications. The last section of this chapter (Section 6.4) considers how energy use patterns in the electric utility industry might change if alternative waste management practices that significantly affect the cost of generating electricity with coal were imposed.

6.1 WASTE DISPOSAL COSTS ASSOCIATED WITH CURRENT DISPOSAL METHODS

The management of utility wastes comprises a series of activities -- from initial waste collection to disposal. These current waste management activities can be classified into five basic components:[2]

1. **Waste Handling and Processing.** This is the initial phase of the disposal process, involving collection of the various waste products after they have been generated and initial treatment of the wastes to prepare them for final disposal.

2. **Interim Waste Storage at the Plant.** Some waste products that are dry when produced, such as fly ash or flue gas desulfurization (FGD) wastes from dry scrubbers, often require interim storage prior to final disposal.

3. **Raw Materials Handling and Storage.** Some disposal processes involve stabilization or chemical fixation of the waste to prepare it for disposal. The raw materials used for this phase, including additives such as lime, Calcilox, and basic fly ash, often require special handling and storage facilities.

4. **Waste Transport to a Disposal Facility.** Environmentally sound disposal requires careful transportation of the waste to the disposal site. Many modes of transportation can be used, including trucks, railroads, barges, pipelines, and conveyor systems.

5. **Waste Placement and Disposal.** This is the final stage of the waste disposal chain. It involves placing the waste in a suitable waste management facility (usually a surface impoundment or landfill) and all activities required after the facility is closed. Alternatively, the final disposition of a waste product may entail utilization of the waste in various applications (such as cement production or sandblasting operations).

Exhibit 6-1 presents a schematic illustration of the current waste management and disposal options for coal ash; Exhibit 6-2 illustrates the options available for FGD wastes. The waste management costs discussed in this

chapter are those associated with the last component of waste management (i.e., waste placement and disposal). These are the costs associated with actual construction of the waste management facility and placement of the wastes into the facility. If current practices for managing coal-fired wastes from electric utilities are altered, it is this final stage in waste management that would probably be most affected. However, as will be explored later in this chapter, some regulatory alternatives may affect other aspects of waste management.

6.1.1 Costs of Waste Placement and Disposal

The wastes from coal-fired combustion at electric utility power plants are often mixed together in the same waste management facility, typically a surface impoundment or landfill. Although surface impoundments were once the preferred method, and are still widely used, landfilling has become the more common practice because less land is required, and it is usually more environmentally sound (because of the lower water requirements, reduced leaching problems, etc.).

The costs of waste disposal can vary substantially. Exhibit 6-3 shows representative capital costs associated with constructing surface impoundments and landfills for coal-fired electric utility wastes. Exhibit 6-4 shows total costs (i.e., annualized capital costs plus operation and maintenance expenses).[3] Costs are shown for power plants that range in size from 100 to 3000 megawatts (Mw); power plants that fall outside of this range may incur

EXHIBIT 6-3

RANGES OF AVERAGE CAPITAL COSTS ASSOCIATED WITH COAL-FIRED ELECTRIC UTILITY WASTE DISPOSAL (4th quarter 1986 dollars per kilowatt)

Type of Waste	Size of Power Plant			
	100 MW	500 MW	1000 MW	3000 MW
Landfills				
Fly Ash	9-14	4-7	3-5	2-3
Bottom Ash	2- 5	2-3	1-2	1-1.3
FGD Waste	6-13	4-7	3-6	2-4
Surface Impoundments				
Fly Ash	27-50	15-27	13-23	10-18
Bottom Ash	10-20	6-11	5- 9	3- 6
FGD Waste	14-30	10-19	9-17	7-14

EXHIBIT 6-4

RANGES OF AVERAGE TOTAL COSTS FOR COAL-FIRED ELECTRIC UTILITY WASTE DISPOSAL (4th quarter 1986 dollars per ton)*

Type of Waste	Size of Power Plant			
	100 MW	500 MW	1000 MW	3000 MW
Landfills				
Fly Ash	9-18	6-11	5-9	2-6
Bottom Ash	10-16	5-9	4-8	2-6
FGD Waste	4-10	4-7	3-6	2-4
Surface Impoundments				
Fly Ash	17-31	9-17	8-14	5-8
Bottom Ash	11-26	8-15	7-13	5-8
FGD Waste	8-17	7-13	6-10	5-7

* Dollar per ton estimates are based on the amount of waste produced each year. For purposes of this illustration, a power plant is assumed to generate annually 308 tons of fly ash per megawatt (MW), 77 tons of bottom ash per MW, and 264 tons of FGD waste per MW. Amounts will vary depending on coal quality, FGD technology, and boiler type, among other factors.

Source: Arthur D. Little, Inc., Full-Scale Field Evaluation of Waste Disposal From Coal-Fired Electric Generating Plants, EPA 600/7-85-028, June 1985.

different waste management costs. Both capital costs and total costs are shown for unlined facilities without ground-water monitoring or leachate control systems. The major factors affecting the cost of waste management are discussed below.

The amount of capital costs for a waste management facility can be attributed primarily to three factors: site preparation, excavation, and construction of containment structures.[4] Capital costs can be substantially reduced if the amount of earthwork can be minimized. Capital costs for surface impoundments, for example, increase significantly if dike construction or excavation is required. However, if existing site features can be used, such as valleys or abandoned pits, capital costs will be lower. Similarly, capital costs for landfills that require little excavation are lower than for those sites requiring extensive earthwork.

As Exhibit 6-3 illustrates, landfills are far less capital intensive than surface impoundments. For example, capital costs for fly ash placement in a surface impoundment at a 500 MW power plant would range from approximately $15 to $27 per kilowatt.[5] In contrast, capital costs for landfills range from about $4 to $7 per kilowatt. Landfills tend to cost less than impoundments primarily because the area required for a given amount of waste is less, and neither dikes nor piping and pumping systems are necessary.

Annual costs for landfills (see Exhibit 6-4) also tend to be less than those for surface impoundments primarily because landfills tend to be far less capital intensive. For example, costs for fly ash management at a 500 MW power plant range from about $9 to $17 per ton when the wastes are placed in surface

impoundments, while the comparable range at a landfill is about $6 to $11 per ton. Similarly, the cost for bottom ash disposal at an impoundment for a 500 MW power plant ranges from $8 to $15 per ton, while the costs to dispose in a landfill range from about $5 to $9 per ton.

Other factors that affect the cost of utility waste disposal include

- **Size of the Power Plant.** Because larger power plants consume more coal than smaller facilities, they generate more waste material. However, more efficient operating procedures allow a larger disposal site to realize economies of scale not available at smaller sites; thus, the cost per ton of waste disposed is typically less.
- **Rate of Operation.** The number of hours that a coal-fired power plant operates varies from plant to plant, ranging from fewer than 3,500 hours per year to more than 6,500 hours. As operating levels increase, the amount of waste generated will increase as more coal is burned to meet the higher generation load.
- **Type of Coal.** The quantity of ash produced is proportional to the ash content of the coal, which ranges from 5 to 20 percent on average. Also, the grade of coal and boiler design will affect the relative proportions of fly ash and bottom ash (see Chapter Three for a discussion of the impact of boiler design on types and amount of wastes generated).
- **FGD Equipment.** Because of the additional materials used in flue gas desulfurization, a power plant that uses this process to remove sulfur dioxide generates substantially more waste than does a power plant with no sulfur dioxide controls. The amount of waste generated also varies from one FGD operation to the next, primarily because of differences in sulfur content among the various coals and, to a lesser extent, because of the type of FGD process employed.

For the few power plants currently disposing their waste in mines or quarries, this disposal method has been economic because of convenient access to the disposal site. Since much of the excavation normally required at a disposal

site has already been performed as a result of the mining or quarrying operation, waste disposal costs can be quite competitive with costs associated with more traditional methods of disposal. The cost of disposing in mines or quarries for power plants that do not have easy access to the mine or quarry could quickly become prohibitive due to the costs of arranging for disposal at a remote site and of transporting the waste. Costs are also affected by whether or not the mine or quarry is still operating, whether the mining was surface or underground, and the amount of additional preparation required to dispose of the wastes, among other factors.

The costs of ocean disposal are not well known because there has been limited experience with this disposal method. Ocean disposal has been considered for unconsolidated waste (i.e., waste material that has not been physically or chemically altered prior to disposal)[6] and for more stabilized forms of waste, such as blocks for artificial reef construction;[7] however, this method has been attempted only for projects such as artificial reef construction, and then only on a trial basis. The most critical factors that would affect the magnitude of costs for ocean disposal are the availability of ash-handling facilities to load ocean-going vessels, the ability to gain easy access to the necessary waterways, and the physical characteristics of the wastes intended for disposal.

Because neither ocean disposal nor mine or quarry disposal is likely to be used on a widespread basis, they have been discussed here only briefly; see Chapter Four for a more detailed discussion of these two disposal options.

6.1.2 Costs Associated with Lined Disposal Facilities

The waste management costs presented above for surface impoundments and landfills do not include the cost of natural or synthetic liners to control the flow of leachate from the disposal area. Traditionally, most waste management sites, both surface impoundments and landfills, have not been lined to retard leaching, although this practice has become more widespread in recent years (see Chapter Four for a detailed discussion of liners). Currently, about 25 percent of all coal combustion waste management sites employ some type of liner system. Most liners are made of clay, synthetic materials, or stabilized utility waste.

Clay is used as a liner material because it is not very permeable, although its permeability will vary depending on the nature of the clay and the degree of compaction. Because clay is expensive to transport, the costs of the various clays used for liner material are directly related to the local availability of the clay. The installed cost of clay liners can range from $4.45 to $15.75 per cubic yard.[8] For a liner 36-inches thick, (liner thicknesses do vary), this results in a cost range of $21,000 to $75,000 per acre, or about $0.70 to $2.55 per ton of waste disposed in a landfill and $2.25 to $8.20 per ton for waste placed in an impoundment for a 500 MW power plant.[9]

Synthetic liner materials come in two basic varieties--exposable and unexposable. The membranes of exposable liners are resistant to degradation from exposure to the elements even if the liner is left uncovered. The membranes of unexposable liners will not function properly if the liner is exposed. Costs for installing exposable liners range from $43,000 to $113,000 per acre, or $1.45 to $3.85 per ton of waste disposed in landfills and from

$4.70 to $12.35 per ton of waste placed in surface impoundments.[10] Costs to install unexposable liners range from $59,000 to $123,000 per acre, or $2.00 to $4.15 per ton of waste disposed in landfills and $6.45 to $13.45 per ton placed in impoundments.[11] The ranges of costs are due primarily to differences in the cost of the material, differences in liner thickness, and allowances for various site-specific costs.

Stabilized utility waste, made from combinations of various ash wastes (such as fly ash or bottom ash), FGD waste, and lime, may be used as liner material when the required materials are available at the plant site. At an installed cost of about $13.70 per cubic yard, liners ranging from 3 feet to 5 feet in thickness can be constructed for $66,000 to $110,000 per acre,[12] which corresponds to total capital costs of $3.0-$5.0 million at a landfill, or about $2.25 to $3.75 per ton of disposed waste from a 500 Mw power plant. Total capital costs at impoundments would be $9.6-$16.0 million, or $7.20-$12.00 per ton of waste managed.[13]

6.2 COSTS OF ALTERNATIVE DISPOSAL OPTIONS

As described above, coal-fired utility wastes are currently exempt from RCRA Subtitle C waste management requirements. In the interim, coal combustion wastes are regulated under state statutes and regulations (see Chapter Four). If these wastes are subject to Subtitle C regulation, the incremental costs will depend on the regulatory option(s) ultimately selected. Section 6.2.1 outlines the major regulatory alternatives and discusses the flexibility allowed EPA under RCRA to promulgate regulations that account for the special nature of coal combustion wastes. Section 6.2.2 presents cost estimates for individual

Subtitle C disposal requirements, and Section 6.2.3 presents cost estimates for three regulatory scenarios if coal combustion wastes are regulated under Subtitle C.

6.2.1 Regulatory Alternatives under Subtitle C

As described in Chapter Five, there are two ways in which coal combustion wastes could be identified as hazardous and thus subject to requirements outlined in Part 264 of RCRA: the characteristic procedure and the listing procedure.

- **Regulation As Characteristic Waste.** Unless otherwise exempted, solid wastes are hazardous under RCRA if they display any of four characteristics: ignitibility, corrosivity, reactivity, or EP toxicity. Coal combustion wastes are unlikely to be ignitable or reactive, but could be corrosive (for aqueous wastes) or EP toxic. Subtitle C regulations would apply only to those waste streams that exhibited any of the hazardous characteristics. As discussed in Chapter Five, it is likely that only a small percentage of all waste generated would be hazardous. However, since some low volume wastes may be corrosive, this could have an impact on utilities that currently co-dispose high- and low-volume wastes. In these cases, the utility could either stop co-disposing or the landfill would have to conform to Subtitle C standards. In the case of surface impoundments, it might still be possible to co-dispose high- and low-volume wastes if the disposal impoundment met the requirements for a neutralization surface impoundment as set forth in 47 FR 1254, January 11, 1982.

- **Regulation as Listed Waste.** In addition to regulation under Subtitle C as characteristic waste, the Administrator may list a waste as hazardous under RCRA if it meets any of the three criteria contained in 40 CFR 261.11: (1) the waste exhibits any of the four characteristics described above; (2) it has been found to be fatal to humans in low doses or is otherwise measured as acutely hazardous; or (3) it contains any of the toxic constituents listed in Appendix VIII of Part 261. The Administrator does not have to list a

waste that contains any of the toxic constituents listed in Appendix VIII if the Agency concludes that "the waste is not capable of posing a substantial present or potential hazard to human health or the environment when improperly treated, stored, transported or disposed of, or otherwise managed". The Administrator could decide to list as hazardous all coal combustion waste streams or only selected ones.

If Subtitle C regulation is warranted for coal combustion wastes, all the requirements for hazardous waste treatment, storage, disposal, and recycling facilities in 40 CFR 264 could be applied to the wastes from coal-fired power plants. Since coal combustion waste is mainly managed in surface impoundments and landfills, the requirements of Subparts A-H, K, and N would apply. In general, the required activities include the following:

- **General Facility Standards.** Facilities must apply for an identification number, prepare required notices when necessary, perform general waste analysis, secure the disposal facility to prevent unauthorized entry, comply with general inspection requirements, provide personnel training, and observe location standards (these include a provision that facilities located in a 100-year flood plain must be designed, constructed, operated, and maintained to prevent washout of any hazardous waste by a 100-year flood). (40 CFR 264 Subpart B)

- **Preparedness and Prevention.** Hazardous waste facility operators must design and operate facilities to minimize the possibility of fire or explosion, equip the facility with emergency equipment, test and maintain the equipment, and provide EPA and other government officials access to communications or alarm systems. (40 CFR 264 Subpart C)

- **Contingency Plan and Emergency Procedures.** The facility operators must have a contingency plan to minimize hazards to human health or the environment in the event of fire or explosion. (40 CFR 264 Subpart D)

- **Manifest System, Recordkeeping, and Reporting.** Hazardous waste facility operators must maintain a manifest system, keep a written operating record, and prepare a biennial report. (40 CFR 264 Subpart E)

- **Ground-water Protection.** Unless a waste management facility meets certain standards,[14] a Subtitle C facility is required to comply with requirements to detect, characterize, and respond to releases from solid waste management units at the facility. These requirements include ground-water monitoring and corrective action as necessary to protect human health and the environment. (40 CFR 264 Subpart F)

- **Closure and Post-closure.** Subtitle C facilities must comply with closure and post-closure performance standards to minimize the risk of hazardous constituents escaping into the environment. (40 CFR 264 Subpart G)

- **Financial Requirements.** Subtitle C facilities must establish a financial assurance plan for closure of the facility and for post-closure care. Possible methods of financial assurance include a closure trust fund, surety bonds, closure letter of credit, closure insurance, or financial test and corporate guarantee.[15] (40 CFR 264 Subpart H)

- **Design and Operating Requirements.** Unless granted an exemption, new surface impoundments or landfills or new units at existing impoundments or landfills must install two or more liners and a leachate collection system between the liners. (40 CFR 264 Subparts K and H)

In recognition of the special nature of coal combustion wastes, Congress afforded EPA some flexibility in designing regulations for coal combustion wastes if they are subject to regulation under Subtitle C. This flexibility allows EPA to exempt electric utilities from some regulations imposed on owners and operators of hazardous waste treatment, storage, and disposal facilities by the Hazardous and Solid Waste Amendments of 1984. Specifically, section 3004(x) of RCRA allows the Administrator to modify the following requirements when promulgating regulations for utility waste.

- Section 3004 (c) prohibits the placement of uncontained liquids in landfills;
- Section 3004 (d) prohibits the land disposal of specified wastes;[16]
- Section 3004 (e) prohibits the land disposal of solvents and dioxins;
- Section 3004 (f) mandates a determination regarding disposal of specified wastes into deep injection wells;
- Section 3004 (g) mandates determinations on continued land disposal of all listed hazardous wastes;
- Section 3004 (o) lists minimum technical requirements for design and operation of landfills and surface impoundments, which specify the installation of two or more liners, a leachate collection system, and ground-water monitoring;
- Section 3004 (u) requires the Administrator to promulgate standards for facilities that burn hazardous waste as fuel; and
- Section 3005 (j) provides that interim-status surface impoundments must also meet minimum technical requirements specified in section 3004 (o).

In addition to the flexibility afforded by 3004 (x), it is possible for EPA to modify any of the standards applicable to waste treatment and disposal facilities if lesser standards are protective of human health and the environment. Section 3004 (a) states "... The Administrator shall promulgate regulations establishing such performance standards, applicable to owners and operators of facilities for the treatment, storage, or disposal of hazardous waste identified or listed under this subtitle, as may be necessary to protect human health and the environment."

There remains substantial uncertainty, however, about the extent to which, in practice, the statutory language of Subtitle C would provide sufficient flexibility to design a waste management program appropriate for high-volume,

low-toxicity coal combustion wastes. EPA may also consider waste management requirements, as needed, under the current Subtitle D provisions for solid wastes, or may seek appropriate additional authorities.

6.2.2 Cost Estimates for Individual RCRA Subtitle C Disposal Standards

If EPA determines that Subtitle C regulation is warranted for coal combustion wastes, there is a wide range of regulatory options that could be undertaken. Required activities could consist of some, all, or variations of the requirements listed in 40 CFR Subparts B-H (and described briefly in Section 6.2.1). This section presents estimates for the costs that would be associated with compliance with individual Subtitle C requirements.

6.2.2.1 General Facility Standards; Preparedness and Prevention; Contingency Plan and Emergency Procedures; and Manifest System

Subparts B through E in Part 264 of the RCRA regulations list general requirements for such activities as preparing written notices and plans for submission to EPA; conducting waste analyses; providing security at the disposal site; and recordkeeping and reporting. Many of these activities would be undertaken during the permitting process, which is set forth in Part 270 of RCRA.

The Part B application must contain the technical information listed in Part 264 B through E. The cost to the electric utility industry to prepare a Part B permit application was estimated in a study done for the Utility Solid Waste Activities Group (USWAG), which calculated that the total cost of submitting

Part B permit analyses would be $721,000 per plant, or about $0.55 per ton of waste disposed.[17] The industry cost, if all power plants filed Part B applications, would be about $370 million, or about $54 million in annualized costs.

Location standards are also specified under Subpart B of Part 264 of RCRA. One such standard is for facilities located in a 100-year flood plain. Part 246.16(b) requires protective measures to prevent washout from flooding.

USWAG estimated the costs for protecting waste disposal facilities located within a 100-year flood plain to be about $740 per acre for surface impoundments and about $1,100 per acre for landfills on an annualized basis.[18] This corresponds to waste management costs of approximately $0.55 per ton of waste at surface impoundments and $0.25 per ton at landfills.[19] Industry-wide costs for flood protection at all impoundments are estimated to be about $92 million for capital expenditures (about $13 million in annualized costs); costs for flood protection at all landfills would be about $146 million for capital expenditures (about $20 million in annualized costs).[20]

6.2.2.2 Ground-water Protection

Subpart F of 40 CFR Part 264 lists requirements for ground-water monitoring systems. The costs of installing and maintaining an acceptable ground-water monitoring program are dependent on the number of monitoring wells required and the frequency of testing. The study conducted by Arthur D. Little for EPA estimated that capital costs for installing six monitoring wells at a facility would range from $18,000 to $25,000.[21] At a sampling frequency of four times

per year, annual operating and maintenance costs would be $10,000 to $14,500. Total ground-water monitoring costs would range from $0.06 to $0.10 per ton of managed waste. In another study conducted for USWAG by Envirosphere, which used different well configurations and cost parameters, somewhat higher costs ($0.10-$0.12 per ton of waste managed) were estimated.[22]

It is not known how many coal-fired power plants currently have adequate ground-water monitoring systems in place. To estimate industry-wide costs, EPA has conservatively assumed that all power plants would be required to install new ground-water monitoring systems. Using the costs developed in the Arthur D. Little study, EPA calculated that total capital costs would be about $9.3 to $12.8 million. Total annualized costs would range from $6.5 to $9.3 million.

6.2.2.3 Corrective Action

Subpart F of 40 CFR Part 264 also lists requirements for corrective action. A variety of actions may be undertaken to correct ground-water contamination problems caused by a hazardous waste disposal facility. The facility owner or operator would need to conduct a site-specific investigation to ascertain the potential degree of contamination and the appropriate response that would be most effective in remedying the situation. Types of remedial responses that might be required would be placing a cap (made of either a clay or synthetic material) on the disposal unit, counter-pumping the ground water to retard contaminant migration, excavating the disposal area and removing the wastes to a Subtitle C landfill, or installing an impermeable curtain around the disposal area to prevent ground-water flow into or out of the disposal area. As one example of the potential magnitude of corrective action costs, this section

evaluates the cost to excavate the existing disposal areas and transfer the wastes to RCRA Subtitle C-approved facilities.

EPA developed the following formula to calculate total excavation costs for Subtitle C units, (including closure of the existing site and removal of the wastes to a Subtitle C facility):

$$\text{Cost} = [(\text{Surface Area} \times \$45) + (\text{Volume} \times \$187)] \times 2.16$$

where the surface area is measured in square meters, and volume is measured in cubic meters.[23]

For a power plant of average size (500 MW), it has been assumed that a 45-acre landfill would be required, or about 182,000 square meters, with a capacity of approximately 5 million cubic meters. Based on the cost equation listed above, costs for excavation and waste transfer for a landfill site would be about $2.0 billion.[24] For surface impoundments, the appropriate parameters are 145 acres, or about 587,000 square meters, and a volume of about 5 million cubic meters, which works out to about $2.1 billion for the same type of corrective action. If this type of corrective action were required at all power plants, compliance costs for the industry would be enormous. At a cost of about $2 billion per plant, industry-wide costs would exceed one trillion dollars.

6.2.2.4 Closure and Post-closure

Subpart G of 40 CFR 264 specifies general closure and post-closure requirements for Subtitle C facilities and 40 CFR 264(K) and (N) list specific

requirements for closure and post-closure care of surface impoundments and landfills, respectively. These requirements, as applied to coal combustion wastes, would require the dewatering of ash ponds, installation of a suitable cover liner made of synthetic materials, application of topsoil to support vegetation, seeding and fertilizing, installation of security fencing, and long-term ground-water monitoring. USWAG estimates that capital costs for closing a waste management facility range from $39,000 to $128,000 per acre for surface impoundments and from $55,000 to $137,000 per acre for landfills.[25] Once the facility is closed, additional costs would be incurred for post-closure care -- about $1,050 per acre annually.[26] Total annual costs for closure of a surface impoundment would range from about $1.0 to $2.8 million for a typical 500 Mw power plant, or $5.00 to $14.75 per ton of waste managed. For a landfill, total annual costs would range from $0.4 to $0.9 million, or $2.10 to $4.90 per ton.[27].

An owner or operator that chooses to close a facility in the event that coal combustion wastes are brought under Subtitle C regulation would not necessarily have to follow the closure and post-closure requirements for hazardous waste facilities listed in 40 CFR Part 264. If regulations are proposed, there would be some period of time before final regulations take effect.[28] If the disposal facility is closed during this interim period, the closure standards that would apply would be those required under state regulations, not Subtitle C regulations.

A facility that closes after the new regulations take effect, however, is subject to Subtitle C closure and post-closure requirements. The USWAG study provides an estimate of the total costs of closing all existing coal combustion

waste disposal facilities and of the costs of closing only unlined facilities (See Exhibit 6-5). Total capital costs required to close all unlined landfills and impoundments would range from $3.5 billion for clay-capped facilities to $9.7 billion for synthetic-capped facilities. If all facilities closed under Subtitle C regulation, total capital costs would be about $4.3 billion for clay-capped closure and $12.0 billion for synthetic-capped closure.[29] Total annualized costs to close only unlined facilities would range from about $575 million for closure with clay caps to about $1.5 billion for synthetic caps. If all current waste management facilities were closed, annualized costs would be about $700 million for clay caps to $1.8 billion for synthetic caps.

6.2.2.5 Financial Responsibility

Subpart H of 40 CFR 264 sets forth requirements for financial responsibility for closure and post-closure care of hazardous waste facilities. A facility owner may use several different financial mechanisms to demonstrate financial responsibility, including purchasing a letter of credit, posting a surety bond, establishing a trust fund, purchasing an insurance policy, providing a corporate guarantee, or passing a financial test. Financial responsibility could be required for closure/post-closure costs or corrective action costs. The magnitude of the costs can vary considerably depending on the financial mechanism that is used and the type of activity for which financial assurance is required. For example, costs to provide a corporate guarantee or pass a financial test may be on the order of a few hundred dollars per facility; on the other hand, annual costs to obtain a letter of credit or to establish a trust fund are often based on some percentage (e.g., one to two percent) of the total

EXHIBIT 6-5

SUMMARY OF COSTS TO CLOSE EXISTING WASTE DISPOSAL FACILITIES

costs of the closure/post-closure or corrective action activity to be undertaken.[30]

6.2.2.6 Design and Operating Requirements for Landfills and Surface Impoundments

The level of effort required to come into compliance with Subtitle C design and operating requirements will depend on many site-specific considerations. In some cases, it may be possible to seal off the portion of the existing disposal site that has been in use and upgrade the remaining portion by installing a liner. In other situations the required changes may be sufficiently different from existing disposal practices that the most cost-effective action may be to open an entirely new disposal facility.

Given the variety of site-specific situations that may arise, and given the regulatory flexibility EPA has in designing coal combustion waste management standards, it is not feasible to estimate how many utility waste management facilities may be affected or what type of waste management measures may be required without conducting site-specific investigations. Nevertheless, to indicate the approximate magnitude of costs that may be involved for different waste management practices, the costs for three management options -- single-lined landfills, single-lined surface impoundments, and double-lined surface impoundments -- are presented below.

Landfills

As noted earlier, single clay liners can be installed in a landfill for

about $0.70 to $2.55 per ton of disposed waste and single synthetic liners for about $1.45 to $4.15 per ton of disposed waste. The costs presented in Exhibit 6-4 indicate that waste disposal costs at a representative 500 Mw power plant with no flue gas desulfurization equipment would average about $5 to $11 per ton of disposed waste for a landfill operation. Adding a single clay liner to the landfill would increase total costs to $5.70 to $13.55 per ton of disposed waste; adding a single synthetic liner would increase costs to $6.45 to $15.15 per ton of disposed waste.

These estimates appear to be similar in magnitude, although somewhat lower than costs estimated in another study of utility waste disposal costs conducted for the Utility Solid Waste Activities Group (USWAG) by Econometric Research, Inc. That study estimated that total costs for complying with requirements related to the construction, operation, and maintenance of a single-lined landfill would range from about $15 to $24 per ton of waste, depending on the type of liner.[31]

The study for USWAG also analyzed the total costs to the electric utility industry if all power plants currently using landfills were required to construct new landfills with single liners. For this scenario, USWAG assumed that existing facilities, even if lined, would have to be replaced to comply with new requirements. Total capital costs for this alternative would range from $2.6 billion for landfills with one synthetic liner to $4.0 billion for landfills with a single clay liner.[32] Estimated annualized costs were about $400 million for installing a single synthetic liner at all landfills and about $600 million for installing a single clay liner.[33]

Surface Impoundments

The costs presented in Exhibit 6-4 for unlined surface impoundments indicated that waste managed at a representative 500 Mw power plant with no FGD waste production would cost about $8 to $17 per ton of waste. Using the cost estimates for liners noted earlier (see Section 6.1.2), adding a single clay liner would increase total management costs to about $10.25-$25.20 per ton of waste, and adding a synthetic liner would increase costs to $12.70-$30.45 per ton of waste.

These cost estimates for single-lined impoundments appear to be reasonably consistent with other estimates. Studies for USWAG indicated that management costs for impoundments with a single synthetic liner were about $19 per ton of waste and $30 per ton of waste for impoundments with a single clay liner.[34]

The USWAG report also estimated the total costs to the electric utility industry to construct new impoundments with single liners (i.e., all power plants currently using surface impoundments would be required to construct new facilities to meet disposal requirements even if the current impoundment is already lined). For this alternative total capital costs would range from $5.8 billion for impoundments with single synthetic liners to $9.5 billion for impoundments with single clay liners.[35] Annualized costs would range from $850 million for single synthetic liners at all impoundments to $1.4 billion for single clay liners.[36]

The study for USWAG also estimated management costs for surface impoundments with two different types of double liners -- a double synthetic liner (each with

a 30 mil thickness) and a double liner system consisting of one synthetic liner (30 mil) and a clay liner (36 inches). Total management costs for double-lined surface impoundments would range from about $29 per ton of waste for a site with two synthetic liners to $36 per ton of waste for a site with one synthetic liner and one clay liner.[37]

Industry-wide costs were also estimated for the installation of new double-lined surface impoundments at all power plants currently using surface impoundments. Total capital costs for installing a double-lined impoundment ranged from $9.3 billion for a double synthetic liner to $11.6 billion for one clay and one synthetic liner.[38] Total annualized costs were estimated at $1.4 billion for all impoundments with a double synthetic liner and $1.7 billion for all impoundments with one clay liner and one synthetic liner. A summary of the costs for the various types of lined disposal facilities discussed herein is presented in Exhibit 6-6.

6.2.2.7 Summary of Costs for Various Waste Management Alternatives

Exhibit 6-7 summarizes the costs to the electric utility industry of each of the waste management options previously discussed. The exhibit presents cost estimates for the total amount of capital required for each waste management standard and for the total amount of annualized costs (i.e., annual capital, operation, and maintenance costs) that would be incurred in order to comply with each requirement if coal-fired combustion wastes were regulated as hazardous wastes.

EXHIBIT 6-6

SUMMARY OF COSTS FOR DIFFERENT TYPES OF LINED WASTE MANAGEMENT FACILITIES

	Cost per ton	Total Annual Costs for the industry a/ (millions of dollars)
Landfills		
Basic Practice--Unlined	$ 5.00-$11.00	N.A.
Single Clay Liner	$ 5.70-$13.55	600
Single Synthetic Liner	$ 6.45-$15.15	400
Surface Impoundments		
Basic Practice--Unlined	$ 8.00-$17.00	N.A.
Single Clay Liner	$10.25-$25.20	1,380
Single Synthetic Liner	$12.70-$30.45	865
Double Synthetic Liners	$29.00	1,360
Double Liners: 1 Synthetic and 1 Clay	$36.00	1,680

---

a/ Total annual costs refer to annualized costs that capture capital, operation, and maintenance expenses. Since these costs were calculated by assuming that the utility industry would have to construct new facilities to comply with hypothetical alternative regulations, these costs are in addition to the current management costs incurred by the industry.

a/ Costs shown are for capital, operation, and maintenance costs for the entire industry since the amount of capital required was not readily available.

A combination of compliance alternatives could occur (e.g., closing existing disposal facilities and constructing new facilities with leachate collection and ground-water monitoring systems). The actual cost to the electric utility industry for complying with RCRA Subtitle C requirements would depend on the regulatory actions taken by the Agency if the temporary exemption under Section 3001 of RCRA is removed. Three possible regulatory scenarios are discussed in the following section.

6.2.3 Potential Costs to the Industry of RCRA Subtitle C Waste Management

Section 6.2.2 presented cost estimates for individual regulatory requirements that could be imposed on utilities if EPA determines that Subtitle C regulation is warranted for coal combustion wastes. In this section, three possible regulatory scenarios are examined to quantify the range of incremental costs that could result from various regulatory options. In the first scenario, the incremental costs of regulating a portion of low volume wastes under Subtitle C are presented. The second scenario assumes that all coal combustion waste would be subject to Subtitle C requirements. The third scenario assumes that high volume coal combustion wastes would be tested for RCRA hazardous characteristics and that a small portion of the waste would be classified as Subtitle C characteristic waste. For all three regulatory scenarios, costs are shown only for bringing all existing power plants into compliance with the assumed RCRA Subtitle C management regulations.

Low Volume Waste Scenario

This scenario evaluates the costs to the utility industry if some low volume waste streams are classified as hazardous wastes under Subtitle C. As discussed in Chapter Three, some of these wastes can exhibit hazardous characteristics such as corrosivity. The information available to EPA at this time does not permit the Agency to quantify the amount of low volume wastes that may exhibit hazardous characteristics. In this scenario, EPA has assumed that all water-side boiler cleaning wastes are regulated as hazardous wastes since these waste streams may exhibit corrosive characteristics. These waste streams are assumed to be hazardous to provide an approximate estimate of the costs to the industry if some low volume wastes display RCRA hazardous characteristics. That is, both high-volume and low-volume wastes could be tested for RCRA hazardous characteristics, but only a small portion of the low-volume wastes (as represented by all water-side boiler cleaning wastes) would need to be treated as hazardous.

As shown in Exhibit 3-19, a representative power plant generates about 180,000 gallons per year of water-side boiler cleaning wastes. The cost to dispose of these wastes as hazardous liquids can vary depending on waste stream variability, regional differences in disposal costs, and quantity to be disposed, among other factors.[39] For purposes of this analysis, an incremental cost of $2 per gallon (including transportation) has been assumed based on a 1985 survey of hazardous waste management prices.[40] With 180,000 gallons generated per year at a representative power plant, annual disposal costs would be about $360,000 per power plant. Since there are 514 power plants in the U.S., annual disposal costs to the utility industry would be about $185 million.

Full Subtitle C Regulation Scenario

If EPA lists high volume coal combustion waste streams in 40 CFR 261.31-261.33, all utilities will be affected. Utilities would be required to manage all coal combustion wastes in Subtitle C permitted facilities. To estimate the incremental costs to the industry of this regulatory scenario, the Agency assumed that all utilities would close existing facilities and open new waste management facilities that complied with Subtitle C standards. This scenario assumes that the costs of managing wastes off-site will equal the costs of managing wastes on-site and that existing facilities would be closed in the six months before Subtitle C regulation took effect, thereby avoiding Subtitle C closure and post-closure requirements.

Under existing state regulations, a clay cap is assumed to be adequate to close existing waste management facilities. The total annual costs of closing all existing facilities with a clay cap would be $700 million. For the new facilities, EPA assumed utilities would prepare a Part B permit application, construct new landfills and surface impoundments with clay/synthetic double liners, install leachate collection systems, make provisions for flood protection, and install ground-water monitoring systems. To determine incremental costs for the industry, EPA assumed that the current proportions of waste management facilities that were landfills and surface impoundments would remain unchanged under Subtitle C regulation. As summarized in Exhibit 6-7, total annual costs of the new Subtitle C facilities would be $54 million for Part B permit applications, $725 million for new double lined landfills,[41] $1700 million for new double lined surface impoundments, $460 million for leachate

collection systems, $33 million for flood protection, and $9 million for ground-water monitoring. Total incremental costs for this regulatory scenario would be $3.7 billion annually.[42]

High Volume Characteristic Waste Scenario

If coal combustion wastes were not exempt from RCRA Subtitle C regulation, utilities would have to test high-volume and low-volume coal combustion wastes for RCRA hazardous characteristics. Based on the RCRA characteristic results in Chapter Five, it appears that only a small portion of coal combustion wastes possess the hazardous characteristics of EP Toxicity or corrosivity. For purposes of this scenario, the Agency assumed that five percent of the wastes generated by utilities would need to be disposed in Subtitle C permitted facilities. The Agency does not have sufficient information to know exactly the amount of coal combustion waste that would exhibit RCRA hazardous characteristics. EPA believes that coal combustion wastes generally would not fail the RCRA hazardous characteristic tests. Based on limited information presented in Chapter Five that indicate about five percent of all ground-water observations at utility sites exceed the Primary Drinking Water Standards, the Agency assumed that five percent of all wastes would require Subtitle C treatment. The total annual cost to the industry if utilities close existing facilities and construct new double lined facilities for five percent of all coal combustion wastes would be $185 million.

6.3 IMPACT OF REGULATORY ALTERNATIVES ON UTILIZATION OF COAL COMBUSTION WASTES

As discussed in Chapter Four, coal-fired utility wastes have been used in a

variety of applications by electric utilities and other industries to replace other types of material. The use of utility wastes as a replacement for other materials has reduced the amount of wastes utilities have had to dispose, while correspondingly reducing the resource requirements of other industries that have managed to find a productive use for the waste material.

In the event that some or all of these wastes were declared hazardous, it is possible that the amount of by-product utilization of coal-fired utility wastes would decline as a result of increased costs for their use and the potential for outright prohibition of their use in some applications. On the other hand, it is possible that certain forms of utilization (e.g., the use of fly ash in cement) may be deemed environmentally acceptable practices if the wastes would be unlikely to pose an environmental threat when used for such purposes. Since costs for other forms of disposal may increase, utilization may also increase. However, for discussion purposes, this section assumes that designation as a hazardous waste would tend to discourage by-product utilization.

The costs that would be incurred as a result of environmental concerns over the utilization of coal-fired utility wastes would depend on the regulatory requirements that would have to be followed to use the wastes. The more stringent the additional regulatory burden imposed, the greater the impact on by-product utilization due to the higher costs of using the wastes.

In the USWAG study referenced above, the potential range of costs associated with reduced use of coal combustion by-products was also evaluated. Three different regulatory scenarios were analyzed.[43]

- The transportation of coal-fired utility wastes is regulated as hazardous waste transportation under Subtitle C of RCRA; use or disposal of the wastes would not be regulated.
- All activities associated with reuse of coal combustion by-products is regulated, and the regulations affect both the transporter and owner/operator of a Subtitle C hazardous waste management facility.
- Reuse of coal combustion by-products is prohibited.

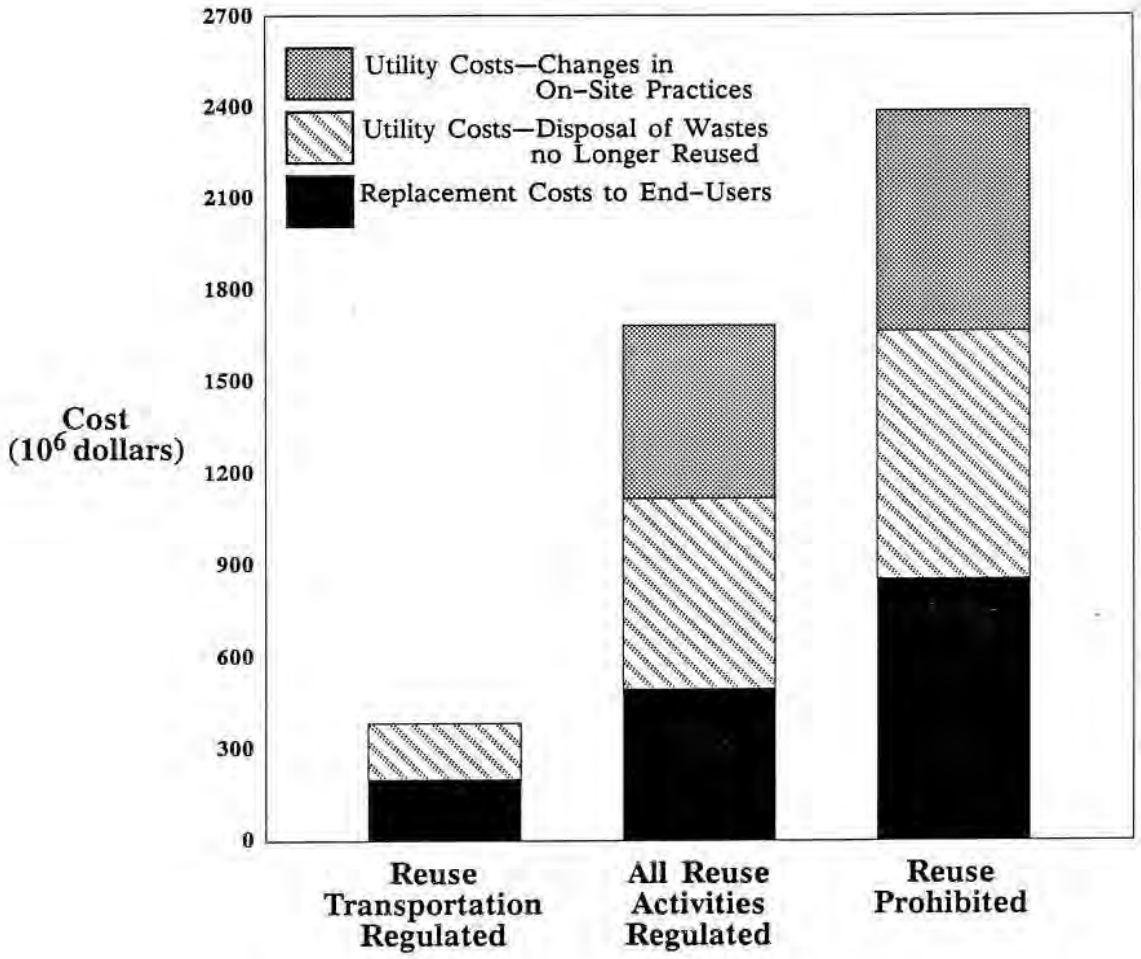
There would be three types of costs incurred under these regulatory scenarios: (1) replacement costs to the end-users who would no longer find it economic to utilize the coal combustion by-products, (2) costs to utilities to dispose of wastes no longer reused by other industries, and (3) additional costs to the utility industry for replacement and disposal of wastes that could no longer be used on-site. A summary of the costs associated with each scenario is provided in Exhibit 6-8.[44]

If the transportation of coal combustion by-products were subject to increased regulation under Subtitle C, the USWAG report estimated that the use of these by-products would decline by nearly 40 percent, increasing overall disposal volumes by about 8 percent.[45] The industries that would be affected the most would be the roofing granules industry (conventional roofing granules would replace bottom ash and boiler slag at a cost of about $115 million in annual costs) and the concrete industry (portland cement would replace fly ash at a cost of about $40 million in annual costs).[46]

If all activities pertaining to reuse of coal combustion wastes were subject to Subtitle C regulations, utilization of coal combustion

EXHIBIT 6-8

Summary of Economic Impacts on By-Product Utilization under Different RCRA Regulatory Scenarios*



*All costs are annualized based on impacts estimated from 1984-2000.

Source: *USWAG, Report and Technical Studies on the Disposal and Utilization of Fossil-Fuel Combustion By-Products, Appendix G, October 26, 1982*

by-products was estimated to decline by about 75 percent, increasing overall disposal volumes by about 14 percent.[47] The greatest impact would be on the concrete industry, which would spend about $270 million annually to replace fly ash with portland cement.[48]

If all reuse of coal combustion by-products were prohibited, industries using these by-products would have to find suitable replacements; total disposal volumes would increase by nearly 20 percent.[49] The largest impacts would be on the asphalt industry, which would be forced to replace ash with asphalt at a cost of approximately $250 million annually, and the concrete industry, which would replace fly ash with portland cement at a cost of about $270 million annually.[50]

6.4 ECONOMIC IMPACTS OF ALTERNATIVE WASTE DISPOSAL OPTIONS

Since many alternative disposal practices discussed in this chapter could impose additional costs on the electric utility industry, this section evaluates the effect that these increased costs might have on electricity generation costs and U.S. coal consumption. This study employs three measures to determine the potential economic impact of alternative disposal practices:

1. Average increase in electricity generation costs at existing coal-fired power plants,

2. Average increase in electricity generation costs at coal-fired power plants yet to be constructed, and

3. Impact on the electric utility industry's consumption of coal.

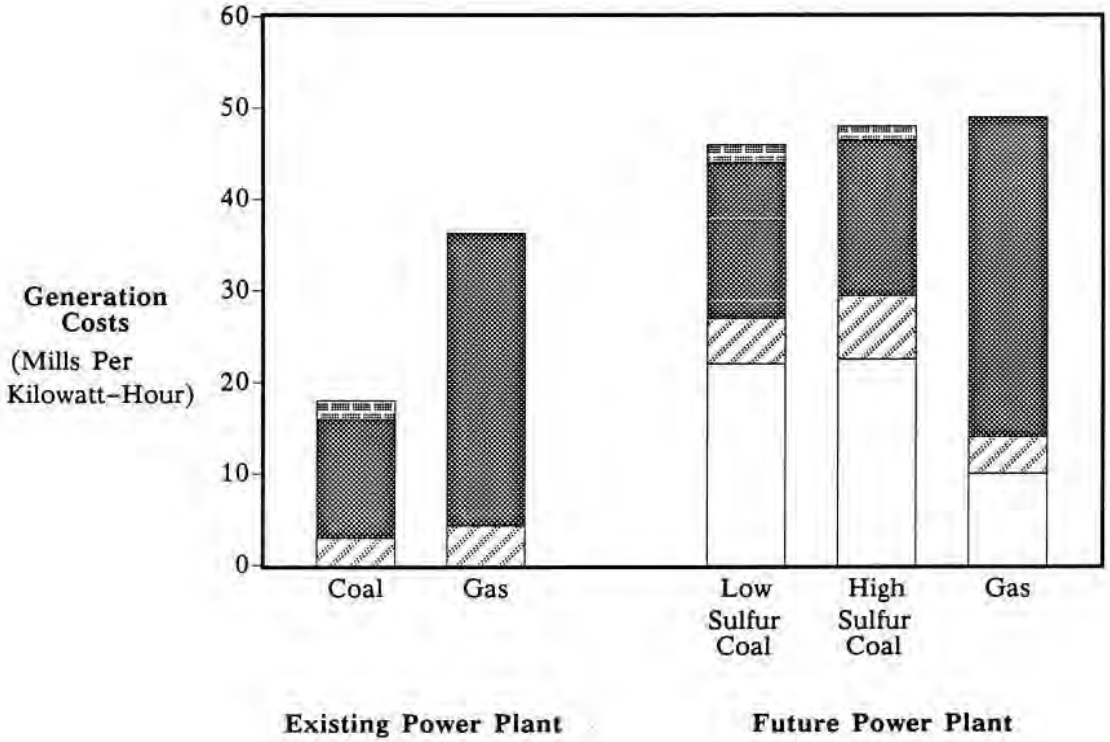
Exhibit 6-9 summarizes the cost of generating electricity at both existing and yet-to-be-constructed power plants (see Appendix G for a detailed discussion of the assumptions used to determine these generation costs).[51] Disposal costs average about 3-5 percent of total generation costs at existing coal-fired power plants, but only about 1-3 percent at future power plants. Although the actual costs of disposal at existing and future power plants are similar, the percentages are different because total generation costs at future power plants are higher than generation costs at existing power plants (resulting in a lower overall percentage for disposal costs at future power plants). Total generation costs are higher at future power plants because they include capital, operation and maintenance, and fuel costs, while the generation costs for existing power plants include operation and maintenance and fuel costs only.[52] Based on the cost assumptions used to develop Exhibit 6-9, coal-fired electricity generation at both new and future baseload[53] power plants is less expensive than generation with natural gas.[54]

The economic impacts likely to result from the use of alternative coal-fired utility waste disposal practices will depend upon several factors, including which disposal options are required, how much the cost of coal-fired electricity generation changes, and whether these changes affect the relative competitiveness between coal and other fuels. To indicate the potential magnitude of these impacts, Exhibit 6-10 summarizes the potential cost impacts on electricity generation rates due to the alternative waste disposal options discussed earlier in this chapter.

As indicated in Exhibit 6-10, some alternative disposal options could

EXHIBIT 6-9

IMPACT OF CURRENT WASTE DISPOSAL COSTS ON TOTAL ELECTRICITY GENERATION COSTS*



* Generation costs are based on typical 500 Mw power plant in the midwest operating at 70 percent utilization rate. Regional costs will vary depending on fuel price and availability, among other factors.

a/ Based on a representative 500 Mw plant operating at a 70 percent utilization rate. Costs are incremental costs only; that is, cost impact of new disposal facilities is only that portion of costs in excess of current disposal costs (see Exhibit 6-4 for these costs). A mill is one-tenth of a cent ($0.001).

b/ Costs for existing waste disposal facilities refer only to the cost of liner installation. Costs for new waste disposal facilities refer to all the costs for site construction and liner installation.

c/ Less than 0.1 percent.

increase electricity generation costs at existing power plants by several percent. In some cases the cost impact could be substantial if several options were combined as part of an integrated waste management strategy. For example, if new waste management regulations led to closure of the current disposal site and the construction of a new lined facility with a leachate control system, flood protection, and ground-water monitoring system, coal-fired generation costs at existing coal-fired power plants could increase by nearly 20 percent (roughly 3.5 mills/kilowatt-hour).

Generation cost increases of this magnitude have the potential to reduce coal consumption at existing coal-fired power plants if these cost increases make it more expensive to generate electricity with coal than with other fuels. A utility decides how much electricity to generate at any existing power plant primarily by comparing the operation and maintenance costs (including fuel) associated with generating electricity at all of its power plants. Power plants with the lowest generation costs will be operated first. Generally, it is less expensive to generate electricity with coal than with other fuels such as oil or gas, but oil-fired electricity generation can be competitive with coal when the price of oil is approximately $10-$15 per barrel.[55] However, whether and to what degree electric utilities would shift away from the use of coal would depend on several factors, including the relative price of coal compared with the price of other fuels, the magnitude of the increase in generation costs if disposal practices were altered, and the overall efficiency of competing power plants.

For power plants yet to be constructed, the impact of higher disposal costs on coal consumption could be more substantial, with possible generation cost

increases approaching 8-10 percent if several options are combined. Generation cost increases of this magnitude could have a substantial effect on the amount of coal consumed at future power plants since many utilities may decide not to build coal-fired power plants. Although currently coal-fired electricity generation may be a more economic option than oil-fired or gas-fired generation at plants yet to be constructed, this situation could change if more expensive disposal practices were required for coal combustion wastes. This is because the higher capital costs of coal-fired electricity generation, compared with oil- or gas-fired generation, reduces the overall cost differential between the use of coal and the use of oil or gas at future power plants (compared to the cost differential between coal and oil or gas at existing power plants). As a result, coal is more likely to be replaced by alternative fuels at future power plants than it is at existing power plants.

In fact, since oil prices dropped below $20 per barrel in early 1986, many utilities have been seriously evaluating the feasibility of building oil- or gas-fired generating capacity in lieu of coal-fired units. As a result, in some instances even an increase of a few percent in coal-fired generation costs could be sufficient to tip the balance in favor of using natural gas or oil to fuel power plants that have not yet been constructed. If increased disposal costs do promote such competition, growth in future U.S. consumption of coal would probably decline. The exact magnitude of this decrease in future coal consumption would depend on many factors, including the type of new waste disposal practices adopted and the price of alternative fuels in different regions of the country. An in-depth analysis of the potential impact of alternative waste management scenarios on electric utility generation practices and investment decisions and, as a result, the level of coal consumption, is

beyond the scope of this Report to Congress. However, EPA intends to seek more information and analysis on the issue of economic impacts through the public hearing process and through its own additional investigations. As required by law EPA will conduct the appropriate regulatory impact analyses, including the economic impact analysis, during the six month public review period following submission of this report to Congress if it is determined that current utility waste management practices for coal-fired combustion wastes are inadequate and additional regulations are warranted.

6.5 SUMMARY

The cost to manage coal combustion waste in basic waste management facilities currently ranges from as little as $2 to as much as $31 per ton. The wide range in management costs is primarily due to differences in (1) the type of facility, (2) the size of the facility and (3) the characteristics of the waste.

- Some facilities currently incur additional costs because they have undertaken additional safeguards against leaching, including liner installation, leachate collection and treatment, and ground-water monitoring.
- Management costs at surface impoundments tend to be greater than those at landfills because of the higher costs of site preparation at impoundments.
- The size of larger waste disposal facilities allows them to operate more efficiently, which tends to reduce the cost per ton of waste management.
- Fly ash is typically more expensive to manage than bottom ash or FGD waste because of additional requirements for collection, handling, and treatment prior to disposal.

- If additional regulations are promulgated requiring electric utilities to alter the current methods by which they manage coal-fired wastes, additional costs may be incurred by the industry as it complies with the new requirements.

- The most common practice for controlling leaching at a waste management site is installation of a liner prior to placement of the waste. Liners are usually made of low permeable clay or a synthetic material and can be installed in one or more layers. The cost of installing a liner ranges from $0.70 to $8.20 per ton of waste for clay liners and $1.45 to $13.45 per ton for synthetic liners. Total disposal costs for single-lined landfills range from about $6 to $15 per ton of waste, while costs for single-lined surface impoundments range from $10 to $30 per ton. Industry-wide costs to construct and install lined management facilities could range from $0.4 to $1.7 billion on an annualized basis, depending on type of facility, type of liner material, and number of liners installed.

- Installation of leachate collection systems to control potential environmental problems that might result from substances leaching from a waste management site could cost about $4 to $5 per ton of waste. Total costs to the utility industry to install leachate collection systems could be $1.2 billion in capital costs, or about $460 million in annualized costs.

- The cost of installing a ground-water monitoring system to detect the presence and concentration of various waste constituents in the ground water surrounding a waste management facility is generally less than $0.25 per ton of waste. Total capital requirements to the industry would likely range from $9 to $13 million, with annual costs of $6 to $9 million.

- If coal combustion wastes were regulated under Subtitle C of RCRA, costs to the utility industry could approach $3.7 billion annually if all wastes were listed as hazardous. Costs would be substantially lower than $3.7 billion annually if coal combustion wastes were tested for hazardous characteristics since only a small portion of coal combustion wastes would be likely to fail the RCRA hazardous characteristic tests. These costs to comply with Subtitle C do not include corrective action costs or the higher costs that may be associated with recycling coal combustion wastes; these costs to the utility industry could be very high.

- New waste management practices could increase the cost of generating electricity at existing coal-fired power plants by nearly 20 percent in some cases. Although coal is generally the preferred boiler fuel at existing power plants, an increase of this magnitude could cause a decline in the amount of coal consumed at these power plants if alternative fuel prices were reasonably competitive.

- If new management practices are required at future power plants, the increase in generation costs is unlikely to exceed 10 percent. Although on a percentage basis this increase would be less than the percentage increase possible at existing power plants, the choice of fuels at future power plants is much more competitive (due to the capital costs that must be included in the costs of a future power plant). In some instances this could lead to a decrease in coal consumption if the use of alternative fuels is found to be more cost effective since many utilities may decide not to build coal-fired power plants.

CHAPTER SIX

NOTES

[1] The disposal costs in this chapter are assumed to apply to high-volume and low-volume wastes since these wastes are often co-disposed in the same disposal facility.

[2] Arthur D. Little, Inc., Full-Scale Field Evaluation of Waste Disposal from Coal-Fired Electric Generating Plants, Final Report, EPA-600/7-85-0286, June 1985, p. 6-1.

[3] The methodology used to develop the cost estimates presented in this chapter is detailed in Appendix G. All costs in this report are presented in fourth quarter 1986 dollars. Costs were escalated to this level based on the GNP price deflator index reported by the U.S. Department of Commerce. The value of this index for fourth quarter 1986 was 115.2 (1982 = 100). Capital charges not already annualized in the various studies cited in this report were annualized by using a 14.5 percent capital recovery factor. This capital recovery factor was chosen to approximate the factors used in the two primary studies cited throughout this chapter -- the ADL study (which used a capital recovery factor of 14.7 percent) and the USWAG study (14.1 percent).

[4] Arthur D. Little, Inc., p. 6-112.

[5] Many of the cost estimates presented throughout this chapter are based on a 500 Mw power plant in order to approximate representative costs for a "typical" size power plant. Capital costs are often expressed on a "per kilowatt" basis to reflect the amount of capital required for each kilowatt of a power plant's capacity. Total disposal costs are often expressed on a "per ton" basis, which refers to each ton that must be disposed over the life of the facility. The amount of waste generated each year from a 500 Mw plant is assumed to be 154,000 tons of fly ash, (308 tons/Mw), 38,500 tons of bottom ash (77 tons/Mw), and 132,000 tons of FGD waste (264 tons/Mw). These estimates are based on average values reported in Full-Scale Field Evaluation of Waste Disposal From Coal-Fired Electric Generating Plants, Arthur D. Little, Inc., June 1985. The actual amount of waste generated at a plant will vary depending on plant size, coal quality, FGD technology, and boiler type, among other factors.

[6] In one study for Consolidated Edison of New York, analyses were conducted on the feasibility of ocean disposal of coal-fired utility wastes from the Arthur Kill and Ravenswood oil-to-coal conversions. Capital costs for this 612,500 tons per year operation were estimated at $36 million. Annual operation and maintenance costs were approximately $2.7 million, for total costs of about $13 per ton of waste disposed. See Energy Resources, Inc., Demonstration of Compliance of Coal-Ash Disposal at the 106-Mile Ocean Waste Disposal Site with Subpart C of the Ocean Dumping Regulations, Attachment I, May 1981, p. I-26.) Capital costs would be about $5.2 million on an annualized basis, resulting in total annualized costs of about $7.9 million.

[7] In one study, the cost of building and operating an artificial reef construction system was estimated to be about $50 per ton, roughly double the amount estimated by the study authors for more conventional waste disposal. In those situations where space constraints or other factors would substantially increase the costs for conventional disposal, ocean disposal through reef construction was seen as an economically viable option. See J.H. Parker, P.M.J. Woodhead, and I.W. Dued all, "A Constructive Disposal Option for Coal Wastes -- Artificial Reefs," in Proceedings of the Second Conference on Management of Municipal, Hazardous, and Coal Wastes, S. Sengupta (Ed.), September 1984, p. 134.

[8] Arthur D. Little, p. 6-132. "Installed cost" of a liner (expressed in terms of cost per ton of disposed waste) refers to the increase in the cost of disposing of one ton of waste as a result of adding a liner to an unlined landfill or surface impoundment.

[9] Ibid. The costs in the Arthur D. Little report were presented for an 18-inch clay liner. Costs were doubled to approximate the costs for installing a 36-inch clay liner, which is currently a more common practice. The dollar per ton estimate was derived by multiplying total capital costs by a 14.5 percent capital recovery factor to determine annual capital charges. Assuming that a 500 Mw power plant has a 45 acre landfill disposal site, total capital charges would range from $945,000 to $3.4 million, or about $140,000 to $490,000 in annualized charges. Assuming that a 500 Mw power plant would need a 145-acre wet surface impoundment, total costs would range from $3.0 to $10.9 million, or $440,000 to $1.6 million in annualized costs. These annualized charges were then divided by the amount of waste produced annually by a 500 Mw power plant with no FGD process, (i.e., 192,500 tons) to determine the dollar per ton cost. This approach is used throughout the report to calculate dollar per ton estimates. See Appendix G for more detail on this methodology.

[10] Ibid. For landfills, total installed costs would range from $1.9 to $5.1 million per plant, assuming a 45-acre disposal site. Annual costs would range from about $280,000 to $740,000. Based on 192,500 tons of waste, the cost is $1.45-$3.85 per ton. For ponds (i.e., impoundments), total installed costs would be $6.2-$16.4 million, or $900,000-$2.4 million annualized. On a dollar per ton basis, this range is $4.70-$12.35.

[11] Ibid. For landfills total installed costs would range from $2.7-$5.5 million, or about $385,000-$800,000 in annual costs per ton. This corresponds to $2.00-$4.15 per ton. Total installed costs for ponding operations are $8.6-$17.8 million, or $1.2-$2.6 million annualized. This corresponds to $6.45-$13.45 per ton.

[12] Ibid.

[13] Total capital costs for landfills of $3.0 to $5.0 million correspond to annual charges of about $430,000 to $720,000. Assuming 192,500 tons of waste, the per ton cost is $2.25 to $3.75. Using the same approach to derive disposal costs at a 145-acre lined impoundment yields $7.20 to $12.00 per ton.

[14] A waste management unit is not subject to regulation under Section 264.1 if the Regional Administrator finds that the unit (1) is an engineered structure, (2) does not receive or contain liquid waste or waste containing free liquids, (3) was designed and is operated in such a way to exclude liquids, precipitation, and other run-on and run-off (4) has both inner and outer layers of containment enclosing the waste, (5) has a leak detection system built into each containment layer, (6) will have continuing operation and maintenance of these leak detection systems during its active life and throughout the closure and post-closure care periods, and (7) is constructed in such a way that, to a reasonable degree of certainty, hazardous constituents will not migrate beyond the outer containment layer prior to the end of the post-closure care period. (40 CFR 264.90(b)(vii).

[15] See 40 CFR 246.143.

[16] These specified wastes are liquid hazardous wastes that have a pH less than or equal to 2.0 and/or (1) free cyanides at concentrations greater than or equal to 1,000 mg/1, (2) arsenic and/or arsenical compounds at concentrations greater than or equal to 500 mg/1, (3) cadmium and/or cadmium compounds at concentrations greater than or equal to 100 mg/1, (4) chromium and/or chromium compounds at concentrations greater than or equal to 500 mg/1 (5) lead and/or lead compounds at concentrations greater than or equal to 500 mg/1, (6) nickel and/or nickel compounds at concentrations greater than or equal to 134 mg/1, (7) mercury and/or mercury compounds at concentrations greater than or equal to 20 mg/1, (8) selenium and/or selenium compounds at concentrations greater than or equal to 100 mg/1, (9) thallium and/or thallium compounds at concentrations greater than or equal to 130 mg/1, (10) polychlorinated biphenyls at concentrations greater than or equal to 50 mg/1, (11) halogenated organic compounds at concentrations greater than or equal to 1,000 mg/kg.

[17] Envirosphere Company, "Report on the Costs of Utility Ash and FGD Waste Disposal", in USWAG, Report and Technical Studies on the Disposal and Utilization of Fossil-Fuel Combustion By-Products, October 19, 1982, p. 21, Appendix F, part 2. Dollar per ton estimates were determined by calculating annual costs ($721,000 x 14.5 percent capital recovery factor = $104,500). The capital recovery factor was applied to all costs since a breakdown of different types of costs required for a Part B permit was not available.

[18] Ibid, p. 18.

[19] Assuming a 145-acre impoundment site, costs would be about $107,000. On a per ton basis, this corresponds to about $0.55. For a 45-acre landfill with costs of $1100 per acre, total costs would be about $50,000, for a per ton cost of $0.25.

[20] Envirosphere, in USWAG, Appendix F, Part 2, p. 27, 32.

[21] Arthur D. Little, p. 6-133. On an annualized basis, capital costs would range from about $2,650 to $3,550.

[22] Envirosphere Company, in USWAG, Appendix F, Part 2, p. 37. Envirosphere estimated that about four wells, one upgradient from the site and three downgradient, would be required for each 100 acre disposal site (or about six wells for a site of 145 acres) at a capital cost of approximately $6,000 per well. Total capital costs for six wells would be $36,000, which is about $5,200 on an annualized basis. It was assumed that the wells would be sampled quarterly the first year, then semi-annually thereafter. The operation and maintenance costs would average about $2,500 to $3,000 per well, for facility costs (assuming six wells) of $15,000 to $18,000 per year. Total annualized costs, therefore, would range from $20,200 to $23,200, or $0.10 to $0.12 per ton of waste disposed.

[23] For a more complete discussion, see ICF Incorporated, Liner Location Risk and Cost Analysis Model, Draft Phase II Report, Appendix F-2, Office of Solid Waste, U.S. Environmental Protection Agency, March 1987.

[24] The cost equation on which this cost estimate is based was developed for typical RCRA Subtitle C landfills. Since these facilities tend to be much smaller than the size of utility disposal areas, extrapolating the cost equation for larger sizes may introduce some errors. Nevertheless, these cost estimates do indicate the approximate magnitude of corrective action costs that would likely be incurred.

[25] Econometric Research, "The Economic Costs of Potential RCRA Regulations Applied to Existing Coal-Fired Electric Utility Boilers," in USWAG, Report and Technical Studies on the Disposal and Utilization of Fossil-Fuel Combustion By-Products, October 26, 1982, p. 15, Appendix F, part 1.

[26] Ibid, p. 15.

[27] Ibid, p. 18. On a per acre basis, total annual costs range from $6,700 to $19,600 for surface impoundments and $9,000 to $21,000 for landfills. For a 145-acre impoundment, this corresponds to $1.0 to $2.8 million in total annual costs, or $5.00 to $14.75 per ton of waste. For landfills the per ton cost would be $2.10 to $4.90 based on total annual costs of $0.4 to $0.9 million.

[28] See Administrative Procedure Act, U.S. Code 5 Sec. part 551.

[29] Ibid, see pages 26 and 31 of the Econometric report for all closure costs.

[30] For further discussion of the potential magnitude of these costs, see ICF Incorporated, Flexible Regulatory and Enforcement Policies for Corrective Action, prepared for U.S. Environmental Protection Agency, September 12, 1985.

[31] Econometric Research, in USWAG, Appendix F, Part 1, p. 15. Econometric Research used capital costs for disposal of about $5.20 per ton of waste produced over a 20-year life of the facility for synthetic liners and about $8.10 per ton for clay liners, plus about $0.06 per ton per year for operation and maintenance costs. Total initial capital outlays would then be $104 per ton ($5.20 per ton times 20 years) for synthetic liners, or about $15.08 per ton on an annualized basis, and $162 per ton ($8.10 per ton times 20 years) for clay liners, or $23.49 per ton on an annualized basis. With the addition of

the $0.06 per ton for operation and maintenance costs, total costs would range from $15.14 per ton for synthetic liners and $23.55 per ton for clay liners for each ton of waste produced annually.

[32] Ibid., p. 27. Total capital costs for existing power plants were assumed to be $2.1 billion for single synthetic liners and $3.2 billion for single clay liners. Since these cost estimates were based on a universe of 412 power plants, costs were adjusted upward by 514/412 to approximate total industry costs for the number of power plants estimated at the time of this study -- 514 power plants. This adjustment was made for all industry-wide costs cited from the USWAG report.

[33] Ibid., p. 32.

[34] Ibid., p. 18. Econometric Research, Inc., calculated that disposal costs for an impoundment with a single synthetic liner were about $0.95 per ton of waste over the life of the facility and about $1.50 per ton of waste for clay-lined impoundments. For a plant generating 192,500 tons each year for 20 years (or 3.85 million tons), that corresponds to 3.85 million tons x $0.95 per ton = $3.7 million for an impoundment with a single synthetic liner (or about $19 per ton based on $3.7 million divided by 192,500 tons of waste annually) and 3.85 million tons x $1.50 per ton = $5.8 million for an impoundment with a single clay liner (or about $30 for each ton of waste disposed in a year).

[35] Ibid, p. 26. The costs in the USWAG report were adjusted by 514/412 to account for the 514 power plants estimated at the time of this study compared to the 412 power plants assumed in the USWAG report.

[36] Ibid. p. 31.

[37] Ibid, p. 18. The double synthetic liner disposal system averages about $1.45 per ton over the life of the facility and a system with one synthetic liner and one clay liner costs about $1.80 per ton. At 3.85 million tons of waste over a 20 year facility life, that is $5.6 million for a double synthetic liner (or about $29 for each ton disposed in a year). For a combination synthetic/clay liner system, 3.85 million tons x $1.80 per ton = $6.9 million (or about $36 per ton).

[38] Ibid, p. 26.

[39] ICF Incorporated, 1985 Survey of Selected Firms In The Commercial Hazardous Waste Management Industry, Prepared for U.S. Environmental Protection Agency, November 6, 1986.

[40] Ibid.

[41] To develop a cost estimate for landfills constructed with clay/synthetic double liners, the ratio of the cost of single clay and synthetic liners at landfills in Exhibit 6-7 to the cost of single clay and synthetic liners at surface impoundments was multiplied by the cost of clay/synthetic liners at surface impoundments.

[42] The costs to close and cap existing facilities have been included in this estimate, while corrective action costs have not been included. Although closure costs will be incurred eventually by the industry, in most cases they would not be incurred for many years to come. To be conservative, EPA has included closure costs as part of potential RCRA Subtitle C compliance costs.

[43] Envirosphere Company, "Economic Analysis of Impact of RCRA On Coal Combustion By-Products Utilization." In USWAG, Report and Technical Studies On the Disposal and Utilization of Fossil-Fuel Combustion By-Products, October 26, 1982, Appendix G.

[44] Envirosphere Company, in USWAG, Appendix G. The costs in Exhibit 6-8 are based on estimated impacts between 1984 and 2000 and adjusted by a capital recovery factor of 14.5 percent to annualize the costs (total capital requirements were not identified). It was estimated that about 203 million tons of coal combustion by-products would be used over this period, with a similar amount used on-site by the utilities. That is, the costs assume that the amount of by-products utilized would have increased over time.

[45] Ibid., p. 89. Total ash generation in 2000 was assumed to be 169.5 million tons, with about 27.3 million tons utilized and therefore, 142.2 million tons destined for disposal areas. Utilization was estimated to decline about 11.5 million tons, so the total amount of waste to be disposed would increase to 153.7 million tons.

[46] Ibid.

[47] Ibid., p. 91. Total utilization was assumed to decline by about 20.3 million tons in 2000. Therefore, the total amount of waste disposed would increase from 142.2 million tons to 162.5 million tons.

[48] Ibid.

[49] Total utilization was assumed to be 27.3 million tons in 2000, thereby increasing total disposal volume from 142.2 million tons to 169.5 million tons.

[50] Envirosphere Company, in USWAG, Appendix G, p. 93.

[51] To estimate the potential impact of alternative disposal practices on electricity generation costs, the first step was to calculate the approximate portion of generation costs due to current basic disposal practices. Current basic disposal practices for coal-fired utility wastes were assumed to be disposal in either an unlined pond or landfill, although other practices are sometimes followed. Generation costs for a typical coal- and gas-fired power plant are shown to indicate the relative competitiveness of these two fuels when current disposal practices for coal-fired utility wastes are followed. See Appendix G for a detailed discussion of the assumptions used to determine these generation costs.

[52] Capital costs are not included in the cost estimates for existing power plants because these are "sunk" costs, i.e., they have already been spent. As a result, the percentage impact on total generation costs at existing power plants is larger because the cost base is smaller compared to future power plants.

[53] Baseload refers to power plants that are operated as much as possible to maximize the amount of electricity these plants can generate. For this analysis a baseload power plant is assumed to operate 70 percent of the time.

[54] The generation costs in Exhibit 6-9 are intended to be representative of typical power plants. However, the actual cost of generation and the relative competitiveness between coal and gas depends on many factors, including plant size, utilization rate, and delivered fuel cost.

[55] This price range is only intended to illustrate the approximate range at which oil becomes competitive with coal at existing power plants. The actual level at which coal might begin to lose market share depends on many factors, including relative price differentials, fuel availability, gas prices vis-a-vis oil prices, types of power plants (i.e., overall plant efficiency), etc.

CHAPTER SEVEN

CONCLUSIONS AND RECOMMENDATIONS

This chapter concludes the Environmental Protection Agency's Report to Congress on fossil fuel combustion wastes. Pursuant to the requirements of Section 8002(n) of the Resource Conservation and Recovery Act (RCRA), the Report addresses the nature and volumes of coal combustion wastes, the environmental and human health effects of the disposal of coal combustion wastes, present disposal and utilization practices, and the costs and economic impacts of employing alternative disposal and utilization techniques. A statement of the scope of the report and a summary of the report's findings are presented below, followed by the Agency's recommendations.

7.1 SCOPE OF REPORT

As discussed in Chapter One, this Report to Congress covers the generation of coal-fired combustion wastes by the electric utility industry. Other fossil fuel combustion wastes not discussed in this report include coal, oil and gas combustion wastes from other industries and oil and gas combustion wastes from electric utilities. Overall, coal combustion by electric utilities accounts for approximately 90 percent of all fossil fuel combustion wastes that are produced. Moreover, this percentage is likely to increase in the future since coal consumption by the electric utility industry is expected to increase substantially while coal use by other sectors remains relatively constant. Electric utility coal consumption will grow as new coal-fired power

plants are constructed to meet increasing electricity requirements in the United States.

7.2 SUMMARY OF REPORT

The Agency's conclusions from the information presented in this report are summarized under seven major groupings paralleling the organization of the report: 1) Location and Characteristics of Coal-Fired Power Plants, 2) Waste Quantities and Characteristics, 3) Waste Management Practices, 4) Potential Hazardous Characteristics, 5) Evidence of Environmental Transport of Potentially Hazardous Constituents, 6) Evidence of Damage, and 7) Potential Costs of Regulation.

7.2.1 Location and Characteristics of Coal-Fired Power Plants

1. There are about 500 power plant sites in the United States that consume coal to generate electricity. Each power plant may be the location for more than one generating unit; at these 500 power plants there are nearly 1400 generating units.

2. The size of coal-fired power plants can vary greatly. The size of a power plant is typically measured by the number of megawatts (Mw) of generating capacity. Coal-fired power plants can range in size from less than 50 Mw to larger than 3000 Mw.

3. Coal-fired power plants are located throughout the United States. Coal is used to generate electricity in every EPA region; almost every state has some coal-fired generating capacity.

4. More coal-fired power plants will be built as the demand for electricity increases. Coal is a fuel often used by the electric utility industry to generate power. This reliance on coal is unlikely to change for many years to come in the absence of greatly increased costs for coal-fired electricity.

5. Coal-fired power plants are located in areas of widely-varying population density. Some power plants are located in remote rural areas, whereas others are located in urban environments. They are usually, although not always, located at least a couple of kilometers from major population concentrations. In general they are located near a major body of surface water such as a lake, river, or stream.

7.2.2. Waste Quantities and Characteristics

1. The amount of wastes generated annually by coal-fired power plants is large by any standard. About 84 million tons of high-volume wastes -- fly ash, bottom ash, boiler slag, and FGD sludge -- are generated annually. The total amount of low-volume wastes generated from equipment maintenance and cleaning operations is not known precisely, but is also substantial.

2. Quantities of waste produced will increase significantly as more electricity is generated by coal. The amount of high-volume wastes produced annually could double by the year 2000. In particular, the amount of FGD sludge produced will triple (to about 50 million tons) as newly-constructed power plants install FGD equipment to remove sulfur dioxide from the flue gases.

3. Coal combustion wastes are a common by-product from the generation of electricity. The noncombustible materials are present in the coal as a result of geologic processes and mining techniques. Given current technologies for generating electricity, wastes from coal combustion will continue to be produced in significant quantities.

4. High-volume coal combustion wastes do contain elements that in sufficient concentrations can pose a potential danger to human health and the environment. Most elements in coal are not hazardous. However, trace elements typically found in coal become concentrated as a result of the combustion process. Certain elements known to pose health risks can be found in the wastes at hazardous levels.

5. Although most low-volume wastes do not appear to be hazardous, there are some waste streams from cleaning that could potentially be hazardous. The waste streams of most concern are water-side boiler cleaning solutions, which may be corrosive or toxic. Because the amount and type of low-volume wastes produced can vary substantially from one power plant to the next, not as much is known about low-volume wastes compared to high-volume wastes.

7.2.3 Waste Management Practices

1. Most coal combustion wastes are typically disposed in landfills or surface impoundments, with recent trends toward increased reliance on landfills. Although some disposal does occur off-site, most wastes are disposed on-site; it is likely that most power plants built in the future will dispose on-site in a landfill.

2. Typical industry practice is to co-dispose low-volume wastes with high-volume wastes or, in some instances, to burn the low-volume wastes in the utility boiler. There are many other types of waste management practices that are also used to alter the physical and chemical characteristics of low-volume wastes prior to disposal. These practices vary widely from plant to plant. There are no reliable data sources that accurately describe the types of low-volume disposal practices used at each power plant.

3. The potential for increased waste utilization as a solution to waste management in the utility industry appears to be limited. About 21 percent of all high-volume wastes are currently recycled; some opportunities appear to exist to increase utilization, but not in a major way.

4. Coal combustion wastes are typically regulated under state solid waste laws, which treat these wastes as non-hazardous materials. The

extent of state regulation can vary significantly from one state to another.

5. Many waste management practices applied to hazardous waste in other industries, such as liners, have only seen limited use for coal combustion waste management. In recent years, some of these practices, including liners and leachate collection systems, have become more common. There is an increasing tendency to manage coal combustion wastes by disposing on-site (at the power plant) in landfills.

6. There are few major innovations under development that would lead to major changes in waste management practices.

7.2.4 Potential Hazardous Characteristics

1. The RCRA hazardous characteristics of most concern are corrosivity and EP toxicity. Coal combustion wastes are generally not ignitable or reactive.

2. Most waste streams would not be considered corrosive under RCRA definitions. Only aqueous wastes, which most coal combustion wastes are not, are considered corrosive under RCRA. There are some aqueous coal combustion waste streams that are very near corrosive levels, particularly low volume wastes such as boiler blowdown or coal pile runoff. In some instances, boiler cleaning wastes may be corrosive, particularly those that are hydrochloric acid-based.

3. Coal combustion wastes generally are not EP toxic, although there are some exceptions. It is rare for coal combustion wastes to fail the EP test (or the TCLP test developed more recently). Extract concentrations in excess of 100 times the Primary Drinking Water Standards have been found only for the elements cadmium, chromium, and arsenic from some FGD sludges and coal ash samples, although these levels are quite rare -- average levels are substantially below 100 times the PDWS.

4. There are insufficient data to determine a priori which waste streams at a power plant will exhibit RCRA hazardous characteristics. Accurate determinations could only be made if site-specific analyses were conducted.

7.2.5 Evidence of Environmental Transport of Potentially Hazardous Constituents.

1. Migration of potentially hazardous constituents has occurred from coal combustion waste sites. From the limited data available, exceedances of the Primary Drinking Water Standards have been observed in the ground water for several elements, including cadmium, chromium, lead, selenium, and arsenic.

2. Ground-water contamination does not appear to be widespread. Only a few percent of all ground-water quality observations indicate that a PDWS exceedance has occurred, although many utility waste management

sites at which ground-water monitoring has been done have had at least one exceedance. However, the observed contamination may not necessarily be chronic since sites at which exceedances have been noted do not consistently register in excess of the PDWS.

3. When ground-water contamination does occur, the magnitude of the exceedance is generally not large. Most PDWS exceedances tend to be no more than 10 or 20 times the PDWS, although a few observations greater than 100 times the PDWS have been noted.

4. Human populations are generally not directly exposed to the groundwater in the vicinity of utility coal combustion waste management sites. Public drinking water intakes are usually at least a few kilometers away. Also, most power plants are located near surface water bodies that dilute the concentration of any elements found in the ground water.

5. Because high-volume and low-volume waste streams are often co-disposed, it cannot be determined if one specific waste stream was the source of contamination.

6. The ground-water quality information on which this evidence is based is limited. Data were only available from a small number of utility waste management sites; no comprehensive database on ground-water contamination potentially attributable to coal combustion wastes exists.

7.2.6 Evidence of Damage

1. There are few cases considered to be documented evidence of damage from coal combustion wastes. Among these cases there is some dispute whether any observed damage can be attributed to the utility waste management facility.

2. Damage cases are dominated by chronic incidents (seepage, periodic runoff) as opposed to catastrophic incidents (sudden releases, spills), although one documented damage case was due to structural failure of a surface impoundment.

3. Documented damage typically involves physical or chemical degradation of ground water or surface water, including fish kills or reduction in biota, but seldom involves direct effects on human health because the water is not consumed for drinking water purposes. Much of the damage has occurred in the immediate vicinity of the waste management site; drinking water intakes are generally far enough away such that any contaminated water is not being directly used for human consumption.

7.2.7 Potential Costs of Regulation

1. If additional regulations are promulgated for utility waste management, the total costs incurred by the industry could vary considerably depending on the extent of the additional regulations.

For example, total annual costs to install and operate ground-water monitoring systems would be unlikely to exceed $10 million. On the other hand, total annual costs for the industry could approach $5 billion if all existing facilities were capped and closed and new facilities were constructed with liners, leachate collection systems, flood protection, and ground-water monitoring. (Corrective action costs, such as excavating all existing facilities for removal of the wastes to RCRA Subtitle C facilities, are not included in this estimate; such costs would be extremely high.)

2. Regulation of utility coal combustion wastes under full RCRA Subtitle C requirements could halt all recycling of coal combustion wastes if recycling was also subject to Subtitle C requirements. Total costs to the industry could approach $2.4 billion annually. If recycled wastes were not subject to Subtitle C disposal requirements, it is possible the amount of recycling could increase as the utility industry increased waste utilization to avoid full Subtitle C disposal costs.

3. The costs to the utility industry for full RCRA Subtitle C compliance could decrease the amount of coal consumed in coal-fired power plants. The costs of generating electricity with coal could increase by several percent (depending on the extent of additional regulations), making it economic to generate electricity with other fuels. These impacts could be felt in two ways: 1) lower coal consumption at existing power plants and 2) construction of fewer coal-fired power plants in the future.

7.3 RECOMMENDATIONS

Based on the findings from this Report to Congress, this section presents the Agency's preliminary recommendations for those wastes included in the scope of this study. The recommendations are subject to change based on continuing consultations with other government agencies and new information submitted through the public hearings and comments on this report. Pursuant to the process outlined in RCRA 3001(b)(3)(C), EPA will announce its regulatory determination within six months after submitting this report to Congress.

First, EPA has concluded that coal combustion waste streams generally do not exhibit hazardous characteristics under current RCRA regulations. EPA does not intend to regulate under Subtitle C fly ash, bottom ash, boiler slag, and flue gas desulfurization wastes. EPA's tentative conclusion is that current waste management practices appear to be adequate for protecting human health and the environment. The Agency prefers that these wastes remain under Subtitle D authority. EPA will use section 7003 of RCRA and sections 104 and 106 of CERCLA to seek relief in any cases where wastes from coal combustion waste disposal sites pose substantial threats or imminent hazards to human health and the environment. Coal combustion waste problems can also be addressed under RCRA Section 7002, which authorizes citizen lawsuits for violations of Subtitle D requirements in 40 CFR Part 257.

Second, EPA is concerned that several other wastes from coal-fired utilities may exhibit the hazardous characteristics of corrosivity or EP toxicity and merit regulation under Subtitle C. EPA intends to consider

whether these waste streams should be regulated under Subtitle C of RCRA based on further study and information obtained during the public comment period. The waste streams of most concern appear to be those produced during equipment maintenance and water purification, such as metal and boiler cleaning wastes. The information available to the Agency at this time does not allow EPA to determine the exact quantity of coal combustion wastes that may exhibit RCRA Subtitle C characteristics. However, sufficient information does exist to indicate that some equipment maintenance and water purification wastes do occasionally exhibit RCRA hazardous characteristics, and therefore, may pose a danger to human health and the environment. These wastes are similar to wastes produced by other industries that are subject to Subtitle C regulation, and waste management practices for coal combustion wastes are often similar to waste management practices employed by other industries. EPA is considering removing the exemption for all coal-fired utility wastes other than those identified in the first recommendation. The effect would be to apply Subtitle C regulation to any of those wastes that are hazardous by the RCRA characteristic tests. EPA believes there are various treatment options available for these wastes that would render them nonhazardous without major costs or disruptions to the utilities.

Third, EPA encourages the utilization of coal combustion wastes as one method for reducing the amount of these wastes that need to be disposed to the extent such utilization can be done in an environmentally safe manner. From the information available to the Agency at this time, current waste utilization practices appear to be done in an environmentally safe manner. The Agency supports voluntary efforts by industry to investigate additional possibilities for utilizing coal combustion wastes.

Through its own analysis, evaluation of public comments, and consultation with other agencies, the Agency will reach a regulatory determination within six months of submission of this Report to Congress. In so doing, it will consider and evaluate a broad range of management control options consistent with protecting human health and the environment. Moreover, if the Agency determines that Subtitle C regulation is warranted, in accordance with Section 3004(x) EPA will take into account the "special characteristics of such waste, the practical difficulties associated with implementation of such requirements, and site-specific characteristics . . .," and will comply with the requirements of Executive Orders 12291 and 12498 and the Regulatory Flexibility Act.

EXECUTIVE SUMMARY

1.0 INTRODUCTION

1.1 BACKGROUND

Section 3001(b)(3)(A)(i) of the Resource Conservation and Recovery Act (RCRA) excludes certain large-volume wastes generated primarily from the combustion of coal or other fossil fuels from being regulated as hazardous waste under Subtitle C of RCRA, pending completion of a Report to Congress required by Section 8002(n) and a determination by the U.S. Environmental Protection Agency (EPA) Administrator either to promulgate regulations under Subtitle C or to deem such regulations as being unwarranted.

In 1988, EPA published the *Report to Congress on Wastes from the Combustion of Coal by Electric Utility Power Plants* (EPA, 1988). The report, however, did not address comanaged utility coal combustion wastes, other fossil fuel wastes that are generated by utilities, and wastes from non-utility boilers burning any type of fossil fuel. Further, because of other priorities, EPA did not complete a regulatory determination on fossil fuel combustion (FFC) wastes at that time.

In 1991, a suit was filed against EPA for failure to complete a regulatory determination on FFC wastes (Gearhart v. Reilly Civil No. 91-2345 (D.D.C.). On June 30, 1992, the Agency entered into a Consent Decree that established a schedule for EPA to complete the regulatory determinations for all FFC wastes. FFC wastes were divided into two categories: (1) fly ash, bottom ash, boiler slag, and flue gas emission control waste from the combustion of coal by electric utilities and independent commercial power producers, and (2) all remaining wastes subject to RCRA Sections 3001(b)(3)(A)(i) and 8002(n). On August 9, 1993, EPA published a determination for the first category of wastes, concluding that regulation under Subtitle C for these wastes was not warranted. To make an appropriate determination for the second category or "remaining wastes," EPA decided that additional study was necessary. Under the current court-ordered deadlines, the Agency must complete this Report to Congress by March 31, 1999, and issue a regulatory determination by October 1, 1999.

In keeping with its court-ordered schedule, and pursuant to the requirements of Section 3001(b)(3)(A)(i) and Section 8002(n) of RCRA, the EPA has prepared this report on remaining FFC wastes. In addition to complying with the Congressional mandate, this report will serve to establish a factual basis for EPA decision-making regarding the appropriate regulatory status, under RCRA, of remaining FFC wastes. The report addresses the following eight study factors required by Section 8002(n) of RCRA for FFC wastes:

1. The source and volumes of such materials generated per year
2. Present disposal practices
3. Potential danger, if any, to human health and the environment from the disposal of such materials
4. Documented cases in which danger to human health or the environment has been proved
5. Alternatives to current disposal methods
6. The costs of such alternatives

7. The impact of those alternatives on the use of natural resources

8. The current and potential utilization of such materials.

In addition, the report includes a review of applicable state and federal regulations so that regulatory decisions that derive from the report will avoid duplication of existing requirements.

1.2 SCOPE AND ORGANIZATION OF THE REPORT TO CONGRESS

This report addresses the remaining wastes from FFC. As defined in the 1992 Consent Decree, remaining wastes comprise the following:

- Fly ash, bottom ash, boiler slag, and flue gas emission control wastes from the combustion of coal by electric utility power plants, when such wastes are mixed with, codisposed, cotreated, or otherwise comanaged with other wastes generated in conjunction with the combustion of coal or other fossil fuels

- Any other wastes subject to Section 8002(n) of RCRA, except fly ash, bottom ash, boiler slag, and flue gas emission wastes from coal combustion by electric utilities.

For the purposes of this report, EPA is addressing the following FFC wastes:

- Comanaged coal combustion wastes, wastes from the combustion of petroleum coke, and wastes from mixtures of coal and other fuels ("coburning") generated by utilities.

- Wastes from the combustion of coal, petroleum coke, and mixtures of coal and other fuels (coburning) generated by non-utilities.

- Wastes from the combustion of coal, petroleum coke, and mixtures of coal and other fuels (coburning) by facilities that employ fluidized bed combustion technology.

- Wastes from the combustion of oil by utilities and non-utilities.

- Wastes from the combustion of natural gas by utilities and non-utilities.

The report is organized into seven chapters that address the study factors required under Section 8002(n) of RCRA. Chapter 2 provides an overview of FFC in the United States, including a brief description of the utility and non-utility sectors and a discussion of projected trends for the industry. Chapters 3 through 7 parallel the categories of remaining wastes listed above in Section 1.2. Chapter 3 focuses on comanaged utility coal combustion waste and also covers coburning by utilities. Chapter 4 examines non-utility coal combustion waste. Chapters 5 and 6 discuss fluidized bed combustion wastes and oil combustion wastes, respectively. Chapter 7 focuses on natural gas combustion wastes. Chapters 3 through 6 each provide overviews of their relevant sectors; describe the wastes generated, their characteristics, and volumes; and examine current waste management practices, potential and documented dangers to human health and the environment, existing regulatory controls, waste management alternatives, and costs and economic impacts. Chapter 7 presents a brief overview of natural gas combustion technology (additional discussion of natural gas combustion wastes is not warranted because of minimal waste generation). Finally, each of the chapters presents the Agency's findings and recommendations.

2.0 INFORMATION SOURCES AND METHODS

In conducting this study, EPA gathered publicly available information from a broad range of sources, including federal and state agencies, industry trade groups, environmental organizations, and open literature. EPA reviewed information on each of the Section 8002(n) study factors for each of the FFC waste sectors. For many study factors, very limited information existed prior to this study. Accordingly, EPA worked closely with the Edison Electric Institute's (EEI) Utility Solid Waste Activities Group (USWAG), the Electric Power Research Institute (EPRI), and the Council of Industrial Boiler Owners (CIBO) as those organizations developed new information in support of EPA's decision process. Because other ongoing EPA projects currently focus on portions of the FFC waste generator universe, EPA also leveraged data collection efforts conducted for air, industrial waste, and hazardous waste programs. In addition, EPA maintained contact with a number of environmental organizations to share information and ideas regarding beneficial uses of some FFC wastes and methods of characterizing the risks associated with FFC wastes.

In the Agency's part 1 fossil fuel combustion regulatory determination (58 FR 42466, 8/9/93), the Agency applied a three-step decision-making process. Under this procedure, the Agency first considers the potential impacts of the wastes in question on human health and the environment. If EPA finds there may be significant impact, the Agency next considers whether there is a need for regulation under RCRA Subtitle C in light of existing waste management practices and existing regulatory controls imposed by states under authorities other than Subtitle C. The Agency also considers whether Subtitle C would effectively address problems associated with the waste without imposing significant unnecessary controls. Finally, if the Agency concludes that additional regulation under Subtitle C is warranted, EPA considers the potential economic impacts and affects on operations and beneficial uses of the wastes from such regulation on the industry.

In this report, EPA has continued to consider the factors previously utilized in the three-step decision-making process, since the Agency believes that these factors appropriately reflect the statutory criteria in Section 8002 of RCRA that EPA must consider in issuing this report. The Agency has modified somewhat, however, how those factors are considered in formulating its recommendations. Rather than apply the statutory criteria in rigid, stepwise fashion, EPA has considered the totality of the relevant factors (i.e., the potential environmental and human health impacts, the need, if any, for additional regulation and, finally, the potential impacts of imposing regulation under subtitle C in developing the report's recommendations). The step-wise approach to making regulatory determinations assumes that it is possible to reach readily discernable, yes-or-no decisions regarding each step in the decision-making process. As we gain experience in evaluating Bevill wastes, however, we have learned that such clear-cut answers may not be possible for each individual decision-making criterion, and that it may be necessary to balance all the relevant factors to reach the appropriate recommendation. For example, where a particular waste poses some potential risk, but existing controls are wholly inadequate and regulation under subtitle C would not cause severe economic dislocation, a determination to regulate the waste may be appropriate. Conversely, where a waste poses more substantial risks but existing controls are generally adequate and the costs of subtitle C controls would be substantial, continuing the exemption might be the appropriate outcome. In both cases, each individual decision criterion may not yield a definitive regulatory determination. Instead, considering the totality of the relevant factors would be most likely to yield a rational conclusion consistent with our statutory mandate. Thus, EPA will take this approach in this report and the regulatory determination to follow, which the Agency believes is consistent with the broad decision-making discretion that Congress intended EPA to exercise in making regulatory determinations for Bevill wastes.

To support each of these analytical steps, and to address data limitations, EPA performed a variety of specific analyses. These included human health and ecological risk assessment, analyses of existing federal and state regulatory programs, and economic impact analyses.

3.0 SUMMARY OF FINDINGS: COAL-FIRED UTILITY COMANAGED WASTES

Coal-fired utilities represent the largest single category of fossil fuel combustion, and likewise generate the greatest proportion of FFC wastes. Each year, utilities burn roughly 900-million tons of coal using a variety of conventional combustion technologies. Utility coal usage results in the generation of roughly 100-million tons of large-volume FFC wastes: fly ash, bottom, ash, boiler slag, and flue gas desulfurization (FGD) sludge. These wastes may be managed in landfills and surface impoundments, or, increasingly, may be applied to a variety of beneficial uses.

In addition to large volume wastes, utilities generate a variety of low-volume wastes that result from supporting processes (see Section 3.1.4) that are ancillary to the combustion and power generation processes. Low-volume wastes include the following:

- Coal pile runoff
- Coal mill rejects/pyrites
- Boiler blowdown
- Cooling tower blowdown and sludge
- Water treatment sludge
- Regeneration waste streams
- Air heater and precipitator washwater
- Boiler chemical cleaning waste
- Floor and yard drains and sumps
- Laboratory wastes
- Wastewater treatment sludge.

In 1993, EPA completed its regulatory determination on large-volume wastes from coal-fired electric utilities and independent power producers (IPPs). The regulatory determination permanently exempts large-volume FFC wastes from utilities and IPPs from hazardous waste regulation. However, the exemption only extends to large-volume wastes that are managed alone. Recent studies conducted by EPRI demonstrate that most utility operators comanage some or all of their large-volume wastes with low-volume wastes. Accordingly, remaining wastes include most utility large-volume wastes as they are actually managed.

EPA estimates that there are roughly 600 FFC waste management units operated at approximately 450 coal-fired utility power plants. These units include equal proportions of landfills and surface impoundments, with recent trends suggesting increasing preference for landfills. Nearly all of the surface impoundments are located onsite, while landfills may be onsite or offsite. Based on utility survey data, EPA estimates that more than 80 percent of these operations comanage large- and low-volume wastes.

Individual surface impoundments and landfills may comanage as many as 15 different low-volume waste streams. Surface impoundments typically comanage more different waste types (a median of eight) than do landfills (a median of four). Coal mill rejects are among the most common wastes to be comanaged in landfill and impoundments, while floor drain wastes, coal pile runoff, and water treatment wastes are also commonly disposed in comanaged waste impoundments. The total quantity of low-volume wastes managed in landfills will generally be small compared with the large-volume wastes. In surface impoundments, however, the low-volume wastes may be very large compared with the quantity

of ash disposed. This relative measure largely reflects the volume of water and not the solids content of the low-volume waste.

The size of comanaged waste units ranges from modest to very large, with some surface impoundments covering 1,500 acres or more. Median landfill and surface impoundment capacities are 3.8- and 3.4-million cubic yards, respectively.

Nearly all comanagement units operate under some sort of regulatory permit. Additionally, more than half of landfills and roughly one quarter of impoundments are lined with compacted clay, asphalt, synthetic, or other type of liner. Significantly, the newer the management unit the more likely it will possess modern environmental controls, such as liners, monitoring requirements, cover requirements, and other features.

In addition to traditional waste management in landfills and surface impoundments, utility coal combustion wastes can be used in a variety of applications. Categories of beneficial use include cement and concrete products, construction fills (including structural fill, flowable fill, and road base), agricultural uses, waste management applications, mining applications, and incorporation into other products. Overall, these uses reportedly account for nearly 30 percent of annual waste generation nationwide. Given the prevalence of comanagement, EPA believes that much of these wastes may be comanaged wastes.

In the 1988 Report to Congress and 1993 Regulatory Determination, EPA evaluated whether large-volume wastes exhibited any of the four characteristics of hazardous waste: corrosivity, reactivity, ignitability, and toxicity. EPA determined that large-volume utility coal combustion wastes are unlikely to be corrosive, reactive, or ignitable. EPA also found that metals generally are not found in leachate above the toxicity characteristic (TC) levels.

Based on limited available data, EPA concludes that comanaged wastes also generally are not corrosive, reactive, ignitable, or toxic. Available data on low-volume waste characteristics show that some low-volume wastes occasionally exhibit RCRA corrosivity (regeneration wastes, boiler chemical cleaning wastes) and RCRA toxicity (coal pile runoff, regeneration wastes, boiler chemical cleaning wastes). However, most comanaged waste units predominantly contain large-volume wastes and/or dilute low-volume waste waters, reducing the likelihood that the combined wastes will exhibit hazardous characteristics. Further, waste characterization data collected from comanaged waste landfills and impoundments show no exceedences of TC levels in any TCLP sample of comanaged wastes, and exhibit only infrequent exceedences of TC levels in *in situ* pore water samples from some impoundments.

EPA also found that coal mill rejects containing pyritic sulfur may result in the generation of acidic leachate from comanaged wastes that exceeed TC levels. In fact, most of the exceedences of TC levels observed in *in situ* pore water samples from comanaged waste impoundments appear to be associated with oxidation of pyrites contained in coal mill rejects.

EPA examined the risks associated with comanaged wastes and focused on metals as constituents of concern. The Agency used the *Composite Model for Leachate Migration with Transformation Products v1.2* (EPACMTP) to evaluate the potential risks associated with human ingestion of contaminated ground water. Additionally, EPA used an integrated, multi pathway exposure model to examine human health and ecological risks from inhalation, ingestion, and direct contact to contaminated media above ground.

EPA selected the EPACMTP to model the movement in ground water of metals of concern released from waste landfills and surface impoundments. Waste management scenarios were developed for use with EPACMTP using site-specific, industry-wide, and general nationwide information to estimate values for parameters describing waste and management unit properties (e.g., unit size, waste density), unit environmental settings (e.g., recharge rate, soil properties, ground-water velocity), and contaminant properties (e.g., retardation factors). Each scenario was used to predict the peak metals concentrations expected to occur in a nearby drinking water well during a 10,000-year study period. Comparing the predicted peak concentration with health-based benchmarks, EPA estimated the risk to an individual receptor exposed through ingestion of contaminated drinking water.

EPA calculated estimated risks for each scenario by selecting combinations of variables most likely to produce high-end (to include the 95th percentile of all possible risks) results. EPA then performed probabilistic modeling to determine where the deterministic results fell within a distribution of estimated risks. Finally, EPA performed sensitivity analyses to improve its confidence in the overall estimate of risks.

Overall, EPA found that the ground-water pathway risks associated with all modeled constituents of concern, except for arsenic, fell below a hazard quotient of 1 or a lifetime cancer risk of 1×10^{-6}. Potential risks associated with arsenic in the landfill and the surface impoundment high-end deterministic scenarios were 3×10^{-4} and 5×10^{-4}, respectively. Monte Carlo probabilistic risks for the landfill and impoundment were 4×10^{-5} and 2×10^{-5}, respectively. For arsenic, the risk for young children increased roughly 25 percent compared to the adult receptors.

EPA also considered the time at which risks were predicted to result from the release of constituents of concern in each of the scenarios. EPA found that the concentration of arsenic in ground water at the receptor well would not reach the health-based level for arsenic (e.g., achieve a risk level of 1×10^{-6}) for roughly 500 years. For the landfill, the predicted time to reach a risk of 1×10^{-6} or more was found to exceed 3,500 years.

As in the case for the ground-water risk assessment, EPA conducted a broad above-ground risk assessment to estimate potential risks associated with direct and indirect exposure to wastes and waste contaminated media. Using the Indirect Exposure Methodology (IEM), EPA estimated the concentration of constituents of concern in air, soils, and plant and animal tissues resulting from airborne and waterborne releases of comanaged wastes. EPA then estimated the human health risks associated with exposure to the contaminated media for a wide range of exposure scenarios. To provide confidence in its model results, EPA conducted sensitivity analyses for each scenario, constituent, and receptor, focusing in particular on those driving parameters for which only limited information was available.

EPA found no risks from the ingestion exposure route in excess of 10^{-6} (cancer), or with hazard quotients in excess of 1, except for arsenic in the case of agricultural applications and when managed in an onsite active landfill. For both the landfill and the impoundment, for arsenic, ingestion risks were found at the 10^{-6} level for both the farmer and the child of the farmer. In the agricultural use scenario, EPA found arsenic risks from this composite and complex pathway to be 5×10^{-5}.

EPA examined potential ecological risks from comanaged waste landfills and impoundments using the modeling results generated for the above-ground human health risk assessment. EPA compared the predicted media concentrations of metals of concern with calculated benchmark values for a wide range of ecological receptors, including mammals, birds, and amphibians, as well as collections of soil, sediment, and surface water organisms. The risk estimates for landfills and land application units suggest that ecological risks associated with the release and surface transport of chemicals of concern are not

likely to be significant for these management/use practices. The risk estimates for comanaged coal ash surface impoundments and associated drainage systems indicate that this scenario is of special concern. In particular, EPA found that the concentrations of some metals of concern (e.g., aluminum, boron, selenium) may be present in surface impoundment waters at levels well in excess of the benchmark values for amphibians, birds, and/or mammals.

EPA reviewed a range of information sources to identify possible cases of documented damages to human health or the environment arising from comanaged waste practices. EPA identified a total of six sites at which comanagement of coal combustion wastes has occurred and which meet one or more "tests of proof" for damage cases. Five of these sites were previously identified in the 1988 Report to Congress and the 1993 Regulatory Determination (58 FR 42473, 8/9/93). A sixth site was more recently identified by EPA. Detrimental effects from these sites included the presence of contaminants in drinking water wells above maximum contaminant levels (MCLs) and vegetative damage in wetlands or streams.

EPA reviewed current state regulations governing management of FFC wastes and found that states currently have more authority to impose controls on utility coal combustion waste management units than in previous years. In addition to regulatory permits, the majority of states are now able to require siting controls, liners, leachate collection systems, ground-water monitoring, closure controls, daily (or other operational) cover, and fugitive dust controls. EPA believes that the use of such controls has the potential to mitigate risks, particularly ground-water pathway risks, from comanaged waste disposal.

The utility sector in recent years has increasingly installed more environmental controls for comanaged waste facilities. Today more than one-half of the landfills and one quarter of the impoundments are lined. Other examples of in-place controls include leachate collection, ground-water monitoring, and operation under regulatory permits, each of which has a high rate of implementation at landfill management units, and significant implementation at surface impoundment management units.

EPA analyzed the costs and economic impacts of a risk mitigation alternative that would require comanaged wastes to be managed in units compliant with RCRA Subtitle D requirements. This alternative was designed to mitigate the potential ground-water human health risks found for unlined management units. The Agency also considered alternatives to mitigate the potential risk from agricultural use of these wastes, including a standard limiting the arsenic concentration in wastes intended for this use.

The alternative technology selected to target the identified risks for landfills and surface impoundments at coal-fired utilities is construction of new, composite-lined units. EPA's estimate of annualized incremental compliance cost for this alternative for the whole industry is from $800 million per year to $900 million per year, with a most likely estimate of $860 million per year. At the individual plant level, incremental compliance costs would reduce net income as a percentage of revenues by 1.5 to 2.1 percent, depending on the plant size. While this incremental cost should not affect the financial viability of coal-fired plants, EPA recognizes that such profit margin reductions may be considered significant by the individual utility. At the industry level, the total incremental cost represents 0.4 percent of the value of sales. Individual operators would likely take this effect into consideration, along with several other factors, in assessing how soon to close marginal coal plants and what type of new plants to build. This implies that a possible effect of the alternative would be a shift to alternative energy sources.

Recommendations: Coal-Fired Utility Comanaged Wastes

Following are the Agency's recommendations for the wastes covered in this chapter. The recommendations are based on EPA's analysis of the eight Congressionally mandated study factors (Section 1.2). These conclusions are subject to change based on continuing information collection, continuing consultations with other government agencies and the Congress, and comments and new information submitted to EPA during the comment period and any public hearings on this report. The final Agency decision on the appropriate regulatory status for these wastes will be issued after receipt and consideration of comments as part of the Regulatory Determination, which will be issued within 6 months.

1. *The Agency has tentatively concluded that disposal of these wastes should remain exempt from RCRA Subtitle C.*

The Agency has tentatively concluded that the comanaged wastes generated at coal-fired utilities, including petroleum coke combustion wastes as well as wastes from other fuels co-fired with coal, generally present a low inherent toxicity, are seldom characteristically hazardous, and generally do not present a risk to human health and the environment. Current management practices and trends and existing state and federal authorities appear adequate for protection of human health and the environment. State programs increasingly require more sophisticated environmental controls, and tend to focus on utility waste management due to the high waste volumes. For example, the frequency of environmental inspections at utilities is among the highest of all the major industry sectors in the United States. Most of the landfills and 40 percent of the impoundments implement ground-water monitoring, reflecting the states' focus on this industry sector. In addition, the Agency has identified relatively few damages cases. Although one damage case identified arsenic as a constituent of concern, none of the damage cases affected human receptors. These types of facilities are typically located in areas of low population and thus present infrequent opportunity for human exposure. The industry trend, as detailed in this chapter, is to line waste disposal units and to use dry ash handling techniques at new facilities; dry ash handling eliminates the use of impoundments for waste management. Currently, more than one-half of the active landfills are lined. Although one-quarter of all existing active impoundments are lined, about 45 percent of the impoundments constructed since 1975 have been lined.

If these wastes were listed as hazardous, and therefore regulated under Subtitle C, coal combustion units would be required to obtain a Subtitle C permit, which would unnecessarily duplicate existing State requirements, and would establish a series of waste unit design and operating requirements for these wastes that would most often be in excess of requirements to protect human health and the environment. The estimated total annual cost to mitigate the potential arsenic risk identified in this study exceeds $800 million. This cost does not represent implementation of full Subtitle C controls, but rather Subtitle C requirements modified by RCRA 3004(x) factors to target the identified risks. The Agency estimates that the total cost of full Subtitle C controls would be several times this amount. Full Subtitle C controls include location restrictions, manifesting, liners, leachate collection, ground-water monitoring, covers, dust control, closure controls, financial assurance, and corrective action.

For these reasons, EPA tentatively concludes that Subtitle C is inappropriate to address any problems associated with disposal of these wastes and that the continued use of site and region specific approaches by the states is more appropriate for addressing the limited human health and environmental risks that may be associated with disposal of these wastes. For the issues discussed below involving agricultural use and management of these wastes in mines (minefill), the Agency is still considering whether some regulation under RCRA Subtitle C may be warranted.

The Agency identified several situations where pyrite materials (sulfur-bearing components of mill rejects) comanaged with coal combustion wastes might have been of concern. The pyritic waste materials had turned acidic and may have caused localized environmental damage. One such situation is considered to be a damage case. While mismanagement of these pyritic wastes can theoretically cause problems because of their inherent chemical properties, such evidence is rare, and the Agency has no means of systematically evaluating the extent to which they would cause or contribute to risks. To address the problem management situations, the Agency has engaged the utility industry in a program to ensure that these particular wastes are appropriately managed, as reflected in the industry's development of technical guidance and an industry education program concerning proper management of pyritic materials. The Agency is encouraged by the industry program, and has tentatively concluded that additional regulation of pyrite disposal is not necessary. EPA, however, will follow-up with oversight on the industry's progress with management of these wastes, and will revisit this issue if necessary.

The Agency identified potential ecological risks from selenium (mammals), although potential risks were also found from arsenic (birds), aluminum (amphibians), and boron (amphibians) for coal combustion wastes that are comanaged in surface impoundments. While the waters in surface impoundments can theoretically pose risks to birds, mammals, and amphibians exposed to them, the Agency has no actual information about the scale and frequency at which receptors are actually exposed, and therefore cannot quantify the magnitude of the actual ecological impacts at these facilities. No documented or anecdotal ecological impact information was available with which to compare with the risk modeling results. Moreover, the Agency was unable to identify any feasible risk mitigation practices for these very large impoundments other than to continue to rely on the Clean Water Act new source standards to move the industry toward dry handling of the coal combustion wastes. (Dry handling methods do not involve surface impoundments and therefore do not present the ecological risks identified for impoundments.) Outright elimination of the large impoundments would impose extremely high costs on the operators. The benefits to be derived from elimination of impoundments are uncertain due to unavailability of information on actual receptor exposure rates and impacts as described above. The Agency solicits information on the practices and techniques that may be effective in mitigating the potential ecological risks, considering the large surface areas involved at these facilities.

2. *The Agency has tentatively concluded that most beneficial uses of these wastes should remain exempt from RCRA Subtitle C.*

No significant risks to human health and the environment were identified or believed to exist for any beneficial uses of these wastes, with the possible exception of minefill and agricultural use as discussed below. This is based on one or more of the following reasons for each use or resulting product: absence of identifiable damage cases, fixation of the waste in finished products which immobilizes the material, and/or low probability of human exposure to the material.

3. *The Agency is tentatively considering the option of subjecting practices involving the use of these wastes for agricultural purposes (i.e., as a soil nutrient supplement or other amendment) to some form of regulation under Subtitle C.*

As mentioned above, the Agency identified potential risk from exposure to arsenic in these wastes when they are used for agricultural purposes. The risks identified with this practice are of sufficient concern to consider whether some form of control under Subtitle C is appropriate, given the increasing trend for use of these materials as agricultural amendments. An example of such controls could include regulation of the content of these materials such that arsenic concentrations could be no higher than that found in agricultural lime. On the other hand, imposition of controls under Subtitle C may not be warranted if sufficient protection may be afforded by the Agency engaging the industry to

establish voluntary controls on this practice. An example of such voluntary controls could consist of an agreement to limit the level of arsenic in these materials. The Agency solicits comment on its tentative conclusion and specific approaches that could be pursued to address the concern. While the part 1 regulatory determination exempted all beneficial uses for the large-volume coal combustion wastes, the tentative conclusion for the comanaged wastes would also affect the status of the part 1 wastes for agricultural use. This is because the source of the identified risk is the metal content of the coal combustion wastes. The Agency has no information indicating that any of the comanaged low-volume wastes significantly affect the identified potential risks and, therefore, the risks should be comparable for the wastes subject to the part 1 regulatory determination. Additionally, the Agency considers its current risk analysis for this practice to be more thorough than that conducted for the part 1 wastes, and accordingly believes it proper to reconsider the part 1 wastes in this respect.

As indicated in the summary above, although the practice of minefilling these wastes is within the scope of this study, the Agency currently lacks sufficient information with which to adequately assess risk associated with this practice. Several factors make the practice of minefilling difficult to assess. First, minefill is occurring in areas where there are often pre-existing environmental concerns, such as acid mine drainage. With its existing data the Agency is unable to determine if elevated contaminants in ground water are due to minefill practices, or rather are associated with pre-existing problems or conditions. Second, although minefill in a surface pit has similarities to landfill situations we have modeled, both surface and subsurface minefill raises complexities beyond the landfill model. Third, these operations, with their pre-existing concerns, may require very site-specific determinations that do not lend themselves to national standards.

The Agency solicits comment on whether there are some minefill practices that are universally poor and warrant specific attention. For example, the Agency has found several situations where cement kiln dust placed in direct contact with the ground-water table has created problems. EPA specifically seeks comment on whether coal or other fossil fuel combustion wastes used as minefill and placed in direct contact with the water table would create other environmental concerns, and if that specific practice should be regulated. Last, with a few exceptions, use of these wastes as minefill is generally a recent practice and therefore long-term practices and environmental data cannot be assessed. The potential for risks associated with this practice may be of sufficient concern to consider whether some form of control under Subtitle C is appropriate, given the increasing trend for use of these materials as minefill. The Agency's focus is on potential risks that may be posed via the ground-water and surface pathways from use of these wastes as minefill. The Agency solicits additional information in the form of additional case studies of actual minefill situations, with the following types of information: minefill project design including areal extent, volumes, depth, environmental controls, mine spoils mixing ratio; characterization of combustion wastes that are involved; the background, pre-existing conditions in ground water at the mine location; and the depth to ground water at the mine location. The Agency is also interested in obtaining information on analytical modeling tools that can simulate fractured flow conditions and facilitate prediction of alkalinity consumption by acid mine drainage intrusion into the combustion wastes. The Agency will consider such comments and information in the formulation of the Regulatory Determination.

4.0 SUMMARY OF FINDINGS: NON-UTILITY COAL COMBUSTION WASTES

Coal-fired non-utilities use the same combustion technologies and fuels as coal-fired utilities. As a result, they generate the same large-volume and low-volume combustion wastes as utilities. In addition, non-utilities have the potential to generate a wide range of process wastes unrelated to the combustion of fossil fuels. These process wastes may be disposed along with combustion wastes.

Coal-fired non-utilities include a larger number of facilities than utilities. Non-utility boilers, however, are smaller in size than utility boilers and include a larger percentage of stoker (as opposed to pulverized coal) boilers. As a result, these facilities use less fuel than utilities. Non-utilities also less frequently use particulate control and flue gas desulfurization (FGD) technologies. As a result of these factors, non-utilities as a population generate much lower quantities of coal combustion waste than do utilities; large-volume coal combustion wastes at non-utilities represent about 6 percent of the amount of similar wastes generated by utilities.

EPA believes that non-utility coal combustion waste characteristics are similar to those of utility coal combustion wastes and that metals are the class of constituents of concern. A comparison of leachate concentrations of metals from the available data representing non-utility wastes suggests that differences are not significant for the purpose of evaluating risk to human health and the environment. Based on the observed similarity of non-utility and utility coal combustion wastes, EPA relied on data for comanaged utility coal combustion wastes to characterize non-utility coal combustion wastes. Comanaged waste data were chosen, rather than data representing large-volume non-utility coal combustion wastes alone, because of the high rate of comanagement at non-utilities and because the comanaged waste data are more extensive.

The predominant management practice for non-utility coal combustion waste is landfilling. Few facilities operate surface impoundments. The available data also suggest a larger proportion of offsite landfills (including commercial facilities) for non-utilities than for utilities. Comingling of large-volume coal combustion wastes and other wastes at non-utilities appears to be as common as at utilities. Low-volume combustion wastes comanaged include the same types reported for utilities, although coal mill rejects in particular are comanaged less frequently at non-utilities. Non-utilities also comingle combustion wastes with a wide variety of noncombustion wastes.

Based on the lower waste generation rates at non-utilities, non-utility landfills are expected to be much smaller than those for utility coal combustion wastes. The available data for onsite landfills suggest these units may less frequently employ environmental controls (particularly liners) than do utility landfills. No data are available on the offsite landfills that manage non-utility coal combustion wastes. Many of these units, however, are expected to be commercial industrial or municipal waste landfills that accept a variety of other wastes and are subject to state solid waste management requirements.

The available data indicate that non-utilities sometimes apply their coal combustion wastes in beneficial uses, including agricultural use and minefilling. EPA believes that nearly all of the beneficial uses applied by utilities also are applicable to non-utility wastes.

EPA modeled potential risks to human health and the environment from non-utility coal combustion wastes managed in small unlined, onsite landfills and applied to agricultural use. In assessing ground-water risks, EPA found that potential high-end risks associated with all modeled constituents of concern, except for arsenic, fell below a hazard quotient of 1 or a lifetime cancer risk of

1×10^{-6}. Potential high-end risks associated with arsenic exceeded 1×10^{-4}. EPA found, however, that the concentration of arsenic in ground water at a receptor well would not achieve a risk level of 1×10^{-6} for 1,400 years. In assessing above-ground multi-pathway risks, EPA found no plausible risks except in agricultural applications, where risks would be similar to those for utility coal combustion wastes.

EPA identified four Superfund Records of Decision involving non-utility coal combustion wastes (codisposed with other wastes). Two of these cases met the "test of proof" for a damage case. In both of these cases, noncombustion wastes are codisposed with coal combustion wastes and the source of the coal combustion waste (utility or non-utility) is unspecified. In one of these cases, the available information does not implicate, or rule out, contributing influences from coal combustion wastes. In the second case, an area used as a fly ash waste pile is identified as a potential source of risk. EPA also reviewed information for about 50 additional sites collected from conversations with state personnel and the review of facility-specific files at state offices. At these latter sites, although releases of waste have been documented and ground-water monitoring results show exceedences of standards in some cases, documentation was not available that would satisfy the "test of proof" for damage cases.

Currently 44 states (representing 87 percent of non-utility coal-fired electrical generating capacity) duplicate the federal policy exempting coal combustion wastes from hazardous waste regulation. Therefore, the majority of non-utility coal combustion wastes would be subject to state solid (non-hazardous) waste requirements because they do not fail the hazardous waste tests and/or are generated in the 44 states that duplicate the federal exemption. These requirements are expected to be essentially the same as those applicable to utility coal combustion wastes—the majority of states have the authority to require permits and to impose physical controls and monitoring requirements on non-utility landfills, at least on a case-by-case basis. The available data on waste management practices suggest that states have exercised their authority to impose controls, although perhaps to a lesser extent at non-utilities than at utilities.

EPA examined in greater detail state requirements in five states (Indiana, Pennsylvania, Wisconsin, North Carolina, and Virginia) accounting for more than 20 percent of coal-fired non-utility electrical generating capacity. EPA found that state requirements have become more stringent over time. States, however, vary in their approaches to regulating landfills that may manage non-utility coal combustion wastes. For example, programs in Indiana and Pennsylvania impose requirements tailored to the characteristics of the waste. North Carolina may impose requirements based on site-specific modeling. In Virginia, requirements apply generically to all industrial wastes. Wisconsin may modify its requirements specifically for landfills designed to receive coal combustion ash. In several of the states studied, coal combustion wastes may be disposed of in landfills that are "grandfathered" out of liner and other requirements.

EPA analyzed the costs and economic impacts of a risk mitigation alternative that would require non-utility coal combustion wastes to be managed in units compliant with RCRA Subtitle D requirements. The Agency also considered alternatives to mitigate the potential risk from agricultural use of these wastes, including a standard limiting the arsenic concentration in wastes intended for this use. EPA has not estimated the costs for such an approach, but believes they would be minimal because of the small quantity of waste that would be affected.

The risk mitigation alternative would require non-utility coal combustors that currently operate unlined landfills to construct new, composite-lined landfills or transport waste to an offsite commercial Subtitle D landfill. EPA's estimate of annualized incremental compliance cost for this alternative for all coal-fired non-utilities is $103 million per year. Facilities in the food processing, pulp and paper, chemical manufacturing, primary metals, and transportation equipment sectors would bear the majority

of these costs. The costs would affect only a small percentage of facilities in each of these sectors (i.e., those that operate coal-fired boilers) At average-sized facilities in these industries, incremental compliance costs would represent 0.2 percent to 0.5 percent of facility sales, depending on the industry. At large facilities in each sector, which are more likely those that operate coal-fired boilers, incremental compliance costs would represent 0.1 percent or less of facility sales. This should not affect the financial viability of individual plants. At the industry level, the total incremental cost represents an even smaller percentage of sales because of the small number of facilities affected compared to the total number in each industry sector.

Recommendations: Non-Utility Coal Combustion Wastes

Following are the Agency's recommendations for the wastes covered in this chapter. The recommendations are based on EPA's analysis of the eight Congressionally mandated study factors (Section 1.2). These conclusions are subject to change based on continuing information collection, continuing consultations with other government agencies and the Congress, and comments and new information submitted to EPA during the comment period and any public hearings on this report. The final Agency decision on the appropriate regulatory status for these wastes will be issued after receipt and consideration of comments as part of the Regulatory Determination, which will be issued within 6 months.

1. *The Agency has tentatively concluded that disposal of these wastes should remain exempt from RCRA Subtitle C.*

As with the utility coal combustion wastes addressed in Chapter 3, the Agency has tentatively concluded that the non-utility CCWs, including wastes from petroleum coke combustion and from other fuels that are co-fired with coal, and also low-volume wastes where they are managed with the combustion wastes, generally present a low inherent toxicity, are seldom characteristically hazardous, and generally do not present a risk to human health and the environment. State programs increasingly require more sophisticated environmental controls at these types of facilities. There are few damage cases and none of the identified damage cases exclusively involved these wastes or affected human receptors. These types of facilities are typically located in areas of low population and thus present infrequent opportunity for human exposure. The Agency believes that no significant ecological risks are posed by disposal of these wastes. The predominant practice is to manage these wastes in landfills, with a much lower frequency of using impoundments. Environmental controls are common at the landfills. For example, nearly all implement ground-water monitoring and runoff controls, and two-thirds have leachate collection. Overall, the Agency believes that when these wastes are disposed, regulation under Subtitle C authority is not warranted. For the issues discussed below involving agricultural use and management of these wastes in mines (minefill), the Agency is still considering whether some regulation under RCRA Subtitle C may be warranted.

There is a very small segment of non-utility coal burners that generates mill rejects, a low-volume waste, that may be comanaged with the CCWs. The Agency has the same concerns about the potential for problem management situations involving pyritic materials as described for utilities in Chapter 3. Although the Agency did not identify any of these situations at non-utility facilities during this study, it is engaging the non-utility sector in a program to ensure that these particular wastes are appropriately managed. This effort parallels the pyrites management program described for utilities in Chapter 3. EPA will follow-up with oversight on the industry's management of these wastes, and will revisit this issue if necessary.

2. *The Agency has tentatively concluded that most beneficial uses of these wastes should remain exempt from Subtitle C.*

No significant risks to human health and the environment were identified or believed to exist for any beneficial uses of these wastes, with the possible exception of minefill and agricultural use as discussed below. This is based on one or more of the following reasons for each use or resulting product: absence of identifiable damage cases, fixation of the waste in finished products which immobilizes the material, and/or low probability of human exposure to the material.

3. The Agency is tentatively considering the option of subjecting practices involving the use of these wastes for agricultural purposes (i.e., as a soil nutrient supplement or other amendment) to some form of regulation under Subtitle C.

As mentioned above, the Agency identified potential risk from exposure to arsenic in these wastes when they are used for agricultural purposes. The risks identified with this practice may be of sufficient concern to consider whether some form of control under Subtitle C is appropriate, given the increasing trend for use of these materials as agricultural amendments. An example of such controls could include regulation of the content of these materials such that arsenic concentrations could be no higher than that found in agricultural lime. On the other hand, imposition of controls under Subtitle C may not be warranted if sufficient protection may be afforded by the Agency engaging the industry to establish voluntary controls on this practice. An example of such voluntary controls could consist of an agreement to limit the level of arsenic in these materials. The Agency solicits comment on its tentative conclusion and specific approaches that could be pursued to address the concern.

Non-utility burners of coal, particularly those that generate significant quantities of combustion wastes, may have opportunities for their wastes to be minefilled, that is, permanently placed in mine voids similar to the practice with some utility combustion wastes. As discussed in Chapter 3, the Agency currently lacks sufficient information with which to adequately assess risk associated with this practice and, therefore, to decide whether this practice should remain exempt from Subtitle C. For the same reasons discussed in Chapter 3's recommendations, the Agency solicits comment on whether there are some minefill practices that are universally poor and warrant specific attention. EPA also seeks comment on whether coal or other fossil fuel combustion wastes used as minefill and placed in direct contact with the water table would create environmental concerns, and if that specific practice should be regulated. The Agency's focus is on potential risks that may be posed via the ground-water and surface pathways from use of these wastes as minefill.

5.0 SUMMARY OF FINDINGS: FLUIDIZED BED COMBUSTION WASTES

Fluidized bed combustion (FBC) is an emerging technology for the combustion of fossil and other fuels. In FBC processes, fuel is burned on a bed of incombustible material (e.g., sand and limestone) while combustion air is forced upward at high velocities, making the particles flow as a fluid. Coal is the most common fossil fuel burned by FBC facilities, although some facilities burn waste coal, petroleum coke, or other fuels. The bed material often includes a sorbent, such as limestone, that allows the capture of sulfur oxides without the end-of-stack scrubbers often required for conventional coal combustion processes.

FBC makes up only a small portion of the fossil fuel combustion universe—approximately 1 percent of fossil fuel-fired capacity. As of December 1996, there were 84 facilities with 123 FBC boilers representing 4,951 megawatts of equivalent electrical generating capacity (CIBO, 1997). Together, these facilities generated more than 9-million short tons of FBC wastes, or roughly 10 percent of the volume of FFC wastes generated by conventional coal-fired utilities.

Like conventional coal boilers, FBC boilers generate fly ash and bottom ash (called bed ash). FBC fly ash and bed ash contain noncombustible mineral matter, sorbent material, and unburned carbon. The major constituents of FBC waste are calcium, sulfur, silicon, iron, aluminum, magnesium, and potassium. As with conventional coal combustion waste, most of these constituents are present in the form of oxides. Due to the presence of sorbent material, however, FBC wastes have a higher content of calcium and sulfate and a lower content of silica and alumina than conventional coal combustion wastes (CIBO, 1997).

Based on the TCLP and EP data, FBC wastes rarely exhibit RCRA characteristic toxicity. Only one FBC site of 24 (4 percent) for which data are available had any samples of waste for which TCLP or EP analyses exceeded the regulatory threshold any metal. At that site, a facility that burns waste coal, one sample of fly ash exceeded the threshold for mercury. Similarly, no sample from seven sites analyzed for organics exceeded a threshold value.

The Council of Industrial Boiler Owners (CIBO) report that landfilling is the most common FBC waste disposal practice. While four FBC waste surface impoundments have been identified, EPA believes the impoundments represent unusual cases. FBC waste landfills are smaller than conventional utility landfills, with a median fill capacity of 1.5-million cubic yards. Nearly all of the landfills for which data are available are permitted disposal units, and roughly half of the landfills are lined.

Like conventional coal combustion wastes, FBC wastes may be applied to useful purposes as an alternative to traditional waste management. In fact, according to CIBO survey statistics, the majority of FBC wastes currently are beneficially used. The most dominant use of these wastes is in minefills (61 percent), followed by waste stabilization (6 percent), construction fills (5 percent), and agricultural uses (1 percent). Overall, roughly 75 percent of all FBC wastes may be beneficially reused.

As with coal-fired utility comanaged wastes, EPA examined the potential human health and ecological risks associated with the disposal of FBC wastes. For the ground-water exposure pathway, EPA modeled the risks associated with landfills. Overall, EPA found that the risks associated with all modeled constituents of concern, except for antimony, arsenic, beryllium, and chromium, fell below a hazard quotient of 1 or a lifetime cancer risk of 1×10^{-6}. Potential risks associated with arsenic in the

high-end deterministic scenario exceeded 1×10^{-4}. Probabilistic results for all of these metals were more than 1 order of magnitude lower than the deterministic results at the same confidence level.

EPA also considered the time at which risks were predicted to result from the release of constituents of concern. EPA found that the concentration of arsenic in ground water at the receptor well would not reach the health-based level for arsenic (i.e., achieve a risk level of 1×10^{-6}) for more than 3,000 years. The times to reach the antimony health-based level and the beryllium MCL in ground water were predicted to be nearly 6,000 years and greater than 6,500 years, respectively.

EPA found no ingestion risks in the above-ground human health risk assessment except for the FBC agricultural use scenario. In the agricultural use scenario, EPA found arsenic risks from this composite and complex pathway to be at five times the 10^{-5} level, for both the farmer and the child of farmer receptors.

EPA found no ecological risks associated with FBC wastes. In addition, EPA found no documented cases of damage associated with FBC waste management.

EPA reviewed current state regulations governing management of FFC wastes and found that states currently have more authority to impose controls on UCCW management units than in previous years. In addition to regulatory permits, the majority of states are now able to require siting controls, liners, leachate collection systems, ground-water monitoring, closure controls, daily (or other operational) cover, and fugitive dust controls. EPA believes that the use of such controls has the potential to mitigate risks, particularly ground-water pathway risks, from comanaged waste disposal.

States increasingly have begun to impose controls on FBC waste management units. In addition to regulatory permit programs, the majority of states now have the authority to require siting controls, liners, leachate collection systems, ground-water monitoring, closure controls, daily or other operational cover, and fugitive dust controls for management of these wastes.

EPA analyzed the costs and economic impacts of a risk mitigation alternative that would require FBC wastes that are currently disposed of to be managed in units compliant with RCRA Subtitle D requirements. The Agency also analyzed the cost of a ban on minefilling and agricultural use for FBC wastes, requiring wastes currently destined for these uses also to be managed in Subtitle D units.

The risk mitigation alternative would require FBC facilities that currently operate unlined landfills to construct new composite-lined landfills or transport waste to an offsite commercial Subtitle D landfill. EPA's estimate of annualized incremental compliance cost for this alternative for all FBC facilities is $32 million per year for currently disposed quantities of waste. If the quantities of FBC waste currently used in minefilling and agricultural applications also were subject to the Subtitle D-based alternative, the additional incremental compliance cost would be an estimated $52 million per year (for a total of some $84 million per year). Other approaches, such as a limit on the arsenic concentration in FBC wastes destined for agricultural use, would substantially reduce this latter cost.

EPA analyzed economic impacts *excluding* costs for quantities currently used in minefilling and agriculture. Half of the potentially affected FBC facilities are in the electric service industry (i.e., independent power producers and utilities). At individual facilities in this sector, incremental compliance costs would reduce net income as a percentage of revenues by 1.4 percent to 1.7 percent, depending on the plant size. While this incremental cost should not affect the financial viability of coal-fired plants, EPA recognizes that such profit margin reductions may be considered significant by the individual firm. At the industry level in the electric service sector, the total incremental cost represents

0.3 percent of the value of sales. In other industrial/institutional sectors, FBC facilities represent an even smaller share of their industries than do conventional non-utility combustors. Thus, individual facility impacts and industry level impacts in these sectors would be similar to or less than those discussed for coal-fired non-utilities.

Recommendations: Fluidized Bed Combustion Wastes

Following are the Agency's recommendations for the wastes covered in this chapter. The recommendations are based on EPA's analysis of the eight Congressionally mandated study factors (Section 1.2). These conclusions are subject to change based on continuing information collection, continuing consultations with other government agencies and the Congress, and comments and new information submitted to EPA during the comment period and any public hearings on this report. The final Agency decision on the appropriate regulatory status for these wastes will be issued after receipt and consideration of comments as part of the Regulatory Determination, which will be issued within 6 months.

1. *The Agency has tentatively concluded that disposal of these wastes should remain exempt from RCRA Subtitle C.*

As with the utility and non-utility coal combustion wastes addressed in Chapters 3 and 4, the Agency has tentatively concluded that FBC wastes, including wastes from petroleum coke combustion and from other fuels that are co-fired with coal, and also low-volume wastes where they are managed with the combustion wastes, generally present a low inherent toxicity, are seldom characteristically hazardous, and generally do not present a risk to human health and the environment. State programs increasingly require more sophisticated environmental controls at these types of facilities. For example, most all of the FBC landfills are subject to regulatory permits and ground-water monitoring requirements; nearly all implement dust suppression and runon/runoff controls. No documented damage cases were identified and no significant ecological risks were identified. These types of facilities are typically located in areas of low population and thus present infrequent opportunity for human exposure. Although arsenic was identified from EPA modeling to pose a potential risk at unlined landfills, there were no documented problem or damage cases identified with arsenic as a constituent of concern. The predominant practice is to manage these wastes in landfills, with a much lower frequency of using impoundments. Nearly half of the landfills are lined and more than half have leachate collection systems and covers. Overall, the Agency believes that regulation under Subtitle C authority is not warranted when these wastes are disposed. For the issues discussed below involving agricultural use and management of these wastes in mines (minefill), the Agency is still considering whether some regulation under RCRA Subtitle C may be warranted.

2. *The Agency has tentatively concluded that most beneficial uses of these wastes should remain exempt from Subtitle C.*

No significant risks to human health and the environment were identified or believed to exist for any beneficial uses of these wastes, with the possible exception of minefill and agricultural use as discussed below. This is based on one or more of the following reasons for each use or resulting product: absence of identifiable damage cases, fixation of the waste in finished products which immobilizes the material, and/or low probability of human exposure to the material.

3. The Agency is tentatively considering the option of subjecting practices involving the use of these wastes for agricultural purposes (i.e., as a soil nutrient supplement or other amendment) to some form of regulation under Subtitle C.

As mentioned above, the Agency identified potential risk from exposure to arsenic in these wastes when they are used for agricultural purposes. The risks identified with this practice may be of sufficient concern to consider whether some form of control under Subtitle C is appropriate, given the increasing trend for use of these materials as agricultural amendments. An example of such controls could include regulation of the content of these materials such that arsenic concentrations could be no higher than that found in agricultural lime. On the other hand, imposition of controls under Subtitle C may not be warranted if sufficient protection may be afforded by the Agency engaging the industry to establish voluntary controls on this practice. An example of such voluntary controls could consist of an agreement to limit the level of arsenic in these materials. The Agency solicits comment on its tentative conclusion and specific approaches that could be pursued to address the concern..

A significant amount of FBC waste, about 60 percent, is used for minefill. Of this amount, large quantities are used specifically for reclamation of old surface coal mine working. EPA recognizes that mine reclamation practices with the highly alkaline FBC wastes can have some significant, positive environmental benefits. For example, the FBC wastes contribute to neutralizing acid mine drainage at the old mine workings, and when mine reclamation activities are completed, new productive uses may be made of the land. The Agency also realizes that there are a number of well-managed state mine reclamation programs that oversee the application of FBC wastes. RCRA, however, does require the Agency to review the management of these wastes. As discussed in Chapter 3's recommendations, the potential for risks associated with this practice may be of sufficient concern to consider whether some form of control under Subtitle C is appropriate, given the increasing trend for use of these materials as minefill. The Agency, however, currently lacks sufficient information with which to adequately assess risk associated with this practice and therefore to decide whether this practice should remain exempt from Subtitle C. The Agency solicits comment on whether there are some minefill practices that are universally poor and warrant specific attention. For example, the Agency has found several situations in which cement kiln dust placed in direct contact with the ground-water table has created problems. EPA also seeks comment on whether coal or other fossil fuel combustion wastes used as minefill and placed in direct contact with the water table would create environmental concerns, and if that specific practice should be regulated. The Agency's focus is on potential risks that may be posed via the ground-water and surface pathways from use of these wastes as minefill.

6.0 SUMMARY OF FINDINGS: OIL COMBUSTION WASTES

Oil combustion wastes (which include fly ash and bottom ash) are generated in significant quantities only when residual fuel oil is burned in oil-fired steam electric boilers. Other technologies (e.g., combustion turbines) and fuels (e.g., distillate oil) generate little or no wastes. Overall, oil combustion wastes are generated in much smaller quantities than other large-volume fossil fuel combustion wastes. Oil-fired utilities, as opposed to non-utilities, generate the majority (more than 80 percent) of these wastes. The majority of oil combustion waste generation and management also takes place in the Northeast, mid-Atlantic, and Florida, consistent with the use of oil by utilities to provide baseload power supplies in these regions.

Metals are the class of constituents of concern in oil combustion wastes. These wastes can contain high levels of vanadium and nickel, and varying levels of other metals. Oil combustion wastes, however, only infrequently exhibit the RCRA characteristic of toxicity (6 percent of available samples). Exceedences for arsenic, cadmium, chromium, lead, and/or selenium were observed in at least one sample from seven (or 18 percent) of the 40 sites for which data were available.

The common management practices at oil-fired utilities include onsite settling basins and offsite landfills, with a few onsite landfills (monofills managing only oil combustion wastes) represented. The most common practice for oil bottom ash is to collect it dry and transport it to an offsite landfill. Fly ash, on the other hand, typically is sluiced wet to an onsite solids settling basin (SSB) where it is managed along with low-volume liquid wastes such as equipment washwaters and boiler chemical cleaning wastes. Solids from these basins are typically dredged on an "as-needed" basis and transported to an offsite landfill. Oil combustion wastes have not been used extensively for beneficial use applications similar to those reported for other fossil fuel combustion wastes. Several oil-fired utilities, however, have reported sending their waste offsite for vanadium recovery as an alternative to offsite landfilling, when economically viable.

Oil combustion waste management units typically are much smaller than those for utility coal combustion wastes. About two-thirds of the SSBs for which data were available are lined. The unlined SSBs are percolation basins permitted under state regulations to discharge to ground water. Limited data for SSBs suggest a trend toward the increasing use of liners. The few onsite landfills observed are lined or partially lined. No data are available on the offsite landfills that manage oil combustion wastes. Because of the small quantities of oil combustion waste generated, however, these units are expected to be commercial industrial or municipal waste landfills that accept a variety of other wastes and are subject to state solid waste management requirements.

EPA modeled potential risks to human health and the environment from oil combustion wastes managed in small, unlined landfills and surface impoundments (solid settling basins). In assessing ground-water risks, EPA found that potential high-end risks associated with arsenic exceeded 1×10^{-5}. For nickel and vanadium, potential high-end hazard quotients exceeded 1. In assessing above-ground multi-pathway risks, EPA found a potential risk at the low 10^{-6} level for arsenic ingestion for a child living near an onsite landfill. No non-groundwater risks were found for the solid settling basins.

EPA identified a total of nine sites managing oil combustion wastes that have ground-water contamination. Only one of these sites, however, met the test of proof for a damage case. The level of contamination at these sites was not always above MCLs or other state standards. In no case was there evidence that the contaminated ground-water is used as drinking water.

Only 26 states extend the federal exemption from hazardous waste requirements to oil combustion wastes. These 26 states, however, represent more than 80 percent of oil-fired utility capacity and, therefore, the majority of waste generation. These states vary in their application of solid (non-hazardous) waste management requirements to oil combustion waste management units. EPA examined state requirements in the states accounting for the greatest share of oil-fired utility capacity (Florida, New York, Massachusetts, and Pennsylvania). EPA found that, in two of these states, oil combustion wastes may be disposed of in landfills that are "grandfathered" out of liner and other requirements. Three of the four states do not impose specific design requirements on the solids settling basins typically used to store oil combustion wastes. Two of these states permit discharges to ground water from these units.

EPA analyzed the costs and economic impacts of a risk mitigation alternative that would require oil combustion wastes to be managed in units compliant with RCRA Subtitle D requirements. Most significantly, this alternative would require oil-fired utilities that currently operate unlined solids settling basins to construct new, composite-lined basins. EPA's estimate of annualized incremental compliance cost for this alternative for the whole industry is from $1.0 million per year to $3.5 million per year, with a most likely estimate of $1.7 million per year. At the individual plant level, incremental compliance costs would reduce net income as a percentage of revenues by 0.1 percent to 0.4 percent, depending on the plant size. This reduction should not affect the financial viability of individual oil-fired plants. At the industry level, the total incremental cost represents less than one-tenth of 1 percent of the value of sales. Thus, the cost of compliance would be a very small percentage of revenues.

Recommendations: Oil Combustion Wastes

Following are the Agency's recommendations for the wastes covered in this chapter. The recommendations are based on EPA's analysis of the eight Congressionally mandated study factors (Section 1.2). These conclusions are subject to change based on continuing information collection, continuing consultations with other government agencies and the Congress, and comments and new information submitted to EPA during the comment period and any public hearings on this report. The final Agency decision on the appropriate regulatory status for these wastes will be issued after receipt and consideration of comments as part of the Regulatory Determination, which will be issued within 6 months.

1. *The Agency is considering two approaches to address the potential risks that may be posed by disposal of these wastes. One approach would be regulatory using Subtitle C authority and the other would be to encourage voluntary changes in industry practices.*

The Agency found in many cases that OCWs, whether managed alone or comanaged with low-volume wastes, are seldom characteristically hazardous and may not present a significant risk to human health and the environment. These cases include situations in which the wastes are managed in lined units with adequate cover. The Agency believes that no significant ecological risks are posed by disposal of these wastes. Only one damage case was identified and it did not affect human receptors.

In light of the results of EPA's risk assessment, however, the Agency is concerned about situations in which the wastes are managed in unlined units, particularly comanagement in settling basins and impoundments that are designed and operated to discharge to ground water. As discussed in this chapter, the Agency's risk analysis suggests that three metals may pose potential ground-water pathway risks at such facilities: arsenic, nickel, and vanadium. While there is a trend in recent years to line new units and the Agency has anecdotal information that some facilities are preparing to either line or close their unlined units, the Agency has particular concerns with the high levels of nickel and vanadium in the wastes and in the leachate that is being discharged to ground water. The Agency's risk analysis

identified high hazard quotients and short time periods to exceedence of health-based risk criteria at potential ground-water receptor locations for nickel and vanadium. The risks identified with these practices may be of sufficient concern to consider whether tailored regulations are necessary to target the potential risks. On the other hand, since the recent industry and state regulatory trends have been toward liners and ground-water monitoring for these waste disposal units, sufficient protection may be obtained by facilitating this trend and engaging the industry to voluntarily establish the appropriate controls. An example would be to line the existing unlined units and, where appropriate, to implement ground-water monitoring. The Agency solicits comment on its tentative conclusion, specific approaches that could be pursued to address these concerns, and the identification of only one damage case.

2. *The Agency has tentatively concluded that the existing beneficial uses of these wastes should remain exempt from Subtitle C.*

There are few existing beneficial uses of these wastes, which include components of cement, concrete, and construction fill as discussed in this chapter. No significant risks to human health exist for the identified beneficial uses of these wastes. This is based on one or more of the following reasons for each use: absence of identifiable damage cases, fixation of the waste in finished products which immobilized the material, and/or low probability of human exposure to the material. In the case of vanadium recovery operations, a valuable product is being produced; however, if the wastes resulting from the metal recovery processes are hazardous, they will be subject to the existing hazardous waste requirements.

Unlike coal combustion wastes, these wastes are not known to be used in minefill or agricultural applications. These wastes are not generated at rates high enough to justify their transport and use for filling mine voids. There are no known benefits to using these wastes for agricultural purposes.

7.0 SUMMARY OF FINDINGS: NATURAL GAS COMBUSTION WASTES

Natural gas is the second most significant fossil fuel used by utilities in the United States. In 1996, gas-fired units accounted for approximately 20 percent of utility generating capacity, but only 9 percent of utility electricity generated. This generation rate represents a decline of 15 percent from the level reported in 1995 due in part to a substantial increase in the cost of gas in 1996. (Use of hydroelectric, oil-fired, and geothermal sources increased in 1996 to make up for the decrease in use of gas) (EIA, 1998). Many gas-fired units are used to generate power during periods of peak demand.

Gas-fired units generate virtually no solid waste. Thus, although a significant portion of capacity is represented by gas combustors, this study does not include extensive analysis of natural gas combustors. The Agency intends to continue the exemption from Resource Conservation and Recovery Act (RCRA) Subtitle C for gas combustors.

Natural gas combustion accounts for a substantial fraction of both utility and non-utility generating capacity. Natural gas combustion technologies are similar to those used for oil combustion. In gas-fired steam electric boilers, gas is injected into the furnace in the presence of excess air. The same burner designs used for oil also are used to inject and combust natural gas. In fact, many combustion units can utilize either oil or gas. Unlike oil, natural gas does not require preparation (atomization) for mixing with combustion air (Stultz and Kitto, 1992). Because of its negligible ash content, combustion of natural gas generates virtually no solid waste; therefore, this study focuses primarily on coal-fired and oil-fired combustors.

Recommendations: Natural Gas Combustion Wastes

Following are the Agency's recommendations for the wastes covered in this chapter. The recommendations are based on EPA's analysis of the eight Congressionally mandated study factors (Section 1.2). These conclusions are subject to change based on continuing information collection, continuing consultations with other government agencies and the Congress, and comments and new information submitted to EPA during the comment period and any public hearings on this report. The final Agency decision on the appropriate regulatory status for these wastes will be issued after receipt and consideration of comments as part of the Regulatory Determination, which will be issued within 6 months.

1. *The Agency has tentatively concluded that it will retain the Subtitle C exemption for natural gas combustors.*

The Agency has tentatively concluded that it will retain the Subtitle C exemption for natural gas combustors. The Agency solicits comment on whether it is appropriate to retain or remove the Subtitle C exemption for natural gas combustion since there are no solid wastes generated by the process.

GLOSSARY*

ACAA – American Coal Ash Association.

air heater or **air preheater** – device that uses flue gases to preheat combustion input air.

air heater and precipitator washwater – wastes resulting from the periodic cleaning of the fireside (i.e., the side exposed to hot combustion products) of heat exchanging surfaces.

air monitoring system – periodic collection and analysis of air samples near a waste management unit.

alkalinity – the amount of carbonates, bicarbonates, hydroxides, and silicates or phosphates in a liquid. Reported as grains per gallon, pH, or parts per million of carbonate. Indicated by a pH of greater than 7.

anthracite – a hard black lustrous rank of coal (see coal rank).

APC – air pollution control.

ash – incombustible material in fuel that can become waste after combustion.

ash fusion temperature – the temperature at which a cone of coal or coke ash exhibits certain melting characteristics.

ASTM – American Society for Testing and Materials.

ASTSWMO – Association of State and Territorial Solid Waste Management Officials.

backfill – a project in which an excavation area is refilled with earth or other materials.

BACT – Best Available Control Technology under the Clean Air Act.

baghouse – an air pollution abatement device used to trap particulates by filtering gas streams through large fabric bags usually made of glass fibers.

baseload – that portion of electricity demand from a station or boiler that is practically constant for long periods.

baseload unit – an electrical generating unit that is used to supply baseload, and thus is operated continuously at an essentially constant rate.

BAT – Best Available Technology Economically Achievable under the Clean Water Act.

bed ash – spent bed material and fuel ash (bottom ash) that settle on the bottom of an FBC boiler.

bituminous coal – A common dense black rank of coal (see coal rank).

* References for this glossary include EIA, 1997d; EPA, 1988; CIBO, 1997c, and Stultz and Kitto, 1992.

BMP – best management practice under the Clean Water Act.

boiler – a closed vessel in which heat from an external combustion source (such as a fossil fuel) is transferred to produce hot water or generate steam.

boiler blowdown – waste generated by removal of a portion of boiler water for the purpose of reducing solid concentration or discharging sludge.

boiler chemical cleaning waste – waste resulting from the cleaning of boiler surfaces using chemical solutions.

boiler slag – melted and fused particles of ash that collect on the bottom of the boiler. Slag forms when operating temperatures exceed ash fusion temperature.

bottom ash – large ash particles that settle on the bottom of a boiler. Bottom ash does not melt and therefore remains in the form of unconsolidated ash.

BPT – Best Practicable Control Technology Currently Available under the Clean Water Act.

Btu – British Thermal Unit, a unit of heat energy.

bubbling fluidized bed system – a fluidized bed combustion system in which excess air passes through the bed in the form of bubbles. These systems have air velocities of 5 to 12 feet per second and larger bed particle size than circulating fluidized bed systems. These conditions result in a dense bed (45 pounds per cubic foot) with a well-defined surface.

Bunker C fuel oil – a residual fuel oil, also characterized as No. 6 fuel oil, which is used for commercial and industrial heating, electricity generation, and to power ships.

CAA – Clean Air Act.

CCW – coal combustion waste.

CERCLA – the Comprehensive Environmental Response, Compensation, and Liability Act, commonly referred to as Superfund.

CIBO – Council of Industrial Boiler Owners.

circulating fluidized bed system – a fluidized bed system that has high air velocities (as high as 30 feet per second) and fine particle sizes. As a result, the fluid bed is less dense (35 pounds per cubic foot) and has no well-defined top surface. Large quantities of bed material are recaptured from the gas stream and recirculated back to the furnace to maintain bed inventory.

CMTP – Composite Model for Leachate Migration with Transformation Products.

coal cleaning – the act of processing coal prior to combustion to change its characteristics (e.g., size, ash content, and/or sulfur content).

coal pile runoff – surface water runoff produced by precipitation falling on coal storage areas.

coal mill rejects – solid waste produced by onsite processing of coal in a mill prior to use.

coal rank – a system of classifying coal corresponding to its degree of metamorphism, geologic age, and heating value. Ranks include anthracite, bituminous, subbituminous, and lignite, with anthracite being the oldest and lignite being the youngest.

cogeneration – the production of electricity and another form of useful thermal energy (steam or hot water) from a single source.

combustion turbine (CT) – a system that uses exhaust from combustion (typically of oil or natural gas) directly to drive turbines.

compaction – the act of compacting waste after placement to reduce or prevent wind and water erosion of the waste and subsequent release to the environment.

condenser – a device that converts low-pressure steam back to water by transferring heat to a cooling water system.

cooling tower/cooling pond – recirculating cooling water system used to transfer heat picked up in the condenser to the atmosphere by evaporative cooling.

cooling tower basin sludge – solids that collect in the bottom of cooling towers and must be removed periodically and disposed.

cooling tower blowdown – water withdrawn from the cooling system in order to control the concentration of impurities in the cooling water.

corrosivity – see RCRA Subtitle C characteristics.

cover – a barrier placed on top of a waste management unit.

culm – refuse from the cleaning of anthracite coal.

CWA – Clean Water Act.

cyclone furnace – A combustion technology that creates a cyclone-like air circulation pattern causing smaller particles to burn in suspension, while larger particles adhere to a molten layer of slag that forms on the barrel walls.

demineralizer regenerant and rinses – see regeneration waste streams.

dioxin – general term for polychlorinated dibenzo-p-dioxins (PCDDs), a class of toxic chemicals.

distillate fuel oil – one of the petroleum fractions produced in conventional distillation operations. Included are products known as No. 1, No. 2, and No. 4 fuel oils.

dry scrubber – a flue gas desulfurization system in which the resulting byproduct is a dry, typically fine, powder.

dust suppression/control – conditioning waste with water or other liquid before and during transport and placement to prevent airborne transport of the waste and to reduce inhalation exposure to site workers.

economizer – a device for transferring heat from combustion exhaust to boiler input water.

EEI – Edison Electric Institute.

EEI database – 1994 EEI Power Statistics Database.

EIA – The U.S. Department of Energy's Energy Information Association.

electrostatic precipitator (ESP) – an air pollution control device that imparts an electrical charge to particulates in a gas stream, causing them to collect on an electrode.

EP – Extraction Procedure.

EPACMTP – EPA's Composite Model for Leachate Migration with Transformation Products.

EPRI – Electric Power Research Institute.

fabric filter – see baghouse.

FGD – flue gas desulfurization.

flue gas – the gaseous products of combustion that exit a boiler through a flue or stack.

flue gas desulfurization (FGD) technology – device that is used to remove sulfur oxides from flue gas after combustion.

flue gas desulfurization (FGD) waste – waste that is generated during the process of removing sulfur oxide gas from the flue gas after combustion.

fluidized bed combustion (FBC) – a combustion process in which fuel is burned on a bed of incombustible material (e.g., sand and limestone) while combustion air is forced upward at high velocities, making the particles flow as a fluid.

fly ash – suspended, uncombusted ash particles carried out of the boiler along with flue gases.

fossil fuel – a naturally occuring organic fuel, including coal, oil, and natural gas.

Furan – general term for polychlorinated dibenzofurans (PCDFs), a class of toxic chemicals.

generating unit – a combination of one or more boilers operated together to produce electricity or other useable thermal energy. May include one or more turbines, fuel processing systems, and/or air pollution control devices.

gigawatt (GW) – one billion watts.

gob – refuse from the cleaning of bituminous coal.

ground water monitoring system – one or several wells from which samples of ground water are periodically collected and analyzed.

HAP – Hazardous Air Pollutant under the Clean Air Act.

HDPE – high density polyethylene.

ignitability – see RCRA Subtitle C characteristics.

kilowatt (kW) – one thousand watts.

landfill – a facility or part of a facility in which wastes are placed for disposal in or on land.

leachate – the liquid resulting from water percolating through waste.

leachate collection system – a series of drains and tubing placed beneath a waste management unit, typically a landfill, that collect leachate for treatment or disposal.

lift – the depth of a cell in a landfill.

lignite – a brownish-black rank of coal (see coal rank).

lime – calcium oxide (CaO).

limestone – calcium carbonate ($CaCO_3$).

liner – a barrier placed underneath a landfill or on the bottom and/or sides of a surface impoundment.

MCL – maximum contaminant level.

mechanical collector – an air pollution control device that forces a cyclonic flow of the exit gas. This flow causes ash particles to be thrown against the walls of the collector and drop out of the gas.

megawatt (MW) – one million watts.

minefill – a project involving placement of fossil fuel combustion wastes in mine voids, whether for purposes of disposal or for beneficial uses such as mine reclamation.

monofill – a landfill that contains only one type of waste.

NAAQS – National Ambient Air Quality Standards under the Clean Air Act.

natural gas – a fossil fuel consisting of a mixture of hydrocarbon and nonhydrocarbon gases found beneath the Earth's surface.

NESHAP – National Emissions Standards for Hazardous Air Pollutants under the Clean Air Act.

No. 1 fuel oil – A light distillate fuel oil intended for use in vaporizing pot-type burners.

No. 2 fuel oil – A distillate fuel oil for use in atomizing-type burners for domestic heating or for moderate capacity commercial-industrial burner units.

No. 4 fuel oil – a fuel oil for commercial burner installations not equipped with preheating facilities. It is used extensively in industrial plants. This grade is a blend of distillate fuel oil and residual fuel oil stocks.

No. 5 fuel oil – a residual fuel oil of medium viscosity.

No. 6 fuel oil – a residual fuel oil used for commercial and industrial heating, electricity generation, and to power ships. Includes Bunker C fuel oil.

non-utility – for purposes of this study, an entity that combusts fossil fuel and whose primary commercial activity is not the production of electricity (see utility).

NPDES – National Pollution Discharge Elimination System under the Clean Water Act.

NSPS – New Source Performance Standards under either the Clean Water Act or Clean Air Act.

OCW – oil combustion waste.

particulates – fine liquid or solid particles such as dust, smoke, mist, fumes, or smog, found in the air or emissions.

PCB – polychlorinated biphenyls, a class of toxic chemicals.

PCDD – polychlorinated dibenzo-p-dioxin.

PCDF – polychlorinated dibenzofuran.

PDWS – Primary Drinking Water Standards established by the Safe Drinking Water Act.

peakload – the maximum electricity demand from a facility or boiler that occurs during a specified period of time.

peakload unit or peaking unit – an electrical generating unit that is used to supply peakload, and thus is used intermittently during periods of high demand.

percolation basin – a surface impoundment in which liquids are allowed to discharge (percolate) into the ground.

petroleum coke – solid carbaceous residue remaining in oil refining stills after the distillation process.

PM – particulate matter.

pore water – interstitial water from borings of waste managed in surface impoundments.

POTW – Publicly Owned Treatment Works.

pozzolanic – forming a strong, slow-hardening cement-like substance when mixed with lime or other hardening material.

PSD – prevention of significant deterioration under the Clean Air Act.

PSES – Pretreatment Standards for Existing Sources under the Clean Water Act.

pulverized coal (PC) boiler or pulverizer – a combustion technology that burns finely ground coal in suspension.

PVC – polyvinyl chloride.

pyrites – iron sulfide (FeS_2) minerals that may oxidize during the combustion process to generate sulfur oxide gases. Pyrites may be a component of coal mill rejects.

RCRA – Resource Conservation and Recovery Act, as amended (Pub. L. 94-580). The legislation under which EPA regulates solid and hazardous waste.

RCRA Subtitle C characteristics – criteria used to determine if an unlisted waste is a hazardous waste under Subtitle C of RCRA.

> corrosivity – a solid waste is considered corrosive if it is aqueous and has a pH less than or equal to 2 or greater than or equal to 12.5, or if it is a liquid and corrodes steel at a rate greater than 6.35 millimeters per year at a test temperature of 55°C.
>
> toxicity – a solid waste exhibits the characteristic of toxicity if, after extraction by a prescribed EPA method, it yields a metal concentration 100 times the acceptable concentration limits set forth in EPA's primary drinking water standards.
>
> ignitability – a solid waste exhibits the characteristic of ignitability if it is a liquid with a flashpoint below 60°C or a non-liquid capable of causing fires at standard temperature and pressure.
>
> reactivity – a waste is considered reactive if it reacts violently, forms potentially explosive mixtures, or generates toxic fumes when mixed with water, or if it is normally unstable and undergoes violent change without deteriorating.

reactivity – see RCRA Subtitle C characteristics.

regeneration waste streams – wastes resulting from periodic cleaning of ion exchange beds used to remove mineral salts from boiler makeup water.

reinjection – the act of returning fly ash to a boiler to use any residual carbon content as fuel.

residual fuel oil – the heavier oils that remain after the distillate fuel oils and lighter hydrocarbons are distilled away in refinery operations. Included are No. 5 fuel oil, Navy Special, and No. 6 fuel oil (which includes Bunker C fuel oil).

RIA – Regulatory Impact Analysis.

run-on and runoff control and collection system – Run-on controls prevent precipitation runoff from other parts of a site from reaching waste management areas. Runoff controls and collection systems prevent precipitation runoff from the waste management unit from being transported offsite.

scrubber – an air pollution control device used to remove particulates or contaminant gases from flue gas (see wet scrubber and dry scrubber).

SDWS – Secondary Drinking Water Standards established by the Safe Drinking Water Act.

SIC – Standard Industrial Classification.

SIP – State Implementation Plan under the Clean Air Act.

slag – molten or fused solid matter.

sluice water – liquid used to transport combustion waste or other material.

sluiced ash – combustion waste that has been transported using liquid.

slurry – a mixture of insoluble matter in a fluid.

SPLP – Synthetic Precipitation Leaching Procedure.

spray canal – recirculating cooling water system used to transfer heat picked up in the condenser to the atmosphere by evaporative cooling.

SSB – solids settling basin.

Standard Industrial Classification (SIC) code – a code developed by the U.S. government that categorizes businesses into groups with similar economic activities.

steam electric boiler – a system that combusts fuel in a boiler to produce steam, which in turn is used to provide heat or steam or drive turbines.

stoker – a combustion technology using a mechanically operated fuel feeding mechanism to distribute solid fuel over a grate for combustion.

subbituminous coal – an intermediate ranked coal between lignite and bituminous with more carbon and less moisture than lignite (see coal rank).

superheater – a device that follows a boiler and uses exhaust gases from combustion to raise the temperature of steam generated in the boiler.

surface impoundment – a facility that is a natural topographic depression, artificial excavation, or diked area formed primarily of earthen materials (although it may be lined with artificial materials), which is designed to hold an accumulation of liquid wastes containing free liquids.

surface water monitoring system – periodic collection and analysis of surface water samples near a waste management unit.

TCLP – Toxicity Characteristic Leaching Procedure.

toxicity – see RCRA Subtitle C characteristics.

TSS – total suspended solids.

UCCW – utility coal combustion waste.

unit – see generating unit or waste management unit.

USWAG – Utility Solid Waste Activities Group.

utility – a private or public organization that generates, transmits, distributes, or sells electricity. For purposes of this study, includes independent power producers regulated under the Public Utility Regulatory Policies Act (PURPA).

waste management unit – a structure, typically a landfill or surface impoundment, in which waste is placed for disposal or storage.

wastewater treatment sludge – waste generated from the treatment in settling basins or other treatment facilities of liquid waste streams.

water treatment sludge – waste resulting from treatment of makeup water for the steam cycle or for non-contact cooling.

watt – a unit of electrical power.

wet scrubber – a device utilizing a liquid, designed to separate particulate matter or gaseous contaminants from a gas stream by one or more mechanisms such as absorption, condensation, diffusion, or inertial impaction.

Fingerprint Analysis of Contaminant Data: A Forensic Tool for Evaluating Environmental Contamination

— Russell H. Plumb, Jr.*

1.0 Introduction

Several studies have been conducted on behalf of the U.S. Environmental Protection Agency (EPA) to identify detection monitoring parameters for specific industries.[1,2,3,4,5] One outcome of these studies was the evolution of an empirical multi-variant contaminant fingerprinting process. This process, Fingerprint Analysis of Leachate Contaminants (FALCON), was developed through the EPA's Technical Support Center (TSC) in response to the need for identifying the source of contaminant plumes. FALCON combines data for several contaminants to develop a distinctive graphical fingerprint or multi-parameter chemical signature. These fingerprint patterns can be used to characterize the source of a contaminant plume, differentiate the contaminant plume from background conditions at the source, and monitor the migration of leachate into the environment. It can be applied to both organic and inorganic contaminants and is effective over a wide range of contaminant concentrations. This data evaluation process is analogous to using fingerprints to identify individuals. However, rather than using the size and location of ridges and swirls on the fingertip, the relative abundance of selected constituents is used to develop distinctive chemical signatures.

The objective of this paper is to demonstrate that FALCON is a quantitative, defensible fingerprinting process. A description of the stepwise FALCON technique is provided in *Section 2.0*. Examples are presented to illustrate the range of situations in which fingerprinting can be applied to characterize the occurrence and distribution of environmental contaminants. These examples were developed using routine monitoring data obtained from a variety of ongoing site characterization and monitoring programs. Case studies of FALCON applications are presented in *Section 3.0*.

2.0 FALCON Procedure

The FALCON procedure is a multi-step process of combining data from two or more measurements to create a distinctive ratio or multi-parameter chemical signature that can be used to characterize a contaminant plume from a particular source. The following example, using data from a dioxin-furan contaminated sawmill site, illustrates the individual steps in this fingerprinting process.

Step 1: Data Review

Data are subjected to an initial review to assess the type and quantity of information available. The data are examined to identify subsets that are representative of the designated source area, background areas, impacted areas, and other potential sources that may be differentiated by fingerprinting. The data are then examined to determine whether there are replicate data to assess the reproducibility of any fingerprint pattern that may be identified. This information may exist as either duplicate analyses, multiple samples from the same area, or samples from the same location over time. The data are also reviewed to ensure each individual set is complete and comparable (there are no missing values, results are expressed in the same concentration units, non-detect limits are specified). Finally, the data are examined for any obvious data quality issues.

Step 2. Data Tabulation

The individual data sets are entered into a spreadsheet to (1) select parameters to be used in the fingerprinting process, (2) prepare graphical plots of the fingerprint patterns, and (3) estimate the statistical reproducibility/comparability of identified fingerprint patterns. In this particular example, the laboratory had reported results for 17 specific dioxin-furan congeners and several "total" congener measurements (e.g., total hexachlorodibenzodioxin). The "total" measurements were excluded from the fingerprint process because the results were vague (specific congeners included in the total were not identified and could not be confirmed with the congener-specific data). Also, Octachlorodibenzodioxin was excluded from the fingerprint because the extremely high concentrations for this specific congener overwhelmed the concentrations for the remaining dioxin-furan congeners. After data review and tabulation, 16 dioxin-furan congeners were selected to develop the sawmill fingerprint. The data from seven soil samples at this site are presented in Table 1. These samples, with a calculated total dioxin-furan congener concentration ranging from 231 nanograms per kilogram (ng/kg) to 1,302,460 ng/kg, were specifically selected to demonstrate the capability of this fingerprinting technique to handle the highly variable contaminant concentrations that can be encountered in a site investigation.

Step 3. Data Normalization

Data used for contaminant fingerprinting are transformed in a multi-step process. First, individual results listed as "not detected" in the original data set are replaced with a numerical value. The convention used in this example is to replace the "ND" result with a value equal to one-half the reported detection limit. Second, a total concentration is calculated for the parameters used in the fingerprint (fingerprint mass). Finally, the reported concentration for each fingerprint constituent in that sample is normalized to the calculated fingerprint mass. Thus, the reported concentrations for the fingerprint constituents are converted to a decimal percentage of the calculated fingerprint mass. The transformed dioxin-furan data for this example are shown in Table 2. The substitution of a numeric value for non-detected constituents and the subsequent data transformation process performs two functions; it permits individual data sets to be plotted on a common y-axis scale for visual inspection of the fingerprint (Step 4) and it permits individual data sets to be statistically compared (Step 5).

Table 1. Dioxin-Furan Monitoring Results for Sawmill Soil Samples*

Dioxin-Furan Congener	Chemical Number	Soil Sampling Locations						
		SM20	SM34	SM41	SM44	SM40	SM46	SM51

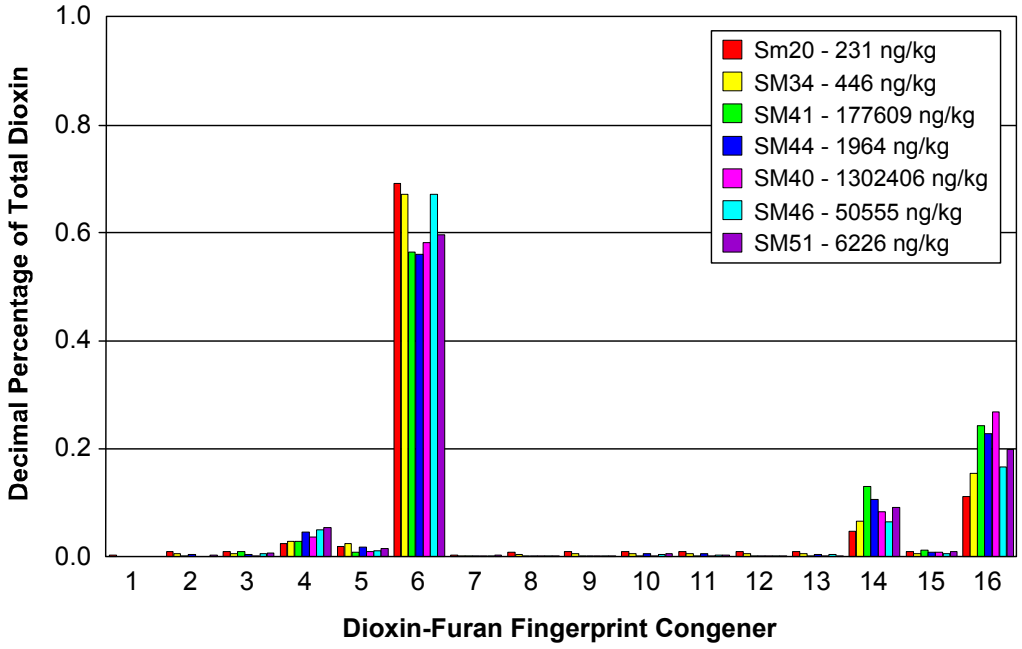
Step 4. Graphical Presentation of Fingerprint

The normalized data in Table 2 are plotted as a series of histograms. The x-axis in these plots is an ordered presentation of the individual fingerprint constituents. The actual order along the x-axis is not critical but it must be consistent in each of the histograms. The y-axis is a plot of the relative abundance of each constituent expressed as a decimal percentage of the calculated fingerprint mass. The data transformation process in Step 3 defines a common y-axis scale of 0.0 to 1.0 decimal percent for each data set since no constituent can be less than 0 percent of the fingerprint mass, no constituent can represent more than 100 percent of the fingerprint mass, and the sum of all constituents must be equal to 100 percent of the fingerprint mass. Therefore, each sample histogram can be plotted on the same scale even though the reported concentrations may vary by orders of magnitude. A visual inspection of Figure 1 demonstrates that the seven data sets presented in Table 1 define a single fingerprint pattern characterized by approximately 60 percent constituent 6, approximately 20 percent constituent 16, approximately 10 percent constituent 14, approximately 4 percent of constituent 4 and trace amounts of the remaining 12 constituents. The dioxin-furan congener number along the x-axis of Figure 1 corresponds to the chemical number listed in Tables 1 and 2.



Regression Analysis Comparison of Sawmill Fingerprint Pattern

	SM20	SM34	SM41	SM44	SM40	SM46	SM51
SM20		0.994	0.912	0.930	0.913	0.989	0.962
SM34			0.950	0.965	0.951	0.998	0.986
SM41				0.997	0.992	0.956	0.985
SM44					0.995	0.971	0.994
SM40						0.959	0.985
SM46							0.991
SM51							

Average regression analysis comparison = 0.970.

Figure 1. Graphical representation and regression analysis comparison of a dioxin-furan fingerprint pattern at a sawmill.

Step 5. Statistical Assessment of Pattern Reproducibility

A statistical estimate of the comparability of the individual histograms is calculated using regression analysis. Each histogram is individually compared with the remaining histograms to calculate an r^2 value (regression coefficient squared). The calculated r^2 values fall into the range of 0.00 (the two patterns are totally dissimilar) to 1.00 (the two patterns are identical) and provides a decimal estimate of the reproducibility or comparability of two patterns. This example produced 21 histogram comparisons (SM20 vs. SM34, SM20 vs. SM41, etc.) with calculated r^2 values ranging from 0.912 to 0.998 that are summarized in the Regression Analysis Table in Figure 1. The estimated reproducibility of the dioxin-furan fingerprint shown in Figure 1 is 0.970 ± 0.027 (97 ± 3 percent). Despite the highly variable dioxin-furan concentrations that spanned four orders of magnitude across the sawmill site and the variable number of non-detected congeners within each set, the FALCON process identified a single, reproducible chemical signature that characterizes the dioxin-furan contamination at this facility.

Step 6. Evaluate Remaining Data

Once a source fingerprint has been identified, regression analysis can be used to compare the dioxin-furan congener distribution at other monitoring locations with the source fingerprint.

These results can be used to:

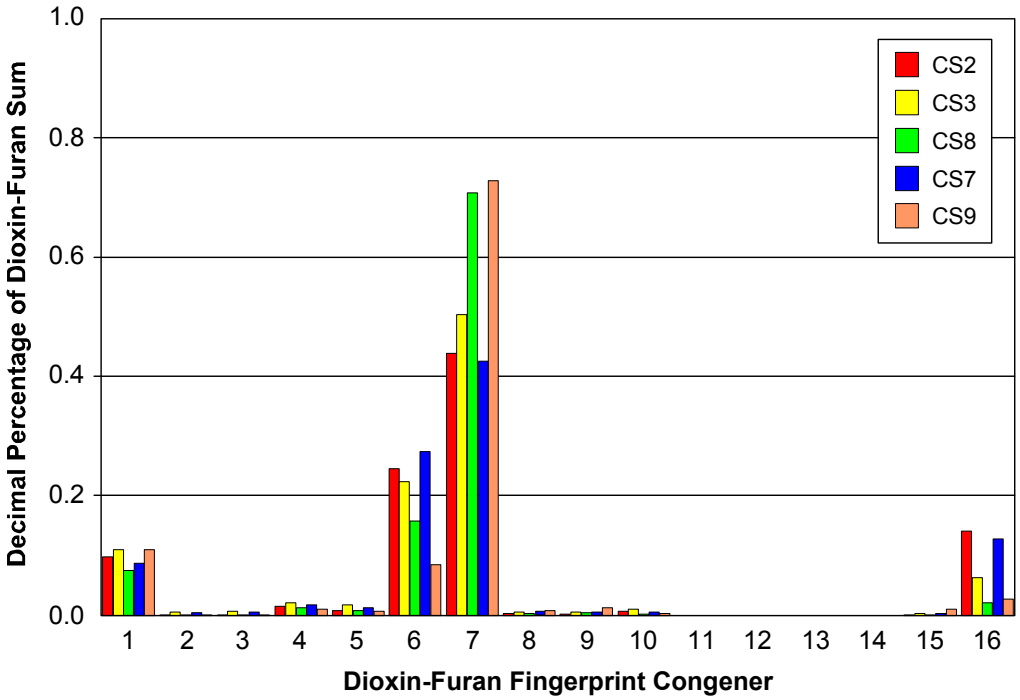
1. differentiate the source from background conditions,
2. demonstrate whether contamination detected at some distance from a site is related to the source,
3. map contaminant migration away from a source,
4. differentiate multiple sources of the same contaminant, and
5. estimate the mixing ratio of two plumes.

3.0 Contaminant Fingerprinting Case Studies

Case studies are presented to illustrate the versatility of FALCON in a variety of contamination scenarios. Data used in these case studies were generated using standard analytical techniques in ongoing site investigation, characterization, and monitoring programs. The intent of these case studies is not to provide detailed site investigation histories for each example, but simply to illustrate the variety of situations in which the FALCON fingerprinting process can be applied to characterize the occurrence and distribution of contaminants.

3.1 Source Characterization of Organic Contaminants - Pulp Mill Case Study

Fingerprinting was conducted to differentiate the impacts of a pulp mill from other potential dioxin-furan sources along the lower Roanoke River in eastern North Carolina. The waste stream from this mill passed through a baffled settling pond and discharged to a tributary of the Roanoke River. Samples were collected from the tributary sediments known to be impacted by the pulp mill. Data from these samples were carried through the FALCON process and produced the dioxin-furan fingerprint pattern shown in Figure 2 (the fingerprint constituents listed by number along the x-axis are identified in Table 1). The 16 dioxin-furan congeners used in this example defined a pattern characterized by 40 to 70 percent constituent 7 (2378-Tetrachlorodibenzofuran), 10 to 25 percent constituent 6 (1234678-Heptachlorodibenzodioxin), 10 percent constituent 1 (2378-Tetrachlorodibenzodioxin), and 2 to 17 percent constituent 16 (Octachlorodibenzofuran (OCDF)).



Regression Analysis for Pulp Mill Fingerprint

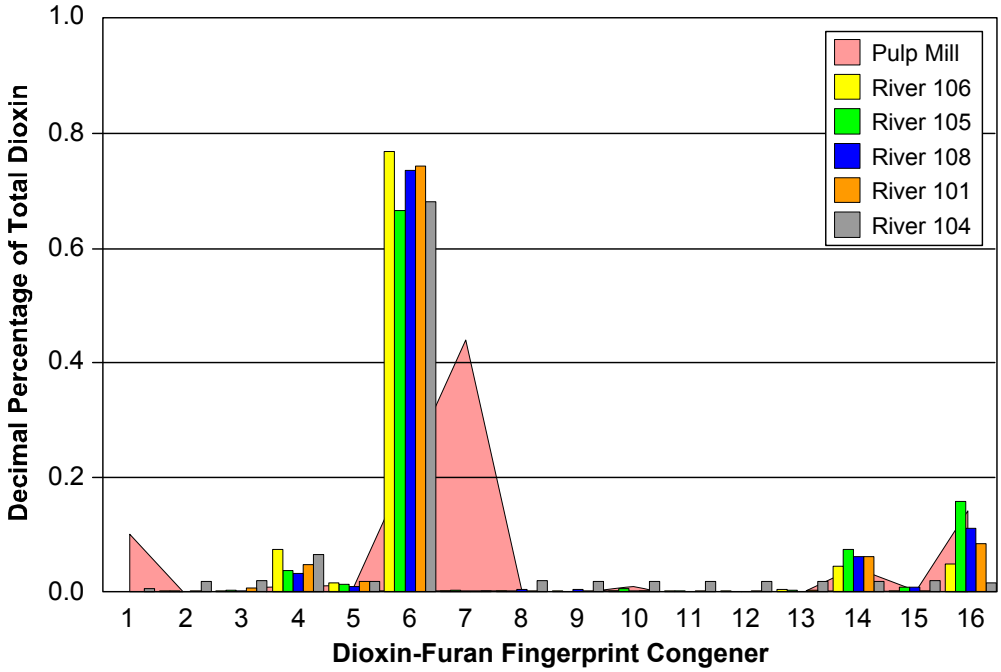
	CS2	CS3	CS8	CS7	CS9
CS2		0.958	0.849	0.993	0.791
CS3			0.948	0.951	0.902
CS8				0.826	0.985
CS7					0.754
CS9					

Average regression analysis comparison = 0.896.

Figure 2. Dioxin-furan fingerprint pattern for a pulp mill effluent.

There were several site-specific factors that influenced the variability of the individual peak heights and the fingerprint pattern for this source. First, the discharge practice to the tributary was terminated in 1987. Changing hydrologic conditions over time (spring runoff, storm events, and tidal cycles) and bioturbation could have affected the dioxin residuals in the sediments. Second, wood fiber accumulation in the sediments complicated the sample collection process. However, despite the possible influence of these factors, the graphical fingerprint for the pulp mill had an estimated reproducibility that ranged from 0.754 (75 percent) to 0.993 (99 percent) with an average value of 0.896 ± 0.08 (90 ± 8 percent).

Roanoke sediment samples were collected upriver from the confluence with the tributary that had been impacted by the pulp mill. These samples defined a second dioxin-furan fingerprint that is contrasted with the pulp mill fingerprint in Figure 3. The upriver sediment fingerprint is presented as a series of histograms and the pulp mill fingerprint is presented as an area plot that was calculated as the average of the tributary samples shown in Figure 2. The upriver sediment fingerprint is characterized by 67 to 78 percent constituent 6 (1234678-HpCDD), 1 to 17 percent constituent 16 (OCDF), 1 to 8 percent constituent 14 (1234678-Heptachlorodibenzofuran), 3 to 6 percent constituent 4, and trace amount of 12 other congeners. The reproducibility of the upriver fingerprint pattern ranged from 0.996 (99+ percent) to 0.999 (99^{+} percent) with an average value of 0.998 ± 0.005 (99+ ± 0.5 percent).



Regression Analysis of Dioxin-Furan Fingerprint Patterns

	River 106	River 105	River 108	River 101	River 104
Pulp Mill	0.063	0.062	0.062	0.061	0.061
River 106		1.000	0.998	0.999	0.998
River 105			0.996	0.998	0.997
River 108				1.000	0.999
River 101					0.999
River 104					

Comparison between mill and upriver sediments = 0.062.
Estimated reproducibility of upriver sediment pattern = 0.998.

Figure 3. Comparison of upriver sediment dioxin-furan fingerprint with the pulp mill dioxin-furan fingerprint.

The presentation in Figure 3 (histogram vs. area plot) permits a rapid visual comparison of the two identified fingerprint patterns at this site. The dioxin-furan fingerprint pattern for the pulp mill impacted tributary and the dioxin-furan fingerprint for the upriver Roanoke sediments can be differentiated both visually and statistically. The Roanoke upriver fingerprint is characterized by a single dominant peak for constituent 6 (1234678-HpCDD) and several minor peaks for constituent 4 (123678-HxCDD), constituent 14 (1234678-HpCDF), and constituent 16 (OCDF). The pulp mill fingerprint is characterized by a major peak for constituent 7 (2378-TCDF), and lesser peaks for constituent 1 (2378-TCDD), constituent 6 (1234678-HpCDD), and constituent 16 (OCDF). The upriver sediment pattern can be distinguished from the pulp mill pattern by the greater relative abundance of constituent 6 (67 to 78 percent versus 10 to 25 percent), the virtual absence of constituent 7 (<1 percent versus 42 to 73 percent), and the virtual absence of constituent 1 (< 1 percent versus 10 percent). For the purpose of this paper, an average pulp mill fingerprint was calculated based on the results presented in Figure 2. This "average" pulp mill fingerprint was compared with each of the Roanoke upriver sediment samples using regression analysis. As summarized in the regression table associated with Figure 3, the comparability of the upriver dioxin-furan fingerprint with the pulp mill dioxin fingerprint ranged from 0.061 (6 percent) to 0.063 (6 percent). A t-Test analysis of the set of r^2 values for the pulp mill and Roanoke sediments comparisons with the set of r^2 values for the Roanoke sediment

reproducibility comparisons demonstrates that the pulp mill dioxin has a significantly different fingerprint pattern at $p = 0.05$. In this case study, FALCON identified a reproducible (90 ± 8 percent) dioxin-furan fingerprint for the pulp mill source (Figure 2), a second highly reproducible (99 ± 0.5 percent) dioxin-furan fingerprint for the upriver source(s) (Figure 3), and the two fingerprint patterns could be easily differentiated both graphically and statistically.

Any dioxin-furan contamination washed out of the tributary will mix with dioxin-furan contamination from the upriver source(s). This will create an unknown mixture of upriver dioxin-furan with pulp mill dioxin-furan in sediments collected below the tributary confluence. Using the two identified FALCON fingerprints, it is possible to calculate the expected congener distribution pattern for possible mixtures of the two source fingerprints. The relative abundance of each congener is known for 100 percent upriver sediment (Figure 3), is known for 100 percent pulp mill waste (Figure 2), and the expected congener distribution was calculated for mixtures of 90 percent upriver sediment plus 10 percent pulp mill waste, 80 percent upriver sediment plus 20 percent pulp mill waste, continuing to 10 percent upriver sediment plus 90 percent pulp mill waste. These results are presented in Table 3 in which each vertical column represents the expected dioxin-furan congener distribution (fingerprint) for the indicated sediment-pulp mill mixture.

If there were no pulp mill dioxin-furan in the lower river sediments, each downriver station would be expected to have a congener distribution pattern similar to the upriver fingerprint (Table 3, 100 percent upriver and 0 percent pulp mill). Therefore, constituent 6 would have a relative abundance of 0.813 (81 percent), constituent 7 would have a relative abundance of 0.016 (2 percent), and the remaining congeners would have the relative abundance indicated. However, if contaminated tributary sediments were entering the river, there would be a characteristic shift in the relative abundance of each congener with increasing amounts of pulp mill dioxin-furan. Thus, the relative abundance of congener 6 would gradually decrease from 0.812 (81 percent) to 0.196 (20 percent) and the relative abundance of congener 7 would simultaneously increase from 0.016 (2 percent) to 0.546 (55 percent) as the mixture changes from 100 percent upriver sediment and 0 percent pulp mill waste to 0 percent upriver sediment and 100 percent pulp mill waste. The relative abundance of each remaining congener in the fingerprint would also be expected to change as indicated in Table 3.

The actual fingerprint pattern in each downriver sample can be compared to the calculated fingerprint patterns in Table 3 using regression analysis. This will produce a range of values for each sample as shown in Table 4. The fingerprint comparison with the best match (maximum r^2 value) provides an estimate of the dioxin-furan mixture at that location. The following examples from Table 4 illustrate the assessment process.

1. The sample from upriver Station R101 produced a match of 0.999 (99+ percent) with the upriver fingerprint. However, this sample only produced a match of 0.924 (92 percent) with the 70 percent upriver - 30 percent pulp mill mixture, a match of 0.437 (44 percent) with the 30 percent upriver - 70 percent pulp mill mixture, and a 0.061 (6 percent) match with the pulp mill fingerprint. Since the maximum fingerprint match for this sample occurred with the 100 percent - 0 percent pulp mill mixture, this location was considered to be 100 percent upriver dioxin-furan.
2. The sample from downriver Station R118 produced a match of 0.904 (90 percent) with the upriver fingerprint and also produced a match of 0.905 (90 percent) with the 90 percent upriver sediment - 10 percent tributary sediment mixture. This sample produced a match of 0.859 (86 percent) with the 70 percent upriver - 30 percent pulp mill mixture, 0.511 (51 percent) with the 30 percent upriver - 70 percent pulp mill mixture, and only 0.198 (20 percent) with the pulp mill fingerprint. Since the maximum fingerprint match for this sample occurred for both the 100 percent upriver sediment - 0 percent tributary sediment mixture and the 90 percent upriver sediment - 10 percent tributary sediment mixture, this location was considered to be 95 percent upriver dioxin-furan and 5 percent pulp mill dioxin-furan.
3. The sample from downriver Station R125 produced a match of 0.718 (72 percent) with the upriver fingerprint. The fingerprint match increased to 0.846 (85 percent) with the 80 percent upriver sediment -

20 percent pulp mill mixture and reached a maximum value of 0.966 (97 percent) with the 50 percent upriver - 50 percent pulp mill mixture. The fingerprint match decreased to 0.846 (85 percent) with the 20 percent upriver - 80 percent pulp mill mixture and 0.662 (66 percent) with the pulp mill fingerprint. This location was considered to have 50 percent upriver dioxin-furan and 50 percent pulp mill dioxin-furan.

4. The sample from downriver station R140 produced a match of only 0.052 (5 percent) with the upriver fingerprint. The fingerprint match increased to 0.231 (23 percent) with the 70 percent upriver - 30 percent pulp mill mixture, 0.696 (70 percent) with the 30 percent upriver - 70 percent pulp mill mixture, and reached a maximum of 0.944 (94 percent) with the pulp mill fingerprint. Since the maximum fingerprint match occurred with the pulp mill source fingerprint, this location was considered to be 100 percent pulp mill dioxin-furan.

The fingerprint analysis results for the lower Roanoke sediment samples are presented in Table 4.

Each of the samples produced a maximum fingerprint match (highlighted and bolded) of 0.832 (83 percent), or higher, with one of the calculated fingerprint patterns. An inspection of Table 4 shows that 90 to 100 percent of the dioxin-furan contamination upriver from the mill could be attributed to upriver sources. However, the influence of the mill is evident downriver from the facility. Samples from downriver stations R120, R127, R128, R143, and R144 have a fingerprint indicating 70 percent upriver dioxin-furan and 30 percent pulp mill dioxin furan. Samples from R133 and R145 have a fingerprint consistent with a 30 percent upriver - 70 percent pulp mill mixture, and samples from R121 and R140 produced a maximum match with the pulp mill source fingerprint (0 percent upriver and 100 percent pulp mill). The spatial variability of the pulp mill dioxin in the downriver samples was attributed to site-specific hydrologic factors such as storm events, channel scouring, tidal effects and eddying. Overall, fingerprinting results from more than 40 downriver locations (only a portion of which are presented in Table 4) indicate that approximately 35 to 40 percent of the dioxin-furan contamination downriver from the tributary confluence could be attributed to the pulp mill. This example demonstrates that the FALCON fingerprinting technique is able to (1) develop a characteristic, reproducible fingerprint for the dioxin-furan source (pulp mill), (2) differentiate pulp mill dioxin-furan from background and/or upriver sources of the same contaminants, (3) quantitatively estimate the mixing that has occurred between pulp mill dioxin-furan and upriver sources, and (4) track the migration of the pulp mill dioxin-furan several miles from the source.

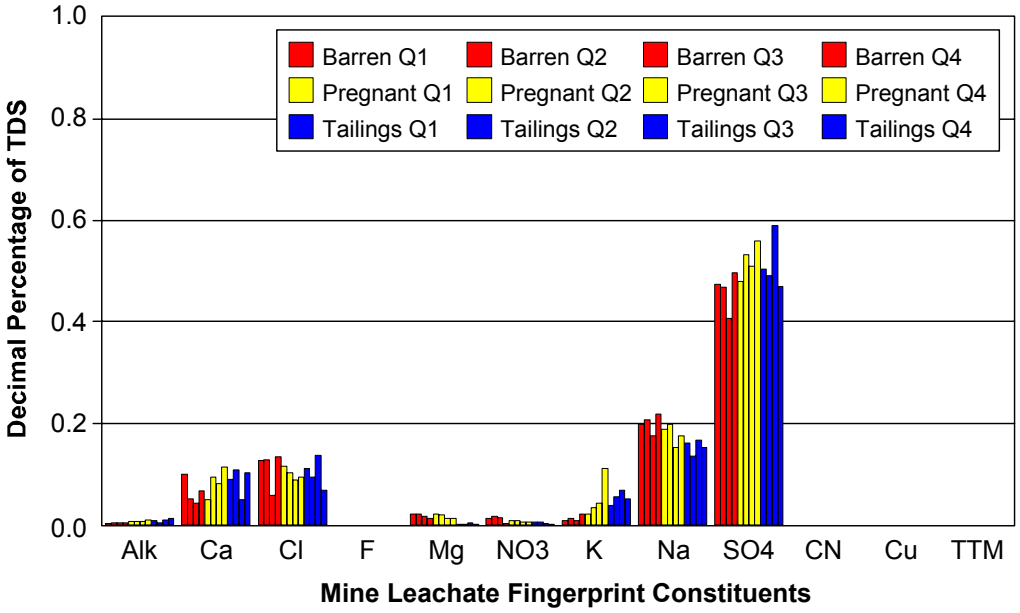
3.2 Inorganic Source Characterization and Leachate Migration Mapping - Gold Mine Case Study

An industry that displayed significant growth in the last quarter of the twentieth century was gold mining utilizing cyanide leaching technology. This process[1] uses a recirculating cyanide solution to extract gold, and other metals, from the ore being processed. An alkaline cyanide solution is prepared in an area referred to as a barren pond. This solution is sprayed on a crushed ore pile to extract gold by complexation as it percolates through the ore. The gold-rich leachate from this process is collected in a second pond referred to as the pregnant pond. Gold and other metals are recovered from the leachate and the cyanide solution is pumped back to the barren pond to repeat the process.

The State of Nevada currently requires heap leaching facilities to conduct quarterly monitoring for 12 geochemical parameters, 28 trace metals, and cyanide at several specified locations (barren pond, pregnant pond, tailings pond, and ground water monitoring wells).[1] Monitoring data from 35 heap leaching facilities were reviewed to develop a better understanding of the composition of mine leachates and to identify a shortened list of potential detection monitoring parameters for this industry.[1] This study demonstrated that nine geochemical parameters were always the most abundant constituents in mine leachates and their relative abundance (expressed as a percentage of total dissolved solids) was a constant at each mine despite the highly variable concentrations. These parameters were alkalinity, calcium, chloride, fluoride, magnesium, nitrate, potassium, sodium, and sulfate.

Data for the nine geochemical parameters specified above from the barren pond, the pregnant pond, and tailings reclaim water at a Nevada heap leaching facility were carried through the fingerprinting process described in *Section 2.0* and plotted as shown in Figure 4. Despite the variability displayed by the individual parameters (e.g., sulfate ranged from 969 to 1720 mg/L, and sodium ranged from 464 to 985 mg/L), the selected parameters define a distinctive chemical signature in which sulfate represents approximately 50 percent of the total dissolved solids concentration, sodium represents approximately 18 percent of the total dissolved solids concentration, chloride represents approximately 10 percent of the total dissolved solids concentration, and the remaining constituents are trace constituents of this pattern. Although cyanide (CN), copper (Cu), and total trace metals (the sum of all trace metal concentrations, TTM) are not significant components of the mine leachate fingerprint, they have been included in Figure 4 for comparison. A separate attempt at using trace metals for fingerprinting mine leachates did not define a distinctive fingerprint.[1]

The reproducibility of the mine leachate fingerprint at this facility is demonstrated in two ways. First, based on quarterly samples, the leachate fingerprint had a reproducibility over time of 0.980 (98 percent) at the barren pond, 0.986 (99 percent) at the pregnant pond, and 0.985 (99 percent) at the tailings reclaim pond. Second, the barren pond, the pregnant pond and the tailings reclaim area are all part of a recirculating system at the mine and a similar fingerprint pattern might be expected at each of these locations. As demonstrated by the regression analysis comparisons tabulated in Figure 4, the monitoring data from these different locations defined a consistent source fingerprint with an average reproducibility of 0.984 (98 percent). Therefore, data over time at a single location (quarterly monitoring data) and data from different locations within the leaching circuit define a reproducible geochemical fingerprint at this facility.



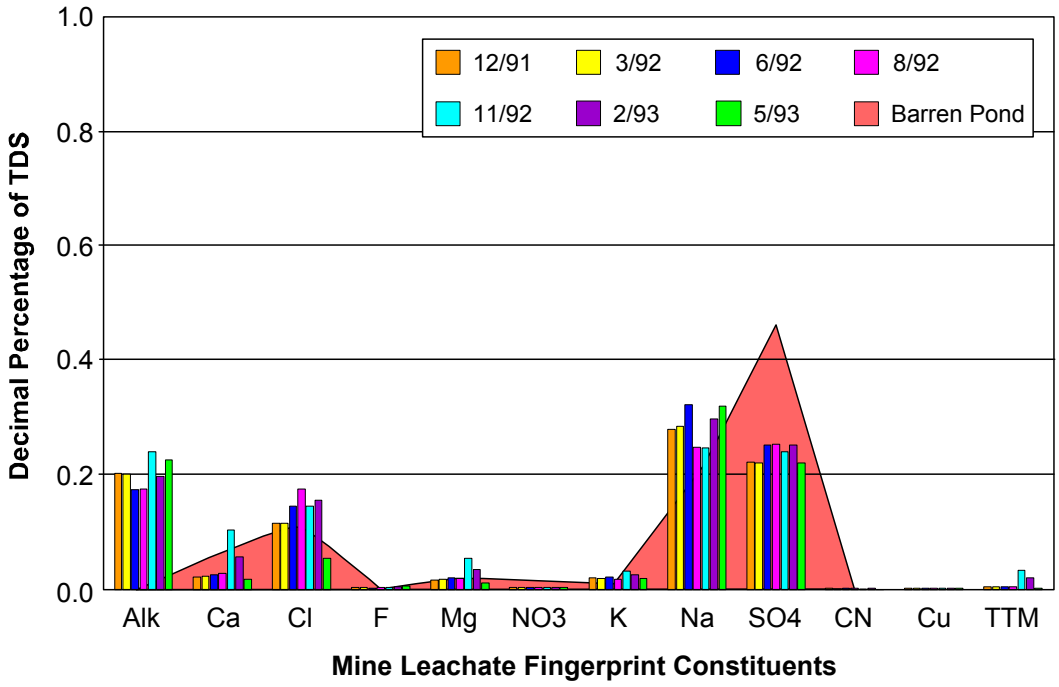
Regression Analysis of Gold Mine Tailings Leachate Fingerprint

	Barren Pond	Pregnant Pond	Tailings Reclaim
Background Ground Water	0.435	0.460	0.406
Barren Pond		0.983	0.972
Pregnant Solution			0.997
Tailings Reclaim			

Estimated reproducibility of mine leachate fingerprint = 0.984.
Comparison between mine leachate and ground water = 0.433.

Figure 4. Geochemical fingerprint at a gold mine using cyanide heap leaching.

A further evaluation of mine site monitoring records demonstrated that the same set of geochemical parameters used to fingerprint leachate at gold mines can also be used to fingerprint ground water in the vicinity of the mine.[1] The ground-water fingerprint developed from two years of quarterly monitoring at an upgradient location is contrasted with the heap leaching fingerprint in Figure 5. The quarterly upgradient ground water data are presented as a series of histograms and the mine leachate fingerprint is presented as an area plot. The first observation is that the ground water data define a single fingerprint pattern characterized by 25 to 30 percent sodium, 20 percent sulfate, 20 percent alkalinity (Alk in the figures), and 10 to 15 percent chloride. The estimated reproducibility of this chemical signature for ground water upgradient of the mine site is 0.941 (94 percent). The second observation is that the ground-water fingerprint developed with the FALCON procedure is visually distinct from the mine leachate fingerprint. Specifically, the mine leachate is enriched in sulfate and depleted in alkalinity when compared to the regional ground water. Despite the fact that the fingerprint constituents are naturally occurring substances and their concentrations are highly variable, the mine leachate and the regional ground water each have a distinctive, reproducible fingerprint that can be differentiated from each other visually and with regression analysis. In this example, there was only a 43 percent comparability between the two fingerprint patterns.



Regression Analysis Matrix for Gold Mine Upgradient Ground Water

	8/91	3/92	6/92	9/92	11/92	2/93	5/93

11/92						0.948	0.857
2/93							0.908
5/93							

Average upgradient fingerprint comparison = 0.941.
Mine fingerprint comparison with upgradient ground water = 0.515.

Figure 5. Comparison of a ground-water fingerprint with the mine leachate fingerprint.

Once a source fingerprint pattern has been established for the mine, it can be used to monitor leachate migration into the environment. This is accomplished by comparing the geochemical pattern at each downgradient monitoring location with either the source fingerprint or the upgradient ground-water fingerprint. If the location was not impacted by fugitive mine leachate, it would be expected to have a geochemical fingerprint that more closely resembled the upgradient fingerprint rather than the mine leachate fingerprint. However, if fugitive leachate was impacting a location, the fingerprint would more closely resemble the mine leachate fingerprint rather than the upgradient fingerprint. Fingerprint analyses for several monitoring wells in the vicinity of a heap leaching facility are summarized in Table 5. An inspection of the results indicates that the wells fall into one of three categories. One category consists of upgradient wells that have a geochemical fingerprint that matches the upgradient fingerprint (80 to 99+ percent) but is different from the mine leachate fingerprint (36 to 63 percent). A second category consists of downgradient wells with a geochemical fingerprint similar to upgradient ground water (84 to 88 percent) and different from the mine leachate fingerprint (48 to 60 percent). The third category consists of wells with a geochemical fingerprint that has a poor match with the upgradient ground-water fingerprint (44 to 75 percent) and a stronger similarity to the mine leachate fingerprint (80 to 93 percent).

The compositional shift from alkalinity-rich and sulfate-poor to sulfate-rich and alkalinity-poor that has occurred in the category three wells is consistent with mine leachate migrating into that area. Once the impacted wells have been identified through the fingerprinting process, the results can be plotted and contoured to delineate specific areas impacted by fugitive mine leachate. This example demonstrates that the FALCON process develops reproducible fingerprints for mine leachate that can be visually and statistically differentiated from background ground-water conditions in the vicinity of the mine. Also, it demonstrates that the mine leachate fingerprint retains its distinctive chemical identity as it migrates through the ground water and can be used as an internal tracer to detect and map its presence some distance from the designated tailings disposal area.

Table 5. Comparison of Ground-water Fingerprints with a Mine Leachate Fingerprint

Classification	Sampling Location	Site Location	Fingerprint Comparison	
			Mine Source	Background GW
Category 1	Well 2	Upgradient	0.433	1.000
	Well 4	Upgradient	0.627	0.937
	Well 22	Upgradient	0.357	0.800

	Well 66	Downgradient	0.897	0.381

Tabulated values are regression analysis comparisons between ground water and the indicated fingerprint pattern.

3.3 Early Detection of Leachate Migration - Copper Mine Case Study

A review of monitoring results from several copper mines demonstrated that the same set of geochemical parameters used at gold heap leaching facilities would also be useful for fingerprinting leachates at copper mines.[1] As indicated in Figure 6, tailings pond data over a period of 14 years produced a series of histograms that defined a single chemical fingerprint characterized by 55 to 60 percent sulfate, 15 percent calcium, 10 percent magnesium, 10 percent total trace metals (TTM), and 5 percent alkalinity. Despite variability in the ore being processed and the long period of record, the tailings pond at this facility had a single characteristic fingerprint with an estimated reproducibility of 0.970 (97 percent). In addition, this pattern was distinctively different from the alkalinity-rich, sulfate-poor background ground-water fingerprint in the vicinity of the mine (fingerprint comparison = 0.016 (2 percent)).[1] Fingerprint comparisons were used to identify several downgradient wells that had been impacted by mine leachate as demonstrated in the previous example. The monitoring results from one impacted well at this copper mine provided a set of data that illustrates another possible application of the FALCON procedure. Relative abundance (actual concentration divided by TDS) for the geochemical fingerprint parameters at well 1225 at this site are plotted as a function of time in Figure 7. Between 1970 and 1976, the dominant geochemical parameter in the ground water at this location was alkalinity while sulfate was almost

negligible. This alkalinity-rich, sulfate-poor pattern, that is typical of most unimpacted freshwater systems, had a 99 percent match with the ground water upgradient of the mining facility and less than a 5 percent match with the tailings pond leachate at the copper mine. However, the ground water composition at this location began to change around 1976. There was a gradual reduction in the relative abundance of alkalinity and a concurrent increase in the relative abundance of sulfate. This compositional shift, that is consistent with a sulfate-rich, alkalinity poor leachate entering the area, continued through 1984 when the Well 1225 fingerprint produced a 95 percent match with the tailings pond leachate. Even though sulfate and alkalinity are naturally occurring substances, fingerprint analysis clearly identifies mine leachate as the causative factor for the ground-water changes observed at this location. Thus, the fact that the geochemical fingerprint retains its distinctive identity as it migrates through the ground water could have been used to provide an early warning of mine leachate migration.

Figure 7. Geochemical fingerprint analysis of ground water downgradient of a copper mine tailings basin.

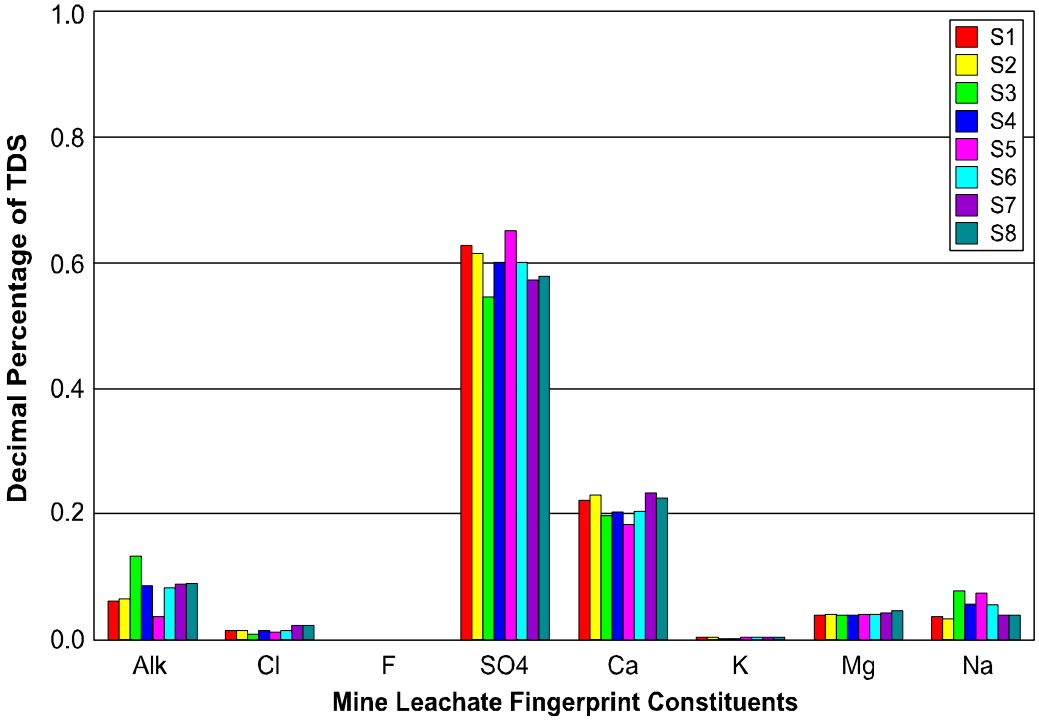
A review of additional monitoring data from this location (Figure 7) provides further insight into the capabilities of FALCON as a mechanism to provide early warning or early detection of leachate migration. The tailings pond at this facility has a total trace metals concentration (sum of 17 trace metals being routinely monitored) of 1963 mg/L and a pH of 2.0. Between 1970 and 1975, while the geochemical fingerprint was essentially identical to upgradient (background) conditions, the total trace metals concentration at this well was in the range of 0.291 to 0.467 mg/L. While the tailings pond fingerprint was being established at Well 1225 between 1976 and 1982, the total trace metals concentration remained in the range of 0.030 to 0.697 mg/L. After the tailing leachate fingerprint was fully established, the total trace metals concentration had only increased slightly to 0.470 to 1.570 mg/L. Also, the pH at this location was still in the range of 6.7 to 7.7 between 1981 and 1985. (The pH data from this set between 1970 and 1981 was missing. However, the pH at upgradient locations and other impacted downgradient locations was in the range of 6.7 to 7.7 between 1970 and 1985.) These field results, and an additional laboratory study[1], demonstrate that the geochemical fingerprint migrates faster through the ground water than other inorganic parameters of environmental concern that may be in mine leachate. Thus, in addition to providing a reliable characterization of mine leachates at their source and acting as an internal tracer, a geochemical fingerprint acts as a good indicator parameter because it migrates faster than mine leachate constituents of higher regulatory concern (pH and trace metals). Fingerprint analysis can provide an early warning so that remedial action can be initiated while a contaminant migration problem is smaller and more manageable.

This example demonstrates that the inorganic fingerprints can be used to characterize mine leachates at their source and to differentiate the leachate from background conditions. In addition, since the fingerprint retains its identity and migrates faster than other contaminants of higher regulatory concern, the fingerprint can function as an effective detection monitoring parameter.

3.4 Ground Water and Surface Water Mixing - Molybdenum Mine Case Study

This facility is located adjacent to the Red River in New Mexico and monitoring was conducted at the mine site, several ground water and seep locations, and the nearby river. The same set of geochemical parameters used in the gold mine and copper mine case studies were also useful at this site. Although the concentrations of the individual fingerprint parameters varied by a factor of 10 across the site, the monitoring results defined a single mine leachate pattern characterized by 60 percent sulfate, 20 percent calcium, 10 percent alkalinity, and small amounts of the remaining geochemical parameters (Figure 8). The regression analysis comparison of eight source samples produced r^2 values ranging from 0.9618 to 0.9999. The estimated reproducibility of this source fingerprint was 0.9894 (99 percent).

Monitoring was conducted at several ground water and surface seep locations between the mine operations and the river. Regression analysis of the geochemical pattern at these locations produced fingerprint comparisons of 94 to 99 percent with the source fingerprint. In addition, surface water data from several gulches that drain from the mine site towards the Red River also produced geochemical fingerprints with a strong similarity to the mine leachate (> 90 percent). Fingerprint analysis indicated that fugitive mine leachate was migrating through the ground water and may be entering the nearby river.



Regression Analysis of Molybdenum Mine Fingerprint

Molybdenum Mine Sampling Locations

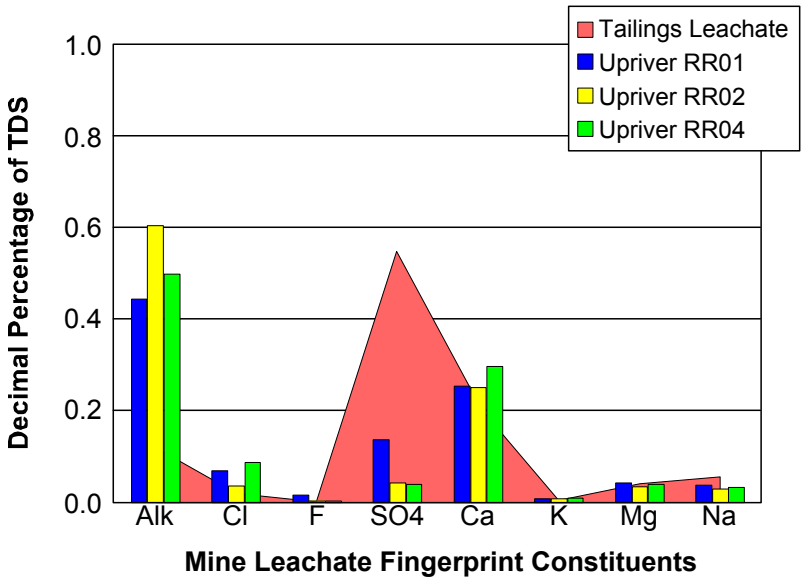
S7								1.000
S8								

Average fingerprint reproducibility = 0.989.

Figure 8. Geochemical fingerprint of molybdenum mine leachate.

The monitoring program at this mine site included 16 sampling stations in the nearby river. Data from three locations upriver from the mine site defined a geochemical fingerprint pattern that is contrasted with the mine leachate fingerprint in Figure 9. The river pattern, presented as a series of histograms, is characterized by 45 to 60 percent alkalinity, approximately 25 percent calcium, approximately 10 percent chloride, and 5 to 15 percent sulfate. This alkalinity-rich, sulfate-poor pattern upriver of the mine is typical of most fresh water systems and can be clearly differentiated from the sulfate-rich, alkalinity-poor mine fingerprint of the mine leachate that is presented as an area plot in Figure 9. The estimated reproducibility of the Red River fingerprint at these three upriver stations was 0.9804 (98 percent) and the comparability with the molybdenum mine fingerprint was only 0.0189 (2 percent). As in previous examples, the two inorganic fingerprint patterns can be readily distinguished from each other both visually and with regression analysis.



Fingerprint Analysis in Red River Near Molybdenum Mine

Figure 9. Comparison of mine leachate fingerprint with the background Red River fingerprint.

An evaluation of the data from the remaining river sampling locations adjacent to and downriver from the mine site demonstrated that the geochemical composition of the river was being altered. At stations adjacent to the mine site (RR03 to RR13), the comparability of the fingerprint with the upriver fingerprint ranged from 46 to 97 percent. At the three stations downriver from the mine site (RR14 to RR16), the comparability with the upriver fingerprint was reduced to 47 to 49 percent. These compositional changes were due to a reduced relative abundance of alkalinity and an increased relative abundance of sulfate as

the river flowed past the mining operation. This shift is consistent with a sulfate-rich, alkalinity-poor leachate characteristic of the mining operation (Figure 8) entering the river and is reflected by the increased comparability of the river fingerprint with the mine leachate fingerprint. The upriver stations only had a 1 percent match with the mine leachate fingerprint. However, as the river passed the site, the leachate fingerprint match increased to 6 to 50 percent at adjacent sampling locations and 47 to 48 percent at downriver sampling locations.

Fingerprint analysis indicated that mine leachate was migrating through the ground water and reaching the Red River in sufficient quantity to alter the geochemical composition. An additional capability of the FALCON technique is that the surface water to mine leachate dilution ratio can be estimated. As in the sediment dioxin case study (Section 3.1), the two source fingerprints can be used to calculate the expected composition for various mixtures of river water and mine leachate (i.e., 90 percent river + 10 percent mine leachate, 80 percent river water + 20 percent mine leachate, etc.). The actual inorganic composition at each river location can then be compared to each of the calculated mixtures to produce a range of fingerprint match values as shown in Table 6. For example:

1. The sample from station RR4 produced a fingerprint match of 0.987 (99 percent) with the upriver fingerprint. As the calculated amount of mine leachate in the mixture increased above 0 percent, the fingerprint match decreased. Since the best match (maximum r^2) occurred with the upriver fingerprint, this location was considered to be 100 percent upriver water.

2. The sample from station RR12 produced a fingerprint match of 0.458 (46 percent) with the upriver fingerprint. The fingerprint match increased to 0.772 (77 percent) for the 80 percent upriver + 20 percent mine leachate mixture and reached a maximum of 0.992 (99 percent) for the 60 percent upriver + 40 percent mine leachate mixture. As the calculated amount of mine leachate in the mixture increased above 40 percent, the fingerprint match decreased. This location was considered to be 60 percent upriver water and 40 percent mine leachate.

Each of the remaining samples was evaluated in a similar manner and the calculated fingerprint mixture that produced the best fingerprint match is highlighted and bolded in Table 6. It should be noted that the maximum fingerprint match for each river sample was 0.981 (98 percent), or higher.

As shown in Table 6 and summarized in Figure 9, the three upriver stations produced a best fingerprint match for mixtures that contained 0 to 10 percent mine leachate. The stations adjacent to the mine site produced the best fingerprint match for mixtures that contained 10 to 40 percent mine leachate and the three downriver locations produced the best match for a mixture of 40 percent mine leachate and 60 percent river water. The fluctuations at the adjacent river stations listed in Table 6 (e.g., RR 11 has a lower percentage of leachate than RR6) are due to runoff entering the river from unimpacted tributaries. In this example, the FALCON technique was able to develop a characteristic fingerprint for the mine leachate and differentiate mine leachate from background ground water conditions and surface water. In addition, based on the properties of the fingerprint, it was possible to track the migration of mine leachate through the ground water, into a nearby river, and develop a quantitative estimate of the mixing that was occurring between river water and fugitive mine leachate.

Figure 10. Fingerprint analysis of PAH contaminated sediments.

3.5 Mixing of Similar Contaminant Plumes - PAH Case Study

Two potential sources of polycyclic aromatic hydrocarbon (PAH) are separated by a small tributary that drains into a river. One potential source is a landfill that included waste tar among its contents. The second potential source was a salvage yard that processed crude tar wastes to recover creosote, phenol, and other chemicals. Wastes from this salvage yard were disposed of on-site. Sediment sampling of the tributary that runs between these two operations produced total PAH concentrations ranging from less than 5 mg/kg to greater than 50,000 mg/kg.

The FALCON procedure was applied to a set of soil samples collected adjacent to the tributary. This effort identified two PAH fingerprint patterns as shown in Figure 10. For brevity, the 53 standard PAH compounds are not listed by name but simply referred to by compound number. One pattern was characterized by a relatively dominant peak for PAH compound 33, smaller peaks for PAH compounds 39, 40, 45, 46, and 20, and the low abundance of PAH compounds 1 to 19. The distinguishing characteristics of the second fingerprint pattern were the relatively large peaks for PAH compounds 1 and 20, several peaks for PAH compounds 2 to 10, and a relatively lower abundance of PAH compounds 39 to 53. The comparability of the two identified PAH fingerprints was only 0.329 (33 percent).

The PAH distribution in collected tributary sediment samples was compared to the two identified PAH fingerprints. One set of samples (T6, T3, T4, T5, T17, T15, S9 and T9) produced strong matches (0.874 to 0.990) with the fingerprint relatively enriched in compounds 33 to 53 and a poor match (0.203 to 0.657) with the fingerprint enriched in compounds 1 to 19. The second set of samples (T1, T2, T10, T14, S7, S8, S10, and S11) produced a strong match (0.781 to 0.986) with the fingerprint enriched in PAH compounds 1 to 20 and a poor match (0.113 to 0.529) with the fingerprint enriched in PAH compounds 33 to 53. Based on the fingerprint assessment, tributary sediments closest to the bank had a low total PAH concentration and a PAH fingerprint enriched with compounds 1 to 20. The mid-channel sediments had a very high total PAH concentration (two orders of magnitude greater than the sediments closest to the bank) and a PAH distribution relatively enriched in compounds 33 to 53.

4.0 FALCON Capabilities

FALCON is a flexible data analysis technique of combining data from two or more contaminants to develop a distinctive chemical signature. The resultant FALCON fingerprint, based on the relative abundance rather than actual concentrations of the individual contaminants, provides a mechanism to identify the source and monitor the environmental behavior of fugitive emissions and leachates. These source patterns provide a visual characterization of contaminants in liquid and solid matrices and generally have a reproducibility of 90 to 99 percent.

The FALCON process can assist in the evaluation and interpretation of site characterization and monitoring data in several ways:

1. The process produces a characteristic fingerprint that associates a contaminant with a particular source. The data normalization process permits a direct visual comparison of fingerprint patterns despite highly variable contaminant concentrations and the use of regression analysis provides a statistical estimate of the reproducibility or comparability of two patterns. Distinctive fingerprints can be developed to characterize organic and inorganic contamination due to spills, leaks, and landfill leaching. In addition to the dioxin-furan, mine site, and PAH examples illustrated in this report, the FALCON technique has also been used to characterize halogenated organic solvent spills, gasoline and diesel fuel spills, and landfill leachates.

2. The fingerprints can differentiate a source fingerprint from background conditions. As illustrated in the gold mine (Section 3.2), copper mine (Section 3.3), and the molybdenum mine (Section 3.4) examples, each source had a characteristic fingerprint that could be visually and statistically differentiated from background ground water and upriver surface water conditions in the vicinity of each facility.

3. FALCON fingerprints provide a mechanism to differentiate multiple sources of the same contaminants. As illustrated in the dioxin example (Section 3.1) and the PAH example (Section 3.5), distinctive fingerprints can be developed for each source.

4. FALCON fingerprints retain their chemical identity and act as an internal tracer as they migrate through the environment. Therefore, fingerprint patterns at established monitoring locations can be directly compared with the source fingerprint as demonstrated with the gold mine example (Section 3.2) to verify the source of detected contaminants and to map the areas that have been impacted by a specific potentially responsible party.

5. FALCON fingerprints can also be used as a tool to characterize the environmental behavior of contaminant plumes. Fingerprint analysis provided a quantitative estimate of the Roanoke sediment contamination that can be specifically attributed to a pulp mill even though there are multiple sources of dioxin-furan contamination to the river (Section 3.1). The molybdenum mine case study (Section 3.4) demonstrated that a source fingerprint could be tracked through the ground water and used to estimate the rate of mixing between mine leachate and surface water. Thus, in addition to source characterization, the fingerprints can be used to characterize the migration of contaminants between environmental phases (ground water, surface water, and sediments) and to quantify the extent of mixing or dilution that has occurred between two source fingerprints. This capability provides a mechanism to apportion responsibility for environmental degradation between potentially responsible parties.

6. Fingerprints also have a potential application as detection monitoring parameters to provide early warning of leachate migration. This capability is illustrated with the copper mine case study (Section 3.4) in which the tailings pond fingerprint was initially detected and then fully developed before the more hazardous constituents associated with mine leachate were detected downgradient from the mine site. Fingerprint analysis would have provided an early warning to implement a corrective action or remediation program while the developing problem was smaller and more manageable. The factors that would permit the FALCON process to be used in this capacity are (a) the fingerprint characterizes the source and differentiates it from background conditions, (b) the fingerprint retains its chemical identity as it migrates away from the source, and (c) the fingerprint migrates faster than the contaminants of higher regulatory concern.

7. Each of the case studies mentioned in this report were developed with routine monitoring data. It is not necessary to use special analytical techniques, that may not produce data compatible with historical site records, in order to use the FALCON technique.

The previous discussion focused on the use of contaminant fingerprinting to evaluate site-specific data. The FALCON process can also provide the technical basis for the development of industry-specific monitoring strategies. For example, a review of the gold mine (Section 3.2), copper mine (Section 3.3), and molybdenum mine (Section 3.4) case studies reveals that the same small set of geochemical parameters defined a characteristic, reproducible fingerprint at each mine as well as the ground water and surface water in the vicinity of the mine. This observation has been verified by evaluating data from more than 30 additional mines.[1] These results suggest the possibility of a uniform two-phased monitoring program at mining facilities based on the set of geochemical parameters that characterize mine leachates. The first phase would utilize the fingerprint parameters to characterize and detect the leachate. As long as

leachate is not detected, contaminants are not entering the ground water and the facility would remain at this monitoring level. However, once the leachate fingerprint is detected, the second phase would be triggered to more fully characterize the slower migrating contaminants that may be present. The factors that support consideration of this approach are that the fingerprint is a reliable indicator of the leachate, the fingerprint retains its identity as it migrates, and the fingerprint migrates faster than other leachate constituents (as illustrated in the copper mine case study, Section 3.3). This approach could reduce monitoring costs and provide a uniform monitoring strategy that would be easier to implement, evaluate, and enforce.

5.0 Summary

FALCON is an empirical data assessment and visualization tool that produces contaminant fingerprint patterns. This technique combines data from two or more parameters to produce visually distinctive and reproducible fingerprints. The resultant fingerprints can be used to:

1. Characterize contaminants at their source,

2. Compare and evaluate background levels of contaminants with anthropogenic sources,

3. Establish an internal tracer to monitor the migration of a contaminant plume through ground water, surface water, and sedimentary environments, and

4. Differentiate two sources of the same contaminant and estimate the relative mixing that has occurred between two contaminant plumes.

Additional information on the FALCON procedure can be obtained from Gareth Pearson, Director of the Technical Support Center, U.S. EPA National Environmental Research Laboratory, Las Vegas, Nevada (pearson.gareth@epa.gov).

ACKNOWLEDGMENTS

Authors are grateful to the input provided by G. Helms, U.S. EPA, Office of Solid Waste and Emergency Response (Washington, D.C.) in helping with the research design and application of improved leaching test methods to provide better characterization data for fly ash and other coal combustion residues.

Overall project planning and integration was carried out jointly by D.S. Kosson and F. Sanchez (Vanderbilt University), and P. Kariher (ARCADIS).

R. Delapp and D. McGill of Vanderbilt University were responsible for the chemical analyses of the leachate samples except for mercury analysis. All other laboratory testing including physical and chemical analysis, sample digestion, and leaching tests of fly ash and other coal combustion residues was conducted by ARCADIS. Technical assistance was provided by A. Garrabrants of Vanderbilt University. Solid phase chromium analysis by X-ray Absorption Fine Structure was carried out under the direction of N.D. Hutson (U.S. EPA). Database management and data presentation technical assistance was provided by L.H. Turner (Turner Technology, LLC) and P. Seignette (Energy Research Centre of the Netherlands).

K. Ladwig and the Electric Power Research Institute (EPRI) are gratefully acknowledged for assistance in obtaining coal combustion residue samples and providing information from the EPRI database on coal combustion residues.

S. Thorneloe provided technical direction for this research. In addition, she was responsible for obtaining samples, communication, and report writing.

ABSTRACT

This report evaluates changes in composition and constituent release by leaching that may occur to fly ash and other coal combustion residues (CCRs) in response to changes in air pollution control technology at coal-fired power plants. The addition of flue-gas desulfurization (FGD) systems, selective catalytic reduction, and activated carbon injection to capture mercury and other pollutants will shift mercury and other pollutants from the stack gas to fly ash, FGD gypsum, and other air pollution control residues. The objective is to understand the fate of mercury and other constituents of potential concern (COPC) in air pollution control residues and support EPA's broader goal of ensuring that emissions being controlled in the flue gas at power plants are not later being released to other environmental media.

This report includes data on 73 CCRs [34 fly ashes, 20 flue gas desulfurization (FGD) gypsum, 7 "other" FGD residues (e.g., scrubbers without oxidation or with inhibited oxidation), and 8 blended CCRs "as managed" (e.g., scrubber sludge mixed with fly ash and lime prior to disposal)]. Each of the CCRs sampled has been analyzed for a range of physical properties, total elemental content, and leaching characteristics for mercury, aluminum, antimony, arsenic, barium, boron, cadmium, chromium, cobalt, lead, molybdenum, selenium and thallium.

The leach testing methods that were used in this research consider the impact on leaching of management conditions. These methods are intended to address concerns raised by the National Academy of Science and the EPA's Science Advisory Board with the use of single-point pH tests. Because of the range of field conditions that CCRs are managed during disposal or use as secondary (or alternative) materials, it is important to understand the leaching behavior of materials over the range of plausible field conditions that can include acid mine drainage and co-disposal of fly ash and other CCRs with pyrites or high-sulfur coal rejects. The methods have also been developed into draft protocols for inclusion in EPA's waste testing guidance document, SW-846, which would make them available for more routine use. (http://www.epa.gov/osw/hazard/testmethods/sw846/index.htm)

The major conclusions from this research include:

- There is great variability in both the range of total constituent concentration values and in leaching values (orders of magnitude). In comparing there results to health indicator values such as the maximum concentration limit or toxicity characteristic, there are multiple COPCs of potential concern.
- Distinctive patterns in leaching behavior have been identified over a range of pH values that would plausibly be encountered for CCR management.
- Total constituent content is not a good indicator of leaching which has been found to be a function of the characteristics of the material (pH) and field conditions in which the material is managed.
- The maximum eluate concentration from leaching test results varies over a wide range in pH and is different for different CCR types and elements. This indicates that there is not a single pH for which testing is likely to provide confidence in release estimates over a wide range of disposal and beneficial use options, emphasizing the benefit of multi-pH testing. Furthermore, for CCRs, the rate of constituent release to the environment is affected by leaching conditions (in some cases dramatically so), and that leaching

evaluation under a single set of conditions will, in many cases, lead to inaccurate conclusions about expected leaching in the field.

The intended use for the data in this report is to support future risk and environmental assessments of the CCRs studied. A follow-up report is planned which will use these data in conducting a probabilistic assessment of mercury and other COPCs release rates based on the range of plausible management scenarios for these materials in either disposal or beneficial use situations. The data summarized in this report will also be made available electronically through a leaching assessment tool (LeachXS Lite®) that can be used to develop source-term inputs needed for using groundwater transport and fate models. The leaching assessment tool will also provide means for data management in viewing data resulting from the of the improved leaching test methods.

EXECUTIVE SUMMARY

This report is the third in a series to evaluate changes in composition and constituent release by leaching that may occur to fly ash and other coal combustion residues (CCRs) in response to changes in air pollution control technology at coal-fired power plants. The addition of flue-gas desulfurization (FGD) systems, selective catalytic reduction, and activated carbon injection to capture mercury and other pollutants will shift mercury and other pollutants from the stack gas to fly ash, FGD gypsum, and other air pollution control residues. The Air Pollution Prevention and Control Division (APPCD) of EPA's Office of Research and Development (ORD) is conducting research to evaluate potential leaching and other cross media transfers of mercury and other constituents of potential concern (COPCs) resulting from the management of CCRs resulting from wider use of state-of-the art air pollution control technology. This research was cited as a priority in EPA's Mercury Roadmap[1] to ensure that one environmental problem is not being traded for another. The objective is to understand the fate of mercury and other COPCs in air pollution control residues and support EPA's broader goal of ensuring that emissions being controlled in the flue gas at power plants are not later being released to other environmental media.

Approximately 40% of the 126 million tons of CCRs produced in the U.S. as of 2006 were utilized in agricultural, commercial, and engineering applications. The remainder (i.e., 75 million tons) was managed in either landfills or impoundments. The physical and chemical characteristics of CCRs make them potentially suitable as replacements for materials used in a wide range of products including cement, concrete, road base, and wallboard. Use of CCRs as an alternative to virgin materials helps conserve natural resources and energy, as well as decrease the amount of CCRs being land disposed.

In developing data to characterize the leaching potential of COPCs from the range of likely CCRs resulting from use of state-of-the-art air pollution control technology, improved leaching test methods have been used[2]. The principle advantage of these methods is that they consider the impact on leaching of management conditions. These methods address concerns raised by National Academy of Science and EPA's Science Advisory Board with the use of single-point pH tests. Because of the range of field conditions that CCRs are managed during disposal or use as secondary (or alternative) materials, it is important to understand the leaching behavior of materials over the range of plausible field conditions that can include acid mine drainage and co-disposal of fly ash and other CCRs with pyrites or high-sulfur coal rejects[3, 4]. The methods have

[2] Improved leaching test methods described in (Kosson et al., 2002) have been developed as draft SW-846 protocols. These methods consider the effect of varying environmental conditions on waste constituent leaching.

[3] National Academy of Sciences (2006). Managing Coal Combustion Residues in Mines, Washington, D.C.

[4] Sanchez, F.; Keeney, R.; Kosson, D., and Delapp, R. Characterization of Mercury-Enriched Coal Combustion Residues from Electric Utilities Using Enhanced Sorbents for Mercury Control, EPA-600/R-06/008, Feb. 2006; http://www.epa.gov/ORD/NRMRL/pubs/600r06008/600r06008.pdf.

also been developed into draft protocols for inclusion in EPA's waste testing guidance document, SW-846, which would make them available for more routine use. (http://www.epa.gov/osw/hazard/testmethods/sw846/index.htm).

The selected testing approach was chosen for use because it evaluates leaching over a range of values for two key variables [pH and liquid-to-solid ratio (LS)] that both vary in the environment and affect the rate of constituent release from waste. The range of values used in the laboratory testing encompasses the range of values expected to be found in the environment for these parameters. Because the effect of these variables on leaching is evaluated in the laboratory, prediction of leaching from the waste in the field is expected to be done with much greater reliability.

The categories into which samples have been grouped are fly ash, flue gas desulfurization (FGD) gypsum, "other" FGD residues (such as from spray drier absorbers), blended CCRs "as managed" (mixtures of fly ash and scrubber residues with and without added lime or mixture of fly ash and gypsum), and wastewater filter cake. In the first report from this research[5], results of leaching from fly ash were reported for mercury, arsenic, and selenium. Report 2 provided leaching results for an expanded list of materials and COPCs to include mercury, aluminum, antimony, arsenic, barium, boron, cadmium, chromium, cobalt, lead, molybdenum, selenium and thallium[6]. In the current report (Report 3), analyses of eluates from CCR samples presented in Report 1 have been included for the expanded list of COPCs. Report 3 also includes the data previously reported in Report 2, and leach test results for an additional 38 CCRs. A total of 73 samples were evaluated, and all results are presented in the current report to facilitate comparisons (Table ES-1).

Each of the CCRs sampled has been analyzed for a range of physical properties, total elemental content, and leaching characteristics. Laboratory leach data are compared to field observations from industry and EPA data from sampling of impoundments and landfills. The laboratory leach results are also compared to reference indicators to provide context for the data including:

- The toxicity characteristic (TC), which is a threshold for hazardous waste determinations;
- The maximum concentration limit (MCL), which is used for protecting drinking water; and,
- The drinking water equivalent level (DWEL), which is used to be protective for non carcinogenic endpoints of toxicity over a lifetime of exposure[7].

These comparisons to reference indicators do not consider dilution and attenuation factors (collectively referred to in this report as attenuation factors) that arise as a consequence of disposal or beneficial use designs and transport from the point of release to the potential receptor. Minimum attenuation factors needed to reduce maximum leach concentrations (based on laboratory test results) to less than MCL or DWEL values are provided to illustrate the importance of consideration of attenuation factors during evaluation of management options.

The intended use for the data in this report is to support future risk and environmental assessments of the CCRs. A follow-up report is planned which will use these data in conducting a probabilistic assessment of mercury and other COPCs release rates based on the range of plausible management scenarios for these materials in either disposal or beneficial use situations.

The data summarized in this report will be made available electronically through a leaching assessment tool that can be used to develop source-term inputs needed for using groundwater

[7]DWEL was developed for chemicals that have a significant carcinogenic potential and provides risk managers with evaluation on non-cancer endpoints, but infers that carcinogenicity should be considered the toxic effect of greatest concern (http://www.epa.gov/safewater/pubs/gloss2.html#D).

transport and fate models[8]. The leaching assessment tool will provide easier access to the leach data for a range of CCRs and potential field conditions. The tool can be used to develop more detailed leach data as input to more refined assessments of CCRs and support environmental decision-making that will ensure protection of human health and the environment.

Summary of Conclusions

In Table ES-2 and Table ES-3, the total metals content of the fly ash and FGD gypsum samples evaluated is provided along with the leach test results. Reference indicators (i.e., TC, MCL, and DWEL) are also provided to provide some context in understanding the leach results. It is critical to bear in mind that the leach test results represent a distribution of potential constituent release concentrations from the material as disposed or used on the land. The data presented do not include any attempt to estimate the amount of constituent that may reach an aquifer or drinking water well. Leachate leaving a landfill is invariably diluted in ground water to some degree when it reaches the water table, or constituent concentrations are attenuated by sorption and other chemical reactions in groundwater and sediment. Also, groundwater pH may be different from the pH at the site of contaminant release, and so the solubility and mobility of leached contaminants may change when they reach groundwater. None of these dilution or attenuation processes is incorporated into the leaching values presented. Thus, comparisons with regulatory health values, particularly drinking water values, must be done with caution. Groundwater transport and fate modeling would be needed to generate an assessment of the likely risk that may result from the CCRs represented by these data.

In reviewing the data and keeping these caveats in mind, conclusions to date from the research include:

1. Review of the fly ash and FGD gypsum (Table ES-2 and Table ES-3) show a range of total constituent concentration values, but a much broader range (by orders of magnitude) of leaching values, in nearly all cases. This much greater range of leaching values only partially illustrates what more detailed review of the data shows: that for CCRs, the rate of constituent release to the environment is affected by leaching conditions (in some cases dramatically so), and that leaching evaluation under a single set of conditions may, to the degree that single point leach tests fail to consider actual management conditions, lead to inaccurate conclusions about expected leaching in the field.
2. Comparison of the ranges of totals values and leachate data from the complete data set supports earlier conclusions[9, 10, 11] that the rate of constituent leaching cannot be reliably estimated based on total constituent concentration.

---

[8] The leaching assessment tool, LeachXS Lite®, will be available for inclusion in the CCR docket (December 2009).

[10] U.S. EPA, Characterization of Mercury-Enriched Coal Combustion Residuals from Electric Utilities Using Enhanced Sorbents for Mercury Control, EPA-600/R-06/008, Feb. 2006; http://www.epa.gov/ORD/NRMRL/pubs/600r06008/600r06008.pdf.

3. The maximum eluate concentration from leaching test results varies over a wide range in pH and is different for different CCR types and elements. This indicates that there is not a single pH for which testing is likely to provide confidence in release estimates over a wide range of disposal and beneficial use options, emphasizing the benefit of multi-pH testing.
4. From the more complete data in this report, distinctive patterns in leaching behavior have been identified over the range of pH values that would plausibly be encountered for CCR disposal, depending on the type of material sampled and the element. This reinforces the above conclusions based on the summary data.
5. Summary data in Table ES-2 on the leach results from evaluation of 34 fly ash samples across the plausible management pH domain of 5.4 to 12.4, indicates leaching concentration ranges over several orders of magnitude as a function of pH and ash source:
    - the leach results at the upper end of the concentration ranges exceeded the TC values for As, Ba, Cd, Cr, and Se.
    - the leach results at the upper end of the concentration ranges exceeded the MCL or DWEL for Sb, As, Ba, B, Cd, Cr, Pb, Mo, Se, and Tl.
6. Summary data in Table ES-3 on the leach results from evaluation of 20 FGD gypsum samples across the plausible management pH domain of 5.4 to 12.4, indicates leaching concentration ranges over several orders of magnitude as a function of pH and FGD gypsum source:
    - the leach results at the upper end of the concentration ranges exceeded the TC values for Cd and Se.
    - the leach results at the upper end of the concentration ranges exceeded the MCL or DWEL for Sb, As, B, Cd, Cr, Mo, Se, and Tl.
7. The variability in total content and the leaching of constituents within a material type (e.g., fly ash, gypsum) is such that, while leaching of many samples exceeds one or more of the available reference indicators, many of the other samples within the material type may be lower than the available regulatory or reference indicators. Additional or more refined assessment of the dataset may allow some distinctions regarding release potential to be made among particular sources of some CCRs, which may be particularly useful in evaluating CCRs in reuse applications.

Work is underway to develop a fourth report that presents such additional analysis of the leaching data to provide more insight into constituent release potential for a wider range of scenarios, including beneficial use applications. This will include calculating potential release

[11]U.S. EPA, Characterization of Coal Combustion Residuals from Electric Utilities Using Wet Scrubbers for Multi-Pollutant Control; EPA-600/R-08/077, July 2008; http://www.epa.gov/nrmrl/pubs/600r08077/600r08077.pdf.

rates over a specified time for a range of management scenarios including use in engineering and commercial applications using probabilistic assessment modeling[12].

In interpreting the results provided in this report, please note that the CCRs analyzed in this report are not considered to be a representative sample of all CCRs produced in the U.S. For many of the observations, only a few data points were available. It is hoped that through broader use of the improved leach test methods (as used in this report), that additional data from CCR characterization will become available. That will help better define trends associated with changes in air pollution control at coal-fired power plants.

1. INTRODUCTION

More wide-spread implementation of multi-pollutant controls is occurring at U.S. coal-fired power plants. Although much research has occurred to characterize high-volume coal combustion residues [i.e., fly ash, bottom ash, boiler slag, and flue gas desulfurization (FGD) solids] extending back to the 1970s, previous research has not considered the wide range of field conditions that occur for coal combustion residues (CCRs) during land disposal and use in agricultural, commercial, and engineering applications. The objective of this research is to characterize the changes in total composition and constituent release potential occurring to CCRs resulting from wider use of multi-pollutant controls at U.S. coal-fired power plants. This characterization includes detailed analysis of the fly ash and other air pollution control residues in relationship to differences in air pollution control configurations and coal rank. The characterization also includes evaluating the leaching potential of constituents of potential concern (COPCs) across the range of plausible management conditions that CCRs are likely to encounter during land disposal or use in agricultural, commercial, and engineering applications. This research was cited as a priority in EPA's Mercury Roadmap (EPA, 2006b) to evaluate the potential for any cross-media transfers from the management of CCRs resulting from more stringent air pollution control at coal fired power plants. This report is part of a series of reports helping to document the findings of this research to provide more credible, up-to-date data on CCRs to identify any potential cross-media transfers.

The focus of this report is to present an evaluation of air pollution control residues that may result from the use of SO_2 scrubbers and other air pollution control technologies being used to control multiple pollutants at coal-fired power plants. The pathway of concern addressed in this report is the potential for transfer of pollutants to water resources or other environmental systems (e.g., soils, sediments). The residues studied for this report were fly ashes, unwashed and washed flue gas desulfurization (FGD) gypsum, scrubber sludge, blended CCR residues "as managed" (mixtures of fly ash and scrubber residues with and without added lime or mixture of fly ash and gypsum), and wastewater filter cake generated from power plants with a range of air pollution control configurations.

In particular, this report focuses on the potential for leaching of mercury and other COPCs during land disposal or beneficial use of the CCRs is the focus of this report. This research is part of an on-going effort by EPA to use an integrated, comprehensive approach to account for the fate of mercury and other metals in coal throughout the life-cycle stages of CCR management (Sanchez et al., 2006; Thorneloe et al., 2009; Thorneloe et al., 2008). Related research and assessment on environmental fate of constituents during CCR management includes conducting thermal stability studies, leach testing, and probabilistic assessment modeling to determine the fate of mercury and other metals that are in coal combustion residues resulting from implementation of multi-pollutant control technology (EPA, 2002; Kilgroe et al., 2001).

CCRs include bottom ash, boiler slag, fly ash, scrubber residues and other miscellaneous solids generated during the combustion of coal. Air pollution control can concentrate or partition metals to fly ash and scrubber residues. The boiler slag and bottom ash are not of interest in this study because air emission controls are not expected to change their composition. Use of multi-pollutant controls minimizes air emissions of mercury and other metals by the transfer of the metals to the fly ash and other CCRs. This research will help determine the fate of mercury and other COPCs from the management of CCRs through either disposal or reuse. Fly ash may

include unburned carbonaceous materials and inorganic materials in coal that do not burn, such as oxides of silicon, aluminum, iron, and calcium. Fly ash is light enough to be entrained in the flue gas stream and captured in the air pollution control equipment.

The type and characteristics of FGD scrubber residue produced is primarily a function of (i) the scrubber sorbent used (i.e., limestone, lime, magnesium enriched lime referred to as Mg lime, or alkaline fly ash), (ii) the extent of oxidation during scrubbing (i.e., forced oxidation, natural oxidation, or inhibited oxidation), (iii) post-scrubber processing, including possibly dewatering or thickening, drying, water rinsing, or blending with other materials, and (iv) coal rank combusted. The presence and leaching characteristics of the COPCs in air pollution control residues is a consequence of the coal combusted, process sequence employed, process conditions, process additives and use or disposal scenario.

Figure 1 illustrates the processes used in the production of materials that were sampled for this study, sample nomenclature, and the typical management pathways for each material. FGD gypsum is defined here as the by-product of the SO_2 wet scrubbing process when the scrubber residue is subjected to forced oxidation. In forced oxidation systems, nearly all of the by-product is calcium sulfate dihydrate ($CaSO_4 \bullet H_2O$). The resulting wet gypsum is partially dewatered and then either disposed in a landfill (unwashed gypsum; Gyp-U) or water rinsed (in some cases) and dried to produce washed gypsum (washed gypsum; Gyp-W) that then potentially can be used in wallboard manufacturing or agricultural applications. Scrubber sludge (ScS) is the by-product of the SO_2 wet scrubbing process resulting from neutralization of acid gases at facilities that use either inhibited oxidation or natural oxidation of scrubber residue. In inhibited oxidation systems, nearly all of the by-product is calcium sulfite hemihydrates ($CaSO_3 \bullet ½H_2O$). In natural oxidation systems, the by-product is a mixture of $CaSO_3 \bullet ½H_2O$ and $CaSO_4 \bullet H_2O$. Scrubber sludge typically will be either partially dewatered in a thickener and then disposed in a surface impoundment, or after thickening, further dewatered and mixed with fly ash to form blended CCRs "as managed[14]." In most cases, additional lime is also blended with the scrubber sludge and fly ash. The blend of fly ash and scrubber sludge is typically between 0.5 to 1.5 parts fly ash to 1 part scrubber sludge on a dry weight basis, with 0 or 2-4% additional lime added. Blended CCRs typically are either disposed in a landfill or supplied to a beneficial use (e.g., fill in mining applications). Facilities that have spray dryer absorbers (SDA) collect fly ash and FGD residues simultaneously as a sample residue stream.

This report evaluates the characteristics of fly ash, FGD gypsum, SDA, scrubber sludge, and blended CCRs "as managed" from thirty one (31) coal combustion facilities. In addition filter cake from waste water treatment was evaluated from four facilities.

[14] As managed is defined as how the material is managed by the coal-fired power plant either through disposal or reuse.

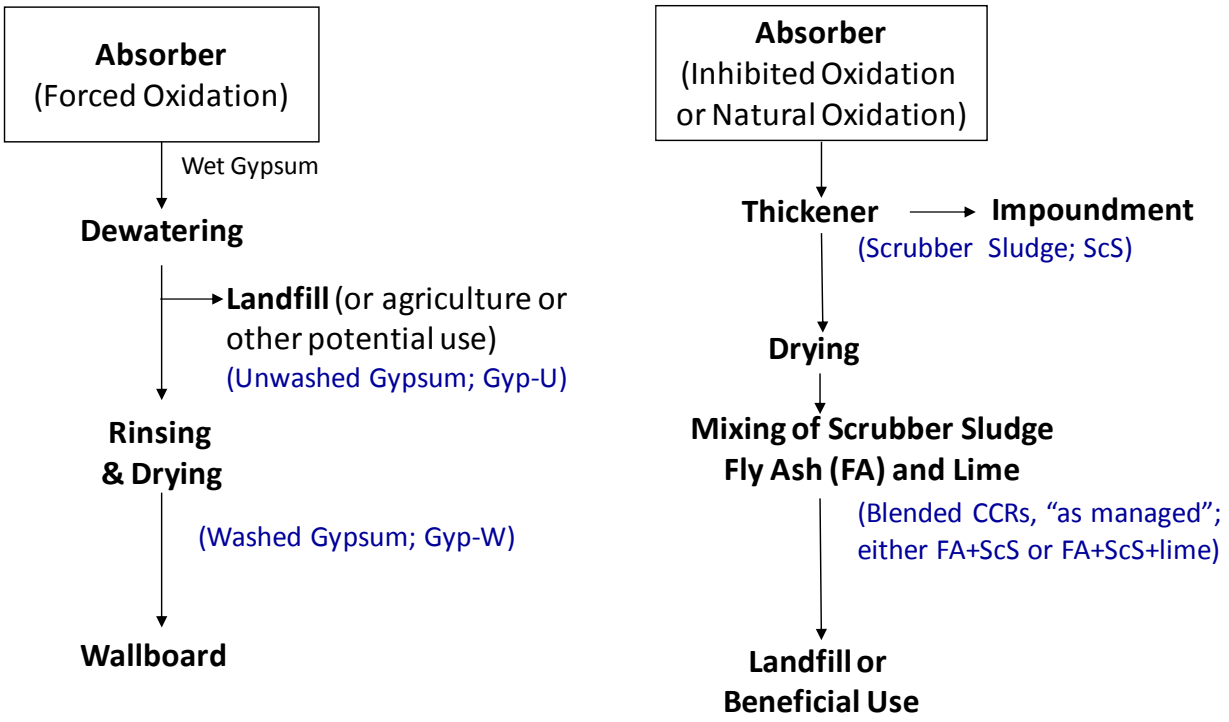

Figure 1. Flow diagram describing processing and nomenclature of FGD scrubber residues and samples included in this study.

When coal is burned in an electric utility boiler, the resulting high combustion temperatures vaporize the Hg in the coal to form gaseous elemental mercury (Hg^0). Subsequent cooling of the combustion gases and interaction of the gaseous Hg^0 with other combustion products may result in a portion of the Hg being converted to gaseous oxidized forms of mercury (Hg^{2+}) and particle-bound mercury (Hg_p). The specific chemical form–known as the speciation-as a strong impact on the capture of mercury and other metals by boiler air pollution control (APC) equipment (EPA, 2001).

Mercury and other elements partition between the combustion gas, fly ash and scrubber residues. Depending upon the gas conditioning, presence or absence of post-combustion NO_x control and other air pollution control technology in use, there may be changes occurring to the fly ash that can affect the stability and mobility of mercury and other metals in the CCRs. Similarly, NO_x control and SO_2 scrubber technology may affect the content, stability and mobility of mercury and other metals in scrubber residues.

The specific objectives of the research reported here are to:

1. Conduct analysis on range of air pollution control residues (i.e., fly ash, FGD residues and other CCRs) resulting from differences in coal rank and air pollution control configurations;
2. Evaluate the potential for leaching to groundwater of mercury and other COPCs (i.e., aluminum, antimony, arsenic, barium, boron, cadmium, chromium, cobalt, lead, molybdenum, selenium, and thallium) removed from the flue gas of coal-fired power plants using multi-pollutant controls to reduce air pollution; and

3. Provide the foundation for assessing the impact of enhanced mercury and multi-pollutant control technology on leaching of mercury and other COPCs from CCR management including storage, beneficial use, and disposal.

This is the third of a series of reports that addresses the potential for cross-media transfer of COPCs from CCRs. The first report focused on the use of sorbent injection (activated carbon and brominated activated carbon) for enhanced mercury control (Sanchez et al., 2006). The second report focused on facilities that use wet scrubbers for multi-pollutant control and includes results for 23 CCRs (fly ash, gypsum, scrubber sludge, fixated scrubber sludge) sampled from eight facilities (Sanchez et al., 2008). This report focuses on CCRs from coal-fired power plants that use air pollution control technologies, other than those evaluated in the first two reports, necessary to span the range of anticipated coal-types and air pollution control technology configurations. A subsequent report will address:

- Assessment of leaching of COPCs under additional management scenarios, including impoundments and beneficial use on the land (report 4); and,
- Broader correlation of CCR leaching characteristics to coal rank, combustion facility characteristics and geochemical speciation within CCRs supported by information and analysis on additional trace elements and primary constituents (report 4).

Sampled CCRs were subjected to multiple leaching conditions according to the designated leaching assessment approach, which is designed to examine leaching potential over a range of pH and LS ratios. Leaching conditions included batch equilibrium[15] extractions at acidic, neutral and alkaline conditions at an LS of 10 mL/g, and LS from 0.5 to 10 mL/g using distilled water as the leachant. In this report, the results of this testing are being used to evaluate the likely range of leaching characteristics during land disposal (i.e., landfill or surface impoundment) scenarios. Results of the laboratory leaching tests carried out in this study were compared to the range of observed constituent concentrations in field leachates reported in a U.S. EPA database (EPA, 2007b) and an Electric Power Research Institute (EPRI) database (EPRI, 2006). The testing results presented here will be used for evaluating disposal and beneficial use scenarios in a subsequent report.

The extensive nature of the results reported here necessitates detailed data presentation with only a broad assessment overview. Future reports will provide more detailed data evaluation and application of the data to evaluation of specific CCR management scenarios.

As part of this research program, a quality assurance/quality control (QA/QC) plan consistent with EPA requirements was developed for the leaching assessment approach (see Section 2.4). The QA/QC methodology included initial verification of acceptable mercury retention during laboratory testing through evaluation of a mass balance around testing procedures (Sanchez et al., 2006). Modifications to the QA/QC program to reduce the experimental and analytical burden while maintaining confidence in the resulting data, based on program results to date, are presented in Report 2 (Sanchez et al., 2008); further modifications are identified in this report.

[15] In the context of leaching tests, the term "equilibrium" is used to indicate that the test method result is a reasonable approximation of chemical equilibrium conditions even though thermodynamic equilibrium may not be approached for all constituents.

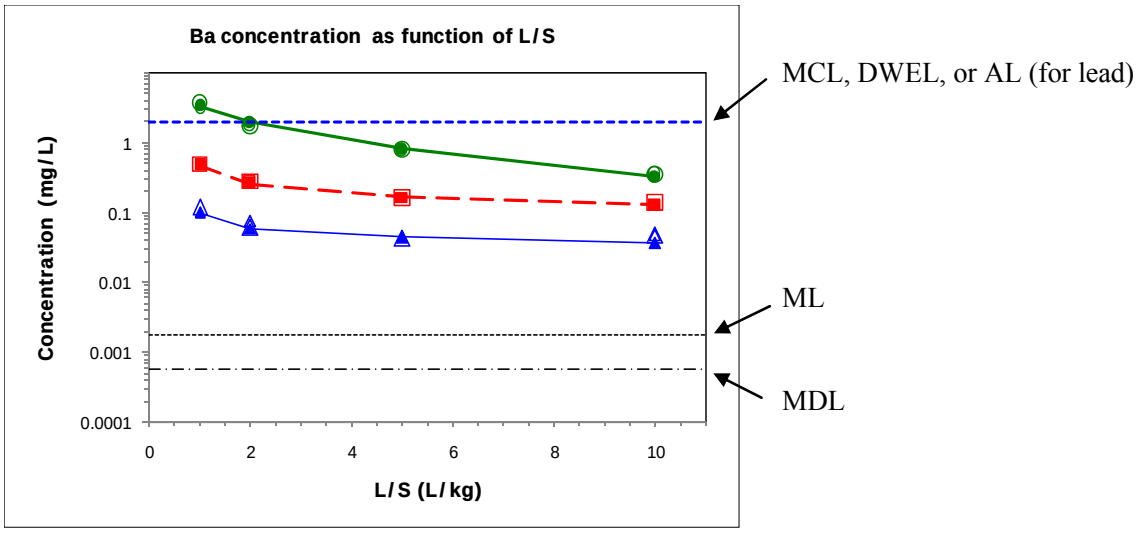

Figure 7. An example of eluate concentrations as a function of LS ratio from SR003.1.

2.5.2. Field pH Probability Distribution

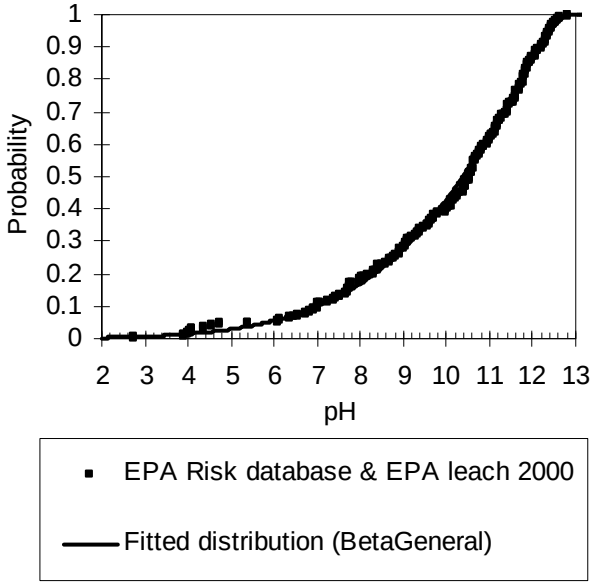
A probability distribution of field leachate pH values from coal combustion waste landfills was derived, as described below, from the set of field pH observations included in the EPA Risk Report (EPA, 2007b). The data set developed for the EPA Risk Report included (i) observations from the comprehensive database of landfill leachate characteristics developed by the EPA's Office of Solid Waste (EPA, 2000), (ii) field observations from literature, primarily from EPRI reports, (iii) additional data reported to EPA, and (vi) pH observations from laboratory leaching tests.

Only pH measurements from field samples (i.e., leachate, pore water) were selected for use in development of the resulting pH probability distribution. The resulting data set included 580 observations from 42 CCR landfill disposal facilities and was highly unbalanced, with some sites having only a few (e.g., less than five) observations and some sites having many observations (e.g., greater than 20). To prevent the unbalanced data from skewing the resulting probability distribution, the minimum, 25th, 50th, 75th percentile, and maximum values of observations for each individual facility were compiled into a single data set. For facilities with fewer than five observations, all observations for that facility were included. This data set then served as the basis for determining a balanced statistical distribution function of field leachate pH values from the disposal sites with reported values. Different distribution functions were used to fit the data and the one providing the best data fit based on the chi-square test was selected. The resulting field pH probability distribution was truncated and normalized to the pH range of the field data (Figure 8) (EPA, 2000; EPA, 2007b; EPRI, 2006).

Field pH observations were also evaluated for surface impoundments that receive CCRs from coal combustion facilities with FGD scrubbers in use. Pore water pH values measured in samples obtained from within the settled CCRs were extracted from the EPRI database. These pH observations were across the same range as the landfill field pH observations, but were insufficient to develop an independent pH probability distribution for surface impoundments.

Therefore, the same pH probability distribution was used for both landfill and surface impoundment facilities.

The resulting 5th and 95th percentiles of observed field pH values, equal to pH 5.4 and 12.4, respectively, are indicated on the figures of eluate concentrations as a function of pH (Figure 6).



pH	Field data	Fitted distribution	Simulated
Min	2.75	-7.42	2.76
5th percentile	5.40	5.84	5.85
50th percentile	10.53	10.38	10.24
90th percentile	12.20	12.18	11.94
95th percentile	12.40	12.43	12.43
Max	12.80	12.81	12.43

ENVIRONMENTAL PROTECTION AGENCY

40 CFR Parts 257, 261, 264, 265, 268, 271 and 302

[EPA–HQ–RCRA–2009–0640; FRL–9149–4]

RIN–2050–AE81

Hazardous and Solid Waste Management System; Identification and Listing of Special Wastes; Disposal of Coal Combustion Residuals From Electric Utilities

AGENCY: Environmental Protection Agency (EPA).

ACTION: Proposed rule.

SUMMARY: The Environmental Protection Agency (EPA or Agency) is proposing to regulate for the first time, coal combustion residuals (CCRs) under the Resource Conservation and Recovery Act (RCRA) to address the risks from the disposal of CCRs generated from the combustion of coal at electric utilities and independent power producers. However, the Agency is considering two options in this proposal and, thus, is proposing two alternative regulations. Under the first proposal, EPA would reverse its August 1993 and May 2000 Bevill Regulatory Determinations regarding coal combustion residuals (CCRs) and list these residuals as special wastes subject to regulation under subtitle C of RCRA, when they are destined for disposal in landfills or surface impoundments. Under the second proposal, EPA would leave the Bevill determination in place and regulate disposal of such materials under subtitle D of RCRA by issuing national minimum criteria. Under both alternatives EPA is proposing to establish dam safety requirements to address the structural integrity of surface impoundments to prevent catastrophic releases.

EPA is not proposing to change the May 2000 Regulatory Determination for beneficially used CCRs, which are currently exempt from the hazardous waste regulations under Section 3001(b)(3)(A) of RCRA. However, EPA is clarifying this determination and seeking comment on potential refinements for certain beneficial uses. EPA is also not proposing to address the placement of CCRs in mines, or non-minefill uses of CCRs at coal mine sites in this action.

DATES: Comments must be received on or before September 20, 2010. EPA will provide an opportunity for a public hearing on the rule upon request. Requests for a public meeting should be submitted to EPA's Office of Resource Conservation and Recovery by July 21, 2010. *See* the **FOR FURTHER INFORMATION CONTACT** section for contact information. Should EPA receive requests for public meetings within this timeframe, EPA will publish a document in the **Federal Register** providing the details of such meetings.

ADDRESSES: Submit your comments, identified by Docket ID No. EPA–HQ–RCRA–2009–0640, by one of the following methods:

- *http://www.regulations.gov:* Follow the on-line instructions for submitting comments.
- *E-mail:* Comments may be sent by electronic mail (e-mail) to *rcra-docket@epa.gov,* Attention Docket ID No. EPA–HQ–RCRA–2009–0640. In contrast to EPA's electronic public docket, EPA's e-mail system is not an "anonymous access" system. If you send an e-mail comment directly to the Docket without going through EPA's electronic public docket, EPA's e-mail system automatically captures your e-mail address. E-mail addresses that are automatically captured by EPA's e-mail system are included as part of the comment that is placed in the official public docket, and made available in EPA's electronic public docket.
- *Fax:* Comments may be faxed to 202–566–0272; Attention Docket ID No. EPA–HQ–RCRA–2009–0640.
- *Mail:* Send your comments to the Hazardous Waste Management System; Identification and Listing of Special Wastes; Disposal of Coal Combustion Residuals From Electric Utilities Docket, Attention Docket ID No., EPA–HQ–RCRA–2009–0640, Environmental Protection Agency, *Mailcode:* 5305T, 1200 Pennsylvania Ave., NW., Washington, DC 20460. Please include a total of two copies.
- *Hand Delivery:* Deliver two copies of your comments to the Hazardous Waste Management System; Identification and Listing of Special Wastes; Disposal of Coal Combustion Residuals From Electric Utilities Docket, Attention Docket ID No., EPA–HQ–RCRA–2009–0640, EPA/DC, EPA West, Room 3334, 1301 Constitution Ave., NW., Washington, DC 20460. Such deliveries are only accepted during the Docket's normal hours of operation, and special arrangements should be made for deliveries of boxed information.

Instructions: Direct your comments to Docket ID No. EPA–HQ–RCRA–2009–0640. EPA's policy is that all comments received will be included in the public docket without change and may be made available online at *http://www.regulations.gov,* including any personal information provided, unless the comment includes information claimed to be Confidential Business Information (CBI) or other information whose disclosure is restricted by statute. Do not submit information that you consider to be CBI or otherwise protected through *http://www.regulations.gov* or e-mail. The *http://www.regulations.gov* Web site is an "anonymous access" system, which means EPA will not know your identity or contact information unless you provide it in the body of your comment. If you send an e-mail comment directly to EPA without going through *http://www.regulations.gov,* your e-mail address will be automatically captured and included as part of the comment that is placed in the public docket and made available on the Internet. If you submit an electronic comment, EPA recommends that you include your name and other contact information in the body of your comment and with any disk or CD–ROM you submit. If EPA cannot read your comment due to technical difficulties and cannot contact you for clarification, EPA may not be able to consider your comment. Electronic files should avoid the use of special characters, any form of encryption, and be free of any defects or viruses. For additional information about EPA's public docket, visit the EPA Docket Center homepage at *http://www.epa.gov/epahome/dockets.htm.* For additional instructions on submitting comments, go to the **SUPPLEMENTARY INFORMATION** section of this document.

Docket: All documents in the docket are listed in the *http://www.regulations.gov* index. Although listed in the index, some information is not publicly available, *e.g.,* CBI or other information whose disclosure is restricted by statute. Certain other material, such as copyrighted material, will be publicly available only in hard copy. Publicly available docket materials are available either electronically in *http://www.regulations.gov* or in hard copy at the Hazardous Waste Management System; Identification and Listing of Special Wastes; Disposal of Coal Combustion Residuals From Electric Utilities Docket, EPA/DC, EPA West, Room 3334, 1301 Constitution Ave., NW., Washington, DC 20460. This Docket Facility is open from 8:30 a.m. to 4:30 p.m., Monday through Friday, excluding legal holidays. The Docket telephone number is (202) 566–0270. The Public Reading Room is open from 8:30 a.m. to 4:30 p.m., Monday through Friday, excluding legal holidays. The

producers, and (2) all remaining wastes subject to RCRA Sections 3001(b)(3)(A)(i) and 8002(n)—that is, large volume coal combustion wastes generated at electric utility and independent power producing facilities that are co-managed together with certain other coal combustion wastes; coal combustion wastes generated at non-utilities; coal combustion wastes generated at facilities with fluidized bed combustion technology; petroleum coke combustion wastes; wastes from the combustion of mixtures of coal and other fuels (*i.e.,* co-burning of coal with other fuels where coal is at least 50% of the total fuel); wastes from the combustion of oil; and wastes from the combustion of natural gas.

On August 9, 1993, EPA published its Regulatory Determination for the first category of wastes (58 FR 42466, *http://www.epa.gov/epawaste/nonhaz/industrial/special/mineral/080993.pdf*), concluding that regulation under subtitle C of RCRA for these wastes was not warranted. To make an appropriate determination for the second category, or "remaining wastes," EPA concluded that additional study was necessary. Under the court-ordered deadlines, the Agency was required to complete a Report to Congress by March 31, 1999, and issue a Regulatory Determination by October 1, 1999.

In keeping with its court-ordered schedule, and pursuant to the requirements of Section 3001(b)(3)(A)(i) and Section 8002(n) of RCRA, EPA prepared a Report to Congress on the remaining FFC wastes in March 1999 (*http://www.epa.gov/epaoswer/other/fossil/volume_2.pdf*). The report addresses the eight study factors required by Section 8002(n) of RCRA for FFC wastes (*see* discussion in section IV. B).

On May 22, 2000, EPA published its Regulatory Determination on wastes from the combustion of fossil fuels for the remaining wastes (65 FR 32214, *http://www.epa.gov/fedrgstr/EPA-WASTE/2000/May/Day-22/f11138.htm*). In its Regulatory Determination, EPA concluded that the remaining wastes were largely identical to the high-volume monofilled wastes, which remained exempt based on the 1993 Regulatory Determination. The high volume wastes simply dominate the waste characteristics even when co-managed with other wastes, and thus the May 2000 Regulatory Determination addressed not only the remaining wastes, but effectively reopened the decision on CCRs that went to monofills.

EPA concluded that these wastes could pose significant risks if not properly managed, although the risk information was limited. EPA identified and discussed a number of documented proven damage cases, as well as cases indicating at least a potential for damage to human health and the environment, but did not rely on its quantitative groundwater risk assessment, as EPA concluded that it was not sufficiently reliable. However, EPA concluded that significant improvements were being made in waste management practices due to increasing state oversight, although gaps remained in the current regulatory regime. On this basis, the Agency concluded to retain the Bevill exemption, and stated we would issue a regulation under subtitle D of RCRA, establishing minimum national standards. Those subtitle D standards have not yet been issued. (Today's proposal could result in the development of the subtitle D standards consistent with the May 2000 Regulatory Determination, or with a revision of the determination, or the issuance of subtitle C standards under RCRA.)

EPA also explicitly stated in the May 2000 Regulatory Determination that the Agency would continue to review the issues, and would reconsider its decision that subtitle C regulations were unwarranted based on a number of factors. EPA noted that its ongoing review would include (1) "the extent to which [the wastes] have caused damage to human health or the environment;" (2) the adequacy of existing regulation of the wastes; (3) the results of an NAS report regarding the adverse human health effects of mercury;[4] and (4) "risk posed by managing coal combustion solid wastes if levels of mercury or other hazardous constituents change due to any future Clean Air Act air pollution control requirements for coal burning utilities" and that these efforts could result in a subsequent revision to the Regulatory Determination. For a further discussion of the basis for the Agency's determination, *see* section IV below.

F. What are CCRs?

CCRs are residuals from the combustion of coal. For purposes of this proposal, CCRs are fly ash, bottom ash, boiler slag (all composed predominantly of silica and aluminosilicates), and flue gas desulfurization materials (predominantly Ca-SO_X compounds) that were generated from processes intended to generate power.

[4] Toxicological Effects of Methylmercury, National Academy of Sciences, July 2000 (*http://books.nap.edu/catalog.php?record_id=9899#toc*). EPA has not taken any actions regarding the May 2000 Regulatory Determination as a result of the NAS report.

Fly ash is a product of burning finely ground coal in a boiler to produce electricity. Fly ash is removed from the plant exhaust gases primarily by electrostatic precipitators or baghouses and secondarily by wet scrubber systems. Physically, fly ash is a very fine, powdery material, composed mostly of silica. Nearly all particles are spherical in shape.

Bottom ash is comprised of agglomerated coal ash particles that are too large to be carried in the flue gas. Bottom ash is formed in pulverized coal furnaces and is collected by impinging on the furnace walls or falling through open grates to an ash hopper at the bottom of the furnace. Physically, bottom ash is coarse, with grain sizes spanning from fine sand to fine gravel, typically grey to black in color, and is quite angular with a porous surface structure.

Boiler slag is the molten bottom ash collected at the base of slag tap and cyclone type furnaces that is quenched with water. When the molten slag comes in contact with the quenching water, it fractures, crystallizes, and forms pellets. This boiler slag material is made up of hard, black, angular particles that have a smooth, glassy appearance.

Flue Gas Desulfurization (FGD) material is produced through a process used to reduce sulfur dioxide (SO_2) emissions from the exhaust gas system of a coal-fired boiler. The physical nature of these materials varies from a wet sludge to a dry powdered material, depending on the process. The wet sludge generated from the wet scrubbing process using a lime-based reagent is predominantly calcium sulfite, while the wet sludge generated from the wet scrubbing process using a limestone-based reagent is predominantly calcium sulfate. The dry powdered material from dry scrubbers that is captured in a baghouse consists of a mixture of sulfites and sulfates.

CCRs are managed in either wet or dry disposal systems. In wet systems, materials are generally sluiced via pipe to a surface impoundment. The material can be generated wet, such as FGD, or generated dry and water added to facilitate transport (*i.e.* sluiced) through pipes. In dry systems, CCRs are transported in its dry form to landfills for disposal.

1. Chemical Constituents in CCRs

The chemical characteristics of CCRs depend on the type and source of coal, the combustion technology, and the pollution control technology employed. For the 1999 Report to Congress and the May 2000 Regulatory Determination, EPA developed an extensive database

Human and Ecological Risk Assessment of Coal Combustion Wastes – Executive Summary

The U.S. Environmental Protection Agency (EPA) is evaluating management options for solid wastes from coal combustion (e.g., fly ash, bottom ash, slag). As part of this effort, EPA is evaluating whether current management practices for coal combustion waste (CCW) pose risks to human health or ecological receptors. To inform this objective, EPA has conducted a nationwide assessment of the risks posed by CCW disposal practices across the country.

This report describes the results of the tiered, site-based, probabilistic (Monte Carlo) risk assessment of onsite CCW disposal practices at coal-fired power plants across the United States. These landfills and surface impoundments represent disposal practices for CCW reported in 1995. Although EPA acknowledges that management practices for CCW have improved since 1995, as documented in U.S. Department of Energy (DOE) (2006), EPA believes that characterizing risks from facilities observed in 1995 provides a snapshot of the potential risks from CCW disposal and can provide useful information as EPA evaluates CCW management options. In addition, the data available on these facilities' locations, environmental characteristics, and waste management units (WMUs) allow EPA to apply a site-based risk assessment approach that the agency believes characterizes the risks to human health and the environment from disposing CCW in landfills and surface impoundments.

In summary, this CCW risk assessment evaluates potential risk results at the 50th and 90th percentile exposure level, adopting a risk criteria of 10^{-5} for excess cancer risks. Potential noncancer and ecological risks are also evaluated at the 50th and 90th percentile levels, adopting a hazard quotient (HQ) risk criteria greater than 1 for noncancer effects to both human and ecological receptors. Overall, when all types of landfills and surface impoundments (as observed in 1995) are evaluated in aggregate, the risk at the 90th percentile exceeds the risk criteria for cancer and noncancer risks for certain constituents. There is no potential risk above the risk criteria (cancer and noncancer) found at the 50th percentile. The risk assessment also suggests that one of the most sensitive parameters in the risk assessment is infiltration rate. Infiltration rate is greatly influenced by whether and how a WMU is lined.

For humans exposed via the groundwater-to-drinking-water pathway, arsenic in CCW landfills poses a 90th percentile cancer risk of $5x10^{-4}$ for unlined units and $2x10^{-4}$ for clay-lined units. The 50th percentile risks are $1x10^{-5}$ (unlined units) and $3x10^{-6}$(clay-lined units). Risks are higher for surface impoundments, with an arsenic cancer risk of $9x10^{-3}$ for unlined units and $3x10^{-3}$ for clay-lined units at the 90th percentile. At the 50th percentile, risks for unlined surface impoundments are $3x10^{-4}$, and clay-lined units show a risk of $9x10^{-5}$. Five additional constituents have 90th percentile noncancer risks above the criteria (HQs ranging from greater than 1 to 4) for unlined surface impoundments, including boron and cadmium, which have been cited in CCW damage cases, referenced above. Boron and molybdenum show HQs of 2 and 3 for clay-lined surface impoundments. None of these noncarcinogens show HQs above 1 at the 50th percentile for any unit type.

Composite liners, which are used in the majority of new facilities constructed after 1995, effectively reduce risks from all pathways and constituents below the risk criteria (cancer and noncancer) for both landfills and surface impoundments[1].

Risks from clay-lined units, as modeled, are about one-third to one-half the risks of unlined

[1] These results suggest that with the higher prevalence of composite liners in new CCW disposal facilities, future national risks from onsite CCW disposal are likely to be lower than those presented in this risk assessment (which is based on 1995 CCW WMUs).

units, but are still above the risk criteria used for this analysis.

Arrival times of the peak concentrations at a receptor well are much longer for landfills (hundreds to thousands of years) than for surface impoundments (most less than 100 years).

For humans exposed via the groundwater-to-surface-water (fish consumption) pathway, selenium (HQ = 2) and arsenic (cancer risk = $2x10^{-5}$) pose risks slightly above the risk criteria for unlined surface impoundments at the 90th percentile. For both constituents, lined 90th percentile risks and all 50th percentile risks are below the risk criteria. No constituents pose risks above the risk criteria for landfills at the 90th or 50th percentile.

Waste type has little effect on landfill risk results, but in surface impoundments, risks are up to 1 order of magnitude higher for codisposed CCW and coal refuse than for conventional CCW.

The higher risks for surface impoundments than landfills are likely due to higher waste leachate concentrations, a lower proportion of lined units, and the higher hydraulic head from the impounded liquid waste. This is consistent with damage cases reporting wet handling as a factor that can increase risks from CCW management.

For ecological receptors exposed via surface water, risks for landfills exceed the risk criteria for boron and lead at the 90th percentile, but 50th percentile risks are well below the risk criteria. For surface impoundments, 90th percentile risks for several constituents exceed the risk criteria, with boron showing the highest risks (HQ = 2,000). Only boron exceeds the risk criteria at the 50th percentile (HQ = 4). Exceedances for boron and selenium are consistent with reported ecological damage cases, which include impacts to waterbodies through the groundwater-to-surface-water pathway.

For ecological receptors exposed via sediment, 90th percentile risks for lead, arsenic, and cadmium exceeded the risk criteria for both landfills and surface impoundments because these constituents strongly sorb to sediments in the waterbody. The 50th percentile risks are generally an order of magnitude or more below the risk criteria.

Background

EPA has conducted risk assessments to evaluate the environmental risks from CCW management practices,[2] including CCW disposal in landfills and surface impoundments. Although EPA determined (in April 2000) that certain CCWs were not subject to hazardous waste regulations and therefore would be subject to regulation as nonhazardous wastes, EPA did not specify regulatory options at that time. This risk assessment was conducted to identify and quantify human health and ecological risks that may be associated with current disposal practices for high-volume CCW, including fly ash, bottom ash, boiler slag, flue gas desulfurization (FGD) sludge, coal refuse waste, and wastes from fluidized-bed combustion (FBC) units. These risk estimates will help inform EPA's decisions about how to treat CCWs under Subtitle D of the Resource Conservation and Recovery Act.

Purpose and Scope of the Risk Assessment

The purpose of this risk assessment is to identify potential risks associated with CCW constituents, waste types, receptors, and exposure pathways, and to provide information about those scenarios that EPA can use to develop CCW management options.

The scope of this risk assessment is CCWs managed onsite at utility power plants. EPA's *Report to Congress: Wastes from the Combustion of Fossil Fuels* (U.S. EPA, 1999a) reports that there are 440 coal-fired utility power plants in the United States. Although these plants are concentrated in the East, they are found in nearly every state, with a broad variety of climate, geologic, and land use settings. The large volumes of waste generated by these plants

[2] Details on EPA's previous CCW work can be found at http://www.epa.gov/epaoswer/other/fossil/ index.htm.

are typically managed onsite in landfills and surface impoundments. This risk assessment was designed to develop national human and ecological risk estimates that are representative of onsite CCW management settings throughout the United States.

Risk Assessment Methodology

To estimate the risks posed by the onsite management of CCW, this risk assessment determined the release of CCW constituents from landfills and surface impoundments, estimated the concentrations of these constituents in environmental media surrounding coal-fired utility power plants, and estimated the risks that these concentrations pose to human and ecological receptors. To evaluate the significance of these risks, the risk criteria adopted for this assessment are:

- An estimate of the excess lifetime cancer risk for individuals exposed to carcinogenic (cancer-causing) contaminants of 1 chance in 100,000 (10^{-5} excess cancer risk)
- An HQ (the ratio of predicted intake levels to safe intake levels) greater than 1 for constituents that can produce noncancer human health effects
- An HQ greater than 1 for constituents with adverse effects to ecological receptors.

In support of this risk assessment, EPA assembled a constituent database that includes leachate and total waste analyses for 41 CCW constituents taken from more than 140 CCW disposal sites around the country. The CCW risk assessment subjected these waste and leachate constituent concentrations to a tiered risk assessment methodology (Figure ES-1) that implemented the following steps to assess the human and ecological risk of CCWs:

- **Hazard Identification**, which collected existing human health and ecological benchmarks for the 41 CCW constituents to identify the 26 chemicals with benchmarks for constituent screening
- **Constituent Screening**, which compared very conservative estimates of exposure concentrations (e.g., whole waste concentrations, leachate concentrations) to health-based concentration benchmarks to quickly and simply eliminate constituents and exposure pathways that do not require further analysis
- **Full-Scale Analysis**, which used a site-based Monte Carlo analysis to characterize at a national level the risks to human health and ecological receptors from onsite disposal (in landfills and surface impoundments) of CCW constituents that were not eliminated in the screening analysis.

The screening analysis looked at all probable exposure pathways from CCW management in landfills and surface impoundments and identified 21 CCW constituents and 3 exposure scenarios to evaluate in the full-scale analysis (Table ES-1). Exposure scenarios evaluated for people include contaminated groundwater being transported to drinking water wells from a CCW landfill or surface impoundment, and contaminated groundwater discharging into surface water and contaminating a nearby stream or lake where people catch and eat fish. The full-scale analysis also addressed ecological risk in the same waterbodies.

Constituents addressed in the full-scale analysis are listed in Table ES-2 along with the potential exposure pathways identified for full-scale modeling in the screening analysis.

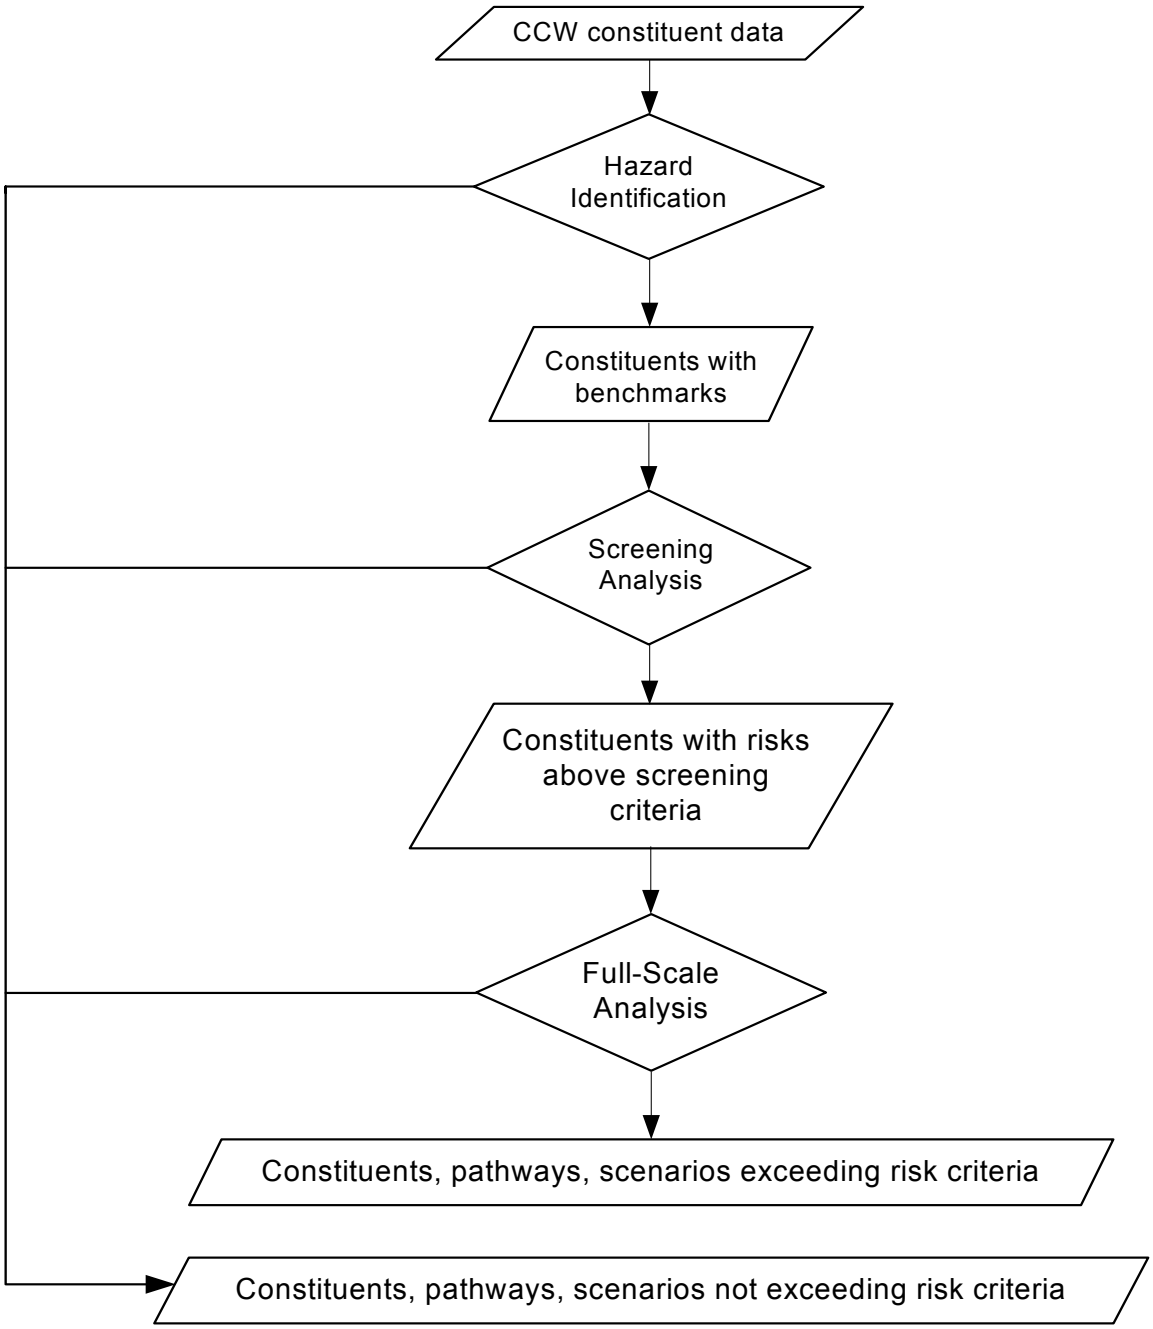

Figure ES-1. Overview of CCW risk assessment.

Table ES-1. Sources, Releases, Exposure Pathways, and Receptors Evaluated in the CCW Risk Assessment

Release Mechanism	Exposure Pathway	Exposure Mechanism	Receptor Type[a]	Screening Result
Landfills				
Leaching	Groundwater-to-drinking-water	Residential well	Resident	Full-scale analysis
	Groundwater-to-surface-water	Stream or lake, uptake by fish; contact with water, sediments	Recreational fisher; aquatic ecosystems	Full-scale analysis
Water erosion	Overland transport to surface water	Stream or lake, uptake by fish; contact with water, sediments	Recreational fisher; aquatic ecosystems	Below screening criteria
	Overland transport to soil	Soil ingestion; uptake from soil by plants, beef, dairy	Subsistence farmer; terrestrial ecosystems	Below screening criteria[b]
Wind erosion	Soil deposition	Soil ingestion; uptake from soil by plants, beef, dairy	Subsistence farmer; terrestrial ecosystems	Below screening criteria
	Fugitive dust	Inhalation	Resident	Below screening criteria
Surface impoundments				
Leaching	Groundwater-to-drinking water	Residential well	Resident	Full-scale analysis
	Groundwater-to-surface water	Stream or lake, uptake by fish; contact with water, sediments	Recreational fisher; ecological receptors	Full-scale analysis

[a] Human receptor types include adults and children.
[b] Except boron for plant toxicity. Also, damage cases indicate soil risks from selenium to terrestrial amphibians (Carlson and Adriano, 1993; Hopkins et al., 2006).

Table ES-2. Screening Analysis Results:
CCW Constituents Selected for Full-Scale Analysis[a]

Constituent	Human Health - Drinking Water		Human Health - Surface Water[b]		Ecological Risk - Surface Water	
	LF	SI	LF	SI	LF	SI
Arsenic	•	•	•	•	•	•
Boron	•	•			•	•

Silver					•	•
Zinc					•	

LF = landfill.
SI = surface impoundment
nd = nondetect—results are inconclusive because all analyses are nondetects.
na = not available—data were not available for cobalt in CCW landfill leachate.

[a] A mark in a cell indicates that the constituent was above the screening criteria for the indicated pathway and WMU type. Blank cells indicate that the constituent was below the screening criteria for a particular pathway/WMU combination. Risk screening was based on 90th percentile risk concentrations and no attenuation.

[b] Fish consumption pathway.

The full-scale analysis was designed to characterize waste management scenarios based on two waste management options (disposal of CCW onsite in landfills and in surface impoundments). The risk assessment was also used to characterize waste management scenarios based on three liner types (unlined units, clay-lined units, and composite-lined units) and three waste types, as follows:

- **Conventional CCW** (ash and FGD sludge), which includes fly ash, bottom ash, boiler slag, and FGD sludge
- **Codisposed CCWs and coal refuse,**[3] which are more acidic than conventional CCWs due to sulfide minerals in the coal refuse
- **FBC wastes**, which include fly ash and bed ash, and which tend to be more alkaline than conventional CCW because of the limestone mixed in during fluidized bed combustion.

These three waste types and the two waste management options provide a good representation of CCW disposal practices and waste chemistry conditions that affect the release of CCW constituents from WMUs.[4],[5]

The full-scale analysis was implemented using a site-based probabilistic approach that produces a distribution of risks or hazards for each receptor by allowing the values of some of the parameters in the analysis to vary. This approach is ideal for this risk assessment because there are many CCW facilities across the United States, and a site-based approach can capture both the variability in waste management practices at these facilities and the differences in their environmental settings (e.g., hydrogeology, climate, hydrology). This probabilistic approach was implemented through the following steps:

1. Characterize the CCW constituents and waste chemistry, along with the WMUs in which each waste stream may be managed (i.e., the size and liner status of CCW landfills and surface impoundments)
2. Characterize the environmental settings for the sites where CCW landfills and surface impoundments are located (i.e., locations of coal-fired power plants)
3. Identify how contaminants are released from a WMU (i.e., leaching) and transported to human and ecological receptors (i.e., via groundwater and surface water)
4. Predict the fate, transport, and concentration of constituents in groundwater and surface water once they are released to groundwater from the WMUs and travel to receptors at each site
5. Quantify the potential exposure of human and ecological receptors to the contaminant in the environment
6. Estimate the potential risk to each receptor from the exposure and characterize this risk in terms of exposure pathways and health effects.

Based on this approach, we characterized the potential risks associated with the waste disposal scenarios and exposure pathways, including the uncertainties associated with the analysis results.

Results and Conclusions

Risks from clay-lined units are lower than those from unlined units, but 90th percentile risks are still well above the risk criteria for arsenic and thallium for landfills and arsenic, boron, and molybdenum for surface impoundments. Composite liners, as modeled in this assessment, effectively reduce risks from all constituents to below the risk criteria for both landfills and surface impoundments. Although it is likely that today, most new landfills have some type of liner (based on more recent data that were not incorporated into this assessment),

[3] Coal refuse is the waste coal produced from coal handling and preparation operations.

[4] Conventional CCW and codisposed CCW and coal refuse were modeled in landfills and surface impoundments and are the focus of the overall analysis. FBC wastes were treated separately because of limited data on FBC waste management units.

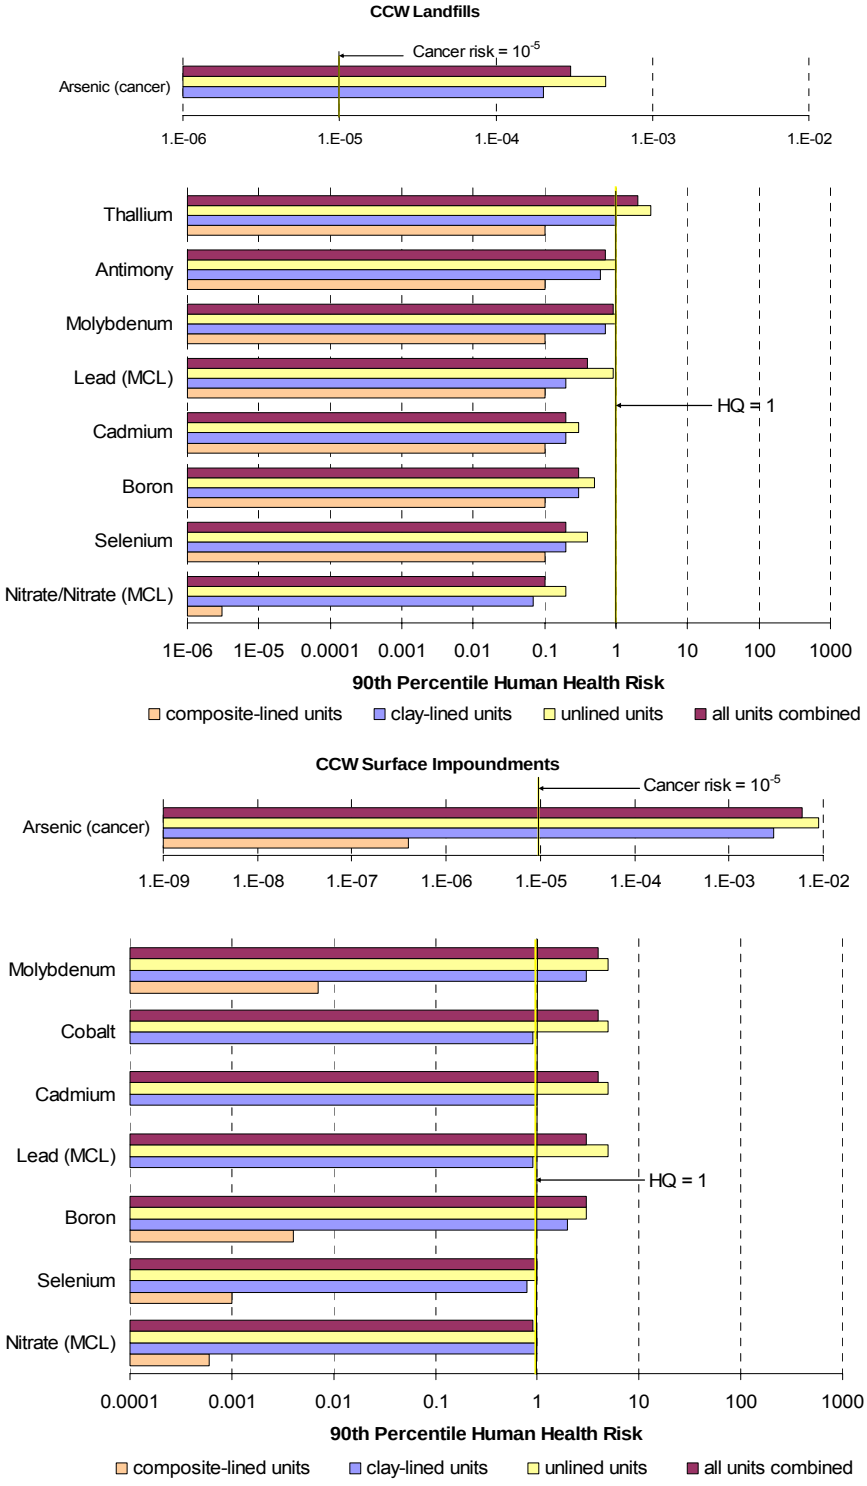
[5] Although different waste chemistries required the separate modeling of conventional CCW and CCW codisposed with coal refuse, the results were combined in this analysis to give an overall picture of the risks from CCW management,

it is not known how many unlined units continue to operate in the United States.

Recent data from a joint DOE/EPA survey suggests that more facilities are lined today than were in the 1995 data set on which this risk assessment is based. This suggests that the risks from CCW may be lower than the results presented in this report, although the older, unlined WMUs represented in this risk assessment may continue to pose potential risks to human health and the environment if they are closed with wastes in place.

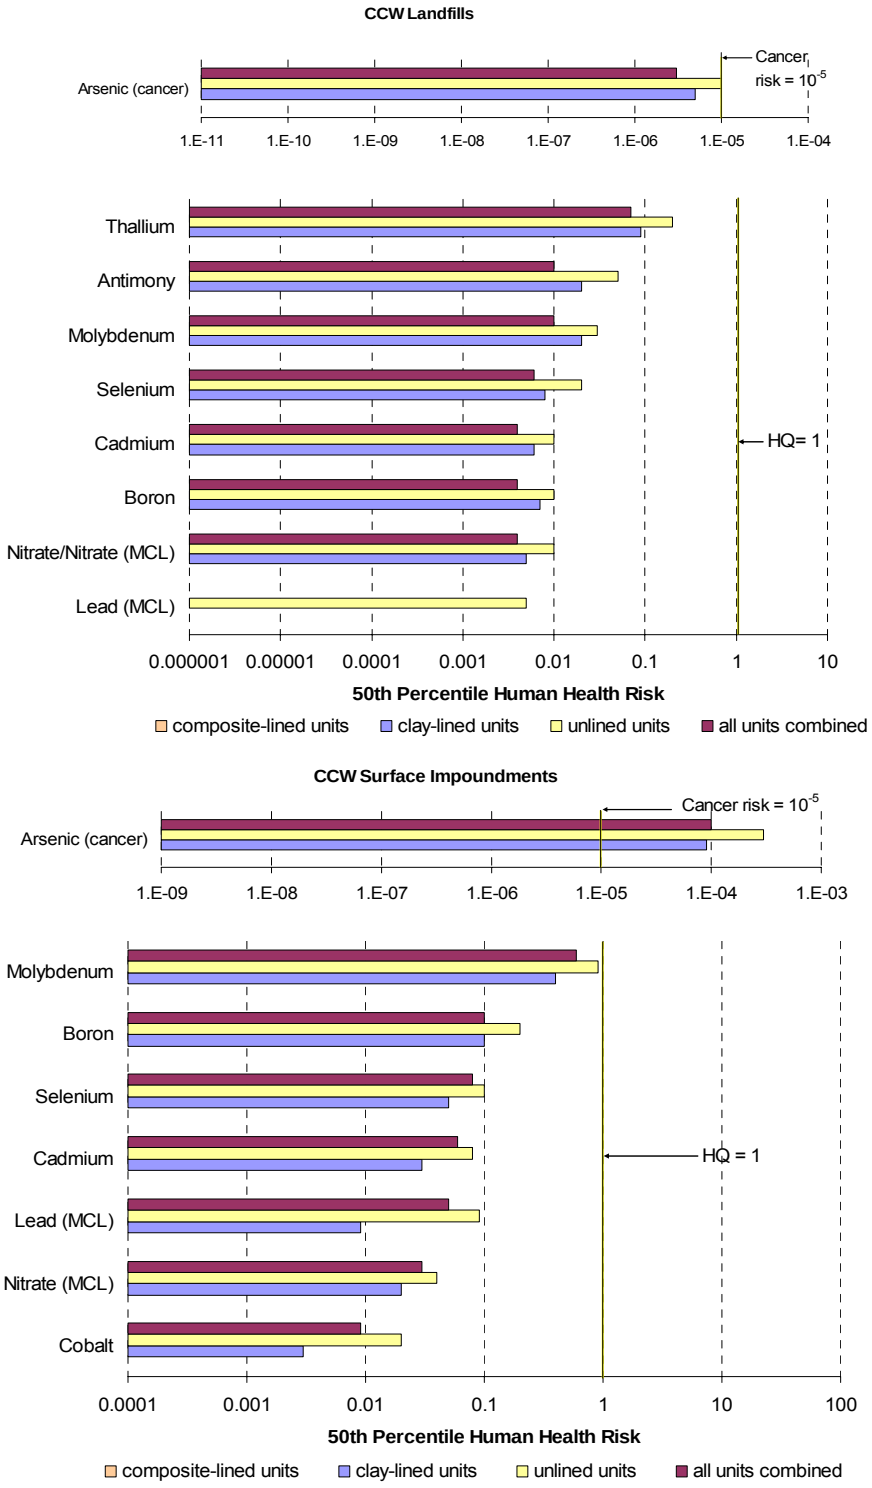
The CCW risk assessment results at the 90th percentile suggest that the management of CCW in landfills and surface impoundments as observed in 1995 for unlined and clay-lined units results in risks greater than the risk criteria of 10^{-5} for excess cancer risk to humans or an HQ greater than 1 for noncancer effects to both human and ecological receptors. Key risk findings include the following:

- 90th and 50th percentile risks for composite-lined units were consistently well below a cancer risk of 10^{-5} and an HQ of 1 for all constituents, waste management scenarios, and exposure pathways modeled in the CCW risk assessment.
- For humans exposed via the groundwater-to-drinking-water pathway (see Figures ES-2 and ES-3), arsenic and thallium show risks to human health above the risk criteria for unlined and clay-lined CCW landfills. Arsenic poses a 90th percentile cancer risk of $5x10^{-4}$ for unlined units and $2x10^{-4}$ for clay-lined units; thallium shows a 90th percentile HQ above 1 for unlined units only. As shown in Figure ES-3, 50th percentile results are at or below risk criteria for all constituents.
- Risks are higher for surface impoundments for the groundwater-to-drinking-water pathway, with a 90^{th}-percentile arsenic cancer risk of $9x10^{-3}$ for unlined units and $3x10^{-3}$ for clay-lined units. For unlined units, 5 additional constituents have noncancer HQs ranging from 3 to 4 for the 90th percentile, including boron, lead, cadmium, cobalt, and molybdenum. Two constituents (boron and molybdenum) have 90th percentile HQs greater than 1 (2 and 3, respectively) for clay-lined surface impoundments. The 50th percentile results are approximately 10-fold greater than the 10^{-5} cancer risk level for arsenic in unlined ($3x10^{-4}$) and clay-lined ($9x10^{-5}$) surface impoundments.
- For humans exposed via the groundwater-to-surface-water (fish consumption) pathway, selenium (HQ = 2) and arsenic (cancer risk = $2x10^{-5}$) show 90th percentile risks for unlined surface impoundments slightly above the risk criteria. All other waste management scenarios and all 50^{th} percentile results show risks at or below the risk criteria for the fish consumption pathway.
- Waste type has little effect on landfill risk results, but surface impoundment risks are higher for codisposed CCW and coal refuse than for conventional CCW.
- Higher risks for surface impoundments than landfills are likely due to a combination of higher waste leachate concentrations, a higher proportion of unlined units, and a higher hydraulic head from impounded liquid waste. This is consistent with damage cases reporting wet handling as a factor that can increase risks from CCW management.
- For ecological receptors exposed via surface water, the 90th percentile risks for landfills exceed an HQ of 1 for boron and lead. For surface impoundments, risks for the 90th percentile for 6 constituents (boron, lead, arsenic, selenium, cobalt, and barium) exceed an HQ of 1, with boron showing the highest risks (HQ over 2,000). The exceedances for boron and selenium are consistent with reported ecological damage cases, which include impacts to waterbodies through the groundwater-to-surface-water pathway (e.g., Carlson and Adriano, 1993; U.S. EPA, 2007). Only boron exceeds the ecological risk criterion for surface water at the 50th percentile, with an HQ of 4.



A cancer risk of 10^{-5} or an HQ of 1 are the risk criteria for this analysis.
Results for "all units combined" are results across all liner types (unlined, clay-lined, composite-lined).
Note: When the composite liner bar does not appear on the chart, the 90th percentile risk index is below the minimum shown on the x-axis.

Figure ES-2. Full-scale 90th percentile risk results for the groundwater-to-drinking-water pathway.



A cancer risk of 10^{-5} or an HQ of 1 are the risk criteria for this analysis.
Results for "all units combined" are results across all liner types (unlined, clay-lined, composite-lined).
Note: When the composite liner bar does not appear on the chart, the 50th percentile risk index is below the minimum shown on the x-axis.

Figure ES-3. Full-scale 50th percentile risk results for the groundwater-to-drinking-water pathway.

- For ecological receptors exposed via sediment, 90th percentile risks for lead, arsenic, and cadmium exceeded a HQ of 1 for both landfills (HQs from 2 to 20) and surface impoundments (HQs from 20 to200) probably because these constituents strongly sorb to sediments. No constituents exceed the ecological risk criterion for sediments at the 50th percentile.

Sensitivity analysis results indicate that for more than 75 percent of the scenarios evaluated, the risk assessment model was most sensitive to parameters related to groundwater flow and transport, including WMU infiltration rate, leachate concentration, and aquifer hydraulic conductivity and gradient. For the groundwater-to-surface water pathway, another sensitive parameter is the flowrate of the waterbody into which the contaminated groundwater is discharging. For strongly sorbing contaminants (such as lead and cadmium), variables related to sorption and travel time (adsorption coefficient, depth to groundwater, receptor well distance) are also important.

The multiple uncertainties associated with the CCW risk assessment include scenario uncertainty (i.e., uncertainty about the environmental setting around the plant), uncertainty in human exposure factors (such as exposure duration, body weight, and intake rates), uncertainty in human and ecological toxicity factors and potential cumulative risks, and uncertainty in estimates of fate and transport of waste constituents in the environment. Scenario uncertainty has been minimized by basing the risk assessment on conditions around existing coal-fired power plants around the United States, as observed in 1995. Uncertainty in environmental setting parameters has been incorporated into the risk assessment by varying these inputs within reasonable ranges when the exact value is not known. Uncertainty in human exposure factors has also been addressed through the use of national distributions.

Some uncertainties not addressed explicitly in the risk assessment have been addressed through comparisons with other studies and data sources, as described below:

- **Appropriateness of CCW leachate data.** Although porewater data were available and used for CCW surface impoundments, available data for landfills were mainly Toxicity Characteristic Leaching Procedure (TCLP) analyses, which may not be representative of actual CCW leachate. Comparisons with recent (2006) studies of coal ash leaching processes show very good agreement for arsenic. However, although the selenium CCW data are within the range of the 2006 data, some of the higher concentrations in the 2006 data are not represented by the TCLP data. This suggests that selenium risks may be underestimated, which is consistent with selenium as a cause for CCW damage cases.
- **Limited CCW leachate data.** Because of a high proportion of nondetect values[6] and a limited number of measurements, mercury could not be addressed in the CCW risk assessment for landfills or surface impoundments, and antimony and thallium could not be assessed in surface impoundments. Mercury levels in leachate were measured in EPA's 2006 leaching study and suggest a limited concern for mercury for the CCW leachates investigated, but additional work is needed to extend these results to all CCW disposal facilities.
- **Clean Air Interstate Rule (CAIR) and Clean Air Mercury Rule (CAMR) impacts.** While CAIR and CAMR will reduce air emissions of mercury and other metals from coal-fired power plants, mercury and other more volatile metals will be transferred from the flue gas to fly ash and other air pollution control residues, including the sludge from wet scrubbers. EPA is conducting research on how much total mercury will increase in CCW from the use of mercury controls, as well as how the leachability of mercury and other metals will be impacted. Preliminary results suggest that the impacts on mercury leaching will depend on the mercury control process.
- **Arsenic speciation.** The current model does not speciate metals during subsurface

[6] Nondetect values are measurements where the concentration of a constituent is below the level that the analytical instrument can detect. The actual level could range from zero to just below the detection limit. Nondetects for constituents other than mercury were modeled at one-half the detection limit for this risk analysis.

transport. Damage cases and other studies suggest that arsenic readily converts from arsenic III in CCW leachate to the less mobile arsenic V in soil and groundwater. However, model runs conducted for both species suggest that the difference in risk between the two species is only about a factor of 2 at the 90th percentile risk level, which is not enough to bring arsenic risks below the risk criteria.

Uncertainties that EPA does not have enough data at this time to evaluate with respect to CCW risk results include the following:

- **Well distance.** Nearest well distances were taken from a survey of municipal solid waste (MSW) landfills because data were not available from CCW sites. EPA believes that this is a protective assumption because MSW landfills generally tend to be in more populated areas, but there are little data available to test this hypothesis.
- **Liner performance.** Liner design and performance for CCW WMUs were based on data and assumptions EPA developed to be appropriate for municipal and nonhazardous industrial waste landfills. EPA believes that CCW landfills should have similar performance characteristics, but does not have quantitative data on CCW WMU liners to verify that.
- **Data gaps for ecological receptors.** Data were insufficient to develop screening levels and quantitative risk estimates for terrestrial amphibians, but EPA acknowledges that damage cases indicate risk to terrestrial amphibians through exposure to selenium (e.g., Hopkins et al., 2006).
- **Ecosystems and receptors at risk.** Certain critical assessment endpoints were not evaluated in this analysis, including impacts on managed lands, critical habitats, and threatened and endangered species. These would be addressed through more site-specific studies on the proximity of these areas and species to CCW disposal units.
- **Synergistic and additive risk.** The impact of exposures to multiple contaminants on human and ecological risks was not evaluated in this analysis. EPA recognizes that a single-constituent analysis may underestimate risks associated with multiple chemical exposures. The risk assessment also does not add risks across pathways (i.e., risks from drinking water and fish consumption), but EPA does not think that doing so would change the results markedly because the constituents of concern differ between pathways.

EPA recognizes that uncertainties in mercury levels in CCW leachate, both with and without the CAIR/CAMR mercury controls, represent a potentially significant gap in our knowledge of CCW risks.

1.0 Introduction

1.1 Background

The U.S. Environmental Protection Agency (EPA) has evaluated the human health and environmental risks associated with coal combustion waste (CCW) management practices, including disposal in landfills and surface impoundments. In May 2000, EPA determined that regulation as hazardous wastes under Subtitle C of the Resource Conservation and Recovery Act (RCRA) was not warranted for certain CCWs, but that regulation as nonhazardous wastes under RCRA Subtitle D was appropriate. However, EPA did not specify regulatory options at that time. This risk assessment was designed and implemented to help EPA identify and quantify human health and ecological risks that may be associated with current management practices for high-volume CCWs. These wastes are fly ash, bottom ash, boiler slag, and flue gas desulfurization (FGD) sludge, along with wastes from fluidized-bed combustion (FBC) units and CCWs codisposed with coal refuse. This risk assessment will help EPA develop CCW management options for these high-volume waste streams. Details on EPA's CCW work to date can be found at http://www.epa.gov/epaoswer/other/fossil/index.htm.

Note that the full-scale risk assessment described in this report was mostly conducted in 2003, meaning that the data collection efforts to support the risk assessment were based on the best information available to EPA at that time. As a result, more recent Agency efforts to characterize CCW wastes and management practices, such as the joint EPA and U.S. Department of Energy (DOE) survey of CCW waste management units (WMUs) (U.S. DOE, 2006) and EPA's recent study of CCW chemistries and leaching behavior (U.S. EPA, 2006), were not considered in the main analysis phase of this risk assessment. However, these more recent efforts are discussed as part of the risk characterization, and EPA is currently evaluating how to best incorporate and address the results and findings of these studies in future efforts to address CCW management practices.

The Agency is making the risk analysis document available in the Docket[1] to allow interested parties to submit comments on the analytical methodology, data, and assumptions used in the analysis and to submit additional information for the Agency to consider. In addition, the risk assessment will undergo independent scientific peer review by experts outside EPA following closure of the public comment period. Public comments will be made available to the peer reviewers for their consideration during the review process. The peer review will focus on technical aspects of the analysis, including the construction and implementation of the Monte Carlo analysis, the selection of models to estimate the release of constituents found in CCW from landfills and surface impoundments and their subsequent fate and transport in the environment, and the characterization of risks resulting from potential exposures to human and ecological receptors. As appropriate, EPA will update this analysis based on both public and peer-review comments.

1.2 Purpose and Scope of the Risk Assessment

The purpose of this risk assessment is to identify CCW constituents, waste types, exposure pathways, and receptors that may produce risks to human and ecological health, and to provide information about those scenarios that EPA can use to develop management options for CCW management.

The scope of this risk assessment is utility CCWs managed onsite at utility power plants. EPA's *Report to Congress: Wastes from the Combustion of Fossil Fuels* (U.S. EPA, 1999a) reports that there are 440 coal-fired utility power plants in the United States. Although these plants are concentrated in the East, they are found in nearly every state, with facility settings ranging from urban to rural. The large volumes of waste generated by these plants are typically managed onsite in landfills and surface impoundments. This risk assessment was designed to develop national human and ecological risk estimates that are representative of onsite CCW management settings throughout the United States.

1.3 Overview of Risk Assessment Methodology

To estimate the risks posed by the onsite management of CCW, this risk assessment estimated the release of CCW constituents from landfills and surface impoundments, the concentrations of these constituents in environmental media surrounding coal-fired utility power plants, and the risks that these concentrations pose to human and ecological receptors.

The size, design, and locations of the onsite CCW landfills and surface impoundments modeled in this risk assessment are based on data from a national survey of utility CCW disposal conducted by the Electric Power Research Institute (EPRI) in 1995 (EPRI, 1997). Data from this survey on facility area, volume, and liner characteristics were used in the CCW risk assessment because they were the most recent and complete data set available at the time the risk assessment was conducted (2003). However, as shown in Table 1-1, the EPA/DOE study conducted since then (U.S. DOE, 2006) shows a much higher proportion of lined facilities than do the 1995 EPRI data.

Table 1-1. Liner Prevalence in EPRI and DOE Surveys

Liner Type	Landfills	Surface Impoundments
1995 EPRI Survey[a] – 181 facilities		
Unlined	40%	68%
Lined (compacted clay or composite [clay and synthetic])	60%	32%
2004 DOE Survey[b] – 56 Facilities		
Unlined	3%	0%
Lined (compacted clay or composite [clay and synthetic])	97%	100%

[a] EPRI (1997)
[b] U.S. DOE (2006)

The releases, and hence media concentrations and risk estimates, are based on leaching to groundwater, wind and water erosion, and overland transport. This analysis does not address direct releases to surface water, which are permitted under the National Pollutant Discharge Elimination System (NPDES) of the Clean Water Act. Thus, the estimated media concentrations and risks do not take into account contributions from NPDES-permitted releases, including discharges due to flooding or heavy rainfall.

To evaluate the significance of the estimated risks, the risk criteria adopted for this assessment are

- An estimate of the excess lifetime cancer risk for individuals exposed to carcinogenic (cancer-causing) contaminants of 1 chance in 100,000 (10^{-5} excess cancer risk)[2]
- A measure of safe intake levels to predicted intake levels, a hazard quotient (HQ) greater than 1 for constituents that can produce noncancer human health effects (an HQ of 1 is defined as the ratio of a potential exposure to a constituent to the highest exposure level at which no adverse health effects are likely to occur)
- An HQ greater than 1 for constituents with adverse effects to ecological receptors.

In 1998, EPA conducted a risk assessment for fossil fuel combustion wastes (which include CCWs) to support the May 2000 RCRA regulatory determination (U.S. EPA, 1998a,b). Since then, EPA has added to the waste constituent database that was used in that effort, expanding the number of leachate and total waste analyses for 41 CCW constituents. The CCW risk assessment subjected these waste and leachate constituent concentrations to the tiered risk assessment methodology illustrated in Figure 1-1. This methodology implemented the following steps to assess the human and ecological risk of CCWs:

- **Hazard Identification**, which collected existing human health and ecological benchmarks for the CCW constituents. Only constituents with benchmarks move on to the next step, constituent screening.
- **Constituent Screening**, which compared very conservative estimates of exposure concentrations (e.g., whole waste concentrations, leaching concentrations) to health-based concentration benchmarks to quickly and simply identify constituents and exposure pathways with risks below the screening criteria.
- **Full-Scale Analysis**, which characterized at a national level the human health and ecological risks for constituents in CCW disposed onsite in landfills and surface impoundments using a site-based Monte Carlo risk analysis.

This document focuses on the full-scale Monte Carlo analysis. Constituent screening results are also presented as part of the problem formulation discussion, along with a summary of the screening methodology.[3]

[2] The typical cancer risk range used by the Office of Solid Waste and Emergency Response is 10^{-4} to 10^{-6}. In hazardous waste listings, the point of departure for listing a waste is 10^{-5}.

[3] Details on the CCW constituent screening analysis can be found in U.S. EPA (2002a).

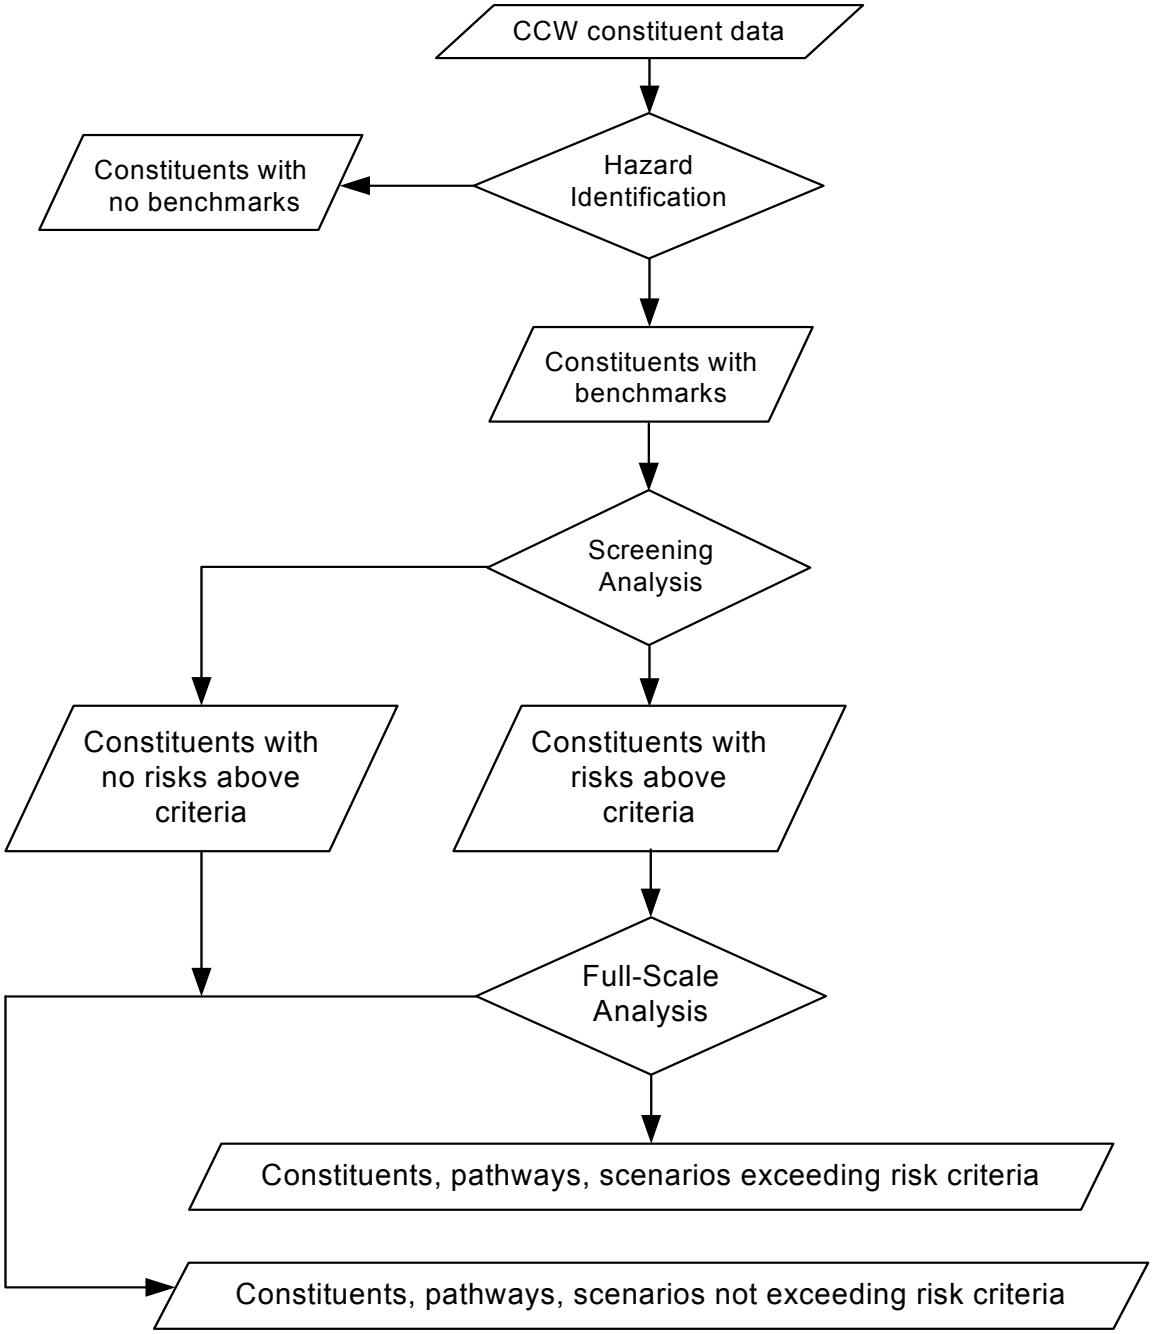

Figure 1-1. Overview of coal combustion waste risk assessment.

1.3.1 Waste Management Scenarios

The full-scale analysis was designed to characterize waste management scenarios based on two waste management options (disposal of CCW onsite in landfills and in surface impoundments) and three waste types, as follows:

- **Conventional CCW**, which includes fly ash, bottom ash, boiler slag, and FGD sludge
- **Codisposed CCWs and coal refuse,**[4] which are more acidic than conventional CCWs due to sulfide minerals in the mill rejects
- **FBC wastes**, which include fly ash and the fluidized bed ash, and which tend to be more alkaline than conventional CCW because of the limestone mixed in during fluidized bed combustion.

Conventional CCW and codisposed CCW and coal refuse are typically disposed of in landfills and surface impoundments that can be lined with clay or composite liners. FBC wastes are only disposed of in landfills in the United States; therefore, surface impoundment disposal was not modeled for FBC waste.

These three waste types, two waste management options, and three liner conditions (unlined, clay-lined, composite-lined) modeled in this analysis provide a good representation of CCW disposal practices and waste chemistry conditions that affect the release of CCW constituents from WMUs.

1.3.2 Approach

The full-scale analysis was implemented using a site-based probabilistic approach that produces a distribution of risks or hazard for each receptor by allowing the values of some of the parameters in the analysis to vary. This approach is ideal for this risk assessment because there are many CCW facilities across the United States, and a site-based approach can capture both the variability in waste management practices at these facilities and the differences in their environmental settings (e.g., hydrogeology, climate, hydrology). This probabilistic approach was implemented through seven primary steps:

Problem Formulation

1. Characterize the CCW constituents and waste chemistry, along with the size and liner status of the WMUs in which each waste stream may be managed
2. Characterize the environmental settings for the sites where CCW landfills and surface impoundments are located

[4] Coal refuse is the waste coal produced from coal handling, crushing, and sizing operations, and tends to have a high sulfur content and low pH from high amounts of sulfide minerals (like pyrite). In the CCW constituent database, codisposed coal refuse includes "combined ash and coal gob," "combined ash and coal refuse," and "combined bottom ash and pyrites."

3. Identify scenarios under which contaminants are released from a WMU and transported to a human receptor

Analysis

4. Predict the fate and transport of constituents in the environment once they are released from the WMUs at each site

5. Quantify the exposure of human and ecological receptors to the contaminant in the environment and the risk associated with this exposure

Risk Characterization

6. Estimate the risk to receptors from the exposure and characterize this risk in terms of exposure pathways, health effects, and uncertainties

7. Identify the waste disposal scenarios and environmental conditions that pose risks to human health or the environment that are above the risk criteria. Evaluate risks at the 50th and 90th percentiles.

1.4 Document Organization

This document is organized into the following sections:

- **Section 2, Problem Formulation,** describes how the framework for the full-scale analysis was developed, including identification of the waste constituents, exposure pathways, and receptors of concern; selection and characterization of waste management practices and sites to model; and development of the conceptual site models for the modeling effort.

- **Section 3, Analysis,** describes the probabilistic modeling framework and the models and methods used to (1) estimate constituent releases from CCW landfills and surface impoundments (source models), (2) model constituent concentrations in the environmental media of concern (groundwater and surface water), (3) calculate exposure, and (4) estimate risk to human and ecological receptors.

- **Section 4, Risk Characterization,** characterizes the human health and environmental risks posed by CCW, including (1) discussion of the methods used to account for variability and uncertainty and (2) identification of the scenarios and conditions that result in risks above the risk criteria. Results are presented as national estimates for CCW landfills and CCW surface impoundments, as well as by waste type and liner status. For risk exceedances, this section identifies the CCW constituents and pathways that exceed the risk criteria, along with any factors (such as liners or facility environmental setting) that might result in higher or lower risk levels. Finally, the risk characterization evaluates the risk results in light of more recent research on CCW waste management practices and the environmental behavior of CCW constituents.

The first three appendices provide detailed information on how wastes, WMUs, and settings were characterized for the risk assessment. Appendix A describes the chemical characteristics of the wastes disposed in the WMUs, including the CCW leachate concentration distributions used. Appendix B describes how EPA characterized the WMUs (landfills and surface impoundments), including surface area, capacities, geometry, and liner status. Appendix C presents the methodologies and data used to characterize the environmental setting at each CCW site, including delineating the site layout and determining the environmental setting (e.g., meteorology, climate, soils, aquifers, and waterbodies).

The remaining appendices provide detailed information on the specific models and data used to calculate risk, including the nonlinear sorption isotherms (Appendix D), the surface water fate and transport and intake equations (Appendix E), the exposure factors (Appendix F), and benchmarks for human health (Appendix G) and ecological risk (Appendix H).

2.0 Problem Formulation

The full-scale CCW risk assessment is intended to evaluate, at a national level, risk to individuals who live near WMUs used for CCW disposal. This section describes how the conceptual framework for the full-scale risk assessment was developed, including

- Constituent selection and screening to identify the CCW constituents, exposure pathways, and receptors to address in this analysis (Section 2.1.1)
- Location and characterization of the CCW landfills and surface impoundments to be modeled as the sources of CCW contaminants in the site-based analysis (Section 2.1.2)
- The conceptual site model used to represent CCW disposal facilities (Section 2.2)
- The general modeling approach and scope (Section 2.3), including data collection, fate and transport modeling to estimate exposure point concentrations, exposure assessment, and the calculation of risks to human and environmental receptors.

2.1 Source Characterization

The main technical aspects of the CCW risk assessment were completed in 2003, and the waste management scenarios modeled in this assessment are based on the best data on industry operations and waste management practices that were available at that time. These data sources include a 1995 industry survey on CCW management practices (the EPRI comanagement survey [EPRI, 1997]) and data collected from a variety of sources before the 2003 risk assessment (e.g., EPA's CCW constituent database). Since 2003, DOE and EPA have completed a survey to characterize CCW waste disposal practices from 1994 to 2004, with a focus on new facilities or facility expansions completed within that same time frame (U.S. DOE, 2006). Although these newer data were not available when this risk assessment was conducted, they are discussed in the risk characterization (Section 4) as an uncertainty with respect to how well the risk assessment represents current WMU liner conditions.

This risk assessment provides a national characterization of waste management scenarios for wastes generated by coal-fired utility power plants. The sources modeled in these scenarios are onsite landfills and surface impoundments, which are the primary means by which CCW is managed in the United States. The characterization of these sources, in terms of their physical dimensions, operating parameters, location, environmental settings, and waste characteristics, is fundamental to the construction of scenarios for modeling. This section describes how the coal combustion waste streams and management practices were characterized (based on the above data sources) and screened to develop the waste disposal scenarios modeled in the full-scale analysis.

2.1.1 Identification of Waste Types, Constituents, and Exposure Pathways

To identify the CCW constituents and exposure pathways to be addressed in this risk assessment, we relied on a database of CCW analyses that EPA had assembled over the past several years to characterize whole waste and waste leachate from CCW disposal sites across the country (see Appendix A). The 2003 CCW constituent database includes all of the CCW characterization data used by EPA in its previous risk assessments, supplemented with additional data collected from public comments, data from EPA Regions and state regulatory agencies, industry submittals, and literature searches up to 2003.

The CCW constituent database represents a significant improvement in the quantity and scope of waste characterization data available from the 1998 EPA risk assessment of CCWs (U.S. EPA, 1998a,b). For example, the constituent data set used for the previous risk assessments (U.S. EPA, 1999a) covered approximately 50 CCW generation and/or disposal sites. With the addition of the supplemental data, the 2003 CCW constituent database covers approximately 140 waste disposal sites.[1] The 2003 database also has broader coverage of the major ion concentrations of CCW leachate (e.g., calcium, sulfate, pH).

2.1.1.1 Waste Types

Comments received by EPA on the previous CCW risk assessment pointed out that the analysis did not adequately consider the impacts of CCW leachate on the geochemistry and mobility of metal constituents in the subsurface. Commenters stated that given the large size of the WMUs and the generally alkaline nature of CCW leachate, it is likely that the leachate affects the geochemistry of the soil and aquifers underlying CCW disposal facilities, which can impact the migration of metals in the subsurface.

To address this concern, EPA statistically evaluated major ion porewater data from the CCW constituent database for the waste streams shown in Table 2-1. Based on this analysis and prevalent comanagement practices, EPA grouped the waste streams into three statistically distinct categories: conventional CCW (ash and FGD sludge) (moderate to high pH); codisposed CCW and coal refuse (low pH); and FBC waste (high pH). As shown in Table 2-1, each of these waste types includes several waste streams that are usually codisposed in landfills or surface impoundments.

Along with the type of WMU (landfill or surface impoundment), the three waste types in Table 2-1 define the basic modeling scenarios to be addressed in the full-scale analysis. To characterize these waste types, the CCW constituent database was queried by waste type to develop the waste concentration data for the constituents and the major ion and pH conditions used to develop waste-type-specific metal sorption isotherms (see Appendix D for a more extensive discussion of the development of CCW waste chemistries and metal sorption isotherms).

[1] Although EPA believes that the 140 waste disposal sites do represent the national variability in CCW characteristics, they are not the same sites as in the EPRI survey. During full-scale modeling, data from the CCW constituent database were assigned to each EPRI site based on the waste types reported in the EPRI survey data.

Table 2-1. Waste Streams in CCW Constituent Database

Waste Type Waste Streams	Number of Sites by Waste Type[a]		
	Landfill Leachate	Surface Impoundment Porewater	Total Waste[b]
Conventional CCW	*97*	*13*	*62*
Ash (not otherwise specified)	43	0	30
Fly ash	61	2	33
Bottom ash and slag	24	3	23
Combined fly and bottom ash	7	4	4
FGD sludge	4	6	5
Codisposed Ash & Coal Refuse	9	5	1
FBC Waste	*58*	*0*	*54*
Ash (not otherwise specified)	18	0	10
Fly ash	33	0	32
Bottom and bed ash	26	0	25
Combined fly & bottom ash	20	0	22

[a] Number of sites by waste type from leachate, porewater, and whole waste data tables in the 2003 CCW constituent database.
[b] Whole waste concentration data.

2.1.1.2 Constituents and Pathways

The CCW constituent database contains data on more than 40 constituents. During the hazard identification step of the CCW risk assessment, constituents of potential concern were identified from this list of constituents by searching EPA and other established sources for human health and ecological benchmarks (e.g., Agency for Toxic Substances and Disease Registry [ATSDR]; see U.S. EPA, 2002a, for a full list of sources). Table 2-2 shows the results of that search for each constituent. Benchmarks were found for 26 chemicals in the constituent database. Constituents without human health or ecological benchmarks were not addressed further in the risk analysis.[2]

To further narrow down the list of constituents, a screening analysis (U.S. EPA, 2002a) was conducted that compared very conservative estimates of exposure concentrations (e.g., whole waste concentrations, leaching concentrations) to health-based concentration benchmarks to quickly, simply, and safely identify constituents and exposure pathways with risks that clearly do not exceed the risk criteria so that these could be eliminated from further analysis. For example, leachate concentrations were compared directly to drinking water standards, which is equivalent to assuming that human receptors are drinking leachate. The technical background document for the CCW screening analysis (U.S. EPA, 2002a) provides further detail on the

[2] The CCW constituents without benchmarks are limited to common elements, ions, and compounds (e.g., iron, magnesium, phosphate, silicon, sulfate, sulfide, calcium, pH, potassium, sodium, carbon, sulfur) that were used to determine overall CCW chemistries modeled in the risk assessment (see Section 3). Although some of these chemicals or parameters (e.g., pH, sulfate, phosphate, chloride) can pose an ecological hazard if concentrations are high enough, they were not addressed in this risk assessment.

Table 2-2. Toxicity Assessment of CCW Constituents

Constituent	CAS ID	HHB[a]	EcoB[b]	Constituent	CAS ID	HHB[a]	EcoB[b]
Metals				***Inorganic Anions***			
Aluminum	7429-90-5	✔	✔	Chloride	16887-00-6

[a] HHB = human health effect benchmark
[b] EcoB = ecological benchmark
[c] Known carcinogen (for chromium VI, inhalation only); although arsenic can act as both a carcinogen and a noncarcinogen, the cancer risk exceeds the noncancer risk at any concentration, so we used the more protective cancer benchmark for human health throughout this assessment.
[d] Probable carcinogen
[e] Safe Drinking Water Act Action Level only

screening analysis. As detailed there, the risks for all above-ground pathways analyzed (soil ingestion, inhalation, gardening, beef and dairy, and erosion and overland transport) for human receptors did not exceed the screening criteria for any constituent, so they were not considered any further in the risk assessment. The above-ground pathway risks for ecological receptors also did not exceed the screening criteria except for boron and selenium. Boron, which showed risks above the risk criterion in above-ground pathways due to plant toxicity in the CCW screening analysis, has been shown to be toxic to plants (Carlson and Adriano, 1993). Selenium has shown toxicity to terrestrial amphibians via above-ground pathways (Carlson and Adriano, 1993; Hopkins et al., 2006). Because the risks posed by these CCW constituents to ecological communities via above-ground pathways is well documented in damage cases and field studies (see above references and U.S. EPA, 2007), we did not believe that a full-scale above-ground

pathway analysis was necessary to confirm this conclusion for two constituents. Thus, the full-scale risk assessment did not include any above-ground pathways, only groundwater pathways.

The groundwater-to-drinking-water and groundwater-to-surface-water pathways (human fish consumption and ecological risks) did show risks above the screening criteria for several CCW constituents in the screening analysis. Table 2-3 lists the 21 constituents that had 90th percentile screening analysis groundwater pathway risks greater than a cancer risk of 1 in 100,000 or a noncancer risk with an HQ greater than 1 for human health and 10 for ecological risk.[3] Note that mercury was not addressed in the screening or full-scale analysis because of a very high proportion of nondetects in the CCW constituent database. Similarly, a high number of nondetects (or a very low number of measurements) prevented screening or full-scale analysis for antimony, thallium, and cobalt in surface impoundments. The uncertainties associated with these limited analytical results are discussed in Section 4.4.3.1.

Resources did not allow full-scale modeling to be conducted for all 21 constituents that had 90th percentile risks above the screening criteria. To reduce the number of constituents to be modeled, those constituents were ranked and divided into two groups to focus the full-scale analysis on the CCW constituents that were likely to pose relatively higher risks to human and ecological receptors. The ranking was based on the magnitude of the HQs and the number of HQs exceeding the screening criteria, and was used to select chemicals for full-scale modeling. Constituents with at least one human health HQ greater than 6 or with ecological HQs greater than 100 for both landfills and surface impoundments were modeled. Arsenic, with cancer risks greater than 1 in 1,000, exceeded the cancer risk criterion by a factor of 100 and was also modeled in the full-scale analysis. Constituents with no human health HQs greater than 6 and only one or no ecological HQs greater than 100 were not modeled, but were addressed in a separate analysis using results from the modeled constituents.

Table 2-3 shows the 21 constituents and which of these constituents exceeded the screening criteria and thus were modeled in the full-scale analysis. As shown, 12 constituents were subjected to the full-scale probabilistic risk assessment described in this document. Nine constituents did not exceed the screening criteria and were addressed using risk factors developed from comparing the screening and full-scale results for the modeled constituents, as described in Section 4.1.5 of this document.

2.1.2 Waste Management Scenarios

The full-scale CCW risk assessment models landfills and surface impoundments managing wastes onsite at coal-fired utility power plants. Because EPA selected a site-based modeling approach for the full-scale analysis, it was necessary to locate these disposal sites across the country to provide the spatial foundation for this analysis. It was also necessary to characterize CCW WMUs to define the scope for source modeling.

[3] An HQ of 10 was used for screening ecological risks to account for conservatism of ecological benchmarks and exposure estimates used in the screening analysis (see Section 4.4.3.4).

Table 2-3. Screening Analysis Results: Selection and Prioritization of CCW Constituents for Further Analysis[a]

Constituent	Human Health – Drinking Water		Human Health – Surface Water[b]		Ecological Risk - Surface Water	
	LF HQ (*Cancer Risk*)	SI HQ (*Cancer Risk*)	LF HQ (*Cancer Risk*)	SI HQ (*Cancer Risk*)	LF HQ	SI HQ
Constituents Modeled in Full-scale Assessment						
Carcinogen						
Arsenic[c]	($1.4x10^{-3}$)	($1.8x10^{-2}$)	($2.2x10^{-4}$)	($1.7x10^{-5}$)	49	640

Aluminum	-	-	-	-	120	270
Antimony	22	5.5	-	-	-	-
Barium	-	-	-	-	400	75
Cobalt	-	11	-	-	-	270
Molybdenum	4.2	6.8	-	-	-	-
Nitrate/ Nitrite	- /1.2	60/1.2	-	-	-	-
Constituents Not Modeled in Full-scale Assessment[d]						
Noncarcinogens						
Chromium VI	2.3	4.2	-	-	18	33
Fluoride	1.8	5.2	-	-	-	-
Manganese	1	5.6	-	-	-	-
Vanadium	2.2	2.3	-	-	23	24
Beryllium	-	-	-	-	24	-
Copper	-	-	-	-	16	31
Nickel	-	1.3	-	-	-	14
Silver	-	-	-	-	110	14
Zinc	-	-	-	-	16	-

HQ = screening hazard quotient.
LF = landfill.
SI = surface impoundment.

[a] A dash in a cell indicates that the screening HQ was less than 1 (or 10 for ecological risk), so the risk did not exceed the screening criteria for the indicated pathway.

[b] Fish consumption pathway.

[c] Although arsenic can act as both a carcinogen and a noncarcinogen, the cancer risk exceeds the noncancer risk at any concentration, so we used the more protective cancer benchmark for human health throughout this assessment.

[d] These constituents were addressed using risk attenuation factors developed from full-scale results from modeled constituents (see Section 4.1.5).

Two primary sources of data on these were used to characterize this population:

- 1998 Energy Information Agency (EIA) data on coal-fired power plants, which identifies approximately 300 coal-fired power plants with onsite waste management
- The 1995 EPRI waste comanagement survey (EPRI, 1997), which contains detailed WMU data (i.e., area, capacity, liner status, and waste type) for 177 of those facilities.[4]

Because of the completeness of the WMU data from the EPRI survey, the EPRI data were used to establish the plant locations and WMU data for the full-scale modeling effort for conventional CCW[5] and CCW codisposed with coal refuse.

Although there is a good amount of FBC data in the constituent database (58 sites; see Table 2-1), there were only 3 FBC landfill sites in the EPRI database and 4 additional sites added by EPA for a total of 7 FBC sites with data on onsite WMUs. Because EPA believes that this small sample is not sufficient to represent the universe of FBC disposal units and, if included in the overall analysis, could bias the Monte Carlo results towards the environmental conditions around these few landfill units, FBC waste were addressed separately from the more conventional CCW types in the full-scale analysis and are not included with the conventional and codisposal CCW management scenarios in the overall results. Section 4.1.3 compares the risk results for each of these waste types, including FBC.

Table 2-4 shows how the plants are distributed across the waste type/WMU scenarios modeled in the full-scale analysis. The distribution across the waste type/WMU scenarios, the geographic distribution of these facilities, and the size and liner status of the WMUs were assumed to be representative of all onsite CCW landfills and surface impoundments in the continental United States as of 1995. As mentioned previously, DOE and EPA have conducted a newer survey on CCW disposal facilities (U.S. DOE, 2006), but the scope of this survey was not as comprehensive as the EPRI survey (e.g., WMU areas and capacity data were not collected). EPA does not believe that the number and locations of onsite CCW landfills and surface impoundments has changed significantly since 1995, although liners are more prevalent in the newer facilities (see further discussion in Section 4.4.1). The DOE/EPA report (U.S. DOE, 2006) supports this conclusion.

[4] Note that although there is overlap, the 140-site CCW constituent database described in Appendix A and the EPRI survey used to characterize CCW landfills and surface impoundments were assembled under separate efforts and represent different populations of disposal sites. As described in Section 3.1.3, these data sets were sampled independently during the Monte Carlo analysis, and constituent data were not assigned to particular sites except by waste type.

[5] Fly ash, bottom ash, boiler slag, and FGD sludge.

Table 2-4. Coal Combustion Plants with Onsite CCW WMUs Modeled in the Full-Scale Assessment

Waste Type and Liner Status	Number of Plants in 1995 EPRI Survey[a] with Onsite:		
	Landfills	Surface Impoundments	Either WMU Type[b]
Conventional CCW[c]	71	38	103
unlined	*38*	*24*	*60*
clay-lined	*28*	*10*	*38*
composite-lined	*10*	*5*	*15*
Codisposed CCW and coal refuse	38	65	100
unlined	*20*	*52*	*69*
clay-lined	*10*	*11*	*21*
composite-lined	*9*	*2*	*11*
FBC waste[d]	7	-	7
unlined	*3*		*3*
clay-lined	*3*		*3*
composite-lined	*1*		*1*
All waste types	108	96	181

[a] EPRI (1997); note that some coal combustion plants have one or more onsite WMUs.
[b] Number of coal combustion plants with onsite landfill(s), surface impoundment(s), or both.
[c] Fly ash, bottom ash, boiler slag, and FGD sludge.
[d] Includes 3 EPRI Survey FBC landfills plus 4 additional FBC landfills added by EPA. FBC was treated separately in the full-scale assessment because of the small number of FBC sites.

2.2 Conceptual Model

The waste stream/WMU combinations discussed above provide the waste management scenarios to be evaluated in the risk assessment. The full-scale assessment used the EPRI survey data to place these scenarios at actual onsite CCW disposal sites across the country. These sites were used as the basis for a national-scale site-based Monte Carlo assessment of risks posed by the onsite disposal of CCW at utility power plants across the United States.

2.2.1 Conceptual Site Model

Figure 2-1 depicts the conceptual site model for CCW disposal that was the basis for the national CCW risk assessment, including contaminant sources, exposure pathways, and receptors. The CCW conceptual site model includes the following exposure pathways:

Human Health

- Groundwater to drinking water (drinking water ingestion)
- Groundwater to surface water (fish consumption)
- Above-ground pathways, including soil ingestion, inhalation, and consumption of produce, beef, and milk.

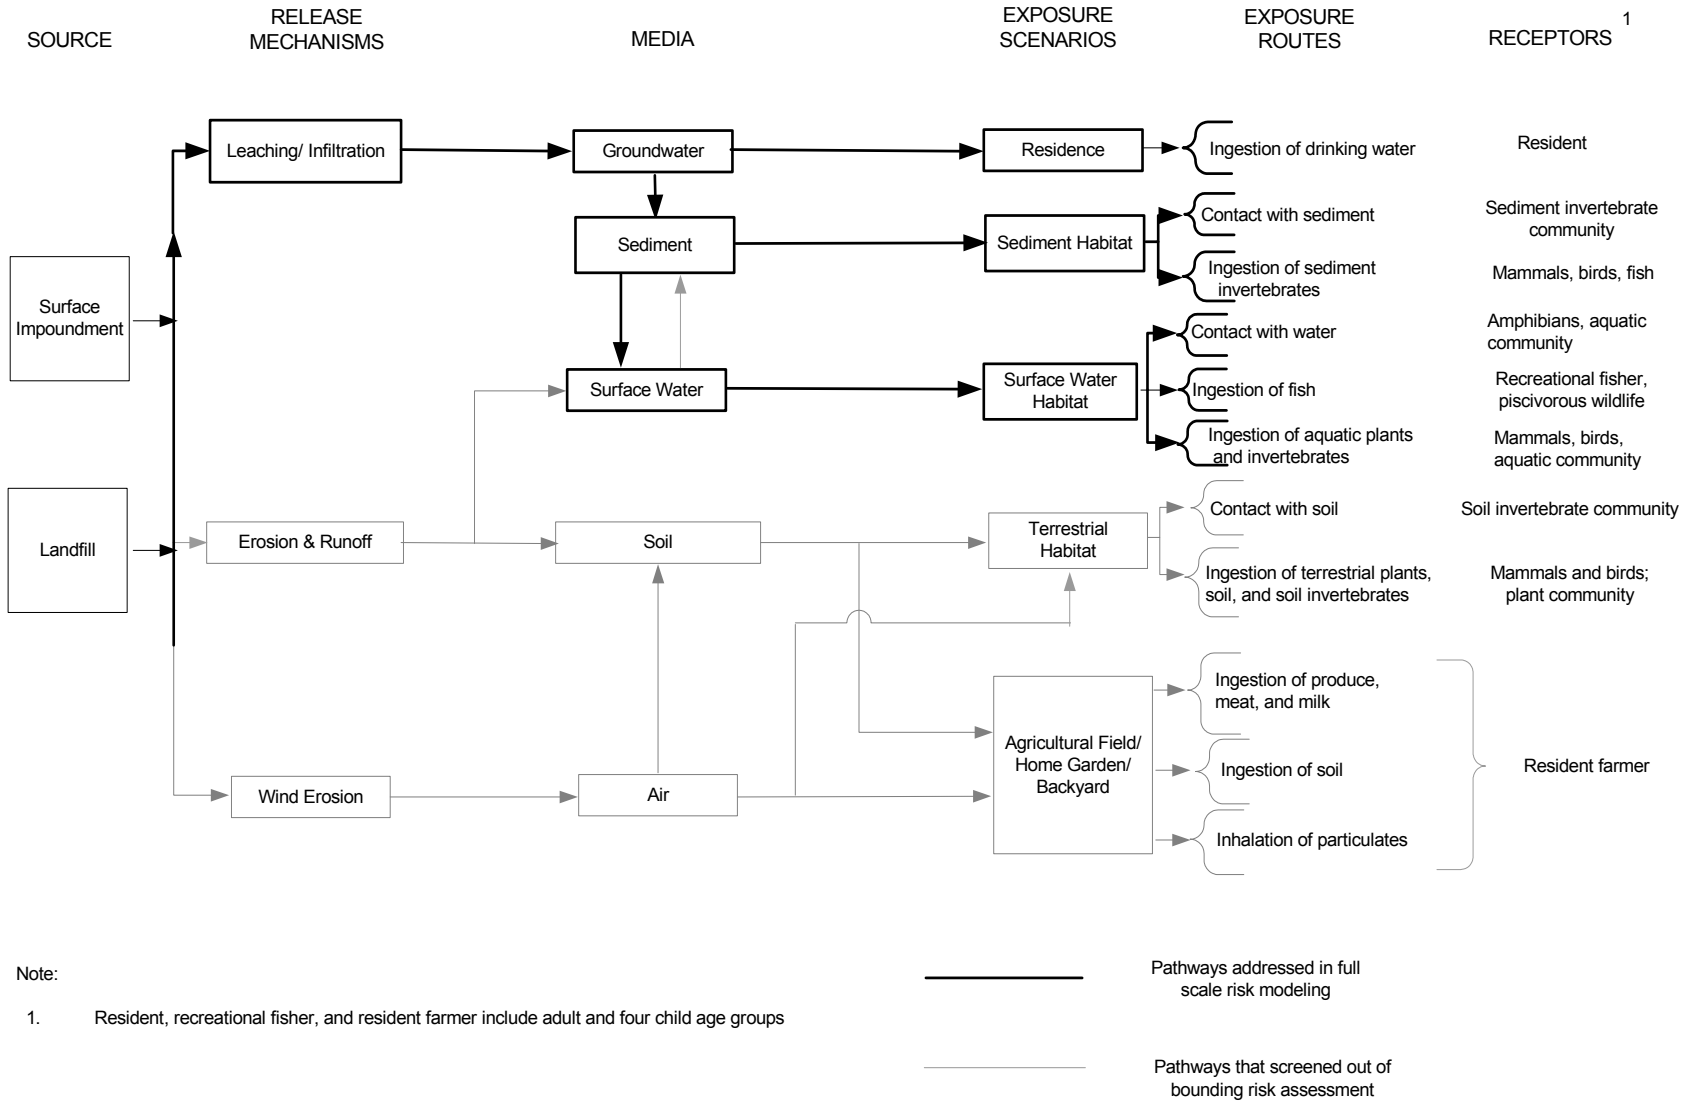

Figure 2-1. Conceptual site model of CCW risk assessment.

Ecological Risk

- Groundwater to surface water
- Above-ground soil
- Above-ground contamination of surface water and sediment.

As described in Section 2.1.1, the CCW screening analysis addressed all of these exposure pathways and receptors. Through that screening analysis, risks for all above-ground pathways (shown in gray instead of black in Figure 2-1) fell below the screening criteria and were not considered further in the full-scale risk assessment.[6] This enabled EPA to focus full-scale modeling on groundwater-to-drinking-water and groundwater-to-surface-water exposure pathways (shown in black in Figure 2-1). This groundwater pathway analysis evaluates exposures through drinking water ingestion and surface water contamination from groundwater discharge. For the groundwater-to-surface-water pathway, the analysis assumes that human exposure occurs through the consumption of contaminated fish and that ecological exposure occurs through direct contact with contaminated surface water and sediment or from the consumption of aquatic organisms.

2.2.2 Conceptual Site Layouts

This risk assessment was based on site layouts that are conceptual rather than site-specific. Although we had plant locations and some site-specific data on WMUs, we did not have the exact locations of each WMU or the residential wells surrounding each facility. Therefore, we had to develop conceptual layouts to place receptors around each WMU.

The conceptual site layouts capture possible relationships between a WMU and human and ecological receptors by locating, with respect to the WMU boundary, the geographic features (i.e., receptor wells, waterbodies) that are important for determining human and ecological exposures to chemicals released from CCW landfills and surface impoundments.

Two site layouts were used to model the land use scenarios of most concern for CCW disposal facilities:

- Residential groundwater ingestion scenario
- Recreational fisher and aquatic ecological risk scenario.

Figures 2-2 and 2-3 show these two conceptual site layouts, including WMU boundaries, waterbodies, and residential wells modeled in this analysis. In the conceptual site layouts, the WMU is represented as a square source. The size of the source is determined by the surface area of the WMU (CCW WMU areas were collected from the EPRI comanagement survey, as described in Appendix B). The WMU is assumed to be located at the property line of the facility to which it belongs.

[6] Although the risks from the aboveground screening analysis did exceed the risk criteria for boron and selenium in soil, to streamline the assessment, these compounds were not included in the full ecological assessment.

Adjacent to the WMU is a buffer area within which there is assumed to be no human activity that would present human risk (i.e., there are no residences or waterbodies in the buffer). The buffer area lies between the WMU boundary and the residential well or waterbody, and represents the distance to well or waterbody discharge point modeled by the groundwater model. Each site layout must also be oriented in terms of direction.

Residential Groundwater-to-Drinking-Water Scenario

The residential groundwater-to-drinking-water scenario calculates exposure through residential use of well water as drinking water. In the Monte Carlo analysis, the receptor well is randomly placed up to 1 mile downgradient from the edge of the WMU (this radial well distance is labeled R_{rw} in Figure 2-2), based on a nationwide distribution of nearest downgradient residential wells from Subtitle D municipal landfills (U.S. EPA, 1988a; this distribution is provided in Appendix C). EPA assumed that this distribution is relevant to onsite CCW landfills and surface impoundments at coal-fired utility power plants, but does not have data on typical distances (or the distributions of distances) of domestic drinking water wells from CCW disposal facilities. (The potential impact on the results of this assumption is discussed in Section 4.4.3.3).

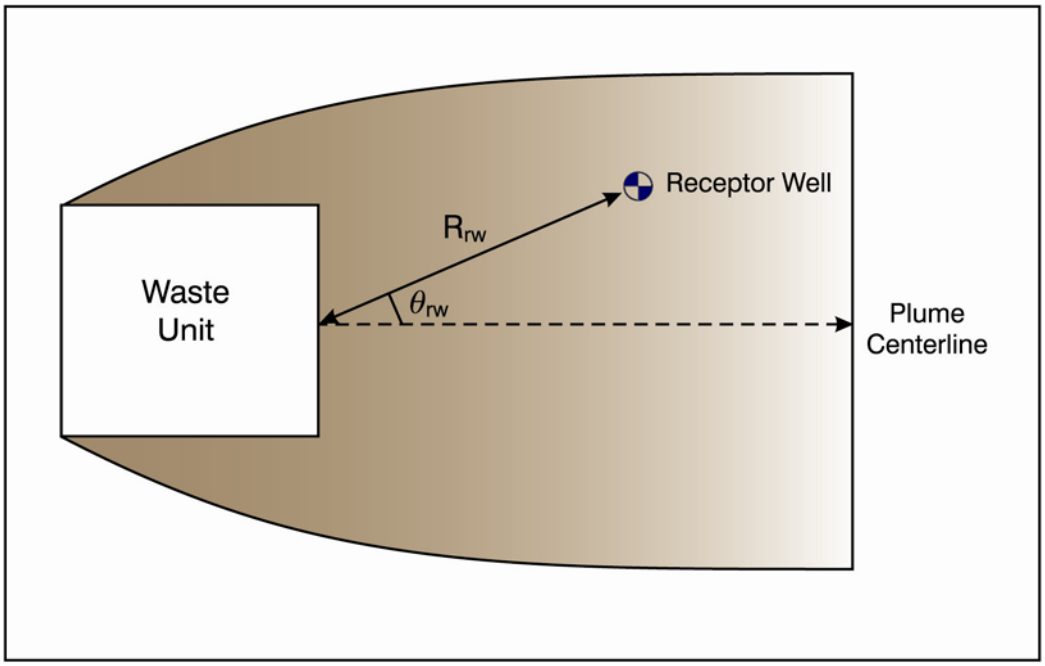

Figure 2-2. Conceptual site layout for residential groundwater ingestion scenario.

The angle off the contaminant plume centerline (θ_{rw} in Figure 2-2) was based on a uniform distribution ranging from 0 to 90°. The depth of the well below the water table was set within the groundwater model based on assumptions that are generally typical of average conditions for surficial aquifers across the United States. These limits are discussed in Section 3.4.3. In this assessment, receptors were always located within the lateral extent of the plume.

The soil and aquifer characteristics needed for the groundwater model were collected using a site-based approach, as described in Appendix C.

Recreational Fisher and Ecological Risk Scenario

The recreational fisher[7] scenario was used to estimate risks to recreational fishers (and their children) who live near the CCW landfills and surface impoundments and catch and consume fish from a waterbody located adjacent to the buffer. Note that the fisher's residence is not the same residence where the residential well is located, and therefore risks are not added across the drinking water and fish consumption pathways.

The waterbody was assumed to be a stream or lake located downgradient from the WMU, beginning where the buffer area ends (see Figure 2-3), and was also used as the most impacted aquatic system for the ecological risk assessment. Waterbody characteristics were determined based on site-specific, regional, or national data (as described in Appendix C), except for stream length, which was determined by the width of the plume as it intersects the waterbody.

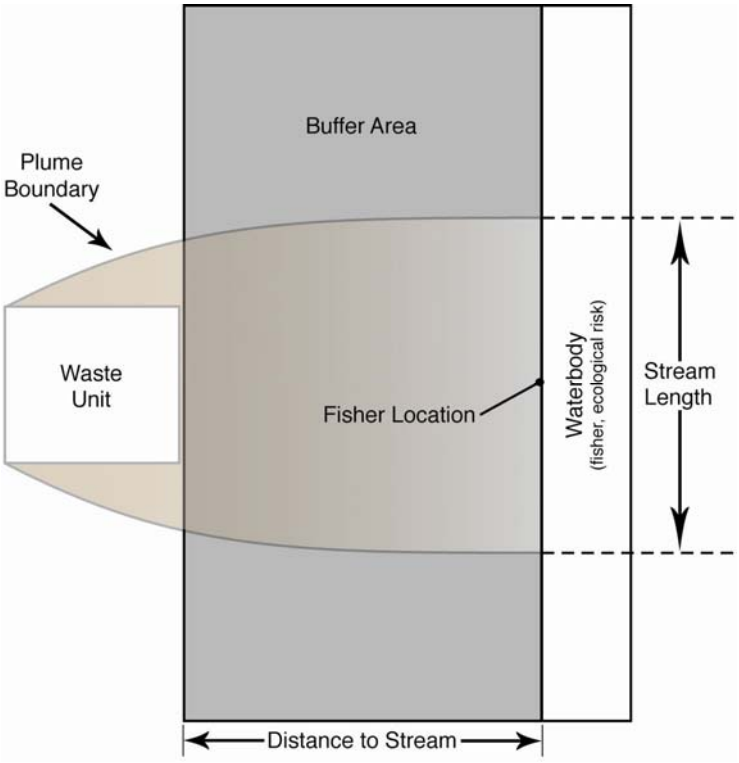

Figure 2-3. Conceptual site layout for residential fisher and aquatic ecological risk scenario.

[7] Only recreational fishers were considered because they represent the reasonable maximum exposed individuals and because the streams, lakes, or rivers that are near CCW plants are not likely to be used by commercial fishing operations.

The downgradient distance to the surface water body was determined from a national distribution developed by measuring this distance (using scaled U.S. Geological Survey [USGS] maps and aerial photographs obtained from the Terraserver Web site [http://terraserver.usa.com/geographic.aspx]) at 59 CCW landfill and surface impoundment sites randomly selected from a larger data set of 204 CCW WMUs, including those modeled in this risk assessment. Appendix C presents that distribution and further details on how the distribution was developed and the sample of 59 facilities used to develop the distribution.

2.3 Analysis Scope and Design

Although the screening analysis identified the potential for risk for a subset of the constituents reported in CCW, the conservative assumptions used precluded an accurate quantitative estimate of these risks. To gain a better understanding of the risks that may be posed by these constituents, EPA conducted a full-scale probabilistic (Monte Carlo) risk assessment to estimate the national distribution of the risks to human health and the environment posed by CCW disposal, and to provide the information needed to assess future management options for these wastes in the context of their risks to human health and the environment. The full-scale CCW Monte Carlo risk assessment was designed to characterize the national CCW risk profile in terms of WMU type, waste type, and constituent, and to use distributions in a probabilistic modeling framework to incorporate variability and uncertainty into the analysis.

The site-based approach used data about waste management practices and environmental conditions at 181 utility CCW disposal sites across the United States.[8] These sites were assumed to represent the universe of CCW onsite waste disposal sites at the time of the EPRI survey (1995) and defined the national framework for the risk assessment. As described in Appendices B and C, site-specific data for the following model inputs were collected for these sites and used in the risk assessment:

- WMU dimensions
- WMU liner status (unlined, clay liner, composite liner)
- Waste type (conventional CCW, CCW codisposed with coal refuse, and FBC wastes)
- Geology (aquifer type)
- Soil texture
- Climate (precipitation, infiltration)
- Surface water type and flow conditions.

One question related to this risk assessment is how CCW facilities may have changed in the decade since the 1995 EPRI survey. Although the DOE/EPA survey does not include all of

[8] These 181 sites include177 sites from the EPRI survey and 4 additional CCW sites added by EPA to better represent FBC waste disposal facilities; see Section 2.1.2.

the data needed to conduct a risk assessment (WMU area and capacity data were not collected), liner conditions were addressed, and by comparing the DOE/EPA survey results to the EPRI data one can assess how liner conditions changed as CCW facilities were built or expanded over the past decade. The 56 WMUs surveyed in the U.S. DOE (2006) study were commissioned between 1994 and 2004. Although the actual number of WMUs that were established in that timeframe cannot be verified, based on proxy data (i.e., CCW available for disposal in those states with identified new WMUs and coal-fired power plant generating capacity), the sample coverage is estimated to be at least between 61 to 63 percent of the total population of the newly commissioned WMUs.[9] With the exception of one landfill, the newly constructed facilities are all lined, with either clay, synthetic, or composite liners. The single unlined landfill identified in the recent DOE report receives bottom ash, which is characterized as an inert waste by the state, and therefore, a liner is not required. There is a marked trend away from unlined WMUs in favor of lined units, with a distinct preference for synthetic or composite liners. Comparison of the 26 coal combustion plants in both the EPRI survey and the DOE/EPA survey (U.S. DOE, 2006) shows that although most of those facilities (17 of 26) were using unlined WMUs in 1995, all 26 are now placing wastes in new or expanded landfills or surface impoundments that are lined with clay, synthetic, or composite liners. However, it is likely that the older unlined units were closed with wastes in place, and that these wastes therefore still pose a threat through groundwater pathways. In addition, the available data cannot be used to determine the number of unlined units that continue to operate in the United States.

Because site-specific data were not readily available for depth to groundwater or receptor location (i.e., distances to nearest drinking water well and surface waterbody), national distributions for those inputs taken from a national hydrogeologic database (Newell et al., 1989 and 1990) developed to support EPA's national groundwater risk assessments were used in the Monte Carlo analysis to characterize the national variability of receptor distances (see Appendix C). This enabled EPA to assess the importance of those variables for the national risk distribution for individuals with reasonable maximum exposure to CCW.

The full-scale assessment was conducted using several modeling components: (1) EPA's Composite Model for Leachate Migration with Transformation Products (EPACMTP; U.S. EPA, 1997a) groundwater model, (2) a simple steady-state surface water and aquatic food web model, and (3) a multipathway exposure and risk modeling system.

2.3.1 Data Collection

For the sites representing each WMU and waste type combination selected for analysis, the Monte Carlo analysis begins with input files that contain, for each Monte Carlo realization, the following site-based variables:

- WMU area, depth, and capacity
- WMU liner status

[9] For additional details as to how these estimates were derived, the reader is referred to the DOE study, pages S-2 to S-3 of the Summary Section and Section 3.1.2.

- Soil texture (for vadose zone properties and infiltration rates)
- Soil pH and organic carbon
- Aquifer type
- Groundwater temperature
- Climate center (for infiltration rates)
- USGS Hydrologic Region (for surface water quality data)
- Surface water flows.

CCW constituent data in the CCW constituent database were used as a national empirical distribution of the concentrations of the constituents of concern in CCW landfill leachate and surface impoundment porewater. Like the WMU database, the CCW constituent data include WMU type and waste type, which enabled constituent concentrations to be assigned to the 181 CCW sites by waste type and WMU type. The CCW constituent database was also used to assign (by waste type) the high, medium, and low leachate pH and ionic strength conditions needed to select the appropriate subsurface sorption isotherms for each model run (see Appendix D).

National distributions were used to populate the following variables by model run:

- Distance to nearest drinking water well
- Distance to nearest surface waterbody
- Aquifer depth, thickness, gradient, and hydraulic conductivity (based on site-specific hydrogeologic setting)
- Soil hydrologic properties (based on site-specific soil type).

The data sources used to develop national distributions for these variables are described in Appendix C. Human exposure factors, such as exposure duration and drinking water and fish consumption rates, were also based on national distributions, which are provided in Appendix F.

2.3.2 Model Implementation

As a first step in the modeling process, the groundwater model (EPACMTP) reads the site-based data files to estimate the following for each model run:

- Drinking water well peak concentration
- Time to drinking water peak concentration
- Peak surface water contaminant flux
- Time to peak surface water contaminant flux.

The groundwater model is run until contaminant concentrations at the receptor point return to zero after the concentration peak or for the maximum simulation time of 10,000 years, whichever comes first.

Groundwater model results are passed to the multimedia modeling system to estimate surface water and sediment concentrations and to calculate human and ecological exposure and risk. Additional inputs sent to the model at this stage include

- Site-based surface waterbody type, dimensions, flows, pH, and total suspended solids (TSS) concentration
- Chemical-specific fish bioconcentration factors (BCFs)
- Human exposure factors (from national distributions)
- Human and ecological health benchmarks.

For human health, the multimedia modeling system calculates risk from drinking water ingestion and fish consumption for each realization. For ecological risk, the model uses surface water and sediment concentrations along with ecological benchmarks to estimate the risks to ecological receptors.

2.3.3 Exposure Assessment

Table 2-5 lists the human and ecological receptors considered in the CCW risk assessment, along with the specific exposure pathways that apply to each receptor. All of the receptors that EPA considered were assumed to live offsite, at a location near the WMU.

Table 2-5. Receptors and Exposure Pathways Addressed in the Full-Scale CCW Assessment

Receptor	Ingestion of Drinking Water	Fish Consumption	Direct Contact with Surface Water and Sediment	Ingestion of Aquatic Organisms
Human Receptors				
Adult resident	✔			
Child resident	✔			
Adult recreational fisher		✔		
Child recreational fisher		✔		
Ecological Receptors				
Aquatic and sediment organisms			✔	
Mammals and birds				✔

For human receptors, the exposure assessment estimates the dose to an individual receptor by combining modeled CCW constituent concentrations in drinking water or fish with intake rates for adult and child receptors. The full-scale CCW risk assessment considered

exposures due to chemicals leaching from WMUs and contaminating groundwater. The groundwater exposures include drinking water ingestion and consumption of recreationally caught contaminated fish from surface waterbodies affected by contaminated groundwater. For the groundwater-to-drinking-water pathway, it was conservatively assumed that well water was the only source of drinking water (although some households may drink bottled or treated water or may drink water outside the home, e.g., at work or at school).

For ecological receptors, exposure assumptions are incorporated into the development of ecological benchmarks (see Appendix H), which are surface water and sediment concentrations corresponding to an HQ of 1.

The time period for the exposure assessment is defined by the peak concentration in the media of concern and the exposure duration. For human receptors, annual average media concentrations were averaged over the randomly selected exposure duration around the peak concentration for each run. To protect against chronic effects to ecological receptors, we consider the exposure duration over a significant portion of the receptor's lifetime, and we believe that one year is the appropriate period of time for that. To be protective, we use the highest (peak) annual average concentration to estimate ecological exposure and risk.

2.3.4 Risk Estimation

Risk was estimated using several risk endpoints as particular measures of human health risk or ecological hazard. A risk endpoint is a specific type of risk estimate (e.g., an individual's excess cancer risk) that is used as the metric for a given risk category. The CCW risk assessment evaluated cancer and noncancer endpoints for humans and noncancer endpoints for ecological receptors. For human risk, the availability of toxicological benchmarks for cancer and noncancer effects determined which endpoints were evaluated for each constituent.

EPA used two risk endpoints to characterize risk for the human receptors and a single risk endpoint, total HQ, to characterize risk for ecological receptors. These endpoints are discussed in Section 3.8; in addition, uncertainty related to these endpoints is discussed in Section 4.4.3.4.

From the distribution of risks for each risk endpoint generated by the Monte Carlo analysis, the 50th and 90th percentile risks were selected and compared to the risk criteria of 1 in 100,000 excess cancers and an HQ greater than 1 for noncarcinogens. An HQ greater than 1 for was also used for the ecological risk criterion in the full-scale risk assessment.

3.0 Analysis

The full-scale analysis evaluates risks from CCWs disposed of in landfills and surface impoundments located onsite at coal-fired utility power plants across the United States based primarily on data collected in 1995 by EPRI (1997).[1] Chemical constituents found in CCW can be released from these WMUs into the surrounding environment by various mechanisms. Releases to the atmosphere and by erosion and overland transport did not pose risks above the screening criteria in the screening analysis; therefore, these were not assessed in the full-scale analysis. Instead, the full-scale analysis focused on groundwater pathways, which exceeded the risk criteria for some constituents in the screening analysis. Leachate forms in both landfills and surface impoundments, migrates from the WMU through soil to groundwater, and is transported in groundwater to drinking water wells (groundwater-to-drinking-water pathway) and into surface waterbodies near the WMU (groundwater-to-surface-water pathway). These are the groundwater pathways evaluated in the full-scale CCW risk assessment.

For the full-scale analysis, EPA used computer-based models and sets of equations to estimate the risk to human health and the environment from current CCW disposal practices.[2] These models include

- **Source** models that simulate the release of CCW constituents in leachate from landfills and surface impoundments[3]
- **Fate and transport** models that estimate contaminant concentrations in groundwater and surface water
- **Exposure** models that estimate daily contaminant doses for humans and ecological receptors exposed to CCW constituents in groundwater and surface water
- **Risk** models that calculate risks to humans and ecological receptors.

This section describes the models and equations used to calculate exposure point concentrations and risk. Section 3.1 provides the overall structure for the analysis, including the spatial and temporal framework and the probabilistic (Monte Carlo) framework for the model runs. Sections 3.2 and 3.3 describe the landfill and surface impoundment source models used to predict environmental releases of constituents from CCW. Sections 3.4 and 3.5 describe the fate and transport modeling used to predict contaminant concentrations in groundwater and surface

[1] The selection and characterization of these CCW WMUs are described in more detail in Appendix B.

[2] As discussed in Section 2, the 1995 EPRI survey data is assumed to represent current CCW management practices. However, new data from a more recent DOE/EPA survey suggest that liners may be more prevalent in new and expanded units built since 1994. Section 4 discusses implications of this uncertainty on the risk assessment results.

[3] EPA used source-term models integrated into EPACMTP to estimate environmental releases of constituents in leachate from landfills and surface impoundments.

water. Section 3.6 describes the human exposure calculations. Section 3.7 describes the health benchmarks used to develop human and ecological risk estimates, and Section 3.8 describes how these risks were calculated for human and ecological receptors.

Supporting detail can be found in the following appendices:

- **Appendix A, Constituent Data**, provides the CCW constituent concentrations used and describes how they were collected and processed
- **Appendix B, Waste Management Unit Data**, describes the location and characteristics of each landfill and surface impoundment modeled and describes how the source model input parameter values were collected
- **Appendix C, Site Data**, describes how environmental data around each CCW waste disposal site were collected to provide inputs for the groundwater and surface water modeling
- **Appendix D, MINTEQA2 Nonlinear Sorption Isotherms**, describes the development and application of the CCW-specific MINTEQ metal sorption isotherms used to model fate and transport in soils and groundwater
- **Appendix E, Surface Water, Fish Concentration, and Contaminant Intake Equations**, documents the algorithms used to calculate surface water concentrations, fish concentrations, and drinking water and fish intake rates
- **Appendix F, Human Exposure Factors**, documents the human exposure parameters and equations
- **Appendix G, Human Health Benchmarks**, describes how the human toxicity benchmarks were selected and developed
- **Appendix H, Ecological Benchmarks**, describes how the ecological toxicity benchmarks were selected and developed.

3.1 General Modeling Approach

This section describes the framework, general assumptions, and constraints for the full-scale probabilistic analysis. Section 3.1.1 describes the temporal and spatial framework. Section 3.1.2 describes the probabilistic framework, and Section 3.1.3 describes how the assessment was implemented within the probabilistic framework.

3.1.1 Temporal and Spatial Framework

The spatial framework for the analysis was determined by the geographic distribution of CCW facilities modeled and by the site layout assumed as the conceptual site model for risk assessment. As described in Section 2.1.2, the geographic distribution of landfills and surface impoundments managing wastes onsite at coal-fired utility power plants was determined from

the 177 sites in the 1995 EPRI survey of the onsite management of CCW (EPRI, 1997). The assessment assumes that these 177 sites and their locations are representative of the approximately 300 coal-fired power plants identified by EIA data as having onsite waste management of conventional CCW and CCW codisposed with coal refuse throughout the United States. For FBC wastes, these 177 sites include only 3 FBC landfills. EPA was able to add 4 additional FBC landfill sites to better represent FBC waste management, for an overall total of 181 sites in this analysis.

The conceptual site layouts applied to each of the sites are described and pictured in Section 2.2.2. Two site layouts were used to define the relationship between a landfill or surface impoundment and (1) a drinking water well (for human risk via the groundwater-to-drinking-water pathway) and (2) a surface water body (for human and ecological risk via the groundwater-to-surface-water pathway). In each case, the receptor point (well or waterbody) was assumed to lie within the boundaries of the groundwater contaminant plume. The distance from the edge of the WMU to the well or waterbody was varied for each model run based on national distributions, with well distance taken from a national distribution for Subtitle D municipal landfills (U.S. EPA, 1988a) and distance to surface water taken from a set of measured distances for CCW landfills and surface impoundments developed for this assessment. Appendix C presents additional details on these distributions.

The temporal framework was mainly defined by the time of travel from the modeled WMU to the well or waterbody, which can be up to one mile away from the edge of the unit, and the exposure duration over which risks were calculated. The subsurface migration of some CCW constituents (e.g., lead) may be very slow; therefore, it may take a long time for the contaminant plume to reach the receptor well or nearest waterbody, and the maximum concentration may not occur until a very long time after the WMU ceases operations. This time delay may be on the order of thousands of years. To avoid excessive model run time while not missing significant risk at the receptor point, the groundwater model was run until the observed groundwater concentration of a contaminant at the receptor point dropped below a minimum concentration (10^{-16} mg/L) or until the model had been run for a time period of 10,000 years. The minimum concentration used for all fate and transport simulations (10^{-16} mg/L) is at least a million times below any risk- or health-based criteria.

For the groundwater-to-drinking-water pathway (human health risk), risks were calculated based on a maximum time-averaged concentration around the peak concentration at each receptor well. The exposure duration (which varies from 1 to 50 years)[4] was applied around the peak drinking well concentration to obtain the maximum time-averaged concentration.

For the groundwater-to-surface-water pathway, the groundwater model produces surface water contaminant loads (based on groundwater concentration and flow) for a stream that penetrates the aquifer. Because the surface water model is a steady-state model, there is no temporal component to it and the receptor is exposed to the same concentration over the entire exposure duration. For human health risk, the loadings from groundwater to surface water were averaged over the exposure duration, bracketing the time of the peak groundwater concentration.

[4] Distributions of exposure duration and other exposure variables were obtained from the *Exposure Factors Handbook* (U.S. EPA, 1997c,d,e)

The exposure duration for sensitive ecological receptors is generally a year or less; therefore, for ecological risk, a single peak annual average surface water concentration was used.

For all scenarios, if the groundwater model predicted that the maximum groundwater concentration had not yet occurred after 10,000 years, the actual groundwater concentration at 10,000 years was used in the exposure calculations instead of a maximum time-weighted average concentration around the peak.

3.1.2 Probabilistic Approach

The full-scale analysis evaluates risk in a probabilistic manner and is based on a Monte Carlo simulation that produces a distribution of exposures and risks. The general Monte Carlo approach is shown in Figure 3-1. The foundation of the Monte Carlo simulation is the source data derived from the EPRI survey. These were combined with data from the national CCW constituent database to conduct a Monte Carlo simulation of 10,000 iterations per waste type/WMU type/constituent combination.

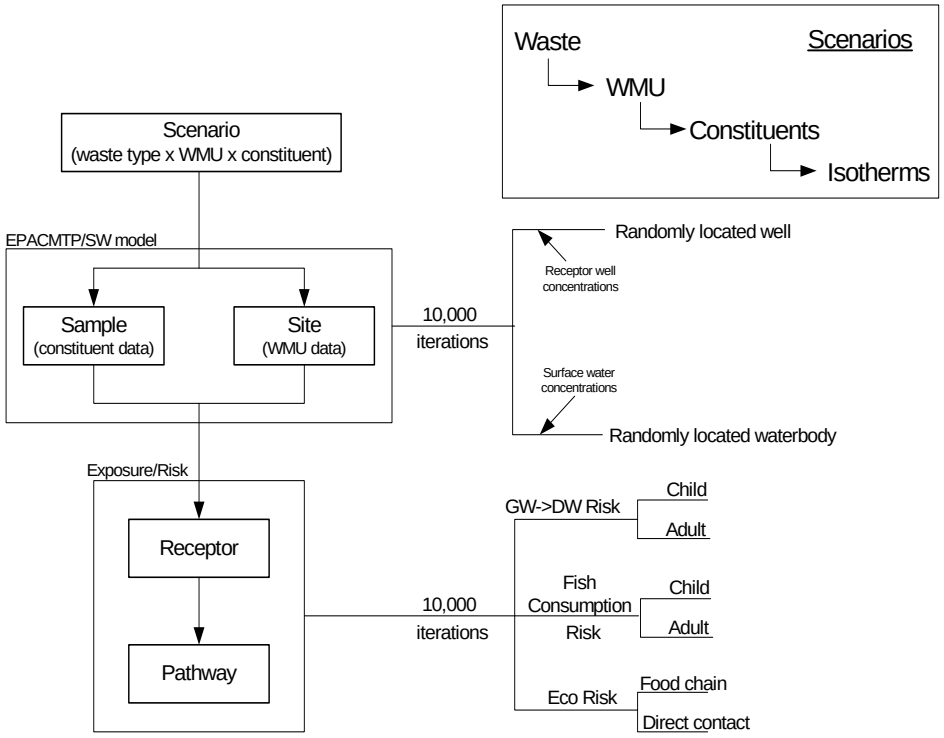

Figure 3-1. Overview of the Monte Carlo approach.

The detailed looping structure for the Monte Carlo analysis is shown in Figure 3-2. For each waste type/WMU combination, two separate loops are run. The first loop (shown with dashed lines in Figure 3-2) prepares a set of input files containing 10,000 sets of WMU and site data (as described in Section 3.1.3). The second loop (shown with solid lines in Figure 3-2) uses those input files to run 10,000 iterations of the source, fate and transport, exposure, and risk models for each constituent.

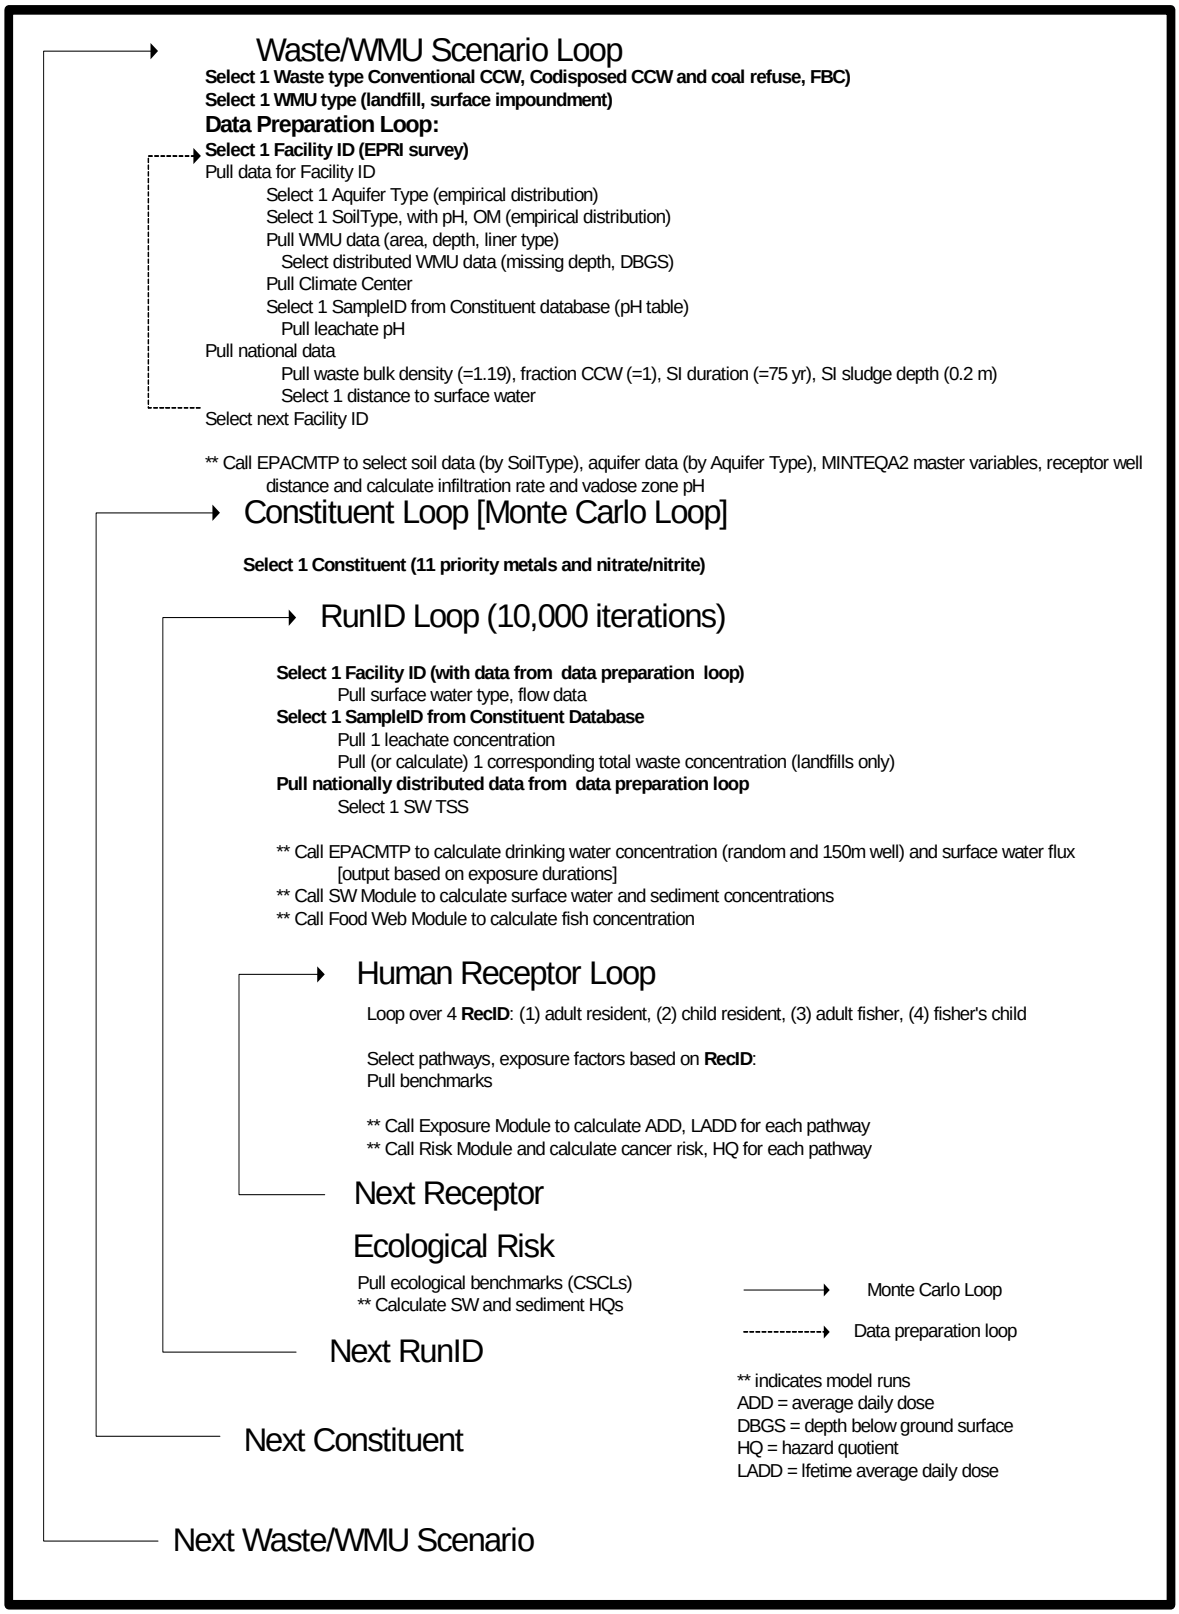

Figure 3-2. Monte Carlo looping structure.

3.1.3 Implementation of Probabilistic Approach

Table 3-1 lists the five waste disposal scenarios addressed in the full-scale analysis. FBC waste landfills were modeled and treated as a separate scenario in the analysis because of the limited number (7) of FBC landfill sites. Each waste disposal scenario modeled in the full-scale assessment included unlined, clay-lined, and composite-lined WMUs. Additional detail on these scenarios can be found in Section 2-1 and Appendix A.

Table 3-1. CCW Waste Management Scenarios Modeled in Full-Scale Assessment

WMU Type	Waste Type
Conventional CCW and CCW Codisposed with Coal Refuse (main analysis)	
Landfill	Conventional CCW (fly ash, bottom ash, boiler slag, FGD sludge)
Landfill	Codisposed CCW and coal refuse
Surface impoundment	Conventional CCW
Surface impoundment	Codisposed CCW and coal refuse
FBC Waste (separate analysis)	
Landfill	FBC waste (fly ash, bottom ash, bed ash)

To capture the national variation in waste management practices for the Monte Carlo analysis, an input database was created with approximately 10,000 iterations for each of the waste type/WMU combinations. This input database provided the source data for 10,000 iterations of the source modeling and the fate and transport modeling. Figure 3-3 provides an overview of the process used to compile these data, which were organized into source data files. As shown in Figure 3-3, seven tasks, some parallel and some sequential, were required to construct these data files, one file for each waste management scenario.

Constructing the source data files for use in the probabilistic analysis involved first developing a 10,000-record data file for each waste type-WMU scenario. This was accomplished by selecting the landfills and surface impoundments from the EPRI survey data that manage each type of waste. Within a scenario, a list of the EPRI plants with that WMU type and waste type was repeated to produce around 10,000 records. For each record, site-based, regional, and national inputs were randomly selected from distributions developed to characterize the regional or national variability in these inputs. Each record in the source data files was identified by a model run identification number (RunID).

The EPRI survey provided most of the WMU data needed, including area, capacity, liner type, and waste type. Additional data were collected to characterize the height and depth below ground surface of typical CCW landfills and surface impoundments (see Appendix B).

The environmental setting in which waste disposal occurs was characterized based on the location of the 181 power plants used in the full-scale analysis. These locations were used to characterize climate, soils, aquifers, and surface water bodies at each site as follows (see Appendix C for details):

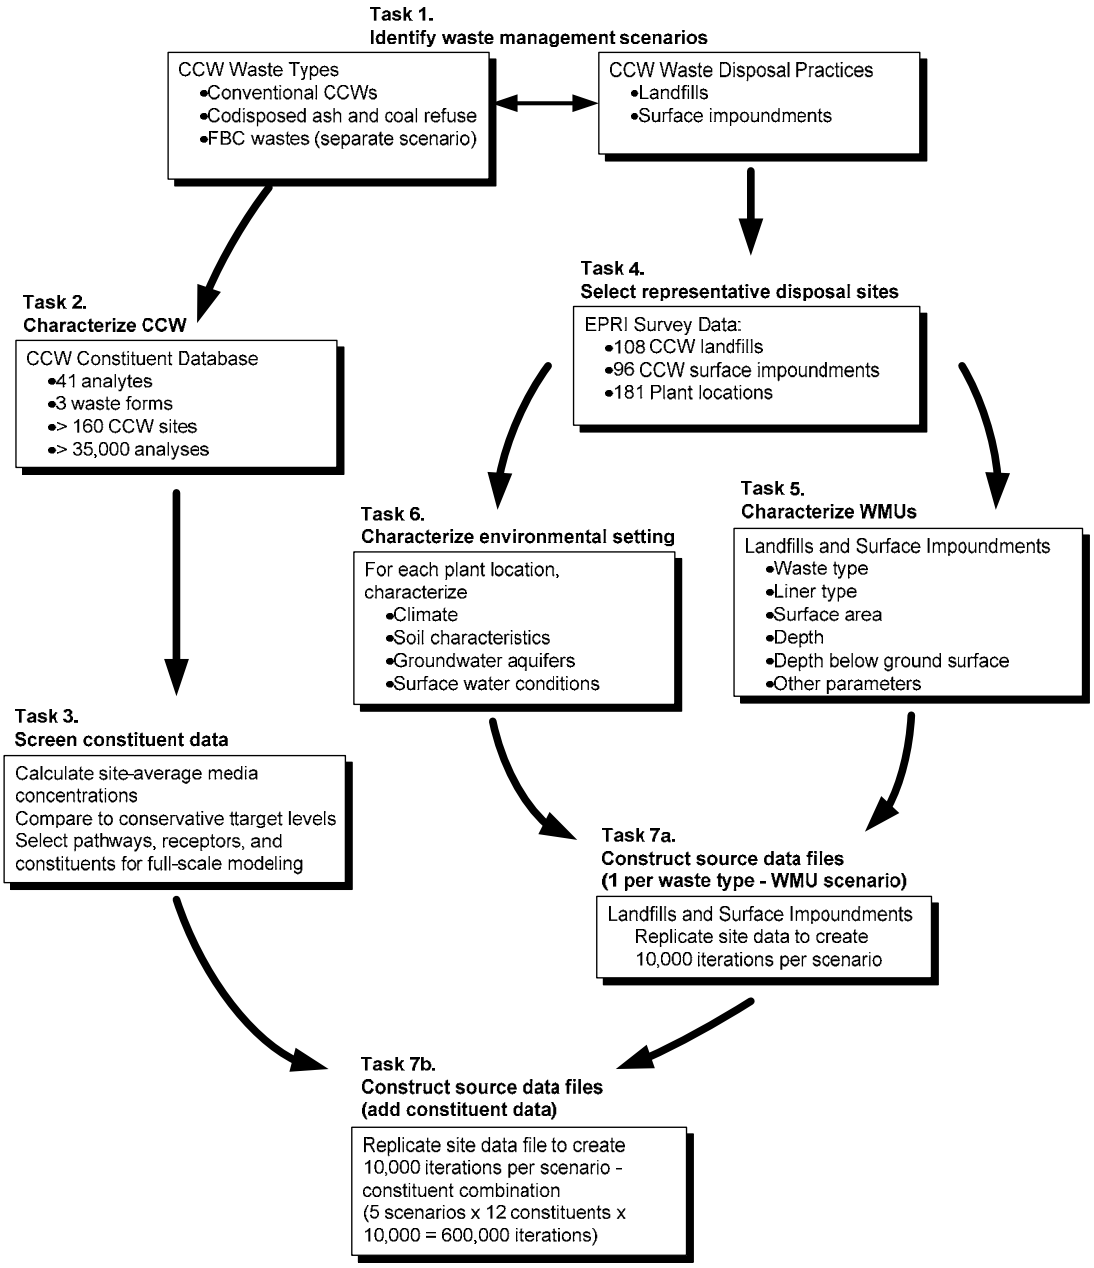

Figure 3-3. Process used to construct the Monte Carlo input database.

- Climatic data, including annual precipitation, temperature, and windspeed, were collected by assigning each site to a nearby meteorologic station.

- Soil and aquifer type were collected within a 5-km radius of each site to account for locational uncertainty for the WMUs.

- Surface water type and flows were collected using a geographic information system (GIS) to identify the nearest stream and by matching plants to the Permit Compliance

System (PCS) database to get the stream segment for each plant's NPDES discharge point.

These site-based data were supplemented with regional data on surface water quality and with national distributions of receptor distances (i.e., distance to drinking water well and distance to nearest surface waterbody). Appendix C describes the site-based approach and data sources used for these site-specific, regional, and national-scale data collection efforts.

The five 10,000-record scenario-specific source data files were then combined with the CCW constituent data for each constituent in the appropriate waste type to develop the final source data files for each scenario. With 12 constituents modeled for most scenarios, this resulted in over 600,000 records in the final input data set.

3.2 Landfill Model

Releases from landfills were modeled using a landfill source-term model contained in EPACMTP. EPA has used EPACMTP and its predecessor models for almost 20 years to conduct groundwater risk assessments in support of regulations for land disposal of hazardous and nonhazardous wastes. In that context, EPACMTP has undergone numerous peer reviews, including multiple reviews by EPA's Science Advisory Board (SAB). Each of these reviews has supported and approved the use of this model for developing national regulations and guidance, including verification that the model and model code are scientifically sound and properly executed. Some of the more important reviews include

- A 1989 review by SAB of the component saturated zone (groundwater) model used in EPACMTP
- A 1993 review by EPA's Office of Research and Development (ORD) of EPACMTP for potential Hazardous Waste Identification Rule applications, which resulted in a number of improvements in the computational modules of EPACMTP
- A 1994 consultation with SAB on the use of EPACMTP for determination of dilution-attenuation factors for EPA's *Soil Screening Guidance*
- A 1994 review by expert modelers Dr. Fred Molz (Auburn University) and Mr. Chris Neville (SS Papadopoulos & Associates), who verified that the mathematical formulation of the model and the code verification testing are scientifically sound
- The peer-reviewed publication of EPACMTP in the *Journal of Contaminant Hydrology* (Kool et al., 1994)
- An in-depth review by SAB related to the use of EPACMTP in the proposed/draft 1995 Hazardous Waste Identification Rule (U.S. EPA, 1995)
- A 1999 peer review by leading modelers of the implementation of EPACMTP in EPA's multimedia, multiple exposure pathway, multiple receptor risk assessment (3MRA) model (U.S. EPA, 1999c)

- A 2003 SAB review of the 3MRA implementation of EPACMTP (SAB, 2004).

An overview and statement of assumptions for the landfill model is presented here, followed by a listing of inputs to the landfill source-term model and a brief discussion of the output generated by the model.

3.2.1 Conceptual Model

The landfill model treats a landfill as a permanent WMU with a rectangular footprint and a uniform depth (see Figure 3-4). If only the area is known (which is the case for the CCW landfills), the landfill source-term model assumes a square footprint. The model assumes that the landfill is filled with waste during the unit's operational life and that upon closure of the landfill, the waste is left in place and a final soil cover is installed.

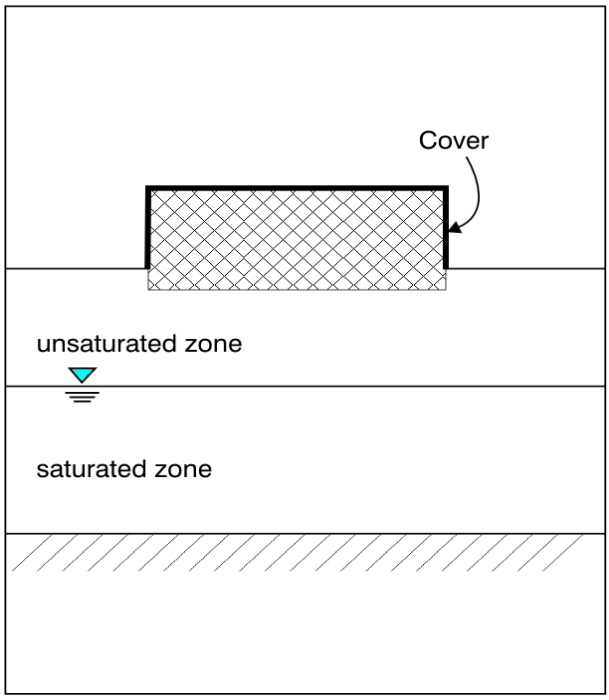

Figure 3-4. Conceptualization of a landfill in the landfill source-term model.

Three liner scenarios were modeled: a no-liner (unlined) scenario, a compacted clay liner, and a composite liner that combines a high-density polyethylene (HDPE) membrane with either geosynthetic or natural clays.

In the unlined scenario, waste is placed directly on local soils, either on grade or excavated to some design depth and without a leachate collection system. After the landfill has been filled to capacity, a 2-foot native soil cover (the minimum required by Subtitle D regulations) is installed and assumed to support vegetation.

In the clay liner scenario, waste is placed directly on a 3-foot compacted clay liner, which is installed on the local soils, either on grade or excavated to some design depth and without a

leachate collection system. After the landfill has been filled to capacity, a 3-foot clay cover is installed and covered with 1 foot of loam to support vegetation and drainage. The hydraulic conductivity of both the liner and cover clays is assumed to be $1x10^{-7}$ cm/sec, the typical design specification for compacted clay liners (U.S. EPA, 1988c).

In the composite liner scenario, wastes are placed on a liner system that consists of a 60 mil HDPE membrane with either an underlying geosynthetic clay liner or a 3-foot compacted clay liner. A leachate collection system is also assumed to exist between the waste and the liner system. After the landfill has been filled to capacity, a 3-foot clay cover is assumed to be installed and covered with 1 foot of loam to support vegetation and drainage (U.S. EPA, 2002b).

As described in Section 3.2.3 (and Appendix B), one of these three liner types was assigned to each CCW landfill or surface impoundment modeled based on the liner type data from the 1995 EPRI Survey (EPRI, 1997).

3.2.2 Modeling Approach and Assumptions

The starting point for the landfill source-term model simulation is the time when the landfill is closed (i.e., when the unit is filled with CCW).[5] As described in detail below, the full-scale analysis modeled contaminants leaching from CCW into precipitation infiltrating the landfill, which exits the landfills as leachate. Contaminant loss in leachate was taken into account at closure by subtracting the cumulative amount of contaminant mass loss that occurred during the unit's active life from the amount of contaminant mass present at the time of landfill closure. Loss calculations in the landfill source-term model continue after closure until the contaminant is depleted from the waste mass in the landfill. This is a conservative assumption, as some metal will not leach from the waste mass.

Infiltration and Leaching

The average rate at which water percolates through the landfill over time (the long-term infiltration rate) drives the leaching process in the landfill, which results from partitioning of the constituent from the waste into the infiltrating water. The methodology, assumptions, and data used to determine infiltration rates for each CCW liner scenario are consistent with the approach used in EPA's Industrial D guidance, as described in Section 4.3 and Appendix A of the *EPACMTP Parameter/Data Background Document* (U.S. EPA, 2003a) and Section 4.2.2 of the *Industrial Waste Evaluation Model (IWEM) Technical Background Document* (U.S. EPA, 2002b). EPA developed the IWEM model as part of a guide for managing nonhazardous industrial wastes in landfills and surface impoundments (http://www.epa.gov/industrialwaste). To help ensure that it was technically sound, the model (including the liner scenarios and algorithms used in the CCW risk assessment) was developed with a large stakeholder working group, including representatives from industry. The model was also subjected to a peer review in 1999 (64 FR 54889–54890, October 8, 1999, *Peer Reviews Associated With the Guide for*

[5] The simple landfill model used in this assessment cannot model a landfill as it is being filled prior to closure. Although leaching does occur during a landfill's operating life, risks from these releases are insignificant when compared to postclosure releases, given the long time it takes metal-bearing wastes to leach and reach peak concentrations in groundwater wells surrounding the landfill. EPA does not believe that the additional risks from the preclosure period justify the additional complexity, data, and effort required to model an operating landfill.

Industrial Waste Management), and the model was updated and improved in response to those comments before its final release in 2003. That update included the addition of a more robust liner leakage database to support the existing algorithms for calculating infiltration rates through composite liner systems.

No-Liner (Unlined) Scenario. For the no-liner scenario, infiltration rates were selected from a database in EPACMTP that contains 306 infiltration rates already calculated using EPA's Hydrologic Evaluation of Landfill Performance (HELP) water balance model (Schroeder, et al., 1994a, 1994b). HELP is a product of an interagency agreement between EPA and the U.S. Army Corps of Engineers Waterways Experiment Station, and was subjected to the Agency's peer and administrative review. All of the infiltration rates were calculated based on the single typical landfill design described in Section 3.2.1, with the only variables that change between HELP simulations being the meteorological data associated with 102 nationwide climate centers and the type of cover soil applied at closure. Three cover soil categories representing coarse-grained soils, medium-grained soils, and fine-grained soils were used. The selection of an infiltration rate from the database depends on the type of cover soil selected for the landfill and the assignment of the landfill to a HELP climate center. The unlined HELP-derived infiltration rates are presented in U.S. EPA (2003a) by climate center. The assignment of HELP climate centers and soil categories to each CCW site modeled is described in Appendix C.

Clay Liner Scenario. The clay liner scenario is very similar to the unlined scenario in that previously calculated HELP infiltration rates for a single clay-lined, clay-capped landfill design were used. The scenario is based on a typical engineered compacted clay liner that is 3 feet thick with a design hydraulic conductivity of $1x10^{-7}$ cm/sec. The one difference from the unlined case is that the clay liner and cover control the rate of water percolation through the landfill and thus infiltration rate does not vary with cover soil (i.e., there is one clay liner infiltration rate per climate center). The clay liner HELP-derived infiltration rates are provided in U.S. EPA (2003a).

Composite Liner Scenario. Composite liner infiltration rates are compiled from monthly average leak detection system (LDS) flow rates for industrial landfill cells reported by TetraTech (2001). The liner configurations are consistent with the composite liner design assumptions presented in Section 3.2.1 and are the same as those assumed for defaults in EPA's Industrial D landfill guidance (U.S. EPA, 2002b). The LDS flow rates were taken from 27 municipal landfill cells and used in the IWEM model (U.S. EPA, 2002b). As shown in Table 3-2, these LDS flow rates include 22 operating landfill cells and 5 closed landfill cells located in eastern United States: 23 in the northeastern region, 1 in the mid-Atlantic region, and 3 in the southeastern region. Each of the landfill cells is underlain by a geomembrane/geosynthetic clay liner which consists of a high-density polyethylene geomembrane of thickness between 1 and 1.5 mm, overlying a 6-mm composite geosynthetic clay layer consisting of two geotextile outer layers with a uniform core of bentonite clay to form a hydraulic barrier. Each liner system is underlain by an LDS.

As described in U.S. EPA (2002b), only a subset of the TetraTech (2001) flow rates were used to develop the composite liner infiltration rates. LDS flow rates for geomembrane/ compacted clay composite-lined landfill cells were not used in the distribution because compacted clay liners (including composite geomembrane/compacted clay liners) can release

water during consolidation and contribute an unknown amount of water to LDS flow, which makes it difficult to determine how much of the LDS flow is due to liner leakage versus clay consolidation. Also, LDS flow rates from three geomembrane/geosynthetic clay lined-cells were not used. For one cell, postclosure flow rates were very high, and were more than twice as high as those recorded during the cell's operating period. Data were not used for two other cells because of inconsistencies with the data for the 27 landfill cells used to develop composite liner infiltration rates (U.S. EPA, 2002b). The composite liner infiltration rates were specified as an empirically distributed input to the landfill model (see U.S. EPA ,2003a).

Table 3-2. Leak Detection System Flow Rate Data Used to Develop Landfill Composite Liner Infiltration Rates

Source Depletion and Mass Balance

For this assessment**,** the landfill source-term model represents releases from landfills as a finite source where the mass of a constituent in a landfill is finite and depleted over time by

leaching. The landfill source-term model is set as a pulse source, where the leachate concentration is constant over a prescribed period of time and then goes to zero when the constituent is depleted from the landfill. A pulse source is appropriate for metals and other constituents whose sorption behavior is nonlinear. Because all but one (nitrate/nitrite) of the constituents addressed in the full-scale analysis are metals, releases from landfills were modeled as pulse sources.

For a pulse source, basic mass balance considerations require leaching from the landfill to stop when all of the constituent mass has leached from the landfill. For the constant concentration pulse source condition, the pulse duration is given by

$$TSOURC = \frac{CWASTE \times DEPTH \times FRACT \times CTDENS}{CZERO \times SINFIL} \quad (3\text{-}1)$$

where

TSOURC = Pulse duration (yr)
CWASTE = Constituent concentration in the waste (mg/kg)
DEPTH = Depth of landfill (m)
FRACT = Volume fraction of the landfill occupied by the waste (unitless)
CTDENS = Waste density (g/cm^3)
CZERO = Initial waste leachate concentration (mg/L)
SINFIL = Annual areal infiltration rate (m/yr).

The landfill source-term model uses the above relationship to determine the leaching duration. More details regarding the waste concentration and WMU parameters in Equation 3-1 are provided below and in Appendices A and B.

3.2.3 Landfill Model Input Parameters

Input parameters required by the landfill source-term model are discussed below. Additional details on how data for these inputs were collected for the CCW risk assessment are provided in Appendix A for leachate and waste concentrations and Appendix B for landfill dimensions and characteristics.

- **Landfill Area.** The model uses landfill area to determine the area over which infiltration rate occurs and, along with landfill depth and waste concentration, to calculate the total contaminant mass in the landfill. CCW landfill area data were obtained from the EPRI comanagment survey (EPRI, 1997). The landfill was assumed to be square.

- **Landfill Depth.** Landfill depth is one of several parameters used by the landfill source-term model to calculate the contaminant mass in the landfill. For CCW landfills, average waste depth was estimated by dividing landfill capacity by landfill area. CCW landfill capacity data were taken from the EPRI comanagement survey (EPRI, 1997).

- **Depth Below Grade.** The depth of the bottom of the landfill below the surrounding ground surface is used, along with depth to groundwater, to determine the thickness of the unsaturated zone. For CCW landfills, depth below grade was determined from a national distribution based on available measurements from a number of CCW landfills (see Appendix B).

- **Waste Fraction.** The landfills were assumed to be CCW monofills, which corresponds to a waste fraction of 1.0.

- **Waste Density.** The average waste bulk density, as disposed, is used to convert waste volume to waste mass. The waste bulk density for all CCW waste types was assumed to be 1.19 g/cm^3 (U.S. EPA, 1998b).

- **Leachate Concentration.** The concentration of waste constituents in leachate was assumed to be constant until all of the contaminant mass initially present in the landfill has leached out, after which the leachate concentration was assumed to be zero. The constant value used for leachate concentration is from EPA's CCW Constituent Database, described in Appendix A.

- **Waste Concentration.** In the finite-source scenario modeled, the total waste concentration is used, along with the waste bulk density and landfill area and depth, to determine the total amount of a constituent available for leaching. Measured total CCW concentrations were paired with leachate concentrations, as described in Appendix A and provided in Attachment A-2.

- **Liner Type.** The type of liner is used to determine the infiltration/leaching scenario used to calculate leachate flux from the landfill. Table 3-3 shows the crosswalk used to assign one of the three liner scenarios to each facility based on the liner data in the 1995 EPRI survey (EPRI, 1997). Attachment B-2 to Appendix B provides these assignments, along with the original EPRI liner type, for each CCW landfill facility modeled. One significant uncertainty in these liner assumptions is how representative the EPRI survey data are of current conditions at coal combustion facilities.

Table 3-3. Crosswalk Between EPRI and CCW Source Model Liner Types

EPRI Liner Type	Model Liner Code	Description
Compacted ash	0	no liner
Compacted clay	1	clay
Composite clay/membrane	2	composite
Double	2	composite
Geosynthetic membrane	2	composite
None/natural soils	0	no liner

3.2.4 Model Outputs

For each year in the simulation, the landfill source-term model uses the average annual leachate concentration and infiltration rate to calculate a constituent flux through the bottom of the landfill. This time series is used as an input for the EPACMTP unsaturated zone model.

3.3 Surface Impoundment Model

Releases from surface impoundments were modeled using a surface impoundment source-term model contained in EPACMTP. An overview and statement of assumptions for the surface impoundment model is presented here, followed by a listing of inputs to the surface impoundment source-term model and a brief discussion of the output generated by the model. The primary differences between the treatment of landfills and surface impoundments are (1) the integration of the surface impoundment source term into the unsaturated flow solution, and (2) clean closure of the impoundment after the operating period is over.

3.3.1 Conceptual Model

The surface impoundment model treats a surface impoundment as a temporary WMU with a prescribed operational life. Unlike the landfill model, clean closure is assumed; that is, at the end of the unit's operational life, the model assumes that all wastes are removed and there is no further release of waste constituents to groundwater. Although this simplifying assumption limits the length of potential exposure, and is not consistent with the practice to close CCW surface impoundments with these wastes in place, the peak annual leachate concentrations on which the CCW risk results are based are not likely to be affected, because they are highest when the surface impoundment is in operation.

Following the unit's closure, the surface impoundment model assumes that the contaminated liquid and sediment in the surface impoundment are replaced by uncontaminated liquid and sediment with otherwise identical configurations and properties. The contaminants that have migrated to the unsaturated zone during operation continue to migrate towards the water table with the same infiltration rate as during operation. By continuing infiltration after the wastes are removed, the infiltration through the surface impoundment unit can be modeled as a single steady-state flow regime until concentrations in groundwater are no longer affected by constituents released from the surface impoundment during its operation.

The EPACMTP surface impoundment model assumes a square footprint and a constant ponding depth during the impoundment's operational life (Figure 3-5). For an unlined impoundment, the model assumes that while the impoundment is in operation, a consolidated layer of sediment accumulates at the bottom of the impoundment. The leakage (infiltration) rate through the unlined impoundment is a function of the ponding depth in the impoundment and the thickness and effective permeability of the consolidated sediment layer at the bottom of the impoundment. The rate of leakage is constrained to ensure that there is not a physically unrealistic high rate of leakage, which would cause groundwater mounding beneath the unit to rise above the ground surface. Underlying the assumption of a constant ponding depth, the surface impoundment source-term model assumes that wastewater in the impoundment is continually replenished while the impoundment is in operation. It also assumes, from the

beginning of the unit's operation, that the sediment is always in equilibrium with the wastewater (i.e., the presence of sediment does not alter the concentration of leachate). Accordingly, the surface impoundment source-term model also assumes that the leachate concentration is constant during the impoundment operational life. Typically, the leachate concentration is equal to the concentration in the wastewater entering the impoundment.

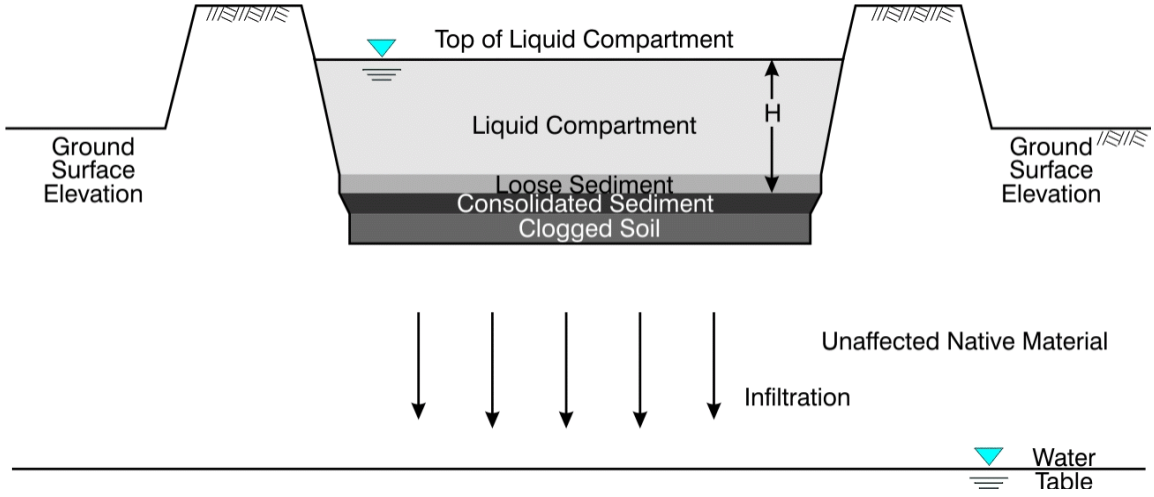

Figure 3-5. Schematic cross-section view of surface impoundment.

Three liner scenarios were modeled: a no-liner (unlined) scenario, a compacted clay liner, and a composite liner.

In the unlined scenario, wastewater is placed directly on local soils and the depth of water is constant over the entire life of the impoundment, pre- and post-closure. As described above, sediments accumulate and consolidate at the bottom of the impoundment and migrate into the underlying native soils, where they clog pore spaces and provide some barrier to flow. The surface impoundment model assumes that the thickness of the consolidated sediments is equal to one-half of the total sediment thickness, which is an input to the model. The sediment thickness was assumed to be 0.2 m for all simulations. The model also assumes that the thickness of the clogged region of native soils is always 0.5 m and has a hydraulic conductivity 10 percent of that of the native soil underlying the impoundment.

In the clay liner scenario, wastewater is placed on a compacted clay liner, which is installed on the local soils. The assumptions for an unlined impoundment also apply to the compacted clay liner scenario, except that a compacted clay liner filters out the sediments that clog the native soils in the unlined case, so the effect of clogging the native materials is not included in the calculation of the infiltration rate. The thickness of the compacted clay liner was assumed to be 3 feet and the hydraulic conductivity was assumed to be $1x10^{-7}$ cm/sec (U.S. EPA, 1988c).

In the composite liner scenario, wastewater is placed on a synthetic membrane with an underlying geosynthetic or natural compacted clay liner with a hydraulic conductivity of $1x10^{-7}$ cm/sec. The membrane liner was assumed to have a number of pinhole leaks of uniform size

(6 mm^2). The distribution of leak densities (expressed as number of leaks per hectare) was compiled from 26 leak density values reported in TetraTech (2001), the best available data on liner leaks. These leak densities are based on liners installed with formal construction quality assurance (CQA) programs. The 26 sites with leak density data are mostly located outside the United States: 3 in Canada, 7 in France, 14 in the United Kingdom, and 2 in unknown locations; we assume that these are representative of U.S. conditions. The WMUs at these sites (8 landfills, 4 surface impoundments, and 14 of unknown type) are underlain by a layer of geomembrane with a thickness varying from 1.14 mm to 3 mm. The majority of the geomembranes (23 of 26) are made from HDPE, and the remaining 3 are made from prefabricated bituminous geomembrane or polypropylene. One of the sites has a layer of compacted clay liner beneath the geomembrane; however, for 25 of the 26 sites, material types below the geomembrane layer are not reported. The empirical distribution used in the analysis can be found in IWEM (U.S. EPA, 2002b), along with a table showing details about the 26 liners used to develop the distribution.

3.3.2 Modeling Approach and Assumptions

Figure 3-5 illustrates a compartmentalized surface impoundment with stratified sediment. Shown in the figure are the liquid compartment, the sediment compartment (with loose and consolidated sediments), and the unsaturated zone (with clogged and unaffected native materials). The model assumes that all sediment layer thicknesses remain unchanged throughout the life of the unit.

The EPACMTP surface impoundment model uses the unsaturated zone flow model to calculate the infiltration rate out of the bottom of the impoundment. This model is designed to simulate steady-state downward flow through an unsaturated (vadose) zone consisting of one or more soil layers. Steady-state means that the rate of flow does not change with time. In the case of flow out of an unlined surface impoundment, the model simulates flow through a system consisting of three layers: a consolidated sediment layer, a clogged soil layer, and a native soil layer.

The native unsaturated soil extends downward to the water table. The steady-state infiltration rate out of the surface impoundment is driven by the head gradient between the water ponded in the impoundment and the head at the water table. The pressure head at the top of the consolidated sediment layer is equal to the water depth in the impoundment plus the thickness of the unconsolidated sediment.

The *EPACMTP Technical Background Document* (U.S. EPA, 2003c) describes the algorithms used in this model to calculate the infiltration rate from surface impoundment units, and discusses in detail the maximum allowable infiltration rate based on the groundwater mounding condition. This information is summarized here.

The EPACMTP surface impoundment source-term model calculates infiltration through the accumulated sediment at the bottom of an impoundment, accounting for clogging of the native soil materials underlying the impoundment, liner conditions, and mounding due to infiltration. The modeled infiltration is governed by the depth of liquid in the impoundment and the following limiting factors:

- **Effective hydraulic conductivity and thickness of the consolidated sediment layer.** As sediment accumulates at the base of the impoundment, the weight of the liquid and upper sediments tends to compress (or consolidate) the lower sediments. The consolidation process reduces the hydraulic conductivity of the sediment layer, and the layer of consolidated sediment will act as a restricting layer for flow out of the impoundment. By contrast, the layer of loose, unconsolidated sediment that overlies the consolidated sediment layer is assumed not to restrict the flow rate out of the unit, so it is not explicitly considered in the surface impoundment flow model.

- **Effective hydraulic conductivity of the clogged native material.** As liquids infiltrate soil underlying the impoundment, suspended particulate matter accumulates in the soil pore spaces, reducing hydraulic conductivity and lowering infiltration rates.

- **Effective hydraulic conductivity and thickness of a clay liner.** When the surface impoundment is underlain by a compacted clay liner, the rate of infiltration is also determined by simulating flow through a three-layer system, substituting the characteristics of the clay liner for those of the clogged soil layer.

- **Leak rate of a composite liner.** For cases where the surface impoundment is underlain by a composite liner (a geomembrane underlain by a low permeability liner such as a compacted clay liner or a geosynthetic clay liner), the surface impoundment source-term model uses a modified equation of Bonaparte et al. (1989) to calculate the infiltration rate. The equation uses, among other inputs, the head generated by the water and unconsolidated sediments in the unit, a leak density selected from an empirical distribution derived from a TetraTech (2001) study of liner leakage, a uniform leak size of 6 mm^2, and an assumed hydraulic conductivity of $1x10^{-7}$ cm/sec for the 3 feet of underlying compacted clay material.

- **Limitations on maximum infiltration rate from mounding.** If the calculated infiltration rate exceeds the rate at which the saturated zone can transport the groundwater, the groundwater level will rise into the unsaturated zone. The model accounts for groundwater mounding when calculating the infiltration rate from the surface impoundment unit and, if necessary, constrains the value to ensure that the groundwater mound does not rise to the bottom of the surface impoundment unit.

3.3.3 Surface Impoundment Model Input Parameters

Input parameters required by the surface impoundment source-term model are discussed below. Additional details on how data for these inputs were collected for the CCW risk assessment are provided in Appendix A for waste concentrations and Appendix B for surface impoundment dimensions and characteristics.

- **Surface Impoundment Area.** The model uses surface impoundment area to determine the area over which infiltration occurs. CCW surface impoundment area data were obtained from the EPRI comanagement survey (EPRI, 1997). The impoundment was assumed to be square.

- **Areal Infiltration Rate.** The surface impoundment leachate infiltration rate (or flux) is computed internally by the surface impoundment source-term model, as described in Section 3.3.2.

- **Depth Below Grade.** The depth of the bottom of the impoundment below the surrounding ground surface is used, along with depth to groundwater, to determine the thickness of the unsaturated zone beneath the impoundment. For CCW impoundments, depth below grade was sampled from an empirical distribution based on available measurements from a number of CCW surface impoundments (see Appendix B).

- **Operating Depth.** The operating (or ponding) depth is the long-term average depth of wastewater and sediment in the impoundment, measured from the base of the impoundment. For CCW surface impoundments, depth was estimated by dividing impoundment capacity by impoundment area. CCW impoundment capacity data were taken from the EPRI comanagement survey (EPRI, 1997).

- **Total Thickness of Sediment.** By default, EPACMTP models unlined surface impoundments with a layer of "sludge" or sediment above the base of the unit. The sediment layer is divided into two sublayers: an upper, loose sediment sublayer and a lower, consolidated sediment sublayer. The consolidated sediment has a relatively low hydraulic conductivity and acts to impede flow. The calculated infiltration rate is inversely related to the thickness of the consolidated sediment sublayer. A thinner consolidated sediment layer will result in a higher infiltration rate and a greater rate of constituent loss from the impoundment. The surface impoundment source-term model uses the total sediment thickness as an input parameter and assumes that it consists of equal thicknesses of loose and consolidated material. Because data were not available on CCW sediment layer thicknesses, the CCW risk assessment used the Tier 1 IWEM model assumption: a total (unconsolidated plus consolidated) sediment layer thickness of 0.2 meters (U.S. EPA, 2002b). It is not known how representative this assumption is with respect to unlined CCW surface impoundments, but it is reasonable to assume that a sediment layer would accumulate and restrict flow from the bottom of a CCW impoundment.

- **Distance to the Nearest Surface Water Body.** The distance to the nearest waterbody is used to determine the location of a fully penetrating surface waterbody at which groundwater mass and water fluxes will be calculated and reported. The distance to the nearest surface waterbody is also used as a surrogate for the distance to the nearest point at which the water table elevation is kept at a fixed value. That distance is used to calculate the estimated height of groundwater mounding underneath the impoundment to ensure that excessively high infiltration rates, which may be calculated for deep, unlined impoundments, do not occur. If necessary, the model reduces the infiltration rate to ensure the predicted water table does not rise above the ground surface. For the CCW sites, distance to surface water was sampled from an empirical distribution developed from aerial photo measurements at 59 coal-fired power plants with onsite landfills or surface impoundments (Appendix C).

- **Leachate Concentration.** The annual average leachate concentration is modeled as a constant concentration pulse with a defined duration. For a particular model run, the leachate concentration was assumed to be constant during the operation of the unit; there is no reduction in leachate concentration until the impoundment ceases operation. Leachate concentrations for CCW impoundments were obtained by waste type from surface impoundment porewater data from EPA's CCW Constituent Database, as described in Appendix A.

- **Source Leaching Duration.** For surface impoundments, the addition and removal of waste during the operational life period are more or less balanced, without significant net accumulation of waste. In the finite-source implementation used for CCW surface impoundments, the duration of the leaching period is assumed to be the same as the operational life of the surface impoundment. Based on industry data (see Appendix B) for CCW surface impoundments, we used a high-end (90th percentile) fixed surface impoundment operating life of 75 years. A high-end value was appropriate because CCW surface impoundments are typically closed with waste in place, while the surface impoundment source-term model assumes clean closure (waste removed). In addition, operating life is not a particularly sensitive parameter in this analysis: the difference between the 50th percentile value (40 years) and the 90th percentile value used (75 years) is less than a factor of two.

- **Liner Type, Thickness, Hydraulic Conductivity, and Leak Density.** The type of liner is used to calculate leachate flux from the impoundment. To assign one of the three liner scenarios to each facility in the EPRI survey (EPRI, 1997), we used the same crosswalk as we used for landfills (see Table 3-2). Attachment B-2 to Appendix B provides these assignments, along with the original EPRI liner type, for each CCW surface impoundment modeled.

As with IWEM (U.S. EPA, 2002b), clay liners were assumed to be 3 feet thick and to have a constant hydraulic conductivity of 10^{-7} cm/s, reflecting typical design specifications for clay liners. For composite liners, infiltration was assumed to result from defects (pin holes) in the geomembrane. The pin holes were assumed to be circular and uniformly sized (6 mm^2). The leak density was defined as the average number of circular pin holes per square meter and was obtained from a study of industrial surface impoundment membrane liner leak rates by Tetra Tech (2001).

3.3.4 Surface Impoundment Model Outputs

For each year in the simulation, the surface impoundment source-term model uses the average annual leachate concentration and calculates an infiltration rate to estimate the constituent flux through the bottom of the impoundment. This time series is used as an input for the EPACMTP unsaturated zone model.

3.4 Groundwater Model

This section describes the methodology and the models that were used to predict the fate and transport of chemical constituents in soil and groundwater to determine impacts on drinking

water wells and surface water that is connected to groundwater. The surface water model used to address the groundwater-to-surface water pathways is described in Section 3.5.

3.4.1 Conceptual Model

The groundwater pathway was modeled to determine the receptor well concentrations and contaminant flux to surface water resulting from the release of waste constituents from a WMU. The release of a constituent occurs when liquid percolating through the WMU becomes leachate as it infiltrates from the bottom of the WMU into the subsurface. For landfills, the liquid percolating through the landfill is from water in the waste and precipitation. For surface impoundments, the percolating liquid is primarily the wastewater managed in the impoundments.

Waste constituents dissolved in the leachate are transported through the unsaturated zone (the soil layer under the WMU) to the underlying saturated zone (i.e., groundwater). Once in the groundwater, contaminants are transported downgradient to a hypothetical receptor well or waterbody. For this analysis, the groundwater concentration was evaluated for three receptor locations, each at a specified distance from the downgradient edge of the WMU:

- The intake point of a hypothetical residential drinking water well (the receptor well), which is used for the residential drinking water pathway
- A nearby river, stream, or lake, which is modeled as a fully penetrating surface waterbody and is used for the fish ingestion and ecological pathways.

Figure 3-6 shows the conceptual model of the groundwater fate and transport of contaminant releases from a WMU to a downgradient receptor well.

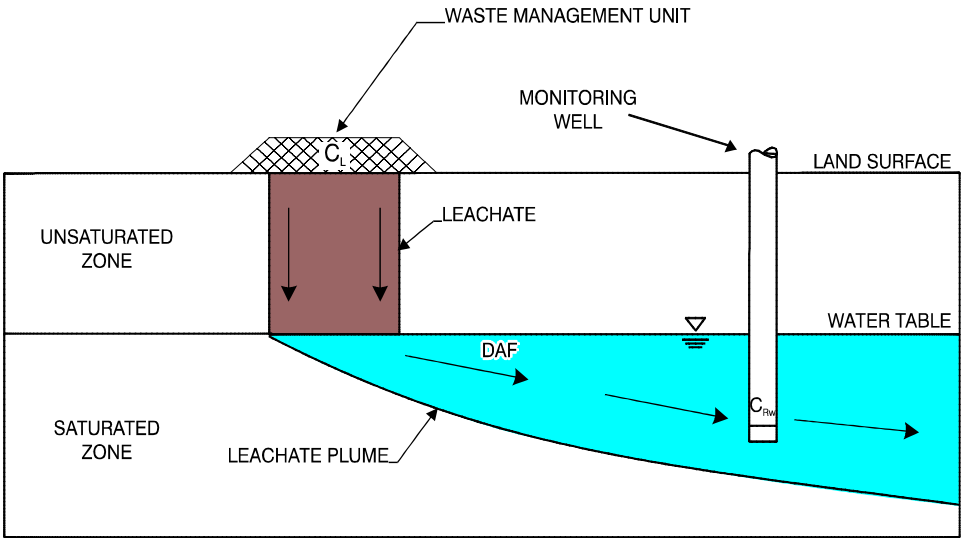

Figure 3-6. Conceptual model of the groundwater modeling scenario.

3.4.2 Modeling Approach and Assumptions

The transport of leachate from the WMU through the unsaturated and saturated zones was modeled using EPACMTP (U.S. EPA, 1996, 1997a, 2003a, 2003d, 2003d). EPACMTP is a

composite model consisting of two coupled modules: (1) a one-dimensional module that simulates infiltration and dissolved contaminant transport through unsaturated soils, and (2) a 3-dimensional saturated zone flow and transport module to model groundwater fate and transport. EPACMTP has been used by EPA to make regulatory decisions for wastes managed in land disposal units (including landfills and surface impoundments) for a number of solid waste and hazardous waste regulatory efforts, and as noted earlier, has undergone extensive peer review. EPACMTP simulates the concentration arriving at a specified receptor location (such as a well or stream).

The primary subsurface transport mechanisms modeled by EPACMTP are (1) downward (1-dimensional) movement along with infiltrating water flow in the unsaturated zone soils and (2) movement and dispersion along with ambient groundwater flow in the saturated zone. EPACMTP models soils and aquifer as uniform porous media and does not account for preferential pathways such as fractures and macropores or for facilitated transport, which may affect migration of strongly sorbing constituents such as metals.

In the unsaturated zone, flow is gravity driven and prevails in the downward direction. Therefore, the flow is modeled in the unsaturated zone as one-dimensional in the vertical direction. The model also assumes that transverse (sideways) dispersion (from both mechanical and molecular diffusion processes) is negligible in the unsaturated zone because the scale of lateral migration due to transverse dispersion is negligible compared with the size of the WMUs. This assumption is also environmentally protective because it allows the leading front of the contaminant plume to arrive at the water table with greater peak concentration in the case of a finite source.

In the saturated zone, the EPACMTP model assumes that movement of chemicals is driven primarily by ambient groundwater flow, which in turn is controlled by a regional hydraulic gradient and hydraulic conductivity in the aquifer formation. The model does take into account the effects of infiltration through the WMU, as well as regional recharge into the aquifer around the WMU. Infiltration through the WMU increases the groundwater flow in all directions under and near the WMU and may result in groundwater mounding. This 3-dimensional flow pattern enhances the horizontal and vertical spreading of the contaminant plume. The effect of recharge (outside the WMU) is to cause a downward (vertical) movement of the contaminant plume as it travels along groundwater flow direction. In addition to advective movement with the groundwater flow, the model simulates mixing of contaminants with groundwater due to hydrodynamic dispersion, which acts along the groundwater flow direction, as well as vertically and in the horizontal transverse direction.

To model sorption of CCW constituents in the unsaturated zone, soil-water partitioning coefficients (K_d values) for metal constituents were selected from nonlinear sorption isotherms generated from the equilibrium geochemical speciation model MINTEQA2 (U.S. EPA, 2001a). Chemicals with low K_d values will have low retardation factors, which means that they will move at nearly the same velocity as the groundwater. Chemicals with high K_d values will have high retardation factors and may move many times slower than groundwater. As described in Appendix D, CCW-specific partition coefficients were developed with MINTEQA2 considering

CCW leachate chemistry, including the highly alkaline chemistries that are characteristic of some CCWs.

MINTEQA2 is a product of ORD, and like EPACMTP, has a long history of peer- and SAB-review during its development, use, and continued improvement for regulatory support over the past two decades. These reviews largely focused on the use of MINTEQA2 to generate sorption isotherms for metals for EPACMTP, which is how it was used in the CCW risk assessment. Two of the more recent peer reviews include one for application within the 3MRA model (U.S. EPA, 1999d) and a review of its use and application to RCRA rulemaking and guidance support, including revisions made to the model to support IWEM and the CCW rulemaking efforts (U.S. EPA, 2003f). In the latter review, three experts found that the revisions made to the MINTEQA2 model were appropriate, but also suggested further improvements in how the model addresses environments with highly alkaline leachate (such as CCW sites). As explained in Appendix D, these comments were addressed in this application of MINTEQA2 to CCW waste transport by the development of sorption isotherms that are specific to geochemical conditions encountered in CCW landfills and surface impoundments.

3.4.3 Model Inputs and Receptor Locations

EPACMTP requires information about soil and aquifer properties as model inputs. For soils, EPACMTP uses soil texture to generate consistent hydrological properties for the unsaturated zone model, and soil pH and organic matter to select appropriate sorption coefficients to model contaminant sorption in the soil. As described in Appendix C, site-specific soil texture, pH, and organic carbon data were collected around each site from the STATSGO soils database. Similarly, the hydrogeological setting around each WMU was used to select appropriate aquifer conditions from EPACMTP's Hydrogeologic Database (HGDB; see Appendix C).

Recharge is water percolating through the soil to the aquifer outside the footprint of the WMU. The recharge rate is determined by precipitation and soil texture. For the CCW landfills and surface impoundments, recharge rates were selected by soil texture and meteorological station assignment from a database of HELP model–derived recharge rates for climate stations across the country that is included in the EPACMTP input files. Further details about how these rates were determined and other options for determining recharge rates outside of the EPACMTP model can be found in the *EPACMTP Parameters/Data Background Document* (U.S. EPA, 2003a).

One of the most important inputs for EPACMTP is receptor location, which for this risk assessment includes residential drinking water wells and surface water bodies. Figure 3-7 shows a schematic of how residential well drinking water intakes were defined in terms of their radial downgradient distance from the WMU and the angle off the contaminant plume centerline. The shaded areas in Figure 3-7 represent the horizontal extent of the contaminant plume.

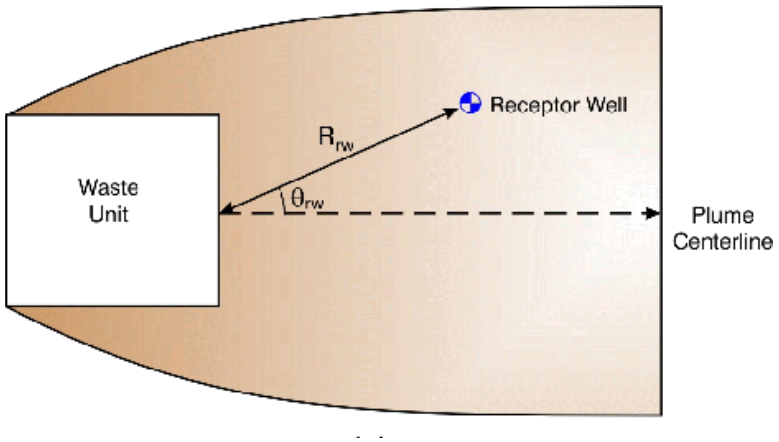

Figure 3-7. Schematic plan view showing contaminant plume and receptor well location.

In this analysis, receptor wells were located randomly within the contaminant plume, as follows:

- Because residential well distance data are not available for CCW WMUs, EPA based the radial downgradient distance on a nationwide distribution of the nearest downgradient residential or municipal wells from a survey of Subtitle D municipal solid waste landfills (U.S. EPA, 1988a; see Appendix C). The maximum radial distance in this survey was 1 mile. EPA believes that this distribution is protective of CCW WMUs, but because information on the actual distance of drinking water wells from CCW facilities is very limited, EPA is seeking comments and additional data that are relevant to this issue.

- The angle off the contaminant plume centerline (θ_{rw} in Figure 3-7) was based on a uniform distribution ranging from zero to ninety degrees.

- Wells were placed within the lateral extent of the contaminant plume (shaded portion in Figure 3-7).

- The depth of the well intake point was based on a uniform distribution with limits of 0 (i.e., well at the water table) to 10 meters (or the total saturated aquifer thickness if the aquifer is less than 10 meters thick).

The location of the surface waterbody intercepting groundwater flow was specified for each flow and transport simulation. The waterbody was constrained to lie across the contaminant plume centerline and its depth was varied uniformly throughout the aquifer thickness or throughout the upper 10 m of the aquifer thickness, whichever was less.

Downgradient distance to the surface waterbody was determined from an empirical distribution of distances measured for CCW landfills and surface impoundments (see Appendix C), which was randomly sampled to develop the distances used in EPACMTP to calculate groundwater concentrations at those distances in the Monte Carlo analysis.

3.4.4 Groundwater Model Outputs

The output of EPACMTP is a prediction of the contaminant concentration arriving at a downgradient groundwater receptor location (either a well or a surface water body). Because a finite-source scenario was used, the concentration is time-dependent. A maximum time-averaged concentration was calculated for each constituent across the exposure duration selected in each Monte Carlo iteration.

3.5 Surface Water Models

For the groundwater-to-surface-water pathway, chemical contaminants leach out of WMUs and into groundwater, and this contaminated groundwater then discharges into a surface waterbody through groundwater discharge. Once in the waterbody, the continued fate and transport of the contaminants is modeled with a surface water model, which uniformly mixes the contaminants in a single stream segment. Surface water flows in and out of the stream segment. Surface water flowing into the stream segment is assumed to have zero constituent concentration, and surface water flowing out has nonzero constituent concentrations due to the groundwater contamination. EPACMTP assumes a fully penetrating stream; therefore, the entire groundwater and contaminant flux is passed to the surface water model. To ensure that an unrealistic flux of contaminated groundwater does not occur, the groundwater flow into the waterbody is compared to the stream flow. If the groundwater flux exceeds the stream flow, it is capped at the stream flow and the contaminant flux is reduced using the ratio of the stream flow to the incoming groundwater flow (i.e., all of the stream flow is assumed to be from groundwater discharge and the total concentration in the stream is equal to the groundwater concentration).

The waterbody considered in the CCW risk assessment is a river, stream, or lake located downgradient of the WMU. As described in Appendix C, the flow characteristics and dimensions for this waterbody are determined by site-specific stream flow data, the width of the groundwater contaminant plume as it intersects the waterbody, and established relationships between flow and stream depth. The stream segment modeled in this assessment is assumed to be homogeneously mixed.

Simple equilibrium partitioning models were used to estimate contaminant concentrations in the water column, suspended and bed sediments (see Section 3.5.1), and aquatic organisms (see Section 3.5.2). Special modeling provisions for aluminum are described in Section 3.5.3.

3.5.1 Equilibrium Partitioning Model

The primary surface water model used to estimate groundwater impacts on waterbodies is a simple steady-state equilibrium-partitioning model adapted from models in EPA's Indirect Exposure Methodology (IEM; U.S. EPA, 1998c) and Human Health Risk Assessment Protocol (HHRAP; U.S. EPA, 1998d). This model is based on the concept that dissolved and sorbed concentrations can be related through equilibrium partitioning coefficients. This model was used for all constituents except aluminum, which was modeled based on a solubility approach (see Section 3.5.3). Although these models have not been specifically peer reviewed in this application, they have been subject to the Agency's peer review process as part of the development of the IEM and HHRAP.

The model partitions the total mass of chemical contaminant in the waterbody into four compartments:

- Constituents dissolved in the water column
- Constituents sorbed onto suspended solids
- Constituents sorbed onto sediment particles at the bottom of the waterbody
- Constituents dissolved in porewater in the sediment layer.

Table 3-4 provides the partitioning coefficients used by the surface water model to estimate contaminant partitioning between water and suspended solids in the water column and between sediment and porewater in the sediment layer. These distributions were derived from published empirical data as described in U.S. EPA (1999b).

Table 3-4. Sediment/Water Partition Coefficients: Empirical Distributions[a]

Chemical	Distribution Type	Minimum	Mean	Maximum	SD
Aluminum	not used				
Antimony	log normal	0.6	3.6	4.8	1.8
Arsenic	log normal	1.6	2.4	4.3	0.7
Barium	log normal	0.9	2.5	3.2	0.8
Boron	log normal	-0.5	0.8	1.4	0.5
Cadmium	log normal	0.5	3.3	7.3	1.8
Cobalt	log normal	2.2	3.9	5.3	0.8
Lead	log normal	2.0	4.6	7.0	1.9
Molybdenum	log normal	1.3	2.2	3.2	0.9
Selenium IV	log normal	1.0	3.6	4.0	1.2
Selenium VI	log normal	-1.4	0.6	3.0	1.2
Thallium	log normal	-0.5	1.3	3.5	1.1
Total Nitrate Nitrogen	constant	0	0	0	0

Source: U.S. EPA (1999b).
SD = standard deviation.
[a] All values are log values.

Following calculation of the constituent loading and loss rates, the surface water model estimates steady-state, equilibrium waterbody contaminant concentrations in each compartment using equations presented in Attachment E-1 to Appendix E. For evaluating risks to human health from fish consumption, the model calculates waterbody concentrations using groundwater loadings that are explicitly averaged over the exposure period for the each human receptor (i.e., adult and child fishers). These average waterbody concentrations are then used to calculate fish concentrations as described in Section 3.5.2. Ecological risks were based on waterbody concentrations calculated using the peak annual groundwater loading value from EPACMTP.

The equilibrium–partitioning model, as implemented, is conservative because there are no loss mechanisms (e.g., burial) for any of the constituents.

3.5.2 Aquatic Food Web Model

An aquatic food web model was used to estimate the concentration of CCW constituents that accumulate in fish. This risk assessment assumes that fish are a food source for a recreational fisher. Trophic level three (TL3) and four (TL4) fish[6] were considered in this analysis because most of the fish that humans eat are T4 fish (e.g., salmon, trout, walleye, bass) and medium to large T3 fish (e.g., carp, smelt, perch, catfish, sucker, bullhead, sauger). The aquatic food web model has been peer reviewed as part of the 3MRA model development effort (see http://www.epa.gov/ epaoswer/hazwaste/id/hwirwste/peer03/aquatic/aqtfooda.pdf).

The aquatic food web model calculates the concentration in fish from the concentration calculated for the waterbody downgradient from the CCW disposal site. The contaminants in the water column consist of dissolved constituents and constituents sorbed to suspended solids. For all constituents, the contaminant concentrations in fish were calculated from the total waterbody concentration (i.e., dissolved plus sorbed to suspended solids) using bioconcentration factors (BCFs), which are presented in Table 3-5. The equations used to model fish tissue concentrations are provided in Attachment E-2 to Appendix E.

Table 3-5. Bioconcentration Factors for Fish

CAS	Chemical	T3 Value	T4 Value	Units	Reference
7429-90-5	Aluminum	ND	ND	L/kg	
7440-36-0	Antimony	0	0	L/kg	Barrows et al. (1980)
22569-72-8	Arsenic (III)	4.0E+00	4.0E+00	L/kg	Barrows et al. (1980)
15584-04-0	Arsenic (V)	4.0E+00	4.0E+00	L/kg	Barrows et al. (1980)
7440-39-3	Barium	ND	ND	L/kg	
7440-42-8	Boron	ND	ND	L/kg	
7440-43-9	Cadmium	2.7E+02	2.7E+02	L/kg	Kumada et al. (1972)
7440-48-4	Cobalt	ND	ND	L/kg	
7439-92-1	Lead	4.6E+01	4.6E+01	L/kg	Stephan (1993)
7439-98-7	Molybdenum	4.0E+00	4.0E+00	L/kg	Eisler (1989)
10026-03-6	Selenium (IV)	4.9E+02	1.7E+03	L/kg	Lemly (1985)
7782-49-2	Selenium (VI)	4.9E+02	1.7E+03	L/kg	Lemly (1985)
7440-28-0	Thallium	3.4E+01	1.3E+02	L/kg	T3: Barrows et al. (1980) T4: Stephan (1993)
14797-55-8	Total Nitrate Nitrogen	ND	ND	L/kg	

ND = No Data. Fish concentrations were not calculated for constituents with no BCF data.

[6] TL3 fish are those that consume invertebrates and plankton; TL4 fish are those that consume other fish.

3.5.3 Aluminum Precipitation Model

A simple precipitation model was used for aluminum in lieu of the equilibrium-partitioning model, because aluminum is generally solubility limited in natural waters. The MINTEQA2 model was used to estimate total soluble aluminum concentrations as a function of pH for a typical surface waterbody (Stumm and Morgan, 1996; Drever, 1988). By assuming the common aluminum silicate mineral gibbsite was the equilibrium solid phase, the computed values of total dissolved aluminum were interpreted as the maximum expected for each pH. If more aluminum were added to the system, it would be expected to precipitate as the mineral gibbsite for the system to maintain equilibrium. Table 3-6 shows the maximum dissolved aluminum concentrations as a function of waterbody pH.

The precipitation model initially calculates the aluminum concentration in the surface water column by assuming that all aluminum in the groundwater flux is dissolved. If this concentration exceeds the maximum soluble concentration based on pH, the dissolved concentration is capped and the excess aluminum is assumed to precipitate as the mineral gibbsite and settle to the benthic sediment layer. The equations used in this model are presented in Appendix E.

Table 3-6. Aluminum Solubility as a Function of Waterbody pH[a]

Minimum pH	Maximum pH	Solubility (mg/L)
3.5	4.5	26.2
4.5	5	1.84
5	5.5	0.196
5.5	6	0.0112
6	6.5	0.00143
6.5	7	0.000662
7	7.5	0.000915
7.5	8	0.00229
8	8.5	0.00682
8.5	9	0.0212
9	9.5	0.0666
9.5	10	0.211
10	10.5	0.668

[a] Computed using MINTEQA2

Only the water column concentration for aluminum was used in subsequent exposure and risk calculations, because there is no available ecological benchmark for aluminum in sediment. The water column concentration was used to calculate human exposure via drinking water ingestion, as well as risk to ecological receptors exposed via direct contact.

3.6 Human Exposure Assessment

The human exposure component of the full-scale analysis assessed the magnitude, frequency, duration, and route of exposure to CCW contaminants that an individual may experience. The term "exposure," as defined by the EPA exposure guidelines (U.S. EPA, 1992), as the condition that occurs when a contaminant comes into contact with the outer boundary of the body. The exposure of an individual to a contaminant completes an exposure pathway (i.e., the course a constituent takes from the WMU to an exposed individual). Once the body is exposed, the constituent can cross the outer boundary and enter the body. The amount of contaminant that crosses and is available for adsorption at internal exchange boundaries is referred to as the "dose" (U.S. EPA, 1992).

This risk assessment evaluated the risk from CCW contaminants to receptors in the vicinity of a WMU. The individuals evaluated were those residents closest to the WMU. The distances from the WMU to the residents were taken from a distribution of distances to the nearest residential drinking water well measured for municipal landfills and, for the recreational fisher, a distribution of the distance of the nearest surface water body from CCW landfills and surface impoundments (see Appendix C).

Section 3.6.1 presents an overview of the receptors and selected exposure pathways considered for this assessment, including a discussion of how childhood exposure is considered in the analysis. Section 3.6.2 presents exposure factors (i.e., values needed to calculate human exposure) used in the analysis. Section 3.6.3 describes the methods used to estimate dose, including average daily dose (ADD) and lifetime average daily dose (LADD).

3.6.1 Receptors and Exposure Pathways

Human receptors may come into contact with constituents present in environmental media through a variety of pathways. The exposure pathways considered in the full-scale analysis were ingestion of drinking water from contaminated groundwater sources and ingestion of fish from surface water contaminated by groundwater.

- **Ingestion of Drinking Water.** Groundwater from an offsite well was assumed to be used for drinking water for residents (adult and child).

- **Ingestion of Fish.** Fish are exposed to constituents via uptake of contaminants from surface water. Adult recreational fishers and their children were assumed to consume fish caught in local waterbodies. Although conservative, EPA considers this assumption to be reasonable and protective for fishers relying on locally caught fish as a food source.

Table 3-7 lists each human receptor type considered in this analysis along with the specific exposure pathways that apply to that receptor. Both adult and child residents are exposed by drinking groundwater, and adult fishers and their children are exposed by eating fish caught in streams and lakes impacted by CCW.

Table 3-7. Receptors and Exposure Pathways

Receptor	Ingestion of Drinking Water	Ingestion of Fish
Adult resident	✓	
Child resident	✓	
Adult recreational fisher		✓
Child of recreational fisher		✓

Childhood Exposure

Children are an important subpopulation to consider in a risk assessment because they may be more sensitive to exposures than adults. Compared with adults, children may eat more food and drink more fluids per unit of body weight. This higher intake-rate-to-body-weight ratio can result in a higher ADD for children than adults.

As children mature, their physical characteristics and behavior patterns change. To capture these changes in the analysis, the life of a child was considered in stages represented by the following cohorts: cohort 1 (ages 1 to 5), cohort 2 (ages 6 to 11), cohort 3 (ages 12 to 19), and cohort 4 (ages 20 to 70). Associated with each cohort are distributions of exposure parameters that reflect the physical characteristics and behavior patterns of that age range. These exposure parameters are required to calculate exposure to an individual. The distributions for the 20- to 70-year-old cohort were the same as those used for adult receptors.

To capture the higher intake-rate-to-body-weight ratio of children, a start age of 1 year was selected for the child receptors. The exposure duration distribution for cohort 1 (a 1- to 5-year-old) was used to define exposure duration for the child receptors for each of the 10,000 iterations in the probabilistic analysis. For each individual iteration, the child receptor is aged through the age cohorts as appropriate until the age corresponding to the selected exposure duration is reached (e.g., if an exposure duration of 25 years was selected for an iteration, the child was aged from 1 year to 25 years, spending 5 years in cohort 1, 6 years in cohort 2, 8 years in cohort 3, and 6 years in cohort 4, for a total of 25 years).

3.6.2 Exposure Factors

The exposure factors used are listed in Table 3-8, along with their data sources and variable type (i.e., whether they were represented as a distribution or a fixed value in the Monte Carlo analysis). These exposure factors were used to calculate the dose of a chemical based on contact with contaminated media or food, the duration of that contact, and the body weight of the exposed individuals.

Table 3-8. Human Exposure Factor Input Parameters and Data Sources

Parameter	Variable Type	Data Source
Body weight (adult, child)	Distribution	U.S. EPA (1997c)
Ingestion rate: fish (adult, child)	Distribution	U.S. EPA (1997d)
Ingestion rate: drinking water (adult, child)	Distribution	U.S. EPA (1997c)
Exposure duration (adult, child)	Distribution	U.S. EPA (1997e)
Exposure frequency (adult, child)	Fixed (constant)	U.S. EPA policy
Fraction contaminated: drinking water	Fixed (constant)	U.S. EPA policy
Fraction contaminated: fish	Fixed (constant)	U.S. EPA policy
Fraction of TL3 fish consumed	Fixed (constant)	U.S. EPA (1997d)
Fraction of TL4 fish consumed	Fixed (constant)	U.S. EPA (1997d)
Human lifetime (used in carcinogenic risk calculation)	Fixed (constant)	U.S. EPA policy

The primary data source of human exposure model inputs used in this risk assessment was EPA's *Exposure Factors Handbook* (EFH; U.S. EPA, 1997c-e). The EFH summarizes data on human behaviors and characteristics related to human exposure from relevant key studies and provides recommendations and associated confidence estimates on the values of exposure factors. These data were carefully reviewed and evaluated for quality before being included in the EFH. EPA's evaluation criteria included peer review, reproducibility, pertinence to the United States, currency, adequacy of the data collection period, validity of the approach, representativeness of the population, characterization of variability, lack of bias in study design, and measurement error (U.S. EPA, 1997c-e). For exposure factors that were varied in the Monte Carlo analysis, probability distribution functions were developed from the values in the EFH.

The data sources and assumptions for intake and other human exposure factors used in this analysis are described below. Appendix F presents the exposure factors used and describes the rationale and data used to select the form of the distributions (e.g., normal, lognormal, gamma, Weibull) for those exposure factors that were varied in the probabilistic analysis.

- **Body Weight.** Distributions of body weight were developed for adult and child receptors based on data from the EFH.

- **Fish Ingestion Rate.** Fish ingestion rates were based on a recreational angler who catches and eats some fish from a waterbody impacted by contaminants released from CCW WMUs. Distributions of fish intake rates were developed for adult fishers based on data from the EFH. Because the EFH does not have fish ingestion rates for children, adult ingestion rates were used (as a conservative assumption).

- **Drinking Water Ingestion Rate.** Distributions of drinking water intake rates were developed for the adult and child resident based on data from the EFH.

- **Exposure Duration.** Exposure duration refers to the amount of time that a receptor is exposed to a contaminant source. Exposure duration was assumed to correspond with the receptor's residence time in the same house. Exposure durations were determined using data on residential occupancy from the EFH. The data used to develop

parameter information for resident receptors were age-specific. Thus, separate exposure duration distributions were developed for adult and child residents.

- **Exposure Frequency.** Exposure frequency is the frequency with which the receptor is exposed to the contaminated source during the exposure duration. Exposure frequency is not expected to vary much, so distributions were not developed for exposure frequency. All receptors were assumed to be exposed to the contaminant source 350 days/year. This value is based on the conservative assumption that individuals are away from their homes (e.g., on vacation) approximately 2 weeks out of the year, but are otherwise exposed daily.

- **Lifetime and Averaging Time.** Averaging time is the period of time over which a receptor's dose is averaged. To evaluate carcinogens, total dose was averaged over the lifetime of the individual, assumed to be 70 years. To evaluate noncarcinogens, dose was averaged over the last year of exposure because noncancer effects may become evident during less-than-lifetime exposure durations if toxic thresholds are exceeded. Essentially, this amounts to setting exposure duration and averaging time equal so that they cancel each other out in the equation for ADD. Thus, neither exposure duration nor averaging time is included in the ADD equation.

3.6.3 Dose Estimates

An exposure assessment estimates the dose to each receptor from the contaminant concentration in the exposure medium (e.g., drinking water, fish) and the intake rate for that medium (e.g., ingestion rate of drinking water, ingestion rate of fish). For this assessment, exposure estimates were based on the *potential* dose (e.g., the dose ingested) rather than the applied dose (e.g., the dose delivered to the gastrointestinal tract) or the internal dose (e.g., the dose delivered to the target organ). Doses from groundwater or fish ingestion were calculated by multiplying the contaminant concentration in groundwater or fish by the respective intake rate on a per kilogram body weight basis. Doses were then summed over the exposure duration, resulting in an ADD received from ingestion exposure. The ADD was used to assess noncancer risk from ingestion exposures and is defined as

$$ADD = C \times IR \tag{3-2}$$

where

C = average concentration (mass/volume or mass/mass)
IR = intake rate (mass/body weight mass/time, or volume/body weight mass/time).

Contaminant concentration represents the concentration of a chemical in a medium that contacts the body. The ADD was calculated from concentrations averaged over the exposure duration for each receptor.

For cancer effects, where the biological response is described in terms of lifetime probabilities even though exposure may not occur over the entire lifetime, dose is presented as a

LADD. The LADD was used to assess cancer risks from each exposure route (i.e., ingestion) and is defined as

$$LADD = \frac{C \times IR \times ED \times EF}{AT \times 365} \quad (3\text{-}3)$$

where

C = average concentration (mass/mass or mass/volume)
IR = intake rate (mass/body weight mass/time, or volume/body weight mass/time)
ED = exposure duration (yr)
EF = exposure frequency (d/yr)
AT = averaging time (yr)
365 = units conversion factor (d/yr).

As with the ADD, contaminant concentration represents the concentration of a chemical in a medium that contacts the body. Intake rate depends on the route of exposure; for example, it might be an inhalation rate or an ingestion rate. Exposure frequency is the number of days per year the receptor is exposed to the contaminated source during the exposure duration.

For cancer effects, biological responses are described in terms of lifetime probabilities, even though exposure may not be lifelong; consequently, the exposure duration (the length of time of contact with a contaminant) was used to average the ADD over a lifetime (70 years). The media concentrations used were averaged over the duration of exposure.

3.7 Toxicity Assessment

A chemical's ability to cause an adverse human health effect depends on the toxicity of the chemical, the chemical's route of exposure to an individual (ingestion, inhalation, or direct contact), the duration of exposure, and the dose received (the amount that a human ingests or inhales). Similar principles apply to ecological receptors, although exposure duration is much shorter than for human receptors because humans generally live longer then ecological receptors. For a risk assessment, the toxicity of a constituent is defined by a human health or ecological benchmark for each route of exposure. A benchmark is a quantitative value used to predict a chemical's possible toxicity and ability to induce an adverse effect at certain levels of exposure. Because different chemicals cause different health effects at different doses, benchmarks are chemical-specific.

Appropriate human health and ecological benchmarks for the constituents of potential concern in CCW wastes were collected as part of the screening assessment. The same benchmarks were used in the full-scale risk assessment, with a few updates. The data sources and collection methodology for these benchmarks are described briefly in Sections 3.7.1 (human health benchmarks) and 3.7.2 (ecological benchmarks), and in more detail in Appendix G (human health benchmarks) and Appendix H (ecological benchmarks). The discussion here is limited to the 12 constituents assessed in the full-scale risk assessment and for humans, covers

only oral benchmarks (because all inhalation pathway risks fell below the screening criteria in the screening assessment). Appendices G and H cover all constituents and routes.

3.7.1 Human Health Benchmarks

Human health benchmarks for chronic oral exposures were needed for the full-scale analysis. These health benchmarks were derived from toxicity data based on animal studies or human epidemiological studies. Each benchmark represents a dose-response estimate that relates the likelihood and severity of adverse health effects to exposure and dose. This section presents the noncancer and cancer benchmarks used to evaluate human health effects that may result from exposure to the constituents modeled.

Chronic human health benchmarks were used to evaluate potential noncancer and cancer risks. These include reference doses (RfDs) to evaluate noncancer risk from oral exposures and oral cancer slope factors (CSFs) to evaluate cancer risk from oral exposures. The benchmarks are chemical-specific and do not vary between age groups.

- The **RfD** is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious noncancer effects during a lifetime. The RfD provides a reference point to gauge the potential effects (U.S. EPA, 2002c). At exposures increasingly greater than the RfD, the potential for adverse health effects increases. Lifetime exposure above the RfD does not imply that an adverse health effect would necessarily occur.

- The **CSF** is an upper-bound estimate (approximating a 95 percent confidence limit) of the increased human cancer risk from a lifetime exposure to an agent. This estimate is usually expressed in units of proportion (of a population) affected per milligram of agent per kilogram body weight per day (mg/kg-d). Unlike RfDs, CSFs do not represent "safe" exposure levels; rather, they relate levels of exposure with a probability of effect or risk.

Human health benchmarks are available from several sources. Health benchmarks developed by EPA were used whenever they were available. Sources of human health benchmarks were used in the following order of preference:

- Integrated Risk Information System (IRIS) (U.S. EPA, 2002c)
- Superfund Technical Support Center Provisional Benchmarks
- Health Effects Assessment Summary Tables (HEAST) (U.S. EPA, 1997f)
- Various other EPA health benchmark sources
- ATSDR minimal risk levels (MRLs) (ATSDR, 2002).

These sources are described in more detail in Appendix G.

The chronic human health benchmarks used in the full-scale analysis are summarized in Table 3-9. For most constituents, human health benchmarks were available from IRIS. Benchmarks for a few constituents were obtained from ATSDR and Superfund Provisional

Benchmarks U.S. EPA (2001c,d). For chemicals for which purely health-based benchmarks were not available (lead), a drinking water action level was used (U.S. EPA, 2002d).

Cadmium has two RfDs, one for exposures via water and one for exposures via food. The RfD for water was used for drinking water ingestion and the RfD for food was used for fish consumption.

Table 3-9. Human Health Benchmarks Used in the Full-Scale Analysis

Constituent	Type of Benchmark	Value	Units	Source[a]
Cancer Benchmark				
Arsenic	CSF	1.5E+00	$(mg/kg-d)^{-1}$	IRIS
Noncancer Benchmarks				
Aluminum	RfD	2.0E+00	mg/kg-d	ATSDR
Antimony	RfD	4.0E-04	mg/kg-d	IRIS
Barium	RfD	2.0E-01	mg/kg-d	IRIS
Boron	RfD	2.0E-01	mg/kg-d	IRIS
Cadmium	RfD (water)[b]	5.0E-04	mg/kg-d	IRIS
	RfD (food)[c]	1.0E-03	mg/kg-d	IRIS
Cobalt	RfD	2.0E-02	mg/kg-d	Superfund
Lead	MCL	0.015	mg/L	DWAL
Molybdenum	RfD	5.0E-03	mg/kg-d	IRIS
Nitrate/Nitrite	MCL[d]	10	mg/L	DWAL
Selenium	RfD	5.0E-03	mg/kg-d	IRIS
Thallium	RfD	8.0E-05	mg/kg-d	IRIS

3.7.2 Ecological Benchmarks

The ecological risk assessment addresses two routes of exposure for ecological receptors, direct contact with contaminated media and ingestion of contaminated food items. For each constituent for which ecological effect data were available, HQs were calculated using chemical-specific media concentrations assumed to be protective of ecological receptors of concern. To calculate ecological HQs, these media concentrations (also known as chemical stressor concentration limits [CSCLs]) were divided by the estimated media concentrations. The CSCLs are media-specific environmental quality criteria intended to represent a protective threshold value for adverse effects to various ecological receptors in aquatic ecosystems (surface water and sediment). The CSCLs were developed to be protective of the assessment endpoints chosen for this assessment. An HQ greater than 1 indicates that the predicted concentration exceeds the CSCL, and therefore, the potential for adverse ecological effects exists. In this regard, the use of

CSCLs to calculate an ecological HQ is analogous to the use of the reference concentration (RfC) for human health where the air concentration is compared to the health-based concentration (the RfC), and an HQ greater than 1 is considered to indicate the potential for adverse health effects.

Table 3-10 shows the receptor types assessed for each exposure route (direct contact and ingestion) in each environmental medium addressed by the CCW risk assessment.

Table 3-10. Ecological Receptors Assessed by Exposure Route and Medium (Surface Water or Sediment)

Receptor Type	Surface Water (water column)	Surface Water Sediment
Direct Contact Exposure		
Aquatic Community	✔	
Sediment Community		✔
Amphibians	✔	
Aquatic Plants and Algae	✔	
Terrestrial Plants		
Ingestion Exposure		
Mammals	✔	
Birds	✔	

Ecological receptors that live in close contact with contaminated media are considered to be potentially at risk. These receptors are exposed through direct contact with contaminants in surface water and sediment. The benchmarks for receptor communities (aquatic or sediment communities) are not truly *community-level* concentration limits in that they do not consider predator-prey interactions. Rather, they are based on the theory that protection of 95 percent of the species in the community will provide a sufficient level of protection for the community (see, for example, Stephan et al., 1985, for additional detail). Appendix H summarizes the benchmark derivation methods for each receptor assessed for the direct contact route of exposure.

The ingestion route of exposure addresses the exposure of terrestrial mammals and birds through ingestion of aquatic plants and prey. Thus, the benchmarks for ingestion exposure represent media concentrations that, based on certain assumptions about receptor diet and foraging behavior, are expected to be protective of populations of mammals and birds feeding and foraging in contaminated areas.

For birds and mammals, the derivation of ingestion benchmarks required the selection of appropriate ecotoxicological data based on a hierarchy of sources. The assessment endpoint chosen for birds and mammals was population viability and therefore, the ingestion benchmarks were based on study data for physiological effects that are relevant to populations. These data included measures of reproductive fitness, developmental success, survival, and other toxicological effects that could have a significant impact on the population rather than just the health of an individual animal. Choosing these measures of effect provided the basis to evaluate

the potential for adverse effects at the population level by inference; this analysis does not evaluate the effects on population dynamics in the sense that a reduction in the population is predicted over time in response to exposure to constituents released from CCW. Population-level modeling was well beyond the scope of this risk assessment.

Once an appropriate ingestion exposure study was identified, a benchmark was calculated. Appendix H describes the basic technical approach used to convert avian or mammalian benchmarks (in daily doses) to the CSCLs (in units of concentration) used to assess ecological risks for contaminated surface water and sediment. The methods reflect exposure through the ingestion of contaminated plants, prey, and various media, and include parameters on accumulation (e.g., BCFs), uptake (e.g., consumption rates), and dietary preferences.

Where multiple ecological benchmarks were available for a pathway of interest, the benchmark that produced the lowest (most sensitive) CSCL for each chemical in each medium was used. For example, several types of receptors (the aquatic community, amphibians, aquatic plants, mammals, birds) can be exposed to contaminants in surface water. The surface water criterion for a given constituent represents the lowest CSCL for these receptors, and thus gives the highest (most protective) HQ. The CSCLs used to assess ecological endpoints in the full-scale analysis and the associated receptor are summarized in Table 3-11. Additional details on the CCW ecological benchmarks and CSCLs and their development can be found in Appendix H.

Table 3-11. Ecological Risk Criteria Used in the Full-Scale Analysis

Constituent	Medium[a]	Exposure Route	CSCL	Units	Receptor
Aluminum	Surface Water	Direct contact	0.09	mg/L	Aquatic biota
Arsenic total	Sediment	Ingestion	0.51	mg/kg	Spotted sandpiper
Arsenic III	Surface Water	Direct contact	0.15	mg/L	Aquatic biota
Arsenic IV	Surface Water	Direct contact	8.10E-03	mg/L	Aquatic biota
Barium	Sediment	Ingestion	190	mg/kg	Spotted sandpiper
	Surface Water	Direct contact	4.00E-03	mg/L	Aquatic biota
Boron	Surface Water	Direct contact	1.60E-03	mg/L	Aquatic biota
Cadmium	Sediment	Direct contact	0.68	mg/kg	Sediment biota
	Surface Water	Direct contact	2.50E-03	mg/L	Aquatic biota
Cobalt	Surface Water	Direct contact	0.02	mg/L	Aquatic biota
Lead	Sediment	Ingestion	0.22	mg/kg	Spotted sandpiper
	Surface Water[b]	Ingestion	3.00E-04	mg/L	River otter
Selenium total	Surface Water	Direct contact	5.00E-03	mg/L	Aquatic biota
Selenium IV	Surface Water	Direct contact	0.03	mg/L	Aquatic biota
Selenium VI	Surface Water	Direct contact	9.5E-03	mg/L	Aquatic biota

Source: U.S. EPA (1998)

[a] If a medium (surface water or sediment) is not listed, there were insufficient data to develop a benchmark for it.

[b] Includes ingestion of fish.

Ecological benchmarks for both the screening and full-scale CCW risk assessment were taken directly from the 1998 fossil fuel combustion risk assessment, *Non-Groundwater*

Pathways, Human Health and Ecological Risk Analysis for Fossil Fuel Combustion Phase 2 (FFC2) (U.S. EPA, 1998a). The receptors and endpoints selected for the 1998 analysis were evaluated and considered appropriate for the goals of this risk assessment. The benchmarks were derived for each chemical and receptor to the extent that supporting data were available.

3.8 Risk Estimation

The final step of the risk assessment process is to estimate the risk posed to human and ecological receptors (e.g., residents, fishers; aquatic organisms). In this step, estimates of toxicity (the human health and ecological benchmarks) and exposure doses or exposure concentrations are integrated into quantitative expressions of risk. For the CCW constituents modeled in the full-scale assessment, the CCW human risk assessment uses estimates of dose and toxicity to calculate individual excess lifetime carcinogenic risk estimates and noncancer HQs (Section 3.8.1). The risk calculations for ecological receptors differ from those for humans because the ecological benchmarks are developed as media concentrations (i.e., they are calculated considering ecological exposure). Thus the CCW risk assessment uses estimates of exposure (media) concentrations and toxicity (media-specific concentration limits) to calculate an ecological HQ (Section 3.8.2).

3.8.1 Human Health Risk Estimation

The full-scale analysis focused on two human health exposure pathways: groundwater-to-drinking-water and groundwater-to-surface-water via fish consumption by recreational fishers. The cancer and noncancer health impacts of ingesting groundwater and fish contaminated by CCW leachate were estimated using the risk endpoints shown in Table 3-12. These endpoints were generated for each iteration of the Monte Carlo analysis. Only the cancer endpoint was used for arsenic, because it is the more sensitive endpoint compared to noncancer effects. For the other 11 constituents, only noncancer HQs were calculated, using the appropriate noncancer endpoint.

Table 3-12. Risk Endpoints Used for Human Health

Risk Category	Risk Endpoints	Definition
Cancer Effects (arsenic only)	Lifetime excess cancer risk by pathway and chemical	Lifetime excess cancer risk resulting from single pathway exposure
Noncancer Effects	Ingestion HQ by pathway and chemical	Ingestion HQ resulting from single pathway exposure
	Ingestion HQ based on drinking water action level for lead and copper	Lead and copper ingestion HQ resulting from drinking water pathway
	Average daily dose for fish consumption for lead	Lead exposure resulting from fish ingestion pathway

Cancer risks for arsenic were characterized using lifetime excess cancer risk estimates, which represent the excess probability of developing cancer over a lifetime as a result of exposure to the chemical of interest. Lifetime excess cancer risk estimates use the LADD (see Section 3.6.3) as the exposure metric. Lifetime excess cancer risk estimates are the product of

the LADD for a specific receptor and the corresponding cancer slope factor, as shown in Equation 3-4.

$$Lifetime\ excess\ cancer\ risk_i = LADD_i \times CSF \quad (3\text{-}4)$$

where

LADD = lifetime average daily dose for ingestion pathway i (mg/kg BW/d)
i = pathway index
CSF = cancer slope factor $(mg/kg\ BW/d)^{-1}$.

Noncancer risk is characterized through the use of HQs, which are generated by dividing an ADD (see Section 3.6.3) for ingestion pathways by the corresponding RfD.[7] An HQ establishes whether a particular individual has experienced exposure above a threshold for a specific health effect. Therefore, unlike cancer risk estimates, HQs are not probability statements. Rather, the RfD represents an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. It can be derived from a no observed adverse effect level (NOAEL), from a low observed adverse effect level (LOAEL), or from a benchmark dose, with uncertainty factors generally applied to reflect limitations of the data used. Equation 3-5 shows the calculation for the ingestion HQ. This calculation was completed for each pathway considered (i.e., drinking water ingestion and fish consumption).

$$HQ_i = \frac{ADD_i}{RfD} \quad (3\text{-}5)$$

where

ADD_i = average daily dose for ingestion pathway i (mg/kg-d)
i = pathway index
RfD = reference dose (mg/kg-d).

The risk results address risk from exposure via the groundwater-to-drinking-water and groundwater-to-surface-water pathway separately. This is appropriate because the resident consuming contaminated groundwater may not be the recreational fisher who is consuming contaminated fish. Also, the arrival time of the contaminant plume to the stream and the human receptor may not be the same for a particular iteration.[8] However, a resident may consume fish caught from a nearby stream or lake and contaminated drinking water if the travel times are similar, so that possibility should be considered as an uncertainty in this analysis.

For each receptor type, lifetime excess cancer risk estimates for arsenic were calculated separately for the drinking water and fish consumption pathways.

[7] HQs calculated for lead in drinking water were based on the drinking water action level (0.015 mg/L); lead exposures from fish ingestion are reported as an ADD.

[8] Stream distance and well distance were sampled independently in the Monte Carlo analysis.

3.8.2 Ecological Risk Estimation

The full-scale analysis addressed two routes of exposure for ecological receptors: direct contact with contaminated media and ingestion of contaminated food items. HQs were calculated using chemical-specific media concentrations assumed to be protective of ecological receptors of concern through either exposure route (CSCLs). As described in Section 3.7.2, these ecological benchmarks were developed for representative organisms and communities in each environmental medium of concern.

For a particular Monte Carlo iteration, HQs were calculated for sediment and surface water as the ratio between the media concentration and the ecological benchmark. Because the CSCLs were derived for an HQ of 1 (for relevant ecological endpoints), the ratio of a constituent concentration in a media to the media-specific CSCL represents the HQ for that constituent and pathway. For surface water, the HQ was calculated as follows:

$$HQ_{surface\ water} = C_{sw} / CSCL_{sw} \quad (3\text{-}6)$$

where

C_{sw} = total concentration in surface water column (mg/L)
$CSCL_{sw}$ = ecological benchmark for surface water (mg/L).

Similarly, for sediment, the HQ was calculated as

$$HQ_{sediment} = C_{sediment} / CSCL_{sediment} \quad (3\text{-}7)$$

where

$C_{sediment}$ = total concentration in sediment (mg/kg)
$CSCL_{sediment}$ = ecological benchmark for sediment (mg/kg).

Because the sediment and surface water benchmarks were based on separate receptor communities, it is not appropriate to add HQs across pathways.

4.0 Risk Characterization

This section summarizes the results of the full-scale Monte Carlo analysis and characterizes those results in terms of significant uncertainties and the scenarios and factors that influence risks to human health and the environment. Results are presented by receptor, pathway, and WMU type.

An overview of the assessment on which these results are based (e.g., waste management scenarios, analysis framework) is provided in Section 2. Section 3 provides more details on analysis methodologies, parameter values, and assumptions. In this section, Section 4.1 presents results from the human health risk assessment and includes an analysis of how liner conditions influence results. Section 4.2 presents the results from the ecological risk assessment. Tables summarizing the human and ecological results are presented in each section. Section 4.3 describes the sensitivity analysis conducted for the CCW risk assessment, and Section 4.4 discusses how variability and uncertainty have been addressed, including a semi-quantitative review of the potential impact of some of the more significant uncertainties on results.

Probabilistic results are based on a Monte Carlo simulation in which many model input parameter values were varied over 10,000 iterations of the model per waste management scenario to yield a statistical distribution of exposures and risks. Per the *Guidance for Risk Characterization* developed by the EPA Science Policy Council in 1995 (http://www.epa.gov/OSA/spc/pdfs/rcguide.pdf), EPA defined the high end of the risk distribution at the 90th percentile risk or hazard estimate generated during the Monte Carlo simulation. Thus, the 90th percentile risk results are shown in this section as the high end estimate of the risk distribution generated during the Monte Carlo simulation of constituent release, fate and transport, and exposure associated with CCW disposal in landfills and surface impoundments. In addition, the 50th percentile results are presented as the central tendency estimate of that risk distribution.

For exposure scenarios describing the waste management unit type (e.g., lined landfill; unlined surface impoundment), location (e.g., meteorological region), receptor (e.g., child), and health endpoint (e.g., cancer), the 90th percentile risk represents the high-end estimate that is compared to the appropriate risk criteria (for cancer or noncancer) to help determine whether CCW disposal practices are protective of public health. The risk criteria used are defined in terms of estimated lifetime cancer risk and noncancer hazard attributable to CCW disposal. The risk criteria adopted for this assessment are

- For chemical constituents that cause cancer (carcinogens), the criterion is an estimated excess lifetime cancer risk for exposed individuals of 1 case in 100,000 (i.e., $1x10^{-5}$)
- For constituents that cause adverse, noncancer health effects (noncarcinogens), the criterion is a HQ of greater than 1, with the HQ being the ratio of the average daily

exposure level to a protective exposure level corresponding to the maximum level at which no appreciable effects are likely to occur.

In general, the full-scale analysis showed lower risks than the screening analysis, but still showed risks above risk criteria for certain CCW constituents, WMU types, pathways, and receptors at the 90th percentile. At the 50th percentile, risks are still above the risk criteria for both WMU types, but for fewer constituents and pathways. The results presented herein are subject to further interpretation, as EPA queries the CCW risk inputs and outputs to investigate how the results may be affected by (1) waste types and environmental and waste management conditions, (2) assumptions made about these conditions in designing the probabilistic analysis, and (3) the availability of facility data.

4.1 Human Health Risks

This section presents the 90th and 50th percentile risk results for the two human exposure pathways evaluated in the full-scale analysis: (1) groundwater-to-drinking-water and (2) groundwater-to-surface-water (fish consumption). Results are presented for the two WMU types addressed in the analysis: landfills and surface impoundments, and show the distribution of risks across all waste types by liner type (from the EPRI survey data). The human health risk criteria for the analysis were a 10^{-5} excess cancer risk for arsenic and an HQ greater than 1 for the other constituents, each of which exhibits noncarcinogenic effects.

4.1.1 Groundwater-to-Drinking-Water Pathway

Tables 4-1 and 4-2 present the 90th and 50th percentile risk results, respectively, for the groundwater-to-drinking water pathway for landfills and surface impoundments. Results are shown across all units combined (i.e., across all liner types), as well as for each of the three unit types modeled in the analysis (unlined, clay-lined, and composite-lined). Except for arsenic, the results presented are for a child resident, because those risks for noncarcinogens were consistently higher than the risks for the adult resident. For arsenic, a carcinogen, adult risks are presented because the longer exposure duration and higher intake rates cause risks to be slightly higher for adults than for children. Results for arsenic and selenium are based on the arsenic III and selenium VI species, which are more mobile in soil and groundwater (causing higher receptor well concentrations). Results for other arsenic and selenium species for comparison can be found in the model uncertainty discussion in Section 4.4.2.

Figures 4-1 and 4-2 show the 90th and 50th percentile risk results. For each constituent, the graphs plot the 90th percentile (Figure 4-1) or 50th percentile (Figure 4-2) HQ or cancer risk level against the risk criteria (10^{-5} cancer risk or an HQ greater than 1) by the liner types reported in the EPRI survey. As in the table, the constituents are shown in order from highest risk in the full-scale analysis to lowest; the risk criteria are shown by the solid vertical line. Composite liners are not plotted in these figures when risks are below the x-axis minimum.

Note that not all 12 chemicals modeled in the full-scale assessment are presented for each pathway/WMU scenario. Only the chemicals for which the risks in the screening assessment exceeded the screening criteria for the scenario and for which constituent data were adequate to model and assess risks were modeled in the full-scale assessment, and only those modeled

chemical/pathway/WMU scenarios are shown in the tables and figures. For example, antimony and thallium risks are not presented for surface impoundments because of a high proportion of nondetects in the surface impoundment data for these CCW constituents. Similarly, adequate cobalt data were available only for surface impoundments. Screening-level human health risks for barium were below the screening criteria; therefore, barium is shown only in the ecological risk tables and figures. The screening analysis results in Section 2.1 and Table 2-3 show which CCW constituents were modeled for each pathway/WMU scenario.

Table 4-1. Summary of 90th Percentile Full-Scale CCW Human Risk Results: Groundwater-to-Drinking-Water Pathway

Chemical[b]	90th Percentile HQ or Cancer Risk Value[a]			
	All Units Combined[c]	Unlined Units	Clay–Lined Units	Composite–Lined Units
Landfills				
Arsenic (cancer)	3E-04	5E-04	2E-04	0
Thallium	2	3	1	0
Antimony	0.7	1	0.6	0
Molybdenum	0.9	1	0.7	0
Lead (MCL)[d]	0.4	0.9	0.2	0
Cadmium	0.2	0.3	0.2	0
Boron	0.3	0.5	0.3	0
Selenium	0.2	0.4	0.2	0
Nitrate/Nitrite (MCL)[d]	0.1	0.2	0.07	3E-06
Surface Impoundments				
Arsenic (cancer)	6E-03	9E-03	3E-03	4E-07
Molybdenum	4	5	3	7E-03
Cobalt	4	5	0.9	0
Cadmium	4	5	1	2E-09
Lead (MCL)[d]	3	5	0.9	1E-20
Boron	3	3	2	4E-03
Selenium	1	1	0.8	1E-03
Nitrate/Nitrite (MCL)[d]	0.9	1	1	6E-04

[a] Values are HQs for all chemicals except arsenic; arsenic values are cancer risk. Zero results indicate that contaminant infiltration rates were too small for the contaminant plume to reach the receptor during the 10,000 year period of the analysis.

[b] Note that not every chemical that was selected for full-scale modeling was modeled in every pathway/WMU scenario: only chemicals with adequate data and that were identified in the screening analysis as needing further assessment (see Section 2.1) were modeled for each scenario.

[c] Results across all unit types combined (unlined, clay-lined, and composite-lined).

[d] Values are ratios of exposure concentration to MCL.

Table 4-2. Summary of 50th Percentile Full-Scale CCW Human Risk Results: Groundwater-to-Drinking-Water Pathway

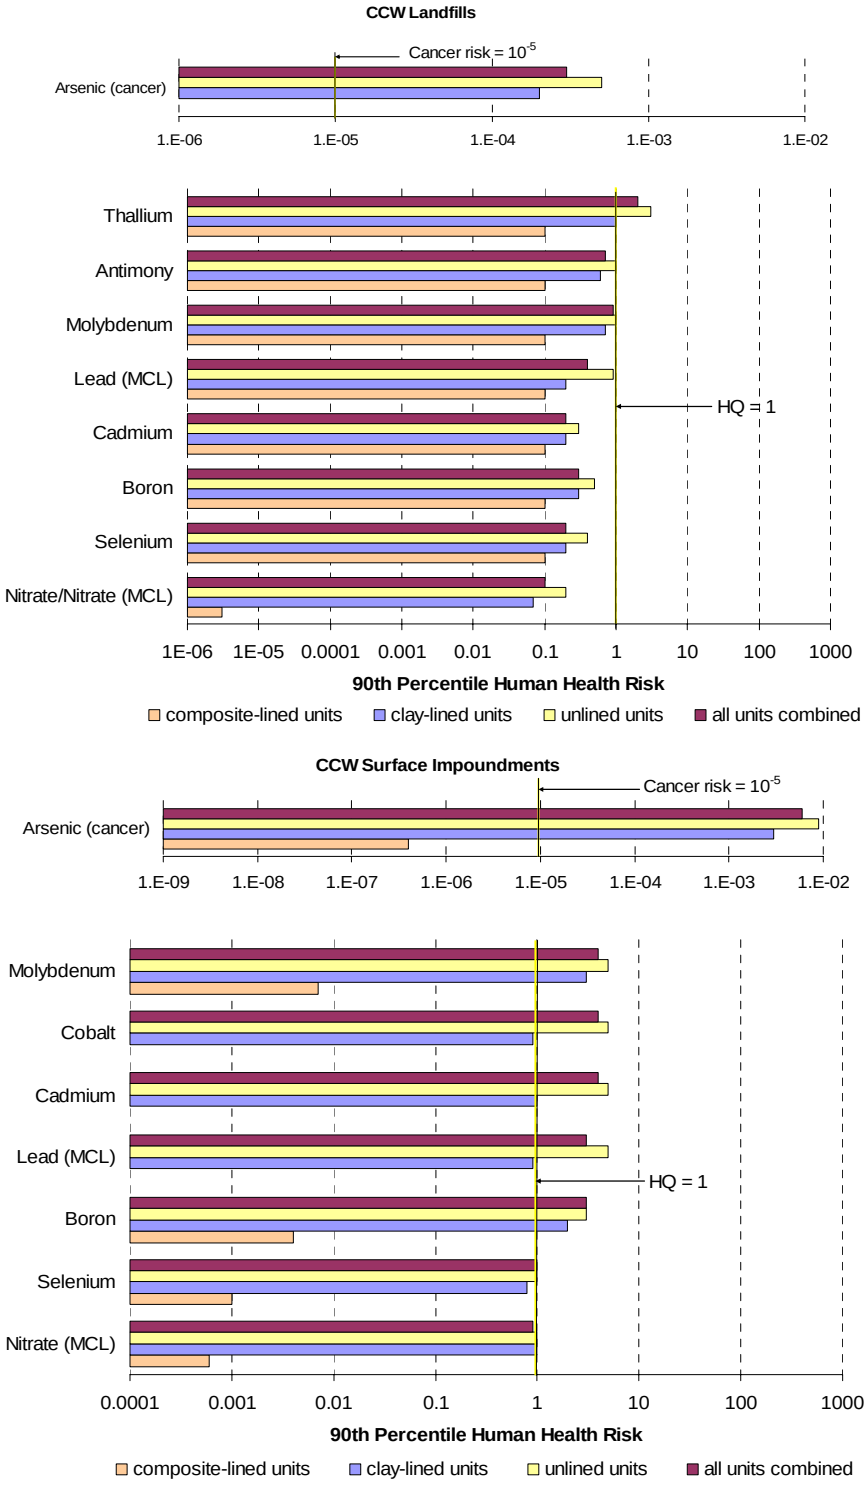
Selenium	0.08	0.1	0.05	5E-12
Nitrate/Nitrite (MCL)[d]	0.03	0.04	0.02	7E-08

[a] Values are HQs for all chemicals except arsenic; arsenic values are cancer risk. Zero results indicate that contaminant infiltration rates were too small for the contaminant plume to reach the receptor during the 10,000 year period of the analysis.

[b] Note that not every chemical that was selected for full-scale modeling was modeled in every pathway/WMU scenario: only chemicals with adequate data and that were identified in the screening analysis as needing further assessment (see Section 2.1) were modeled for each scenario.

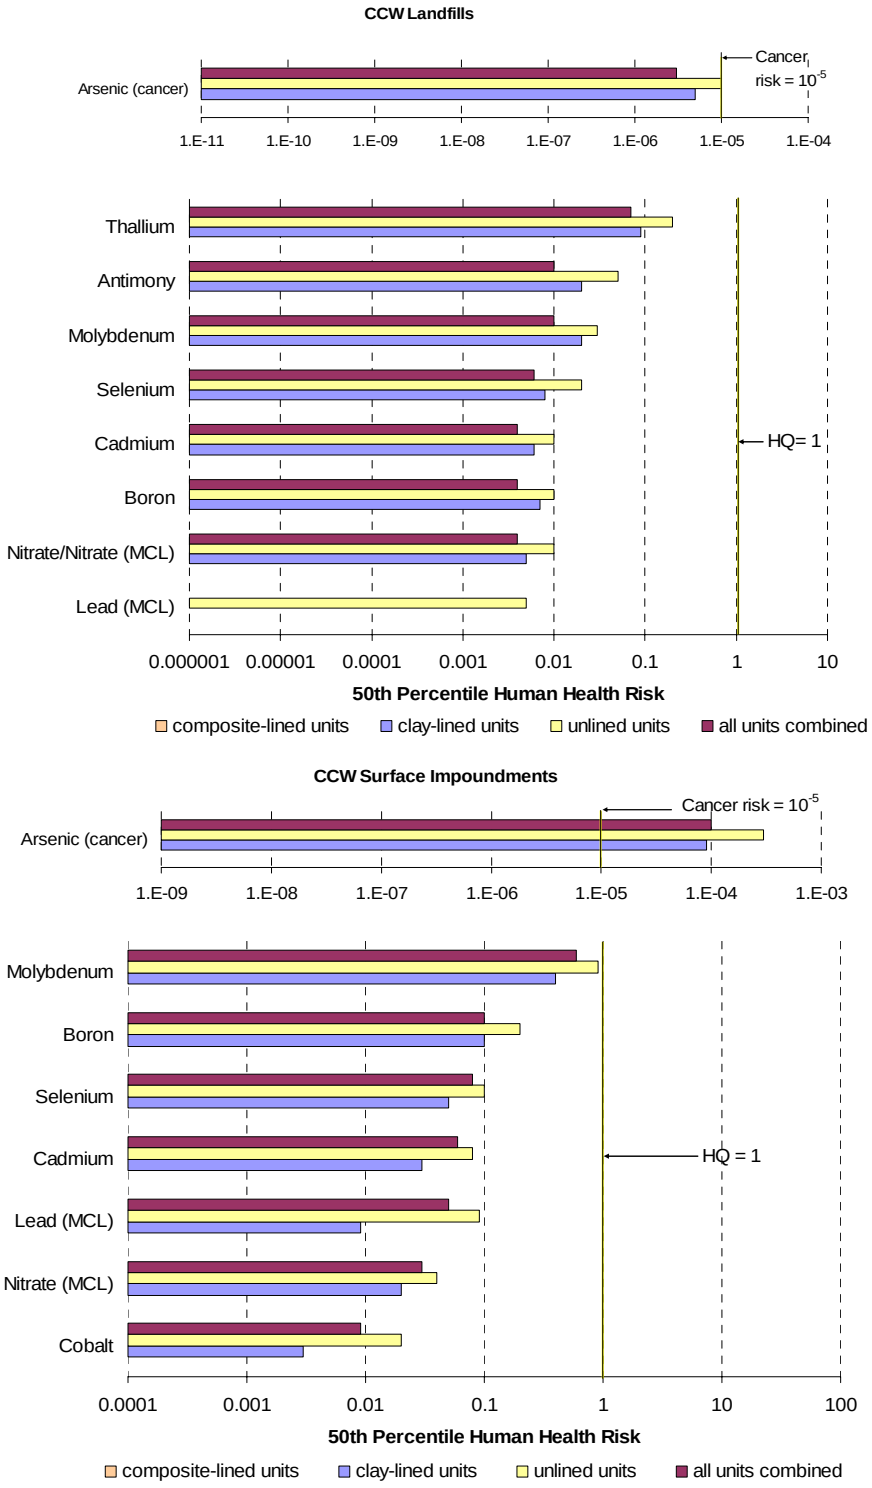
[c] Results across all unit types combined (unlined, clay-lined, and composite-lined).

[d] Values are ratios of exposure concentration to MCL.



A cancer risk of 10^{-5} or an HQ greater than 1 are the risk criteria for this analysis.
Results for "all units combined" are results across all liner types (unlined, clay-lined, composite-lined).
Note: When the composite liner bar does not appear on the chart, the 90th percentile risk index is below the minimum shown on the x-axis.

Figure 4-1. Full-scale 90th percentile risk results for the groundwater-to-drinking-water pathway.



A cancer risk of 10^{-5} or an HQ greater than 1 are the risk criteria for this analysis.
Results for "all units combined" are results across all liner types (unlined, clay-lined, composite-lined).
Note: When the composite liner bar does not appear on the chart, the 50th percentile risk index is below the minimum shown on the x-axis.

Figure 4-2. Full-scale 50th percentile risk results for the groundwater-to-drinking-water pathway.

As can be seen in Figure 4-1, the full-scale analysis produced lower risks for landfills than surface impoundments. For landfills, at the 90th percentile, arsenic shows risks above a cancer risk of $1x10^{-5}$ for both unlined units ($5x10^{-4}$) and clay-lined units ($2x10^{-4}$) and thallium shows a noncancer risk (3) above an HQ of 1 only for unlined units. Figure 4-2 shows that at the 50th percentile, all risks were at or below the risk criteria. Composite-lined units show zero or negligible risks (well below the risk criteria) for all constituents and percentiles examined.

For surface impoundments, the full-scale analysis produced arsenic risk estimates at the 90th percentile above a cancer risk of $1x10^{-5}$ for both unlined units ($9x10^{-3}$) and clay-lined units ($3x10^{-3}$) and a noncancer HQ above the criteria for boron (3), lead (5), cadmium (5), cobalt (5), and molybdenum (5) for unlined units, and for boron (2) and molybdenum (3) for clay-lined units. At the 50th percentile, only arsenic has risks above the 10^{-5} risk criterion for unlined ($3x10^{-4}$) and clay-lined ($9x10^{-5}$) surface impoundments. And as with landfills, the risks from composite-lined surface impoundments are well below the risk criteria.

The higher risks for surface impoundments as compared to landfills reflect higher constituent concentrations in the surface impoundment wastes, a higher proportion of unlined units (see Section 4.1.4), and a higher hydraulic head in an impoundment that drives leachate into the underlying soil with greater force than infiltration in landfills. This higher head results in a greater flux of contaminants to groundwater during the active life of the surface impoundment, especially in unlined units. In combination with the higher CCW constituent concentrations in surface impoundment porewater and a greater proportion of unlined units, these factors lead to more and higher risk exceedances for surface impoundments than for landfills.

The analysis demonstrates that the presence of liners, especially composite liners, reduce leaching and risks from CCW landfills and surface impoundments. Note that 90th percentile risks from composite liners are zero for most constituents for landfills, which means that in 90 percent of the cases, the contaminant did not reach the receptor well in the 10,000 year limit for this analysis. These zero values reflect the liner leakage rates in the empirical data set used to develop composite landfill liner infiltration rates used in this risk assessment (from U.S. EPA, 2002b; see Section 3.2.2), which are mostly zero values or very low in terms of infiltration rate. Although these infiltration rates are based on the best data available to EPA, these data are not specific to CCW facilities and therefore represent an uncertainty in this analysis (see Sections 3.2.2 and 4.4.3.2).

Composite liners also significantly reduced risks for surface impoundments for several constituents at the 90th percentile by 4 to 10 orders of magnitude and generated risk results well below the risk criteria for this analysis. Infiltration rates for composite-lined surface impoundments are largely controlled by leak density (see Section 3.3), which is an empirical distribution from the same source as the landfill infiltration rates (U.S. EPA, 2002b), and are subject to similar uncertainties.

Arrival times for the peak arsenic concentration used to calculate risks are plotted as cumulative distributions for surface impoundments and landfills in Figure 4-3. As can be seen in the figure, the peak arrival time for surface impoundments is usually less than 100 years (i.e., peak concentration occurs shortly after closure); the 50th percentile is 78 years, and the 75th

percentile is 105 years.[2] Arrival times for landfills are much longer, ranging from hundreds to thousands of years; the 50th percentile is 618 years and the 75th percentile is 3,343 years. The shorter arrival times for surface impoundments are primarily due to the hydraulic head of the waste liquids in the unit and the lower prevalence of liners in surface impoundments; by contrast, landfill leaching is driven by infiltration of precipitation through the cap and liner of the unit.

The arrival time of the peak concentration corresponds to the arrival of the maximum risk; however, for runs where the risk exceeds the risk criteria, the concentration that results in risk at the risk criteria will arrive somewhat before the peak concentration. Overall, however, the time to reach the risk criteria should be similar to the peak arrival times shown in Figure 4-3.

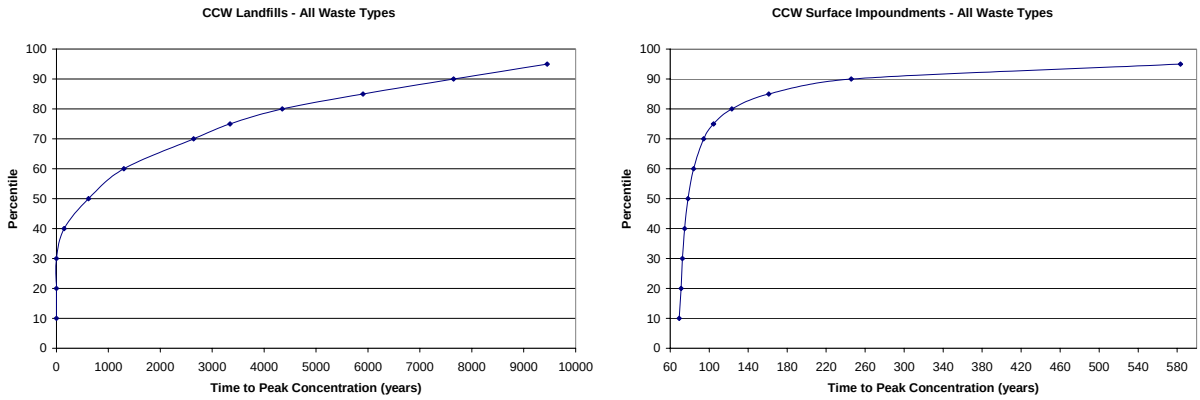


Figure 4-3. Comparison of peak arrival times for arsenic for CCW landfills and surface impoundments.

4.1.2 Groundwater-to-Surface-Water (Fish Consumption) Pathway

Tables 4-3 and 4-4 present the 90th and 50th percentile risk results, respectively, for the fish consumption pathway, where fish are contaminated by groundwater seeping into a waterbody downgradient from the WMU. The results presented are for a fisher's child because those risks were consistently higher than the risks for the adult fisher. Results for arsenic are based on arsenic III, which is more mobile in soil and groundwater (and so had higher receptor concentrations). The selenium results are based on selenium VI, which also represents the highest receptor concentrations. The uncertainty resulting from the model's inability to speciate metals during transport is discussed in Section 4.4.2.

For surface impoundments, 90th percentile selenium and arsenic risks for unlined units are slightly above a cancer risk of $1x10^{-5}$ ($2x10^{-5}$, arsenic) and slightly above a noncancer HQ of 1 (2 for selenium). Risks are below the risk criteria for clay-lined and composite-lined surface impoundments. Again, risks are higher for surface impoundments than for landfills (where risks are below risk criteria for all constituents) because of the higher waste concentrations, higher hydraulic head in these units, and a lower prevalence of liners, as discussed previously for the drinking water pathway. Fish consumption pathway 50th percentile results are well below the risk criteria for all constituents, waste management scenarios, and liner types.

[2] In other words, 50 percent of the arrival times are less than 78 years and 75 percent are less than 105 years.

As with the groundwater-to-drinking-water pathway analysis, the absence of risk from composite-lined units suggests that the composite liners modeled in this analysis are effective at preventing contaminants from reaching the surface waterbodies of interest.

Table 4-3. Summary of 90th Percentile Full-Scale CCW Human Risk Results: Groundwater-to-Surface-Water (Fish Consumption) Pathway

Chemical[b]	90th Percentile HQ or Cancer Risk Value[a]			
	All Units Combined [c]	Unlined Units	Clay-Lined Units	Composite–Lined Units
Landfills				
Arsenic (cancer)	6E-07	1E-06	3E-07	0
Selenium	0.3	0.7	0.1	0

[a] Values are HQs for all chemicals except arsenic; arsenic values are cancer risk. Zero results indicate that contaminant infiltration rates were too small for the contaminant plume to reach the receptor during the 10,000 year period of the analysis.

[b] Note that not every chemical that was selected for full-scale modeling was modeled in every pathway/WMU scenario: only chemicals with adequate data and that were identified in the screening analysis as needing further assessment (see Section 2.1) were modeled for each scenario.

[c] Results across all unit types combined (unlined, clay-lined, and composite-lined).

4.1.3 Results by Waste Type/WMU Scenario

As described in Section 3.1, the CCW risk assessment was organized by waste type so that different waste chemistries could be accounted for in the fate and transport modeling. The results discussed so far in this report address conventional CCW (fly ash, bottom ash, boiler slag, FGD sludge) and conventional CCW codisposed with coal refuse.[3] Section 4.1.3.1 presents these results by waste type. FBC wastes were also modeled in this assessment, but because of the small number of FBC waste disposal sites (7) in the EPRI/EPA database, the results are treated separately in Section 4.1.3.2.

4.1.3.1 Conventional CCW and CCW Codisposed with Coal Refuse

Tables 4-5 and 4-6 show 90th- and 50th-percentile risk results, respectively, by waste type and unit type for CCW landfills for the groundwater-to-drinking-water pathway. There was little difference in results between waste types for landfills, which showed very similar risks for conventional CCW and codisposed CCW and coal refuse. Risks are a factor of 2 or 3 greater for unlined landfills than for clay-lined landfills. For conventional CCW in landfills, arsenic cancer risks are $4x10^{-4}$ for unlined units, $2x10^{-4}$ for clay-lined units, and 0 for composite-lined units at

[3] Coal refuse is the waste coal produced from coal handling, crushing, and sizing operations, and tends to have a high sulfur content and low pH. In the CCW constituent database, codisposed coal refuse includes "combined ash and coal gob," "combined ash and coal refuse," and "combined bottom ash and pyrites."

the 90th percentile. Noncancer risks at the 90th percentile exceeded 1 for only thallium in unlined units (3) and clay-lined units (2) and antimony in unlined units (2). For codisposed CCW and coal refuse in landfills, arsenic cancer risks are $5x10^{-4}$ for unlined units, $2x10^{-4}$ for clay-lined units, and 0 for composite-lined units at the 90th percentile. Noncancer hazard quotients at the 90th percentile exceeded 1 for only thallium in unlined units (2) and molybdenum in unlined units (2). 50th percentile risks for the groundwater-to-drinking-water pathway were below the risk criteria for all waste types in all types of landfills. Landfills with composite liners show zero risks as modeled in this assessment (see Section 4.1.4 for a further discussion of risks by liner type).

The difference in risks between waste types is greater for surface impoundments. Tables 4-7 and 4-8 show 90th and 50th percentile risk results, respectively, by waste type and liner type for CCW surface impoundments (for the drinking water pathway). For conventional CCW in surface impoundments, arsenic cancer risks are $2x10^{-3}$ for unlined units, $9x10^{-4}$ for clay-lined units, and below the risk criteria for composite-lined units at the 90th percentile. Noncancer hazard quotients at the 90th percentile exceeded 1 for nitrate/nitrite (20), molybdenum (8), boron (7), selenium (2), and lead (3) in unlined units, and nitrate/nitrite (10), molybdenum (5) and boron (4) in clay-lined units. None of the risk criteria were exceeded at the 90th percentile in composite-lined units. For codisposed CCW and coal refuse in surface impoundments, arsenic cancer risks are $2x10^{-2}$ for unlined units, $7x10^{-3}$ for clay-lined units, and below the risk criteria for composite-lined units at the 90th percentile. Noncancer hazard quotients at the 90th percentile exceeded 1 for cadmium (9), cobalt (8), lead (9), and molybdenum (3) in unlined units, and cadmium (3), cobalt (3), and molybdenum (2) in clay-lined units. None of the risk criteria were exceeded at the 90th percentile in composite-lined units. As noted above, codisposal of CCW and coal refuse in surface impoundments results in risks up to 10-fold greater than those seen for conventional CCW managed in surface impoundments. This is likely due to the higher metal concentrations and the acidity of coal refuse leachate[4] for surface impoundments in the CCW database. As with landfills, clay-lined units show lower risks by a factor of 2 or 3 than unlined units, and composite liners show negligible or zero risks for either waste type.

[4] Metals tend to show greater solubility and mobility in acidic leachate.

Table 4-5. 90th Percentile Risk Results by CCW Type: Landfills, Groundwater-to-Drinking-Water Pathway

[c] Values are ratios of exposure concentration to MCL.

4.1.3.2 FBC Wastes

Tables 4-9 and 4-10 show the 90th- and 50th-percentile risk results for FBC landfills by unit type. At the 90th percentile in landfills, arsenic cancer risks are $3x10^{-5}$ for unlined units, $6x10^{-5}$ for clay-lined units, and 0 for composite-lined units. Noncancer hazard quotients exceed 1 for only thallium (4) and antimony (3) in clay-lined units. No risks exceeded the risk criteria at the 50th percentile. These results suggest lower risks than for conventional CCW and CCW codisposed with coal refuse. The difference may be attributed to lower FBC leachate concentrations and the alkaline nature of FBC waste.

Note that clay-lined FBC landfills show higher risks than unlined facilities, which is counterintuitive considering how clay-lined and unlined units are designed and operated. This

result reflects the characteristics of the limited number and locations of FBC landfills[5] and illustrates how the probabilistic analysis design and availability of facility data can impact risk results (and why FBC results are treated separately in the risk characterization). As presented in Section 3.1.2 and in Figure 3-2, the Monte Carlo analysis was designed to evaluate risks posed by current waste management practices for a given WMU type, waste type, and waste constituent. This approach limits the effects of data availability for the different liner configurations when the risks are aggregated over all units (lined and unlined) combined. However, when the risk results of an exposure pathway are viewed at a resolution finer than the analysis design, a small sample size for a particular waste and WMU type scenario (as occurs for FBC waste), along with the interactions of liner type with other site-based inputs (notably infiltration rate and the size of the WMU), can produce unexpected results. In the case of FBC wastes, the characteristics (primarily infiltration rate and areas) of the three unlined landfills were such that their risks were lower than the clay-lined FBC landfills.

Table 4-9. 90th Percentile Risk Results for FBC Wastes: Landfills, Groundwater-to-Drinking-Water Pathway

Chemical	90th Percentile HQ or Cancer Risk Value[a]			
	All Units Combined[b]	Unlined Units	Clay-Lined Units	Composite-Lined Units

Boron	2E-04	0	0.003	0

[a] Values are HQs for all chemicals except arsenic; arsenic values are cancer risk. Zero results indicate that contaminant infiltration rates were too small for the contaminant plume to reach the receptor during the 10,000-year period of the analysis.
[b] HQ or risk across all unit types combined (unlined, clay-lined, and composite-lined).
[c] Values are ratios of exposure concentration to MCL.

4.1.4 Results by Unit Type

The effect of unit type on human health risk for the groundwater-to-drinking-water pathway can be seen in Tables 4-1 and 4-2, which compare 90th and 50th percentile risks, respectively, for WMUs that are unlined, clay lined, and lined with composite liners from the 1995 EPRI survey data (EPRI, 1997). At the 90th percentile, lined units produced lower risk estimates than unlined units for all constituents modeled. Composite liners produced very low to zero risk estimates as compared to clay liners for all constituents modeled for both landfills and surface impoundments. For surface impoundments, clay liners produced higher risk estimates for all constituents as compared to clay liners in landfills. Similar trends are evident at the 50th percentile, where composite liners produced risk estimates of zero or near zero for all constituents for surface impoundments.

Table 4-11 shows the frequency of each of the unit types in the 1995 EPRI survey data modeled in this analysis, and it compares these data with the unit type frequency in the more recent DOE/EPA study (U.S. DOE, 2006). The 56 WMUs surveyed in the U.S. DOE 2006 study were commissioned between 1994 and 2004. Although the actual number of WMUs that were established in that timeframe cannot be verified, based on proxy data (i.e., CCW available for disposal in those states with identified, new WMUs and coal-fired power plant generating capacity), the sample coverage is estimated to be at least between 61 and 63 percent of the total

population of the newly commissioned WMUs.[6] With the exception of one landfill, the newly constructed facilities are all lined, with either clay, synthetic, or composite liners. The single unlined landfill identified in the recent DOE report receives bottom ash, which is characterized as an inert waste by the state, and therefore, a liner is not required. As Table 4-11 shows, there is a marked trend away from unlined WMUs in favor of lined units, with a distinct preference for synthetic or composite liners. Comparison of the 26 coal combustion plants in both the EPRI survey and the DOE/EPA survey (U.S. DOE, 2006) shows that although most of those facilities (17 of 26) were using unlined WMUs in 1995, all 26 are now placing wastes in new or expanded landfills or surface impoundments that are lined with clay, synthetic, or composite liners. However, it is likely that the older unlined units were closed with wastes in place, and that these wastes therefore still pose a threat through groundwater pathways. Also, the number of unlined unit that continue to operate in the United States cannot be determined from the available data.

Table 4-11. Unit Types in EPRI Survey

Liner Type	Landfills	Surface Impoundments
1995 EPRI Survey[a] – 181 facilities		
Unlined	40%	68%
Compacted clay	45%	27%
Synthetic or composite (clay and synthetic)	16%	5%
Total	100%	100%
2004 DOE Survey[b] – 56 Facilities		
Unlined	3%	0%
Compacted clay	29%	17%
Synthetic or composite (clay and synthetic)	68%	83%
Total	100%	100%

[a] EPRI (1997)
[b] U.S.DOE (2006)

As described in Sections 3.2.1 and 3.3.1, the characteristics of the liners used in the CCW risk were taken from the IWEM model as representative of the general performance of each liner type. For landfills, an engineered compacted clay liner (3 feet thick, with a hydraulic conductivity of 1 x 10^{-7} cm/s) reduced the 90th percentile risk by a factor of about 2 to 4 compared to no liner, but did not change the constituents at or above the risk criteria (arsenic and thallium). For surface impoundments, clay liners did reduce the risk to just below the risk criteria for cobalt, lead, and selenium.

Composite (clay and synthetic) liners, as modeled in this risk assessment (see Sections 3.2 and 3.3), were much more effective at reducing risk for all constituents; 90th (and

[6] For additional details as to how these estimates were derived, the reader is referred to the DOE study, pages S-2 – S-3 of the Summary Section and Section 3.1.2..

50th) percentile risks with composite liners for landfills were zero[7] for arsenic and metals and very low or zero for nitrate/nitrite, and were well below the risk criteria for all constituents for surface impoundments. The analysis used data collected for composite liner performance at industrial waste management facilities, including liner leakage rate for landfills and the number of liner perforations for surface impoundments (TetraTech, 2001). Because data on CCW liner leakage rates are not available, there is some uncertainty in applying these Industrial D liner performance data to CCW disposal units. Still, these rates do reflect actual performance data from liners under real WMUs, and they demonstrate that composite liners can be effective in reducing leaching from CCW WMUs and suggest that there will be a significant decrease in risk from CCW disposal if more facilities line their WMUs with composite liners. Information from the more recent DOE/EPA study (U.S. DOE, 2006) indicates that composite liners are much more prevalent in newly constructed facilities, so the risks from CCW disposal should be lower for newer CCW landfills and surface impoundments.

4.1.5 Constituents Not Modeled in the Full-Scale Assessment

As described in Section 2.1.1.2, resources did not allow full-scale modeling to be conducted for all 21 constituents that were above the screening criteria in the initial screening analysis; nine constituents that were judged to likely have generally lower risks to human health and ecological risks were not modeled in the full-scale risk assessment.[8] Five of these chemicals (chromium, fluoride, manganese, vanadium, and nickel) had drinking water pathway HQs in the screening analysis ranging from 1 to less than 6 for surface impoundments, and three (chromium, fluoride, and vanadium) had screening HQs of 2 for landfills.

To address these constituents, we developed surrogate risk attenuation factors by dividing the screening risk results by the full-scale risk results, across all unit types combined, for the constituents modeled in the full-scale assessment. This comparison was done only for the drinking water exposure pathway, the only human health exposure pathway for which the risks for these constituents were above the screening criteria. Table 4-12 shows the risk attenuation factor statistics for the modeled constituents, and Table 4-13 shows the results of applying the median and 10th percentile attenuation factors to the screening risk results for the marginal constituents. Differences in attenuation among the modeled constituents reflects differences in contaminant sorption and mobility. The 10th percentile attenuation factor was selected as a conservative value representing the more mobile constituents, such as arsenic, selenium, and molybdenum. The 50th percentile (or median) risk represents a central tendency value.

For landfills, the risk attenuation factors ranged from 6 to 40, with the lower attenuation factors mainly representing the more mobile constituents (i.e., those with lower soil sorption potential). Both the median and 10th percentile risk attenuation factors were adequate to reduce risks for all nine constituents below an HQ of 1.

[7] The absence of risk indicates that contaminant infiltration rates were too small for the contaminant plume to reach the receptor well during the 10,000 year period of the analysis. See Section 3.2.2 for a discussion of the empirical liner infiltration data used in this analysis.

[8] These constituents of marginal concern had no human health HQs greater than 6 and only one or no ecological HQs greater than 100.

For surface impoundments, risk attenuation factors were considerably lower, ranging from 1 to 9, reflecting higher contaminant mobility due to the higher hydraulic head in surface impoundments (as compared to landfills) and a lower proportion of liners. For the same reason, the screening HQs for surface impoundments were higher than the landfill HQs. As a result of this combination of higher HQs and lower risk attenuation factors, only the HQ for nickel was reduced to below 1 by applying the attenuation factors. The other constituents (chromium, fluoride, manganese, and vanadium) still show risks slightly above the risk criteria, with HQs ranging from 1.4 to 3.5. This is consistent with the general trend in this analysis of surface impoundments showing higher risks and more risks exceeding the risk criteria than CCW landfills.

Table 4-12. Risk Attenuation Factor[a] Statistics for Modeled Constituents—Groundwater to Drinking Water Pathway

Statistic	Landfill	Surface Impoundment
10th percentile	7	1.6
50th percentile	12	2.6
Average	16	3.3
Maximum	40	9.3
Number of data points	9	8

[a] The risk attenuation factor is the ratio of the full-scale analysis risk and screening analysis risk for a constituent modeled in the full-scale analysis.

Table 4-13. Summary of Risk Results for Constituents Using Risk Attenuation Factors—Groundwater-to-Drinking-Water Pathway

	Landfill			Surface Impoundment		
WMU/Pathway	Screening HQ	HQ with Median Attenuation	HQ with 10th Percentile Attenuation	Screening HQ	HQ with Median Attenuation	HQ with 10th Percentile Attenuation
Chromium VI	2.3	0.2	0.3	4.2	1.6	2.6
Fluoride	1.8	0.2	0.3	5.2	2.0	3.3
Manganese	1	0.1	0.1	5.6	2.2	3.5

Nickel	-	-	-	1.3	0.5	0.8

4.2 Ecological Risks

EPA defines ecological risk characterization in terms of (1) the risk estimation, which integrates the exposure and stressor-response profile to estimate the likelihood of adverse ecological effects and (2) the risk description, which synthesizes the overall conclusion of the assessment and addresses assumptions, uncertainty, and limitations.

For assessments that are based on a HQ approach, as this one is, the comparison of modeled exposure concentrations to CSCLs to estimate risk has a binary outcome: either the constituent concentration is above the environmental quality criteria (HQ greater than 1) or the concentration is below the criteria (HQ less than or equal to 1). For the full-scale analysis, an ecological HQ greater than 1 was selected by EPA as a criterion for decision making. Because the CSCLs were based on *de minimis* ecological effects, it is generally presumed that an HQ at or below 1 indicates a low potential for adverse ecological effects for those receptors included in the analysis for which data are available. However, it is important to recognize that although this method provides important insight into the potential for adverse ecological effects, the results are relevant only to those receptors that were included in the assessment and for which data were available. The results have limited utility in interpreting the ecological significance of predicted effects, and caution should be exercised in extrapolating to ecosystems (e.g., wetlands) and receptors (e.g., threatened and endangered species) not explicitly modeled.

This section presents risk results for the two groundwater-to-surface-water ecological exposure pathways investigated in the full-scale analysis: (1) receptors exposed to CCW constituents in the water column (surface water receptors) and (2) receptors exposed to CCW constituents in bed sediment (sediment receptors). Results are presented for the two WMU types addressed in the analysis: landfills and surface impoundments. The ecological risk results are presented for all unit types combined and were not broken out separately for the different unit types.

The ecological risk results suggest the potential for adverse ecological effects to aquatic systems from CCW releases into the subsurface and subsequent connection with surface waters, particularly for CCW managed in unlined surface impoundments. As with human health risks, the higher prevalence of liners in newer facilities should result in lower risks in current and future CCW disposal facilities than those presented in this risk assessment.

4.2.1 Surface Water Receptors

Table 4-14 presents the 90th and 50th percentile results for the groundwater-to-surface-water pathway for surface water receptors for landfills and surface impoundments. For landfills, only boron (200) and lead (4) show HQs above the risk criteria at the 90th percentile. For surface impoundments, boron (2000), lead (20), arsenic (10), selenium (10), cobalt (5), and barium (2) showed 90th percentile risks above the risk criteria. The 50th percentile results are well below an HQ of 1 for landfills and only exceed an HQ of 1 for boron (4) in surface impoundments.

The difference in the number and magnitude of HQs that exceed the risk criterion between landfills and surface impoundments is likely the result of higher CCW constituent concentrations in surface impoundment porewater and the greater flux of contaminants to

groundwater predicted during the active life of the surface impoundment. As discussed in Section 4.1, the higher infiltration rates for surface impoundments result from a higher hydraulic head in the impoundment and a higher proportion of unlined surface impoundments than landfills.

Table 4-14. Summary of Full-Scale CCW Ecological Risk Results: Groundwater-to-Surface-Water Pathway, Aquatic Receptors[a]

Chemical	90th Percentile HQ	50th Percentile HQ	Pathway	Receptor
Landfills				
Boron	200	0.04	direct contact	aquatic biota
Lead	4	2E-08	ingestion	river otter
Selenium	1	3E-04	direct contact	aquatic biota
Arsenic	0.7	9E-10	direct contact	aquatic biota
Barium	0.8	3E-18	direct contact	aquatic biota
Cadmium	0.3	3E-05	direct contact	aquatic biota
Aluminum	0.008	1E-09	direct contact	aquatic biota
Surface Impoundments				
Boron	2000	4	direct contact	aquatic biota
Lead	20	0.02	ingestion	river otter
Arsenic	10	0.01	direct contact	aquatic biota
Selenium	10	0.02	direct contact	aquatic biota
Cobalt	5	0.007	direct contact	aquatic biota
Barium	2	0.003	direct contact	aquatic biota
Cadmium	1	0.004	direct contact	aquatic biota
Aluminum	0.02	0.0003	direct contact	aquatic biota

[a] Zero results indicate that contaminant infiltration rates were too small for the contaminant plume to reach the receptor during the 10,000 year period of the analysis.

4.2.2 Sediment Receptors

Table 4-15 presents the 90th and 50th percentile results of the ground-water-to-surface-water pathway for sediment receptors for landfills and surface impoundments. For landfills, lead, (20), arsenic (6), and cadmium (2) show 90th percentile risks above the risk criteria. For surface impoundments, lead (200), arsenic (100), and cadmium (20) showed 90th percentile risks above the risk criteria. Although cadmium was not above the risk criterion in surface water, it did have an HQ of 20 in sediments at the 90th percentile. None of the constituents modeled showed sediment risks at or above the risk criteria at the 50th percentile.

Table 4-15. Summary of Full-Scale CCW Ecological Risk Results: Groundwater-to-Surface-Water Pathway, Sediment Receptors[a]

Chemical	90th Percentile HQ	50th Percentile HQ	Pathway	Receptor
Landfills				
Lead	20	3E-08	ingestion	spotted sandpiper
Arsenic	6	7E-04	ingestion	spotted sandpiper
Cadmium	2	6E-05	direct contact	sediment biota
Antimony	0.9	4E-05	direct contact	sediment biota
Molybdenum	0.05	1E-05	ingestion	spotted sandpiper
Barium	0.002	6E-21	ingestion	spotted sandpiper
Surface Impoundments				
Lead	200	0.05	ingestion	spotted sandpiper
Arsenic	100	0.2	ingestion	spotted sandpiper
Cadmium	20	0.009	direct contact	sediment biota
Molybdenum	0.7	0.002	ingestion	spotted sandpiper
Barium	0.007	8E-06	ingestion	spotted sandpiper

[a] Zero results indicate that contaminant infiltration rates were too small for the contaminant plume to reach the receptor during the 10,000 year period of the analysis.

4.2.3 Constituents Not Modeled in the Full-Scale Assessment

As described in Section 2.1.1.2, resources did not allow full-scale modeling to be conducted for 6 constituents with generally lower risks to ecological receptors.[9] These chemicals (chromium, vanadium, beryllium, copper, silver, and zinc), had surface water pathway HQs in the screening analysis ranging from 16 to 110 for landfills, and four (chromium, vanadium, copper, and silver) had screening HQs ranging from 14 to 33 for surface impoundments.

These constituents were addressed using risk attenuation factors developed by dividing the screening risk results by the full-scale risk results for the constituents modeled in the full-scale assessment. Tables 4-16 and 4-17 show the results of this comparison for the surface water ecological risk exposure pathway. Table 4-16 shows the risk attenuation factors for the modeled constituents, and Table 4-17 shows the results of applying the median (central tendency) and 10th percentile (conservative) attenuation factors to the screening risk results for constituents that were not modeled.

For landfills, the risk attenuation factors ranged from 50 to 2,000. Both the median and 10th percentile risk attenuation factors were adequate to reduce risks to an HQ below 1 for all constituents except for silver. Although silver shows an HQ of 1.5 using the 10th percentile

[9] These constituents had only one or no ecological HQs greater than 100.

attenuation factor, silver's low mobility would probably result in a higher attenuation factor (i.e., at the median or greater).

For surface impoundments, risk attenuation factors ranged from 7 to 64, reflecting higher contaminant mobility from the higher hydraulic head in the surface impoundments and a lower prevalence of liners (compared to landfills). HQs were reduced below 1 for all four unmodeled constituents with the median attenuation factor (38), and the HQ for silver was reduced to 0.8 by applying the 10th percentile attenuation factor (17). The other three constituents (chromium, vanadium, and copper) show risks only slightly above the risk criteria with the10th percentile attenuation (HQs ranging from 1.4 to 1.9). It is unlikely that these results represent true risks above the risk criteria: vanadium and copper are likely less mobile than the 10th percentile attenuation factor reflects (thus the true risk is likely lower), and the risks for chromium are based on the highly conservative assumption of 100 percent hexavalent chromium.

Table 4-16. Risk Attenuation Factor[a] Statistics for Modeled Constituents—Ecological Risk, Surface Water Pathway

Statistic	Landfill	Surface Impoundment
10th percentile	75	17
50th percentile	178	38
Average	483	38
Maximum	2,000	64
Number of data points	6	7

[a] The risk attenuation factor is the ratio of the full-scale analysis risk and screening analysis risk for a constituent modeled in the full-scale analysis.

Table 4-17. Summary of Risk Results Using Risk Attenuation Factors—Ecological Risk, Surface Water Pathway

WMU/Pathway	Landfill			Surface Impoundment		
	Screening HQ	HQ with Median Attenuation	HQ with 10th Percentile Attenuation	Screening HQ	HQ with Median Attenuation	HQ with 10th Percentile Attenuation
Chromium VI	18	0.1	0.2	33	0.9	1.9
Vanadium	23	0.1	0.3	24	0.6	1.4
Beryllium	24	0.1	0.3	-	-	-
Copper	16	0.09	0.2	31	0.8	1.8
Silver	110	0.6	1.5	14	0.4	0.8
Zinc	16	0.09	0.2	-	-	-

4.3 Sensitivity Analysis

EPA conducted a sensitivity analysis on the probabilistic risk assessment to determine which model inputs were most important to risk, which in turn will help focus additional analyses or data collection efforts on the most important drivers of risk, and help identify the important factors to consider when evaluating regulatory and management options for CCW. The sensitivity analysis also can help identify parameters that are both sensitive and highly uncertain, which affects the confidence in the results. This sensitivity analysis used a response-surface regression method that derives a statistical model for risk (as the dependent variable) based on the input parameters from the probabilistic analysis (as independent variables).

Environmental concentration (rather than risk) was chosen as the dependent variable for the sensitivity analysis because (1) there is a direct, linear relationship between environmental concentrations and risks and (2) the additional inputs used to calculate risk from environmental concentration (i.e., exposure factors, such as body weight, ingestion rates) are lifestyle variables that are not amenable to regulation to reduce or manage risk. Furthermore, these variables have well-established, peer-reviewed, national distributions, which are regularly used in the probabilistic national risk analyses conducted by EPA. Therefore, the contribution of the exposure factors to the variability in risk is not particularly useful for the purposes of the sensitivity analysis: to help direct additional analyses in support of developing CCW regulatory options, to help focus any future data collection efforts on the most sensitive variables, or to better understand sources of uncertainty in the CCW risk results.

The outputs from the sensitivity analysis are the goodness-of-fit values for the regression models and the relative importance of each input parameter in determining environmental concentrations across different WMU, waste type, and constituent scenarios. The goodness-of-fit values of the regression models were moderate to very good for the drinking water pathway (R^2=0.53–0.90) and good to very good for fish consumption (R^2=0.76–0.90). In general, the drinking water pathway had a larger number of input parameters that were significant (seven) than the fish consumption pathway (three). The most sensitive parameters for most (over 75 percent) of the drinking water scenarios[10] evaluated were parameters impacting groundwater flow:

- Infiltration rate within the WMU footprint
- Leachate concentration from the WMU
- Aquifer hydraulic conductivity and gradient (i.e., groundwater velocity).

For strongly sorbing contaminants (i.e., metals with high soil/water partition coefficients), sorption and travel time parameters become more important, including

- Adsorption isotherm coefficient
- Depth to groundwater
- Receptor well distance.

[10] Scenarios represent unique combinations of WMU, waste type, chemical, exposure pathway, and receptor.

For the fish consumption pathway, only three variables were consistently significant across scenarios:

- Infiltration rate within the WMU footprint
- Leachate concentration from the WMU
- Waterbody flow rate.

Additional detail on how the CCW sensitivity analysis was conducted can be found in U.S. EPA (2005). In terms of the model inputs, the sensitivity analysis found that the most consistent drivers of the risk results are constituent concentration in waste leachate (i.e., the source term for the risk assessment and infiltration rate through the WMU), which is largely controlled by the liner conditions and, to a lesser extent, soil type and (for landfills only) precipitation. These variables and their uncertainties are discussed in the following section.

4.4 Variability and Uncertainty

Variability arises from true heterogeneity in characteristics, such as body weight differences within a population or differences in contaminant levels in the environment.

Uncertainty represents a lack of knowledge about factors such as the nature of adverse effects from exposure to constituents, which may be reduced with additional research to improve data or models.

Variability and uncertainty are different conceptually in their relevance to a probabilistic risk assessment. Variability represents true heterogeneity in characteristics, such as body weight differences within a population or differences in pollutant levels in the environment. It accounts for the distribution of risk within the exposed population. Although variability may be known with great certainty (e.g., age distribution of a population may be known and represented by the mean age and its standard deviation), it cannot be eliminated and needs to be treated explicitly in the assessment. Uncertainty is a description of the imperfection in knowledge of the true value of a particular parameter. In contrast to variability, uncertainty can be reduced through additional information-gathering or analysis (i.e., better data, better models). EPA typically classifies the major areas of uncertainty in risk assessments as scenario uncertainty, model uncertainty, and parameter uncertainty. Scenario uncertainty refers to missing or incomplete information needed to fully define exposure and dose. Model uncertainty is a measure of how well the model simulates reality. Parameter uncertainty is the lack of knowledge regarding the true value of a parameter used in the assessment.

Uncertainty and variability can be addressed two ways:

- By varying parameter values in a probabilistic assessment such as a Monte Carlo analysis
- By comparing the data or results to other data or other studies such as damage cases or alternative results based on different assumptions.

In planning this assessment, we addressed as much of the variability as possible, either directly in the Monte Carlo analysis or through aggregation of the data into discrete elements of the analysis. For example, spatial variability in soil, aquifer, and climate data is accounted for by using distributions for soil and aquifer properties around the facility when the actual

environmental characteristics around a WMU are uncertain. Conversely, variability in waste leachate concentrations was represented by a national database of CCW constituent concentrations from disposal sites around the country. These data were aggregated by waste and WMU types that were defined by statistically significant differences in concentration. Variability in human exposure factors (e.g., body weight, ingestion rates) was accounted for using national distributions that represent the range of possible values.

Because CCW is generated nationwide, its disposal may occur anywhere in the United States. Thus, this assessment characterized environmental conditions that influence the fate and transport of constituents in the environment using site-specific data collected around coal-fired power plants with onsite CCW disposal facilities. Spatial variability in environmental setting was accounted for by the site-to-site variables for the 181 CCW disposal sites modeled in the analysis using 41 different climate regions and 9 different resources regions throughout the contiguous 48 states.

In summary, a distribution of exposures was developed that includes specific consideration of the variability in the following sensitive model parameters

- WMU characteristics, in particular liner type (which strongly influences infiltration rate)
- CCW constituent concentrations in waste leachate
- Distance to nearest well
- Site-specific environmental conditions (especially groundwater flow conditions)
- Human exposure factors.

Uncertainty also was considered in the analysis by using reasonable ranges and distributions when variables were not known exactly. For example, when a soil texture or groundwater flow conditions could not be precisely assigned at a site, multiple soil types or hydrogeologic environments would be sampled based on the soil and aquifer types that are likely to be present at the site.

The treatment of variability and uncertainty in model parameters using a Monte Carlo simulation forms the basis for the national exposure distributions used in this analysis to estimate risk. Previous sections of this document describe how we generated distributions and estimated input parameter values and then used these values in models to estimate risk. The discussion in this section focuses on how this treatment of variability and uncertainty affects the analysis results and on various comparisons we performed on the results or critical input data to evaluate uncertainty.

4.4.1 Scenario Uncertainty

Sources of scenario uncertainty include the assumptions and modeling decisions that are made to represent an exposure scenario. Because this risk assessment attempts to characterize current conditions by estimating risks from actual CCW disposal sites across the country, it is subject to less scenario uncertainty than risk assessments that rely on hypothetical conceptual models. However, certain aspects of the scenario are uncertain.

CCW Management Unit Data. The landfills and surface impoundments modeled in this risk assessment were placed, sized, and lined according to data from the 1995 EPRI survey (EPRI, 1997). New data collected by EPA and DOE since this risk assessment was conducted (U.S. DOE, 2006) indicate that liners are much more prevalent in WMUs constructed or expanded from 1994 through 2004 than in units in place before that. This suggests that the risks may be lower for future CCW disposal facilities (although most of the unlined WMUs have been closed with wastes remaining in the units).

Liner-related questions are especially important because liner configurations greatly influence infiltration rates, one of the most sensitive parameters in the risk assessment. In terms of risks through groundwater pathways, this risk assessment has shown that liners, in particular composite (combined clay and synthetic) liners, can limit risks through subsurface exposure pathway, and the DOE/EPA survey shows that liners are more prevalent in newly constructed WMUs and WMU expansions. Although the DOE/EPA survey does not shed light on how many unlined facilities are still operating today, it does indicate that more units are lined today than were in the 1995 EPRI survey data set on which this risk assessment is based.

Receptor Populations Evaluated. The human receptors evaluated for the CCW risk analysis are a family with children residing near the CCW disposal facility, drinking from a private well screened in a surficial aquifer or eating fish caught from a nearby stream or lake impacted by CCW leachate. Additionally, except for a 15-day vacation, it is assumed that adults and children are exposed daily and that the private well is the only source of drinking water. Although it is possible for other types of individuals to be exposed, the use of the resident adult and child as protective of other receptors and pathways is a conservative, simplifying assumption of the analysis. The lack of information to define and model actual exposure conditions also introduces uncertainty into this assessment, but EPA believes that the national distribution of exposure factors used is appropriate for a national assessment.

Additive Risks Across Pathways. The human receptors evaluated in the CCW risk assessment are assumed not to consume both contaminated fish and drinking water. Although this could potentially miss some higher exposures for a maximally exposed individual, analysis of the individual pathway results does not indicate that adding such risks would significantly change the conclusions of this risk assessment in terms of the constituents and exceeding the risk criteria.

Co-Occurrence of Ecological Receptors and Constituents. As a simplification for national-scale analyses in the absence of site-based data, co-occurrence of the ecological receptors and the constituents of concern is typically assumed. However, the prior probability that a receptor will be found in waterbodies affected by constituent releases from CCW WMUs is not known, nor is it known whether a receptor will forage for food in contaminated areas or if those areas do, in fact, support the type of habitat needed by the receptor. Although the assumption of co-occurrence was necessary for this analysis, relatively few field studies are available to demonstrate the relationship between adverse ecological effects and constituent releases from CCW as it is currently managed.

Ecosystems and Receptors at Risk. One of the most intractable problems in conducting a predictive ecological risk assessment intended to reflect risks at a national scale is evaluating *all* of the receptors and ecosystems at risk. In *Wastes from the Combustion of Coal by Electric Utility Power Plants - Report to Congress* (U.S. EPA, 1988b), the authors pointed out that plants or animals of concern were located within a 5-km radius of the CCW WMUs at 12 to 32 percent of the sites. Although these figures are of limited spatial resolution, they suggest the possibility that threatened and endangered species or critical habitats may be at risk from CCW constituents. Examples of other critical assessment endpoints not evaluated in this analysis include the following:

- **Managed Lands:** Because ecosystem degradation is proceeding at an unprecedented rate, and because protected lands play a critical role in preserving plant and animal species, managed areas in the United States represent well-recognized ecological values. Managed lands refer to a variety of lands designated by the federal government as worthy of protection, including National Wildlife Refuges, National Forests, Wilderness areas, and National Recreation areas.
- **Critical Habitats:** Although critical habitats may be defined in a number of ways (e.g., presence of threatened species, decreasing habitat area), wetlands are widely recognized as serving critical ecological functions (e.g., maintenance of water quality). The U.S. Fish and Wildlife Service estimates that approximately 45 percent of the Nation's threatened and endangered species directly depend on aquatic and wetland habitats. Consequently, impacts of chemical stressors on wetland habitats may have high ecological (and societal) significance. The presence of critical habitats such as wetlands is also used to inform the selection of ecological receptors (e.g., amphibians, waterfowl) and the construction of appropriate food webs.
- **Threatened and Endangered Species:** For most ecological risk assessments of chemical stressors, available data on toxicity and biological uptake are sufficient to support the evaluation of effects on representative species populations or generalized communities (e.g., aquatic community). However, despite their obvious value, threatened and endangered species are frequently excluded from the analytical framework for national rulemakings. The assessment of threatened and endangered species requires a site-based approach in which locations, habitats, and species of concern are identified and characterized with respect to the spatial scale of constituent releases.

4.4.2 Model Uncertainty

Model uncertainty is associated with all models used in a risk assessment because models and their mathematical expressions are simplifications of reality that are used to approximate real-world conditions and processes and their relationships. Computer models are simplifications of reality, requiring exclusion of some variables that influence predictions but that cannot be included in models either because of their complexity or because data are lacking on a particular parameter. Models do not include all parameters or equations necessary to express reality because of the inherent complexity of the natural environment and the lack of sufficient data to describe the natural environment. Because this is a probabilistic assessment that predicts what may occur with the management of CCW under actual scenarios, it is possible to compare the results of these models to specific situations.

The risk assessor needs to consider the importance of excluded variables on a case-by-case basis because a given variable may be important in some instances and not important in others. A similar problem can occur when a model that is applicable under one set of conditions is used for a different set of conditions. In addition, in some instances, choosing the correct model form is difficult when conflicting theories seem to explain a phenomenon equally well. In other instances, EPA does not have established model forms from which to choose to address certain phenomena, such as facilitated groundwater transport.

Models used in this analysis were selected based on science, policy, and professional judgment. These models were selected because they provide the information needed for this assessment and because they are generally considered to reflect the state of the science. Even though the models used in this analysis are used widely and have been accepted for numerous applications, they each retain significant sources of uncertainty. These limitations are well documented in the model development references cited in Section 3.

Although the sources of model uncertainty in this assessment could result in either an overestimation or an underestimation of risk, the models employed in this assessment have been developed over many years to support regulatory applications. As a result they have been designed to be protective towards the impacted populations that they represent. In other words, where simplifying assumptions are necessary, the assumptions are made in a way that will not underestimate risk.

Arsenic Speciation. Because the models used in this assessment do not speciate metals during soil or groundwater transport, arsenic speciation in the subsurface is a significant groundwater modeling uncertainty in this analysis. Arsenic can occur in either a +3 (arsenic III) or +5 (arsenic V) oxidation state in groundwater, with arsenic III being the more mobile form. Because the soil and groundwater models assume one form for each model run, the risk results presented for arsenic are based on arsenic III, which is a conservative, protective assumption (i.e., arsenic III has higher risks than arsenic V). Although arsenic is generally thought to occur in the +3 form in leachate, there is evidence from damage cases at CCW disposal sites that suggests that arsenic III is rapidly converted to arsenic V during subsurface transport, with the result that drinking water standards are rarely exceeded in offsite groundwater in spite of high landfill leachate concentrations (see, for example, U.S. EPA, 2000; U.S. EPA, 2003e; Lang and Schlictmann, 2004; Zillmer and Fauble, 2004). To address this uncertainty (i.e., how much an arsenic III assumption might overpredict offsite well concentrations) the models were run assuming arsenic V as the arsenic species in soil and groundwater. Figure 4-4 compares the risk results for arsenic III and arsenic V. Arsenic V has lower risks than arsenic III by about a factor of two, but the 90th percentile risks are still above risk criteria.

Bioavailability of Constituents to Ecological Receptors. For the purposes of this analysis, the model assumes that all forms of a constituent are equally bioavailable to ecological receptors, and therefore, the actual exposures that may occur in the field tend to be overestimated, thus making this a protective assumption. Both the chemical form and the environmental conditions influence bioavailability and ultimately the expression of adverse effects. For example, as discussed above, the form of arsenic has been shown to profoundly influence mobility and toxicity.

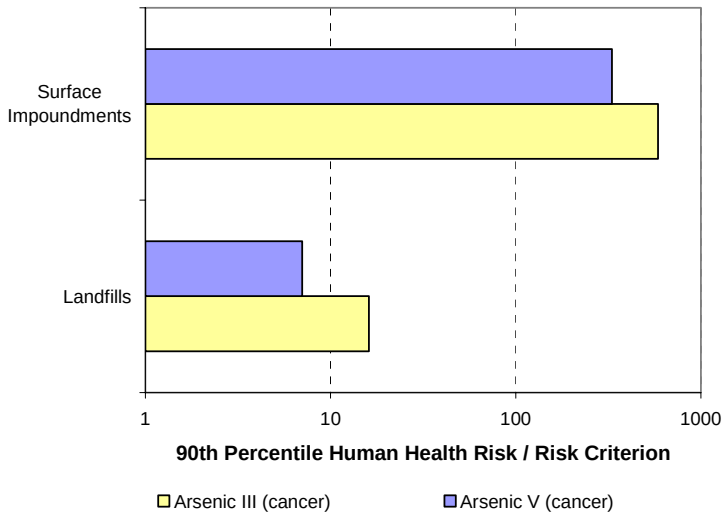

Figure 4-4. Comparison of risk results for arsenic III and arsenic V (based on results for all units combined).

Multiple Constituent Exposures to Receptors. The risk from each constituent was considered separately in this analysis. However, the waste concentration data on CCWs (as well as recent field studies such as U.S. EPA, 2006) suggest that exposure to multiple constituents is highly likely. The synergism or antagonism between different constituent combinations may elicit unexpected adverse impacts to humans and ecosystems. Hence, a single-constituent analysis may underestimate risks associated with multiple chemical stressors.

4.4.3 Parameter Uncertainty and Variability

Parameter uncertainty occurs when (1) there is a lack of data about the values used in the equations, (2) the data that are available are not representative of the particular instance being modeled, or (3) parameter values have not been measured precisely or accurately because of limitations in measurement technology. Random, or sample, errors are a common source of parameter uncertainty that is especially critical for small sample sizes, as illustrated by the FBC waste results discussed in Section 4.1.3.2. More difficult to recognize and address are nonrandom or systematic errors that can bias the analyses from sampling errors, faulty experimental designs, or bad assumptions.

Spatial and temporal variability in parameters used to model exposure account for the distribution in the exposed population. For example, the rainfall or precipitation rates used to calculate infiltration and recharge to groundwater are measured daily by the National Weather Service at many locations throughout the United States, and statistics about these parameters are well documented. Although the distributions of these parameters may be well known, their actual values vary spatially and temporally and cannot be predicted exactly. Thus, the annual average infiltration rates used in the source model for a particular climate station will provide information on average conditions appropriate for this analysis. Additionally, using data from multiple climate stations located throughout the United States can account for some, but not all, spatial variability.

4.4.3.1 Waste Concentrations

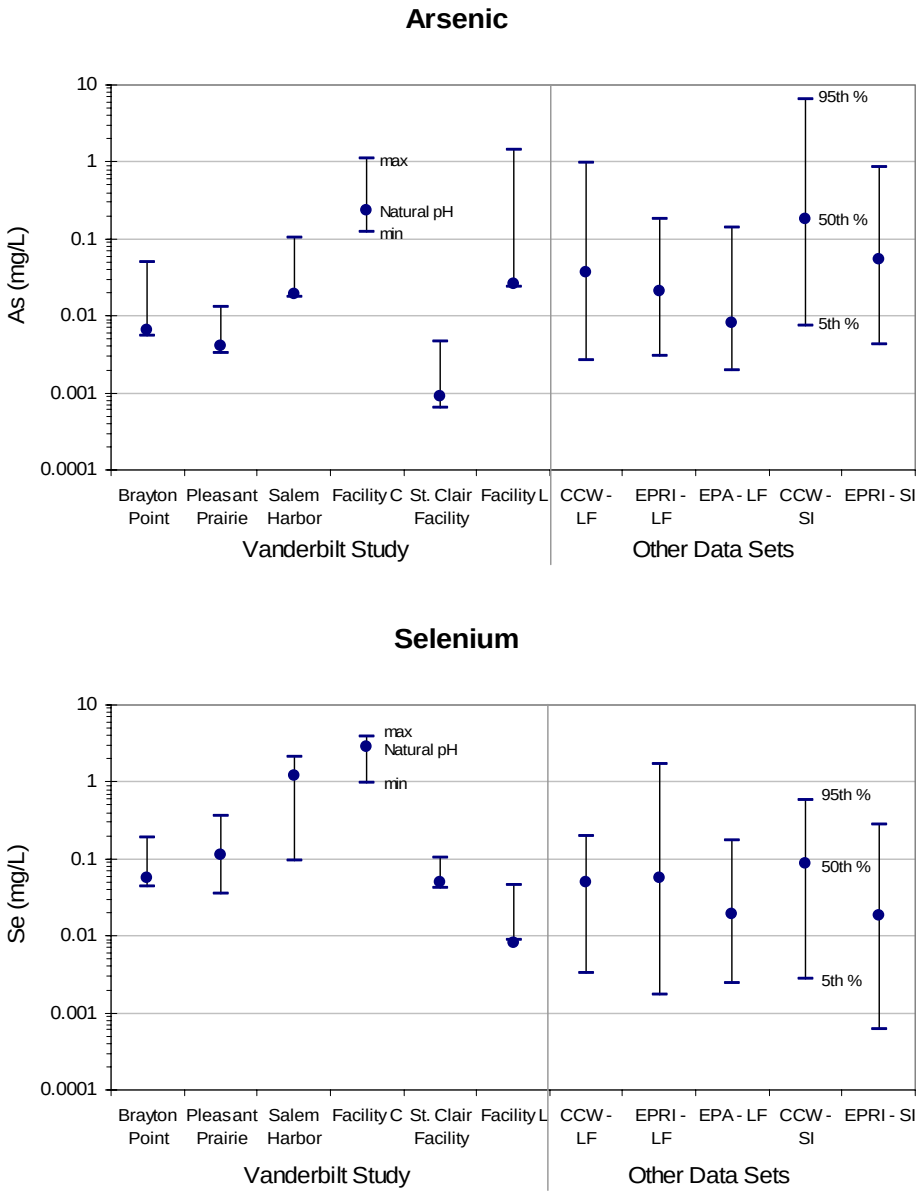
The CCW constituent database used to represent CCW total waste and waste leachate concentrations is arguably the most important data set in terms of driving the risk assessment results. The constituent data are subject to two primary uncertainties beyond the normal sampling and analysis uncertainty associated with environmental measurements: (1) the appropriateness of the landfill leachate data used in the analysis and (2) high percentages of nondetect analyses for some CCW constituents.

Appropriateness of Leachate Data. The CCW leachate data were collected from a varying number of sites using a variety of methods. The available landfill data are largely derived from the TCLP, a laboratory test designed to estimate leachate concentrations in municipal solid waste (MSW) landfills. The TCLP has been shown to both over and underpredict leachate concentrations for other waste disposal scenarios, so the use of the TCLP data to represent CCW leachate is another source of uncertainty. However, as noted below, this does not appear to be a significant source of uncertainty for this analysis.

Surface impoundment leachate is represented by porewater data taken beneath actual impoundments, but although these data arguably should better represent leachate concentrations, they are fewer in number than the landfill data and therefore subject to uncertainty as to how representative they are of all CCW wastes. Antimony, cobalt, mercury, and thallium are represented by one to only a few sites and only a few measurements, and results associated with these metals should be interpreted with caution. Results for surface impoundments for antimony, mercury, and thallium are not presented due to the paucity of leachate data (1 or 2 sites, and 11 or fewer values).

Since the CCW risk assessment was been conducted in 2003, EPA-sponsored research conducted by Vanderbilt University has improved the scientific understanding of the generation of leachate from CCW, in particular for mercury, arsenic, and selenium (U.S. EPA, 2006). Figure 4-5 plots the results from this study for arsenic and selenium, along with data from EPA's Leach2000 database and EPRI (as provided in U.S. EPA, 2006), against the data used for landfills and surface impoundments used in the CCW analysis. For the Vanderbilt leaching study, data are provided for each ash tested, with the minimum, maximum, and value at natural pH plotted on the chart. Percentile values (95th, 50th, 5th) are plotted for the compiled data sets (EPA, EPRI, and CCW), and mercury is not modeled for landfills because of a high number of nondetects.

For arsenic, the CCW values bracket the range found in the other studies. Selenium values also agree fairly well for CCW landfill data, although the CCW landfill values appear to be lower than some of the values from the other studies, suggesting that selenium risks may be somewhat underestimated for landfills in this analysis. This is significant even though selenium risks from landfills were not above the risk criteria in this analysis, because selenium is often reported as a constituent of concern (along with arsenic and boron) in CCW damage cases (U.S. EPA, 2000; U.S. EPA, 2003e; Lang and Schlictmann, 2004; Zillmer and Fauble, 2004).



Key to data sets:

Vanderbilt = U.S. EPA (2006)
CCW = CCW Constituent Database (this analysis)
EPRI = EPRI Leachate data (from U.S. EPA, 2006)
EPA = Leach 2000 data (from U.S. EPA, 2000)
LF = landfills
SI = surface impoundments

Figure 4-5. Comparison of CCW leachate data with other leachate data.

Although the Vanderbilt Study does not cover all of the metals addressed in the CCW analysis, its general agreement with the CCW arsenic and selenium levels does help allay concerns that the TCLP CCW leachate values used in the analysis markedly overestimate or underestimate the concentrations actual CCW leachate.

Mercury and Nondetect Analyses. For certain of the CCW constituents addressed in this analysis, the CCW leachate database contains a large number of nondetect measurements (concentrations below an analytical instrument's ability to measure). Table 4-18 illustrates this point by showing, by WMU type and chemical, the overall percent of nondetect values for each chemical and the percent of site-averaged values[11] that are composed entirely of nondetect measurements. Constituents that could not be addressed in this analysis because of a high number of nondetects include mercury (for landfills and surface impoundments) and thallium, antimony, and cobalt (for surface impoundments only). Mercury is of particular interest because it is the only constituent with significant concern through the fish consumption pathway, and because there is the potential for mercury concentrations in CCW to increase as flue gas mercury controls are installed on coal-fired power plants in response to the Clean Air Interstate Rule (CAIR) and the Clean Air Mercury Rule (CAMR).

Recent work by Vanderbilt University (U.S. EPA, 2006) sheds some light on mercury concentrations in leachate from some CCWs. Figure 4-6 plots the CCW distribution of mercury concentrations (assuming half the detection limit for mercury values below detection) against results from the Vanderbilt work and recent data collected by EPRI (U.S. EPA, 2006). Assuming half the detection limit, the CCW mercury leachate values are about an order of magnitude or more higher than the Vanderbilt or EPRI data. With a single CCW leachate analysis available for surface impoundments, it is difficult to draw firm conclusions, but the concentration value, which corresponds to a 90th percentile HQ of 20, is above the maximum value shown in the other studies. In short, the mercury levels in the CCW database are not useful because of high detection limits. In addition, the Vanderbilt study found that older mercury analyses, like the ones in the CCW database, could be biased high because of cross-contamination issues.

Finally, U.S. EPA (2006) and preliminary results of ongoing EPA studies suggest that both mercury levels and mercury leachability in CCW can vary depending on the flue gas mercury controls used at a power plant. Additional work is underway in this area.

[11] As explained in Appendix A, the CCW risk assessment uses site-averaged constituent concentrations. That is, an average value was used when there were multiple measurements for a chemical at a particular site.

Table 4-18. Proportion of Nondetect Analyses for Modeled CCW Constituents

Chemical	Measurements		Sites	
	Number	% nondetects	Number	% with all nondetects
Landfills				
Aluminum	397	18%	61	5%
Antimony	496	50%	66	41%
Arsenic	1182	49%	128	20%
Barium	1225	11%	126	5%
Boron	930	8%	83	2%
Cadmium	1237	50%	124	31%
Cobalt	559	56%	52	19%
Lead	1109	60%	125	30%
Mercury	***974***	***91%***	***101***	***58%***
Molybdenum	373	24%	58	10%
Nitrate/Nitrite	141	48%	20	15%
Selenium	1227	49%	131	17%
Thallium	402	60%	40	45%
Surface Impoundments				
Aluminum	158	10%	16	6%
Antimony	***11***	***100%***	***2***	***100%***
Arsenic	155	16%	16	6%
Barium	161	14%	16	13%
Boron	164	7%	171	6%
Cadmium	164	68%	16	50%
Cobalt	49	59%	4	50%
Lead	138	78%	14	36%
Mercury	***1***	***100%***	***1***	***100%***
Molybdenum	161	37%	17	24%
Nitrate/Nitrite	267	59%	14	7%
Selenium	140	33%	15	20%
Thallium	***11***	***100%***	***2***	***100%***

Results for constituents shown in ***bold italics*** were not presented in this report because of high detection limits or limited data.

4.4.3.2 WMU Locations and Characteristics

The locations of the specific sites in the United States where CCW is disposed are known, and EPA used the soil and climatic characteristics of these sites in the Monte Carlo analysis. Because most locations were facility front gates or centroids, the exact location of the CCW landfill or surface impoundment was not known. To account for this uncertainty, soil data were collected for an area around the plant and soil type distributions were sampled in the Monte Carlo analysis. Climate center assignments were combined with the soil texture distributions to select infiltration and recharge rates to use in the analysis.

WMU area, depth, volume, and liner type were not varied in the Monte Carlo analysis because values for these variables were known from the EPRI survey data. More uncertain parameters, like depth below grade, were varied within reasonable ranges. These data were used in the source model calculations to generate the distribution of environmental releases used by the fate and transport modeling.

Three standard WMU liner scenarios (clay, composite, and unlined) were assigned to each facility based on best matches to data in the EPRI survey on liner type. Infiltration through these liners was then modeled using assumptions, models, and data developed in support of EPA's Industrial Subtitle D guidance. How well these assumptions and models represent the

performance of CCW WMU landfills and surface impoundments is an uncertainty in this analysis.

4.4.3.3 Fate and Transport Model Variables

The parameter values required to model contaminant fate and transport in groundwater were obtained from site-specific, regional, and national databases. Hydrogeologic environment was assigned to each site, based on geologic maps and soil conditions; where assignments were uncertain, two or three settings might be used in the Monte Carlo analysis. Because aquifer properties are highly variable and uncertain, reasonable sets of aquifer properties were selected, based on hydrogeologic environment, from a hydrogeologic database.

Receptor Location (Drinking Water Wells). The sensitivity analysis (Section 4.3) showed that distance of a receptor from the contaminant source is an important influence on media concentration, especially for contaminants that strongly sorb to soil and aquifer materials. For the groundwater-to-drinking-water pathway, receptor location was represented as the distance and position, relative to a contaminant plume, of residential drinking water wells from the WMU. Because no data were readily available on the distance of CCW disposal sites from residential wells, EPA used data from a survey of well distances from MSW landfills. Whether or not this is an accurate representation of well distance for CCW landfills and surface impoundment is one of the larger uncertainties in this analysis. EPA believes that the MSW well distance distribution used is protective for CCW landfills and surface impoundments.

Location and Characteristics of Waterbodies. One aspect of the site configuration of particular relevance to the aquatic food chain modeling is the locations and characteristics of the waterbodies. The size of the waterbodies (and the distance from the WMU) affects constituent concentrations and loadings predicted for that waterbody. The location of the waterbody was based on an empirical distribution of measurements, taken from actual CCW sites, of the distance from the edge of the WMU to the nearest stream or lake. The uncertainty posed in this analysis is the sampling of this distribution as compared to a more certain measurement of the actual distance at each CCW site. Surface water variables, including flow and water quality parameters, were collected for the stream reach being modeled, or for a larger hydrologic region where data were not available for a particular reach.

Environmental Parameters. Uncertainties related to environmental parameters (soil, aquifer, surface water, climate data) have already been mentioned. The parameters with the largest impact on results are aquifer hydraulic conductivity and gradient, which are selected from a national database of aquifer properties.

Fish Bioconcentration and Bioaccumulation Factors. For fish consumption, exposure dose is calculated using BCFs to estimate the transfer of pollutants from environmental media into fish. Uncertainty is associated with models used to estimate BCFs for aquatic biota. The aquatic BCFs were developed based on total surface water concentrations and concentrations in aquatic biota.

4.4.3.4 Exposure and Risk Modeling Variables

Exposure parameters and benchmarks for human and ecological risk also contribute to parameter variability and uncertainty.

Human Exposure Factors. Individual physical characteristics, activities, and behavior are quite different, and thus the exposure factors that influence the exposure of an individual, including ingestion rate, body weight, and exposure duration, are quite variable. Exposure modeling relies heavily on default assumptions concerning population activity patterns, mobility, dietary habits, body weights, and other factors. The probabilistic assessment for the adult and child exposure scenario addressed the possible variability in the exposure modeling by using statistical distributions for these variables for each receptor in the assessment: adult and child resident and adult and child recreational fisher. Data on fish consumption rates are not available for children; thus the adult data were used for children in this analysis, which could overestimate risk from this pathway for children. For all exposure factors varied, a single exposure factor distribution was used for adults for both males and females. For child exposures, one age (age 1) was used to represent the age at the start of exposure, because this age group is considered to be most sensitive for most health effects.

The *Exposure Factors Handbook* (U.S. EPA, 1997c,d,e) provides the current state of the science concerning exposure assumptions, and it was used throughout this assessment to establish statistical distributions of values for each exposure parameter for each receptor. There are some uncertainties, however, in the data that were used. Although it is possible to study various populations to determine various exposure parameters (e.g., age-specific soil ingestion rates or intake rates for food) or to assess past exposures (epidemiological studies) or current exposures, risk assessment is about prediction. Therefore, long-term exposure monitoring in this context is infeasible.

Diet Assumptions for Ecological Receptors. National-scale assessments often assume maximum intake of contaminated prey in the diets of primary and secondary consumers (i.e., 100 percent of the diet originates from the contaminated area). Under field conditions, many receptors are opportunistic feeders with substantial variability in both the type of food items consumed as well as the geospatial patterns of feeding and foraging. The actual proportion of wildlife receptors' diets that would be contaminated depends on a number of factors such as the species' foraging range, quality of food source, season, intra- and interspecies competition. Consequently, the exclusive diet of contaminated food items tends to provide a very conservative estimate of potential risks.

Human Health Benchmarks. EPA routinely accounts for uncertainty in its development of RfDs and other human health benchmarks. For example, if certain toxicological data are missing from the overall toxicological database (e.g., reproductive data), EPA accounts for this by applying an uncertainty factor. In general, EPA human health benchmarks are derived using a health-protective approach.

Ecological Criteria. CSCLs were developed for constituents when sufficient data were available. In many cases, sufficient data were unavailable for a receptor/constituent combination, and therefore, the potential risk to a receptor could not be assessed. In particular, insufficient

data were available to derive chronic effects CSCLs for amphibians. Because the risk results can only be interpreted within the context of available data, the absence of data can not be construed to mean that adverse ecological effects will not occur.

In addition to the effects of data gaps on ecological benchmarks, the ecological criteria tend to be fairly conservative because the overall approach is based on "no effects" or "lowest effects" study data. In site-specific assessments, a *de minimis* effects approach is often replaced with an effects level similar to natural population variability (e.g., sometimes as high as a 20 percent effects level). As a result, the CSCLs used in this analysis are likely to overestimate risks for representative species and communities assumed to live in surface waters impacted by CCW WMUs. Because the difference between a lowest observed adverse effect level (LOAEL) and a NOAEL is often about a factor of 10, an HQ exceedance of roughly 10 may not be ecologically significant. In contrast, CSCLs based on no effects data that are developed for the protection of threatened and endangered species are presumed to be protective.

4.5 Summary and Conclusions

One of the most sensitive parameters in the risk assessment is infiltration rate. Infiltration rate is greatly influenced by whether and how a WMU is lined. The 1994 to 2004 DOE/EPA survey results (U.S. DOE, 2006) do not include how many unlined facilities are still operating today, but do indicate that more facilities are lined today than were in the 1995 EPRI survey data set on which this risk assessment is based. This suggests that the risks from future CCW disposal facilities are likely to be lower than the results presented in this report. EPA will continue to work to integrate the DOE/EPA survey data into the CCW risk assessment and is seeking comments on how to address data gaps, in particular: (1) how to estimate the overall prevalence of liners in the CCW disposal facilities today, (2) how to determine the area and capacity of newer CCW landfills and surface impoundments, and (3) how the liners currently in CCW WMUs perform when compared to the industrial liner conditions assumed in this risk assessment.

Composite liners, as modeled in this risk assessment, effectively reduce risks from all pathways and constituents below the risk criteria for both landfills and surface impoundments.[12] The CCW risk assessment suggests that the management of CCW in unlined landfills and unlined surface impoundments may present risks to human health and the environment. Risks from clay-lined units, as modeled, are about one-third to one-half the risks of unlined units, but are still above the risk criteria used for this analysis. These risk results are largely consistent with damage cases compiled by EPA (U.S. EPA, 2000, 2003e, 2007) and others (Lang and Schlictmann, 2004; Zillmer and Fauble, 2004; Carlson and Adriano, 1993). Key risk findings include the following:

- For humans exposed via the groundwater-to-drinking-water pathway, arsenic in CCW landfills poses a 90th percentile cancer risk of $5x10^{-4}$ for unlined units and $2x10^{-4}$ for clay-lined units. The 50th percentile risks are $1x10^{-5}$ (unlined units) and $3x10^{-6}$(clay-lined

[12] These results suggest that with the higher prevalence of composite liners in new CCW disposal facilities, future national risks from onsite CCW disposal are likely to be lower than those presented in this risk assessment (which is based on 1995 CCW WMUs).

units). Risks are higher for surface impoundments, with an arsenic cancer risk of $9x10^{-3}$ for unlined units and $3x10^{-3}$ for clay-lined units at the 90th percentile. At the 50th percentile, risks for unlined surface impoundments are $3x10^{-4}$, and clay-lined units show a risk of $9x10^{-5}$. Five additional constituents have 90th percentile noncancer risks above the criteria (HQs ranging from greater than 1 to 4) for unlined surface impoundments, including boron and cadmium, which have been cited in CCW damage cases referenced above. Boron and molybdenum show HQs of 2 and 3 for clay-lined surface impoundments. None of these noncarcinogens show HQs above 1 at the 50th percentile for any unit type.

- Arrival times of the peak concentrations at a receptor well are much longer for landfills (hundreds to thousands of years) than for surface impoundments (most less than 100 years).
- For humans exposed via the groundwater-to-surface-water (fish consumption) pathway, selenium (HQ = 2) and arsenic (cancer risk = $2x10^{-5}$) pose risks slightly above the risk criteria for unlined surface impoundments at the 90th percentile. For both constituents, lined 90th percentile risks and all 50th percentile risks are below the risk criteria. No constituents pose risks above the risk criteria for landfills at the 90th or 50th percentile.
- Waste type has little effect on landfill risk results, but in surface impoundments, risks are up to 1 order of magnitude higher for codisposed CCW and coal refuse than for conventional CCW.
- The higher risks for surface impoundments than landfills are likely due to higher waste leachate concentrations, a lower proportion of lined units, and the higher hydraulic head from the impounded liquid waste. This is consistent with damage cases reporting wet handling as a factor that can increase risks from CCW management.
- For ecological receptors exposed via surface water, risks for landfills exceed the risk criteria for boron and lead at the 90th percentile, but 50th percentile risks are well below the risk criteria. For surface impoundments, 90th percentile risks for several constituents exceed the risk criteria, with boron showing the highest risks (HQ = 2,000). Only boron exceeds the risk criteria at the 50th percentile (HQ = 4). Exceedances for boron and selenium are consistent with reported ecological damage cases, which include impacts to waterbodies through the groundwater-to-surface-water pathway.
- For ecological receptors exposed via sediment, 90th percentile risks for lead, arsenic, and cadmium exceeded the risk criteria for both landfills and surface impoundments because these constituents strongly sorb to sediments in the waterbody. The 50th percentile risks are generally an order of magnitude or more below the risk criteria.

Sensitivity analysis results indicate that for most of the scenarios evaluated (over 75 percent), the risk assessment model was most sensitive to parameters related to groundwater flow and transport: WMU infiltration rate, leachate concentration, and aquifer hydraulic conductivity and gradient. For strongly sorbing contaminants (such as lead and cadmium), variables related to sorption and travel time (adsorption coefficient, depth to groundwater, receptor well distance) are most important.

There are uncertainties associated with the CCW risk assessment, but scenario uncertainty (i.e., uncertainty about the environmental setting around the plant) has been minimized by basing the risk assessment on conditions around existing U.S. coal-fired power plants around the United States. Uncertainty in environmental setting parameters has been incorporated into the risk assessment by varying these inputs within reasonable ranges when the exact value is not known. Uncertainty in human exposure factors (such as exposure duration, body weight, and intake rates) has also been addressed through the use of national distributions.

Some uncertainties not addressed explicitly in the risk assessment have been addressed through comparisons with other studies and data sources.

- **Appropriateness of CCW leachate data.** Data on another highly sensitive parameter, leachate (porewater) constituent concentration, were available and used for CCW surface impoundments. However, available data for landfills were mainly TCLP analyses, which may not be representative of actual CCW leachate. Comparisons with recent (2006) studies of coal ash leaching processes show very good agreement for arsenic. However, although the selenium CCW data are within the range of the 2006 data, some of the higher concentrations in the 2006 data are not represented by the TCLP data. This suggests that selenium risks may be underestimated, which is consistent with selenium as a common driver of the damage cases.
- **Impacts of mercury rules (CAIR and CAMR).** While CAIR and CAMR will reduce emissions of mercury and other metals from coal-fired power plants, mercury and other more volatile metals will be transferred from the flue gas to fly ash and other air pollution control residues, including the sludge from wet scrubbers. EPA ORD has research underway to evaluate changes to CCW characteristics and leaching of mercury and other metals from CAIR and CAMR. Data from the first report (U.S. EPA, 2006) suggest that although total mercury will increase in CCW from the use of sorbents as mercury controls, the leachability of mercury may be reduced, but this work is ongoing and should be regarded as preliminary and limited at this time. For example, wet scrubbers have yet to be addressed, and initial data from both EPA and industry studies suggest that mercury may not be as stable as found from fly ash in the first report. As these data become available, EPA will consider how best to use them to update the existing risk assessment.
- **Mercury and nondetect analyses.** Because of a high proportion of nondetect values and a limited number of measurements, the risks from mercury in CCW could not be evaluated for either landfills or surface impoundments and for antimony and thallium in surface impoundments. The 2006 leaching study data suggest that mercury levels are fairly low in fly ash from coal combustion, but additional data and analyses would be required to estimate the risks from these levels.
- **Arsenic speciation.** The current model does not speciate metals in the subsurface, which is of particular concern for arsenic. Damage cases and other studies suggest that arsenic readily converts from arsenic III in CCW leachate to the less mobile arsenic V in soil and groundwater. However, model runs conducted for both species suggest that the difference in risk between the two species is only about a factor of 2, which is not enough to reduce the 90th percentile cancer risks to below the risk criteria.

Uncertainties that are more difficult to evaluate with respect to CCW risk results include the following:

- **Well distance.** Nearest well distances were taken from a survey of MSW landfills, as data were not available from CCW sites. EPA believes that this is a protective assumption because MSW landfills generally tend to be in more populated areas, but there are little data available to test this hypothesis.
- **Liner conditions.** Liner design and performance for CCW WMUs were based on data and assumptions EPA developed to be appropriate for nonhazardous industrial waste landfills. EPA believes that CCW landfills should have similar performance characteristics, but does not have the quantitative data to verify that.
- **Data gaps for ecological receptors.** Insufficient data were available to develop screening levels and quantitative risk estimates for terrestrial amphibians, but EPA acknowledges that damage cases indicate risk to terrestrial amphibian and plant communities through exposure to selenium and boron.
- **Ecosystems and receptors at risk.** Certain critical assessment endpoints were not evaluated in this analysis, including impacts on managed lands, critical habitats, and threatened and endangered species. These would be addressed through more site-specific studies on the proximity of these areas and species to CCW disposal units.
- **Synergistic risk.** The impact of exposures of multiple contaminants to human and ecological risks was not evaluated in this analysis. EPA recognizes that a single-constituent analysis may underestimate risks associated with multiple chemical exposures.

These are potentially the more significant uncertainties associated with the CCW risk assessment. Other uncertainties are discussed in Section 4.4.

Appendix A. Constituent Data

The coal combustion waste (CCW) risk assessment addresses metals and inorganic constituents identified by EPA as potential constituents of concern in CCW (Table A-1). U.S. Environmental Protection Agency (EPA) derived waste concentrations for these constituents from its CCW constituent database, which includes analyte concentration data in three tables representing different types of waste samples: landfill leachate analyses (in mg/L), surface impoundment and landfill porewater analyses (in mg/L), and analyses of whole waste samples (in mg/kg). Each database table specifies, for most samples, the type of waste sampled and the type of coal burned at the facility.

Table A-1. Constituents Addressed in the Screening Analysis

Constituent	CAS ID	Constituent	CAS ID
Metals		***Inorganic Anions***	
Aluminum	7429-90-5	Chloride	16887-00-6
Antimony	7440-36-0	Cyanide	57-12-5
Arsenic	7440-38-2	Fluoride	16984-48-8
Barium	7440-39-3	Total Nitrate Nitrogen	14797-55-8
Beryllium	7440-41-7	Phosphate	14265-44-2
Boron	7440-42-8	Silicon	7631-86-9
Cadmium	7440-43-9	Sulfate	14808-79-8
Chromium	7440-47-3	Sulfide	18496-25-8
Cobalt	7440-48-4	***Inorganic Cations***	
Copper	7440-50-8	Ammonia	7664-41-7
Iron	7439-89-6	Calcium	7440-70-2
Lead	7439-92-1	pH	12408-02-5
Magnesium	7439-95-4	Potassium	7440-09-7
Manganese	7439-96-5	Sodium	7440-23-5
Mercury	7439-97-6	***Nonmetallic Elements***	
Molybdenum	7439-98-7	Inorganic Carbon	7440-44-0
Nickel	7440-02-0	Total Elemental Sulfur	7704-34-9
Selenium	7782-49-2	***Measurements***	
Silver	7440-22-4	Total Dissolved Solids	none
Strontium	7440-24-6	Total Organic Carbon	none
Thallium	7440-28-0	Dissolved Organic Carbon	none
Vanadium	7440-62-2		
Zinc	7440-66-6		

A.1 Data Sources

EPA prepared the CCW constituent database in 2002 and 2003. The 2003 CCW constituent database includes all of the waste characterization data used by EPA in its risk assessments in support of the March 1999 *Report to Congress: Wastes from the Combustion of Fossil Fuels* (the RTC) (U.S. EPA, 1999). In addition to the data set from the March 1999 RTC, EPA supplemented the database with the following data:

- Data submitted with public comments to EPA on the 1999 RTC
- Data submitted with public comments to EPA concerning the May 22, 2000, Final Regulatory Determination
- Data collected by and provided to EPA since the end of the public comment period on the Final Regulatory Determination
- Data identified from literature searches.

The primary sources of these additional data include the electric power industry, state and federal regulatory agencies, and scientific literature. Attachment A-1 is a complete list of the sources of data contained in the 2003 CCW constituent database.

The additional data represent a significant expansion in the quantity of characterization data available to EPA for analysis. For example, the data set used for the risk assessments supporting the RTC covered approximately 50 CCW generation and/or disposal sites. With the addition of the supplemental data, the 2003 CCW constituent database now covers more than 160 sites. The 1999 data set included approximately 10,000 individual samples of CCW. The 2003 CCW constituent database now includes more than 35,000 individual samples.

The additional data also represent an expansion in the scope of characterization data available to EPA for analysis. The 1999 data were obtained exclusively from the electric power industry. As shown in Attachment A-1, the 2003 data set includes data from other sources, such as scientific literature and state and federal regulatory agencies. The 1999 data set included analyses of whole waste samples, surface impoundment and landfill porewater analyses, and analyses of extracts obtained using the Toxicity Characteristic Leaching Procedure (TCLP), the Synthetic Precipitation Leaching Procedure (SPLP), and Extraction Procedure (EP) Toxicity leaching methods. The 2003 data set adds analyses of actual landfill leachate (e.g., obtained from leachate collection systems), analyses of extracts obtained using other leaching methods (including higher retention time leaching methods), and porewater analyses.

The 2003 CCW constituent database represents CCW characteristics across a broad cross section of the generating universe. Not only does the database include data from a large number of sites, but these sites are distributed throughout the United States, as shown in Table A-2. The database includes data for all major types of CCW (i.e., fly ash, bottom ash, flue gas desulfurization [FGD] sludge, fluidized bed combustion [FBC] fly ash, and FBC bed ash), from mixtures of CCW types that are commonly created during disposal operations (e.g., combined fly ash and bottom ash), and from CCW mixed with coal refuse (a common disposal practice). Section A.2 discusses waste types in more detail.

Table A-2. States Included in the CCW Constituent Database

Alaska	Illinois	Maryland
Arkansas	Indiana	Michigan
California	Kentucky	Ohio
Colorado	Missouri	Oklahoma
Connecticut	North Carolina	Pennsylvania
Florida	North Dakota	Tennessee
Georgia	Nebraska	Texas
Hawaii	New Mexico	Wisconsin
Iowa	Louisiana	West Virginia

The database also includes data for CCW generated from combustion of all major coal ranks: bituminous, sub-bituminous, lignite, and anthracite. Although the database does include coal type designations for most of the entries, in many cases the type is not specified. In addition, many coal plants mix coal from different sources (e.g., eastern and western coals), depending on prices and the need to reduce sulfur levels. As a result, correlations of risk results with coal types may be difficult and may not produce significant results.

A.2 Data Preparation

Table A-3 lists the waste types evaluated in the CCW risk assessment, along with the number of sites representing each waste type in the CCW constituent database. Key steps in preparing these data for screening include (1) selection and grouping of waste types to be addressed, (2) selection of the analyte data to be used, and (3) processing of these data to develop the analyte concentrations for the screening analysis.

Table A-3. Waste Streams in CCW Constituent Database

Waste Type **Waste Streams**	**Number of Sites by Waste Type[a]**		
	Landfill Leachate	**Surface Impoundment Porewater**	**Total Waste**
Conventional Combustion Waste	*97*	*13*	*62*
Ash (not otherwise specified)	43	0	30
Fly ash	61	2	33
Bottom ash & slag	24	3	23
Combined fly & bottom ash	7	4	4
FGD sludge	4	6	5
Codisposed Ash & Coal Refuse	9	5	1
Fluidized Bed Combustion Waste	*58*	*0*	*54*
Ash (not otherwise specified)	18	0	10
Fly ash	33	0	32
Bottom and bed ash	26	0	25
Combined fly & bottom ash	20	0	22

[a] Site counts by waste type from leachate, porewater, and whole waste data tables in the 2003 CCW constituent database.

A.2.1 Selection and Grouping of Waste Types of Concern

The CCW constituent database contains a variety of waste types. Some selection and grouping of these types was appropriate so that the risk assessment could evaluate risks consistently for groups of wastes that are expected to behave similarly when disposed in landfills and surface impoundments.

Combustion ash types in the CCW constituent database include fly ash, bottom ash, bed ash, slag, combined fly and bottom ash, and coal ash not otherwise specified. Based on a statistical analysis that showed no significant difference in leachate and porewater chemistry, the analysis combines data for these ash types for landfills and surface impoundments. FGD sludge is also combined with these conventional combustion ash types based on insignificant differences in porewater chemistry and the fact that FGD sludge is usually codisposed with varying amounts of fly ash and bottom ash.

CCW porewater constituent data did show that FBC wastes and codisposed ash and coal refuse (coal waste from coal crushers and other coal preparation and handling operations[1]) differ significantly from coal combustion ash in their composition and leachate chemistry, so these wastes were addressed separately in the risk analysis. FBC waste chemistry is impacted by the limestone injected with coal in FBC units for sulfur capture and tends to be very alkaline with high levels of calcium and sulfate. Coal refuse is high in pyrite, which generates sulfuric acid when disposed. As a result, combustion wastes exhibit a lower pH when codisposed with coal refuse.

A.2.2 Selection of Appropriate Analyte Data

CCW analyte concentration data represent leachate from landfills and surface impoundments and whole waste in landfills, as follows:

- Whole waste analyte concentrations (in mg/kg) represent landfill waste.
- Analyte concentrations (in mg/L) in porewater sampled from surface impoundment sediments represent surface impoundment leachate.
- Analyte concentrations for extracts from leaching methods, analyses of actual landfill leachate, and landfill porewater analyses represent landfill leachate. Because the CCW constituent database includes analyte concentrations from several leaching methods, a decision hierarchy was used to select leachate analyses to use in the risk assessment (Table A-4).

As shown in Table A-4, the methods thought to best represent long-term waste monofill porewater composition (i.e., methods with long equilibration times and low liquid-to-solid ratios) represent only a few sites, with most sites having TCLP and/or SPLP measurements. To best represent CCW landfill waste concentration at a wide variety of sites, the hierarchy rank shown in Table A-4 was used to select the best method for a particular site. For sites where two or more

[1] Coal refuse is the waste coal produced from coal handling, crushing, and sizing operations. In the CCW constituent database, codisposed coal refuse includes “combined ash and coal gob”, “combined ash and coal refuse”, and “combined bottom ash and pyrites”.

methods are available in the same rank (which often occurs for SPLP and TCLP analyses), the screening analysis uses the method with the highest analyte concentrations. This ensures that the data used in the risk assessment are the best that are available and represent a broad variety of waste disposal conditions.

Table A-4. Comparison/Hierarchy of Leaching Methods for Landfills Represented in CCW Constituent Database

Method (Rank)	Description	Advantages	Disadvantages
Landfill leachate (1)	Direct samples of landfill leachate	Most representative of leachate chemistry	Low number of sites represented
Landfill porewater (1)	Direct porewater samples from landfill	Most representative of leachate chemistry	Low number of sites represented
High retention time and low liquid-to-solid ratio (L:S) methods (2)	Waste extractions with long equilibration times (days to weeks) and low L:S	Better representation of landfill equilibration times and L:S	Low number of sites represented
Low L:S methods (3)	Waste extractions with low L:S	Better representation of landfill L:S	Low number of sites represented; equilibrium times relatively short
High retention time methods (3)	Waste extractions with long equilibration times (days to weeks)	Better representation of landfill equilibration times	Low number of sites represented; L:S relatively high
TCLP (4)	Toxicity Characteristic Leaching Procedure waste extractions	Most representative in terms of number of sites, waste types covered	High L:S (20:1) can dilute leachate concentrations; short equilibration time (18 hours) may not allow equilibrium to develop; Na-acetate buffer can overestimate leaching for some constituents (e.g., Pb)
SPLP (4)	Synthetic Precipitation Leaching Procedure and other dilute water waste extractions	More representative in terms of number of sites, waste types covered; extract similar to precipitation	High L:S (20:1) can dilute leachate concentrations; short equilibration time (18 hours) may not allow equilibrium to develop

A.2.3 Development of Waste Constituent Concentrations

To allow risk assessment results to be organized by waste constituent and waste type, CCW data were processed to produce a single concentration per waste stream (surface impoundment porewater, landfill leachate, and landfill whole waste), analyte, and site for use in the risk assessment. Data processing to prepare these analyte concentrations for the CCW risk assessment involved two steps:

1. **Calculation of average constituent concentrations by site for landfill leachate, surface impoundment porewater, and total ash concentrations.** Site averaging avoids potential bias toward sites with many analyses per analyte. During site averaging, any separate waste disposal scenarios occurring at a site (e.g., non-FBC and FBC ash) were treated as separate "sites" and were averaged independently. This approach is consistent with that used in the 1998 CCW risk analysis. As in 1998, nondetects were averaged at one-half the reported detection limit.

2. **Selection of waste concentrations from site-averaged values.** For the Monte Carlo analysis, the analysis randomly selected, by waste type/waste management unit (WMU) scenario, site-averaged leachate concentrations. For landfills, a corresponding total waste analysis was pulled from the database or calculated from a constituent-specific relationship between landfill leachate and total waste analyses.

A.3 Constituent Screening and Selection

The CCW risk assessment employed two steps to narrow the list of CCW constituents for the full-scale Monte Carlo risk assessment. Two steps were conducted to focus the full-scale analysis on the CCW constituents of most concern:

1. **Hazard Identification**, which involved collection of existing human health and ecological benchmarks for the constituents of concern. Only chemicals with benchmarks moved on to risk screening.
2. **Constituent Screening**, which compared health-based concentration benchmarks against very conservative estimates of exposure concentrations (e.g., whole waste concentrations, leaching concentrations) to quickly and simply "screen out" constituents and exposure pathways of no significant concern.

During the hazard identification step of the CCW risk assessment, constituents of potential concern were first identified by searching, from EPA and other reputable sources, for human health and ecological benchmarks for each chemical in the CCW constituent database. Table A-5 shows the result of that search; of the 41 chemicals in the database, 26 chemicals were found to have benchmarks.

Table A-5. Toxicity Assessment of CCW Constituents

Constituent	CAS ID	HHB	EcoB	Constituent	CAS ID	HHB	EcoB
Metals				***Inorganic Anions***			
Aluminum	7429-90-5	✔	✔	Chloride	16887-00-6

HHB = human health effect benchmark; EcoB = ecological benchmark.
[a] Carcinogen.
[b] Safe Drinking Water Act Action Level only.

To further narrow the list of constituents, a screening analysis (RTI, 2002) was conducted that compared health-based concentration benchmarks against very conservative estimates of exposure concentrations (e.g., 95th percentile whole waste and leachate concentrations) to quickly and simply "screen out" constituents and exposure pathways posing no significant risk to human health or the environment. Based on the number of pathways with screening failures and how much each chemical exceeded a benchmark, the constituents failing this screen were divided into two groups: (1) those of marginal concern and (2) those of greater concern. Table A-6 shows each of these groups. Constituents of greater concern were subjected to the full-scale probabilistic risk assessment described in this document.

Table A-6. Screening Analysis Results: Selection and Prioritization of CCW Chemicals for Further Analysis

Analyte	Human Health – Drinking Water		Human Health – Surface Water[a]		Ecological Risk – Surface Water		Modeling Priority
	LF Rank [maxHQ]	SI Rank [maxHQ]	LF Rank [maxHQ]	SI Rank [maxHQ]	LF Rank [maxHQ]	SI Rank [maxHQ]	
Constituents of Greater Concern (Full-Scale Analysis)							
Arsenic[b]	1 [140]	1 [1,800]	2 [22]	5 [1.7]	7 [4.9]	3 [64]	1
Boron	6 [4.0]	3 [28]	-	-	2 [660]	1 [4,700]	1
Cadmium	7 [3.4]	7 [8.9]	5 [1.4]	4 [3.7]	11 [2.0]	9 [5.2]	1
Lead	4 [16]	5 [12]	-	-	3 [79]	4 [59]	1
Mercury	-	-	1 [700]	1 [65]	1 [1,400]	2 [132]	1
Selenium	11 [1.2]	13 [2.4]	4 [4.7]	3 [9.5]	8 [3.5]	8 [7.1]	1
Thallium	3 [21]	4 [19]	3 [6.3]	2 [5.7]	-	-	1
Aluminum	-	-	-	-	5 [12]	6 [27]	2
Antimony	2 [22]	10 [5.5]	-	-	-	-	2
Barium	-	-	-	-	4 [40]	7 [7.5]	2
Cobalt		6 [11]	-	-	-	5 [27]	2
Molybdenum	5 [4.2]	8 [6.8]	-	-	-	-	2
Nitrate/Nitrite	- / 12 [1.2]	2 [60]/ 15 [1.2]	-	-	-	-	2
Constituents of Marginal Concern							
Chromium VI	8 [2.3]	12 [4.2]	-	-	12 [1.8]	10 [3.3]	3
Fluoride	10 [1.8]	11 [5.2]	-	-	-	-	3
Manganese	13 [1]	9 [5.6]	-	-	-	-	3
Vanadium	9 [2.2]	14 [2.3]	-	-	10 [2.3]	12 [2.4]	3
Beryllium	-	-	-	-	9 [2.4]	-	4

Analyte	Human Health – Drinking Water		Human Health – Surface Water[a]		Ecological Risk – Surface Water		Modeling Priority
	LF Rank [maxHQ]	SI Rank [maxHQ]	LF Rank [maxHQ]	SI Rank [maxHQ]	LF Rank [maxHQ]	SI Rank [maxHQ]	
Constituents of Greater Concern (Full-Scale Analysis)							
Copper	-	-	-	-	14 [1.6]	11 [3.1]	4
Nickel	-	16 [1.3]	-	-	-	13 [1.4]	4
Silver	-	-	-	-	6 [11]	14 [1.4]	4
Zinc	-	-	-	-	13 [1.6]	-	4

LF = landfill; maxHQ = maximum hazard quotient; SI = surface impoundment.
[a] Fish consumption pathway.
[b] Arsenic values for human health are [excess cancer risk / target risk (1E-05)].

A.4 Results

Attachment A-2 provides the site-averaged constituent data used in the full-scale CCW risk assessment by waste type/WMU scenario.

Appendix B. Waste Management Units

The source models supporting the coal combustion waste (CCW) risk assessment require inputs describing the characteristics of CCW waste management units (WMUs). To satisfy this requirement, the assessment used a data set of WMU area, capacity, liner type, geometry, and waste type managed for a set of individual CCW landfills and surface impoundments that are representative of the national population of coal combustion facilities that are managing their wastes onsite.

The sources for these data sets were responses to two voluntary industry surveys: an Electric Power Research Institute (EPRI) comanagement survey (for conventional utility coal combustion WMUs units) and a Council of Industrial Boiler Owners (CIBO) fluidized bed combustion (FBC) survey (for FBC WMUs). In addition to the individual WMU data, certain assumptions were required regarding (1) liner types and characteristics, (2) surface impoundment operating life, and (3) above- and below-grade geometries for WMUs. The sections below describe the two industry surveys, then discuss the data sources and assumptions made.

B.1 EPRI Comanagement Survey

For conventional utility coal combustion WMUs, the source of data for area, capacity, liner type, and waste type managed was the EPRI Coal Combustion By-Products and Low-Volume Wastes Comanagement Survey (EPRI, 1997a). In 1995, EPRI sent a 4-page questionnaire to all electric utilities with more than 100 megawatts (MW) of coal-fired generating capacity. The survey gathered data on the design of coal combustion management units and the types and volumes of waste managed. From the survey responses, EPRI prepared an electronic database and provided it to the U.S. Environmental Protection Agency (EPA) in support of the March 1999 *Report to Congress: Wastes from the Combustion of Fossil Fuels* (the RTC) (U.S. EPA, 1999a). EPRI also published a report (EPRI, 1997a) documenting the survey format and providing a brief summary of the results.

The EPRI survey responses include information on 323 waste management facilities serving 238 power plants located in 36 states. The total annual volume of CCW reported disposed by respondents to the EPRI comanagement survey is nearly 62 million tons. This quantity is two-thirds of the total generation of CCW in 1995. Therefore, the survey sample encompasses the majority of CCW disposed in terms of volume. Based on comparison with data from other sources, the EPRI survey sample appears representative of the population of coal combustion WMUs in terms of the types of units included (i.e., landfills and surface impoundments). The EPRI survey sample also is believed to be generally geographically representative of the population of conventional utility WMUs, although it may under-represent certain management practices in a few states. The EPA document, *Technical Background Document for the Supplemental Report to Congress on Remaining Fossil Fuel Combustion Wastes: Industry Statistics and Waste Management Practices* (U.S. EPA, 1999b), discusses the

representativeness of the EPRI survey in greater detail and provides extensive summary statistics on the survey responses.

The EPRI comanagement survey includes questions requesting the respondent to report the location of the WMU (by state) and the WMU area, capacity, liner type, and waste type managed. Therefore, the data set used for modeling these variables was extracted directly from the EPRI database for all active landfills and surface impoundments responding to the EPRI survey. Mine placement sites and closed WMUs were excluded from the data set. Also excluded from the data set were three responding WMUs that managed FBC waste. Data for these units were instead combined with the data set for FBC WMUs from the CIBO FBC survey (described below).

The EPRI survey data were provided in blinded form. That is, the original database did not report the identity of each respondent and identified WMU location only by state. To provide a more complete identification of the EPRI waste management locations, each unit in the EPRI database had to be matched with a specific electric utility facility. This matching was accomplished by applying professional judgment in comparing the state, waste quantity, and waste management practice information in the EPRI database with similar data from responses to the U.S. Department of Energy's Energy Information Administration (EIA) Form EIA-767 (Steam-Electric Plant Operation and Design Report) for the same year as the EPRI survey (1995). The latitude and longitude plant locations in the EIA database allowed the pairing of the EPRI WMU data with environmental setting information.

B.2 CIBO Fluidized Bed Combustion Survey

For FBC WMUs, the primary source of data for area, capacity, liner type, and waste type managed was the CIBO Fossil Fuel Fluidized Bed Combustion (FBC) Survey. In 1996, CIBO sent a voluntary questionnaire to every fossil-fuel-fired FBC plant, both utility and nonutility, in the United States. This survey collected general facility information, characterized process inputs and outputs, gathered data on waste generation and characteristics, and captured details of FBC waste management practices. From the survey responses, CIBO prepared an electronic database and provided it to EPA in support of the March 1999 RTC. CIBO also published a report (CIBO, 1997) that includes documentation of the survey format and provides a brief summary of the results.

CIBO reports a total of 84 facilities using FBC technology. Forty-five of these responded to the CIBO FBC survey, with 20 of the respondents providing information about waste management practices. The facilities with waste management data cover 24 percent of all U.S. facilities using FBC. The CIBO sample is geographically representative of the full population, with the exception of two states that appear under-represented in the sample—Pennsylvania and Illinois. EPA's technical background document on industry statistics and waste management practices (U.S. EPA, 1999b) discusses the representativeness of the EPRI survey in greater detail and provides extensive summary statistics on the survey responses.

The CIBO survey includes questions requesting the respondent to report WMU area, capacity, liner type, and waste type managed. Therefore, the data set used for modeling these variables was extracted directly from the CIBO database. The CIBO respondents include both

utility and nonutility (i.e., industrial or institutional facilities that burn coal, but are not primarily engaged in the business of selling electricity) facilities. Because nonutilities are outside the scope of this risk assessment, nonutilities were excluded from the data set. Three additional utility facilities were excluded from the data set because their responses contained insufficient data on the variables of interest (area, capacity, liner type, and waste type). Mine placement sites also were excluded from the data set. Data for the FBC units responding to the EPRI survey (see above) were added to the data set. This resulted in a sample of seven FBC landfills and one FBC surface impoundment for modeling. Table B-1 compares this sample to the waste management practices of the full utility FBC population.

As shown in Table B-1, FBC facilities frequently avoid waste disposal units by directing all of their waste to mine placement or beneficial use. Therefore, although only 8 of the 41 utility FBC facilities are included in the model data set, these 8 facilities represent nearly all of the known FBC landfills and surface impoundments.

Table B-1. Utility FBC Waste Management Practices and Units Modeled

Number of Facilities...	Total	Landfill	Surface Impoundment	Minefill or Beneficial Use	Unknown
in the full population	41	11	1	16	13
modeled	8	7	1	Not applicable	Not applicable

The CIBO survey database identified the location of each WMU in detail (latitude and longitude). Therefore, no additional analysis was necessary to pair the WMU data with environmental setting information.

B.3 Liner Type

The EPRI survey data included information on the liner (if any) for each WMU. For this assessment, the WMUs were assigned to one of three liner scenarios based on the EPRI liner data: an unlined (no liner) scenario, a compacted clay liner, and a composite liner that combines a plastic (e.g., high-density polyethylene (HDPE) membrane) over either geosynthetic or natural clays. These three scenarios correspond to the following conceptual liner scenarios, developed in support of EPA's Industrial Subtitle D guidance (U.S. EPA, 2002), which can be selected in the landfill and surface impoundment models used in this assessment.

- **Unlined Scenario.** For landfills, waste is placed directly on local soils, either on grade or excavated to some design depth and without a leachate collection system. After the landfill has been filled to capacity, a 2-foot native soil cover (the minimum required by Subtitle D regulations) is installed and assumed to support vegetation. For surface impoundments, wastewater is placed directly on local soils, and the depth of water is constant over the entire life of the impoundment, pre- and post-closure. Sediments accumulate and consolidate at the bottom of the impoundment and migrate into the underlying native soils, where they clog pore spaces and provide some barrier to flow.

- **Clay Liner Scenario.** For landfills, waste is placed directly on a 3-foot compacted clay liner, which is installed on the local soils, either on grade or excavated to some design depth and without a leachate collection system. After the landfill has been filled to capacity, a 3-foot clay cover is installed and covered with 1 foot of loam to support vegetation and drainage. The hydraulic conductivity of both the liner and cover clays is assumed to be $1x10^{-7}$ cm/sec. For surface impoundments, wastewater is placed on a compacted clay liner, which is installed on the local soils. The assumptions for an unlined impoundment also apply to the compacted clay liner scenario, except that a compacted clay liner filters out the sediments that clog the native soils in the unlined case, so the effect of clogging the native materials is not included in the calculation of the infiltration rate. The thickness of the compacted clay liner was assumed to be 3 feet and the hydraulic conductivity was assumed to be $1x10^{-7}$ cm/sec.

- **Composite Liner Scenario.** For landfills, wastes are placed on a liner system that consists of a 60 mil HDPE membrane with either an underlying geosynthetic clay liner with a maximum hydraulic conductivity of $5x10^{-9}$ cm/sec, or a 3-foot compacted clay liner with a maximum hydraulic conductivity of $1x10^{-7}$ cm/sec. A leachate collection system is also assumed to exist between the waste and the liner system. After the landfill has been filled to capacity, a 3-foot clay cover is assumed to be installed and covered with 1 foot of loam to support vegetation and drainage. For surface impoundments, wastewater is placed on a synthetic membrane with an underlying geosynthetic or natural compacted clay liner with a hydraulic conductivity of $1x10^{-7}$ cm/sec. The membrane liner was assumed to have a number of pinhole leaks of uniform size (6 mm^2). The number of these leaks was based on an empirical distribution of membrane leak density values obtained from TetraTech (2001), as described in the *IWEM Technical Background Document* (U.S. EPA, 2002).

Table B-2 shows the crosswalk used to assign one of the three liner scenarios to each facility based on the liner data in the EPRI survey data (EPRI, 1997a). Attachment B-2 provides these assignments, along with the original EPRI liner type, for each CCW landfill facility modeled.

Table B-2. Crosswalk Between EPRI and CCW Source Model Liner Types

EPRI Liner Type	Model Liner Code	Description
Compacted ash	0	no liner
Compacted clay	1	clay
Composite clay/membrane	2	composite
Double	2	composite
Geosynthetic membrane	2	composite
None/natural soils	0	no liner

B.4 Surface Impoundment Operating Life

The model runs for surface impoundments required a general assumption about the length of the operating life for these WMUs. Of the surface impoundments in the EPRI comanagement survey, 86 provided responses to questions about both the unit's opening date and expected closure date. From these two dates, an expected operating life for each impoundment can be calculated. An additional 30 impoundments provided an opening date, but no closure date. One possible interpretation of these responses is that these facilities do not expect to close in the foreseeable future, corresponding to a very long or indefinite operating life with dredging of waste to maintain capacity. Figure B-1 shows the distribution of the calculated operating lives, along with a bar showing the facilities with no closure date.

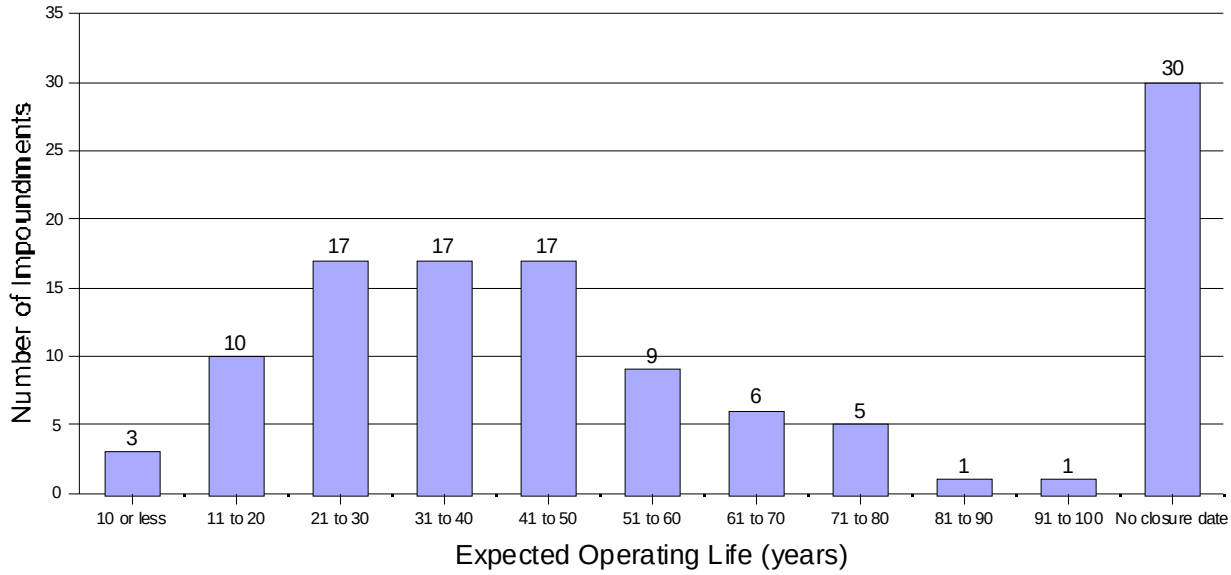

Figure B-1. Operating life of impoundments in the EPRI survey.

Based on these data, a 75-year operating life was chosen. This value corresponds to the 95th percentile of the observed distribution. While the use of a 95th percentile value may appear conservative, if many of the facilities with no closure date do, in fact, plan to operate indefinitely, 75 years would correspond to a much lower percentile in the distribution. More significantly, many CCW surface impoundments close with wastes in place. The selection of 75 years minimizes the underestimation of chronic risks for this scenario, given that EPA's Composite Model for Leachate Migration with Transformation Products (EPACMTP) surface impoundment model assumes clean closure after the operating life.

B.5 Above- and Below-Grade Geometry

The model runs for surface impoundments and landfills required general assumptions about the geometry of these units with respect to the ground surface (i.e., how much of the unit's depth is below grade). The CIBO FBC survey included data on this geometry, so, for FBC units, these data were extracted directly from the database along with the other individual WMU data

(e.g., capacity). The EPRI comanagement survey did not contain data describing above- and below-grade geometry. Therefore, for conventional utility coal combustion WMUs, EPA reviewed 17 site-characterization reports published by EPRI (EPRI 1991; 1992; 1994a,b; 1996a,b; 1997b-k) and determined an above- versus below-grade geometry for each unit described in those reports based on schematic diagrams and site descriptions. EPA also extracted data from another CIBO voluntary survey that covered conventional (non-FBC) nonutility coal combustors. Figures B-2 and B-3 display the distributions of the data thus collected.

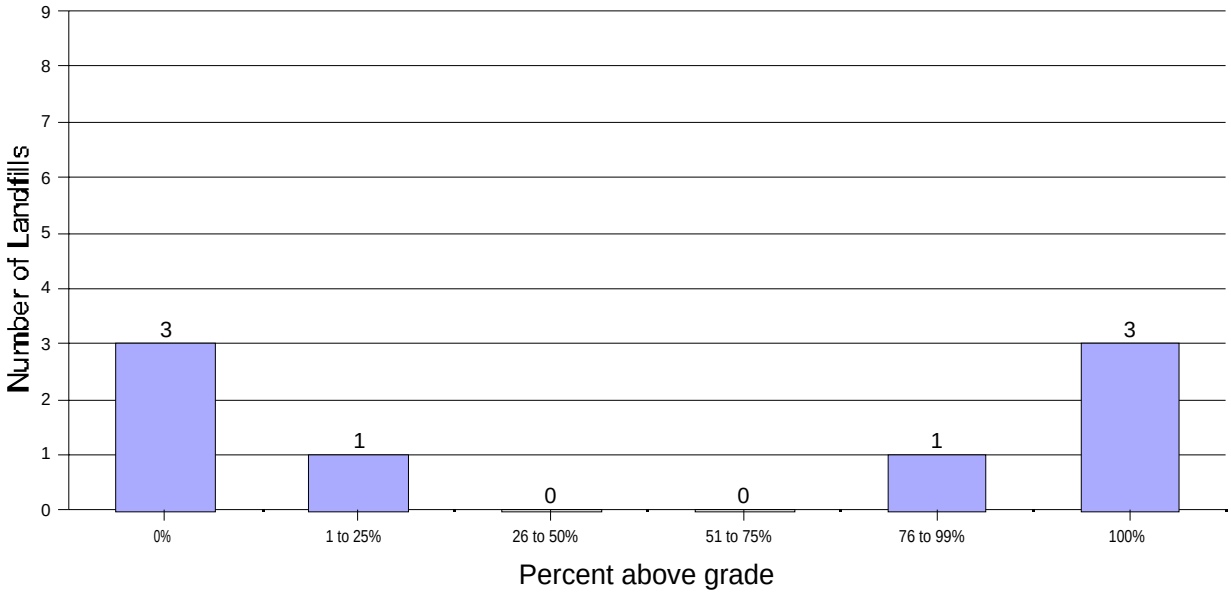

Figure B-2. Above- and below-grade geometry for landfills.

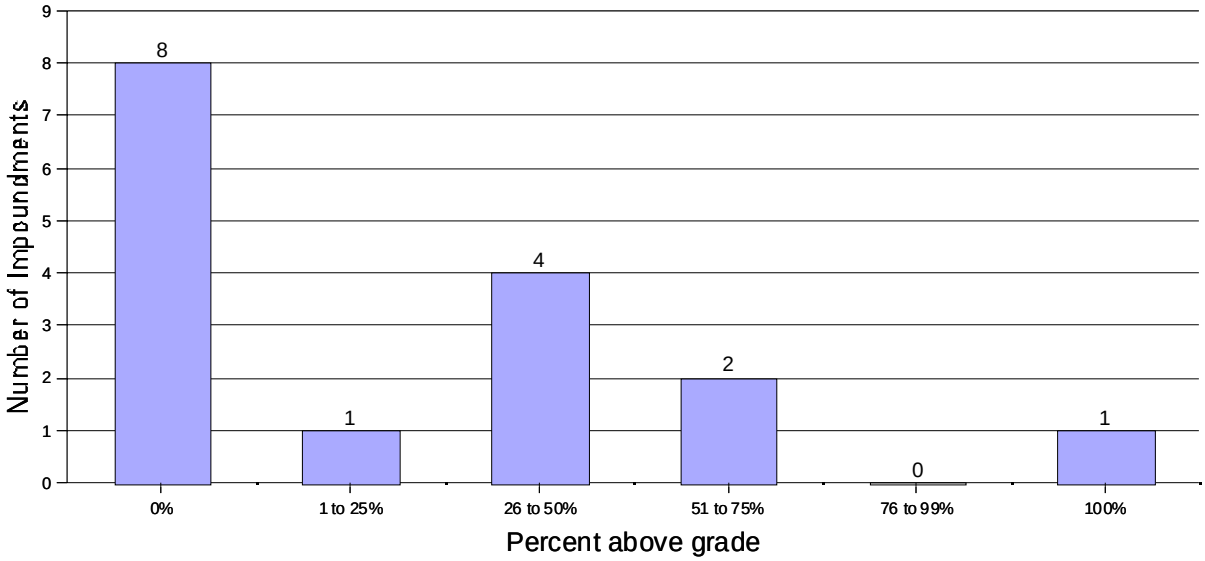

Figure B-3. Above- and below-grade geometry for impoundments.

For landfills, because the data were limited (8 sites), the model runs assume that the percent below grade ranges from 1 to 100 and is uniformly distributed. For each landfill iteration, a random value for percent below grade is picked and applied to the landfill depth to determine depth below ground surface. This value is constrained to be no deeper than the water table and is checked to see that EPACMTP groundwater mounding constraints are not violated.

For surface impoundments, more data were available (16 sites), with 8 sites being constructed entirely below grade and the remaining 8 sites ranging from 7.5 to 45 feet above grade. For each surface impoundment iteration, height above grade at these 15 sites is randomly sampled as an empirical distribution and applied to the overall surface impoundment depth to determine depth below ground surface.

B.6 Calculation of WMU Depth and Imputation of Missing WMU Data

The EPRI survey includes information on the total area and total waste capacity of each landfill and surface impoundment included in the survey. To calculate average depth for each WMU (a necessary EPACMTP model input), the total waste capacity was divided by the area. The resulting depths were then checked for reasonableness. For surface impoundments, one depth (1 foot) was culled as being unrealistically low and one (700 feet) as too high. Two landfill depths less than 2 feet and one depth greater than 350 feet were also removed from the database. In these cases the EPRI waste capacity data were culled and replaced using the regressions described below (i.e., WMU areas are considered more reliable than the capacity estimates in the survey data), and new capacities were estimated as described below.

In addition, four landfills and six surface impoundments had neither area nor capacity data in the EPRI survey. In these cases, the EIA facility locations were used to find the plants and their WMUs on aerial photos from the Terraserver Web site (http://terraserver-usa.com/geographic.aspx), and a geographic information system (GIS) was used to measure the areas of the units in question. Capacities were then estimated as described below.

To impute data for facilities missing either area or capacity data in the EPRI survey, linear regression equations were developed based on WMUs with both area and capacity data, one to predict area from capacity, and one to predict capacity from area. The final regression equations are shown in Figures B-4 and B-5 for landfills and Figures B-6 and B-7 for surface impoundments. In each case, a standard deviation around the regression line was also computed and used during source data file preparation to randomly vary the area or capacity from iteration to iteration within the bounds of the existing data set.

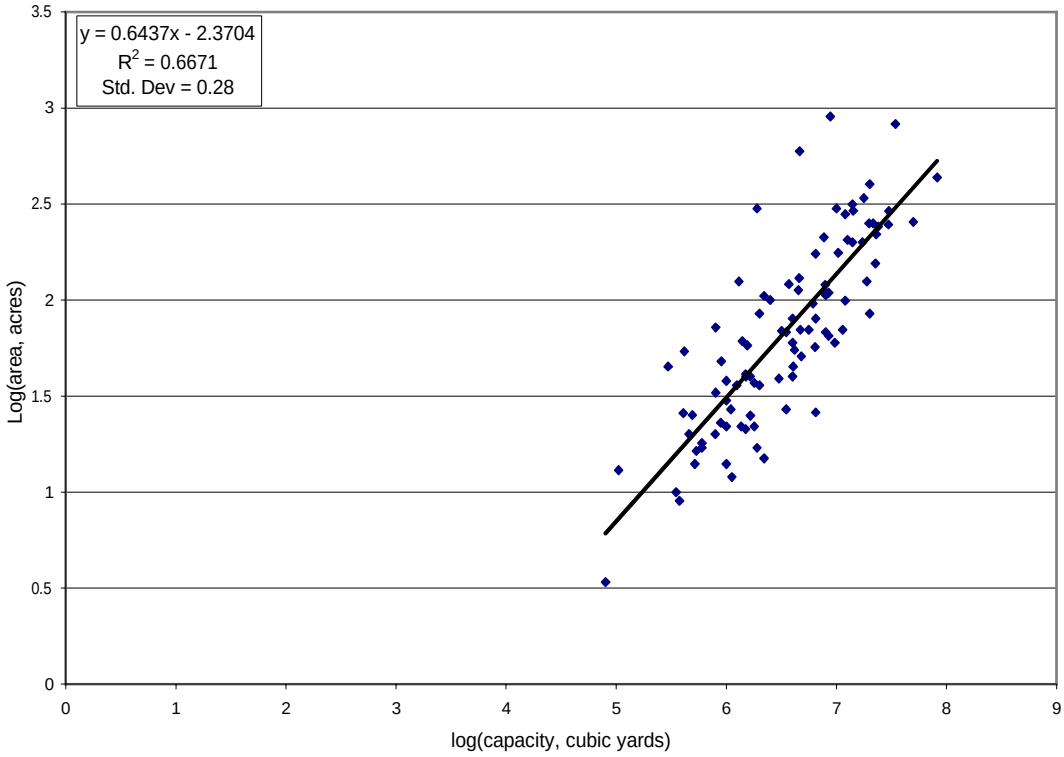

Figure B-4. Linear regression to impute landfill area from capacity.

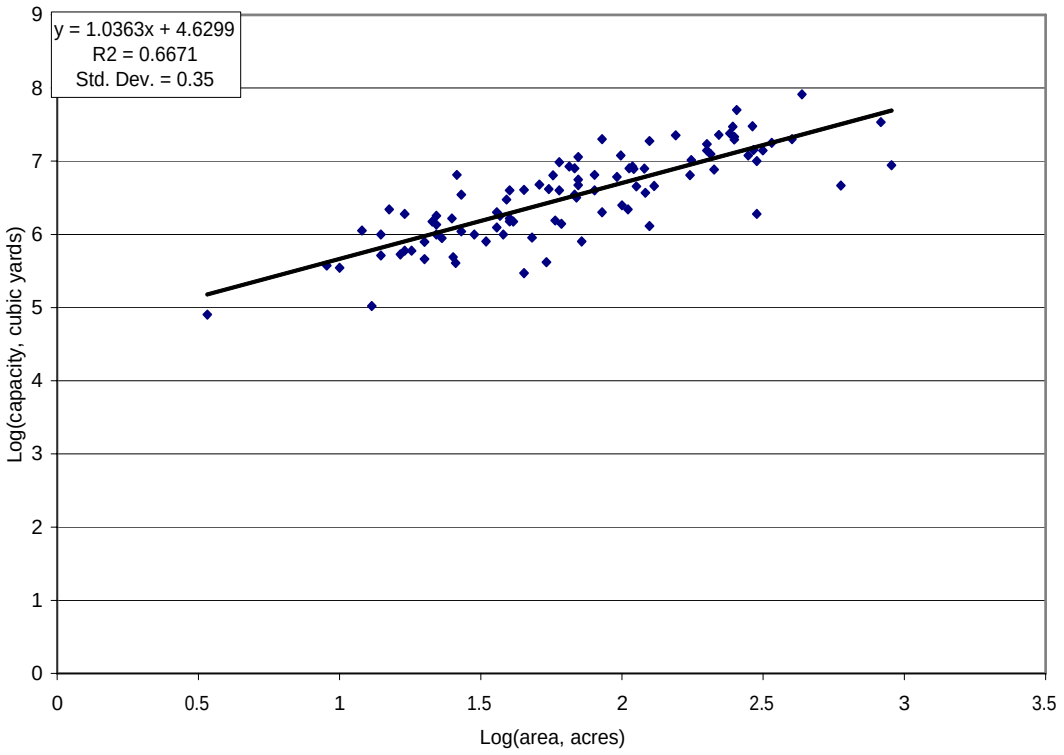

Figure B-5. Linear regression to impute landfill capacity from area.

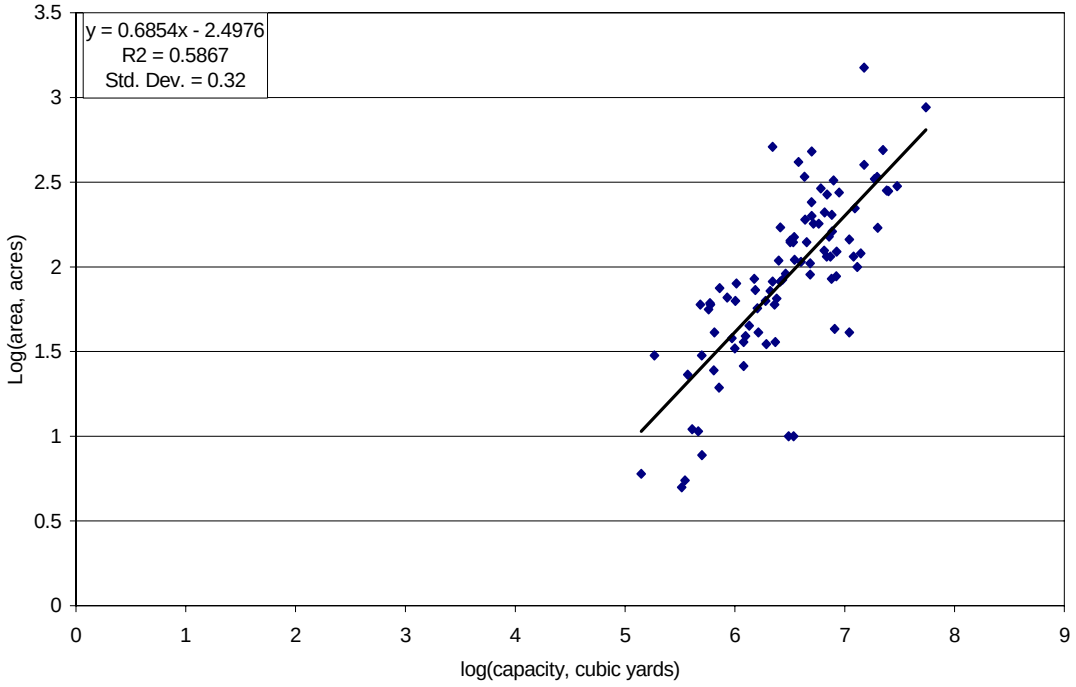

Figure B-6. Linear regression to impute surface impoundment area from capacity.

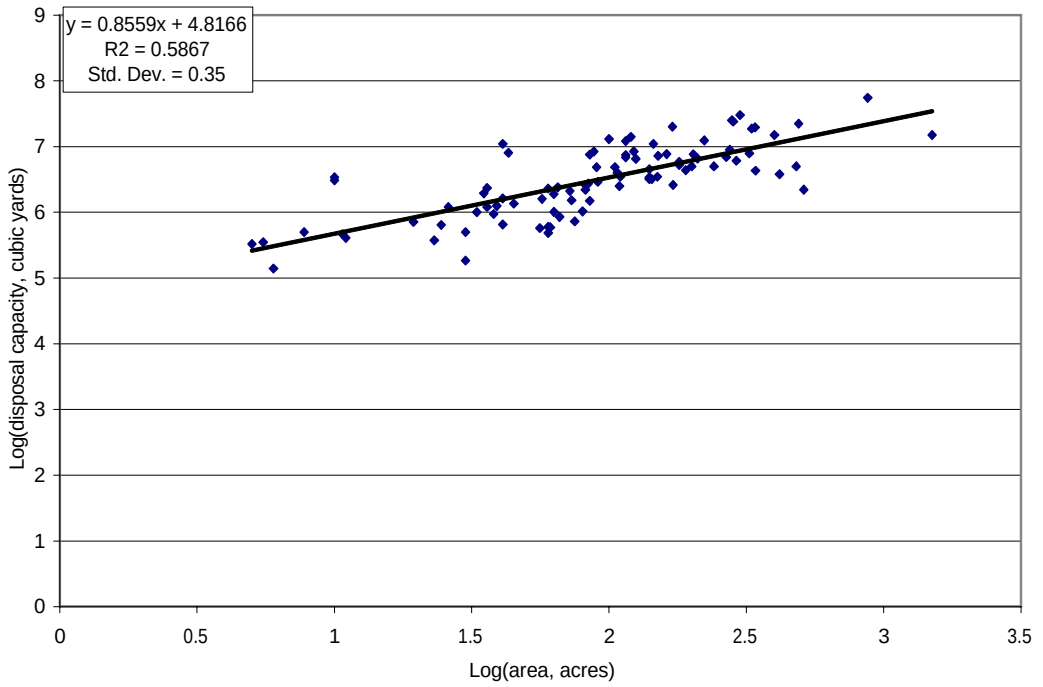

Figure B-7. Linear regression to impute surface impoundment capacity from area.

B.7 Results

Attachment B-1 lists the 181 CCW disposal sites modeled in this risk assessment and their locations. The WMU data used in the CCW risk assessment for each of the 108 landfills and 96 surface impoundments at these coal combustion facilities are presented in Attachment B-2. Missing data that were randomly replaced as described above are not represented in the table (i.e., the fields are left blank).

Appendix C. Site Data

The site characteristics used in this analysis were based on site-specific, regional, and national data sources to provide the environmental parameters necessary for modeling the fate and transport of coal combustion waste (CCW) constituents released in landfill or surface impoundment leachate. Site-specific data were collected for the area in the immediate vicinity of the waste management unit (WMU), and included the geographic relationship among important features such as the WMU boundary, residential well location, and streams and lakes. These data were collected at each of the 181 coal-fired power plants selected for the analysis. These 181 locations across the continental United States are intended to represent the geographic distribution of onsite WMUs used for disposal of CCW and were used to capture national variability in meteorology, soils, climate, aquifers, and surface waterbodies at the disposal sites.

C.1 Data Collection Methodology

The CCW risk assessment employed a site-based data collection method. This method used the CCW plant locations from the Energy Information Administration (EIA) database to obtain data for each facility that were representative of the environment immediately surrounding the plant. Depending on the availability of information, data were collected on either a site-specific, regional, or national scale. Where appropriate, distributions were used in the Monte Carlo analysis to capture site-to-site and within-site variability in the parameters collected.

Site-based data were collected using a geographic information system (GIS) that allowed (1) site-specific data to be assembled from the area immediately surrounding the facility and (2) the site to be assigned to a region to collect regional data. To account for locational uncertainty for the CCW WMUs[1], a 5-km radius was used to define the data collection area for aquifer type and soil data. If multiple soil or aquifer types occurred within this radius, multiple types were sent to the model, weighted by the fraction of the collection area that they occupied. Surface waterbody type and stream flows also were collected for each site by identifying the nearest stream segment.

Climate and water quality data were collected by assigning each site to a meteorological station and a U.S. Geological Survey (USGS) hydrologic region. The EPA STOrage and RETrieval (STORET) database was used as the source for water quality data, with parameters selected from distributions queried from this database for each region.

Because the EIA locations were not exact for the WMUs being modeled, a national distribution of stream distances was developed by manually measuring the distance between the WMU and the waterbody at a random sample of the CCW sites. Similarly, a national distribution

[1] The EIA latitudes and longitudes usually represent a facility centroid or front-gate location for each power plant. Because these facilities are often large, the WMUs are frequently located some distance from the plant itself and not at the EIA location.

was used to represent the distance of the nearest residential wells from the CCW WMUs being modeled.

C.2 Receptor Location (National Data)

The residential scenario for the CCW groundwater pathway analysis calculates exposure through use of well water as drinking water. During the Monte Carlo analysis, the receptor well is placed at a distance of up to 1 mile from the edge of the WMU, by sampling a nationwide distribution of nearest downgradient residential well distances taken from a survey of municipal solid waste landfills (U.S. EPA, 1988).

EPA believes that this MSW well-distance distribution (presented in Table C-1) is protective for onsite CCW landfills and surface impoundments at coal-fired utility power plants, but recognizes that this is a significant uncertainty in this analysis. Because CCW plants tend to be in more isolated areas than MSW landfills and because CCW WMUs tend to be larger than municipal landfills, EPA believes that the MSW well distance distribution is a conservative representation of actual well distances at CCW disposal sites. However, data on residential well distances from CCW landfills or surface impoundments will be needed to verify this hypothesis.

As discussed in Section 3.4.3, the groundwater model used in the CCW risk assessment places limits on the lateral direction from the plume centerline (i.e., angle off plume centerline) and depth below the water table to ensure that the well remains within the plume and at a depth appropriate for surficial aquifers across the United States. These limits are consistent with other recent national risk assessments conducted by EPA OSW and provide a protective approach to siting wells for this analysis.

C.2.1 Recreational Fisher and Ecological Risk Scenario (Distance to Waterbody)

The recreational fisher scenario was used to estimate risks to recreational fishers and their children who live in the vicinity of the CCW landfills and surface impoundments and catch and

consume fish from a waterbody located adjacent to the buffer. The waterbody was assumed to be a stream or lake located downwind of the WMU, beginning where the buffer area ends (see Figure 2-4), and was also used as the reasonable worst case aquatic system for the ecological risk assessment. Waterbody characteristics were determined based on site-specific, regional, or national data (as described in Section C.6), except for stream length, which was determined by the width of the plume as it intersects the waterbody.

The downgradient distance to the surface water body was determined from a national distribution developed by measuring this distance at 59 CCW landfill and surface impoundment sites randomly selected from the 204 WMUs modeled in this risk assessment. Table C-2 presents this distribution. Figure C-1 provides a map and aerial photo of one of the facilities used to develop this distribution. The development of this distribution is described in Section C.6.4.

C.3 Soil Data

The groundwater model used in the CCW risk assessment—EPA's Composite Model for Leachate Migration with Transformation Products (EPACMTP)—requires soil properties for the entire soil column to model leachate transport through the vadose zone to groundwater. As with aquifer type, soil data were collected within a 5-km radius of each CCW plant. A GIS was used to identify soil map units within a 20-mile radius around each meteorological station. Database programs were then used to assemble and process soil texture, pH, and soil organic matter data for these map units from the State Soil Geographic (STATSGO) database. Both pH and soil organic matter were processed and indexed by the soil textures present within the 5-km radius. Soil properties are listed by texture for each of the 181 CCW plants in Attachment C-1.

C.3.1 Data Sources

The primary data source for soil properties was the STATSGO database. STATSGO is a repository of nationwide soil properties compiled primarily by the U.S. Department of Agriculture (USDA) from county soil survey data (USDA, 1994). STATSGO includes a 1:250,000-scale GIS coverage that delineates soil map units and an associated database containing soil data for each STATSGO map unit. (Map units are areas used to spatially represent soils in the database.)

In addition, two compilations of STATSGO data, each keyed to the STATSGO map unit GIS coverage, were used in the analysis as a convenient source of average soil properties:

- **USSOILS.** The USSOILS data set (Schwarz and Alexander, 1995) averages STATSGO data over the entire soil column for each map unit.

- **CONUS.** The Conterminous United States Multi-Layer Soil Characteristics (CONUS) data set (Miller and White, 1998) provides average STATSGO data by map unit and a set of 11 standardized soil layers.

Soil organic matter and pH were derived directly from USSOILS and STATSGO data. A complete set of hydrological soil properties[2] was not available from STATSGO. To ensure consistent and realistic values, EPACMTP relies on established, nationwide relationships between hydrologic properties and soil texture. Peer-reviewed publications by Carsel and Parrish (1988) and Carsel et al. (1988) provide a consistent set of correlated hydrologic properties for each soil texture. Soil texture data for the entire soil column were collected from the CONUS database.

C.3.2 Methodology

The soil data collection methodology begins with GIS programs (in Arc Macro Language [AML]). These programs overlay a 5-km radius around each CCW plant location on the STATSGO map unit coverage to determine the STATSGO map units and their area within the radius. These data are then passed to data processing programs that derive soil properties for

[2] Hydrological soil properties required by EPACMTP include bulk density, saturated water content, saturated hydraulic conductivity, and the van Genuchten soil moisture retention parameters alpha and beta.

each site, either through direct calculations or by applying established relationships in lookup tables.

EPACMTP utilizes three soil textures to represent variability in hydrologic soil properties and (along with climate data) to assign infiltration rates to each site. Because STATSGO soils are classified into the 12 U.S. Soil Conservation Service (SCS) soil textures, the crosswalk shown in Table C-3 was used to assign the SCS textures to the EPACMTP megatextures and to calculate the percentage of each megatexture within the 5-km data collection radius. These percentages were sampled for each site when preparing the source data file for each site.

Both soil pH and soil organic matter were derived for each EPACMTP soil megatexture at a site. During source data file preparation, when a megatexture was picked for a particular iteration of a site, the corresponding pH and organic matter values were selected as well.

Table C-3. EPACMTP Soil Texture Crosswalk

C.3.3 Results

Attachment C-1 lists the STATSGO soil textures and EPACMTP megatexture assignments and percentages for each CCW disposal site.

C.4 Hydrogeologic Environments (Aquifer Type)

To assign aquifer properties used by EPACMTP, it was necessary to designate hydrogeologic environments (or aquifer types) for each of the locations modeled so that correlated, national aquifer property data could be used in the analysis. EPACMTP uses the Hydrogeologic Database (HGDB) developed by the American Petroleum Institute (API) (Newell et al., 1989; Newell et al., 1990) to specify correlated probability distributions, which are used to populate the following four hydrogeologic parameters during the Monte Carlo analysis:

- Unsaturated zone thickness
- Aquifer thickness

- Hydraulic gradient
- Saturated hydraulic conductivity.

The HGDB provides correlated data on these hydrogeologic parameters and an aquifer classification for approximately 400 hazardous waste sites nationwide, grouped according to 12 hydrogeologic environments described in Newell et al. (1990). The *EPACMTP User's Guide* (U.S. EPA, 1997) provides the empirical distributions of the four hydrogeologic parameters for each of the hydrogeologic environments.

Average aquifer/vadose zone temperature was also required for the groundwater model and was obtained from a digitized map of groundwater temperatures for the continental United States from the *Water Encyclopedia* (van der Leeden et al., 1990).

The hydrogeologic environment approach to assigning EPACMTP aquifer variables relies upon a hydrogeologic framework originally developed for an attempt by EPA to classify and score groundwater environments according to their potential to be polluted by pesticide application. Although this DRASTIC[3] scoring system was not widely applied to determining groundwater vulnerability to pesticide pollution, the hydrogeologic framework established for the effort has proven very useful in categorizing geologic settings in terms of the aquifer characteristics needed for groundwater modeling. The major components of this modeling framework are Groundwater Regions, hydrogeologic settings, and hydrogeologic environments, as described below:

- The fifteen **Groundwater Regions**, defined by Heath (1984), provide a regional framework that groups hydrogeologic features (i.e., nature and extent of dominant aquifers and their relationship to other geologic units) that influence groundwater occurrence and availability.

- **Hydrogeologic settings** were developed within each Heath region by Aller et al. (1987)[4] to create mappable geological units that are at the proper scale to capture differences in aquifer conditions. Note that there may be the same or similar settings across different regions (e.g., the alluvial settings). Within each region, Aller et al. (1987) describe each setting with a written narrative and provide a block diagram to visualize the geology, geomorphology, and hydrogeology.

- **Hydrogeologic environments** were developed by Newell et al. (1990) as the geologic framework for the API's HGDB. To create the 12 environments, Newell et al. rolled up similar hydrologic settings across the Groundwater Regions to group settings with similar aquifer characteristics (hydraulic conductivity, gradient, thickness, and depth-to-water). Table C-4 shows the crosswalk between hydrologic environment and hydrogeologic setting, organized by Groundwater Region.

[3] The DRASTIC scoring factors are Depth to water, net Recharge, Aquifer media, Soil media, Topography, Impact of the vadose zone media, and aquifer hydraulic Conductivity.

[4] Aller et al. (1987, p. 14) did not develop settings for Region 15 (Puerto Rico and the Virgin Islands) and reincorporated Region 12 (Alluvial Valleys) into each of the other regions as "river alluvium with overbank deposits" and "river alluvium without overbank deposits."

Because EPACMTP utilizes the HGDB for national and regional analyses (using a regional site-based approach), it was necessary to assign the CCW sites to a hydrogeologic environment so that the correct HGDB data set will be used for modeling each site. The data sources and methodology used to make these assignments are described below.

C.4.1 Data Sources

Data sources used to make hydrogeologic assignments for the sites include:

- A USGS inventory of state groundwater resources (Heath, 1985)
- GIS coverages from *Digital Data Sets Describing Principal Aquifers, Surficial Geology, and Ground-Water Regions of the Conterminous United States* (Clawges and Price, 1999a-d)
- GIS coverages of principal aquifers from the USGS *Groundwater Atlas* (Miller, 1998)
- STATSGO soil texture data (described in Section C.3.2).

These coverages were used in a GIS overlay process to determine the principal aquifers, surficial geologic units, groundwater region, productive aquifers, and general hydrogeologic settings for a 5-km radius around each CCW facility location. Attributes for each of these items were passed to a database for use in assigning hydrogeologic environments.

C.4.2 Assignment Methodology

For each CCW site, hydrogeologic environments were assigned by a professional geologist as follows:

- Determine Heath Groundwater Region (for the Alluvial Valleys region, determine the region in which the alluvial valley is located)
- Assign hydrogeologic setting using state geological descriptions from Heath (1985); aquifer, soil, and surficial geology information obtained using GIS; and narratives and block diagrams from Aller et al. (1987)
- Using the look-up table from Newell et al. (1990), determine hydrogeologic environment from hydrogeologic setting.

In general, the surficial geology coverage had better resolution than the aquifer coverages and was used to develop setting percentages for the 5-km radius. In most cases, there were two settings per site. In cases where a single setting accounted for over 80 percent of the 5-km area, a single setting was assigned.

Because Newell et al. (1990) define two alluvial environments (6, River alluvium with overbank deposits, and 7, River alluvium without overbank deposits), it was necessary to determine which environment an alluvial site fell into. The survey soil layer information was used to distinguish between these two settings by determining whether there were significant fine-grained overbank deposits in the soil column.

Quality assurance/quality control (QA/QC) measures included independent review of the assignments by other geologists with expertise in assigning settings.

C.4.3 Data Processing

HGDB hydrogeologic environment fractions (i.e., the portion of the region assigned to each of the 12 hydrogeological environments) were defined and used in the CCW risk assessment as follows. If the 5-km radius around a site contained only one HGDB environment, the fraction assigned was 1.0 and all groundwater model runs for this location were associated with that hydrological environment. If more than one HGDB environment was present, each environment was assigned a fraction based on the areal percentages of each setting within the 5-km radius.

These fractions were used to generate the hydrogeologic environment for that location for each iteration of the Monte Carlo groundwater modeling analysis. For example, if two hydrogeologic environments were assigned to a CCW site with a fraction of 0.5, half of the realizations would be modeled with the first hydrogeologic environment and half with the second.

Once the hydrogeologic environments were assigned, a preprocessing run of EPACMTP was conducted to construct a set of randomly generated but correlated hydrogeologic parameter values for each occurrence of the hydrogeologic environments in the source data files. Missing values in the HGDB data set were filled using correlations, as described in U.S. EPA (1997).

C.4.4 Results

Attachment C-2 lists the hydrogeologic environment assignments for each CCW disposal site. Table C-4 summarizes these results showing the crosswalk between Groundwater Regions, hydrogeologic settings, and hydrogeologic environments used to make the assignments, along with the number of CCW sites for each setting. Table C-5 totals the number of CCW disposal sites for each hydrogeologic environment sent to EPACMTP.

Table C-4. Groundwater Regions, Hydrogeologic Settings, and Hydrogeologic Environments: CCW Disposal Sites

Hydrogeologic Setting		Hydrogeologic Environment	Number of CCW Sites
Alluvial Basins			
2C	Alluvial Fans	5	1
2E	Playa Lakes	5	1

11	Coastal Beaches	1
12	Solution Limestone	20

C.5 Climate Data

The CCW risk assessment selected EPACMTP meteorological (or climate) stations for each CCW disposal site to collect the climatic data necessary for fate and transport modeling. For each station, the following data were compiled:

- Mean annual windspeed
- Mean annual air temperature
- Mean annual precipitation.

With respect to precipitation, EPACMTP uses the climate station, along with soil texture, to select the HELP- (Hydrologic Evaluation of Landfill Performance-) modeled infiltration rates to use in the landfill source model and recharge rates to use in EPACMTP (see Section 3.2.2). The surface water model uses mean annual windspeed and average air temperature to estimate volatilization losses from the surface waterbodies modeled in the analysis.

To assign the EPACMTP climate centers to each CCW site, a GIS was used to determine the three meteorological stations closest to the plant. These assignments were passed to a meteorologist, who reviewed the closest stations against plots of the CCW sites and the climate centers on a downloadable map (http://www.nationalatlas.gov/prismmt.html) of annual average precipitation rates for the period from 1961 to 1990 across the contiguous United States. (Figure C-2). The meteorologist compared the 5-year average precipitation range for each EPACMTP climate center to precipitation ranges for each plant from the map. In most cases, the precipitation rate for the nearest climate center fell within the site's expected precipitation range, and the nearest climate center was assigned in those cases. In some cases, the precipitation rates from the nearest climate center did not fall within the site's expected range. When this occurred, the second or third closest climate center was examined and matched based on:

- A 5-year precipitation average within or close to the site's predicted precipitation range

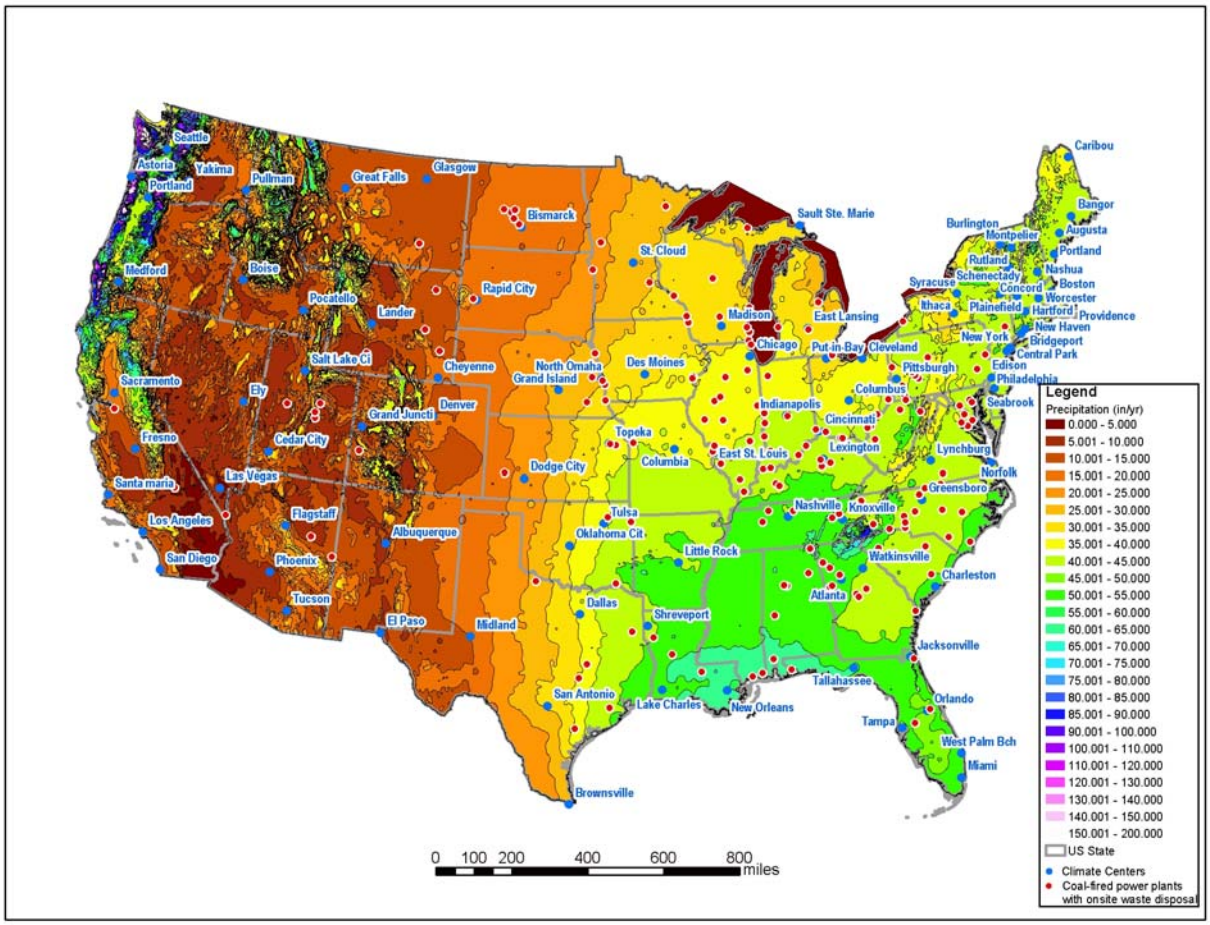

Figure C-2. EPACMTP climate centers, precipitation ranges, and CCW disposal sites.

- Confirmation of a site's average annual rainfall on http://www.weather.com and van der Leeden et al. (1990)
- Geographic similarities between plant and climate center locations
- Best professional judgment.

In a few cases, the three closest climate centers did not reflect the average precipitation rates for a plant's location. In these cases, other nearby stations were examined and the plant was assigned to the closest climate center with similar geography and average precipitation rates. Each assignment was independently checked for accuracy. Attachment C-3 lists the climate center assigned to each CCW disposal site, along with notes for plants not assigned to the nearest center. Table C-6 lists all the climate centers used in the CCW risk assessment along with the number of CCW sites assigned to each station.

Table C-6. EPACMTP Climate Centers Assigned to CCW Disposal Sites

C.6 Surface Water Data

The surface water model used in the CCW risk assessment requires information on surface waterbody type (river or lake), flow conditions, dimensions, and water quality. In addition, the groundwater model requires the distance between the waterbody and the WMU being modeled. Surface waterbody data were collected on a site-based, regional, or national basis depending on the variable and data availability. Collection methods are described below by data source. Attachment C-4 provides a summary of waterbody assignments, waterbody types, and flow conditions.

C.6.1 Waterbody Type, Stream Flow Conditions, and Dimensions

Waterbody type and flow parameters were obtained by matching the CCW plants to stream segments in the Reach File Version 1.0 (RF1) database (U.S. EPA, 1990). Stream flow estimates for all RF1 flowing reaches were estimated in the early 1980s. Statistics developed for each flowing reach are mean annual flow, low flow (approximately $7Q10^5$), and mean monthly flow. RF1 also contains velocities corresponding to mean annual and low flow, estimated from a compendium of time-of-travel studies. For streams and rivers, the CCW risk assessment used the low flow statistic and the corresponding flow velocity, along with a waterbody type also included in the RF1 database. All RF1 data are indexed by USGS cataloging unit and stream segment (CUSEG).

To assign the CCW plants to the nearest downgradient reach (i.e., the nearest waterbody in the direction of groundwater flow), a GIS was used to identify the closest RF1 stream segment to each CCW plant location. Because of several uncertainties in the nearest reach approach (i.e., inaccurate WMU location, unknown direction of groundwater flow, and limited lake coverages), the CCW plants also were matched to standard industrial classification (SIC) code 4911 facilities

[5] The minimum 7-day average flow expected to occur within a 10-year return period (i.e., at least once in 10 years).

in EPA's Permit Compliance System (PCS) database (http://www.epa.gov/enviro/html/pcs/index.html), to obtain the PCS information (e.g., name, CUSEG) on the receiving waterbody for the plants' National Pollutant Discharge Elimination System (NPDES) discharge point(s). When the two sources matched, the reach was selected for modeling. When they differed, the PCS data were used, because it was judged more likely that the NPDES receiving waterbody would also be receiving loads from the WMU through the groundwater-to-surface-water pathway. CCW plants that could not be matched to the PCS database were simply assigned the nearest RF1 waterbody.

The next step in the assignment process was to review the waterbody names (especially those from PCS) to identify lakes and reservoirs. Finally, visual review, using aerial photos and topographic maps from the Terraserver Web site (http://terraserver.usa.com), was used to check all low-flow streams and RF1 reaches whose identity was not clear. Attachment C-4 provides the RF1 stream assignments, flows, and waterbody types for the CCW disposal sites.

With respect to waterbody type, the RF1 data include several types of waterbodies, including streams and rivers, and types with zero flows such as lakes, Great Lakes, wide rivers, and coastline features. Each of these waterbody types needed to be designated as a river or a lake for the simple waterbody model used in the full-scale CCW risk assessment. Because only the streams and rivers have flow data in RF1 (i.e., are flowing reaches), all other types were assigned to the lake modeling category. Modeling these features as a simple model lake is a considerable uncertainty in the CCW risk assessment and risk results for these waterbodies should be regarded as preliminary until a more sophisticated surface water model can be parameterized for these special cases. Table C-7 lists the RF1 waterbody types for the waterbodies assigned to the CCW disposal sites, along with the number of CCW plants assigned to each type and the crosswalk to the river (R) or lake (L) waterbody type used in this risk assessment.

Table C-7. RF1 Reach Types Assigned to CCW Disposal Sites

RF1 Code	RF1Name	Description	Reach Model Type[a]	Number of CCW Plants
Flowing Reaches				
M	Artificial Open Water Reach	An artificial reach within any open water, other than a lake or reservoir, to provide connection between input and output reaches of the open water.	R	1
R	Regular Reach	A reach that has upstream and downstream reaches connected to it and that is not classified as another type of reach.	R	106
S	Start Reach	A headwater reach that has no reaches above it and either one or two transport reaches connected to its downstream end.	R	16
T	Terminal Reach	A reach downstream of which there is no other reach (for example, a reach that terminates into an ocean, a land-locked lake, or the ground). This type of reach has either one or two reaches connected to its upstream end.	R	2

(continued)

Table C-7. (continued)

RF1 Code	RF1Name	Description	Reach Model Type[a]	Number of CCW Plants
Reaches with Zero RF1 Flow				
C	Coastal/Continental Shoreline Segment	A reach that represents a segment of a shoreline of a gulf, sea, or ocean.	L	3
G	Great Lakes Shoreline Segment	A reach that represents a segment of a shoreline of the Great Lakes.	L	12
L	Lake Shoreline Segment	A segment that follows the shoreline of a lake other than one of the Great Lakes.	L	36
W	Wide-River Shoreline Segment	A reach that represents a segment of the left or right bank of a stream.	L	5

[a] R = river; L = lake.

Stream dimensions were calculated from the flow data as follows. First, the length of the modeled stream segment was set to be the width of the groundwater plume as it enters the waterbody. Stream width was then determined from flow (Q) using a liner regression equation derived from empirical data by Kocher and Sartor (1997):

$$Width = 5.1867Q^{0.4559} \quad \text{(C-1)}$$

Water column depth (dwc) was derived from width, velocity (V), and flow using the continuity equation:

$$dwc = \frac{Q}{v \times Width} \quad \text{(C-2)}$$

C.6.2. Lake Flow Conditions and Dimensions

Areas and depths for many of the lakes assigned to the CCW plant sites were not readily available from RF1, Reach File Version 3 (RF3), the National Hydrography Dataset (NHD), or other sources. In addition, many plants are located on very large waterbodies (e.g., the Great Lakes, wide rivers, or coastlines) where applying the simple steady-state, single-compartment model used in this analysis to the entire lake would not be appropriate. For these reasons, a model lake approach was used to represent all lakes and other nonflowing waterbodies assigned to the CCW disposal site.

The model lake chosen was Shipman City Lake in Illinois, a well-characterized 13-acre lake that EPA has chosen as the index reservoir for modeling drinking water exposures to pesticides (Jones et al., 1998). The parameter values shown in Table C-8 for Shipman City Lake were used to model all lakes in this initial analysis. Given that many of the lakes assigned to CCW plants are much larger than 13 acres, this will produce conservative risk results. However, given that many of the plants are located on very large waterbodies, this necessary simplification is one of the largest uncertainties in defining the environmental settings for the CCW risk

assessment. Options can be developed to more accurately parameterize and model such large nonflowing waterbodies.

Table C-8. Model Lake Used in CCW Risk Assessment

Parameter	Value
Area [a]	13 acres
Water column depth (dwc)[a]	9 feet
Hydraulic residence time (HRT)	Random, triangular distribution: Minimum = 1 month Mean = 6 months Maximum = 24 months
Annual flow mixing volume	= (Area × dwc) / HRT

[a] Source: Shipman City Lake, IL (Jones et al., 1998).

C.6.3 Water Quality Data

Surface water temperature, total suspended solids (TSS), and pH data were collected by USGS hydrologic region from the STORET database. EPA's STORET system is the largest single source of water quality data in the country. The Legacy STORET database contains over 275 million analyses performed on more than 45 million samples collected from 800,000 stations across the United States for the period 1960 through 1998. STORET can be accessed from the Web at http://www.epa.gov/OWOW/STORET.

STORET water quality data are notoriously "noisy" because they are influenced by hydrology, point sources, nonpoint sources, stream/lake morphology, and varying data quality. The following issues in using STORET data must be considered before using the data:

- Not all of the data have undergone rigorous QA/QC.
- STORET site locations can be biased, especially to known "problem" waters.
- The sample times are often at critical periods, such as summer low flows.

Statistical analysis techniques were employed taking into account the above issues (including coordination with gage statistical analysis and Reach Files, the use of median values to avoid bias in central tendency estimates, and specification of a minimum number of measurements to estimate median values). As a result of these techniques, which can be thought of as extracting the underlying "signal" of water quality from the inherent "noise" of water quality data, the above issues were manageable.

Surface water temperature data were collected as median values for each hydrologic region. These data are shown in Table C-9 along with the number of the modeled CCW plants in each region.

Table C-9. Regional Surface Water Temperatures: CCW Disposal Sites

Hydrologic Region	Surface Water Temperature (°C)	Number of CCW Plants
2	16	12
3	21	37
4	14	14
5	17	43
6	18	6
7	15	20
8	20	2

11	17	8
12	21	6
14	9	5
15	17	4
16	9	1
18	15	2

Data source: Legacy STORET database.

Total suspended solids data were collected separately for streams/rivers and lakes because lakes tend to have lower TSS levels. Annual median values were used to develop statistics. For rivers, the minimum, maximum, and geometric mean values were used to define log triangular distributions for each hydrologic region (Table C-10); these distributions were then sampled during the preparation of the source data files. (The geometric means were weighted by the annual number of measurements.) For lakes, data were limited and national statistics were developed, with the geometric mean of the median values being weighted by the number of measurements per year and the number of annual values in each region.

Table C-10. Surface Water Total Suspended Solids (TSS) Distributions

Hydrologic Region	Number of CCW Plants	No. of Measure-ments	No. of Annual Medians	Annual Median TSS (log triangular distribution)			Geometric Mean
				Minimum	Maximum	Weighted Geometric Mean	
1	0	9,007	33	3.2	40	8.0	6.0

Lakes (national)	56	4,360	99	1	398	25	25

Data source: Legacy STORET database.

For **surface water pH**, the minimum, maximum, and weighted average annual median values were used to specify triangular distributions for each hydrologic region. Table C-11 provides these regional statistics, which were applied to both rivers and lakes.

To prepare the water quality data for the source datafile, the 181 CCW disposal sites were assigned to a hydrogeologic region using a GIS. For each region, 10,000-record TSS and pH data sets were created by sampling the distributions shown in Tables C-10 and C-11. During source data file preparation, TSS data were pulled from the appropriate regional data set sequentially for each iteration at a site.

Table C-11. Regional Surface Water pH Distributions

Hydrologic Region	Number of CCW Plants	No. of Measurements	No. of Annual Median Values	Annual Median pH (triangular distribution)			Average Median pH
				Minimum	Maximum	Weighted Average	
1	0	232,025	38	5.9	7.7	6.5	6.8
2	12	447,166	39	7.2	7.6	7.4	7.4

Data source: Legacy STORET database.

C.6.4 Distance to Surface Water

Because the CCW plant locations were not accurate in terms of locating the WMUs, a national empirical distribution of distances between the WMU and the nearest downgradient surface waterbodies (discussed in Appendix C, Section C.2.1) was developed using manual measurements on online maps and aerial photographs for a random selection of 30 CCW landfills and 29 CCW surface impoundments. Scaled USGS maps and aerial photographs were obtained from the Terraserver Web site (http://terraserver.usa.com/geographic.aspx) by entering each plant's longitude and latitude. Labels on the maps, features on the photographs, and best professional judgment were used to identify the power plant and the surface impoundment or landfill in question, along with the nearest downgradient waterbody.

The nearest waterbody matching one of the following descriptions was used in the analysis:

- Lakes or rivers beyond the facility boundary
- Streams originating in or passing through the facility boundary and then coursing downstream beyond the property boundary
- Streams with an order of 3 or greater (i.e., fishable waterbodies).

Stream order was determined by tracing the convergence of tributaries with order 1 assigned to the furthest upstream segment indicated on the map (both ephemeral and perennial streams were assigned as order 1). Topography on the map was used to determine if the waterbody was downgradient of the plant. Many CCW WMUs in the sample were located on a large waterbody.

Once the waterbody was identified, the scale provided on the maps and photos was used to measure the horizontal distance between the CCW impoundment or landfill and the waterbody. All assignments and measurements were independently checked for accuracy.

The two distributions (landfills and surface impoundments) were statistically compared using (1) a Wilcoxon Rank Sum Test (to determine whether one distribution is shifted to the right or left of the other distribution) and (2) a Quantile Test (to test for differences, that is, differing numbers of observations) between the two distributions for the values above a given percentile. The results of the Wilcoxon test showed a p value of 0.64, indicating no significant difference in the shape of the distributions. The Quantile Test evaluated every decile from 0.1 to 0.9, with adjustments to the lower percentiles to be estimated for large numbers of ties in the ranks for the lower end of the data. The nonsignificant p values ranged from 0.33 (for 90th percentile) to 0.17 (for the 40th percentile). One significant p value indicating differences between the two distributions occurred at the 17th percentile (p value = 0.066), but the remainder of the tests showed no significant differences. Based on these results, the distributions were judged to be similar and combined to produce the single distribution of 59 values used to produce a single empirical distribution (previously shown in Table C-2) that was applied nationally to both landfills and surface impoundments at the CCW sites.

Attachment C-2: Hydrogeologic Environment

Plant	Hydrogeologic Setting		Hydrogeologic Environment		Percentage	Comment
	Code	Description	Code	Description		
Big Cajun 2	10Ba	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	100	Predominant alluvial setting (100% alluvium); soils have significant fines (SCL+SLT = 95%)
A B Brown	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	100	Predominant alluvial setting; soils have significant fines (SCL+SLT = 95%)
A/C Power-Ace Operations	2C	Alluvial Fans	5	Alluvial Basins Valleys and Fans	100	Based on surficial geology; consistent with alluvial fan setting
Allen	10Ba	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	100	Setting based on aquifer coverages, surficial geology; Heath (1985) and soils indicate overbank deposits
Alma	7Ea	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	50	Percentage based on SNL/SCL soils; setting based on productive aquifers and surficial geology
Alma	7Eb	River Alluvium Without Overbank Deposits	7	River Valleys and Floodplains without Overbank Deposits	50	Percentage based on SNL/SCL soils; setting based on productive aquifers and surficial geology
Antelope Valley	7G	Thin Till Over Bedded Sedimentary Rock	3	Till Over Sedimentary Rock	100	Based on principal aquifer and surficial geology coverages
Arkwright	8D	Regolith	1	Metamorphic and Igneous	100	Most common Piedmont setting (residuum)
Asheville	8B	Alluvial Mountain Valleys	5	Alluvial Basins Valleys and Fans	100	Appropriate for alluvial blue ridge valley (colluvium)
Baldwin	7Ea	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	70	Percentage based on surficial geology (74% Floodplain and alluvium gravel terraces)
Baldwin	7G	Thin Till Over Bedded Sedimentary Rock	3	Till Over Sedimentary Rock	30	Percentage based on surficial geology (74% Floodplain and alluvium gravel terraces)

(continued)

Hydrogeologic Environment (continued)

Plant	Hydrogeologic Setting		Hydrogeologic Environment		Percentage	Comment
	Code	Description	Code	Description		
Barry	10Ba	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	100	Predominant alluvial setting, significant fine grained soils = overbank deposits
Bay Front	7Bb	Outwash Over Bedded Sedimentary Rock	2	Bedded Sedimentary Rock	70	Percentage based on productive aquifers
Bay Front	7D	Buried Valley	4	Sand and Gravel	30	Percentage based on productive aquifers
Bay Shore	7Ac	Glacial Till Over Solution Limestone	12	Solution Limestone	100	Closest setting considering carbonate aquifers, high SCL soils, and lake deposits surficial geology
Belews Creek	6H	Triassic Basins	2	Bedded Sedimentary Rock	50	Sources somewhat dissimilar; fraction based on surficial geology; Triassic basin
Belews Creek	8D	Regolith	1	Metamorphic and Igneous	50	Sources somewhat dissimilar; fraction based on surficial geology
Ben French	6Da	Alternating Sandstone, Limestone and Shale - Thin Soil	2	Bedded Sedimentary Rock	60	Percentage, thin soils based on surficial geology
Ben French	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	40	Percentage based on surficial geology; significant fine soils (25% SCL)
Big Sandy	6Da	Alternating Sandstone, Limestone and Shale - Thin Soil	2	Bedded Sedimentary Rock	50	Percentage based on surficial geology; thin soils inferred from colluvium
Big Sandy	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	50	Percentage based on surficial geology; soils have significant fines (SCL+SLT = 95%)
Big Stone	7Ba	Outwash	8	Outwash	100	Based on surficial geology
Black Dog Steam Plant	7Bb	Outwash Over Bedded Sedimentary Rock	2	Bedded Sedimentary Rock	100	Based on surficial geology, aquifer coverages
Blue Valley	7Aa	Glacial Till Over Bedded Sedimentary Rock	3	Till Over Sedimentary Rock	80	Percentage based on Heath (1985), productive aquifers

(continued)

Hydrogeologic Environment (continued)

Plant	Hydrogeologic Setting		Hydrogeologic Environment		Percentage	Comment
	Code	Description	Code	Description		
Blue Valley	7Ea	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	20	Percentage based on Heath (1985), productive aquifers
Bowen	6Db	Alternating Sandstone, Limestone and Shale - Deep Regolith	2	Bedded Sedimentary Rock	100	Based on aquifers, surficial residuum (massive red clay); metamorphic surficial geology not consistent with Valley and Ridge
Brandon Shores	10Ab	Unconsolidated and Semi-Consolidated Shallow Surficial Aquifer	10	Unconsolidated and Semiconsolidated Shallow Aquifers	100	Assigned based on location and aquifer and surficial geology coverages; Heath region incorrect (it's Atlantic Coastal Plain, not Piedmont)
Buck	8E	River Alluvium	6	River Valleys and Floodplains with Overbank Deposit	100	Based on productive aquifer & Heath region coverages
Bull Run	6Db	Alternating Sandstone, Limestone and Shale - Deep Regolith	2	Bedded Sedimentary Rock	60	Percentage based on surficial geology
Bull Run	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	40	Percentage based on surficial geology; high SCL (77%) = overbank deposits
C D McIntosh Jr	11A	Solution Limestone and Shallow Surficial Aquifers	12	Solution Limestone	100	Based on both aquifer coverages
C P Crane	10Aa	Regional Aquifers	4	Sand and Gravel	50	Appears to be on border between Piedmont and Coastal Plain
C P Crane	8D	Regolith	1	Metamorphic and Igneous	50	Appears to be on border between Piedmont and Coastal Plain
Cape Fear	6H	Triassic Basins	2	Bedded Sedimentary Rock	20	Percentage based on productive aquifer & Heath region coverages; Triassic basin
Cape Fear	8E	River Alluvium	6	River Valleys and Floodplains with Overbank Deposit	80	Percentage based on productive aquifer & Heath region coverages
Carbon	4B	Consolidated Sedimentary Rock	2	Bedded Sedimentary Rock	100	Setting based on aquifer and surficial geology coverages

(continued)

Hydrogeologic Environment (continued)

Plant	Hydrogeologic Setting		Hydrogeologic Environment		Percentage	Comment
	Code	Description	Code	Description		
Cardinal	6Da	Alternating Sandstone, Limestone and Shale - Thin Soil	2	Bedded Sedimentary Rock	30	Percentage based on surficial geology; soils with low (<1%) SNL
Cardinal	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	70	Percentage based on surficial geology; soils with low (<1%) SNL
Cayuga	7D	Buried Valley	4	Sand and Gravel	100	Glaciofluvial aquifer overlaid by alluvial deposits
Chalk Point	10Ab	Unconsolidated and Semi-Consolidated Shallow Surficial Aquifer	10	Unconsolidated and Semiconsolidated Shallow Aquifers	100	Predominant setting
Cholla	4B	Consolidated Sedimentary Rock	2	Bedded Sedimentary Rock	20	Percentage based on surficial geology (83% Floodplain and alluvium gravel terraces)
Cholla	4C	River Alluvium	7	River Valleys and Floodplains without Overbank Deposits	80	Percentage based on surficial geology (83% Floodplain and alluvium gravel terraces)
Cliffside	8D	Regolith	1	Metamorphic and Igneous	100	Based on surficial geology
Clover	6H	Triassic Basins	2	Bedded Sedimentary Rock	20	Percentage based on surficial geology; Triassic Basin from Heath (1985) and principal aquifer coverage
Clover	8E	River Alluvium	6	River Valleys and Floodplains with Overbank Deposit	80	Percentage based on surficial geology
Coal Creek	7G	Thin Till Over Bedded Sedimentary Rock	3	Till Over Sedimentary Rock	100	Based on principal aquifer and surficial geology coverages
Coleto Creek	10Ab	Unconsolidated and Semi-Consolidated Shallow Surficial Aquifer	10	Unconsolidated and Semiconsolidated Shallow Aquifers	100	Setting based on aquifer and surficial geology coverages
Colstrip	6da	Alternating Sandstone, Limestone and Shale - Thin Soil	2	Bedded Sedimentary Rock	100	Based on all coverages

(continued)

Hydrogeologic Environment (continued)

Plant	Hydrogeologic Setting		Hydrogeologic Environment		Percentage	Comment
	Code	Description	Code	Description		
Hammond	6Db	Alternating Sandstone, Limestone and Shale - Deep Regolith	2	Bedded Sedimentary Rock	100	Based on aquifers, surficial residuum (massive red clay)
Harllee Branch	8E	River Alluvium	6	River Valleys and Floodplains with Overbank Deposit	100	Assigned based on predominant surficial geology (99% floodplain and alluvium gravel terraces)
Harrison	6Da	Alternating Sandstone, Limestone and Shale - Thin Soil	2	Bedded Sedimentary Rock	20	Percentage based on surficial geology; thin soils inferred from surficial geology
Harrison	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	80	Percentage based on surficial geology; 0%SNL = overbank deposits
Hatfield's Ferry	6Da	Alternating Sandstone, Limestone and Shale - Thin Soil	2	Bedded Sedimentary Rock	40	Percentage based on surficial geology; thin regolith inferred from colluvium
Hatfield's Ferry	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	60	Percentage based on surficial geology; soils < 1% SNL
Hennepin	7Aa	Glacial Till Over Bedded Sedimentary Rock	3	Till Over Sedimentary Rock	30	Percentage to capture uncertainty in soils, surficial geology, principal aquifer
Hennepin	7Bb	Outwash Over Bedded Sedimentary Rock	2	Bedded Sedimentary Rock	30	Percentage to capture uncertainty in soils, surficial geology, principal aquifer
Hennepin	7Ea	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	40	Percentage to capture uncertainty in soils, surficial geology, principal aquifer
Heskett	7Ea	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	100	Predominant alluvium surficial geology(96%); mixed soils
Holcomb	5Gb	River Alluvium Without Overbank Deposits	7	River Valleys and Floodplains without Overbank Deposits	100	Alluvial valley with very coarse soils
Homer City	6Da	Alternating Sandstone, Limestone and Shale - Thin Soil	2	Bedded Sedimentary Rock	100	Setting based on aquifer coverages & Heath (1985); thin regolith inferred from colluvium

(continued)

Plant	Hydrogeologic Setting		Hydrogeologic Environment		Percentage	Comment
	Code	Description	Code	Description		
Hoot Lake	9E	Outwash	8	Outwash	100	Based on productive aquifer, soils, surficial geology
Hugo	6Da	Alternating Sandstone, Limestone and Shale - Thin Soil	2	Bedded Sedimentary Rock	40	Percentage based on surficial geology; soil/regolith thickness inferred from Heath (1985)
Hugo	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	60	Percentage based on surficial geology; fine soils with about 10% SNL
Hunter	4B	Consolidated Sedimentary Rock	2	Bedded Sedimentary Rock	100	Setting based on aquifer and surficial geology coverages
Huntington	4B	Consolidated Sedimentary Rock	2	Bedded Sedimentary Rock	100	Setting based on aquifer and surficial geology coverages
Intermountain	2E	Playa Lakes	5	Alluvial Basins Valleys and Fans	100	Setting based on surficial geology coverage, Heath (1985)
J H Campbell	7F	Glacial Lake Deposits	4	Sand and Gravel	100	Based on surficial geology, soils
J M Stuart	6E	Solution Limestone	12	Solution Limestone	50	Percentage based on surficial geology; low (< 2%) SNL
J M Stuart	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	50	Percentage based on surficial geology; low (< 2%) SNL
J R Whiting	7F	Glacial Lake Deposits	4	Sand and Gravel	100	Based on surficial geology
Jack McDonough	8C	Mountain Flanks	2	Bedded Sedimentary Rock	100	Assigned based on predominant surficial geology (94% stony colluvium on metamorphic rocks; less silt and clay than in colluvium over limestone)
Jack Watson	10Ab	Unconsolidated and Semi-Consolidated Shallow Surficial Aquifer	10	Unconsolidated and Semiconsolidated Shallow Aquifers	100	Based on all coverages
James H Miller Jr	6Da	Alternating Sandstone, Limestone and Shale - Thin Soil	2	Bedded Sedimentary Rock	20	Percentage based on surficial geology; soils have significant fines (SCL+SLT > 25%)

(continued)

Hydrogeologic Environment (continued)

Plant	Hydrogeologic Setting		Hydrogeologic Environment		Percentage	Comment
	Code	Description	Code	Description		
James H Miller Jr	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	80	Percentage based on surficial geology; soils have significant fines (SCL+SLT > 25%)
Jim Bridger	4B	Consolidated Sedimentary Rock	2	Bedded Sedimentary Rock	100	Based on aquifer and surficial geology coverages, Heath (1985)
John E Amos	6da	Alternating Sandstone, Limestone and Shale - Thin Soil	2	Bedded Sedimentary Rock	40	Percentage based on surficial geology; thin soils inferred from surficial geology
John E Amos	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	60	Percentage based on surficial geology; 0%SNL = overbank deposits
John Sevier	6E	Solution Limestone	12	Solution Limestone	50	Percentage based on surface geology; setting based on surface geology and aquifer type, with possibility of solution limestone from Heath (1985)
John Sevier	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	50	Percentage, setting based on surface geology; low (<1%) SNL = overbank deposits
Johnsonville	6E	Solution Limestone	12	Solution Limestone	30	Percentage based on surface geology; setting based on aquifer coverages, Heath (1985); placed in Nonglaciated Central region based on aquifer coverages and Heath (1985)
Johnsonville	6Fa	River Alluvium With Overbank Deposits	6	River Valleys and Floodplains with Overbank Deposit	70	Percentage, setting based on surface geology; low (3%) SNL = overbank deposits; placed in Nonglaciated Central region based on aquifer coverages and Heath (1985)
Joliet 29	7Aa	Glacial Till Over Bedded Sedimentary Rock	3	Till Over Sedimentary Rock	100	Based on aquifers, soils; soils don't suggest outwash like surficial geology does
Keystone	6Da	Alternating Sandstone, Limestone and Shale - Thin Soil	2	Bedded Sedimentary Rock	100	Setting based on aquifer coverages & Heath (1985); thin regolith inferred from colluvium
Killen Station	6E	Solution Limestone	12	Solution Limestone	30	Percentage based on surficial geology; low (< 2%) SNL

(continued)

Hydrogeologic Environment (continued)

Plant	Hydrogeologic Setting		Hydrogeologic Environment		Percentage	Comment

Attachment C-3: Climate Center Assignments

Plant	Climate Center	Explanation If Not Closest Climate Center
A B Brown	Indianapolis, IN	Closest Met Station (Nashville) receives much more precipitation (12.26" out of range) than the site location. Used second closest because only slightly below (1.3) expected precipitation range for plant.
A/C Power- Ace Operations	Las Vegas, NV	
Allen	Little Rock, AR	
Alma	Madison, WI	Closest Met Station (St. Cloud) receives less rain than plant location. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant.
Antelope Valley	Bismarck, ND	
Arkwright	Watkinsville, GA	Closest Met Station (Atlanta) receives 6.96" more precipitation than plant location. Used second closest Met Station because 5-year averages are only slightly above (0.2) expected precipitation range for the plant.
Asheville	Knoxville, TN	
Baldwin	East St. Louis, IL	
Barry	Tallahassee, FL	Closest Met Station (New Orleans) receives much more precipitation (5.06" out of range) than the site location. Used second closest because only slightly above (3.4) expected precipitation range for plant.
Bay Front	Madison, WI	
Bay Shore	Put-in-Bay, OH	
Belews Creek	Greensboro, NC	
Ben French	Rapid City, SD	
Big Cajun 2	Lake Charles, LA	Closest Met Station (New Orleans) receives much more precipitation (5.06" out of range) than the site location. Used second closest because only slightly below (2.77) expected precipitation range for plant.
Big Sandy	Cincinnati, OH	Closest Met Station (Lexington) receives much more precipitation (8.35" out of range) than plant location. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant.
Big Stone	St. Cloud, MN	

(continued)

Climate Center Assignments (continued)

Plant	Climate Center	Explanation If Not Closest Climate Center
Black Dog Steam Plant	Madison, WI	Closest Met Station (St Cloud) is dryer (<27.5") than the 28-33" that the site receives. Madison fits in precipitation range (32.5") and is second closest.
Blue Valley	Topeka, KS	
Bowen	Atlanta, GA	
Brandon Shores	Seabrook, NJ	
Buck	Greensboro, NC	
Bull Run	Knoxville, TN	
C D McIntosh Jr	Orlando, FL	Closest Met Station (Tampa) receives less precipitation (5.31" out of range) than site location. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant.
C P Crane	Seabrook, NJ	
Cape Fear	Greensboro, NC	
Carbon	Salt Lake City, UT	
Cardinal	Pittsburgh, PA	
Cayuga	Indianapolis, IN	
Chalk Point	Seabrook, NJ	
Cholla	Phoenix, AZ	Closest Met Station (Flagstaff) receives much more precipitation (13.92" out of range) than plant location. Used second closest Met Station because 5-year averages were close (.31 higher) than the expected precipitation range for the plant.
Cliffside	Greensboro, NC	
Clover	Lynchburg, VA	
Coal Creek	Bismarck, ND	
Coleto Creek	San Antonio, TX	
Colstrip	Glasgow, MT	
Conemaugh	Pittsburgh, PA	
Conesville	Columbus, OH	
Council Bluffs	North Omaha, NE	
Crawford	East St. Louis, IL	
Crist	Tallahassee, FL

E D Edwards	Chicago, IL	
E W Brown	Lexington, KY	
Eckert Station	East Lansing, MI	
Edgewater	Madison, WI	
Elmer W Stout	Indianapolis, IN	
F B Culley	Indianapolis, IN	Closest Met Station (Nashville) receives much more precipitation (12.26” out of range) than plant location. Used second closest Met Station because 5-year & 30-year averages fell within expected precipitation range for the plant.
Fayette Power Prj	San Antonio, TX	
Flint Creek	Columbia, MO	Used http://www.weather.com and Envirofacts to determine that avg. precipitation for site was ~47”. The closest Met Station (Tulsa) receives much less (~17”) precipitation per year. Used second closest station.
Fort Martin	Pittsburgh, PA	
Frank E Ratts	Indianapolis, IN	
G G Allen	Greensboro, NC	
Gadsden	Atlanta, GA	

(continued)

Climate Center Assignments (continued)

Plant	Climate Center	Explanation If Not Closest Climate Center
Gallatin	Nashville, TN	
Gen J M Gavin	Cincinnati, OH	Closest Met Station (Columbus) receives less rain than plant location. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant. Also average precipitation for the second closest Met Station was nearest to http://www.weather.com
Genoa	Madison, WI	
Gibson	Indianapolis, IN	
Gorgas	Atlanta, GA	
Green River	Indianapolis, IN	Closest Met Station (Nashville) receives much more precipitation (12.26" out of range) than plant location. Used third closest Met Station because 5-year averages fell within expected precipitation range for the plant.
Greene County	Atlanta, GA	
H B Robinson	Charleston, SC	
Hammond	Atlanta, GA	
Harllee Branch	Watkinsville, GA	
Harrison	Pittsburgh, PA	
Hatfield's Ferry	Pittsburgh, PA	
Hennepin	Chicago, IL	
Heskett	Bismarck, ND	
Holcomb	Dodge City, KS	
Homer City	Pittsburgh, PA	
Hoot Lake	St. Cloud, MN	
Hugo	Shreveport, LA	Closest Met Station (Dallas) receives less precipitation (6.45" out of range) than plant location. Used second closest because only slightly above (2.07) expected precipitation range for plant.
Hunter	Grand Junction, CO	Closest Met Station (Salt Lake City) receives 8.6" more precipitation than plant location. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant.
Huntington	Cedar City, UT	Two closest Met Stations are out of range. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant.
Intermountain	Ely, NV	Closest Met Station (Salt Lake City) receives 6.1" more precipitation than plant location. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant.
J H Campbell	East Lansing, MI	

(continued)

Climate Center Assignments (continued)

Plant	Climate Center	Explanation If Not Closest Climate Center
J M Stuart	Cincinnati, OH	
J R Whiting	Put-in-Bay, OH	
Jack McDonough	Atlanta, GA	
Jack Watson	Tallahassee, FL	Closest Met Station (New Orleans) receives much more precipitation (5.06" out of range) than the site location. http://www.weather.com predicted average precipitation at plant location to be 65.2. Used third closest because its average was closest.
James H Miller Jr	Atlanta, GA	
Jim Bridger	Lander, WY	
John E Amos	Cincinnati, OH	The two closest Met Stations are out of the site's precipitation range. Used third closest Met Station because 5-year averages fell within expected precipitation range for the plant. Also average precipitation for the second closest Met Station was nearest to http://www.weather.com average.
John Sevier	Knoxville, TN	
Johnsonville	Nashville, TN	
Joliet 29	Chicago, IL	
Keystone	Pittsburgh, PA	
Killen Station	Cincinnati, OH	
Kingston	Knoxville, TN	
Kraft	Charleston, SC	
L V Sutton	Charleston, SC	
Lansing	Madison, WI	
Laramie R Station	Cheyenne, WY	
Lawrence EC	Topeka, KS	
Lee	Greensboro, NC	
Leland Olds	Bismarck, ND	
Lon Wright	North Omaha, NE	
Louisa	Des Moines, IA	
Marion	East St. Louis, IL	
Marshall	Greensboro, NC	

(continued)

Climate Center Assignments (continued)

Plant	Climate Center	Explanation If Not Closest Climate Center
Martin Lake	Shreveport, LA	
Mayo	Lynchburg, VA	
Meramec	East St. Louis, IL	
Merom	Indianapolis, IN	
Miami Fort	Cincinnati, OH	
Milton R Young	Bismarck, ND	
Mitchell - PA	Pittsburgh, PA	
Mitchell - WV	Pittsburgh, PA	
Mohave	Las Vegas, NV	
Monroe	Put-in-Bay, OH	
Morgantown	Norfolk, VA	
Mountaineer (1301)	Cincinnati, OH	Closest Met Station (Columbus) receives more rain than plant location. Although second closest site also falls within range, used third closest Met Station because site geography was similar and the station's 5-year averages fell within expected precipitation range for the plant.
Mt Storm	Pittsburgh, PA	
Muscatine Plant #1	Des Moines, IA	
Muskogee	Tulsa, OK	
Neal North	North Omaha, NE	
Neal South	North Omaha, NE	
Nebraska City	North Omaha, NE	
New Castle	Pittsburgh, PA	
Newton	Indianapolis, IN	Closest Met Station (East St. Louis) receives less rain than plant location. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant. Also average precipitation for the second closest Met Station was nearest to http://www.weather.com
North Omaha	North Omaha, NE	
Northeastern	Tulsa, OK	
Nucla	Grand Junction, CO	

(continued)

Climate Center Assignments (continued)

Plant	Climate Center	Explanation If Not Closest Climate Center
Oklaunion	Oklahoma City, OK	
Paradise	Cincinnati, OH	Closest Met Station (Nashville) receives much more precipitation (12.26" out of range) than plant location. Used third closest Met Station because 5-year averages fell within expected precipitation range for the plant.
Petersburg	Indianapolis, IN	
Pleasant Prairie	Chicago, IL	
Port Washington	Madison, WI	
Portland	Philadelphia, PA	
Possum Point	Norfolk, VA	
Potomac River	Seabrook, NJ	
Presque Isle	Sault Ste. Marie, MI	
R Gallagher	Cincinnati, OH	Closest Met Station (Lexington) receives much more precipitation (8.35" out of range) than plant location. Used second closest Met Station because 5-year & 30-year averages fell within expected precipitation range for the plant.
R M Schahfer	Chicago, IL	
Reid Gardner	Las Vegas, NV	
Richard Gorsuch	Columbus, OH	
Riverbend	Greensboro, NC	
Rodemacher	Lake Charles, LA	
Roxboro	Greensboro, NC	
Sandow	San Antonio, TX	
Scherer	Watkinsville, GA	Closest Met Station (Atlanta) receives 6.96" more precipitation than plant location. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant.
Shawnee	East St. Louis, IL	
Shawville	Pittsburgh, PA	
Sheldon	North Omaha, NE	

(continued)

Climate Center Assignments (continued)

Plant	Climate Center	Explanation If Not Closest Climate Center
South Oak Creek	Chicago, IL	
Springerville	Albuquerque, NM	Closest Met Station (Flagstaff) receives much more precipitation (8.92" out of range) than plant location. Used second closest Met Station because 5-year averages were within the expected precipitation range for the plant.
St Johns River Power	Jacksonville, FL	
Stanton Energy Ctr	Orlando, FL	
Stockton Cogen Company	Sacramento, CA	
Syl Laskin	St. Cloud, MN	
Tecumseh EC	Topeka, KS	
Texas-New Mexico	San Antonio, TX	Closest Met Station (Dallas) received less precipitation than site location. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant. Also average precipitation for the second closest Met Station was nearest to http://www.weather.com
Titus	Philadelphia, PA	
Trimble County	Cincinnati, OH	
Tyrone	Lexington, KY	
Valley	Madison, WI	
Vermilion	Chicago, IL	Closest Met Station (Indianapolis) receives more precipitation than plant location. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant.
Victor J Daniel Jr	Tallahassee, FL	Closest Met Station (New Orleans) receives much more precipitation (5.06" out of range) than the site location. Used second closest because only slightly above (3.4) expected precipitation range for plant.
W A Parish	Shreveport, LA	2 Closest Met Stations (Lake Charles & San Antonio) are more than 4" out of range. Used third closest because only slightly above (1.65") expected precipitation range for plant.
W H Weatherspoon	Greensboro, NC	
W S Lee	Watkinsville, GA	
Wabash River	Indianapolis, IN	
Walter C Beckjord	Cincinnati, OH	
Wansley	Atlanta, GA	
Warrick	Indianapolis, IN	Closest Met Station (Nashville) receives 12.2" more precipitation than plant location. Used second closest Met Station because 5-year averages fell within expected precipitation range for the plant.

Appendix D. MINTEQA2 Nonlinear Sorption Isotherms

D.1 Overview of MINTEQA2 Modeling

Chemicals in leachate can be subject to complex geochemical interactions in soil and groundwater, which can strongly affect their rate of transport in the subsurface. The U.S. Environmental Protection Agency's Composite Model for Leachate Migration with Transformation Products (EPACMTP) treats these interactions as equilibrium sorption processes. The equilibrium assumption means that the sorption process occurs instantaneously, or at least very quickly relative to the time scale of constituent transport. Although sorption—or the attachment of leachate constituents to solid soil or aquifer particles—may result from multiple chemical processes, EPACMTP lumps these processes together into an effective soil-water partition coefficient (K_d). The retardation factor (R) accounts for the effects of equilibrium sorption of dissolved constituents onto the solid phase. R, a function of the constituent-specific K_d and the soil or aquifer properties, is calculated as:

$$R = 1 + \frac{\rho_b \times K_d}{\Phi} \qquad \text{(D-1)}$$

where

R = Retardation factor
ρ_b = Soil or aquifer bulk density (mg)
K_d = Solid-water partition coefficient (g/cm^3)
ϕ = Water content (in unsaturated zone) or porosity (in saturated zone).

An isotherm is an expression of the equilibrium relationship between the aqueous concentration and the sorbed concentration of a metal (or other constituent) at a constant temperature. For metals, EPACMTP accounts for more complex geochemical reactions by using effective sorption isotherms generated using EPA's geochemical equilibrium speciation model for dilute aqueous systems, MINTEQA2 (U.S. EPA, 1991).

The MINTEQA2 model is used to generate one set of isotherms for each metal reflecting the range in geochemical environments expected at waste sites across the nation. The variability in geochemical environments at coal combustion waste (CCW) sites across the country is represented by five geochemical master variables (groundwater composition, pH, concentration of iron oxide adsorption sites, leachate ionic strength, and concentration of dissolved and particulate natural organic matter), and the MINTEQA2 modeling is repeated (separately for each metal) for numerous combinations of master variable settings. This procedure results in nonlinear K_d versus aqueous metal concentration curves for combinations of master variable settings spanning the range of reasonable values (U.S. EPA 2003a).

For each metal, the resulting set of isotherms is tabulated into a supplementary input data file for use by the EPACMTP model, hereafter referred to as an "empirical nonlinear isotherm." In the fate and transport modeling for a particular metal, EPACMTP is executed and the national probability distributions for these five master variables form the basis for the Monte Carlo selection of the appropriate adsorption isotherm.

In modeling metals transport in the unsaturated zone, EPACMTP uses a range of K_d values from the nonlinear sorption isotherms. However, in modeling metals transport in the saturated zone, EPACMTP selects the lowest from all available K_d values corresponding to concentrations less than or equal to the maximum water table concentration. For more details see the *EPACMTP Technical Background Document* (U.S. EPA, 2003b).

This simplification in the saturated zone is required for all solution options and is based on the assumption that after dilution of the leachate plume in groundwater, the concentrations of metals will typically be in a range where the isotherm is approximately linear. However, this assumption may not be valid when the metal concentrations in the leachate are exceedingly high. Although EPACMTP is able to account for the effect of the geochemical environment at a site on the mobility of metals, the model assumes that the geochemical environment at a site is constant and not affected by the presence of the leachate plume. In reality, the presence of a leachate plume may alter the ambient geochemical environment.

D.2 Previous CCW Metals Modeling Effort

In a previous risk assessment for fossil fuel combustion wastes (FFCWs) conducted in 1998 (U.S. EPA, 1998), sorption isotherms generated using MINTEQA2 were used in EPACMTP to account for metal partitioning. However, these isotherms were not calculated specifically for use in FFCW modeling—they had been computed using MINTEQA2 in 1995 for use in modeling support for the Hazardous Waste Identification Rule (HWIR).

The disposal scenario for HWIR was the industrial Resource Conservation and Recovery Act (RCRA) Subtitle D nonhazardous waste landfill. In fact, the MINTEQA2 modeling that produced the isotherms had originally been designed to represent municipal solid waste landfills, and leachate from those landfills had been sampled so that appropriate forms of leachate organic acids at various concentrations could be included in the modeling. For the HWIR analysis, the scenario was changed to industrial Subtitle D, and only the isotherms corresponding to low concentrations of the leachate organic acids were used for HWIR modeling. The same isotherms were used in the 1998 FFCW risk assessment. As in the HWIR modeling, only the isotherms corresponding to the lowest setting of leachate organic carbon were used.

In 1999, EPA received review comments concerning the use of the industrial Subtitle D metal partitioning isotherms in the 1998 risk assessment. The most comprehensive review was prepared by Charles Norris and Christina Hubbard on behalf of the Environmental Defense Fund and other environmental advocacy groups (Norris and Hubbard, 1999). The Norris and Hubbard report criticized the 1998 risk assessment for using MINTEQA2 isotherms designed for a different scenario (nonhazardous industrial landfills). Norris and Hubbard also offered 20 specific criticisms on the input parameters and other factors involved in the MINTEQA2 modeling. EPA responded by evaluating each of these criticisms through review and assessment

of MINTEQA2 input values, model sensitivity tests, and consultations with experts. This review is documented in U.S. EPA (2000, 2001a). The evaluation of the Norris and Hubbard comments resulted in suggested revisions in the MINTEQA2 modeling strategy, as described in U.S. EPA (2001b).

Based on a review of available information on CCW leachate composition and an analysis of the potential effects of this composition on metals mobility, EPA (U.S. EPA, 2001b) also determined that if MINTEQA2 is to be used at CCW sites, leachate from CCW facilities should be studied to look for trends in composition, especially with regard to the concentrations of constituents that may

- Contribute to elevated groundwater pH
- Compete with the contaminant metal for sorption sites and thus result in reduced metal sorption (e.g., Ca, Mg, SO_4, other metals)
- Complex with the contaminant metal so that the metal is less likely to be sorbed (e.g., SO_4, CO_3, organic ligands)
- Precipitate with the contaminant metal (e.g., SO_4, CO_3).

D.3 MINTEQA2 Modeling Revisions for CCW Risk Assessment

Many of the suggested revisions from U.S. EPA (2001b) were implemented in the MINTEQA2 modeling for the current CCW risk assessment. Some of the suggested revisions were not implemented, either because they are not applicable (e.g., organic carbon assumptions should not be changed because CCW leachate has negligible organic carbon) or because models or data were not adequate to carry forth the recommendation. These revisions are discussed in greater detail in U.S. EPA (2003c).

In addition to revising the MINTEQA2 model, EPA compiled leachate characteristics into the CCW constituent database (see Appendix A) and statistically analyzed these data to identify three chemically distinct CCW leachate types: conventional CCW (including ash and flue gas desulfurization [FGD] sludge), codisposed CCW and coal cleaning wastes, and fluidized bed combustion (FBC) waste. Leachate concentration ranges for major ions (e.g., Ca, SO_4, Mg, Na, Cl, etc.) and pH were developed for each of these waste types and were used to represent CCW leachate during MINTEQA2 modeling.

As needed, sorption reactions were included for those CCW constituents known to undergo significant sorption. Including elevated concentrations of leachate constituents and their corresponding sorption reactions in the MINTEQA2 model allows for full competition with the contaminant metal for sorption sites. The metal solubilizing effect through complexation between the contaminant metal and dissolved ligands is also included, as is the potential for metal precipitation. Because precipitation of the metal can serve to attenuate the transportable concentration, the equilibrium fraction in all three phases (dissolved, sorbed, and precipitated) were stored and made available for use by EPACMTP. The precipitated fraction was used to develop a solubility limit that was used during EPACMTP modeling (U.S. EPA, 2003c).

D.4 MINTEQA2 Modeling for CCW Risk Assessment

The expected natural variability in K_d for a particular metal was represented during the MINTEQA2 modeling effort by varying the input parameters that most impact K_d: groundwater type (carbonate or noncarbonate), pH, concentration of aquifer sorbents, composition and concentration level of CCW leachate, and concentration of the contaminant metal. The natural pH range for the two groundwater types was sampled from a range of 7 to 8 for carbonate aquifers and 4 to 10 for noncarbonate aquifers (U.S. EPA, 2003c).

In addition, CCW leachate ranges from acidic (pH < 2) to highly alkaline (pH > 12) and can impact vadose zone and groundwater pH. To account for this possibility, the CCW leachate/ groundwater system was equilibrated at a series of pH values that span the range of expected variability in mixed CCW leachate-groundwater systems (U.S. EPA, 2003c).

To account for the variability in the sorption capacity of soil and aquifer materials, the soil and groundwater systems were equilibrated with various concentrations of two commonly occurring natural sorbents: ferric (iron) oxyhydroxide (FeOx) and particulate organic matter (POM). CCW leachate can include elevated concentrations of inorganic constituents such as calcium, sulfate, sodium, potassium, and chloride, which may reduce sorption of metals due to competition for sorption sites or complexation with metals in solution. To account for this effect, these leachate components were added to the MINTEQA2 model inputs at concentrations representative of the three CCW waste types (conventional CCWs, codisposed CCW and coal cleaning wastes, and FBC wastes). This new MINTEQA2 master variable is termed leachate "richness" or ionic strength (U.S. EPA, 2003c).

The results of each MINTEQA2 model run were compiled as the equilibrium distribution of the contaminant metal among dissolved, sorbed, and precipitated fractions for each metal concentration, and were saved in a separate file indexed with the settings of all variables used to define the system. These files were produced for all possible values for the variables defining the system, and were compiled into a database of indexed K_d values for use in the EPACMTP fate and transport model (U.S. EPA, 2003c).

D.5 EPACMTP Modeling Revisions to Accommodate MINTEQA2 Updates

EPA updated EPACMTP to support the new system variable (leachate ionic strength) for isotherm selection, to address issues regarding the impacts of leachate pH on ambient soil and aquifer pH, and to address issues regarding solubility limits for metals in solution. A brief description of these model changes are discuss below, with more detail provided in U.S. EPA (2003d).

Ionic Strength. A new system or "master" variable was added to include ionic strength as a key for choosing the representative isotherm from the database for both the unsaturated and saturated zones.

Leachate Effects on Geochemical Environment. These effects were addressed in EPACMTP under the following constraints: (1) no significant impairment of the computational efficiency for probabilistic applications; (2) data requirements limited to readily available data;

and (3) a scientifically defensible approach, given significant uncertainties with respect to the true impacts of leachate pH on the subsurface. Two modifications to the EPACMTP were considered: (1) determine the governing pH in the soil column (either the pH of the leachate or the native soils); and (2) determine the pH of the saturated zone as a result of the infiltrating leachate.

The approach selected for determining the governing pH of the soil column (vadose zone) beneath the waste management unit (WMU) compares the operational life of the WMU (the duration of leaching) to an estimate of the first arrival time of the contaminant front at the water table (a surrogate for the residence time of the contaminant in the soil column). If the operational life of the WMU is *relatively* long compared to the time required for the contaminant to migrate to the water table, there is a high likelihood that the leachate permeates the soil column and that the pH environment is governed by the leachate.

Conversely, a relatively short operational life and retarded contaminant migration would favor ambient soil pH conditions. An analysis of the relationship between operational life and travel time indicated that a ratio of approximately 5 (operational life over travel time) would, in many cases, result in a balanced selection of cases where leachate pH governs versus cases where soil pH governs over approximately 10,000 Monte Carlo iterations.

For each iteration of EPACMTP, the operational life was compared to a travel-time estimate based on a K_d averaged from isotherms selected based on the leachate pH and soil pH. If the ratio was greater than 5, the pH of the leachate was assumed to govern, and the pH of the leachate was used to select the isotherm for transport in the unsaturated zone. If the ratio was less than 5, the soil pH was used to select the isotherm.

In the saturated zone, the impacts of leachate pH were handled using a simple homogeneous mixing calculation. The volume of leachate released from the WMU was mixed with the volume of the aquifer that was likely to be impacted by a plume. The resulting mixed pH was used to select the isotherm for transport in the saturated zone with one limitation: in carbonate environments, the mixed pH in the aquifer was not allowed to drop below a pH of 6. Such acid conditions would likely result in significant dissolution of the soil matrix.

Metal Solubility Limits. As mentioned above, each sorption isotherm comprises equilibrium concentrations of the three contaminant phases (dissolved, sorbed, and precipitated) over a range of total concentration values. An examination of the change in the dissolved-phase concentrations relative to changes in the total concentration in any isotherm reveals solubility behavior for that contaminant: if the dissolved component does not change with increasing total concentration, a solubility limit has been achieved. If, however, the dissolved component increases along with the total concentration, then there is capacity for more dissolved mass in the groundwater or soil porewater.

EPACMTP uses this information (contained in each isotherm file) to determine if a solubility limit should be imposed in the saturated zone. Once an isotherm has been selected (after pH considerations have been addressed), the equilibrium states corresponding to the three highest total concentrations are examined. If the dissolved concentration changes more than one tenth of one percent over the last three points, then EPACMTP assumes there is no solubility

limit. If the change in dissolved concentration is less than one tenth of one percent, EPACMTP assumes a solubility limit has been reached and caps the concentration of the leachate entering the saturated zone at the water table to that limit.

Appendix E. Surface Water, Fish Concentration, and Contaminant Intake Equations

This appendix presents the equations used to model surface water and fish concentrations and intake of drinking water and fish. These equations are presented in the following attachments:

- Attachment E-1 provides the equations comprising the surface water equilibrium partitioning model, including equations that estimate steady state concentrations in the water column (dissolved and total) and sediments.
- Attachment E-2 provides the equations that use bioconcentration factors (BCFs) to calculate fish tissue concentrations from total.
- Attachment E-3 provides the equations used to calculate daily contaminant intake rates from drinking water and fish consumption.

E.1 Aluminum Surface Water Precipitation

Because the fate and transport of aluminum is controlled more by solubility than by sorption in surface water, the surface water model includes algorithms to estimate aluminum concentrations in the water column and sediments by accounting for precipitation and fallout of aluminum in the water column. These calculations proceed in a stepwise fashion, as follows.

Step 1. Initially, assume all influent aluminum is dissolved in the water column.

Fraction in water column (fwater) = 1
Fraction in sediment layer (fbenth) = 0
Fraction dissolved (fd) = 1

Total water column concentration (Cwctot) = dissolved water column concentration (Cwd).

Step 2. Compare the dissolved water column concentration (Cwd) to the maximum soluble concentration (Csol) calculated in MINTEQA2 for the waterbody pH (see Section 3.5.4, Table 3-6 for aluminum solubilities and Appendix C, Section C.6.3, Table C-11 for waterbody pH).

Step 3. If the dissolved water concentration (Cwd) is greater than the solubility limit (Csol), reset the dissolved water concentration to the solubility limit, and precipitate and settle out the excess aluminum to the benthic sediment layer.

If Cwctot > Csol, then

Fwater	=	Csol / Cwctot
Fbenth	=	(Cwctot - Csol) / Cwctot
Cwbs	=	(Cwctot - Csol) * dwc / db
Cwtot	=	Cwctot * dwc / dz
Cdw	=	Csol
Cwctot	=	Csol

Else

Cdw	=	Cwctot
Cwbs	=	0
Cwtot	=	Cwctot * rsParam!dwc / rsParam!dz

End If

where:

Cdw	=	issolved waterbody concentration
Csol	=	maximum soluble concentration
Cwbs	=	total concentration in bed sediment
Cwtot	=	total waterbody concentration from loading
db	=	depth of the upper benthic layer
dwc	=	depth of the water column
dz	=	depth of the waterbody
fbenth	=	fraction in sediment layer
fd	=	fraction dissolved
fwater	=	fraction in water column

Table E-1-1. Fraction of Contaminant in Water Column (unitless)

f_{Water}

$$d_w = d_z - d_b$$

$$f_{Water} = \frac{\left[1 + \left(K_{dsw} \times TSS \times 0.000001\right)\right] \times \frac{d_w}{d_z}}{\left[\left[1 + \left(K_{dsw} \times TSS \times 0.000001\right)\right] \times \frac{d_w}{d_z}\right] + \left[\left(bsp + K_{dbs} \times bsc\right) \times \frac{d_b}{d_z}\right]}$$

Cw_{Tot}	Total Waterbody Concentration from Loading (g/m^3 or mg/L)	Calculated
d_b	Depth of upper benthic layer (m)	0.03
d_w	Depth of water column (m)	Site Data; See Appendix C
d_z	Depth of the waterbody (m)	Calculated

Table E-2-1. Concentration in Fish at Different Trophic Levels (mg/kg)

C_{fish}

For Non-Volatile Metals:

$$C_{fish} = Cw_{tot} \times BCF$$

Name	Description	Value
BCF	Bioconcentration factor for specified trophic level (L/kg)	Chemical Data; See Section 3
C_{dw}	Dissolved waterbody concentration (mg/L)	Calculated
Cw_{Tot}	Total waterbody concentration from loading (g/m^3 or mg/L)	Calculated
0.15	Fraction of dissolved mercury assumed to be methyl mercury (unitless)	

Table E-2-2. Average Fish Fillet Concentration Ingested by Humans (mg/kg)

C_{fish_fillet}

$$C_{fish_fillet} = F_{T3} \times C_{fishT3F} + F_{T4} \times C_{fishT4F}$$

Name	Description	Value
$C_{fishT3F}$	Concentration of contaminant in fish at different trophic levels (mg/kg)	Calculated
$C_{fishT4F}$	Concentration of contaminant in fish at different trophic levels (mg/kg)	Calculated
F_{T3}	Fraction of trophic level 3 intake (unitless)	0.36
F_{T4}	Fraction of trophic level 4 intake (unitless)	0.64

Table E-3-1. Contaminant Intake from Drinking Water (mg/kg-d)

Idw

$$I_{dw} = \frac{C_{dw} \times CR_{dw} \times F_{dw}}{BW * 1000}$$

Name	**Description**	**Value**
BW	Body weight (kg)	Exposure Data; See Appendix F
C_{dw}	Dissolved waterbody concentration (mg/L)	Calculated
CR_{dw}	Consumption rate of water (mL/day)	Exposure Data; See Appendix F
F_{dw}	Fraction of drinking water ingested that is contaminated (unitless)	1
1000	Conversion factor (mL/L)	

Table E-3-2. Daily Intake of Contaminant from Fish Ingestion (mg/kg BW/day)

I_{fish}

$$I_{fish} = \frac{C_{fish_fillet} \times CR_{fish} \times F_{fish}}{1000 \times BW}$$

Name	**Description**	**Value**
BW	Body weight (kg)	Exposure Data; See Appendix F
C_{fish_fillet}	Average fish fillet concentration ingested by humans (mg/kg)	Calculated
CR_{fish}	Consumption rate of fish (g WW/day)	Exposure Data; See Appendix F
F_{fish}	Fraction of fish intake from contaminated source (unitless)	1
1000	Conversion factor (g/kg)	

Appendix F. Human Exposure Factors

Exposure factors are data that quantify human behavior patterns (e.g., ingestion rates of fish and drinking water) and characteristics (e.g., body weight) that affect a person's exposure to environmental contaminants. These data can be used to construct realistic assumptions concerning an individual's exposure to and subsequent intake of a contaminant in the environment. The exposure factors data also enable the U. S. Environmental Protection Agency (EPA) to differentiate the exposures of individuals of different ages (e.g., a child vs. an adult). The derivation and values used for the human exposure factors in this risk assessment are described below, and the exposure factors selected for the probabilistic analyses are also presented.

F.1 Exposure Parameters Used in Probabilistic Analysis

F.1.1 Introduction

The general methodology for collecting human exposure data for the probabilistic analysis relied on the *Exposure Factors Handbook*, or EFH (U.S. EPA, 1997a-c), which was used in one of three ways:

1. When EFH percentile data were adequate (most input variables), maximum likelihood estimation was used to fit selected parametric models (gamma, lognormal, Weibull, and generalized gamma) to the EFH data. The chi-square measure of goodness of fit was then used to choose the best distribution. Parameter uncertainty information (e.g., for averages, standard deviations) also was derived using the asymptotic normality of the maximum likelihood estimate or a regression approach.

2. When EFH percentile data were not adequate for statistical model fitting (a few variables), models were selected on the basis of results for other age cohorts or, if no comparable information was available, by assuming lognormal as a default distribution and reasonable coefficients of variation (CVs).

3. When data were not adequate for either 1 or 2 above, variables were fixed at EFH-recommended mean values or according to established EPA policy.

Table F-1 lists all of the parameters used in the probabilistic analysis. Both fixed variables and the values used to define distributed data are provided.

Probabilistic risk analyses involve "sampling" values from probability distribution functions (PDFs) and using the values to estimate risk. In some cases, distributions are infinite, and there is a probability, although very small, that very large or very small values might be selected from the distributions. Because selecting extremely large or extremely small values is unrealistic (e.g., the range of adult body weights is not infinite), maximum and minimum values

were imposed on the distributions. The minimum and maximum values are included in Table F-1.

F.1.2 Exposure Parameter Distribution Methodology

This section describes how stochastic or distributed input data for each exposure factor were collected and processed. Exposure parameter distributions were developed for use in the Monte Carlo analysis. For most variables for which distributions were developed, exposure factor data from the EFH were analyzed to fit selected parametric models (i.e., gamma, lognormal, Weibull). Steps in the development of distributions included preparing data, fitting models, assessing fit, and preparing parameters to characterize distributional uncertainty in the model inputs.

For many exposure factors, EFH data include sample sizes and estimates of the following parameters for specific receptor types and age groups: mean, standard deviation, standard error, and percentiles corresponding to a subset of the following probabilities: 0.01, 0.02, 0.05, 0.10, 0.15, 0.25, 0.50, 0.75, 0.85, 0.90, 0.95, 0.98, and 0.99. These percentile data, where available, were used as a basis for fitting distributions. Although in no case were all of these percentiles actually provided for a single factor, seven or more are typically present in the EFH data. Therefore, using the percentiles is a fuller use of the available information than fitting distributions simply based on the method of moments (e.g., selecting models that agree with the data mean and standard deviation). For some factors, certain percentiles were not used in the fitting process because sample sizes were too small to justify their use. Percentiles were used only if at least one data point was in the tail of the distribution. If the EFH data repeated a value across several adjacent percentiles, only one value (the most central or closest to the median) was used in most cases (e.g., if both the 98^{th} and 99^{th} percentiles had the same value, only the 98^{th} value was used).

The EFH does not use standardized age cohorts across exposure factors. Different exposure factors have data reported for different age categories. Therefore, to obtain the percentiles for fitting the four standardized age cohorts (i.e., ages 1 to 5, 6 to 11, 12 to 19, and more than 20), each EFH cohort-specific value for a given exposure factor was assigned to one of these four cohorts. When multiple EFH cohorts fit into a single cohort, the EFH percentiles were averaged within each cohort (e.g., data on 1- to 2-year-olds and 3- to 5-year-olds were averaged for the 1- to 5-year-old cohort). If sample sizes were available, weighted averages were used, with weights proportional to sample sizes. If sample sizes were not available, equal weights were assumed (i.e., the percentiles were simply averaged).

Table F-1. Summary of Exposure Parameters Used in Probabilistic Analysis

Parameter	Units	Variable Type	Constants	Mean (or shape)	Std Dev (or scale)	Minimum	Maximum	Reference
Averaging time for carcinogens	yr	Constant	7.00E+01					U.S. EPA (1989)
Body weight (adult)	kg	Lognormal		7.12E+01	1.33E+01	1.50E+01	3.00E+02	U.S. EPA (1997a); Tables 7-2, 7-4, 7-5
Body weight (child 1)	kg	Lognormal		1.55E+01	2.05E+00	4.00E+00	5.00E+01	U.S. EPA (1997b); Tables 7-3, 7-6, 7-7
Body weight (child 2)	kg	Lognormal		3.07E+01	5.96E+00	6.00E+00	2.00E+02	U.S. EPA (1997a); Tables 7-3, 7-6, 7-7
Body weight (child 3)	kg	Lognormal		5.82E+01	1.02E+01	1.30E+01	3.00E+02	U.S. EPA (1997a); Tables 7-3, 7-6, 7-7
Consumption rate: fish (adult, child)	g/d	Lognormal		6.48E+00	1.99E+01	0.00E+00	1.50E+03	U.S. EPA (1997b); Table 10-64
Exposure duration (adult resident)	yr	Weibull		1.34E+00	1.74E+01	1.00E+00	5.00E+01	U.S. EPA (1999) (ACS)
Exposure duration (child)	yr	Weibull		1.32E+00	7.06E+00	1.00E+00	5.00E+01	U.S. EPA (1999) (ACS)
Exposure frequency (adult resident)	d/yr	Constant	3.50E+02					U.S. EPA Policy
Fraction contaminated: drinking water	Fraction	Constant	1.00E+00					U.S. EPA Policy
Fraction contaminated: fish	Fraction	Constant	1.00E+00					U.S. EPA Policy
Fraction of fish consumed that is trophic level (T3) fish	Fraction	Constant	3.60E-01					U.S. EPA (1997b); Table 10-66
Fraction of fish consumed that is trophic level 4 (T4) fish	Fraction	Constant	6.40E-01					U.S. EPA (1997b); Table 10-66
Ingestion rate: drinking water (adult resident)	mL/d	Gamma		3.88E+00	3.57E+02	1.04E+02	1.10E+04	U.S. EPA (1997a); Table 3-6
Ingestion rate: drinking water (child 1 resident)	mL/d	Gamma		2.95E+00	2.37E+02	2.60E+01	3.84E+03	U.S. EPA (1997a); Table 3-6
Ingestion rate: drinking water (child 2 resident)	mL/d	Gamma		3.35E+00	2.35E+02	3.40E+01	4.20E+03	U.S. EPA (1997a); Table 3-6
Ingestion rate: drinking water (child 3 resident)	mL/d	Gamma		2.82E+00	3.42E+02	3.30E+01	5.40E+03	U.S. EPA (1997a); Table 3-6

Because the EFH data are always positive and are almost always skewed to the right (i.e., have a long right tail), three two-parameter probability models commonly used to characterize such data (gamma, lognormal, and Weibull) were selected. In addition, a three-parameter model (generalized gamma) was used that unifies them[1] and allows for a likelihood ratio test of the fit of the two-parameter models. However, only the two-parameter models were selected for use in the analysis because the three-parameter generalized gamma model did not significantly improve the goodness of fit over the two-parameter models. This simple setup constitutes a considerable improvement over the common practice of using a lognormal model in which adequate EFH data are available to support maximum likelihood estimation.

Lognormal, gamma, Weibull, and generalized gamma distributions were fit to each factor data set using maximum likelihood estimation (Burmaster and Thompson, 1998). When sample sizes were available, the goodness of fit was calculated for each of the four models using the chi-square test (Bickel and Doksum, 1977). When percentile data were available but sample sizes were unknown, a regression F-test for the goodness of fit against the generalized gamma model was used. For each of the two-parameter models, parameter uncertainty information (i.e., mean, standard deviation, scale, and shape) was provided as parameter estimates for a bivariate normal distribution that could be used for simulating parameter values (Burmaster and Thompson, 1998). The information necessary for such simulations includes estimates of the two model parameters, their standard errors, and their correlation. To obtain this parameter uncertainty information, the asymptotic normality of the maximum likelihood estimate (Burmaster and Thompson, 1998) was used when sample sizes were available, and a regression approach was used when sample sizes were not available (Jennrich and Moore, 1975; Jennrich and Ralston, 1979). In either case, uncertainty can be expressed as a bivariate normal distribution for the model parameters.

Section F.1.3 discusses fixed parameters. Section F.1.4 describes, for each exposure factor, the EFH data used to develop the distributions, along with the final distributional statistics.

F.1.3 Fixed Parameters

Certain parameters were fixed, based on central tendency values from the best available source (usually EFH recommendations), either because no variability was expected or because the available data were not adequate to generate distributions. Fixed (constant) parameters are shown in Table F-2 along with the value selected for the risk analysis and the data source. These constants include variables for which limited or no percentile data were provided in the EFH: exposure frequency, fractions of T3 and T4 fish consumed, and fraction contaminated for the various media. Most of these values were extracted directly from the EFH. When evaluating carcinogens, total dose is averaged over the lifetime of the individual, assumed to be 70 years.

[1] Gamma, Weibull, and lognormal distributions are all special cases of the generalized gamma distribution.

Table F-2. Summary of Human Exposure Factor Data Used in Modeling: Constants

Description	Value	Units	Source
Fraction contaminated: drinking water	1	Fraction	EPA policy
Fraction contaminated: fish	1	Fraction	EPA policy
Fraction of T3 fish consumed	0.36	Fraction	U.S. EPA (1997b); Table 10-66
Fraction of T4 fish consumed	0.64	Fraction	U.S. EPA (1997b); Table 10-66
Exposure frequency (adult, child)	350	d/yr	EPA policy
Averaging time for carcinogens (adult, child)	70	yr	U.S. EPA (1989)

The fraction contaminated for drinking water was assumed to be 1 (i.e., all drinking water available for consumption at a site is potentially contaminated), with actual concentrations depending on fate and transport model results. Thus, households for which the drinking water pathway was analyzed were assumed to get 100 percent of their drinking water from groundwater. Exposure frequency was set to 350 days per year in accordance with EPA policy, assuming that residents take an average of 2 weeks' vacation time away from their homes each year.

F.1.4 Variable Parameters

F.1.4.1 Fish Consumption

Table F-3 presents fish consumption data and distributions. Fish consumption data were obtained from Table 10-64 of the EFH (U.S. EPA, 1997b). Data (in g/d) were available for adult freshwater anglers in Maine. The Maine fish consumption study was one of four recommended freshwater angler studies in the EFH (U.S. EPA, 1997b). The other recommended fish consumption studies (i.e., Michigan and New York) had large percentages of anglers who fished from Great Lakes, which is not consistent with the modeling scenarios used in this risk analysis. The anglers in the Maine study fished from streams, rivers, and ponds; these data are more consistent with our modeling scenarios. Although the Maine data have a lower mean than the Michigan data, the Maine data compared better with a national U.S. Department of Agriculture (USDA) study. Also, the Maine study included percentile data, which were necessary to develop a distribution.

Percentile data were used to fit parametric models (gamma, lognormal, and Weibull), and measures of goodness of fit were used to select lognormal as the most appropriate model. The fraction of fish intake that is locally caught was assumed to be 1 (in accordance with EPA policy). The fraction of consumed T3 and T4 fish was 0.36 and 0.64, respectively (Table 10-66, U.S. EPA, 1997b).

Table F-3. Fish Consumption Data and Distribution

EFH Data (g/d)									Distribution		
Age Cohort	N	Data Mean	Data SD	P50	P66	P75	P90	P95	Distribution	Pop-Estd Mean	Pop-Estd SD
All ages	1,053	6.4		2	4	5.8	13	26	Lognormal	6.48	19.9

N = Number of samples; P50–P95 = Percentiles; Pop-Estd = Population-estimated; SD = Standard deviation.

F.1.4.2 Drinking Water Intake

Table F-4 presents drinking water intake data and distributions. Drinking water intake data were obtained from Table 3-6 of the EFH (U.S. EPA, 1997a). Data (in mL/d) were presented by age groups. Weighted averages of percentiles, means, and standard deviations were calculated for the three child age groups and adults. Percentile data were used to fit parametric models (gamma, lognormal, and Weibull) using maximum likelihood estimation. Measures of goodness of fit were used to select the most appropriate model. The fraction of drinking water contaminated was assumed to be 1 (in accordance with EPA policy).

Table F-4. Drinking Water Intake Data and Distributions

EFH Data (mL/d)													Distributions		
Age Cohort	N	Data Mean	Data SD	P01	P05	P10	P25	P50	P75	P90	P95	P99	Distribution	Pop-Estd Mean	Pop-Estd SD
1–5	3,200	697.1	401.5	51.62	187.6	273.5	419.2	616.5	900.8	1,236	1,473	1,917	Gamma	698	406
6–11	2,405	787	417	68	241	318	484	731	1,016	1,338	1,556	1,998	Gamma	787	430
12–19	5,801	963.2	560.6	65.15	241.4	353.8	574.4	868.5	1,247	1,694	2,033	2,693	Gamma	965	574
20+	13,394	1,384	721.6	207.6	457.5	607.3	899.6	1,275	1,741	2,260	2,682	3,737	Gamma	1,383	703

N = Number of samples; P01–P99 = Percentiles; Pop-Estd = Population-estimated; SD = Standard deviation.

F.1.4.3 Body Weight

Table F-5 presents body weight data and distributions. Body weight data were obtained from Tables 7-2 through 7-7 of the EFH (U.S. EPA, 1997a). Data (in kg) were presented by age and gender. Weighted averages of percentiles, means, and standard deviations were calculated for 1- to 5-year-olds, 6- to 11-year-olds, 12- to 19-year olds, and adult age groups; male and female data were weighted and combined for each age group. These percentile data were used as the basis for fitting distributions. These data were analyzed to fit parametric models (gamma, lognormal, and Weibull) using maximum likelihood estimation. Measures of goodness of fit were used to select the most appropriate model.

Table F-5. Body Weight Data and Distributions

EFH Data (kg)													Distributions		
Age Cohort	N	Data Mean	Data SD	P05	P10	P15	P25	P50	P75	P85	P90	P95	Distribution	Pop-Estd Mean	Pop-Estd SD
1–5	3,762	15.52	3.719	12.5	13.1	13.45	14.03	15.26	16.67	17.58	18.32	19.45	Lognormal	15.5	2.05
6–11	1,725	30.84	9.561	22.79	24.05	25.07	26.44	29.58	33.44	36.82	39.66	43.5	Lognormal	30.7	5.96
12–19	2,615	58.45	13.64	43.84	46.52	48.31	50.94	56.77	63.57	68.09	71.98	79.52	Lognormal	58.2	10.2
20+	12,504	71.41	15.45	52.86	55.98	58.21	61.69	69.26	78.49	84.92	89.75	97.64	Lognormal	71.2	13.3

N = Number of samples; P05–P95 = Percentiles; Pop-Estd = Population-estimated; SD = Standard deviation.

F.1.4.4 Exposure Duration

Table F-6 presents exposure duration data and distributions. Exposure duration was assumed to be equivalent to the average residence time for each receptor. Exposure durations for adult and child residents were determined using data on residential occupancy from the EFH Table 15-168 (U.S. EPA, 1997c). The data represent the total time a person is expected to live at a single location, based on age. The table presents male and female data combined. Adult residents aged 21 to 90 were pooled. For child residents, the 3-year-old age group was used for the 1- to 5-year-olds. The 6- and 9-year-old age groups were pooled for the 6- to 11-year-old cohort.

Table F-6. Exposure Duration Data and Distributions

EFH Data		Distributions		
Age Cohort	Data Mean (yr)	Distribution	Pop-Estd Shape (yr)[a]	Pop-Estd Scale (yr)
1–5	6.5	Weibull	1.32	7.059
6–11	8.5	Weibull	1.69	9.467
Adult	16.0	Weibull	1.34	17.38

Pop-Estd = Population-estimated.
[a] Distributions used in risk assessment.

In an analysis of residential occupancy data, Myers et al. (U.S. EPA, 2000) found that the data, for most ages, were best fit by a Weibull distribution. The Weibull distribution as implemented in Crystal Ball® is characterized by three parameters: location, shape, and scale. Location is the minimum value and, in this case, was presumed to be 0. Shape and scale were determined by fitting a Weibull distribution to the pooled data, as follows. To pool residential occupancy data for the age cohorts, an arithmetic mean of data means was calculated for each age group. Then, assuming a Weibull distribution, the variance within each age group (e.g., 6-year-olds) was calculated in the age cohort. These variances in turn were pooled over the age cohort using equal weights. This is not the usual type of pooled variance, which would exclude the variation in the group means. However, this way, the overall variance reflected the variance of means within the age groups (e.g., within the 6-year-old age group). The standard deviation was estimated as the square root of the variance. The coefficient of variation was calculated as the ratio of the standard deviation divided by the Weibull mean. For each cohort, the population-estimated parameter uncertainty information (e.g., shape and scale) was calculated based on a Weibull distribution, the calculated data mean for the age cohort, and the CV.

Appendix G. Human Health Benchmarks

The coal combustion waste (CCW) risk assessment will require human health benchmarks to assess potential risks from chronic oral and inhalation exposures. The U.S. Environmental Protection Agency (EPA) uses reference doses (RfDs) and reference concentrations (RfCs) to evaluate noncancer risk from oral and inhalation exposures, respectively. Oral cancer slope factors (CSFs), inhalation unit risk factors (URFs), and inhalation CSFs are used to evaluate risk for carcinogens.

This appendix provides the human health benchmarks used in the CCW screening and risk assessment. Section G.1 describes the data sources and general hierarchy used to collect these benchmarks. Section G.2 provides the benchmarks along with discussions of individual human health benchmarks extracted from a variety of sources.

G.1 Methodology and Data Sources

Several sources of health benchmarks are available. The hierarchy used health benchmarks developed by EPA to the extent that they were available. The analysis used available benchmarks from non-EPA sources for chemicals for which EPA benchmarks were not available, and ranked human health benchmark sources in the following order of preference:

- Integrated Risk Information System (IRIS)
- Superfund Technical Support Center Provisional Benchmarks
- Health Effects Assessment Summary Tables (HEAST)
- EPA health assessment documents
- Various other EPA health benchmark sources
- Agency for Toxic Substances and Disease Registry (ATSDR) minimal risk levels (MRLs)
- California Environmental Protection Agency (CalEPA) chronic inhalation reference exposure levels (RELs) and cancer potency factors.

G.1.1 Integrated Risk Information System (IRIS)

Benchmarks in IRIS are prepared and maintained by EPA, and RTI used values from IRIS whenever available. IRIS is EPA's electronic database containing information on human health effects (U.S. EPA, 2002). Each chemical file contains descriptive and quantitative information on potential health effects. Health benchmarks for chronic noncarcinogenic health

effects include RfDs and RfCs. Cancer classification, oral CSFs, and inhalation URFs are included for carcinogenic effects. IRIS is the official repository of Agency-wide consensus of human health risk information.

Inhalation CSFs are not available from IRIS, so we calculated them from inhalation URFs (which are available from IRIS) using the following equation:

$$inh\ CSF = inh\ URF \times 70\,kg \div 20\,m^3/d \times 1000\,\mu g/mg$$

In this equation, 70 kg represents average body weight; 20 m^3/d represents average inhalation rate; and 1000 µg/mg is a units conversion factor (U.S. EPA, 1997). EPA uses these standard estimates of body weight and inhalation rate in the calculation of the URF; therefore, we used these values to calculate inhalation CSFs.

G.1.2 Superfund Provisional Benchmarks

The Superfund Technical Support Center (EPA's National Center for Environmental Assessment [NCEA]) derives provisional RfCs, RfDs, and CSFs for certain chemicals. These provisional health benchmarks can be found in Risk Assessment Issue Papers. Some of the provisional values have been externally peer reviewed. These provisional values have not undergone EPA's formal review process for finalizing benchmarks and do not represent Agency-wide consensus information.

G.1.3 Health Effects Assessment Summary Tables

HEAST is a listing of provisional noncarcinogenic and carcinogenic health toxicity values (RfDs, RfCs, URFs, and CSFs) derived by EPA (U.S. EPA, 1997). Although the health toxicity values in HEAST have undergone review and have the concurrence of individual EPA program offices, either they have not been reviewed as extensively as those in IRIS or their data set is not complete enough to be listed in IRIS. HEAST benchmarks have not been updated in several years and do not represent Agency-wide consensus information.

G.1.4 Other EPA Health Benchmarks

EPA has also derived health benchmark values in other risk assessment documents, such as Health Assessment Documents (HADs), Health Effects Assessments (HEAs), Health and Environmental Effects Profiles (HEEPs), Health and Environmental Effects Documents (HEEDs), Drinking Water Criteria Documents, and Ambient Water Quality Criteria Documents. Evaluations of potential carcinogenicity of chemicals in support of reportable quantity adjustments were published by EPA's Carcinogen Assessment Group (CAG) and may include cancer potency factor estimates. Health benchmarks derived by EPA for listing determinations (e.g., solvents) or studies (e.g., Air Characteristic Study) are also available. Health toxicity values identified in these EPA documents are usually dated and are not recognized as Agency-wide consensus information or verified benchmarks.

G.1.5 ATSDR Minimal Risk Levels

The ATSDR MRLs are substance-specific health guidance levels for noncarcinogenic endpoints (ATSDR, 2002). An MRL is an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified duration of exposure. MRLs are based on noncancer health effects only and are not based on a consideration of cancer effects. MRLs are derived for acute, intermediate, and chronic exposure durations for oral and inhalation routes of exposure. Inhalation and oral MRLs are derived in a manner similar to EPA's RfCs and RfDs, respectively (i.e., ATSDR uses the no observed adverse effect level/uncertainty factor [NOAEL/UF] approach); however, MRLs are intended to serve as screening levels and are exposure duration specific. Also, ATSDR uses EPA's (U.S. EPA, 1994) inhalation dosimetry methodology in the derivation of inhalation MRLs.

G.1.6 CalEPA Cancer Potency Factors and Reference Exposure Levels

CalEPA has developed cancer potency factors for chemicals regulated under California's Hot Spots Air Toxics Program (CalEPA, 1999a). The cancer potency factors are analogous to EPA's oral and inhalation CSFs. CalEPA has also developed chronic inhalation RELs, analogous to EPA's RfC, for 120 substances (CalEPA, 1999b, 2000). CalEPA used EPA's (U.S. EPA, 1994) inhalation dosimetry methodology in the derivation of inhalation RELs. The cancer potency factors and inhalation RELs have undergone internal peer review by various California agencies and have been the subject of public comment.

G.1.7 Surrogate Health Benchmarks

If no human health benchmarks were available from EPA or alternative sources, we sought benchmarks for similar chemicals to use as surrogate data. For example, the health benchmark of a mixture could serve as the surrogate benchmark for its components or a benchmark of a metal salt could serve as the surrogate for an elemental metal.

G.2 Human Health Benchmarks

The chronic human health benchmarks used to calculate the health-based numbers (HBNs) in the CCW risk assessment are summarized in Table G-1, which provides the Chemical Abstract Service Registry Number (CASRN), constituent name, RfD (mg/kg-d), RfC (mg/m^3), oral CSF ($mg/kg\text{-}d^{-1}$), inhalation URF [$(\mu g/m^3)^{-1}$], inhalation CSF ($mg/kg\text{-}d^{-1}$), and reference for each benchmark. A key to the references cited and abbreviations used is provided at the end of the table.

For a majority of constituents, human health benchmarks were available from IRIS (U.S. EPA, 2002), Superfund Provisional Benchmarks, or HEAST (U.S. EPA, 1997). Benchmarks also were obtained from ATSDR (2002) or CalEPA (1999a, 1999b, 2000). This section describes benchmarks obtained from other sources, along with the Superfund Provisional Benchmarks values and special uses of IRIS benchmarks.

Provisional inhalation health benchmarks were developed in the Air Characteristic Study (U.S. EPA, 1999) for several constituents lacking IRIS, HEAST, alternative EPA, or ATSDR

values. For vanadium, the study on which the ATSDR acute inhalation MRL is based was used but was adjusted for chronic exposure. Additional details on the derivation of this inhalation benchmark can be found in the *Revised Risk Assessment for the Air Characteristic Study* (U.S. EPA, 1999).

The provisional RfD of 0.02 mg/kg-d developed by NCEA for the Superfund Technical Support Center (U.S. EPA, 2001a) was used for cobalt.

Table G-1. Human Health Benchmarks Used in CCW Risk Assessment

Constituent Name	CASRN	RfD (mg/kg-d)	Ref	RfC (mg/m^3)	Ref	CSFo (per mg/kg-d)	Ref	URF (per µg/m3)	Ref	CSFi (per mg/kg-d)	Ref	MCL (mg/L)	Notes
Aluminum	7429-90-5	2.0E+00	A										RfD is for intermediate duration
Ammonia	7664-41-7	9.7E-01	H	1.0E-01	I								RfD= 34 mg/L
Antimony	7440-36-0	4.0E-04	I	2.0E-04	I								RfC is for antimony trioxide
Arsenic, inorganic	7440-38-2	3.0E-04	I	3.0E-05	Cal00	1.5E+0	I	4.3E-3	I	1.5E+1	calc		
Barium	7440-39-3	7.0E-02	I	5.0E-04	H								
Beryllium	7440-41-7	2.0E-03	I	2.0E-05	I			2.4E-3	I	8.4E+0	calc		
Boron	7440-42-8	9.0E-02	I	2.0E-02	H								
Cadmium	7440-43-9	5.0E-04	I	2.0E-05	Cal00			1.8E-3	I	6.3E+0	calc		RfD for H_2O (food = 1E-3)
Chloride	16887-00-6											250	
Chromium (III), insoluble salts	16065-83-1	1.5E+00	I										
Chromium (VI)	18540-29-9	3.0E-03	I	1.0E-04	I			1.2E-2	I	4.2E+1	calc		
Cobalt (and compounds)	7440-48-4	2.0E-02	SF	1.0E-04	A			2.8E-3	SF	9.8E+0	calc		
Copper	7440-50-8											1.3	
Cyanide (amenable)	57-12-5	2.0E-02	I										
Divalent mercury		3.0E-04	H										RfD is for mercuric chloride; used for food, water, soil
Divalent mercury		1.0E-04	I										RfD is for methyl mercury; used for fish only
Fluoride	16984-48-8	1.2E-01	I										RfD is for fluorine; the alternative IRIS value (for skeletal, rather than dental, fluorosis) was used
Iron	7439-89-6											0.3	
Lead and compounds (inorganic)	7439-92-1											0.015	
Manganese	7439-96-5	1.4E-01	I	5.0E-05	I								RfD for food; H_2O and soil = 4.7E-2 mkd
Molybdenum	7439-98-7	5.0E-03	I

A = ATSDR MRLs (ATSDR, 2002)
AC = Developed for the Air Characteristic Study (U.S. EPA, 1999)
calc = Calculated
Cal00 = CalEPA chronic REL (CalEPA, 2000)
H = HEAST (U.S. EPA, 1997)
I = IRIS (U.S. EPA, 2002)
SF = Superfund Risk Issue Paper (U.S. EPA, 2001a,b)

For several constituents, IRIS benchmarks for similar chemicals were used as surrogate data. The rationale for these recommendations is as follows:

- The RfC for antimony trioxide (2E-04 mg/m^3) was used as a surrogate for antimony.
- Fluoride was based on fluorine. The IRIS RfD for fluorine is based on soluble fluoride. The primary RfD cited in IRIS (6E-02 mg/kg-d) is for dental fluorosis, a cosmetic effect. In this analysis, an alternative IRIS value (1.2E-01 mg/kg-d) for skeletal fluorosis in adults was used instead.
- The RfC for mercuric chloride (9E-05 mg/m^3) was used as a surrogate for elemental mercury. The RfDs for mercuric chloride (3E-04 mg/kg-d) and methyl mercury (1E-04 mg/kg-d) were used as surrogates for elemental mercury for assessing potential risks from food, soil, and water ingestion, and fish ingestion, respectively.
- Thallium was based on thallium chloride. There are several thallium salts that have RfDs in IRIS. The lowest value among the thallium salts (8E-05 mg/kg-d) is routinely used to represent thallium in risk assessments.

Appendix H. Ecological Benchmarks

Both the screening and full-scale CCW assessments include an ecological risk assessment that parallels the human health risk assessment. The ecological risk assessment addresses two routes of exposure for ecological receptors: direct contact with contaminated media and ingestion of contaminated food items. For each CCW chemical for which ecological effect data were available, hazard quotients (HQs) were calculated using chemical-specific media concentrations assumed to be protective of ecological receptors of concern.

This appendix provides the ecological benchmarks used in both the CCW screening and full-scale risk assessment. Section H.1 describes the data sources and methods used to develop these benchmarks. Additional details can be found in U.S. EPA (1998). Section H.2 provides the benchmarks.

H.1 Data Sources and Methodology

To calculate ecological HQs, the concentration-based ecological benchmarks (also known as chemical stressor concentration limits, or CSCLs) were divided by the estimated concentrations of constituents in environmental media contaminated by CCW. The CSCLs are environmental quality criteria intended to represent a protective threshold value for adverse effects to various ecological receptors in terrestrial (soil) and aquatic ecosystems (surface water and sediment). An HQ greater than target of 1 indicates that the predicted concentration will be above the CSCL and, therefore, the potential for adverse ecological effects exists. In this regard, the use of CSCLs to calculate an ecological HQ is analogous to the use of the reference concentration (RfC) for human health where the air concentration is compared to the health-based concentration (the RfC), and an HQ greater than the target value of 1 is considered to indicate the potential for adverse health effects. Table H-1 shows the receptor types assessed for each exposure route in each environmental medium addressed by the CCW risk assessment.

Table H-1. Ecological Receptors Assessed by Medium Impacted by CCW

Receptor Type	Surface Water	Sediment	Soil
Direct Contact Exposure			
Aquatic Community	✔		
Sediment Community		✔	
Soil Community			✔
Amphibians	✔		
Aquatic Plants and Algae	✔		
Terrestrial Plants			✔
Ingestion Exposure			
Mammals	✔		✔
Birds	✔		✔

Ecological benchmarks for the CCW risk assessment were taken directly from the 1998 fossil fuel combustion risk analysis, *Non-Groundwater Pathways, Human Health and Ecological Risk Analysis for Fossil Fuel Combustion Phase 2 (FFC2)* (U.S. EPA, 1998). The receptors and endpoints selected for the 1998 analysis were evaluated and considered appropriate for the goals of this risk assessment. The benchmarks were derived for each chemical and receptor to the extent that supporting data were available.

As in 1998, the lowest (most sensitive) benchmark for each chemical in each medium was selected to calculate HQs in the CCW risk assessment. For example, several receptors (soil invertebrates, terrestrial plants, mammals, and birds) are exposed to constituents in soils. The soil HQ for a given chemical was calculated using whichever soil benchmark was lowest and would thus give the highest (most conservative) HQ.

H.1.1 Direct Contact Exposure

Ecological receptors that live in close contact with contaminated media are considered to be potentially at risk. These receptors are exposed through direct contact with contaminants in surface water, sediment, and soil. The receptors selected to assess the direct contact exposure route for each medium were previously summarized in Table H-1. The benchmarks for receptor communities are not truly *community-level* concentration limits in that they do not consider predator-prey interactions. Rather, they are based on the theory that protection of 95 percent of the species in the community will provide a sufficient level of protection for the community (see, for example, Stephan et al., 1985, for additional detail). The following sections summarize the benchmark derivation methods for each receptor assessed for the direct contact route of exposure.

Aquatic Community Benchmarks

The aquatic community receptor comprises fish and aquatic invertebrates exposed through direct contact with constituents in surface water. For the aquatic community, the final chronic value (FCV), developed either for the Great Lakes Water Quality Initiative (U.S. EPA, 1993) or the National Ambient Water Quality Criteria (NAWQC) (U.S. EPA, 1995a,b), was the preferred source for the benchmark. If an FCV was unavailable and could not be calculated from available data, a secondary chronic value (SCV) was estimated using methods developed for wildlife criteria for the Great Lakes Initiative (e.g., 58 FR 20802; U.S. EPA, 1993). The SCV methodology is based on the original species data set established for the NAWQC; however, it requires fewer data points and includes statistically derived adjustment factors. For benchmark derivation, the minimum data set required at least one data point.

Amphibian Benchmarks

For amphibian populations, data availability severely limited benchmark development. A review of several compendia presenting amphibian ecotoxicity data (e.g., U.S. EPA, 1996; Power et al., 1989), as well as primary literature sources, found a lack of standard methods on endpoints, species, and test durations necessary to derive a chronic benchmark for amphibians. Consequently, an acute benchmark was derived for aqueous exposures in amphibians by taking a geometric mean of LC_{50} (i.e., concentration lethal to 50 percent of test subjects) data identified in studies with exposure durations less than 8 days. Although the use of acute effects levels is not

consistent with other benchmarks, the sensitivity of these receptors warrants their use in lieu of chronic concentration limits. Recent studies (Hopkins and Rowe, 2004; Hopkins et al., 2006) have confirmed that amphibians are among the most sensitive taxa to metals found in CCW, and selenium appears to be a significant stressor in CCW disposal scenarios. The endpoints considered in these studies were related to population sustainability and, consequently, are highly relevant to ecological risk assessment. However, these field studies are confounded by the fact that wildlife were exposed to multiple chemical pollutants (including radionuclides) and, as a result, acute effects data on individual metals remain the most appropriate source for quantitative benchmarks to assess the potential for adverse effects in amphibians.

Sediment Community Benchmarks

For the sediment community, benchmarks were selected based on a complete assessment of several sources proposing sediment benchmark values. Primary sources evaluated for developing sediment community benchmarks are shown in Table H-2.

Table H-2. Primary Sources Evaluated for Developing Sediment Community Benchmarks

Soil Community Benchmarks

For the soil community, the preferred methods for deriving benchmarks are analogous to those used in deriving the NAWQC. Benchmark values for soil fauna were estimated to protect 95 percent of the species found in a typical soil community, including earthworms, insects, and various other soil fauna. The methodology presumes that protecting 95 percent of the soil species with a 50^{th} percentile level of confidence will ensure long-term sustainability of a functioning soil community. The toxicity data on soil fauna were taken from several major compendia and supplemented with additional studies identified in the open literature.

The approach to calculating benchmarks for the soil community is based on efforts by Dutch scientists (i.e., the Netherlands' National Institute of Public Health and Environmental Protection [RIVM] methodology) to develop hazardous concentrations (HCs) at specified levels

of protection (primarily 95 percent) at both a 95th percentile and a 50th percentile level of confidence (Sloof, 1992). For the soil fauna benchmarks, the 50th percentile level of confidence was selected because the 95th percentile appeared to be overly conservative for a "no effects" approach. The RIVM methodology follows two steps: (1) fitting a distribution to the log of the selected endpoints, and (2) extrapolating to a benchmark concentration based on the mean and standard deviation of a set of endpoints. The key assumptions in the Dutch methodology are that (1) lowest observed effects concentration (LOEC) data are distributed logistically, and (2) the 95 percent level of protection is ecologically significant. The following formula was used to calculate soil fauna benchmarks:

$$HC_{5\%} = \left[x_m - k_1 s_m\right] \quad \text{(H-1)}$$

where

$HC_{5\%}$ = soil concentration protecting 95 percent of the soil species
x_m = sample mean of the log LOEC data
k_l = extrapolation constant for calculating the one-sided leftmost confidence limit for a 95 percent protection level
s_m = sample standard deviation of the log LOEC data.

Sufficient data were available to develop benchmarks using this methodology for four of the metals of concern: cadmium, copper, lead, and zinc. For the remaining constituents, benchmark studies identifying effects to earthworms and other soil biota proposed by Oak Ridge National Laboratory (Efroymson et al., 1997a) or criteria developed by the Canadian Council of Ministers of the Environment (CCME, 1997) were used to estimate protective soil concentrations.

Algae and Aquatic Plant Benchmarks

For algae and aquatic plants, adverse effects concentrations are identified in the open literature or from a data compilation presented in *Toxicological Benchmarks for Screening Potential Contaminants of Concern for Effects on Aquatic Biota: 1996 Revision* (Suter and Tsao, 1996). For most contaminants, studies were not available for aquatic vascular plants, and lowest effects concentrations were identified for algae. The benchmark for algae and aquatic plants was based on (1) an LOEC for vascular aquatic plants or (2) an effective concentration (EC_{xx}) for a species of freshwater algae, frequently a species of green algae (e.g., *Selenastrum capricornutum*). Because of the lack of data for this receptor group and the differences between vascular aquatic plants and algae sensitivity, the lowest value of those identified was usually chosen.

Terrestrial Plant Benchmarks

For the terrestrial plant community, ecotoxicological data were identified from a summary document prepared at the Oak Ridge National Laboratory: *Toxicological Benchmarks for Screening Contaminants of Potential Concern for Effects on Terrestrial Plants: 1997 Revision* (Efroymson et al., 1997b). The measurement endpoints are generally limited to growth and yield parameters because (1) they are the most common class of response reported in phytotoxicity studies and, therefore, will allow for criterion calculations for a large number of

constituents, and (2) they are ecologically significant responses both in terms of plant populations and, by extension, the ability of producers to support higher trophic levels. As presented in Efroymson et al. (1997a), benchmarks for phytotoxicity were selected by rank ordering the LOEC values and then approximating the 10^{th} percentile. If there were 10 or fewer values for a chemical, the lowest LOEC was used. If there were more than 10 values, the 10^{th} percentile LOEC was used.

H.1.2 Ingestion Exposure

The ingestion route of exposure addresses the exposure of terrestrial mammals and birds through ingestion of plants and prey and incidental soil ingestion. Thus, the CCW ecological benchmarks for ingestion exposure express media concentrations that, based on certain assumptions about receptor diet and foraging behavior, are expected to be protective of populations of mammals and birds feeding and foraging in contaminated areas.

The derivation of ingestion benchmarks begins with the selection of appropriate ecotoxicological data based on a hierarchy of data sources. The assessment endpoint for the CCW ecological risk assessment is population viability; therefore, ecological benchmarks were developed from measures of reproductive/developmental success or, if unavailable, from other effects that could conceivably impair population dynamics. Population-level benchmarks are preferred over benchmarks for individual organisms; however, very few population-level benchmarks have been developed. Therefore, the CCW risk assessment uses benchmarks derived from individual organism studies, and protection is inferred at the population level.

Once an appropriate ingestion exposure study was identified, a benchmark was calculated using a three-step process. The remainder of this section outlines the basic technical approach used to convert avian or mammalian benchmarks (in daily doses) to the media concentration benchmarks (in units of concentration) used to assess ecological risks for surface water and soil contaminated by CCW waste constituents. The methods reflect exposure through the ingestion of contaminated plants, prey, and various media, and include parameters on accumulation (e.g., bioconcentration factors), uptake (e.g., consumption rates), and dietary preferences.

Step 1: Scale Benchmark

The benchmarks derived for test species can be extrapolated to wildlife receptor species within the same taxon using a cross-species scaling equation (Equation H-2) (Sample et al., 1996). This is the default methodology EPA proposed for carcinogenicity assessments and reportable quantity documents for adjusting animal data to an equivalent human dose (57 FR 24152).

$$Benchmark_w = LOAEL_t \times \left(\frac{bw_t}{bw_w} \right)^{1/4} \quad \text{(H-2)}$$

where

$Benchmark_w$ = scaled ecological benchmark for species *w* (mg/kg/d)
$LOAEL_t$ = lowest observed adverse effects level for test species (mg/kg/d)
bw_t = body weight of the surrogate test species (kg)
bw_w = body weight of the representative wildlife species (kg).

Step 2: Identify Bioconcentration Factors / Bioaccumulation Factors

For metal constituents, whole-body bioconcentration factors (BCFs) and bioaccumulation factors (BAFs) were identified for aquatic and terrestrial organisms that may be used as food sources (e.g., fish, plants, earthworms). The Oak Ridge National Laboratory has proposed methods and data that are useful in predicting bioaccumulation in earthworms and small mammals (Sample et al. 1998a,b). These values were typically identified in the open literature and EPA references.

Step 3: Calculate Benchmarks

The following equation provides the basis for calculating surface water benchmarks using a population-inference benchmark (e.g., endpoint on fecundity).

$$Benchmark = \frac{\left[I_{fish} \times \left(BAF \;\; C_w\right)\right] + \left(I_w \times C_w\right)}{bw} \quad \text{(H-3)}$$

where

I_{fish} = intake of contaminated fish (kg/d)
BAF = whole-body bioaccumulation factor (L/kg)
bw = weight of the representative species (kg)
I_w = intake of contaminated water (L/d)
C_w = total concentration in the water (mg/L).

For chemicals that bioaccumulate significantly in fish tissue, the ingestion of contaminated food will tend to dominate the exposure (i.e., $[I_{fish} \times C_{fish}] >> [I_w\ C_w]$), and the water term (i.e., $[I_w \times C_w]$) can be dropped from Equation H-3, resulting in Equation H-4:

$$Benchmark \;=\; \frac{I_{fish} \;\times\; \left(BAF \;\times\; C_w\right)}{bw} \quad \text{(H-4)}$$

At the benchmark dose (mg/kg/d), the concentration in water is equivalent to the chemical stressor concentration limit for that receptor as a function of body weight, ingestion rate, and the bioaccumulation potential for the chemical of concern. Hence, Equation H-4 can be rewritten to solve for the surface water ($CSCL_{sw}$) as follows:

$$CSCL_{sw} \;=\; \frac{benchmark \;\times\; bw}{I_w \;+\; \left(I_{fish} \;\times\; BAF\right)} \quad \text{(H-5)}$$

For wildlife populations of mammals and birds in terrestrial systems, the soil benchmark ($CSCL_{soil}$) for a given receptor was calculated using Equation H-6:

$$CSCL_{soil} = \frac{benchmark \times bw}{I_{food} \sum \left(BCF_j \times F_j \times AB_j\right) + I_{soil}} \quad \text{(H-6)}$$

where

bw	=	body weight (kg)
I_{food}	=	total daily food intake of species (kg/d)
I_{soil}	=	total daily soil intake of species (kg/d)
BCF_j	=	bioaccumulation factor in food item *j* (assumed unitless)
F_j	=	fraction of diet consisting of food item *j* (unitless)
AB_j	=	absorption of chemical in the gut from food item *j*.

H.2 Ecological Benchmarks

The ecological benchmarks used to calculate ecological HQs in the CCW risk assessment are summarized in Table H-3, which provides the constituent name; the criterion and receptor for soil, sediment, and aquatic receptors; and the source for each benchmark.

Table H-3. Ecological Benchmarks Used in the CCW Risk Assessment

Constituent	Soil Criterion (mg/kg)	Terrestrial Receptor	Sediment Criterion (mg/kg)	Sediment Receptor	Aquatic Criterion (mg/L)	Aquatic Receptor	Source

PEER REVIEWERS

The 2010 Risk Assessment was reviewed by an external panel of experts. The panel was composed of the following individuals:

- Dr. Nicholas Basta, Ohio State University
- Dr. Charles Harvey, Massachusetts Institute of Technology
- Dr. William Hopkins, Virginia Polytechnic Institute and State University
- Dr. Kerry Rowe, Queens University
- Dr. Donna Vorhees, The Science Collaborative

Executive Summary

Purpose

The purpose of the risk assessment is to characterize the risks that may result from the current disposal practices for coal combustion residuals (CCRs) and provide a scientific basis for the development of regulations necessary to protect human health and the environment under the Resource Conservation and Recovery Act (RCRA).

Scope

CCR is a broad term used to refer to the byproducts that are generated either directly by coal combustion or as a result of applying certain pollution control devices to emissions from coal-fired combustion units. The distinct CCR categories identified in the rulemaking include fly ash, bottom ash, boiler slag, and flue gas desulfurization (FGD) materials. All coal-fired electric utility plants in the United States generate at least one of these wastes. These different CCR wastes may be generated separately or mixed together. Once generated, CCRs may be either beneficially used or disposed of in surface impoundments and landfills (collectively referred to as "waste management units" or "WMUs"). The regulatory scope of this rulemaking is limited to current disposal practices for CCRs generated by coal-fired electric utilities and independent power producers covered by the North American Industry Classification System (NAICS) code 221112. The scope of this risk assessment is limited accordingly. The United Stated Environmental Protection Agency (EPA) did not evaluate disposal of wastes other than CCRs, disposal of CCRs at off-site locations, WMUs that have ceased receiving waste, or historical disposal of CCRs by facilities that are no longer operating or not otherwise covered by NAICS code 221112.

Some coal-fired power plants conduct coal preparation activities prior to combustion. These activities may include, but are not limited to, coal handling by conveyor systems, coal washing for removing mineral matter, and coal "sizing" to reduce the average particle size of coal. The wastes generated from these coal preparation activities are collectively referred to as "coal refuse." However, some facilities are known to dispose of coal refuse together with CCRs because the chemical characteristics of the coal refuse can have a pronounced effect on the release of chemical constituents from CCRs, EPA also considered the codisposal of this additional waste stream (referred to as "ash and coal refuse") in the risk assessment.

Overview of Risk Assessment

EPA used mathematical models to determine the rate at which chemical constituents may be released from different WMUs, to predict the fate and transport of these constituents through the environment, and to estimate the resulting risks to human and ecological receptors. Modeling was conducted in a stepwise fashion, with more refined analyses used at each subsequent step. The findings at each of the analyses conducted for this risk assessment are summarized below.

Problem Formulation

EPA first developed conceptual models to illustrate a general layout of surface impoundments and landfills, the chemical constituents that may be released from these WMUs, the routes through which these constituents may migrate through environmental media, and the types of exposures that may result. These conceptual models were used as the basis for all subsequent data collection efforts. EPA first collected data on the coal-fired power plants and CCR WMUs located across the United States. EPA then collected regional and national data to characterize the environment and receptor population surrounding each WMU. The data assembled represent the most current and comprehensive information available to the Agency at the time this risk assessment was conducted. Using the data collected, EPA first conducted a simplified hazard identification to determine which constituents warranted further evaluation. At this stage, EPA considered the presence of a constituent in CCR waste, combined with the availability of at least one toxicity benchmark, sufficient evidence of hazard potential. **Table ES-1** presents a summary of the different chemical constituents retained as constituents of potential concern (COPCs) for further analysis.

Table ES-1. List of Chemical Constituents Evaluated in the CCR Risk Assessment

▪ Aluminum	▪ Cadmium	▪ Iron	▪ Molybdenum	▪ Strontium
▪ Ammonia	▪ Calcium	▪ Lanthanum	▪ Nickel	▪ Sulfate
▪ Antimony	▪ Chloride	▪ Lead	▪ Nitrate / Nitrite	▪ Sulfide
▪ Arsenic	▪ Chromium	▪ Lithium	▪ Selenium	▪ Thallium
▪ Barium	▪ Cobalt	▪ Magnesium	▪ Silicon	▪ Uranium
▪ Beryllium	▪ Copper	▪ Manganese	▪ Silver	▪ Vanadium
▪ Boron	▪ Fluoride	▪ Mercury	▪ Sodium	▪ Zinc

All risks identified in subsequent analyses were compared against risk criteria of cancer risk greater than 1×10^{-5} or a noncancer hazard quotient (HQ) greater than 1. EPA typically relies on a risk range to determine the point at which regulation is appropriate. EPA uses as an initial cancer risk "level of concern" a calculated risk level of 1×10^{-5} (one in one hundred thousand) or an HQ above 1.0 for any noncarcinogens. For example, waste streams for which the calculated high-end individual cancer-risk level is 1×10^{-5} or higher generally are considered candidates for regulation. Waste streams whose risks are calculated to be 1×10^{-4} or higher generally will be considered to pose a substantial present or potential hazard to human health and the environment and generally will be regulated. Waste streams for which these risks are calculated to be 1×10^{-6} or lower, and lower than 1.0 HQs or EQs for any noncarcinogens, generally will be considered not to pose a substantial present or potential hazard to human health and the environment and generally will not regulated. See 59 FR 66075–66077, December 22, 1994.

Screening Analysis

EPA conducted separate screening analyses for each exposure pathway to identify which COPCs are most likely to pose risk to receptors. The results of this screening generally do not provide a

precise characterization of individual risks that may occur, but rather identify those COPCs that are most likely to exceed risk criteria. In cases where well established, post-construction management practices ("controls") have been shown to minimize releases from WMUs, EPA considered exposures for both an uncontrolled and controlled management scenario.

This screening analysis identified potential risks to human and ecological receptors resulting from the releases of particulate matter and the chemical constituents contained therein through wind and run-off. Under an uncontrolled management scenario, risks to human receptors resulted from the inhalation of windblown particulates in ambient air and the ingestion of soil and animal products (i.e., meat and dairy), while risks to ecological receptors resulted from exposures to soil and sediment. Under a controlled management scenario, which consisted of fugitive dust controls and run-on/run-off controls, all risks associated with these exposure pathways decreased to below the criteria. Due to the conservative nature of the screening, there is a great deal of uncertainty surrounding the specific risks calculated for these exposure pathways. These risks represent a protective, but unlikely, combination of conditions that reflect at least an upper bound on potential exposures. Thus, the cumulative effect of these uncertainties results in an overestimation of nationwide risks to most or all receptors. Therefore, EPA makes no direct findings concerning the magnitude of the risks that may occur under either an uncontrolled or controlled management scenario, but concludes with a high degree of confidence that the reductions achievable with standard management practices are sufficient to be protective even under this conservative screening assessment. Based on these lines of evidence, EPA concluded that no further characterization was warranted for these exposure pathways.

These screening analyses identified potential risks to human and ecological receptors from leaching of chemical constituents from CCR waste into surrounding environmental media. Risks to human health resulted from ingestion of ground water and fish, while risks to ecological receptors resulted from exposure to surface water. There was no simple method to estimate the effect controls may have for these pathways. However, considerable dilution and attenuation may occur before COPCs reach downgradient private wells and surface water bodies. Therefore, EPA retained all of the COPCs found to be above risk criteria in ground water and surface water for further characterization. In addition, EPA used the uncontrolled screening results for the above ground sediment pathway as a conservative proxy for the ground water to surface water sediment pathway. As a result, sediment exposures of four COPCs were retained for further characterization. **Table ES-2** presents a summary of the chemical constituents retained as COPCs for each pathway.

Table ES-2. List of Chemical Constituents Retained for Probabilistic Analysis

Human Health		Ecological					
Ingestion of Ground Water	Ingestion of Fish	Surface Water Exposure				Sediment Exposure	
▪ Antimony	▪ Arsenic	▪ Aluminum	▪ Iron			▪ Antimony	
▪ Arsenic	▪ Cadmium	▪ Arsenic	▪ Lead			▪ Arsenic	
▪ Boron	▪ Mercury	▪ Barium	▪ Molybdenum			▪ Silver	
▪ Cadmium	▪ Selenium	▪ Beryllium	▪ Nickel			▪ Vanadium	
▪ Cobalt	▪ Thallium	▪ Boron	▪ Selenium				
▪ Fluoride		▪ Cadmium	▪ Silver				
▪ Lead		▪ Chloride	▪ Vanadium				
▪ Lithium		▪ Chromium	▪ Zinc				
▪ Molybdenum		▪ Cobalt					
▪ Thallium		▪ Copper					

These screening analyses also identified potential risks to ecological receptors from direct exposure to impoundment wastewater. Unlike the other exposure pathways, no dilution or attenuation will occur within impoundment wastewater prior to ecological exposures. Thus, the direct exposures considered in the screening analysis provide a reasonable estimate of the relative magnitude of risks. Based on the screening analyses, EPA concluded that HQs for ecological receptors exceeded 1 for the following constituents (listed from highest to lowest potential): arsenic (100), barium (50), aluminum (30), boron (30), selenium (20), cadmium (10), vanadium (10), beryllium (2), chloride (2) and chromium (2). Because the screening analysis provides sufficient characterization of these exposures, this pathway was not carried forward for further analysis.

Probabilistic Analysis

EPA conducted a national-scale, probabilistic analysis to better characterize the potential risks to human and ecological receptors associated with leachate released from surface impoundments and landfills. The specific exposure routes evaluated for these releases were human ingestion of ground water used as a source of drinking water and fish caught from freshwater lakes or streams, as well as ecological contact with and ingestion of surface water and sediment. A combination of models was used to predict COPC fate and transport through the environment, receptor exposures, and the resulting risks. Site-specific data were used, supplemented by regional and national data sets, to capture the national variability of disposal practices, environmental conditions and receptor behavior. EPA modeled risks for both highly exposed individuals (90th percentile risks) and more moderately exposed individuals (50th percentile risks). In instances where the speciation of a COPC has been shown to greatly affect fate and transport, EPA modeled multiple species to provide a bounding on potential exposures.

Table ES-3 shows the 90th percentile human health risks to the most sensitive age cohorts for constituents that exceeded the risk criteria. Risks are presented for arsenic modeled entirely as two different species (III and V) to provide a bounding on potential risks. Values that exceed the selected risk criteria (cancer risk > 1×10^{-5} or noncancer HQ > 1) are shown in **bold**. No 90th percentile risks above ecological criteria were identified for either surface impoundment or landfills. No 50th percentile risks above human health or ecological criteria were identified for either surface impoundment or landfills.

Table ES-3. 90th Percentile Nationwide Probabilistic Risk Results

COPC	Ingestion of Ground Water	
	Surface Impoundments	Landfills
Cancer Risks		
Arsenic III	**2×10^{-4}**	5×10^{-6}
Arsenic V	1×10^{-5}	7×10^{-8}
Noncancer Risks		
Arsenic III	**5**	0.1
Arsenic V	0.4	< 0.01
Lithium	**2**	--[a]
Molybdenum	**2**	< 0.01

a) Leachate data were not available to model this COPC for landfills.

- **Surface Impoundments:** Ingestion of ground water was the only exposure pathway that resulted in risks above a cancer risk of 1×10^{-5} or noncancer HQ of 1. 90th percentile cancer risks above 1×10^{-5} were identified for arsenic III (2×10^{-4}). The 90th percentile noncancer risks above an HQ of 1 were identified for arsenic III (5), lithium (2) and molybdenum (2).
- **Landfills:** All 90th percentile cancer and noncancer risks were below human health criteria.

High-end risks identified for surface impoundments are consistently higher than those for landfills. These results are attributed to the higher infiltration rates through surface impoundments, which are driven by the hydraulic head of the ponded water. Median risks for both surface impoundments and landfills were substantially lower than both the high-end risks in this risk assessment and the median risks modeled in the 2010 Risk Assessment (U.S. EPA, 2010a). This decrease is attributed primarily to the interception of ground water by surface water bodies, which is accounted for in the revised risk assessment to provide a more accurate mass balance of constituent mass during transport. It is common for coal-fired utilities to be located near water bodies, which are used as a source of cooling water and conveyance of waste. As a result, in the majority of model iterations, the interception of ground water by surface water bodies resulted in negligible downstream well concentrations.

Based on the results of the probabilistic analysis, EPA concludes that leaching from CCR waste management units has the potential to pose risk to receptors. Arsenic, lithium and molybdenum are the chemical constituents found to pose the greatest risks from surface impoundments, while

arsenic posed the greatest risks from landfills. Available toxicological profiles indicate that risks from arsenic ingestion are linked to an increased likelihood of cancer in the skin, liver, bladder and lungs, as well as nausea, vomiting, abnormal heart rhythm, and damage to blood vessels;[1] risks from lithium ingestion are linked to neurological and psychiatric effects, decreased thyroid function, renal effects, cardiovascular effects, skin eruptions, and gastrointestinal effects;[2] and risks from molybdenum ingestion are linked to higher levels of uric acid in the blood, gout-like symptoms, and anemia.[3]

Sensitivity and Uncertainty Analyses

The modeled probabilistic risks capture the range of current, nationwide CCR disposal practices. However, because of the broad scope of the analysis, there are a number of sources of variability and uncertainty present. Therefore, to confirm the results of the probabilistic analysis and to better understand whether any particular subset of disposal practices drives the risks identified, EPA conducted additional sensitivity and uncertainty analyses.

EPA reviewed the models used, as well as the data and assumptions input into these models, to better understand the sources of variability and uncertainty inherent in the probabilistic analysis. The Agency then qualitatively and, to the extent possible, quantitatively analyzed these sources to understand the potential effects each may have on the modeled risk results. During this review, specific attention was focused on the parameters shown to have the greatest influence on model results. As a further method of validation, EPA compared the results of the sensitivity and uncertainty analyses with proven and potential damage cases. Together these analyses and comparisons show that there is a high degree of confidence in the principal findings of the probabilistic analysis. However, the review of sensitive parameters revealed some specific disposal practices that may result in greater risks than identified in the probabilistic modeling.

Through these additional sensitivity and uncertainty analyses, which explored different subsets of national disposal practices, EPA identified the potential for higher risks than those identified in the broader, national analysis. In particular, consideration of different waste pH values showed higher risks for arsenic at more acidic and basic pH values, as well as additional risks for boron, cobalt, fluoride and mercury at these more extreme pH values. Consideration of specific liner types showed that ground water risks are driven by disposal in unlined units and, in particular, unlined surface impoundments. For these units, EPA identified higher risks for arsenic and molybdenum, as well as additional risks for thallium. Clay-lined units were found to pose lower risks than unlined units. Composite-lined units were found to be the most protective disposal practice, resulting in risks far below all criteria identified in this risk assessment.

[3] Profile for molybdenum available online at: www.epa.gov/iris/subst/0425.htm

Conclusions

Based on the analyses presented in this document, EPA concludes that current management practice of placing CCR waste in surface impoundments and landfills poses risks to human health and the environment within the range that OSWER typically regulates. On a national scale, surface impoundments presented higher risks than landfills. Risks to ecological receptors were identified from exposures to aluminum, arsenic, barium, beryllium, boron, cadmium, chloride, chromium, selenium and vanadium through direct exposure to impoundment wastewater. Risks to residential receptors were identified primarily from exposures to arsenic and molybdenum in ground water used as a source of drinking water, but additional risks from boron, cadmium, cobalt, fluoride, mercury and thallium were identified for specific subsets of national disposal practices.

Sensitivity analyses on liner type indicate that disposal of CCR wastes in unlined surface impoundments and landfills presents the greatest risks to human health and the environment. As modeled, the national risks from clay-lined units are lower than those for unlined units, but such units can exceed risk criteria at individual sites. Composite liners were the only liner type modeled that effectively reduced risks from all pathways and constituents far below human health and ecological criteria in every sensitivity analysis conducted. Sensitivity analyses on waste type indicate that the acidic conditions that result from codisposal of CCR waste with coal refuse and the basic conditions that result from disposal of FGD waste result in higher risks from arsenic and other constituents than CCR waste disposed alone.

The risk results are consistent with the ground water damage cases compiled by EPA. These damage cases were primarily associated with unlined units and were most frequently associated with releases of arsenic. Recent surveys of the industry indicate the majority of newly constructed units are lined, and that that the practice of codisposal with coal refuse has declined. However, this risk assessment presents a static snapshot of current disposal practices. While newer units may be managed in a more protective manner, older units, which still comprise the majority of current units, continue to operate in a manner that poses risks to human health and the environment within the range that OSWER typically regulates.

1 Introduction

The U.S. Environmental Protection Agency (EPA or the Agency) has taken many steps toward characterizing the risks that may result from the current disposal practices for coal combustion residuals (CCRs) and developing the regulations necessary to protect human health and the environment under the Resource Conservation and Recovery Act (RCRA). A full timeline of the Agency's previous work on CCRs can be found on the EPA website.[4]

The revised risk assessment presented in this document builds on the two most recently completed analyses in that timeline, *Non-ground water Pathways, Human Health and Ecological Risk Analysis for Fossil Fuel Combustion Phase 2* (U.S. EPA, 1998) and *Human and Ecological Risk Assessment of Coal Combustion Wastes* (U.S. EPA, 2010a). Specifically, EPA has revised the 2010 Risk Assessment to incorporate new data and to address the comments received from both independent external peer reviewers and public commenters on the methodology, data sources and assumptions used by the Agency. The scope of the peer review was a draft of the 2010 Risk Assessment. The scope of public comments was a 2007 Notice of Data Availability (NODA), the 2010 Risk Assessment, and two subsequent NODAs in 2011 and 2013.[5] The Agency responses to these comments are available in separate documents for the peer review and the public in the docket for the final rule.

1.1 Purpose and Scope of the Risk Assessment

The purpose of this document is to characterize the risks associated with current CCR disposal practices to aid in the review and revision of the Agency's 2010 proposed rulemaking. To accomplish this, EPA characterized the current state of CCR disposal practices, identified the different releases that may occur from these waste management units (WMUs), and evaluated the resulting risks to human and ecological receptors. The regulatory scope of the rulemaking is limited to current disposal practices for CCRs generated by coal-fired electric utilities and independent power producers covered by the North American Industry Classification System (NAICS) code 221112. The scope of this risk assessment is limited accordingly. EPA did not evaluate disposal of wastes other than CCRs, disposal of CCRs at off-site locations, WMUs that have ceased receiving waste, or historical disposal of CCRs by facilities that are no longer operating or not otherwise covered by NAICS code 221112.

1.2 Overview of Risk Assessment Methodology

In total, this risk assessment is divided into seven main sections and eleven appendices. The main text summarizes the different data sources relied upon, analyses performed, model results and final Agency conclusions. The appendices provide a more detailed discussion of the data and models underlying the analyses summarized in the main text. The remainder of this section provides

[4] Available online at: www.epa.gov/osw/nonhaz/industrial/special/fossil/regs.htm

[5] Available online in docket numbers EPA-HQ-RCRA-2011-0392 and EPA-HQ-RCRA-2012-0028 at: www.regulations.gov

further information about the contents of each section and appendix, while **Figure 1-1** provides a decision flowchart followed throughout the risk assessment.

- **Section 2, Problem Formulation:** describes the conceptual models used to identify the potential exposure pathways associated with CCR WMUs, summarizes the sources of data available to characterize these exposure pathways, and presents the results of hazard identification used to identify an initial list of constituents of potential concern (COPCs) carried forward for further analysis.
- **Section 3, Screening Analysis:** describes the framework used to conduct a conservative screening analysis for human and ecological receptors. The results of this screening analysis are presented and used to identify pathways and constituents for further modeling.
- **Section 4, Probabilistic Analysis:** describes the probabilistic modeling used to (1) estimate the magnitude of COPC releases from CCR WMUs for all pathways not sufficiently characterized in the screening analysis, (2) model the fate and transport of constituents through environmental media, (3) calculate potential exposures for human and ecological receptors, and (4) estimate resulting risks to these receptors. The results of this analysis are presented as separate national estimates for impoundments and landfills.
- **Section 5, Sensitivity and Uncertainty Analyses:** describes the various sources of variability and uncertainty present in the risk assessment. To the extent possible, these sources are quantitatively and qualitatively characterized to identify the potential for higher or lower risks than those modeled in the probabilistic analysis.
- **Section 6, Final Risk Characterization:** synthesizes available information from all sections of the risk assessment to reach final conclusions about the risks that may result from current CCR disposal practices.
- **Section 7, References:** provides citations for all documents referenced throughout the text.

The first five appendices provide the underlying data used in the risk assessment. **Appendix A** describes the site-based data used to characterize CCR surface impoundments and landfills (e.g., geographic location, surface area, capacity, geometry, liner status). **Appendix B** describes the regional and national data used to characterize the environmental setting around each facility and WMU (e.g., meteorology, climate, soils, aquifers and water bodies). **Appendix C** describes the chemical constituents present in and released from different CCR wastes. **Appendix D** details the collection and prioritization of human exposure factors. **Appendix E** details the collection and prioritization of toxicity benchmarks for human and ecological receptors.

The next six appendices provide detailed information on the specific models and equations used in the various analyses. **Appendix F** provides models and data used to estimate COPC concentrations suspended in ambient air and deposited on downgradient plants. **Appendix G** provides the equations and data used to estimate the accumulation of COPCs within the food chain. **Appendix H** details the development of soil-water partitioning coefficients used to model COPC concentrations in ground water. **Appendix I** describes the development of the landfill source term. **Appendix J** provides the models and data used to estimate COPC concentrations in surface water

and sediment. **Appendix K** provides a summary of several of the sensitivity and uncertainty analyses performed.

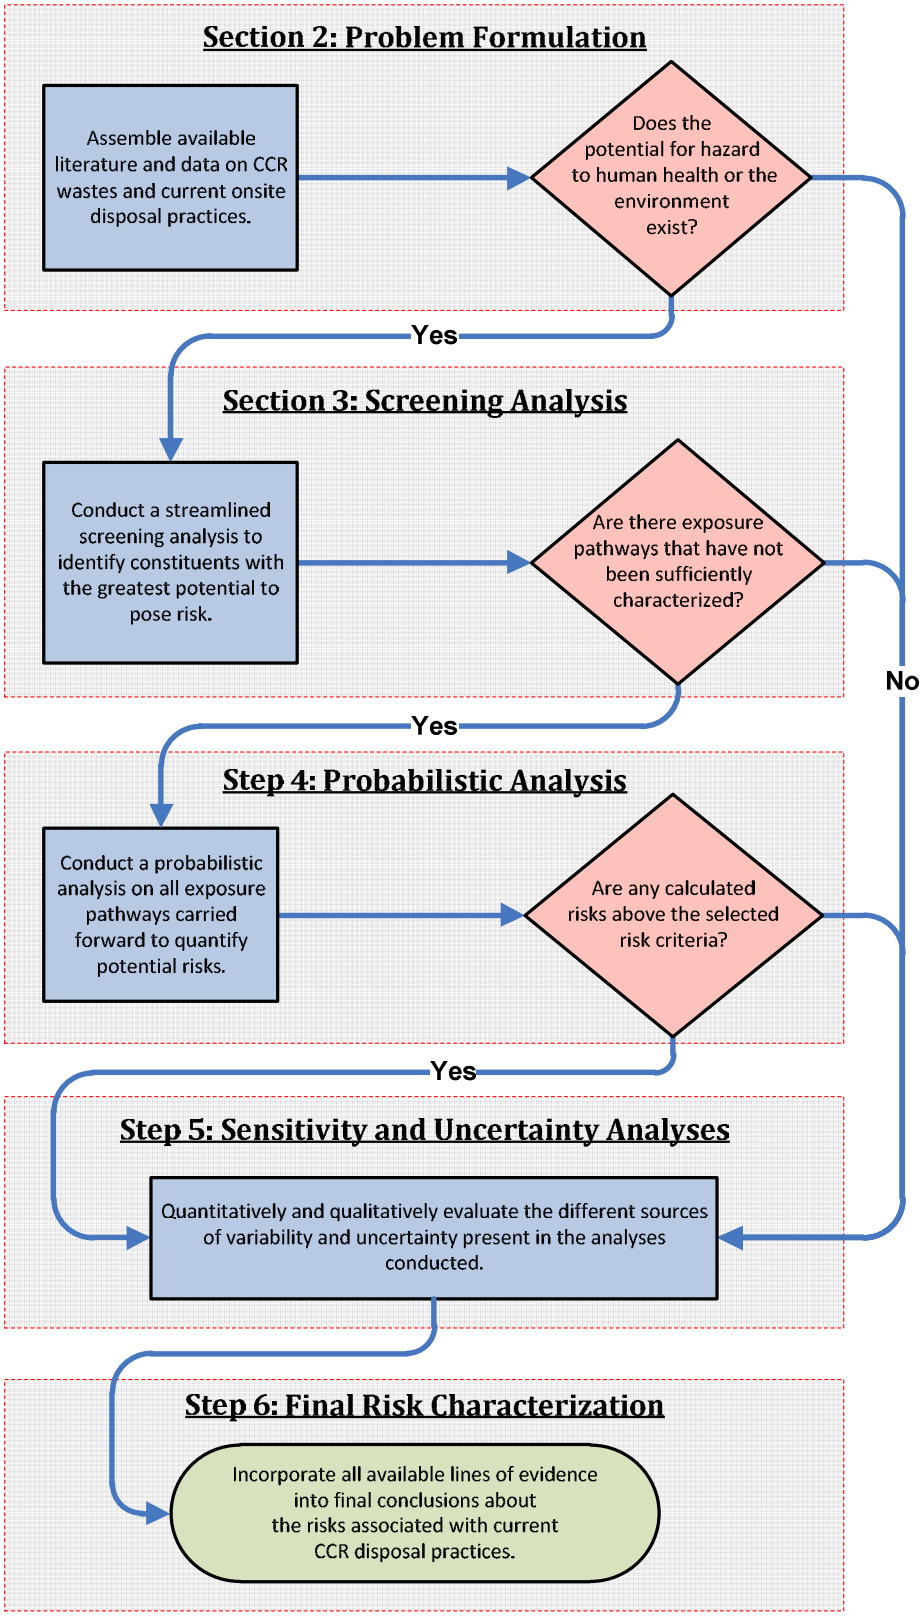

Figure 1-1. Decision flowchart for CCR risk assessment.

[This Page Intentionally Left Blank]

2 Problem Formulation

This purpose of this section is to describe the development of the conceptual models that form the basis for the analysis of surface impoundments and landfills. This section also provides a summary of the data sources used to characterize coal-fired facilities, waste management practices, constituent releases and receptor behavior. Finally, this section includes a preliminary hazard identification to identify the COPCs to be carried forward for further analysis. This section is divided into the following subsections:

- **Section 2.1** provides an overview of the source and properties of each major type of CCR.
- **Section 2.2** provides the conceptual models developed for surface impoundments and landfills that identify each relevant release route, transport pathway, and receptor.
- **Section 2.3** summarizes the data sources incorporated into the risk analysis.
- **Section 2.4** provides the risk criteria used to evaluate risks throughout the assessment.
- **Section 2.5** identifies the potential hazards that warrant further evaluation.

2.1 Overview of Coal Combustion and Residuals

CCR is a broad term used to refer to the byproducts that are generated either directly by coal combustion or as a result of applying certain pollution control devices to emissions from coal-fired combustion units, with the resulting wastes destined for disposal. CCRs may be generated wet or dry; however, this composition may change after generation. Some CCRs are dewatered, while others are mixed with water to facilitate transport (i.e., sluiced). When multiple types of CCRs are generated at the same facility, mixing and codisposal may occur. The distinct CCR categories identified in the 2010 Proposed Rulemaking include fly ash, bottom ash, boiler slag, and flue gas desulfurization (FGD) materials:

- **Fly ash** is the fraction of combusted coal that becomes suspended in plant flue gases. It is a very fine, powdery material composed primarily of silica. Fly ash is removed from the plant exhaust gases primarily by electrostatic precipitators (ESPs) or baghouses that contain fabric filters. In facilities that use activated carbon injection (ACI) before fly ash collection, the fly ash waste stream will also contain the carbon, along with other mercury control wastes. However, where ACI occurs after fly ash collection, a separate waste stream may result.
- **Bottom ash** consists of ash particles that are too large to become entrained in the flue gas during combustion. It is coarse, with grain sizes that range from fine sand to fine gravel, and quite angular, with a porous surface structure. Bottom ash is collected from the furnace after it collides with and agglomerates to furnace walls or falls through open grates to an ash hopper beneath the furnace.
- **Boiler slag** is molten bottom ash that has been quenched with water. When the molten ash comes in contact with the water, it crystallizes, fractures and forms pellets that are hard with

a smooth, glassy appearance. Boiler slag is collected from the base of either slag tap or cyclone type furnaces.

- **FGD materials** are produced through a process used to reduce sulfur dioxide (SO_2) emissions from the exhaust gas system of a coal-fired boiler. The physical nature of these materials varies from a wet sludge to a dry powdered material, depending on the pollution control technology, and the composition consists of sulfites, sulfates or a mixture thereof.

These different CCR wastes may be generated separately or mixed together. Even when generated separately, facilities often codispose of multiple waste types in a single WMU. **Figure 2-1** provides the layout of a hypothetical coal-fired plant. This simplified layout is intended to demonstrate some of the major pollution control technologies, waste streams and collection points associated with coal combustion. It is intended to be illustrative and does not capture all possible control technologies or plant layouts.

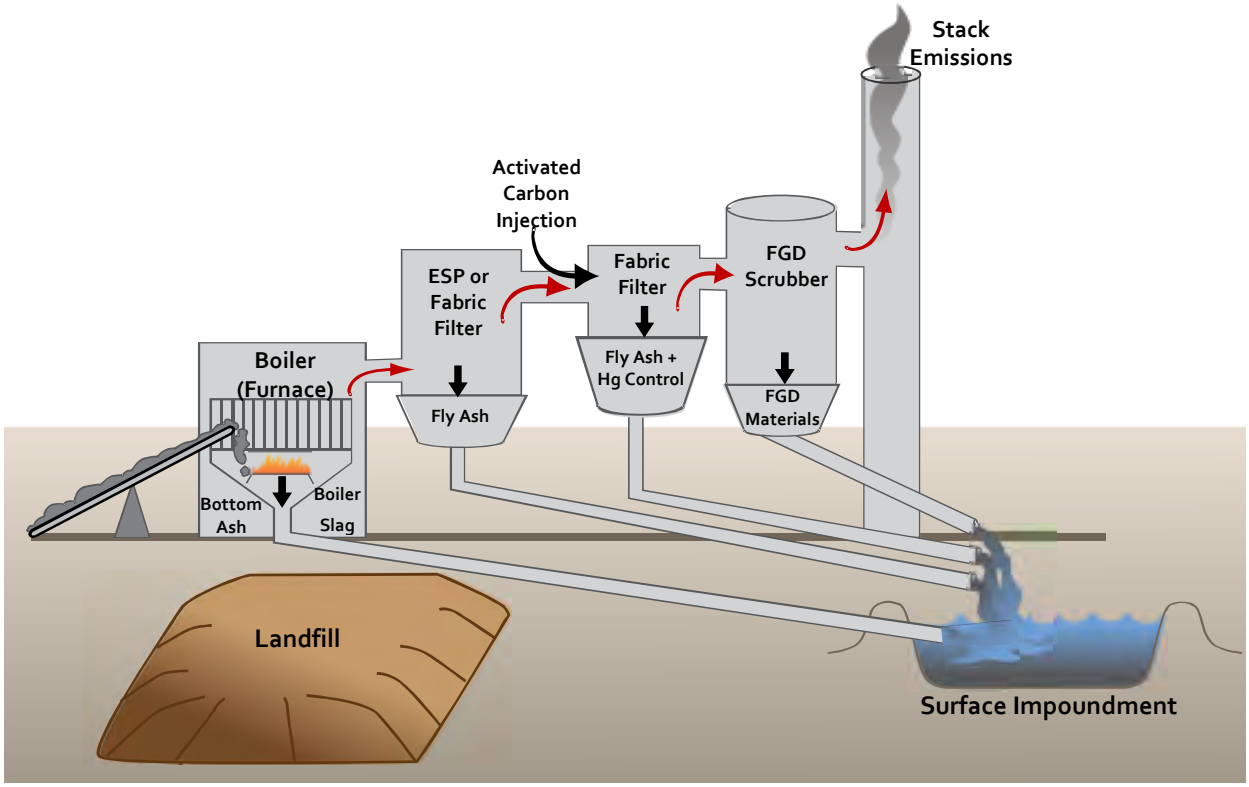

Figure 2-1. Generalized coal-fired power plant layout.

2.2 Conceptual Models

Once disposed in WMUs, the chemical constituents present in CCRs may be released to the surrounding environment. To evaluate the risks to human health and the environment that may result from these releases, EPA first developed conceptual models to specify the layout of surface impoundments and landfills, the types of releases that may occur from these WMUs, and the types of exposures that may result. These conceptual models were developed to represent generic WMU layouts and are not intended to reflect any specific facility or WMU. These conceptual models were used to form the basis for data collection and modeling efforts.

Neither conceptual model includes direct, point source discharges to surface water. These types of releases are permitted under the National Pollutant Discharge Elimination System of the Clean Water Act and have been evaluated separately in the *Environmental Assessment for the Proposed Effluent Limitation Guidelines and Standards for the Steam Electric Power Generating Point Source Category* (U.S. EPA, 2013). The risk assessment for direct discharges was conducted in support of proposed effluent limitation guidelines (ELG) for the steam electric power generating point source category.[6] That assessment is under revision by EPA in response to the public comments received on the proposal and will be released in conjunction with the final ELG rule.

Surface water used as a source of potable water is not included in either conceptual model. Surface water is assumed to be routed through a municipal water treatment facility prior to consumption, reducing constituent levels present. Furthermore, neither conceptual model includes incidental ingestion of, inhalation of, or dermal contact with COPCs in surface water that may occur during swimming or other activities near a water body. For human receptors, it is assumed that these exposures are infrequent and small in comparison to similar exposures from ground water.

2.2.1 Surface Impoundment Conceptual Model

Surface impoundments are conceptualized as square units that are constructed anywhere from entirely above grade to entirely below ground surface. During operation, a surface impoundment receives waste sluiced from the facility. Over time, impoundment water may be lost to some combination of infiltration, evaporation, and controlled discharges to other impoundments and nearby water bodies, while the CCR solids either accumulate until the surface impoundment's capacity is reached or are periodically dredged for final disposition elsewhere. To reflect that the majority of impoundments are periodically dredged, the conceptual model assumes that dredging losses are balanced out by continued loading from the facility, resulting in a constant ponding depth over the operational life. It is assumed that all waste is removed from most units prior to closure (i.e., clean closure). However, in some instances, waste is left in place and the unit is closed and capped. Closed surface impoundments are assumed to behave the same as a closed landfill. **Figure 2-2** depicts a cross-section of the conceptual layout for operating impoundments.

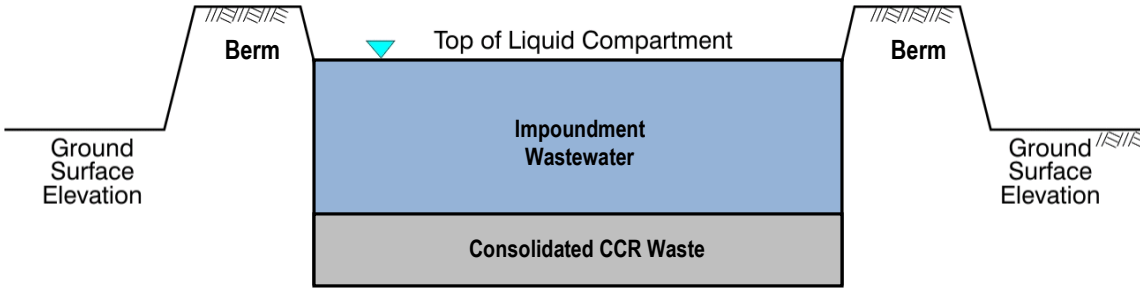

Figure 2-2. Cross-sectional view of generic surface impoundment site model.

Chemical constituents can be released from surface impoundments through the leaching of soluble constituents into the water that comes in contact with the CCRs and percolation of the resulting

[6] Available online in docket number EPA-HQ-OW-2009-0819 at: www.regulations.gov.

leachate into the subsurface soil and ground water. Constituents can then be transported underground through the ground water (GW) to downgradient drinking water (DW) wells (GW→DW pathway), where residents may be exposed through ingestion of contaminated drinking water, as well as dermal contact with and inhalation of constituents through bathing and showering in that water. Contaminated ground water may also discharge to surface water (SW) bodies (GW→SW pathway), where human receptors may be exposed through the ingestion of fish that live in the surface water body and ecological receptors may be exposed by living in or foraging in contaminated surface water or sediment. The CCR solids, along with any constituents contained within them, may also be released aboveground from operating impoundments through particulate matter disturbed by wind or runoff if the water level above the waste decreases. Additional aboveground exposures may result from ecological receptor contact with surface impoundment wastewater. **Figure 2-3** depicts the different exposure pathways considered for impoundments.

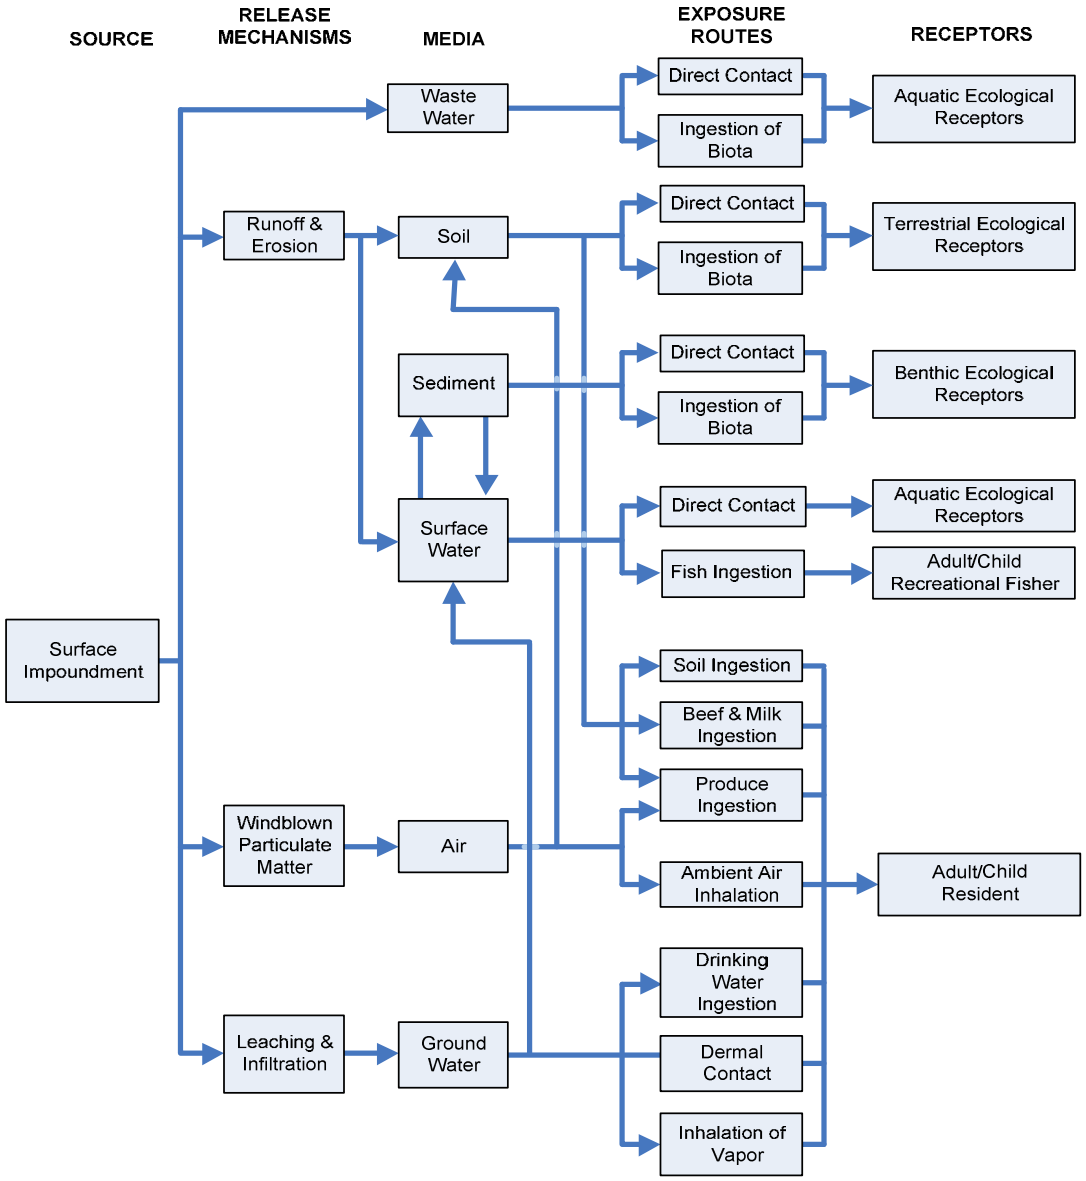

Figure 2-3. Surface impoundment conceptual exposure model.

2.2.2 Landfill Conceptual Model

Landfills are conceptualized as square units that are constructed anywhere from entirely above grade to entirely below ground surface. During operation, landfills gradually accumulate CCRs in a smaller, active portion of the landfill, until the capacity is reached. During closure, waste is left in place and the entire landfill is capped. **Figure 2-4** depicts a cross-section of the conceptual layout for closed landfills.

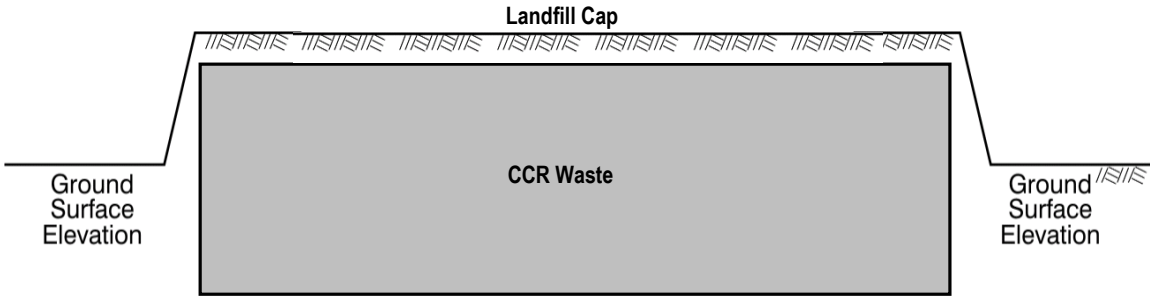

Figure 2-4. Cross-sectional view of generic landfill site model.

Chemical constituents can be released from landfills through leaching of soluble constituents into the water that comes in contact with the CCRs and percolation of the resulting leachate into subsurface soil and ground water. Constituents can then be transported underground through the ground water to downgradient drinking water wells, where residents may be exposed through ingestion of contaminated drinking water, as well as dermal contact with and inhalation of constituents through bathing and showering in that water. Contaminated ground water may also discharge to surface water bodies, where human receptors may be exposed through the ingestion of fish that live in the surface water body and ecological receptors may be exposed through living in or foraging in contaminated surface water or sediment. The CCR solids, along with any constituents contained within them, may also be released aboveground from operating landfills through particulate matter disturbed by wind; overland run-off; and mechanical disturbances, such as truck traffic, unloading operations, or spreading and compacting operations. These constituents are then transported downgradient where they may be directly inhaled by residents or settle out onto nearby soils and produce, where they may be ingested by ecological receptors or accumulated in crops and livestock that are subsequently ingested by residents. **Figure 2-5** depicts the different exposure pathways considered for landfills.

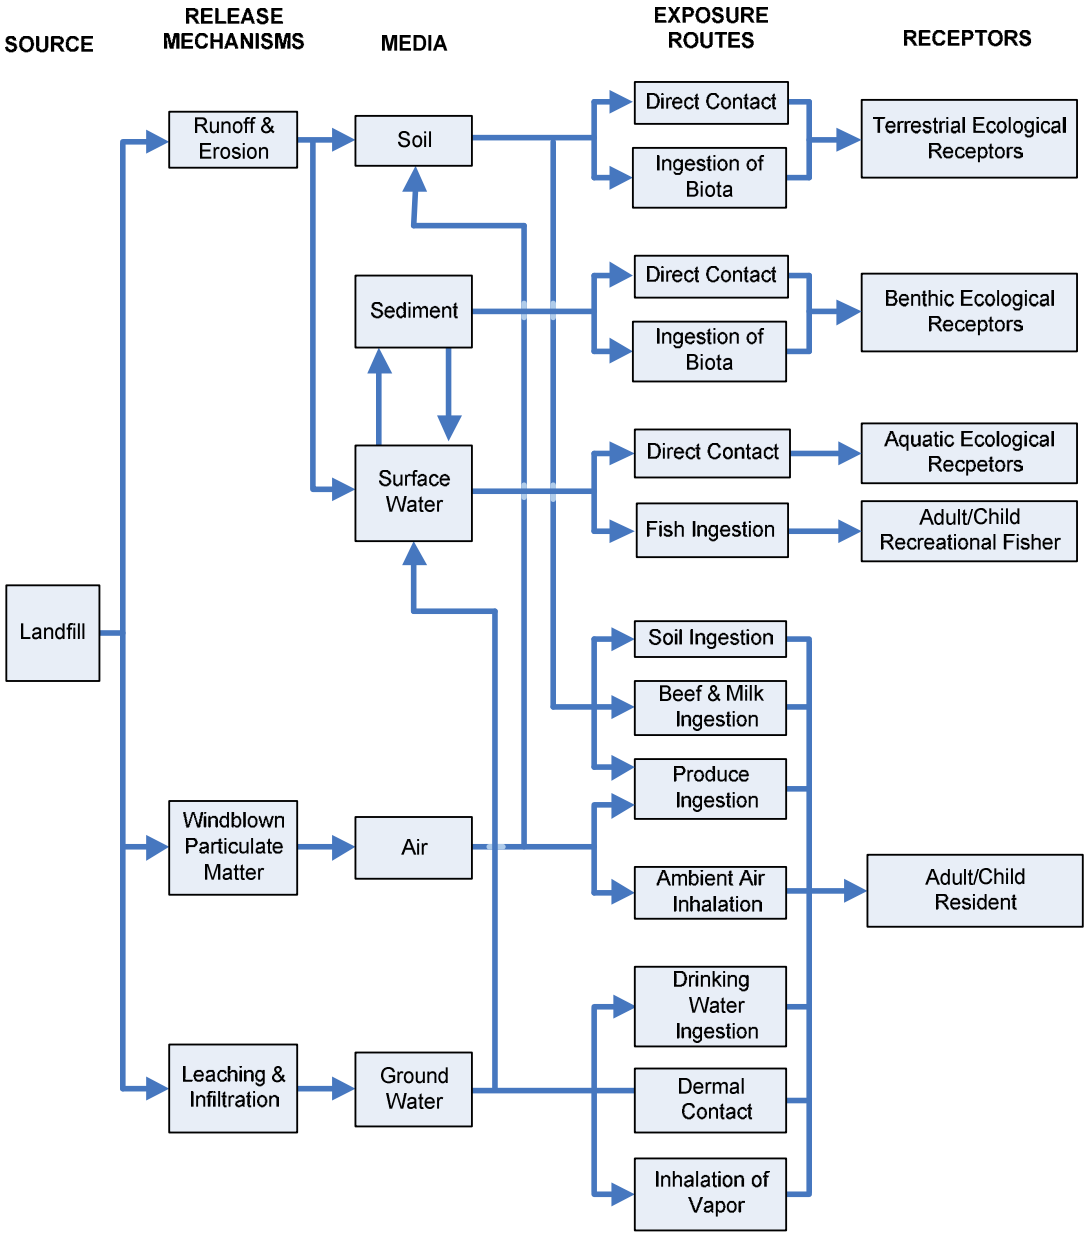

Figure 2-5. Landfill conceptual exposure model.

2.3 Data Collection

2.3.1 Facility and Waste Management Unit Data

EPA relied on the U.S. Department of Energy (DOE) Energy Information Agency (EIA) Database for information on the location, generating capacity and coal burned for each coal-fired utility power plant (hereafter referred to as "facilities"). The 2005 EIA Database used in the 2010 Risk Assessment reported a total of 495 facilities in operation, while the 2009 EIA database used in the revised risk assessment updated this number to 507 facilities. At the time that these data were collected, the 2009 EIA database was the most recent version available.

Although the EIA Database provides information on the tons of CCRs generated annually, as well as their disposition (e.g., landfilled), it does not provide information on the characteristics of the WMUs where the disposed CCRs are managed. The 2010 Risk Assessment (U.S. EPA, 2010a) relied on a 1997 Electric Power Research Institute (EPRI) survey to characterize the type, size, design and location of CCR surface impoundments and landfills. However, two more-recent EPA surveys of on-site WMUs have since been completed:

- 2009 *Information Request Responses* [obtained under Section 104(e) of the Comprehensive Environmental Response, Compensation, and Liability Act][7] together with *Impoundment Assessment Reports*,[8] hereafter jointly referred to as "the 2009 EPA Survey"; and
- 2010 Questionnaire for the Steam Electric Power Generating Effluent Guidelines, hereafter referred to as "the 2010 EPA Survey."[9]

The new data from these EPA surveys are hereafter collectively referred to as the "CCR WMU database." Although facilities and WMUs are constantly opening and closing, the CCR WMU database comprehensively covered all operating facilities at that time it was compiled. As a result, these surveys identified more than twice as many facilities with on-site disposal, as well as substantially more individual WMUs located at these facilities. Thus, the revised risk assessment provides a more complete snapshot of current disposal practices. **Table 2-1** shows the increase in coverage provided by the updated data sets.

Table 2-1. Number of On-site Surface Impoundments and Landfills Contained in the 1995 EPRI Survey and CCR WMU Database

Data Source	EIA Facilities	Facilities with On-site WMUs	Total On-site Impoundments	Total On-site Landfills
1995 EPRI Survey	495	181	96	108
CCR WMU Database	507	384	953	431

The CCR WMU database represents the most current and complete data on WMUs available and provides a significant increase in coverage of the relevant facilities. However, some data gaps remain in the CCR WMU database. Information on some parameters, such as WMU size, is missing for a subset of WMUs. To fill these data gaps, EPA probabilistically sampled from distributions compiled from the available data for other WMUs. Further information about the methods used to collect and analyze these data is provided in **Appendix A**, with the underlying raw data available in following attachments:

[7] Available online at: www.epa.gov/osw/nonhaz/industrial/special/fossil/surveys/index.htm

[8] Additional impoundment assessment reports have been conducted since the model inputs were developed. Available online at: www.epa.gov/osw/nonhaz/industrial/special/fossil/surveys2/index.htm

[9] Available online at: water.epa.gov/scitech/wastetech/guide/steam_index.cfm

- **Attachment A-1** provides data collected for each facility geographic location, number of surface impoundments and landfills present, amount of coal burned and the associated coal use quartile.
- **Attachment A-2** provides the WMU-specific data used in the CCR risk assessment, including geographic locations, CCR type, dimensions, liner type and first year of operation for each of the surface impoundments and landfills modeled.

2.3.2 Environmental Parameters Data

EPA collected data on the surrounding environmental conditions with the aid of geographic information system (GIS) software. In the 2010 Risk Assessment, these data were selected based on the geographic location of each facility. The latitudes and longitudes reported in the EIA Database often represent a centroid or front gate location for each facility. However, WMUs can be located some distance away from the main facility. Therefore, where possible, the revised risk assessment used the newly available data from the CCR WMU database to identify the locations of individual WMUs, and only relied on facility locations when no WMU-specific data were available. The reported locations for both facilities and WMUs were then reviewed based on visual inspection of aerial photography using Google Earth and adjusted as appropriate.

EPA used the facility and WMU locations to identify site-specific data on soil type, hydrogeologic environment and distance to nearest water body. However, because uncertainty remained about the precise location for some units, EPA pulled data from a two-kilometer radius around the reported location to effectively capture local variability. Regional data were collected by assigning each facility to the nearest reference point in national databases, such as the Hydrologic Evaluation of Landfill Performance (HELP) model climate stations and the U.S. Geological Survey (USGS) hydrological regions. Whenever environmental parameters could not be linked based on location, EPA relied on national distributions. Further information about the methods used to collected and analyze these data is provided in **Appendix B**, with the data available in the following attachments:

- **Attachment B-1** provides the specific soil texture, pH and organic carbon content associated with each facility.
- **Attachment B-2** provides hydrogeologic environments.
- **Attachment B-3** provides climate center, precipitation rate and infiltration rate.
- **Attachment B-4** provides USGS Hydrologic Region; distance to nearest water body; and water body mean recharge, area, length, mean annual flow and mean annual velocity.

Figure 2-6 maps the coal-fired utilities within the contiguous United States for which on-site disposal of CCRs is known to take place. Although these facilities are concentrated in the eastern United States, they are located in nearly every state, in both urban and rural settings. One additional facility in Alaska, with a single on-site surface impoundment, is not shown on this figure. Because soil and hydrogeologic data were unavailable for Alaska, data on this one facility and surface impoundment were not incorporated in the revised risk assessment.

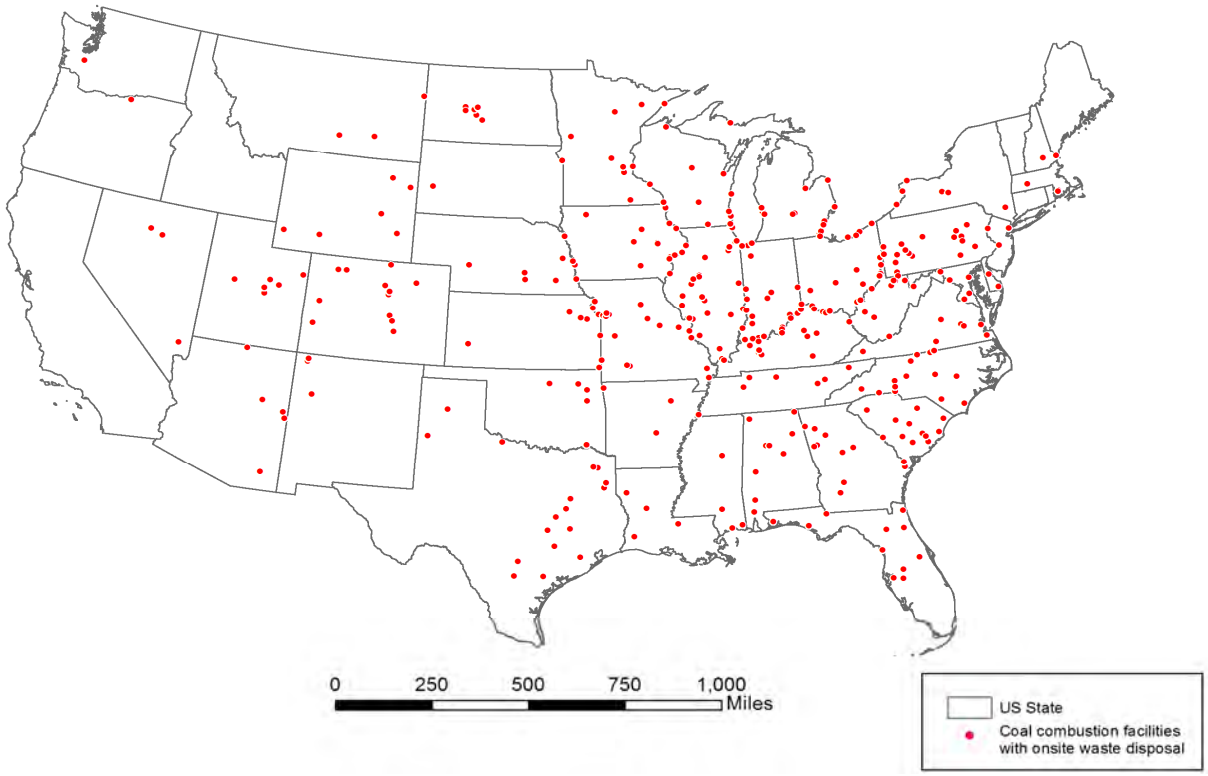

Figure 2-6. Coal-fired facilities in the conterminous United States with both on-site disposal and available soil and hydrogeological data.

2.3.3 Constituent Data

The revised risk assessment relies on a database that contains all of the constituent data collected since the 1998 Risk Assessment (U.S. EPA, 1998a,b), referred to as the "CCR constituent database." This database includes information on both the identity and concentrations of the different constituents that may be present in and released from different CCRs. EPA has continued to incorporate new data as it becomes available through public comment and Agency collection efforts. The available data comprise the most recent and complete data set available at the time of this assessment. Further information about this database is provided in **Appendix C**, with the data available in the following attachments:

- **Attachment C-1** provides a complete list of data sources in the updated database.
- **Attachment C-2** provides the surface impoundment pore water concentration data used to characterize leaching from these units.
- **Attachment C-3** provides the surface impoundment wastewater concentration data used to characterize surface water within these units.
- **Attachment C-4** provides the whole waste concentration data ("totals") used to characterize the mass of COPCs present in the CCR waste.
- **Attachment C-5** provides leachate data collected with EPA Leaching Evaluation Assessment Framework (LEAF) methods used to characterize landfills.

2.3.4 Exposure Factors

EPA previously used data from the 1997 *Exposure Factors Handbook* (EFH) (U.S. EPA, 1997b,c,d) to characterize human exposure factors. In the revised risk assessment, EPA reviewed and incorporated the data and recommendations from the 2008 *Child-Specific Exposure Factor's Handbook* (CSEFH; U.S. EPA, 2008a), including the subdivision of child receptors into specific age cohorts. Because the 2008 CSEFH does not provide additional data for adult exposures, the data from the 1997 EFH were retained for these adult receptors. Where sufficient data were available, the percentiles and corresponding data points drawn from these two sources were used to develop a distribution in order to reflect the variability within the U.S. population. Otherwise, EPA relied on point values selected based on either the recommendations of the EFH/CSEFH or established Agency guidance.

The 2011 *Exposure Factors Handbook* (U.S. EPA, 2011) has been completed and updates some of the data from the 1997 EFH. During the finalization of this risk assessment, EPA released *OSWER Directive 9200.1-120* (U.S. EPA, 2014c). Although this document provides default exposure factors to use for point estimates, EPA is still in the process of updating the full distributions necessary for probabilistic analysis. Therefore, this risk assessment does not incorporate the data from the 2011 EFH. Further information about the methods used to collected and analyze these exposure data is provided in **Appendix D.**

2.3.5 Toxicity Benchmarks

Ingestion Benchmarks

For human health exposures from the ingestion of soil and water, EPA updated the chronic toxicity values used in the 2010 Risk Assessment. The benchmarks collected in this report reflect current toxicity data as of January 2012. Values were selected according to the hierarchy established in the 2003 *Office of Solid Waste and Emergency Response Directive 9285.7-53* (U.S. EPA, 2003f), which encourages the prioritization of toxicity values from sources that are current, transparent and publicly available, and that have been peer reviewed. During this update, two new benchmarks were identified: a noncancer benchmark for lanthanum was identified from the National Sanitation Foundation International and a cancer benchmark for chromium VI from the New Jersey Department of Environmental Protection (NJDEP). Benchmarks were drawn from the following sources:

- **Tier I:** EPA Integrated Risk Information System (IRIS).
- **Tier II:** Provisional Peer-Reviewed Toxicity Values for Superfund.
- **Tier III:** Agency for Toxic Substances and Disease Registry minimal risk levels, California Environmental Protection Agency (CalEPA) cancer potency factors, the International Toxicity Estimates for Risk database, NJDEP, and the EPA Health Effects Assessment Summary Table.

For lead, there is currently has no consensus on the development or identification of an effect threshold needed to develop benchmarks within these tiers. Therefore, the maximum contaminant level (MCL) was used as an alternative benchmark for approximating human health risk.

Inhalation Benchmarks

EPA collected National Ambient Air Quality Standards (NAAQS) for evaluating inhalation of particulate matter (PM) and lead. Because the fugitive dust screening summarized in the 2010 Risk Assessment identified the potential for acute exposures to exceed these standards, EPA also collected acute inhalation toxicity values to evaluate additional constituents that may be sorbed to the particulate surface. Guidelines intended to protect against mild adverse health effects (e.g., respiratory irritation) were gathered. If these guidelines were not available, the severe effect guidelines were used with a safety factor of 10 to approximate a milder effect level, based on the recommendations in *Human Health Risk Assessment Protocol for Hazardous Waste Combustion Facilities* (U.S. EPA, 2005). All sources considered have either undergone peer review or were developed based on a peer-reviewed process. In addition, the reference exposure levels (RELs) and acute exposure guideline levels (AEGLs) have been made available for public review and comment. Benchmarks for inhalation were drawn from the following sources, listed in order of preference:

- CalEPA acute RELs,
- U.S. EPA AEGLs,
- American Industrial Hygiene Association emergency response planning guidelines ,
- U.S. DOE temporary emergency exposure limits, and
- National Institute for Occupational Safety and Health immediately dangerous to life or health divided by an uncertainty factor of 10.

Ecological Benchmarks

EPA updated the concentration-based benchmarks used in the 2010 Risk Assessment for ecological exposures that result from direct contact with and foraging in soil, surface water and sediment. These benchmarks are based on classes of receptors (e.g., invertebrates, mammals) and do not consider predator–prey interactions. Ecological benchmarks for the revised risk assessment were obtained from the following sources listed below in order of preference for each medium, with further information about each source provided in **Appendix E**:

- **Surface Water:** Criterion Continuous Concentrations developed under the EPA National Ambient Water Quality Program, Final Chronic Values implemented under the Great Lakes Water Quality Initiative, and Secondary Chronic Values presented in Suter and Tsao (1996).
- **Sediment:** Threshold Effect Level drawn from Buchman (2008) and Effects Range Low Levels drawn from various literature sources.
- **Soil:** Ecological Soil Screening Levels developed by multi-stakeholder workgroup led by EPA and Oak Ridge National Lab screening benchmarks developed for the U.S. DOE.

2.4 Risk Criteria

One of the primary goals of this risk assessment is to identify the likelihood of adverse effects. An adverse effect is a broad term for any abnormal, harmful, or undesirable change that may results from chemical constituent exposures. These effects can be divided into two broad types: carcinogenic and noncarcinogenic. Carcinogenic effects are those that ultimately result in the occurrence of cancer somewhere in the individual. The likelihood of carcinogenic effects is expressed as the increased lifetime probability of cancer that results from an incremental exposure. Noncarcinogenic effects are those that result in adverse health effects other than cancer. The likelihood of noncarcinogenic effects is expressed as a ratio of the exposure level and the level below which no adverse effects are known or anticipated to occur. To evaluate adverse effects in this risk assessment, EPA used the following criteria:

- **Human Health Cancer Risk:** EPA considered excess lifetime cancer risks within the OSWER risk range of between a 1 in 1,000,000 (1×10^{-6}) and a 1 in 10,000 (1×10^{-4}) excess cancer risk. EPA has historically used a 1×10^{-5} excess cancer risk as the point of departure for RCRA hazardous waste listings (59 FR 66075). Thus, in determining whether to retain constituents for further analysis, EPA used a 1×10^{-5} excess lifetime cancer risk. Cancer risk represents the increased risk of developing cancer for members of the exposed population over their lifetime.
- **Human Health Noncancer Risk:** An HQ > 1 was selected, based on the recommendations of U.S. EPA (1989). An HQ represents the ratio of actual exposure and the highest exposure level at which no adverse health effects are likely to occur. An HQs > 1 indicates that an adverse effect may occur, with a higher HQ indicating a greater likelihood of occurrence. However, this ratio does not correspond to an exact probability of noncancer adverse effects for members of the exposed population.
- **Ecological Risk:** An HQ > 1 was selected to evaluate adverse effects to ecological receptors.

2.5 Hazard Identification

Hazard potential exists where a constituent is present and is either known or anticipated to cause adverse effects to human health or the environment. For purposes of this preliminary stage of the assessment, EPA considered the presence of a constituent with one or more toxicity benchmarks sufficient evidence of hazard potential. A review of available data identified a total of 34 constituents for which both concentration data and toxicity benchmarks were available. EPA retained each of these constituents for further evaluation as COPCs. The hazard identification results are shown in **Table 2-2**. Those constituents that had no toxicity value or concentration for a given pathway could not be carried forward for further quantitative analysis. Instead, these exposures are further discussed qualitatively as part of the uncertainty analyses in **Section 5**.

3 Screening Analysis

EPA conducted a screening analysis for each of the exposure pathways identified in the conceptual models developed in **Section 2**. Consistent with the regional screening tables used in the Superfund program, EPA screened risks using children and adult age cohorts, but not infants. The results of this screening are not intended to provide a precise characterization of individual risks that may occur, but rather to identify those COPCs that are most likely to pose risk. Because this screening analysis is deterministic, it does not account for site-based variability. Based on the results of this screening, EPA determined which pathways and associated COPCs to retain for further characterization with more refined, probabilistic modeling summarized in **Section 4**. The discussion of the screening analysis is divided into the following sections:

- **Section 3.1** discusses the development of source concentrations used to characterize releases from WMUs in the screening.
- **Section 3.2** provides an overview of the screening for exposures through ambient air that result from transport of CCR waste by wind.
- **Section 3.3** provides an overview of the screening for exposures through soil, sediment, produce and livestock that result from transport of CCR waste by wind and overland run-off.
- **Section 3.4** provides an overview of the screening for exposures through ground water, surface water, and fish that result from transport of leachate through ground water.
- **Section 3.5** summarizes the results and conclusions of the screening and identifies the COPCs and exposure pathways retained for further probabilistic modeling.

3.1 Waste Source Concentrations

EPA used the data contained in the CCR constituent database (**Appendix C**) as the basis for calculating COPC concentrations present in and released from surface impoundments and landfills. These data have been collected over time from many facilities and are intended to capture national variability. EPA calculated 90th percentile concentrations to represent high-end releases from WMUs. Prior to calculation, all available data were processed to minimize bias, as described below. The resulting 90th percentile values are presented in **Table 3-1** at the end of this subsection.

- **Treatment of Nondetects:** Nondetect measurements represent constituent concentrations below the capability of an analytical methodology to differentiate from background noise and do not provide definitive evidence that a constituent is or is not present. However, nondetect measurements do indicate that the constituents are not present at concentrations above the detection limit. Thus, eliminating nondetects outright will unduly bias the remaining, truncated data set toward the higher, detected values. The revised risk assessment replaced nondetect values with half of the reported detection limit according to the recommendations in *Risk Assessment Guidance for Superfund (RAGS) Part A* (U.S. EPA, 1989) and *EPA Region 3 Guidance on Handling Chemical Concentration Data near the Detection Limit in Risk Assessments* (U.S. EPA, 1991).

- **Data for Mercury.** With the exception of mercury, EPA used all available data in the CCR constituent database to characterize exposures. The majority of mercury data measured prior to 2010 had high detection limits and a large proportion of nondetects. Newer data made available to the Agency since the 2010 Risk Assessment (U.S. EPA, 2010a) were measured using newer methods with significantly lower detection limits. In many cases, the mercury concentrations detected with the new methods were less than half the older detection limits. Because use of the older mercury data has the potential to introduce a large bias into the analysis, EPA chose to use only the post-2010 mercury data in the revised risk assessment. These data contain few nondetects and are more likely to accurately represent the mercury concentrations present in and released from CCR WMUs.
- **Development of Waste Types:** Given the large size of the WMUs and the generally basic nature of CCR leachate, it is possible that leachate could alter the subsurface geochemistry that governs the migration of inorganic constituents. Therefore, a statistical analysis of the concentrations of major ions (e.g., calcium, sulfate, hydrogen ions) in the pore water was conducted to identify distinct waste types (**Appendix H**). These waste types are considered separately to better capture the behavior of COPCs released from these wastes in the subsurface environment. The three distinct waste types considered in this analysis are:
  - **Ash and Coal Refuse:** Includes any CCR that is codisposed with coal refuse, which is waste coal produced from coal handling, crushing and sizing operations. This waste type is characterized by a low to moderate pH (1.7–8.2) and high levels of sulfate, iron and manganese.
  - **FGD Wastes:** Includes any type of wet or dry FGD waste when disposed in dedicated monofills. This waste type is characterized by a moderate to high pH (8.7–11.3) and high levels of calcium, sulfate, sodium and chlorine.
  - **Combined Ash:** Includes any CCRs other than those listed above (e.g., fly ash, bottom ash, boiler slag) either monofilled or in combination with each other. Due to the variability in disposal practices, this waste type is characterized by a broad range in pH (3.9–12.3), sulfate and calcium levels.
- **Site Quartiles:** Some sample sites in the CCR constituent database have many data points, while others have only a few. Thus, the available data would tend to bias concentrations toward those sites where more samples were collected. To avoid this, EPA developed quartiles of the COPC concentrations for each site. This approach provides equal weighting to each site while also retaining some of the intrasite variability that would be lost through the use of a single summary statistic for each site, such as an average. To develop the site quartiles, EPA first separated the data at each site into the different waste types reported at that site. This was done because combining the data for the different waste types into a single set of quartiles for a site might bias concentrations toward the most sampled waste types. Where only one sample was available for a waste type at a sample site, all of the quartiles were set to this value to ensure equal weighting. For the purposes of this screening, all

quartiles developed were then combined into a single distribution representing all sites and all waste types, from which a 90th percentile concentration was drawn.

Table 3-1. 90th Percentile Concentrations Used for Screening Analysis

Constituent	Impoundment Pore Water (mg/L)	Impoundment Wastewater (mg/L)	Whole Waste (mg/kg)
Aluminum	12.3	2.3	91,500
Ammonia	5.1	–	–
Antimony	0.04	0.02	47.0
Arsenic	0.78	0.13	106
Barium	0.21	0.43	1,103
Beryllium	0.001	0.001	18.3
Boron	97.8	36.2	388
Cadmium	0.06	0.003	3.8
Calcium	592	577	114,750
Chloride	2,023	345	384
Chromium	0.2	0.03	153
Cobalt	0.05	0.02	65.9
Copper	0.13	0.01	226
Fluoride	21.3	–	25
Iron	11.9	0.04	42,426
Lanthanum	–	–	58.6
Lead	0.10	0.0006	75.3
Lithium	0.45	1.99	–
Magnesium	174	1,990	17,550
Manganese	1.8	0.56	413
Mercury	0.000007	0.00003	1.1
Molybdenum	7.1	0.42	31.0
Nickel	0.3	0.07	199
Nitrate	13.7	–	0.25
Nitrite	5.0	–	–
Potassium	221	40	9,622
Selenium	0.32	0.10	18.2
Silicon	19.0	12.7	262,700
Silver	0.005	0.0001	11.1
Sodium	3,288	743	3,557

Table 3-1. 90th Percentile Concentrations Used for Screening Analysis

Constituent	Impoundment Pore Water (mg/L)	Impoundment Wastewater (mg/L)	Whole Waste (mg/kg)
Strontium	9.1	4.3	891
Sulfate	4,398	10,400	9,630
Sulfide	–	–	26.2
Sulfur	3,842	–	36,000
Thallium	0.003	0.009	33.9
Uranium	0.01	0.004	5.0
Vanadium	0.52	0.23	562
Zinc	0.19	0.06	269

These 90th percentile values represent the concentrations present in and released from CCR wastes. Impoundment pore water is the water present within interstitial spaces of the settled CCRs. Impoundment wastewater is the free water ponded on top of the settled CCR waste. Whole waste represents the concentrations present within CCRs at the time of generation. However, most receptors will not come in direct contact with CCR wastes. Instead, receptors are exposed to environmental media, such as air; soil and water, that have been contaminated by releases from these wastes. To estimate the concentrations that may be present in these environmental media, EPA used conservative assumptions to account for fate and transport of COPCs through the environment. The calculation of these media-specific exposure concentrations are discussed in the following subsections.

3.2 Ambient Air Screening

This subsection summarizes the screening for exposure pathways associated with two management scenarios: uncontrolled and controlled releases. Uncontrolled releases occur when no action is taken to reduce particulate emissions. Controlled releases occur when management practices are put in place to minimize the rate of particulates emissions. The controls considered in this analysis include wetting and/or the use of surfactants.[10] Yet, even with the best available management practices, some emissions may still occur. Relevant exposure pathways include human inhalation of particulate matter and any COPCs contained therein. The greatest source of these pathways are landfills during operation, as water cover for impoundments and postclosure cap for landfills will limit the release of particulate matter. Therefore, EPA screened these pathways for landfills and the results were also used to identify any COPCs for surface impoundments.

[10] Surfactants refer to compounds that lower the surface tension (or interfacial tension) between a liquid and a solid, and can increase the effectiveness of water as a dust control mechanism.

3.2.1 Exposure Concentrations

EPA used the 90th percentile whole waste concentrations presented in **Table 3-1** to estimate exposures to ambient air. However, these whole waste concentrations represent the mass of COPCs present within CCR wastes. To translate the concentrations in CCR waste to those in ambient air, EPA conducted modeling in two phases with the American Meteorological Society/Environmental Protection Agency Regulatory Model (AERMOD) and the corresponding screening model, AERSCREEN. Unitized particulate emission rates of 1 g/s and 1 µg/s-m^2 were used as inputs for AERSCREEN and AERMOD, respectively, to calculate a set of unitized dispersion factors. The purpose of these unitized factors was to allow for quick and easy scaling of the model results and to minimize the number of model runs required. Further discussion of this approach and the inputs used to run and scale these models is provided in **Appendix F**.

EPA first used AERSCREEN to calculate maximum unitized dispersion factors that could occur over one hour with weather data from a number of climate stations. This 1-hour averaging time was chosen as the most appropriate value to represent short-term exposures. AERSCREEN also calculates maximum air concentrations for other averaging times (i.e., 3-hour, 8-hour, 24-hour, annual) by scaling the 1-hour concentration. However, for area sources such as landfills, the screening model uses a scaling factor of 1 for these longer averaging times, which results in overly conservative long-term concentrations that are equal to the 1-hour concentration. Instead, a second phase of modeling was conducted with AERMOD to calculate unitized dispersion factors for 24-hour, monthly and annual averaging times. To minimize the resources required, EPA conducted a single AERMOD model run using five years of weather data from the climate station associated with the 90th percentile unitized dispersion factor from AERSCREEN. For both models, EPA selected the modeled unitized dispersion factors from the distance that resulted in the highest value and scaled each using **Equation 3-1**:

(3-1) $$C_{air} = \frac{E \cdot DF \cdot C_{waste}}{A \cdot \left(10^9 \frac{\mu g}{kg}\right)}$$

Where:

C_{air} = Air concentration of constituent (mg/m^3),
E = Aggregate emission rate (g/s),
DF = Unitized dispersion factor (µg/m^3 per g/m^2-s),
C_{waste} = 90th percentile constituent-specific whole waste concentration (mg/kg),
A = Active area of landfill (m^2).

Emission rates were calculated for particles 10 micrometers in diameter or smaller (PM_{10}), and were separately scaled for the fraction of PM_{10} that are 2.5 micrometers in diameter or smaller ($PM_{2.5}$). These are the particles most likely pass through the nose and throat and enter the lungs, dramatically increasing the risk of adverse health effects. Emission rates were calculated for four specific sources: wind erosion, vehicular activity, loading/unloading and spreading/compaction using equations from *AP-42: Compilation of Air Pollutant Emission Factors* (U.S. EPA, 1985a) and *Rapid Assessment of Exposure to Particulate Emissions from Surface Contamination Sites*

(U.S. EPA, 1985b). To capture the variability of national meteorological conditions, emission estimates were developed for a range of active landfill sizes with data from more than 40 meteorological stations that represent locations throughout the conterminous United States where CCR disposal in landfills are known to occur. Each of these emission rates was developed for both uncontrolled and controlled management scenarios. For each set of conditions evaluated, EPA summed the contributions from the four sources together to obtain an aggregate PM_{10} emission rate (E_{10}) and an aggregate $PM_{2.5}$ emission rate ($E_{2.5}$).

AERSCREEN and AERMOD results were scaled using every combination of PM_{10} emission rates, whole waste concentrations from **Table 3-1**, and active landfill sizes drawn from EPA surveys to obtain COPC concentrations in ambient air. A second scaling was conducted without the whole waste concentration data, to obtain PM_{10} and $PM_{2.5}$ concentrations in ambient air. From each of these sets of calculations, EPA selected the highest air concentrations from each management scenario for comparison in the screening.

3.2.2 Air Risks

EPA used the calculated air concentrations of particulates and COPCs to estimate risks for human receptors. EPA considered human health risks from inhalation of particulates and the COPCs contained on or in those particulates. Because air concentrations can vary considerably over time, EPA considered multiple averaging times to screen both short-term (i.e., acute) and long-tem (i.e., chronic) exposures.

Acute Human Inhalation Risks

Acute human health risks associated with the inhalation of COPCs present in ambient air were evaluated using concentration-based benchmarks (**Appendix E**). These benchmarks represent air concentrations below which no acute adverse effects are known or anticipated to occur for short exposure durations. Acute risks were evaluated by comparing these benchmarks to the maximum 1-hour concentrations calculated with AERSCREEN. The resulting noncancer risks were calculated using **Equation 3-2**:

(3-2) $$HQ_A = \frac{C_{air}}{RfC_A}$$

Where:

HQ_A = Acute hazard quotient (unitless)
C_{air} = 1-hour air concentration (mg/m^3)
RfC_A = Acute reference concentration (mg/m^3)

Table 3-2 presents these screening results for acute health risks resulting from inhalation of the COPCs from airborne particulates. These conservative results are presented for each COPC under both the controlled and uncontrolled management scenarios. Values found to be above the selected risk criteria (i.e., an $HQ_A > 1$) are shown in **bold**.

Table 3-2. Screening Results for Acute Human Health Risks Resulting from the Inhalation of Ambient Air

COPC	Management Scenario	
	Uncontrolled	Controlled
Aluminum	0.1	0.03
Antimony	< 0.01	< 0.01
Arsenic	**2**	0.5
Barium	< 0.01	< 0.01
Beryllium	0.02	< 0.01
Boron	< 0.01	< 0.01
Cadmium	< 0.01	< 0.01
Calcium	0.01	< 0.01
Chloride	< 0.01	< 0.01
Chromium	< 0.01	< 0.01
Cobalt	< 0.01	< 0.01
Copper	< 0.01	< 0.01
Fluoride	< 0.01	< 0.01
Iron	0.02	0.01
Lanthanum	< 0.01	< 0.01
Lead	< 0.01	< 0.01
Magnesium	0.01	< 0.01
Manganese	< 0.01	< 0.01
Mercury (elemental)	< 0.01	< 0.01
Molybdenum	< 0.01	< 0.01
Nickel	0.1	0.03
Nitrate/Nitrite	< 0.01	< 0.01
Potassium	0.2	0.05
Selenium	< 0.01	< 0.01
Silicon	0.02	< 0.01
Silver	< 0.01	< 0.01
Sodium	< 0.01	< 0.01
Strontium	< 0.01	< 0.01
Sulfate	< 0.01	< 0.01
Thallium	< 0.01	< 0.01
Uranium	< 0.01	< 0.01
Vanadium	< 0.01	< 0.01
Zinc	< 0.01	< 0.01

Noncancer risks above the risk criteria were identified for arsenic by a factor of 2 under the uncontrolled management scenario, but decreased below risk criteria when fugitive dust controls were considered. All other COPCs were below the risk criteria under the uncontrolled management scenario, and were over an order of magnitude below the criteria for the controlled management scenario.

Chronic Human Inhalation Risks

Chronic human health risks associated with the inhalation of COPCs present in ambient air were evaluated using concentration-based benchmarks. These benchmarks represent air concentrations below which no adverse effects are known or anticipated to occur over a lifetime of chronic exposure. Chronic risks were evaluated by comparing these benchmarks to the maximum annual concentrations calculated with AERMOD. Cancer risks were calculated using **Equation 3-3**:

(3-3) $$\mathrm{Risk_{Inhal}} = \mathrm{C_{air}} \cdot \mathrm{URF_{inhal}} \cdot 1{,}000 \left(\frac{\mu g}{mg}\right)$$

Where:

$\mathrm{Risk_{Inhal}}$ = Individual cancer risk from inhalation of contaminants (unitless)
$\mathrm{C_{air}}$ = Annual air concentration (mg/m^3)
$\mathrm{URF_{inhal}}$ = Inhalation unit risk factor (per $\mu g/m^3$)

While noncancer HQs were calculated using **Equation 3-4**:

(3-4) $$\mathrm{HQ_C} = \frac{\mathrm{C_{air}}}{\mathrm{RfC_C}}$$

Where:

$\mathrm{HQ_C}$ = Chronic hazard quotient (unitless)
$\mathrm{C_{air}}$ = Annual air concentration (mg/m^3)
$\mathrm{RfC_C}$ = Chronic reference concentration (mg/m^3).

Table 3-3 presents the screening results for both cancer and noncancer risks. Where benchmarks were available for multiple species of a constituent, the most conservative was used in the screening calculations. These conservative results are presented for each COPC under controlled and uncontrolled management scenarios. No values were found to be above either the cancer or noncancer criteria for either scenario.

Table 3-3. Screening Results for Chronic Human Health Risks Resulting from Inhalation of Ambient Air

COPC	Management Scenario	
	Uncontrolled	Controlled
Carcinogenic Risks		
Arsenic	2×10^{-6}	7×10^{-7}
Beryllium	2×10^{-7}	7×10^{-8}
Cadmium	4×10^{-8}	1×10^{-8}
Chromium	9×10^{-6}	3×10^{-6}
Cobalt	3×10^{-6}	9×10^{-7}

(continued)

Table 3-3. Screening Results for Chronic Human Health Risks Resulting from Inhalation of Ambient Air

COPC	Management Scenario	
	Uncontrolled	Controlled
Noncarcinogenic Risks		
Aluminum	0.6	0.2
Antimony	< 0.01	< 0.01
Arsenic	0.2	0.07
Beryllium	0.03	0.01
Cadmium	0.01	< 0.01
Chromium	0.05	0.02
Cobalt	0.4	0.1
Manganese	0.3	0.09
Mercury	< 0.01	< 0.01
Nickel	0.08	0.02
Selenium	< 0.01	< 0.01
Sulfide	< 0.01	< 0.01
Uranium	< 0.01	< 0.01
Vanadium	0.2	0.06

National Ambient Air Quality Standards

NAAQS are concentration-based regulatory limits developed for several priority pollutants by EPA. These benchmarks represent air concentrations protective of public health, including sensitive populations, such as asthmatics, children and the elderly. NAAQS exceedances were evaluated by comparing these benchmarks to the concentrations calculated with AERMOD for the available averaging time closest to that specified by the NAAQS standards. Annual concentrations were used for PM_{10} while both annual and 24-hour concentrations were used for $PM_{2.5}$. The specified averaging time for lead is a rolling 3-month average, which is not an available output from either AERSCREEN or AERMOD. Instead, lead concentrations were evaluated using a more protective monthly average concentration. The HQs were calculated using **Equation 3-5**:

$$\textbf{(3-5)} \quad \text{Ratio} = \frac{C_{air}}{NAAQS}$$

Where:

Ratio = Exposure ratio (unitless)
C_{air} = 24-hour/monthly/annual air concentration (mg/m^3)
NAAQS = National ambient air quality standard (mg/m^3).

Table 3-4 presents the screening results for both NAAQS standards. These conservative results are presented for each COPC under both the controlled and uncontrolled management scenarios. Values found to be above the selected risk criteria (i.e., a ratio > 1) are shown in **bold**.

Table 3-4. Screening Results for NAAQS

COPC	Averaging Time	Management Scenario	
		Uncontrolled	Controlled
PM_{10}	24-hour	0.4	0.1
$PM_{2.5}$	Annual	0.5	0.3
$PM_{2.5}$	24-hour	**2**	1
Lead	Monthly	0.03	0.02

An air concentration above the NAAQS for 24-hr $PM_{2.5}$ by a factor of 2 was identified under an uncontrolled management scenario, but decreased below relevant NAAQS when fugitive dust controls were considered.

3.3 Soil, Sediment, Plant and Animal Screening

This section summarizes the screening for all exposure pathways that result from aboveground transport of COPCs to downgradient soil and sediment. Aboveground transport occurs through windblown dust and particulates suspended in overland run-off. Two management scenarios are considered: uncontrolled and controlled releases. Uncontrolled releases occur when no action is taken to control particulate releases. Controlled releases occur when there is active management of CCR waste to minimize the rate of particulates emissions. These management practices include the use of wetting and surfactants to reduce windblown dust, and run-on/run-off controls to collect or otherwise control run-off from all rainfall events less than the maximum storm predicted for each 25-year interval in the area.

Relevant human exposure pathways include incidental ingestion of contaminated soils, as well as ingestion of any crops or livestock raised on contaminated soils. Relevant ecological exposures include direct contact with and ingestion of contaminated soils and sediment, as well as ingestion of any biota living around contaminated soil and sediment. Sediment exposures were screened through this pathway under the assumption that overland transport would contribute substantially higher loadings to downgradient water bodies than subsurface transport through ground water. Each of these exposure pathways are primarily associated with landfills during operation, as the constant water cover in impoundments and the postclosure cap in landfills will limit the transport of particulates by wind and overland run-off.

3.3.1 Exposure Concentrations

EPA used the 90th percentile whole waste concentrations listed in **Table 3-1** to estimate exposures to soil, sediment, produce and animal products. However, these whole waste concentrations represent the total mass of COPCs present in CCR wastes. To translate the concentrations in CCR waste to those in soil, sediment, produce and livestock, additional calculations were necessary.

Soil and Sediment Concentrations

EPA used dilution attenuation factors (DAFs) to estimate the COPC concentrations that may accumulate in downgradient soils and sediments under the uncontrolled management scenario. A DAF is a ratio of the initial constituent concentration at the point of release to the final constituent concentration at the point of exposure. EPA identified an appropriate DAF for the uncontrolled management scenario from the 1998 Risk Assessment (U.S. EPA, 1998a), which considered unmitigated transport of CCR waste from uncovered CCR landfills by wind and overland runoff. **Figure 3-1** plots the DAFs for each modeled constituent against the corresponding soil–water partition coefficient (K_d). K_d values are a measure of the tendency of a constituent to distribute between the solid and liquid phases. A strong inverse relationship can be seen between the DAFs and the K_d values for the COPCs. This is because the constituents most likely to leach out (i.e., those with low K_d values) will not accumulate in surficial soils to the same degree as those least likely to leach out (i.e., those with high K_d values).

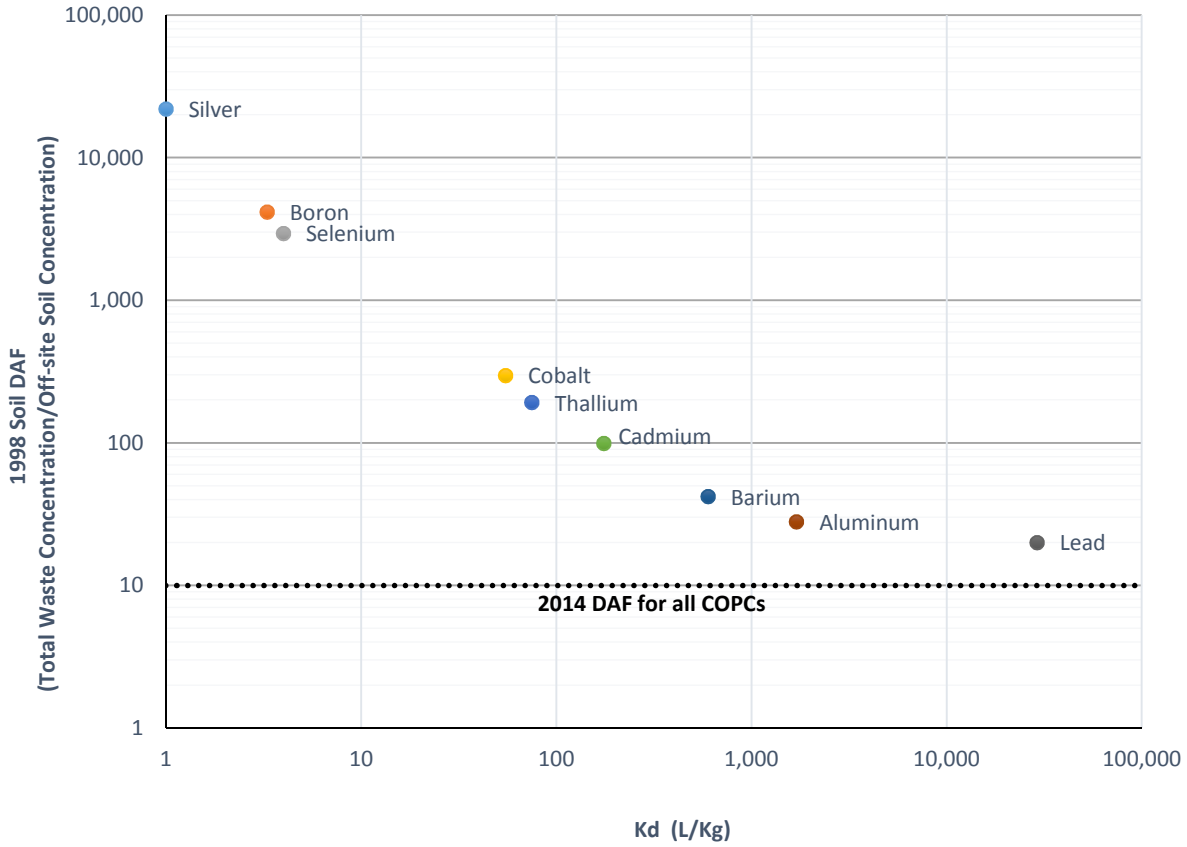

Figure 3-1. Dilution-attenuation factors as a function of K_d values as modeled in the 1998 risk assessment (adapted from U.S. EPA, 1998a).

For ease of calculation and to ensure that potential exposures were not underestimated, the revised risk assessment applied a single DAF of 10 to all COPCs for the uncontrolled management scenario. The selected DAF is below the lowest value identified in U.S. EPA (1998a) for lead, which had the highest K_d value of any COPC modeled. EPA divided the 90th percentile whole

waste concentrations by the DAF of 10 to generate downgradient concentrations used to screen exposures to both soil and sediment for the uncontrolled management scenario.

For the controlled management scenario, run-on and run-off controls for landfills require collection and control of all run-off up to that of a 24-hour, 25-year event. These controls would essentially eliminate all off-site migration through overland run-off on an annual basis. Thus, EPA assumed that run-off was negligible. Instead, soil and sediment concentrations were calculated assuming that transport resulted only from the deposition of windblown particulates onto soil. EPA calculated a total deposition rate onto soils with **Equation 3-6**:

(3-6) $$D_p = \left[\frac{E_{10} \cdot C_{waste}}{A \cdot \left(10^6 \frac{mg}{kg}\right)}\right] \cdot \left[D_{ydp} + D_{wdp}\right]$$

Where:

D_p = Deposition rate (g/m^2-yr)
E_{10} = PM_{10} emission rate (g/s)
C_{waste} = 90th percentile constituent-specific whole waste concentration (mg/kg)
A = Active landfill area (m^2)
D_{ydp} = Unitized dry deposition rate (g/m^2-yr per g/m^2-s)
D_{wdp} = Unitized wet deposition rate (g/m^2-yr per g/m^2-s).

The unitized dry and wet deposition rates are outputs generated by AERMOD during the model runs conducted to screen ambient air concentrations. Thus, all inputs were the same. Further detail on the inputs used for AERMOD is provided in **Appendix F**. The soil and sediment concentrations that result from deposition under the controlled management scenario were calculated using the conservative assumption that the deposition of particulates occurs continuously without any losses over the course of 10 years, consistent with an average exposure duration for adults. The settled particulates are uniformly mixed within the first centimeter of topsoil and surface sediment, which has a fixed density of 1,300 kg/m^3.

Concentrations in Produce

COPCs present in the soil can be drawn into plants through the root systems and consumed along with the edible portion of the plant. Plants may also become contaminated from windblown particulates that settle out on the plant surface. Both root uptake and air deposition may happen simultaneously, and thus, the resulting exposures are assumed to be additive. However, air deposition will not contribute to exposures for some produce categories because the plants have protective outer layers that are discarded prior to consumption. **Table 3-5** provides a breakdown of the different types of plants considered. Some of these plant categories (i.e., silage, forage) are considered as feed for cattle raised as a source of beef and milk for human consumption.

Table 3-5. Potential Routes of Contamination for Different Plant Types

Produce/Plant Category	Example	Root Uptake	Air Deposition
Exposed Fruits	Strawberry	✓	✓
Exposed Vegetables	Lettuce	✓	✓
Silage	Alfalfa	✓	✓
Forage	Grass	✓	✓
Protected Fruit	Watermelon	✓	–
Protected Vegetables	Onion	✓	–
Grains	Wheat	✓	–
Root Vegetables	Carrot	✓	–

The degree to which COPCs are taken up from the soil by different plants varies. To represent these differences, EPA used bioconcentration factors (BCFs) drawn from the available literature for each of the eight plant types listed above. BCFs provide information on the amount of uptake and accumulation of a substance from soil and are expressed as a concentration in the plant per unit of concentration in the soil. The COPC concentration in the edible portion of the plant was calculated by multiplying the concentration in the soil by the appropriate BCF. The resulting concentrations are in terms of dry weight, but human consumption data are available on a wet weight basis. Therefore, the calculated dry weight concentrations were multiplied by a water adjustment factor to scale to wet weight. The specific equations, BCFs and other inputs used for this pathway are presented in **Appendix G**.

In addition to soil uptake, several plant types also accumulate particulates on exposed surfaces from air deposition. The deposition to soils in **Equation 3-6** was adjusted to account for the fraction of deposition that will not adhere to the plant surface, resulting in **Equation 3-7**:

(3-7)
$$D_p = \left[\frac{E_{10} \cdot C_{waste}}{A \cdot \left(10^6 \frac{mg}{kg}\right)}\right] \cdot \left[D_{ydp} + \left(F_w \cdot D_{wdp}\right)\right]$$

Where:

D_p = Deposition rate (g/m^2-yr)
E_{10} = PM_{10} emission rate (g/s)
C_{waste} = 90th percentile constituent-specific whole waste concentration (mg/kg)
A = Active landfill area (m^2)
D_{ydp} = Unitized dry deposition rate (g/m^2-yr per g/m^2-s)
D_{wdp} = Unitized wet deposition rate (g/m^2-yr per g/m^2-s)
F_w = Fraction of wet deposition adhering to plant surface (unitless).

As with deposition onto soil, the unitized dry and wet dry deposition rates are outputs generated by AERMOD during the model runs conducted to screen ambient air concentrations. Thus, all weather data, active landfill area, emission rates and other inputs were the same. **Appendix G**

provides the plant-specific parameters (i.e., F_w) used in this equation, as well as the other equations used to convert the deposition rate into a concentration for aboveground produce.

Concentrations in Livestock

COPCs may concentrate in livestock through the ingestion of contaminated soil and feedstock. To represent this accumulation, EPA used biotransfer factors (BTFs) drawn from the available literature. BTFs provide information on the amount of accumulation of a chemical compound in animal products (e.g., beef, milk) based on the rate of consumption of feed and soil. The COPC concentrations in beef and milk were calculated for uncontrolled and controlled management scenarios by multiplying the mass of contaminant consumed each day by the appropriate BTF. The mass consumed was calculated by multiplying the quantity of feed or soil consumed by the concentration in the feed or soil and then summed across the types of feed plus soil. For both the uncontrolled and controlled management scenarios, EPA assumed all feedstock consumed by cattle were grown on contaminated soils, and that any soil consumed while foraging was also contaminated. The specific equations and BTFs used are presented in **Appendix G.**

3.3.2 Receptor Risks

EPA used the COPC concentrations calculated for each environmental media to estimate risks for human and ecological receptors under both uncontrolled and controlled management scenarios. EPA considered human health risks from ingestion of media from around home-based farm and ecological risks from ingestion of and direct contact with media. All pathways were evaluated for adverse effects resulting from chronic exposures. Generally, adverse effects from chronic exposures occur at lower media concentrations than acute exposures. Therefore, the constant, high-end concentrations used to screen chronic exposures will also be protective of acute exposures.

Human Health Risk from Ingestion

Human health risks associated with ingestion are evaluated using dose-based benchmarks. In order to translate the calculated exposure concentrations for each medium into risks, EPA first had to characterize the potential receptors. This was done for each receptor cohort by calculating an average daily dose (ADD), which is the intake rate averaged over specified exposure duration and expressed as a daily dose per unit of body weight. For noncancer risks, the dose was averaged on an annual basis using **Equation 3-8**.

(3-8) $$ADD = \sum_{i=s}^{n} \left[\frac{I_i \cdot ED_i}{ED_{total}} \right]$$

Where:

ADD = Average daily dose (mg/kg-day)
I_i = Intake for receptor age cohort i (mg/kg-day) (calculated in **Appendix G**)
ED_i = Exposure duration of age cohort i (yr) (cannot exceed length of age cohort)
ED_{total} = Total exposure duration (yr).

For cancer risks, the dose averaged over the lifetime of the individual using **Equation 3-9**, resulting in a lifetime average daily dose (LADD).

(3-9) $$\text{LADD} = \sum_{i=s}^{n} \left[\frac{\text{ADD} \cdot \text{ED}_i \cdot \text{EF}_i}{\text{AT} \cdot \left(365 \frac{\text{days}}{\text{year}}\right)} \right]$$

Where:

LADD = Lifetime average daily dose (mg/kg-day)
EF_i = Exposure frequency for age cohort i (day/yr)
AT = Averaging time (yr).

To calculate these dose rates, EPA used central tendency exposure factors. These factors were chosen to balance some of the conservatism present elsewhere in the screening. Exposures were considered separately for receptors starting in seven different age cohorts (i.e., 1 to < 2 yrs, 2 to < 3 yrs, 3 to < 6 yrs, 6 to < 11 yrs, 11 to < 16 yrs, 16 to < 21 yrs, and > 21 yrs). Since some exposure factors were specific to an age cohort, exposure calculations aged receptors from the beginning of the specified cohort through subsequent cohorts until the full exposure duration had been reached.

ADD and LADD were calculated on a COPC-specific basis for each age cohort. The calculated doses were compared to human health benchmarks for noncancer and cancer effects, respectively. A reference dose (RfD), which is an estimate of a daily exposure that is likely to be without appreciable risk, was used to estimate HQs for noncancer effects. These HQs were calculated using **Equation 3-10**.

(3-10) $$\text{HQ}_C = \frac{\text{ADD}}{\text{RfD}}$$

Where:

HQ_C = Noncancer risk from ingestion (unitless)
RfD = Reference dose (mg/kg-day).

A cancer slope factor (CSF), which is an upper-bound estimate of the increased human cancer risk from a lifetime of daily exposure, was used to estimate cancer risks. These cancer risks were calculated using **Equation 3-11**.

(3-11) $$\text{Risk}_{\text{Ing}} = \text{LADD} \cdot \text{CSF}_{\text{oral}}$$

Where:

$Risk_{Ing}$ = Cancer risk from ingestion (unitless)
CSF_{oral} = Oral cancer slope factor (risk per mg/kg-day)

Table 3-6 presents the screening results for human exposures to soil, produce, and animal products. Where benchmarks were available for multiple species of a constituent, the most conservative was used in the screening calculations. Results are presented for both the controlled and uncontrolled management scenarios. For both scenarios, these conservative results are based on the most sensitive age cohorts for cancer risks and noncancer risks. For cancer risks, this was 1 to < 2-year-olds for soil ingestion and adults for produce, beef, and milk ingestion. For noncancer risks, this was 1 to < 2-year-olds for all pathways. Results are presented under both the controlled

and uncontrolled management scenarios. Values found to be above the selected risk criteria (i.e., an HQ > 1) are shown in **bold**.

Table 3-6. Screening Results for Human Health Risks Resulting from Soil, Produce, Beef and Milk Ingestion

COPC	Uncontrolled				Controlled

Uranium	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01
Vanadium	0.04	0.03	0.01	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01
Zinc	< 0.01	0.08	0.07	0.1	< 0.01	< 0.01	< 0.01	< 0.01

– Indicates that no BCF or BTF was available

All cancer risks fell below human health risk criteria under both uncontrolled and controlled scenarios. Noncancer risks were identified above human health criteria for thallium in soil (2), beef (10) and milk (8) under the uncontrolled management scenario. When management controls were considered, all human health risks fell below the risk range.

Ecological Risk

Ecological risks from direct contact with and ingestion of environmental media were evaluated using concentration-based benchmarks (**Appendix E**). These benchmarks, which represent concentrations below which no adverse effects are known or anticipated to occur, were used to estimate HQs using **Equation 3-12**.

(3-12) $$HQ = \frac{C_{soil}}{Eco_{soil}} \text{ or } \frac{C_{sed}}{Eco_{sed}}$$

Where:

C_{soil} = Soil concentration (mg/kg)
C_{sed} = Sediment concentration (mg/kg)
Eco_{soil} = Ecological soil benchmark (mg/kg)
Eco_{sed} = Ecological sediment benchmark (mg/kg).

Table 3-7 presents the screening results for ecological exposures to soil and sediment. Where benchmarks were available for multiple species of a constituent, the most conservative was used in the screening calculations. Results are presented for both the controlled and uncontrolled management scenarios. For both scenarios, these conservative results are based on the most sensitive receptors, specified by the toxicity benchmarks. Values that exceed the selected risk criteria (i.e., HQ > 1) are shown in **bold**.

Table 3-7. Screening Results for Ecological Risks Resulting from Soil and Sediment Exposures

COPC	Uncontrolled		Controlled	
	Soil	Sediment	Soil	Sediment
Antimony	**20**	**2**	0.1	< 0.01
Arsenic	0.6	**2**	< 0.01	< 0.01
Barium	0.3	0.6	< 0.01	< 0.01
Beryllium	0.1	–	< 0.01	–
Boron	**80**	–	0.6	–
Cadmium	1	0.7	< 0.01	< 0.01
Chromium	0.6	0.4	< 0.01	< 0.01
Cobalt	0.5	–	< 0.01	–
Copper	0.8	0.6	< 0.01	< 0.01
Lead	0.7	0.2	< 0.01	< 0.01
Manganese	0.2	–	< 0.01	–
Mercury	1	0.6	< 0.01	< 0.01
Molybdenum	0.1	0.1	< 0.01	< 0.01
Nickel	0.5	1	0.01	< 0.01
Selenium	**3**	–	0.03	–
Silver	0.3	**2**	< 0.01	< 0.01
Vanadium	**7**	**3**	0.1	< 0.01
Zinc	0.6	0.2	< 0.01	< 0.01

– Indicates that no benchmark was available for these receptors

Ecological soil risks above an HQ of 1 were identified were identified for the following constituents: boron (80) antimony (20) vanadium (7) and selenium (3). Ecological sediment risks were also identified above an HQ of 1 for the following constituents: vanadium (3), antimony (2), arsenic (2) and silver (2). When fugitive dust and run-off controls were considered, all ecological risks fell below the ecological risk criteria.

3.4 Ground Water, Surface Water, Wastewater and Fish Screening

This section summarizes the screening for all exposure pathways that result from leaching of COPCs into water. These exposure pathways are associated with both landfills and surface impoundments as a result of rainfall and/or wastewater percolating through the WMU. Relevant pathways include ecological exposures to impoundment wastewater, ecological exposure to downgradient surface waters, human consumption of ground water and fish, and human dermal and inhalation exposure through bathing and showering. While these pathways may be present for both impoundments and landfills, the 2010 Risk Assessment demonstrated that risks from surface impoundments are consistently higher than those from landfills. Therefore, EPA screened these pathways for surface impoundments and the results also were used to identify COPCs for landfills.

3.4.1 Exposure Concentrations

EPA used the 90th percentile concentrations for impoundment pore water and wastewater listed in **Table 3-1** to estimate exposures to ground water, surface water, wastewater and fish. Impoundment wastewater concentrations were used to screen exposures for ecological receptors that live in and around surface impoundments. These concentrations were collected from the surface water within surface impoundments after CCR solids settled out. Since wastewater concentrations are representative of the environment that these ecological receptors would inhabit, the measured concentrations were used directly in the screening. Impoundment pore water concentrations were used to screen human exposures to ground water and fish, as well as exposures for ecological receptors that live in and around downgradient surface water bodies. Pore water concentrations were collected from the interstitial water between waste particles at the bottom of the surface impoundment. These concentrations are representative of leachate released from impoundments to downgradient receptor wells and surface water bodies.

Dilution Attenuation Factors

DAFs were used to conservatively account for the reduction in concentrations that would occur during subsurface transport between a WMU and a downgradient water body. The 2010 Risk Assessment yielded a 10th percentile DAF of approximately 2 across all modeled constituents. For ease of calculation and to ensure that potential exposures were not underestimated, the revised risk assessment applied a single DAF of 1 to all water pathways. This DAF is equivalent to direct exposure to pore water. The 90th percentile pore water concentrations were divided by the selected DAF to generate exposure concentrations.

Bioconcentration in Fish

The fish caught and consumed by recreational fishers and their families were assumed to be exposed to undiluted pore water. EPA assumed that all of the fish consumed by receptors originated from the third trophic level (TL3) and fourth trophic level (TL4). TL3 consists of carnivores that eat herbivores or secondary consumers such as invertebrates and plankton (e.g., carp, smelt, perch, catfish, sucker, bullhead, sauger), while TL4 consists of carnivores that eat other carnivores (e.g., salmon, trout, walleye, bass). While specific fish may not fit entirely into one category, EPA chose conservative categorizations for these fish to remain protective of human health. Because the degree of bioconcentration may differ between these two trophic levels, the Agency used separate BCFs for these two trophic levels, when available. For BCFs and the equations used to calculate fish concentrations, see **Appendix G**.

3.4.2 Ground Water, Surface Water, Wastewater and Fish Risks

EPA used the calculated concentrations in the different media to calculate risks for human and ecological receptors. EPA considered human health risks from ingestion of ground water and fish, as well as dermal contact with ground water and inhalation of volatilized COPCs. EPA considered ecological risks from ingestion of and direct contact with impoundment wastewater and downgradient surface water. All pathways were evaluated for adverse effects resulting from chronic exposures. Generally, adverse effects from chronic exposures occur at lower media concentrations than acute exposures. Therefore, the constant, high-end concentrations used to screen chronic exposures will also be protective of acute exposures.

Chronic Human Ingestion Risks

Human health risks associated with ingestion were evaluated using dose-based benchmarks. In order to translate the calculated exposure concentrations for each media into risks, EPA first had to characterize the potential receptors. For most COPCs, this was done for each receptor cohort by calculating either a noncancer ADD using **Equation 3-8** or a cancer LADD using **Equation 3-9**. The calculated ADD and LADD were then used to calculate HQs using **Equation 3-10** and cancer risks using **Equation 3-11**, respectively. In contrast, lead risks were characterized by comparing the ground water concentrations directly to the concentration-based MCL because no dose-based benchmark is currently available. This was done using **Equation 3-13**.

(3-13) $$\text{Ratio} = \frac{C_{DW}}{MCL}$$

Where:

Ratio = Exposure Ratio (unitless)
C_{DW} = Drinking water concentration (mg/L)
MCL = Maximum contaminant level (mg/L).

Table 3-8 presents the screening results for chronic exposures to ground water and fish. Where benchmarks were available for multiple species of a constituent, the most conservative was used in the screening calculations. For both scenarios, these conservative results are based on the most

sensitive age cohorts for cancer risks (adults) and noncancer risks (children ages 1 to < 2). Values that exceed the selected criteria (i.e., a cancer risk > 1×10^{-5} or an HQ > 1) are shown in **bold**.

Table 3-8. Screening Results for Human Health Risks Resulting from Ground Water and Fish Ingestion

COPC	Ground Water Ingestion	Fish Ingestion
Cancer Effects		
Arsenic	**3×10^{-3}**	**4×10^{-5}**

Ingestion of ground water resulted in risks above the human health criteria. Cancer risks above 1×10^{-5} were identified for arsenic (3×10^{-3}) and chromium VI (3×10^{-4}). Noncancer risks above an HQ of 1 were identified were identified for: arsenic (50), molybdenum (30), boron (10), fluoride (7), lead (7) thallium (6), lithium (4), cobalt (3), antimony (2) and cadmium (2).

Ingestion of fish resulted in risks above the human health criteria. Cancer risks above 1×10^{-5} were identified for arsenic (4×10^{-5}). Noncancer risks above an HQ of 1 were identified were identified for: selenium (10), mercury (7), thallium (4) and cadmium (2).

Human Health Risks from Inhalation

In addition to dermal exposure during showering and bathing, receptors may also be exposed to volatile COPCs present in the ground water through inhalation of any vapors released. The elevated temperature and physical disturbance of water as it is forced through faucets and showerheads for baths and showers may facilitate the volatilization of COPCs. The extent to which a constituent will volatilize from shower water depends on a number of factors, including chemical properties, the water temperature, the type of shower nozzle, and the duration of showering. Elemental mercury is the only COPC identified that may volatilize to any appreciable degree under the relevant range of household conditions. Based on an estimate of air concentrations calculated by multiplying the 90th percentile mercury pore water concentration by the Andelman volatilization factor of 0.5 L/m^3 (U.S. EPA, 1991), this exposure pathway resulted in an HQ below the risk criteria using **Equation 3-4**. Therefore, this pathway was not retained for further evaluation.

Human Health Risks from Dermal Contact

Human receptors may be exposed to COPC concentrations in ground water through prolonged dermal contact with contaminated water during showering or bathing. EPA screened these dermal exposures based on the recommendations in *Risk Assessment Guidance for Superfund Volume I: Human Health Evaluation Manual* (*Part E, Supplemental Guidance for Dermal Risk Assessment*) (U.S. EPA, 2004), which recommends that dermal exposure should be retained for evaluation if the dermal exposure is greater than 10 percent of oral exposure. Prior performing the calculations, EPA reviewed the literature to ensure the use of the most appropriate values. Based the *Public Health Goals for Chemicals in Drinking Water: Hexavalent Chromium (Cr VI)* (CalEPA, 2011), the dermal permeability coefficient (K_p) was updated to 7×10^{-6} cm/hr and gastrointestinal absorption updated to 1% for Chromium VI. Values provided by RAGS Part E were used for all other constituents. Using the process demonstrated in Exhibit B-4 of RAGS Part E, EPA determined that a screening assessment should be conducted for barium, beryllium, cadmium, chromium III, manganese, mercury (divalent), silver, vanadium, and zinc.[11]

Risk calculations were performed for a showering adult, identified in RAGS Part E as the most highly exposed receptor, using *Inorganic Chemicals in Water* spreadsheet provided in U.S. EPA (2004). The spreadsheet was updated to reflect residential exposure assumptions consistent with

[11] Because gastrointestinal adsorption of zinc is listed as highly variable, a conservative value of 1% was used for the purposes of this screening.

the ingestion screening (see **Appendix D**). **Table 3-9** Results are presented for each COPC under controlled and uncontrolled management scenarios. No values were found to be above noncancer criteria.

Table 3-9. Screening Results for Human Health Risks Resulting from Dermal Contact

COPC	Dermal Contact
Noncancer Risks	
Barium	< 0.01
Beryllium	< 0.01
Cadmium	0.7
Chromium	< 0.01
Manganese	0.09
Mercury	< 0.01
Silver	< 0.01
Vanadium	0.3
Zinc	0.2

Ecological Risk

Ecological risks associated with direct contact with and ingestion of environmental media were evaluated using concentration-based benchmarks. These benchmarks, which represent media concentrations below which no adverse effects are known or anticipated to occur for the species, were used to estimate HQs using **Equation 3-13**.

(3-13) $$HQ = \frac{C_{sw}}{Eco_{water}} \text{ or } \frac{C_{ww}}{Eco_{water}}$$

Where:

HQ = Hazard quotient (unitless)
C_{sw} = Surface water concentration (mg/L)
C_{ww} = Wastewater concentration (mg/L)
Eco_{water} = Ecological water benchmarks (mg/L).

Table 3-10 presents the screening results for direct ecological exposures to surface water and impoundment wastewater. Where benchmarks were available for multiple species of a constituent, the most conservative was used in the screening calculations. These results are based on the most sensitive receptors for each COPC, specified by the selected toxicity benchmark. Values that exceed the selected risk criteria (i.e., an HQ > 1) are shown in **bold**.

Table 3-10. Screening Result for Ecological Risks Resulting from Surface Water and Impoundment Water Exposure

COPC	Surface Water	Impoundment Wastewater
Aluminum	**100**	**30**
Antimony	1	0.7
Arsenic	**100**	**20**
Barium	**50**	**100**
Beryllium	**2**	**2**
Boron	**100**	**30**
Cadmium	**200**	**10**
Chloride	**9**	**2**

Silver	**10**	0.3
Thallium	0.3	0.7
Vanadium	**30**	**10**
Zinc	**2**	0.5

Direct contact with and ingestion of surface water resulted in risks above ecological criteria. Ecological risks above an HQ of 1 were identified were identified for, listed from highest to lowest: cadmium (200), aluminum (100), arsenic (100), boron (100), selenium (60), barium (50), lead (40), vanadium (30), chromium III (20), molybdenum (20), copper (10), iron (10), silver (10), chloride (9), nickel (6), beryllium (2), cobalt (2) and zinc (2).

Direct contact with and ingestion of impoundment wastewater resulted in risks above ecological criteria. Ecological risks above an HQ of 1 were identified were identified for, listed from highest to lowest: arsenic (100), barium (50), aluminum (30), boron (30), selenium (20), cadmium (10), vanadium (10), beryllium (2), chloride (2) and chromium (2).

3.5 Screening Analysis Conclusions

EPA conducted this screening analysis to determine which COPCs are most likely to pose risk to receptors for each of the exposure pathways identified in **Section 2**. Based on the results of this

conservative screening, EPA determined which pathways to retain for further characterization with more refined, probabilistic modeling discussed in **Section 4**. The following subsection summarizes the results of the different screening analyses and the Agency's conclusions.

3.5.1 Ambient Air Conclusions

EPA calculated ambient air concentrations that result from windblown dust from landfills under uncontrolled and controlled management scenarios. Risks were estimated for based on short-term (i.e., acute) and long-term (i.e., chronic) exposures. Under the uncontrolled management scenario, concentrations of arsenic were found to pose acute risks and $PM_{2.5}$ was found to exceed the 24-hour NAAQS. However, all risks fell below selected criteria under the controlled management scenario. Based on these results, EPA did not retain exposures to ambient air for further analysis. Even with the conservative assumptions used here, risks fell below selected criteria when dust controls were considered. Thus, these screening results are sufficient to characterize high-end risks for this pathway, and the controls required by the rule are considered protective.

3.5.2 Soil, Sediment, Produce and Animal Product Conclusions

EPA calculated downgradient soil, sediment, produce, beef and milk concentrations that result from windblown dust and run-off from landfills under uncontrolled and controlled management scenarios. Under the uncontrolled management scenario, thallium was found to pose human health risks for multiple pathways, while multiple constituents were found to pose ecological risks for soil and sediment. However, all risks fell below selected criteria under the controlled management scenario. Based on these results, EPA did not retain these aboveground pathways for further analysis. Even with the conservative assumptions used here, risks fell below all benchmarks when fugitive dust and run-on/run-off controls were considered. Thus, these screening results are sufficient to characterize high-end risks for this pathway, and the controls required by the rule are considered protective.

Although aboveground transport of CCR waste was not retained for further analysis, the sediment screening was used as a more conservative estimate of sediment concentrations than may occur due belowground transport of leachate from CCR waste water. Thus, these results were used to identify COPCs for subsurface transport through ground water. As a result, EPA retained antimony, arsenic, silver and vanadium for further characterization through the ground water to surface water sediment pathway.

3.5.3 Ground Water, Surface Water, Wastewater and Fish Conclusions

These conservative screening analyses identified potential risks to human and ecological receptors from leaching of chemical constituents from CCR waste into surrounding environmental media. Risks to human health resulted from ingestion of ground water and fish, while risks to ecological receptors resulted from exposure to surface water. While EPA did not consider the various controls that may mitigate these releases, considerable dilution and attenuation may occur before COPCs reach downgradient private wells and surface water bodies. Nevertheless, EPA retained all of the COPCs found to be above risk criteria in ground water and surface water for further

characterization in the probabilistic analysis. A summary of the COPCs retained for ground water, surface water, and sediment is presented in **Table 3-11**.

Table 3-11. Summary of the Exposure Pathways and COPCs Carried Forward for Probabilistic Analysis

These screening analyses also identified potential risks to ecological receptors from direct exposures to impoundment wastewater. Unlike the other exposure pathways, no dilution or attenuation will occur within impoundment wastewater prior to ecological exposures. Because of this, the screening analysis provides sufficient characterization of these exposures. Based on these results, EPA concludes that there is the potential for risks to ecological receptors from aluminum, arsenic, barium, beryllium, boron, cadmium, chloride, chromium, selenium and vanadium based on direct contact with surface impoundment wastewater. Therefore, this exposure pathway was not carried forward for further analysis, but is discussed in the risk characterization.

4 Probabilistic Analysis

The screening analysis presented in **Section 3** identified the potential for risks to human health and the environment through multiple exposure pathways. This screening provided adequate characterization of the risks associated with several of the evaluated pathways. However, due to the conservative nature of the screening, additional characterization of human ingestion of ground water and fish, as well as ecological contact with and ingestion of surface water and sediment, were necessary to support a robust set of conclusions about current CCR disposal practices. The Agency conducted this further analysis using a probabilistic, site-based approach that combined site-specific data with regional and national data. This section describes the overarching analytical framework, as well as the specific models and inputs used within this framework to predict the fate and transport of COPCs through subsurface soils and ground water. The discussion of the probabilistic analysis is divided into the following sections:

- **Section 4.1:** Outlines the probabilistic modeling framework used by EPA to quantify the potential risks to human and ecological receptors that result from WMU leaching.
- **Section 4.2:** Details the selection of modeled leachate concentrations.
- **Section 4.3:** Details the selection of modeled leaching durations.
- **Section 4.4:** Details the selection of modeled infiltration rates.
- **Section 4.5:** Details the selection of modeled depth of WMUs below ground surface.
- **Section 4.6:** Details the selection of modeled receptor locations.
- **Section 4.7:** Provides an overview of subsurface transport modeling used to calculate exposures resulting from drinking water ingestion (human health).
- **Section 4.8:** Provides an overview of the surface water models used to calculate exposures resulting from ingestion of fish (human health) and direct contact with both surface water and sediment (ecological).
- **Section 4.9:** Provides an overview of the exposure and risk models used to quantify the risks associated with calculated exposure concentrations.
- **Section 4.10**: Presents the modeled probabilistic risks results.

4.1 General Analytical Framework

Ground water fate and transport modeling was conducted with the EPA Composite Model for Leachate Migration with Transformation Products (EPACMTP) (U.S. EPA, 1996a, 1997a, 2003a,b,c). EPACMTP consists of two coupled modules: a one-dimensional module that simulates infiltration and dissolved constituent transport through unsaturated soils in the vadose zone and a three-dimensional module that simulates transport through ground water. EPACMTP models ground water concentrations present at a specified location (such as a private well or a stream) as

a function of time. The outputs from EPACMTP were fed into additional models that calculate surface water concentrations, sediment concentrations, receptor exposure rates, and receptor risks.

The probabilistic framework used in this risk assessment is a Monte Carlo analysis, which is a statistical technique where a quantity (in this case, risk) is calculated through repeated simulations using values selected probabilistically from an assigned parameter distribution for each model run (or iteration). The results approximate the range of possible outcomes and the likelihood of each outcome. This framework includes a separate data preparation loop and calculation loop. The data preparation loop created a single file that contained all of the input data necessary for every iteration of EPACMTP and the other models. In this file, approximately 100 entries were created for each WMU, with each entry representing the data for a distinct model iteration. EPA selected this number of entries to effectively sample the variability of each site. Where site-specific data were known for a WMU, a fixed value was assigned to all entries for that unit and held constant for each model iteration. Otherwise, a distribution was assigned based on available site, regional or national data sources, and a different value was probabilistically sampled during each model iteration. **Table 4-1** provides a list of the different data included in this file.

Table 4-1. Summary of Parameters in the Probabilistic Analysis

Description	Resolution	Fixed or Variable*	Source
WMU Type	Site-Based	Fixed	Appendix A

* In some cases, variables listed as "fixed" were not known for a subset of WMUs, and were probabilistically selected instead.

Once the data preparation loop was complete, the generated data file was fed into the calculation loop. Each calculation loop consisted of numerous model iterations, one for each entry in the data file. In total, approximately 100,000 model iterations were conducted for all WMUs, which forms the basis for the probabilistic risk results presented in this section. Each model iteration pulled a different set of values from the data files based on the assigned probability distributions. **Figure 4-1** shows the looping structure of the Monte Carlo framework used in this risk assessment.

The majority of the site, regional or national data used in the probabilistic analyses could be applied directly to the models in the probabilistic framework as collected. However, in certain instances, it was necessary to account for additional considerations to appropriately reflect the conditions present in surface impoundments and landfills. The following subsections describe the various considerations involved in the selection and application of these inputs to the modeling framework.

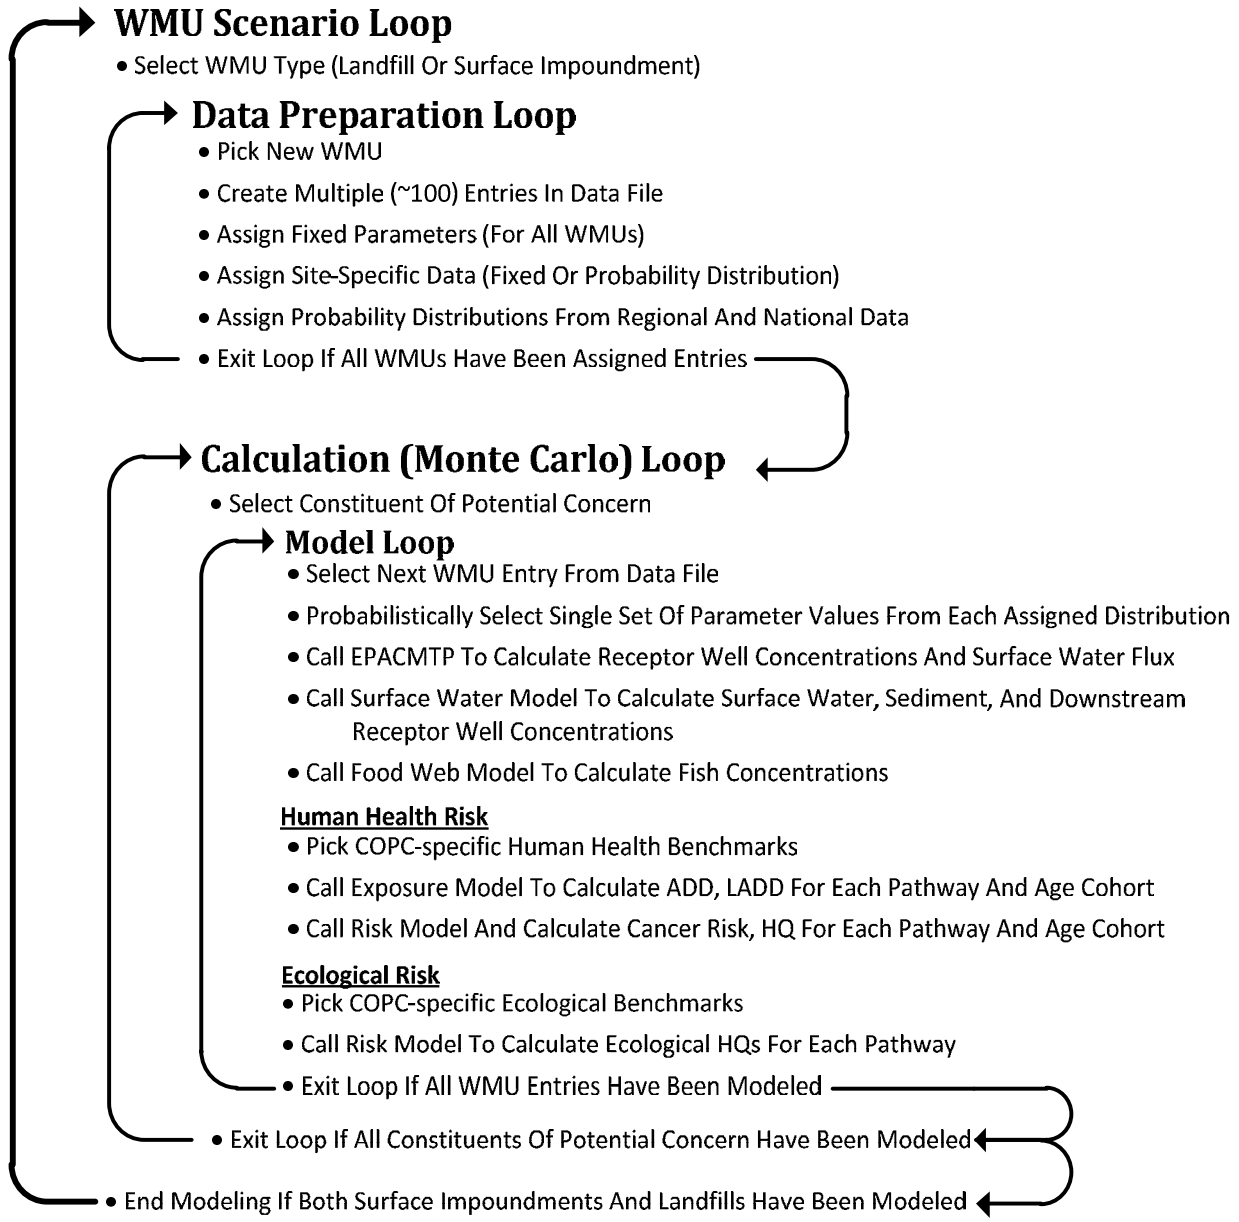

Figure 4-1. Looping structure of the CCR probabilistic modeling framework.

4.2 Source Leachate Concentrations

The following subsection summarizes the approach used to assign leachate concentrations to each WMU within the probabilistic framework. Over time, EPA has compiled a great deal of leachate data, collected and analyzed through different methods. While all of these data represent leaching

from CCR waste, some better reflect the specific environmental conditions present at surface impoundments and landfills. Therefore, to make the best use of the available data, EPA used different data sets to characterize leachate from surface impoundments (**Section 4.2.1**) and landfills (**Section 4.2.2**).

4.2.1 Surface Impoundments

Similar to the screening analysis described in **Section 3**, EPA relied on pore water concentrations to characterize leaching from impoundments. These concentrations are collected from the interstitial water between waste particles in surface impoundments as it occurs in the field, and best reflect leachate as it is released into underlying soils. Within the CCR constituent database, some facilities have more than one sample site. Some of these sample sites have many data points, while others have only a few. Similarly, some of the waste types (i.e., combined ash, ash and coal refuse, and FGD waste) disposed at these sites may have more data points than others. Thus, combining all of the available data into a single distribution would bias the modeled concentrations toward individual facilities, sites, and waste types with more samples. To avoid this, EPA developed quartiles from the pore water data available for each waste type at each sample site. Where only one sample was available for a waste type or a sample site, all of the quartiles were set equal to that one value. This approach provides equal weighting while also retaining some intra-site variability that would have been lost through the use of a single summary statistic, such as an average.

Unlike the screening analysis, the quartiles were combined into three separate probability distributions, one for each waste type. During the data preparation loop, a fixed waste type was assigned to each surface impoundment if known from survey data. In the absence of site-specific data, a probability distribution was assigned based on the prevalence of waste types known to be present in other surface impoundments. From the assigned waste type, the data preparation loop assigned a waste-specific probability distribution for the pore water concentration of each COPC. During the calculation loop, the models probabilistically sampled from the assigned concentration distribution for every entry in the data file. The selected concentration was held constant for the entire duration of leaching.

4.2.2 Landfills

To characterize leaching from landfills, EPA collected samples of CCR waste from over 30 facilities that reflect the range of coal rank burned and likely air pollution control technology configurations at the time of this risk assessment. The leaching behavior of these samples was characterized with the SW-846 LEAF methods. These methods, described in greater detail in **Appendix C**, provide information on the leaching behavior of each sample under a range of environmental conditions. Because of this information available for each sample, it was not necessary to combine these samples into separate waste types to capture the variability of potential behavior in the subsurface environment.

During the data preparation loop, a single pH distribution that ranged between 2.8 and 12.8 was assigned to all landfill entries based on nationwide field measurements (U.S. EPA, 2009a). The

data preparation loop also assigned a specific waste sample to each landfill entry, with an equal probability assigned to each sample. During the calculation loop, the models probabilistically sampled the assigned pH distribution during each model iteration. This pH was used to identify the pH-specific leachate concentration measured with LEAF Method 1313. The modeled leachate concentration was calculated in one of two ways, based on the type of leaching behavior exhibited by the waste sample at that pH (discussed further in **Appendix I**):

- **Solubility-Controlled Leaching** occurs when the total COPC mass available to be released from the waste is greater than the maximum amount that can be dissolved in the mass of water present. Because the solubility limit is reached at the higher liquid-to-solid ratio (L/S ratio) of 10:1 used in Method 1313, it will also be reached at the lower L/S ratio of around 1:2 typical of landfills. Thus, the concentrations measured with Method 1313 accurately reflect solubility-controlled leaching from landfills and the measured concentration was used for the model iteration.
- **Washout-Controlled Leaching** occurs when the total COPC mass available to be released from the waste is less than or equal to the maximum amount that can be dissolved in the mass of water present. Because the solubility limit is not reached for the higher L/S ratio of 10:1 used in Method 1313, the water concentration will increase as the L/S ratio decreases until the solubility limit is reached. Thus, washout-controlled leaching from landfills will be higher than the concentrations measured with Method 1313. To account for the difference in L/S ratios between Method 1313 and landfills, the measured Method 1313 concentration was multiplied by a factor of 20. This calculated concentration was used for the model iteration.

4.3 Leaching Duration

The following subsection summarizes the approach used to assign leaching durations to each WMU within the probabilistic framework. Leaching duration is the length of time that a WMU releases leachate into underlying soils. Because the aim of this probabilistic analysis is to provide an accurate estimate of peak concentrations, the leaching duration of interest for a WMU may not be the same as the total leaching duration. The duration of interest differs for surface impoundments and landfills because of the distinct leaching behavior of the two WMUs during operation and postclosure. Therefore, EPA used different data to characterize the leaching duration for surface impoundments (**Section 4.3.1**) and landfills (**Section 4.3.2**).

4.3.1 Surface Impoundments

Most surface impoundments are known to be periodically dredged. Since this dredging would remove any potential source postclosure, only the operational phase of a surface impoundment was modeled. The highest releases from surface impoundments are anticipated to occur during operational life due to the presence of a large hydraulic head that will drive infiltration rates. As a result, the length of the operating life was a key parameter for this analysis. Data on impoundment operating life were drawn from EPRI (1997a). A total of 86 of the 116 surveyed impoundments provided both an opening date and projected closure date, from which EPA calculated the expected operating life. No projected closure date was provided for the other 30 surface impoundments.

Figure 4-2 shows the distribution of the calculated operating lives, along with a separate bar representing units with no reported closure date.

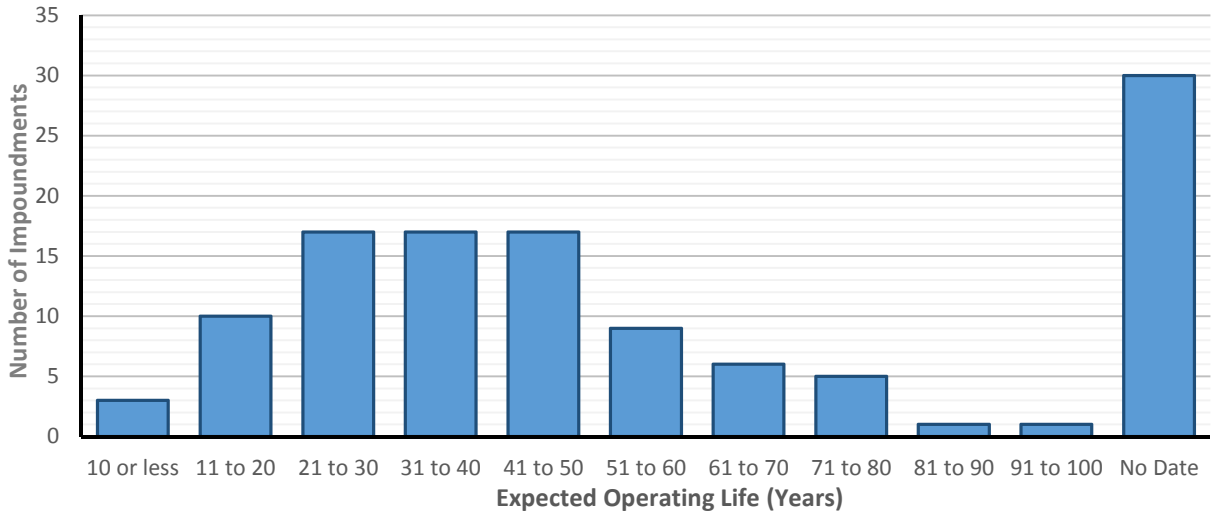

Figure 4-2. Distribution of operating life for surface impoundments from EPRI (1997a).

The calculated 50th percentile impoundment operating period was 40 years, while the 95th percentile value was 75 years. More recent information available in the CCR WMU database corroborates the distribution of expected operating life, and shows that many impoundments are currently approaching 40 years of age. At the same time, the EIA reported a large decrease in wet handling between 2009 and 2012 and many facilities have publicly announced plans to close surface impoundments.[12] Due to the uncertainty in operational lifetime for nearly a quarter of these units, and the potential for extended operational life through dredging, EPA selected a 95th percentile value of 75 years was assigned to all surface impoundments during the data preparation loop.

4.3.2 Landfills

Leaching from landfills was assumed to start at closure when the unit is filled to capacity with CCR waste. This point was chosen because EPACMTP requires a fixed WMU size, and the size at closure represents the largest possible footprint. Postclosure landfills were modeled as a finite source because the buried waste is not replenished as it leaches. For all COPCs except arsenic, leaching was idealized as a single, constant source that continued until the total available mass of a COPC had been depleted. For these COPCs, the total available mass was estimated as the maximum mass released at any pH over the range of 2.8 and 12.8 measured with Method 1313. The exact leaching duration varied between model iterations based on the modeled leachate concentration, total available mass and the leaching rate.

[12] Wilson, Mark. 2009. "Coal ash disposal varies from company to company." Evansville Courier & Press. October 24. Available online at: www.courierpress.com/lifestyle/health-and-fitness/coal-ash-disposal-varies-from-company-to-company

For arsenic, the available data collected with the LEAF methods have demonstrated that the leaching of arsenic can be limited through oxidation by and complexation with calcium. As a result, the duration of arsenic leaching from CCRs is better represented by accounting for the presence of calcium. Arsenic leaching from landfills was modeled as having one of the following two relationships with dissolved calcium concentrations as a function of the cumulative L/S ratio (discussed further in **Appendix I**):

- **Case 1, Low Calcium Concentration (≤ 5,000 mg/kg):** Arsenic leaching begins at an initial concentration defined by the LEAF Method 1313 data and is held constant until the total available mass is depleted.
- **Case 2, High Calcium Concentration (> 5,000 mg/kg):** Arsenic leaching begins at an initial concentration defined by the LEAF Method 1313 data and is held constant until all of the free arsenic has been depleted. Empirical data available in LEACHXS Lite have shown that this generally occurs when the cumulative amount of water that has infiltrated through the ash relative to the mass of waste present approaches a ratio of 1. A typical landfill may take around a hundred years of leaching to reach this cumulative L/S ratio. At this point, further arsenic leaching is inhibited by the calcium present and effectively ceases until the time at which around 90 percent of the available calcium has been leached away. Arsenic then begins to leach again at the previous concentration until all remaining available arsenic is depleted.

4.4 Infiltration Rate

The following subsection summarizes the approach used to assign infiltration rates to each WMU within the probabilistic framework. Infiltration is the process through which water migrates through WMUs and enters the subsurface environment. The rate at which water can pass through a WMU is limited primarily by the hydraulic conductivity of the liner (if any) present. The 2009/2010 EPA Surveys contained information on the type of liner at different WMUs. Based on the descriptions of liners reported in survey responses, each surface impoundment and landfill was assigned one of three modeled liner types: no liner, clay liner or composite liner. These three liner types are the conceptual liner scenarios developed in support of EPA's Industrial Subtitle D Guidance (U.S. EPA, 2006b), and are described as follows:

- **No Liner Scenario:** Waste is placed directly on local soils, either on grade or excavated to some design depth and without a leachate collection system. At closure, two feet of native soil cover, the minimum required by Subtitle D regulations, is installed and assumed to support vegetation.
- **Clay Liner Scenario:** Waste is placed on a three-foot compacted clay liner that is installed over local soils without a leachate collection system, either on grade or excavated to some design depth. At closure, a three-foot clay cover is installed and covered with one foot of loam to support vegetation and drainage.
- **Composite Liner Scenario:** Waste is placed on a liner system that consists of a plastic liner (e.g., high-density polyethylene membrane) underlain by either a natural or geosynthetic clay

liner. A leachate collection system is assumed to exist between the waste and the liner system. At closure, a three-foot clay cover (graded and otherwise designed to prevent ponding) or functional equivalent is assumed to be installed and covered with a one foot of loam to support vegetation and drainage.

During the data preparation loop, liner types were assigned to each WMU where known from survey data. In cases where available survey data indicated that a WMU was lined, but did not specify the type of liner, a clay or composite liner was selected probabilistically based on the relative prevalence of those liner types. In cases where neither the presence nor absence of a liner was specified in the available survey data, one of these three types was probabilistically assigned to that WMU based on the prevalence of liner types reported for other surface impoundments or landfills, as appropriate. During the Monte Carlo loop, EPACMTP used the assigned liner type, together with the assigned WMU type and local climate data to calculate an infiltration rate, as described in Appendix A of the EPACMTP background document (U.S. EPA, 2003b).

4.5 Depth Below Grade

The following subsection summarizes the approach used to assign a depth below grade to each WMU within the probabilistic framework. Depth below grade represents the total depth that a given WMU extends below the ground surface. This parameter was used during model iterations to determine the distance from the bottom of the WMU to the ground water table. EPA used the following two data sources to characterize this parameter for both surface impoundments and landfills:

- A collection of site-characterization reports published by EPRI (EPRI 1991; 1992; 1994a,b; 1996a,b; and 1997b-k); and
- A Council of Industrial Boiler Owners (CIBO) voluntary survey (CIBO, 1997).

The EPRI/CIBO reports provide diagrams of the layout of different WMUs that EPA used to determine the total depth that each extended below ground. These data were used to compile distributions that were probabilistically sampled during each model iteration. Because the designs of surface impoundments and landfills differ, separate distributions were developed for each. The selected value was constrained to be no deeper than the water table present in that model iteration. During a given model iteration, if the resulting depth below grade resulted in a unit below the ground water table, a new value was selected until the unit fell at or above the water table.

Figure 4-3 below displays the distributions of the data collected for surface impoundments. EPRI and CIBO provided data on a total of 16 surface impoundments. These reported depths tended to be mostly or entirely below-grade. The measured depths below grade at these 16 facilities were used to create an empirical distribution that was sampled during each model iteration.

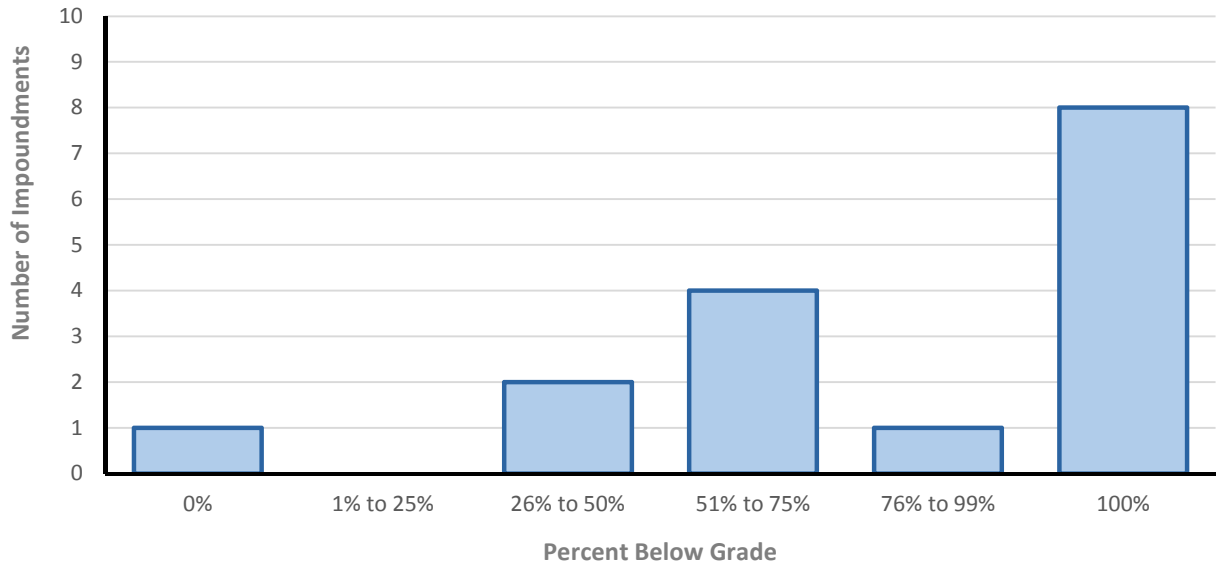

Figure 4-3. Distribution of below-grade geometry for surface impoundments from EPRI/CIBO reports.

Figure 4-4 below displays the distributions of the data collected from landfills. EPRI and CIBO provided data on a total of eight landfills. The depths reported ranged from entirely below-grade to entirely above-grade. Due to the symmetry of the available data and the relatively small available data set, EPA assumed that the percentage below-grade was uniformly distributed over the probabilistic analysis. Thus, a random value for percentage below grade between 0 and 100 percent was probabilistically sampled for each model iteration.

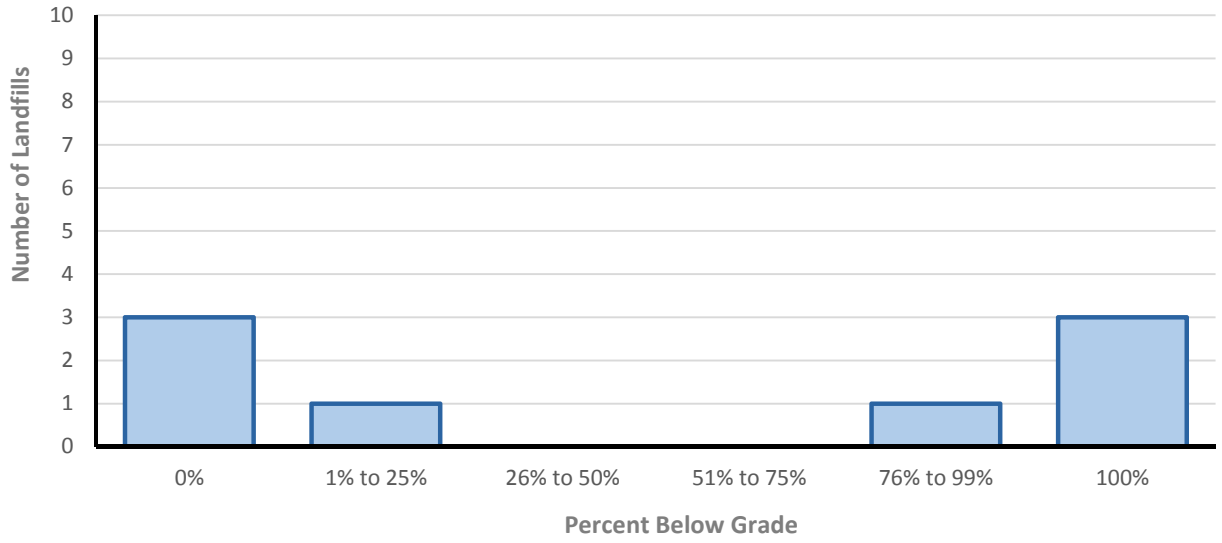

Figure 4-4. Distribution of below-grade geometry for landfills from EPRI/CIBO reports.

4.6 Receptor Location

The following section summarizes the approach used to assign receptor locations to each WMU within the probabilistic framework. After the characteristics of the WMU have been selected, a receptor location was identified. The receptor location is the geographic location of residential drinking water wells or surface water bodies relative to the WMU. To capture the highly exposed individual (HEI), receptor wells and surface water bodies were placed probabilistically within the areal extent of the ground water plume, as estimated from the modeled WMU size and soil properties selected for that model iteration. **Figure 4-5** shows a schematic of how residential well drinking water intakes and surface water bodies were defined by the model. This figure is intended to be illustrative and does not capture all possible receptor well and water body locations.

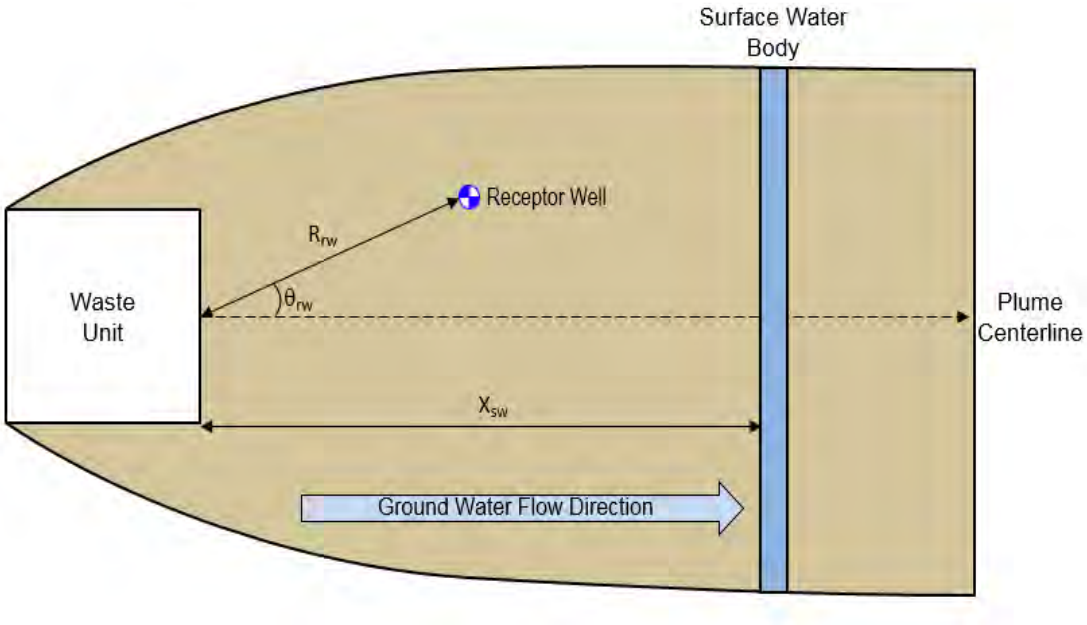

Figure 4-5. Aerial view of conceptual model for receptor location.

For wells, a radial distance (R_{rw}) from the downgradient edge of the WMU was probabilistically selected from a nationwide distribution developed by EPA based on known WMU locations and predicted household locations that incorporate 2000 Census data. The angle offset from plume centerline (θ_{rw}) was then selected from a uniform distribution ranging from 0 to 90 degrees. If the selected receptor well fell within the maximum boundary of the plume, then that well location was used. Otherwise, new values for R_{rw} and θ_{rw} were generated until the well fell within the plume. Once located, the depth of the well intake point was based on a uniform distribution ranging from the top of the water table to either the full saturated thickness of the aquifer or ten meters, whichever was less. This constraint is further discussed in U.S. EPA (2003b).

For surface water bodies, the straight-line distance (X_{sw}) from the downgradient edge of the WMU to the nearest surface water body was probabilistically selected from a nationwide distribution developed by EPA using GIS. The GIS tool used the geographic locations of the WMU and surrounding water bodies, along with topographical data, to determine the shortest flow path to nearby water bodies.

4.7 Subsurface Transport

The following subsection provides an overview of the subsurface modeling conducted with EPACMTP. This model consists of two coupled modules that address subsurface transport through unsaturated and saturated zones. These modules treat soils as a uniform, porous medium and do not account for preferential pathways or facilitated transport. In the unsaturated zone, the flow of water is driven primarily by gravity. Therefore, flow is modeled entirely in the vertical direction, with negligible lateral (i.e., sideways) migration. This assumption can be made because the scale of lateral migration due to dispersion will be orders of magnitude less than the scale of vertical migration through WMU footprints (U.S. EPA, 2003b). In the saturated zone, EPACMTP assumes that the movement of COPCs is driven primarily by the ground water advection. Flow in the saturated zone is controlled primarily by the hydraulic conductivity of the aquifer and the regional hydraulic gradient. However, the flow may be altered both by mounding underneath the WMU from high volumes of leachate, which enhances the spreading of the constituent plume in all directions, and by uncontaminated recharge from precipitation that falls around the WMU, which increases mixing in the vertical direction. In addition to advection, EPACMTP also accounts for the mixing of ground water due to dispersion, which occurs to some degree in all directions.

During transport through both the unsaturated and saturated zones, COPCs may sorb to the surrounding soils. This process is represented by K_d. For most inorganics, K_d values are strongly dependent on the concentration present in leachate, with the K_d values generally decreasing with higher concentrations. For most COPCs[13], the K_d values used in this analysis were drawn from COPC-specific distributions of K_d values versus leachate concentrations, also known as sorption isotherms. EPA selected nonlinear isotherms as the most representative of changes in sorption as leachate concentrations decrease during transport through soil and ground water. CCR-specific nonlinear sorption isotherms were generated by Metal Speciation Equilibrium Model for Surface and Ground Water (MINTEQA2) (U.S. EPA, 2001) for this risk assessment based on CCR leachate chemistry. The development of these isotherms is described in detail in **Appendix H**.

- **Surface Impoundments.** To select K_d values for surface impoundments, one of the three waste types was probabilistically assigned to the surface impoundment at the start of each model iteration. A pore water sample was then selected based on the selected waste type to provide leachate pH.[14] Where pH data were not available for a particular waste sample, a value was probabilistically selected from the empirical distribution of pH data available for that waste type. Iron oxide, natural organic matter and leachate ionic strength were then probabilistically selected based on the selected waste type. These data were used together with COPC concentrations to identify isotherms for that model iteration. The pore water concentrations exiting the surface impoundment were used to select K_d values for the

[13] A single (constant) soil K_d value from Baes et al. (1984) was used for iron and both chloride and lithium were modeled as conservative tracers (Eriksson and Kunakasem, 1969) by setting the K_d values to 0 because data were not available to determine valid ranges or distributions for these three COPCs.

[14] No leachate data were available for antimony, beryllium, lithium, and thallium in ash and coal refuse.

unsaturated zone module, while the soil pore water concentrations at the boundary of the unsaturated and saturated zones were used to select K_d values for the saturated zone module.

- **Landfills.** Because of inherent differences between the pore water samples used for surface impoundments and the LEAF data used for landfills, MINTEQA2 isotherms were selected somewhat differently for landfills. During the sampling conducted to develop the LEAF data set, EPA determined that the range and variability of waste pH was best represented by a single leachate pH distribution across all waste types (U.S. EPA, 2009a). To accommodate this single pH distribution, all other waste data, such as iron oxide, were drawn from the same distributions developed for the combined ash waste type. To select a MINTEQA2 isotherm for each model iteration, a leachate pH was randomly selected from the distribution. Based on the pH, iron oxide, natural organic matter and leachate ionic strength were probabilistically selected from the distributions. These data were used together with COPC concentrations to identify isotherms for that model iteration. The leachate concentrations exiting the landfill were used to select K_d values for the unsaturated zone module, while the soil pore water concentrations at the boundary of the unsaturated and saturated zones were used to select K_d values for the saturated zone module.

Constituents with low K_d values will have low retardation factors and may move at nearly the same velocity as the ground water. Constituents with high K_d values will have high retardation factors and may move much more slowly than ground water. The subsurface migration of some constituents may be very slow and it may take a substantial amount of time for the constituent plume to reach the downgradient receptors. As a result, the maximum concentration may not occur until thousands of years after the WMU has ceased operations. To prevent prohibitive model run times, while not missing significant risks to potential receptors, EPA ran the model until either the observed ground water concentration of a constituent at the receptor point peaked and then fell below a model-specified minimum concentration (10^{-16} mg/L), or the model had been run for a total duration of 10,000 years.

4.8 Surface Water Modeling

The following section provides an overview of the surface water modeling within the probabilistic framework. Downgradient surface water bodies can be impacted through the discharge of contaminated ground water. EPA first developed a separate surface water model used in conjunction with EPACMTP to calculate the fraction of the ground water plume that is intercepted by a surface water body (**Section 4.8.1**). Next, an equilibrium partitioning model, which calculated the steady-state into water and sediment (**Section 4.8.2**), and a precipitation model specifically for aluminum, which partitioned based on the maximum amount that may be dissolved in a water body (**Section 4.8.3)** were used to calculate the equilibrium COPC concentrations present in surface water and sediments. Finally, a food web model was used to calculate the COPC concentrations in fish (**Section 4.8.4**). Further discussion of each of these models and the associated inputs is presented in **Appendix J**.

4.8.1 Interception by Water Body

EPACMTP outputs COPC concentrations at a downgradient receptor location as a function of time. A separate surface water model used these ground water concentrations, together with the velocity of both the ground water and surface water, to calculate a mass flux of ground water into a water body. To do so, the following simplifying assumptions were required:

- The direction of regional ground water flow is perpendicular to the water body;
- The water body intercepts the entire width of the ground water plume;
- The water body receives flow from the ground water year-round;
- Lakes always intercept the entire vertical extent of the ground water plume;
- Smaller streams may only partially penetrate the shallow aquifer, allowing some or all of the mass in the contaminated ground water to be transferred to the surface water;
- If the average annual stream flow in a reach was less than the rate of ground water flow, all of the stream flow is assumed to originate from ground water discharge, and the total COPC concentration in the stream is equal to the concentration in ground water;
- There is instantaneous mixing in the stream, resulting in full and homogenous mixing of the ground water with the surface water in the stream segment.

EPACMTP is not designed to account for the mass loss calculated by other models. Instead, EPACMTP first calculated well concentrations as though water bodies were not present. A second model adjusted these well concentrations to account for surface water interception. If the entire ground water plume was intercepted, the model revised the well concentration to zero. If some of the ground water plume was not intercepted and continued to migrate toward the receptor well, then the model used the rate of discharge into the water body to iteratively solve the ground water fate and transport equations used by EPACMTP and calculate a new well concentration by translating the mass lost to the water body into additional dilution and dispersion in ground water.

4.8.2 Equilibrium Partitioning Model

A steady-state equilibrium-partitioning model was used to determine the relative amounts of each COPC entering a water body that would remain dissolved in the water and that would sorb to sediments. This model was adapted from the EPA Indirect Exposure Methodology (U.S. EPA, 1998b) and Human Health Risk Assessment Protocol (U.S. EPA, 2005k), and was used for all constituents except aluminum (see **Section 4.8.3**). With this model, COPC loading rates (mass/time) were first divided by the water body flow rates (volume/time) to yield an overall water body concentration. The model then used partitioning coefficients to divide the mass of each COPC entering the water body into the separate fractions dissolved in the water column, sorbed onto suspended solids, sorbed onto sediment particles at the bottom of the water body, and dissolved in pore water in the sediment layer. This risk assessment does not account for potential COPC losses due to burial.

4.8.3 Aluminum Precipitation Model

A separate model was used to identify the concentration of aluminum in surface water bodies. Unlike the other constituents modeled, the maximum concentration of aluminum that can be present in natural waters can be limited by solubility as a result of changes in the prevailing environmental conditions (e.g., pH) between ground water and a surface water body. Therefore, a precipitation model from MINTEQA2 was used to calculate aluminum concentrations in place of the equilibrium-partitioning model used for other COPCs. The maximum soluble aluminum concentration was calculated as a function of pH for a simplified surface water body using relationships drawn from the literature (Stumm and Morgan, 1996; Drever, 1988). The common aluminum mineral gibbsite (aluminum hydroxide) was assumed to be the solid phase for all precipitant, and the upper bound on dissolved water concentrations was assumed to be the highest solubility limit reported for each pH value. The precipitation model initially calculated the aluminum concentration in the surface water column by assuming that all aluminum entering the water body was dissolved. If this concentration exceeded the maximum soluble concentration based on the pH of the water body, the dissolved concentration was capped and all excess aluminum precipitated out as the mineral gibbsite to the benthic sediment layer.

4.8.4 Aquatic Food Web Model

An aquatic food web model was used to estimate the COPC concentrations in fish. The model uses COPC concentrations dissolved in the water column and sorbed to suspended solids to calculate the resulting concentration in fish tissue based on BCFs that account for both sources. The Agency considered exposures to TL3 and TL4 fish separately because the degree of bioconcentration may differ between these two trophic levels. TL3 consists of carnivores (i.e., carp, smelt, perch, catfish, sucker, bullhead, sauger) that eat herbivores or secondary consumers, while TL4 consists of carnivores (i.e., salmon, trout, walleye, bass) that eat other carnivores. Together, these two trophic levels are assumed to comprise all of the fish consumed by receptors.

4.9 Exposure and Risk

Each model iteration generated COPC concentrations at a specified location (receptor well or water body) as a function of time. For every model iteration, the maximum (i.e., peak) concentration at each time step was identified. Next, the single year of highest concentration across all modeled time steps was identified. Finally, a time-weighted exposure concentration was calculated by averaging the peak concentrations for each COPC at each time step over the specified exposure duration, centered around the year of highest concentration. For the GW→DW pathway, HEI exposures were calculated using a probability distribution of exposure durations that ranged anywhere from one to fifty years, based on the amount of time spent at a given residence. For the GW→SW pathway, HEI exposures were calculated based on the same distribution. Due to uncertainties about the ecological exposure durations, these exposures were based on the single year of highest concentration. In cases where the ground water concentration was found to still be increasing after 10,000 years, EPACMTP stopped modeling and used the ground water concentration at that final year to estimate exposures for all receptors.

Risks were calculated using the same equations as the screening analysis in **Section 3**. However, to the extent that data were available, full probability distributions were used to characterize each of the human exposure factors (See **Appendix D**). The risks calculated for each model iteration were aggregated into separate probability distributions for the different combinations of WMU, exposure pathway, and receptor type. From these distributions, EPA selected high-end and median risk estimates to characterize the range of risks posed to human health and the environment from current CCR disposal practices. For the purposes of this risk assessment, EPA defined high-end risk based on the recommendations of the *Guidance for Risk Characterization* (U.S. EPA, 1995) as the 90th percentile of risks to the exposed population generated by the Monte Carlo simulation. These risks were compared to the selected risk criteria of cancer risks > 1×10^{-5} and HQs > 1.

4.10 Probabilistic Risk Analysis Results

EPA modeled the full universe of facilities, landfills and impoundments discussed throughout this document. However, after modeling was completed, a number of facilities, surface impoundments and landfills were discovered to be outside the scope of the rule for one of the following reasons:

- The facility was no longer a coal-fired electric utility according to the 2012 EIA database;
- The landfill or surface impoundment was found to be inactive or retired; or
- The surface impoundment was not designed to accumulate CCRs (e.g., cooling water ponds).

In total, 218 surface impoundments and 122 landfills that were modeled met these criteria, and were filtered from the results. A column denoting whether or not a WMU was excluded can be found in **Attachment A-2**. For the remaining impoundments, risks are presented for all COPCs found to exceed risk criteria in the screening analysis in **Section 3**. Because the 2010 Risk Assessment (U.S. EPA, 2010) demonstrated that risks from surface impoundments are consistently higher than those from landfills, these impoundment results were used as a secondary screening to identify COPCs to be modeled for landfills. To ensure that this approach did not underestimate risks, landfill modeling included all COPCs found to exceed risk criteria for any subset of surface impoundments during subsequent sensitivity analyses discussed in **Section 5**.

4.10.1 Human Health Risk Results

90th percentile risks for human receptors are presented in **Table 4-2**. These risks represent all of the modeled impoundments and landfills subject to the rulemaking. Both cancer and noncancer risks are presented for the highest exposed receptor group. For drinking water ingestion, the highest cancer risks were for adults (Ages > 21 years), while the highest noncancer risks were for infants (Age < 1 year). For fish ingestion, the highest cancer and noncancer risks were for children (Ages 1 to < 2 years). Values that exceed the selected risk criteria (i.e., cancer risk > $1x10^{-5}$ or HQ > 1) are shown in **bold**.

Table 4-2. 90th Percentile Nationwide Risk Results for Human Health

COPC	Surface Impoundments		Landfills	
	Drinking Water Ingestion	Fish Ingestion	Drinking Water Ingestion	Fish Ingestion
Carcinogenic Effects				
Arsenic III	**2×10^{-4}**	2×10^{-7}	5×10^{-6}	–
Arsenic V	1×10^{-5}	5×10^{-9}	7×10^{-8}	–
Chromium VI	6×10^{-7}	–	7×10^{-8}	–
Noncarcinogenic Effects				
Arsenic III	**5**	–	0.1	–
Arsenic V	0.4	–	< 0.01	–
Boron	0.6	–	< 0.01	–
Cadmium	0.04	< 0.01	–	–
Cobalt	0.01	–	< 0.01	–
Fluoride	0.2	–	– [a]	–
Lead	< 0.01	–	–	–
Lithium	**2**	–	– [b]	–
Mercury	–	0.02	–	0.01
Molybdenum	**2**	–	< 0.01	–
Selenium IV	–	< 0.01	–	–
Selenium VI	–	0.05	–	–
Thallium	0.9	0.04	0.08	–

– Constituent was not modeled for this pathway

a) Fluoride was found to slightly exceed risk criteria during one sensitivity analyses conducted for surface impoundments; however, Method 1313 data were not available to model this COPC for landfills.

b) Lithium was found to slightly exceed risk criteria in the probabilistic analysis for surface impoundments; however, Method 1313 data were not available in the literature to model this COPC for landfills.

For impoundments, the 90th percentile risks associated with ingestion of ground water were above cancer and noncancer criteria for arsenic III (risk = 2×10^{-4}, HQ = 5) and noncancer criteria for both lithium (HQ = 2) and molybdenum (HQ = 2). No risks above the human health criteria were identified for ingestion of fish. For landfills, no risks above the human health criteria were identified for any pathway. Consistent with the findings of the 2010 Risk Assessment, risks from landfills are consistently lower than those from surface impoundments. 50th percentile risks were also calculated for both surface impoundments and landfills, but are not shown because risks fell below all criteria.

4.10.2 Ecological Risk Results

90th percentile risks for ecological receptors are presented in **Table 4-3**. These risks represent all of the modeled impoundments and landfills subject to the rulemaking. For all surface water and sediment risks, the sensitive ecological receptor is defined by the available benchmarks.

Table 4-3. 90th Percentile Nationwide Risk Results for Ecological Receptors

COPC	Surface Impoundments		Landfills	
	Surface Water	Sediment	Surface Water	Sediment
Aluminum	< 0.01	–	–	–
Antimony	–	0.06	–	–
Arsenic III	0.02	0.1	–	0.02
Arsenic V	< 0.01	< 0.01	< 0.01	–
Barium	< 0.01	–	–	–
Beryllium	< 0.01	–	–	–
Boron	0.3	–	< 0.01	–
Cadmium	0.1	–	–	–
Chloride	0.03	–	–	–
Chromium III	< 0.01	–	–	–
Chromium VI	< 0.01	–	–	–
Cobalt	< 0.01	–	–	–
Copper	< 0.01	–	–	–
Iron	< 0.01	–	–	–
Lead	< 0.01	–	–	–
Molybdenum	0.09	–	–	–
Nickel	< 0.01	–	–	–
Selenium IV	< 0.01	–	–	–
Selenium VI	0.1	–	–	–
Silver	0.06	0.02	–	–
Vanadium	< 0.01	< 0.01	–	–
Zinc	< 0.01	–	–	–

– Constituent was not modeled for this pathway

No 90th percentile risks above the ecological criteria were identified for either surface water or sediment for either surface impoundments or landfills. 50th percentile risks were also calculated for both surface impoundments and landfills, but are not shown because all fell well below the selected risk criteria.

4.10.3 Summary of Probabilistic Analysis

EPA conducted the probabilistic analysis described in this section to better characterize the potential risks to human and ecological receptors associated with leaching from WMUs to ground water. The potential exposure routes identified for this pathway were human ingestion of ground water and fish and ecological contact with and ingestion of surface water and sediment. To evaluate each of these exposure routes, the probabilistic analysis combined site-specific data with regional and national data to conduct a total of approximately 100,000 model iterations per COPC that

capture the full range and frequency of disposal practices known to occur. These iterations form the basis for the risk results.

The modeling results showed 90th percentile risks above the human health criteria from surface impoundments. Human health exposures from the ingestion of ground water resulted in the highest risks, with a cancer risk of 2×10^{-4} and noncancer HQ of 5 for arsenic III and a noncancer HQ of 2 for molybdenum. Human health exposures from ingestion of fish, as well as all ecological exposures fell below risk criteria. All 90th percentile risks for landfills also fell below these thresholds.

[This Page Intentionally Left Blank]

5 Sensitivity and Uncertainty Analyses

The probabilistic analysis presented in **Section 4** identified the potential for risks to human health through the ingestion of ground water that results from leaching of arsenic and molybdenum from surface impoundments. These risks reflect the full range of current, nationwide CCR disposal practices and, because of this broad scope, there are numerous sources of uncertainty present within the probabilistic analysis. To better understand the effect of these uncertainties on the modeled risks and to determine if any particular subset of disposal practices drive the risks identified, EPA conducted additional sensitivity and uncertainty analyses. The purpose of this section is to describe the results of these additional analyses, to identify the model parameters with the greatest potential to influence calculated risks and, to characterize the potential effects of these parameters on the principal results of the probabilistic analysis. This discussion is divided into the following subsections:

- **Section 5.1** provides an overview of the major sources of uncertainty in the probabilistic analysis, as well as a qualitative and, where possible, quantitative characterization of each.
- **Section 5.2** presents a summary of the sensitivity analysis conducted in support of the 2010 Risk Assessment (U.S. EPA, 2010a) and compares the sensitive parameters identified with the findings of the revised sensitivity and uncertainty analyses;
- **Section 5.3** compares trends in the characteristics of proven and potential damage cases with the findings of the revised sensitivity and uncertainty analyses;
- **Section 5.4** summarizes the results for the revised sensitivity and uncertainty analyses, as well as for the comparisons of these results with the previous sensitivity analysis and the proven and potential damage cases.

5.1 Variability, Data Uncertainty and Model Error

Uncertainty exists to some degree in any quantitative evaluation, and it may bias the calculated results higher or lower than actual values. It is important to understand both the direction and magnitude of uncertainties present in a risk assessment. The direction of uncertainty is the tendency for that uncertainty to push a predicted value higher or lower than the actual value, while the magnitude of uncertainty is the extent to which that uncertainty may push a predicted value away from the true value. Characterizing these uncertainties helps to ensure that the overall conclusions of the evaluation would not change with the consideration of additional information. There are three primary causes of uncertainty:

- Variability is the extent to which characteristics of environmental systems are heterogeneous, and is reflected in the parameter distributions used as inputs for the models. Although variability can be better captured by collecting additional data, it cannot be eliminated and must be treated explicitly in the assessment.

- Data uncertainty is a description of the imperfection in knowledge of the true value of a particular parameter. Uncertainty is generally reducible through additional research and information-gathering.
- Model error occurs because models and their mathematical expressions are simplifications of reality that are used to approximate real-world conditions, processes and their relationships. These assumptions are sometimes necessary to solve complex mathematical equations or to fill gaps in available knowledge. However, the simplification of complex systems may misrepresent real-world conditions to an unknown degree.

The uncertainties identified in the probabilistic analysis were managed to the extent practicable to minimize potential effects on the model results. Variability was addressed to the extent possible by compiling available data into probabilistic distributions for each parameter. Uncertainty about the exact range or distribution of a parameter was addressed through the use of estimated point values or distributions intended to appropriately bound the true range, biased toward protection of human health and the environment. **Table 5-1** lists the general categories of uncertainties identified, along with the different portions of the document text where these topics are discussed.

Table 5-1. Summary of the Categories of Uncertainty Present in the Probabilistic Analysis and the Discussion Locations within the Risk Assessment Text

Uncertainty	Location of Original Discussion	Location of Corresponding Uncertainty Discussion
CCR WMU Database	Section 2 and Appendix A	Section 5.1.1

EPACMTP Ground Water Model	Section 4 and Appendix I	Section 5.1.9
Surface Water Model	Section 4 and Appendix J	Section 5.1.10
Risk Models	Section 4	Section 5.1.11

5.1.1 CCR WMU Database

The CCR WMU database was populated with data from two EPA surveys conducted in 2009 and 2010. These surveys provide data on a total of 952 surface impoundments and 431 landfills at 383 facilities out of the known universe of 507 facilities that burn coal and dispose of the resulting waste on-site. The inclusion of data from these surveys greatly increased the information available on the characteristics of WMUs. The total number of facilities and WMUs will fluctuate over time. However, the CCR WMU database provides broad representation of operating facilities at the time

it was compiled. Some gaps do exist in the database as a result of survey design, erroneous or unclear responses, and claims of confidential business information. These gaps were filled probabilistically, based on the distributions of available data. As discussed below, because the available data are far more representative sample than previously available and cover a large proportion of existing facilities, it is unlikely that this represent a major source of uncertainty.

Geographic Location Data

When locations were known for a specific WMU, the probabilistic analysis held this parameter constant for all model iterations associated with that unit. Because many of the environmental parameters used in the models were selected based on geographic location, the location does influence the analysis. Specific geographic coordinate locations were known for 67 percent of surface impoundments and for 81 percent of landfills. In cases where locations were not known, the location of the facility front gate or centroid reported in the 2009 EIA were used to place these units as close to actual locations as possible. In addition, where possible, the locations were verified by reviewing geo-referenced aerial photographs in GIS. While there is still some uncertainty associated with exact locations for a portion of WMUs in the full data set, the influence on results is anticipated to be small given the regional-scale resolution of most environmental data.

WMU Dimension Data

When area, thickness, or capacity was known for a specific WMU, the probabilistic analysis held these parameters constant for all model iterations associated with that unit. When no data were available or reported values were found to be unrealistic, these data gaps were filled during each model iteration by sampling probabilistically from the distributions developed from WMUs with data (see **Appendix A**). Area measurements were known for 92 percent of the surface impoundments and for 39 percent of landfills.

The full distribution of known area measurements for both surface impoundments and landfills were divided into separate distributions based on the annual amount of coal burnt (or "coal use"), available in the 2009 EIA database. First, the coal use reported for every facility was compiled into a single distribution and then divided into quartile ranges. The area measurements for the surface impoundments and landfills present at each facility in a coal use quartile range were combined into a total of four new area distributions. Where area measurements were unknown for a given unit, a fixed area distribution was assigned and probabilistically sampled based on the coal use reported for the corresponding facility. This approach ensured that the larger area measurements for large WMUs were not inadvertently assigned to smaller facilities. This coal use quartile-based probabilistic sampling may over- or underestimate dimensions for individual model iterations. However, the aggregate results reflect a national distribution with the best available data. As a result, this approach is unlikely to introduce much additional uncertainty.

Liner Data

When liner types were known for a specific WMU, the probabilistic analysis held these parameters constant for all model iterations associated with that unit. Specific liner types were known for 64 percent of surface impoundments and for 53 percent of landfills. When no data were available on

liner type, this data gap was filled during each model iteration by sampling probabilistically from the distribution developed from WMUs with data. In cases where survey responses indicated the presence of a liner, but did not specify the type (additional 5 percent of surface impoundments and 34 percent of landfills), each model iteration sampled probabilistically from the distribution developed from WMUs with liners. This probabilistic sampling may not accurately represent liner type for specific WMUs, but the aggregate results likely reflect the larger national distribution due to the high proportion of known liner types. Thus, this approach is unlikely to result in much additional uncertainty.

Liner Assignment

The three liner types modeled in the probabilistic analysis are unlined, clay-lined and composite-lined. Although a number of different liner configurations were reported in the 2009/2010 EPA surveys, each was modeled as one of these three types. WMUs reported as lined with CCR waste, concrete, asphalt or other nonstandard liner materials were categorized as unlined because of the high likelihood cracks that would eliminate the effectiveness of the liner without constant maintenance. WMUs reported as lined with some form of natural or synthetic clay were categorized as clay-lined. WMUs reported as lined with some form of composite or flexible membrane liner were categorized as composite-lined. These three liner types were assigned because site-specific information on the effective hydraulic conductivities in the field were not readily available. Even if this type of data were available, the hydraulic conductivity of these liners as designed or currently measured may not capture higher leakage rates that result from cracks and tears that develop over time without proper monitoring and corrective action. The binning of reported liners into the three modeled categories is believed to best represent the range of liner behavior and introduce a small amount of uncertainty into the probabilistic analysis.

Liner Prevalence

A recent 2006 study conducted jointly by EPA and DOE (U.S. DOE, 2006) found that liners are more likely to be present in newly constructed WMUs and new expansions of existing WMUs. Between 1994 and 2004, 100 percent of the new impoundments (out of 20) and 97 percent of the new landfills (out of 42) included in the study contained some type of liner. **Table 5-2** provides a full comparison of the liner information in the CCR WMU database.

Table 5-2. Number and Percentages of WMUs with Different Liner Types Constructed Before and After 2000

Liner Type	Surface Impoundments						Landfills					
	Pre-2000		Post-2000		Unknown Date		Pre-2000		Post-2000		Unknown Date	
Total	**952**						**431**					
Unlined	371	(48%)	7	(12%)	28	(24%)	154	(52%)	12	(20%)	7	(10%)
Lined	198	(25%)	38	(63%)	16	(14%)	140	(47%)	48	(80%)	13	(17%)
Unknown	207	(27%)	15	(25%)	72	(62%)	3	(1%)	0	(0%)	54	(73%)

Note: Counts are derived by start year using the 2009/2010 EPA surveys. Some WMUs did not contain start years (unknown date column), while others may contain start years but not liner type information (unknown row).

Even though most of the recently constructed surface impoundments and landfills are lined in some fashion, the majority of units currently in operation remain unlined. Because this risk assessment evaluated current waste management practices, it does not examine the potential for future changes in liner types. However, because the majority of units in operation are unlined, EPA did consider the extent to which these units drive the modeled risks presented in **Section 4**. This sensitivity analysis was conducted by filtering the full distribution of risks into three separate distributions, one for each liner type, for surface impoundments and for landfills.

Table 5-3 shows the 90th percentile human and ecological risks separated out for unlined, clay-lined and composite-lined surface impoundments. Risks are presented for each constituent modeled in the probabilistic analysis that was also above risk criteria in this sensitivity analysis. Arsenic V risks are provided even where below criteria to provide a bound on arsenic speciation. Values that exceed the risk criteria (i.e., cancer risk > $1x10^{-5}$ or HQ > 1) are shown in **bold**.

Table 5-3. 90th Percentile Risk Exceedances by Liner Type: Surface Impoundments

COPC	Liner Type	Percent of Iterations	Human Health		Ecological	
			GW→DW Tap Water Ingestion	GW→SW Fish Ingestion	GW→SW Surface Water	GW→SW Sediment
Cancer Risk						
Arsenic III	Unlined	65%	**3×10^{-4}**	7×10^{-7}	—	—
	Clay Lined	18%	7×10^{-6}	2×10^{-9}	—	—
	Composite Lined	17%	$< 1 \times 10^{-10}$	$< 1 \times 10^{-10}$	—	—
Arsenic V	Unlined	65%	**4×10^{-5}**	3×10^{-8}	—	—
	Clay Lined	18%	1×10^{-7}	$< 1 \times 10^{-10}$	—	—
	Composite Lined	17%	$< 1 \times 10^{-10}$	$< 1 \times 10^{-10}$	—	—
Noncancer Risk						
Arsenic III	Unlined	65%	**8**	—	0.06	0.4
	Clay Lined	18%	0.2	—	< 0.01	< 0.01
	Composite Lined	17%	< 0.01	—	< 0.01	< 0.01
Arsenic V	Unlined	65%	1	—	0.06	0.02
	Clay Lined	18%	< 0.01	—	< 0.01	< 0.01
	Composite Lined	17%	< 0.01	—	< 0.01	< 0.01
Lithium	Unlined	65%	**3**	—	—	—
	Clay Lined	18%	**2**	—	—	—
	Composite Lined	17%	< 0.01	—	—	—
Molybdenum	Unlined	65%	**4**	—	0.2	—
	Clay Lined	18%	0.1	—	< 0.01	—
	Composite Lined	17%	< 0.01	—	< 0.01	—
Thallium	Unlined	65%	**2**	0.1	—	—
	Clay Lined	18%	0.02	< 0.01	—	—
	Composite Lined	17%	< 0.01	< 0.01	—	—

As seen in the table above, unlined units present the greatest risks. These unlined units result in cancer risks above 1×10^{-5} for arsenic III (3×10^{-4}) and arsenic V (4×10^{-5}), as well as noncancer risks above an HQ of 1 for arsenic III (8), molybdenum (4) and thallium (2). In many cases, due to the prevalence of unlined units, the risks for these units alone are similar to those for all units in the full-scale probabilistic modeling (**Section 4**). Clay-lined units present risks lower than unlined units, with noncancer risks above an HQ of 1 for lithium (2). Composite-lined units present risks far below all relevant risk criteria for all constituents.

Table 5-4 shows the 90th percentile human and ecological risks separated out for unlined, clay-lined and composite-lined landfills. Risks are presented for each constituent modeled in the probabilistic analysis that was also above risk criteria in this sensitivity analysis. In some instances, arsenic V risks are provided even where below criteria to provide a complete bounding on arsenic speciation. Values that exceed the selected risk criteria (i.e., cancer risk > $1x10^{-5}$) are shown in **bold**. No noncancer risks above human health criteria were identified.

Table 5-4. 90th Percentile Risk Exceedances by Liner Type: Landfills

COPC	Liner Type	Percent of Iterations	Human Health	
			GW→DW Tap Water Ingestion	GW→SW Fish Ingestion
Cancer				
Arsenic III	Unlined	42%	**2×10^{-5}**	—
	Clay Lined	25%	1×10^{-5}	—
	Composite Lined	33%	$< 1 \times 10^{-10}$	—
Arsenic V	Unlined	42%	1×10^{-6}	—
	Clay Lined	25%	3×10^{-7}	—
	Composite Lined	33%	$< 1 \times 10^{-10}$	—

Similar to surface impoundments, unlined landfills present the greatest risks. Unlined landfills result in cancer risks above 1×10^{-5} for arsenic III (2×10^{-5}). Clay-lined landfills present risks lower than unlined units and composite-lined units present risks far below all relevant risk criteria.

Impoundment Waste Type Assignment:

Waste pH is the primary factor used to determine appropriate K_d values, which dictate the rate at which COPCs move through the subsurface environment. EPA identified insufficient data to develop a national pH distribution for wastes disposed in surface impoundments. Instead, this risk assessment divided the available data into discrete waste types that reflect similar leachate pH conditions and ion concentrations. The modeled waste types include combined ash, ash and coal refuse, and FGD waste. When the type of CCR type disposed in an impoundment was known, the analysis assigned a fixed waste type based on the CCRs disposed for all model iterations. CCR types were known for 97 percent of the impoundments. When no data were available on the CCR type disposed in a unit, this data gap was filled during each model iteration by sampling probabilistically from the distribution of known waste types for other WMUs. This probabilistic sampling may over- or under-estimate leachate concentrations for individual model iterations.

However, given that waste types are known for the vast majority of units, this uncertainty is likely to have a negligible impact on the modeled national-scale risks.

Landfill Waste Type Assignment

Waste pH is the primary factor used to determine appropriate K_d values, which determine the rate at which COPCs move through the subsurface environment. Unlike for surface impoundments, a representative national distribution of pH values was available for landfills. This information was drawn from a nation-wide distribution of CCR waste pH compiled as part of U.S. EPA (2009a). **Figure 5-1** provides a graph of this pH distribution for landfills. Because a representative distribution was available for landfills, the segregation of different waste types was not needed to identify appropriate K_d ranges for each unit.

The pH of CCR wastes as managed range from around 3 to 13. Although the total pH range is wide, the majority of wastes are more basic, with a median value between 10 and 11. CCR wastes managed with coal refuse can be substantially more acidic, which accounts for some of the distribution far below a pH of 7. Similarly, FGD materials can be very basic, which accounts for some of the distribution above a pH of 11. Because this pH distribution provides the full range and relative frequency for different waste pH, treatment of CCRs disposed in landfills as a single waste type still captures the possible variations in K_d values. Thus, this introduces minimal uncertainty.

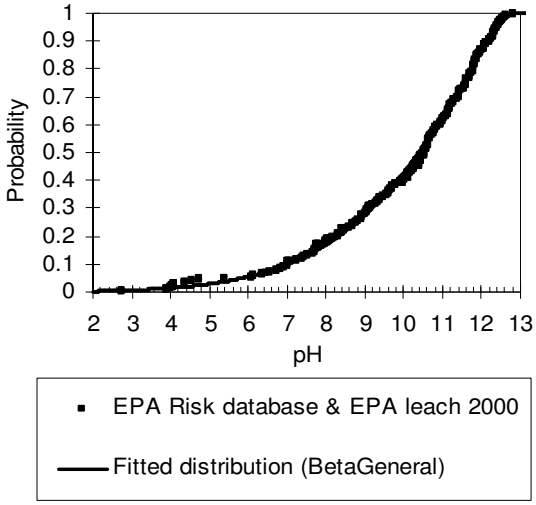

Figure 5-1. Measured landfill CCR waste pH values [Adapted from U.S. EPA (2009a)].

Waste Type Prevalence

A survey conducted by EPRI in 1995 showed that 34 percent of unlined landfills and 68 percent of unlined surface impoundments actively managed CCR wastes with coal refuse. However, the more recent 2009/2010 EPA surveys indicate that this management practice has declined significantly to around five percent of current units. At present, EPA has no data on trends in the generation of FGD waste. Because this risk assessment evaluated current waste management practices, it does not examine the potential for future shifts in the relative amounts of different waste types disposed. Yet, waste pH has been shown to be a key factor in leachate concentrations and these two waste types are more likely to have an extreme pH. Therefore, EPA did consider the extent to which management of these different waste types may drive the probabilistic risks presented in **Section 4**.

For surface impoundments, this sensitivity analysis was conducted by filtering the full distribution of risks into three separate distributions, one for each waste type. **Table 5-5** shows the 90th percentile human and ecological risks separated out for combined ash, ash and coal refuse, and FGD wastes. Risks are presented for each constituent modeled in the probabilistic analysis that was also above risk criteria in this sensitivity analysis. Values that exceed the risk criteria (i.e., cancer risk > 1×10^{-5} or HQ > 1) are shown in **bold**.

Table 5-5. 90th Percentile Risk Exceedances by Waste Type: Surface Impoundments

Constituent	Waste Type	Percent of Iterations	Human Health		Ecological	
			GW→DW Tap Water Ingestion	GW→SW Fish Ingestion	GW→SW Surface Water	GW→SW Sediment
Cancer Risks						
Arsenic III	Combined Ash	85%	**2×10^{-4}**	2×10^{-7}	—	—
	Ash & Coal Refuse	5%	**1×10^{-3}**	1×10^{-6}	—	—
	FGD Waste	10%	**2×10^{-4}**	2×10^{-7}	—	—
Arsenic V	Combined Ash	85%	1×10^{-5}	3×10^{-9}	—	—
	Ash & Coal Refuse	5%	**4×10^{-4}**	3×10^{-7}	—	—
	FGD Waste	10%	**2×10^{-5}**	1×10^{-8}	—	—
Noncancer Risks						
Arsenic III	Combined Ash	85%	**4**	—	0.02	0.1
	Ash & Coal Refuse	5%	**26**	—	0.1	0.8
	FGD Waste	10%	**5**	—	0.02	0.1

	Ash & Coal Refuse	5%	**14**	—	0.7	0.2
	FGD Waste	10%	0.5	—	0.03	< 0.01
Boron	Combined Ash	85%	0.6	—	0.3	—
	Ash & Coal Refuse	5%	0.2	—	0.3	—
	FGD Waste	10%	**2**	—	**5**	—
Cadmium	Combined Ash	85%	0.03	< 0.01	0.1	—
	Ash & Coal Refuse	5%	0.6	0.04	**3**	—
	FGD Waste	10%	0.06	< 0.01	0.2	—
Cobalt	Combined Ash	85%	0.01	—	< 0.01	—
	Ash & Coal Refuse	5%	**13**	—	0.05	—
	FGD Waste	10%	0.02	—	< 0.01	—
Fluoride	Combined Ash	85%	0.1	—	—	—
	Ash & Coal Refuse	5%	0.2	—	—	—
	FGD Waste	10%	**2**	—	—	—
Lithium	Combined Ash	89%	**3**	—	—	—
	Ash & Coal Refuse	—	—[a]	—	—	—
	FGD Waste	11%	0.4	—	—	—
Mercury	Combined Ash	85%	—	0.02	—	—
	Ash & Coal Refuse	5%	—	**5**	—	—
	FGD Waste	10%	—	< 0.01	—	—
Molybdenum	Combined Ash	85%	**2**	—	0.1	—
	Ash & Coal Refuse	5%	1	—	0.1	—
	FGD Waste	10%	1	—	0.03	—

a) Leachate data were not available to model ash & coal refuse.

Disposal of combined ash resulted in risks very similar to those identified in the full probabilistic modeling because this waste type comprised the majority of model iterations. Codisposal of ash

and coal refuse resulted in risks for select constituents higher than for combined ash and above human health and ecological criteria. Cancer risks above 1×10^{-5} were identified for arsenic III (1×10^{-3}) and arsenic V (4×10^{-4}) from ingestion of ground water. Noncancer risks above an HQ of 1 were identified for arsenic III (26), arsenic V (14), and cobalt (13) from ingestion of ground water; for mercury (5) from fish ingestion; and for cadmium (3) from ecological exposure to surface water. Disposal of FGD waste also resulted in higher risks for select constituents than for combined ash. Cancer risks above 1×10^{-5} were identified for arsenic III (2×10^{-4}) and arsenic V (2×10^{-5}) from ingestion of ground water. Noncancer risks above an HQ of 1 were found for arsenic III (5), boron (2) and fluoride (2) from ingestion of ground water.

For landfills, this sensitivity analysis was conducted by filtering the full risk distribution into discrete pH ranges. Since it was the main risk driver for landfills, this sensitivity analyses was conducted for arsenic (both III and V). **Table 5-6** shows the 90th percentile human and ecological risks separated out for the target pH ranges specified by Method 1313 (U.S. EPA, 2012d). No risks were found to be above either the cancer or noncancer criteria. (i.e., cancer risk > 1×10^{-5} or HQ > 1).

Table 5-6. 90th Percentile Ground Water Ingestion Risk Exceedances by Waste pH: Landfills

pH Range	Percent of Iterations*	Cancer		Noncancer	
		As (III)	As (V)	As (III)	As (V)
3.5 – 4.5	1%	5×10^{-6}	4×10^{-6}	0.2	0.2
5.0 – 6.0	3%	3×10^{-6}	7×10^{-7}	0.1	0.02
6.5 – 7.5	6%	4×10^{-6}	$< 1 \times 10^{-10}$	0.1	< 0.01
7.5 – 8.5	9%	5×10^{-6}	$< 1 \times 10^{-10}$	0.2	< 0.01
8.5 – 9.5	13%	4×10^{-6}	2×10^{-10}	0.1	< 0.01
10.0 – 11.0	20%	4×10^{-6}	3×10^{-9}	0.1	< 0.01
11.5 – 12.5	22%	5×10^{-6}	8×10^{-7}	0.1	0.03
12.5 – 13.5	4%	1×10^{-5}	6×10^{-6}	0.2	0.1

* The pH ranges reflect specific ranges specified by Method 1313 for reference. Because the pH distribution is not continuous, the percentage of runs does not add up to exactly 100%.

Exclusion of FBC Waste Type

In addition to the waste types modeled in this risk assessment, EPA also identified fluidized-bed combustion (FBC) wastes as a distinct waste type. The 2010 Risk Assessment modeled the FBC waste type separately for landfills, but not surface impoundments, because of the lack of impoundment pore water data available. This modeling showed that the risks associated with disposal of FBC waste in landfills were lower than those for other CCR waste types and below all risk criteria. Given these results and the lack of additional leachate data available since 2010, EPA did not re-evaluate FBC wastes in the revised risk assessment. Disposal of FBC as a monofill is only known to occur at two facilities. Given the rarity of this waste type and the lower risks modeled, exclusion of FBC waste from the revised risk assessment is unlikely to have an appreciable impact on modeled national-scale risks.

Below-Grade Geometry

The WMU depth below grade was used along with depth to water table to calculate the distance from the bottom of the WMU to ground water (the "depth to ground water" used in the unsaturated zone transport model). A data set drawn from an EPRI 1997 survey was utilized to generate the distribution of WMU depths below grade. The 2009/2010 EPA surveys indicate the potential for a larger proportion of surface impoundments to have above-grade construction, and fewer impoundments that are mostly or entirely below grade than modeled. This difference could result in greater depths to ground water associated with the 2009/2010 EPA survey data when compared with the EPRI 1997 data used in the risk assessment. EPA conducted a sensitivity analysis to assess the extent to which depth to ground water changes the risk results. For this analysis, depths were broken out into quartiles and model results were filtered into the four corresponding bins. Results are presented in **Table 5-7**. The 90th percentile results for the middle two quartiles, which make up the inner-quartile range, were the same for all constituents, and are reported as a single value. Values that exceed the risk criteria (i.e., cancer risk > 1×10^{-5} or HQ > 1) are shown in **bold**.

Table 5-7. 90th Percentile Ground Water Ingestion Risk Exceedances by Depth to Ground Water: Surface Impoundments

COPC	Depth to Ground Water Quartiles			
	Full Range of Depths	Lower Quartile (≤ 0.95 m)	Inner-Quartile (0.95 to ≤ 19 m)	Upper Quartile (> 19 m)
Cancer Risks				
Arsenic III	**2×10^{-4}**	**3×10^{-4}**	**1×10^{-4}**	**7×10^{-5}**
Arsenic V	1×10^{-5}	**2×10^{-5}**	1×10^{-5}	4×10^{-6}
Noncancer Risks				
Arsenic III	**5**	**6**	**4**	**2**
Arsenic V	0.4	0.6	0.3	0.1
Lithium	**2**	**2**	**2**	**3**
Molybdenum	**2**	**3**	**2**	1

While data from the 2009 EPA survey for surface impoundments indicates that a greater number of units may be constructed above grade, the focus of many of these surveys was on above-grade impoundments at risk of structural failure. Therefore, these data may be biased toward units with a greater fraction of the unit above the water table. Conversely, it is known from reported damage cases that some CCR WMUs come in direct contact with the water table for at least part of the year. The probabilistic analysis limited the depth of every WMU to the boundary of the water table because EPACMTP is not designed to solve for leaching from within the water table. Furthermore, EPACMTP considers the annualized transport of constituents. Modeling WMUs below the water table would effectively treat WMUs as submerged year-round, which is often not realistic given seasonally fluctuating water tables. Thus, the probabilistic analysis may over- or underestimate risk on a case-by-case basis. The exact magnitude of this uncertainty is unknown. However, even with greater depths to ground water, risks above cancer and noncancer criteria were still identified.

Given that there is potential for both higher and lower risks than modeled, this uncertainty is unlikely to have an appreciable effect on the principal findings of the probabilistic analysis.

Pollution Control Technology

Because this risk assessment evaluated current management practices, it did not examine the potential for future changes in air pollution technologies to alter the composition of CCR wastes. However, it has been established that mercury pollution controls can affect both the mercury content and the general leaching behavior of ash (U.S. EPA, 2006a, 2008b, 2009a). Therefore, EPA considered the extent to which these mercury-control wastes may drive the modeled risks presented in **Section 4**. This sensitivity analysis was conducted by filtering the full risk results for the subset of fly ash samples generated by facilities with ACI. These samples were collected from a total of five different facilities with the ACI system turned on and off. This comparison allows a consistent frame of reference to judge the effect of ACI on releases from fly ash. **Table 5-8** shows a comparison of 90th percentile risk results for these samples. The table presents results for arsenic because it is the primary risk driver and mercury because public commenters raised concerns about the potential for new pollution control technologies to result in higher releases of this constituent.

Table 5-8. Comparison of 90th Percentile Landfill Risks for Facilities with Activated Carbon Injection (ACI) Turned On and Off

Constituent	ACI Status	Percent of Iterations per COPC	Human Health		Ecological	
			GW→DW Tap Water Ingestion	GW→SW Fish Ingestion	GW→SW Surface Water	GW→SW Sediment
Cancer Risks						
Arsenic III	Turned On	9%	8×10^{-6}	—	—	—
	Turned Off	9%	1×10^{-5}	—	—	—
Arsenic V	Turned On	9%	6×10^{-8}	—	—	—
	Turned Off	9%	8×10^{-8}	—	—	—
Noncancer Risks						
Arsenic III	Turned On	9%	0.2	< 0.01	< 0.01	0.04
	Turned Off	9%	0.2	< 0.01	< 0.01	0.03
Arsenic V	Turned On	9%	< 0.01	< 0.01	< 0.01	< 0.01
	Turned Off	9%	< 0.01	< 0.01	< 0.01	< 0.01
Mercury	Turned On	9%	< 0.01	< 0.01	< 0.01	< 0.01
	Turned Off	9%	< 0.01	0.01	< 0.01	< 0.01

There is some difference in landfill risks modeled for ashes generated with and without ACI. In some instances, risks actually decreased slightly with the addition of activated carbon. Yet, the observed decreases were small enough that they may be an artifact of the relatively small number of model iterations conducted for these wastes. Based on the data available, the variations in risk observed would not alter the principal findings of the risk assessment that current disposal practices pose risks within the range where OSWER typically regulates. However, EPA draws no

conclusions about the exact effects of changing pollution control technologies (including ACI) on future risks.

Summary

A summary of the different uncertainties associated with the CCR WMU database, as well as the potential for each to affect the risks modeled in the probabilistic analysis is shown in **Table 5-9**. The majority of uncertainties identified are unlikely to have an appreciable impact on the principal risk results. However, the sensitivity analyses conducted for specific liner types and specific waste pH identified subsets of disposal practices that result in appreciably higher risks than identified in the full probabilistic modeling.

Table 5-9. Likely Effect on Modeled Risks from CCR WMU Database Uncertainties

Uncertainty	Potential to Affect Probabilistic Analysis Results		
	Uncertain	Low	High

Pollution Control Technology		●	

5.1.2 Environmental Parameters

This risk assessment characterized the environmental conditions that may influence the fate and transport of constituents in the environment using region-specific data collected around each WMU or facility, based on the availability of geographic data. As discussed in **Section 5.1.1** above, some uncertainty exists with respect to the locations of WMUs which were derived from the 2009 EIA facility centroids. This section discusses how the variability and uncertainty associated with each location-based parameter were addressed.

Soil Data

For soil data, variability was accounted for through a probabilistic sampling of all soil types that fall within the WMU footprint (where available) or a two-kilometer radius around the facility centroid. The soil types were drawn from national databases that provide a regional resolution for these soil types. The use of these soil data sets have been thoroughly peer-reviewed and documented as part of the development and implementation of EPACMTP (see **Section 5.1.9**). In

instances where the exact location of a WMU was not known, EPA addressed this uncertainty by collecting information on the different soil types present within a two kilometer radius around the centroid of the facility. The different soil types were sampled probabilistically during each model iteration based on relative prevalence at a given WMU. This approach effectively captures regional variability. Even though soil properties can be highly variable, the regional averaging of these parameters is believed to provide a good resolution for the transport distances considered in the probabilistic analysis. Therefore, the uncertainty introduced by the use of these data is believed to be minimal.

Aquifer Data

EPA assessed risks that result from contamination of surficial aquifers. For each WMU, the hydrogeologic environment of the surficial aquifer was assigned based on the geology and soil megatextures identified beneath the WMUs (see **Appendix B**). In instances where the exact location of a WMU was not known, EPA addressed this uncertainty by collecting information on the different hydrogeologic environments present within a two kilometer radius around the centroid of the facility. These environments were sampled probabilistically based on relative prevalence at a given WMU during each model iteration. The EPACMTP parameters with the largest impact on results are aquifer hydraulic conductivity and gradient. These parameters were selected from a database that contains regional aquifer properties across the conterminous United States. Even though aquifer properties can be highly variable, these regional data are believed to provide a good resolution for the transport distances considered in the probabilistic analysis. Therefore, the uncertainty introduced by the use of these data is believed to be minimal.

Ground Water Flow Direction and Water Body Selection

EPA used a raindrop tool to identify the nearest surface water body and to assign a ground water flow direction and distance (see **Appendix B**). The raindrop tool estimates the direction of overland run-off based on topographic elevations and is therefore an indirect representation of ground water flow. EPA received multiple public comments on the Agency's use of the tool, pointing to site-specific factors that may lead to alternate ground water flow directions, including:

- Localized ground water mounding;
- Ground water flow parallel to the surface water body;
- Water bodies that lose water to underlying aquifers for some or all of the year;
- Seasonal variations in the water table height and flow directions; and
- Anthropogenic influences, such as nearby ground water pumping.

EPA agrees that the direction of ground water flow can differ from the direction of the surface topographic gradient. However, without external stresses (e.g., pumping) or unique hydrogeologic conditions, ground water flow directions will generally mimic surface topographic gradients. Accurate characterization of ground water flow conditions at specific WMUs would require extensive site-specific spatial and temporal hydrogeologic data collection and analysis. Such effort was not feasible in support of this annualized, national-scale analysis. The method adopted by the

Agency incorporated potential variability by allowing multiple transport pathways from each WMU with multiple nearby surface water bodies potentially receiving ground water (e.g., if the WMU was surrounded by more than one water body). In this way, a range of potential transport distances and receiving water bodies for each WMU were incorporated into the probabilistic analysis. The assumption of a straight-line ground water flow direction may overestimate risks in some model iterations due to the decreased sorption and dispersion from shorter than actual transport distances. However, the approach may also underestimate risks for other model iterations if the actual flow of ground water to surface water is more direct than suggested by topographic gradients. Overall, this uncertainty is anticipated to have a minimal effect on calculated risks. For GW→DW pathways, a stream that fully intercepts ground water will do so regardless of the exact distance from the WMU, resulting in a negligible well concentration. The high-end ground water risks for these pathways will be driven by model iterations where no surface water interception occurs. For GW→SW pathways, many plants are located very close to the water body due to the use of water in facility operations. The high-end surface water risks for these pathways will be driven by the WMUs directly adjacent to the water bodies, and any variations in the already short transport distances will have minimal impact on modeled risks.

Water Body Flow Rate

One of the most sensitive parameters identified for the GW→SW pathways was the surface water flow rate. In this risk assessment, EPA used average annual flow rates to estimate surface water risks. These rates are considerably higher than the low flow rates used in the 2010 Risk Assessment. Public commenters pointed out that average annual flows may not represent the typical flow of a water body because of lower median and low flow rate conditions that occur over most of the year. One specific example provided by commenters is Lick Creek in Indiana. **Table 5-10** presents the flow rate data provided by the commenters for this water body.

Table 5-10. Example Flow Rate Data for Lick Creek, Indiana

Annual Flow Rates			Ratios	
Average Annual	Median	Low	Average / Median	Average / Low
21 ft^3/s	7 ft^3/s	< 1 ft^3/s	3	> 20

As seen in the table above, the average flow rate is three times higher than the median flow rate, and over twenty times higher than the low flow rate. For this water body, and similarly behaving ones, the use of an average annual flow represents a stage of the river that occurs less than half of the year. Thus, use of an annual average value could overestimate the volume of water present in the water body and, consequently, the dilution of ground water concentrations entering the water body at certain times throughout the year. However, both EPACMTP and the surface water model used in this risk assessment consider fate and transport in yearly time steps. Therefore, EPA considered how best to reflect seasonal fluctuations when developing annualized inputs for these models.

Ground water and surface water are interconnected. Just as the surface water flow rates vary throughout the year, hydraulic gradients are also subject to change in response to precipitation rates, among other factors (Sophocleous, 2002). Precipitation rates, ground water flow, and many other annual variables used in this risk assessment may all vary seasonally. Thus, varying one (i.e., surface water flow rates) but not the others would not capture actual interactions. Periods of naturally low ground water (e.g., drought) that also lead to low flow rates would be accompanied by decreased flux from the ground water to surface water, or could even transition to a net losing water body, as shown in **Figure 5-2**. Thus, while the use of average annual flow rates may overstate the volume of water passing through a water body for some portion of the year, this is the most appropriate flow rate in light of the annual increments used for all other variables.

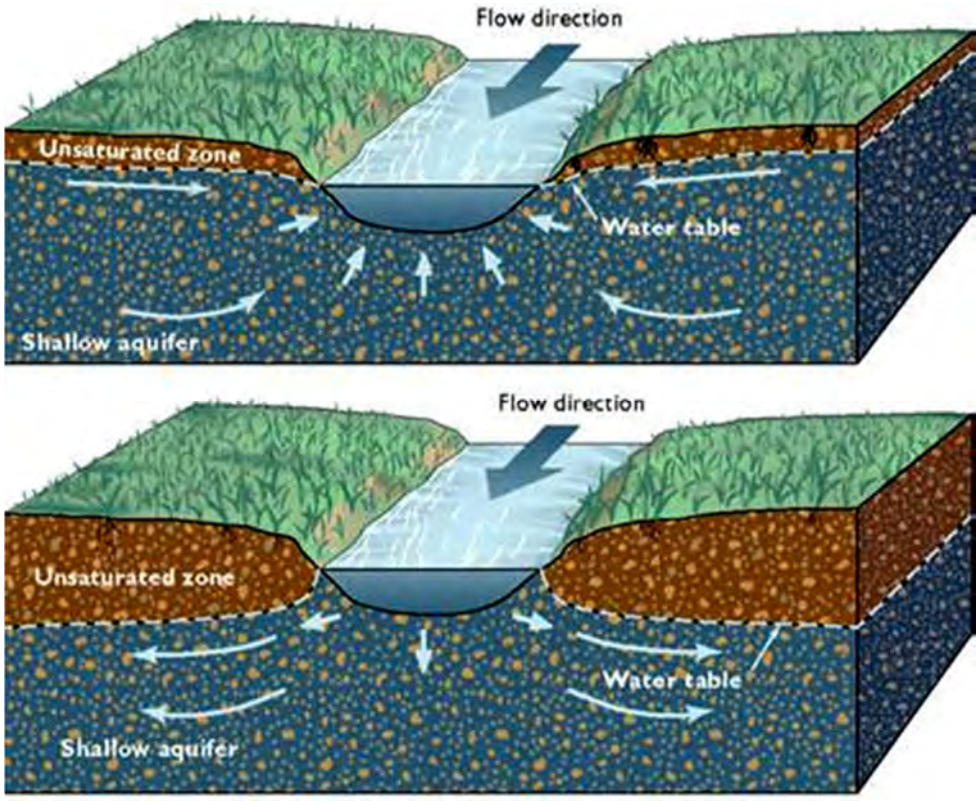

Figure 5-2. Interaction of ground water and surface water flow [reproduced from Winter et al., 1998).

Climate Data Selection

Climate regions were developed for this risk assessment to represent climate patterns within specified geographic regions. Data were collected for each WMU from the closest climate data center within each region that best matched the precipitation reported at that facility location. To the extent that actual climate data (e.g., precipitation rates) from a climate data center does not reflect the conditions at a specific WMU location, there is the potential to either overestimate or underestimate climate data on an annual basis. However, because EPA matched each unit with the most representative center, the potential effect of this uncertainty on modeled risks is likely to be small.

Climate Change

The climate data used in this risk assessment was collected for a period from 1961 through 1990. Therefore, some uncertainty is introduced because any potential effects from climate change that have occurred since 1990 are not reflected in this data set. The National Climate Assessment Report documents region-specific changes in rainfall, temperature and episodic rainfall events over recent decades (Melillo et al., 2014). This may result in an increase or decrease in risk on a case-by-case basis. The potential effect of this uncertainty on modeled risks is unknown.

Distance to Nearest Ground Water Receptor

EPA used a probability distribution to characterize the distance to nearest ground water receptor for surface impoundments created from combining U.S. Census data with the locations of a total of 729 impoundments drawn from the 2009 EPA survey. This distribution was compiled and incorporated into the analysis before data on an additional 223 impoundments from the 2010 EPA survey were processed and available for use. Much of the data on the additional surface impoundments were incorporated into the probabilistic analysis through further model iterations; however, due to the time intensive nature of the process to link receptor and WMU location, the distribution of distances to nearest receptor was not updated at that time. To characterize the uncertainty associated with the use of a distribution based on a subset of 729 surface impoundments, EPA later generated a revised probability distribution based on all 952 surface impoundments. **Figure 5-3** compares this combined nearest-receptor distribution with both the distribution used for modeling, as well as the distribution utilized in the 2010 Risk Assessment, which was based on receptor distances from municipal solid waste landfills.

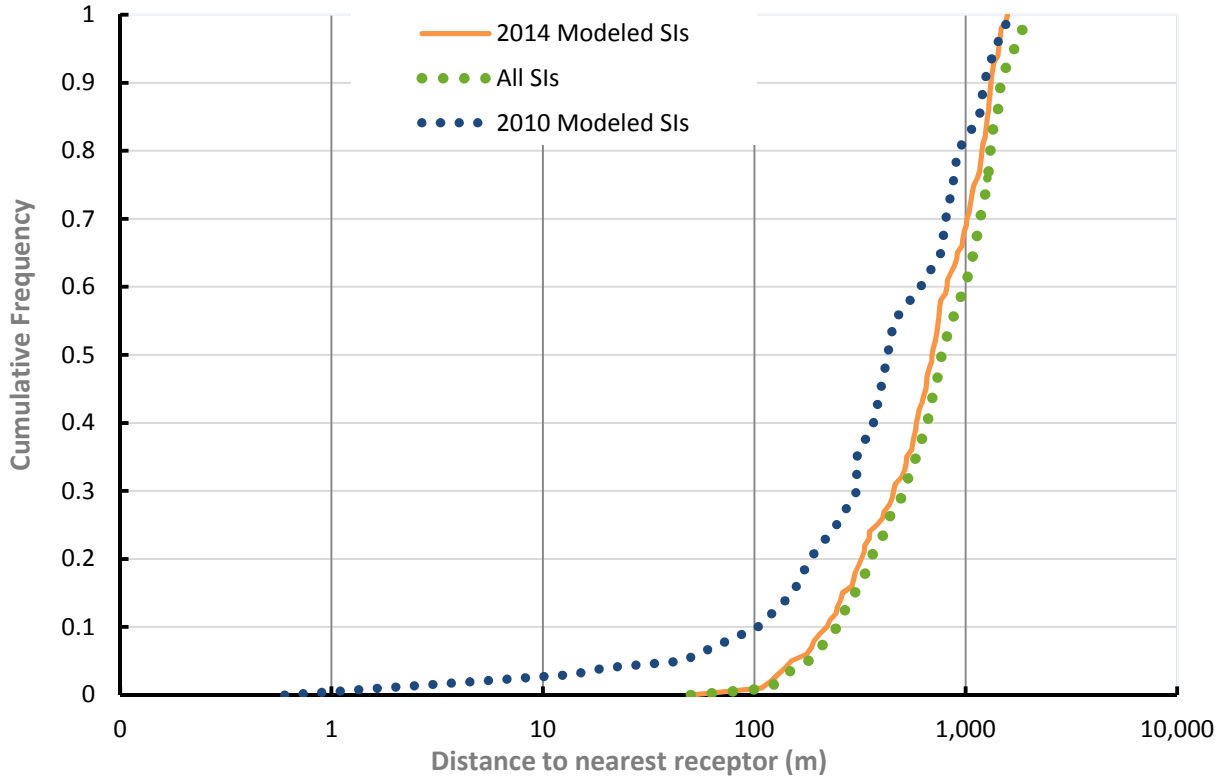

Figure 5-3. Distance to nearest ground water receptor distribution among data sets.

As seen in the figure above, the combined surface impoundment data set results in slightly greater distances to ground water receptors. It also shows that the distribution for 729 impoundments used in the revised risk assessment is far more similar to the distribution of all 952 impoundments than to the distances used previously in the 2010 Risk Assessment. Given the small difference between the distributions for the 729 and all 952 surface impoundments, the potential impact of this uncertainty on the modeled risks is negligible.

Summary

A summary of the different uncertainties associated with environmental parameter data, as well as the potential for each to affect the risks modeled in the probabilistic analysis is shown in **Table 5-11**. The majority of uncertainties identified are unlikely to have an appreciable impact on the principal risk results. EPA was not able to characterize the potential magnitude or direction of the uncertainties associated with climate change. The Agency relied on the best data available at the time of the analysis; however, the potential of these uncertainties to overestimate or underestimate risk results is uncertain.

Table 5-11. Likely Effect on Risk from Environmental Parameter Uncertainties

Uncertainty	Potential to Affect Probabilistic Analysis Results		
	Uncertain	Low	High
Soil Data		●	
Aquifer Data		●	
Ground Water Flow Direction & Water Body Selection		●	
Water Body Flow Rate		●	
Climate Data Selection		●	
Climate Change	●		
Distance to Nearest Residential Receptor		●	

5.1.3 CCR Constituent Database

Where possible, EPA used government sources and peer-reviewed primary literature for input data. EPA also preferentially used sources where the test methods and quality assurance/quality control protocols were well documented. Although additional data were made available through public comments received since the 2010 proposed rulemaking, there are relatively few data points available for some constituents (e.g., mercury). As a result, there is some uncertainty regarding how well these data reflect the range of CCR waste types.

Representativeness

Pore water data were determined to be the most representative data available for impoundments because these data are field-measured concentrations of leachate present at the bottom of these WMUs. In instances where the risks identified for surface impoundments are based on a limited

data set, uncertainty exists with respect to the representativeness of the results. Of the modeled constituents found to be near or above risk criteria, thallium was the single one with a limited data set. Thallium had a total of 38 pore water samples from 14 distinct sample sites. In contrast, arsenic, boron, cadmium, fluoride, molybdenum and selenium had a much greater number of measurements (~ 200) from a greater number of sample sites (~ 30). While the more limited data set for thallium adds some uncertainty for this one constituent, it will not impact the principal results of the probabilistic analysis based on other risk drivers with more robust data sets.

Nondetects

The CCR constituent database contains a large number of nondetect data for some constituents. For each of these data points, EPA substituted half the reported detection limit. Because the evaluation relied on a value halfway between zero and the detection limit, the true value is equally likely to be higher or lower than the value assigned. Typically, the upper percentile risks calculated in the probabilistic assessment are associated with higher, detectable, concentrations rather than nondetects. Unless nondetect data account for a high percentage of the total data set or the detected values fall near the detection limit, the specific treatment of nondetect values has little effect on the upper percentile risks relied upon in this risk assessment.

Table 5-12 lists the constituents for which 50 percent or more of site data for impoundment wastewater were nondetects. These constituents are beryllium, lead, iron and silver. Beryllium is the only constituent that both failed the screening and has a high percentage of sites with nondetects (73 percent). All other constituents that failed the screening for this exposure pathway have nondetect percentages less than 25 percent. This introduces considerable uncertainty for beryllium. However, given the risks identified for multiple other constituents with well-defined data, these uncertainties do not change the ultimate conclusions that direct contact with impoundment wastewater has the potential to pose risk to ecological receptors.

Table 5-12. Review of Nondetects for Impoundment Wastewater

Constituent	Individual Nondetect Measurements		Sample Sites with All Nondetects	
	Total Count	Percent	Total Count	Percent
Silver	26	100%	11	100%
Beryllium	26	81%	11	73%
Iron	26	58%	11	64%
Lead	26	69%	11	55%

Table 5-13 lists the constituents for which 50 percent or more of site data for impoundment pore water were nondetects. These constituents are beryllium, chromium and silver. None of these constituents were found near risk criteria in the full probabilistic analysis; however, chromium did fall above a risk of 1×10^{-5} in the sensitivity analysis for waste types for both ash and coal waste (3×10^{-5}) and FGD waste (4×10^{-5}). Therefore, there is the potential for somewhat higher risks associated with chromium risks. However, because high-end risks are likely associated with the

50 percent of higher, detected chromium concentrations, any increase is likely to be small. Of the constituents that posed risks in the full probabilistic analysis, arsenic and molybdenum have nondetect percentages of 19% and 36%, respectively. These relatively low nondetect percentages result in low uncertainty for these results. Therefore, the uncertainties associated with pore water are unlikely to change the ultimate conclusions that ingestion of ground water has the potential to pose risk to human receptors.

Table 5-13. Review of Nondetects for Impoundment Pore Water

Constituent	Individual Nondetect Measurements		Sample Sites with All Nondetects	
	Total Count	Percent	Total Count	Percent
Beryllium	38	97%	14	93%
Silver	76	95%	20	85%
Chromium	194	71%	30	50%

Table 5-14 lists the constituents for which 50 percent or more of site data for whole waste were nondetects. These constituents are nitrate, thallium and uranium. Thallium was the single constituent that failed the uncontrolled soil exposures for human health screening based on whole waste concentration; however, all risks fell below criteria based on consideration of dust and run-off controls. Because high-end risks are likely associated with the 45 percent of higher, detected thallium concentrations, any increase is likely to be small. Thus, the treatment of nondetects does not add significant uncertainty to these data.

Table 5-14. Review of Nondetects for Whole Waste

Constituent	Individual Nondetect Measurements		Sample Sites with All Nondetects	
	Total Count	Percent	Total Count	Percent
Nitrate	2	100%	2	100%
Uranium	9	100%	1	100%
Thallium	55	55%	18	50%

The LEAF data used in this analysis originated from CCR concentration data collected from CCR management operations that were selected to represent the range of coal-fired power plants, control technologies, and coal types in current use across the United States (U.S. EPA, 2009a). U.S. EPA (2006a, 2008b and 2009a) all contained data with low detection limits. Thus, for landfill leachate, nondetect percentages were very low (less than 1%) for most constituents, and still low for mercury (25%). Thus, the treatment of nondetects does not add significant uncertainty to these data.

Site Quartiles

This risk assessment divided pore water and whole waste constituent concentration data into quartiles (i.e., 25th, 50th, 75th) for each sample site and waste type. Compared to the site averages used in the 2010 Risk Assessment, this approach better captures the variability at each sample site. **Table 5-15** below shows the 2010 site averaged pore water distribution and 2014 site quartile

distributions for arsenic. The ash waste type used previously in the 2010 Risk Assessment was separated into the combined ash waste type and the FGD waste type.

Table 5-15. Comparison of Arsenic Pore Water Concentrations Resulting from Data Processing: 2010 Averages versus 2014 Quartiles

Waste Type Name	Year	Data Treatment	Arsenic Pore Water Concentration Percentile (mg/L)				
			25th	50th	75th	90th	95th
Conventional Ash	2010	Average	0.02	0.07	0.29	1.0	1.3
Combined Ash	2014	Quartile	0.04	0.07	0.16	0.26	0.49
FGD Waste	2014	Quartile	0.02	0.21	0.80	2.86	6.41
Codisposed Ash	2010	Average	0.02	0.02	0.12	0.63	0.63
Ash & Coal Refuse	2014	Quartile	0.01	0.18	0.53	3.41	7.85

In general, the median and low-end concentrations changed very little as a result of the use of quartiles. Decreases in the combined ash arsenic concentrations in high-end percentiles are attributed to the separation of FGD waste data. The considerable increase ash and coal refuse arsenic concentrations in high-end percentiles is attributed to better characterization of intra-site variability. While some uncertainty remains because the quartile approach does not fully capture extreme values at some sites, these individual samples are reflected in the quartiles without assigning an undue weight to what may be an outlier within the larger site by using an empirical distribution. Because the use of quartiles provides much better resolution on the variability of pore water concentrations, EPA believes the uncertainty associated with this approach is minimal.

Summary

A summary of the different uncertainties associated with constituent data, as well as the potential for each to affect the risks modeled in the probabilistic analysis is shown in **Table 5-16**. The uncertainties identified are unlikely to have an appreciable impact on the principal risk results.

Table 5-16. Likely Effect on Risk from Constituent Data Uncertainties

Uncertainty	Potential to Affect Probabilistic Analysis Results		
	Unknown	Low	High
Representativeness		●	
Nondetect Data		●	
Site Quartiles		●	

5.1.4 Human Exposure Factors

This risk assessment relied on the 1997 *EFH* (U.S. EPA, 1997b,c,d) and the 2008 *CSEFH* (U.S. EPA, 2008a) for information on human exposure factors for the U.S. population. EPA's evaluation criteria included peer-review status, reproducibility, pertinence to the United States, currency, adequacy of the data collection period, validity of the approach, representativeness of the

population, characterization of the variability, lack of bias in study design, and measurement error. The data contained in these documents were used throughout this risk assessment to establish distributions for each exposure parameter and receptor. Both documents have undergone extensive external peer review.

2011 Exposure Factor Updates

The 2011 *Exposure Factors Handbook* (U.S. EPA, 2011b) has been completed and updates some of the data from the 1997 EFH. During the finalization of this risk assessment, EPA released OSWER Directive 9200.1-120 (U.S. EPA, 2014c). While this document provides default exposure factors to use for point estimates, EPA is still in the process of updating the full distributions necessary for probabilistic risk assessment. Therefore, this risk assessment does not incorporate the data from the 2011 EFH. The adult water consumption rates provided in the U.S. EPA (2011b) are somewhat lower than those found in the 1997 *EFH*, while adult body weights are somewhat higher. All other exposure factors used in the CCR risk assessment remained the same between the 1997 and 2011 Handbooks. As a result, risks for the drinking water ingestion and fish ingestion pathways may be slightly overestimated.

Drinking Water Ingestion Rate

Drinking water ingestion rate data for infants that consume formula (birth to < 1 month, 1 to < 3 months, 3 to < 6 months, and 6 to < 12 months) are available from the *CSEFH* (U.S. EPA, 2008a). As drinking water concentrations are provided by the model as annual averages, the consumption rate data were averaged to estimate a full year of exposure. The distribution of infant drinking water ingestion rates used in this analysis reflects sampling from percentiles averaged across all infant age ranges. The sample size associated with each age range was used to calculate a weighted average for each percentile. The data were weighted by sample size because the small sample sizes did not meet minimum requirements as described in the *Third Report on Nutrition Monitoring in the United States* (Life Sciences Research Office, 1995) for percentiles in several subcohorts. The resulting average percentiles were sampled to develop the infant drinking water distribution. As noted by the CSEFH, some of the reported sample sizes did not meet minimum requirements. These small sample sizes for certain infant subcohorts introduce some amount of uncertainty to the modeled risk results. Because infants were found to be the most sensitive age cohort for some exposure pathways, EPA conducted a sensitivity analysis comparing the drinking water risks for the infant cohort with those for other age cohorts to determine the potential magnitude of this uncertainty. **Table 5-17** provides the results of this comparison for each constituent that was modeled in the probabilistic analysis and that was above risk criteria in this sensitivity analysis for one or more age cohorts. Arsenic V risks are provided even where below criteria to provide a complete bounding on arsenic speciation. Values that exceed the risk criteria (i.e., cancer risk > $1x10^{-5}$ or HQ > 1) are shown in **bold**.

Table 5-17. 90th Percentile Human Health Risk Results for Surface Impoundment GW→DW Pathway by Age Cohort

COPC	Age Cohorts							
	Infant	1 to < 2	2 to < 3	3 to < 6	6 to < 11	11 to < 16	16 to < 21	Adult
Cancer								
Arsenic III	**1×10^{-4}**	**1×10^{-4}**	**9×10^{-5}**	**8×10^{-5}**	**8×10^{-5}**	**8×10^{-5}**	**8×10^{-5}**	**2×10^{-4}**
Arsenic V	1×10^{-5}	7×10^{-6}	7×10^{-6}	6×10^{-6}	6×10^{-6}	6×10^{-6}	6×10^{-6}	1×10^{-5}
Noncancer								
Arsenic III	**5**	**3**	**3**	**3**	**2**	**2**	**2**	**3**
Arsenic V	0.4	0.2	0.2	0.2	0.2	0.1	0.1	0.2
Lithium	**2**	1	1	1	1	0.8	0.9	1
Molybdenum	**2**	1	1	1	0.8	0.7	0.8	1

As seen in the table above, the infant cancer risks for arsenic are slightly less than the adult cancer risks. Because infants were not the most sensitive receptors for these exposures, the magnitude of uncertainty introduced by the small sample sizes of the infant exposure factors is minimal. Infants are the most sensitive receptor for noncancer risks. However, the infant risk estimates are no more than a factor of two higher than the values modeled for other cohorts. In addition, exceedances of the arsenic risk criteria were identified for all age cohorts. Because the infant exposures are not the most sensitive age group for cancer risks and noncancer risks do no differ substantially across age groups, any uncertainty associated with the infant drinking water ingestions rates will have minimal impact on the final conclusions of the risk assessment.

Human Fish Consumption

Data on site-specific fish consumption rates were not available for use in this analysis. Instead, fish consumption rates were drawn from a study of Maine anglers that fished from streams, rivers, and ponds. This study was one of four recommended freshwater angler studies in the 1997 *Exposure Factors Handbook*. This evaluation selected the Maine data based on the completeness of the data set and because it agrees most closely with a separate U.S. Department of Agriculture (USDA) study of national fish consumption (USDA, 1992). However, applying Maine angler consumption rates to other parts of the country may under- or overestimate exposures on a case-by-case basis. For example, subsistence fishers were not evaluated, as the wide variety of possible consumption rates makes evaluation more appropriate at a site-specific level, rather than the national assessment conducted here. Additionally, data were available only for adult anglers. Because age-specific data for children were not available, all child cohorts were assumed to consume the same amount of fish as the adult cohort. This issue introduces uncertainty into the analysis, and likely results in an overestimate of risks from fish consumption among child cohorts. Furthermore, all fish consumed by both adult and child receptors is assumed to be contaminated. This assumption will also overestimate risks from contaminated fish consumption. The magnitude

of these overestimations are unknown; however, given that all risks associated with the fish ingestion pathway fell at least an order of magnitude below risk criteria, the potential for this overestimation to alter the conclusions of the probabilistic analysis is negligible.

Bioavailability

A host of different environmental factors such as the pH, particle size, moisture, and redox potential of the environment influence bioavailability. The individual receptor's age, sex, nutritional state, and physiological state also affect bioavailability (U.S. EPA, 2007a). For the purposes of this analysis, the model conservatively assumed that all forms of a constituent were equally bioavailable. For example, although U.S. EPA (2012b) recommends the use of a default bioavailability rate of 60 percent for arsenic in soils, EPA assumed 100 percent bioavailability in this risk assessment. Therefore, the actual exposures that may occur in the field will tend to be overestimated, making this a high-end assumption that will tend to overestimate risk. That magnitude of these overestimations are unknown; however, given that all risks associated with the soil, produce, beef, and milk ingestion screened out under a controlled management scenario, the potential for this overestimation to alter the conclusions of the probabilistic analysis is negligible.

Noncorrelation of Exposure Factors

While exposure factors were selected for specific age groups, the distributions for each exposure factor were not correlated with each other within each of these age groups. Instead, for each modeling run, each exposure factor was selected from its age-group-based distribution independently. Insufficient data are currently available to correlate these variables. This introduces some uncertainty into the evaluation because some combinations of exposure factors, such as a high fish consumption rate combined with small body weight, while possible, are unlikely. Therefore, this remains an uncertainty in the analysis that may under- or overestimate exposures for individual model iterations. The magnitude and direction of this uncertainty are unknown.

Consumption of Wildlife/Game

Neither the screening analysis nor the full-scale CCR risk assessment considered ingestion of game, which may pose non-negligible risks if humans consume wildlife contaminated by CCR constituents. Results of the screening analysis (**Section 3.5.2**) of the revised risk assessment show that consumption of contaminated beef and dairy from cows that consume contaminated soil and produce grown in contaminated soil may pose risks to human health for thallium. **Table 5-18** provides a comparison of the per capita intake rates for beef, dairy and game.

Table 5-18. Comparison of Per Capita Beef, Dairy & Wild Game Consumption Rates

Food	Percent of Population	Percentile (g/kg-day)								
		1st	5th	10th	25th	50th	75th	90th	95th	99th
Beef	91%	0	0	0.06	0.27	0.63	1.2	1.8	2.3	3.5
Dairy	97%	0	0.16	0.40	1.4	3.6	8.2	18.7	29.7	72.2
Game	1.2%	0	0	0	0	0	0	0	0	0.1

Rounded values drawn from EFH (U.S. EPA, 1997c) Tables 11-2, 11-3, and 11-6

Although EPA did not collect biotransfer factors for deer and other game, the following considerations make this pathway less of a concern than the beef and dairy pathways evaluated. First, only 1.2 percent of the population consumes game species. Second, the table also shows that the consumption rates for game species are typically orders of magnitude below the consumption rates of beef and dairy. Finally, beef and dairy cattle are assumed to get 100 percent of their diet from contaminated soil, forage, silage, and grains, whereas game species would forage throughout their natural habitat range, with direct ingestion of CCRs the only exposure pathway available. Thus, EPA does not consider the exclusion of this pathway to be a significant uncertainty nationally.

Summary

A summary of the different uncertainties associated with human exposure factors, as well as the potential for each to affect the risks modeled in the probabilistic analysis is shown in **Table 5-19**. The majority of uncertainties identified are unlikely to have an appreciable impact on the principal risk results. EPA was not able to characterize the potential magnitude or direction of the uncertainties associated with the correlation of exposure factors. The Agency relied on the best data available at the time of the analysis; however, the potential of these uncertainties to overestimate or underestimate risk results is uncertain.

Table 5-19. Likely Effect on Risk from Human Exposure Factor Uncertainties

Uncertainty	Potential to Affect Probabilistic Analysis Results		
	Uncertain	Low	High
2011 Exposure Factor Updates		●	
Drinking Water Ingestion Rate		●	
Human Fish Consumption		●	
Bioavailability		●	
Noncorrelation of Exposure Factors	●		
Consumption of Wildlife/Game		●	

5.1.5 Human Health and Ecological Benchmarks

Use of Chronic Human Health Benchmarks for Less Than Lifetime Exposures

The uncertainties generally associated with human health benchmarks are discussed in detail in EPA's *Guidelines for Carcinogen Risk Assessment* (U.S. EPA, 2005) and the IRIS website (U.S. EPA, 2012a). EPA defines the RfD as "an estimate of a daily exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime." The CSF is an upperbound estimate of the human cancer risk per mg of chemical per kg body weight per day. Because calculated exposures were often less than lifetime, some uncertainty was introduced in the noncancer hazard and cancer risk estimates, though the magnitude and direction of this uncertainty is unknown.

Use of MCL for Lead

For lead, EPA has no consensus on the development of an RfD or CSFo because of the difficulty associated with identifying an effect threshold needed to develop these benchmarks. Therefore, the MCL for drinking water was used as an alternative method of approximating human health risk. To ensure that risks were not underestimated, EPA separately considered lead exposures with the Integrated Exposure and Uptake Biokinetic (IEUBK) model (U.S. EPA, 2010b) to predict blood lead levels that may result from CCR disposal. The conservative exposure concentrations developed in **Section 3** for soil, fish, and drinking water were used to evaluate lead through separate IEUBK model runs. The methodology and default parameters EPA used are described in detail in the IEUBK *User's Guide* (U.S. EPA, 2007b). With the exception of drinking water, the estimated screening blood levels were below the current CDC target blood level of 5 μg/dL. However, lead was already retained for the GW→DW pathway because screening lead concentrations exceeded the MCL. The national-scale probabilistic modeling conducted in **Section 4** showed that lead concentrations fell several orders of magnitude below risk criteria based on the MCL. Thus, consideration of a lower blood lead level with IEUBK may have resulted in somewhat higher risks, these results would not have changed the findings of the risk assessment for this constituent.

Use of Proxy Benchmarks

Chemical-specific health benchmarks were used for all constituents assessed in the analyses. However, the RfD for fluoride was based on fluorine and the RfD for thallium was based on thallium chloride. The use of these surrogate data provides the best estimate of potential risks available, but may over- or underestimate risks to an unknown degree. However, because risks were identified for other constituents, this uncertainty is unlikely to affect the final conclusions of the risk assessment.

Ecological Benchmarks

Ecological benchmarks were obtained for CCR constituents when available and compared with the modeled media concentrations (e.g., surface water, sediment) to estimate the HQs used to characterize ecological risk. These benchmarks represent the best available estimates of receptor responses based "no effects" (NOAEL) or "lowest effects" (LOAEL) study data. In some scenarios, these benchmarks may be represent species not actually present in the field. In others, these benchmarks may not capture the most sensitive possible receptor at every site or for each constituent. While some benchmarks have factors of safety included to account for these or other uncertainties, there remains is the potential for the ecological benchmarks used to underestimate risks for the specific species and communities that live in surface waters impacted by CCR WMUs. The magnitude of this uncertainty is unknown. Consideration of any additional sensitive species not captured by the current benchmarks may result in some additional constituents above risk criteria in the probabilistic analysis. EPA notes that these some of these ecological risks are reflected in damage cases. However, this site-specific uncertainty is unlikely to affect the final, national conclusions of the risk assessment.

Constituents with No Benchmarks

Constituents with no human health or ecological benchmarks could not be quantitatively evaluated in either the screening or full-scale modeling. Only three constituents (carbon, phosphate and potassium) for which constituent data were available did not have corresponding toxicity values for any pathway. However, most of these constituents are known to be essential human nutrients that are likely to be harmful only at very high doses. Other constituents have toxicity values available for some, but not all, exposure pathways evaluated. In these cases, the potential risks to receptors in these media could not be quantified. In particular, ecological benchmarks for chronic effects on amphibians are not available for many constituents. The absence of a toxicity value is not necessarily equivalent to the absence of risk. These constituents may pose pathway-specific risks or may influence either the fate and transport or toxicity of another constituent, resulting in an underestimation of rusk. The magnitude of this underestimation is unknown. However, because risks were identified for the available benchmarks, it is unlikely that this uncertainty would affect the final conclusions of the risk assessment.

Summary

A summary of the different uncertainties associated with toxicity benchmarks, as well as the potential for each to affect the risks modeled in the probabilistic analysis is shown in **Table 5-20**. The majority of uncertainties identified are unlikely to have an appreciable impact on the principal risk results. EPA was not able to characterize the potential magnitude or direction of the uncertainties associated with the use of chronic benchmarks for less than lifetime exposures and the use of proxy benchmarks. The Agency relied on the best data available at the time of the analysis; however, the potential of these uncertainties to overestimate or underestimate risk results is uncertain.

Table 5-20. Likely Effect on Modeled Risk from Human Health and Ecological Benchmark Uncertainties

Uncertainty	Potential to Affect Probabilistic Analysis Results		
	Uncertain	Low	High
Use of Chronic Human Health Benchmarks for Less Than Lifetime Exposures	●		
Use of MCL for Lead		●	
Use of Proxy Human Health Benchmarks		●	
Ecological Benchmarks		●	
Constituents with No Benchmarks		●	

5.1.6 Bioconcentration Factors

Human exposures to constituents from fish consumption were calculated using BCFs for TL3 and TL4 freshwater fish to estimate the accumulation of constituents from surrounding environmental media into fish tissue. **Appendix G** lists the BCFs used in this risk assessment, as well as the literature sources from which they were drawn. BCFs are developed by dividing measured constituent concentrations in aquatic biota by total surface water constituent concentrations. In the

revised risk assessment, the evaluation only used BCFs empirically measured from laboratory or field studies of TL3 and TL4 fish, rather than values estimated from physical or chemical properties [e.g., octanol-water partition coefficient (K_{ow})]. There are several sources of uncertainty associated with the models used to estimate BCFs for aquatic biota:

- Error may originate from the relatively short exposure timeframe used in a study compared to lifetime exposure (Arnot and Gobas, 2006; and CalEPA, 2012);
- Laboratory-prepared water may have constant and unrealistically high concentrations (Arnot and Gobas, 2006; and CalEPA, 2012);
- Radiolabeled compounds may be used without adequate correction for the parent signal (Arnot and Gobas, 2006; and CalEPA, 2012);
- Imprecise analytical methods may be used to analyze samples (Arnot and Gobas, 2006; and CalEPA, 2012);
- BCFs may be based on whole-body concentrations for fish which include organs and muscle tissues, rather than just the edible portion of the fish (du Preez et al., 1993);
- BCFs may be measured from juvenile fish, whereas metal concentrations in tissues decrease as fish size or weight increases (Liao et al., 2003, as cited by CalEPA, 2012);
- BCFs are based only on concentrations in environmental media, whereas consumption of sediment-dwelling invertebrates by bottom-dwelling fish species may also contribute to metal uptake by these fish (CalEPA, 2012); and
- BCFs may be collected for a particular species of fish that may or may not be present at the sites modeled in this risk assessment.

Significantly more research has been conducted for mercury than for other constituents. This mercury-specific data allowed EPA to address some of the concerns above (e.g., consumption of sediment-dwelling invertebrates) through the use of a bioaccumulation factor for methylmercury that takes into account accumulation in the entire food chain rather than just the water column. However, for the reasons stated above, reliance on BCFs to estimate fish exposure may overestimate or underestimate the actual accumulation of inorganics in fish tissue.

Summary

A summary of the different uncertainties associated with bioconcentration, as well as the potential for each to affect the risks modeled in the probabilistic analysis is shown in **Table 5-21**. EPA was not able to characterize the potential magnitude or direction of the uncertainties associated with the use of bioconcentration factors. The Agency relied on the best data available at the time of the analysis; however, the potential of these uncertainties to overestimate or underestimate risk results is uncertain.

Table 5-21. Likely Effect on Modeled Risk from Toxicity Benchmark Uncertainties

Uncertainty	Likely Effect on Risk		
	Uncertain	Low	High
Bioconcentration Factor	•		

5.1.7 WMU Source Term Models

Scaling of Washout Constituent Concentrations

Leaching profiles of washout phase constituents are characterized by an initial high-concentration pulse of 20 times the Method 1313 equilibrium concentration followed by a lower concentration pulse that continues until the leachable content is depleted. The use of a factor of 20 is supported by field data, as seen in U.S. EPA (2014b). However, in some cases, preferential flow or other considerations may result in concentrations only 10 times the Method 1313 equilibrium concentration. Therefore, this is unlikely to result in a significant uncertainty to the analysis.

Constant Leachate Concentrations

The nonlinear fate and transport solution used for inorganic constituents in the unsaturated zone module of EPACMTP requires constituent concentrations leached from the bottom of WMUs to remain constant for the entire duration of leaching (U.S. EPA, 2003b). However, empirical evidence reported in U.S. EPA (2009a) indicates that constituents can exhibit a leaching profile that changes over time. EPA conducted a sensitivity analysis to estimate the potential magnitude of error introduced by modeling a single, high-concentration pulse for washout constituents. This analysis, presented in **Appendix I**, found that there was a negligible (< 1 percent) difference in the peak time-averaged drinking water concentrations using a single, high-concentration pulse until depletion, or two pulses representing a high concentration followed by a low-concentration pulse until depletion. Although a leaching profile that changes over time may be more realistic, the simplified leaching profile used by the model provides very good approximations for peak ground water concentrations overall, and thus has a minimal effect on the risk results.

Surface Impoundment Leaching Duration

Leaching from surface impoundments was modeled based on the assumption that these units are periodically dredged during operation, resulting in a constant source that is continuously replenished. To reflect this assumption, the leachable mass was set equal to the total constituent mass in EPACMTP. This indirectly accounted for the constant source because an operating time of 75 years for impoundments is not enough to deplete the entire constituent mass present in CCR waste. After this timeframe, the model assumed clean closure of impoundments. EPA received public comments that indicated this approach is not consistent with the current practice of closing with wastes in place at some surface impoundments.
