or mechanical ventilation may be accomplished by using a fan to blow air into or out of the building. Increased ventilation is easiest and least costly to implement in locations where the air is not conditioned (heated or cooled). If indoor air is conditioned, increased ventilation can be a costly option because the conditioned air is ventilated to the outdoors. This drawback can be partly overcome by use of heat exchangers, but they are also costly. Another concern is that exhausting air from the building will generally contribute to under-pressurization of the building, relative to the subsurface, thereby potentially resulting in an increased rate of soil gas entry (i.e., vapor intrusion) unless ambient air entry into the building is increased equivalently. EPA recommends appropriate monitoring of indoor air concentrations be conducted to ensure that ventilation attains and sustains sufficient reduction in exposures to vapor-forming chemicals. In some cases, ventilation may not be capable of reducing indoor air concentrations to acceptable levels. In addition, building occupants may find it uncomfortable to increase the air exchange rate by more than a factor of three or four. EPA generally recommends that this response option be supplanted, when feasible, by installing, operating, and maintaining an engineered exposure control that reduces or eliminates vapor entry into the building until remediation of subsurface vapor sources is complete and terminated.

- Commercially available indoor air cleaners, which include both in-duct models and portable air cleaners, is another response option. These devices operate on various principles, including zeolite and carbon sorption and photocatalytic oxidation. Methods that rely on adsorption generate a waste that must be disposed of appropriately or regenerated and warrant periodic replacement of the adsorption medium. EPA recommends appropriate monitoring of indoor air concentrations be conducted to ensure that adequate treatment is sustained throughout the building. EPA generally recommends that this response option be supplanted, when feasible, by installing, operating, and maintaining an engineered exposure control that reduces or eliminates vapor entry into the building until remediation of subsurface vapor sources is complete and terminated.

- Temporary relocation may be implemented for buildings where conditions warranting prompt response action (see Section 7.5) and cannot be adequately addressed by other means.[218]

None of these options entails reducing the level of vapor-forming contamination in the subsurface medium (see Section 8.1). EPA generally recommends that these response options be supplanted, when feasible, by installing, operating, and maintaining an engineered exposure

[218] For response actions carried out under Sections 104(a) and 106(a) of CERCLA, OSWER Directive 9230.0-97 (*Superfund Response Actions: Temporary Relocations Implementation Guidance* (EPA 2002d)) states: "Temporary relocation should not be selected if health and safety risks or circumstances that pose an unreasonable inconvenience can be adequately addressed by other means without significantly increasing the overall cost or duration of the response action." Similarly, OSWER Directive 9355.0-71P (*Interim Policy on the Use of Permanent Relocations as Part of Superfund Remedial Actions* (EPA 1999f)) states: "EPA's preference is to address the risks posed by the contamination by using well-designed methods of cleanup which allow people to remain safely in their homes and business." OSWER Directive 9230.0-97 provides recommended procedures and other policies for temporarily relocating residents when this response action is selected and implemented under Sections 104(a) and 106(a) of CERCLA.

control that reduces or eliminates vapor entry into the building (see Section 8.2.2), until remediation of subsurface vapor sources is complete and terminated.

8.2.2 Active Depressurization Technologies for Existing Buildings

This section provides a brief overview of engineered systems that can be used to reduce or eliminate soil vapor intrusion in existing buildings, along with a summary of steps and considerations for selecting an appropriate technology for a given building. The focus is on active depressurization technologies most commonly employed for reducing soil vapor intrusion into buildings. This focus does not mean, however, that active depressurization technologies are always preferred over other mitigation methods or that they will be the best option for every site. More detailed information on vapor intrusion mitigation systems for existing buildings, including sub-membrane ventilation systems and passive technologies,[219] can be found in several EPA publications (e.g., EPA 2008c).

Active depressurization technologies (ADT) have been used successfully to mitigate the intrusion of radon into buildings and have also been successfully installed and operated in residential, commercial, and school buildings to control vapor intrusion from subsurface vapor-forming chemicals. ADT systems are widely considered the most practical vapor intrusion mitigation strategy for most existing buildings, including those with basement slabs or slab-on-grade foundations. ADT systems are generally recommended for consideration for vapor intrusion mitigation because of their demonstrated capability to achieve significant concentration reductions in a wide variety of buildings[220] and their moderate cost.

Sub-slab depressurization (SSD) systems, a common type of ADT system, function by creating a pressure difference across the building slab to prevent soil gas entry into the building (i.e., overcoming the building's natural under-pressurization, which is the 'driving force' for vapor intrusion; see Section 2.3). Creating this pressure difference is accomplished by extracting soil gas from beneath the slab and venting it to the atmosphere.[221] For the system to be effective by this mechanism,[222] this soil depressurization must be established and maintained at least near the primary openings for soil gas entry (EPA 1993a). Construction of SSD systems entails opening one or more holes in the existing slab, removing soil from beneath the slab to create a "suction pit" (6–18 inch radius), placing vertical suction pipes into the holes, and sealing the

[219] As noted in Section 3.3, engineered exposure controls that do not involve mechanical operations (e.g., creating a barrier between the soil and the building that blocks openings from soil gas entry into the building) are referred to as "passive."

[220] Folkes and Kurz (2002) describe a case study of a vapor intrusion mitigation program in Denver, Colorado. Sub-slab depressurization systems and/or sub-membrane depressurization systems were installed in 337 residential homes to control indoor air concentrations of 1,1-dichloroethylene (DCE) resulting from migration of vapors from groundwater with elevated 1,1-DCE concentrations. Over three years of monitoring data for 301 homes have shown that these systems are capable of achieving the very substantial reductions in concentrations in indoor air. Approximately one quarter of the systems warranted minor adjustment or upgrading after initial installation in order to achieve the state standards established for indoor air exposure.

[221] Depending, in part, upon location and prevailing statutes and regulations, governmental permits or authorizations may be required for venting systems that exhaust to the atmosphere.

[222] A second mechanism by which ADT systems can function is diluting the vapor concentrations beneath the slab and foundation (EPA 1993a, 2008c). Engineered controls designed and operated to use this mechanism predominately are often referred to as sub-slab ventilation systems.

openings around the pipes. These pipes are then connected together to a fan, which draws soil gas from the sub-slab area through the piping and vents it to the outdoors.[223] Sealing known and accessible openings in the slab and foundation can reduce the flow rate of conditioned indoor air that can be pulled into the sub-slab region by the suction wells and the sub-slab depressurization (EPA 2008).

SSD systems were first developed for radon reduction (EPA 1993a) and operate under similar design principles as radon mitigation methods. Figure 8-1 illustrates such an SSD system.

When sumps and associated drain tile systems are present, they may also be depressurized to prevent soil gas entry into the building (again, overcoming the building's natural under-pressurization). This variation on active depressurization is often referred to as drain-tile depressurization (DTD). Depressurization of drain tiles located near a foundation wall can help control soil gas entry at the joint between the foundation wall and slab. Figure 8-2 illustrates such a DTD system.

If the building has hollow block walls, the usual sub-slab suction point may not adequately mitigate the wall cavities, which may be particularly important if the outside surfaces are in contact with the soil. In these situations, the void network within the wall may be depressurized by drawing air from inside the wall and venting it to the outside. This method, called "block-wall depressurization" (BWD) is often used in combination with SSD. Because uniform depressurization of block walls can be difficult, BWD is generally recommended only when sub-slab or DTD prove inadequate to control vapor intrusion. Figure 8-3 illustrates such a BWD system.

In buildings with a crawl space foundation or a basement with a dirt floor, a flexible membrane may be installed over the floor to facilitate depressurization of the soil gas beneath the membrane, which prevents vapors from intruding into the crawl space or basement air. To maximize the effectiveness of a sub-membrane depressurization (SMD) system, EPA recommends the membrane cover the entire floor area and be sealed at all seams and penetrations. Figure 8-4 illustrates such an SMD system.

Extensive guidance is available for the design, sizing, installation, and testing of ADT systems for radon control in existing and new homes and large institutional (e.g., school) and commercial buildings. EPA recommends that ADT systems be designed and installed by qualified persons, typically environmental professionals and licensed radon contractors. EPA guidance for design of ADT systems can be found in several publications (e.g., EPA 1993a, 2008c). EPA recommends documenting each constructed ADT system via a system manual, as described further in Section 8.5.

The Vapor Intrusion Mitigation Quick Guide provided in Table 8-1 summarizes a list of steps for selecting and implementing a vapor intrusion mitigation system in existing buildings.

[223] A central issue that determines the design and effectiveness of ADT systems is the ease with which suction at one location can extend to other subsurface areas underneath the building. Where a good and uniform layer of aggregate (e.g., gravel or crushed rock) was placed underneath a slab foundation during construction, for example, such hydraulic control and communication can generally be expected to be good (EPA 1993a). Where the layer of aggregate under a slab is interrupted or uneven to a significant degree, additional suction pipes will generally be needed and their location will be increasingly important.

TABLE 8-1
VAPOR INTRUSION MITIGATION QUICK GUIDE FOR EXISTING BUILDINGS

Step 1: Consider Prompt Response Actions

It may be appropriate to implement certain interim measures before engineered controls are constructed and operated, as warranted and feasible. For example, building ventilation can be increased, cracks and other openings in the floor or foundation (that otherwise allow soil gas entry) can be sealed, or indoor air treatment can be conducted (refer to Section 8.2.1).

Step 2: Select a Building Mitigation System

The initial step in selecting the appropriate vapor intrusion mitigation technology is to conduct a visual inspection of an existing building. The selection of a vapor intrusion mitigation system primarily depends on building characteristics and contaminant concentrations. In the majority of cases, a type of active depressurization technology (ADT) can be an efficient, reliable, and cost-effective vapor intrusion mitigation technique. In some cases, however, other approaches may be preferable.

Factors that may prompt consideration of vapor intrusion mitigation approaches other than ADT include foundation conditions that prevent development and extension of a suction field below the building.

If there are no factors that would rule out an ADT technology, appropriate systems that can be considered include:

- Sub-slab depressurization (SSD) systems, particularly in houses having slabs (basements and slabs on grade) where drain tiles are not present.
- Drain-tile depressurization (sump/DTD or remote discharge/DTD) when drain tiles are present.
- Sub-membrane depressurization (SMD) in buildings with a crawlspace foundation or a basement with a dirt floor,
- Block-wall depressurization (BWD), usually used only as a supplement to SSD, DTD, or SMD to better mitigate vapors found to be migrating through the wall.

Step 3: Design Building Mitigation System

EPA recommends the final detailed design of the selected vapor intrusion mitigation technology specify the number and location of suction points, location and size of piping, suction fan, piping network and exhaust system, and sealing options to be used in conjunction with the ADT technology. Pre-mitigation diagnostic testing can provide information about the suction field underneath a building and pressure differences that will need to be overcome (EPA 1993a) if the ADT system is to be effective. Diagnostic testing during installation can also help verify the adequacy of the design.

Step 4: Install Building Mitigation System

EPA recommends that the vapor intrusion mitigation system be installed consistent with design specifications by equipment manufacturers, local permit conditions and regulations, and relevant industry standards.

Step 5: Confirm the Installed System is Operating Properly

EPA recommends a visual inspection of the installed system as a routine quality assurance step to confirm that all construction details have been completed. Post-construction monitoring is recommended (refer to Section 8.4) to demonstrate the ADT system is operating appropriately and effectively. Where a vapor intrusion mitigation system is not performing adequately, post-construction diagnostic tests can be helpful in trouble-shooting (EPA 1993a).

Step 6: Ensure Proper Operation and Maintenance of Vapor Intrusion Mitigation System (refer to Sections 8.3 and 8.4)

EPA recommends proper system maintenance and periodic inspections and monitoring to ensure the system is operating as designed and is effective at reducing indoor air concentrations to (or below) target levels. EPA recommends that site managers provide the building owner/occupant with information to help ensure proper operation and maintenance of the system.

EPA recommends that periodic inspections include periodic measurements to confirm that the building mitigation system is continuing to perform adequately.

The U.S. Navy has issued a concise fact sheet that contains useful technical information (DoN 2011b).

8.2.3 Approaches and Considerations for New Buildings

The ADT systems described above are generally available for new buildings also. However, a wider array of approaches and technical options is typically available to mitigate or avoid vapor intrusion for new buildings, compared to existing buildings. These options potentially include the choice of building location and opportunities to modify the building design and construction, which are not available for existing buildings. For example:

- At some sites, contaminated areas most likely to produce unacceptable vapor intrusion exposures can be avoided and designated for another purpose, such as recreational space or undeveloped landscape.

- Mitigation needs can also be considered in the selection of heating and cooling systems, which are normally selected based only on economics, aesthetics, preference, and custom. A system design that avoids creating under-pressurization inside the structure and maintains over-pressurization inside the structure may be effective in mitigating vapor intrusion.

- Passive barriers, such as a low-permeability membrane, can be more readily installed between the soil and the building during new building construction. Passive barriers are intended to reduce vapor intrusion by limiting openings for soil gas entry. However, passive barriers as stand-alone technologies may not adequately reduce vapor intrusion owing to difficulties in their installation and the potential for perforations of the barrier during or after installation. They are commonly combined with ADT systems or with sub-membrane ventilation systems to help improve their efficiency.

- Venting layers can be more readily installed between the soil and the building during new building construction.[224]

- New buildings may be designed to include a highly ventilated, low-occupancy area at ground level, such as an open parking garage.

Steps 2-6 of the Vapor Intrusion Mitigation Quick Guide provided in Table 8-1 are also pertinent to newly constructed buildings. EPA guidance for selecting, designing, and installing vapor intrusion mitigation systems for new buildings can be found in several publications (e.g., EPA 2008c). The U.S. Navy has issued a concise fact sheet that contains useful technical information (DoN 2011c).

[224] Constructed sub-slab ventilation systems typically consist of: a venting layer (e.g., filled with porous media such as sand or pea gravel; or suitably fabricated with continuous voids) below a floor slab to allow soil gas to move laterally to a collection piping system for discharge to the atmosphere; and a sub-slab liner that is installed on top of the venting layer to reduce entry points for vapor intrusion. These and other sub-slab ventilation systems function by drawing outside air into and through the sub-slab area, which dilutes and reduces concentrations of vapor-forming chemicals, and provides a route for soil gas to vent to the atmosphere or migrate outside the building footprint, rather than into a building.

8.2.4 Owner/Occupant Preferences and Building Access

Building owners and occupants can initially be notified in various ways that their home or building warrants construction and operation of a building mitigation system. Section 9.5 provides information regarding such notifications and other messages pertaining to building mitigation.

Whereas EPA managers and mitigation system designers may be primarily concerned with the performance, cost-effectiveness, and reliability of any mitigation system, the building owners and occupants may have additional perspectives and opinions that warrant consideration during technology selection, design, construction, and operation. For example, owners and tenants will often have strong opinions about where fans and piping are located, what level of fan noise is acceptable, and what quality of construction craftsmanship is satisfactory. When there are multiple mitigation options (for example, at a large commercial building), EPA recommends these options be presented fairly to the building owner and tenants, explaining the advantages and disadvantages associated with each and describing the rationale for the preferred alternative.

In some cases, obtaining and scheduling access to a building can be difficult, whether the structure is a commercial or institutional building or a private residence. Commercial building tenants may not want construction activities disrupting business operations. Some homeowners/tenants may resist granting access to their home. Other homeowners/tenants may prefer to schedule tests before or after their work-day. To address these practical and logistical concerns, EPA recommends that an access agreement(s) be executed between the property owner, any tenants, and the mitigating entity to ensure appropriate access as needed to operate, maintain, and monitor the engineered exposure controls in each impacted building.

8.3 Operation and Maintenance of Vapor Intrusion Mitigation Systems

For purposes of this Technical Guide, operation and maintenance (O&M) is used generically to refer to periodic inspections, component maintenance or replacements, repairs, and related activities that are generally necessary to ensure continued operation and effectiveness of engineered exposure controls to mitigate vapor intrusion. EPA generally recommends that such O&M activities be conducted routinely, be documented in an O&M plan (as described further in Section 8.5), and consider recommendations of equipment manufacturers, if any, and site-specific factors. Additional information about ensuring continued effectiveness of systems is available in EPA (2009b).

Design specifications for vapor migration systems may include (1) a maintenance frequency that varies over the operating period of the mitigation system and/or (2) a provision to evaluate and modify the frequency based on data or information obtained during monitoring and maintenance. For example, it may be acceptable to reduce inspection or maintenance frequency once efficient system operation has been demonstrated for at least an initial year, with triggers for additional, unscheduled inspections following alarms (from warning devices) and floods, earthquakes, and building modifications, if any.

Typical O&M activities for either passive or active systems may include, but are not limited to:

- Routine inspection of all visible components of the vapor intrusion mitigation system, including fans, piping, seals, membranes and collection points, to ensure there are no

signs of degradation or blockage. EPA recommends that the as-built drawing for the vapor intrusion mitigation system be examined to verify the system configuration has not been modified.

- Visual inspection of the building to evaluate whether any significant changes were made (such as remodeled basement, new furnace) that would affect the design of the vapor intrusion mitigation system or the general environment in which it is operated. A crawl space SMD membrane, for example, may warrant repair or replacement if its integrity is compromised.

- Visual inspection of the area of concern (including basement floor and wall seals, sumps, floor drains and utility penetrations) to ensure there are no significant changes in conditions that would warrant modification of the system design.

- Routine monitoring of vent risers for flow rates and pressures generated by the fan to confirm the system is working and moisture is draining correctly.

- Routine maintenance, calibration and testing of functioning components of the venting system consistent with the manufacturers' specifications.

    - Pressure readings for both active and passive depressurization systems as well as positive pressurization systems (e.g., periodic verification of measurable pressure differences across the slab).

    - Confirmation that the extraction fan is operating.

    - SSD system fans generally can function well for prolonged periods without maintenance; however, EPA recommends fans be replaced periodically throughout the operating life of the system (e.g., every 4 to 10 years) to avoid breakdowns and associated problems.

- Inspection of external electrical components to identify undesirable conditions, such as excessive noise, vibration, moisture, or corrosion, and to verify that the fan cut-off switch is operable.

    - Inspection of the fan(s) is important throughout the operating period but may be particularly important near the end of its expected lifespan. Noisy fans typically indicate problems with ball bearings and warrant replacement on that basis.

    - Confirmation of adequate operation of the warning device or indicator.

- Confirmation that building owner/occupants are knowledgeable about how to maintain system operation. Confirmation that a copy of the O&M manual is present in the building and has been updated as necessary.

EPA also recommends that the site team determine if there has been any change in ownership/occupant. If such a change has occurred, EPA recommends the site manager work with the new owner/occupant to ensure continued integrity and operation of the vapor intrusion mitigation system.

8.4 Monitoring of Vapor Intrusion Mitigation Systems

Regardless of the type of system selected for mitigating vapor intrusion in a given building, EPA recommends monitoring to demonstrate that performance standards are achieved at the time of installation and that those performance standards continue to be met throughout the operating period of the mitigation system. EPA recommends that any monitoring program developed for a building mitigation system be based upon site-specific considerations, including the degree of risk or hazard being mitigated, the building use, the technology used to mitigate vapor intrusion, whether the subsurface vapor source(s) is stable in extent and concentration, and coordination with site remediation efforts. For example:

- An older building with highly volatile chemicals at high concentrations may need a more intense level of monitoring than a new building with lower concentrations of less volatile chemicals.

- Passive systems are generally less predictable and less efficient at preventing vapor intrusion than active systems and, therefore, typically warrant more intensive monitoring, all else being equal.

- When contaminated groundwater plumes are migrating to new areas (i.e., expanding) or concentrations in shallow groundwater are increasing, increased frequency and intensity of mitigation monitoring may be warranted.

- During start-up, some remediation methods have the potential to alter soil gas conditions in ways and to a degree that may be difficult to predict. Increased frequency and intensity of mitigation monitoring may be warranted when such remediation methods are implemented near buildings undergoing mitigation.

Mitigation monitoring will generally entail two phases: (i) an initial post-construction phase, which is generally more intensive; and (ii) a subsequent phase, which may be comprised of fewer diagnostic tests to be conducted periodically. As with radon mitigation systems (EPA 1993a, Section 11.1.2), results of indoor air sampling during initial post-construction monitoring may be used to demonstrate that the occupant's exposure to vapor-forming subsurface contaminants has been reduced as anticipated. In addition, pressure field measurements in the subslab region can be used to demonstrate that the system has attained hydraulic control and communication (e.g., depressurization in the case of an ADT system) over the footprint of the building (or portion of a large building, as appropriate, considering the extent of subsurface contamination). Adjustments to the mitigation system and/or additional diagnostic testing (EPA 1993a, 1993c) may be warranted if the results of such testing do not clearly demonstrate that the system is achieving its intended performance and effectiveness. Once an adequate demonstration of effectiveness has been made for the vapor intrusion mitigation system, periodic monitoring is recommended to verify that this performance is sustained; for this purpose, monitoring may be comprised of fewer types of tests than during the immediate post-construction (i.e., start-up) phase at the discretion of EPA when the subsurface vapor source(s) is stable. Examples of various monitoring scenarios for these two phases are provided in Table 4 of CalEPA (2011), Table 6-2 of NJDEP (2012), and Table 3-1 of MADEP (2011). Additional information about ensuring continued effectiveness is available in the *Operational and Functional Determination and the Transfer of Fund-lead Vapor Intrusion Mitigation Systems to the State* (EPA 2009b).

When monitoring to assess the performance and effectiveness of building mitigation technologies, EPA recommends employing the methods, approaches described in Sections 5.4, 6.2, 6.4 and 7.0 of this Technical Guide. EPA also recommends that monitoring programs that assess the performance and effectiveness of remediation and mitigation systems be documented, preferably in work plans similar to those recommended herein for characterizing and assessing the vapor intrusion pathway (see Section 6.2). Such vapor intrusion monitoring plans may be incorporated as part of a comprehensive remedial design and operations manual or as a stand-alone document, depending upon site-specific circumstances. In addition, EPA recommends that data and other results obtained through such monitoring programs be documented (e.g., in the administrative record), as they become available.

The remainder of this section identifies and further discusses some elements commonly incorporated in monitoring programs for active depressurization technologies.

Pressure Measurements

Sub-slab probes can be used to monitor differential pressures for a direct indication of the hydraulic performance of ADT systems (i.e., the pressure difference across the slab prevents soil gas entry); see Section 2.3. For basements, the walls that are underground become part of the critical building envelope that must prevent soil gas entry. For subsurface depressurization systems, EPA recommends that the pressure gauge be monitored quarterly to verify the system is operating efficiently. A reduced monitoring frequency may be appropriate after one year of successful operation of the remedial system.

Tracer Testing

Openings within the building or leaks in the mitigation system can affect system performance. Tracers can be used either for leak detection through barriers, building materials or system components (piping, for example) or to measure the air exchange rate in the building.

Smoke testing is a qualitative form of tracer testing used to detect leaks (e.g., at seams and seals of membranes in SMD systems or at potential leakage points (openings) through floors above sealed crawl space systems or through conduits that facilitate preferential vapor migration), or to test airflow patterns. A limitation of smoke testing in existing structures is that non-noxious smokes can be expensive, and cheaper high-volume smoke sources can leave undesirable residues. The efficacy of smoke testing in some applications has been questioned on the grounds that many leaks are too small for visual detection using this method (Maupins and Hitchins 1998, Rydock 2001), and that leaks large enough to detect using smoke could be detected other ways. More quantitative methods have been recommended, such as tracer testing with instrumentation for quantitative results.

Air Sampling

Once an adequate demonstration of vapor intrusion mitigation system effectiveness has been made, indoor air quality generally will be acceptable as long as an adequate pressure difference is maintained throughout the footprint of the building. Periodic or intermittent sampling of indoor air, nevertheless, warrants consideration, since indoor air data can provide direct confirmation that the system is reducing exposure levels of vapor-forming chemicals and because depressurization technologies can be expected to alter the distribution of vapors in the vadose zone and available for soil gas entry, if any.

Weather-Related Considerations

EPA recommends that weather conditions be noted during monitoring activities (EPA 1993a). Weather conditions, such as temperature and precipitation, can affect the performance of a vapor intrusion mitigation system. For example, cold temperatures may increase the building depressurization created by the thermal stack effect and thus increase the driving force for soil gas entry, depending upon the height of the house and the temperature difference between indoors and outdoors (see Section 2.3). As a result, the ADT system may need to overcome more building depressurization than originally considered when designed. Precipitation may also increase moisture in the fill under the slab, which may affect the performance of the system, and is a factor to consider in developing a monitoring program.

Alarms

Alarms generally are used as part of a monitoring program to ensure that malfunctions of vapor intrusion mitigation systems are timely and readily detected and addressed. According to ASTM (2003), "All active radon mitigation systems shall include a mechanism to monitor system performance (air flow or pressure) and provide a visual or audible indication of system degradation and failure" (i.e., an 'alarm'). ASTM goes on to say, "The mechanism shall be simple to read or interpret and be located where it is easily seen or heard. The monitoring device shall be capable of having its calibration quickly verified on site." Such devices may indicate operational parameters (such as on/off or pressure indicators) or hazardous gas buildup (such as percent LEL indicators). EPA concurs with the cited advice from ASTM and recommends it be considered when monitoring and maintaining mitigation systems for vapor-forming chemicals and sites addressed by this Technical Guide.

In particular, EPA recommends that system failure alarms be installed on active depressurization systems, and appropriate responses to alarms be communicated by the building owner/occupants. EPA also recommends that alarms be placed in readily visible, frequently trafficked locations within the respective building and their proper operation be confirmed on installation and monitored periodically.

Placards

EPA also recommends that permanent placards be placed on the system to describe the system's purpose and operational requirements (e.g., power source) and instructions on what to do if the system does not operate as designed (for example, a phone number to call for corrective action). EPA recommends the placard provide information about how to read and interpret the monitoring instruments or warning devices provided. EPA also recommends that these placards be placed as close to the monitoring/alarm part of the system as possible, as well as close to the fan or other active parts of the system.

8.5 Documentation of Engineered Exposure Controls for Vapor Intrusion Mitigation

EPA recommends that documentation be provided to building owners and occupants and appropriate regulatory agencies[225] describing the vapor intrusion mitigation system (i.e., a 'system manual') and its associated O&M (i.e., an 'O&M plan'). The system manual provides a detailed record about the mitigation system, including as-built drawings, permits (if any), copies of agreements, and construction/layout plans, whereas the O&M manual describes the O&M activities to be conducted routinely and identifies which party is responsible for these O&M activities. Additional information about ensuring continued effectiveness is available in *Operational and Functional Determination and the Transfer of Fund-lead Vapor Intrusion Mitigation Systems to the State* (EPA 2009b).

O&M Plan

O&M plans generally are prepared on a site-specific basis, and they often are particularly useful at sites where:

- Monitoring is needed to verify remedial effectiveness.
- The remedial system warrants periodic adjustments and maintenance.
- Human health risk would result if the system fails or if site conditions change.
- Conditions that would trigger specific contingent response may occur sporadically or episodically.

Some site remedial systems may also warrant the use of a regulatory agency-approved contingency plan or similar corrective response document approved by the regulatory agency to identify conditions that may trigger the need for additional maintenance, collection of additional data, modifications of monitoring frequency, or other responses to ensure the remedy remains effective.

Communication with building owners and occupants about vapor intrusion and the O&M of a vapor intrusion mitigation system is critically important. For example, building owners may be concerned about some aspect of system operation and decide to turn it off. It is important to communicate that turning off the system may result in harmful indoor air concentrations inside the building.

System Manual

The specific contents of the system manual will depend on the type of system. EPA recommends, however, that the system manual generally include at least the following information or items:

- Cover/transmittal letter;

[225] For example, EPA recommends the potentially responsible party (PRP) provide a system manual and O&M plan to EPA at PRP-lead Superfund sites.

- Description and diagram of final as-built system layout with components labeled;
- Building permits for a vapor intrusion mitigation system;
- Pre- and post-mitigation air and gas sampling data;
- Pre- and post-mitigation diagnostic test data;
- Copies of contracts and warranties;
- Proper operating procedures of the system;
- Contact information of the contractor or installer;
- Copy of signed access agreement;
- Copy of vapor mitigation system O&M agreement;
- Copy of pre-mitigation sample result letter (see Section 9.4);
- Copy of post-construction sample result letter;
- Contact information in case of future questions; and
- Inspection and maintenance guidelines.

User's Guide

Documentation typically is also provided to the property owner and occupant in the form of a user's guide suitable to keep lay persons informed about the system and to provide a summary reference in case questions or issues arise pertaining to the system.

A user's guide is a brief summary of why a vapor intrusion mitigation system was installed at a property and how the system works, and may include the following: (1) a brief description of the system and its proper range of operation; (2) contact information for the party responsible for responding to malfunctions and ensuring the system performs properly; and (3) information about routine maintenance to be conducted by the owner/occupant, if any. EPA recommends that a user's guide be placed near the system for quick access and easy reference (e.g., into a clear protective sleeve and attached to the main extraction pipe of the ADT system). An easy-to-read user's guide may be especially helpful at rental properties because the guide informs each new tenant about what the system is and why it was installed.

8.6 Use of Institutional Controls

ICs may be used to restrict certain land uses, buildings, or activities that could otherwise pose an unacceptable human exposure via the vapor intrusion pathway.

Response actions for vapor intrusion may include ICs to restrict land use for protection of human health regardless of whether a vapor intrusion mitigation system provides interim measures to control (i.e., reduce, limit) human exposures. ICs can be used as either an interim

response until site cleanup goals are reached or as part of a long-term response where vapor-forming waste remains in place.

General EPA guidance on ICs is provided in *Institutional Controls: A Guide to Planning, Implementing, Maintaining, and Enforcing Institutional Controls at Contaminated Sites* ("PIME IC Guidance") (EPA 2012d). As discussed in the PIME IC Guidance, ICs are non-engineered instruments, such as administrative or legal controls, that help to minimize the potential for human exposure to contamination and protect the integrity of a response action. ICs typically operate by imposing land or resource use restrictions at a given site or by conveying notice to stakeholders regarding subsurface contamination or the possible need to refrain from certain actions that may result in human exposure to hazardous chemicals. For example, ICs may be used to restrict the development and use of properties for certain land uses (e.g., prohibiting residential housing, hospitals, schools, and day care facilities).

In some situations, ICs can be used to restrict access to a property, facilitate response activities conducted by a responsible party or EPA, such as the installation or maintenance of vapor intrusion mitigation systems, or help ensure the integrity of vapor mitigation systems. ICs may also be used to help inform the need for vapor intrusion mitigation for future construction where vapor-forming waste remains in place and may pose unacceptable human health risk due to vapor intrusion.

As described further in Section 2.2 of the PIME IC Guidance, ICs can be described in four general categories:

- Proprietary controls.
- Governmental controls.
- Enforcement and permit tools with IC components.
- Informational devices.

The first three categories (i.e., proprietary controls, governmental controls, and enforcement and permit tools with IC components) typically memorialize and prescribe substantive use restrictions concerning the land or resource use, while informational devices generally operate to provide notice of contamination and any remedial activities to parties. Depending on the nature of the site and the particular jurisdiction in which it is located, certain instruments may not be available or feasible for a particular site. Certain ICs may help facilitate how interim response actions and subsurface remediation are carried out, such as provisions addressing access, O&M of vapor intrusion mitigation systems, and design specifications for buildings (see Example #3 box below).

8.6.1 Evaluating ICs in the Overall Context of Response Selection

As a site moves through a program's response selection process (for example, a Superfund remedial investigation/feasibility study [RI/FS] or RCRA facility investigation/corrective measures study [RFI/CMS]), EPA recommends that site managers develop information about reasonably anticipated future land uses and infer reasonably expected exposure pathways related to land use. This information may be incorporated in the conceptual site model and often can be used to evaluate whether ICs will be needed to ensure protectiveness of current and

reasonably anticipated future land uses over time. EPA's land use guidance (EPA 1995a, 2010c) recommends that the site manager discuss reasonably anticipated future land uses of the site with local land use planning authorities, local officials, property owners, and the public, as appropriate, as early as possible during the scoping phase of the RI/FS, RFI/CMS, or equivalent phase under other cleanup programs.

EPA recommends that the Region's decisions to implement ICs be documented in proposed cleanup plans and in final cleanup decision documents. For example, for CERCLA cleanups, the proposed restriction, and need for ICs would normally be identified in the Proposed Plan for notice and opportunity to comment by potentially affected landowners and the public. Such use restrictions or notices typically are then selected and memorialized in the Record of Decision (ROD).

In some cases, unanticipated changes in land use may occur after the response action is implemented, which may impact the protectiveness of a completed response action and raise questions concerning the effectiveness of the ICs. As a result, vapor intrusion may be identified as a potential human exposure pathway in a subsequent periodic review. In this case, EPA recommends that site managers evaluate options for modifying the original response decision, including the need for new or additional ICs consistent with existing and reasonably anticipated future land uses and other response selection considerations.

8.6.2 Common Considerations and Scenarios Involving ICs

The evaluation of whether an IC is needed at a contaminated site, including one where the vapor intrusion pathway poses a current or potential threat to human health, is a site-specific determination. When evaluating whether an IC will be needed, EPA recommends that EPA Regional staff consider whether the site meets unlimited use and unrestricted exposure (UU/UE), among other factors. UU/UE is generally the level of cleanup at which all exposure pathways present an acceptable level of human health risk for all land uses, including reasonably anticipated future land use scenarios that are considered during response selection.

Common scenarios where ICs may be a useful instrument for fostering protectiveness at a site involving vapor intrusion threats include, but are not limited to, the following:

1. Existing buildings overlie soil or groundwater contamination, or a migrating groundwater plume that is moving toward existing buildings potentially poses a future vapor intrusion threat;

2. Future construction is planned or is reasonably anticipated on a site that overlies subsurface contamination with vapor-forming chemicals;

3. Changes to building construction/design (such as remodeling or ventilation changes) or building use (such as commercial building converted for residential use) potentially affect exposure to the vapor intrusion pathway;

4. Vapor intrusion mitigation systems are needed in buildings, or existing ventilation systems are being utilized for vapor intrusion mitigation, and continued access is sought to facilitate their O&M;

5. Response actions to reduce source contamination will not immediately meet response objectives; and

6. Response actions to reduce or eliminate source contamination will not be taken (for example, where it is technically impracticable to treat groundwater that is the source of vapor intrusion).

Informational ICs may also serve to provide notice to parties, including prospective purchasers, about what land or building uses are compatible with human health risk that may be posed by vapor intrusion at the site. For example, modifications to a building's ventilation or air conditioning system may affect building under-pressurization in a way that fosters a greater potential vapor intrusion threat. Various ICs can be tailored to address construction and design specifications of both existing and future buildings—a local ordinance, for example, may require parties to submit a building design to its building department that incorporates mitigation measures as determined appropriate by a Professional Engineer (P.E.) (see IC Example #1).

In addition to restricting land, building, or resource use, some types of ICs may provide an effective means for addressing O&M at vapor intrusion sites consistent with decision documents and enforcement documents. This could happen, for instance, when an IC specifies that mitigation systems be installed and maintained in future construction or if the use of an existing building changes (e.g., industrial building use changes to mixed commercial or residential uses). Provisions regarding access to and periodic maintenance and testing of the mitigation systems, and other site-specific obligations may be incorporated into the IC (see IC Example #2).

IC EXAMPLE 1:

City of Mandan, North Dakota Ordinance No. 1002 (City of Mandan 2006)

In 2006, the City of Mandan, North Dakota, enacted an ordinance that created an Environmental Institutional Control Zoning District to define an area of downtown Mandan impacted by petroleum contaminated soil and groundwater and to establish ICs for the protection of human health and the environment. Among other provisions, the ordinance requires any person proposing redevelopment, demolition, excavation, grading, or construction activities at properties within the District to submit to the city administrator or their appointee a contingency plan, approved by the North Dakota Department of Health, to evaluate and manage any petroleum contaminated soils or groundwater and any potential petroleum vapor impacts. The contingency plan must be prepared by a P.E. with experience in the environmental field, and the plan must consider and protect against, among other things, the vapor intrusion pathway. In addition, the ordinance also provides for restrictions on construction of new structures within the District. In pertinent part, the ordinance provides:

"Any person proposing to construct a new structure within the District shall submit a design for that structure that incorporates engineered controls to mitigate the effects of the potential presence of petroleum in the subsurface to the city administrator or their appointee. The design must be prepared by a P.E. and the design must be approved by the North Dakota Department of Health and must meet additional applicable codes and standards relative to the presence of petroleum. The design shall protect the public health and the environment by considering, at a minimum a) historic water/product intrusion; b) historic petroleum vapor/odor issues; c) potential future water/product intrusion; and d) potential future petroleum vapor/intrusion. The design shall incorporate vapor barriers, venting system, groundwater suppression/collection, and specialized HVAC as determined appropriate by a P.E."

IC EXAMPLE 2: State IC Legislation

Some states have enacted statutes that directly authorize proprietary controls for the purpose of preventing use in conflict with environmental contamination or remedies. These state statutes divide into ones modeled after the Uniform Environmental Covenants Act (UECA)[226] and other non-UECA statutes.[227] These UECA and non-UECA state statutes tend to provide advantages over traditional common law proprietary controls by reducing certain legal and management complications associated with their use. The Model UECA, for instance, contemplates that the grantee or "holder" of the "environmental covenant" may be given specific rights or obligations with respect to future implementation of the environmental covenant.[228] This ability to oblige parties to undertake affirmative actions at a site, such as long-term maintenance of a cap or O&M of a vapor intrusion mitigation system, through a UECA environmental covenant, is different from traditional common law proprietary controls.

Proprietary controls that bind current and subsequent landowners (that is, the proprietary control "runs with the land") to use restrictions at properties, as well as oblige them to undertake affirmative obligations, may have utility at vapor intrusion sites. For instance, at a contaminated site in Bucks County, Pennsylvania, an environmental covenant executed pursuant to the Pennsylvania Uniform Environmental Covenants Act contained provisions to address vapor intrusion threats. In addition to provisions for access, annual inspections, compliance reporting, and other specifications related to cleanup activities, parties to the environmental covenant agreed to construct slab-on-grade buildings without basements and install vapor barriers as an engineered control to mitigate the potential for vapor intrusion as part of the eventual development of the property. Further, the environmental covenant provided that engineering plans for the vapor barriers first be submitted to and approved by EPA prior to construction. For examples of environmental covenants executed pursuant to the Pennsylvania Uniform Environmental Covenants Act, Act No. 68 of 2007, 27 Pa. C.S. §§ 6501-6517: http://www.depweb.state.pa.us/portal/server.pt/community/land_recycling_program/20541/uniform_environmental_covenants_act/1034860

[226] UECA was developed by the National Conference of Commissioners on Uniform State Laws. See: www.uniformlaws.org.

[227] See, for example, Colo. Rev. Stat. § 25-15-320 (2011); Cal. Civ. Code § 1471 (2011).

[228] "Grantee" is a traditional property law term describing a person to whom property is conveyed. States that have passed legislation based on UECA have created different legal concepts specific to those jurisdictions. For example, UECA jurisdictions typically define "holder" and "environmental covenant" to reflect, respectively, the grantee and the servitude that imposes the land or resource use restrictions. The model UECA provides that "[h]older means the grantee of an environmental covenant…" See definition 6 in Section 2.0 of the model UECA.

8.6.3 Selecting the Right Instrument(s)

When evaluating potential IC instruments, EPA recommends that site managers and site attorneys balance the relative advantages and limitations of IC instruments under consideration—for example, consider legal implementation issues, jurisdictional questions, permanence and enforceability concerns—and select those that best achieve the response objectives. (IC Example #3 describes how these factors were considered at the Middlefield-Ellis-Whisman Study Area.)

EPA guidance on ICs provides detailed considerations regarding the selection of ICs and the relative strengths of the different categories of IC instruments.[229] Ultimately, the selection of ICs is a site-specific evaluation based on the characteristics of the site (for example, the nature and extent of the vapor intrusion threat) and the particular jurisdiction in which it is located. There are times when multiple IC instruments can be "layered" to best ensure protectiveness of the response action while meeting the response objectives outlined in the decision documents.[230]

Because many ICs are created pursuant to state and other non-federal laws, the authority to implement and otherwise oversee these ICs resides with government entities other than EPA. Units of local governments, for instance, typically have jurisdiction to implement, maintain, enforce, and terminate certain governmental controls, such as zoning ordinances and building permit conditions. Therefore, it is important to evaluate the capacity (financial, technical, etc.) and willingness of the entity ultimately responsible for taking over IC responsibilities prior to IC selection.[231] Site managers and site attorneys are encouraged to coordinate early with IC stakeholders so that adequate assurances may be acquired and then subsequently maintained as necessary over time.

Given the potential role of non-EPA entities, it may be appropriate for EPA to facilitate or recommend a process by which IC stakeholders provide similar assurances or otherwise reach a common understanding[232] regarding their respective IC responsibilities to ensure that selected ICs are effectively implemented, maintained, and enforced. At a vapor intrusion site, for example, a zoning ordinance may be effective in preventing or ensuring responsible future development of properties overlying a contaminated groundwater plume that presents a vapor intrusion pathway threat. Such zoning ordinances generally are designed and enacted by the local government. Once enacted, the ordinance must be followed and enforced for it to serve as an effective IC over its lifespan. One inherent limitation of governmental controls, however, is that their implementation, modification, and termination generally follow a legislative process

[229] See Site Manager's IC Guide and Section 3.2 of the PIME IC Guide for a framework to consider when deciding among available ICs.

[230] See Section 3.2 of the PIME IC Guide for more discussion on layering ICs.

[231] See Section 3.8 of the PIME IC Guide on IC stakeholder capacity considerations.

[232] Parties may be able to provide assurances or otherwise reach a common understanding regarding their respective IC roles and responsibilities through various mechanisms that may be available under state law (for example, a Memorandum of Understanding, Memorandum of Agreement, Administrative Order on Consent, contract, City Resolution, or enforceable agreement, etc.). For additional discussion about obtaining or memorializing IC assurances, see Sections 3.3, 3.8, and 4.3 of the PIME IC Guide.

IC EXAMPLE 3: Efforts to Address VI at the Middlefield-Ellis-Whisman Study Area

The Middlefield-Ellis-Whisman (MEW) Study Area is composed of four separate CERCLA sites—Raytheon Corp., Intel Corp. (Mountain View Plant), Fairchild Semiconductor Corp. (Mountain View Plant), and portions of the former Naval Air Station Moffett Field Superfund site—and many distinct parcels with land uses including residential, commercial, and light industrial. In 2009, EPA finalized a Supplemental FS for the MEW Study Area that presented an evaluation of a variety of remedial alternatives that could be used to mitigate potential vapor intrusion into current and future buildings overlying the shallow plume of contaminated groundwater. The FS provided an analysis of ICs using the NCP evaluation criteria: overall protection of human health and the environment; long-term protectiveness and permanence; compliance with applicable or relevant and appropriate requirements; reduction of toxicity, mobility, or volume through treatment; short-term effectiveness; implementability; and cost. The other two NCP evaluation criteria, state acceptance and community acceptance, were evaluated in the ROD Amendment for the vapor intrusion pathway remedy at the MEW Study Area.

In 2009, EPA published the Proposed Plan for the MEW Study Area that identified EPA's preferred alternatives for the vapor intrusion remedy. The Proposed Plan identified the adoption of a municipal ordinance as EPA's preferred IC, but the City of Mountain View and concerned property owners raised concerns that this was not necessary. Instead, EPA worked with the City of Mountain View, California, to have the City formalize its permitting procedures that apply to future construction. These permitting procedures oblige those proposing new building construction within the MEW Study Area to obtain EPA approval of construction plans to ensure that, where necessary, the appropriate vapor intrusion control system is integrated into building construction. In a 2010 ROD Amendment, EPA presented its selected remedy for the vapor intrusion pathway for the MEW Study Area. The ROD Amendment identified a combination of ICs for use at the site. In place of a municipal ordinance as called for in the Proposed Plan, the ROD Amendment selected reliance upon the internally modified permitting procedures by the City of Mountain View's Building, Planning, and Permitting Departments. The City will also implement remedy requirements for projects subject to the California Environmental Quality Act through that law's procedures. With regard to existing commercial buildings where an active remedy is necessary, EPA selected the use of recorded agreements that will help provide notice to current and future owners and occupants, notice to EPA and the MEW Companies when there is a change in building ownership or configuration, and the necessary access to install, maintain and operate the vapor intrusion remedy. These agreements will be binding on and enforceable against future property owners. Additionally, EPA selected the use of a tracking service to provide notice when changes are made to properties within the MEW Study Area. Additional controls that will be implemented by the City of Mountain View include creation of a mapping database to help ensure that parties interested in properties within the MEW Study Area are informed of the appropriate construction specifications when making inquiries with the City.

For more information on the MEW Study Area, see the *Final Supplemental Feasibility Study for the Vapor Intrusion Pathway* (June 2009), *Proposed Plan for the Vapor Intrusion Pathway* (July 2009), and *Record of Decision Amendment for the Vapor Intrusion Pathway* (August 2010), available at: www.epa.gov/region9/mew

outside the authority of EPA that may raise questions regarding the reliability and continued sustainability of the IC. Obtaining early and continued assurances from a local government specifying its commitment to the governmental control is recommended to help address this limitation prior to its selection as part of a final cleanup plan.

Certain IC instruments may not be available for use at a site, depending on federal, state, local, tribal, or other applicable laws. Therefore, after determining the universe of ICs available for use at a particular site, the practical and legal limitations can be evaluated. For example, large sites with widespread contamination pose unique IC challenges. These challenges could arise, for instance, where a contaminated groundwater plume underlies many distinct parcels with multiple property owners/occupants and vapor intrusion is the exposure pathway of concern. Negotiating and implementing proprietary controls with many property owners, some of whom may not be PRPs, may present legal, administrative, and other challenges.[233]

8.6.4 Long-term Stewardship

Long-term stewardship (LTS) activities are intended to help ensure that cleanups remain protective of human health and the environment over time and that reuse activities remain compatible with residual site contamination and associated human health risk potentially posed by the vapor intrusion pathway. LTS procedures vary widely, but they generally are intended to help assure compliance with the response actions at the site, including IC compliance, by providing relevant information in a timely manner to stakeholders who may use the property (e.g., owners, excavators, developers, prospective purchasers or tenants) or to parties who otherwise have IC responsibilities (i.e., an entity with enforcement authority). LTS procedures, for example, may entail provisions to monitor and then inform those responsible for the response actions of potential changes in land use, ownership, tenancy, or building construction at a site. Also, LTS procedures may facilitate monitoring IC(s) so that they remain effective and reliable over time. EPA guidance on ICs generally speaks to LTS procedures in terms of IC maintenance[234] and enforcement activities.[235]

Periodic Reviews

A key part of IC maintenance is a periodic process over the IC life cycle to critically review and evaluate the IC instrument(s). Site managers and other stakeholders can evaluate the status of IC implementation, maintenance and enforcement activities at a site and address any potential IC deficiencies during the periodic review. The CERCLA FYR process,[236] for example, allows site managers to evaluate overall protectiveness of the remedy, including ICs.[237]

---

[233] See Section 4.4 of the PIME IC Guide for strategies for implementing proprietary controls.

[234] The term "maintenance" generically refers to those activities, such as monitoring and reporting, that ensure ICs are implemented properly and functioning as intended.

[235] See Sections 8 and 9 of the PIME IC Guide discussing IC maintenance and enforcement activities.

[236] See CERCLA section 121(c).

[237] For general FYR guidance, see *Comprehensive Five-Year Review Guidance* (EPA 2001) at www.epa.gov/superfund/cleanup/postconstruction/5yr.htm. For a more detailed discussion on IC considerations during the CERCLA FYR process, see *Recommended Evaluation of Institutional Controls: Supplement to the "Comprehensive Five-Year Review Guidance,"* (EPA 2011c).

A list of possible IC-specific issues arising from any periodic review of a vapor intrusion site may include:

- ICs that are specified by the decision documents but are not yet in place;
- ICs that are in place but are not attaining compliance with the use restrictions specified by the decision documents (e.g., land use not compatible with IC-specified use restrictions);
- ICs are not identified in the decision documents but are necessary for the remedy to be protective of human health because of the vapor intrusion pathway; and
- Response selection assumptions change (e.g., toxicity values, potential exposure pathways, or land uses change) and warrant the need for new or different response actions, including additional IC(s).

IC Planning Documents

Responsibilities to monitor and report on IC compliance, among other obligations, may be documented in an Institutional Controls Implementation and Assurance Plan (ICIAP)[238] or other IC-related planning documents.[239] An ICIAP can serve to: (1) document the activities necessary to implement and ensure the long-term effectiveness and permanence of ICs (that is, the IC life cycle); and (2) identify the person(s) or organization(s) who, under state or local law, are responsible for conducting those activities. Some ICs generally fall within the jurisdiction of a particular category of stakeholders. Therefore, in addition to developing a comprehensive planning document, such as an ICIAP, it may be useful for parties who share IC responsibilities (e.g., a PRP and local government regarding the use of governmental controls, such as an ordinance or permitting system) to reach a common understanding and acknowledge various IC roles and responsibilities in a formalized manner. Where possible, EPA recommends that these types of arrangements among IC stakeholders be documented to describe commonly understood roles and responsibilities for proper and effective monitoring, reporting, and other IC maintenance and enforcement activities.

8.6.5 Community Involvement and ICs

EPA recommends that site managers and site attorneys provide adequate opportunities for public participation (including potentially affected landowners and communities) when considering appropriate use of ICs (EPA 2012e). Those opportunities may include providing appropriate notice and soliciting comments about cleanup plans. Community acceptance of the need for ICs to provide protection from residual contamination and public understanding of the legal and administrative steps for maintaining ICs often are important to the long-term effectiveness of ICs.

---

[238] For further guidance on developing ICIAPs, EPA developed *Institutional Controls: A Guide to Preparing Institutional Control Implementation and Assurance Plans at Contaminated Sites* (EPA 2012e).

[239] For example, other types of documents may address IC-related activities and responsibilities at a site, such as a ROD, O&M plan, and land use control and implementation plan for federal facility sites.

8.7 Termination/Exit Strategy

This sub-section focuses on the termination/exit strategy for vapor mitigation response actions. Termination for vapor mitigation activities implemented under CERCLA, RCRA, Brownfields, and federal facilities cleanups can occur when the objectives of these cleanup activities have been met. For purposes of this sub-section, termination refers to the cessation of all activities related to building mitigation, control of subsurface vapor source(s), ICs, and monitoring.

When mitigating vapor intrusion through subsurface source remediation, building mitigation, and ICs, it is important to develop termination criteria, including the rationale for their selection, early in the remedy planning (e.g., alternatives development) process. (Termination criteria generally refer to numeric cleanup levels for each site-specific contaminant and narrative cleanup objectives that are to be attained by the response actions.) EPA recommends that these termination criteria be recorded in decision documents, in any other planning reports, and in monitoring reports. EPA generally recommends also developing and documenting an exit strategy, which clarifies how it will be determined that the termination criteria have been attained (e.g., monitoring data and associated statistics that will be used to demonstrate attainment). This document could be developed in conjunction with the O&M plan and monitoring program so that all stakeholders are provided with a clear and comprehensive set of termination criteria for the remediation and mitigation systems and ICs. If site conditions (e.g., building usage, vapor flux) change during the cleanup activities, it may become necessary to modify the termination criteria and/or strategy.

When reviewing vapor intrusion activities, considerations for evaluating termination activities may include:

- Termination of subsurface remediation activities;
- Termination of engineered exposure controls (building mitigation);
- Termination of the associated ICs; and
- Termination of monitoring.

8.7.1 Termination of Subsurface Remediation Activities

Where feasible, the preferred response to address vapor intrusion is to eliminate or substantially reduce the level of volatile chemical contamination in the source media (e.g., groundwater and subsurface soil) to levels that eliminate the need to mitigate or monitor vapor intrusion, as noted in Section 8.1 of this Technical Guide. If subsurface remediation activities are being conducted at the site, termination of these activities will be contingent on demonstrating that the chemical-specific cleanup levels for the subsurface media have been attained. EPA recommends that the termination criteria and exit strategy for these remediation activities be documented to foster collection and evaluation of appropriate data to support eventual termination of these subsurface activities.

EPA recommends that site-specific monitoring data be evaluated to determine if the termination criteria have been met. Typically, monitoring will continue until the source(s) are remediated to cleanup levels that eliminate the need to mitigate vapor intrusion at the point of exposure. As appropriate, the exit strategy may provide criteria for phased remediation, resulting in a

termination evaluation as source cleanup levels are achieved in parts of the contaminated area. If the subsurface vapor source(s) is not remediated, it is generally anticipated that remediation (and monitoring and any building mitigation) will continue.

Monitoring, in part, could be based on data similar to those that were used in a multiple-lines-of-evidence approach for characterizing the pathway and human health risk or for supporting the decision to undertake preemptive mitigation/early action (e.g., soil gas sampling, sub-slab sampling, or vapor sampling within potentially affected structures). EPA recommends identifying and documenting target concentration(s) that would allow for remediation termination, along with recommended monitoring/sampling frequencies.

If evaluation of the site-specific data indicates an increase in subsurface vapor concentrations during the monitoring period, it may be appropriate to evaluate whether the subsurface remediation plan and the CSM are adequate and appropriate.

Typically, once it is preliminarily determined that the subsurface remediation system(s) may be terminated, EPA recommends a period of attainment monitoring. During the attainment period, EPA recommends that the remediation system (e.g., reagent delivery equipment, soil vapor extraction wells) not be operated for a sufficient period to allow subsurface vapors reach equilibrium and indicate post-remediation conditions. The type and frequency of data collected during attainment monitoring entails a site-specific determination. Additionally, EPA recommends that criteria be described and documented, as part of exit strategy development, to determine when ending the attainment monitoring period is appropriate. To develop an exit termination strategy, site-specific fate and transport data may be used to identify an appropriate time period to allow the vapor concentrations to equilibrate. In addition, the termination of the attainment monitoring period may involve an evaluation of the contaminant attenuation in the vadose zone.

8.7.2 Termination of Building Mitigation

For purposes of this Technical Guide, “termination of building mitigation” refers to ending the use of an engineered exposure control(s) that reduces or eliminates human exposure via the vapor intrusion pathway. Typically, vapor mitigation is implemented when it is determined that (1) unacceptable human health risk to inhabitants is identified, or (2) the system(s) was(were) installed as part of an early action strategy (see Sections 3.3 and 7.8 for a discussion of building mitigation as an early action).

As described in Section 8.2, vapor intrusion can be mitigated in specific buildings using either an active or passive vapor mitigation system (or a combination thereof).

Active Building Mitigation

Generally, building mitigation systems are implemented in conjunction with the investigation and remediation of subsurface vapor source(s). Typically, building mitigation systems will be operated until the source(s) are remediated to attain the cleanup levels (e.g., for the subsurface vapor source(s)) that eliminate the need to mitigate vapor intrusion at the point of exposure. If subsurface vapor source(s) are not remediated, it is generally anticipated that mitigation activities will continue indefinitely. As appropriate, the termination strategy may provide criteria for phased evaluation of system cessation as source cleanup levels are achieved in parts of the contaminated area.

Generally, once the subsurface vapor source(s) is remediated to levels that meet the remedial objectives and protect human health from the vapor intrusion pathway, EPA recommends that the site-specific monitoring data be evaluated to determine if the termination criteria for the building mitigation system have been met. These monitoring data, in part, could be based on data similar to those that were used for characterizing human health risk or for supporting the decision to undertake preemptive mitigation/early action during the vapor intrusion investigation (e.g., sub-slab soil gas sampling and/or indoor air sampling). EPA recommends identifying and documenting target concentration(s) that would allow for system termination, along with recommended monitoring/sampling frequencies. In addition, certain site-specific performance assessment data (e.g., standpipe vapor sampling) may also warrant consideration to make this determination.

Typically, once it is determined that the building mitigation system may be terminated, EPA recommends a period of attainment monitoring. During the attainment period, EPA recommends that the mitigation system (e.g., subslab suction wells or ventilation fans) be offline for a sufficient period to allow vapors beneath the structure reach equilibrium and indicate post-remediation conditions. The type and frequency of data collected during attainment monitoring entails a site-specific determination. Additionally, EPA recommends that criteria be established in the exit strategy to determine when ending the attainment monitoring period is appropriate. To develop an exit termination strategy, site-specific fate and transport data may be used to identify an appropriate time period to allow the vapor concentrations to equilibrate. In addition, the termination of the attainment monitoring period may involve an evaluation of the contaminant attenuation in the vadose zone.

If the attainment criteria evaluation indicates that cleanup levels and objectives are not being met, it may be necessary to continue or resume subsurface remediation and mitigation activities. Once it is determined that the cleanup levels and objectives have been met, the active components of the system may be removed from the building; on the other hand, the building owner may elect to continue to operate the mitigation system under their own discretion and for their own purposes (e.g., radon reduction and moisture control). Once the cleanup levels and objectives have been met, all O&M and monitoring of active mitigation systems specified by EPA can cease.

Passive Building Mitigation

The termination of passive vapor mitigation systems will typically be similar to the criteria established for the termination of active mitigation systems. In summary:

- Like active mitigation systems, passive mitigation systems are typically implemented in conjunction with the investigation and remediation of subsurface vapor source(s).

- Generally, once the subsurface vapor source(s) is remediated to levels that meet the cleanup levels and objectives that will protect human health from the vapor intrusion pathway, EPA recommends that the site-specific monitoring data be evaluated to determine if the termination criteria have been met.

If the site-specific criteria evaluation indicates that cleanup levels and objectives are not being met, it may be appropriate to evaluate the current system's effectiveness or the possible application of an active mitigation system. Once it is determined that contaminant cleanup levels and objectives have been met, all O&M and monitoring specified by EPA can cease. EPA

generally does not have a need to seek removal of barriers or seals that comprise a passive mitigation system as part of termination activities.

8.7.3 Termination of ICs

"Termination of ICs," as used in this Technical Guide, refers to discontinuing any and all ICs specified by EPA because restrictions on land or resource use and/or notices and other informational devices are no longer necessary to help ensure protectiveness of human health (i.e., human health risk from exposures to vapor intrusion, if any, are expected to be acceptable in the absence of all IC(s)). Generally, ICs are implemented in conjunction with the investigation and remediation of source(s). It is anticipated that ICs selected and implemented will be needed until (1) subsurface vapor source(s) are adequately remediated, or (2) restrictions on land, resource, or building use are no longer necessary based on current and reasonably anticipated future exposure scenarios. Therefore, when developing a termination strategy for ICs that have been selected as part of a response action, the strategy is typically based on data collected from the affected media.

EPA recommends that the exit strategy consider and identify cleanup levels for the subsurface vapor source(s). As long as the subsurface vapor source exceeds such cleanup levels, it is generally anticipated that the associated ICs will continue. As appropriate, the termination/exit strategy may provide criteria for a phased IC termination evaluation as source cleanup levels are achieved in parts of the contaminated area.

If the site-specific criteria evaluation indicates that terminating the ICs is appropriate, EPA may conclude that site conditions no longer warrant ICs being used as part of the response action for the vapor intrusion pathway. At this point, EPA could notify the appropriate entity(s), such as local or state government, tribe, affected landowner, or responsible parties, in writing that EPA's response objectives have been met and that the IC need not be maintained. As such, EPA's oversight of the IC(s) can cease.

8.7.4 Termination of Monitoring

For purposes of this Technical Guide, monitoring includes activities conducted to verify that the vapor intrusion pathway does not pose a health concern to building inhabitants while remediation and mitigation activities are underway and in the event that the remediation and mitigation activities are terminated. "Termination of monitoring," for purposes of this Technical Guide, refers to ending any monitoring that was needed to verify that no further response action, including IC-related activity, is necessary to protect human health from indoor air exposures posed by vapor intrusion. When developing termination criteria for monitoring, the decision is generally based on data collected from all the affected media.

As noted above, monitoring is generally implemented in conjunction with the remediation of subsurface vapor sources(s). EPA recommends that the exit strategy consider cleanup levels for all contaminated media. Typically, monitoring will continue until the source(s) are remediated to cleanup levels that eliminate the need to mitigate vapor intrusion at the point of exposure (i.e., allow building mitigation systems to be terminated). If the subsurface vapor source is not remediated, it is generally anticipated that any associated monitoring will continue. As appropriate, the exit strategy may provide criteria for phased monitoring, resulting in a termination evaluation as source cleanup levels are achieved in parts of the contaminated area.

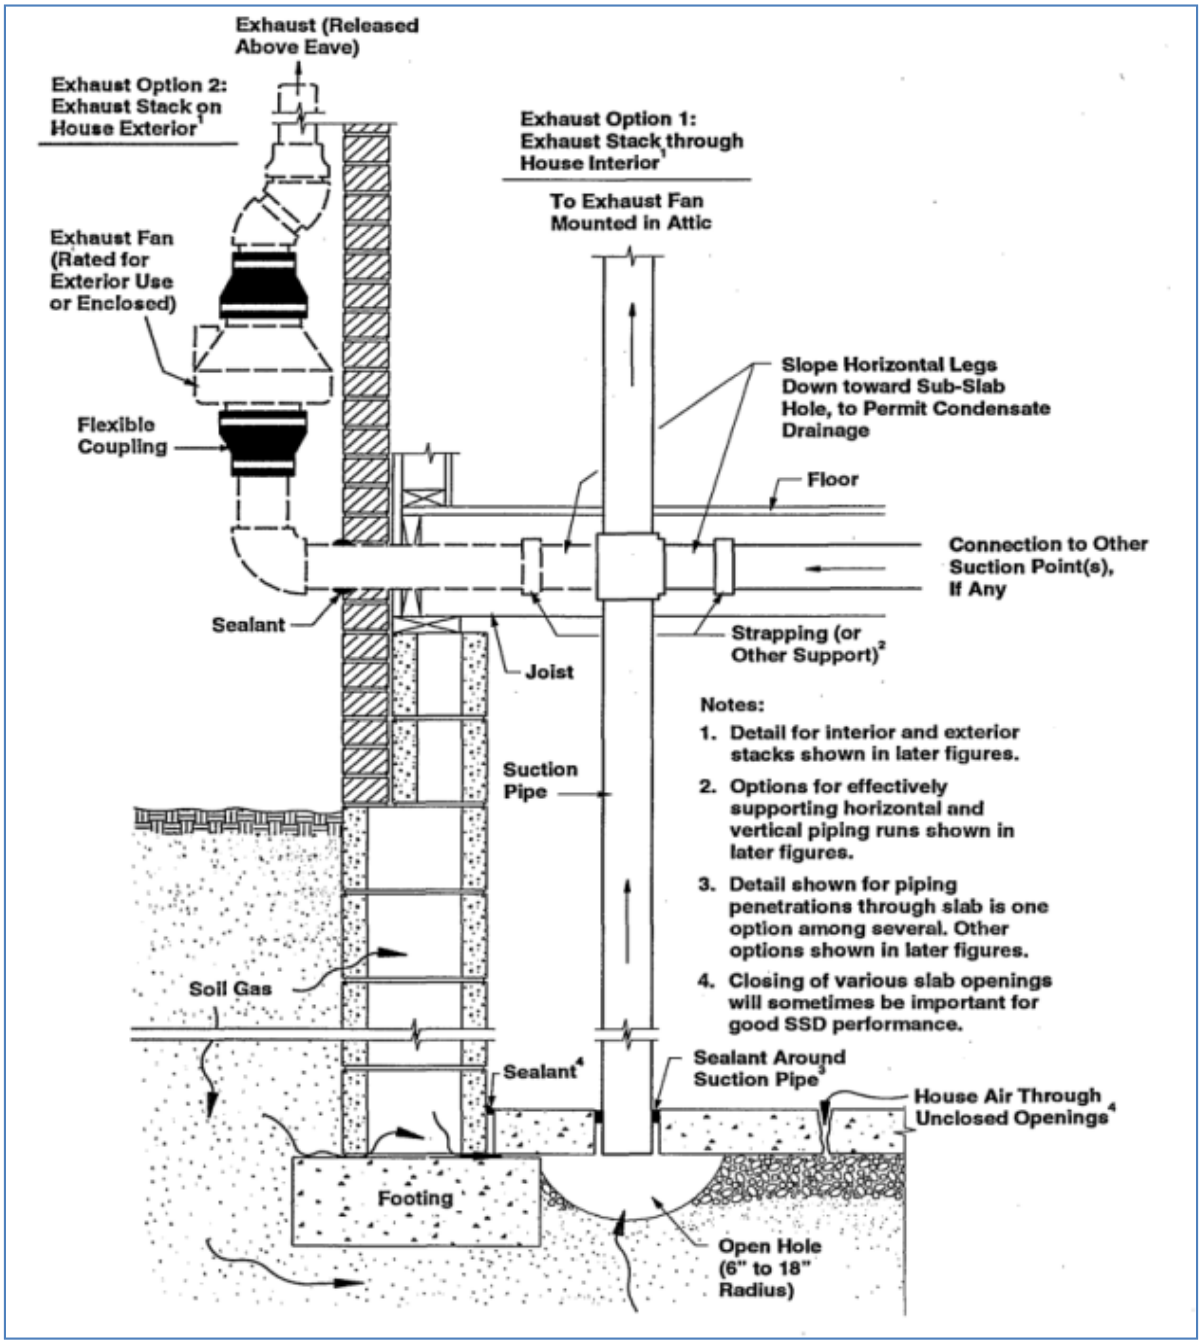

Figure 8-1 Illustration of Sub-slab Depressurization (SSD) System

Note: Shows one example of how a sub-slab depressurization system might be constructed. In this case, the example suction pipe has been inserted vertically downward through the slab from inside the house. Two options are indicated for location of the exhaust fan: one exterior to the building; and the other within an attic. In both of these cases, the exhaust gas stream is to be vented outside and above the building.

Source: EPA (1993a; Figure 1)

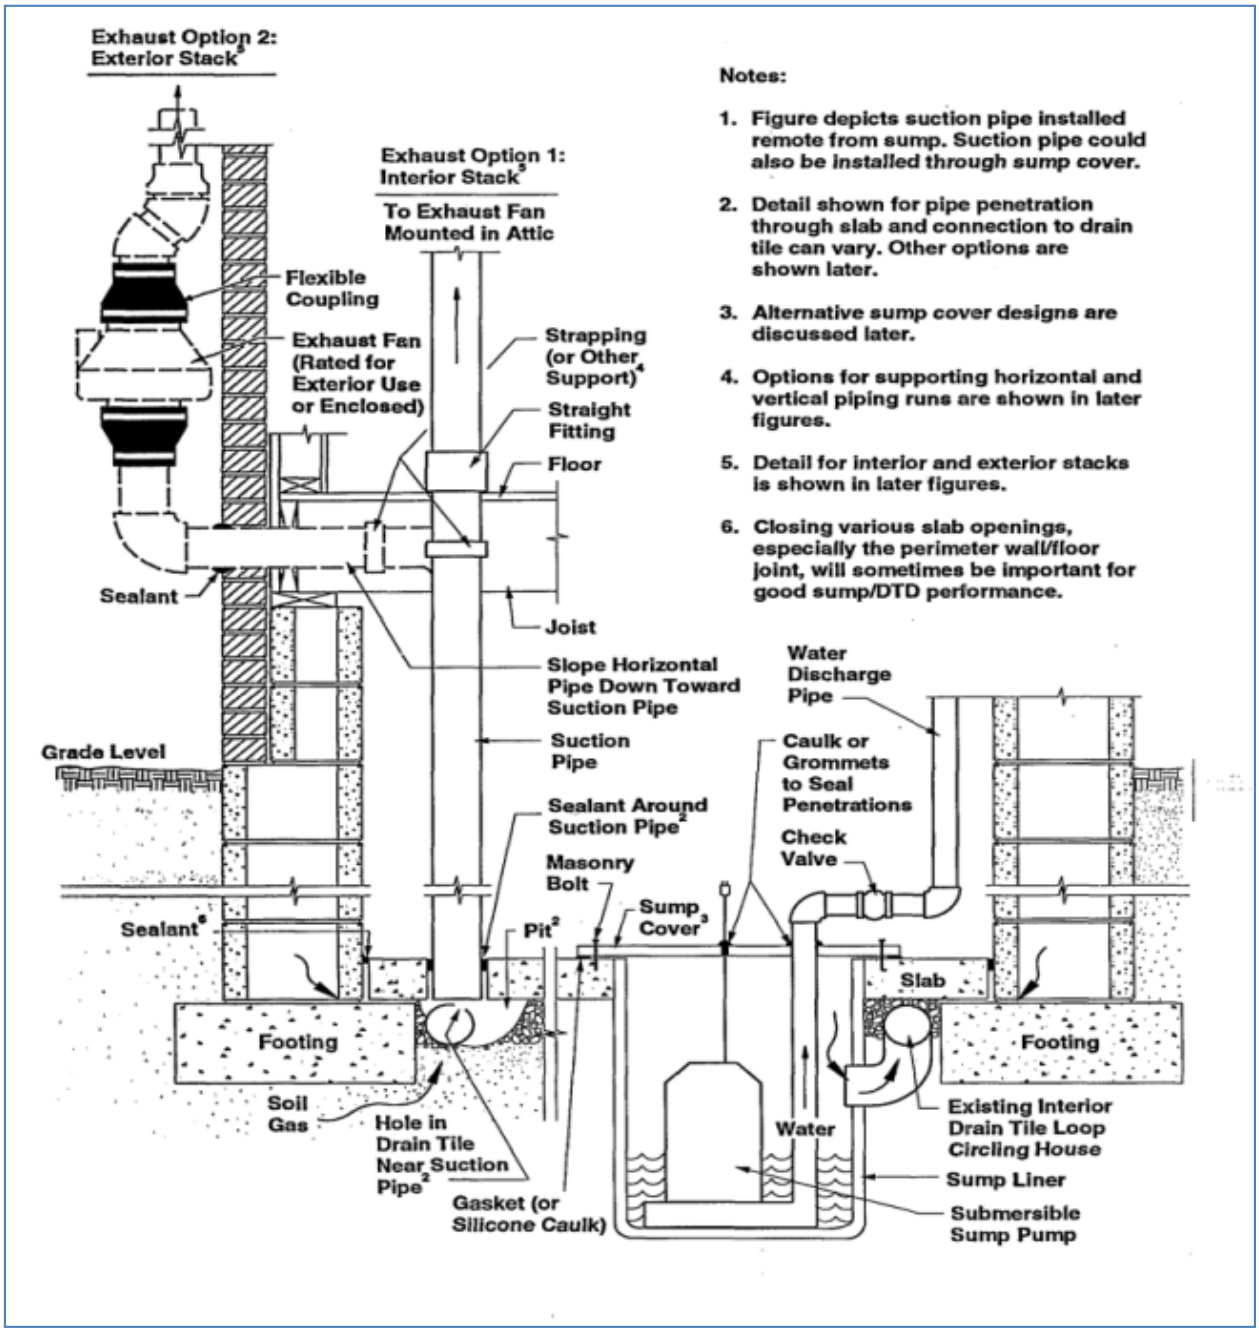

Figure 8-2 Illustration of Drain-tile Depressurization (DTD) System

Note: Shows one example of how a drain-tile depressurization system might be constructed. In this case, tiles are shown draining to a sump in the basement, to which an air-tight cover is sealed. The example suction pipe has been inserted vertically downward through the slab at a location remote from the sump. Two options are indicated for location of the exhaust fan: one exterior to the building; and the other within an attic. In both of these cases, the exhaust gas stream is to be vented outside and above the building.

9.0 PLANNING FOR COMMUNITY INVOLVEMENT

Communicating information about environmental risk is one of the most important responsibilities of site managers and community decision-makers. Simply stated, risk communication, whether written, verbal, or visual statements concerning risk, is the process of informing people about potential and perceived hazards to their person, property, or community.

EPA recommends that human health risk be described in context, recognizing there are personal, cultural and societal dimensions of risk. EPA also recommends providing advice about risk-reduction behavior and encouraging a dialogue between the sender and receiver of the message. The best risk communication occurs in contexts in which the participants are informed about risks they are concerned about, the process is fair, and the participants are free and able to solve whatever communication difficulties arise. *Risk Communication in Action: The Risk Communication Workgroup* (EPA 2007) is one of several resources available that explain the elements of successful risk communication and describe communication tools and techniques.

Thus, community involvement is a key component of any site investigation or other EPA response action. Members of the public affected by environmental contamination can be made aware of what EPA is doing in their community and have a say in the decision-making process. Stakeholder and community involvement is particularly important for sites with vapor intrusion issues, in part because the exposure to toxic vapors may pose a significant human health risk that is unknown to inhabitants (in the absence of mitigation systems), as they potentially arise in homes, workplaces, schools, and places of commerce and gathering. Because of the potentially intrusive nature of assessment and mitigation for vapor intrusion, stakeholder involvement is important throughout the process.

EPA generally recommends that stakeholder and community involvement be conducted from the earliest stage of the site assessment and risk assessment process, with on-going education, two-way communication, and discussion throughout the entire process to create community trust and acceptance. For example, EPA recommends initiating community involvement activities as soon as possible after determining that vapor intrusion may exist at a particular site.

Informing the community about vapor intrusion concerns and plans to conduct an assessment, including sampling, can be resource intensive. Thus, EPA recommends evaluating each project, in coordination with appropriate state and tribal officials, to assess the level of stakeholder interest and need for community involvement during various stages of the decision-making process.

Public Participation and Risk Communication

A meaningful community involvement process is founded upon knowledge of effective public participation and risk communication practices. Public participation refers to the full range of activities that EPA uses to engage communities in the Agency's decision-making process. In 2003, EPA updated its Public Involvement Policy.[240] Its foundation includes seven basic steps to support effective public participation:

[240] EPA Public Involvement Policy (2003): http://www.epa.gov/publicinvolvement/policy2003/index.htm.

1) Plan and budget.

2) Identify those to involve.

3) Consider providing assistance.

4) Provide information.

5) Conduct involvement.

6) Review and use input and provide feedback to the public.

7) Evaluate involvement.

To help implement the steps, EPA developed a series of brochures[241] on effective public participation that outline how to budget for, plan, conduct, and evaluate public participation.

EPA Program-Specific Community Involvement Guidance and Recommendations

CERCLA and other EPA regulations[242] identify specific community involvement activities that are appropriate at certain points throughout the cleanup process. Specifically, in 2005, OSWER published the *Community Involvement Handbook*[243] (EPA 540-K-05-003). The handbook presents legal and policy motivations for Superfund community involvement and includes additional suggestions for involving the community in the Superfund process. In addition, EPA's *Proposed Guidelines for Brownfields Grants* encourages applicants to describe their plans for involving community-based organizations in site cleanup and reuse decisions.[244] The *Grant Funding Guidelines for State and Tribal Response Programs* for brownfields funding also encourage programs to establish, at a minimum, "mechanisms and resources to provide meaningful opportunities for public participation."[245] In addition, in 1995, EPA promulgated the *RCRA Expanded Public Participation* rule (60 FR 63417-34, December 11, 1995)[246] which created additional opportunities for public involvement in the permitting process and increased access to permitting information.[247]

[245] EPA Brownfields State and Tribal Response Program Grants website: http://www.epa.gov/brownfields/state_tribal/fund_guide.htm

[246] Section 7004(b) of the Resource Conservation and Recovery Act provides EPA broad authority to encourage and assist public participation in the development, revision, implementation, and enforcement of any regulation, guideline, or program under RCRA.

[247] EPA *RCRA Public Participation Manual*: http://www.epa.gov/osw/hazard/tsd/permit/pubpart/manual.htm

At sites with vapor intrusion issues, EPA recommends that the site planning team (i.e., the remedial project manager (RPM) or on-scene coordinator (OSC); community involvement coordinator (CIC); risk assessor; the enforcement case team; EPA contractor; state, tribal, or local agency staff; federal agency staff relevant to the site; or others) to consider the following:

- Develop a community involvement plan (CIP) or update the existing CIP.
- Learn about the site and the community to foster development of a CIP that highlights key community needs, concerns and expectations.
- Commit to ongoing, sustained communication activities throughout vapor mitigation and site cleanup efforts.
- Develop a communication strategy[248] and conduct outreach to inform stakeholders about the facts and findings pertaining to the site.
- Obtain written permission, if appropriate and necessary, for building/property access, and involve the property owner/occupant in identifying or removing potential indoor air contamination sources, including inspection of residence and completing an occupant survey.
- Fully communicate and interpret sampling results, and evaluate mitigation options, if any are warranted.
- Recognize preference of owners and occupants for confidentiality with regards to property-specific data.

When considering the most effective community involvement strategies, EPA recommends that its previous involvement be considered, as well as the existence of community or neighborhood groups and the phase of the regulatory process in which vapor intrusion is being addressed. Additional resources for planning and implementing effective community involvement activities are discussed in Section 9.2: Communication Strategies and Conducting Community Outreach.

9.1 Developing a Community Involvement or Public Participation Plan

A CIP is a site-specific strategy to enable meaningful community involvement throughout the cleanup process.[249] CIPs specify EPA-planned community involvement to address community needs, concerns, and expectations that are identified through community interviews and other means. A CIP will enable community members to understand the ways in which they can participate in decision-making throughout the cleanup process. That is, the CIP is a way for EPA to plan for informing and involving the community in the cleanup process and can be a powerful

[248] A communication strategy can be one component of a CIP, but it addresses a specific event, issue, or concern, such as an emergency response to a release, or communicating risk at a site. The CIP, on the other hand, describes an overall strategy for conveying information throughout the cleanup process at a site.

[249] Community involvement plans available at: http://www.epa.gov/superfund/community/pdfs/toolkit/ciplans.pdf

way to communicate EPA's commitment to listening and responding to community concerns, and provide timely information and opportunities for community involvement.

The CIP is intended to be a "living" document and is most effective when it is updated or revised as site conditions change. When developing the CIP document, EPA recommends that the site planning team consider the following steps:

Describe the Environmental Setting and Cleanup Process

Describe the release and affected areas (the site). This includes information about the site, its history, the key issues related to site contamination, and how vapor intrusion fits into EPA's overall cleanup effort at the site.

Describe and Learn about the Community

Describe the community. The community profile is a description of the affected community that summarizes demographic information and identifies significant subgroups in the population, languages spoken, and other important characteristics of the affected community, such as whether the site is located in an area with environmental justice concerns or includes sensitive populations. EPA recommends that the community profile also document information sources and describe how the profile was developed.

Learn about community needs, concerns and expectations: Issues of concern to residents and business owners can be identified through community interviews, informal discussions and interactions, local media reports, and other insights about the affected community. Questions may include:

- What are public perceptions and opinions of EPA and the cleanup process?
- How do people want to be kept informed (i.e., mechanisms to deliver information)?
- How do people want to be included in the decision-making process?
- What are the perceived barriers to effective public participation?
- Are there other sources of pollution that affect the community?
- Have there been past experiences of mistrust or any unique concerns?

This information can be used to recommend any special services to be provided, including technical assistance, formation of a Community Advisory Group, facilitation/conflict resolution, or translation services.

Write and Compile the CIP

Once the site planning team has learned about the community, it is time to put the information together in a way that will be useful to EPA and the community. In addition to the site description, community description, and community needs and concerns, the CIP also may include a reference listing of contacts (name, address, phone, email) useful for the

community or the site planning team. EPA recommends that the contact list generally include contact information for:

- The site planning team.
- Community groups and community leaders.
- Local elected officials.
- Local, state, tribal, and federal agency staff relevant to the site.
- Media contacts (including social media outlets and community journalists).
- Others, as appropriate.

To ensure that the CIP is indeed informed by the community, EPA recommends that a draft of the CIP be shared with the community, and their input and feedback be invited as it evolves. Again, the CIP is intended to be a "living" document and is most effective when it is updated or revised as site conditions change. In some cases, particularly when the CIP is updated or revised for a FYR or where community interest is minimal, a short CIP outlining EPA's plan for community involvement may be all that is needed. For most sites, EPA recommends that the CIP be written to address the community directly, and their active involvement be invited at each stage of the cleanup process.

9.2 Communication Strategies and Conducting Community Outreach

EPA recommends that community outreach activities be initiated as soon as possible after determining that vapor intrusion may exist at a particular site. Informing and educating the community includes distributing information and providing opportunities for EPA to listen to community concerns. EPA recommends community outreach activities be tailored to the community based on information gleaned from community interviews and other methods used in developing the CIP. Public health officials from state, tribal, or local agencies may be helpful in communicating risk information and answering questions from the community.

Communication Strategies

Communication strategies are plans for communicating information related to a specific issue, event, situation, or audience. They serve as the blueprints for communicating with the public, stakeholders, or even colleagues. EPA recommends that communication strategies:

- Outline the objective and goals of the communication.
- Identify stakeholders.
- Define key messages.
- Pinpoint potential communication methods and vehicles for communicating information and obtaining information from the community for a specific purpose.

When developing a communication strategy, the first step is to determine why the communication is necessary and define its desired objectives, and then to focus on defining the audiences and how to reach them. Keep in mind that the demographics, knowledge, and concerns of the audiences play an important role in defining the key messages. Once the key messages are defined, the outreach vehicle can be determined.

Conducting Community Outreach

The site planning team likely will use several different outreach techniques during the course of the cleanup process. When planning community outreach, EPA generally recommends that the site planning team collaborate with internal and external partners, such as local, state, and tribal officials and departments of health; faith-based organizations; and community groups. It is important to accommodate hearing-impaired or limited English proficiency (LEP)[250] persons in all outreach efforts by providing spoken or sign language interpreters at meetings and translating printed outreach materials. It also is important to ensure that the community understands the concept of vapor intrusion.

Examples of community outreach techniques to consider are described below.

Public Meetings/Gatherings

Public meetings are a useful opportunity to explain environmental conditions at the site, potential health impacts, intended indoor air sampling, and remediation strategies. It may be helpful to hold meetings prior to and following key sampling events to describe sampling strategies and consequent results, respectively. EPA recommends that the meeting include a period to address specific questions from the public regarding sampling results or any other specific concerns, as well as visual aids and maps and spoken or sign language interpreters to facilitate communication and discussion. The use of a CSM, for example, is useful in public meetings to graphically reinforce the messages. It may be helpful to follow up with meeting participants to inquire about the effectiveness of the meeting and whether it met their needs. Other meeting follow-up activities could include responding to requests for information, distributing meeting notes, and creating a mailing list.

Additional opportunities for the site planning team to communicate with the community in a group setting include public availability sessions and public forums or poster sessions at community group meetings or neighborhood board meetings. These options are a more informal way of interacting with community members and they allow a casual “question and answer” or discussion format as compared to the more formal presentation at a public meeting.

Mass Media

The media can be the best means of reaching a large audience quickly. Extending invitations to the media for important meetings, providing opportunities for media questions

[250] Executive Order 13166, *Improving Access to Services for Persons with Limited English Proficiency*, directs federal agencies to examine the services they provide, identify any need for services to those with LEP, and develop and implement a system to provide those services so LEP persons can have meaningful access to them.

to be addressed in a timely manner, and recognizing that the media control the content of their publications all are important considerations when working with the media. The site planning team can work with the Agency's regional site press officer to foster a relationship with the media by sharing the Agency's rationale for its plans and actions. It is appropriate to use the media to publicize a site-related decision, an upcoming meeting, changes in schedule, or changes in activities or expectations. Press releases can be used to inform the media of major site-related milestones.

Fact Sheets

Communities appreciate concise, easy-to-understand, and technically accurate fact sheets on the history of the contamination, chemicals of concern, human health risk, planned cleanup activities, and the vapor intrusion assessment and response actions. Be sure to include who to contact for more information.

Because sites involving vapor intrusion can be complex, it may be useful to include additional information in the fact sheets for home owners and renters, including information about household products that may be potential sources of indoor air contamination, as well as steps that can be taken to minimize these sources. EPA recommends preparing and distributing periodic status updates and fact sheets to concerned community members throughout the cleanup process.

Letters

Whenever there are plans to conduct indoor air sampling, EPA recommends sending a letter to each building owner and renter explaining plans to conduct indoor air sampling and requesting written permission for voluntary access to do so. In addition, a one-on-one meeting with the building owner or renter is generally recommended to discuss sampling efforts and access agreements in detail (see Section 9.3).

EPA also recommends that letters be sent to each building owner and renter to report sampling results in a timely manner (see Section 9.4). These letters and meetings often are part of a larger effort that also includes use of other communication strategies, such as community meetings and in-person visits.

In-person Visits

EPA recommends individual, one-on-one communication with each property owner and renter whenever possible.

- Try to schedule in-person visits with individual property owners and renters. These visits also may include owners and renters of properties located outside the planned investigation area. The initial visit can be used to explain sampling plans in more detail, answer questions, and obtain written permission to sample.

- During the visit, the property owner or renter can be briefed about any instructions to follow during sampling activities (for example, keep doors and windows closed during sampling). A general survey of the building could be conducted to determine likely sources of indoor air contaminants.

- EPA recommends the site planning team also describe to owners and renters the sampling devices that will be used, what they look like, where they will be located, and any restrictions or impediments to daily activities that may arise from the ongoing sampling activities.

Information Repository

An information repository can be established and maintained prior to, during, and following site activities, which is generally required for sites where remedial action or removal actions (where on-site action is expected to exceed 120 days) are undertaken pursuant to CERCLA. The information repository is intended to include the administrative record, fact sheets, question-and-answer sheets, and other site-related documents and be located reasonably near the site. However, given the tremendous change in information technology, it may also be appropriate to set up an Internet-based or digital repository (webpages) to share key information. This depends on the community's ability to access and utilize this technology. EPA recommends that community members be made aware of the information repository through the other public outreach mechanisms described above (e.g., local media, newsletters, and public meetings).

Electronic Notification

It also may be useful to establish a registration capability that allows interested community members to sign up for automatic alerts to updates posted on the site website or email listserv.

9.3 Addressing Building Access for Sampling and Mitigation

EPA recommends that all requests for access, as well as provision of access, be in writing in order to document EPA's due diligence to protect human health at the site. EPA recommends that the site planning team provide building owners and occupants with information about the sampling device(s)) being used, including what they look like, where they will be located and any restrictions or impediments to daily activities that may arise due to ongoing sampling.

In the case of an initial refusal to provide access, additional attempts for access are generally recommended, although regional practices may vary. EPA recommends documenting all attempts to gain access, for example using telephone conversation records, emails, or letters sent to home or building owners.

Gaining access to owner-occupied residences for vapor intrusion sampling and mitigation may be handled differently than for commercial buildings or rental properties.

Owner-Occupied Residences: Allowing EPA to sample or install mitigation systems in an owner-occupied residence is a voluntary action. EPA generally encourages owners to take advantage of an offer for an assessment and mitigation system, if necessary.

Rental Properties: Access may be voluntary or involuntary. Site planning teams often deal with both owners and renters when there is a need to sample on, in, or under a rental property. There are different legal and communication issues for owners and renters. For example, the owner is responsible for granting access for sampling and for installation of mitigation measures, if they are necessary; however, if the owner grants access, logistics normally are

arranged with the renter. EPA recommends apprising both the owner and the renter of human health risk that may be posed by vapor intrusion, which includes providing building-specific sampling results to both parties when available. If the owner of a rental property refuses access, EPA may, nevertheless, pursue access, in the interest of protecting the occupants, for determining the need for response, choosing a response action, taking a response action, or otherwise enforcing CERCLA or RCRA (EPA 1986, 1987, 2010a). Notifying the owner of a rental property of this statutory authority may help to avoid the need for legal action.

Nonresidential Buildings: Site managers also may need to sample on, in, or under nonresidential buildings, such as schools, libraries, hospitals, hotels, and stores. In these situations, broader outreach to the public may be appropriate in addition to maintaining direct contact with the property owner. Similar to rental properties, access for sampling and for implementation of mitigation methods, if they are necessary, may be voluntary or involuntary. If the owner of a nonresidential building refuses access, EPA may, nevertheless, pursue access, in the interest of protecting the occupants, for determining the need for response, choosing a response action, taking a response action, or otherwise enforcing CERCLA or RCRA (EPA 1986, 1987, 2010a).

Property Ownership Changes: For owners of homes or buildings who did not provide access for assessment sampling or installation of a mitigation system, EPA recommends that the site planning team make reasonable attempts to track ownership changes, although the appropriate state, tribal, or local agency or PRP may be in a better position to track this information. For example, reasonable attempts to make contact can be done by annually conducting drive-bys or inspections and noting homes or buildings for sale, periodically checking on-line real estate sales or title insurance listings, or using other mechanisms. Homes that were initially targeted but not sampled can be reconsidered during the review or if there are major changes to the toxicity values for the site contaminants of concern. Annually mailing notifications to buildings not previously sampled is a means to foster reconsideration of testing with a change in ownership. If ownership changes are noted, appropriate follow-up can be conducted with the new home owner or building owner.

Federal statutory authority to access private property to conduct investigations, studies and cleanups pursuant to CERCLA and RCRA is discussed in Section 1.2 of this Technical Guide.

9.4 Communication of Indoor Sampling Efforts and Results

The community involvement plan or public participation plan is intended to address community concerns and participation regarding indoor air and sub-slab sampling. In addition to the general community involvement activities occurring throughout the cleanup process (see Section 9.2), the site planning team may choose to hold a community meeting to discuss indoor sampling efforts and results. EPA recommends sending a letter to each home or building owner and renter explaining plans to conduct sampling or providing sampling results. EPA recommends that this letter be in addition to a one-on-one meeting with the building or home owner to discuss access agreements, sampling efforts, and sampling results. Prompt communication of sampling results to building or home owners is important as some people may choose to make precautionary decisions prior to regulatory decisions on remediation or mitigation measures.

EPA recommends the site planning team inquire about stakeholder preferences for confidentiality with regards to property-specific data. It may be appropriate to segregate data for private residential properties versus community properties (e.g., schools, daycare centers,

commercial buildings) or provide different types of property identifiers for these respective building types in reports and maps and tables displayed at public meetings or otherwise made available to the community.

Letters Transmitting Sampling Results[251]

EPA recommends that the site planning team provide validated sampling results and interpretations (e.g., chemicals of concern, associated risk assessment implications) in plain English (and translations, if necessary) to property owners and renters in a timely manner (e.g., within approximately 30 days of receiving the results). EPA also recommends the transmittal letter indicate what future actions (e.g., mitigation options), if any, are contemplated,[252] based on the sampling results, and contain additional site-specific and possibly building-specific information, including, but not limited to:

- Site and Home/Building Information.
  - Site name and location of contamination.
  - Date of sampling.
  - Address of sampled home or building.
  - Locations sampled (both indoor and outdoor).

- Sampling Results
  - Sampling results for site-related, vapor-forming chemical(s) and for any other chemicals, if detected, including an explanation of results believed to be attributable to background sources, if known.[253]
  - Risk-based screening levels (for example, VISLs described in Section 6.5) or other risk-based benchmarks used to explain and interpret the sampling results.
  - Explanation and interpretation of sampling results, if known, which may include a summary of the human health risk assessment, if available (see Section 7.4).[254]

[251] Within the community of risk professionals, the phrase 'risk communication' has come to mean communication that supplies lay people with the information they need to make informed independent judgments about human health risk or public safety (Morgan et al. 1992). In this case about vapor intrusion, the ultimate goal of risk communication is to assist stakeholders and the general public in understanding the investigation data and the rationale behind any risk-informed decision, so they may arrive at a balanced judgement that reflects the factual evidence in relation to their own interests and values.

[252] This section may include an explanation of mitigation process and responsibilities and a timeline for further contact regarding system installation and options. If a building mitigation system is recommended on the basis of a human health risk assessment, EPA recommends that the site planning team explain that the risk calculation reflects conservative, health-protective factors.

[253] With such information, EPA can help advise citizens about the environmental and public health threats they face that are within their control (e.g., from indoor sources). In cases where 'background' contamination may pose a human health risk, but its remediation is beyond the authority of the applicable statute, risk communication to the public may be most effective when coordinated with public health agencies (EPA 2002e). The public may also be advised about the scope and limits of EPA's statutory authorities.

[254] Assessment uncertainty is generally an important factor in deciding how to act (Frewer 2004); i.e., whether to reduce risk through response action or reduce uncertainty (e.g., through additional monitoring and data collection). Risk professionals, therefore, generally recommend that risk communication to stakeholders and the general public characterize the sources of uncertainty, as well as the magnitude of uncertainty associated with a particular hazard (see, for example, Frewer (2004) and Markon and Lemyre 92013)).

  - Simple tabulated and color-coded results (representing exceedances of human health risk levels or no exceedance).

- Diagrams/Illustrations
  - Diagrams and illustrations of sampling devices.
  - Diagrams and illustrations of sampling locations
  - Diagrams of specific mitigation systems (e.g., how a SSD system works and looks).

- Next Steps
  - Actions that property owners and occupants can take to reduce vapor intrusion exposure until mitigation systems are in place.

- Information Sources
  - Contact information for a person who can answer questions or supply further explanations.
  - The location of the site information repository or site website can be included as a resource for public access to more detailed information and site documents.

9.5 Transmitting Messages Regarding Mitigation Systems

The initial notification to residents or building owners about mitigating vapor intrusion can be delivered in various ways. A primary mechanism is a face-to-face meeting with the building owner or occupant to explain the sampling results and discuss next steps, including installation of a vapor intrusion mitigation system. EPA recommends that this meeting include a member of the site planning team (RPM or OSC and risk assessor, for example), a representative from the local health department or the Agency for Toxic Substances and Disease Registry (ATSDR), and the mitigation contractor scheduler. This meeting could discuss topics such as:

- Sampling Results: Describe where samples were taken and the chemicals of concern, and explain the results as related to site action levels. Any questions related to human health risk can be answered by the risk assessor or public health representative at this time. For questions or concerns regarding personal health, EPA recommends that residents and building owners contact their medical professional.

- Mitigation System Details: Describe the need for a mitigation contractor to visit the residence to identify potential locations for the mitigation system. The property owner will need to be present for the visit and will have input about where the system is installed, if they agree to install such a system. Photos of a mitigation system (piping, system fan, number of holes drilled in the slab, height of the vent on the outside of the residence, etc.) may be helpful. EPA recommends that plans and schedules for periodic inspection, maintenance, and monitoring also be described.

- Access: EPA recommends advance planning to ensure building access to install, monitor and maintain any mitigation system. Arrangements could be made at this meeting to sign an additional access agreement for these activities, if needed.

- Cost of the Mitigation System: Identify which party will pay for installation of the mitigation system and anticipated property-owner costs. For example, EPA or a PRP may pay for the

system installation, and the property owner or PRP may take responsibility to pay for the monthly costs associated with the mitigation system.

- Project Schedule and Next Steps: The meeting may be concluded by giving an overview of the overall project timeline, including the appointment for the mitigation contractor visit and system installation.

Notification also can be provided through the data transmittal letter. In many cases, however, the decision to install mitigation systems will not have been made prior to the transmittal of sampling results. In these situations, data transmittal letters can convey that EPA is reviewing all data results for the affected area and considering appropriate next steps. Once the decision document is signed, the site planning team can develop and mail a fact sheet to all community members in the affected area, followed by a community meeting.

In addition, if a vapor intrusion mitigation system is installed, EPA recommends that the property owner or renter be informed that the system normally is designed to protect the home or building only against vapor-forming chemicals coming from the subsurface. A vapor intrusion mitigation system generally will not protect the home against continuing indoor sources because vapor intrusion mitigation systems typically are not indoor air filtration systems.

EPA recommends that current owner-occupants be advised that if they decline or waive an offer to install a vapor mitigation system, they might be responsible for the costs of installing and maintaining their own system if they decide to do so at a later time. EPA also recommends documenting any declination or waiver.

9.6 Addressing Community Involvement at Legacy Sites

Ongoing site activities with assessment components, such as remedial investigations and monitoring, allow EPA to continually evaluate site conditions and adjust cleanup actions as warranted. During periodic reviews or conducting other site activities, such as the FYR pursuant to CERCLA, EPA has evaluated vapor intrusion where appropriate. In some instances, EPA has newly identified vapor intrusion as an exposure pathway. These mature or “legacy” sites present a unique challenge to site planning teams.

Conducting community involvement at legacy sites may be complicated by several factors including:

- A remedy for the control of exposure to volatile chemicals already has been installed, proposed, or is under construction as part of the cleanup plan.

- Ownership of properties previously exposed to VOCs has changed hands through resale, foreclosure, or assumption of the property by second-generation homeowners. These owners were not part of any original resolution of exposure issues and in many cases may not be aware that a remediation or treatment was put in place.

- Property owners and other community members who participated in prior cleanup efforts may be reluctant to fully engage with efforts to reopen lines of investigation at their properties.

In these and similar circumstances, the challenge for Agency representatives is to resume contact with communities who have put past difficulties behind them. In many cases, mailing lists are outdated, previous reliable contacts no longer are available, and elected officials may not have institutional memory of the events that prompted the remediation.

Strategies for Revitalizing Community Involvement at Legacy Sites

Every legacy re-entry will be a site-specific situation. Therefore, EPA recommends that events and activities be planned to acknowledge and accommodate the inevitable changes in the makeup of a community. In addition to the communication strategies and community involvement techniques described in Sections 9.1 through 9.5, additional suggestions to ease re-entry and revitalize community involvement at a legacy site include:

- Reassess the community and the site by revisiting the site and the surrounding areas and taking note of new construction.
- Reintroduce yourself and the Agency to current municipal staff and check previously used public venues for viability. Determine if new venues may be closer or more accessible to the community.
- If contacts within the community are still extant, reconnect; ask for updates on the growth and stability of the community. If no viable contacts exist, attempt to cultivate new ones.
- Revise and update mailing lists and fact sheets.

As with all sites affected by vapor intrusion issues, be prepared to meet with property owners door to door and to hold public meetings or forums to explain the current investigation and its importance to protecting human health.

9.7 Property Value Concerns for Current and Prospective Property Owners

EPA recognizes that vapor intrusion impacts may have implications for property values. In some instances, mitigation systems and other clean-up measures may help to restore property values.

Nevertheless, property value issues are outside the scope of Agency authority. In general, if asked, EPA recommends that regional staff suggest that prospective buyers and sellers contact real estate professionals and lenders from the local area with questions about property values. If a home owner or renter has questions about vapor intrusion mitigation systems, EPA regions can provide information that explains how vapor intrusion systems are designed to reduce exposure to chemicals found in indoor air and to avert human health-related problems.

9.8 Additional Community Involvement Resources

EPA's Superfund Community Involvement Program:

EPA's Superfund Community Involvement website contains many resources that may be helpful for planning community involvement activities for other cleanup programs. This resource includes a list of regional Superfund community involvement points of contact, a list of technical

assistance and training resources, and descriptions and links to community involvement policies, guidance and publications (see http://www.epa.gov/superfund/community/).

EPA's Superfund Community Involvement Toolkit (CI Toolkit):

While targeted to a Superfund Program audience, the CI toolkit may be helpful to a wide variety of users because it is a practical, easy-to-use aid for designing and enhancing community involvement activities and contains tips on how to avoid some of the pitfalls common to the community involvement process. The toolkit enables users to quickly review and adapt a variety of community involvement tools to engage the community during all stages of the cleanup process. Relevant tools include tips for conducting public availability and poster sessions and public meetings, developing fact sheets, working with the media, planning communication strategies, developing a Community Involvement Plan, and establishing an information repository (see http://www.epa.gov/superfund/community/toolkit.htm).

EPA's Community Engagement Initiative:

The OSWER CEI is designed to enhance OSWER and regional offices' engagement with local communities and stakeholders to help them participate meaningfully in government decisions on land cleanup, emergency preparedness and response, and the management of hazardous substances and waste (see http://www.epa.gov/oswer/engagementinitiative/).

10.0 GLOSSARY

The following definitions are provided for purposes of this Technical Guide:

accumulate ..... Increase gradually in amount as time passes. Note that there will be a finite maximum amount, which will be determined by site- and building-specific conditions and will reflect a balance among physical processes (e.g., soil gas entry, air exchange).

active ..... Involving mechanical operations; Compare with *passive*.

active depressurization technology..... Vapor intrusion mitigation method that creates a driving force for air flow from the building into the subsurface by lowering the pressure below the slab, thereby reducing vapor intrusion (soil gas entry into a building).

acute ..... Refers to repeated or single exposure for 24 hours duration or less. Compare with *short-term* and *subchronic*.

advection ..... As it pertains to soil gas, refers to bulk movement in the vadose zone induced by spatial differences in soil gas pressure. The direction of advective vapor transport is always toward the direction of lower air pressure.

aerobic ..... Describes a process or activity requiring oxygen. Compare with *anaerobic*.

air exchange rate ..... Rate of air infiltration into a building through windows, doorways, intakes and exhausts, 'adventitious openings' (e.g., cracks and seams that combine to form the building envelope), plus natural and mechanical ventilation.

ambient air ..... The outdoor air surrounding a building or site.

anaerobic ..... Describes a process or activity requiring the absence of oxygen. Compare with *aerobic*.

analyte..... A substance for which identification (of presence) and/or quantification (of amount, such as concentration) is/are sought by instrumental measurement.

attenuation ..... Decrease in vapor concentration in soil gas emanating from a subsurface vapor source along the migration route towards and into a building (indoor air)

attenuation factor..... The ratio of the indoor air concentration arising from vapor intrusion to the soil gas concentration at the source or a depth of interest in the vapor migration route.

background ..... Refers to a vapor-forming chemical(s) or location(s) that is(are) not influenced by the releases from a site, and is usually described (EPA 1989, 1995c, 2002e) as naturally occurring or anthropogenic: 1) *Anthropogenic* – natural

	and human-made substances present in the environment as a result of human activities and not specifically related to the site-related release in question; and, 2) *Naturally occurring* – substances present in the environment in forms that have not been influenced by human activity. Background may include a vapor-forming chemical(s) present in indoor air due to human activities that is(are) not related to vapor intrusion or site-related contamination.
background vapor concentration	This term may include the concentration of a vapor-forming chemical in indoor air that fits within the definition of "background" above. Information on background concentrations of vapor-forming chemicals in indoor air "is important to risk managers because generally EPA does not clean up to concentrations below natural or anthropogenic background levels" (EPA 2002e).[255]
background vapor source.....	The origin(s) and location(s) of a vapor-forming chemical(s), other than vapor intrusion, and not associated with or emanating from a site-related release(s) to the environment. Background vapor sources may include indoor or outdoor sources. See also *indoor vapor source, outdoor vapor source,* and *background vapor concentration;* compare to *subsurface vapor source*.
biodegradation.....	Decomposition or breakdown of a substance through the action of microorganisms (such as bacteria or fungi).
brownfield	A parcel of real estate that is abandoned or inactive or may not be operated at its fully beneficial use and on which expansion or redevelopment is contemplated or reasonably expected; distinguished from "greenfield" because expansion or redevelopment may be complicated by the presence of vapor-forming chemicals in the subsurface environment.
building.....	a structure that is intended for human occupancy and use. This would include, for instance, homes, offices, stores, commercial and industrial buildings, etc., but would not normally include sheds, carports, pump houses, or other structures that are not intended for human occupancy.
building survey.....	Refers generically to gathering -- by observation, interviews, reviewing documents and records or other means -- information about existing buildings, including,

[255] It should, however, be noted that some EPA regulations (e.g., indoor radon standards under 40 CFR 192.12) are inclusive of background.

	but not limited to, location, use, occupancy, basic construction (e.g., foundation type), heating ventilation and cooling systems, potential indoor sources of vapor-forming chemicals, and anticipated susceptibility to soil gas entry (e.g., presence of radon mitigation system).
capillary fringe	The porous material just above the ground water table which may hold water by capillarity (a property of surface tension that draws water upwards) in the smaller void spaces.
chlorinated hydrocarbon (CHC)	Compound comprised solely of the elements chlorine, hydrogen and carbon. Includes dry-cleaning solvents such as tetrachloroethylene (PCE) and degreasing solvents such as trichloroethylene (TCE) and 1,1,1-trichloroethane (TCA).
chronic	Refers to repeated exposure for more than approximately 10% of the life span (approximately seven years) in humans. Compare with *subchronic*.
concentration	Amount (mass) of a vapor-forming chemical contained in a unit quantity (e.g., volume) of a specific medium (e.g., air, soil gas).
conceptual site model (CSM)	Narrative description of the current understanding of the site-specific conditions, which, in the case of vapor intrusion, include the nature, location, and spatial extent of the source(s) of vapor-forming chemicals in the subsurface and the location, use, occupancy, and basic construction of existing buildings. A CSM represents an adaptation of a general *conceptual model* to account for and reflect site- and/or building-specific conditions. See also *model*.
crawl space	A type of basement in which one cannot stand up — the height may be as little as one foot, and the bottom surface is often bare soil.
complete (vapor intrusion) pathway	The vapor intrusion pathway is referred to as “complete” for a building or collection of buildings when five conditions are met under current conditions: (1) a subsurface source of vapor-forming chemicals is present underneath or near the building(s); (2) vapors form and have a route along which to migrate (be transported) toward the building(s); (3) the building(s) is (or are) susceptible to soil gas entry, which means openings exist for the vapors to enter the building(s) and driving forces exist to draw the vapors from the subsurface into the building(s); (4) one or more vapor-forming chemicals comprising the subsurface vapor source(s) is (or are) present in the indoor environment; and (5) the building(s)

	is (or are) occupied by one or more individuals when the vapor-forming chemical(s) is (or are) present indoors.
data objectivity	Refers to the accuracy, reliability, and absence of bias in the information; scientific information will generally attain this criterion when the original or supporting data are generated using sound research, investigatory, or statistical methods.
data quality objective (DQO)	Performance and acceptance criteria that clarify study objectives, define the appropriate type of data, and specify tolerable levels of potential decision errors that will be used as the basis for establishing the quality and quantity of data needed to support decisions.
data utility	Refers to the usefulness (e.g., relevance, importance) of the information to reaching a conclusion or judgment (e.g., is the vapor intrusion pathway complete or incomplete? Does the vapor-forming chemical in indoor air arise from background sources or vapor intrusion? Does vapor intrusion pose an unacceptable human health risk in a specific building?)
diffusion	Random motion that affects the distribution of molecules when there are spatial differences in chemical concentrations in the fluid (e.g., soil gas, indoor air, groundwater). The net direction of diffusive transport is toward the direction of lower concentrations.
driving force	refers to the combination of: (i) pressure differences between a building interior and the subsurface or ambient air, which foster vapor intrusion and infiltration, respectively, via advection; and (ii) concentration differences between a building interior and the subsurface or ambient air, which foster vapor transport via diffusion.
early action	Refers to a response action undertaken early in the cleanup process to achieve prompt risk reduction. Also see *response action* and *pre-emptive mitigation.*
evidence	A fact or other information (i.e., datum) ascertainable by direct observation, interviews, review of records and documents, instrumental analysis in a lab or field setting, research and testing, sampling of environmental media (e.g., indoor air, soil gas, groundwater), statistical analysis, or other means, which is useful for forming a conclusion or judgment; each distinguishable datum is referred to as a line of evidence, which may be categorized into scientific realms (e.g., geology, biology, physics) or investigatory objectives (e.g., characterization of subsurface vapor source, accounting for background sources)

exposure	Opportunity to come into contact with vapor-forming chemicals (via inhalation, in the case of vapor intrusion).
exposure assessment	Process of characterizing the magnitude, frequency, and duration of exposure to a vapor-forming chemical, along with the characteristics of the population exposed.
exposure control	Modification of a property or building intended to reduce or eliminate human exposure to hazardous vapors in buildings or explosive vapors in structures, which arise from the vapor intrusion; such controls may include engineered methods (e.g., active depressurization technologies, mechanical ventilation, indoor air treatment) or non-engineered methods (e.g., institutional controls, such as deed notices and land use restrictions)
exposure pathway	The physical course a vapor-forming chemical takes from its source (e.g., groundwater) to the individual (in a building in the case of vapor intrusion).
exposure route	The way in which a vapor-forming chemical enters a human body (i.e., inhalation in the case of vapor intrusion).
flux	The rate of movement of mass through a unit cross-sectional area per unit time in response to a concentration gradient or a driving force for advection.
gas	A fluid (as air) that has neither independent shape nor volume but tends to expand indefinitely; a state of matter in which the matter concerned occupies the whole of its container irrespective of its quantity.
grab sample	A sample of air collected over a short (practically instantaneous) duration. Compare with *time-integrated sample*.
hazard index (HI)	The sum of hazard quotients for substances that affect the same target organ or organ system. Because different pollutants can cause similar adverse health effects, it is often appropriate to combine hazard quotients associated with different substances.
hazard quotient (HQ)	The ratio of the potential exposure to the substance and the level at which no adverse effects are expected. If the HQ is calculated to be equal to or less than 1, then no adverse health effects are expected as a result of exposure. If the HQ is greater than 1, then adverse health effects are possible.
hazardous	Involving or exposing one to threat of adverse health effects (due to toxicity) or loss of loss of life or welfare (due to explosiveness).

Henry's Law Coefficient or Constant	Ratio of a chemical's vapor pressure in air to its solubility in water. Generally reported for standard reference temperature, such as 25 °C.
human exposure pathway	A way that people may come into contact with environmental contaminants while performing their day-to-day indoor activities.
human health risk assessment	The evaluation of scientific information on the hazardous properties of vapor-forming chemicals (hazard assessment and characterization), the dose-response relationship, and the extent of human exposure to those agents. The product of the risk assessment is a statement regarding the probability that populations or individuals so exposed will be harmed and to what degree and describing the principal technical uncertainties (i.e., risk characterization).
hydrocarbon	Compound comprised solely of the elements hydrogen and carbon. See also *chlorinated hydrocarbon* and *petroleum hydrocarbon*.
inclusion zone	Land area within which EPA recommends assessing the vapor intrusion pathway, which extends beyond the aggregate boundaries of the site-specific source(s) of vapor-forming chemicals.
indoor vapor source	Refers to a vapor-forming chemical(s) in indoor air which originates within a building. Indoor sources of vapor-forming chemicals may include, but are not limited to, use and storage of consumer or household products, use or storage of industrial materials or products, combustion processes, activities or operations within a building, and releases from interior building materials (e.g., off-gases from furniture or clothing); for example, operational use or storage of chemicals in an industrial building may represent an indoor vapor source separate from a site-related release. Also see *background vapor source;* compare to *subsurface vapor source*.
infiltration	Air leakage into a building through random cracks, interstices, and other unintentional openings in the building envelope.
institutional control (IC)	Non-engineering measures intended to affect human activities in such a way as to prevent or reduce exposure to hazardous substances. For example, ICs may be used to restrict certain land uses, buildings, or activities that could otherwise result in unacceptable exposure to the vapor intrusion pathway. Generally, four categories of ICs are recognized: governmental controls; proprietary controls; enforcement tools; and informational devices. They are almost always used in conjunction with, or as a

	supplement to, other cleanup measures such as treatment or containment.
interim action	Refers to a response action that is undertaken to protect human health, but is limited in scope and objective (e.g., does not accomplish complete or final remediation of subsurface vapor sources). Also see *response action.*
interzonal air flow	Movement or transport of air through doorways, ductwork, and service chaseways that interconnect rooms or zones within a building.
lines of evidence	Data collected and weighed together in supporting assessments of the vapor intrusion pathway, which are identified and described throughout Sections 2 through 7 inclusive. See also *evidence*.
lower explosive limit (LEL)	The lowest concentration at which a gas or vapor is flammable or explosive at ambient conditions.
mitigation	Interim actions taken to reduce or eliminate human exposure to vapor-forming chemicals in a specific building arising from the vapor intrusion pathway; compare with *remediation.*
model	Refers to a description of a system. In the case of vapor intrusion the 'system' will generally consist of a subsurface source of vapors, one or more buildings potentially subject to soil gas entry, and the soil underlying the building(s). *Conceptual models* (i.e., models that are conceptual) are comprised of narrative descriptions that identify the primary physical elements and processes of the system and the interactions between and relationships among them; for example, Section 2 of this document provides a general conceptual model of how vapor intrusion can arise and why it may be variable over time and in space. A *mathematical model* is an expression of a conceptual model, which uses mathematical symbols and language to identify key elements (e.g., variables) and processes. Generally, mathematical models are highly idealized or simplified descriptions, compared to the complex systems they represent. For example, Johnson and Ettinger (1991) formulated an idealized mathematical model of vapor intrusion. In the case of a *physical model,* the description is provided using physical objects, which may or may not have full functionality; for example, a physical model of a construction project might differ from a planned system in its scale, but would necessarily show significant elements in relationship to each other.

near-source	Refers to a soil gas sample collected within a practically short distance from subsurface vapor source
nonresidential building	Refers to a building other than a home; includes, but is not limited to, institutional buildings (e.g., schools, libraries, hospitals, community centers and other enclosed structures for gathering, gyms and other enclosed structures for recreation); commercial buildings (e.g., hotels, office buildings, many (but not all) day care centers, and retail establishments); and industrial buildings where vapor-forming chemicals may or may not be routinely used or stored. Compare with *residential building*; see also *building*.
outdoor vapor source	Refers to a vapor-forming chemical(s) present in outdoor (ambient) air. Sources of vapor-forming chemicals in outdoor air may include, but are not limited to, releases from industrial facilities, vehicle exhaust, yard maintenance equipment, fuel storage tanks, paint or pesticide applications, agricultural activities, and fires, as well as site-related contamination, activities, and operations (e.g., emissions from remediation equipment). Also see *background vapor source;* compare to *subsurface vapor source*.
passive	Not involving mechanical operations; Compare with *active*.
petroleum hydrocarbon (PHC)	Hydrocarbons derived from petroleum and present in various refined products of petroleum (such as automotive gasoline, diesel fuel, lubricating oils). See also *hydrocarbon*.
potentially complete (vapor intrusion pathway)	The vapor intrusion pathway is referred to as 'potentially complete' for a building when: a subsurface source of vapor-forming chemicals is present underneath or near an existing building or a building that is reasonably expected to be constructed in the future; vapors can form from this source(s) and have a route along which to migrate (be transported) toward the building; and three additional conditions are reasonably expected to all be met in the future, which may not all be met currently (i.e., the building is susceptible to soil gas entry, which means openings exist for the vapors to enter the building and driving forces exist to draw the vapors from the subsurface through the openings into the building; one or more vapor-forming chemicals comprising the subsurface vapor source(s) is (or will be) present in the indoor environment; and the building is or will be occupied by one or more individuals when the vapor-forming chemical(s) is (or are) present indoors.

preemptive mitigation (PEM)	Implementation of systems or control measures to mitigate the vapor intrusion pathway as an early action, even though all pertinent lines of evidence have not yet been completely developed to characterize the vapor intrusion pathway for the subject building(s). Also see *early action* and *response action.*
preferential migration route	Naturally occurring subsurface feature (e.g., gravel lens, fractured rock) or anthropogenic (human-made) subsurface conduit (e.g., utility corridor or vault, subsurface drain) that is expected to exhibit little resistance to vapor flow in the vadose zone (i.e., exhibits a relatively high gas permeability) or groundwater flow (i.e., effectively exhibits a relatively high hydraulic conductivity), depending upon its location and orientation relative to the water table and ground surface, thereby facilitating the migration of vapor-forming chemicals in the subsurface and towards or into buildings
pressure difference/differential pressure	Difference between the air pressure within a building and the subsurface environment or ambient air. Can promote advective flow of gas into or out of a building through pores, cracks, or openings in the building foundation or envelope.
radon	A radioactive gas formed during the radioactive decay of radium, which occurs naturally in many geologic settings.
reasonable maximum exposure (RME)	A semi-quantitative term, referring to the lower portion of the high end of the exposure distribution; conceptually, above the 90th percentile exposure but less than the 98th percentile exposure.
reasonable worst case	A semi-quantitative term, referring to the upper portion of the high end of the exposure distribution, but less than the absolute maximum exposure.
reference concentration (RfC)	An estimate of the continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime.
remediation	Refers to interim and final cleanups, whether conducted pursuant to RCRA corrective action, the CERCLA removal or remedial programs, or using EPA brownfield grant funds with oversight by state and tribal response programs. In addition to permanent remedies for subsurface vapor sources, site remediation may also entail implementation of institutional controls and construction and operation of engineered systems.

residential building	refers to a building used as or intended for use as a home; includes, but is not limited to, single-family detached homes with foundations, trailer homes, multi-unit apartments and condominiums. Compare with *non-residential building;* see also *building*.
response action	any action taken to reduce or eliminate human exposure to or risk posed by hazardous vapors in buildings and structures, which arise from the vapor intrusion pathway; these actions may include engineered exposure controls in a specific building(s), non-engineered exposure controls, remediation of subsurface vapor sources, and associated monitoring to assess effectiveness and protectiveness. Also see *remediation* and *mitigation.*
risk	Probability of an adverse human health effect (due to toxicity) or physical hazard (e.g., due to potential for explosion) caused under specific circumstances by a vapor-forming chemical.
risk communication	The process of exchanging information about health threats and levels or significance of human health risk.
risk management	The process of determining whether response action(s) is(are) warranted to protect human health and, if so, selecting response actions to implement.
screening	Process of comparing concentrations of vapor-forming chemicals in a specific medium (e.g., indoor air, soil gas, crawl space air, groundwater) to screening levels to identify sites, buildings, or chemicals unlikely to pose a health concern through the vapor intrusion pathway versus those warranting further investigation or analysis.
screening level	Risk-based concentrations derived from standardized equations combining exposure information and assumptions with toxicity values.
short-term	Refers to repeated exposure for more than 24 hours, up to 30 days. Compare with *acute* and *subchronic*.
significant opening	Refers to refer to an atypical form and amount of an opening in a building (e.g., a sump, an unlined crawl space, an earthen floor), which could facilitate greater amounts of soil gas entry, all else being equal. Forms of openings typically expected to be present in all buildings include cracks, seams, interstices, and gaps in basement floors and walls or foundations and perforations due to utility conduits.
site	The geographical area where investigation and evaluation of the presence of vapor-forming chemicals is desired; in many situations, it includes areas surrounding

	a facility where a release to the subsurface environment is known or suspected to have originated.
soil gas	The gas present underground in the pore spaces between soil particles.
soil gas concentration	Vapor concentration in a soil gas sample. Sub-slab soil gas is found immediately beneath a building. Near-source or exterior soil gas samples are collected at other depths and typically outside the building footprint.
source strength	Vapor concentration(s) of vapor-forming chemical(s) arising from a subsurface vapor source.
stakeholder	A person, group, community, or corporate entity with an interest in activities at a site with subsurface contamination.
subchronic	Refers to repeated exposure for more than 30 days, up to approximately 10% of the life span (approximately seven years) in humans. Compare with *short-term* and *chronic*.
subsurface remediation	Response action that eliminates or substantially reduces the level of vapor-forming chemicals in the subsurface vapor source via treatment or physical removal. Compare with *mitigation.*
subsurface vapor source	Refers to a vapor-forming chemical(s) present in the subsurface environment arising from a release(s) to the environment. A subsurface vapor source may occur as a non-aqueous-phase liquid (NAPL), adsorbed-phase contamination, or dissolved-phase contamination, which may be present in the vadose zone, in groundwater, or within sewers and other conduits. Information on subsurface vapor sources is important to risk managers because response actions are generally warranted when vapor intrusion is determined to pose unacceptable human health risks. Compare with *background vapor source* and *background vapor concentration*.
termination criteria	Refers to numeric cleanup levels for each site-specific contaminant and narrative cleanup objectives that are to be attained by the response actions.
time-integrated sample	Sample collected over an extended period of time to account for temporal variations in vapor concentrations. Compare with *grab sample*.
toxicity value	Refers to an inhalation unit risk (IUR) for potential cancer effects or an inhalation reference concentration (RfC) for potential non-cancer effects of a vapor-forming chemical.

vadose zone	The soil zone between land surface and the groundwater table within which the moisture content is less than saturation (except in the capillary fringe). Soil pore spaces not occupied by moisture contain (soil) gas. Also referred to as the "unsaturated zone."
vapor	A substance in the gaseous state as distinguished from the liquid or solid state.
vapor intrusion	The migration of potentially hazardous vapors from any subsurface contaminant source, such as contaminated soil or groundwater, through the vadose zone and into a building or structure.
vapor source	The place and form of origin of chemical vapors. Also see *background vapor source*, *indoor vapor source*, *outdoor vapor source*, and *subsurface vapor source*.
vapor-forming chemical	A volatile chemical that EPA recommends be routinely evaluated during a site-specific vapor intrusion assessment, when it is present as a subsurface contaminant.
volatile chemical	Chemical with a vapor pressure greater than 1 milliliter of mercury (mm Hg), or Henry's law constant greater than 10^{-5} atmosphere-meter cubed per mole.
volatility	The tendency of a substance to form vapors, which are molecules in a gaseous state, and escape from a liquid or solid source. This tendency is directly related to a substance's vapor pressure and Henry's law constant and is indirectly related to a substance's molecular weight (i.e., substances with lower molecular weights tend to volatilize more readily than substances with similar molecular structures that have higher molecular weights).
water table	The water surface in an unconfined aquifer at which the fluid pressure in the pore spaces is at soil gas pressure.
weight of evidence	Refers to a conceptual approach to data evaluation, in which each of several lines of evidence is critically appraised for its quality (e.g., utility, objectivity) and systematically assessed for its logical support for a particular conclusion, as well as alternative conclusions; the appraisals consider lines of evidence individually and in light of other lines of reliable evidence for purposes of determining whether a particular conclusion is supported by the preponderance of the evidence and is consistent with the conceptual site model; this 'weighing' concept does not entail a quantitative (*a priori*) scheme to score or rank the individual lines of evidence. See also *evidence*.

work plan	A site-specific document that includes a project description, project objective(s), historical information about the site.
worst case	A semi-quantitative term, referring to the absolute maximum plausible exposure (i.e., a bounding – high-impact – case).

RECOMMENDED SUBSURFACE-TO-INDOOR AIR ATTENUATION FACTORS

A.1 INTRODUCTION

This Technical Guide includes recommended medium-specific (groundwater, soil gas, and indoor air) Vapor Intrusion Screening Levels (VISLs) that are intended to help identify those sites unlikely to pose a health concern from vapor intrusion and identify areas or buildings that may warrant further investigation of the vapor intrusion pathway. These VISLs are recommended for use in evaluating the concentrations of vapor-forming chemicals measured in groundwater, "near-source" exterior soil gas, and sub-slab soil gas in residential and nonresidential settings where the potential for vapor intrusion is under investigation.

The subsurface VISLs are developed considering a generic conceptual model for vapor intrusion consisting of a groundwater or vadose zone source of vapor-forming chemicals that diffuse upwards through unsaturated soils towards the surface and enter buildings. The underlying assumption for this generic model is that subsurface characteristics will tend to reduce or attenuate soil gas concentrations as vapors migrate upward from the source and into structures. Section 6.5.2 describes this conceptual model further. In general, EPA recommends considering whether the assumptions underlying the generic conceptual model are attained at each site. The *Vapor Intrusion Screening Level (VISL) Calculator User's Guide* (EPA 2015a) provides additional information about the technical basis for deriving the VISLs.

Comparison of sampling results to medium-specific VISLs (see Section 6.5.4) comprises one line of evidence in the multiple-lines-of-evidence approach described in this Technical Guide (see, for example, Sections 7.1 and 7.2). The subsurface (groundwater and soil gas) VISLs (C_{VISL}) are calculated using risk-based, screening levels for indoor air ($C_{target,ia}$) and a medium-specific, subsurface-to-indoor air attenuation factor (α_{VI}), as follows:

$$C_{VISL} = \frac{C_{target,ia}}{\alpha_{VI}} \qquad \text{Equation A.1}$$

The risk-based, indoor air screening levels ($C_{target,ia}$) are calculated according to the guidance provided in *Risk Assessment Guidance for Superfund (RAGS) Part F* (EPA 2009) as implemented in EPA's Regional Screening Levels (RSLs) for Chemical Contaminants at Superfund Sites (http://www.epa.gov/reg3hwmd/risk/human/rb-concentration_table/). The medium-specific, attenuation factors (α_{VI}) recommended for calculating the subsurface VISLs are derived from information in *EPA's Vapor Intrusion Database: Evaluation and Characterization of Attenuation Factors for Chlorinated Volatile Organic Compounds and Residential Buildings* (EPA 2012a).

This appendix describes the technical basis for the selection of the subsurface-to-indoor air attenuation factors (α_{VI}) that are recommended for use in calculating the VISLs for groundwater, sub-slab soil gas, "near-source" exterior soil gas, and crawl space air, according to Equation A.1.

A.2 DEFINITION AND DESCRIPTION OF ATTENUATION FACTOR

Vapor attenuation refers to the reduction in concentration of vapor-forming chemicals that occurs during vapor migration in the subsurface, coupled with the dilution that can occur when the vapors enter a building and mix with indoor air (Johnson and Ettinger 1991). The aggregate effect of these physical and chemical attenuation mechanisms can be quantified through the use of a subsurface-to-indoor air vapor intrusion attenuation factor (α_{VI}), which is defined as the ratio of the indoor air concentration arising from vapor intrusion ($C_{IA\text{-}VI}$) to the subsurface vapor concentration (C_{sv}) at the source or a depth of interest in the vapor migration route (EPA 2012a):

$$\alpha_{VI} = \frac{C_{IA-VI}}{C_{SV}} \alpha_{VI} = \frac{C_{IA-VI}}{C_{SV}} \qquad \text{Equation A.2}$$

As defined here, the vapor attenuation factor is an inverse measurement of the overall dilution that occurs as vapors migrate from a point of measurement in the subsurface into a building; i.e., attenuation factor values decrease with increasing dilution of vapor concentration.

Subsurface vapor concentrations (C_{SV}) may be measured directly under a building (often called sub-slab soil gas or just sub-slab), measured exterior to a building at any depth in the unsaturated zone (often called exterior soil gas), or derived from groundwater concentrations by converting the dissolved concentration to a vapor concentration assuming equilibrium conditions (i.e., by multiplying the groundwater concentration by the chemical's dimensionless Henry's law constant for the groundwater temperature *in situ*) (EPA 2001); also see Appendix C of this Technical Guide.

Subfloor vapor concentrations may also be measured in building crawl spaces. Although crawl space samples are not strictly subsurface samples, they represent the vapor concentration underlying a building's living space. Thus, crawl space samples may be evaluated in a manner similar to subsurface vapor samples.

A.3 RECOMMENDED ATTENUATION FACTORS

This section summarizes the technical basis and rationale for EPA's recommended attenuation factors for groundwater, sub-slab soil gas, exterior soil gas, and crawl space air, as follows:

- Section A.3.1 summarizes EPA's database of empirical attenuation factor values and the results of analyzing that database.
- Section A.3.2 identifies the recommended empirically based attenuation factors for groundwater.
- Section A.3.3 identifies the recommended attenuation factor for sub-slab soil gas and presents a theoretical analysis that supports the selection of the recommended empirically based value.
- Section A.3.4 recommends a generic attenuation factor for exterior soil gas and discusses its basis, justification, and limited applications.

- Section A.3.5 identifies the recommended attenuation factor for crawlspace vapor.
- Section A.3.6 presents a reliability analysis of the recommended generic attenuation factors.

A.3.1 EPA'S VAPOR INTRUSION DATABASE (EPA 2012A)

The information in *EPA's Vapor Intrusion Database: Evaluation and Characterization of Attenuation Factors for Chlorinated Volatile Organic Compounds and Residential Buildings* (EPA 2012a) is used to derive recommended attenuation factor values for use in evaluating subsurface sample concentrations collected as part of vapor intrusion investigations. EPA's vapor intrusion database consists of numerous pairings of concentrations in indoor air and subsurface samples (groundwater, sub-slab soil gas, exterior soil gas, and crawlspace vapor) from actual sites. It represents the most comprehensive compilation of vapor intrusion data for chlorinated hydrocarbons (CHCs) available at this time.

EPA's vapor intrusion database was analyzed and screened to reduce the impacts of background sources to indoor air concentrations. The resulting data distributions are considered representative of vapor intrusion of CHCs from subsurface vapor sources into residential buildings for most conditions. These distributions serve as the basis for identifying the high-end (conservative) attenuation factors for those media.

Table A-1 and Figure A-1 (Table 19 and Figure 34, respectively, in EPA (2012a)) present and compare the distributions of the attenuation factors (groundwater, exterior soil gas, sub-slab soil gas, and crawl space) that remain after applying the respective source strength and indoor air screens considered most effective at reducing the influence of background contributions to indoor air concentrations. These data demonstrate that the attenuation factor distributions obtained for groundwater, sub-slab soil gas, and crawl spaces for multiple buildings and sites are consistent with the conceptual model for vapor intrusion, which predicts that greater attenuation is expected with greater depths to the vapor sources or vapor samples. As shown in Table A-1 and Figure A-1, the paired groundwater–indoor air data generally exhibit greater attenuation (lower attenuation factors) than the paired sub-slab soil gas–indoor air data, which in turn exhibit greater attenuation than the paired crawl space-indoor air data.

A.3.2 RECOMMENDED ATTENUATION FACTORS FOR GROUNDWATER

To account for the inherent temporal and spatial variability in indoor air and subsurface vapor concentrations, the 95th percentile value of the "source-screened" groundwater data subset in EPA 2012a is recommended as a reasonably conservative generic attenuation factor, after considering a range of values. **Thus, for groundwater, the recommended generic attenuation factor (α_{gw}) is 0.001.** This value is considered to apply for any soil type in the vadose zone (excepting where preferential vapor pathways are present; see Section 5.4) in cases where the groundwater is greater than five feet below the ground surface. If the depth to groundwater is less than five feet below the building foundation, investigation of the indoor space is recommended, as there is potential for contaminated groundwater to contact the building foundation, either because the capillary fringe intersects the building foundation or groundwater fluctuations results in groundwater wetting the foundation.

Table A-2 (Table 13 in EPA (2012a)) provides statistics and Figure A-2 (Figure 28 in EPA (2012a)) shows box-and-whisker plots for individual sites compared with the statistics for the combined set of screened groundwater attenuation factors. This table and figure show that the 95th percentile value of the combined groundwater-indoor air measurements is considered appropriate for estimating reasonable maximum indoor air concentrations that might be observed at a site due to vapor intrusion. The majority of sites and buildings would be expected to exhibit lower indoor air concentrations.

A factor that commonly results in greater attenuation (lower attenuation factors) is the presence of laterally extensive, unfractured fine-grained sediment in the vadose zone. Table A-3 (Table 14 in EPA (2012a)) provides selected statistics and Figure A-3 (Figure 29 in EPA (2012a)) shows the box-and-whisker plots for the groundwater attenuation factors for three soil types. Comparing each descriptive statistic (except for the 25th percentile values) indicates that the attenuation factor values for residences overlying soils classified as "very coarse" generally are larger than those for residences overlying soils classified as "coarse," which are larger than those for soils classified as "fine." This pattern is consistent with the conceptual model for vapor intrusion; smaller attenuation factors, which indicate greater reduction in vapor concentration, would be expected in vadose zones with finer-grained soils, when all other factors (e.g., depth to groundwater, biodegradability of the volatile chemicals) are the same. The 95th percentile value of the coarse-grained soil is equal to the generic value, as expected, since coarse-grained soil provide low resistance to vapor transport and thus would be expected to yield high-valued attenuation factors. Where fine-grained sediments underlay buildings, however, more attenuation is expected and observed in the database. **Thus, a semi-site-specific attenuation factor of 0.0005 may be used at sites where laterally extensive fine-grained sediment has been demonstrated through site-specific sampling to underlay buildings being investigated for vapor intrusion**.

A.3.3 RECOMMENDED GENERIC ATTENUATION FACTOR FOR SUB-SLAB SOIL GAS

To account for the inherent temporal and spatial variability in indoor air and subsurface vapor concentrations, the 95th percentile value of the "source-screened" sub-slab data subset in EPA (2012a) is recommended as a reasonably conservative generic attenuation factor, after considering a range of values. Thus, **for sub-slab soil gas, the recommended generic attenuation factor (α_{ss}) is 0.03.**

The selection of this value can be supported by theoretical analysis. Specifically, a simple mass balance analysis, assuming a well-mixed interior volume and steady-state conditions, indicates that the theoretical (true) sub-slab soil gas attenuation factor can be expressed as the ratio of the soil gas entry rate to the building ventilation rate (Song et al., 2011; EPA 2012a) for cases where there is no background contribution to the indoor air concentration. Using median values for residential building volume and air exchange rate (395 m^3 and 0.45 ACH, respectively) provided in the *Exposure Factors Handbook 2011 Edition* (EPA, 2011) and a mid-range value of 5 L/min for soil gas entry rate in sandy materials (EPA 2002, Appendix G), the central tendency value of the sub-slab soil gas attenuation factor (according to Equation 4a therein), is expected to be approximately 0.002. Using upper-end (10th percentile) values for residential building volume and air exchange rate (154 m^3 and 0.18 ACH, respectively (EPA 2011)) and soil gas entry rate (10 L/min), an upper-end value of 0.02 for the sub-slab soil gas attenuation factor is obtained. These values agree well with the 95th percentile and 50th percentile (median) values

(0.03 and 0.003, respectively) obtained from the source-screened data. These calculations buttress the conclusion that the sub-slab attenuation factor distributions summarized in EPA's vapor intrusion database report can be considered representative of vapor intrusion of CHCs into residential buildings for most conditions.

Table A-4 (Table 10 in EPA (2012a)) provides statistics and Figure A-4 (Figure 25 in EPA (2012a)) shows box-and-whisker plots for individual sites compared with the statistics for the combined set of screened sub-slab attenuation factors. This table and figure show that the 95th percentile value of the combined sub-slab-indoor air measurements is considered appropriate for estimating reasonable maximum indoor air concentrations that might be observed at a site due to vapor intrusion. The majority of sites and buildings would be expected to exhibit lower indoor air concentrations.

A.3.4 RECOMMENDED ATTENUATION FACTOR FOR "NEAR-SOURCE" EXTERIOR SOIL GAS

Based upon the conceptual model for vapor intrusion, the attenuation factors for exterior soil gas data would be expected to be less than those for sub-slab soil gas, because the former includes an additional contribution from attenuation through the vadose zone, and greater than those for groundwater vapors for a given building at a site where groundwater is the primary subsurface source of vapors. The distributions of exterior soil gas attenuation factors shown in Table A-1 and Figure A-1 do not exhibit this expected relationship. In addition, a comparison of exterior soil gas to sub-slab soil gas concentrations for buildings where both types of samples were collected, shown in Figure A-5 (see Figure 6 in EPA (2012a)), suggests that a substantial proportion of the exterior soil gas data in the database, particularly shallow soil gas data, may not be representative of soil gas concentrations directly underneath a building. On this basis, shallow exterior soil gas sampling data generally are not recommended for purposes of estimating indoor air concentrations and the exterior soil gas attenuation factors in Table A-1 are not recommended for use in deriving generic attenuation factors.

Based upon the data in Figure A-5, "deep" exterior soil gas data appear to more reliably reflect sub-slab concentrations beneath buildings. On this basis, "near-source" soil gas sampling data (i.e., collected in the vadose zone immediately above each vapor source) generally are allowed for purposes of assessing vapor concentrations that may be in contact with the building's sub-slab, as discussed further in Section 6.4.4. However, the same conservative attenuation factor value for sub-slab soil gas is recommended for use with "near-source" exterior soil gas data for this purpose. **Thus, for "near-source" exterior soil gas, the recommended generic attenuation factor is 0.03**.

A.3.5 RECOMMENDED ATTENUATION FACTOR FOR CRAWLSPACE VAPOR

The distribution of attenuation factors presented in Figure A-1 show that attenuation between building crawlspaces and living spaces is limited. To account for the inherent temporal and spatial variability in indoor air and crawlspace vapor concentrations, the 95th percentile value of the "indoor air-screened" crawlspace data subset in EPA (2012a) is recommended as a reasonably conservative generic attenuation factor, after considering a range of values. **Thus, for crawl space vapor the recommended generic attenuation factor is 1.0** (0.9 rounded up to 1.0).

A.3.6 RELIABILITY ANALYSIS OF THE RECOMMENDED SUBSURFACE-TO-INDOOR AIR GENERIC ATTENUATION FACTORS

An analysis was performed to determine the reliability of these recommended attenuation factors for screening in residences in EPA's vapor intrusion data base with measured indoor air concentrations exceeding target levels corresponding to a cancer risk of 10^{-6} and a hazard quotient of 1. The reliability analysis was performed separately for each medium by determining the number of correct assessments and the number of false negatives for a range of attenuation factors. The potential incidence of false negatives is a critical criterion, because the primary objective of risk-based screening is to identify sites or buildings unlikely to pose a health concern through the vapor intrusion pathway (see Section 6.5.1).

For the purposes of this analysis:

- A correct assessment is deemed to occur either: (1) when a chemical's measured indoor air concentration exceeds the target level and the measured subsurface vapor concentration also exceeds the appropriate medium-specific VISL calculated using the specified generic attenuation factor, or (2) when a chemical's measured indoor air concentration is below the target level and the measured subsurface vapor concentration also is below the appropriate medium-specific VISL calculated using the recommended generic attenuation factor. Correct assessments in this analysis represent a correct decision based on subsurface concentration data regarding the potential for vapor intrusion to pose indoor air concentrations that exceed target risk-based concentrations in affected buildings.

- A false negative is deemed to occur when a chemical's measured indoor air concentration exceeds the target level, but the measured subsurface vapor concentration does not exceed the appropriate medium-specific VISL calculated using the specified generic attenuation factor. False negatives in this analysis represent the potential for making an incorrect decision based on subsurface concentration data regarding the potential for vapor intrusion to pose indoor air concentrations that exceed target risk-based concentrations in affected buildings.

This assessment uses the Data Consistency Subset of the EPA's vapor intrusion database for residential buildings (i.e., before screening to minimize the impacts of background contributions to indoor air as described in EPA (2012a)). This subset was chosen to allow for the possibility that background indoor air contributions were incorrectly identified and removed from further analysis in the "source-screened" data subsets presented in EPA (2012a). Thus, false negatives may appear if indoor or ambient (outdoor) sources of VOCs are present and they exceed the

indoor air target level. This choice of datasets provides a conservative estimate of the frequency of false negatives identified by this reliability analysis. Even lower rates of false negatives would be obtained when considering the "source-screened" data subsets, described in EPA (2012a), in which the impacts of background contributions to indoor air are minimized.

The results of this assessment are shown in Figures A-6 through A-8 for sub-slab soil gas, groundwater, and exterior soil gas.[256] The essential results are as follows:

- The recommended generic attenuation factors yield low rates of false negatives (< 2%) for all three media when individual pairs of samples are evaluated together.

- The recommended generic attenuation factors for groundwater, exterior soil gas, and sub-slab soil gas provide generally high rates of correct assessments when individual pairs of samples are evaluated together: 78% for groundwater; 76% for exterior soil gas; and 87% for sub-slab soil gas. Higher rates of correct assessments are expected for sub-slab soil gas than for the other subsurface media, likely due to the closer spatial correspondence of building sub-slab soil gas and indoor air samples.

- The rates of correct assessments appear to level off in Figure A-6 through A-8 at about the point on the x-axis where the recommended generic attenuation factors occur.

- The rates of false positives using the Data Consistency Subset can be inferred from Figure A-6 through A-8. This analysis indicates that use of ground water data or exterior soil gas data is more likely to incorrectly identify a site or building as warranting further investigation than is use of sub-slab soil gas data.

Compared to the values estimated in Figures A-6 through A-8, significantly higher rates of a correct assessment (and, hence, lower rates of false negatives and false positives) are reasonably anticipated to be realized by following this Technical Guide. Specifically, collecting multiple samples to characterize spatial and temporal variability (see, for example, Section 6.4), collecting multiple lines of additional evidence (see, for example, Section 6.3 and 7.1), and weighing this information together (see, for example, Sections 6.3 and 7) are reasonably expected to significantly reduce the "error rates" estimated in this reliability analysis, which are based upon comparison of individual pairs of indoor air and subsurface sample concentrations.

As previously stated, this Technical Guide includes subsurface VISLs that are intended to help identify those sites with the potential to pose a vapor intrusion concern. The reliability analysis described above suggests the recommended attenuation factors, on which the recommended VISLs are based, can reasonably be expected to provide an acceptably small probability of 'screening out' sites that pose a vapor intrusion concern and a high probability of correctly identifying sites or buildings that may pose a vapor intrusion concern.

[256] The reliability assessment was not conducted for crawlspace data, because the distribution of attenuation factors presented in Figure A-1 show that attenuation between building crawlspaces and living spaces is limited.

A.4 CONSIDERATIONS FOR NONRESIDENTIAL BUILDINGS

The recommended attenuation factors (see Sections B.3.2 through B.3.5) are proposed for use for nonresidential buildings as well as residential buildings. The rationale is that, in many geographic locations, some commercial enterprises have been established in converted residential buildings. Although used for commercial purposes, such buildings can reasonably be expected to exhibit similar susceptibility to vapor intrusion and similar interior mixing and dilution (and, hence, similar attenuation factors) as residential buildings represented in EPA's vapor intrusion database. In addition, McDonald and Wertz (2007) found that sub-slab attenuation factors for commercial and institutional buildings in Endicott, New York, which were not "extraordinarily large", were not substantially different than those for residential buildings in the same area.

There are theoretical considerations to support expectations that larger nonresidential buildings that are constructed on thick slabs will have lower attenuation factors than residential buildings. These considerations include:

- Given that the size (e.g., interior height and footprint area) and air exchange rate tend to be larger for many nonresidential buildings (see, for example, Table A-5), it is expected that building ventilation rates for many nonresidential buildings would be higher than those for residential buildings. A higher ventilation rate is expected to result in greater overall vapor dilution as vapors migrate from a subsurface vapor source into a building. On this basis, many nonresidential buildings would be expected to have lower attenuation factors than those for residential buildings, all else being equal.

- Comparing buildings with slab-on-grade construction, nonresidential buildings tend to have thicker slabs than residential buildings. With thicker slabs, a given amount of differential settling would be expected to lead to less cracking in the slab and would be less likely to create cracks that extend across the entire slab thickness. Buildings with thicker slabs would, therefore, be expected to exhibit lower soil gas entry rates, all else being equal.

Where appropriate, EPA may consider appropriate building-specific data, information, and analysis when evaluating vapor intrusion into large nonresidential buildings.

APPENDIX B
DATA QUALITY ASSURANCE CONSIDERATIONS

B.1 INTRODUCTION

Site-specific investigations of the vapor intrusion pathway will generally entail the collection and evaluation of environmental data and possibly the use of modeling. As noted in Exhibit B-1, EPA generally recommends the use of a quality assurance project plan (QAPP) for the collection of primary (and existing or secondary) data. A QAPP is a tool for project managers and planners to document the type and quality of data needed to make environmental decisions and to describe the methods for collecting and assessing the quality and integrity of those data. A QAPP is a plan or roadmap intended to help a project team document how they plan, implement, and evaluate a project. It applies the systematic planning process and the graded approach for collecting environmental data for a specific intended use. EPA standards governing the collection of data are outlined in Exhibit B-1.

Exhibit B-1. EPA Data Standards

CIO 2105 (formerly EPA Order 5360; *Policy and Program Requirements for the Agency-wide Quality System*, May 2000) is intended to promote the organization collecting or using the data to (1) establish a Quality System and prepare and approve a QAPP for each project.

For clarity, CIO 2105 will be replaced by the following two standards:

- CIO 2106-S-01 is the *Quality Standard for Environmental Data Collection, Production, and Use by EPA Organizations*, also called "Internal Standard" (EPA 2013a); and
- CIO 2106-S-02 is the *Quality Standard for Environmental Data Collection, Production, and Use by Non-EPA (External) Organizations*, also called "External Standard" (EPA 2013b).

These standards conform to *EPA Quality Policy*, CIO 2106.0, "Quality Policy" (EPA 2008a), *Procedure for Quality Policy,* CIO 2106-P-01.0, "Quality Procedure" (EPA 2008b), and the American National Standards Institute (ANSI) consensus standard, *Quality Systems for Environmental Data and Technology Programs – Requirements with Guidance for Use* (ANSI/ASQ 2004).

Two guidance documents accompany these standards:

- *EPA Guidance on Quality Management Plans* (EPA 2012b, CIO 2106-G02-QMP), documents the quality system of the organization conducting environmental data collection or using the data for EPA.
- *EPA Guidance on Quality Assurance Project Plans* (EPA 2012a, CIO 2106-G-05) focuses on projects requiring the collection of new data, projects using existing data, and projects involving modeling.

EPA also encourages the use of the *Uniform Federal Policy for Quality Assurance Project Plans (UFP-QAPP)* (EPA/DoD 2005) as a collaborative approach to fulfill the purposes of a QAPP, especially for Federal Facilities. OSWER Directive 9272.0-17, *Implementation of the Uniform Federal Policy for Quality Assurance Project Plans (UFP-QAPP) at Federal Facility Hazardous Waste Sites* (EPA 2005a) and OSWER Directive 9272.0-20 (EPA 2005b) state that QAPPs prepared and approved under the UFP conform to EPA's quality standards and are consistent with EPA Standards CIO 2106-S-0 and CIO 2106-S-02, EPA's Quality Policy (EPA 2008a), and ANSI/ASQ 2004.

B.2 RECOMMENDATIONS

This appendix provides two recommendations concerning the key components of QAPP development. These recommendations are not exhaustive, but are included as a starting point as considerations before studying or applying EPA or UFP QAPP guidance.

Recommendation 1: Using the conceptual site model (CSM), develop the project plan and QAPP through a process that involves all key players and share these materials with interested parties in draft form so that potential study weaknesses can be addressed early. The CSM is developed to portray the current understanding of site conditions, the nature and extent of contamination, routes of contaminant transport, potential contaminant pathways, and potentially exposed human population. Developing the CSM is the first step in EPA's DQO process.

Recommendation 2: Use systematic planning in developing project documents, including the QAPP. Systematic planning is a science-based, common-sense approach designed to ensure that the level of documentation and rigor of effort in planning is commensurate with the intended use of the information and available resources. DQOs are a key component of systematic planning and play a central role in the systematic planning process. DQOs generally are addressed within the QAPP and typically are a critical element in the planning for environmental investigations. *Guidance on Systematic Planning Using the Data Quality Objectives Process (QA/G-4)* (EPA 2006) provides guidance addressing implementation of DQOs and application of systematic planning to generate performance and acceptance criteria for collecting environmental data.

Table B-1 summarizes the steps in the DQO process, the purpose of each step, and provides some examples of how plans could be structured.

TABLE B-1. EXAMPLE OF STEPS IN THE DQO PROCESS

DQO Step	Purpose of the DQO Step	Example Application for Vapor Intrusion
1. State the Problem	Summarize the problem (e.g., the monitoring hypothesis, the investigation objective(s)) for which new environmental data will be collected or modeling or analysis will be performed.	Indoor air in one or more buildings overlying a shallow plume of PCE-contaminated groundwater is (are) to be sampled to determine whether PCE is present. The original PCE release occurred at an industrial site approximately 1,000 feet away from the closest building.
2. Identify the Decision	Identify the decision that will be supported by the new data, modeling or analysis.	The data will be used to support decisions about whether additional indoor air sampling or preemptive vapor intrusion mitigation will be pursued in one or more buildings.
3. Identify the Inputs to the Decision	Identify the information needed to support the decision, including data gaps that warrant collection of new information.	Indoor air sampling data for one or more buildings, in conjunction with information about measured or interpolated concentrations in groundwater near or underneath the building(s).
4. Define the Boundaries of the Study	Specify the spatial and temporal aspects of the environmental media or endpoints that the data are to represent to support the decision.	The boundaries of this initial study area extend a prescribed distance outside the lateral extent of the plume. Eventually, the boundaries of a vapor intrusion impact zone will be defined by the extent to which indoor air contamination can be associated with site-related contamination.
5. Develop a Decision Rule	Develop a logical "if…then" statement that defines the conditions that will inform the decision-maker to choose among alternative decisions.	Buildings with detectable concentrations of PCE in indoor air samples will be considered for additional indoor air sampling or preemptive vapor intrusion mitigation.
6. Specify Tolerable Limits on Decision Errors	Specify acceptable limits on decision errors, which are used to establish performance goals for limiting uncertainty in the analysis.	EPA recommends analytical limits of detection be less than risk-based screening levels for PCE to ensure that a building's indoor air concentration is not misidentified.
7. Optimize the Design for Obtaining Data	Identify the most resource-effective sampling and analysis design for generating the information needed to satisfy the DQOs.	Time-integrated samples will be collected in basements and in the first above-ground level of each building. The sampling and analysis plan and approach will be documented in a QAPP.

APPENDIX C
CALCULATING VAPOR SOURCE CONCENTRATION FROM GROUNDWATER SAMPLING DATA

Correcting the Henry's Law Constant for Groundwater Temperature

In the case of groundwater as the vapor source, the subsurface source concentration (C_{sv}) is estimated assuming that the vapor and aqueous phases are in local equilibrium according to Henry's law such that:

$$C_{sv} = H'_{TS} \times C_w \qquad \text{Equation C.1}$$

where:

C_{sv} = vapor concentration at the source of contamination (g/cm^3-v),

H'_{TS} = Henry's law constant at the system (groundwater) temperature (dimensionless), and

C_w = concentration of volatile chemical in groundwater (g/cm^3-w).

The Henry's law constants generally are reported for a temperature of 25 degrees Celsius (^{o}C). **Table C-1** provides these values for the chlorinated hydrocarbons (CHCs) in the vapor intrusion database. Average groundwater temperatures, however, are typically less than 25^{o}C. In such cases, use of the Henry's law constant at 25^{o}C may over-predict the volatility of the contaminant in water.

As described in EPA's *Soil Screening Guidance* (EPA 1996), the dimensionless form of the Henry's law constant at the average groundwater temperature (H'_{gw}) may be estimated using the Clapeyron equation:

$$H'_{gw} = \frac{\exp\left[-\frac{\Delta H_{v,gw}}{R_c} \times \left(\frac{1}{T_{gw}} - \frac{1}{T_R}\right)\right] H_R}{R \times T_{gw}} \qquad \text{Equation C.2}$$

where:

$\Delta H_{v,gw}$ = enthalpy of vaporization of the specific chemical at the groundwater temperature (cal/mol),

T_{gw} = groundwater temperature (^{o}K = ^{o}C + 273.15),

T_R = reference temperature for the Henry's law constant (298.15^{o}K),

R_C = gas constant (= 1.9872 cal/mol-^{o}K),

H_R = Henry's law constant for the specific substance at the reference temperature (atm-m^3/mol), and

R = gas constant (= 8.205 E-05 atm-m^3/mol-^{o}K).

The enthalpy of vaporization at the groundwater temperature can be approximated from the enthalpy of vaporization at the normal boiling point, as follows:

$$\Delta H_{v,gw} = \Delta H_{v,b}\left[\frac{\left(1-T_{gw}/T_C\right)}{\left(1-T_B/T_C\right)}\right]^{\eta} \qquad \text{Equation C.3}$$

where:

$\Delta H_{v,gw}$ = enthalpy of vaporization at the groundwater temperature (cal/mol),

$\Delta H_{v,b}$ = enthalpy of vaporization at the normal boiling point (cal/mol),

T_C = critical temperature for specific chemical (^oK),

T_B = normal boiling point for specific chemical (^oK),

η = exponent (unitless), and

all other symbols are as defined previously. **Table C-1** provides the chemical-specific property values used for temperature corrections to the Henry's law constant. **Table C-2** provides the value of η as a function of the ratio T_B/T_C. If site-specific data are not readily available for the groundwater temperature, then Figure 1 of the EPA fact sheet, *Correcting the Henry's Law Constant for Soil Temperature* (EPA 2001) can be used to generate an estimate.

U.S. EPA 83 FR 11584, Hazardous and Solid Waste Management system: Disposal of Coal Combustion Residuals from Electric Utilities; Amendments to the National Minimum Criteria (Phase one); Proposed Rule, March 15, 2018.

ENVIRONMENTAL PROTECTION AGENCY

40 CFR Part 257

[EPA–HQ–OLEM–2017–0286; FRL–9973–31–OLEM]

RIN 2050–AG88

Hazardous and Solid Waste Management System: Disposal of Coal Combustion Residuals From Electric Utilities; Amendments to the National Minimum Criteria (Phase One); Proposed Rule

AGENCY: Environmental Protection Agency (EPA).

ACTION: Proposed rule.

SUMMARY: On April 17, 2015, the Environmental Protection Agency (EPA or the Agency) promulgated national minimum criteria for existing and new coal combustion residuals (CCR) landfills and existing and new CCR surface impoundments. The Agency is proposing a rule that will address four provisions of the final rule that were remanded back to the Agency on June 14, 2016 by the U.S. Court of Appeals for the D.C. Circuit. The Agency is also proposing six provisions that establish alternative performance standards for owners and operators of CCR units located in states that have approved CCR permit programs (participating states) or are otherwise subject to oversight through a permit program administered by EPA. Finally, the Agency is proposing an additional revision based on comments received since the date of the final CCR rule.

DATES: *Comments.* Written comments must be received on or before April 30, 2018. Comments postmarked after the close of the comment period will be stamped ''late'' and may or may not be considered by the Agency.

Public Hearing. EPA will hold a hearing on this proposed rule on April 24, 2018 in the Washington, DC metropolitan area. Additional information about the hearing will be posted in the docket for this proposal and on EPA's CCR website (*https://www.epa.gov/coalash*).

ADDRESSES: *Comments.* Submit your comments, identified by Docket ID No. EPA–HQ–OLEM–2017–0286, at *https://www.regulations.gov.* Follow the online instructions for submitting comments. Once submitted, comments cannot be edited or removed from *Regulations.gov*. The EPA may publish any comment received to its public docket. Do not submit electronically any information you consider to be Confidential Business Information (CBI) or other information whose disclosure is restricted by statute. Multimedia submissions (audio, video, etc.) must be accompanied by a written comment. The written comment is considered the official comment and should include discussion of all points you wish to make. The EPA will generally not consider comments or comment contents located outside of the primary submission (*i.e.*, on the web, cloud, or other file sharing system). For additional submission methods, the full EPA public comment policy, information about CBI or multimedia submissions, and general guidance on making effective comments, please visit *https://www.epa.gov/dockets/commenting-epa-dockets.*

Instructions. Direct your comments on the proposed rule to Docket ID No. EPA–HQ–OLEM–2017–0286. The EPA's policy is that all comments received will be included in the public docket and may be made available online at *https://www.regulations.gov,* including any personal information provided, unless the comment includes information claimed to be CBI or other information whose disclosure is restricted by statute. Do not submit information that you consider to be CBI or otherwise protected through *https://www.regulations.gov* or email. The *https://www.regulations.gov* website is an ''anonymous access'' system, which means the EPA will not know your identity or contact information unless you provide it in the body of your comment. If you send an email comment directly to the EPA without going through *https://www.regulations.gov,* your email address will be automatically captured and included as part of the comment that is placed in the public docket and made available on the Internet. If you submit an electronic comment, the EPA recommends that you include your name and other contact information in the body of your comment and with any disk or CD–ROM you submit. If the EPA cannot read your comment due to technical difficulties and cannot contact you for clarification, the EPA may not be able to consider your comment. Electronic files should avoid the use of special characters, any form of encryption, and be free of any defects or viruses.

Docket. The EPA has established a docket for this action under Docket ID No. EPA–HQ–OLEM–2017–0286. The EPA has previously established a docket for the April 17, 2015, CCR final rule under Docket ID No. EPA–HQ–RCRA–2009–0640. All documents in the docket are listed in the *https://www.regulations.gov* index. Although listed in the index, some information is not publicly available, *e.g.*, CBI or other information whose disclosure is restricted by statute. Certain other material, such as copyrighted material, will be publicly available only in hard copy form. Publicly available docket materials are available either electronically at *https://www.regulations.gov* or in hard copy at the EPA Docket Center (EPA/DC), EPA WJC West Building, Room 3334, 1301 Constitution Ave. NW, Washington, DC. The Public Reading Room is open from 8:30 a.m. to 4:30 p.m., Monday through Friday, excluding holidays. The telephone number for the Public Reading Room is (202) 566–1744, and the telephone number for the EPA Docket Center is (202) 566–1742.

FOR FURTHER INFORMATION CONTACT: For information concerning this proposed rule, contact Mary Jackson, Office of Resource Conservation and Recovery, Environmental Protection Agency, 5304P, Washington, DC 20460; telephone number: (703) 308–8453; email address: *jackson.mary@epa.gov.* For more information on this rulemaking please visit *https://www.epa.gov/coalash.*

SUPPLEMENTARY INFORMATION:

Submitting CBI. Do not submit information that you consider to be CBI electronically through *http://www.regulations.gov* or email. Send or deliver information identified as CBI to only the following address: ORCR Document Control Officer, Mail Code 5305–P, Environmental Protection Agency, 1200 Pennsylvania Avenue NW, Washington, DC 20460; Attn: Docket ID No. EPA–HQ–OLEM–2017–0286.

Clearly mark the part or all of the information that you claim to be CBI. For CBI information in a disk or DC–ROM that you mail to the EPA, mark the outside of the disk or CD–ROM as CBI and then identify electronically within the disk or CD–ROM the specific information that is claimed as CBI. In addition to one complete version of the comment that includes information claimed as CBI, a copy of the comment that does not contain the information claimed as CBI must be submitted for inclusion in the public docket. If you submit a CD–ROM or disk that does not contain CBI, mark the outside of the disk or CD–ROM clearly that it does not contain CBI. Information marked as CBI will not be disclosed except in accordance with procedures set forth in 40 Code of Federal Regulations (CFR) part 2.

Public Hearing. This notice also announces that EPA will be holding a

public hearing on this proposed rule. A public hearing provides interested parties the opportunity to present data, views, or arguments concerning the proposed rule. EPA may ask clarifying questions during the oral presentations, but will not respond formally to any comments or the presentations made. Additional information about the hearing will be posted in the docket for this proposal and on EPA's CCR website (*https://www.epa.gov/coalash*).

I. General Information

A. Executive Summary

1. Purpose of the Regulatory Action

The EPA is proposing to amend the regulations for the disposal of coal combustion residuals (CCR) in landfills and surface impoundments in order to: (1) Address provisions of the final rule that were remanded back to the Agency on June 14, 2016; (2) to provide States with approved CCR permit programs (or EPA where it is the permitting authority) under the Water Infrastructure Improvements for the Nation (WIIN) Act the ability to set certain alternative performance standards; and (3) address one additional issue raised by commenters that has arisen since the April 2015 publication of the final rule, namely the use of CCR during certain closure situations.

2. Summary of the Major Provisions of the Regulatory Action

EPA is proposing two categories of revisions plus one additional revision to the regulations at 40 CFR 257 subpart D. The first category is associated with a judicial remand in connection with the settlement agreement entered on April 18, 2016 that resolved four claims brought by two sets of plaintiffs against the final CCR rule. See *USWAG et al.* v. *EPA,* No. 15–1219 (D.C. Cir. 2015). The second category is a set of revisions that are proposed in response to the WIIN Act. The last revision in the proposal deals with an issue that has been raised by commenters since the publication date of the final CCR rule. In the 2015 CCR final rule, EPA organized the regulations for the recordkeeping requirements, notification requirements and publicly accessible internet site requirements into 40 CFR 257.105, 257.106, and 257.107, respectively.[1] There are recordkeeping, notification and internet posting requirements associated with the revisions that are in this proposal. Those requirements have not all been added to the regulatory language. Those requirements will be added to §§ 257.105–257.107 when the final rule is developed.

a. Proposals Associated With Judicial Remand

The Agency is proposing four changes from the CCR final rule that was promulgated on April 17, 2015 associated with the judicial remand. The proposed revisions would: (1) Clarify the type and magnitude of non-groundwater releases that would require a facility to comply with some or all of the corrective action procedures set forth in 40 CFR 257.96–257.98 in meeting their obligation to clean up the release; (2) add boron to the list of constituents in Appendix IV of part 257 that trigger corrective action and potentially the requirement to retrofit or close the CCR unit; (3) determine the requirement for proper height of woody and grassy vegetation for slope protection; and (4) modify the alternative closure provisions.

b. Proposals Associated With the WIIN Act

The Agency is proposing six alternative performance standards that would apply in participating states (*i.e.*, those which have an EPA-approved CCR permit program under the WIIN Act) or in those instances where EPA is the permitting authority. Those alternative performance standards would allow a state with an approved permit program or EPA to: (1) Use alternative risk-based groundwater protection standards for constituents where no Maximum Contaminant Level exists; (2) modify the corrective action remedy in certain cases; (3) suspend groundwater monitoring requirements if a no migration demonstration can be made; (4) establish an alternate period of time to demonstrate compliance with the corrective action remedy; (5) modify the post-closure care period; and (6) allow Directors of states to issue technical certifications in lieu of the current requirement to have professional engineers issue certifications. These alternative standards are discussed in more detail later in this proposal.

Under the WIIN Act, EPA is the permitting authority for CCR units located in Indian County. EPA would also serve as the permitting authority for CCR units located in nonparticipating states subject to a Congressional appropriation to carry out that function. At this time, Congress has not provided appropriations to EPA to serve as the permitting authority in nonparticipating states. EPA is therefore proposing that in those cases where it is the permitting authority, it will have the same ability as a Director of a State with an approved CCR program to apply the alternative performance standards. In addition, EPA seeks comment on whether and how these alternative performance standards could be implemented by the facilities directly (even in States without a permit program), given that the WIIN Act provided authority for EPA oversight and enforcement.

c. Proposal To Allow CCR To Be Used During Certain Closure Situations

EPA is proposing to revise the current regulations to allow the use of CCR in the construction of final cover systems for CCR units closing pursuant to § 257.101 that are closing with waste-in-place. EPA is also proposing specific criteria that the facility would need to meet in order to allow for the use of CCR in the final cover system.

With this action EPA is not reconsidering, proposing to reopen, or otherwise soliciting comment on any other provisions of the final CCR rule beyond those specifically identified as such in this proposal. EPA will not respond to comments submitted on any issues other than those specifically identified in this proposal and they will not be considered part of the rulemaking record.

3. What are the incremental costs and benefits of this action?

This action is expected to result in net cost savings amounting to between $32 million and $100 million per year when discounting at 7 percent and annualized over 100 years. It is expected to result in net cost savings of between $25 million and $76 million per year when discounting at 3 percent and annualized over 100 years. Further information on the economic effects of this action can be found in Unit V of this preamble.

B. Does this action apply to me?

This rule applies to all CCR generated by electric utilities and independent power producers that fall within the North American Industry Classification System (NAICS) code 221112 and may affect the following entities: Electric utility facilities and independent power producers that fall under the NAICS code 221112. This discussion is not intended to be exhaustive, but rather provides a guide for readers regarding entities likely to be regulated by this action. This discussion lists the types of entities that EPA is now aware could potentially be regulated by this action. Other types of entities not listed in the table could also be regulated. To determine whether your entity is regulated by this action, you should

[1] Unless otherwise specified, all references to part 257 in this preamble are to title 40 of the Code of Federal Regulations (CFR).

carefully examine the applicability criteria found in § 257.50 of title 40 of the Code of Federal Regulations. If you have questions regarding the applicability of this action to a particular entity, consult the person listed in the **FOR FURTHER INFORMATION CONTACT** section.

II. Background

A. CCR Rule

On April 17, 2015, EPA finalized national regulations to regulate the disposal of CCR as solid waste under subtitle D of the Resource Conservation and Recovery Act (RCRA) titled, ''Hazardous and Solid Waste Management System; Disposal of Coal Combustion Residuals from Electric Utilities,'' (80 FR 21302) (CCR rule). The CCR rule established national minimum criteria for existing and new CCR landfills and existing and new CCR surface impoundments and all lateral expansions of CCR units that are codified in Subpart D of Part 257 of Title 40 of the Code of Federal Regulations. The criteria consist of location restrictions, design and operating criteria, groundwater monitoring and corrective action, closure requirements and post-closure care, and record keeping, notification and internet posting requirements. The rule also required any existing unlined CCR surface impoundment that is contaminating groundwater above a regulated constituent's groundwater protection standard to stop receiving CCR and either retrofit or close, except in limited circumstances.

The rule was challenged by several different parties, including a coalition of regulated entities and a coalition of environmental organizations. See, *USWAG et al.* v. *EPA,* No. 15–1219 (D.C. Cir. 2015). Four of the claims, a subset of the provisions challenged by the industry and environmental Petitioners, were settled. The rest were briefed and are currently pending before the U.S. Court of Appeals for the D.C. Circuit, awaiting resolution.

As part of that settlement, on April 18, 2016 EPA requested the court to remand the four claims back to the Agency. On June 14, 2016 the U.S. Court of Appeals for the D.C. Circuit granted EPA's motion.

One claim, which was settled by the vacatur of the provision allowing inactive surface impoundments to close early and thereby avoid groundwater monitoring, cleanup, and post-closure care requirements, was the subject of a recent rulemaking. See, 81 FR 51802 (August 5, 2016).

The remaining claims that were remanded back to the Agency are the subject of this proposed rule. As part of the settlement, EPA committed to issue a proposed rule or rules to: (1) Establish requirements for the use of vegetation as slope protection on CCR surface impoundments; (2) Clarify the type and magnitude of non-groundwater releases for which a facility must comply with some or all of the rule's corrective action procedures; and (3) Add Boron to the list of contaminants in Appendix IV, whose detection trigger more extensive monitoring and cleanup requirements. Each of these are discussed further in Unit III of the preamble. As specified in the settlement, EPA presently intends to take final action on these proposals by June 2019. The issue of alternative closure requirements (due to lack of capacity for non-CCR wastestreams) was also remanded, but was not part of the settlement agreement. That issue is also discussed in Unit III of this preamble.

In addition, on September 13, 2017, EPA granted petitions from the Utility Solid Waste Activities Group (USWAG) and from AES Puerto Rico LLP requesting the Agency initiate rulemaking to reconsider provisions of the 2015 final rule.[2] EPA determined that it was appropriate and in the public interest to reconsider provisions of the final rule addressed in the petitions, in light of the issues raised in the petitions as well as the new authorities in the WIIN Act.

This determination raised some questions as to how the remaining issues in the CCR litigation should be handled. In response to various motions filed with U.S. Court of Appeals for the D.C. Circuit, the court ordered EPA to submit a status report indicating which provisions of the final CCR rule were being or were likely to be reconsidered by the Agency and a timeline for this reconsideration. EPA filed that status report on November 15, 2017 indicating that the following provisions were or were likely to be reconsidered. These included issues that were before the court as well as those that were not:

Provision of the CCR rule	Description
Provisions under Reconsideration Subject to Challenge in Litigation	
§ 257.50(c), § 257.100	EPA Regulation of Inactive Surface Impoundments.
§ 257.53—definition of beneficial use	The Criteria for Determining Whether Activities Constitute Beneficial Use or Disposal.
§ 257.95(h)(2)	Use of Risk-Based Alternative Standards for Remediating Constituents Without an MCL.
§ 257.53—definition of CCR pile	The criteria for determining Whether a Pile will be Regulated as a Landfill or as Beneficial Use.
§ 257.96–98	Regulatory Procedures Used to Remediate Certain Non-Groundwater Releases.
§§ 257.73(a)(4), 257.73(d)(1)(iv), 257.74(a)(4), 257.74(d)(1)(iv).	Requirements for Slope Protection on Surface Impoundments, Including Use of Vegetation.
§ 257.103(a) and (b)	Whether to Allow Continued Use of Surface Impoundments Subject to Mandated Closure if No Capacity for Non-CCR Wastestreams.
§ 257.50(e)	Regulation of Inactive Surface Impoundments, Including Legacy Ponds.
§ 257.100	Exemption for Certain Remediation and Post-Closure Requirements for Inactive Surface Impoundments that Close by April 17, 2018. Note: EPA completed reconsideration of the issues associated with this claim. See 81 FR 51802 (August 5, 2016).
Appendix IV to Part 257; §§ 257.93(b), 257.94(b), 257.95(b), 257.95(d)(1).	Addition of Boron to the List of Constituents that Trigger Corrective Action.

[2] A copy of both rulemaking petitions are included in the docket to this proposed rule.

Provision of the CCR rule	Description
Provisions under Reconsideration Not Before the Court	
§ 257.97	Whether to Allow Modification of the Corrective Action Remedy.
§ 257.90	Whether to Suspend Groundwater Monitoring Requirements Where ''No Migration'' Demonstration is Made.
§ 257.98(c)	Whether to Allow Alternate Period of Time to Determine Remediation is Complete.
§ 257.104	Whether to Allow Modification of the Post-Closure Care Period.
§ 257.101, 257.102	Whether to Allow CCR to be Used to Close Surface Impoundments Subject to Mandated Closure.
§ 257.53	Clarify Placement of CCR in Clay Mines.

EPA further stated that it anticipates it will complete its reconsideration of all provisions identified in two phases. EPA indicated that in the first phase EPA would continue its process with respect to those provisions which were remanded back to EPA in June of 2016. These provisions are: The requirements for use of vegetation as slope protection; the provisions to clarify the type and magnitude of non-groundwater releases that would require a facility to comply with some or all of the corrective action procedures set out in §§ 257.96–257.98 in meeting its obligation to clean up the release; and provisions to add Boron to the list of contaminants in Appendix IV of the final rule that trigger corrective action. As noted elsewhere, the settlement agreement associated with the remand contemplates final action on these by June 14, 2019. EPA also indicated that as part of Phase One it would review the additional provisions to determine whether proposals to revise or amend some of these could be developed quickly enough so that they could be included in this first phase, and meet the schedule set out in the settlement agreement (*i.e.*, final action by June 2019). A number of these are associated with the WIIN Act which is discussed in detail in Unit II.B of this preamble.

EPA also indicated in its status report that it factored in two separate 90-day interagency review periods and assumed a 90-day public comment period as the minimum amount of time needed to provide comment based on the complexity of the issues involved. However, in developing this proposal, EPA now believes that a 90-day public comment period would be unnecessary. Instead, based on its assessment of the contents of the proposal, EPA will seek public comment for a period of 45 days. This proposal addresses four issues that were subject to legal challenge and included in the 2016 judicial remand. The legal authorities and policy options associated with these provisions have been addressed in comments to the 2015 CCR rule, as well as the litigation briefs filed by the United States and the industry and environmental petitioners. The remaining proposals included in this proposed rule largely reflect policy options that were discussed in the preamble to the 2015 final CCR rule and are based in large measure on the established record supporting the longstanding regulations for Municipal Solid Waste Landfills codified at 40 CFR part 258. By focusing this proposal on specific regulatory proposals that are largely rooted in existing requirements for how other nonhazardous waste is already regulated under Part 258, EPA has sought to minimize potential confusion and unnecessary burden on the public by basing many of these proposed changes to the 2015 CCR rule on well-understood legal theories and an existing scientific record.

EPA stated that it plans to complete review of all remaining matters identified on the chart and not covered in the Phase One proposal and determine whether to propose revisions to the provisions. EPA currently expects that if further revisions are determined to be warranted it will sign a Phase Two proposed rule no later than September 2018 and complete its reconsideration and take final action no later than December 2019.

Thus, this proposal includes those provisions where EPA has completed its review and has sufficient information to propose revisions. EPA continues to evaluate the other matters and will make a determination as to whether revisions are appropriate and if so anticipates signing a proposal by September of this year.

B. Water Infrastructure Improvements for the Nation Act

As noted in this preamble, the CCR rule was finalized in April 2015. As discussed in detail in the preamble to the final rule in the **Federal Register** (80 FR 21310–21311, April 17, 2015), these regulations were established under the authority of sections 1006(b), 1008(a), 2002(a), 3001, 4004, and 4005(a) of the Solid Waste Disposal Act of 1970, as amended by the Resource Conservation and Recovery Act of 1976 (RCRA), as amended by the Hazardous and Solid Waste Amendments of 1984(HSWA), 42 U.S.C. 6900(B), 6907(A), 6912(A), 6944, and 6945(a). ''Subtitle D of RCRA establishes a framework for federal, state, and local government cooperation in controlling the management of non-hazardous solid waste.'' (80 FR 21310, April 17, 2015). EPA's role is to create national minimum criteria; however, states are not required to adopt or implement them; thus under subtitle D, these self-implementing criteria operate even in the absence of a regulatory entity to oversee them. ''As a consequence of this statutory structure—the requirement to establish national criteria and the absence of any requirement for direct regulatory oversight—to establish the criteria EPA must demonstrate, through factual evidence available in the rulemaking record, that the final rule will achieve the statutory standard (''no reasonable probability of adverse effects on health or the environment'') at all sites subject to the standards based exclusively on the final rule provisions. This means that the standards must account for and be protective of all sites, including those that are highly vulnerable.'' (80 FR 21311, April 17, 2015).

Given the existing statutory authorities, the final rule provided very limited site-specific flexibilities and did not provide for a State program which could adopt and be authorized to implement the federal criteria.

In December 2016, the Water Infrastructure Improvements for the Nation (WIIN) Act was enacted, establishing new statutory provisions applicable to CCR units, including: (a) Authorizing States to implement the CCR rule through an EPA-approved permit program; and (b) authorizing EPA to enforce the rule and in certain situations to serve as the permitting authority.[3]

[3] Public Law 114–322.

The legislation amended RCRA section 4005, creating a new subsection (d) that establishes a Federal permitting program similar to other environmental statutes. States may submit a program to EPA for approval and permits issued pursuant to the approved state permit program operate in lieu of the Federal requirements. 42 U.S.C. 6945(d)(1)(A). To be approved, a State program must require each CCR unit to achieve compliance with the part 257 regulations (or successor regulations) or alternative State criteria that EPA has determined are ''at least as protective as'' the part 257 regulations (or successor regulations). State permitting programs may be approved in whole or in part. 42 U.S.C. 6945(d)(1)(B). States with approved CCR permitting programs are considered ''participating states''.

In states without an approved program, EPA is to issue permits, subject to the availability of appropriations specifically provided to carry out this requirement. 42 U.S.C. 6945(d)(2)(B). In addition, EPA must issue permits for CCR units in Indian Country. The legislation also authorized EPA to use its RCRA subtitle C information gathering and enforcement authorities to enforce the CCR rule or permit provisions, both in nonparticipating and participating States subject to certain conditions. 42 U.S.C. 6945(d)(4).

The statute expressly provides that facilities are to continue to comply with the CCR rule until a permit (issued either by an approved state or by EPA) is in effect for that unit. 42 U.S.C. 6945(d)(3), (6).

C. What is the agency's authority for taking this action?

These regulations are established under the authority of sections 1008(a), 2002(a), 4004, and 4005(a) and (d) of the Solid Waste Disposal Act of 1970, as amended by the Resource Conservation and Recovery Act of 1976 (RCRA), as amended by the Hazardous and Solid Waste Amendments of 1984 (HSWA) and the Water Infrastructure Improvements for the Nation (WIIN) Act of 2016, 42 U.S.C. 6907(a), 6912(a), 6944, and 6945(a) and (d). While the 2015 final CCR rule, and today's proposed revisions, implement EPA's authority under RCRA, as amended by HSWA and the WIIN Act, EPA does not intend for these proposed revisions to impose any other separate requirements under any other statute or regulation, including under the Clean Water Act and its implementing regulations.

III. What amendments associated with the judicial remand is EPA proposing?

A. Addition of Boron to Appendix IV of Part 257

The final CCR rule establishes a comprehensive system of groundwater monitoring and corrective action so that facilities detect and address groundwater releases. (80 FR 21396, April 17, 2015). The final rule requires facilities to employ a two-stage groundwater monitoring program. The first stage is ''detection monitoring'' for the constituents listed in Appendix III of the rule. Appendix III constituents are intended to provide an early detection as to whether contaminants are migrating from the disposal unit into groundwater.

If during detection monitoring, the facility determines there to be a statistically significant exceedance of any constituent over the established background level, the facility must begin the second stage of the monitoring program, ''assessment monitoring,'' by sampling for an expanded set of constituents, which are listed in Appendix IV of the rule. Appendix IV constituents are those that EPA has determined present risks of concern to human health or the environment. These are generally determined by risk assessment and/or damage cases, and are based on the characteristics of the wastes in the unit.

If an owner or operator determines, based on assessment monitoring, that concentrations of one or more of the constituents listed in Appendix IV have been detected at statistically significant levels above the site's established groundwater protection standards, that facility must initiate corrective action as described in the final rule. This determination (*i.e.*, that constituent concentrations are at statistically significant levels above the site's established groundwater protection standard) also triggers the requirement that an existing unlined CCR surface impoundment retrofit or close. Thus, the primary difference between listing on Appendix III and IV is that detection of a constituent on Appendix III initiates requirements for more extensive monitoring, while detection of a constituent on Appendix IV compels a facility to initiate remedial actions to clean up the contamination and, in some cases, to close the unit.

In the proposed CCR rulemaking (June 21, 2010), EPA included boron in both the detection monitoring (Appendix III) and the assessment monitoring (Appendix IV) lists, 75 FR 35253. The parameters that EPA proposed that facilities use as early indicators of groundwater contamination (Appendix III) were boron, chloride, conductivity, fluoride, pH, sulfate, sulfide, and total dissolved solids (TDS). EPA selected these constituents because they are present in CCR and would move rapidly through the subsurface and thus provide an early detection as to whether contaminants were migrating from the disposal unit. EPA also proposed a list of constituents for inclusion on Appendix IV. The list included all of the constituents found in CCR or leachate based on the data EPA had at the time: Aluminum, antimony, arsenic, barium, beryllium, boron, cadmium, chloride, chromium, copper, fluoride, iron, lead, manganese, mercury, molybdenum, selenium, sulfate, sulfide, thallium, and TDS. EPA then specifically asked for comment on this list and received a number of comments on these specific constituents.

In developing the final rule EPA generally relied on the same considerations it had relied on in the proposed rule. However, in response to comments, the final rule removed boron from Appendix IV, 80 FR 21500, April 17, 2015. The primary reason was that a Maximum Contaminant Level (MCL) had not yet been established under the Safe Drinking Water Act for boron. EPA generally preferred to include on Appendix IV only constituents that had established MCLs, as MCLs provide clear risk-based clean up levels in the event that corrective action is required. EPA also reasoned that because boron would remain on Appendix III it was unnecessary to include it on Appendix IV as facilities would be required to continue monitoring its concentration. Out of all the coal ash constituents modeled by EPA, boron has the fastest travel time, meaning that boron is likely to reach potential receptors before other constituents. Therefore, boron is expected to be one of the earliest constituents detected if releases to groundwater are occurring; consequently, EPA reasoned that retaining boron on Appendix III was more appropriate as it would function as a ''signal'' constituent that would ensure that assessment monitoring was quickly triggered in response to any release.

After the final rule was published, this decision was challenged as one claim in the multiparty litigation on the final rule. *See USWAG* v. *EPA,* No. 15–1219 (D.C. Cir.). In response to the litigation, EPA reexamined its decision to remove boron and concluded at that time that removing boron from Appendix IV had been inconsistent with other actions taken in the final rule. Specifically, fluoride had been included

on both Appendix III and Appendix IV. Removing boron from Appendix IV because of a lack of a MCL was also inconsistent with the approach to other constituents: Lead, molybdenum, cobalt and lithium were included on Appendix IV, and they lack MCLs. EPA also concluded, as discussed in greater detail below, that the facts independently warranted reconsidering the exclusion of boron from Appendix IV. In light of these conclusions, EPA settled this claim, agreeing to reconsider its decision through a new rule making. The settlement of this claim was presented to the Court without challenge, and on June 14, 2016, the Court severed this claim from the rest of the litigation over the final rule.

Accordingly, EPA is proposing to add boron to Appendix IV of part 257. This proposal is based on a number of considerations. First, the risk assessment (RA) conducted to support the final CCR rule shows that boron is one of nine constituents determined to present unacceptable risks under the range of scenarios modeled.[4] Of these constituents, boron is the only one associated with risks to both human and ecological receptors. Specifically, the 2014 risk assessment shows that boron can pose developmental risk to humans when released to groundwater and can result in stunted growth, phytotoxicity, or death to aquatic biota and plants when released to surfacewater bodies. EPA is proposing to rely on the existing 2014 risk assessment to support this part of this proposal, and EPA seeks public comment on whether this reliance is appropriate. The risks identified therein support including boron on Appendix IV along with arsenic, cadmium, cobalt, fluoride, lithium, mercury, molybdenum and thallium.

Second, when reviewing damage cases collected for the CCR rulemaking, EPA identified one or more ''contaminants of concern'' (COCs) for each damage case. Boron is a COC in more damage cases (approximately 50 percent of the total) than any Appendix IV constituent with the exception of arsenic. The damage cases reflect a range of waste types disposed in both surface impoundments and landfills. These damage cases corroborate the findings of the RA and also capture other risk scenarios that were not modeled in the RA, such as units that intersect with the groundwater table.

Third, as noted, out of all the coal ash constituents modeled by EPA, boron has one of the shortest travel times, meaning that boron is likely to reach potential receptors before other constituents. As such, including it on Appendix IV would ensure corrective action occurs soon after a potential release, prior to the appearance of slower-moving constituents hydrologically downstream from the source of contamination. Early detection and remediation would better protect human health and the environment by allowing for a response to contamination more quickly and preventing further and more extensive contamination, thereby limiting the exposures to human and ecological receptors. And although this consideration is not relevant under RCRA section 4004(a), early action will also have the benefit of reducing the costs to the facility of remediation, as the cost is necessarily greater to remediate more numerous contaminants and more extensive contamination.

Finally, inclusion of boron on Appendix IV would also be consistent with EPA's previous decisions for other constituents. EPA added cobalt, molybdenum, and lithium to Appendix IV even though these constituents do not currently have MCLs because they were found to be risk drivers in the 2014 risk assessment (80 FR 21404, April 17, 2015).

EPA included lithium on Appendix IV even though it does not have an MCL because it was detected in ''several'' damage cases (80 FR 21404, April 17, 2015). Lead was also detected in at least nine damage cases; and, as noted above, boron is a COC in approximately 51 percent of the total damage cases. By contrast, EPA removed aluminum, copper, iron, manganese and sulfide from Appendix IV because ''they lack maximum contaminant levels (MCLs)'' and were not shown to be constituents of concern based on either the risk assessment conducted for the rule or the damage cases (80 FR 21404, April 17, 2015).

In light of all of the information presented above, EPA is proposing to add boron to Appendix IV of part 257 and seeks comment on the appropriateness of including boron on Appendix IV in the absence of an MCL for the constituent.

B. Performance Standards To Increase and Maintain Slope Stability

As part of the Assessment Program [5] EPA determined that slope protection is an essential element in preventing slope erosion and subsequent deterioration of CCR unit slopes, and that the protective cover of slopes was a significant factor in determining the overall condition rating of all units.

So, in the final CCR rule EPA promulgated specific requirements for all CCR surface impoundments (except incised units) to install and maintain adequate slope protection. Specifically, the final rule required facilities to document that ''the CCR unit has been designed, constructed, operated, and maintained with . . . [adequate slope protection to protect against surface erosion, wave action, and adverse effects of sudden drawdown.'' §§ 257.73(d)(1)(ii); and 257.74(d)(1)(ii).

In developing the specific technical requirements for the final rule, EPA relied on existing dam safety technical literature, which universally recommends that vegetative cover not be permitted to root too deeply beneath the surface of the slope. Deep roots can potentially introduce internal embankment issues such as pathways for water intrusion and piping, precipitating erosion internally, or uprooting which is the disruption of the embankment due to the sudden uplifting of the root system. Based on these data, the final rule also required a vegetative cover height limitation to prevent the establishment of rooted vegetation, such as a tree, a bush, or a shrubbery, on the CCR surface impoundment slope, 80 FR 21476, April 17, 2015, and to prevent the obscuring of the slope during routine and emergency inspection. Based on the available information, EPA concluded that a vegetative cover height limitation of six inches above the face of the embankment was adequate to achieve these dual goals of preventing woody vegetation, while allowing inspectors adequate observation of the slope.

After the final rule was published, this provision was challenged on the grounds that EPA had failed to provide adequate notice of this requirement in the proposal. See, *USWAG et al.* v. *EPA,* No. 15–1219 (D.C. Cir. 2015). In response, EPA reexamined its decision, and agreed to reconsider this provision. This claim was settled, and the court vacated the requirement that vegetation on all slopes ''not . . . exceed a height of 6 inches above the slope of the dike'' within §§ 257.73(a)(4), 257.73(d)(1)(iv), 257.74(a)(4), and 257.74(d)(1)(iv). EPA is not proposing to reopen any other

[4] USEPA, ''Human and Ecological Risk Assessment of Coal Combustion Residuals'', December 2014; docket identification number EPA–HQ–RCRA–2009–0640–11993.

[5] In March 2009, the Agency's CCR Assessment Program (herein referred to as the Assessment Program) was initiated to evaluate the structural stability and safety of coal ash impoundments throughout the country. By September 2014, 559 impoundments had been assessed at over 230 coal-fired power plants. 80 FR 21313, April 17, 2015.

provisions of §§ 257.73 and 257.74, and will not respond to any comments received on those provisions. Because, as described below, slope protection is an essential element in preventing destabilization of a CCR surface impoundment, EPA is proposing to expand on the existing general performance standard with more specific slope protection requirements for existing and new surface impoundments. EPA is also proposing to establish distinct definitions and height limitations for grassy vegetation and woody vegetation to replace the vacated requirement. Finally, EPA is also proposing definitions for engineered slope protection measures, pertinent surrounding areas, slope protection, and vegetative height.

1. Performance Standards

Slope protection is an essential element in preventing destabilization of a CCR surface impoundment. Surficial and internal erosion, wave action, and rapid drawdown are some phenomena that can destabilize a surface impoundment. Surficial erosion is the removal of surface material, typically resulting from regular, intermittent physical phenomena such as surface run-off and wind action. Internal erosion, due to seepage and piping, is the removal of material beneath the surface of an embankment through the infiltration and transmission of water into and through the embankment. Wave action can cause erosion of embankment material typically caused by wave run-up in wind or storm events. Rapid drawdown is the rapid lowering of the water level of a reservoir which may precipitate slope failure due to residual high pore-water pressure in the embankment with a lack of counteracting pressure from the reservoir. In each of these phenomena, slope protection provides mitigating effects to counteract the phenomena through cohesion of the surface of the embankment. Furthermore, slope protection is necessary to ensure that dike or embankment erosion does not occur, both from the surface of the upstream or downstream slope, crest, or adjacent areas or from internal areas of the unit. Erosion of the embankment can precipitate more significant structural or operational deficiencies, such as beaching upstream from wave action, sloughing or sliding of the crest, discharge of solids to adjacent surface waters, and increased internal erosion. Finally, slope protection is necessary to maintain the stability of the CCR surface impoundment slope under rapid drawdown events [6] and low pool conditions of water bodies that may abut the CCR surface impoundment and are outside the reasonable control of the owner or operator, *e.g.,* a natural river which the slopes of the CCR surface impoundment intercept and abut. Accordingly, EPA is proposing to establish a number of new performance standards to ensure the stability of CCR surface impoundments.

First, EPA is proposing to modify the current regulation to require the owner or operator to ensure that both the slopes and the pertinent surrounding areas of any CCR surface impoundment (both existing and new) are designed, constructed, operated, and maintained with one or more of the forms of slope protection specified in the regulation. EPA has defined slope protection for this proposal as measures installed on the upstream or downstream slope of the CCR unit that protect the slope against wave action, erosion or adverse effects of rapid drawdown. Slope protection includes but is not limited to grassy vegetation, rock riprap, concrete revetments, vegetated wave berms, concrete facing, gabions, geotextiles, or fascines. EPA's proposed definition was developed from the available technical literature for dam safety, geotechnical engineering, and hydrology and hydraulics. The definition of slope protection includes examples of common modes of slope protection utilized in embankment dams, levees, dikes, and other engineering structures which interface with water or other impounded fluids.

EPA is proposing to define pertinent surrounding areas because adequate slope protection in surrounding areas is critical to the overall stability of the CCR surface impoundment. EPA has defined pertinent surrounding areas for this proposal as all areas immediately surrounding the CCR surface impoundment that have the potential to affect the structural stability and condition of the CCR surface impoundment, including but not limited to the toe of the downstream slope, the crest of the embankment, abutments, and unlined spillways. EPA intends this term to include all areas in the vicinity of the CCR unit that may influence the condition of the CCR unit. This would include all areas that good engineering practice dictates should be protected against adverse effects of erosion. See *e.g.,* Federal Emergency Management Agency's ''FEMA 534: Technical Manual for Dam Owners, Impacts of Plants on Earthen Dams'' (September 2005), a copy of which is available in the docket to this rulemaking.

However, the slope protection requirement would exclude certain areas on, adjacent, or near the CCR unit for which it is infeasible, impractical, or unsafe to maintain vegetation. These areas include specific design features of the unit that may occupy portions of the surface of the CCR unit. Such design features may include lined spillways, decant structures, access ways such as roads, paths, or stairs, or sluice pipes. Therefore, an owner or operator does not need slope protection to be designed, constructed, operated, and maintained in these areas. Furthermore, by the nature of these engineered structures, the integrity of the slope or pertinent surrounding area is typically maintained through the construction of the structure or the potential adverse effects to the integrity of the slope or pertinent surrounding area are limited by the nature of the structure. For instance, a properly designed, constructed, and maintained sluice pipe or decant structure may include preventative measures, such as a collar or a boot, which prevents the infiltration of water and potential erosion of the slope at the exit-point of the structure on the slope. An additional example of limited potential adverse effects would be that of a road or path on the crest of the embankment of the impoundment. Due to regular vehicle traffic, it may prove difficult to maintain vegetative cover on the surface of the travel path. Furthermore, due to the location and typical characteristics of the road, *e.g.,* located on the crest of the embankment with ample clearance from the edge of the upstream and downstream slopes, EPA does not anticipate substantial adverse effects due to erosion of the roadway based on its observations during the Assessment Program. Finally, the existing inspection and monitoring requirements of the final rule provide protection against the deterioration of the slopes and pertinent surrounding areas of the CCR surface impoundment in the locations where these structures are found. The integrity of these appurtenant design structures must be ensured by the professional engineer (PE) during regular assessments required in § 257.73 and § 257.74, to confirm that effects from erosion, wave

[6] In this provision, EPA is concerned with the rapid drawdown of adjacent water bodies acting upon the downstream slope of the CCR surface impoundment rather than the rapid drawdown of the impounded reservoir of the CCR surface impoundment acting upon the upstream slope of the CCR surface impoundment. Presumably, the water body of concern acting upon the downstream slope of the impoundment is outside the control of the owner or operator.

action, or other adverse phenomena are not introduced by the structures.

Similar to the original rule, EPA is proposing to require that slope protection consist of either grassy vegetation, engineered slope protection measures, or a combination of such measures. EPA is also proposing to establish specific performance standards that all slope protection measures must meet. First, the proposed rule would require that the owner or operator ensure that the slope protection measures are maintained in such a manner that allows for the adequate observation of and access to the CCR surface impoundment during routine and emergency events. Second, the regulation would require that the cover provide effective protection against surface erosion, wave action, and adverse effects of rapid drawdown.

2. Vegetative Cover

Grassy Vegetation. Adequate slope protection can be achieved in most climates through vegetation, typically a healthy, continuous dense stand of low-growing native grass species, or other similar vegetative cover. The most desirable form of slope protection, based on the technical literature, is a cover of native grass that creates cohesive coverage across the slope; this is due to its feasible maintenance, low cost of installation, and effective performance in maintaining slope integrity. In arid climates or submerged areas of the unit where the upkeep of vegetation is inhibited, alternate engineered slope protection measures, including rip-rap, or rock-armor, are typically used.

EPA is proposing to define grassy vegetation for this proposal as vegetation which develops shallow roots that do not penetrate the slope or pertinent surrounding areas of the CCR unit to a depth that introduces the potential of internal erosion or risk of uprooting and improves on the condition of the slopes and pertinent surrounding areas of the CCR unit. This definition is being proposed to provide a distinction between grassy vegetation—which EPA acknowledges can improve embankment slope stability, provided the vegetation does not inhibit adequate observation of or access to the slope or pertinent surrounding areas of the CCR unit—and woody vegetation, which can create unacceptable adverse risk to the structural stability and operational ability of the CCR unit. EPA has based the definition of grassy vegetation on ''FEMA 534: Technical Manual for Dam Owners, Impacts of Plants on Earthen Dams'' (September 2005) and the U.S. Army Corps of Engineers' ''ETL 1110–2–583: Guidelines for Landscape Planting and Vegetation Management at Levees, Floodwalls, Embankment Dams, and Appurtenant Structures'' (April 30, 2014).[7] This proposed definition helps to ensure that any vegetation installed by the owner or operator has a net positive effect on the condition of the unit. A continuous cover of grassy vegetation will prevent erosion of the surface or interior areas of the embankment, protect against the effects of wave action, and mitigate the effects of run-off from the CCR unit. EPA has identified some species of non-woody vegetation that do not provide protection against these adverse effects. These species would be considered weeds, which typically create a patch work of vegetative cover that do not provide a benefit to slope stability and are not intentionally installed by the owner or operator, and therefore do not meet the definition of grassy vegetation.

Weeds for this proposal can be wild vegetation that develops shallow-roots and are non-woody plants that do not create a contiguous cover, inhibit adequate observation of the slope and pertinent surrounding areas of the CCR unit and do not provide an advantageous effect on the condition of the slopes and pertinent surrounding areas of the CCR unit. EPA's description of weeds is based on FEMA guidance titled ''FEMA 534: Technical Manual for Dam Owners, Impacts of Plants on Earthen Dams'' (September 2005). EPA intends for all non-woody, grassy vegetation that do not provide an advantageous effect to the condition of the CCR unit to fall within this definition. Some examples of commonly found species considered to be weeds are: Herbaceous plants, vines, pigweed, ragweed, and thistle.

Woody Vegetation. EPA has defined woody vegetation for this proposal as vegetation that develops woody trunks, root balls, or root systems which can penetrate the slopes or pertinent surrounding areas of the CCR unit to a substantial depth and introduce the potential of internal erosion or risk of uprooting. Woody vegetation is not desirable when located on slopes or pertinent surrounding areas of CCR units; technical guidance consistently identifies the substantial risk of uprooting and internal erosion as a result of root system development from woody vegetation. This can lead to dam failure. Some examples of woody vegetation, as defined by the rule, include: Trees, bushes, and shrubbery.

Height Restrictions. The Assessment Program showed that the ability to adequately observe the surface of the slope and pertinent surrounding areas of the CCR surface impoundment are critical to early detection of deficiencies and overall maintaining of structural and operational integrity of the CCR units so EPA finalized height limitations in the CCR rule. However, EPA is now proposing new height limitations for any grassy and woody vegetative cover. Based on comments submitted from industry after the final rule was published, relating to the feasibility of vegetation management on CCR surface impoundments and the varied nature of technical guidance from federal agencies and organizations with jurisdiction or oversight over dam safety,[8] [9] EPA has subsequently determined that the 6 inch height limitation for grassy vegetation was overly restrictive and presented implementation problems for owners and operators.

In reviewing technical guidance from federal and state agencies and organizations, EPA found that the original 6 inch vegetative height limitation was a more conservative technical standard than is typically recommended in guidance. The U.S. Army Corps of Engineer's EM 1110–2–583 generally recommends that vegetation be limited to 12 inches in a ''vegetation free zone'' on and around embankment dams. In addition, the U.S. Army Corps of Engineer's EM 1110–2–583 recommends a minimum height of 3 inches to ensure the health of the grass species providing erosion protection and EPA agrees with this recommendation. The FEMA 534 technical manual does not prescribe a specific vegetative height limitation, but recommends that vegetation be maintained on the basis of achieving several dam safety goals, *e.g.*, permitting effective inspection and monitoring of the embankment, allowing adequate access, discouraging rodent, varmint, or other animal activity through elimination of habitat. Industry commenters have stated that maintaining a 6 inch or less vegetative cover in many regions of the United States was impractical during seasons of high precipitation, when the growth of grassy vegetation is at its greatest rate and access to the slopes of the

[7] A copy of these documents are available in the docket of this rulemaking.

[8] U.S. Army Corps of Engineers, EM 1110–2–583, ''Guidelines for Landscape Planting and Vegetation Management at Levees, Floodwalls, Embankment Dams, and Appurtenant Structures,'' April 30, 2014.

[9] Federal Emergency Management Agency, ''FEMA 534: Technical Manual for Dam Owners, Impacts of Plants on Earthen Dams,'' September 2005.

embankment is limited due to precipitation. They have also stated that when the slopes of the embankments are saturated due to precipitation, mowing may present undue risk of damaging the slopes of the embankment by mowing equipment.

In light of the above, EPA is proposing a vegetative height maximum limitation of 12 inches for grassy and woody vegetation. The 12-inch limit is drawn from the U.S. Army Corps of Engineer's EM 1110–2–583, which as previously noted, generally recommends that grassy vegetation be limited to 12 inches.

EPA is also proposing to define vegetative height as the linear distance measured between the ground surface where the vegetation penetrates the ground surface and the outermost growth point of the vegetation. This definition is being proposed in order to accurately identify the measurable height of vegetation for use in complying with the vegetative height limits of this rule. EPA intends this definition to reflect the maximum exposed length of the vegetative member along the main stalk of the member.

Woody Vegetation Maintenance. Finally, EPA is proposing to require that the vegetative cover be maintained so that all woody vegetation is removed and that any removal of woody vegetation with a diameter greater than ½ inch be directed by a qualified person, who must ensure that removal is conducted in a manner that does not introduce adverse risk to the stability and safety of the CCR unit or personnel undertaking the removal. EPA is proposing the specific numeric value of ½ inch for the maximum diameter of woody vegetation based on ease of reference and because the diameter represents the threshold for what EPA considers substantial woody vegetation. EPA seeks public comment as to whether a specific numeric value of greater than ½ inch for the maximum diameter of woody vegetation would be more appropriate.

Vegetative maintenance, particularly removal of a large tree or a shrubbery, must be undertaken with care so as not to allow for the uprooting of the root system and disturbance of substantial portions of the slope or surrounding pertinent areas of the CCR unit.[10] The removal and maintenance of such vegetation needs to be undertaken under the supervision of personnel familiar with the design and operation of the unit and in consideration of the complexities of removal of a tree or a shrubbery. Furthermore, the removal of vegetation must be conducted in a manner to ensure compliance with relevant environmental statutes, *e.g.*, National Environmental Policy Act, Endangered Species Act. EPA also seeks comment on requiring a specific timeframe in which woody vegetation must be removed.

Alternatives to Vegetative Cover. To accommodate climates or areas where it is infeasible for the owner or operator to maintain a vegetative cover, EPA is proposing to allow alternative forms of slope protection, *i.e.,* engineered cover or combination cover. EPA has proposed these alternative engineered slope protection measures to allow flexibility for owners or operators in maintaining an adequate slope protection cover system in locations where maintenance of vegetation may prove infeasible or where they do not wish to use grassy vegetation. These engineered slope protection measures, *i.e.,* engineered cover or combination cover, are available and effective in certain circumstances, and include but are not limited to rock or concrete revetments, vegetated wave berms, concrete facing, gabions, geotextiles, or fascines.

C. Clarify the Type and Magnitude of Non-Groundwater Releases That Would Require a Facility To Comply With Some or All of the Corrective Action Procedures in §§ 257.96–257.98

The CCR final rule establishes a number of requirements related to the detection and remediation of releases from a CCR unit. First, the groundwater monitoring and corrective action regulations in § 257.90 state that in the event of a release from a CCR unit, the owner or operator must immediately take all necessary measures to control the source(s) of releases so as to reduce or eliminate, to the maximum extent feasible, further releases of contaminants into the environment. The regulation specifies detailed procedures that must be followed in such cases, requiring that the owner or operator of the CCR unit comply with all applicable requirements in §§ 257.96, 257.97, and 257.98.

Section 257.96(a) also establishes two different standards for triggering corrective action, one for groundwater releases and one for non-groundwater releases. The requirement that a facility commence corrective action ''immediately upon detection of a release from a CCR unit'' applies only to non-groundwater releases. By contrast, the regulation requires corrective action for groundwater releases only upon a determination that contaminants are present in concentrations exceeding the groundwater protection standards in § 257.95(h).

In a separate section, the regulations also require that if a deficiency or release is identified during an inspection of a surface impoundment or landfill, the owner or operator must remedy the deficiency or release as soon as feasible, and prepare documentation detailing the corrective measures taken. See, §§ 257.73(d)(2), 257.74(d)(2), 257.83(b)(5), and 257.84(b)(5). However, these provisions do not require the facility to follow a particular process in cleaning up such releases.

After the final rule was published, the requirement that a facility must remediate any non-groundwater release using the same procedures applicable to the corrective action of groundwater releases in §§ 257.96–257.98 was challenged on the ground that EPA had failed to provide adequate notice of this requirement in the proposal. See, *USWAG et al.* v. *EPA,* No. 15–1219 (D.C. Cir. 2015). In response, EPA reexamined the provision and determined that some revision might be warranted to tailor the procedural requirements to the size or magnitude of the release. Specifically, EPA agreed that, in principle, for some non-groundwater releases, it may not be necessary for facilities to follow all of the corrective action procedures in §§ 257.96–257.98 in cleaning up or remedying the releases. Rather, for certain releases, such as releases that are small in scale, it might be preferable for the facility to focus primarily on the rapid remediation of these releases, consistent with §§ 257.90(d), 257.73(d)(2), and 257.83(b)(5), without requiring adherence to all of the corrective action procedures in §§ 257.96–257.98. Accordingly, EPA settled this claim by agreeing to reconsider the procedures a facility must use to clean up non-groundwater releases in a subsequent rulemaking. The settlement of this claim was presented to the Court without challenge, and on June 14, 2016, the Court severed this claim from the rest of the litigation over the final rule.

This portion of the proposed rule addresses whether the entire set of procedural requirements for corrective actions from the final CCR rule should apply to all non-groundwater releases. EPA is proposing to establish a subset of the corrective action procedures currently found in §§ 257.96–257.98 that would apply to non-groundwater releases that can be completely

[10] U.S. Department of Interior, Bureau of Reclamation, ''Water Operation and Maintenance, Bulletin No. 150'' which includes Guidelines for Removal of Trees and Vegetative Growth from Earth Dams, Dikes, and Conveyance Features, December 1989.

remediated within 180 days from the time of detection. Under these modified procedures, EPA would compress the reporting requirements into two steps: The initial notification of a release and the documentation that the release has been remediated. These revised procedures would be consolidated in a new section at § 257.99.

EPA designed many of the specific procedural requirements for non-groundwater releases in sections §§ 257.96–257.98 based on several notable ''catastrophic'' releases from CCR surface impoundments in recent history, such as the release of CCR materials from CCR surface impoundments from the Tennessee Valley Authority's (TVA) Kingston Fossil Plant in Harriman, TN, and the Duke Energy Dan River Steam Station in Eden, NC. However, EPA recognizes that all non-groundwater releases are not of a ''catastrophic'' nature, and may in some instances, be quite minor. Consequently, EPA is proposing to establish revised provisions to facilitate the most expeditious response to a release from a CCR unit from the owner or operator, and thereby to mitigate degradation.

EPA is proposing a 180-day time limit to complete remediation of the non-groundwater release. This time frame effectively serves to limit these provisions to releases that are expected to have limited potential for harm to human health and the environment. In this regard, EPA considers that the size and magnitude of the release, *i.e.,* the volume of harmful constituents released, is directly related to the time required to remedy the release.

EPA has identified a number of types of releases that may occur at CCR surface impoundments, and from those, identified the subset that EPA believes could be completely remediated under the existing performance standards within 180 days. Releases that can be cleaned up within 180 days are necessarily of a minimal volume. EPA expects that these reduced procedures are most likely to apply to incidental releases (including fugitive dust) that occur from seepage through the embankment, minor ponding of seepage at the toe of the embankment of the CCR unit, seepage at the abutments of the CCR unit, seepage from slopes, or ponding at the toe of the unit, rather than releases that of a ''catastrophic'' nature, as catastrophic releases are normally of a magnitude that remediation cannot be completed within 180 days. EPA seeks comment on whether 180 days is the appropriate timeframe in which an owner/operator would be expected to complete remediation of a non-groundwater release under this proposed provision, or whether a shorter deadline, *e.g.,* 120 days, or a longer deadline, *e.g.,* 240 days, would be more appropriate for remediating non-groundwater releases that are expected to have minimal impact to human health and the environment. EPA anticipates that these releases will typically be detected by qualified personnel or qualified professional engineers during weekly or annual inspections or during periodic assessments, as specified in the design and operating criteria of the CCR rule. These types of releases can indicate concerns regarding the structural stability of the unit and that further assessment for structural stability issues is warranted, but they do not typically constitute a substantial release of constituents to the environment in and of themselves.

On this basis, EPA has preliminarily concluded that this subset of small releases may not warrant all of the corrective action procedures specified in §§ 257.96–257.98. In these cases, it is preferable that the owner/operator focus on the rapid remediation of the release. However, EPA requests comment on whether 180-days is the appropriate time frame that best balances EPA's objective to ensure that small releases are remediated expeditiously, with the public's interest in understanding the practices occurring at the site that have the potential to affect their exposures and their groundwater.

Consistent with the proposed overall 180-day deadline for completing the cleanup, EPA is proposing to remove certain deadlines and to waive or compress certain reporting requirements found in the existing regulation, either because under the current regulation the requirement would fall due after the 180-day deadline, or because EPA considers that the benefit from the additional reporting requirement may be outweighed by the more expeditious clean-up of the site. Specifically, § 257.96 requires a facility to complete a written assessment of corrective measures within 90 days of detecting a release, place that assessment in the operating record, hold a public meeting to discuss the results of the corrective action assessment at least 30 days before selecting a remedy, and post the corrective action assessments to the publicly accessible facility website. Section 257.97 further requires a semiannual report describing the progress in selecting and designing a remedy, as well as a report upon selection of a remedy, describing the selected remedy and how it meets the standards in the regulation. Upon completion of the cleanup, section 257.98 requires the facility to prepare a report stating that the remedy has been completed, along with a certification from a qualified professional engineer attesting that the remedy has been completed in compliance with the regulation. This potentially multi-year structure was designed primarily to address releases that are large scale or that will otherwise require a substantial amount of time to remediate. It is less clear that this full process is truly necessary for smaller scale releases that could easily be completely cleaned up within a short period of time.

In lieu of the existing procedures EPA is proposing that within 15 days of discovering a non-groundwater release, the owner or operator must prepare a notification of discovery of a non-groundwater release, and place it in the facility's operating record as required by § 257.105. EPA is proposing this requirement to provide transparency, consistent with EPA's overall approach to corrective action under the existing regulations. Additionally, EPA is proposing that within 30 days of completing the corrective action of a non-groundwater release, the owner or operator must prepare a report documenting the completion of the corrective action. This report must include: (1) The facility's assessment of corrective measures to prevent further releases, to remediate any releases and to restore the affected area to original conditions; (2) the selected remedy, with an explanation of how it meets the standards specified in § 257.97; and (3) the certification by a professional engineer that the remedy has been completed in accordance with the regulation. Consistent with the existing regulation, the proposal also specifies that the remedy has been completed when the certification has been placed in the facility's operating record. The proposed rule would also require that the owner or operator comply with the recordkeeping requirements specified in § 257.105(h), the notification requirements specified in § 257.106(h), and the internet requirements specified in § 257.107(h). In the event the remedy has not been successfully completed within 180 days, the owner or operator must comply with the entire suite of corrective action requirements in §§ 257.96–257.98.

Under these modified procedures, EPA would compress the reporting requirements into two steps: The initial notification of a release and the documentation that the release has been remediated. Note that the same basic analytical steps would continue to apply—*e.g.,* the criteria for assessing the

corrective measures in § 257.96(c) and for evaluating the effectiveness of the remedy in § 257.97(b) remain in place. EPA is proposing that the facility document these analyses and solicit public input after conducting the cleanup, instead of before the cleanup. EPA is also proposing to waive the requirement in § 257.97(a) to prepare a semiannual report describing the progress in selecting and designing the remedy. Given that the remedy must be entirely completed within 180 days of discovering the release, a semiannual progress report is likely to be superfluous.

EPA recognizes that requiring public notification after the fact is different than requiring public consultation before the remedy is completed, and that in some situations the difference can be quite significant. For small or contained releases, EPA generally believes that the balance of interests is best struck in ensuring that these releases are remediated as quickly as possible, because the potential impact on the public is likewise limited. That balance shifts, however, as the potential for public impact increases. EPA therefore requests comment on whether some limited public involvement prior to completion of the clean-up would be appropriate. This could be achieved, for example, by delaying the initial notification and requiring the facility to provide details about the release and the planned remediation. Another alternative would be to require some kind of brief interim report to provide that information.

As noted, under the existing requirements, remediation is considered complete when a professional engineer has certified that the corrective action has met all the requirements of the section and the certification has been placed in the facility's operating record as required by § 257.105. Following the revisions to RCRA in the WIIN Act, EPA is proposing to expand this to allow a permitting authority in a participating state to make this determination.

As also noted previously, EPA is not proposing to modify the requirement to clean up all non-groundwater releases or the substantive performance standards that all remediation actions must meet. EPA is only proposing to revise the procedures the owner/operator must follow for non-groundwater releases that can be cleaned up within 180 days. However, in the interest of clarity, EPA is considering whether to incorporate the existing performance standards into the new subsection § 257.99 or whether it is sufficient to rely on cross-references to sections §§ 257.96–257.98. EPA specifically solicits comment on which approach would be most useful.

The provisions set forth in this rulemaking are intended solely to facilitate and expedite corrective action, without modifying the existing requirements to address all releases that occur or to ensure the protectiveness of the remedy. Therefore, no risk assessment was conducted to support this provision of the rulemaking.

D. Alternative Closure Requirements

The current regulations require that an owner or operator of a unit closing for cause pursuant to § 257.101, cease placing CCR and non-CCR wastestreams in the unit within six months of an event triggering closure. The current regulations provide a limited exception to this requirement in two narrow circumstances. First, an owner or operator may certify that CCR must continue to be managed in a CCR unit due to the absence of alternative disposal capacity. Section 257.103(a). Second, an owner or operator may certify that the facility will cease operations of the coal-fired boilers no later than dates specified in the final rule. Section 257.103(b). Under either of these alternative closure provisions, owners or operators may continue to place CCR, and only CCR, in a unit designated to close for cause for an extended period of time. Furthermore, the facility must continue to comply with all other provisions of the rule including groundwater monitoring and corrective action.

These exemptions were challenged as part of the litigation on the final rule on the ground that the exemption was too narrow. See, *USWAG et al.* v. *EPA,* No. 15–1219 (D.C. Cir. 2015). Specifically, plaintiffs alleged that during the rulemaking, commenters had informed EPA that facilities were using the same units to manage both CCR and non-CCR wastestreams, but the exemption only allowed the facility to continue to use the unit to dispose of CCR alone. The plaintiffs argued that EPA had failed to address their comments, and to provide any explanation for limiting the exemption to exclude the continued disposal of non-CCR wastestreams.

In response, EPA reexamined the record and concluded that it had failed to address these comments, and to explain the basis for its decision to restrict the exemption to the continued disposal of CCR alone. Accordingly, EPA settled this claim by agreeing to consider whether to expand this provision to situations in which a facility needs to continue to manage wastestreams other than CCR in the waste unit. The settlement of this claim was presented to the Court without challenge, and on June 14, 2016, the Court of Appeals for the D.C. Circuit remanded ''all of 40 CFR 257.103 (a) and (b)'' back to EPA to allow the Agency for further consideration.

Industry-Provided Information

On December 12, 2016, USWAG sent EPA a letter outlining the need for § 257.103 to include non-CCR wastestreams.[11] This letter has been placed in the docket of this proposed rule. The letter laid out four key premises for such an expansion of the alternative closure provisions. First, the letter explained that power plant operations produce volumes of non-CCR wastestreams in excess of the volumes of CCR wastestreams. These include boiler blowdown, boiler cleaning wastes, demineralizer regeneration washwater, cooling tower blowdown, air heater washwater, stormwater, and water treatment plant waste. Second, the letter explained that power plants do not have contingency plans in place to cover the inoperability of CCR surface impoundments. One anonymous company represented that the only time ponds are taken out of service for repairs and maintenance is during unit outages. Third, the letter provided examples of the new wastewater treatment systems that facilities would be forced to construct, including: Brine concentrators, surface impoundments, tank systems, filtration systems, chemical treatment facilities, and wastewater treatment systems. These systems were expected to take between 1.75 years and 7 years to construct. Finally, USWAG represented that 64,000 MW of coal, oil, and gas-fired capacity were at risk of shutdowns as a consequence of the current closure requirements.

USWAG followed up this letter with an executive summary of an EEI (Edison Electric Institute) reliability analysis.[12] This analysis evaluated electric reliability during peak summer electricity usage when removing the capacity of all boilers with unlined CCR impoundments receiving non-CCR wastewaters. This analysis assumed that the CCR impoundments had to be shut down, and that no alternative capacity

[12] EEI (Edison Electric Institute). 2017. *Potential Electric Reliability Risks Due to Cessation of Power Generation as a Result of the Closure of Unlined Surface Impoundments Under 40 CFR part 257.101 for the Failure to Meet Groundwater Protection Standards.* This document is available in the docket for this proposal.

was available for the non-CCR wastewaters. According to the executive summary, the resulting boiler shut downs would result in substantial impacts in three NERC (North American Electric Reliability Corporation) regions (SERC–E (Southeastern Electric Reliability Council-East), SERC–N (Southeastern Electric Reliability Council-North), and MISO (Midcontinent Independent System Operator)), minor impacts in three NERC regions (ERCOT (Electric Reliability Council of Texas), PJM, and SERC–SE (Southeastern Electric Reliability Council-South East)), and no impacts in remaining NERC regions. The analysis considered substantial impacts to be those where peak demand may not be met without shedding load and/or relying on imports. Minor impacts were those where reserves may fall below FERC standards.

EPA Proposal

EPA is not proposing to modify the alternative closure provisions of § 257.103(a) and will not respond to comments on those provisions. EPA is however, proposing to add a new paragraph (b) to allow facilities to qualify for the alternative closure provisions based on the continued need to manage non-CCR wastestreams in the unit. EPA is also not proposing to modify the alternative closure requirements of § 257.103(b) and will not respond to comments on those provisions (although EPA is proposing to redesignate § 257.103(b) as (c) as stated below). EPA is however, proposing to add a new paragraph (b) in this section to allow facilities to qualify for the alternative closure provisions based on the continued need to manage non-CCR wastestreams in a CCR unit that will cease operation of its coal-fired boilers within timeframes specified in the rule. Thus the facility, if it met the conditions, would be allowed to manage both CCR and non-CCR waste streams in the unit. EPA is also proposing to redesignate existing paragraphs (b) and (c) as paragraphs (c) and (e), respectively, and make conforming changes to this paragraph to reflect the non-CCR waste streams.

As noted previously, currently the alternative closure provisions remain unavailable for non-CCR wastestreams. The current regulation is explicit that the alternative closure provisions only allows for continued disposal of CCR, and therefore facilities must continue to comply with the current rule until an amendment is finalized.

EPA is proposing this exemption because substantial volumes of non-CCR wastestreams are generated at power plants, and may currently be managed in CCR surface impoundments. In the 2015 CCR rule, EPA discussed that the risks to the wider community from the disruption of power over the short-term outweigh the risk associated with the increased groundwater contamination from continued use of these units. 80 FR 21423, April 17, 2015. As it did for CCR in the 2015 CCR rule, this same concern would apply to non-CCR wastestreams if the CCR unit were unavailable for use and the community was left without power for an extended period of time. EPA solicits comment on ways to evaluate whether sustained loss of power to community will occur.

Based on the appendix provided in the December 12, 2016 letter from USWAG, these non-CCR wastestreams can range from insignificant (*e.g.,* 300 gallons per day for Company C's polisher regeneration waste) to massive (*e.g.,* 47.99 million gallons per day for Company C's stormwater). However, volumes alone do not adequately explain the difficulties that facilities may face. Some volumes are discharged to surface waters without treatment, and may be more amenable to alternative capacity or recirculation at the facility. For example, cooling water wastestreams may be recirculated.[13] Such wastestreams may be manageable through simple modifications of plant water flows and/or use of other existing capacity. However, other non-CCR wastestream volumes are treated in the CCR surface impoundments through settling of suspended solids to meet Clean Water Act permits. For example, coal pile runoff may be treated through settling in surface impoundments before being discharged.[14] These non-CCR wastestream volumes may require some level of pond or tank treatment that would not be sufficient in other existing, or easily constructible technology. Finally, some waste streams are primarily solids being sluiced for disposal, and require a long-term, permanent resting place of sufficient cumulative volume. For instance, pyrites at some power plants are combined with bottom ash in sluice conveying systems to ponds for their ultimate disposal. This wastestream may continue to be sluiced, in which case disposal impoundment volumes may still be necessary. However, it may also be managed jointly with bottom ash in wet-to-dry conversions, in which case landfill capacity may be necessary.[15]

As a result of the differences between these various non-CCR wastestreams, capacity may mean different things in different contexts. For other non-CCR wastestreams, capacity may mean the capacity to handle daily volumes of wastewater flowing between areas of the facility. Thus, EPA is proposing to provide a definition of capacity for the new section 257.103(b) which would be a basis for qualifying for the exemption. EPA solicits comment on the proposed use of this definition, as well as whether any additional clarification is warranted.

The differences discussed above also demonstrate why various non-CCR wastestreams may require more simple or more complex alternative capacity. This can impact the amount of time necessary to construct or otherwise locate that capacity. In the December 12 USWAG letter, timeframes to construct alternative capacity varied from 1.75 to 7 years. To achieve closure in the fastest practicable timeframe, owners and operators of facilities should transition each non-CCR wastestream to alternative capacity as such capacity becomes available. Thus, EPA is considering adding a condition requiring the facility to demonstrate that it lacks alternative capacity for *each* wastestream that continues to be managed under the alternative closure provisions and seeks comment on the proposed regulatory text. Under this proposed condition, any waste stream for which that finding cannot be made may not be managed in the unit. This condition would apply not only to the original determination, but to any subsequent determinations. Under the existing terms of the current regulation, the ability to continue to use the unit lasts only as long as no alternative capacity is available. Once the alternative capacity is identified, the owner or operator must arrange to use such capacity as soon as feasible. Section 257.103(a)(2)(ii). In addition, the current regulation requires the facility to annually document the continued lack of alternative capacity and the progress towards the development of alternative capacity. Section 257.103(a)(2)(iii). EPA is proposing to clarify that these

conditions apply to each individual waste stream that will continue to be managed in the unit and seeks comment on this approach.

In developing this provision, EPA relied on information from commenters to determine that this five-year period was feasible. The December 12, 2016 USWAG letter provides construction timeframes for a further 10 alternative disposal methods. All but one of these methods takes less than five years to construct. It appears these timeframes are therefore generally consistent with the timeframes on in the existing regulation; however, EPA solicits comment on alternative technologies and associated construction timeframes that have the potential to impact this period.

As noted previously, USWAG submitted an executive summary of an EEI reliability analysis. EPA understands that this analysis indicates that in some instances there may be an impact on electric reliability caused by surface impoundment closure. Consequently, EPA is proposing to limit the new alternative closure requirements to facilities that have the potential to impact electric reliability. Specifically, EPA is proposing to limit the expanded exemption to facilities in one of the three FERC regions that the EEI analysis concludes are likely to suffer substantial reliability impacts.

EPA notes that the EEI executive summary cautioned:

''Those reviewing the EEI findings should recognize that our findings were not part of any detailed planning study and provide a very high level review of possible worst case impacts on a regional level.''

Although EPA was able to review only the executive summary of this analysis, and therefore cannot draw definitive conclusions, EPA agrees that these impacts appear to be worst-case for several reasons that were clear from the executive summary alone. First, the EEI analysis assumes that all unlined CCR impoundments leak above the groundwater protection standards and the CCR units would have to be closed for cause. Second, the analysis assumes that non-CCR wastestreams were being managed in all of those CCR impoundments. Third, the analysis assumes that alternative capacity for those non-CCR wastestreams could not be found or constructed within the six-month period for closure to commence. Finally, the analysis assumes that the lack of capacity would cause the associated coal boilers to cease operation. EPA considered each of these assumptions to be worst-case as explained below.

First, the assumption that *all* unlined surface impoundments leak above the groundwater protection standard is contrary to EPA's 2014 risk assessment. This conclusion is further bolstered by the final risk assessment which showed that even input porewater concentrations from some surface impoundments were below the groundwater protection levels. Thus, the assumption that all surface impoundments leak above groundwater protection standards is worst-case rather than a best estimate.

Similarly, not all unlined CCR units manage non-CCR wastestreams. Rather than use either the non-CBI (confidential business information) data available from the 2010 Office of Water (OW) questionnaire or some other industry-provided data set, EEI has assumed that all unlined CCR units also manage non-CCR wastestreams. A quick scan of the information available in the non-CBI OW questionnaire reveals dozens of CCR surface impoundments that do not receive non-CCR wastewaters.[16]

Third, the assumption that no facility could construct alternative capacity within the time frames in the current regulation is contrary to other information presented in the USWAG letter. This letter documents several alternative disposal methods that take only two or three years to construct. It thus appears to generally be feasible for facilities with knowledge of leaking units to begin and complete the construction of these ponds, tanks, and other capacity in the time that the rule lays forth for closure to commence. If the facilities that believe that their units are leaking, or likely leaking, had already begun this construction when they first learned of the regulatory requirements, many would be nearing completion as of this rulemaking.

When taken as a whole, these worst-case assumptions result in an analysis may overestimate the effects to the electricity grid. In EPA's final rule Regulatory Impact Analysis (RIA),[17] EPA modeled electricity impacts using the Integrated Planning Model (IPM). This model exercise showed minimal retirements or effects on total capacity over the timeframe modeled. However, while the EEI analysis may be an overestimate of impacts on reliability, other entities have found that the combination of several environmental regulations may nevertheless contribute to regional reliability issues. For instance, in 2012 the GAO (Government Accountability Office) found that 18 percent of coal-fired capacity in the Midwest could retire.[18] Although the GAO concluded that EPA regulations were not expected to pose widespread concerns, it did find that these regulations could contribute to challenges in some regions. Similarly, NERC reviewed the potential reliability effects of combined EPA regulations on the power sector in 2010 and 2011.[19] [20] In those long-term reliability analyses, NERC made several recommendations. NERC recommended that EPA defer compliance targets and grant extensions where there is a demonstrated reliability need. NERC also recommended that industry make investments to retrofit or replace capacity that might be affected by (at the time) forthcoming EPA regulations.

While the NERC and GAO reports both took account of numerous EPA regulations that have since been stayed, EPA nevertheless acknowledges that the impacts of environmental regulations can potentially affect reliability when deadlines are not flexible. As a result, EPA is considering restricting the alternative closure provisions to facilities in the NERC regions and sub-regions showing the potential for substantial impacts in the EEI report. The three regions are MISO, SERC–E, and SERC–N. For facilities that are located in, or regularly provide the majority of generated electricity to, those regions, the facilities may qualify for the alternative closure provisions due to non-CCR wastestreams provided the other requirements are met.[21] EPA notes that to demonstrate that a facility regularly provides the majority of its generated electricity to one of these regions, it is not necessary that the facility provide such quantities with a high frequency. For instance, if a facility outside of one of these regions only provided a majority of its generation to that region during peak times in summer months, the fact that this is

done regularly, year after year, would be sufficient.

EPA solicits comment on the proposal to limit the exclusion under proposed new paragraphs (b) and (d) of § 257.103 for non-CCR wastestreams to the three specific NERC regions and sub-regions that have a demonstrated reliability need. Without the EEI analysis, EPA can only conservatively assume, as industry does, that the three regions and sub-regions showing substantial impacts in the EEI analysis have such a demonstrated need. EPA also solicits comment on the appropriateness of allowing facilities outside a NERC region to qualify if they provide electricity to that region, as well as other reasonable standards for determining which facilities qualify.

IV. What amendments associated with the WIIN Act is EPA proposing?

During the rulemaking for the current regulations for CCR in 40 CFR part 257, EPA received numerous comments requesting that EPA adopt alternative performance standards that would allow state regulators (or facilities) to ''tailor'' the requirements to particular site conditions. Many requested EPA adopt particular performance standards found in EPA's municipal solid waste landfill (MSWLF) regulations in 40 CFR part 258. As discussed in the preamble to the final 1991 rule establishing the part 258 requirements, EPA incorporated the concept of ''differential protection of groundwater'' as a basis for allowing regulatory flexibility depending on the quality of the groundwater source.[22] Although the CCR rule was largely modeled on the MSWLF regulations, as explained in both the proposed and final rules, under the statutory provisions relevant to the CCR rule, EPA lacked the authority to establish a program analogous to part 258, which relies on approved states to implement the federal criteria through a permitting program. In the absence of a mandated state oversight mechanism to ensure that the alternative standards would be technically appropriate, EPA concluded it could not adopt many of the ''more flexible'' performance standards in part 258 that commenters requested.

As fully explained in the preamble to the April 2015 CCR rule, the statutory structure established by Congress requires EPA to establish national minimum criteria that ensure there is ''no reasonable probability of adverse effects on health or the environment.'' States may, but are not required to adopt or implement these criteria; thus the national minimum criteria apply to all facilities even in the absence of a regulatory entity to implement or oversee them. EPA in establishing these national minimum criteria had to show through its rulemaking record that the final rule would achieve the statutory standard of ''no reasonable probability of adverse effects on health or the environment'' at all sites subject to the standards. This means that the standards must be protective of all sites, including the most highly vulnerable sites. The statute provided no mechanism for site specific flexibility as in the MSWLF program in part 258.

However, in 2016 Congress amended RCRA to establish a permit program analogous to that established for MSWLFs. See Unit II.B for additional detail. Under these new provisions, States may now apply to EPA for approval to operate a permit program to implement the CCR rule. As part of that process, a State program may also establish alternative State technical standards, provided EPA has determined they are ''at least as protective as'' the CCR regulations in part 257. 42 U.S.C. 6945(d)(1)(B), 6945(d)(1)(C).

In light of the legislation, EPA returned to the existing 40 CFR part 258 regulations to evaluate the performance standards that rely on a state permitting authority. EPA evaluated whether there was sufficient evidence in the record for those regulations to support incorporating either the part 258 MSWLF provision or an analogue into the part 257 CCR regulations. One complication is the statutory standard for the part 258 regulations is different than the standard for the CCR regulations. The CCR regulations are based on RCRA section 4004(a), which requires the regulations to ensure ''there is no reasonable probability of adverse effects on health or the environment from disposal of solid waste at such facility.'' 42 U.S.C. 6944(a). By contrast, EPA was authorized to ''take into account the [facility's] practicable capability'' in developing the part 258 regulations. 42 U.S.C. 6949a(c). As a consequence, the rulemaking record for some part 258 provisions may not fully support a determination that a particular provision meets the RCRA section 4004(a) standard or will be ''at least as protective'' as EPA's CCR regulations.

Based on the results of this evaluation, EPA is proposing to adopt several provisions modeled after the following in part 258: (1) The State Director may establish alternative risk-based groundwater protection standards for constituents for which Maximum Contaminant Levels (MCLs) have not been established (see § 258.55(i) and (j)); (2) The State Director may determine that remediation of a release of an Appendix IV constituent is not necessary under certain conditions (see § 258.57(e) and (f)); (3) The State Director may determine that groundwater monitoring requirements under §§ 257.91–257.95 may be suspended if there is evidence that there is no potential for migration of hazardous constituents to the uppermost aquifer during the active life of the unit and post-closure care (see § 258.50(b)); (4) The State Director may specify an alternative length of time to demonstrate that remedies are complete (see § 258.58(e)(2)); (5) The State Director may modify the length of the post-closure care period (see § 258.61(b)); and (6) The State Director may decide to certify that the regulatory criteria have been met in lieu of the exclusive reliance on a qualified professional engineer. These part 258 provisions in the MSWLF regulations were adopted based solely on a finding that they would protect human health and the environment, which is not appreciably different from the standard under RCRA section 4004(a). See, 75 FR 35193 (June 21, 2010). Thus, in proposing these flexibilities, EPA believes that the statutory standard under RCRA section 4004(a) is met.

In addition, under the WIIN Act, EPA is the permitting authority for CCR units located in Indian County. EPA would also serve as the permitting authority for CCR units located in nonparticipating states subject to a Congressional appropriation to carry out that function. EPA is proposing that where it is the permitting authority, it will have the same authority as the Director in an approved or participating state to apply the alternative performance standards. In order to make this clear, EPA is proposing to revise the definition of State Director in § 257.53 to clarify that the term ''State Director'' includes EPA where EPA is the permitting authority (that is on Tribal lands and in nonparticipating states if EPA were to receive appropriations specifically for the purpose of issuing permits). EPA seeks comment on this approach or on the alternative of adding the words ''or EPA where it is the permitting authority'' to each of the proposed flexibilities.

Further EPA is considering further modifications to these provisions, analogous to the 2010 proposal, and is seeking comment on whether it is appropriate and consistent with the WIIN Act for these alternative performance standards to apply directly to a facility in a nonparticipating State

[22] 56 FR 50978, 50995–96 (Oct. 9, 1991).

on the basis that the units in the nonparticipating states are subject to oversight by EPA through the enforcement authorities provided directly to EPA under the WIIN Act. As discussed below, EPA seeks comment on alternatives for implementing such flexibilities, for example, through appropriate detailed technical analyses, certification(s) by an independent professional engineer (or other appropriate technical expert or experts), reliance on state ground water standards, notifications to EPA, posting on the facility's publically available website, etc.

In addition, EPA is seeking comment on whether it would be appropriate and consistent with EPA's authority for an approved State or EPA in a nonparticipating state, or an owner or operator subject to EPA oversight, to establish alternative, risk-based location restrictions in lieu of the location restrictions found at §§ 257.60–257.64. For example, in the 2010 proposed CCR rule, EPA proposed a location restriction requiring demonstration that a CCR unit be located a minimum of two feet above the upper limit of the natural water table.[23] The final rule changed the requirement to five feet above the uppermost limit of the uppermost aquifer.[24] An owner or operator could also satisfy the location restriction by demonstrating the absence of an intermittent, recurring, or sustained hydraulic connection between the CCR unit and the uppermost aquifer.[25] EPA seeks comment on whether a State, or an owner/operator through a detailed technical analysis or certification(s) by an independent professional engineer (or other appropriate technical expert or experts), could establish alternative location restrictions that would satisfy the standard in RCRA section 4004(a). EPA also seeks comment on whether the October 17, 2018 compliance deadline for the location restrictions at §§ 257.60–257.64 is appropriate in light of the WIIN Act or whether an alternative deadline, either through a permit program established under the WIIN Act or one that applies directly to the facility itself during an interim period, would be more appropriate to facilitate implementation of the WIIN Act and any changes as a result of this rulemaking.

Moreover, for any adopted site specific performance standards (whether approved by the State, EPA, or implemented by the facility itself), EPA is requesting comments on whether the facility or owner operator should be required to post the specific details of the modification of the performance standard to the facility's publically accessible website or require any other recordkeeping options.

Finally, as described in Unit IV.G below, EPA is proposing one modification to the closure section in a certain situation to allow the use of CCR in construction of the cover system.

A. Alternative Risk-Based Groundwater Protection Standards

The current regulations at § 257.95(h) require the CCR unit owner or operator to set the groundwater protection standard (GWPS) at the MCL or background for all constituents from Appendix IV to part 257 that are detected at a statistically significant level above background. The GWPS must be set at the MCL for all Appendix IV constituents for which there is a promulgated level under section 1412 of the Safe Drinking Water Act. If no MCL exists for a detected constituent, then the GWPS must be set at background. In cases where the background level is higher than the promulgated MCL for a constituent, the GWPS must also be set at the background level.

In the 2010 proposal, EPA proposed allowing an owner or operator to establish an alternative GWPS for constituents for which an MCL has not been established provided that the alternative GWPS has been certified by an independent registered professional engineer and placed in the operating record and on the owner's or operator's publicly available website. In finalizing the GWPS requirements, EPA declined to allow a qualified professional engineer to establish alternative GWPS because EPA determined it was ''inappropriate in a self-implemented rule, as it was unlikely that a facility would have the scientific expertise necessary to conduct a risk assessment, and was too susceptible to potential abuse.'' [26]

In this rulemaking EPA is proposing to adopt a provision analogous to 40 CFR 258.55(i), the regulations applicable to MSWLFs. Under the existing part 258 provision, the Director of a state permitting authority in a state with an approved MSWLF permitting program may establish an alternative GWPS for constituents without an MCL, provided that it is an appropriate health-based level established in accordance with the specific criteria in this regulation. The only constituents listed in Appendix IV of the final CCR rule that currently have no MCL (and therefore, the only ones that fall under this proposal) are cobalt, lead, molybdenum and lithium. Boron, which is proposed for addition to Appendix IV, also does not have an MCL. First, these are ''health based levels,'' which means that the only relevant consideration is whether the alternate standard will protect potential receptors (both human and environmental); costs or any similar considerations may not be considered. In addition, 40 CFR 258.55(i) specifies that all of the following criteria must be met: (1) The level is derived in a manner consistent with Agency guidelines for assessing the health risks of environmental pollutants (51 FR 33992, 34006, 34014, 34028, Sept. 24, 1986); (2) The level is based on scientifically valid studies conducted in accordance with the Toxic Substances Control Act Good Laboratory Practice Standards (40 CFR part 792) or the equivalent; (3) For carcinogens, the level represents a concentration associated with an excess lifetime cancer risk level (due to continuous lifetime exposure) within the 1×10^{-4} to 1×10^{-6} range; and (4) For systemic toxicants (*i.e.,* chemicals that cause effects other than cancer), the level represents a concentration to which the human population (including sensitive subgroups) could be exposed to on a daily basis that is likely to be without appreciable risk of deleterious effects during a lifetime. For purposes of this subpart, systemic toxicants include toxic chemicals that cause effects other than cancer or mutation.

The Agency is proposing to allow participating states to set an alternative groundwater protection standard that is largely based on the four criteria specified in this part 258 provision. However, the criteria specified under the proposed revisions to § 257.95(h) would not be identical to those in 40 CFR 258.55(i). Rather EPA is proposing to use modified criteria in the CCR rule that would account for more recent science policies and for the specific characteristics of these wastes. EPA requests comments on the use of the modified criteria for CCR. These proposed modifications are described below.

As in the part 258 MSWLF regulation, EPA is proposing to allow the Director of a state with an EPA-approved CCR permitting program (and EPA where it is the permitting authority) to establish an alternative GWPS ''health-based level'' for constituents without an MCL. Consistent with part 258, this alternative GWPS is to be a health-based standard that will be protective of potential receptors (both human and ecological) and is not based on any non-

[23] 75 FR 35128, 35241 (June 21, 2010).

[25] Id.

[26] 80 FR at 21405 (April 17, 2015).

risk based factors, such as the cost to achieve that standard. EPA is proposing to adopt these provisions without change. As an alternative, similar to the language in the 2010 proposal for § 257.95(h), EPA is also considering further modifying this provision and is seeking comment as to whether an alternative risk-based GWPS could be established by an independent technical expert or experts (where there is no approved permitting authority, that is in a ''nonparticipating state''). That expert(s) would be required to derive the standard in a manner consistent with Agency guidelines (as described below); however, that alternative standard could be implemented by the facility without the intervention of a permitting authority, for example, through the use of a certified technical expert(s) or by reliance on state groundwater standards or other risk-based approach. EPA seeks comment on this approach and whether such an approach would satisfy the underlying statutory requirement of no reasonable probability of adverse effects on health or the environment from disposal of solid waste at such a facility and whether the new authorities provided to EPA in the WIIN Act for oversight and enforcement make such an approach feasible and adequate to address the concerns EPA identified in the preamble to the 2015 CCR rule that an owner or operator would not be expected to have the requisite experience necessary to conduct a risk assessment and that such an approach would be susceptible to abuse. Depending on the comments received and EPA's analysis thereof, EPA may ultimately adopt such an approach.

The current § 257.95 establishes the requirements for an assessment monitoring program, including a series of 90-day time periods in which an owner or operator has to perform the required analysis and demonstrations. The 90-day time periods are based on similar requirements and time periods in the part 258 requirements. However, EPA seeks comment on whether 90 days is an appropriate time period for the assessment monitoring requirements for CCR in light of the WIIN Act or whether alternative time periods, e.g., 120 days or 150 days, are necessary to perform the required analysis and demonstrations for CCR and whether such alternative time periods would be more appropriate to facilitate implementation of the WIIN Act and any changes as a result of this rulemaking.

EPA is also proposing to adopt the part 258 provision that requires an alternative groundwater protection standard to be derived in a manner consistent with Agency guidelines. However, some of the guidelines cited in part 258 have since been replaced or supplemented. Therefore, EPA is proposing to replace the citations with the updated versions. Specifically, EPA is proposing to cite to the *Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures,*[27] which supplements 51 FR 34014 (September 24, 1986); the *Guidelines for Developmental Toxicity Risk Assessment,*[28] which amends 51 FR 34028 (September 24, 1986); and the *Guidelines for Carcinogen Risk Assessment,*[29] which amends 51 FR 33992 (September 24, 1986). In addition, EPA proposes to add the guidance on deriving a reference dose, *Reference Dose (RfD): Description and Use in Health Risk Assessments.*[30] These are the current guidance documents that are most relevant to the constituents of concern for the wastes at issue. EPA seeks comment on this proposal.

EPA is also proposing to adopt, without modification, the part 258 provision that requires the alternative standard to be based on scientifically valid studies conducted in accordance with the Toxic Substances Control Act Good Laboratory Practice Standards (40 CFR part 792) or the equivalent. EPA requests comment on this approach.

EPA is proposing to adopt, with modifications, the part 258 provisions specifying that the alternative standard is set at a level that is associated with an excess lifetime cancer risk within the 1×10^{-4} to 1×10^{-6} range for carcinogens and that is likely to be without appreciable risk of deleterious effects from daily exposures for systemic toxicants. For carcinogens, EPA is also proposing to require that States use a cancer slope factor to establish the alternate GWPS within the relevant risk range. For non-carcinogens, EPA is proposing to require that States use a reference dose to establish the alternative GWPS, with a hazard quotient (HQ) of 1 as the upper bound on risk. This is the same methodology used to establish the technical criteria in the existing CCR regulation. Reliance on his methodology is also reasonable in this regulation as it ensures that this provision (and any alternative GWPS under this provision) will meet the requisite statutory standards. Some examples of groundwater values consistent with these requirements (indeed all of the proposed requirements) are Action Levels promulgated under the Safe Drinking Water Act and the Regional Screening Levels for Chemical Contaminants at Superfund Sites.[31] EPA requests comment on this approach.

In addition, EPA is considering requiring that for systemic toxicants (i.e., for chemicals that cause effects other than of deleterious effects during a lifetime. This is largely the same as the current part 258 requirement; however cancer), the alternate level represents a concentration to which potential receptors (including sensitive subgroups) could be exposed to on a daily basis that is likely to be without appreciable risk, EPA seeks comment on whether it should revise the relevant target from ''human population'' to ''potential receptors.''

Although this proposed rulemaking sets a target risk based on a risk range of 1×10^{-4} to 1×10^{-6} for carcinogens and an HQ = 1 for non-carcinogens, States would not be precluded from setting more stringent standards. The existing regulation in 40 CFR 258.55(j) identifies three other site-specific factors that may indicate the need to establish a risk level for a particular contaminant that is more protective than these levels. These are: (1) The presence of multiple contaminants in the groundwater; (2) exposure threats to sensitive environmental receptors; and (3) other site-specific exposure or potential exposure to groundwater. These factors are equally relevant to CCR facilities, and so EPA is proposing to incorporate them without any modifications. EPA requests comment on this approach.

Because any alternate GWPS will be based on established risk levels, it is reasonable that a state may set a level above background so long that it is equal to or lower than this alternate threshold. Thus, any alternate GWPS that meets the requirements specified in this proposal would still protect potential receptors from the reasonable

maximum exposures identified in the final risk assessment.

B. Modification to Corrective Action Remedy

Once corrective action is triggered, the current regulations at § 257.97 require the CCR unit owner or operator to select a remedy for corrective action. In addition, § 257.98 requires the CCR unit owner or operator to begin implementing that remedy within 90 days of remedy selection.

EPA is proposing to adopt a provision analogous to 40 CFR 258.57(e) for municipal solid waste landfills (MSWLF). This part 258 provision allows the Director of a state permitting authority in participating states to determine that remediation of a release of an Appendix II to part 258 constituent from a MSWLF unit is not necessary if the owner or operator can make certain demonstrations to the satisfaction of the Director. Specifically, § 258.57(e) specifies that the Director may determine that remediation is not necessary if the owner or operator demonstrates to the satisfaction of the Director of a participating State that:

(1) The groundwater is additionally contaminated by substances that have originated from a source other than a MSWLF unit and those substances are present in concentrations such that cleanup of the release from the MSWLF unit would provide no significant reduction in risk to actual or potential receptors; or

(2) The constituent is present in groundwater that:

a. Is not currently or reasonably expected to be a source of drinking water; and

b. Is not hydraulically connected with waters to which the hazardous constituents are migrating or are likely to migrate in a concentration that would exceed the groundwater protection standards; or

(3) Remediation of the release is technically infeasible; or

(4) Remediation would result in unacceptable cross-media impacts.

Part 258 also states that even if the Director of a participating state does determine that remediation of the release is not necessary, this shall not affect the authority of the State to require the owner or operator to undertake source control measures or other measures that may be necessary to eliminate or minimize further releases to the groundwater, to prevent exposure to the groundwater, or to remediate the groundwater to concentrations that are technically practicable and significantly reduce threats to human health or the environment. 40 CFR 258.57(f).

EPA is proposing to adopt this same provision into part 257 with one modification. EPA is proposing that a State Director may, on a site-specific basis, decide not to require cleanup of part 257 Appendix IV constituents released to groundwater from a CCR disposal unit where: (1) The groundwater is contaminated by multiple sources and cleanup of the CCR release would provide no significant reduction of risk; or (2) the contaminated groundwater is not a current or potential source of drinking water and is not hydraulically connected with waters to which the part 257 Appendix IV constituents are migrating or likely to migrate in a concentration(s) that would exceed the groundwater protection standards; or (3) remediation is not technically feasible; or (4) remediation would result in cross-media impacts. In part 258, an owner or operator is not required to undertake source control measures unless ordered by a State Director to do so. Although today's proposal includes § 257.97(g), which would make source control measures mandatory in a departure from part 258, EPA is considering making the source control measures for CCR units discretionary, similar to part 258, and seeks comment on this approach. For example, while the Director may determine that total remediation is not required, EPA seeks comment on whether source control measures (*e.g.,* covers and/or flow control measures or closure, if triggered by § 257.101(a)–(c)) to minimize or eliminate further releases could not be waived. In other words, EPA seeks comment on whether a State or EPA as the permitting authority in a nonparticipating state, or a facility directly implementing the requirements of this rule and subject to EPA oversight and public notice, should have discretion not to require or perform source control measures, including closure, in certain situations, *e.g.,* where there is no reasonable probability of adverse effect to human health or the environment. In addition, partial remediation of groundwater to concentrations that are technically feasible and that significantly reduce risks would also be required. EPA also seeks comment on this proposed approach. EPA describes each of these in further detail below. Under part 258, these provisions are discretionary. Depending on the comments EPA receives, EPA may modify the proposed requirements at § 257.97 to more closely reflect the source control measures contained in part 258. If EPA makes any such changes to § 257.97, it may also make conforming changes to § 257.101.

As noted, the Agency is proposing that participating states may waive the clean-up requirements where the groundwater is already contaminated by multiple sources and clean-up of the CCR release would provide no significant reduction of risk. In some cases, CCR units releasing part 257 Appendix IV constituents to the groundwater may be located in areas that already are significantly contaminated by other sources. Where releases from the CCR units are minor compared to the overall area-wide contamination, or where remedial measures aimed at the CCR unit would not significantly reduce risk, EPA believes that remediation of releases from the CCR unit would not be necessary or appropriate. Proposed § 257.97(f) is intended to address such situations.

Section 258.57(e)(1) applies only where sufficient evidence exists that the groundwater is contaminated by a source other than the CCR unit. In such cases, the owner or operator must demonstrate that cleanup of a release from its unit would provide no significant reduction in risk to receptors due to concentrations of constituents from the other source. EPA has previously characterized this provision as requiring facilities to make a robust demonstration that other sources are significant contributors to the contamination; this provision is not intended to provide facilities with a general opportunity to seek a waiver from the existing cleanup requirements under part 257.

The Agency is not proposing to define ''significant reductions'' in risk in this rulemaking, but consistent with the MSWLF rules, believes the decision is best made on a case-by-case basis by the State. The Agency understands and anticipates that states may have difficulties in defining ''significant reduction of risk'' but expects that States will be able to draw from their experience in implementing the analogous requirement in § 258.57(e)(1). Consistent with that provision, participating states should take a protective approach when evaluating requests for such a waiver. As one potential example, EPA considers that where the facility could document that the risks to potential receptors from non-CCR constituents would still exceed acceptable levels of concern (*i.e.,* risks greater than 1×10^{-4} to 1×10^{-6} for carcinogens, or an HQ greater than 1 for non-carcinogens) even if all CCR constituents had been removed, the facility could demonstrate there would be no significant reduction of risk from remediation of the CCR constituents. However, EPA solicits comment on whether there are additional criteria that

would be useful in further defining the proposed regulatory provision under § 257.97(f)(1), *e.g.,* criteria that states have used in implementing the analogous provision in part 258.

Under proposed § 257.97(f)(2), the State may also determine that a hazardous constituent that has been released from a CCR unit to groundwater does not pose a threat to human health and the environment and, therefore, does not require remediation if: (1) The groundwater is not a current or potential source of drinking water and (2) the groundwater is not hydraulically connected with waters that could be a current or potential source of drinking water or are not likely to migrate in a concentration(s) that would exceed the groundwater protection standards established under § 257.95(h). EPA generally interprets this to require a determination that the quality of the water in the aquifer is such that it could not reasonably be expected to be used as drinking water, even if treated to remove the contaminants. The provision does not allow a waiver on the grounds that the cost of treating the water to remove the contaminants is too high. EPA realizes that it is difficult to predict future improvements in treatment technologies, or to determine hydraulic connection. In interpreting whether the aquifer meets these regulatory criteria, States may use the approach outlined in the Agency's Ground-Water Protection Strategy (August 1984) as guidance.[32] As described in this guidance, typically Class III groundwaters will be considered to meet the requirements specified in § 257.97(f)(2). Class III groundwaters are groundwaters not considered potential sources of drinking water. They are groundwaters with high salinity, total dissolved solids levels over 10,000 mg/l, or are otherwise contaminated beyond levels that allow cleanup using methods reasonably employed in public water system treatment. These groundwaters also must not migrate to Class I or II groundwaters or have a discharge to surface water that could cause degradation. The need to remediate Class III groundwaters should be assessed on a case-by-case basis. Under the second criterion, the owner or operator must also demonstrate that the uppermost aquifer is not hydraulically connected with a lower aquifer. The owner or operator may nevertheless seek an exemption if it can be demonstrated that attenuation, advection/dispersion or other natural processes can remove the threat to interconnected aquifers. The owner or operator may also seek the latter exemption if the contaminated zone is not a current or potential drinking water source.

EPA is also proposing under § 257.97(f)(3) and (4) to allow the State to determine that remediation of a release is not required when remediation is not technically feasible or when remediation presents unacceptable cross-media impacts. Such a determination may be made, for example, in some cases where the nature of the hydrogeologic setting would prevent installation and operation of an effective groundwater pump and treat system (or other effective cleanup technology), *e.g.,* where the installation and operation of such a system could potentially increase environmental degradation by introducing the contaminant into groundwater that was not previously affected by the release. Additional examples of factors that may affect the efficacy of groundwater remediation can be found in EPA Guidance for Evaluating the Technical Impracticability of Ground-Water Restoration (OSWER Directive 9234.2–25, September 1993).[33] The Agency is specifically soliciting comment on the types of situations that might warrant a determination that remediation of a release is technically impracticable or presents unacceptable impacts and would not, therefore, be required.

A successful demonstration that remediation is not technically feasible must document specific facts that attribute to this demonstration. Technical infeasibilities may be related to the accessibility of the groundwater to treatment, as well as the treatability of the groundwater using existing treatment technologies. If the owner or operator can demonstrate that unacceptable cross-media impacts are uncontrollable under a given remedial option (e.g., movement in response to groundwater pumping) and that the no action option is a less risky alternative, then the Director of approved participating state may determine that remediation is not necessary.

As noted, EPA is generally relying on the factual record developed for the part 258 regulations to support this rule. However, the record for that rule does not contain information that would demonstrate that removing the existing regulatory requirement that all CCR units impose source control would meet the RCRA section 4004(a) protectiveness standard. These existing CCR requirements were established to address the well-documented risks associated with CCR units, as detailed in the risk assessment and the numerous damage cases in the rulemaking record.[34] The part 258 regulations apply only to landfills, while the CCR regulations apply to both landfills and surface impoundments, the latter being of particular concern. Surface impoundments by their very nature pose a potential for releases to groundwater that is different than landfills (e.g., presence of a hydraulic head) that may impact the importance of source control for these types of units. As discussed above, EPA requests comment on whether the proposal is appropriate, and whether the record for either the existing CCR rule or the part 258 rules includes information, or whether other information exists, to support adoption of the more flexible corrective action provision based on part 258 for CCR units, which could allow an owner or operator to undertake corrective action for unlined surface impoundments in lieu if closure. Depending on comments received, EPA may revise this provision to more closely reflect the existing source control and corrective actions requirements in part 258 that would allow source control, including closure, to be discretionary in certain situations.

C. Modification of Groundwater Monitoring Requirements

The current regulations at § 257.90 require all CCR units, without exception, to comply with the groundwater monitoring and corrective action requirements of §§ 257.90–257.98. The final CCR rule at § 257.91(a)(2) requires the installation of groundwater monitoring wells at the waste boundary of the CCR unit.

EPA is proposing to adopt a provision analogous to 40 CFR 258.50(b), which allows the Director of an approved participating state to suspend the groundwater monitoring requirements under § 258.51 through § 258.55 if the

[32] In addition to federal guidance, EPA is aware that States may currently use different or more sophisticated groundwater classification systems. In the preamble to the October 9, 1991 Final Rule promulgating the MSW landfill standards, on the matter of groundwater classification EPA noted that ''States are expected to use groundwater classification and resource evaluations in making their State decisions.'' 56 FR 50995.

[33] Additional documents related to technical impracticability may be found at *https://www.epa.gov/superfund/superfund-groundwater-groundwater-response-selection#TI_anchor.*

[34] For example, risk estimates for unlined surface impoundments were the highest of all CCR unit types evaluated (80 FR 21319, April 17, 2015) and EPA's documented record of confirmed damage cases was dominated by ''wet disposal'' (e.g., impoundments; 80 FR 21456, April 17, 2015).

owner or operator can demonstrate that there is no potential for migration of hazardous constituents from that MSWLF unit to the uppermost aquifer during the active life of the unit and the post-closure care period. Under part 258, the demonstration must be certified by a qualified groundwater scientist and approved by the Director of a participating state, and must be based upon:

(1) Site-specific field collected measurements, sampling, and analysis of physical, chemical, and biological processes affecting contaminant fate and transport, and

(2) Contaminant fate and transport predictions that maximize contaminant migration and consider impacts on human health and environment.

The Agency recognizes that certain hydrogeologic settings may preclude the migration of hazardous constituents from CCR disposal units to groundwater resources. Requiring groundwater monitoring in these settings would provide little or no additional protection to human health and the environment. Therefore, EPA is proposing to incorporate a nearly identical provision into the part 257 regulations. This would allow the Director of a participating state to suspend the groundwater monitoring requirements in § 257.91 through § 257.95 for a CCR unit upon demonstration by the owner or operator that there is no potential for migration of hazardous constituents from the unit to the uppermost aquifer during the active life, closure, or post-closure periods. However, the requirements of § 257.96 through § 257.98 would not be suspended. As discussed below, the provision being proposed for the part 257 regulations would be identical to that in the part 258 regulations with the exception for the requirement to periodically demonstrate that conditions have not changed, that is, there is still no migration of Appendix III or IV constituents from the CCR unit to the uppermost aquifer.

EPA recognizes it may be difficult for many facilities to meet the ''no potential for migration'' standard in the regulations. The suspension of monitoring requirements is intended only for those CCR units that are located in hydrogeologic settings in which hazardous constituents will not migrate to groundwater during the active life of the unit, closure, and post-closure periods. The Agency reminds readers that the ''no migration'' waiver has been a component of both the part 258 and the RCRA subtitle C groundwater monitoring programs for many years, and; based on its experience under these programs, the Agency expects that cases where these criteria are met will be rare.

The part 258 requirements allow the Director of a state program to establish the relevant point of compliance; in an unapproved state, the point of compliance is set by regulation at the waste management unit boundary. EPA does not believe the record for the part 258 requirements would support an alternative means for establishing the relevant point of compliance for CCR groundwater monitoring wells under RCRA section 4004(a). EPA requests comment on whether a State Director or EPA in a nonparticipating state, or an owner/operator subject to EPA oversight and public notice, could establish an alternative point of compliance consistent with the flexibility already allowed under the part 258 rules that would satisfy the standard of no reasonable probability of adverse effect on human health or the environment under section 4004(a).

In this action, EPA is not proposing to provide waivers from groundwater monitoring requirements except where the owner or operator in a participating state can demonstrate no potential for migration of hazardous constituents to the uppermost aquifer during the active life of the unit, closure, or post-closure periods. Consistent with the part 258 regulation, the Agency is proposing to allow this waiver only under the following conditions. EPA seeks comment on the use of each of these conditions. First, the suspension of groundwater monitoring requirements in § 257.91 through § 257.95 is available only for owners and operators of CCR units located in participating states or in those instances where EPA is the permitting authority. The Agency has limited the availability of the waiver because the Agency recognizes the need for the State to review a no-migration demonstration prior to granting a waiver from groundwater monitoring. However, the Agency seeks comment on an approach where a technical expert could make this demonstration (under the criteria described in the following paragraphs) and the facility could implement without the intervention of a permitting authority. In such an approach, the facility would keep records and post its determination on its web site and EPA would use the authorities in the WIIN act to oversee such a determination.

Second, the rule requires demonstrations of no potential for migration to be supported by both predictions that maximize contaminant migration and actual field data collected at the site. Field testing is necessary to establish the site's hydrogeological characteristics and must include an evaluation of unsaturated and saturated zone characteristics to ascertain the flow rate and pathway by which contaminants will migrate to groundwater. Any demonstration must be based on site-specific field measurements and sampling and analyses to determine the physical, chemical, and biological processes affecting the fate and transport of hazardous constituents. Site-specific information must include, at a minimum, the information necessary to evaluate or interpret the effects of the following properties or processes on contaminant fate and transport:

(1) Aquifer Characteristics, including hydraulic conductivity, hydraulic gradient, effective porosity, aquifer thickness, degree of saturation, stratigraphy, degree of fracturing and secondary porosity of soils and bedrock, aquifer heterogeneity, groundwater discharge, and groundwater recharge areas;

(2) Waste Characteristics, including quantity, type, and origin;

(3) Climatic Conditions, including annual precipitation, leachate generation estimates, and effects on leachate quality;

(4) Leachate Characteristics, including leachate composition, solubility, density, the presence of immiscible constituents, Eh, and pH;

(5) Engineered Controls, including liners, cover systems, and aquifer controls (e.g., lowering the water table). These should be evaluated under design and failure conditions to estimate their long-term residual performance.

(6) Attenuation of contaminants in the subsurface, including adsorption/desorption reactions, ion exchange organic content of soil, soil water pH, and consideration of possible reactions causing chemical transformation or chelation.

(7) Microbiological Degradation, which may attenuate target compounds or cause transformations of compounds, potentially forming more toxic chemical species.

Modeling may also be useful for assessing and verifying the potential for migration of hazardous constituents. However, any models used should be based on actual field collected data to adequately predict potential groundwater contamination. When owners or operators prepare a no migration demonstration, they must use transport predictions that are based on the maximum contaminant migration (i.e., worst case scenario) both from the unit and through the subsurface media. Assumptions about variables affecting transport should be biased toward over

estimating transport and the anticipated concentrations. Assumptions and site-specific data that are used in the fate and transport predictions should conform with transport principles and processes, including adherence to mass-balance and chemical equilibria limitations. Within these physicochemical limitations assumptions should be biased toward the objective of assessing the maximum potential impact on human health and the environment.

Third, the proposed rule would require the demonstrations to be certified by a qualified professional engineer and approved by the Director of a participating state to ensure that there is a high degree of confidence that no contamination will reach the uppermost aquifer.

Finally, the proposed rule would require the owner or operator of the CCR unit to make periodic demonstrations every 10 years in order to retain the suspension of groundwater monitoring. The Agency received comments on suspending the groundwater monitoring requirements for MSWLFs in part 258 that suggested EPA require periodic demonstrations every five or ten years. See, 56 FR 51061 (October 9, 1991). The Agency decided against requiring periodic demonstrations for MSWLFs because the demonstration required must be extremely rigorous and because of the additional costs associated with the continual reapplication for the suspension. As mentioned earlier in this proposed rulemaking, the statutory standard for the part 258 regulations is different than the standard for the CCR regulations: The CCR regulations are based on RCRA section 4004(a), which requires that the regulations ensure ''there is no reasonable probability of adverse effects on health or the environment from disposal of solid waste at such facility.'' 42 U.S.C. 6944(a). This is a risk-only standard. By contrast, EPA was authorized to ''take into account the [facility's] practicable capability'' in developing the part 258 regulations. 42 U.S.C. 6949a(c). Also, the part 258 regulations apply only to landfills, while the CCR regulations apply to both landfills and surface impoundments, the latter being of particular concern. Surface impoundments by their very nature pose a potential for releases to groundwater that is different than landfills (*e.g.,* presence of a hydraulic head) that may impact the importance of source control for these types of units. The risk assessment for the CCR rule found that, even when key variables are controlled (*e.g.,* liner type, waste type) for the long-term risks from surface impoundments are greater than from landfills. This is because the high and sustained hydraulic head present in these surface impoundments drives leachate into the groundwater table at an accelerated rate. Based on these factors, EPA is proposing to require an owner or operator to conduct a new demonstration once every 10 years to show that the suspension of groundwater monitoring continues to be appropriate. See proposed § 257.90(g). This new demonstration should be submitted to the State Director one year before the existing groundwater monitoring suspension is due to expire. If the suspension expires for any reason, the unit must begin groundwater monitoring according to § 257.90(a) within 90 days.

Further guidance for conducting these evaluations can be found in the OSWER Solid Waste Disposal Facility Criteria Technical Manual for MSWLFs (EPA530–R–93–017, 1993) and the Ground-Water Monitoring Guidance Document for Owners and Operators of Interim Status Facilities (1983).

D. Alternate Period of Time To Demonstrate Compliance With Corrective Action

The current regulations at § 257.98(c)(2) require that facilities demonstrate that compliance with the groundwater protection standards (GWPS) established under § 257.95(h) have been achieved by monitoring results documenting that concentrations of constituents listed in Appendix IV to part 257 have not exceeded the groundwater protection standard(s) for a period of three consecutive years using the statistical procedures and performance standards in § 257.93(f) and (g). EPA is proposing to modify this by adopting a provision analogous to 40 CFR 258(e)(2). Both the part 258 regulation and the proposed § 257.98(c)(4) counterpart allow the Director of a participating state to specify an alternative length of time during which the owner or operator must demonstrate that concentrations of Appendix II to part 258 constituents (or in the case of the proposed part 257 counterpart, Appendix IV to part 257 constituents) have not exceeded the groundwater protection standard(s). Under the current part 258 regulations, the State must make this determination after taking into consideration: (1) The extent and concentration of the release(s); (2) behavior characteristics of the hazardous constituents in the groundwater; (3) accuracy of monitoring or modeling techniques, including any seasonal, meteorological, or other environmental variabilities that may affect the accuracy; and (4) characteristics of the groundwater.

When establishing an alternative compliance period, the proposed regulation would require a State to consider the following site-specific conditions under § 257.98(c)(4): (1) The extent and the concentration of the release; (2) the behavior characteristics (fate and transport) of the part 257 Appendix IV constituents in the groundwater (e.g., mobility, persistence, toxicity); (3) the accuracy of monitoring or modeling techniques, including any seasonal, geotechnical/geophysical, meteorological, or other environmental variabilities that may affect the accuracy; and (4) the characteristics of the groundwater (e.g., flow rate, pH). These are the same factors included in part 258; consideration of these factors will allow the State to set an appropriate time period for demonstrating compliance with the groundwater protection standards rather than relying on an arbitrary time period for all facilities or all situations at the same facility. In large part, EPA is relying on the longstanding experience with these criteria under part 258 for municipal solid waste landfills.

In summary, § 257.98(c)(2) and (4) of this proposal requires that the groundwater protection standard be achieved for a period of three consecutive years at all points within the plume of contamination unless an alternative period of time is established by a participating state. Those states may set an alternative period of compliance after taking site-specific conditions into consideration. In demonstrating compliance with the groundwater protection standard, the owner or operator would be required to use the statistical procedures in § 257.93.

E. Length of Post-Closure Care Period

The current regulations at § 257.104(c)(1) state that the owner or operator of a closed CCR unit must conduct post-closure care for 30 years unless at the end of the 30 years corrective action is on-going, or the CCR unit is operating under assessment monitoring, in which case the owner or operator must continue to conduct post-closure care until the unit has returned to detection monitoring.

EPA is proposing to adopt a provision analogous to 40 CFR 258.61(b), which allows the Director of a participating state to decrease the length of the post-closure care period if the owner or operator demonstrates that the reduced period is sufficient to protect human health and the environment and this demonstration is approved by the

Director of approved participating state. It also allows the Director of the participating state to increase the length of the post closure period if the Director determines a lengthened period is necessary to protect human health and the environment.

The Agency is proposing this provision to account for situations where a 30-year post-closure care period may be inappropriate based on site-specific conditions. Overall, providing for variances in the post-closure care period in these states allows the flexibility to accommodate differences in geology, climate, topography, resources, demographics, etc. In all cases, however, these decisions must be reviewed carefully by the State to ensure units are monitored and maintained for as long as is necessary to protect human health and the environment.

In determining whether a revised post-closure care period is warranted, one critical factor is ensuring that the cover will continue to function effectively. EPA recognizes that no final cover, however well-constructed, will last forever. In 1988, EPA stated that ''even the best liner and leachate collection system will ultimately fail due to natural deterioration . . . .'' [35] Although any impermeable barriers used in a final cover system will eventually fail, studies have shown that such natural deterioration can take thousands of years (Needham et al., 2006; Rowe & Islam, 2009).[36] [37] This is consistent with the concept of bathtub (or U shaped) failure rate in reliability analysis (Shehla & Khan, 2016).[38] This failure pattern begins with a wear-in period where failure rates are high due to design and manufacturing problems. The failure rate then decreases to a low, constant rate for a period of time before rising in the third, wear-out phase.

Though this wear-out phase may take thousands of years, the wear-in phase for waste management unit covers is much shorter. In the context of CCR units, the wear-in phase of a closed unit would be due to imperfections in covers, either from a manufacturing defect or faulty installation. Manufacturing defects may include items such as pin holes, whereas faulty installation may be the result of a tear or failure to properly seal joints (Bonaparte et al, 1989).[39]

Settlement resulting from factors, such as the gradual dissolution of more soluble components within the ash mixture, is also a potential issue. Depressions caused by settlement may lead to ponding and should be filled with soil. Excessive settlement may warrant reconstructing or adding to portions of the infiltration layer. Settlement can also damage the cover through tension cracks and tears in the synthetic membrane. For example, topographic surveys of the unit(s) may be used every few years until settlement behavior is established, to determine whether settlement has occurred.

Consequently, EPA is proposing to require that part of determining whether a shorter post-closure care period will protect human health and the environment, a state must ensure that the post-closure care period is long enough to detect such issues. This would require the state to consider not only the type of cover placed on the unit (*e.g.,* compacted soil), but also the placement of the groundwater monitoring wells with respect to the waste management unit. For instance, where a waste management unit is close to the groundwater table and the groundwater monitoring wells are located at the unit boundary, one would generally expect transit time of any contamination to be short, and thus a shorter post-closure monitoring period might be sufficient to catch wear-in defects in the cover system. However, where the unit is located further from the groundwater table, constituents may not have sufficient time to reach the monitoring wells under such a curtailed post-closure period.

In addition, under the current CCR regulations, once detection monitoring yields a statistically significant increase above background levels of any Appendix III constituent, assessment monitoring is triggered, and the unit continues to be subject to the rule's post-closure care requirements so long as the CCR unit is operating under assessment monitoring. Section 257.104(c)(2). EPA is not proposing to amend this requirement, or to allow States to do so as part of this new provision. Thus, the State could not allow a facility to end the post-closure care period, once the detection of contamination above background triggers assessment monitoring. This would hold, even if the State had previously authorized a shorter post-closure care period. EPA is proposing to include language in this provision that clarifies how these two requirements interact.

F. Allowing Directors of Participating States To Issue Certifications in Lieu of Requiring a PE Certification

To ensure that the RCRA subtitle D requirements would achieve the statutory standard of ''no reasonable probability of adverse effects on health and the environment'' in the absence of regulatory oversight, the current CCR regulations require facilities to obtain third party certifications and to provide enhanced state and public notifications of actions taken to comply with the regulatory requirements. Specifically, in the final CCR rule EPA required numerous technical demonstrations made by the owner or operator be certified by a qualified professional engineer (PE) in order to provide verification of the facility's technical judgments and to otherwise ensure that the provisions of the rule were properly applied. While EPA acknowledged that relying upon a third party certification was not the same as relying upon a state or federal regulatory authority and was not expected to provide the same level of independence as a state permit program, the availability of meaningful third party verification provided critical support that the rule would achieve the statutory standard, as it would provide a degree of control over a facility's discretion in implementing the rule. However, the situation has changed with the passage of the WIIN Act, which offers the opportunity for State oversight under an approved permit program. To reflect that, EPA is proposing to revise the regulations to allow the Director of a state with an approved CCR permit program (a participating state) to certify that the regulatory criteria have been met in lieu of the exclusive reliance on a qualified PE. EPA expects that States will generally rely on the expertise of its own engineers to evaluate whether the technical criteria have been met. Alternatively, States might choose to retain the required certification by a qualified PE and use its own expertise to evaluate that certification. Finally, EPA notes that under the existing regulations, a facility may already rely on a certification provided by a qualified PE in a State agency, who reviews the facility actions as part of a purely State-law mandated process. Thus, EPA is confident that the

additional layer of oversight provided by the State under this proposal will be at least as protective than the status quo under the existing regulations.

G. Revision To Allow the Use of CCR During Certain Closure Situations

EPA is proposing to revise the current regulations to allow the use of CCR in the construction of final cover systems for CCR units closing pursuant to § 257.101 that are closing with waste-in-place. EPA is also proposing specific criteria that the final cover system must meet in order to allow for the placement of CCR in the final cover system. EPA is proposing two performance standards: One that applies directly to facilities in any ''non-participating state'' and a second that applies to facilities that operate in states with an approved CCR permit program (''participating'' state). Specifically, EPA is proposing to allow for the continued placement of CCR in units triggered for closure to construct a cover system under the following conditions: (1) Only CCR generated on-site may be used in the construction of the cover system; (2) CCR may be used exclusively for the purposes of grading and contouring of the cover system; (3) CCR must be placed within the vertical plane of the boundary of the unit; and (4) must be at either no steeper than a 5 percent grade or at a steeper grade, as determined by the Director of an approved program based on a stability analysis. These criteria are intended to ensure that the CCR utilized in construction of the final cover system does not exceed the necessary amount for grading and contouring.

The current CCR rules require that certain units must close for cause, as laid forth in § 257.101(a)–(c). As written, the regulation expressly prohibits ''placing CCR'' in any units required to close for-cause pursuant to § 257.101. This includes unlined CCR surface impoundments whose groundwater monitoring shows an exceedance of a groundwater protection standard (§ 257.101(a)(1)); existing CCR units that do not comply with the location criteria (§ 257.101(b)(1)); and CCR surface impoundments that are not designed and operated to achieve minimum safety factors (§ 257.101(b)(2) and (c)(1)). Note that the rule does not distinguish between placement that might be considered beneficial use and placement that might be considered disposal. All further placement of CCR into the unit is prohibited once the provisions of § 257.101 are triggered. By contrast, the regulations do not restrict further placement or use of CCR when the unit is closing under other provisions.

Proposal for Closure With CCR

After publication of the final rule, EPA received numerous requests that EPA clarify whether use of CCR in completing the closure of a unit was permitted under the regulation, either as part of a closure plan or under the theory that such an activity was ''beneficial use.'' After evaluating the issue, EPA is proposing an exemption that would allow further placement of CCR in a CCR unit closing pursuant to § 257.101 for the purposes of construction of the final cover system. EPA is not proposing any other revisions to the existing closure requirements; therefore, owners and operators who choose to place CCR as part of the final cover system as part of closure ''for cause'' will still need to comply with all of the existing closure requirements in §§ 257.101–104.

EPA is proposing this revision because there are environmental and health benefits in allowing use of CCR in this fashion, and as discussed below in more detail, provided the conditions outlined in this rule are met, the existing information demonstrate that the use of CCR in this fashion would not measurably affect the risks from the unit. Allowing the use of on-site CCR in lieu of other material to construct the cover furthers the general goal in § 257.102(d)(1)(v) of closing as quickly as possible. As EPA identified in the final rule, the process for procuring at-specification earthen material in the volumes necessary for the final cover system construction can complicate completion of closure requirements within the required time frames. This was explicitly described as a factor that could support an extension of the closure deadlines under § 257.102(f)(2)(i)(C). Thus, this proposed revision is expected to allow facilities to complete closure more quickly, and accordingly realize reduced risks more quickly.

This proposal is a narrow modification of the § 257.101 prohibition on CCR placement, and contains four requirements to ensure that the use of CCR is to accelerate closure rather than merely allow the facility continue the disposal of CCR in a deficient unit. First, the material placed under this exemption must have been generated on-site and be present at the time of closure. Second, the material may only be used for the grading and contouring of the cover system, not to fill up a partially full unit. Third, the placement of the material must be within the boundary or the vertical plane of the boundary of the waste management unit. Finally, the material may only be used to construct a cover at either no steeper than a 5 percent grade or at a steeper grade, as determined by the Director of an approved program (or EPA where it is the permitting authority). Each of these requirements is discussed further below.

On-site materials. EPA is proposing that all CCR material utilized for construction of the final cover system must have been generated by the facility, *i.e.,* by the coal-fired boilers that generated electricity at the facility and associated air pollution control devices, and that the CCR be located at the facility since the time of generation. CCR sourced exclusively from on-site will allow for timely construction of the final cover system. Moreover, EPA does not intend this proposed rule to allow owners and operators to continue disposal into a waste management unit that is closing for cause pursuant to § 257.101. Limiting the source of material will help to ensure that. Rather, the exemption is meant to allow for the genuine use of available materials for the closure of a waste management unit.

For grading and contouring. EPA is also proposing to limit the exemption to the design and construction of the final cover system. As noted previously, § 257.102(d)(2) requires that dewatering and stabilization be achieved prior to installation of a cover, and § 257.102(d)(3) requires that several protective layers be constructed at the uppermost areas of the final cover system. As a practical matter, these two existing provisions (which EPA is not proposing to modify or take comment on) would effectively limit the placement of CCR to grading and contouring. Nevertheless, to avoid confusion, EPA is proposing to include a specific condition to make this explicit. For the purposes of this rule, EPA considers grading and contouring as activities specifically related to creating elevation differences and travel pathways to encourage free drainage of liquids out of and away from the CCR surface impoundment. Accordingly, EPA is proposing to define grading to mean placement of CCR for the sole purpose of creating differences in elevation to support positive stormwater drainage. EPA is also proposing to define contouring to mean placement of material to provide a continuous downward slope on the surface of a drainage area (*i.e.,* the final cover system), except for erosion control features (*e.g.,* swales, contour banks).

This proposal would not allow placement of CCR for the purposes of waste stabilization or to otherwise fill

the unit to capacity. Placement of CCR for these purposes would involve the placement of substantial volumes of CCR into a leaking or otherwise deficient unit, and EPA lacks information that such further placement would be protective. To achieve this, EPA is proposing different criteria based on the construction of the unit. Many surface impoundments consist of an incised portion, or portion which is excavated below the surrounding grade. Incised units are units that hold an accumulation of CCR entirely below the adjacent natural ground surface, and do not consist of any constructed diked portion. For incised CCR surface impoundments, EPA is proposing that any CCR utilized for the final cover system must be placed above the highest elevation of the surrounding natural ground surface where the CCR unit was constructed.

EPA intends for this requirement to account for the preexisting topography in the area where the incised CCR unit was constructed. The owner or operator would be responsible for determining the preexisting topography of the CCR unit through means of historical documentation or by identifying the highest point of the perimeter of the excavated portion of the unit.

A primary purpose of a final cover system is to encourage free surface drainage in order to limit infiltration from precipitation into the underlying waste. CCR units with incised portions can present an issue with free drainage of liquids because much of the unit is located below the surrounding grade and does not allow for drainage by gravity, *i.e.,* the drainage must occur mechanically, by evapotranspiration, or by infiltration. Placement of CCR below the highest elevation of the surrounding topography would no longer serve the purpose of encouraging drainage, and therefore would not be considered part of constructing the final cover system.

For all other units, including CCR surface impoundments that consist of a diked portion, *e.g.,* diked impoundments, cross-valley impoundments, side-hill impoundments, or some combination thereof, EPA is proposing to require the owner or operator to establish a baseline elevation above which all CCR would need to be placed when constructing the final cover system. EPA is proposing that this baseline elevation be defined as the highest elevation of CCR in the unit, following dewatering and stabilization as required by § 257.102(d)(2).[40] From that point forward, CCR material may only be placed above that elevation for grading and contouring.

These requirements are designed to establish clear and objective geometric boundaries for the permissible placement of CCR. With these two performance standards, EPA is effectively establishing a ''lowest bound'' plane; placement below that elevation would be considered to be disposal, and would still be prohibited. EPA is also proposing to establish an upper bound to ensure that only the amount of CCR necessary for grading and contouring is used. The ''upper bound'' is represented by the maximum final grade of the final cover system of 1:20, *i.e.,* 5 percent (discussed further below). Furthermore, the ''vertical plane'' criteria discussed later in this preamble would also establish ''horizontal bounds'' for placement of CCR material in the cover system. In order to fulfill the ''free drainage'' criteria set forth in § 257.102(d)(1)(ii), the geometry of the waste in the unit must allow for free drainage of all water, sediment, and slurry from any point within the CCR surface impoundment out of the breached portion of the embankment.

Collectively, these criteria are designed to ensure owners and operators place only the amount of CCR necessary to achieve adequate grading and contouring for free drainage.

For example, this proposal would not allow the owner or operator to raise the breached invert elevation and place CCR material above the previously placed ''waste-in-place'' CCR and effectively raise the invert elevation for drainage. EPA intends for the final level of CCR within the CCR unit to essentially be the ultimate height of the surface of the final cover system, with allowance for limited addition of material to ensure effective drainage from the unit. EPA does not intend for this proposal to allow the facility to unnecessarily raise the invert elevation of the breached portion of the embankment, as a means of further disposal of CCR in the interim space between initial invert and adjusted invert elevations.

Within the vertical plane. EPA is proposing that CCR used for construction of the final cover system may not be placed outside the vertical plane. The vertical plane for non-incised units is established as the line which extends from the intersection between the crest of the CCR within the surface impoundment and the berm or dike of the CCR surface impoundment. For incised CCR surface impoundments, the vertical plane is established as the line that extends at the intersection where the cap of the CCR surface impoundment with a slope of no steeper than 5 percent meets the natural topography of the land prior the construction of the CCR unit. Placement beyond this boundary would constitute a lateral expansion as defined in § 257.53.[41] EPA is proposing this requirement in order to prevent the potential release of CCR constituents outside of the waste boundary without the protections EPA deliberately included in the final rule for such lateral expansions.

At no steeper than a 5 percent grade. EPA is proposing that the final cover system using CCR for grading and contouring be constructed with slopes no steeper than 1:20. This ratio of vertical rise to horizontal rise is equal to a 5 percent grade. EPA has identified 5 percent to generally be the maximum necessary grade to promote positive drainage in a vegetated slope runoff, as steeper grades may lead to erosion and deterioration of the final cover system.[42] EPA is proposing a maximum grade for the final cover system to minimize the potential for abuse whereby a facility might unnecessarily grade a cover steeply in order to dispose of additional CCR. EPA intends the grade of the final cover system to allow for free drainage to the invert elevation of the breached portion of the embankment.

However, in rare instances it may be possible that a cover requires a steeper grade. Consequently, EPA is proposing that the Director of a participating state may approve a grade steeper than 5 percent in a permit if such a grade is necessary for the proper function of the cover system. To support a steeper grade, a stability analysis must be performed to evaluate possible erosion potential. A stability analysis looks at the ability of soil to resist sliding on itself on the slope. The analysis, at a minimum, must evaluate: (1) The site geology, (2) characterize soil shear strength, (3) construct a slope stability model, (4) establish groundwater and seepage conditions, if any, (5) select loading conditions, (6) locate critical

[40] As noted, under the existing regulations the owner or operator must first breach and dewater the CCR unit, allowing for free drainage of water, sediment, or slurry out of the CCR surface impoundment via surface runoff, prior to construction of the final cover system. Additionally, if the owner or operator intends to leave waste-in-place, the owner or operator must ''preclude the probability of future impoundment of water, sediment, or slurry,'' per the requirements of § 257.102(d)(1)(ii).

[41] *Lateral expansion* means a horizontal expansion of the waste boundaries of an existing CCR landfill or existing CCR surface impoundment made after October 19, 2015.

[42] USEPA, Solid Waste Disposal Facility Criteria-Technical Manual, EPA Document EPA530–R–93–017.

failure surface, and (7) iterate until minimum factor of safety is achieved.

Finally, EPA recently issued an interpretation that under the current regulations, the prohibition on the placement a unit closing for cause did not preclude the movement of additional wastes (stormwater and associated/accompanying CCR) between the units that operate as part of a multiunit treatment system. The current regulations allow the facility to treat such units as a single unit. See, *e.g.,* § 257.91(d)(1). Based the longstanding interpretation that EPA does not regulate the movement of wastes within a unit, EPA concluded that where the impoundments are being treated as a singular system, the movement of CCR within that system (*i.e.,* from one impoundment to another) would not be considered ''placing CCR'' under the prohibitions of § 257.101. Under this same logic, a facility could conceivably consolidate the CCR from other units in the system into a single unit, even though the unit was deficient. There can be benefits to such a practice; for example, it may facilitate clean closure and allow owners and operators to focus their long term monitoring, care, and cleanup obligations on a single unit rather than many units. And presuming the unit meets all of the performance standards for closure with waste in place, it may be the risks associated with such consolidation are acceptable. However, there are also potentially significant risks associated with the continued placement of large volumes of CCR in a deficient unit. As discussed in the next section, although EPA has preliminarily concluded that the use of CCR in the construction of the cover system will meet the RCRA section 4004(a) standard, there were limitations in the assessment that raise questions about further extrapolation of that assessment to support the placement of large volumes of CCR in these units (*e.g.,* EPA's risk assessment did not model the addition of CCR to partially-filled leaking units). Thus an interpretation that allowed consolidation of CCR into a single unit of a multi-unit system could be seen as inconsistent with the approach outlined in this proposal.

EPA has not determined whether allowing such a practice meets the statutory standard, and is therefore soliciting comment on two potential alternatives. Under one approach EPA would rely on its longstanding interpretation to allow the consolidation of CCR from units operating within a multi-unit system, when the facility treats the system as a single unit for purposes of closure (*i.e.,* all units within the system are closing). Alternatively, EPA would revise the regulations to explicitly clarify that only the use of CCR for purposes of grading and contouring is permitted, even between units within a multi-unit system closing for cause. Note that under either approach, EPA does not intend to revise its interpretation that the movement of stormwater (and associated CCR) between units within a multi-unit system that is closing for cause is permissible. EPA is concerned about the potential risks associated with the continued placement of large volumes of CCR, and similar concerns are not raised by the movement of stormwater and de minimis amounts of CCR between units in the process of clean closing.

Analytic Support of Risk Assessment Results

U.S. EPA (2009) [43] used a response-surface regression method to derive a statistical model for groundwater concentration (as the dependent variable) based on the input parameters from the probabilistic analysis (as independent variables). Concentration, rather than risk, was chosen as the dependent variable for the sensitivity analysis because the additional exposure factors used to calculate human health risk from environmental concentration (*e.g.,* body weight) have well established, peer-reviewed distributions based on EPA policy. The outputs of the sensitivity analysis were goodness-of-fit values used to determine the relative importance of each input parameter. The most sensitive parameters identified are presented in Table 1.

TABLE 1—SENSITIVE PARAMETERS

Pathway:	GW to DW pathway		GW to SW pathway
Constituents:	All constituents	Strongly sorbing	All constituents
Sensitive Parameters	• Infiltration rate • Leachate concentration • Hydraulic gradient • Hydraulic conductivity.	• K_d value • Depth to groundwater • Distance to receptor well	• Infiltration rate. • Leachate concentration. • Water body flow rate.

Note: GW = Groundwater; DW = Drinking Water; SW = Surface Water.

As seen in the table above, the groundwater to drinking water exposure pathway had more input parameters that were highly sensitive (seven) than the groundwater to surface water exposure pathways (three). The most sensitive parameters for the groundwater to drinking water pathways were parameters that impact flux (infiltration rate and leachate concentration) and groundwater flow (hydraulic conductivity and gradient). When modeling strongly sorbing constituents, the K_d values and distance to receptor also become important. The most sensitive parameters for the groundwater to surface water exposure pathways were parameters impacting flux (infiltration rate to groundwater and leachate concentration) and the water body flow rate.

Depth to groundwater was a sensitive parameter for strongly sorbing constituents. However, the sensitivity analysis did not find total waste depth (*i.e.,* total thickness of CCRs disposed in a unit filled to capacity) to be a sensitive parameter for closed landfills and surface impoundments. However, EPA sought to verify this through further analysis of the final risk assessment results (U.S. EPA, 2014).[44]

The risks EPA sought to further evaluate were those from surface impoundments closed for cause with waste in place. In Appendix K of the final risk assessment, EPA modeled dewatered surface impoundments post-closure with waste in place as

[43] U.S. EPA (Environmental Protection Agency). 2009. Sensitivity Analysis for the Coal Combustion Waste Risk Assessment. Draft Technical Report. Prepared by RTI International for U.S. EPA, Office of Solid Waste, Washington, DC.

[44] U.S. EPA. 2014. Human Health and Ecological Risk Assessment of Coal Combustion Residuals. Final. Office of Resource Conservation and Recovery. December. RIN: 2050–AE81.

equivalent to closed landfills. Because the results driving EPA's final rule were those for trivalent arsenic [As(III)] cancer risks, EPA selected As(III) cancer risk results from landfills as the appropriate results on which to conduct this sensitivity analysis.

EPA used the probabilistic model inputs for waste depth to calculate 25th, 50th, and 75th percentile waste depths. These cutoffs were used to filter the model runs into four quartiles. For each quartile EPA calculated a 90th percentile As(III) cancer risk. Below are the As(III) cancer risk results EPA obtained when filtering the landfill risk results for the depth of the waste. As waste depth changed, EPA did not see significant changes in risk for any liner type. This confirms the findings of the sensitivity analysis where depth was not shown to be a sensitive parameter.

TABLE 2—90TH PERCENTILE AS(III) CANCER RISKS ACROSS WASTE DEPTH QUARTILE

	1st Quartile	2nd Quartile	3rd Quartile	4th Quartile
Liner Type:				
Unlined	1.50E–05	1.28E–05	2.66E–05	1.79E–05
Clay Lined	1.28E–05	1.11E–05	1.32E–05	1.93E–05
Composite	1.39E–20	5.34E–29	3.84E–27	<1.00E–30

EPA also notes that the volume of infiltration from precipitation relative to the volume of waste present in a unit is very small. This would lead to a low liquid-to-solid (L/S) ratio for water passing through landfills and dewatered surface impoundments. The low L/S ratio ensures that the leachate is saturated with constituent mass before it exits the bottom of the landfill or surface impoundment. Because the leachate is in equilibrium with the waste, the addition of more mass would not further increase leachate concentrations. Instead, the increased total mass would affect the time necessary for constituent mass to fully deplete from the waste. A majority of the model runs for arsenic already reached a steady state concentration at the well within the modeled timeframe. Therefore, an increase in leaching duration would not substantially alter long-term risks.

The addition of larger volumes of ash for purposes other than expediting closure would result in a greater amount of time without a cap and other appropriate controls in place. This would result in greater opportunity for precipitation to infiltrate into the unit prior to closure. The additional volume of water would increase the hydraulic head within the unit and, ultimately, the rate of infiltration down to the groundwater table. EPA identified infiltration to groundwater as one of the most sensitive variables when modeling risks. Thus, EPA concludes that the addition of ash for purposes other than expediting closure has the potential to increase the transport of constituent mass to groundwater and the associated risks.

Under this proposal, utilities could add ash to construct the cover system for closure of a unit for the purpose of achieving the necessary grade to safely close with waste in place. A review of both the 2009 sensitivity analysis and the final risk assessment found that the comparatively minor addition of CCR mass applied solely for grading purposes would not alter potential risks to receptors. Therefore, EPA finds that the use of ash for grading would remain protective of human health and the environment.

V. The Projected Economic Impacts of This Action

A. Introduction

EPA estimated the costs and benefits of this action in a Regulatory Impact Analysis (RIA) which is available in the docket for this action. The RIA estimates costs and cost savings attributable to the provisions of this action against the baseline costs and cost savings of the 2015 CCR final rule. The RIA estimates that the net annualized impact of these eleven provisions over a 100 year period of analysis will be cost savings of between $32 million and $100 million when discounting at 7 percent and cost savings between $25 million and $76 million when discounting at 3 percent. This action is considered an economically significant action under Executive Order 12866.

B. Affected Universe

The universe of affected entities for this rule consists of the same entities affected by EPA's 2015 CCR final rule. These entities are coal-fired electricity generating plants operated by the electric utility industry. They can be identified by their North American Industry Classification System (NAICS) designation 221112 ''Fossil Fuel Electric Power Generation''. The RIA estimates that there are 414 coal-fired electricity generating plants operating 922 CCR management units (landfills, disposal impoundments, and storage impoundments) that will be affected by this rule.

C. Baseline Costs

The baseline costs for this rule are the costs of compliance with EPA's 2015 CCR final rule, as the provisions of this rule modify the provisions of the 2015 CCR final rule or modify the implementation of the 2015 CCR rule by WIIN Act participating states. The RIA for the 2015 CCR final rule estimated these costs at an annualized $509 million when discounting at 7 percent and an annualized $735 million when discounting at 3 percent.

D. Cost Savings, Other Benefits, and Adjustments to the Baseline

The RIA estimates costs and costs savings for the four proposals associated with the 2015 CCR rule judicial remand as well as the six alternative performance standards that will apply in participating states under the WIIN Act, and the use CCR during certain closure situations. The RIA estimates that the net annualized impact of these eleven provisions over a 100 year period of analysis will be an annualized cost savings of between $32 million and $100 million when discounting at 7 percent, and an annualized cost savings of between $25 million and $76 million when discounting at 3 percent.

The RIA also estimates potential adjustments to the baseline costs of the CCR final rule due to plant closures that occurred after the rule was published but before the effective date of the rule. The RIA accompanying the 2015 CCR final rule assigned compliance costs to these plants, which they are exempt from because they closed before the final rule's effective date. In all, 23 plants closed before the effective date of the final rule that were not accounted for in 2015 final rule RIA. The annualized compliance costs avoided for these plants equals between $22 million and $25 million per year when discounting at 7 percent and between $22 million and $31 million when

discounting at 3 percent. This cost adjustment is detailed in the RIA that accompanies this rulemaking, however it is not factored into the baseline or the benefit estimates for this rule to keep comparisons with the 2015 CCR final rule straight forward.

E. Solicitation of Comments on the Projected Economic Impacts

EPA is soliciting comments on the following aspects of the Regulatory Impact Analysis (RIA), which is available in the docket for this rulemaking. The Agency is soliciting comment primarily on the assumptions and the data sources used in the analysis.

- Do you have information that would refine the RIA assumptions about the number of facilities both in and serving affected NERC regions that would request alternative closure under Additional Provision 1 (the amendment discussed in Unit III.D of this preamble)?
- Do you have information that would refine the RIA assumption that facilities seeking alternative closure requirements under Additional Provision 1 (the amendment discussed in Unit III.D of this preamble) would delay closure by five years (the maximum allowed under the rule)?
- Do you have information that would refine the RIA assumptions about the maximum or minimum number of states that would likely adopt alternative performance standards under the WIIN Act?
- Do you have information that would refine the RIA assumptions about the changes in total corrective action costs for a release due to the Alternative Performance Standard 1 (the amendment discussed in Unit IV.A of this preamble)?
- Do you have information that would refine the RIA assumptions about the total number of CCR units that may avoid corrective action costs due to the Alternative Performance Standard 2 (the amendment discussed in Unit IV.B of this preamble)?
- Do you have information that would refine the RIA assumptions about the number of units that will receive a ''no migration'' waiver under Alternative Performance Standard 3 (the amendment discussed in Unit IV.C of this preamble)?
- Do you have information that would refine the RIA assumption that states adopting Alternative Performance Standard 4 (the amendment discussed in Unit IV.D of this preamble) would on average reduce the post-remedy monitoring from three years to one year?
- Do you have information that would refine the RIA assumption that states adopting Alternative Performance Standard 5 (the amendment discussed in Unit IV.E of this preamble) would on average reduce the period from 30 years to five years?
- Do you have information that would refine the RIA assumptions about the total number of CCR units that would use CCR as allowed under Additional Provision 2 (the amendment discussed in Unit IV.G of this preamble)?
- Do you have information that would refine the RIA assumptions about the average annual number of CCR units closing (RIA page 4–14)?
- Do you have information that would refine the RIA assumptions about the estimated tonnage of CCR that could be used for closure (RIA page 4–14)?
- Do you have information that would refine the RIA description and estimates of impacts related to interactions among CCR Remand Rule provisions (RIA pp. 5–1 through 5–3)?

VI. Statutory and Executive Order (EO) Reviews

A. Executive Order 12866: Regulatory Planning and Review and Executive Order 13563: Improving Regulation and Regulatory Review

This action is a significant regulatory action that was submitted to the Office of Management and Budget (OMB) for review. Any changes made in response to OMB recommendations have been documented in the docket. The EPA prepared an analysis of the potential costs and benefits associated with this action. This Regulatory Impact Analysis (RIA), entitled *Regulatory Impact Analysis; EPA's 2017 RCRA Proposed Rule; Disposal of Coal Combustion Residuals from Electric Utilities; Amendments to the National Minimum Criteria (October 2017),* is summarized in Unit V of this preamble and the RIA is available in the docket for this proposal.

B. Executive Order 13771: Reducing Regulation and Controlling Regulatory Costs

This action is expected to be an Executive Order 13771 deregulatory action. Details on the estimated cost savings of this proposed rule can be found in EPA's analysis of the potential costs and benefits associated with this action.

C. Paperwork Reduction Act (PRA)

The information collection activities in this proposed rule have been submitted for approval to the Office of Management and Budget (OMB) under the PRA. The Information Collection Request (ICR) document that the EPA prepared has been assigned EPA ICR number 1189.27, OMB control number 2050–0053. This is an amendment to the ICR approved by OMB for the Final Rule: Hazardous and Solid Waste Management System; Disposal of Coal Combustion Residuals from Electric Utilities published April 17, 2015 in the **Federal Register** at 80 FR 21302. You can find a copy of the ICR in the docket for this action, and it is briefly summarized here. This rulemaking, specifically the provision clarifying the type and magnitude of non-groundwater releases that would require a facility to comply with some or all of the corrective action procedures set forth in §§ 257.96–257.98, reduces the paperwork burden attributable to provisions of the April 17, 2015 CCR Final Rule.

Respondents/affected entities: Coal-fired electric utility plants that will be affected by the rule.

Respondent's obligation to respond: The recordkeeping, notification, and posting are mandatory as part of the minimum national criteria being promulgated under Sections 1008, 4004, and 4005(a) of RCRA.

Estimated number of respondents: 414.

Frequency of response: The frequency of response varies.

Total estimated burden: EPA estimates the total annual burden to respondents to be *a reduction in burden of* approximately 4,267 hours from the currently approved burden. Burden is defined at 5 CFR 1320.3(b).

Total estimated cost: The total estimated annual cost of this rule is a *cost savings* of approximately $5,713,027. This cost savings is composed of approximately $519,832 in annualized avoided labor costs and $5,193,195 in avoided capital or operation and maintenance costs.

An agency may not conduct or sponsor, and a person is not required to respond to, a collection of information unless it displays a currently valid OMB control number. The OMB control numbers for the EPA's regulations in 40 CFR are listed in 40 CFR part 9.

D. Regulatory Flexibility Act (RFA)

I certify that this action will not have a significant economic impact on a substantial number of small entities under the RFA. In making this determination, the impact of concern is any significant adverse economic impact on small entities. An agency may certify that a rule will not have a significant economic impact on a

substantial number of small entities if the rule relieves regulatory burden, has no net burden or otherwise has a positive economic effect on the small entities subject to the rule. This action is expected to result in net cost savings amounting to approximately $32 million per year to $100 million per year when discounting at 7 percent and annualized over 100 years. It is expected to result in net cost savings of between $25 million and $76 million when discounting at 3 percent and annualized over 100 years. Savings will accrue to all regulated entities, including small entities. Further information on the economic effects of this action can be found in Unit V of this preamble and in the Regulatory Impact Analysis, which is available in the docket for this action. We have therefore concluded that this action will relieve regulatory burden for all directly regulated small entities.

E. Unfunded Mandates Reform Act (UMRA)

This action does not contain any unfunded mandate of $100 million or more as described in UMRA, 2 U.S.C. 1531–1538, and does not significantly or uniquely affect small governments. This action imposes no enforceable duty on any state, local or tribal governments or the private sector. The costs involved in this action are imposed only by participation in a voluntary federal program. UMRA generally excludes from the definition of ''federal intergovernmental mandate'' duties that arise from participation in a voluntary federal program.

F. Executive Order 13132: Federalism

This action does not have federalism implications. It will not have substantial direct effects on the states, on the relationship between the national government and the states, or on the distribution of power and responsibilities among the various levels of government.

G. Executive Order 13175: Consultation and Coordination With Indian Tribal Governments

This action does not have tribal implications as specified in Executive Order 13175. For the ''Final Rule: Hazardous and Solid Waste Management System; Disposal of Coal Combustion Residuals from Electric Utilities'' published April 17, 2015 in the **Federal Register** at 80 FR 21302, EPA identified three of the 414 coal-fired electric utility plants (in operation as of 2012) which are located on tribal lands; however, they are not owned by tribal governments. These are: (1) Navajo Generating Station in Coconino County, Arizona, owned by the Arizona Salt River Project; (2) Bonanza Power Plant in Uintah County, Utah, owned by the Deseret Generation and Transmission Cooperative; and (3) Four Corners Power Plant in San Juan County, New Mexico owned by the Arizona Public Service Company. The Navajo Generating Station and the Four Corners Power Plant are on lands belonging to the Navajo Nation, while the Bonanza Power Plant is located on the Uintah and Ouray Reservation of the Ute Indian Tribe. Moreover, since this action is expected to result in net cost savings to affected entities amounting to approximately $32 million per year to $100 million per year when discounting at 7 percent and annualized over 100 years, or in net cost savings of between $25 million per year and $76 million per year when discounting at 3 percent and annualized over 100 years, it will not have substantial direct effects on one or more Indian tribes. Thus, Executive Order 13175 does not apply to this action.

H. Executive Order 13045: Protection of Children From Environmental Health Risks and Safety Risks

This action is not subject to Executive Order 13045 because the EPA does not believe the environmental health or safety risks addressed by this action present a disproportionate risk to children. This action's health and risk assessments are contained in the document titled ''Human and Ecological Risk Assessment of Coal Combustion Residuals'' which is available in the docket for the final rule as docket item EPA–HQ–RCRA–2009–0640–11993.

As ordered by EO 13045 Section 1–101(a), for the ''Final Rule: Hazardous and Solid Waste Management System; Disposal of Coal Combustion Residuals from Electric Utilities'' published April 17, 2015 in the **Federal Register** at 80 FR 21302, EPA identified and assessed environmental health risks and safety risks that may disproportionately affect children in the revised risk assessment. The results of the screening assessment found that risks fell below the criteria when wetting and run-on/runoff controls required by the rule are considered. Under the full probabilistic analysis, composite liners required by the rule for new waste management units showed the ability to reduce the 90th percentile child cancer and non-cancer risks for the groundwater to drinking water pathway to well below EPA's criteria. Additionally, the groundwater monitoring and corrective action required by the rule reduced risks from current waste management units. This action does adversely affect these requirements and, in fact it enhances the groundwater monitoring requirements by adding boron to the list of constituents in Appendix IV that trigger corrective action. Thus, EPA believes that this rule will be protective of children's health.

I. Executive Order 13211: Actions Concerning Regulations That Significantly Affect Energy Supply, Distribution or Use

This action is not a ''significant energy action'' because it is not likely to have a significant adverse effect on the supply, distribution or use of energy. For the 2015 CCR rule, EPA analyzed the potential impact on electricity prices relative to the ''in excess of one percent'' threshold. Using the Integrated Planning Model (IPM), EPA concluded that the 2015 CCR Rule may increase the weighted average nationwide wholesale price of electricity between 0.18 percent and 0.19 percent in the years 2020 and 2030, respectively. As the proposed rule represents a cost savings rule relative to the 2015 CCR rule, this analysis concludes that any potential impact on wholesale electricity prices will be lower than the potential impact estimated of the 2015 CCR rule; therefore, this proposed rule is not expected to meet the criteria of a ''significant adverse effect'' on the electricity markets as defined by Executive Order 13211.

J. National Technology Transfer and Advancement Act (NTTAA)

This rulemaking does not involve technical standards.

K. Executive Order 12898: Federal Actions To Address Environmental Justice in Minority Populations and Low-Income Populations

The EPA believes that this action does not have disproportionately high and adverse human health or environmental effects on minority populations, low-income populations and/or indigenous peoples, as specified in Executive Order 12898 (59 FR 7629, February 16, 1994).

The documentation for this decision is contained in EPA's Regulatory Impact Analysis (RIA) for the CCR rule which is available in the docket for the 2015 CCR final rule as docket item EPA–HQ–RCRA–2009–0640–12034.

EPA's risk assessment did not separately evaluate either minority or low income populations. However, to evaluate the demographic characteristics of communities that may be affected by the CCR rule, the RIA compares the demographic characteristics of populations surrounding coal-fired electric utility

plants with broader population data for two geographic areas: (1) One-mile radius from CCR management units (*i.e.,* landfills and impoundments) likely to be affected by groundwater releases from both landfills and impoundments; and (2) watershed catchment areas downstream of surface impoundments that receive surface water run-off and releases from CCR impoundments and are at risk of being contaminated from CCR impoundment discharges (*e.g.*, unintentional overflows, structural failures, and intentional periodic discharges).

For the population as a whole 24.8 percent belong to a minority group and 11.3 percent falls below the Federal Poverty Level. For the population living within one mile of plants with surface impoundments 16.1 percent belong to a minority group and 13.2 percent live below the Federal Poverty Level. These minority and low-income populations are not disproportionately high compared to the general population. The percentage of minority residents of the entire population living within the catchment areas downstream of surface impoundments is disproportionately high relative to the general population, *i.e.*, 28.7 percent, versus 24.8 percent for the national population. Also, the percentage of the population within the catchment areas of surface impoundments that is below the Federal Poverty Level is disproportionately high compared with the general population, *i.e.*, 18.6 percent versus 11.3 percent nationally.

Comparing the population percentages of minority and low income residents within one mile of landfills to those percentages in the general population, EPA found that minority and low-income residents make up a smaller percentage of the populations near landfills than they do in the general population, *i.e.*, minorities comprised 16.6 percent of the population near landfills versus 24.8 percent nationwide and low-income residents comprised 8.6 percent of the population near landfills versus 11.3 percent nationwide. In summary, although populations within the catchment areas of plants with surface impoundments appear to have disproportionately high percentages of minority and low-income residents relative to the nationwide average, populations surrounding plants with landfills do not. Because landfills are less likely than impoundments to experience surface water run-off and releases, catchment areas were not considered for landfills.

The CCR rule is risk-reducing with reductions in risk occurring largely within the surface water catchment zones around, and groundwater beneath, coal-fired electric utility plants. Since the CCR rule is risk-reducing and this action does not add to risks, this action will not result in new disproportionate risks to minority or low-income populations.

List of Subjects in 40 CFR Part 257

Environmental protection, Beneficial use, Coal combustion products, Coal combustion residuals, Coal combustion waste, Disposal, Hazardous waste, Landfill, Surface impoundment.

Dated: March 1, 2018.

E. Scott Pruitt,

Administrator.

For the reasons set out in the preamble, title 40, chapter I, of the Code of Federal Regulations is proposed to be amended as follows:

PART 257—CRITERIA FOR CLASSIFICATION OF SOLID WASTE DISPOSAL FACILITIES AND PRACTICES

■ 1. The authority citation for part 257 is revised to read as follows:

Authority: 42 U.S.C. 6907(a)(3), 6912(a)(1), 6944(a), 6945(d); 33 U.S.C. 1345(d) and (e).

■ 2. Section 257.53 is amended by:
■ a. Adding in alphabetical order the definition of ''Contouring'', ''Engineered slope protection measures'', ''Grading'', ''Grassy vegetation'', ''Non-groundwater releases'', ''Participating state'', ''Pertinent surrounding areas'', ''Vegetative height'', and ''Woody vegetation'' in alphabetical order.
■ b. Revising the definition of ''Slope protection'' and ''State director.''

The revisions and additions read as follows:

§ 257.53 Definitions.

* * * * *

Contouring means the placement of material to provide a continuous downward slope on the surface of a drainage area, except for erosion control features (e.g., swales, contour banks).

* * * * *

Engineered slope protection measures means non-vegetative cover systems, which include but are not limited to rock riprap, concrete revetments, vegetated wave berms, concrete facing, gabions, geotextiles, or fascines.

* * * * *

Grading means the placement of CCR only to the extent necessary to create sufficient differences in elevation to support stormwater drainage.

Grassy vegetation means vegetation that meets both of the conditions described in paragraphs (1) and (2) of this definition:

(1) The vegetation develops shallow roots which both do not penetrate the slopes or pertinent surrounding areas of the CCR unit to a substantial depth and do not introduce the potential of internal erosion or risk of uprooting; and

(2) The vegetation creates a continuous dense cover that prevents erosion and deterioration of the surface of the slope or pertinent surrounding areas, thereby preventing deterioration of the surface.

* * * * *

Non-groundwater releases mean releases from the CCR unit other than the releases directly to the groundwater that are detected through the unit's groundwater monitoring system. Examples of non-groundwater releases include seepage through the embankment, minor ponding of seepage at the toe of the embankment of the CCR unit, seepage at the abutments of the CCR unit, seepage from slopes, ponding at the toe of the unit, a release of fugitive dust and releases of a ''catastrophic'' nature such as the release of CCR materials from CCR surface impoundments from the Tennessee Valley Authority's (TVA) Kingston Fossil Plant in Harriman, TN and the Duke Energy Dan River Steam Station in Eden, NC.

* * * * *

Participating state means a state with a state program for control of CCR that has been approved pursuant to Section 4005 of the Resource Conservation and Recovery Act.

Pertinent surrounding areas means all areas of the CCR surface impoundment or immediately surrounding the CCR surface impoundment that have the potential to affect the structural stability and condition of the CCR surface impoundment, including but not limited to the toe of the downstream slope, the crest of the embankment, abutments, and unlined spillways.

* * * * *

Slope protection means measures installed on the slopes or pertinent surrounding areas of the CCR unit that protect the slope against wave action, erosion or adverse effects of rapid drawdown. Slope protection includes grassy vegetation and engineered slope protection measures.

* * * * *

State Director means the chief administrative officer of any State agency operating an approved CCR permit program or the delegated representative of the State Director. If responsibility is divided among two or

more State agencies, State Director means the chief administrative officer of the State agency authorized to perform the particular function or procedure to which reference is made. On Tribal Lands and in non-participating States where Congress has specifically provided appropriations to EPA to administer a CCR permit program, State Director means the EPA Administrator or their designee.

* * * * *

Vegetative height means the linear distance between the ground surface where the vegetation penetrates the ground surface and the outermost growth point of the vegetation.

* * * * *

Woody vegetation means vegetation that develops woody trunks, root balls, or root systems which can penetrate the slopes or pertinent surrounding areas of the CCR unit to a substantial depth and introduce the potential of internal erosion or risk of uprooting.

■ 3. Section 257.73 is amended by:

■ a. Revising paragraphs (a)(4) and (d)(1)(ii); and

■ b. Removing and reserving paragraph (d)(1)(iv).

The revisions read as follows:

§ 257.73 Structural integrity criteria for existing CCR surface impoundments.

(a) * * *

(4) The slopes and pertinent surrounding areas of the CCR unit must be designed, constructed, operated, and maintained with one of the forms of slope protection specified in paragraph (a)(4)(i) of this section that meets all of the performance standards of paragraph (a)(4)(ii) of this section.

(i) Slope protection must consist of one of the following:

(A) A vegetative cover consisting of grassy vegetation;

(B) An engineered cover consisting of a single form or combination of forms of engineered slope protection measures; or

(C) A combination of the forms of cover specified in paragraphs (a)(4)(i)(A) or (a)(4)(i)(B) of this section.

(ii) Any form of cover for slope protection must meet all of the following performance standards:

(A) The cover must be installed and maintained on the slopes and pertinent surrounding areas of the CCR unit;

(B) The cover must provide protection against surface erosion, wave action, and adverse effects of rapid drawdown;

(C) The cover must be maintained to allow for the observation of and access to the slopes and pertinent surrounding areas during routine and emergency events;

(D) Woody vegetation must be removed from the slopes or pertinent surrounding areas. Any removal of woody vegetation with a diameter greater than ½ inch must be directed by a person familiar with the design and operation of the unit and in consideration of the complexities of removal of a tree or a shrubbery, who must ensure the removal does not create a risk of destabilizing the unit or otherwise adversely affect the stability and safety of the CCR unit or personnel undertaking the removal; and

(E) The vegetative height of grassy and woody vegetation must not exceed 12 inches.

* * * * *

(d) * * *

(1) * * *

(ii) Slope protection consistent with the requirements under paragraph (a)(4) of this section.

* * * * *

■ 4. Section 257.74 is amended by:

■ a. Revising paragraphs (a)(4) and (d)(1)(ii); and

■ b. Removing and reserving paragraph (d)(1)(iv).

The revisions read as follows:

§ 257.74 Structural integrity criteria for new CCR surface impoundments and any lateral expansion of a CCR surface impoundment.

(a) * * *

(4) The slopes and pertinent surrounding areas of the CCR unit must be designed, constructed, operated, and maintained with one of the forms of slope protection specified in paragraph (a)(4)(i) of this section that meets all of the performance standards of paragraph (a)(4)(ii) of this section.

(i) Slope protection must consist of one of the following:

(A) A vegetative cover consisting of grassy vegetation;

(B) An engineered cover consisting of a single form or combination of forms of engineered slope protection measures; or

(C) A combination of the forms of cover specified in paragraphs (a)(4)(i)(A) or (a)(4)(i)(B) of this section.

(ii) Any form of cover for slope protection must meet all of the following performance standards:

(A) The cover must be installed and maintained on the slopes and pertinent surrounding areas of the CCR unit;

(B) The cover must provide protection against surface erosion, wave action, and adverse effects of rapid drawdown;

(C) The cover must be maintained to allow for the observation of and access to the slopes and pertinent surrounding areas during routine and emergency events;

(D) Woody vegetation must be removed from the slopes or pertinent surrounding areas. Any removal of woody vegetation with a diameter greater than ½ inch must be directed by a person familiar with the design and operation of the unit and in consideration of the complexities of removal of a tree or a shrubbery, who must ensure the removal does not create a risk of destabilizing the unit or otherwise adversely affect the stability and safety of the CCR unit or personnel undertaking the removal; and

(E) The vegetative height of grassy and woody vegetation must not exceed 12 inches.

* * * * *

(d) * * *

(1) * * *

* * * * *

(ii) Slope protection consistent with the requirements under paragraph (a)(4) of this section.

* * * * *

■ 5. Section 257.83 is amended by revising paragraph (b)(5) to read as follows:

§ 257.83 Inspection requirements for CCR surface impoundments.

* * * * *

(b) * * *

(5) If a deficiency or release is identified during an inspection, the owner or operator must remedy the deficiency or release in accordance with applicable requirements in §§ 257.96 through 257.99.

* * * * *

■ 6. Section 257.84 is amended by revising paragraph (b)(5) to read as follows:

§ 257.84 Inspection requirements for CCR surface landfills.

* * * * *

(b) * * *

(5) If a deficiency or release is identified during an inspection, the owner or operator must remedy the deficiency or release in accordance with applicable requirements in §§ 257.96 through 257.99.

* * * * *

■ 7. Section 257.90 is amended by revising paragraphs (a) and (d) and adding paragraph (g) to read as follows:

§ 257.90 Applicability.

(a) All CCR landfills, CCR surface impoundments, and lateral expansions of CCR units are subject to the groundwater monitoring and corrective action requirements under §§ 257.90 through 257.99, except as provided in paragraph (g) of this section.

* * * * *

(d) The owner or operator of the CCR unit must comply with all applicable

requirements in §§ 257.96, 257.97, and 257.98, or, if eligible, must comply with the requirements in § 257.99.

* * * * *

(g) *Suspension of groundwater monitoring requirements.* (1) Except as provided by paragraph (g)(2) of this section, the State Director of a participating state may suspend for up to ten years the groundwater monitoring requirements under §§ 257.90 through 257.95 for a CCR unit if the owner or operator provides written documentation that there is no potential for migration of the constituents listed in appendices III and IV to this part from that CCR unit to the uppermost aquifer during the active life of the CCR unit and the post-closure care period. This demonstration must be certified by a qualified professional engineer and approved by the State Director, and must be based upon:

(i) Site-specific field collected measurements, sampling, and analysis of physical, chemical, and biological processes affecting contaminant fate and transport; and

(ii) Contaminant fate and transport predictions that maximize contaminant migration and consider impacts on human health and the environment.

(2) The owner or operator of the CCR unit may secure an additional ten years for the suspension of the groundwater monitoring requirements provided the owner or operator provides written documentation that there continues to be no potential for migration of the constituents listed in appendices III and IV to this part. The documentation must be supported by, at a minimum, the information specified in paragraphs (g)(1)(i) and (g)(1)(ii) of this section and must be certified by a qualified professional engineer and approved by the State Director. The owner or operator must submit the documentation of their re-demonstration for the state's review and approval of their extension one year before their groundwater monitoring suspension is due to expire. If the existing groundwater monitoring extension expires, the owner or operator must begin groundwater monitoring according to paragraph (a) of this section within 90 days. The owner or operator may obtain additional ten-year groundwater monitoring suspensions provided the owner or operator continues to make the written demonstration. The owner or operator must place each completed demonstration, if more than one ten-year suspension period is sought, in the facility's operating record.

■ 8. Section 257.95 is amended by revising paragraph (h)(2) and adding paragraph (j) to read as follows:

§ 257.95 Assessment monitoring program.

* * * * *

(h) * * *

(2) For constituents for which an MCL has not been established, the background concentration for the constituent established from wells in accordance with § 257.91, except as provided by paragraph (j) of this section; or

* * * * *

(j) The State Director of a participating state may establish an alternative groundwater protection standard for constituents listed in appendix IV to this part for which MCLs have not been established.

(1) The alternative groundwater protection standards must be appropriate health-based levels that are protective of potential receptors (both human and ecological) and satisfy all of the following criteria:

(i) The alternative groundwater protection standard is at a level derived in a manner consistent with EPA guidelines for assessing the health risks of environmental pollutants, including ''Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures'', ''Guidelines for Developmental Toxicity Risk Assessment'', and ''Reference Dose, (RfD): Description and Use in Health Risk Assessments'' (incorporated by reference);

(ii) The alternative groundwater protection standard is at a level based on scientifically valid studies conducted in accordance with the Toxic Substances Control Act Good Laboratory Practice Standards (40 CFR part 792) or equivalent; and

(iii) For systemic toxicants, the level represents a concentration to which the human population could be exposed to on a daily basis that is likely to be without appreciable risk of deleterious effects during a lifetime; this must be the level that ensures a Hazard Quotient no greater than 1. For purposes of this subpart, systemic toxicants are toxic chemicals that cause effects other than cancer.

(2) In establishing alternative groundwater protection standards under paragraph (j)(1) of this section, the State Director may consider the following:

(i) Multiple contaminants in the groundwater;

(ii) Exposure threats to sensitive environmental receptors; and

(iii) Other site-specific exposure or potential exposure to groundwater.

(3) The owner or operator of the CCR unit must document in the annual groundwater monitoring and corrective action report required by § 257.90(e) or § 257.100(e)(5)(ii) the constituent(s) and level(s) for which an alternative groundwater protection standard has been established by the State Director.

■ 9. Section 257.97 is amended by adding paragraphs (f) and (g) to read as follows:

§ 257.97 Selection of remedy.

* * * * *

(f) The State Director of a participating state may determine that remediation of a release of a constituent listed in appendix IV to this part from a CCR unit is not necessary if the owner or operator demonstrates to the satisfaction of the State Director that:

(1) The groundwater is additionally contaminated by substances that have originated from a source other than a CCR unit and those substances are present in concentrations such that cleanup of the release from the CCR unit would provide no significant reduction in risk to actual or potential receptors; or

(2) The constituent(s) is present in groundwater that:

(i) Is not currently or reasonably expected to be a source of drinking water; and

(ii) Is not hydraulically connected with waters to which the constituent(s) is migrating or are likely to migrate in a concentration(s) that would exceed the groundwater protection standards established under § 257.95(h) or (i); or

(3) Remediation of the release(s) is technically impracticable; or

(4) Remediation results in unacceptable cross-media impacts.

(g) A determination by the Director of approved participating state pursuant to paragraph (f) of this section shall not affect the requirement under § 257.90(d) and § 257.97(b) for the owner or operator to undertake source control measures or other measures (including closure if triggered) that may be necessary to eliminate or minimize further releases to the groundwater, to prevent exposure to the groundwater, or to remediate the groundwater to concentrations that are technically feasible and significantly reduce threats to human health or the environment.

■ 10. Section 257.98 is amended by revising paragraph (c) to read as follows:

§ 257.98 Implementation of the corrective action program.

* * * * *

(c) Remedies selected pursuant to § 257.97 shall be considered complete when:

(1) The owner or operator of the CCR unit demonstrates compliance with the groundwater protection standards established under § 257.95(h) has been achieved at all points within the plume of contamination that lie beyond the groundwater monitoring well system established under § 257.91;

(2) Except as provided by paragraph (c)(4) of this section, compliance with the groundwater protection standards established under § 257.95(h) has been achieved by demonstrating that concentrations of constituents listed in appendix IV to this part have not exceeded the groundwater protection standard(s) for a period of three consecutive years using the statistical procedures and performance standards in § 257.93(f) and (g); and

(3) All actions required to complete the remedy have been satisfied.

(4) The Director of a participating state may specify an alternative length of time to that specified in paragraph (c)(2) of this section during which the owner or operator must demonstrate that concentrations of constituents listed in appendix IV to this part have not exceeded the groundwater protection standard(s) taking into consideration:

(i) Extent and concentration of the release(s);

(ii) Behavior characteristics of the constituents in the groundwater;

(iii) Accuracy of monitoring or modeling techniques, including any seasonal, meteorological, or other environmental variabilities that may affect the accuracy; and

(iv) Characteristics of the groundwater.

* * * * *

■ 11. Add § 257.99 to read as follows:

§ 257.99 Corrective action procedures to remedy eligible non-groundwater releases.

(a) *General.* This section specifies the corrective action requirements that apply to non-groundwater releases from CCR units that can be completely remediated within 180 days from the detection of the release. A release is completely remediated when either a qualified professional engineer or the permitting authority of a participating state completes the certification required in subsection (c)(2) of this section. If the owner or operator determines, at any time, that the release will not be completely remediated within this 180-day timeframe, the owner or operator must comply with all additional procedural requirements specified in §§ 257.96, 257.97, and 257.98.

(b) *Corrective action requirements.* Upon detection of a non-groundwater release from a CCR unit, the owner or operator must comply with all of the following requirements:

(1) Meet the requirement in § 257.90(d) to ''immediately take all necessary measures to control the source(s) of releases so as to reduce or eliminate, to the maximum extent feasible, further releases of contaminants into the environment;''

(2)(i) Determine the corrective measures that will meet the substantive standards in §§ 257.96(a) to prevent further releases, to remediate any releases and to restore the affected area to original conditions; and

(ii) Analyze the effectiveness of potential corrective measures in meeting all of the requirements and objectives of the remedy as described in § 257.96(c);

(3) Select the corrective action that will remedy the non-groundwater release, taking into account, at a minimum, the results of the assessment in paragraph (b)(2)(ii) of this section and the factors specified in § 257.97(c); and

(4) Remediate the non-groundwater release to meet the standards specified in § 257.97(b)(1), (3), (4), and (5).

(5) Complete remedy within 180 days of the date of discovery of the release.

(c) *Required notices and reports.* An owner or operator of a CCR unit that complies with the requirements of this section to remediate a non-groundwater release is responsible for ensuring that the notices and reports specified in paragraphs (c)(1) through (c)(3) of this section are completed in accordance with this section. All required notices and reports must be signed by the owner or operator.

(1) Within 15 days of discovering a non-groundwater release, the owner or operator must prepare a notification of discovery of a non-groundwater release. The owner or operator has completed the notification when it has been placed in the facility's operating record as required by § 257.105(h)(15).

(2) Within 15 days of completing the analysis of the effectiveness of potential corrective measures as required by paragraph (b)(2)(ii) of this section, place the completed analysis in the facility's operating record.

(3) Within 30 days of completion of a corrective action of a non-groundwater release, the owner or operator must prepare a report documenting the completion of the corrective action. The report must, at a minimum, describe the nature and extent of the non-groundwater release, the CCR unit(s) responsible for the non-groundwater release, and how the remedy selected achieves the corrective action requirements specified in paragraph (b) of this section. The notification must include a certification by a qualified professional engineer that the corrective action has been completed in accordance with the requirements of paragraph (b) of this section. The owner or operator has completed the notification when it has been placed in the facility's operating record as required by § 257.105(h)(16).

(d) The owner or operator of the CCR unit must comply with the recordkeeping requirements specified in § 257.105(h), the notification requirements specified in § 257.106(h), and the internet requirements specified in § 257.107(h).

■ 12. Section 257.102 is amended by adding paragraph (d)(4) to read as follows:

§ 257.102 Criteria for conducting the closure or retrofit of CCR units.

* * * * *

(d) * * *

(4) *Use of CCR in Design and Construction of Final Cover System.* (i) This paragraph specifies the allowable uses of CCR in the closure of CCR units closing pursuant to § 257.101. Notwithstanding the prohibition on further placement in § 257.101, CCR may be placed in such units but only for the purposes of grading and contouring in the design and construction of the final cover system, based either on:

(A) A determination by the Director of a participating state that the criteria in paragraph (d)(4)(ii) of this section have been met; or

(B) The certification by a qualified professional engineer that the criteria in (d)(4)(ii) of this section have been met, as required in paragraph (d)(4)(iii) of this section.

(ii) *Use of CCR in Design and Construction of Final Cover System Requirements.*

(A) The owner or operator of a CCR unit subject to § 257.101 may continue to place CCR in the unit after initiating closure in order to construct the final cover system required under paragraph (d)(3) of this section but only for the following activities:

(1) Grading; and

(2) Contouring.

(B) The owner or operator of a CCR unit must meet all of the following criteria when placing CCR within a CCR unit for the purposes of grading or contouring:

(1) The CCR placed for construction of the final cover system must have been generated at the facility and be located at the facility at the time closure was initiated;

(2)(i) For incised CCR surface impoundments the CCR must be placed entirely above the highest elevation of

the surrounding natural ground surface where the CCR surface impoundment was constructed;

(ii) For all other CCR units, CCR must be placed entirely above the highest elevation of CCR in the unit, following dewatering and stabilization as required by § 257.102(d)(2);

(3) The CCR must not be placed outside the plane extending vertically from the line formed by the intersection of the crest of the CCR surface impoundment and the upstream slope of the CCR surface impoundment; and

(4) The final cover system must be constructed with either:

(i) A slope not steeper than 5% grade after allowance for settlement; or

(ii) At a steeper grade, if the Director of a participating state determines that the steeper slope is necessary based on conditions at the site, to facilitate run-off and minimize erosion, and that side slopes are evaluated for erosion potential based on a stability analysis to evaluate possible erosion potential. The stability analysis, at a minimum, must evaluate the site geology; characterize soil shear strength; construct a slope stability model; establish groundwater and seepage conditions, if any; select loading conditions; locate critical failure surface; and iterate until minimum factor of safety is achieved.

(iii) If required by paragraph (d)(4)(i)(B) of this section, the owner or operator of the CCR unit must also include in the notification required by § 257.102(h) a certification by a qualified professional that the CCR unit was closed in accordance with the requirements of paragraph (d)(4) of this section.

* * * * *

■ 13. Section 257.103 is amended by:

■ a. Revising § 257.103 introductory text; and

■ b. Redesignating paragraphs (b), (c), and (d) as (c), (e), and (f); and adding new paragraphs (b) and (d).

The revisions and additions read as follows:

§ 257.103 Alternative closure requirements.

The owner or operator of a CCR landfill, CCR surface impoundment, or any lateral expansion of a CCR unit that is subject to closure pursuant to § 257.101(a), (b)(1), or (d) may continue to receive CCR and/or non-CCR wastestreams in the unit provided the owner or operator meets the requirements of either paragraph (a), (b), (c) or (d) of this section.

* * * * *

(b) *No Alternative capacity for non-CCR wastestreams.* (1) Notwithstanding the provisions of § 257.101(a), (b)(1), or (d), a CCR unit may continue to receive non-CCR wastestreams if the owner or operator of the CCR unit certifies that the wastestreams must continue to be managed in that CCR unit due to the absence of alternative capacity both on-site and off-site the facility. For these non-CCR wastestsreams, capacity means the capacity of impoundments, tanks, and other conveyances to manage daily flows currently handled by the unit that is closing pursuant to § 257.101(a) or (b)(1), or (d). To qualify under this paragraph (b)(1), the owner or operator of the CCR unit must document that all of the following conditions have been met for each non-CCR wastestream that will continue to be received by the CCR unit:

(i) No alternative disposal capacity is available. An increase in costs or the inconvenience of existing capacity is not sufficient to support qualification under this section;

(ii) The owner or operator has made, and continues to make, efforts to obtain additional capacity. Qualification under this subsection requires that efforts to obtain additional capacity were made at the earliest date that an owner or operator knew, or had reason to know, that such a unit may become subject to closure under § 257.101(a), (b)(1), or (d). Qualification under this subsection lasts only as long as no alternative capacity is available. Once alternative capacity is identified, the owner or operator must arrange to use such capacity as soon as feasible;

(iii) The owner or operator must certify that the facility generating any wastestream that continues to be placed into a CCR unit pursuant to this section would need to cease generating power and is located in or regularly provides the majority of generated electricity to, one of the following three North American Electric Reliability Corporation regions and sub-regions: the Midcontinent Independent System Operator, the Southeastern Electric Reliability Council-East, and/or the Southeastern Electric Reliability Council-North;

(iv) The owner or operator must remain in compliance with all other requirements of this subpart, including the requirement to conduct any necessary corrective action; and

(v) The owner or operator must prepare an annual progress report documenting the continued lack of alternative capacity and the progress towards the development of alternative capacity for the given wastestream.

(2) Once alternative capacity is available for a given wastestream, the CCR unit must cease receiving that wastestream, and in the case that alternate capacity has been found for all wastestreams, the facility must initiate closure of the CCR unit following the timeframes in § 257.102(e) and (f).

(3) If no alternative capacity is identified within five years after the initial certification as required under (b)(1) of this section, the CCR unit must cease receiving all wastestreams and close in accordance with the timeframes in § 257.102(e) and (f).

* * * * *

(d) *Permanent cessation of a coal-fired boiler(s) by a date certain.* (1) Notwithstanding the provisions of § 257.101(a), (b)(1), and (d), a CCR unit may continue to receive non-CCR wastestreams if the owner or operator certifies that the facility will cease operation of the coal-fired boilers within the timeframes specified in paragraphs (d)(2) and (3) of this section, but in the interim period (prior to closure of the coal-fired boiler), the facility must continue to use the CCR unit due to the absence of alternative capacity. For wastewaters capacity means the capacity of impoundments, tanks, and other units to manage daily flows currently handled by the unit closing pursuant to § 257.101(a) or (b)(1). To qualify under this paragraph (d)(1), the owner or operator of the CCR unit must document that all of the following conditions have been met for each wastestream that will continue to be received by the CCR unit:

(i) No alternative capacity is available. An increase in costs or the inconvenience of existing capacity is not sufficient to support qualification under this section.

(ii) The owner or operator must certify that the facility is located in or regularly provides the majority of generated electricity to one of the following three North American Electric Reliability Corporation regions and sub-regions: The Midcontinent Independent System Operator, the Southeastern Electric Reliability Council-East, and/or the Southeastern Electric Reliability Council-North.

(iii) The owner or operator must remain in compliance with all other requirements of this subpart, including the requirement to conduct any necessary corrective action; and

(iv) The owner or operator must prepare an annual progress report documenting the continued lack of alternative capacity and the progress towards the closure of the coal-fired boiler.

(2) For a CCR surface impoundment that is 40 acres or smaller, the coal-fired boiler must cease operation and the CCR surface impoundment must have

completed closure no later than October 17, 2023.

(3) For a CCR surface impoundment that is larger than 40 acres, the coal-fired boiler must cease operation, and the CCR surface impoundment must complete closure no later than October 17, 2028.

* * * * *

■ 14. Section 257.104 is amended by revising paragraph (c) to read as follows:

§ 257.104 Post-closure care requirements.

* * * * *

(c) *Post-closure care period.* (1) Except as provided by paragraphs (c)(2) and (3) of this section, the owner or operator of the CCR unit must conduct post-closure care for 30 years.

(2) If at the end of the post-closure care period the owner or operator of the CCR unit is operating under assessment monitoring in accordance with § 257.95, the owner or operator must continue to conduct post-closure care until the owner or operator returns to detection monitoring in accordance with § 257.95.

(3)(i) The Director of a participating state may establish an alternate post-closure period upon a determination that the alternate period is sufficient to protect human health and the environment.

(ii) To reduce the post closure care period, the Director must ensure that the post-closure care period is long enough to establish settlement behavior and to detect to wear-in defects in the cover system. At a minimum, the Director must consider the type of cover placed on the unit (*e.g.*, geosynthetic clay liner) and the placement of the groundwater monitoring wells with respect to the waste management units and the groundwater table.

(iii) A determination that a reduced post-closure care period is warranted does not affect the obligation to comply with paragraph (b) of this section.

* * * * *

■ 15. Section 257.105 is amended by adding paragraphs (h)(14) through (h)(16) and paragraph (i)(14) to read as follows:

§ 257.105 Recordkeeping requirements.

* * * * *

(h) * * *

(14) The demonstration, including long-term performance data, supporting the suspension of groundwater monitoring requirements as required by § 257.90(g).

(15) The notification of discovery of a non-groundwater release as required by § 257.99(c)(1).

(16) The report documenting the completion of the corrective action as required by § 257.99(c)(2).

(i) * * *

(14) The demonstration, including long-term performance data supporting the reduced post-closure care period as required by § 257.104(c)(3).

* * * * *

■ 16. Section 257.106 is amended by adding paragraphs (h)(11) through (h)(13) and paragraph (i)(14) to read as follows:

§ 257.106 Notification requirements.

* * * * *

(h) * * *

(11) Provide the demonstration supporting the suspension of groundwater monitoring requirements specified under § 257.105(h)(14).

(12) Provide notification of discovery of a non-groundwater release specified under § 257.105(h)(15).

(13) Provide notification of the availability of the report documenting the completion of the corrective action specified under § 257.105(h)(16).

(i) * * *

(14) Provide the demonstration supporting the reduced post-closure care period specified under § 257.105(i)(14).

* * * * *

■ 17. Section 257.107 is amended by adding paragraphs (h)(11) through (h)(13) and adding paragraph (i)(14) to read as follows:

§ 257.107 Publicly accessible internet site requirements.

* * * * *

(h) * * *

(11) The demonstration supporting the suspension of groundwater monitoring requirements specified under § 257.105(h)(14).

(12) The notification of discovery of a non-groundwater release specified under § 257.105(h)(15).

(13) The report documenting the completion of the corrective action specified under § 257.105(h)(16).

(i) * * *

(14) The demonstration supporting the reduced post-closure care period specified under § 257.105(i)(14).

* * * * *

■ 18. Revise Appendix IV to part 257 to read as follows:

Appendix IV to Part 257—Constituents for Assessment Monitoring

COMMON NAME [1]
Antimony
Arsenic
Barium
Beryllium
Boron
Cadmium
Chromium
Cobalt
Fluoride
Lead
Lithium
Mercury
Molybdenum
Selenium
Thallium
Radium 226 and 228 combined

[1] Common names are those widely used in government regulations, scientific publications, and commerce; synonyms exist for many chemicals.

13. SUPPLEMENTARY NOTES

14. ABSTRACT

This handbook provides information on conducting environmental forensic investigations for polychlorinated biphenyls (PCBs) at sediment sites. The document includes a discussion of: 1) the general forensic approach including relevant background information and benefits to Department of Defense (DoD); (2) a general summary of the technical methods that are used in a PCB environmental forensics investigation; and (3) a summary of the application of the described procedures in two demonstration case studies.

1.0 GENERAL FORENSICS APPROACH

1.1 Introduction

Defining the source of anthropogenic contamination from military facilities into sediments can be a difficult task. This is particularly true in waterways and coastal settings where multiple point sources are present along with persistent non-point sources such as urban background. This situation often results in complex mixtures of contaminants in sediments.

For sediment sites under the Environmental Restoration (ER) Program, Navy Remedial Project Managers (RPMs) are required to implement cleanup programs that include identifying the sources of contaminants at their sites; thus, there is a need for technical guidance on the application of techniques that can be used to determine these sources. Environmental forensics is a methodology to unambiguously identify the contamination and its source or sources.

This handbook provides information on conducting environmental forensic investigations for polychlorinated biphenyls (PCBs) at sediment sites and should give RPMs and their contractor's useful guidance to perform such studies. This document provides an overview of the site-specific information that is needed and the type of technical activities to be conducted. The approach described in this handbook includes the combined use of rapid screening technologies to characterize the distribution of sediment contamination and advanced chemical fingerprinting (ACF) on a subset of samples to more definitively identify sources. This provides a cost-effective, technically advanced, and defensible approach to characterizing the PCB contamination and its sources at a given site.

Handbook Roadmap

This handbook is intended to be a useful guide for determining when a forensics investigation of a PCB contaminated sediment site may be considered and is comprised of the following sections:

- **Section 1:** Summarizes the requirements of Navy policy for source identification at sediment sites and provides background information on PCBs and their analysis. It reviews a step-wise process for implementing environmental forensics as part of a contaminant source study. This section will be of interest to RPMs and contractors wanting to familiarize themselves with the use of environmental forensics for PCBs.

- **Section 2:** Provides more information on PCB chemistry and a summary of the techniques that are used in a PCB environmental forensics investigation. This section covers sample design, sample collection, analysis methods, data analysis, and reporting. While the site-specific information and technical resources required are discussed in detail, this handbook is not intended as a "how to" manual for the actual conduct of a forensics investigation.

- **Section 3:** Summarizes the application of two case study examples to demonstrate the methodology. Discusses both a remedial cleanup and a dredging project case study to provide RPMs with example case studies that may be useful for their sites.

1.1.1 Navy Policy for Source Identification

Determining the original source of contamination is a requirement for cleanup programs within the military. Understanding the source(s) of contaminants to a contaminated sediment site is a prerequisite to implementing any proposed sediment remedial options under cleanup programs [1]. This is because sources must be controlled prior to remedial efforts to ensure that recontamination can be avoided.

It is Navy policy on sediment site investigations and response actions to determine all sources of sediment contamination prior to the start of remediation efforts in order to eliminate ongoing sources that could re-contaminate a closed site and to ensure that government funding is directed towards cleaning up contamination from Navy sources [2]. Under Navy policy, sediment investigations and response actions performed under the ER Program must be directly linked to Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) contaminant releases. The term "directly linked" means that the sediment contamination is scientifically connected to a Navy ER site. Therefore, all potential sources of Navy and non-Navy contamination at a site should be identified. At complex sediment sites, it may be appropriate to apply ACF techniques to support this source determination.

It should also be noted that, consistent with Navy policy, ER Program funding can only be used to perform forensic studies for the purpose of identifying the presence of other sources and/or to verify if the Navy is a contributor. The forensic study can only identify sources as non-Navy or Navy and cannot name a potentially-responsible party. RPMs should consult with the appropriate legal representatives regarding this matter.

1.1.2 PCB Chemistry and Fate Overview

PCBs are not a single compound, but a class of chlorinated organic compounds comprised of a biphenyl backbone with substitutions of from one to 10 chlorine atoms. Although there are 209 possible unique patterns in which these chlorines can be substituted onto the biphenyl rings, in practice there are about 100 to 150 individual compounds (termed congeners) that are present in the PCB formulations that have been in use and found in environmental samples. This is because PCBs are generally released into the environment as a limited set of a few distinct mixtures of congeners, termed Aroclors. It should be noted that while the term "Aroclor" is often thought of as synonymous with "PCB," Monsanto manufactured non-PCB products that also carried their Aroclor trade name. Aroclor 5460 for example was a polychlorinated terphenyl (PCT) product. PCB Aroclors did, however, account for the majority of Monsanto Aroclor production, and the term Aroclor refers to PCB Aroclors throughout this handbook. Less than 10 PCB Aroclor formulations were widely used. They were manufactured for specific industrial uses in the US from the 1930s through the 1970s when production was banned. Old equipment containing PCBs are still in use today, and therefore releases to the environment are still occurring. In addition, contaminated upland sites and runoff from many industrial environments continue to contribute PCBs to aquatic systems. PCBs were also used in caulk, paint, sealants, gasket materials, and numerous other industrial applications, a few of which did not use Aroclor formulations but relied on individual PCB congeners or non-Aroclor mixtures.

Because of their stable and persistent nature, historic PCB contamination can be widely found. In addition, certain PCBs accumulate in fatty biological tissue and the food web. Bioaccumulating contaminants such as PCBs are a concern because past contamination in sediments may represent a continuing source to aquatic food webs, and PCBs are frequently a driver in contaminated sediment management. Human and ecological health risks due to consumption of fish and shellfish are an issue at many Department of Defense (DoD) sites contaminated with PCBs. Because of the wide use of PCBs, many PCB-contaminated sediments near DoD sites may have been contaminated from multiple sources. Delineating the PCB sources is therefore an important concern where the DoD site may represent only one of many potential sources.

Definitions

This section presents a brief overview of PCB chemistry and its fate in the environment. More detailed information on PCB chemistry can be found in Section 2.

- A **PCB congener** is any individual chemical compound in the PCB category. The name of the congener is based on the total number of chlorine substituents and the position of each chlorine. Click here for a complete list of all PCB congeners.
- **PCB homologues** are subcategories of PCB congeners with equal numbers of chlorine substituents. Click here for a list of all PCB homologues.
- **PCB Aroclors** are mixtures of PCB congeners. These PCB mixtures were what was most commonly sold and used for a variety of commercial applications.

1.1.3 PCB Analysis and Environmental Forensics

PCBs can be measured by a number of different techniques depending on the intended use of the data. These techniques range from simple, rapid methods such as immunoassays that can provide total PCB estimates (including near real-time data in the field) to comprehensive PCB congener methods using laboratory gas chromatography (GC) separations with mass spectrometry (MS) detection. In between are laboratory methods that measure total Aroclor, PCB homologues, and limited sets of PCB congeners. Aroclor analysis has been widely used, and the identification of Aroclors is based on using only five to 10 key "representative" congeners selected from an unaltered single Aroclor standard. However, in environmental samples, multiple Aroclor sources with overlapping congeners are often present, and/or the PCB pattern may be altered by a number of natural processes once released into the environment. Aroclor analysis is thus often highly unreliable for identifying the type and amount of PCBs in environmental samples. In order to characterize and more fully understand the PCB contamination, and determine the PCB sources, it may be necessary to generate more detailed PCB data and unravel the alterations that may be "hiding" the original source patterns. Forensic studies may use a combination of sample and data analysis methods to achieve their goals, ranging from identifying sources for initial source control to later use for remedial cost apportionment. Often, forensic investigations are successfully used to eliminate a suspected

source (e.g., a DoD source) as the primary source rather than quantitatively allocate attribution of each source component, which can be much more difficult.

Environmental forensic studies are fairly mature for petroleum contaminated sites [3], but less common for other contaminants. Work on PCB fingerprinting is developing and there is clearly a need for reliable PCB forensics because of the abundance of this contaminant; it is often a decision driver at contaminated sediment sites. PCB forensics is particularly challenging because PCBs do not "weather" (i.e., change in chemical composition) merely in accordance with molecular weight, solubility, or other predictable factors. Some of the diagnostic principles used for polycyclic aromatic hydrocarbon (PAH) fingerprinting can be applied to PCB fingerprinting, but PCB mixtures are vastly different from PAH/petroleum mixtures; many factors need to be considered in addition to the most common weathering factors and interpretation methods need to be modified and new data interpretation and analysis considerations developed [4]. In addition to the mainly physically-based environmental processes (e.g., selective dissolution, adsorption, and volatilization), other environmental transformation and degradation processes (including microbial dechlorination) are also important and must be considered. Emerging PCB fingerprinting techniques have successfully been applied at a few sites in the US [5-9], but there is a need to more fully develop, demonstrate, and validate the utility of fingerprinting PCB contamination. More detailed information on PCB analysis and environmental forensic techniques can be found in Section 2.4.

1.2 General Approach

This section of the handbook presents the general approach (much of which will be discussed in more detail in Section 2.0 and applied to the case study sites in Section 3.0). The case studies provide examples of how to apply the approach described here at a range of sites. The case studies in this document should be viewed as examples and a start in defining the overall usefulness of forensics studies at Navy sediment sites.

Integrated Forensic Approach

This handbook demonstrates an integrated forensic approach to identify sources of sediment PCB contamination that combines sediment screening technologies on a large number of field samples, detailed PCB congener analysis on a subset of samples, followed by environmental forensic data interpretation to identify sources. The sample analysis and contaminant characterization is comprised of two major components:

- **Rapid sediment characterization (RSC)** technologies which provide for wide spatial coverage to delineate sediment contaminant heterogeneity and semi-quantitative characterization in a cost-effective manner; and
- **Advanced chemical fingerprinting (ACF)** on a selected subset of samples to delineate sources. ACF includes both advanced laboratory chemical analysis of samples, along with the application of sophisticated data analysis and interpretation methods.

The objective of combining RSC with ACF is to maximize the benefits of each method and control costs. For example, RSC provides a cost-effective technique for obtaining spatial

concentration information (and perhaps temporal with sediment core age dating), allowing chemical gradients to be determined for initial assessment of the significance of the contamination and preliminary indications of potential sources. However, individual PCB congener data (a component of the ACF) are usually required for actually fingerprinting sources unless the sources are composed of different Aroclor signatures. ACF may require specialty analyses that are beyond the scope of most regulatory requirements and beyond the capabilities of many commercial laboratories. For example, in the case of PCBs, many regulatory programs only require PCB concentrations be determined as total Aroclors, or possibly a limited set of PCB congeners (e.g., the 18 National Oceanic and Atmospheric Administration [NOAA] Status and Trend congeners), while ACF often requires that up to 100 PCB congeners be determined, at a higher cost. Therefore, this integrated approach is a cost-effective and technically defensible methodology to identify PCB sources in sediments at DoD sites.

This combination of relatively inexpensive RSC analyses to map contaminant gradients combined with a subset of ACF analyses with advanced statistical analyses can tease out source compositions. The relative contributions of each source to the impacted sediments can also be estimated depending upon the nature of the co-mingled sources and the degree of weathering. RSC can help cost effectively answer the question of "where" there are sediments with contamination issues, the general distribution of the contamination, and generally where possible sources may be located, while ACF can confirm "what" those potential source fingerprints are, and more definitively link them to physical sources. Contaminant "fingerprinting" using RSC and ACF methods can also have many applications within the regulatory process relative to sediment investigations and response actions. Fingerprinting techniques applied early in the remedial investigation (RI) can be effectively used for source identification to augment the Watershed Contaminated Source Document (WCSD) and/or verification of background locations and concentrations. Fingerprinting methods can also be employed in the later stages of the feasibility study (FS) to evaluate baseline conditions and the potential for natural attenuation in remedy selection and/or setting appropriate cleanup goals. Both source fingerprints, as well as weathering patterns (due to differences in solubility, dechlorination, etc.), can often be discerned using these advanced chemical and statistical analyses [8, 10]. Although it is difficult to isolate all possible changes in PCB congener patterns, the selection of Hunters Point Shipyard (HPS) and Ashtabula River as case studies provides two examples to demonstrate the methodology. Providing both a remedial cleanup (HPS) and a dredging project (Ashtabula River) example will provide the RPMs with example case studies that may be useful for their sites.

1.2.1 Six Step Integrated Forensics Approach

This handbook demonstrates how to apply the techniques used in RSC and ACF to a variety of PCB sites. This handbook follows the approach outlined in Stout et al. [3] for developing a PAH forensics study, but applies this approach to case study sites with PCB contamination. The combined use of RSC and ACF, however, is only one step in the overall integrated forensics approach described in this document. The six steps that are important to follow for conducting a contaminant source study are summarized in Figure 1-1.

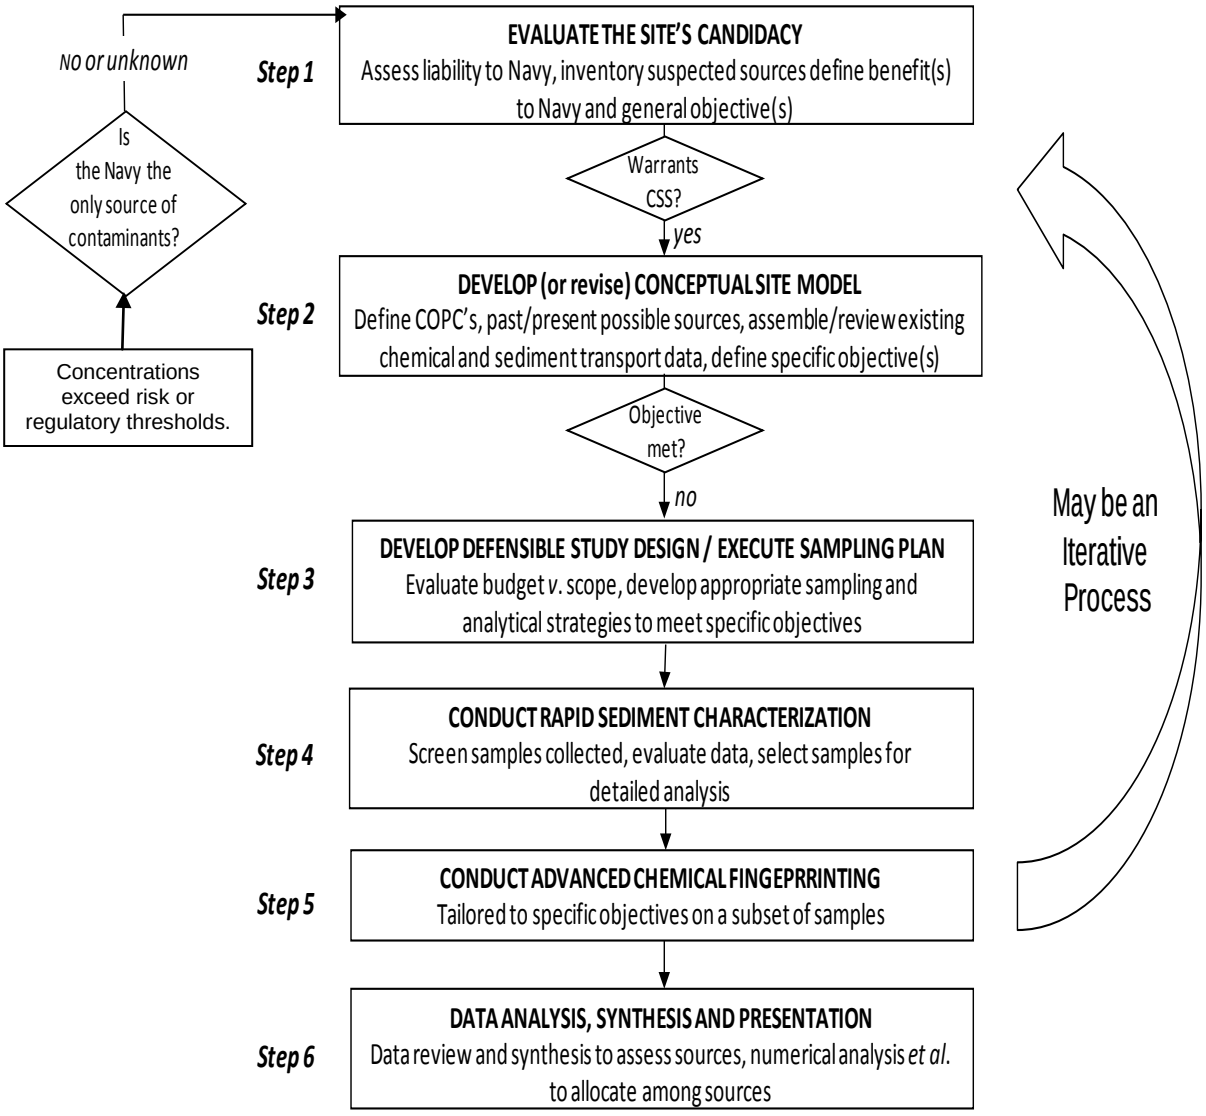

Figure 1-1. Flowchart Showing Considerations, Steps, and Decision Points for Conducting a Contaminant Source Study

1.2.1.1 Step 1: Evaluate Site for Forensic Study

The most obvious and common consideration when evaluating a site's potential for a forensics study is whether or not it is possible that non-site sources may have contributed to the known or suspected contamination at the site. Other questions that may be posed are summarized below. Each question must be considered and weighed in determining if the site will serve as a good candidate to apply forensic techniques.

Step 1: Evaluate Site for Forensic Study

1) Has it been determined that background cannot be established and/or concentrations exceed risk or regulatory thresholds?

2) Is it possible that non-site sources may have contributed to the known or suspected contamination at the site?

3) What known or suspected PCB contaminant sources existed on the site property (now or in the past)?

4) What known or suspected industries and potential sources are (or were) located on nearby properties?

5) What are (or were) the known typical contaminants associated with those industries?

6) What are the general sediment transport dynamics of the area (i.e., could contamination get from "here to there")?

1.2.1.2 Step 2: Develop Conceptual Site Model

The conceptual site model (CSM) is a mental "picture" of the site. It typically includes graphical representations of the contamination (e.g., contaminant contour maps) and fate and transport processes at the site. Once a site's candidacy has been established, a CSM for the ensuing contaminant source study should be developed to help understand how a source, or multiple sources, may have contributed to the contamination. At the completion of a CSM, it should be possible to accomplish the following:

1) Identify (or confirm the identity of) the known or suspected contaminants of potential concern (COPCs) for the site;
2) Identify all of the known or suspected sources or source areas of the COPCs within the study area; and
3) Develop specific objectives (hypotheses or forensic questions) to be evaluated by the study that address the potential PCB sources.

There is obvious overlap with some of the questions in Step 1, but those will be explored in more detail in Step 2. The forensic questions developed under Step 2 will then guide the development

of the sampling design in Step 3 (Sampling and Analysis Plan [SAP]). Specific samples will need to be collected to answer the CSM questions, so this will focus the scope of the forensic study. This does not preclude unforeseen findings, and it is likely that some surprises will occur at most sites. However, this directed development of the forensics study will ensure a cost-effective and well defined study.

An important step in the identification of COPCs is a review of the pre-existing information for the study area, including environmental data. The pre-existing data from past work typically only represent a start in providing defensible interpretations surrounding the source(s) of contamination within the study area. Thoroughly researching existing data, including the history of industries and potential sources in the area, changes over time that could impact contaminant transport (e.g., runoff/drainage, combined sewer outfall/overflow [CSO] activity, site/source cleanup, etc.) are all key components of the records research phase of any forensics investigation. Comprehensive records research is a crucial part of any environmental forensics investigation and is often overlooked or not given the priority it should have.

The case study examples used for this handbook had pre-existing data that were determined to be of sufficient quantity and quality for use in developing the forensics approach in this document, without needing to collect or analyze additional samples. It is rare to be able to conduct a forensics investigation solely using available data, but these case studies were selected, in large part, because of the availability of such data. For instance, all of the PCB data were generated by the same laboratory using consistent procedures, ensuring data comparability and reliable use.

Step 2: Develop a CSM

The CSM is a mental "picture" of the site. It includes graphical representations of the contamination (e.g., contaminant contour maps) and fate and transport processes at the site. CSM development should include the following elements:

- It should provide an understanding of contaminant fate and sediment transport processes at the given site (such as sediment dynamics, identifying areas of net accretion or loss, prop scour, review of dredging records, and more).
- It should include a review of pre-existing information and environmental data to identify COPCs and all of the known or suspected sources or source areas.
- It should support the development of specific objectives (hypotheses or forensic questions) to be evaluated by the study that address the potential PCB sources.

1.2.1.3 Step 3: Develop and Execute a Technically Defensible Sampling Plan

The development of a technically defensible sampling strategy requires a balance between meeting project objectives and data quality objectives (DQOs) within the budget of the project. This often leads to the practical question of how many samples will be used in the study and the type of analyses to be performed. Ultimately, it is the number of samples and analytical costs that will largely determine the cost of the project. By using a tiered study design that allows

RSC data to first characterize the PCB concentrations, the study can be designed to more cost-effectively produce and use the more costly ACF data.

Since forensic investigations are not part of the standard investigation processes, RPMs should contact their Quality Assurance Officer to ensure adherence to Navy policy on the development of SAPs under the Uniform Federal Policy for Quality Assurance Project Plans (UFP-QAPPs). Forensic specialists should also be involved in the DQO and SAP development process as early as possible to ensure proper data collection and analysis.

At some sites, it may be beneficial to include the collection of sediment cores to capture a record of the historic PCB contributions to the sediments. Some of the cores should be age dated to determine sediment chronology (i.e., the rate of sediment deposition and the dates the sediments at different depths were deposited). If only surface sediments are collected, only recent contamination can be assessed and only recent sources can be determined. This may be sufficient if the only objective is to identify and contain current sources prior to a remedial effort to control recontamination, but these are the types of issues that must be considered during the development of a study design. Many of these types of considerations are addressed in outside references (e.g., [11]), to assist with study design.

Step 3: Develop and Execute and Defensible Sampling Plan

- Develop defensible DQOs and SAPs that follow Navy and UFP-QAPP policies.
- Determine how many samples will be used and the type of analyses to be performed.
- Plan for a tiered study approach that implements RSC first to characterize the PCB extent followed by ACF techniques for source determination.

1.2.1.4 Step 4: Conduct Rapid Sediment Characterization

RSC of semi-volatile organics can be conducted using various immunoassay techniques. The techniques for the RSC of PCBs in sediments have been adapted from methods developed for use in soils (U.S. Environmental Protection Agency [U.S. EPA] Method 4020). Total PCB analysis by the standard laboratory Aroclor method (U.S. EPA Method 8082) may not qualify as a *rapid* sediment characterization method, but is a widely available analytical method that provides general PCB concentration information without the information detail of ACF, and such data can be used similarly to RSC data. More detailed information on the use of RSC methods can be found in the *Navy Guide for Using Rapid Sediment Characterization Methods in Ecological Risk Assessments* [12]. Some limitations in the sensitivity and specificity of RSC methods are also discussed in Section 2.4.1.

The PCB concentration data and variations are plotted using geographic contour plots, or other suitable graphical representation of the concentration distribution at the site. RSC data interpretation can benefit from additional physicochemical information for the sediments, such as the grain size distribution and total organic carbon (TOC) content, as PCBs tend to be preferentially associated with fine-grained and higher TOC content sediment. Grain size and

TOC information also may assist in interpretation of sediment transport and sources of the sediment at sample locations. PCBs can be normalized to TOC in order to better visualize the correlation behavior. With additional sediment transport information, the chemical gradients (PCBs sorbed on sediments generally move from high concentration source areas to lower concentration depositional zones) can be used to suggest various PCB sources. The contour maps (both surface and subsurface) thus can, if properly interpreted, display chemical gradients that indicate potential sources, and additional three-dimensional (3D) plumes (i.e., contoured subsurface information) may be defined because a higher number of samples can cost effectively be analyzed. These spatial presentations of the data allow different source areas to be proposed for validation by the more detailed laboratory analysis (ACF). The benefit of using a tiered approach (using RSC to select ACF samples) is a cost-effective study design in a heterogeneous matrix such as sediment. If only higher cost ACF samples are used, fewer locations would be sampled and source areas may be overlooked due to heterogeneity.

Regardless of the approach used in the generation and evaluation of RSC data, it is important to remember that the goal of the RSC analysis is to develop a sufficient set of visual or conceptual displays to aid in the selection of samples for ACF (and not to alone achieve the objectives of the study).

Step 4: Conduct RSC

- RSC of PCBs in sediment is conducted primarily using immunoassay techniques, but total PCB analytical methods may also be employed for site wide screening of PCB levels.
- The benefit of a tiered approach (e.g., using RSC to select ACF sample locations) is a cost-effective study design for a heterogeneous matrix such as sediment.
- The goal of the RSC analysis is ultimately to develop a sufficient set of visual or conceptual displays to aid in the selection of samples for ACF.
- Physicochemical data, such as the grain size distribution and TOC for sediment, may assist in interpretation of sediment transport and provide useful correlations to PCB concentrations.

1.2.1.5 Step 5: Conduct Advanced Chemical Fingerprinting

This section discusses how to select the location of ACF samples and provides an overview of the types of PCB analyses and statistical techniques to be applied to interpret results. More detailed information can be found in Section 2.4.2.

Determining the Number and Location of ACF Samples. The analytical strategy and budget will largely determine the number of samples that will be selected for ACF. It is not possible to define a fixed percent value of RSC samples to be used for ACF because this depends upon the level of detail in the RSC characterization, the heterogeneity of the sediment, and the overall complexity of the site. Therefore, the task of selecting samples for ACF is largely a matter of selecting a reasonable and justified subset from the complete set of RSC samples. Some guiding principles for the selection of samples for ACF are as follows:

1) Select samples that provide ample spatial coverage of the entire study area (try to represent all areas of the study and do not completely ignore any area on the basis of RSC alone),
2) Select a sufficient number of samples from specific location(s) within the study area that address a specific project objective(s) (i.e., select sufficient samples in areas of specific concern or interest [source areas and mixing zones], potentially including accessible upland sites of interest), and
3) Select samples that represent the range of RSC concentrations observed, including those that are (apparently) representative of the ambient/background conditions (i.e., do not exclude all the low concentration samples as they may provide important information on "background" conditions).

The selection of samples for ACF to meet these guidelines is in large part driven by cost. Thus, a degree of professional judgment is needed in the selection of samples for ACF.

Selecting Analytical Method(s) for the ACF Study. The need for an ACF methodology rests with the limitations of standard U.S. EPA methods (SW-846) to meet the objectives of a contaminant source study [3]. The fundamental shortcoming with virtually every conventional U.S. EPA SW-846 method of analysis, when used for measuring contaminants, particularly organic contaminants in sediment and other media, is a lack of detailed measurements of those diagnostic chemicals known to comprise these complex mixtures. Instead, the standard methods are focused on compounds identified as "priority pollutants," which are quite pervasive in contaminant mixtures, and are generally inadequate to distinguish different sources of otherwise similar contaminants [13]. In addition, standard PCB methods are primarily intended to generate bulk PCB concentration information (i.e., total PCB), and not information for identifying compositional and source differences.

Because of these limitations, standard U.S. EPA methods have been modified at some laboratories to yield the data necessary to support detailed contaminant source investigations. With respect to these modified methods, note that U.S. EPA SW-846 guidelines allow flexibility in the deployment of the 'standard' analytical methods, including modification of the list of target compounds. While most commercial laboratories apply unmodified standard methods, some laboratories have the experience and flexibility to optimize methods to meet project goals without violating method guidelines and project DQOs. When properly planned, most data generated by ACF methods can support contaminant source studies, as well as conventional regulatory assessment requirements. In other words, the ACF data can be considered defensible and accepted by regulatory agencies if the DQOs are clearly defined and met. While RSC and most ACF analyses do not require validation or accreditation review/oversight, it is emphasized that any data that will also be used for definitive purposes (e.g., risk assessment or site close out) must be from a laboratory accredited by the DoD-Environmental Laboratory Accreditation Program. RPMs should consult with their Quality Assurance Officer for an evaluation of accreditation requirements.

Aroclor analysis may, in a few rare circumstances, provide sufficient fingerprinting information to indentify sources. However, because many of the Aroclor formulations consist of overlapping congeners and weathering processes further complicate forensic resolution, more advanced ACF

methods are usually needed. The ACF techniques available for the assessment of semi-volatile organic contaminants in sediments (e.g., PCBs) are based on high-resolution GC (HRGC), usually operated in conjunction with compound-specific detectors (e.g., electron capture detection [ECD] or MS). Some laboratories have developed state-of-the-art PCB analytical methods using HRGC with low-resolution MS operating in selected ion monitoring mode (HRGC/LRMS-SIM), which are both highly cost-effective and provide detailed, high-quality data [14, 15]. The method employs components of U.S. EPA Method 680 (HRGC/LRMS PCB homologue and total PCB method) and Method 1668 (HRGC/HRMS PCB congener method). The base methods have been modified to include a large number of non-standard environmentally important and diagnostic PCB congeners that permit data analysis for differentiating potential sources and environmental processes.

Interpreting ACF Results. Once a subset of samples has been selected for ACF, a forensic analysis for PCBs will typically include the characterization of more than 100 discrete PCB congeners (congeners that comprise >98% of the total and possible PCB contamination), which enables scientists to apply a variety of powerful data interpretation methods. In some cases, a smaller set of 50 to 75 congeners may suffice, but the incremental increase in the cost is fairly small relative to the benefit of having the longer analyte list. PCB forensics data reduction and analysis include:

- Various types of statistical and other numerical analyses,
- Forensics graphing/plotting/mapping,
- Cross plotting,
- Cluster and principal component analysis (PCA) for similarity and dissimilarity analysis,
- Analysis for determining the age of the contamination, and
- Determination of degradation and dechlorination activity.

More detailed descriptions of these forensics methods, including specifically for PCBs, have been presented and documented elsewhere [5-10, 14], and some are further described and applied in this document.

PCA is one commonly used multivariate classification data analysis technique for identifying PCB compositional similarities and dissimilarities among samples and source materials. Receptor modeling (e.g., polytopic vector analysis [PVA]) is another often useful chemometric technique that was applied for the HPS and Ashtabula River case studies, in accordance with methodologies outlined by Johnson et al. [9]. For PCA, PVA, and most chemometric data analyses, the data are first carefully reviewed to assess their quality and usefulness, and the potential impact of low concentration samples, non-detects, and the presence of outliers. Data screening is summarized in Section 2 and also outlined by Johnson et al. [9] and may include: (1) data correction; (2) removal of samples from the data set; and (3) removal of congeners/peaks from the data set. After the data are prepared, the resultant data matrix is analyzed using the multivariate receptor modeling method. The first step in this process is the determination of the number of 'fingerprints' in the system. The next step in the receptor modeling process is to resolve the end member compositions (source profiles) and mixing proportions (source contributions) within each sample. The final step in the process is to: (1) compare the resolved end-member congener profiles with known or suspected source patterns (i.e., Aroclors) and

alteration mechanisms (e.g., literature reported dechlorination methods [16]) and (2) map the end-member mixing proportions both temporally and geographically.

PVA can be a useful component of the ACF data analysis because it is a well-established method that has been applied extensively in PCB forensics applications [5, 8, 9, 17]. Other receptor modeling methods (alternating least squares [ALS], positive matrix factorization [PMF], and Unmix [9]) should also be considered for individual studies. Recent receptor modeling method comparisons [9, 18, 19] indicate that results of these various methods are usually comparable, assuming the use of high quality and diligently screened data sets. The more important consideration is experience of the analyst, and their sensitivity to the scientific/chemical context of the problem.

Step 5: Conduct ACF

- The number of ACF samples depends upon the level of detail in the RSC characterization, the heterogeneity of the sediment, and the complexity of the site.
- ACF techniques typically include the characterization of over 100 PCB congeners.
- The PCB analytical methods employ HRGC usually operated in conjunction with compound-specific detectors (e.g., ECD or MS).
- Some laboratories have developed state-of-the-art PCB analytical methods using HRGC with low-resolution MS operating in selected ion monitoring mode (HRGC/LRM-SIM).
- Statistical techniques such as PCA, PVA, and others are then used to determine the number of "fingerprints" in the system, the source profiles, and the mixing proportions within each sample.
- This information is compared to known or suspected source patterns (i.e., Aroclors) and degradation mechanisms.

1.2.1.6 Step 6: Data Analysis, Synthesis, and Presentation of Results

The data analysis, synthesis, and information interpretation is most effective when multiple lines of evidence are used to develop the findings and draw the final conclusions. If multiple lines of evidence support the findings, it provides confidence and lends credibility to the conclusions. If multiple methods to evaluate the data provide confounding or inconsistent results, then that may mean that additional investigations may be warranted, or that there is no strong evidence of discrete and clearly identifiable sources. The multiple approaches to data analysis include:

1) A site history and records research component,
2) Incorporating contaminant/sediment transport and hydrodynamic information,
3) Evaluating the PCB concentrations across a site,
4) Evaluating the PCB composition of samples from across a site and possible sources,
5) Applying one or several available chemometric statistical methods to the PCB data, and
6) Integrated data analysis and interpretation incorporating these multiple approaches to draw conclusions related to potential sources of the contamination.

Section 2.5 provides examples of figures for the synthesis and presentation of ACF data. The manner by which the results and conclusions of a contaminant source study are conveyed needs to consider the audience, particularly whether they are highly technical or non-technical decision-makers and stakeholders. The target audience will dictate the level of technical detail conveyed in a report or presentation. Chemical 'fingerprinting' data in graphical and/or tabular form can be very confusing to all but an experienced chemist. Their interpretation is easier (and thereby useful) when the results of a contaminant source study are reported using different visual displays that either convey the data spatially or by some other easily interpreted visual (e.g., contour maps, bubble plots, histograms, etc.). Such visuals can be readily explained to and interpreted by most audiences. This is important since the value of any contaminant source study will be undermined if the audience cannot understand the results and conclusions.

Step 6: Data Analysis, Synthesis, and Presentation of Results

- Using RSC, it is possible to have the data density to support two-dimensional (2D) and 3D contour mapping, which provides a good visual display of the concentration gradients.
- Other visual displays (such as bubble plots, transect charts, or histograms) can be used with the RSC data. Bubble plots are often used as visual displays of the lower density ACF data when there is not enough data for support contour mapping.
- PCB compositional histograms are useful for illustrating and describing the contaminant composition, relationships among the samples and to potential sources, and link the field samples to source material (e.g., Aroclor formulations or mixtures).
- Single horizon pie chart or multi-horizon core diagram inserts on a map view of sample locations can be used to show the distribution of end members around the site.

The ACF data by themselves only provide information of compositional similarity and dissimilarity in the data set, and must be viewed along with other information (e.g., site history, sediment and contaminant transport, etc.) to determine where sources can be found. In addition, the PCB information and linkages to potential sources must make sense from a chemical reasonableness perspective, and it must be possible for a PCB chemist to understand and justify the observations and source identifications; statistical software packages and graphical representations by themselves are insufficient for explaining sources. The previously mentioned RSC contour maps provide a first impression of where sources are located. By combining this data with other site information (including site contaminant use history, other upland and upstream contaminant studies, sediment transport studies, contaminant deposition history with dated cores, etc.), it may be possible to tell not only what sources are present, but where they are located and when they contaminated the sediments.

2.0 GENERAL SUMMARY OF TECHNICAL METHODS

2.1 Introduction to PCBs and PCB Chemistry

Environmental forensics methodologies are well developed for petroleum-originating contamination, and less so for PCB contamination. PCBs were intentionally produced through chlorination of the biphenyl molecule, unlike petroleum and one of their primary constituent PAHs, which are naturally produced and introduced into the environment both by man and through natural processes. This chemical process that produces PCBs places from one to 10 chlorines on available substitution locations on the six-sided biphenyl molecule (Figure 2-1). Multiple naming conventions have been developed to differentiate the 209 possible congeners (a term given to distinguish different PCB compounds with unique combinations of attached chlorines). Early naming conventions relied on substituted chlorine positions to differentiate congeners. These early methods numbered the six "corners" of each ring in the biphenyl structure, and referred to the individual congener by the numbers where substituted chlorines resided (for example see Figure 2-1 where ortho "corners" are at positions labeled 2,6,2',6'; meta "corners" are at 3,5,3',5'; and para is at 4 and 4'). The International Union of Pure and Applied Chemistry (IUPAC) naming conventions later simplified things by sequentially numbering all congeners by increasing chlorine content, from PCB 1 through PCB 209. PCBs can also be simply divided into homolog groups based on the number of chlorine substitutions on the biphenyl rings (mono-, di-, tri-, tetra-, penta-, hexa-, hepta-, octa-, nona-, or deca-chlorobiphenyl). These naming conventions are all shown in Table 2-1. Information on the 10 homologs, including the number of possible PCB congeners for each level of chlorination (i.e., each homolog), is also summarized in Table 2-2.

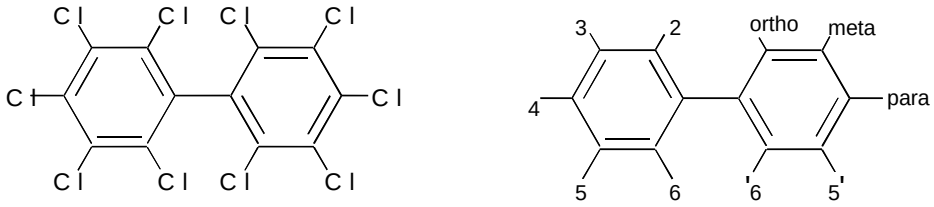

Figure 2-1. PCB Molecule Showing Possible Chlorine Positions

PCBs were produced commercially in the US from 1929 through 1977 by Monsanto Chemical Company. They were produced in specific PCB congener mixtures (termed Aroclors) to obtain chemical properties that were desired for specific industrial applications. PCBs have increasing density, boiling point, and hydrophobicity with increasing levels of chlorination. High molecular weights and boiling points lead to a viscous fluid with low flammability that can tolerate high temperatures without substantial chemical degradation. Most of the PCBs were produced for use in transformers and capacitors, with other uses including hydraulic fluids, carbonless copy paper, printing inks, and other applications [20]. When manufactured in the US by Monsanto, these mixtures were termed Aroclors; those manufactured outside the US by others had trade names such as Clophen (Germany), Prodolec (France), and Phenoclor (Japan). Monsanto reportedly produced from 500,000 to 600,000 metric tons of PCBs (about half the world-wide total) during its almost 50 years of production [21], although most PCBs are no longer being used, some are still held in older equipment and materials (e.g., in landfills) and potentially available for release to the environment.

Deca-chlorobiphenyl	$C_{12}Cl_{10}$	10	1

Only a limited number of Aroclor mixtures were produced in the US, each with a distinct homolog and congener fingerprint. Table 2-3 lists the nine major Aroclors produced in the US, and their PCB homolog composition; Aroclors 1016, 1242, 1254, and 1260 together comprised more than 90% of the PCBs that were produced in the US. A few additional Aroclors were produced, but only in small quantities. Aroclors carried a four digit numbering convention. For many years it was reported/repeated in the literature, and often taken as fact that the first two digits in the Aroclor naming convention represented the number of carbon atoms on the molecule and the last two digits represented the average weight percent chlorine in the formulation. The latter half of that explanation is true: the "60" in Aroclor 1260 indicates that is has a mixture of PCB congeners that result in 60% chlorine by weight. A recent paper by Erickson and Kaley [22] suggest that the 12-carbon part of that common explanation may be incorrect. While PCB congeners do indeed contain 12 carbons, the "12" indicates only that the product is refined PCB.

Hence, nearly all PCB Aroclors follow the naming convention "12xx" (Aroclor 1016 which was produced as a replacement for Aroclor 1242 being the sole exception). Erickson and Kaley [22] point out that if the "12=12 carbon atoms" myth was true, the first two digits of Monsanto's line of PCT products would have been "18," since there are 18 carbon atoms in the terphenyl molecule, assuming the same naming rules were used for PCT as for PCB. But PCT products were named using a 5000 series convention (such as Aroclor 5460 – a PCT product with 60% chlorine).

Table 2-3. PCB Homolog Composition of the Nine Major Aroclors Produced in the US

From Frame et al., 1996 [23] and Kannan et al., 1997 [24].

*Aroclors 1016, 1242, 1254, and 1260 accounted for >90% of the PCB production.

Each Aroclor mixture was a unique combination of up to approximately 50 individual congeners of significant relative concentration, formulated to provide specific chemical properties. A total of a little more than 100 of the possible 209 PCB congeners were included in the different Aroclor formulations at easily detectable levels, and a few additional congeners may be detected in environmental samples as a result of environmental transformation processes. A set of about 120 PCB congeners can describe more than 99% of the total PCB in all Aroclor formulations and environmental samples, and most of the rest of the possible congeners were never produced or are rarely detected above ultra-trace levels. Information on the PCB congener composition of Aroclors is presented in Appendix A (based on Rushneck et al. [25]), including a series of plots showing the concentrations of a set of 80 major PCB congeners.

Given that only a few distinct Aroclors were produced, and their generally stable chemical characteristic, one might assume fingerprinting the distinct Aroclor sources should be a relatively easy exercise. Figure 2-2 shows the composition of 18 major PCB congeners in fresh Aroclor 1248 and 1260 PCB material, illustrating that one can easily discriminate individual Aroclors even with this relatively small subset of 18 NOAA Status and Trends Program congeners. However, environmental PCB contamination is rarely from a single Aroclor and environmental PCB contamination rarely resembles a fresh Aroclor material; environmental processes and comingling from multiple sources significantly complicate PCB environmental forensics. Furthermore, the changes due to environmental processes (i.e., "weathering" processes) can be difficult to predict (i.e., they are not simply correlated to molecular weight or solubility).

PCB Materials

This section presents an overview of PCB chemistry and its behavior in the environment. PCBs are typically described as:

- **PCB Congeners.** The individual PCB compounds. There are 209 PCB congeners, a subset of which were present in commercial PCB formulations and found in PCB contamination.
- **PCB homologues.** The categories of PCB congeners with equal numbers of chlorine substitutions, or levels of chlorination. There are 10 PCB homologues.
- **PCB Aroclors.** Mixtures of PCB congener mixtures that were most commonly sold and used in the US. A total of nine Aroclors are most commonly described, but a few other rare Aroclors also existed.

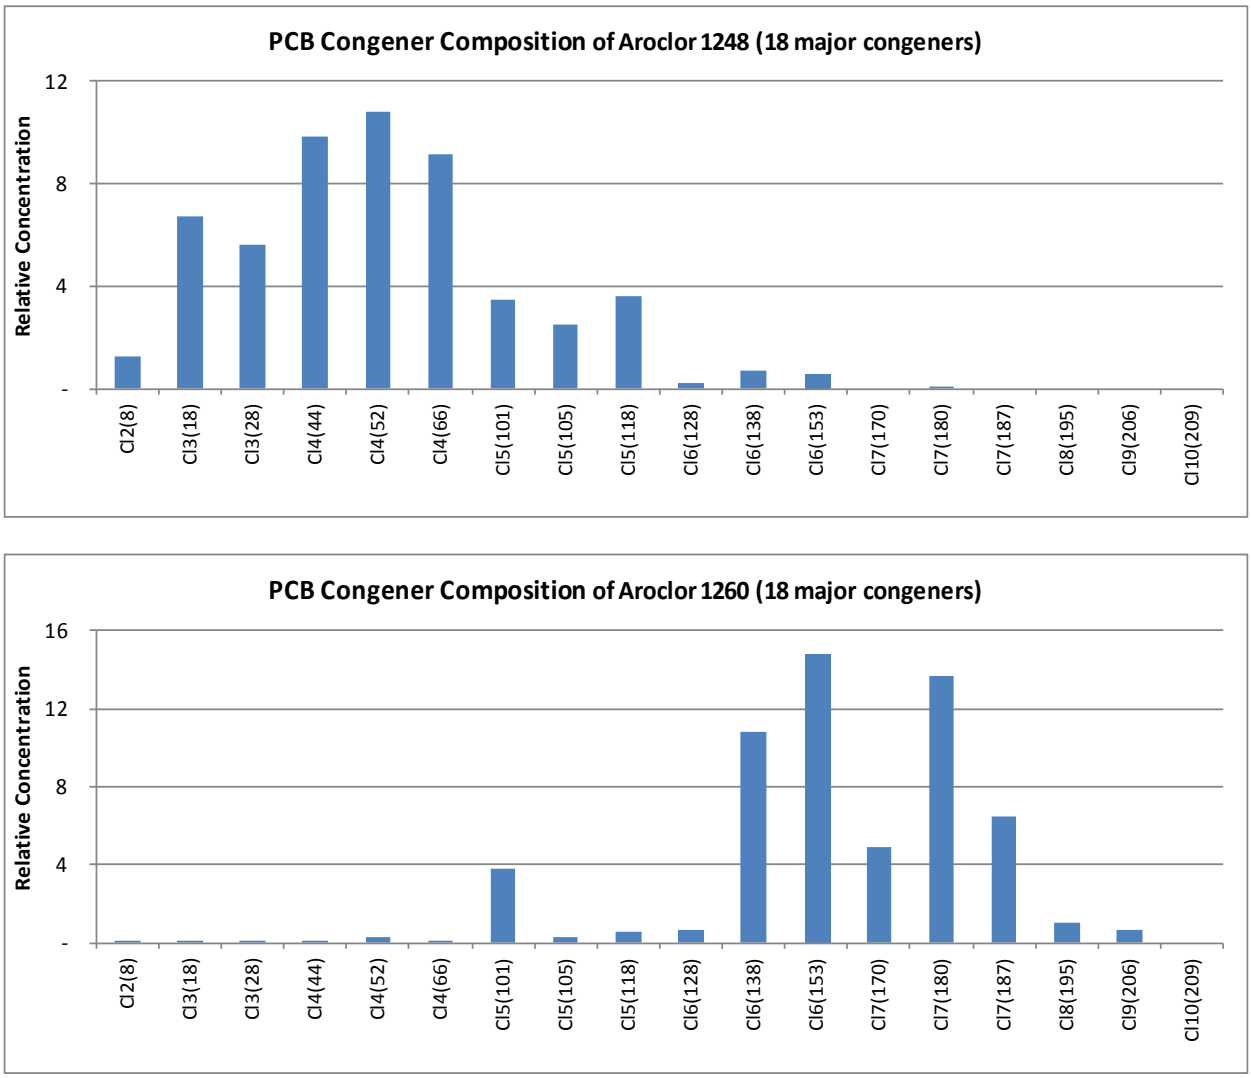

Figure 2-2. PCB Congener Composition of Aroclors 1248 (top) and 1260 (bottom)

The same properties that led to their usefulness for industrial applications also led to PCBs becoming an environmental problem. PCBs resist thermal and other degradation processes; they are stable and thus persist in the environment. The chemical characteristics of PCB also mean that they have low water solubility and adhere to solid soil and sediment particles rather than freely dissolving in water or volatilizing to air; they have high octanol/water partitioning coefficients (k_{ow}) and are therefore lipophilic ("fat loving" rather than hydrophilic or "water loving") and tend to partition into organic phases.

Their hydrophobic nature means that PCBs are usually associated with the organic carbon fractions of soils and sediments (i.e., they concentrate in organic rich sediment, as opposed to sandy sediment); they also accumulate in fatty biological tissue. When organisms consume PCB-containing material (e.g., organic matter or other organisms) some become associated with the lipid fraction of the organism, and some may not be readily metabolized or excreted. This process results in some of the PCBs biomagnifying, or increasing in concentration as PCBs are consumed by higher trophic level organisms, rather than being lost from the organism. Although PCBs may be persistent in the environment because they are recalcitrant, they can still undergo some degradation and alteration in the environment, as well as within the tissue of organism. PCBs as a group are considered very stable and persistent, but they are in fact a diverse mixture of molecules (PCB congeners) with varying chemical properties, including large congener-to-congener differences in the rates of and susceptibility to degradation and alteration. In general, the less chlorinated congeners will be more soluble and volatile. More chlorinated congeners are more hydrophobic and tend to accumulate in organic rich sediments, bioaccumulate up the food chain, and fractionated into the fatty tissues in organisms to a higher degree. Within organisms, different congeners will bioaccumulate and metabolize at different rates, so additional biological fractionation can occur. PCB congeners can also undergo microbial dechlorination, particularly in anaerobic sediments, and the susceptibility to dechlorination is highly dependent on the structure of the PCB molecule (i.e., the degree of chlorination and position of the chlorines on the biphenyl molecule); the environmental PCB composition can thus also be altered by dechlorination processes.

PCB dechlorination can be a particularly confounding PCB transformation process that complicates PCB source identification and PCB analytical chemistry. In anaerobic sediments, certain bacterial groups have been found to be able to dechlorinate PCBs given the right conditions. Long-term studies of contaminated sediments [26, 27] have shown specific bacterial groups have distinctive dechlorination patterns, transforming certain PCB congeners to less chlorinated congeners as chlorines are removed. Specific dechlorination pathways have been documented, and can be predicted [16]. Figure 2-3 illustrates a few examples of potential dechlorination pathways. The dechlorination potential is rather complicated, and depends on factors such as the position of the chlorine subject to dechlorination as well as the number and positions of other chlorines on the molecule, and the overall level of chlorination.

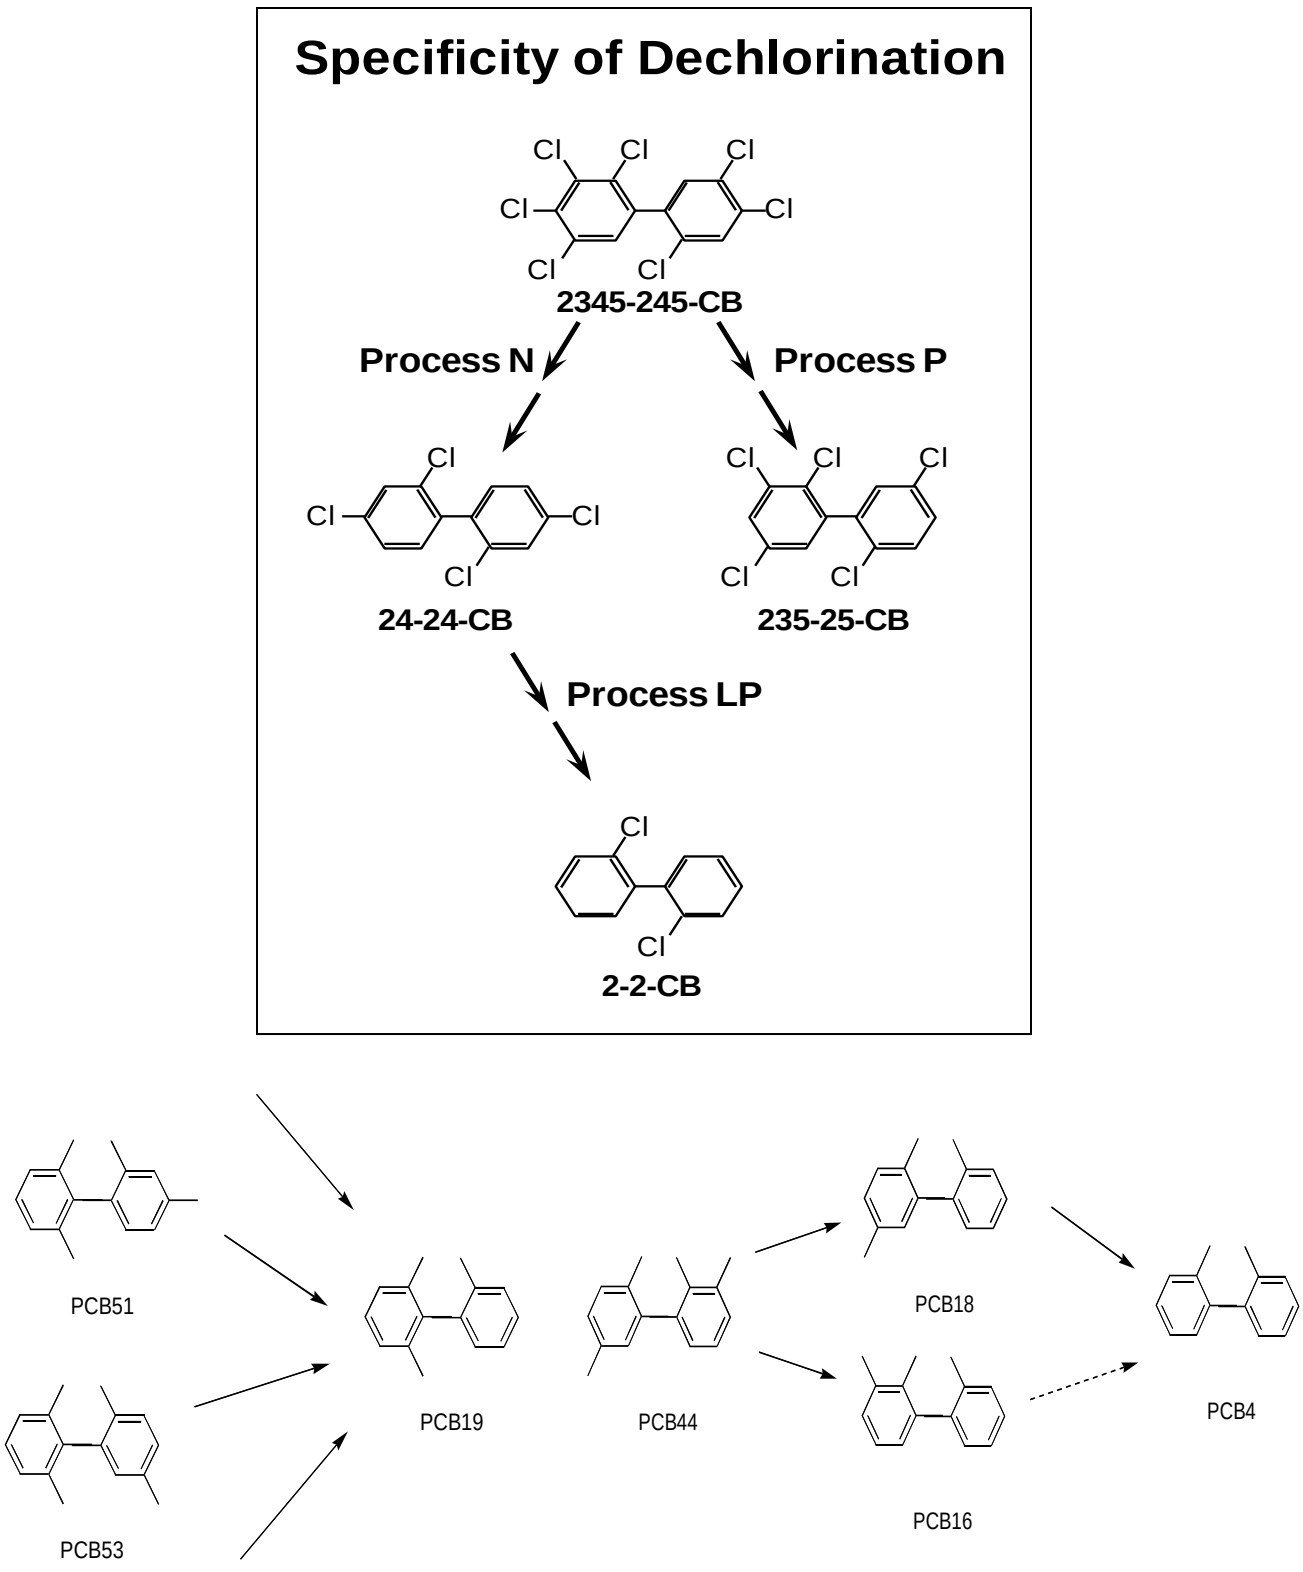

Figure 2-3. Example of Documented PCB Dechlorination Processes and Pathways, Including Pathways Resulting in an Increase in PCB19 and PCB4 Concentrations

Bolded and italicized congeners are present at ~0.25% or more in Aroclors 1016/1242, 1248, 1254, and/or 1260.
Only congeners with up to six chlorines are listed; more chlorinated congeners are less susceptible to dechlorination.

In general, meta-substituted chlorines are dechlorinated most readily (process N in Figure 2-3), followed by para-substituted chlorines (process P in Figure 2-3). The presence of adjacent chlorines (i.e., "flanked" meta- and para-substituted chlorine) increases the susceptibility to dechlorination. A double-flanked meta-substituted congener (i.e., with also a chlorine in the adjacent para- and ortho-positions) is particularly susceptible to dechlorination of the chlorine in the meta position [28, 29]. Ortho-substituted chlorines are significantly less likely to be removed through dechlorination and, over time, the primarily ortho-substituted PCB congeners therefore increase in relative concentration if a significant amount of anaerobic dechlorination is occurring in the sediment. The most heavily chlorinated PCB congeners (e.g., hepta-, octa-, nona- and deca-chlorobiphenyls; Table 2-1) tend to be less susceptible to dechlorination than the less chlorinated congeners (e.g., tri-, tetra-, penta-, and hexa-chlorobiphenyls). Table 2-4 presents a summary of congeners (by IUPAC congener number) that are particularly susceptible to dechlorination because of the described chlorine substitution on their molecules, as well as congeners that are relatively resistant to dechlorination. Congeners with high relative concentrations in common Aroclor formulations and much environmental contamination are indicated in bold. PCB dechlorination, in and of itself, does not remove PCBs; it only alters the composition of the PCB congeners. However, dechlorination does transform the PCB into forms that are more amenable to mineralization processes that can occur.

Dechlorination pathways have been used in fingerprinting studies to follow the changes in PCB composition to reconstruct the original source fingerprints [8]. Figure 2-4 (top) illustrates the PCB composition in surface sediment samples from a site in Lake Hartwell, NC, which closely resembles that of the known contamination source (a mixture of Aroclors 1242 and 1254). The bottom portion of Figure 2-4 illustrates the PCB composition in buried sediment which has been significantly dechlorinated and no longer resembles the known source material.

Figure 2-5 illustrates the difference in the PCB congener composition of the deeper and the surface sediment. The dechlorinated sediments have an increase in and very high relative proportion of PCB congeners with primarily ortho substitution (e.g., PCB4 [chlorines in the 2,2' positions], PCB10 [2,6], and PCB19 [2,6,2']), and a decrease in concentration of congeners with meta-substituted chlorines highly susceptible to dechlorination (e.g., PCB22, PCB28, PCB33, PCB44); see Tables 2-1 and 2-4, and Figures 2-1 and 2-3. The deeper, "older", sediments had no PCB compositional resemblance to Aroclors 1242 and 1254, or any other Aroclor, but could be linked to Aroclors 1242 and 1254 as the source material by understanding the chemical processes and through dechlorination pathway and deconvolution analysis [8]. Another important result of significant dechlorination is that PCB-as-Aroclor analysis, which remains the most widely used laboratory PCB analytical method, often results in large errors in the reported PCB concentration of such samples, and may even miss the presence of PCBs altogether. It would not be surprising, for instance, if the sample illustrated in Figure 2-4 (bottom) would be reported as "no PCB detected", even though the sample had very high PCB concentrations, simply because the PCB composition no longer resembles Aroclor material.

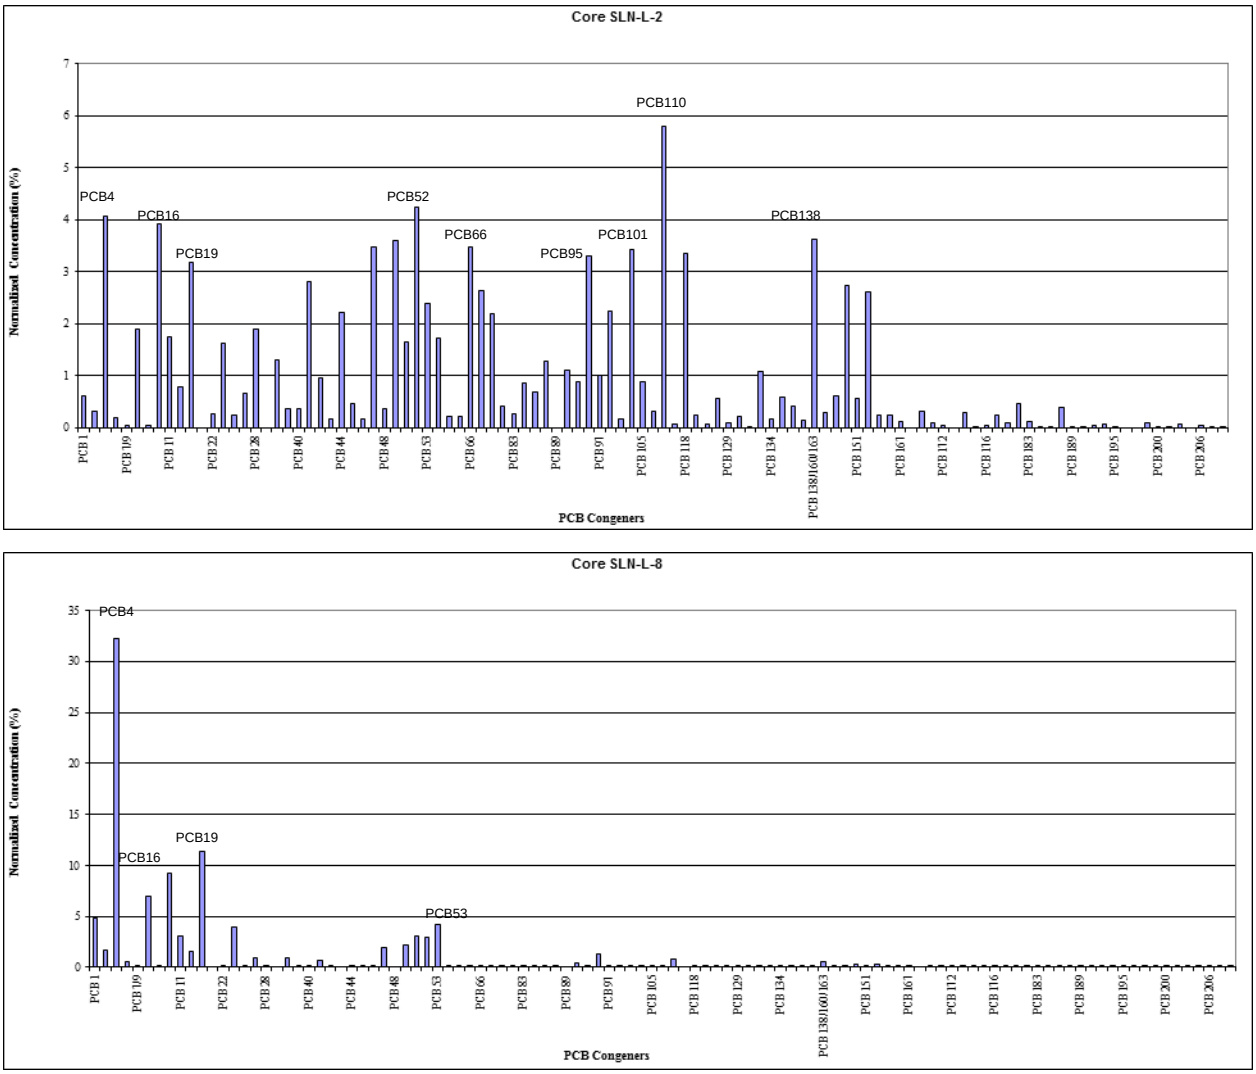

Figure 2-4. PCB Congener Distribution in a Surface (top) and Deep (bottom) Sediment Sample Collected at Location L at Lake Hartwell [6]

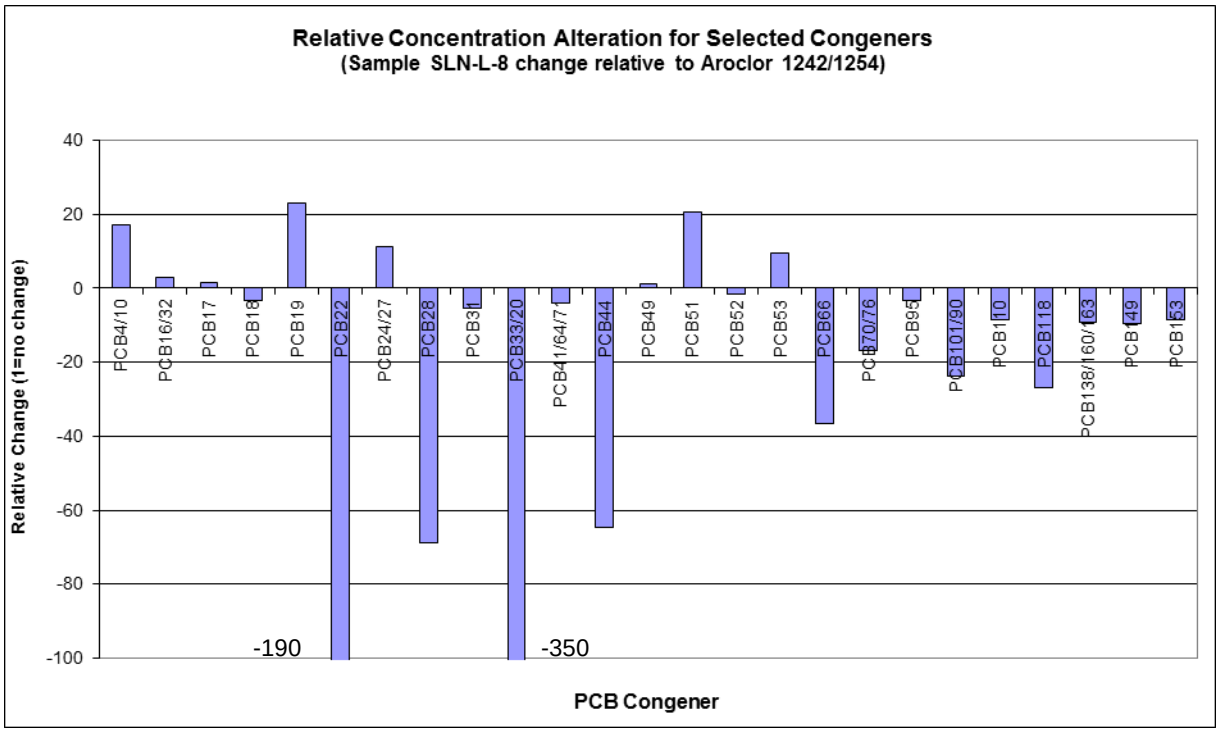

Figure 2-5. Change in Relative PCB Congener Concentrations in a Deep Sediment Sample from Location L at Lake Hartwell Compared to Aroclor 1242/1254

Linking PCB contamination in biological tissue to sources is particularly challenging since one must consider not only the alterations in the environment prior to animal exposure (e.g., selective dissolution, adsorption, and dechlorination processes), but also the biological fractionation in PCB patterns due to differences in uptake and loss of different PCB congeners. The more chlorinated congeners are more lipophilic and have a greater affinity for bioaccumulation, but some congeners also may pass across cell membranes differently from other congeners due to the chlorine substitution pattern on the molecule; different types of biological fractionation occur.

Planar congeners (those with no chlorines in the ortho positions, allowing the molecule to be "flat") are more likely to pass through cell membranes than PCB molecules with ortho-substituted chlorines across from each other (i.e., in the 2,2' and 6,6' positions; Figure 2-1). The World Health Organization (WHO) has identified a set of 13 planar, or mono-ortho substituted, congeners that are of particular concern for human health (Table 2-5). Likewise during metabolism different congeners may show preferential losses, so again biological fractionation can occur. For these and other reasons, it becomes increasingly difficult to trace PCB patterns from tissues back to original sources. But linking PCB tissue data to sediment sources has been done, and some studies [4] have even attempted to fingerprint human blood samples to match ingested fish as likely exposure sources for PCBs in human health studies. This short review demonstrates the need to understand the very complex PCB fate and transport processes in the environment since they impact the observed PCB congener composition in the different environmental matrices, and the ability to associate with sources. If exposure pathways are

going to be traced back to original sources, these types of physical, chemical and biological processes must be better understood (see [4]; and references therein).

Table 2-5. World Health Organization (WHO) List of Toxic PCB Congeners and Their 2,3,7,8-TCDD Toxic Equivalency Factors for Mammals

PCB Congener		Toxic Equivalency Factor (relative to 2,3,7,8-TCDD[a])
Congener Number (IUPAC)	Congener "Type" (chlorine substitution characteristics)	
PCB77	Non-ortho substituted (coplanar)	0.00010
PCB81	Non-ortho substituted (coplanar)	0.00030
PCB105	Mono-ortho substituted	0.00003
PCB114	Mono-ortho substituted	0.00003
PCB118	Mono-ortho substituted	0.00003
PCB123	Mono-ortho substituted	0.00003
PCB126	Non-ortho substituted (coplanar)	0.10000
PCB156	Mono-ortho substituted	0.00003
PCB157	Mono-ortho substituted	0.00003
PCB167	Mono-ortho substituted	0.00003
PCB169	Non-ortho substituted (coplanar)	0.03000
PCB189	Mono-ortho substituted	0.00003

[a] 2,3,7,8-TCDD toxicity is commonly used as a reference for the toxicity of "dioxin like" PCB congeners.

Although PCBs were produced as specific Aroclor mixtures of congeners because of the physical/chemical (solubility, adsorption, volatility, etc.) and biological (bacterial dechlorination, organism metabolism, etc.) processes described, environmental samples are often found with different mixtures and with very different PCB congener composition, and confound the PCB fingerprinting [4, 16, 30]. These various processes alter the congener patterns once the PCB is released into the environment. The impact of weathering and degradation on source patterns is always a concern in environmental forensics; given a situation of multiple sources, and patterns modified by one or more alteration processes, source apportionment can be difficult. For instance, one can easily imagine an onshore spill or source of PCB oil that results in a soil contaminated with PCBs. Subsequent erosion can bring soil particles into surface water bodies where they can deposit out as PCB-contaminated sediments. In aqueous settings, lower weight congeners are more easily dissolved and transported away, and higher molecular weight congeners are more strongly adsorbed to organic matter, so the remaining sediment PCB composition possesses a greater proportion of high molecular weight congeners than that found in the original mixture. If the sediments are anaerobic, microbial dechlorination may occur, and more so for congeners with specific molecular structure. The PCB in the sediments would have a very different composition than the original PCB release due to these environmental processes, and the compositional alteration continues as long as the PCB is exposed to the natural environment.

Taken together, the potential alteration processes demonstrate that the "simple" exercise in fingerprinting environmental samples using a few possible PCB source signatures (i.e., Aroclor patterns, or even a set of PCB congeners) may in fact become a substantially more difficult problem. The compositional analysis and interpretation often require knowledge of the potential

alteration mechanisms to "back out" their effects before identifying the actual original source fingerprints, and associating field samples and sources. In addition, the fact that the PCB congener composition changes in the environment limits the use of Aroclor analyses for identifying contamination sources to only fresh samples (for example, PCB oils or soils with freshly spilled PCB); typical environmental samples require more extensive congener analysis in conjunction with data analysis methods and an understanding of PCB chemistry to be able to determine sources. However, even given the complex PCB compositional alteration scenarios, the data analysis methods discussed in this document are valuable tools to identify sources and estimate both the original source profiles and alteration patterns [8, 31-35].

2.2 Establishing a General Understanding of the Site

It is important to establish an understanding of the site that goes well beyond the PCB contamination characteristics to fully understand the contaminant situation and establish the relationship between the sediment contamination and potential sources. Two key components are: (1) establishing the site history through records and other information research, and (2) establishing the hydrodynamics and sediment transport characteristics of the site.

2.2.1 Site History and Records Research

A crucial aspect of a PCB forensics investigation is determining a relationship between the contamination observed in the sediments and historical activities at or near the site, including recent and historical operations and releases. This requires an understanding of site history, and the history of the area around the site that could have impacted the site. If one cannot identify historical industrial activities, processes, material handling, and possible release and transport scenarios that can explain the sediment contamination, the forensic investigation would be missing an important puzzle piece.

The availability of records can vary widely from project to project, but it is important to devote significant effort to the site history and records research as part of the forensic investigation, and preferably early in the process during the planning phase. In terms of determining potential sources of PCBs in sediments, the types of information that are usually the focus of a records search include:

1. Identifying current and historical production/operations for the properties that could have contaminated the sediments through intentional or unintentional discharge/runoff.
2. Identifying PCB-related activities (e.g., transformer/capacitor use, carbonless copy paper, hydraulic fluid, marine paints) by the potential contributors of sediment contamination, and the timeframe of their use.
3. Identifying historical waste handling and disposal for PCB containing materials/waste.
4. Identifying possible migration pathways to sediment (e.g., waste disposal, landfills, drainage ditches and creeks receiving runoff), and how those have changed over time.
5. Reviewing historical environmental investigation reports and data.
6. Reviewing historical remedial activities, and summarizing their implications on the history of the contamination.

7. Summarizing the activities and site characteristics that may have involved PCBs, the possible history (years) of releases, and possible migration pathways to the sediments.

Conducting a comprehensive site history investigation can be difficult and time consuming, depending on how readily available the information is. The challenges include:

- The nature, volume, and availability of relevant documents vary greatly from project to project.
- Unlike when generating new data, the existence of useful historical information cannot be guaranteed.
- Even information that exists may be forgotten or inaccessible in archived files.
- Identifying the specific information that is relevant to a PCB forensics study, as it may be a small percentage of the available material. Historical document review can become a time-consuming search for a few relevant needles in a very large haystack.
- Obtaining historical information may be particularly challenging if it is perceived that it may implicate them as a PCB source.
- It is often difficult to develop a plan or scope of work for conducting historical records research because the types, locations, and availability of information may be unknown.

However, the potential importance of a thorough historical investigation often far outweighs the challenges, and should be pursued. The following is a summary of possible sources of potentially important historical information, which are described in more detail in Section 2.5.3.

- **Internal Corporate/Facility Documents**. Internal communications and other records of their operations over time, and maybe also study reports of prior site investigations.
- **State and Federal Regulatory Files**. If environmental investigations have been conducted at a site under regulatory authority, then data and reports should be publically available.
- **Publications**. Published literature may provide general information on industrial/commercial use of PCBs, but site-specific studies may also be in the published literature.
- **Interviews**. Interviews with current and past workers and residents can be very useful.
- **Aerial Photographs/Remote Sensing**. Aerial photographs and other remote imaging and sensing information can be purchased, and can be very useful to document the characteristics and changes at a site.

2.2.2 Sediment Transport and Hydrodynamics

It is critical to understand the water and sediment dynamics of a system to be able to understand how contaminants may move from their sources to where they were sampled and measured. This includes drainage, runoff, and discharge from a potential source location, to the movement of waters and sediment in the receiving environment which usually is the primary study site.

Contaminant fate and transport in aquatic systems are influenced by a range of physical, chemical, and biological processes. Physical processes significantly affect the fate and transport of hydrophobic organic contaminants (HOCs), such as PCBs, as well as many inorganic contaminants such as lead and mercury, because they are naturally adsorbed to particles in the sediment bed or suspended in the water column. Often, sediment resuspension, transport, and deposition are the largest components of contaminant transport at a given site. Moreover, the success of many remediation approaches such as in situ capping, dredging, and natural recovery is directly affected by physical sediment transport processes. The effects of physical processes must be evaluated in conjunction with the effects of chemical and biological processes to assess overall fate and transport at a site.

Many Navy sediment sites are located in areas of relatively low hydrodynamic energy such as rivers, bays, and estuaries, where sediments and contaminants tend to accumulate over time. In some cases, the original source(s) of contamination have been eliminated, reduced, or controlled as environmental management practices improved over the past 50 years. At some sites, the deposition of newer, relatively clean sediment on top of more contaminated sediment has resulted in burial of contamination. The most common sediment management questions associated with these sites are as follows:

- Could erosion of the sediment bed lead to the exposure of buried contamination?
- Will sediment transport lead to the redistribution of contamination within the site, or movement of contamination off site?
- Will natural processes lead to the burial and isolation of contamination by relatively clean sediment?
- If a site is actively remediated, could sediment transport lead to the recontamination of the site?

Blake et al. [36] developed a user's guide to address these sediment transport issues. It focuses on the collection and analysis of data needed to address these primary questions. A combination of regional and historical data, site-specific measurements, empirical data evaluation methods, and numerical modeling techniques can be used to characterize sediment transport at a given site. Empirical approaches are particularly useful for characterizing the past and present effects of sediment transport; however, numerical models are more useful for predicting the effects of future events and sediment deposition patterns. The appropriate method(s) and tool(s) should be selected and used on a site-specific basis to qualitatively and/or quantitatively characterize sediment transport, and assess the viability of various remedial options. The approach for a given site will depend upon the size and complexity of the site, the CSM, the specific site objectives, and the available resources.

Information on sediment stability, sediment transport, and other hydrodynamic information (e.g., circulation, currents, tides) are not only important for sediment management considerations, but are essential to help understand the distribution of contamination in a system, and link the contamination to potential sources. An understanding of contaminant transport is essential in any environmental forensic investigation to explain how contamination from a source can be

found where it is ultimately detected in the environment. Sometimes, these locations are not simply immediately downstream from the release.

2.3 Sampling Design and Sample Collection

As noted in the previous section, PCBs tend to be particle bound and selectively associated with such environmental matrices. Even in studies of PCBs in water samples [17], the majority of the PCBs tend to be associated with the suspended solids in the water. By studying suspended material in water samples, recent source information may be determined, possibly identifying active sources that can be targeted in compliance programs such as total maximum daily loads (TMDLs). Surface sediments obtained with surface grab samples similarly provide data on recently deposited sediments and potentially active sources, and often provide similar information as the suspended material in water samples. Deeper, buried sediment samples (ideally with the aid of a sediment age dating technique) may provide a historical record of source contributions to a water body. Depending on the temporal and spatial information needs developed in the study design, a combination of sample matrices and sampling types may be required. Some forensics studies have sampled both sediment and biological tissue (e.g., fish) at the same locations to also follow PCB pathways through the food web. If fish consumption is a risk driver at a site, it may be important to identify the source of the PCBs. Regardless of the management driver (e.g., a sediment or tissue PCB concentration), it is important that the source(s) is identified to ensure it is controlled before considering any remediation.

The sampling design is typically based on some sort of a statistical based sampling (e.g., random, systematic, stratified, cluster, etc.) or professional judgment that can be justified technically, based upon the information assembled in the CSM. Sampling designs are often site-specific and require consideration of many aspects of the study design. These types of considerations are addressed in many references (e.g., [12], and references herein). The extent and density of sampling (i.e., spatial coverage) is usually the issue requiring the greatest consideration in developing a sampling design strategy. It is the number of samples that will largely determine the cost of the project and the confidence in the data analysis. By using a tiered study design that allows RSC data to first characterize the overall PCB concentration (e.g., through geographic information system [GIS]-based concentration contouring), it can be designed to more cost effectively generate the ACF data.

Sediments can be collected with either surface grabs or subsurface coring systems, depending on the objectives of the particular study. Surface grabs (such as Van Veen grabs; Figure 2-6) recover only the surface sediments and therefore are used to recover sediments that represent more recent conditions. Subsurface sediment cores (such as Vibracores or piston cores; Figure 2-7) are used to recover subsurface sediments which cover a longer time period and therefore may provide a historical record of sediment deposition. Sediment cores can also be collected and analyzed for age dating, using lead and cesium isotope (Pb-210 and Cs-137) techniques, to determine the age (approximate year of deposition) of the sediment deposition at different depths, by determining the rate of sediment deposition (usually in cm/yr). Such information on specific years that subsurface sediment was deposited can be extremely useful for associating the contamination at different depths with site and other historical activities, and, generally, helps to better understand the contamination history.

Figure 2-6. Van Veen Sediment Grab Sampler and Sediment from Inside the Grab

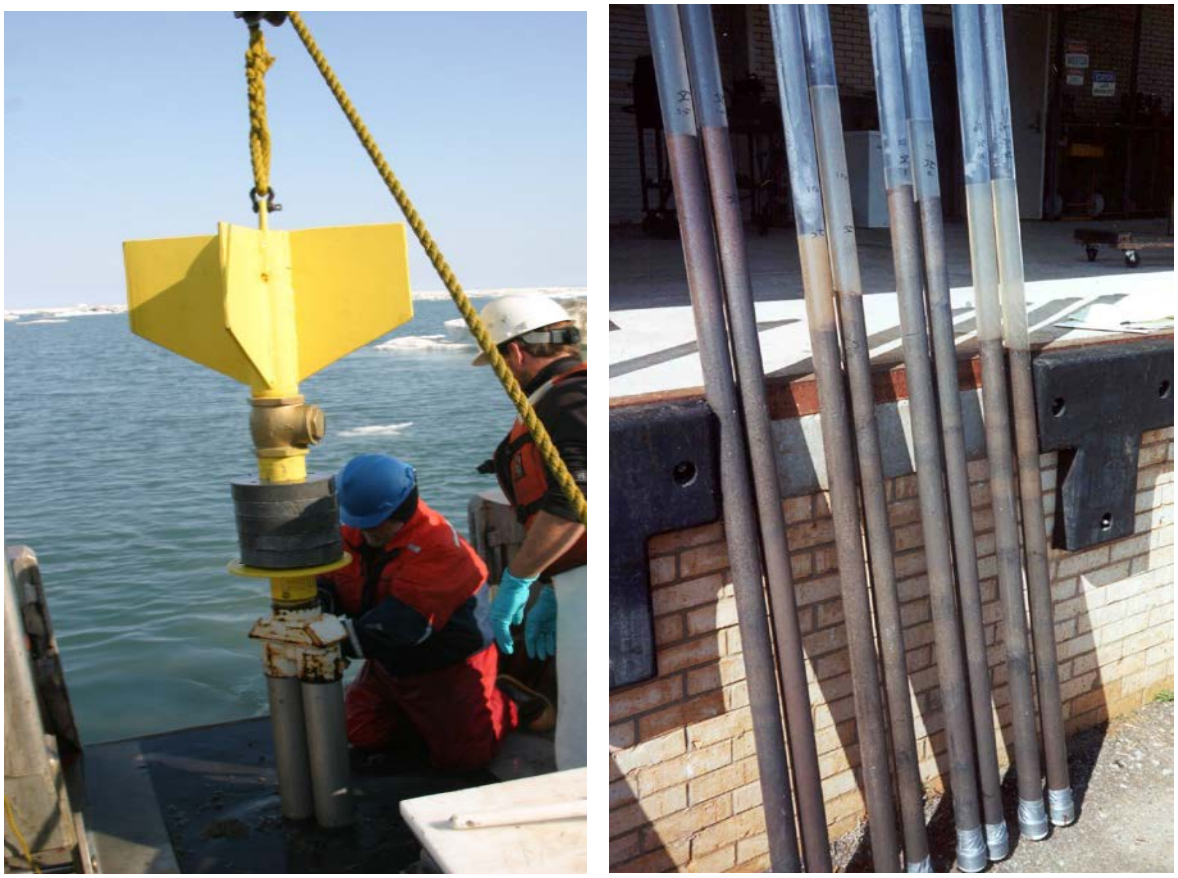

Figure 2-7. Sediment Corer and Collected Sediment Cores in Core Liners

2.4 Sample Analysis

A variety of options are available to determine PCB concentrations in environmental samples. There is also a significant amount of confusion about the benefits and drawbacks of the different methods, and for what purposes one method may be suitable while it is unsuitable for a different purpose. Many of the standard PCB analytical methods that were developed for regulatory programs may not be appropriate for forensic studies, similarly to analysis of samples for petroleum and PAH forensics [3]. For instance, U.S. EPA analytical methods developed for regulatory programs (such as the Superfund Program) require strict adherence to procedures outlined in U.S. EPA's SW-846 Methods [37]. The goal of many of these regulatory programs is to determine the "nature and extent" of the contamination, often of highly contaminated samples, which is not always sufficient to determine the sources of contamination in a forensics study. Forensics studies may require modifications of standard methods, including lower limits of detection and the analysis of additional diagnostic analytical parameters, to obtain the necessary data. U.S. EPA has recognized this for a variety of environmental investigations and is moving towards performance based measurement systems (PBMSs) rather than strict adherence to SW-846 methods. The types of analyses discussed in this document for forensic applications meet the PBMS requirements and, with adequate planning, the data can be used for both forensic and regulatory purposes. There may also be a need to use a combination of analytical methods to most effectively meet the goals of a well-developed forensics study.

Before choosing a PCB analytical method, it must be determined whether all that is needed is a measure of the total PCB concentration, or if more detailed PCB information is needed. For forensic investigations it is often useful to obtain two sets of information, and thus implement the project in a tiered manner – an initial set of Total PCB analysis using RSC or other Total PCB analysis approach, followed by a detailed congener-specific ACF analytical method on a sub-set of the samples to obtain more detailed information for more comprehensive forensic data interpretation.

Total PCB analysis can be conducted using (1) a semi-quantitative enzyme-linked immunosorbent assay (ELISA) screening method, (2) a widely used total PCB as Aroclor laboratory method, (3) a less widely used total PCB as homologs method, or (4) using a method that quantifies individual congeners which are then summed to represent the total PCB, either with or without the application of a Total PCB correction factor.[1] Individual PCB congener analysis can also be performed in a few different ways, the primary differences being the

[1] Total PCB concentrations can be estimated by summing the individual PCB congener concentrations, if those congeners are expected to capture a sufficiently large proportion of the total PCB. The PCB Aroclor compositional information in Appendix A can be useful for estimating the total PCB in a given PCB contamination, recognizing that environmental processes, including dechlorination (Table 2-4), can alter the actual environmental concentrations, as described in this document. A well selected set of a little over 100 PCB congeners, such as the 117 PCB congeners used in the Ashtabula River case study (Appendix B), can capture 97-98% of the total PCB in most environmental samples, and summing the concentrations of those congeners provides a good estimate of the Total PCB. It has been shown that the 18 NOAA National Status and Trends Monitoring Project PCB congeners capture about 50% of the Total PCB in most US coastal sediment environments, and summing the concentrations of those congeners and then multiplying that by 2 has been widely used to estimate the Total PCB concentration in such sediments. Other corrections factors can be developed for other sets of congeners using the information in Appendix A, once the type of contamination is understood.

analytical instrument that is used and the number of PCB congeners that are quantified. These analytical methods are discussed further below.

2.4.1 Total PCB Sample Analysis Techniques (including RSC)

This section describes three analytical methods, based on U.S. EPA Methods 4020, 8082, and 680, that are available for determining the Total PCB concentration in environmental samples. These methods can all be considered for RSC, and the first analytical step in gaining a general understanding of the PCB contamination at a site.

Total PCB Immunoassay Methods

ELISA analysis is a simple and relatively inexpensive immunoassay (IA) option for Total PCB analysis. Recent advances in the environmental field have followed the medical field in the application of ELISA methods for environmental contaminants. The ELISA PCB method is captured with U.S. EPA Method 4020. This is also the method recommended in this handbook for the Tier I, rapid RSC analysis of sediment samples for most situations.

The immunoassay method includes a simple extraction step followed by a reaction step for a competitive reaction between unknown sample PCBs and kit-provided PCB conjugates (PCBs with added color indictors that are activated in later reaction steps). A modification to U.S. EPA Method 4020, which is required for sediment analysis, is the dewatering of the sediment to below about 30% moisture by placing on filter paper to remove excess water. Antibody sites where this competitive reaction occurs have traditionally been on the "frosted" sides of test tubes, but more recent advances have led to antibody sites on free floating particles within the test tube solutions to provide better precision and accuracy. Contaminant concentrations are related to a color change that is either visually observed or quantified using a calibrated spectrometer, and compared to that of PCB calibration solutions with known PCB concentrations. Samples tend to be analyzed in large batches (20 to 50 samples) along with a series of Aroclor calibration standards.

These ELISA methods can be employed in the field as a near real-time method, or in the laboratory with often higher level of control of environmental factors (e.g., temperature) and quality control (QC) (e.g., replicates and calibration standards). ELISA methods are highly specific, and the PCB ELISA method has been developed to be particularly responsive to a limited set of PCB congeners. Although the immunoassay detects individual PCB congeners, individual congener quantities are not determined and total quantities are reported in Aroclor equivalents relative to the standard Aroclor series that was run along with the particular batch. This specificity can provide an advantage in that it is not sensitive to analytical interferences (i.e., it primarily responds to what it was developed to respond to), but this can also be a limitation if the concentrations of the method-specific PCB congeners is low or if the relative composition of those method-specific PCB congeners in the environmental samples and the calibrant differ. For instance, PCB101 is one of the major congeners the PCB ELISA was developed to respond to, and this congener comprises about 10% of the Total PCB in Aroclor 1254, about 4% in Aroclor 1260, and about 1% in Aroclor 1242 (see Appendix A), which impact the response to the PCB ELISA method. The PCB ELISA kit is provided with Aroclor 1254 as the calibrant, even though different Aroclors respond differently in the PCB ELISA method (Table 2-6). The PCB ELISA kit calibrated with Aroclor 1254 as supplied would determine a 10

parts per million (ppm) concentration of Aroclor 1254 to indeed be 10 ppm. However, a 10 ppm concentration of Aroclor 1260 would be reported as 16 ppm Total PCB and a 10 ppm concentration of Aroclor 1242 would be reported as 4 ppm Total PCB. Another way to describe this would be that a Total PCB concentration determined to be 10 ppm could be the result of 52 ppm Aroclor 1232, 24 ppm of Aroclor 1242, 10 ppm of Aroclor 1254, or 6 ppm of Aroclor 1260. Mixtures of Aroclors and environmental transformation would further confound the analysis. However, two simple methods can improve the accuracy of the PCB ELISA IA test results; two techniques that are, unfortunately, not always used or well communicated.

Table 2-6. Sensitivity and Selectivity of PCB ELISA IA Method to Different Aroclors

Compound	PCB Kit Sensitivity	
	Limit of Detection (ppb)	Relative Response
Aroclor	22.6	0.022
Aroclor	2.61	0.19
Aroclor	1.22	0.41
Aroclor	3.56	0.14
Aroclor	0.59	0.85
Aroclor	0.5	1
Aroclor	0.32	1.6
Aroclor	0.66	0.76
Aroclor	3.03	0.17

- Analyze a set of representative site samples using both the PCB ELISA method and a recognized accurate laboratory instrument method, correlate the results, and determine a "correction factor" if the correlation is acceptable. For instance, the ELISA immunoassay results were compared to highly reliable fixed laboratory results for a set of HPS samples (Figure 2-8), and the immunoassay results were determined to be about 1.12 times the laboratory results with a correlation coefficient (r^2 value) of 0.95; the immunoassay results were 12% higher than the "true" concentration. A correction factor could thus be generated; if the immunoassay results were divided by 1.12, the "true" concentration would be obtained. However, this approach is highly site specific and it is important to demonstrate that it applies across the site, or identify subsets of samples that may have different composition and correction factors.
- Analyze a set of representative site samples using a recognized accurate laboratory instrument method, and determine the Aroclor(s) present in the samples, and their relative composition. Prepare a site-specific Aroclor, or mixed Aroclor, calibration solution that represents the Aroclor(s) at the site, rather than simply relying on the Aroclor 1254

standard assumed to be used with the PCB ELISA kit, and measure the field sample concentrations using this site-specific Aroclor standard.

The PCB ELISA method has some analytical limitations, most of which can be avoided as described above. However, it is an excellent semi-quantitative screening method for relatively cost effectively and rapidly obtaining approximate Total PCB concentrations to characterize the PCB distribution within a set of samples and across a site and develop a general understanding of the PCB contamination at a site. A plan for more detailed sampling and analysis can then be developed, as needed.

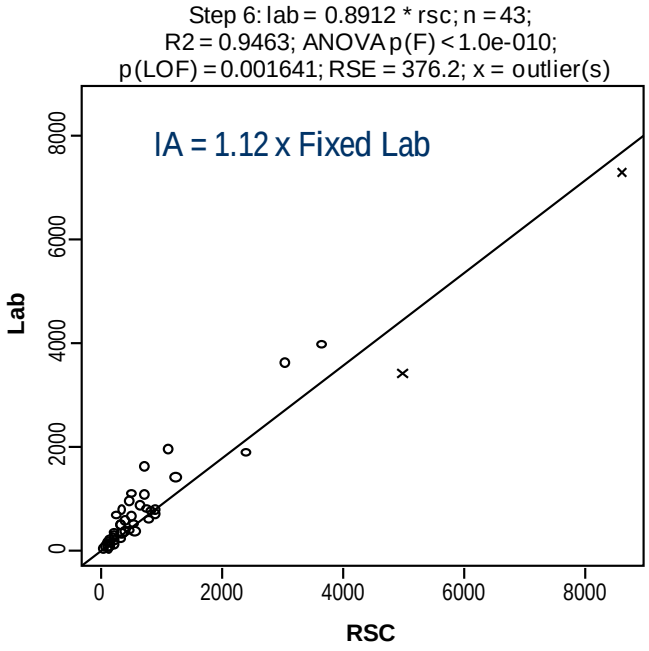

Figure 2-8. Correlation between Laboratory-based and ELISA-based Total PCB Measurements of Hunters Point Shipyard Sediment Samples

Total PCB as Aroclor Methods

U.S. EPA Methods 608 and 8082 have historically been the most widely used analytical methods for providing Total PCB data; Method 608 is for the analysis of water samples and Method 8082 for solid samples (e.g., sediment). The methods are based on identifying and quantifying the predominant Aroclor(s) in the samples. The methods assume a standard extraction technique is used, which is then followed by the method described instrumental analysis which is GC separation and ECD detection. GC columns ensure that the PCB congeners move through the GC column and reach the ECD at different rates generally based on the volatility and molecular weight of the PCB congeners (i.e., the mono- and di-chlorobiphenyls are detected first, and the nona- and deca-chlorobiphenyls last).

The ECD provides a rather unsophisticated detection capability, sensing electro-negative constituents including chlorinated PCBs and chlorinated pesticides. It is considered relatively specific to halogenated organic compounds, but, in fact, can respond to a variety of compounds

and is, thus, quite susceptible to matrix interferences and false positives. GC/ECD instrument output consists of a chromatogram showing a series of peaks, with the PCB congeners spread out by elution time in the x-direction and the peak height/area in the y-direction related to the congener concentration. Identification is made through comparison of the chromatogram to Aroclor standards that are analyzed under the same conditions as the field samples. Quantification is based on the peak area counts of a set of (generally four to eight) representative peaks, or peak clusters, and comparing to the same in the Aroclor standards. Multiple Aroclors may be identified in a sample, and the Total PCBs would be determined by summing the individual Aroclor concentrations. However, multiple Aroclor quantitation is not only complicated by environmental weathering, but mixtures of Aroclors can significantly confound the identification and quantitation of the Aroclors due to the limitations of this method. The relatively non-selective nature of the ECD can result in non-PCB contributions from other sample constituents to the targeted peaks, possibly resulting in erroneous quantitation; this is particularly common with complex environmental matrices, such as sediment or tissue samples. As discussed earlier, the PCB composition undergoes a variety of compositional changes once released to the environment, so it may not closely resemble the Aroclor standards the samples are compared to and quantified against; the Aroclor determination is a "best fit" to the peaks from the Aroclor standards even when they may not be present in the environmental samples, or present at dramatically altered relative composition. This can result in inaccurate quantification or, even worse, identifying a sample as not having any PCBs when there may be significant concentrations of a highly altered PCB. For instance, the PCB composition of the sample illustrated in the bottom of Figure 2-4 does not resemble any Aroclor, and using U.S. EPA Method 608 or 8082 may easily be identified as a "non detect" for PCBs, even though it contained high concentrations of significantly weathered/dechlorinated PCBs.

The standard Total PCB as Aroclor methods (U.S. EPA Methods 608 and 8082) are susceptible to significant identification and quantitation problems due to Aroclor mixing, environmental weathering of PCB, and complex sample matrices, as described above. The method should not be used by itself identifying the type and source of the PCB contamination, unless it is a recent release and there is certainty that the environmental samples have not been subjected to environmental weathering. This may be the case with some soil samples collected near a recent spill, but is otherwise rarely the case. However, assuming the samples have not been weathered to the point where PCB can no longer be identified, the Total PCB as Aroclor methods may be a useful semi-quantitative method for obtaining approximate Total PCB concentrations, and some limited additional compositional information (Figure 2-9) to characterize the PCB distribution within a set of samples and develop a general understanding of the PCB contamination at a site. A plan for more detailed sampling and analysis can then be developed, as needed.

Total PCB Homologue Methods

U.S. EPA Method 680 is available for providing reliable Total PCB data, along with concentration data for each of the 10 levels of chlorination (the Total PCB value is the sum of the 10 levels of chlorination data). The methods are based on identifying and quantifying the concentrations of the 10 levels of chlorination (Tables 2-2 and 2-3) by summing all the "peaks" that represent each level of chlorination separately. The method assumes a standard extraction technique is used, which is then followed by the method described instrumental analysis (GC separation and MS detection).

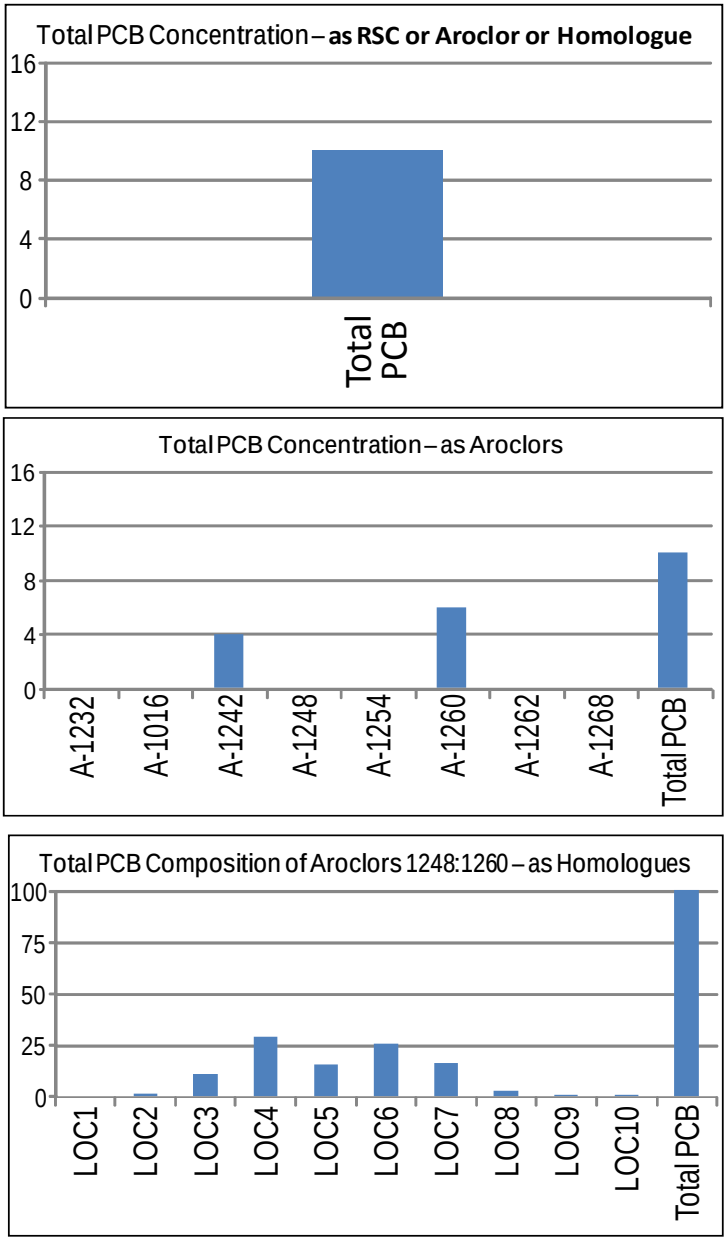

Figure 2-9. The Amount of PCB Information That May Be Available with ELISA (Method 4020), PCB as Aroclor (Method 8082), and PCB as Homologue (Method 680) Total PCB Analytical Methods

The instrument is calibrated by using the first and last eluting PCB congener for each level of chlorination (which has been well established), to obtain information on the chromatographic region for each level of chlorination and the response factor for each level of chlorination (for quantitation; by averaging the response factor for the two congeners). The MS detector provides a significant advantage over the previously described ECD detector. The MS detector is set to within a certain time window in each analysis to detect certain molecule and mass fragments based on their particular mass weight to unit charge, all of which are unique to the originating

molecule. For instance, all tri-chlorobiphenyls will produce two to three unique molecules and mass fragments, the tetra-chlorobiphenyls will produce two to three other molecules and mass fragments, and so on. The MS detector is programmed to detect the molecules and masses that are typical to PCBs. This means that the analysis is highly specific to PCBs and not as prone to interfering compounds and matrix components. Mass spectral detection is not affected by weathering/alteration of the PCB; the PCB composition of an environmental sample may no longer closely resemble an Aroclor, but this is irrelevant in the MS analysis as it reliably quantifies PCBs by level of chlorination regardless of the composition. Another possible advantage with Method 680 is that the MS analysis method can be set up so that PCB congener methods are acquired and stored, for cost-effective reduction of those data at a later time to generate PCB congener results.

The primary drawback of the Total PCB as homologues (level of chlorination) method (U.S. EPA Method 680) is that it is not an analysis that is widely offered by analytical laboratories. The method is an excellent choice for obtaining reliable Total PCB data, regardless of the composition of the PCB (i.e., it is not affected by environmental transformation or Aroclor mixtures), and also provides some level of compositional information by also generating concentration data for each of the 10 levels of chlorination. The method provides accurate Total PCB concentrations, some additional compositional information (Figure 2-9), and can be useful for characterizing the PCB contamination at a site. A plan for more detailed sampling and analysis can then be developed, as needed.

2.4.2 Congener-specific Sample Analysis Techniques (including ACF)

This section summarizes three analytical methods that are available for determining PCB congener concentration in environmental samples; a GC/ECD-based method suitable for approximately 20 PCB congeners (Method 8082), a GC/low-resolution mass spectrometer (LRMS)-based method suitable for 40 to 120 congeners (modified Method 680/1668), and a GC/high-resolution mass spectrometer (HRMS)-based method suitable for more than 100 PCB congeners (Method 1668a).

Congener-specific Methods

U.S. EPA Method 8082, the previously described Total PCB as Aroclor GC/ECD method, can be applied to PCB congener analysis and can provide data for a limited set of congeners (usually about 20 congeners). The NOAA National Status and Trends Project 18-22 PCB congeners are often monitored using this method. However, many of the limitations discussed for GC/ECD and Method 8082 in Section 2.4.1 also apply to its application to PCB congener analysis. The GC/ECD is highly susceptible to interferences from other compounds or sample matrix components, which can, at times, make it difficult to accurately resolve and quantify discrete PCB congeners in the analysis, and can result in inaccurate quantitation (both incorrectly elevated *and* reduced concentrations may be observed, depending on how and to what interferences contribute in the chromatogram). Because of the interference and resolution limitations of conducting PCB congener analysis using a GC/ECD instrument, PCB congener analysis by Method 8082 is generally limited to no more than about 25 PCB congeners.

The previously described method for analyzing PCB homologues using GC/MS and Method 680 can be modified for identifying and quantifying a large set of individual PCB congeners. The

method, as widely used by a number of high-quality analytical laboratories, is generally referred to as a modification and combination of U.S. EPA Methods 680, 8270, and 1668, and can reliably be used to quantify more than 100 PCB congeners (or about 99% of the PCBs in most environmental samples). It is a LRMS method, like Methods 680 and 8270; the "low resolution" refers to the accuracy in the identification of masses that the detector is capable of (to +/- 1 mass unit). The method operated the MS in SIM mode, unlike the base full-scan mode described in Method 8270, but like Method 1668, to obtain a higher degree of specificity and more sensitivity. The method uses individual congener calibration for a very extensive set of PCB congeners, like Method 1668, and many of the QC guidelines from Methods 8270 and 1668. Although this is considered a modified method, it does fall within the general guidelines permitted under Method 8270, adapted for PCB congeners, and is like the widely applied high-quality methods for PAH analysis [3], just adapted to PCB rather than PAH compounds. This PCB analysis method has been available for more than 10 years [6, 14, 15], and is increasingly being used in high quality environmental analytical laboratories.

U.S. EPA Method 1668 is also a GC method but uses a HRMS as the detector, also operating in SIM mode. The "high resolution" refers to the accuracy in the identification of masses that the detector is capable of, which may be to within 0.001 mass units (or better), compared to within 1 mass unit for a LRMS detector. For instance, the molecular mass of trichlorobiphenyl is 255.9613. A HRMS with a 0.001 mass unit resolution would be set to detect this compound with a mass of 255.961 +/- 0.001, while a LRMS would be set to detect it with a mass of 256. This higher mass resolution of the HRMS provides additional compound specificity. However, this additional resolution is rarely needed for most PCB analyses. A benefit to using HRMS is that it can accurately resolve and detect a few of the 12 WHO toxic congeners when other methods may not be able to. Some of the WHO congeners are only present at very low concentrations in PCB contamination (see Appendix A), and the added specificity and sensitivity of HRMS is a benefit for detecting those congeners (e.g., PCB77, PCB81, PCB126). These congeners are often important in human health risk assessment investigations, but are of no significant value for a PCB forensics investigation. Method 1668a can also discretely separate slightly more PCB congeners than a LRMS analysis, but the additional congeners are ultra-trace level congeners that generally do not provide important additional information for PCB forensics.

Recent Analytical Advances in Fingerprinting Techniques

Recent advances in fingerprinting analysis include isotope ratio MS analysis, which allows for the use of isotopic variations between different molecules that are otherwise the same to assist in fingerprinting PCBs and potentially differentiate sources. The use of this technique began in the mid 1990s with carbon isotopic variations in primarily single-compound organic contaminants, such as organic solvents (e.g., trichloroethylene). In recent years isotope ratio MS has been evaluated for use for multi-component contaminants, such as PAHs [3] and PCBs [17]. One of the most important recent advances in the technology has been compound specific isotopic analysis (CSIA) to allow for individual PCB congeners to be analyzed separately, rather than all congeners together producing a bulk isotopic signal. So for carbon isotopic analysis the GC is used to separate the congeners, then each is combusted separately to form carbon dioxide gas which is analyzed by isotope ratio MS. For forensic studies this allows selection of specific PCB congeners that are more resistant to alteration to be used for analysis to avoid changes in source patterns that might be related to environmental alteration rather than differences in original

source signatures. Although the CSIA techniques show great promise, continued work is required to lower detection limits and reduce interference from coeluting components; isotope-ratio mass spectrometry and CSIA are methods that may be considered for a PCB forensics investigation, but are not further discussed in this document.

2.4.3 Selecting Analysis Methods for Forensics Investigations

When selecting the most appropriate analytical method, it is most important to determine what types of data are needed to answer the questions at hand, and then select the method accordingly. Data quality and cost are also important considerations, and it usually becomes a matter of balancing the information needs with the data quality and analytical costs (Figure 2-10).

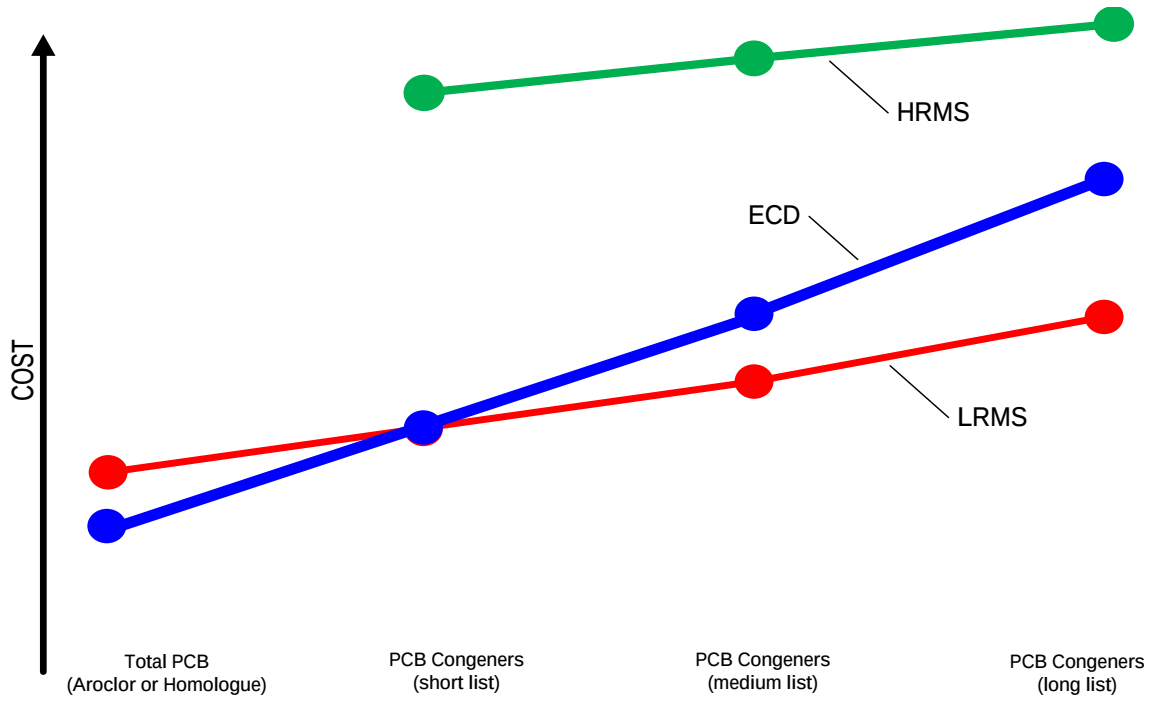

Figure 2-10. General Evaluation of Analytical Costs for Different PCB Analytical Instrument Methods, by the Type (Total PCB or Congeners) and Amount of Data (Number of Congeners) Produced

Total PCB analytical method options (i.e., RSC) were summarized in Section 2.4.1, and some key aspects of the three method options (including relative cost) are also summarized in Table 2-7. As discussed, the ELISA IA technique (Method 4020) is a rapid and cost-effective method for conducting Total PCB analysis, and is usually suitable for RSC (Tier I) analyses. This is also what was used for the two case studies described in this document. The Total PCB as Aroclor (Method 8082) method is an alternative for generating screening-level Total PCB data, as long as the PCB composition has a relatively close resemblance to Aroclors (see discussion in Section 2.4.1). Because Method 8082 is the most widely used Total PCB method, PCB data may have been generated for regulatory or other purposes for the site using this method, and may be available for use in a Tier I assessment. The Total PCB as homologue method (Method 680)

produces the most reliable and highest quality Total PCB data, and additional useful information by producing results for each of the 10 PCB homologues; this is the method of choice, if the slightly higher cost can be justified. However, Method 4020 (ELISA IA analysis) is the most suitable RSC method for most purposes, and can often provide Total PCB analysis for about $100/sample, with sensitivity and data quality that meet most RSC needs. The speed of the ELISA IA analysis is also a significant advantage, with the potential benefit of being able to map out PCB concentration gradients while still in the field and adjust subsequent sampling in a timely manner; the two other Total PCB methods are both laboratory-based and require several days, at best, to obtain the results.

Table 2-7. Comparison of Total PCB Analytical Methods

Method	Approximate Unit Analytical Cost ($)	Approximate Sediment Detection Limit (ppb)	Key Technical Advantages and Disadvantages
ELISA IA Method (Method 4020)	75-150	50	Advantage: Rapid Disadvantage: Potential calibration issues (can be avoided, as discussed)
PCB-as-Aroclor Method (Method 8082)	150-225	10	Advantage: Widely available; slightly more information than IA Disadvantage: Susceptible to interferences and misidentification
PCB-as-Homologue Method (Method 680)	250-325	1	Advantage: Accurate; not impacted by PCB alteration; more information than both IA and PCB-as-Aroclor Disadvantage: Not widely available

PCB congener analytical method options (i.e., ACF) were summarized in Section 2.4.2, and some key aspects of the three method options (including relative cost) are also summarized in Table 2-8. When selecting the detailed PCB congener ACF analytical method (Tier II), balancing the information needs with data quality and cost generally becomes an even more involved consideration than when selecting the RSC method. It is important to select enough PCB congeners and an appropriate set of diagnostic PCB congeners to be able to identify and differentiate potential PCB sources. Using information such as the PCB congener composition of Aroclor formulations (Appendix A and Table 2-3), and possible PCB dechlorination pathways (Table 2-4), it is possible to select a set of congeners that represent common environmental PCB contamination, including possible degradation products that may be of interest. A total of 80 to 120 well-selected PCB congeners are typically sufficient to provide the necessary PCB analytical data. For instance, the 117 PCB congeners reported for the Ashtabula River case study (Appendix B) represent 97 to 98% of the Total PCB in all Aroclor formulations and most environmental samples; the 92 additional possible PCB congeners are either not present in Aroclor formulations or environmental samples, or present at such ultra-trace levels that they would not be detected and/or useful for forensic purposes. Aroclor mixtures are generally the most appropriate PCB source material for assessing potential environmental PCB contamination, but a few non-Aroclor unique PCB source materials are possible. A few individual congeners, including PCB11 and PCB209, have been identified as being used for some industrial applications (e.g., PCB11, as part of some industrial pigment process [38]), and a process

involving the production of titanium tetrachloride has been identified to generate a small set of highly-chlorinated PCB congeners (in the octa- to deca-chlorobiphenyl range [39]). It is usually possible to conduct a high quality PCB forensic investigation with less than 100 PCB congeners. A smaller set of 44 PCB congeners was used in the HPS work (Appendix B), and this did provide solid information for general PCB characterization, but was somewhat limiting for forensic purposes. It can be difficult to predict which congeners will be important for the data analyses, and it is a fairly small increase in analytical cost to analyze 100 to 120 PCB congeners versus, for instance, 60 to 80 PCB congeners.

Table 2-8. Comparison of PCB Congener Analytical Methods

Method	Approximate Unit Analytical Cost ($)	Approximate Sediment Detection Limit (ppb)	Key Technical Advantages and Disadvantages
GC/ECD Congener Method (Method 8082) ~20 PCB congeners	250-400	0.25	Advantage: Widely available Disadvantage: Susceptible to interferences and misidentification
GC/LRMS Congener Method (Modified Method 680/1668) ~40-120 PCB congeners	450-650	0.05	Advantage: Accurate; not significantly impacted by interferences; can determine more congeners than GC/ECD method Disadvantage: Not suitable for a few WHO congeners
GC/HRMS Method (Method1668a) >100 PCB congeners (including WHO congeners)	800-1,200	0.01	Advantage: Accurate and sensitive; not impacted by interferences; can quantify all 12 WHO congeners Disadvantage: Costly

The three different PCB congener analytical instrument options that are available (Section 2.4.2) are suitable for somewhat different sets of information, provide different data quality, and have different costs (Table 2-9 and Figure 2-10). The information in Table 2-9 and Figure 2-10 is quite general, and different scientists may arrive at slightly different conclusions for Table 2-9, for instance. However, they are a general relative assessment, and illustrate a method consideration process that is useful when selecting an analytical method for an investigation.

Table 2-9. General Evaluation of PCB Congener Analytical Method for Method Selection (5="good"; 1="bad")

Performance Measure	ECD	LRMS	HRMS
Data Quality			
Sensitivity/detection limit	3	4	5
Accuracy	2	4	5
Precision/reproducibility	2	4	5
Matrix interference	2	4	5
Lab/field contamination interference	2	5	4
Analyte confirmation	2	4	5
Calibration performance	2	5	5
PCB Information			
Data generation: total PCB	3	5	4
Data generation: PCB homologues	1	5	3
Data generation: PCB congeners (short list)	3	5	5
Data generation: PCB congeners (long list)	2	5	5
Data generation: PCB congeners (WHO list)	1	3	5
Cost			
Cost – initial lab investment	4	3	1
Cost – maintenance/operation	3	4	2
Cost – sample analysis (project price)	3	4	1

As mentioned earlier, Method 8082 is generally considered inadequate for generating PCB congener data for a PCB forensic investigation. The GC/HRMS method (Method 1668a) is widely considered the ultimate PCB congener method for forensics studies, providing the highest quality data; it is, however, a costly analysis (often in excess of $1000 per sample). The GC/LRMS method (modified Method 680/1668) generally provides data of almost equal quality to GC/HRMS, often for about half the analysis cost of GC/HRMS analysis. The number of PCB congeners, sensitivity, and data quality in general that can be obtained with a GC/LRMS is generally adequate for the Tier II ACF analyses. GC/LRMS most often provides the optimum balance between information needs, data quality, and cost for most ACF projects.

A tiered analytical approach is recommended for a PCB forensic investigation, as was also described for PAH forensics [3]. By combining a larger numbers of less expensive RSC immunoassay Total PCB analyses with fewer more costly ACF PCB congener analyses, a high quality, yet cost effective, study design can be developed. The larger number of RSC samples allow for sufficient spatial coverage to map out the contamination and gain a general understanding of the situation, including the possibility of one or more potential sources. The PCB information from the RSC can be used to select a subset of samples for ACF analysis to provide the unique PCB congener diagnostic data needed to match the site samples to potential sources. The initial contour mapping provides an initial understanding of the site to better formulate a conceptual model that makes optimum use of the subsequent ACF analyses. In this manner, the more costly PCB congener analyses are not wasted by analyzing samples with no detectable PCB or generating redundant PCB information. In summary, combining the ELISA IA method (Method 4020) for the RSC Total PCB analysis with the GC/LRMS method (modified Method 680/1668) for the ACF congener-specific analysis generally provides an

effective analytical plan, although the other described methods can also generate useful information, assuming their listed strengths and weaknesses are recognized and accommodated.

Common PCB Analytical Options

This section presents an overview of common available PCB analysis methods, and their advantages and limitations

- **Total PCB Methods.**
  - PCB Immunoassay Method (e.g., RSC)
  - PCB-as-Aroclor Method
  - PCB Homologue Method
- **Individual PCB Congeners Methods**
  - Limited Congener Set Analysis using GC/ECD
  - Extensive Congener Set Analysis using GC/LRMS
  - Extensive Congener Set Analysis using GC/HRMS

2.4.4 Laboratory Data Quality Control

There are several components to a program to ensure that reliable and high quality data are generated, so that such data can be used with confidence, including the analysis of a series of laboratory QC samples and the subsequent evaluation of the resulting data. QC is an integral part of the laboratory activities. It demonstrates the quality of operations and analyses, provides analysts with metrics about method performance, and aids project managers in identifying and correcting systematic and random problems that can plague the laboratory operations.

The laboratory PCB analysis QC measures should allow for an assessment of processing effectiveness, potential laboratory contamination/interference, accuracy, and precision. A routine set of QC samples should accompany every batch of samples processed and analyzed at the laboratory; the following is a description of types of QC samples that are suitable for analysis with each batch of samples; suitable types of performance objectives are summarized in Table 2-10. The exact criteria used should be designated by the PM to ensure the results are suitable for site- and project-specific data needs and decision making. This laboratory QC program is suitable for the ACF analysis, but samples that demonstrate that contamination is controlled and analytical accuracy and precision should also be incorporated with the RSC analyses.

Table 2-10. Example Laboratory Performance Objectives (additional field QC samples may also be included in a project QA Program)

QC Sample Type	Example Performance Objective[a]	Corrective Action
Procedural blank (PB)	< 5× method detection limit (MDL), or field sample concentration >10×blank value	Re-extraction, re-analysis, and/or document and justify per PM; all corrective actions documented
Laboratory control sample (LCS)	40 – 120% recovery	Re-extraction, re-analysis, and/or document and justify per PM; all corrective actions documented
Matrix spike (MS)	40 – 120% recovery Spike levels >5× unspiked field sample concentration for DQO to apply	Re-extraction, re-analysis, and/or document and justify per PM; all corrective actions documented
Matrix spike duplicate precision	Relative percent difference (RPD) < 30% Spike levels >5× unspiked field sample concentration for DQO to apply	Re-extraction, re-analysis, and/or document and justify per PM; all corrective actions documented
Duplicate Precision	RPD < 30% Field sample concentration >5× MDL for DQO to apply	Re-extraction, re-analysis, and/or document and justify per PM; all corrective actions documented
Standard reference material (SRM)	Values to be within 30% of designated certified value on average for all compounds. Target concentration > 5× MDL for DQO to apply	Re-extraction, re-analysis, and/or document and justify per PM; all corrective actions documented
Surrogate internal standard (SIS) recovery	40 – 120% recovery	Re-extraction, re-analysis, and/or document and justify per PM; all corrective actions documented
Initial calibration	< 25% relative standard deviation (RSD) in relative response factors (RRFs), or correlation coefficient $r \geq 0.99$	Re-extraction, re-analysis, and/or document and justify per PM; all corrective actions documented
Continuing calibration	< 25% percent difference (PD) from expected concentration	Re-extraction, re-analysis, and/or document and justify per PM; all corrective actions documented

[a] These are ***example*** performance objectives that may be considered for PCB instrumental analysis. Actual performance objectives or criteria should be set on a project-specific basis to meet project-specific objectives.

- Procedural Blank (PB) - A PB is a combination of solvents, surrogate internal standard (SIS) compounds, and all reagents used during sample processing, processed concurrently with the field samples. It is intended to monitor purity of reagents and potential laboratory contamination and interferences.
- Laboratory Control Sample (LCS) - An LCS is a contaminant-free matrix-specific sample (e.g., Ottawa sand or sodium sulfate). It is spiked with the analytes of interest and processed identically to the field samples to assess analyte recoveries and effectiveness of the method with no influence by the sample matrix.
- Matrix spike - A matrix spike is a field sample spiked with the analytes of interest at approximately 10 × the method detection limit (MDL), processed concurrently with the field samples. It is intended to monitor the recoveries and effectiveness of the method in the presence of the sample matrix.
- Sample duplicate - A duplicate is a second aliquot of a field sample processed and analyzed to monitor precision. The duplicate may be a second matrix spike sample.

- Standard reference material (SRM) – An SRM is prepared like a field sample to assess the accuracy of the analytical procedures. This is natural sediment that has been certified by the National Institute of Standards and Technology (NIST) to contain certified concentrations of the target compounds.
- Instrument Check (IC) – An IC sample is prepared by spiking a small amount of solvent with target compounds obtained from a vendor that is different from that used for the calibration standards, and then analyzing the IC as a sample. The IC sample is used as an independent measure of accuracy in the absence of sample processing.

In addition, a suite of SIS compounds are added to all field and QC ACF samples prior to sample preparation. These compounds are added to determine the efficiency of the sample extraction and analysis procedures, and to aid in the accurate quantification of native concentrations of the target analytes in the field sediment samples. A set of at least three SIS compounds with varying molecular size should be used to represent the range of target analytes (e.g., a trichlorobiphenyl, a pentachlorobiphenyl, and a heptachlorobiphenyl, at a minimum). It is also important that the SIS compounds are representative of the target compounds in the analytical procedure (i.e., have similar behavior). PCB congeners that are not expected to be in environmental samples (i.e., not present in Aroclor formulations and not expected to be generated through environmental processes), and well resolved analytically from PCB congeners that are present, are particularly suitable for use as SIS compounds. Isotopically labeled PCB congeners are also an excellent choice. A PCB chemist should be involved to assist in the selection of these SIS compounds.

Method Detection Limit

The MDL is defined as the minimum concentration that can be measured and reported with 99% confidence that the analyte concentration is greater than zero, and is generally determined by the method outlined in the U.S. Federal Register [37]. However, MDLs are not always the best measure of analytical sensitivity, and are one of several ways to evaluate the sensitivity of an analytical method. Reporting limits (RLs, sometimes referred to as minimum levels [MLs]) are defined by the sample concentration of a compound that is equivalent to the final extract concentration based on the low calibration standard concentration, and is often used to qualify data. However, uncensored data are most useful and should be reported for most environmental forensics studies based on a careful review of the analytical chromatogram by an experienced analytical chemist. Target compounds *confidently* detected below the RL (typically to a concentration with a signal-to-noise ratio criterion of 3:1, and identified with confidence by an experienced PCB analytical chemist) should be reported and qualified appropriately, regardless of how it compares to the calculated MDL. Target compounds detected between the RL and MDL are reported and typically also qualified, with a unique qualifier.

2.5 Data Analysis and Interpretation

Environmental forensics and statistics/data analysis often intersect because forensics projects typically depend on the analysis of large amounts of chemical data that need to be interpreted. PCB environmental forensics investigations often involve the collection of hundreds, if not thousands, of samples. If such data are analyzed by congener-specific methods, each sample will have associated with it 50 to more than 100 chemical measurements. Such large chemical data sets translate to major data management and data analysis challenges. As such, it often makes

sense that multivariate statistical methods are one important tool used to analyze such data. Unfortunately, there are very large sets of different data analysis methods that can be and have been used in environmental forensics investigations. The majority of these have been borrowed from scientific disciplines that predate by decades the current practice of environmental forensics (e.g., diagnostic ratio analysis in petroleum geochemistry, PCA in psychometrics, geology, and countless other disciplines). The methods discussed herein are based on the authors' collective experience. A comprehensive discussion of methods available to PCB forensics investigations goes beyond the scope of this document.

Given the wide range of potentially useful methods, it is best to begin in terms of general data analysis objectives and philosophy. The major objective of a PCB forensics investigation is generally the identification and delineation of multiple sources in an impacted system. Given data from a well-designed sampling plan that spans the desired geographical and temporal range of the study, three things should be determined:

1. The number of chemical patterns contributing to a chemical system. Ideally, different sources produce different chemical patterns, but this is not always the case.
2. The unique chemical composition ("fingerprint") of each chemical pattern.
3. The relative contribution of each fingerprint in each sample.

The systems under study (sites with historical contamination) are not well-designed experiments. Rather, they are the results of inadvertent releases ("accidental experiments") that generally occurred long before any detailed environmental investigations were undertaken. The contamination is often decades old, and records associated with the chemical releases are often sparse or nonexistent. This makes for an extremely complex system with many unknowns: site history, source chemistry, timing of release, and the presence of additional, unsuspected sources. A priori knowledge of all contaminant sources that have impacted a system is rare. A philosophy of exploratory data analysis (EDA) must be adopted, rather than classical hypothesis testing. The objective of EDA is to allow patterns and correlations to be derived directly from the analysis of ambient data, with minimal a priori hypotheses. A number of proven methods are discussed below (e.g., PCA, receptor models, ratio methods, simple graphics), but any number of methods that meet the above listed objectives, and conform to EDA philosophy, are potentially applicable to PCB forensics investigations.

2.5.1 Background and History of Data Analysis

While the term environmental forensics began seeing widespread use in the late 1990s, the data analysis methods most often used (and discussed herein) predate their application to environmental forensic by years, if not decades. The following sections discuss the history of some of the more commonly used methods.

2.5.1.1 Chromatograms and Simple Compositional Analysis

A forensic investigation includes several key steps of information and data analysis, including (1) review of site history and records research, (2) analysis of sediment/contaminant transport and hydrodynamic data, (3) review of the PCB concentrations, (4) initial review of the PCB composition, and (5) comprehensive chemometric analysis of the PCB data. The most basic

assessment of the PCB data and its potential association with sources is to review how the PCB concentration is distributed across a site; attempts to link PCB contamination with potential sources through PCB concentration contours and geographic distribution is the simplest and oldest approach to PCB forensics. Although not statistically rigorous, it has always been a useful first use of the PCB data to develop an image of the source association.

PCB composition (i.e., relative concentrations of PCB homologues and PCB congeners) is generally the next step in the initial PCB characterization of a site to develop ideas of potential sources. This can be done by carefully reviewing analytical chromatograms, or using bar graphs which are, in essence, recreated chromatograms with only the PCB data (e.g., Figure 2-2). Again, although not statistically rigorous, samples that have similar PCB composition may have a contaminant source relationship and understanding which sub-sets of samples have similar PCB compositional characteristics is useful initial information.

Analyzing PCB congener ratios is another type of PCB compositional analysis. Compound ratios have been used to infer sources of contaminants (e.g., [40, 41]) and to identify PCB transformation, including dechlorination [8, 10]. The idea is that if one can identify pairs of source-diagnostic congeners, then ratios between those compounds will retain the initial source signature. Conversely, if one can identify compounds that are susceptible to dechlorination and those that are resistant to dechlorination (Table 2-4), one can monitor the degree of dechlorination, assuming the original type of PCB contamination was a constant. Figure 2-11 illustrates active dechlorination, with the increase in the relative amount of PCB4/10 (dechlorination products) and the simultaneous decrease in PCB118 (a congener susceptible to dechlorination) with depth (time) in the sediment. Active dechlorination was confirmed multiple ways for the Lake Hartwell sediments, including with PCA analysis (Figure 2-12); deeper sediments with “old” PCB contamination exhibited a significant dechlorination, with a unique PCB composition that did not resemble any Aroclor (Figures 2-4 and 2-12). A potential drawback of ratio analysis is that the data analyst must make a decision regarding which chemical pairs are diagnostic of source, and have similar affinities to weathering. This requires a priori knowledge and/or assumption, and generally an uncommon depth of understanding PCB chemistry. As for most (if not all) of the PCB forensics methods discussed herein, diagnostic ratio-based methods were widely used in geochemistry applications prior to being adopted for forensics, most notably in fingerprinting of oil and source rocks in petroleum geochemistry applications [41, 42]. In the HPS demonstration study (Section 3.1), the ratio of PCB28 to PCB153 was used to evaluate the hypothesis of a source of less chlorinated PCB material in Yosemite Creek (a tributary that outfalls near HPS).

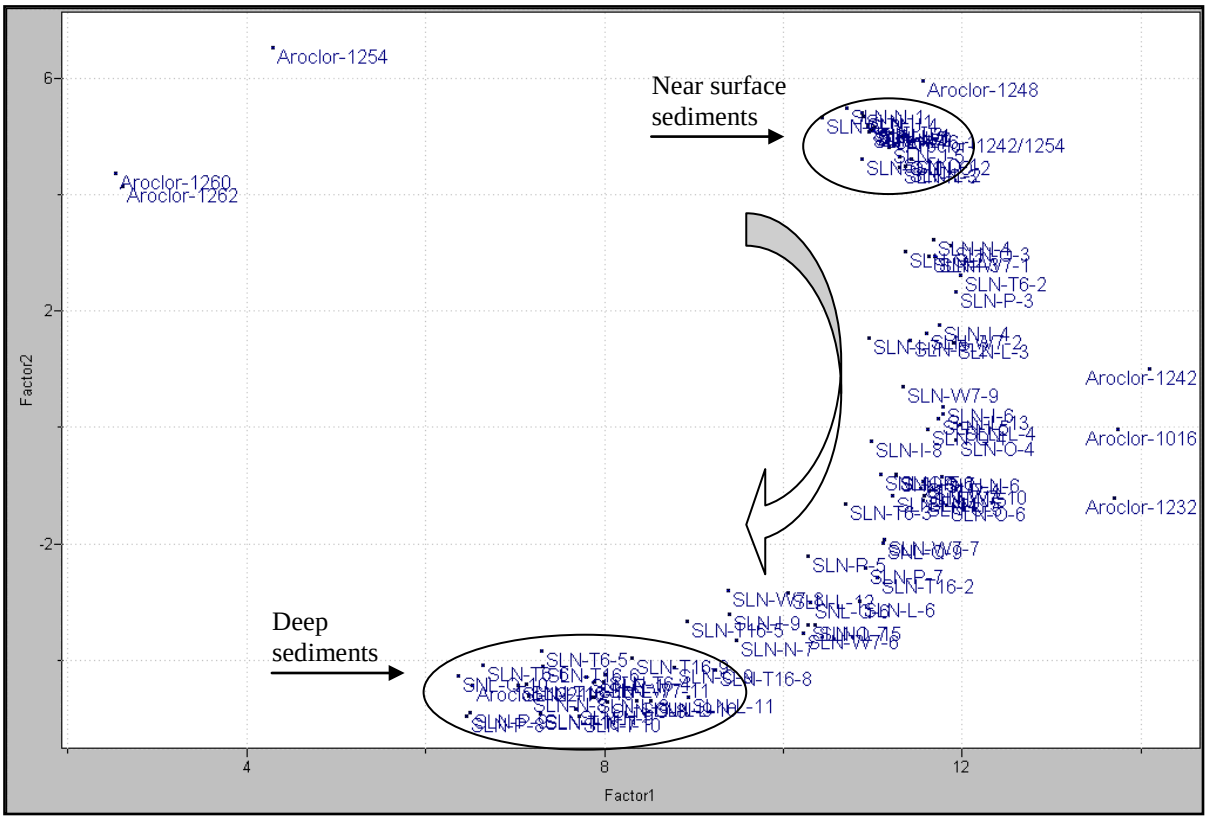

Figure 2-12. Principal Component Analysis Plot Using PCB Congener Data from Lake Hartwell Surface and Subsurface Sediment Samples
(Subsurface samples exhibit dechlorination and have no resemblance to Aroclors.)

2.5.1.2 Multivariate Analysis (Classification Analysis)

Several different classification multivariate analysis methods are available, of which PCA is the most widely used in PCB forensics. PCA is widely used for environmental forensics as a whole and in many scientific disciplines far removed from environmental chemistry. It is used both as an exploratory data analysis method on its own, and as an intermediate step in receptor modeling. PCA was used in many scientific disciplines long before the terms *environmental forensics* or *chemical fingerprinting* were ever coined, and long before the development of quantitative congener-specific PCB analysis. The roots of PCA go back to at least 1904 and psychologist/statistician Charles Spearman [43]. PCA methods began seeing widespread use in the earth sciences in the early 1960s [44]. In those early days, the method was generally referred to by geologists as *factor analysis* (FA) – a term borrowed from the psychologists that followed Spearman. There is considerable confusion on the relationship between PCA and FA. Much of this is due to the fact that there is little agreement on terminology across scientific disciplines (e.g., chemometrics, psychometrics, engineering, mathematical geology, etc.). The confusion still remains. However, *PCA* is generally the term of choice in environmental forensics, and *scores* and *loadings* are generally used for the chemometric definitions.

2.5.1.3 Receptor, Chemical Mass Balance, and Mixing Models

An increasingly common method used in environmental forensic investigations involves the use of receptor models. These methods are designed to resolve three parameters of concern in a multivariate mixed system: (1) the number of components in the mixture, (2) the identity (i.e., chemical composition) of each component, and (3) the relative proportions of each component in each sample.

Receptor methods often (but not always) use PCA as an intermediate step to (1) determine the number of "significant" principal components (i.e., the number of potential sources), and (2) provide a reduced dimensional reference space for resolution of the model. If source compositions are known a priori, then those compositions may be used as a training data set in the receptor model, and source contributions may be found via regression methods such as chemical mass balance [45, 46]. However, in environmental forensics, one typically does not know and/or wishes not to assume knowledge of sources. For such situations, it usually is preferable to use a self-training receptor model method: a class of algorithms designed to resolve the number of sources, and provide feasible estimates of the multivariate source patterns and source contributions, without a priori assumption of sources. Methods in common use in environmental forensics include PVA, multivariate curve resolution/alternating least squares (MCR-ALS), PMF and Unmix.

Based strictly on the environmental forensics literature, it might appear that there was an evolution of methods from less sophisticated PCA applications in the mid to late 1990s to the development and implementation of more sophisticated algorithms in the new millennium. However, once again, all of these methods actually existed long before the term environmental forensics was in widespread use, and certainly well before being applied to PCB congener data. The PVA method used in recent PCB applications (e.g., [8]), and for the HPS and Ashtabula River case studies in this research (Sections 3.1 and 3.2) is essentially the same algorithm published 30 years ago by Full et al. [47, 48]. Similarly, PMF was first published in 1994 [49] and MCR-ALS in 1993 [50]. While not called Unmix at the time, the development of that algorithm can be traced back to the early 1990s [51, 52], and was an extension of self-modeling curve resolution work from the 1970s [53]. These methods have been modified and new options published since they were originally introduced, but the algorithms remain largely unchanged since the early 1990s.

There are a number of likely reasons why it may appear that the receptor model methods came along later than they did. Firstly, there is a big difference in accessibility and user friendliness of receptor model software as compared to more common data analysis techniques such as PCA. In the mid-1980s one needed to use Fortran software running on a main-frame computer to apply PVA. In the 1990s, if one wanted to use PVA, ALS, or PMF one had to contact the academician that had developed it and determine how to apply it. The software was primarily developed for academic research purposes, and as such was neither intuitive nor particularly user friendly. Today, one can download a much improved version of Unmix or PMF from the U.S. EPA Web site (http://www.epa.gov/ttnamti1/unmixmtg.html), and commercial data exploration and analysis software products (e.g., Pirouette from Infometrix) include an ALS module.

The application and comparison of these methods has been presented in the literature [9, 19, 54]. Given high quality chemical data (and data that have undergone rigorous quality assurance [QA]/QC to identify and address any problems with non-detects, interferences, and other analytical issues), each of these methods perform well and resolve similar source patterns and apportionment. However, like PCA, these methods require that the user has a certain level of experience and familiarity with environmental data structures.

2.5.2 Data Review and Preparation

2.5.2.1 Laboratory Data Quality Review

The laboratory QC sample data should be reviewed against the DQO to assess the key QC measures for potential contamination, accuracy, and precision, to ensure that the analytical data represent the PCB concentrations in the samples. The DQOs for the laboratory QC samples included with the ACF analyses from the HPS and Ashtabula River case studies are presented in Table 2-11. A summary of the QC sample results are summarized in Table 2-12. As can be seen, the vast majority of the QC samples prepared and analyzed along with the PCB samples produced QC results that met the DQOs for these sample sets. For instance, 96% of the SIS recoveries and 100% of the LCS recoveries determined with the HPS samples met the DQOs. In general, the QC sample results were of uncommonly high quality for both case studies.

Table 2-11. Comparison of Project Results to Data Quality Objectives – PCB Congener Analysis of Hunters Point Shipyard Sediment Samples

QC Sample or Measurement Type	Data Quality Objective	Total Number of QC Measure Data Points[a]	Number of QC Data Points that Met the DQO	% of QC Data Points that Met the DQO
SIS Recovery	40 to 120% recovery	560	540	96.4
Method/Procedural Blank	No compound to exceed 5 times the RL, unless sample is >10 times blank amount	308	308	100
LCS Recovery	40 to 120% recovery for spiked compounds	308	308	100
Matrix Spike/Duplicate Recovery	40-120% recovery for spiked compounds. Applies to analytes with spiked concentration >5 times the native sample concentration.	616	609	98.6
Matrix Spike/Duplicate Precision	RPD <30%. Applies to analytes with spiked concentration >5 times the native sample concentration.	308	236	76.6
Instrument Check Accuracy/Precision	PD <20%.	308	308	100

[a] Total number of data points of the indicated QC measure. For instance, for surrogate recovery it would be the number of surrogate compounds in each sample multiplied by the total number of samples. For the method blank it would be the numbers of method blank samples analyzed with the sample set, multiplied by the number of target analytes measured.

Table 2-12. Comparison of Project Results to Data Quality Objectives – Ashtabula Sediment Samples (EPA-ORD and GLNPO Project Combined)

QC Sample or Measurement Type	Data Quality Objective	Total # of QC Measure Data Points[a]	# of QC Data Points that Met the DQO	% of QC Data Points that Met the DQO
SIS Recovery	40 to 120% recovery	992	987	99.5
Method/Procedural Blank	No compound to exceed 5 times the MDL, unless sample amount is >10 times blank amount	1,902	1,902	100
LCS Recovery	40 to 120% recovery for spiked compounds	1,902	1,899	99.8
Matrix Spike Recovery	40 to 120% recovery for spiked compounds Applies to analytes with spiked concentration >5 times the native sample concentration.	1,902	1,900	99.9
Sample Duplicate Precision	RPD <30%. Applies to analytes with concentration >5 times the MDL.	1,902	1,899	99.8

[a] Total number of data points of the indicated QC measure. For instance, for surrogate recovery it would be the number of surrogate compounds in each sample multiplied by the total number of samples. For the method blank it would be the numbers of method blank samples analyzed with the sample set, multiplied by the number of target analytes measured.

Some DQO exceedances can be expected with challenging sample matrices and when applying ultra-trace level analytical methods. Analytical results that do not meet the listed DQOs should always be reviewed by a senior analytical chemist for assessment of the potential impact of the results. Affected samples may be reanalyzed if needed to ensure high quality data. QC sample data that are accepted outside the DQOs should be indicated with the appropriate data qualifier, and the rationale for accepting the analysis should be documented, so that subsequent data users can assess if there was any potential impact on the data quality. Overall, the QA program, including the analysis of laboratory QC samples processed and analyzed with the field samples, produced data that demonstrate that the methods were appropriate and that the analyses were under control, generating high quality and reliable data that can be used with confidence.

2.5.2.2 Data Preparation

Typical data assessment and preparation are summarized below, using examples from the Ashtabula River data set for illustration. The laboratory ensures that the data have met the analytical data quality expectations (Section 2.5.2.1), and deliver the data to end users. Additional preparation (Section 2.5.2.2) and quality/usability review and screening (Section 2.5.2.3) are then performed before the final data (and potentially reduced data set) are interpreted for forensic purposes.

Data are typically received in a variety of formats (e.g., spreadsheets, databases, GIS files). Regardless of the format, the first step is to put all data into a format that is readily useable for review and data analysis. A common format is Excel spreadsheets, with samples as rows in the spreadsheet, variables (PCB congeners or homologs) as columns, or vice versa. It is important to compile as much information about the data and samples as possible in the data preparation stage. Additional important sample information to capture in the spreadsheet or data transmission includes:

- **Unambiguous Sample Identification (ID).** Often, the same sample will carry different sample names/numbers, and it is important to be able to cross reference. A common example is a field station ID, field sample ID (the sample name assigned by field personnel) and the lab sample ID (the analytical laboratory's internal tracking number).
- **Laboratory Analytical Batch ID.** It is often valuable to know what analytical batch the sample was analyzed with to be able to associate field samples to laboratory QC sample results (which tend to be analytical batch specific), and should there be a need to discuss the data with the analytical laboratory.
- **Sampling Date.** It is critical to know when the sample was collected to understand what period in time the data represent. This is particularly important if data are available from different time periods for the site, but is important for any sample since putting contamination into a historical perspective is important in any forensic investigation.
- **Sample Sediment Depth.** It is important to know sediment depth interval below surface that the sample represents to understand how samples can be compared with each other, and to link the data to source input history, among other things. The top and bottom depth of the sample (e.g., 5 cm to 10 cm) is important to know. If the sample is a surface sediment sample, it is critical to know to what depth the sample was collected, as surface sediments are collected differently in different projects (it may be just the top 1 cm representing very recent contamination, or as deep as the top 1 ft potentially representing decades of contamination). Samples that represent a wide range of sediment depth (e.g., from the surface to 1 ft deep) are often less useful for a forensics investigation than samples representing smaller depth intervals.
- **Concentration Information.** Having information on the concentration units (e.g., ng/g,), and whether the data are on a dry or wet weight basis, is important to be able to put the contamination into perspective, and to support a variety of data analyses. It is best to avoid the ppm and parts per billion (ppb) nomenclature, and instead use units in a format such as mg/kg and µg/kg. Although some data analysis (e.g., pattern recognition methods) use data normalization and transformations to optimize the analysis, it is important to also maintain a data set with concentration information.
- **Sampling Location.** It is critical to be able to link a sample with a specific sampling location. Manually indicated "dots on a map" showing the approximate locations will not suffice for a forensics investigation; accurate global positioning system (GPS)-based location information (latitude-longitude, northing-easting) are needed. Although some chemometric analysis may be performed with less detailed location information, a high degree of accuracy and location certainty may prove crucial to evaluating the

fingerprinting data, and supporting the results. Location-specific geochronology data (e.g., ^{210}Pb or ^{137}Cs data; Section 2.5.3.2) are extremely valuable, and often critical, for understanding the history of the contamination and support rigorous statistical and other data analysis.

ACF PCB congener analysis requires the application of high QA/QC standards to produce data of sufficiently high quality to support a forensic interpretation. Experienced PCB analysts should be overseeing and conducting the laboratory analyses and reviewing the analytical results. The analyst should have a familiarity with PCB chemistry and sensitivity to common as well as PCB-specific analytical QA/QC issues. The data should be accompanied by information related to the QC sample results and the overall data quality (a QC narrative; Section 2.5.2.1). Data qualifiers should be applied as appropriate to help data users understand potential laboratory data quality limitations, or other important sample or value-specific issues (see below). Additional data quality, reasonableness and usability assessment should be performed separately and independently following the laboratory's delivery of the data, and is discussed in Section 2.5.2.3.

The application of laboratory data qualifiers (sometimes referred to as data "flags") can vary from project to project depending on the project-specific DQOs, but widely applicable DQOs and an example laboratory QC sample program were described in Section 2.4.4. Chemical data reporting conventions and the use of data qualifiers may vary from lab to lab, but such information should accompany the data delivery and QC narrative to be able to understand and use the analytical data.

The "value" reported for non-detects is particularly important to understand for data assessment purposes. Some laboratories will report an empty/blank field if not detected, some laboratories will report a zero, and some laboratories will insert a value based on the laboratory's separately determined detection level (e.g., the MDL, half the MDL, or the RL or ML). Whatever the reporting convention for non-detects, it should be well documented with the data delivery and, ideally, also accompanied by a qualifier in the data set that identifies it as being non-detect. The data qualifier "U" is most commonly used to indicate a non-detect. Additional common laboratory data qualifiers are summarized below, but different qualifying conventions can be used as long as they are appropriately documented.

- **U** – Analyte not detected based on the careful review of the chromatogram by an experienced PCB analyst. A criterion of a signal-to-noise ratio of approximately 3 to 5:1 for the analyte peak in the chromatogram, and acceptable peak shape, is often used, and preferably manually assessed and confirmed.
- **J** – Most laboratories use this qualifier to indicate the identification of an analyte (using the criteria listed for the "U" qualifier), and reporting of a concentration that is below a common reference point; sometimes referred to as an estimated concentration. It is often assigned when a data value is near the detection limit, and below some commonly calculated reference value (e.g., the RL or ML, which is the field sample concentration that produces a final sample extract with a concentration that is equivalent to the low calibration standard). The RL/ML are generally more useful sensitivity and detestability reference values than the MDL, which is a periodically calculated performance measure

that incorporates precision and method performance, but may not be the best measure to represent analytical sensitivity.

- **ME** – This is a common qualifier to use to indicate that there was matrix interference (i.e., not a "clean," well resolved analytical peak in the chromatogram) and that the value should be considered an estimate.
- **N** – This is a common qualifier to use to indicate a value that did not meet the recovery, precision, or accuracy DQO, but is deemed by the laboratory to not impact the overall quality of the field sample results (as discussed in the QC narrative). This qualifier may be used for surrogate compound recoveries of field samples, or recovery, accuracy, and precision results for various QC samples.
- **R** – Rejected. The reported value for this data point was rejected by some laboratory criterion and/or through review by the laboratory, determining that the laboratory could not produce a reliable value or even an estimate. The "reject" assessment may apply to an individual compound, or an entire sample, as indicated, and should be discussed in the QC narrative.
- **D** – Diluted. Sample had to be diluted, usually due to a high concentration of the analyte (i.e., the concentration was above the calibration curve in the initial analysis).
- **C** – Coelution. For PCB congener analysis, some laboratories will report this flag for PCB congeners that coelute with some other congener, usually indicating which congener it coelutes with using the IUPAC number (e.g., C4 for PCB10). Other labs will not report "C" but will identify the analyte as the coeluting set of congeners (e.g., PCB4/PCB10).

If the laboratory qualifying system (i.e., lab-flag scheme) and non-detect reporting method are not clear from the deliverable provided, it is important to contact the laboratory to obtain clarification before proceeding with the data analysis. Such information is extremely useful in deciding which samples/analytes to include in an analysis, determining the proper course of action in handling outliers, and evaluating the validity of a chemometric model's interpretation.

Standard graphics resulting from statistical data analysis (e.g., PCA scores plots) are useful, but are by themselves often insufficient. In any environmental forensics investigation, one must be able to put results in a spatial context, creating maps or other geographical representations. It is often very useful to incorporate the data into a GIS, and producing GIS files of the site; sampling locations are ideally part of the project planning or, at a minimum, an early part of the information analysis. If the primary data interpreter is not proficient in GIS mapping, they should solicit the help of somebody who is. In the case of the Ashtabula data set, GIS information was available in the form of GIS shapefiles, which were used to construct a simple base map, showing key geographic features of the study area (Figure 2-13). The HPS site also had good GIS information available, as will be shown in Section 3. The objective initially is not necessarily to generate report-ready graphics, but to have the ability to quickly put data and analysis results in geographic context.

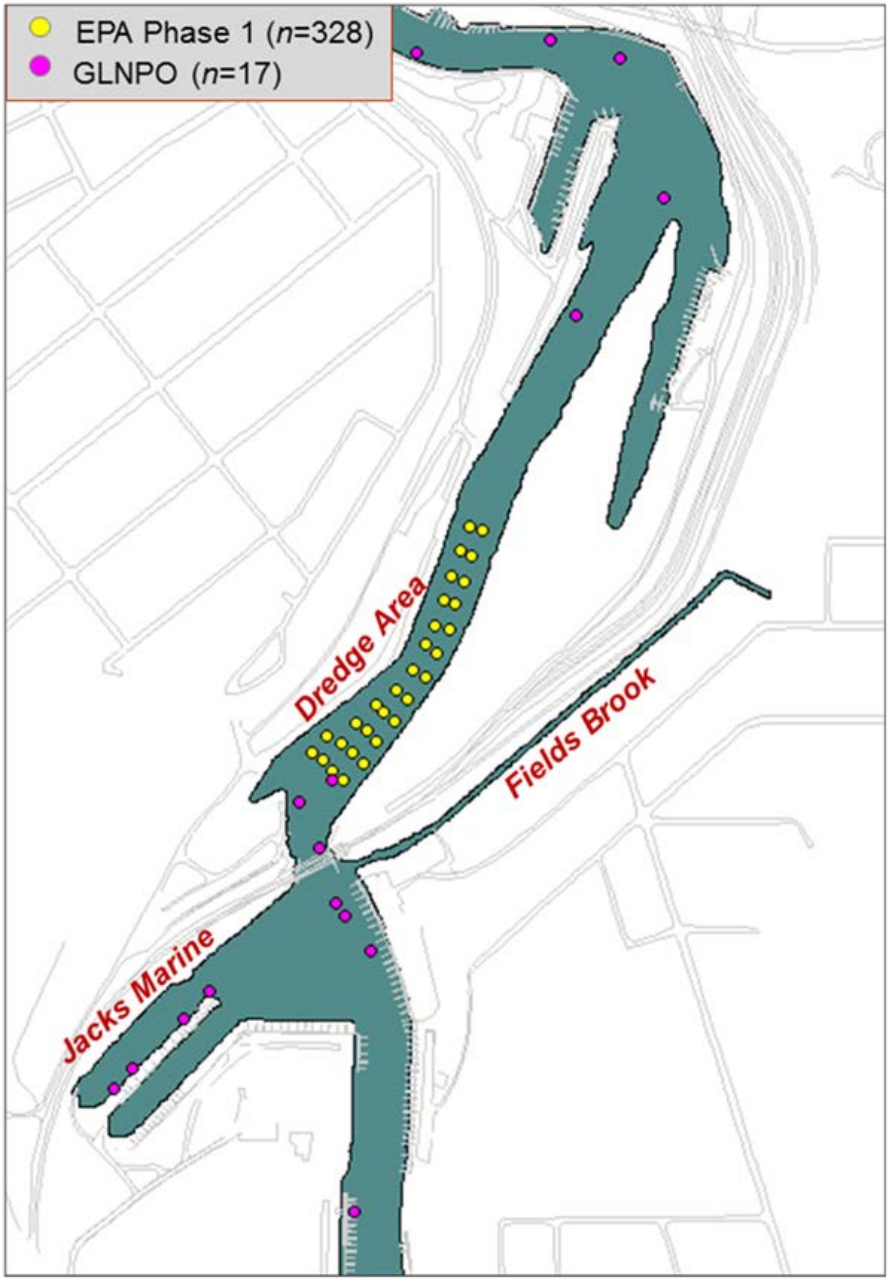

Figure 2-13. Simple Base Map of the Ashtabula River Study Site Showing Sampler/Core Locations

Historical PCB data from a site are commonly available only as hardcopy in old reports. In such cases, a time-consuming first step may be a hand-entry of data into spreadsheets, or the application of a scanning-to-digital information translation software (which, if used, needs to be carefully verified), and digitization of sample locations off of hard-copy maps such that the data can be analyzed in geographic context.

Using PCB congener data from multiple laboratories is another common challenge. Often, when historical PCB data are available for a site, samples may have been analyzed by different laboratories and perhaps using different analytical methods (often with different coelutions characteristics and different PCB congener analyte lists). The ability to perform PCB congener pattern comparisons between samples analyzed by different labs is dependent on (1) determining which reported analytes are most comparable between data sets and (2) reducing both data sets to a PCB congener list that is most comparable.

The solution to such a challenge with merging data from multiple laboratories and/or methods is usually project specific, taking into account the different analytical methods that were used, considering the reported quality of the QC sample results, the age of the data, etc. (for example, PCB153 coelutes with different congeners in different laboratory method systems). On a GC/ECD system using a DB1 column, PCB153 often coelutes with PCB184. In contrast, on a GC/MS system using a DB5 column, PCB153 may coelute with PCBs 168 and 132 [55]. Fortunately, when comparing data from these two analytical systems, it is not unreasonable to compare these two peaks as "PCB153", because PCB153 is more abundant of these potentially coeluting congeners in Aroclors and most environmental compartments. The key to compiling comparable analyte lists is a peak-by-peak comparison between the two data sets, done in context of (1) analytical method comparability considerations, (2) known or suspected sources and potential alteration processes, and (3) the media sampled (e.g., keeping sediment data together, but separate from biota). Most aspects of the data preparation, review, and screening are best performed by a highly experienced PCB environmental chemist.

2.5.2.3 Data Review and Screening

Prior to detailed data analysis and interpretation, the investigator or his/her PCB environmental chemist team member, should conduct a data review focused on assessing data quality and overall usability for forensic purposes, which goes beyond what the laboratory performed when generating the data. This step is an evaluation data quality assessment, but from the data analyst/statistician's perspective rather than that of the laboratory chemist (Section 2.5.2.1).

It is important to point out that in a step-wise framework, as in this handbook, this task has been positioned as a discrete step in a linear process (between data generation, preparation and data analysis). Ideally, data screening should take place before data analysis. However, in practice, that is not always possible. Or it may become an iterative process. Data outliers, for instance, may not be clearly evident during the conduct of the data analysis itself. The outlier issue(s) should then be addressed and the data analysis process repeated. Data quality assessment is an ongoing process, starting with the analytical chemist (long before the end user ever receives the data) and continuing to final analysis and report preparation (as the project team seeks to explain the subtlest bits of variation in the data set). Regardless of specific approach, a key component of this process is outlier detection and sample screening. Johnson et al. [9] discusses statistical and graphical methods for sample screening. A brief overview is provided here.

In environmental forensics investigations, detection and evaluation of outliers is a crucial part of the process. As such, the data analyst should develop a systematic approach for summarizing and reviewing PCB congener data to determine data reliability and usability, with a goal of obtaining a robust data matrix for subsequent chemical fingerprinting. Beyond this general

guidance, the specific approach is often a function of one's training and preferred workflow, and generally an experienced chemist's "chemical reasonableness" assessment that cannot easily be described in a written step-wise fashion.

A common data preprocessing challenge is how one deals with low concentration samples and/or samples with numerous congeners reported at or below the limit of reliable detection. Clearly, such samples will be of limited utility when it comes to congener pattern comparisons, as they either have no concentration reported, tend to have higher uncertainty in the reported value than the rest of the data, and are, simply, of low relative significance in the data set. As such, it is usually advisable to review total PCB concentrations for each sample, as well as a tabulating the number of non-detects in each sample. In the experience of these authors, there are no hard-and-fast rules on what total PCB concentration is acceptable, or what percentage of non-detects is considered too high. These decisions are usually project specific, with logic and analytical accuracy being the key considerations.

Similarly, the analyst should screen the data set for problematic variables (congeners). This typically includes identifying congeners with a high percentage of non-detects, which may have to be omitted from the analysis. One may also want to determine congener concentration as percent of total PCB and the variability in the contribution (as percent relative standard deviation [%RSD]), to identify congeners with significant variability and uncertainty, but ensuring that it cannot be attributed to source or other "real" differences. Any number of approaches can be employed, but the ultimate objective is to determine if variability within a variable is due to "real" composition differences (e.g., different sources or dechlorination) or a function of noise or censored data (i.e., non-detects).

Finally, when outlier samples or congeners are identified, it is important to understand that causes for each may differ, so the appropriate action required to address outliers may vary. For example, if the outlier is the result of data entry error, the appropriate action would be to correct the error and rerun the analysis. If, however, the cause is uncorrectable matrix interference or other analytical issues, the only reasonable course of action might be to delete the sample from the data analysis. Another possible explanation of an apparent outlier may be that the reported concentrations are completely reliable and accurate, but the sample is truly unique. An example of such an outlier might be a single or limited set of samples with significant dechlorination in an otherwise unaltered suite of samples. In this case, the outlier represents a true fingerprint observed in the field, should be possible to identify using PCB chemistry knowledge and sample investigation, and should not be omitted from the analysis solely because it is unique.

Most chemometric studies will include some criterion for handling data points where an analyte was not identified and reported below laboratory detection limits (non-detects). Common reporting and data qualifying of non-detects was discussed in Section 2.5.2.2. If, as part of the data reporting, an artificially inserted value was inserted for the non-detect (e.g., half the MDL), and qualified with a "U", then such values are typically best replaced with a zero in the data screening process, prior to data analysis. Non-detects with an empty value cell often need to be populated with a zero, as many data analysis software cannot handle empty cells. The handling of non-detects is an important project decision, and should be discussed within the project team and the agreed on approach justified and documented.

It is important to conduct a rigorous review and pre-screening of the data before conducting any statistical, chemometric, or other key data presentation and analysis so only the most reliable data are used in subsequent analysis; only data for which there is a high degree of confidence. All samples and all parameters (PCB congeners) are generally not needed to conduct a solid forensics interpretation, and the quality of and confidence in the data analysis is greater if data of low reliability are removed. As discussed, it is difficult to develop strict quantitative screening methods for when to include and when to reject a sample or parameter, and it is important to include an experienced PCB chemist in the data evaluation process to ensure that a solid "chemical reasonable" assessment is part of the data review and screening process. The following are some considerations that may be included in such a data screening process.

***Samples** Inclusion/Removal Assessment*

- Identify the overall PCB concentration below which it is unlikely that reliable results are consistently generated for the sample, and remove those samples from the data set. The following are example guidelines, but project-specific, sample-specific, and analyte-specific decisions are often most appropriate, with accompanying documentation.
  - If >50% of the PCB congeners are non-detect, those samples may be removed.
  - If the sum of the PCB concentrations is low compared to most samples in the data set, and/or low concentrations are contributing to unusually high variability and overall data uncertainty; the congener composition does not appear to be technically reasonable. The PCB concentration is near the limit of detection. This sum of the PCB congener's screening level was in the 80 to 100 ppb range for the Ashtabula River sediment samples; samples with a sum of congener concentrations below that were not used. Most samples had much higher PCB concentrations.
  - If the relative concentration of PCB congeners is unusual for a large number of congeners in the sample (Figure 2-14), and cannot be explained by expected sources or weathering differences, that sample can be removed from the data set (once it has been assured that it cannot be explained by sampling or laboratory error, or the presence of another source).

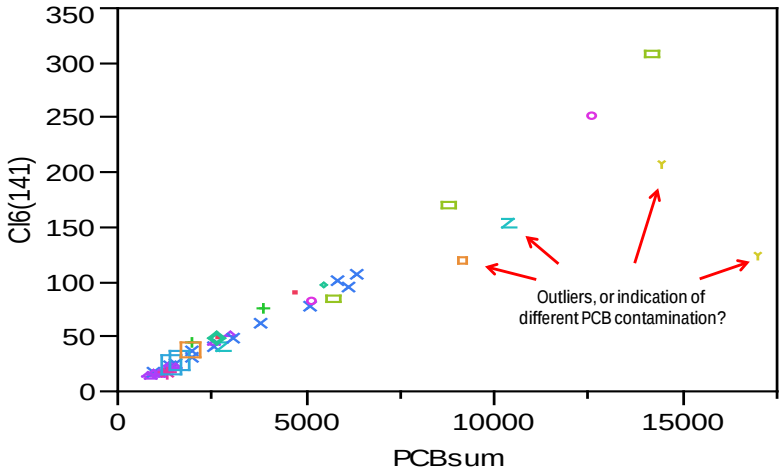

Figure 2-14. PCB Congener Ratio Analysis to Determine Potential Outliers

***PCB Congeners** Inclusion/Removal Assessment*

Considerations for whether to include or exclude specific congeners from a data-set are similar to deciding whether to include or exclude samples (see above), but there are some differences.

- Identify the PCB congeners with inconsistent, unexplainable, or otherwise unreliable results, and remove those congeners from the data set. It is important that the congener is removed altogether from the data set (not only for the samples with low congener data reliability), as it is important that the same set of congeners be used for all samples. The following are example guidelines, but project-specific, sample-specific, and analyte-specific decisions are often most appropriate, with accompanying documentation.
    - If the congener concentration is consistently near the limit of detection in the data set, that PCB congener can be removed from the data set. For the Ashtabula River sediment samples, for example, a congener was removed from the data set if >50% of the samples had a concentration of <1 ppb for that congener.
    - If, after removal of unreliable samples, >50% of the samples have non-detects for a PCB congener, that PCB congener may be removed from the data set.
    - If the relative concentration of a PCB congener is uncommonly low or high for a large proportion of the samples, and cannot be explained by possible source or other weathering differences, that PCB congener can be removed from the data set. For instance, calculating the percent contribution to the total PCB for the congeners in each sample is a useful component of the data assessment. If the percent relative standard deviation (% RSD) in the percent contribution to the total PCB is >100 %RSD, and that high variability cannot be explained by different sources or weathering in the data set, that PCB congener can be removed from the data set. This assessment can also be performed with ratio plots (Figure 2-14).
    - If, using PCB chemical reasonableness evaluation, the results for a congener are frequently anomalous and cannot be reasonably explained by its composition in Aroclor formulations or by degradation or other weathering/transformation processes, that PCB congener can be removed from the data set. For instance, if a PCB congener concentration is relatively constant and does not co-vary with the overall PCB concentration, or if a PCB is detected at high frequency in some analytical batches and not in other analytical batches of samples from the same site, such anomalies can likely be assumed to be due to analytical issues, and the PCB congener should not be used.

The values indicated above are *not* strict criteria, and should only be used as general guidelines (e.g., 50% non-detects for excluding a sample from the data set). The actual assessment cutoff will likely be different from data set to data set, and may also vary from sample to sample and congener to congener, and needs to be determined on a project-specific basis by an experienced PCB chemist. In addition, it is critical that it be determined if any data outliers and apparent anomalies may be the result of different sources, or dechlorination or other weathering processes, before data are removed from the data set; if the variability or anomaly can be explained using an understanding of PCB chemistry, or if there is any doubt about it being a “real” PCB signature, then it may be best to kept such data in the data set. For the Ashtabula River data set, for

instance, there were 345 sediment samples with available data, and 53 of those were removed during the data screening process. In addition, 38 of the 120 PCB congeners were removed, providing a final data set of 292 samples and 82 PCB congeners for the data analysis and interpretation exercises.

2.5.3 Data Analysis and Interpretation

This section describes several common data analysis approaches. This discussion will move from relatively simple graphics through to more sophisticated statistical methods. However, the simpler methods should not be considered less helpful. Often, the most effective method of gaining an intuitive understanding of data is through use of simple graphs or maps.

The primary information analysis components in an environmental forensics investigation are:

- Determine the site history and history of the surrounding area
- Determine the contaminant/sediment transport characteristics and hydrodynamics
- Determine the PCB concentrations across the site, and in relation to potential sources
- Determine the PCB composition across the site, and in relation to potential sources
- Conduct chemometric data analysis, ideally using multiple techniques
- Integrate the data analyses and findings through multiple lines of evidence to identify potential sources, and, if multiple sources, their relative significance.

It is absolutely critical that these components are addressed in an integrated manner. These types of studies are often conducted with the interpretation being limited to basic chemical "fingerprinting" of analytical chromatograms and/or a single statistical analysis method, with other potentially critical information not being used, and conclusions drawn with insufficient knowledge and a low degree of confidence.

Even for more sophisticated data analysis methods, lucid, well-conceived graphics are important. An ideal graphic must, first and foremost, be faithful to the data. But it should also be lucid and simple to understand. These general guidelines provide constraints, but also leave room for considerable creativity.

2.5.3.1 Site History and Record Research

The components of conducting a record research were discussed in Section 2.2.1. This is an important, and often overlooked, component of a forensics investigation, and is conducted to help determine a relationship between the observed contamination and historical activities at or near the site. This requires an understanding of the history of the site and area surrounding the site that could have impacted the site. If one cannot identify historical industrial activities, processes, material handling, and possible release and transport scenarios that can explain the sediment contamination, the forensics investigation would be missing an important puzzle piece.

As discussed in Section 2.2.1, the availability of records can vary widely from project to project, but it is important to devote significant effort to the site history and records research as part of the forensics investigation, and preferably early in the process during the planning phase. In

terms of determining potential sources of PCBs in sediments, the types of information that are usually the focus of records search include:

1. Identifying current and historical production/operations for the properties that through intentional or unintentional discharge/runoff could have contaminated the sediments.
2. Identifying PCB-related activities (e.g., transformer/capacitor use, carbonless copy paper, hydraulic fluid, marine paints) by the potential contributors of sediment contamination, and the timeframe of their use.
3. Identifying historical waste handling and disposal for PCB containing materials/waste.
4. Identifying possible migration pathways to sediment (e.g., waste disposal, landfills, drainage ditches and creeks receiving runoff), and how those have changed over time.
5. Reviewing historical environmental investigation reports and data.
6. Reviewing historical remedial activities, and summarizing their implications on the history of the contamination.
7. Summarizing the activities and site characteristics that may have involved PCBs, the possible history (years) of releases, and possible migration pathways to the sediments.

Obtaining historical information can be challenging because it is rarely readily available and can require creative and atypical research techniques. The elements of a record research investigation were described in Section 2.2.1, and the following summarizes possible sources of potentially important historical information.

- **Internal Corporate/Facility Documents**. Available internal communications and other records that document the operations that may have used PCBs. Documentation of remediation that may have been conducted at the site, as well as past environmental studies and related data and reports. Such information is sometimes publicly available, and at other times may not be made available.
- **State and Federal Regulatory Files**. If environmental investigations have been conducted at a site under regulatory authority, then a case file should exist, and all information should be available in the public domain. Access to such files varies greatly, depending on the regulatory agency. In some instances, many or all case files are available online, and can be searched and downloaded. In other cases, a formal request may be required under the Freedom of Information Act. It may take weeks or months before access is approved, and the agency may require that files be reviewed on their premises. In yet another scenario, regulatory programs may require that a local library or other public facility serve as a document repository, and key documents can then be accessed at that location with no pre-arrangements.
- **Publications**. Published reports and other literature may provide general information on industrial/commercial use of PCBs (e.g., [5, 20, 22, 56]). Such papers are useful, but generally provide information on an industry-wide basis (not a specific facility or site). If one can find specific case study papers or presentations or reports that focus on the specific site, or a similar site, that may provide useful historical information. If such a

document includes citations for such information, it will usually be well worth the effort to track down the original source.

- **Interviews**. Interviews with current and past residents of the area, and workers at the facilities potentially responsible for the contamination or nearby facilities, can often produce a wealth of useful information about past activities. This is a particularly valuable way to obtain information on important activities and site matters that are not well documented.
- **Aerial Photographs/Remote Sensing**. Aerial photographs and other remote imaging and sensing information are publically available from commercial sources and sometimes also from public sources. A wide range of such imagery and information can be purchased if it is not part of the readily available information. Such information can be obtained from many past decades to help reconstruct physical and industrial changes over time to better understand the PCB contamination.

2.5.3.2 Sediment Transport and Hydrodynamics

As discussed in Section 2.2.2, a general approach for a sediment transport evaluation is presented in Blake et al. [36]. Initially, the project team will collect all available data, conduct a site inspection, and develop a site-specific CSM for sediment transport. The team also will formulate the preliminary sediment management questions, define the overall study objectives, and identify the most critical data gaps. After this initial evaluation, the team can conduct a Tier 1 sediment transport evaluation. The goal of the Tier 1 evaluation is to address the most common sediment management questions, using readily available data from the RI and relatively uncomplicated data analysis methods. The Tier 1 evaluation has relatively simple data needs, a lower cost, a shorter timeframe, and a higher level of uncertainty than a Tier 2 evaluation. The Tier 1 results can be used to refine the sediment transport CSM and address the relevant site-specific sediment management questions. Depending on the questions asked at a specific site, this level of analysis may be sufficient.

For large or complex sites, a higher degree of certainty may be needed to characterize sediment transport processes and address sediment management questions. In this case, collection of additional site-specific data may be necessary and more detailed and complex data analysis methods may be warranted, including the possible development and use of predictive models. These activities comprise the Tier 2 evaluation. The scope of data collection and analysis for the Tier 2 evaluation will depend on the complexity of the site, the type of data needed to address the most critical data gaps, and the available project budget. Tier 2 results will be used to refine the CSM until the uncertainty associated with the sediment management decision(s) is reduced to an acceptable level.

The sediment transport and hydrodynamic studies, and associated data generation, conducted as part of a forensics investigation are intended to help determine how contaminants move and deposit at the site. This means understanding runoff and discharge characteristics at potential sources, input characteristics to the study site (e.g., creeks, drainage ditches, discharge pipes, CSOs), and the hydrodynamic and sediment transport conditions that impact how the contaminants are distributed in the aquatic system, and eventually settled to the sediments. It is therefore important to understand and obtain the appropriate data to explain factors including:

- All water and sediment input sources to the study site, including their history and activity
- Water circulation (currents) and their consistency and fluctuation
- Tides and their potential impact on currents and sediment movement
- Suspended sediment transport, suspension, resuspension, transport, and depositional characteristics
- Areas of erosion and deposition
- Sediment deposition rate in areas of demonstrated deposition
- Sediment stability and susceptibility to erosion under different conditions (e.g., storms).

Understanding the hydrodynamic conditions, and particularly the transport and fate of sediments, is crucial to explaining the movement of contaminants, and how the identified sediment contamination may be related to a distant source.

2.5.3.3 PCB Concentrations

One of the first steps in assessing the PCB contamination at a site, and to begin to get an understanding of the contaminant situation in terms of source association, is to review the overall (total) PCB concentration information for the site. Surface sediment data provide information on recent contamination, and subsurface sediment data provide information on historical contamination and needs to incorporate the sediment depth and the rate of sediment deposition. Factors to consider include how high, in general, the PCB concentrations are across the site, how variable the PCB concentrations are across the site, and determining if there are any PCB concentration "hot spots" and spatial gradients that could help understand potential sources. The PCB concentration information is then considered together with the historical site information (Section 2.5.3.1) and hydrology and contaminant transport for the site (Sections 2.5.3.2), to develop a preliminary understanding of the contaminant distribution and how it may relate to potential sources.

In environmental contaminant studies, the highest concentrations of contaminants are, more often than not, found in close proximity to their source. The hydrodynamics of the site and sediment stability and transport (e.g., areas of erosion where sediments do not settle or are resuspended and moved, and areas of deposition where suspended sediment settle) must be considered to support the contaminant distribution interpretation, and to ensure that there are no surprising contaminant transport characteristics that are not being considered. PCB concentration contouring is a widely used, and very useful, technique for understanding the approximate PCB concentration distribution to obtain an initial understanding of the contamination situation, and potential source areas. Thus, a simple map showing concentrations of contaminants in the sediment is a powerful and useful initial analysis, and may be more insightful than some sophisticated statistical technique. Figure 2-15, for instance, illustrates the surface contaminant concentration in a lake with two significant locations where run-off and other input to the lake occur. One of those (the northern one), appears to be associated with contaminating the sediment, while the other does not appear to be, assuming there are no unusual contaminant transport characteristics in the lake. In addition, given that the ultimate audience for

an environmental forensics investigation is not often scientists (an arbitrator, community representatives, a court of law), a map is familiar and easier to explain to a layman. Maps and aerial photos that include data can be simple and powerful tools in environmental forensics. If GIS capabilities are not readily available, then simple histograms can be used to illustrate the concentration changes in sampling stations away from a potential source location (e.g., with stations represented along the x-axis), accompanied by a map or aerial photograph for illustration purposes.

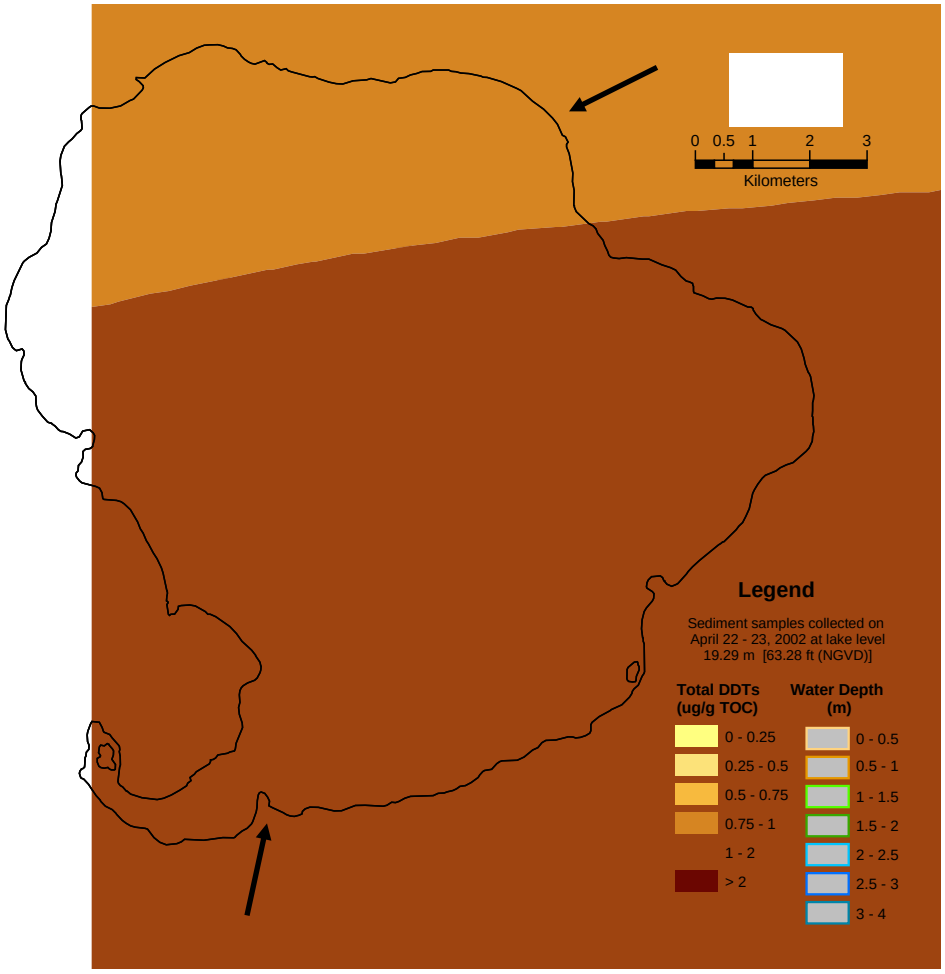

Figure 2-15. Florida Lake with Two Sources of Runoff/Input and Potential Sources of Contamination Indicated
(Contours indicate surface sediment DDT concentrations.)

It is usually important to understand the PCB concentrations both horizontally (i.e., surface sediment concentrations) and vertically (using sediment core data) to understand the history of the contamination. Histograms of sediment core concentrations, ideally linked to a year of contamination by incorporating sedimentation rate information (i.e., sediment dating data), are very useful (Figure 2-16). 3D extrapolations and contouring of sediment core data can further help in developing an understanding of the contamination (Figure 2-17).

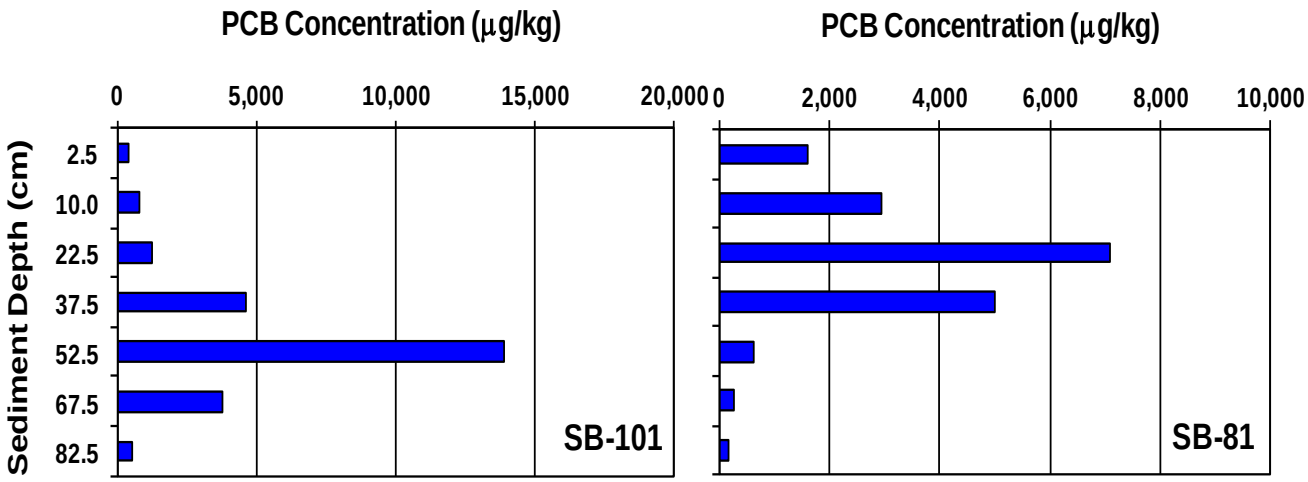

Figure 2-16. Total PCB Concentrations in a Sediment Core Collected on the West (SB-101) and East (SB-81) Side of Hunters Point Shipyard South Basin

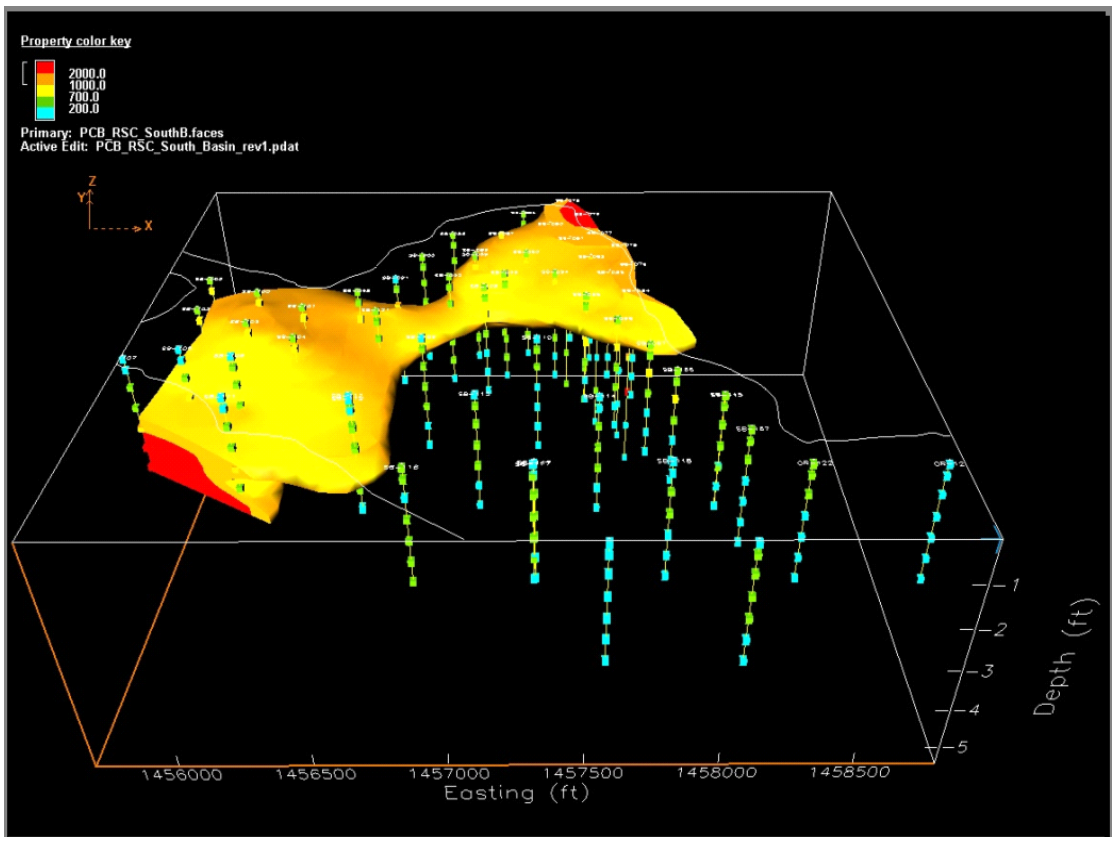

Figure 2-17. Illustration of Subsurface Sediment Total PCB Concentrations and Sediment Coring Locations in the Hunters Point Shipyard Study Area

2.5.3.4 PCB Composition

Once there is a good understanding of the overall PCB concentration distribution and characteristics of a site, the next level of detail in the analysis of the data usually comes with studying the *composition* of the PCB contaminating the sediment – the relative concentrations of the PCB congeners or homologues. One might assume that the PCB composition correlates with concentration gradients and this should then be confirmed as it would provide support to the initial assumptions about sources. If PCB concentrations and PCB composition do not appear to be closely related, then the compositional characteristics need to be more carefully studied and explained.

It is usually important to understand the PCB composition, like the concentrations, both horizontally (i.e., surface sediment concentrations) and vertically (using sediment core data) to understand the history of the contamination. If there is only one source, and that source has been the only source for a long time, the surface PCB composition is likely similar across the site. The subsurface PCB concentrations may be similar to the surface sediment composition if the source has been constant, or it can be altered depending on if dechlorination and other weathering factors have affected the composition. In sandy, aerobic sediment, there may be little alteration of the PCB composition over time (i.e., with sediment depth), although some reduction of congeners with a low level of chlorination has been shown to occur in some environments. However, in some highly organic and anaerobic sediment, with the appropriate microbial conditions, the PCB composition may change significantly over time (Figures 2-4 and 2-5), even if the source and PCB type (e.g., a specific Aroclor) have remained the same.

As with concentrations, it is important to consider what the PCB composition is, in general, across the site, how the PCB composition changes and how variable it is across the site, and determining if there are any PCB composition "hot spots" where the composition is particularly similar to a fresh Aroclor or Aroclor mixture, suggesting proximity to a source and recent contamination. The PCB composition information is then considered together with the PCB concentration information, the historical site information, and hydrology and contaminant transport, to further develop the understanding of the contamination and how it may relate to potential sources.

Compositional information is generally presented using simple bar graphs, and can be done using PCB homologue data presenting the relative concentrations of the 10 levels of chlorination (Figure 2-9), but is most often done using a larger set of PCB congeners (e.g., Figures 2-2 and 2-4). Analytical chromatograms can also be useful for compositional illustrations, but they are often more difficult to compare and decipher than "recreated" chromatograms using simple histogram plots. Comparing the sample compositional information to the composition of Aroclor formulations (see figures in Appendix A), or mixtures of Aroclors, can be useful to help better understand the contamination. Figure 2-18 shows the composition of 18 PCB congeners in sediment samples collected from the west and east sides of HPS South Basin, together with the composition for a mixture of Aroclor 1254/1260 and only Aroclor 1260. The PCB congener composition of the sample from the west side resembles that of the mixed Aroclor, but the sample from the east side resembles that of just Aroclor 1260.

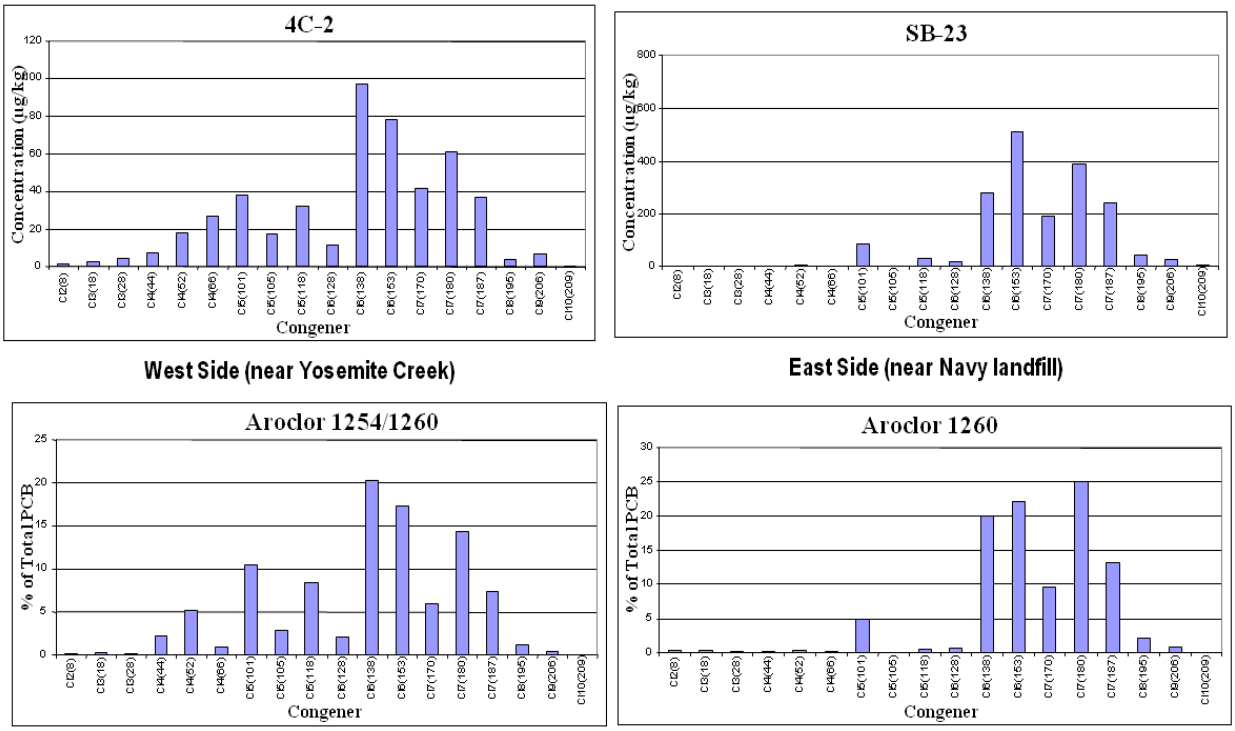

Figure 2-18. PCB Congener Composition in a Sediment Sample Collected on the West (4C-2) and East (SB-23) Side of Hunters Point Shipyard South Basin, and the PCB Composition in a Mixture of Aroclors 1254/1260 and Only Aroclor 1260

Another technique for illustrating compositional characteristics is to plot simple or double ratios of key diagnostic congeners – congeners with a concentration relationship that are resistant to change (i.e., stable congeners; Table 2-4) and unique to a source (e.g., an Aroclor), or that illustrate an active process (e.g., dechlorination/weather) but still can be associated with a source, or a combination of both. Diagnostic ratio analysis requires an in-depth understanding of the PCB chemistry and behavior of different PCB congeners, but when applied correctly can be a powerful technique (Figure 2-19). PCB compositional information can also be integrated with maps to further enhance the power of the information presentation. This can be done using a GIS system and illustrating diagnostic ratios (Figure 2-19) or PCB composition bar graphs for different locations directly on the map, or by presenting the compositional graphics accompanied by maps or aerial photographs.

While direct visual inspection of PCB composition and congener patterns is extremely useful and is often a valuable tool for gaining an intuitive insight into the source of PCBs in samples, it is often also useful to employ some statistical chemometric method, and generate some semi-quantitative similarity metric (Section 2.5.3.5). A similarity metric may assign a value to the degree of similarity between patterns, but no scalar measure will provide information on why or how two patterns differ. Visual pattern analysis allows the user to take qualitative information into account, and explain the observation from a PCB chemistry and environmental processes perspective, which ultimately is critical to the interpretation. Thus, regardless of the numerical methods used for pattern recognition and comparison, the data analyst is well advised to devote

significant effort to direct, visual inspection of congener patterns, and simple graphical presentation analyses. While there may be some comfort in reliance on an objective, quantitative similarity metric, it does not replace qualitative visual pattern analysis and the application of PCB chemical reasonableness considerations.

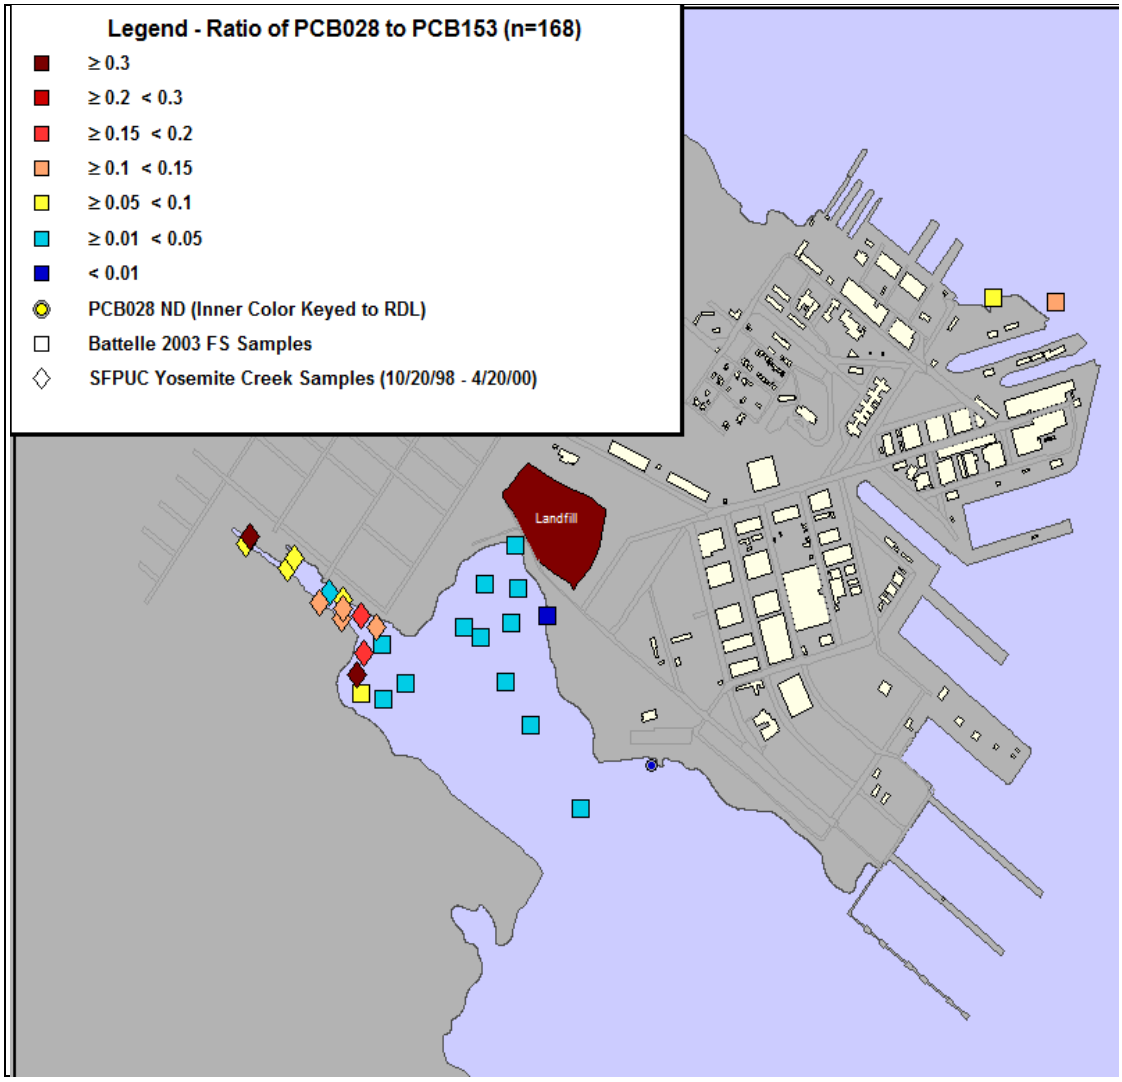

Figure 2-19. Ratio of PCB28 to PCB153 in Sediments near HPS South Basin

2.5.3.5 Chemometric Statistical Methods

Environmental forensics projects typically involve large chemical data sets with many samples and variables. This presents a data management and analysis problem: an inherently multivariate problem. There are numerous multivariate methods in the literature that are potentially applicable, a complete description of which is beyond the scope of this handbook. Three such approaches are presented: (1) cluster analysis, (2) PCA, and (3) mixing model analysis. Cluster analysis and PCA are perhaps the most widespread of these, primarily because of their ease of

use, and the fact that there are cluster analysis and PCA modules available in many different commercial statistical software packages. Mixing models can provide a more detailed insight into a PCB data set, but require more extensive experience, and are often available only as specialty software packages.

Cluster/Classification Analysis

Cluster analysis/classification refers to a general category of algorithms designed to classify samples into discrete groups or clusters. A PCB-related example of a cluster might be all samples in a data set with an Aroclor 1254 congener pattern. Samples that exhibited a different pattern (e.g., Aroclor 1242) would hopefully be grouped in a different cluster.

The most common of these methods is hierarchical cluster analysis (HCA). HCA is an exploratory method that operates on calculation of similarity between samples. Different mathematical criteria are used to group similar samples into clusters. The most common similarity metrics are based on distances calculated in multivariate space. In HCA, distances between individual samples are calculated. When distances between samples are relatively small, this implies that the samples are similar, at least with respect to PCB composition. The most similar samples are linked as a single cluster, and the process is repeated. Numerous linkage criteria/options are usually available in commercial software packages. Dissimilar samples will be separated by larger distances. HCA can be performed on either samples or variables (PCB congeners). The example that follows is HCA conducted in sample space.

The standard graphical method used for visualization of HCA results is the dendrogram. Figure 2-20 shows a dendrogram for HCA of PCB congener data from Lake Hartwell, South Carolina [8, 10]. This data set is composed of 237 samples (211 sediment samples, and 26 pure Aroclor standards), and 54 PCB congeners. HCA was run on samples. While difficult to read, each of the 237 sample names are listed down the left side of the dendrogram. The red lines link samples based on their distance (x-axis) from each other. Samples shown at the bottom of the dendrogram are very different from those at the top.

A hierarchical cluster approach will work well, provided that a data set is “hard-clustered.” In other words, HCA works well if one can safely assume that each sample belongs in one, and only one, cluster. In Lake Hartwell, this was not the case. Most samples were mixtures of two or three Aroclors, and/or were dechlorinated to some degree. As such, numerous samples that were mixtures of Aroclor 1242 and Aroclor 1254 did not cluster with either of the two Aroclor sources that contribute to it. The Lake Hartwell example is not at all unusual. More often than not, PCB forensics studies involve mixing multiple sources and/or weathering. As such, it is recommended to use hard cluster algorithms only in those instances where one can safely preclude mixing and weathering. HCA is readily available in many commercial statistical software packages, including Pirouette, Statistica, and SAS among others. Other classification methods have been described in the literature, which while not considered cluster analysis, are somewhat similar in that they seek to classify samples into discrete groups. One of these methods is SIMCA, which is available as a module in many software packages, primarily those that are focused on general chemometrics applications (e.g., Pirouette and Unscrambler).

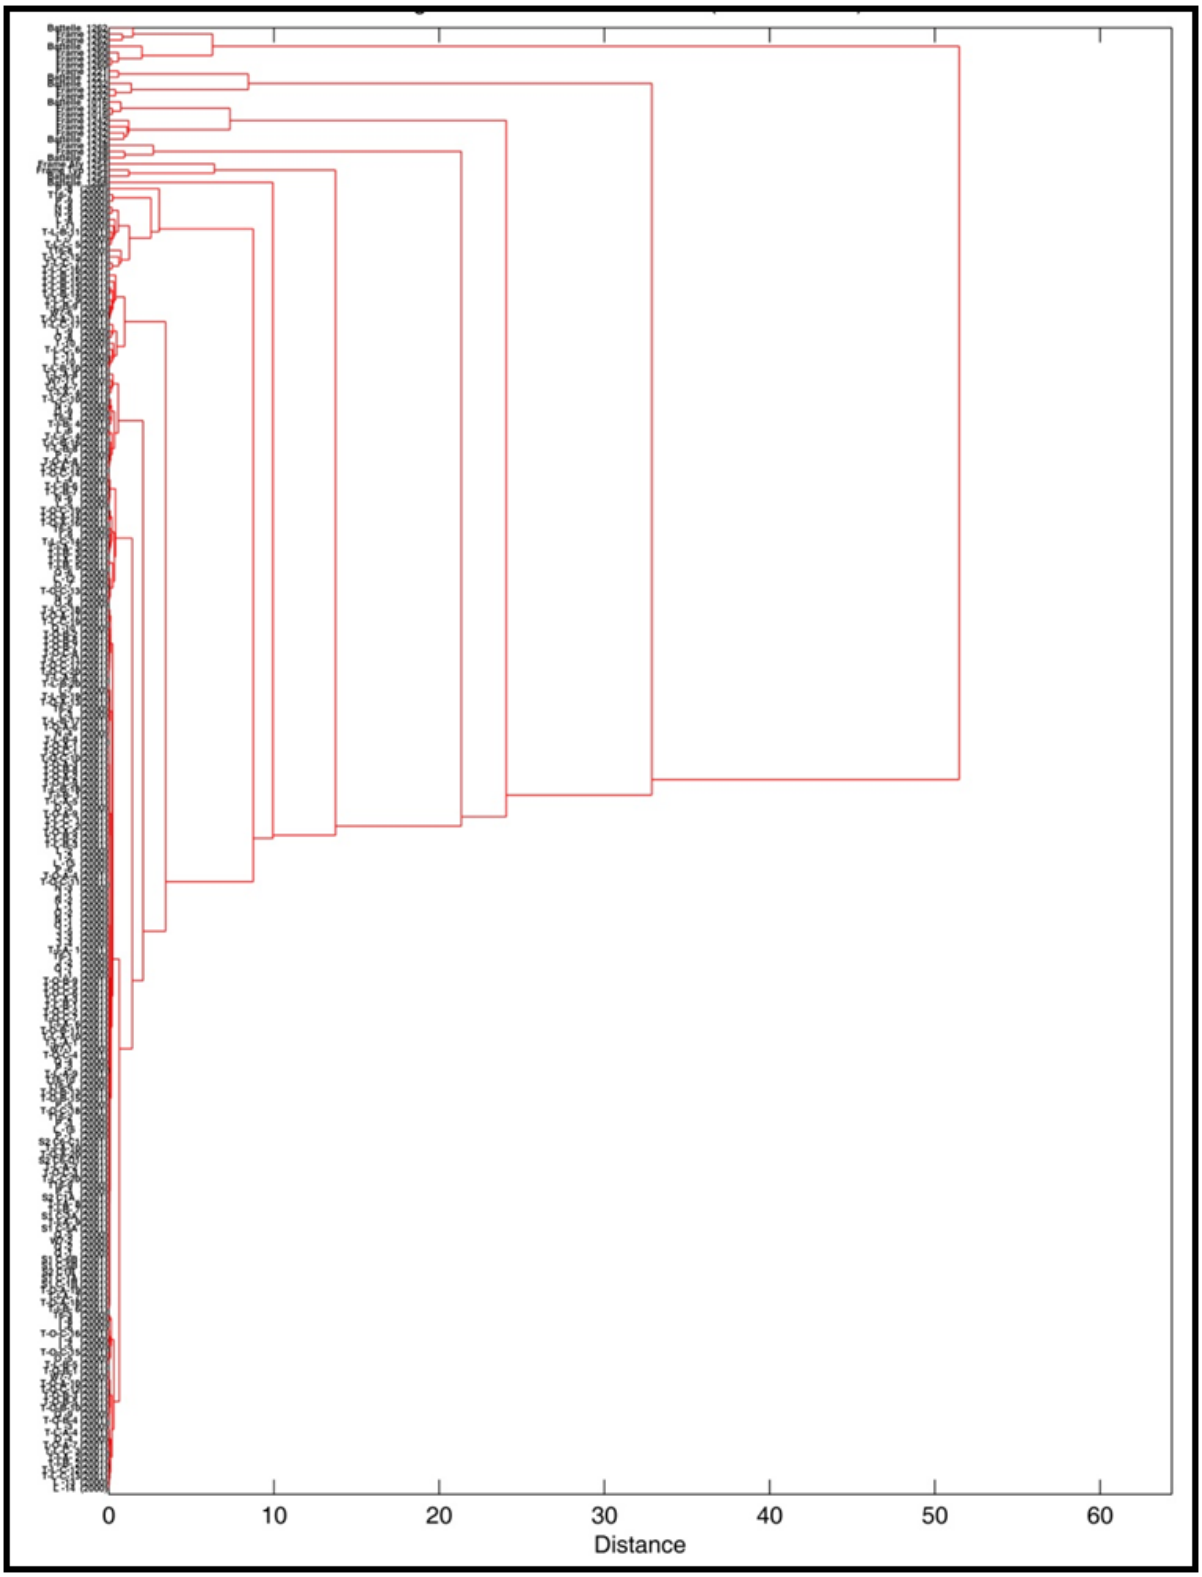

Figure 2-20. HCA Dendrogram of 211 Sediment Samples and 26 Aroclor Standards, Using Ward's Clustering and Euclidean Distance

Another alternative to HCA (especially if one is dealing with gradational data structures such as mixing and dechlorination) is fuzzy-c-means clustering (FCM [57, 58]). FCM is an exploratory data analysis method similar to HCA in that it operates on similarity between samples by calculation of Euclidean distance between samples. It differs in that it allows for a conceptual model of gradations between clusters. Thus, a sample that is a mixture of two Aroclors could be classified as having membership in two different clusters (e.g., a 0.50 membership in the Aroclor 1242 cluster and a 0.50 membership in the Aroclor 1254 cluster). FCM is not as widely used, and therefore is often not included as a module in general purpose statistical software packages. It is, however, available within the fuzzy logic toolbox for use with the software package Matlab.

Principal Component Analysis

PCA is commonly used in environmental forensics as a stand-alone exploratory data analysis method, and as an intermediate step in other chemometric methods (including SIMCA and receptor modeling methods). PCA reduces the dimensionality of a data set so that the similarities and differences between samples can be assessed by direct inspection of 2D or 3D graphs called "score plots" (Figures 2-21 and 2-22). These simple plots carry the advantage of being a single graphic that quickly provides the analyst a genuinely deeper insight into the PCB compositional characteristics of the samples in the system. An advantage of PCA over HCA is that the algorithm does not carry with it the implicit assumption of discrete classes or clusters. Rather, it offers a more objective visualization of the data. If the data are indeed hard clustered, that will be evident on a scores plot (Figure 2-21).

If, however, the data are not hard clustered, but are gradational/mixed, that will also be evident. It will not be hidden on an ambiguous dendrogram or confounded by inherent cluster assumptions. Figure 2-22 shows a scores plot for the same Lake Hartwell data shown on the dendrogram in Figure 2-20. It is now apparent that the vast majority of Lake Hartwell samples are gradational intermediates between pure Aroclor patterns or dechlorination end-products.

There is a natural appeal to being able to reduce such a large multivariate data to a simple 2D plot. However, to the inexperienced practitioner, there are a number of potential pitfalls. Contaminant sources and alteration mechanisms may be inferred from these simple 2D plots, but a more rigorous evaluation of the number of principal components that carry source-relevant information actually show even more. A typical PCA implementation may be limited by graphical limitations of two or three axis score plots. Potential pitfalls for PCA in forensics applications are discussed in detail by Johnson et al. [9]. Like HCA, PCA is readily available in many commercial statistical software packages, including Pirouette, Statistica, SAS, and Matlab.

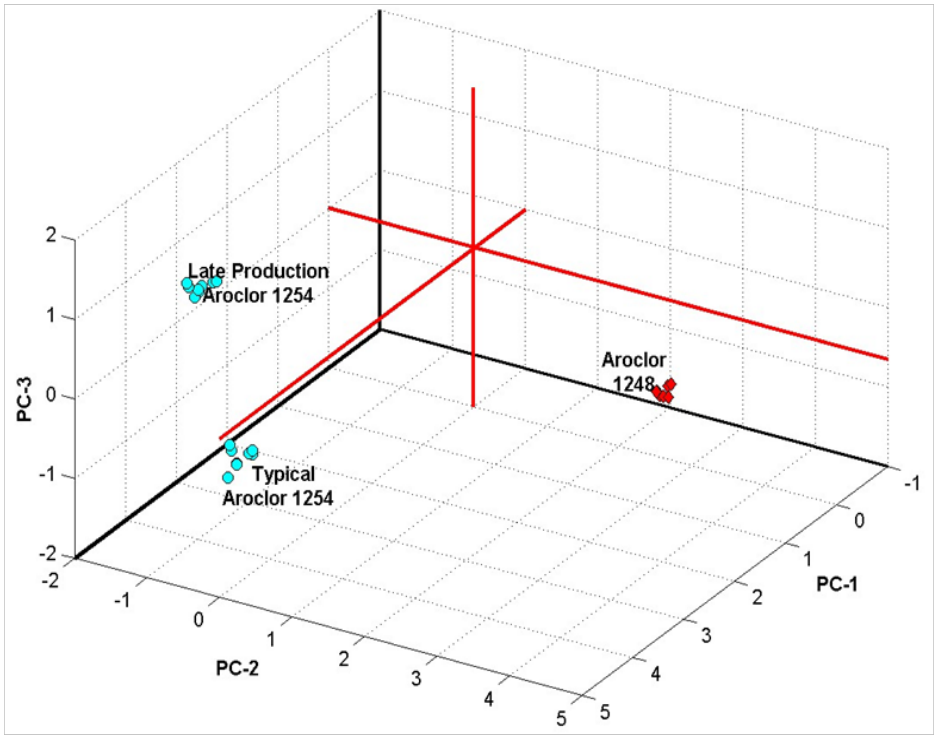

Figure 2-21. A Hard Clustered Three Source Data Set as Observed on a PCA Scores Plot (from Johnson et al., 2007 [9])

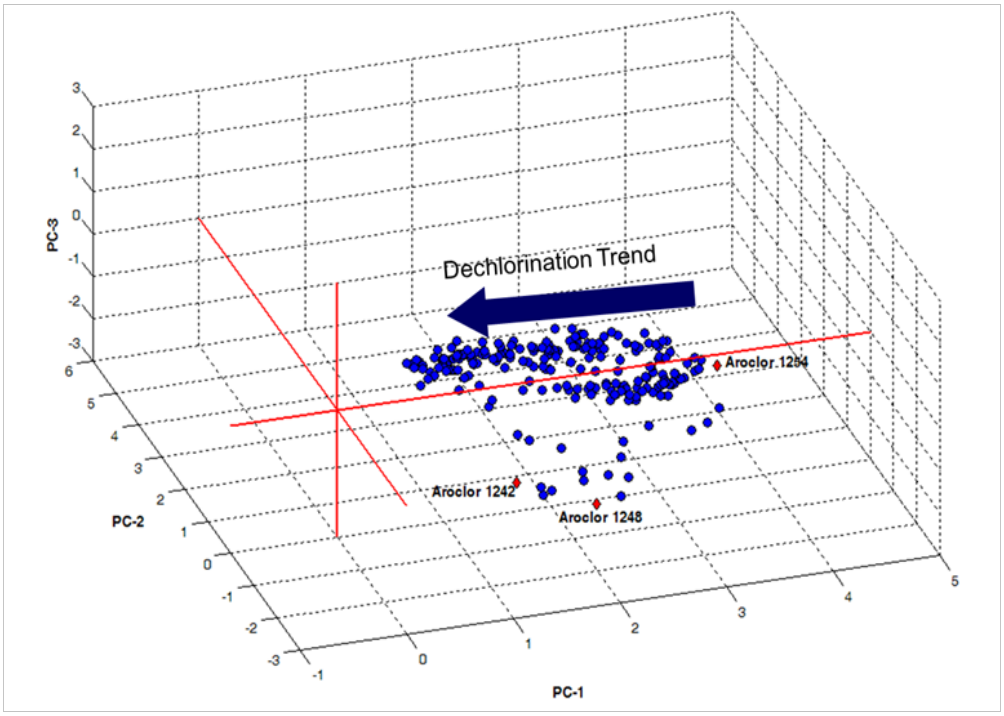

Figure 2-22. Lake Hartwell Data (from Magar, et al., 2005 [8]) Plotted on a Three-dimensional PCA Scores Plot

Receptor/Mixing Model Analysis

An increasingly common method used in environmental forensics investigations involves the use of receptor models. These methods are designed to resolve three parameters of concern in a multivariate mixed system: (1) the number of components in the mixture, (2) the identity (i.e., chemical composition) of each component, and (3) the relative proportions of each component in each sample. Stated mathematically, given a matrix X of m samples and n variables, and the unknown number of components k, one wishes to find a feasible solution to the following equation:

	X	=	A	F
Dimensions	(*m* x *n*)		(*m* x *k*)	(*k* x *n*)

Receptor methods often use PCA as an intermediate step to (1) determine the number of "significant" principal components (i.e., the number of sources), and (2) provide a reduced dimensional reference space for resolution of the model. The number of sources (*k*) essentially reduces the problem of choosing the number of significant principal components.

Within *k* dimensional space, receptor models then resolve the chemical compositions of the sources (F) and the contributions of the sources in each of the samples (**A**). If source compositions are known a priori, then those compositions may be used as the row vectors of **F** or as a training data set. Source contributions can be found via regression methods such as chemical mass balance.

However, in environmental forensics, one typically does not know and/or wishes not to assume such a priori knowledge of sources. For such situations, it is usually preferable to use a self-training receptor model method: a class of algorithms designed to resolve the number of sources, and feasible estimates of the multivariate source patterns and source contributions, without a priori assumption of sources. Receptor model methods in common use in environmental forensics include PVA [48, 49], MCR-ALS [51], PMF [50] and Unmix [59]. Application and comparison of these methods have been presented in the literature [9, 19]. These methods have some differences in the mathematics of their implementation, but all will provide estimates of contributing source fingerprints in a mixed system, without a priori knowledge or assumption of the number or chemical composition of those sources.

In addition to method comparisons cited in the literature above, the DoD Environmental Security Technology Certification Program (ESTCP) research that preceded development of this handbook [19] included a comparison of these four receptor model methods, as part of project performance objectives. That comparison included running these four algorithms on each of three data sets: (1) an artificial data recently published in the peer-reviewed literature [54]; (2) an artificial PCB data set originally published by [9]; and (3) the HPS data set. All four methods have since been analyzed on the second demonstration site data as well (Ashtabula), and reproduced the method comparison of the Henry data set below. The reader is referred to Johnson, et al. [9] for the method comparison applied to the Johnson data. The results of these methods applied to the two demonstration sites (HPS and Ashtabula River) will be included in the case-study discussions (Sections 3.1.7.5 and 3.2.7.5).

The Henry data set offered the advantage that it was created by two researchers that have published extensively on receptor model development and deployment, but who are not involved

in this particular project (the ESTCP research or the development of this handbook). Henry and Christensen [54] proposed a statistical performance criterion to measure the success of the methods that they tested: the standard deviation of the true source composition subtracted from the receptor-model estimated composition ($\sigma_{Est-True}$). This was adopted as one of the performance criterion for the method comparison exercise. Their published results were used for Unmix (the method Henry developed and has used extensively: [51, 56]) and PMF (a method Christensen has published on [34, 35]). For PVA, Dr. Glenn Johnson (co-investigator on this research) ran the Henry data set using Matlab code that he wrote and which he has used in many studies [5, 8, 10]. For ALS [51, 60] Dr. Scott Ramos (Chief Scientist at Infometrix, Inc., Bothell, WA) implemented the ALS. Dr. Ramos is also an experienced ALS practitioner [60]. The Henry data set is an artificial data set with 200 samples and eight chemical compounds, with 1% multiplicative error in the concentrations and three sources. The data set was included in the supporting information on the publishing journal's Web site (http://pubs.acs.org/journal/esthag).

Table 2-13 shows a comparison of true values of source compositions to those estimated by Unmix, three versions of PMF, PVA and ALS. As noted by Henry and Christensen, $\sigma_{Est-True}$ indicates that results from Unmix and the U.S. EPA PMF3 (with fpeak = -0.1) yielded estimated source compositions that were very close to true compositions ($\sigma_{Est-True} < 1$). PMF with other options chosen did not fare as well. The performance evaluation metric ($\sigma_{Est-True}$) was much larger. This observation is confirmed using the two similarity metrics from Johnson et al. [4]: $\cos\theta$ and $\boldsymbol{r}$. Similarity was low for B-PMF and U.S. EPA's PMF without f-peak. The estimated source compositions from PVA and ALS solutions (run by Johnson and Ramos) were added to this table. These methods also performed very well with low $\sigma_{Est-True}$ values, and $\cos\theta$ and $\boldsymbol{r}$ values ≥ 0.99 for all three source compositions.

Before concluding that any of these is the "best" method, note that one could argue that PMF performed among the best (see results for PMF3 with fpeak = -0.01) or that PMF performed the worst (see results for PMF NNLS; Table 2-13. There are many similarities between these methods, and "best performance" is not necessarily a function of the acronym one uses to label their method. Rather, it is often a function of options chosen, the expertise of the analyst, and their sensitivity to the data structure. The results of this method comparison were presented at the Society of Environmental Toxicology and Chemistry North America 31st Annual Meeting in Portland, OR [61].

This receptor model method comparison shows that given good quality chemical data (or data that have undergone rigorous QA/QC to identify and address any issues) these receptor model methods usually perform well and resolve similar source patterns and apportionment estimates. But like PCA, these methods require a certain level of experience and sensitivity to common environmental data structures. When faced with bad data, any or all of these methods can produce spurious results. One of the most crucial steps in the data analysis process is vigilant outlier detection and data cleaning. Even with good data, these methods can be problematic in the hands of an inexperienced user and/or a user without sensitivity to chemistry and environmental science. In the hands of an experienced practitioner, these methods should result in source patterns and contributions that are consistent.

Table 2-13. Comparison of True Source Compositions for Data Set 1 (Henry Data Set) with Values Determined from Unmix, PMF (four versions), PVA, and ALS

	compd #	True value	UNMIX	B-PMF NNLS	B-PMF penalty functions	EPA PMF3	EPA PMF3 fpeak=-0.1	Johnson Matlab PVA	Pirouette MCR-ALS

The use of receptor model methods are not as widespread as PCA and HCA, and are therefore not as commonly included in general purpose chemometrics software. Pirouette does, however, include an ALS module. A free Matlab version of ALS is available at the Web site of its developer (Roma Tauler http://www.ub.edu/mcr/ndownload.htm). A free version of PMF is available at http://www.epa.gov/heasd/products/pmf/pmf.html. The developer of PMF (Pentii Paatero offers a commercial version of the software with more features and options than the free version. Unmix is available free at www.epa.gov/heasd/products/unmix/unmix.html. A commercial version of PVA software was available for many years through one of its

developers, Dr. Robert Ehrlich. Current availability of the software is unknown. A Matlab version of PVA can be obtained from the authors of this handbook.

2.5.3.6 Integrated Data Analysis and Interpretation

Integrated data analysis and interpretation is the process of synthesizing information and interpretations from multiple lines of evidence to arrive at scientific interpretations that answer the key questions of a forensics investigation. Various lines of evidence are combined, compared, inconsistencies analyzed, and the "full story" developed. Lines of evidence typically considered include the site history, contaminant transport, PCB concentration distribution, PCB composition considerations, and chemometric statistical analyses, as described in Sections 2.5.3.1 through 2.5.3.5, in addition to conducting the chemical reasonableness assessment and incorporating less easily identifiable pieces and linking the information into one cohesive understanding of the sources of contamination.

Common lines of evidence based on the data that to be integrated and compared include:

- Typically congener patterns will have been analyzed in several different ways, including simple chromatogram inspection (Section 2.5.1.1) and one or more chemometric analysis methods. The inferred congener patterns identified by each of these methods should be compared for consistency across methods. In addition, the geographic distribution of the observed congener patterns should be compared. As an example, if an Aroclor 1242 fingerprint is observed in one specific area of the field by one method, is that in agreement with the geographic distribution for that pattern observed by another method.
- If congener pattern analyses result in inference of a source, determine if that conclusion is supported by concentration gradient mapping. One key tenant of environmental forensics investigations is that the highest concentrations are typically observed near sources or outfalls, but this should be supported by hydrodynamic and sediment transport data.
- Are the locations of sources as inferred through data analysis consistent with known site history? For example, if an Aroclor 1260 congener pattern was observed in high concentrations near a former electrical transformer manufacturing facility, all three independent lines of evidence (concentrations, congener patterns and site history) would support a transformer source interpretation because Aroclor 1260 was often used in transformers.
- If a congener pattern does not match any known Aroclor source patterns, it is often useful to review literature that describes alteration processes. Reference data for common PCB alteration mechanisms such as dechlorination and volatilization may be found in the literature [4, 16].

Ideally, this process leads to an internally consistent and lucid interpretation of contaminant sources and environmental history. However, this is not always the case. Often, there will be one or more ambiguous lines of evidence, and (hopefully) another line of evidence will shed light on that ambiguity confirming that it may not be of value in the overall analysis, and move the final interpretation in the right direction. There may occasionally even be independent lines of evidence that seemingly contradict each other. In such a case, integrated data analysis is

equally important, because in the process of evaluating multiple lines of evidence, an investigator may better decide which lines of evidence deserve more weight and why. The decisions need to be justifiable using sound science, with an understanding of PCB chemistry and reasoning related to the behavior of PCB in the environment often the most critical component. As with other aspects of this workflow, there are no prescribed steps for this task. In fact, the investigator will likely have most success if they are resourceful and creative in finding new lines of evidence that might help shed light on such questions.

Example of a multiple lines of evidence approach to integration of interpretations is provided with the two case studies conducted as part of developing this handbook: HPS (Section 3.1.7.6) and Ashtabula River (Section 3.2.7.6). The summary presented below in this section is from Lake Hartwell, South Carolina. The summary describes aspects of that study integrating multiple lines of evidence to arrive at a conclusion that might not otherwise be apparent. Specifically, aspects of the study where an integrated data analysis approach helped clear up an ambiguous story, or resolve seemingly conflicting lines of evidence are focused on.

A receptor model method (PVA) was used to resolve contributing PCB fingerprints [8]. Dechlorination pathway analyses were performed as part of that study to associate dramatically varying PCB composition across the site to a single source, and the elevated PCB concentrations could be associated with known high historic releases. One of the resolved source patterns in that analysis was consistent with published Aroclor 1248 congener patterns. When this information was compared to historical information, it was learned that the primary suspected source to the lake (a former capacitor manufacture) had not used Aroclor 1248, but had used Aroclor 1242. While these two pieces of evidence apparently conflict, a third line of evidence resulted in a simple, lucid and consistent story. Previously published empirical experimental data [30] had shown that weathering (volatilization) of Aroclor 1242 could result in a residual pattern in sediments that more closely resembles Aroclor 1248 than the original Aroclor 1242. As a result, the apparent Aroclor 1248 fingerprint was entirely consistent with an Aroclor 1242 source. The PCB pattern in buried highly dechlorinated samples, which did not resemble any Aroclor, was also linked to Aroclor 1242 and the primary source through dechlorination pathway analysis.

Data Analysis and Interpretation

This section presents an overview of the data analysis and interpretation, including the inclusion of information other than PCB data, data preparation, and PCB data interpretation.

- **Site History and Records Research**
- **Sediment Transport and Hydrodynamics**
- **Preliminary PCB Concentration Assessment**
- **Preliminary PCB Composition Assessment**
- **Chemometric Statistical Analysis,** such as
    - Cluster analysis
    - Principal component analysis
    - Mixing model analysis

2.6 Presentation and Reporting

The presentation of results of a PCB forensics investigation will vary greatly, depending on the purpose and the venue. For example, given two projects that involve identical technical issues, the context of one might require verbal reporting, where the other might require a detailed technical report. In terms of presentation of results, there are a few guidelines that apply and can be used for most purposes. It is important to find an effective means of data visualization. Standard graphical presentations (e.g., histograms) of concentration and composition information can be useful, and any GIS-based illustration of the contamination and unique signatures are especially useful (e.g., Figures 2-15 and 2-17). Most statistical software packages include standard graphical output for data analysis results (e.g., cross-plots, score plots, loadings plots, etc.) but these graphics may mean little to the non-user and may require simplification; it is important to produce graphics that are intuitive to a non-scientist. The primary objectives of a PCB forensic investigation are identification of contributing chemical patterns (i.e., Aroclor sources and/or alteration patterns) and their geographic and temporal distribution. Summarizing historical industrial practices and local activities that can explain the observations, and using hydrological information to describe how sediments and potential contaminants move around in the system, can also be important to support the PCB chemistry. When describing the findings, it is useful to do so in a step-wise fashion, clearly lining up multiple lines of evidence, showing how they point towards the same findings and support each other.

As discussed in the beginning of this section, the format for presentation of results depend largely on project context and target audience/reader. The following scenarios may involve the exact same technical approach and forensic investigations, but the context of the project dictates different presentation formats.

If the audience does not have extensive technical knowledge (e.g., the public, managers, lawyers), it is likely that they are not intimately familiar with environmental chemistry, statistics, or PCB industrial history. Therefore, a presentation to this audience may require an element of introductory chemistry, statistics, and/or industrial history. In addition, the first communication of results is then often verbal, rather than written. Therefore, the presentation format is less formal than a report (e.g., a conference call, or a face-to-face meeting, perhaps with PowerPoint slides).

A second common context is a presentation to other scientists. This is likely a more formal context than the first example. However, the approach to the presentation will also be different in other ways. In a more technical context (among peers), it is assumed the audience knows much of the prerequisite science. A paper or presentation will then include a great deal of technical short-hand. In this venue, one may summarize important foundational material with no more than a citation at the end of a single sentence summary.

A third, and again, completely different example is a venue where contributions from multiple sources are not widely understood or agreed-on, and is common for forensics investigations. This may include what could be considered expert opinion, and to support that the expert is more likely to produce a report that errs on the side of completeness, even if it means a pedantic narrative and extensive appendices.

3.0 DEMONSTRATION CASE STUDIES

3.1 Site I: Hunters Point Shipyard

3.1.1 Site Description

The HPS site is located in the San Francisco Bay as shown in Figure 3-1. HPS is a former Navy installation located on a peninsula in the southeast corner of San Francisco, CA. The peninsula is bounded on the north, east, and south by San Francisco Bay and on the west by the Bayview Hunters Point district. HPS comprises about 955 acres, with approximately 457 acres of offshore sediment (Parcel F). From 1945 to 1974, the Navy maintained and repaired ships at HPS. The facility was deactivated in 1974 and remained relatively unused until 1976, when it was leased to Triple A Machine Shop, a private ship repair company. In 1986, the Navy resumed occupancy of HPS. The facility was closed in 1991 under the Defense Base Realignment and Closure Act of 1990 and is in the process of conversion to non-military use.

The shipyard is divided into several parcels with the offshore sediments designated as Parcel F. The specific area of interest for a PCB forensics investigation is the Parcel F (offshore) sediments near Parcel E and E-2 in the South Basin (Figure 3-1). This area is shown in more detail in Figure 3-2, where it is labeled Area X. South Basin's current configuration reflects filling activities that took place from the 1940s to the 1970s (Figure 3-3). Previous studies have shown potential PCB source areas associated with the former Navy landfill and multiple CSOs in nearby Yosemite Creek. Of particular concern is whether these different sources have contributed PCBs to sediments in the South Basin area, and to what degree. This site has been under regulatory study and RI/FS has been completed as part of the CERCLA program. The data used in this case study example were collected as part of the RI/FS study, most of it from a comprehensive data gaps investigation [62].

South Basin is a shallow embayment on the south side of HPS, with water depths ranging from 6 ft to less than 2 ft. No streams or rivers enter South Basin except for Yosemite Creek, a shallow, tidally-influenced channel with no permanent flow. Circulation in South Basin is restricted and tidal currents are very weak. The basin is open to the southeast, which is the direction of the maximum winds during winter storms. Although the prevailing winds in the area are westerly, the acute storm waves responsible for sediment resuspension are generated by southeast storm winds. Yosemite Creek enters South Basin at the southwest corner of HPS. Yosemite Creek is listed as a site of concern under the Bay Protection and Toxic Cleanup Program in 1997. Prior to 1965, three CSOs discharged to this area: one at the head of Yosemite Creek (Figure 3-2), one on the north side of the creek near Griffith Street, and one on the south side near Fitch Street. All wet weather overflows were directed to the CSO at the head of Yosemite Creek after 1965. Contaminants identified during investigations of Yosemite Creek by the City and County of San Francisco included PCBs, PAHs, pesticides and metals.

(Note Former Landfill to the north and City Outfalls to the west.)

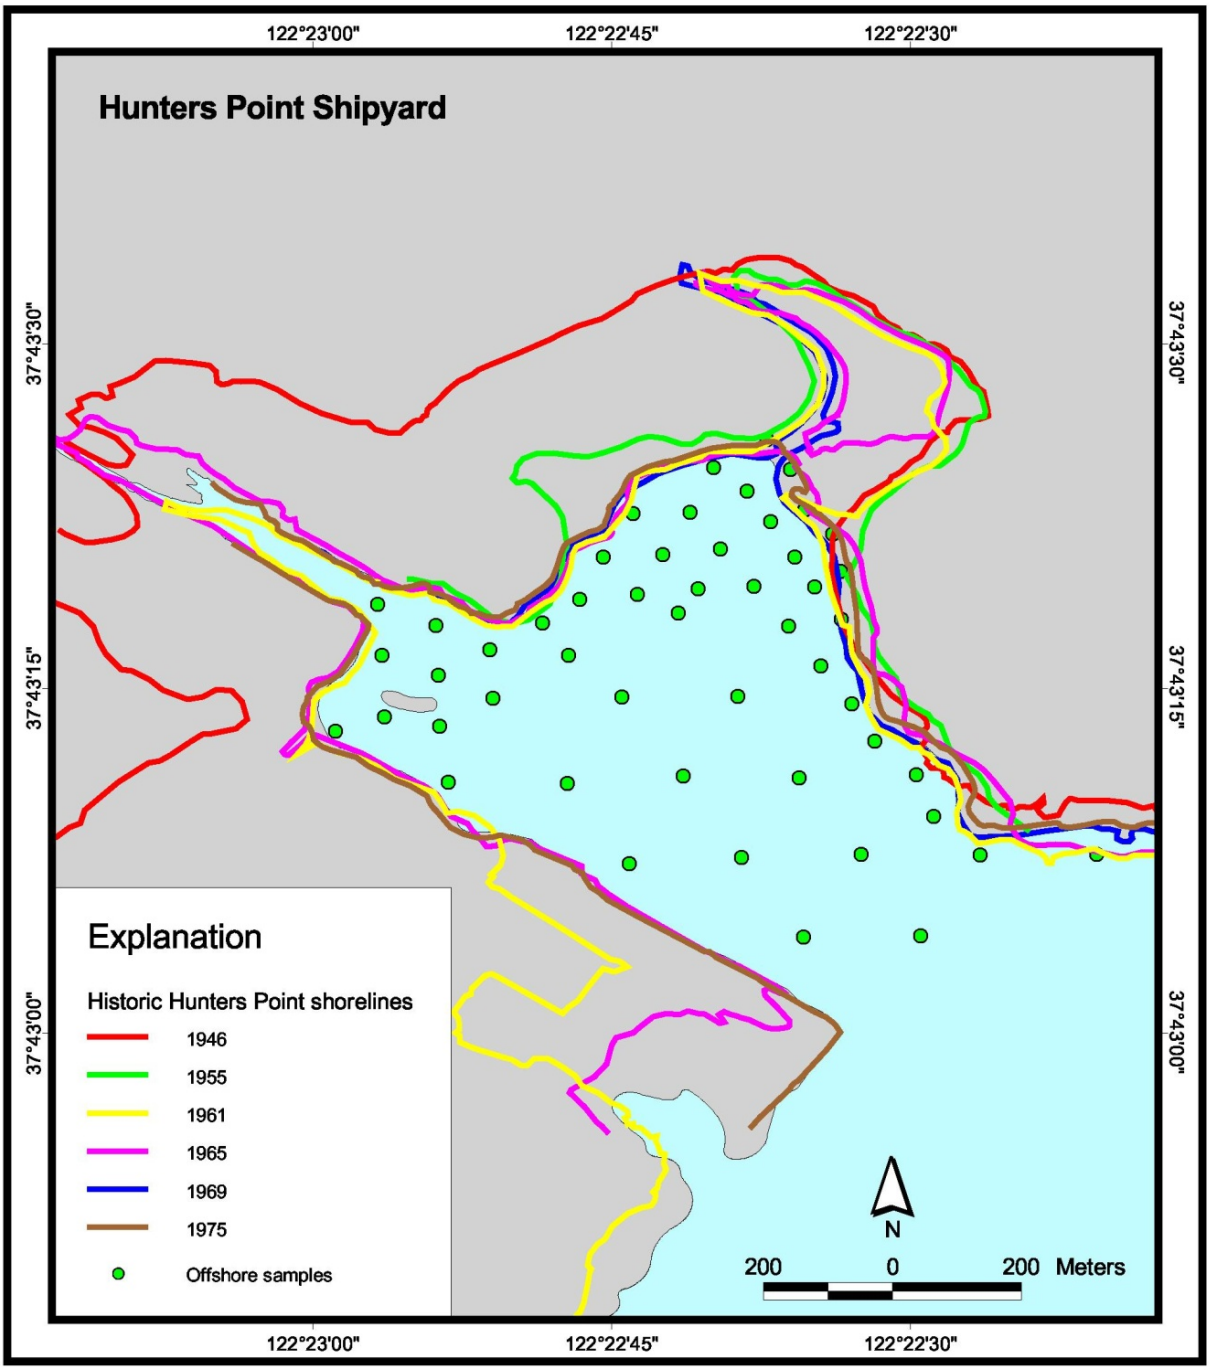

Figure 3-3. Shoreline Evolution in HPS South Basin and 2003 Offshore Sample Locations

3.1.2 Evaluate Site for Forensic Study

To evaluate whether the site is a candidate for a forensic study, the questions posed in Section 1.2.1.1 should be answered. The HPS site has a former landfill in Parcel E-2 (near the northeastern shore of South Basin; Figure 3-2) with records showing wastes (including transformers with PCB oils) deposited at the site from the 1950s through the 1970s. Other records indicate that PCBs with an Aroclor 1260 composition have been detected in some groundwater wells near the shoreline. Related to Questions 2 and 3, there have been known discharges from CSOs in and near Yosemite Creek, and previous studies by the City of San Francisco [63] have shown sediments upstream in Yosemite Creek contain PCBs with both Aroclor 1254 and 1260 contamination. Addressing Question 4, there was a sediment transport study conducted as part of the RI/FS [31, 62] that shows South Basin to be a relatively quiet depositional basin with occasional wind derived local resuspension and local redeposition. This conclusion is further supported by the persistent PCB concentration gradients shown in the sediment contour maps in later sections of this handbook. For Question 5 (i.e., how amenable regulators would be to the use of forensic information), the answer varies depending on when in the process such information would be used. There was a consensus early in the RI/FS process that a forensics study would be useful, and there were plans to incorporate such a study in the RI/FS. Later, there were questions from both the regulators and the Navy about whether they could use such a forensics study at HPS. After the samples for the RI/FS were collected, it was decided not to complete the forensics study as part of the RI/FS. The information from the HPS site was available for use in this handbook to help promote the use of forensics studies at Navy sites, but a dedicated PCB contaminant forensics investigation has not been conducted at HPS. The data generated in the RI/FS, and used in this handbook, support the contention that there appear to be at least two potential sources for PCBs to the offshore sediments in South Basin (one from the former Navy landfill area and one possibly from CSOs in the Yosemite Creek area) and a forensics study could defensibly document this and better understand the relative contributions from the multiple source to the offshore sediments.

3.1.3 Develop Conceptual Site Model

Figure 3-4 shows a contour map of surface PCB concentrations, based on ELISA IA RSC analysis, that assisted in early CSM development at HPS. These data were collected early in the regulatory RI/FS project, and they suggest a potential PCB source in the northeast along the Navy shoreline near the former landfill. An additional source is also suggested at the creek on the west side of the site where PCB concentrations are also elevated. Other data from CSOs in and near this creek have shown PCB levels similar to those along the Navy shoreline. The sampling design for a forensics investigation should therefore be placed strategically to confirm that these two areas represent sources and also in other areas (for example along the south shore of South Basin where construction of Candlestick Park Stadium may have contributed contamination) to ensure that there are no additional unidentified sources to the offshore sediments in the area. Samples should also be placed in all areas of comingling sources and where it is appropriate to determine source contribution and apportioned, for the Navy to share or recover any remedial costs.

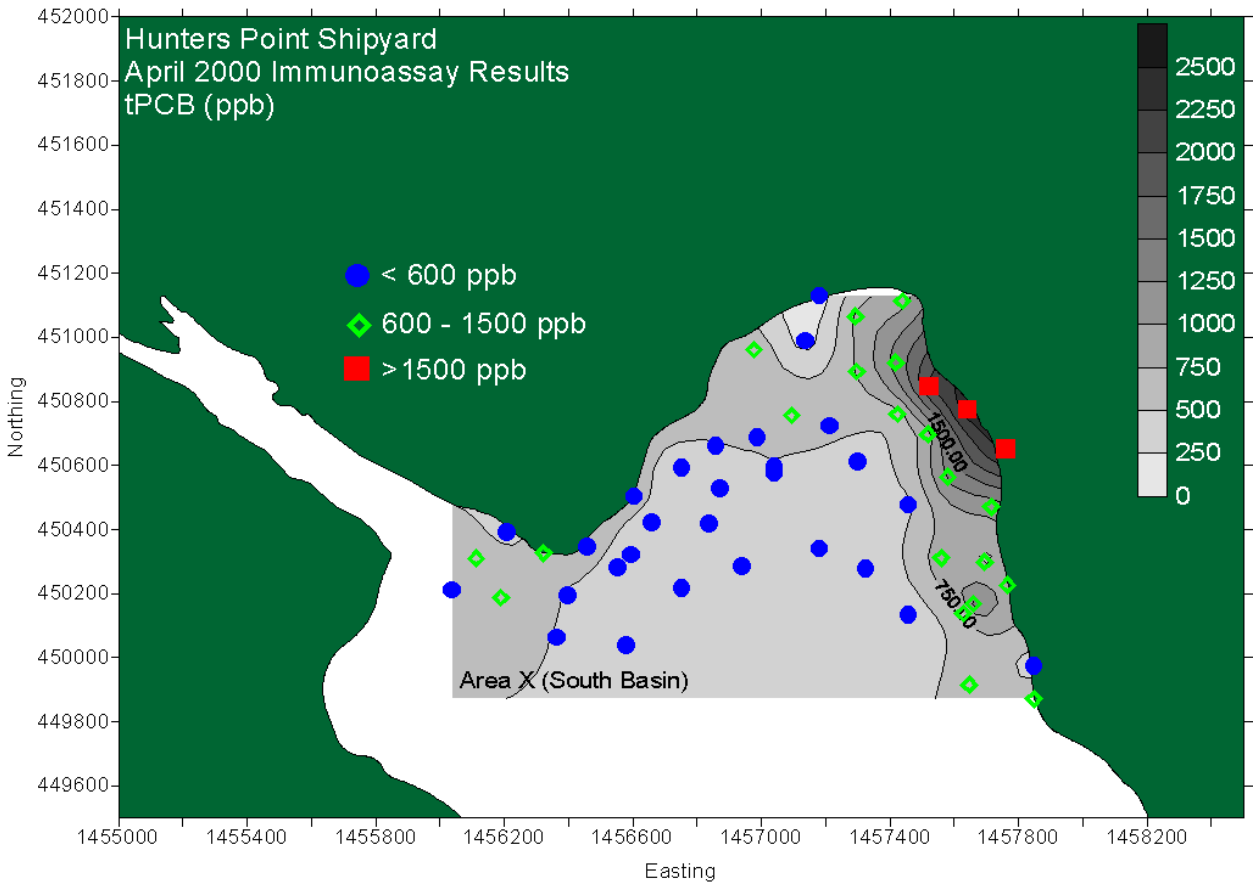

Figure 3-4. Contour Map of PCB Concentrations in Surface Sediments in South Basin at HPS

Since this case study was not a stand-alone project, there were no resources to conduct extensive records research and build a separate CSM. However, a CSM was developed by the regulatory RI/FS program (Figure 3-5) and could be used for some project considerations. The major pathways for PCB contaminant transport to the South Basin sediments are indicated as originating from: (1) historic filling and disposal practices associated with the landfill area, which allowed PCBs to be transported via the historic slough, or channel, out into the South Basin sediments; (2) releases from CSO outfalls in Yosemite Creek area (shown as active red arrows) transports PCBs out into sediments; and (3) erosion of contaminated fill that was used around Yosemite Creek releases PCBs into the sediments. One might consider making the minor active pathway arrow from the "Shoreline Erosion/Runoff" box to the "Sediment" box into a bolder major pathway arrow, indicating the potential for PCB releases from erosion of the fill material along the beach in front of the former landfill. This may be the major continuing active source (although current plans include a removal action to remove this contaminated beach material and stabilize the shoreline) based on the high surface sediment concentrations observed in this area (Figure 3-4). This CSM serves to focus the SAP in the next section, by identifying the locations where samples should be taken to answer the forensic questions raised during development of the CSM.

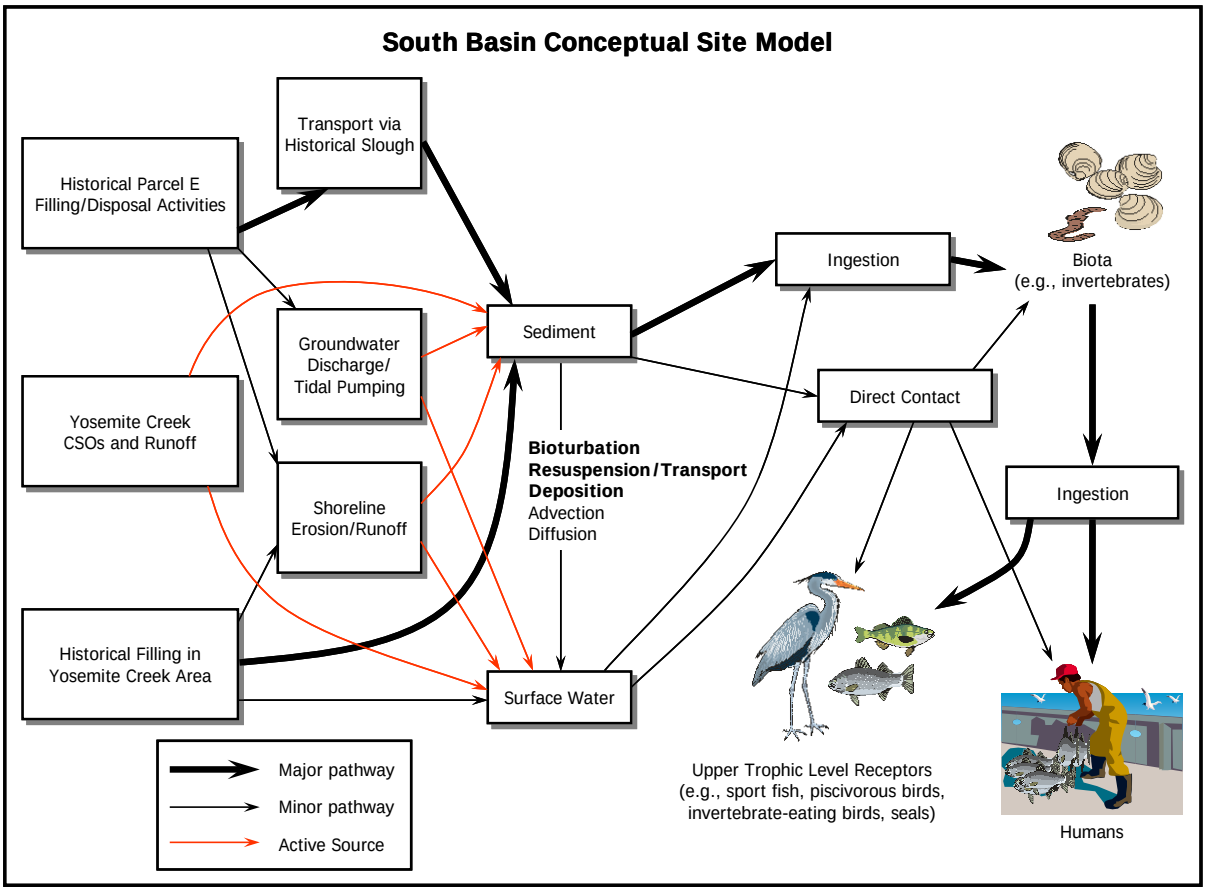

Figure 3-5. HPS South Basin CSM from Regulatory Program RI/FS

3.1.4 Develop and Execute a Technically Defensible Sampling Plan

In the HPS case, the regulatory RI/FS project included a grid design for samples with spacing that would allow for the detection of hotspots larger than a predetermined size. This grid sampling design is shown in Figure 3-6. Higher density sampling is seen in the potential source areas with lower density in the farther offshore sediments. Figure 3-6 also shows the core intervals that would be composited for initial RSC analysis, with only a subset of these samples being later analyzed for ACF. This resulted in about 400 samples being analyzed for RSC and about 100 samples for ACF. Unfortunately, the regulatory project was restricted to sampling primarily on Navy property, so no samples were collected further upstream in Yosemite Creek near several CSOs that were additional potential sources. In addition, additional samples in the zone where the PCB sources are well mixed would have benefitted a forensics investigation.

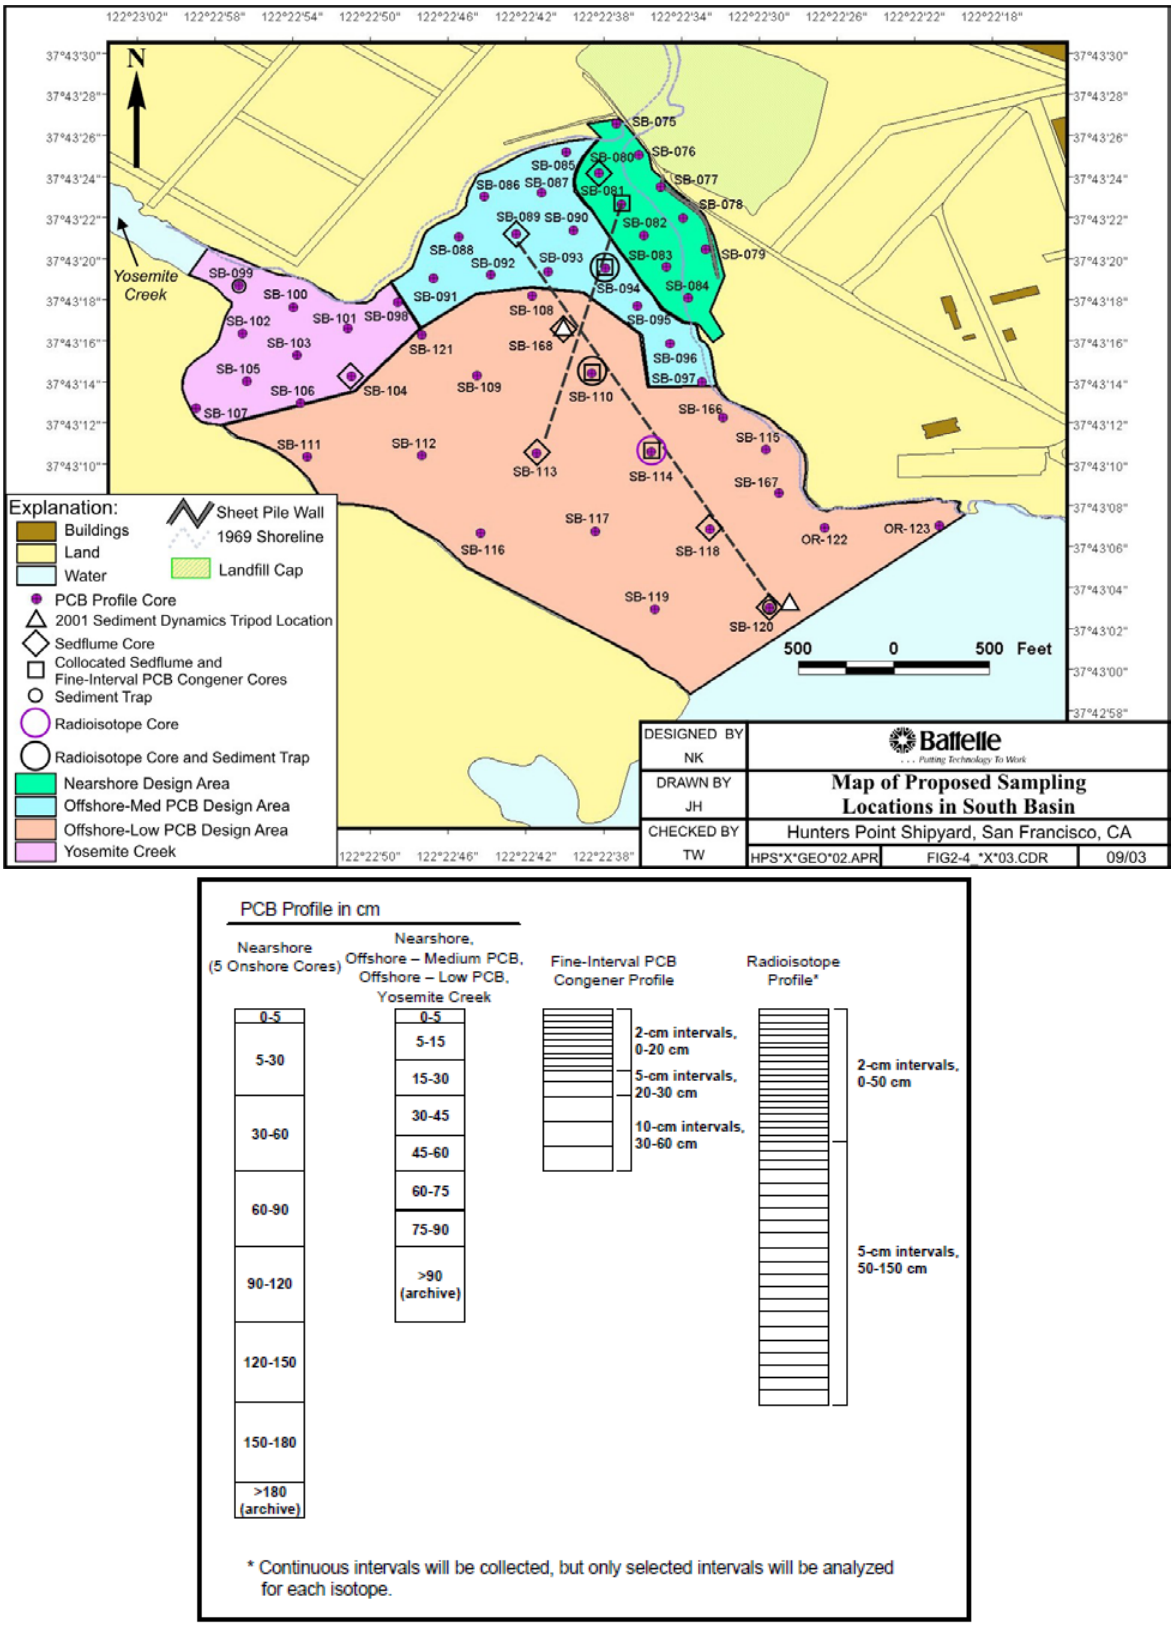

Figure 3-6. Sampling Design Map for the HPS Feasibility Study [62]
(This includes the cores that provided the data used in the forensics demonstration at HPS.)

The HPS case study is based on using existing data from study designs that had not been optimized for a forensics investigation. There are clearly advantages and limitations of designing a forensics study with only pre-existing data. Although using pre-existing data provides a large cost savings, the shortcomings of not being able to design a sampling plan to collect all the samples desired must be accepted. As stated earlier, even in the best designed forensics study, there are likely to be surprises, such as those seen with this case study using only pre-existing data. For example, if additional sources are indicated by some of the study samples (e.g., Yosemite Creek), then there is a need to conduct additional sampling and analysis to identify such sources. That has not been conducted for the HPS site. So although it may be easier to grasp a forensics study that follows a linear process (Figure 1-1), it may be more realistic to assume the process will be iterative with a need to obtain information on additional unknown sources, and fill in additional information gaps.

While it is cost-effective to use pre-existing data (no additional field or analytical costs), the limitations are that the study design may not meet all of the objectives of a well executed forensics study. Fortunately, in the HPS case, the study plans, although not intended to satisfy a forensics study, did include relatively detailed sediment sampling and rather comprehensive PCB congener analysis; significantly more useful information was produced than would be typical in a standard RI. However, detailed sampling and analysis in proximity to a potential second source is missing.

3.1.5 Conduct Rapid Sediment Characterization

For HPS, the ELISA IA technique was used to obtain the RSC data, generating a comprehensive data-set of Total PCB concentrations. The HPS study was tiered, as described earlier, with the 450 RSC analyses followed by a smaller subset of 120 ACF analyses of frozen archived splits. The RSC data were used to generate the contour maps that aided in selecting the ACF samples. The HPS RSC data are summarized in Appendix C. The HPS RSC Total PCB data compared well with Total PCB based on laboratory congener analysis; the laboratory-based Total PCB determination was made by the widely used approach of summing the concentrations of the 18 NOAA National Status and Trend monitoring project congeners, and multiplying that by two [62-63]. On average, the RSC results provided a Total PCB concentration approximately 12% higher than the laboratory congener-based Total PCB analysis (Figure 2-8). This is as can be expected, since the RSC analysis kit "as received" uses Aroclor 1254 as the calibrant, and the HPS samples contained significant amounts of Aroclor 1260 type contamination, which has a greater response than Aroclor 1254 (Table 2-6). This response difference can be corrected for, as discussed in Section 2.4.1, by either calibrating with an Aroclor standard that better represents the Aroclor composition of the field samples or by using a correction factor that represents the response correlation (Figure 2-8). However, these adjustments to the RSC data are not needed as long as the data are mainly to be used to gain a general understanding of the Total PCB concentrations across the site (Figures 2-16 and 2-17).

3.1.6 Conduct Advanced Chemical Fingerprinting

The ACF analysis of the HPS sediment samples consisted of determining the concentrations of 44 PCB congeners using modified Method 680/1668 (a HRGC/LRMS analysis technique), as described in Sections 2.4.2 and 2.4.3. Again, the HPS study was not conducted as a forensics investigation, but the ACF analyses were conducted on a subset of the RSC samples following

review of the full RSC dataset. In addition, the 44 PCB congeners were selected primarily to generate data that were comparable to historical data for San Francisco Bay, and not for forensic purposes. The HPS ACF data are summarized in Appendix B.

During the data review and screening (Section 2.5.2.3) about 14 of the 120 samples were identified as candidates for potentially excluding from the data analysis because of lower data reliability (e.g., low overall PCB concentration [e.g., sum of congeners less than ~50 to 100 ppb] and a high percentage of the 44 PCB congeners with non-detects). Six PCB congeners were also identified as potential candidates for exclusion from the data set prior to detailed data analysis because of possible reliability issues (e.g., high percent non-detect of the congener, low congener concentration, a high %RSD in the percent contribution of the congener to the Total PCB, or other data outlier issues).

3.1.7 Data Analysis, Synthesis, and Presentation of Results

3.1.7.1 Site History and Records Research

The specific area of interest for the PCB forensics investigation was the Parcel F (offshore) sediments near Parcel E and E-2 in the South Basin; the area labeled Area X in Figure 3-2. Previous studies have shown potential PCB source areas associated with the former Navy landfill and multiple CSOs in nearby Yosemite Creek. Historical activities in adjacent upland Parcel E-2 that may have contributed to contamination of sediments in South Basin include filling and disposal activities, residual onshore contamination, and surface runoff. Groundwater discharge was also evaluated as a potential transport pathway of PCBs to South Basin from Parcel E-2, however, the magnitude of PCB release via this pathway is not likely to be significant given the limited extent of PCBs detected in groundwater and their low solubility. A former landfill at Site IR-01/21 in Parcel E-2 (Figures 3-1 and 3-2) was used from 1958 to 1974 for the disposal of materials such as construction and industrial debris and waste, domestic refuse, sandblast waste, paint sludge, solvents, waste oils, transformers and electrical equipment and other potentially contaminating materials. No records that document landfill contents or disposal practices are available. In the mid-1970s, the Navy placed 2 feet of compacted imported fill on top of the landfill and graded the entire site to facilitate storm water drainage. In the 1990s, a sheet pile wall was installed and riprap was placed along the Parcel E-2 shoreline to control the movement of contaminants into South Basin. In 2001, an interim landfill cap was constructed and placed over most of the landfill. The cap consists of a multilayer system of sub-base soil, high density polyethylene membrane, synthetic drainage layer, and topsoil.

South Basin was originally a marshy wetland area. Its current configuration reflects filling activities that took place from the 1940s to the 1970s. Figure 3-3 shows the South Basin shoreline in 1946, 1955, 1961, 1965, 1969, and 1975. The shoreline positions were mapped by digitizing historical aerial photographs. The greatest period of land expansion was between 1946 and 1955, in which the northern, western, and southern portions of the basin were filled, forming the areas now occupied by Parcel E-2, Yosemite Creek, and Candlestick Point, respectively. The second largest period of land expansion occurred between 1965 and 1969, in the northern part of South Basin. This fill event formed a slough, apparent in the 1969 (blue) shoreline contour, through the middle of the waste disposal area now known as the Parcel E-2 landfill. This slough, or channel, drained an unmarked outfall located at the north end of this channel up behind the marked landfill boundary. By 1975 (brown color), this outfall was closed off and the slough had

been filled; today's shoreline is virtually the same as the 1975 contour, and therefore is not shown. Between each recorded shoreline, it is uncertain when each fill event occurred. The sources of material used to fill these areas are not documented. The Navy operated the shipyard during the periods of the major filling events. The property was leased to the Triple A Machine Shop after the current shoreline was established (ca. 1975).

The historical information suggests that there could be sources of PCB from activities at the Navy facility, contributing PCBs to the northeastern side of Area X in South Basin (Figure 3-2), particularly from the landfill near that shoreline and the historical slough that discharged to that area. Historical information also suggests that there could be sources of PCBs associated with runoff to Yosemite Creek, and historical CSOs that discharge into Yosemite Creek and to the west just outside the mouth of Yosemite Creek (Figure 3-2). Review of historical records shows that there were commercial and industrial activities along city streets just north of Yosemite Creek, including a drum recycling facility. The Consent Decree shows that drum recycling activities at the site from 1948 to 1988 likely resulted in releases of PCBs that may have served as a source for PCB contamination to surrounding areas.

3.1.7.2 Sediment Transport and Hydrodynamics

At HPS, a leveraged sediment transport study was conducted as part of the RI/FS, and is reported as a case study in Appendix B of Blake et al. [36]. Sediment stability and transport studies were also conducted as part of the RI/FS data gaps investigation [62]. Blake at al. reported that "PCBs tend to adsorb to fine-grained sediment particles and organic matter, so sediment transport processes (i.e., resuspension, transport, and deposition) are important contaminant transport pathways in South Basin. Because of its restricted circulation, tidal currents in South Basin are very weak. Waves are likely to be the dominant sediment resuspension mechanism because the basin is shallow and open to the southeast, which is the direction of the prevailing winds during winter storms. The primary source of sediment to the basin appears to be suspended sediment from San Francisco Bay; shoreline erosion may contribute some sediment. The basin appears to be a net depositional environment with a net accumulation rate of about 1 cm/yr. The dispersal pattern of PCBs, with higher concentrations near shore and decreasing concentrations offshore, is consistent with wave-influenced and tidally influenced sediment transport. Storm waves breaking along the shoreline suspend fine, low-density sediments in the near shore region. A return flow near the bottom of the water column (balancing the shoreward flow due to waves at the surface of the water column) transports the sediments away from the shoreline and into South Basin. Tidally induced currents may facilitate additional transport across the mudflats and extend the influence of waves further offshore during low tide, potentially carrying material further offshore into South Basin. The deposition of cleaner background sediments transported in from San Francisco Bay and deposited in South Basin results in the dilution and burial of the nearshore and offshore sediments. As new sediments are deposited, mixing processes (physical and biological) act to mix surface and subsurface sediments, resulting in the gradual decrease in surface PCB concentrations over time. The smooth vertical PCB profiles in sediment cores (i.e., gradual increase and then decrease in concentration with increasing depth) indicate that overall, the sediment bed in South Basin appears to be relatively stable and undisturbed."

Sediment stability work conducted in South Basin is also reported in Battelle et al. [62]. The primary purpose of this work was to determine the erosion and deposition characteristics of the South Basin to estimate the fate of the contamination in the sediments, assuming sources were controlled and background level sediments were depositing. The average net deposition was determined to be approximately 1 cm/yr, and the most contaminated zone was expected to, over time, progressively become deeper and deeper in the sediment (Figure 3-7), and surface sediment PCB concentrations would eventually reach background levels (Figure 3-8). The current sediment deposition information in this study was also useful for understanding contaminant transport. The findings indicated that South Basin is a relatively quiet depositional basin with occasional wind derived local resuspension and local redeposition. The information did not indicate any unusual transport characteristics, and suggested that the contamination would be expected to show a gradual decline away from sources. This conclusion is further supported by the PCB concentration gradients shown in the sediment contour maps (Section 3.1.7.3).

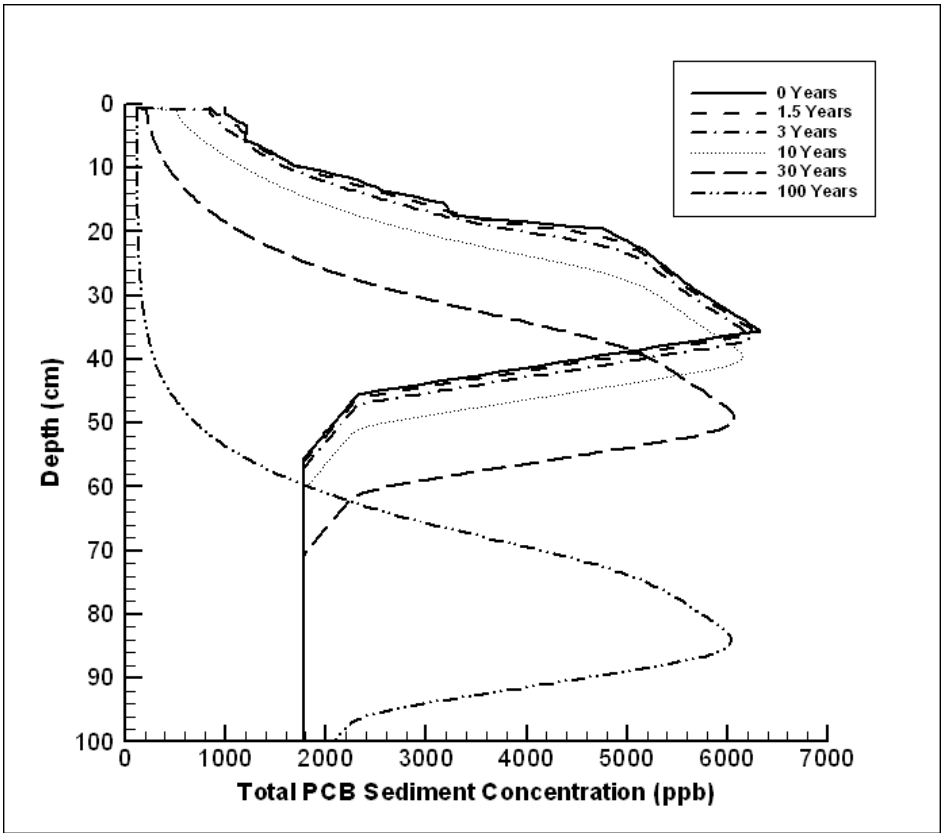

Figure 3-7. Predicted Total PCB Profiles over Time at HPS Station SB-081

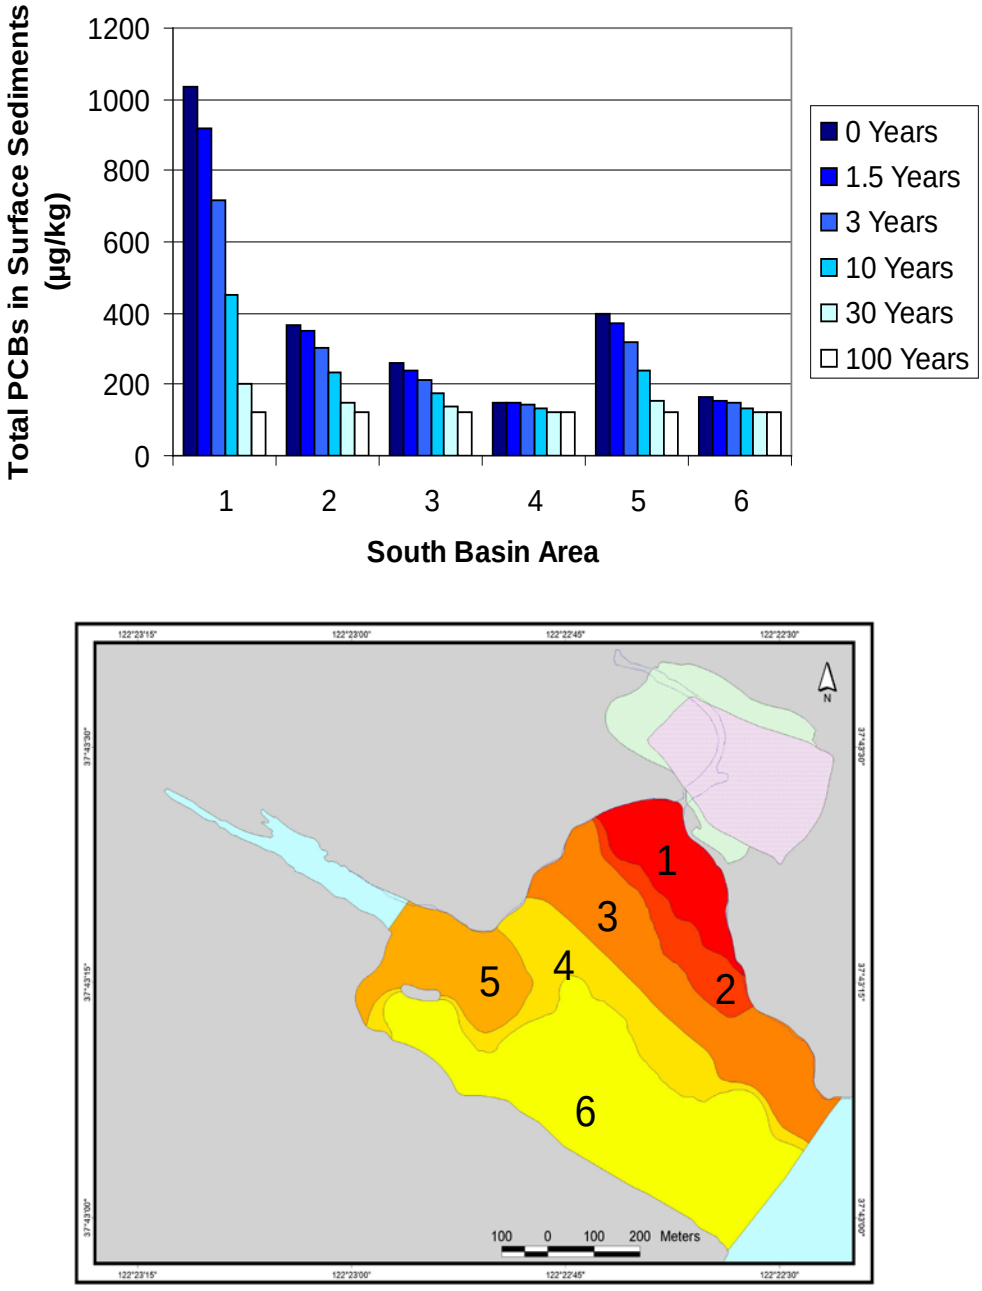

Figure 3-8. Areas Evaluated for PCB flux (top), and Predicted Surface PCB Concentrations over Time (bottom)

3.1.7.3 PCB Concentrations

Elevated PCB concentrations were measured in the northern portions of HPS South Basin; particularly in the northeastern parts near Parcel E-2 and the northwestern parts near the mouth of Yosemite Creek (Figure 3-1). The South Basin sediments with elevated PCB concentrations near Parcel E-2 are also near shoreline locations where high PCB concentrations have been measured (Figure 3-9; [62]).

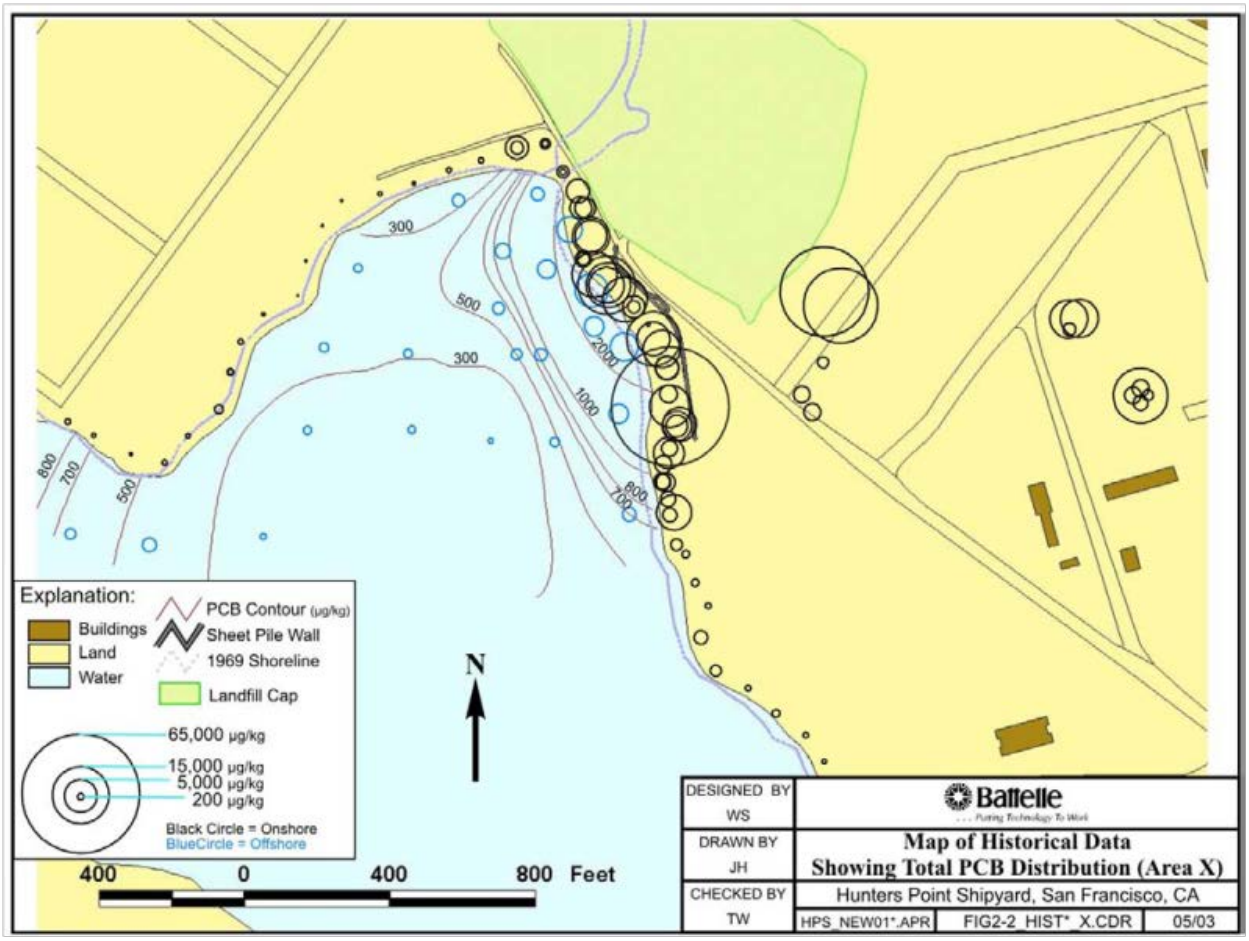

Figure 3-9. Upland Shoreline PCB Concentrations along South Basin

Figures 3-10 and 3-11 show examples of contour maps produced with the HPS RSC data, which can be useful to aid in selection of ACF samples. These contour maps show different PCB concentrations, with the standard red, for instance, representing 2,000 ppb and higher and the deep red representing above 5,000 ppb. It should be noted, and cautioned, that these represent extrapolations using data points spaced well apart, and the actual concentration at a specific location is not known except for where samples were collected (see core and sample locations in top of Figure 3-11). Contouring is, however, a widely used technique for understanding the approximate PCB concentration distribution.

The 3D visualization (Figure 3-11) makes it easy to assess the mass of PCB-contaminated sediment, and its distribution, while the 2D maps (Figure 3-10) are easier to use for directly comparing concentrations at different locations for samples from the same depth. Figure 3-10 features plan view maps of PCB concentrations with increasing depth below the mudline based on the 2003 FS Data Gaps Investigation data [62]. The plan view maps represent horizontal slices at 0.5-ft intervals. Observations based on these maps include the following:

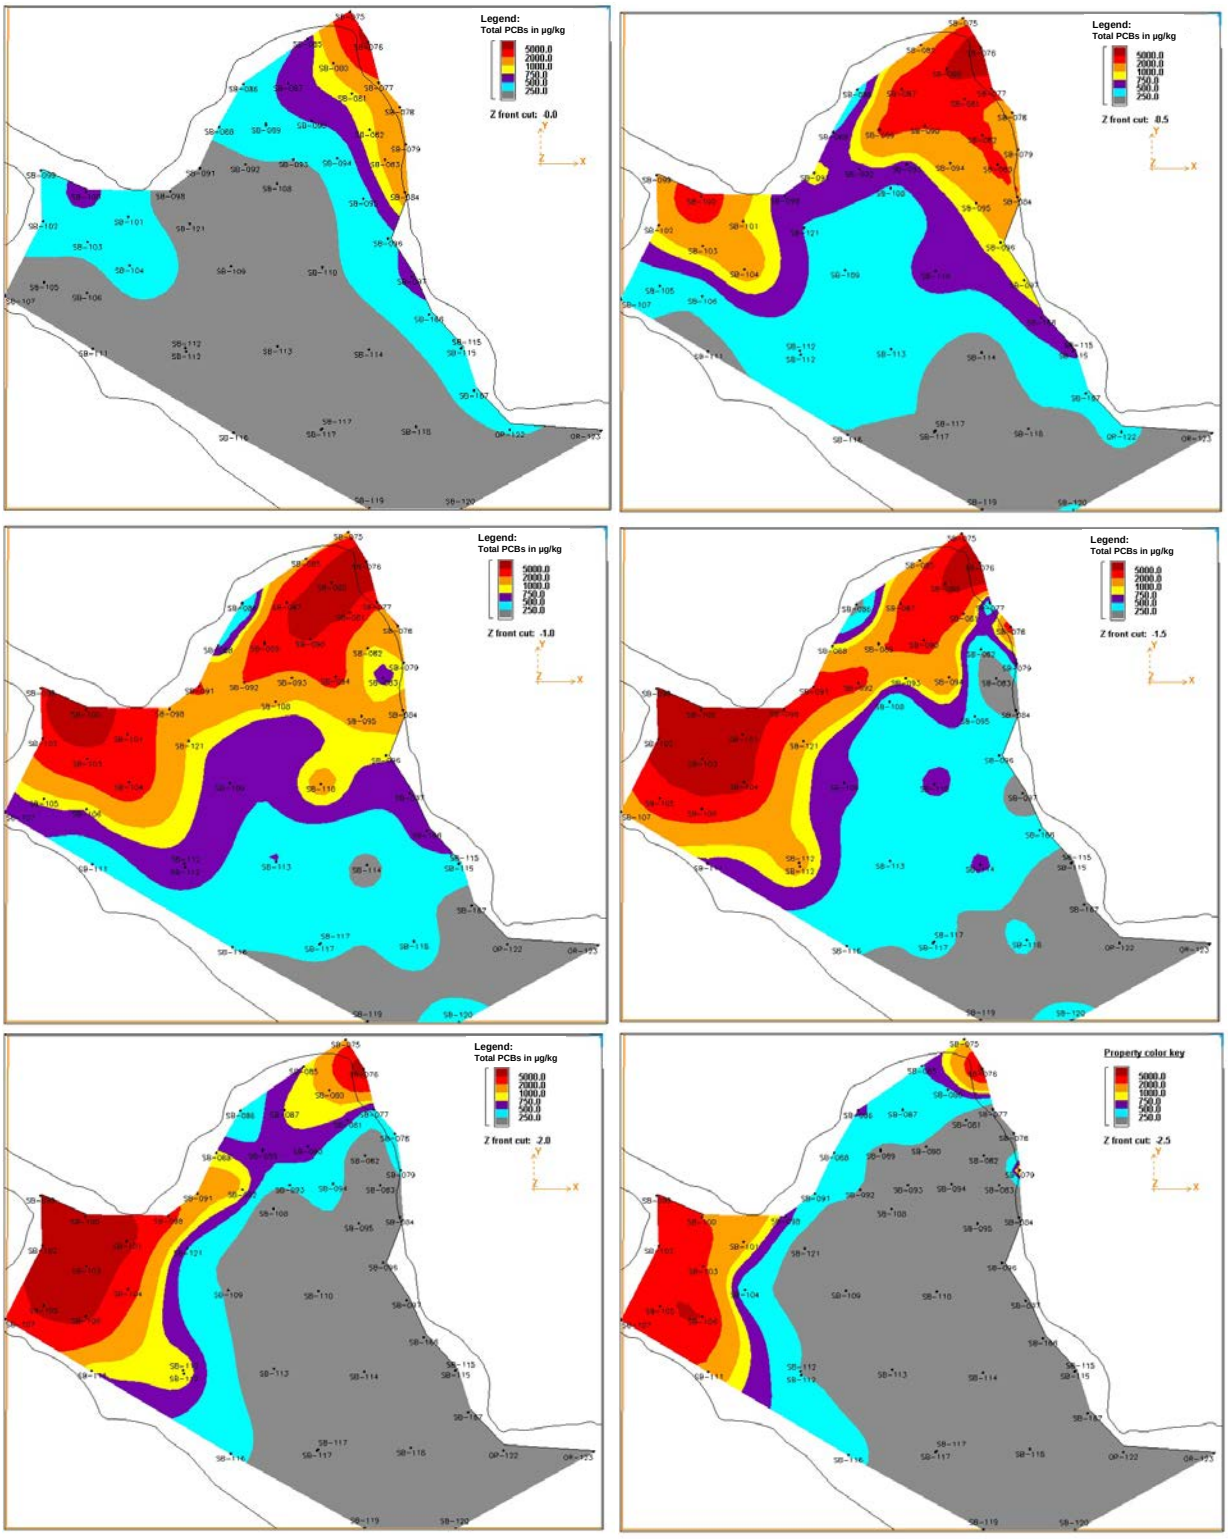

Figure 3-10. HPS Total PCB Concentration in Sediments from Surface, 0.5 ft Depth, 1 ft Depth, 1.5 ft Depth, 2 ft Depth, and 2.5 ft Depth, Respectively, from Top Left to Right

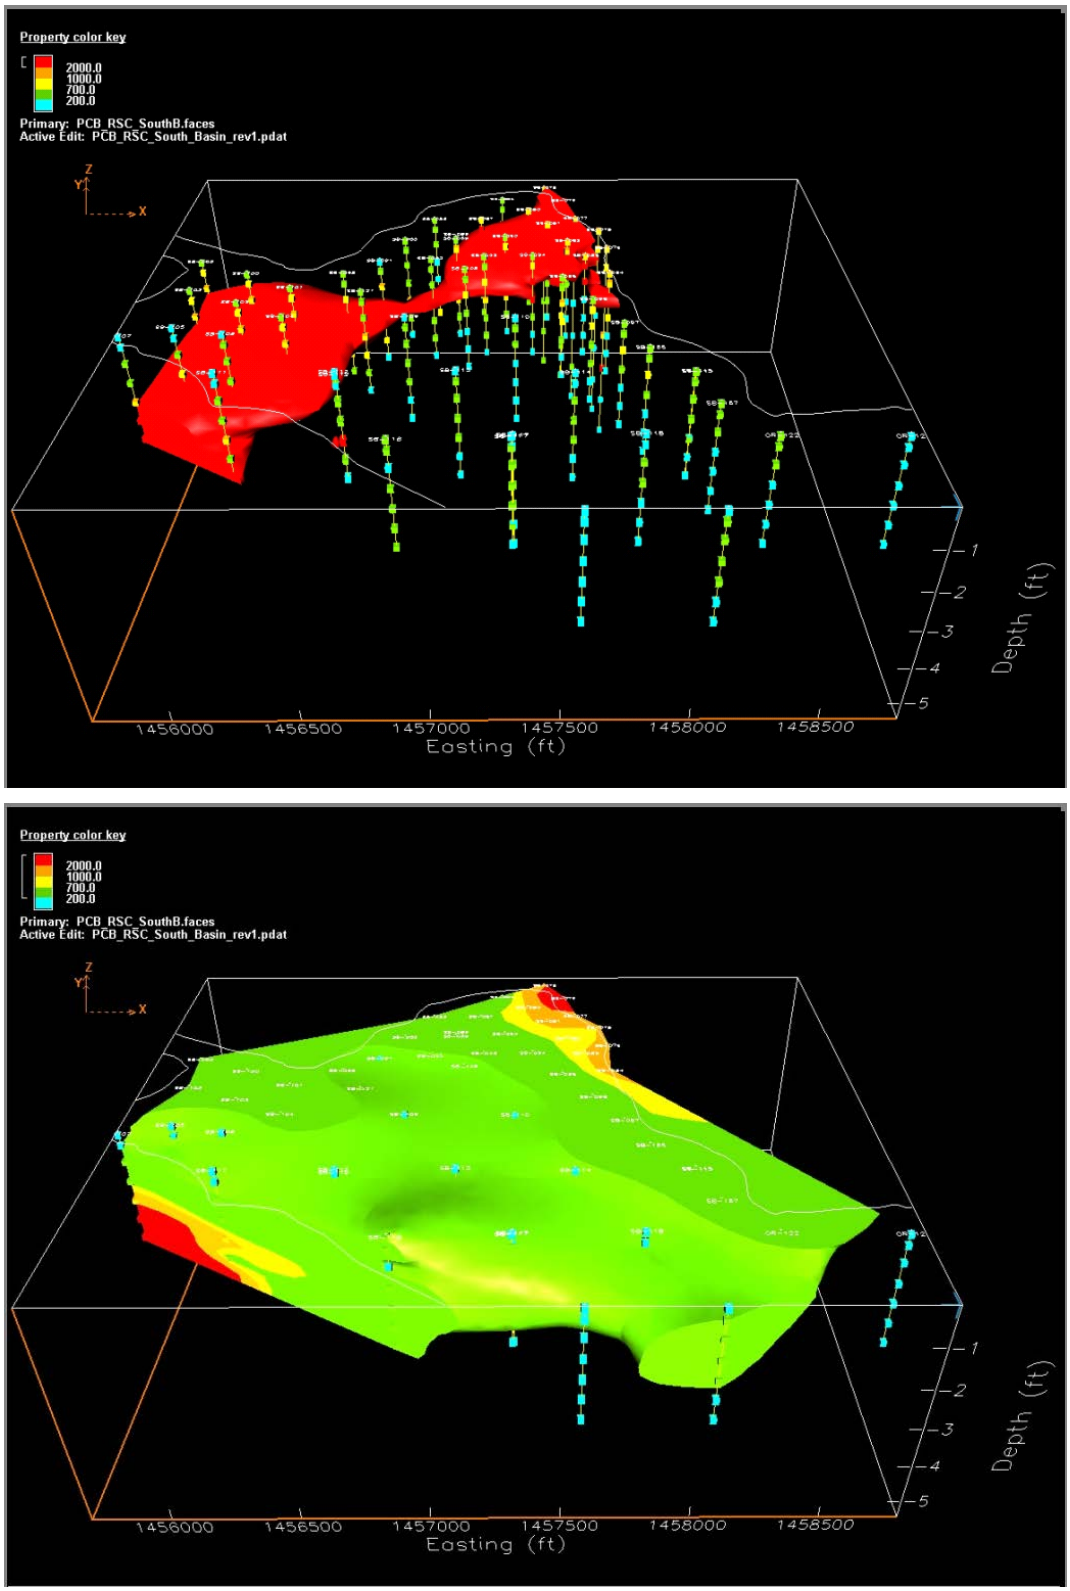

Figure 3-11. 3D Contour Maps from HPS Showing Total PCB Concentrations and Color Coded Core Horizons

(Upper map shows concentrations >2000 ppb in red [62].)

- PCB concentrations in surface sediment are highest (>2,000 µg/kg) at the north end of South Basin, near the area where the former slough connected with South Basin. Surface PCB concentrations decrease with increasing distance from the Parcel E-2 shoreline on the northeast side of South Basin. An area of slightly elevated surface concentrations (i.e., greater than 250 µg/kg) is also apparent near the mouth of Yosemite Creek.
- At a depth of 1-ft below the mudline, the area with PCB concentrations >2,000 µg/kg is more extensive, both at the north end of South Basin and at the mouth of Yosemite Creek. Overall, concentrations are higher 1-ft below the surface than at the surface, and the mass of highly contaminated sediment is greater in the 1 to 2 ft depth zone.
- At 1.5-ft below the mudline, the area of highest PCB concentrations decreases in extent at the north end of South Basin, and increases in extent at the mouth of Yosemite Creek. At 2.5-ft below the mudline, PCB concentrations of >2,000 µg/kg at the north end of South Basin are limited, whereas the affected area at the head of Yosemite Creek has not diminished substantially.

Figure 3-12 shows the surface sediment Total PCB concentrations at each sample station in South Basin and Yosemite Creek, and along the shoreline, based on combined data sets from multiple years (i.e., from 1999-2003). This map uses older historical data for the Yosemite Creek site; Yosemite Creek was not included in the detailed 2003 investigations of HPS. Three regions with the most highly-elevated PCB concentrations can be identified on this map: (1) the Parcel E-2 shoreline south of the Parcel E-2 landfill (shown as blue boxes along the shoreline); (2) the outlet of the former slough at the north end of South Basin; and (3) near the mouth of Yosemite Creek. The highest shoreline PCB concentrations are found to the south of the Parcel E-2 landfill, whereas the highest offshore PCB concentrations are found at the outlet of the former slough and at the mouth of Yosemite Creek.

These PCB data indicate that the South Basin sediment areas with the highest PCB concentrations adjacent to the Parcel E-2 shoreline, and particularly areas in close proximity to the former landfill and slough, and at the mouth of Yosemite Creek, do not appear to be continuous or linked (Figure 3-9), and the elevated PCB near the mouth of Yosemite Creek is at a greater depth than near Parcel E-2. These PCB concentration data suggest that there may be two separate sources of PCBs in South Basin: one associate with Parcel E-2 shoreline and the other with Yosemite Creek. The data also indicate that the contamination near Yosemite Creek is primarily historic and that this source has, for the most part, been controlled, and that the source of most of the contamination near Parcel E-2 is more recent and may still be contributing to the surface sediments (when these samples were collected, in 2003).

(Sampled 1999-2003)

3.1.7.4 PCB Composition

Comparisons of the PCB patterns of samples and Aroclors are often part of PCB contamination assessments. The similarity of a samples' PCB composition to that of an Aroclor formulation can provide information related to potential source(s) and changes that may have occurred since the contaminant was released to the environment. It is rare that one finds a perfect match in the PCB composition of a sediment field sample and an Aroclor formulation. A close match may be observed for samples that represent a recent release to the environment and are also near the source. However, the PCB composition begins to change as soon as the material enters the environment, and selective PCB congener alterations occur due to different weathering processes, as discussed earlier. Similarities and dissimilarities in the PCB composition were assessed using exploratory data analysis techniques, as described in Section 3.1.7.5.

General PCB composition is usually best studied using simple bar graphs (bar chart "fingerprints"), with the PCB congeners from low to high molecular weight along the x-axis and normalized (percent of Total PCB) concentration along the y-axis. Given the environmental

transformation considerations, it is particularly notable that the PCB compositions of most of the surface sediment field samples were similar to that of one Aroclor formulation – Aroclor 1260.

The PCB composition data suggest that there may also have been partial contributions from Aroclor 1254 source(s), particularly in the Yosemite Creek area and in deeper sediments also on both sides of South Basin, but the majority of the recent PCB clearly appears to be from an Aroclor 1260 source in most of South Basin. The resemblance to Aroclor 1260 was particularly good in surface and near-surface samples collected near the shore of Parcel E-2, in proximity to the historic landfill and slough (Figure 3-13).

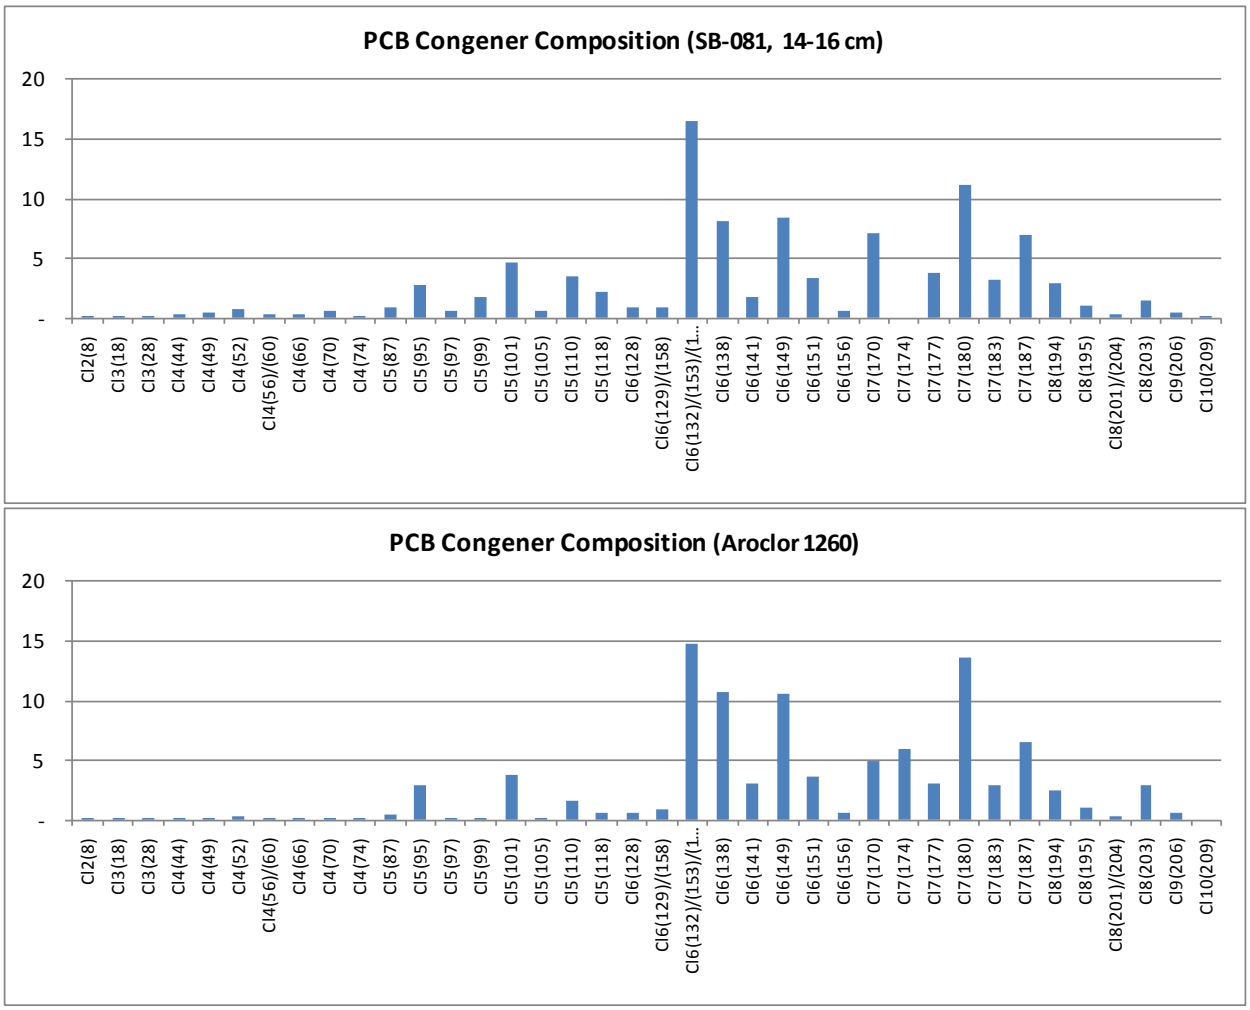

Figure 3-13. PCB Fingerprint of Surface Sediment Samples from the East Side of Hunters Point South Basin Compared to Reference Aroclor 1260

Samples from Yosemite Creek and the westernmost part of the basin, and some of the deeper sediments from the east, showed evidence of PCBs other than Aroclor 1260 contributing to the dominant Aroclor 1260 signature. Lower molecular weight PCB congeners, such as from Aroclor 1254 and possibly also 1242/1248, were evident. This inclusion of lower molecular

weight PCB became increasingly evident in the deeper, more contaminated, sediments from the west side of South Basin (Figure 3-14). The influence of Aroclor 1254 was evident in all samples from and near Yosemite Creek, and the PCB composition was similar throughout the Creek [62]. In contrast, the Aroclor 1260 signature dominated the PCB composition in the surface sediments throughout the basin, including the western parts. There were, proportionately higher concentrations of less chlorinated PCB congeners in the subsurface sediments than in the surface sediments, including in deep sediments from the east side. Slightly higher levels of Aroclor 1254 and/or other less chlorinated Aroclors in historic loadings to the basin may partly explain the subtle difference.

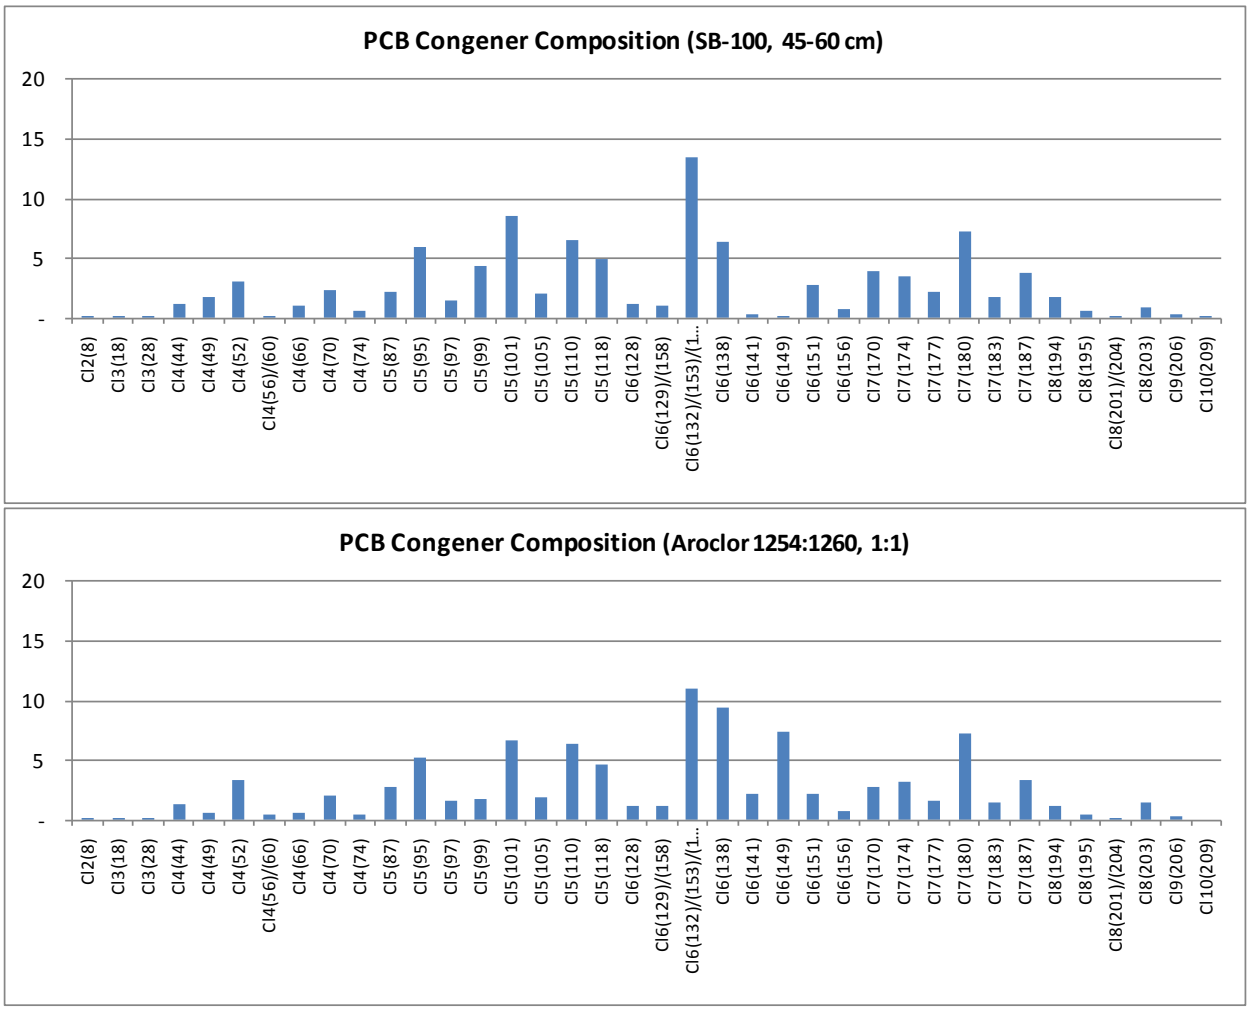

Figure 3-14. PCB Fingerprint of Deeper Sediment Samples from the West Side of Hunters Point South Basin Compared to a Mixture of Reference Aroclors 1254 and 1260 in a 1:1 Proportion

It can sometimes also be useful to examine ratios of key diagnostic PCB congeners (see Tables 2-1 and 2-4) to assess compositional characteristics. For instance, a change in composition (i.e., PCB congener ratios) may represent a change in source composition, and may be linked with

such data for other Aroclors or source material. Changes may also be due to alteration from environmental processes, and the distinction would need to be determined if changes are observed.

After comparing the bar chart fingerprints, one may use techniques such as congener-to-congener cross plots to assess compositional variations in the data. Figure 3-15 shows a cross plot of congeners PCB187 and PCB52 in segments of a core collected at Station SB94, an age-dated core located just offshore from the former landfill. If all depths in the core had similar congener composition, data would fall along a single trend (slope or ratio) which could be interpreted to represent a single source of PCBs over time. However, a change in composition with depth is noted where the ratio of these congeners in the shallow segments (0-20 cm) is about 7.2 and in the deeper/older sediments (30-60 cm) it falls to 1.8. This change may represent a change in source composition (or a change due to compositional alteration, such as dechlorination), so rather than having contamination from one PCB type (e.g., Aroclor 1260) there appears to be two distinct PCB signatures (e.g., Aroclor 1260 as well as another Aroclor), representing different time periods, with intermediate depth samples showing a progression from one ratio to the other. The more recent (shallow) sediments from 0-20 cm show a bar chart fingerprint similar to Figure 3-13 indicating an Aroclor 1260 source. The deeper sediments (30-60 cm) show bar chart fingerprints similar to Figure 3-14, indicating deeper sediments on both sides of the embayment show a mixed Aroclor 1254/1260 pattern. The difference in PCB composition does not necessarily reflect contamination from two different *physical* PCB sources, but indicates that the type of PCB that contaminated the sediments at this location changed over time, which may or may not originate from different locations. This dated core shows the change in composition at about 30 cm (the two highest concentration samples are duplicates of 30-40 cm interval) occurs in sediment deposited around 1965-1970. The timing of this basin-wide compositional shift will be discussed later, but this shows the importance of identifying PCB congener compositional differences to interpret potential source information. It would be tedious to view each possible individual congener cross plots if data for up to 100 different PCB congeners are available, but Aroclor compositional and congener behavioral information (Appendix A and Table 2-4) are available to help focus such an analysis on Aroclor/source-specific diagnostic ratios. Multivariate techniques (Section 3.1.7.5) are more suitable for analyzing comprehensive PCB compositional patterns with large data sets at one time.

In summary, the observed PCB compositional match to Aroclor 1260 in the northeastern part of South Basin suggests that there may be a current (2003) or recent, and possibly also historic, source of PCB in the vicinity of Parcel E-2. It is possible that the type of PCBs entering South Basin from the northeast was slightly different in the past. There is also PCB compositional evidence that there may have been a second source of a slightly different type of PCB (e.g., Aroclors 1254/1260, possibly also with some other Aroclor contribution) in the vicinity of Yosemite Creek, and that this source was more significant historically than recently. This source may have also contributed to the PCB contamination historically throughout South Basin, and not only near Yosemite Creek. The relative contribution of these sources has changed over time, with an apparent decline in the loadings from both sources in the past decades. The combined Aroclor 1254/1260 loadings have declined the most; Aroclor 1260 is dominating the Aroclor composition in the more recently deposited sediments throughout South Basin.

3.1.7.5 Chemometric Statistical Analysis

As per Section 2.5.2.2, the data were reviewed and processed prior to statistical analysis. For the HPS project, PCB congener data had already been compiled and delivered as part of the Hunters Point FS data gaps investigation deliverable [62]. This data spreadsheet contained all of the information listed in Section 2.5.2.2, including: sample ID, sample coordinates, sample depths, analyte identifiers (i.e., congener names), laboratory results, and laboratory qualifiers (e.g., non-detect flags). A digital base map was received in the form of a GIS shapefile, which was used to construct a simple base map (Figure 3-16) showing key geographic features of the study area and sample/core locations. The data set initially considered for statistical analysis was comprised of 120 samples and 44 congeners. As per Sections 2.5.2.2 and 2.5.2.3, the data were assessed and run through an initial multivariate analysis to assess data usability. This process resulted in the removal of 35 samples and eight congeners from the chemometric analysis. For the sake of brevity, every individual decision point that led to these data screening decisions will not be recounted here. However, some of these are discussed below, to provide an idea of the types of considerations in this process. Refer to Johnson et al. [9] for discussions on data screening, outlier identification and general considerations that the data analyst should consider when screening a data set prior to statistical analysis.

Eight samples from two cores (PA-139 and PA-162) were omitted from the analysis because they were not located in or near the South Basin; they were located on the north side of HPS, in the Port Avisadero area (Area III on Figure 3-2). In addition, only those samples with a total

PCB concentration > 100 µg/kg, and samples with fewer than nine non-detects were retained for statistical analysis. It should be noted, and as discussed in Section 2.5.2.2, that these or other thresholds are not solid numbers that can be applied generally to any data set. It is typically an iterative and data set-specific process whereby the user balances a need to keep as much data in the analysis as possible with the desire for a robust data set, where chemical fingerprints are not influenced by less reliable data, such as low concentration samples with multiple non-detects.

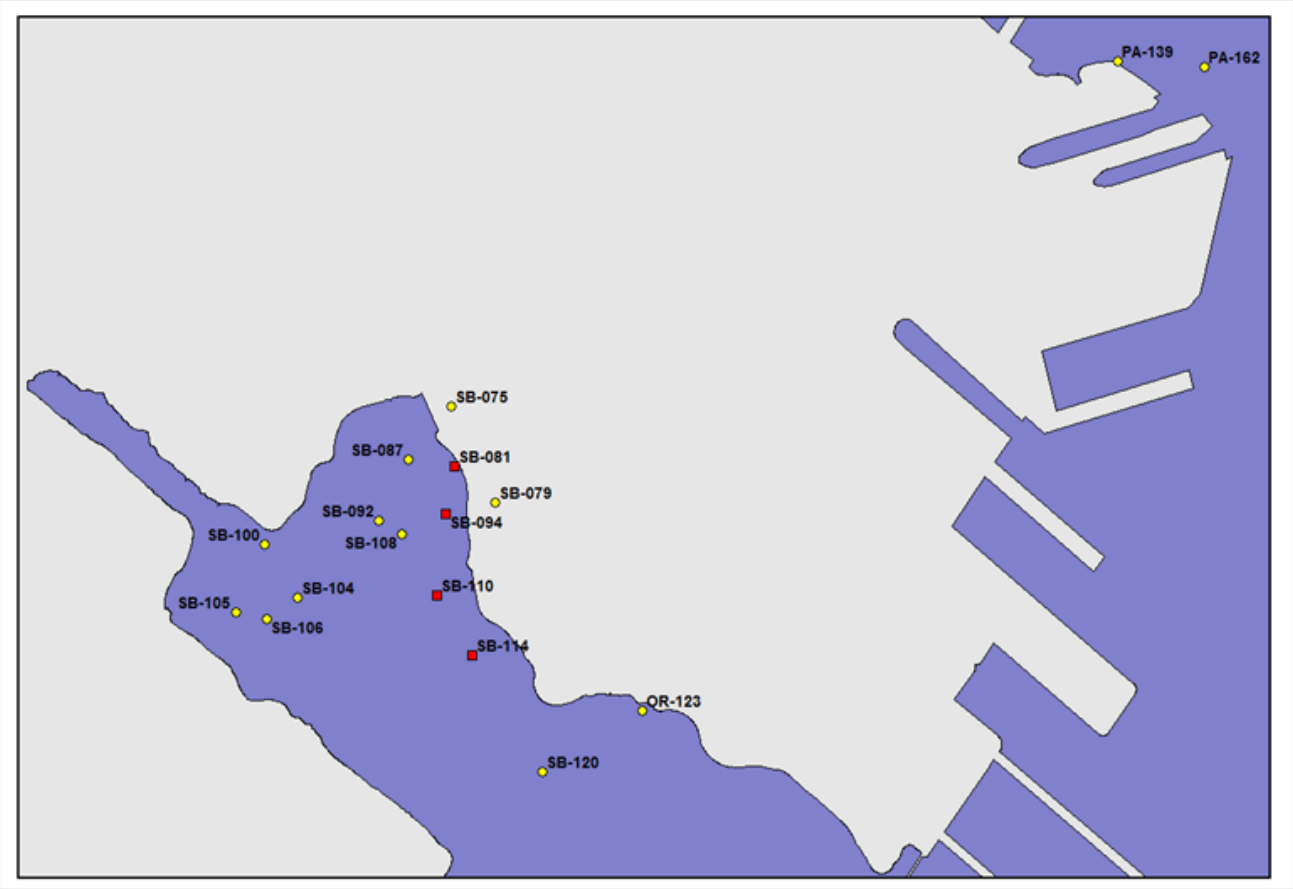

Figure 3-16. Simple Base Map Showing Sample/Core Locations
(Red squares are fine interval cores collected as part of a separate phase of sampling and analysis.)

Criteria used to screen congeners varied. PCB77 and PCB126 were both omitted because they were reported as non-detect in more than 98% of the samples. PCB141 was removed from the analysis for a very different reason. Initial data screening showed a strong bias in the proportion of PB141 as a function of the phase of investigation. Samples from four cores all showed systematically higher concentrations of PCB141, when expressed as percent of total PCBs (Figure 3-17). All other samples from other cores showed systematically lower concentrations.

These cores are not geographically separated from each other. As such, the team concluded that this bias was probably due to an issue such as matrix interference or analytical method bias between investigation phases, rather than a true compositional difference between these two sets

of samples. As such, PCB141 was removed from the analysis. The final data set submitted for analysis using receptor models was 85 samples and 36 congeners.

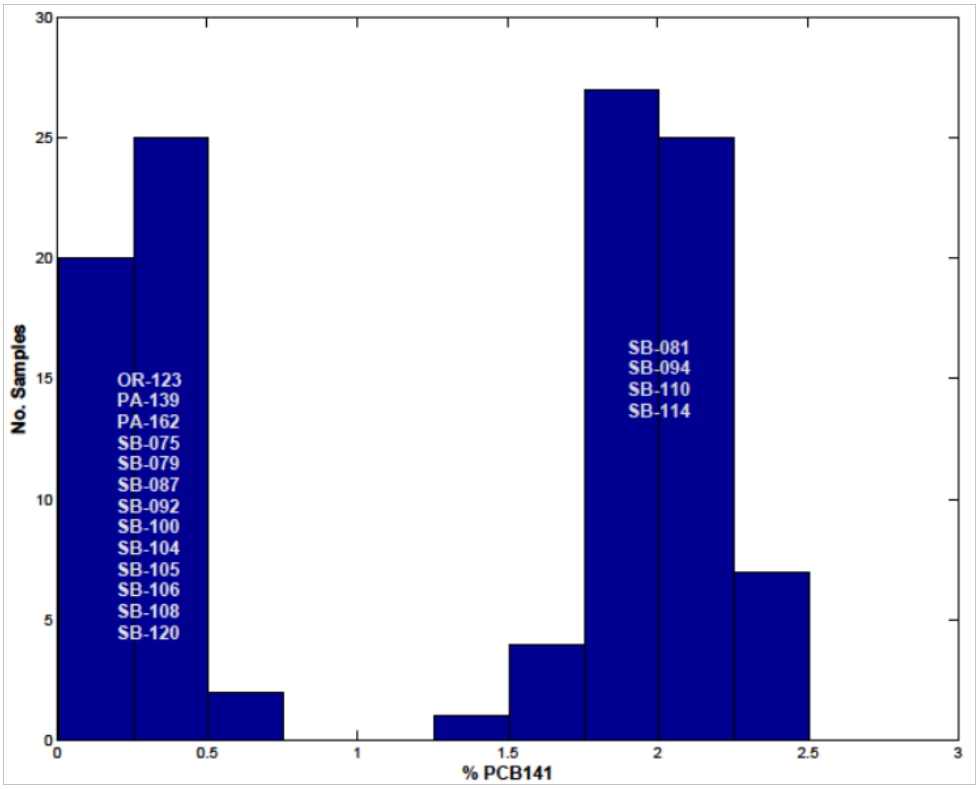

Figure 3-17. Histogram Showing Systematic Bias in PCB141 (as percent of total PCB) between Primary HPS Cores and Subsequent Fine-interval Cores SB-081, SB-094, SB-110 and SB-114

A review/summary of a number of chemometric/statistical analysis methods was presented in Section 2.5.3.5. For analysis of HPS congener data, PCA was applied as an initial exploratory data analysis method, followed by four different receptor model methods (PVA, ALS, Unmix, and PMF). Implementation of four different receptor models is not necessary. Most published applications use one [8-9, 34, 35, 64]. However, as all four have been applied as part of the method comparison, those results will be presented below.

A number of goodness of fit diagnostics were examined to determine the number of end-members (see [9]). One of these methods is shown in Figure 3-18, which is a coefficient of determination (CD) scatter plot array showing the fit of each of the 36 variables for a three end-member model. Each square graph on the array represents a PCB congener (or coeluting peak comprised of two or more congeners). The x-axis of each graph shows the measured amount of that congener/peak. The y-axis shows the amount as back-calculated from a three source model. A perfect fit would show all samples plotting on the 45 degree line that bisects each graph (a 1:1 fit). In PCA based receptor models, the number of principal components retained equals the number end-members. Fit always improves as additional principal components are added, so

one needs to decide at what point the fit is sufficient, without over-fitting and modeling noise. In the case shown on Figure 3-18 (three principal components/end-members), most of the congeners show a fairly good fit between the modeled values on the y-axis and the measured values on the x-axis, indicating that three end-members is a reasonable solution and that no more are needed. Scatter plots and other goodness of fit diagnostics are discussed in more detail by Johnson et al. [9].

Note, however, that some congeners exhibit at best a fair fit (e.g., PCB49 exhibits a wide scatter about the 1:1 fit line [Figure 3-18]). This may suggest the presence of another fingerprint in the system, and/or that this congener is particularly susceptible to environmental alteration or analytical issues (which is, ideally, identified during data screening). The feasibility of a fourth end-member was evaluated and will be discussed later in this section.

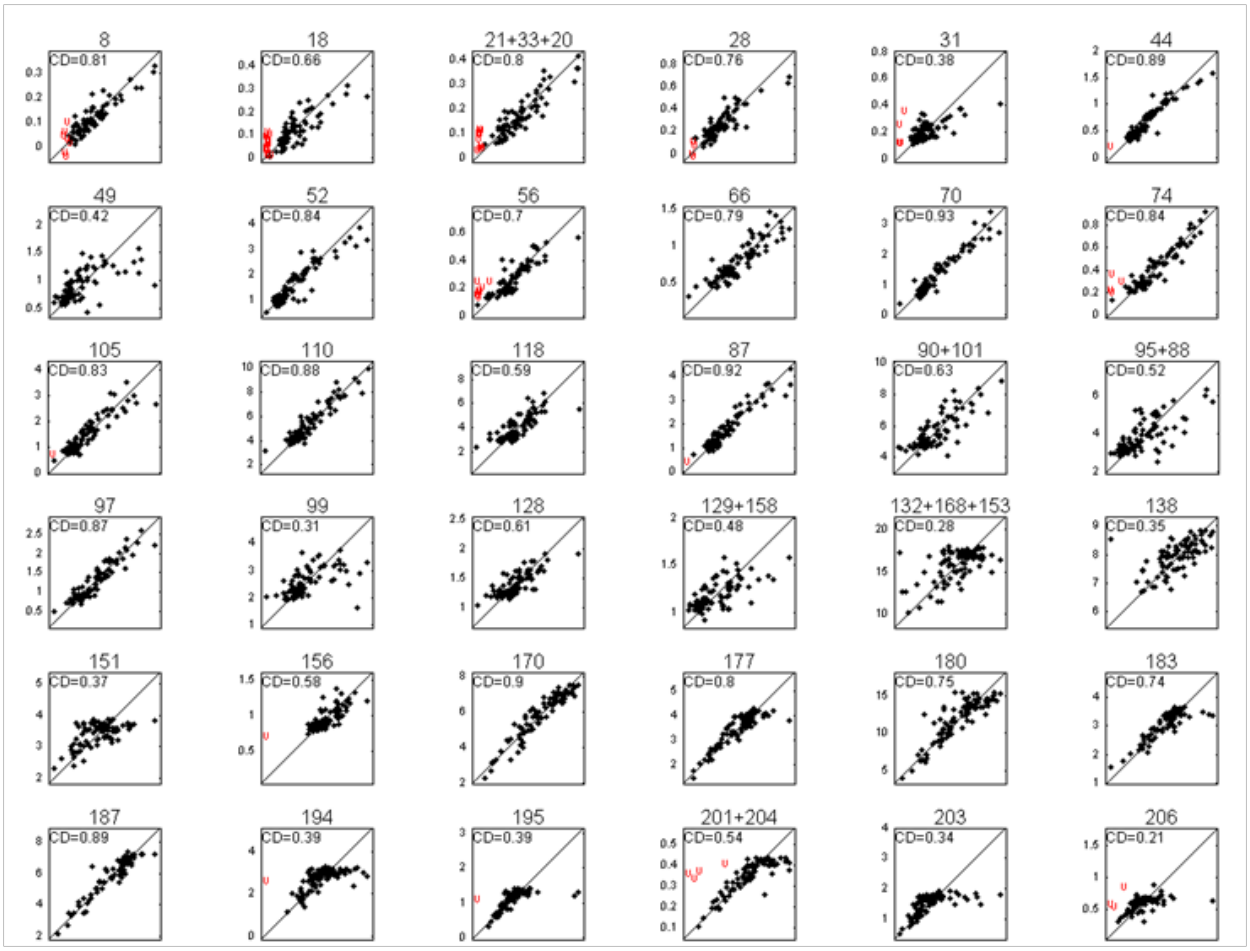

Figure 3-18. CD Scatter-plot Array for 85 Sample, 36 Analyte PCB Data Set from South Basin, Hunters Point Shipyard
(Non-detect samples are indicated as "U".)

This data set was analyzed using the four receptor model methods, each for a three source system. The congener patterns resolved by each of these four methods are shown in Figure 3-19 as blue bar graphs. At the top of each column of bar graphs, the congener pattern of an Aroclor (or a mixture of Aroclors) is shown. Each of the four receptor model methods resolved very similar profiles, and each matched known Aroclor profiles.

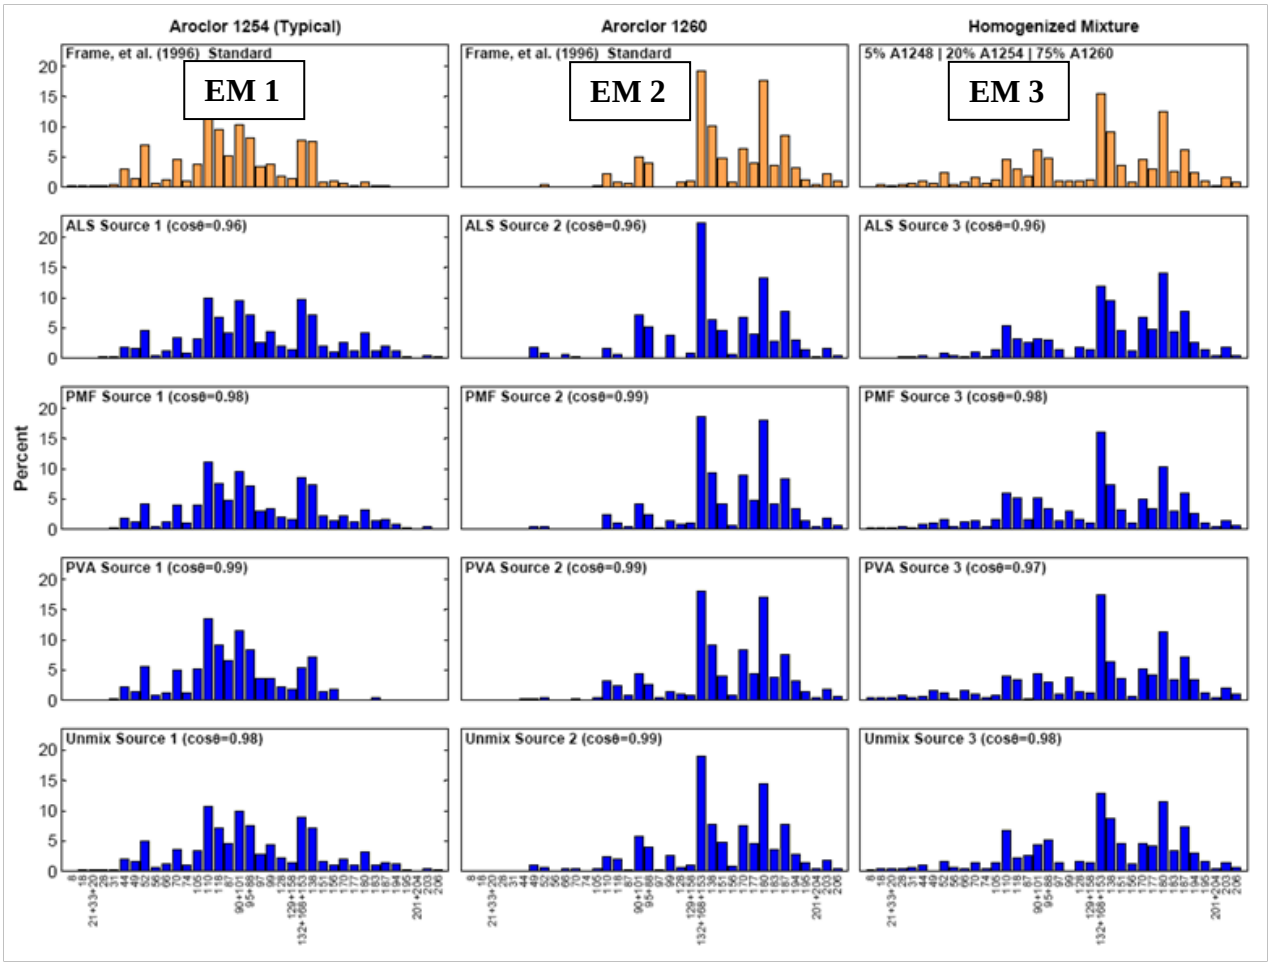

Figure 3-19. Congener Profiles (end-members, source profiles) Derived from Four Receptor Model Methods

Note that the congener patterns of the middle panel (Aroclor 1260) and the right panel (homogenized mixture) are very similar. Both are heavier congener patterns dominated by Aroclor 1260 congeners. The difference is that the "homogenized mixture" also has secondary amounts of congeners in the lighter Aroclors 1248 and 1254 molecular weight range. The discussions that follow evaluate whether these slightly different congener patterns represent real differences in the field.

Figure 3-20 shows the geographic distribution of each source as resolved by each of the four methods. Again, the geographic distribution of the three congener patterns is similar for each of the four receptor model methods. Note also that the slightly lower molecular weight Source 3 pattern is generally higher in proportion to the southwest, near the mouth of Yosemite Creek. This geographic distance suggests that a real PCB compositional pattern difference is being observed in the field.

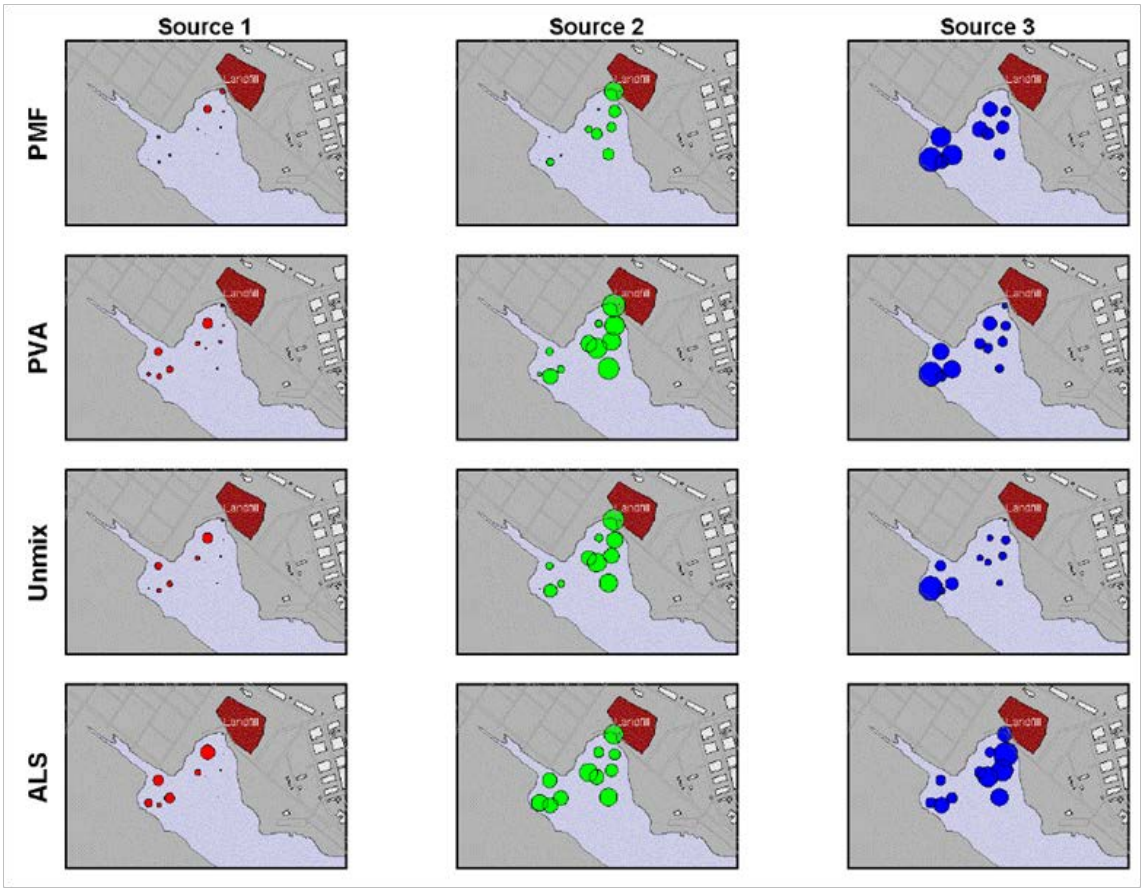

Figure 3-20. Maps of Three Receptor Model Derived End Members (potential sources) in Surface Sediments of the South Basin at Hunters Point Shipyard

Note on Figure 3-20 also that Source 1 (Aroclor 1254) is not present in high proportions in surface sediments. This is because it is much more abundant at depth, as is apparent on the cross section through cores (Figure 3-21). Also note that the terminology "source" in Figure 3-21 may be misleading, as it refers to the differentiation of different PCB compositional characteristics in the sample set (i.e., "end-members", in Figure 3-19), and not necessarily geographically different sources of the PCB. For instance, the three different PCB characteristics identified may be originating with just two different sources.

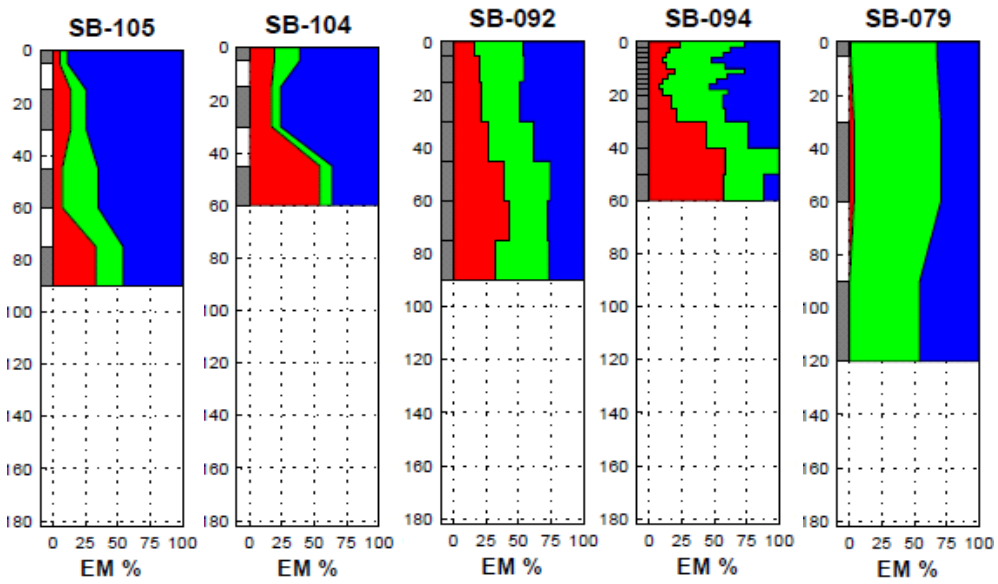

Figure 3-21. HPS EM Compositions in Selected Cores
(Red=EM-1; Green=EM-2; Blue=EM-3)

This three-composition interpretation was confirmed using another chemometric method, PCA (Figure 3-22), which can be used to summarize much of the information in this section. This PCA figure shows the HPS sediment sample PCB data plotted in 3D PCA space. The data cloud exhibits a generally triangular shape (indicative of mixtures, not clusters). This PCA scores plot has also been annotated to show the locations of these three source end-members as vertices of a triangle (i.e., a mixing diagram or, more specifically, a ternary mixing diagram).

Each sample point in the PCA illustration in Figure 3-22 represents the PCB congener data from a separate sample (see Appendix D for sample numbers) that could, for instance, be represented by separate bar chart fingerprints. The closer together samples plot in the PCA graphic the more similarity their bar chart fingerprints would be. A sample point located at the corner of the triangle marked EM1 has a bar chart fingerprint that closely matches Aroclor 1254. A sample point at the corner of the triangle marked EM2 has a fingerprint that matches Aroclor 1260. The third corner of the triangle at EM3 does not appear to match any single Aroclor, and since no evidence of dechlorination was observed, this pattern was intended to match the mixtures of Aroclors. The best fit was obtained with the mixture shown at the bottom of Figure 3-22 (a mixture of 80/15/5 of Aroclors 1260/1254/1248, in this case), which showed a cosine theta (cos θ) value of 0.97 (1.0 represents a perfect match). In summary, the PCA scores plot in Figure 3-22 shows the surface sediments to the east near the former landfill plot (e.g., sample point 5 is the surface sample from core SB79 in front of landfill) closer to the bottom left corner marked EM2 (with a Aroclor 1260 source pattern) and surface samples from near Yosemite Creek (e.g., sample 26 from core SB105) closer to the top corner of the triangle marked EM3 (representing a mixture of Aroclors 1260/1254/1248). Deeper samples from both sides of South Basin plot further to the right near EM1 (e.g., sample point 25 is 45-60 cm in core SB104 and sample point 55 is 30-40 cm in core SB81), which indicates approximately a 50/50 mix of Aroclors 1260 and 1254. One can easily see this change in composition with depth in core SB81, where deeper

samples from 30-60 cm (e.g., sample points 54, 55, 56, 57) all plot close together with the same 50/50 mixture of Aroclors 1260 and 1254. Shallower samples (0-20 cm) plot to the left close to EM2 (e.g., sample points 45 to 51), with a few intermediate depths (e.g., sample points 52 and 53) showing the transition in patterns.

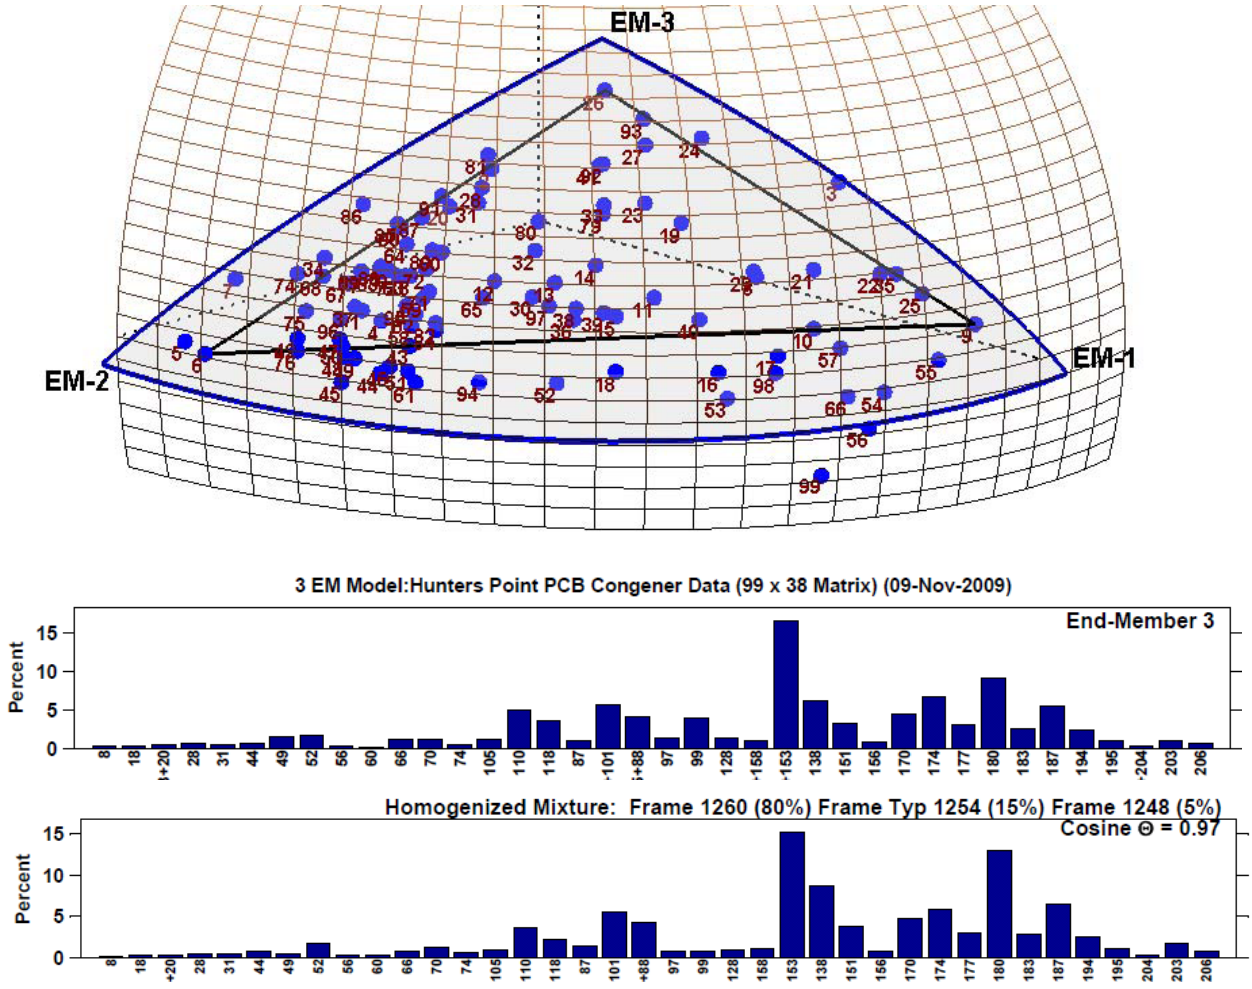

Figure 3-22. Conceptual PCA Model for PVA at HPS
(Each dot represents a sample. Samples plotting close together have similar PCB compositions.)

This is similar to the previous discussions of Figure 3-15 for core SB94, which was a dated core that showed this same transition in PCB composition at depths in the sediment from around 1965 to 1970. There appears to be similar historic PCB composition at depth on both sides of South Basin represented by samples on the right side of the triangle in Figure 3-22, with a composition similar to a 50/50 mix of Aroclors 1260 and 1254. As discussed earlier, the compositional similarities do not necessarily mean they are from one and the same physical source of PCB; this information needs to be combined with other forensic lines of evidence to better understand potential source implications. We might speculate that around 1970 when the CSOs in South Basin were all realigned to the head of Yosemite Creek, some Aroclor 1260 contaminated fill

material was used to close off the former channel that ran through the landfill on the east side (see high concentrations onshore in Figure 3-9). This contaminated fill material along the beach in this area may have become the EM2 source to the east side sediments after about 1970 through continuing erosion along the beach in front of the landfill. On the west side by Yosemite Creek, when the CSOs were realigned and the sewer capacity expanded, overflows were dramatically reduced so PCB loadings (and surface sediment PCB concentrations) were reduced and in recent years appear to have a mixed composition of Aroclor 1260/1254/1248. The remaining questions are whether this third composition pattern (EM3) represents a real and distinctly different pattern, and a different source physically and in time, rather than a mixture of the other two patterns (EM1 and EM2), and whether there is any evidence of an alteration or dechlorination pattern, both of which are addressed in the next few paragraphs.

Confirmation of a Third Source Pattern

All four receptor models resolved a third PCB congener profile that differed subtly from one of the other two. Two PCB congener profiles were consistent with a predominant Aroclor 1260 congener pattern (EM-2 and EM-3; Figure 3-19). End-member 3, however, also included some less chlorinated congeners within the Aroclor 1254 and Aroclor 1248 range (Figure 3-19). These two patterns were somewhat separated geographically (Figure 3-20), although this should be interpreted with care as the relative contribution of the end members can have a fairly substantial amount of uncertainty associated with it. Much of the pure Aroclor 1260 congener pattern appears to be associated with the Navy facility. The PCB composition of Aroclor 1260 together with less chlorinated congeners was observed in higher proportions in the western parts of the study area, near Yosemite Creek. Given the subtle difference in these two congener patterns, it was important to independently confirm the compositional differences to understand if it was possible that there was a different source of Aroclor 1260-like PCB also in Yosemite Creek, based only on the congener pattern information. There was no way to do this purely within the realm of this chemometric analysis so another independent line of evidence was investigated.

Several years before the collection of the congener data used in the chemometric analysis described above (Section 3.1.7.5), the San Francisco Public Utilities Commission (SFPUC) had sampled sediments from Yosemite Creek. Only surface sediment samples had been collected, and the number of congeners reported was much smaller than that available in the South Basin. However, knowing which congeners were important in the distinction between the two PCB patterns discussed above, a simple ratio analysis approach (Section 2.5.1.1) was used to see if the SFPUC data supported the hypothesis of a slightly less chlorinated PCB source up Yosemite Creek. The ratio of two congeners included in both the FS and the SFPUC data sets was calculated: PCB28 and PCB153. PCB28 is a tri-chlorinated congener typical of an Aroclor 1248 source. PCB153 (a hexachlorinated congener) is prominent in both Aroclors 1254 and 1260, but present in low proportions in Aroclors 1242 and 1248. The PCB28/PCB153 ratio was calculated for samples from both data sets and plotted on a map (Figure 3-23); the ratio is approximately 76, 17, 0.03, and 0.003 for Aroclors 1242, 1248, 1254, and 1260, respectively (Appendix A). The combined data set clearly shows a higher ratio (i.e., lower chlorinated pattern) in Yosemite Creek sediments – a ratio that is higher than can be explained by combinations of only Aroclors 1254 and 1260. The augmentation of the main data set with useable data from a completely independent investigation helped confirm (1) the subtle difference in PCB patterns observed in surface sediments in the South Basin (near the landfill and near Yosemite Creek) likely reflects

different sources; and (2) there is/was indeed a lower molecular weight PCB source in Yosemite Creek that contributes some to the PCBs in the South Basin.

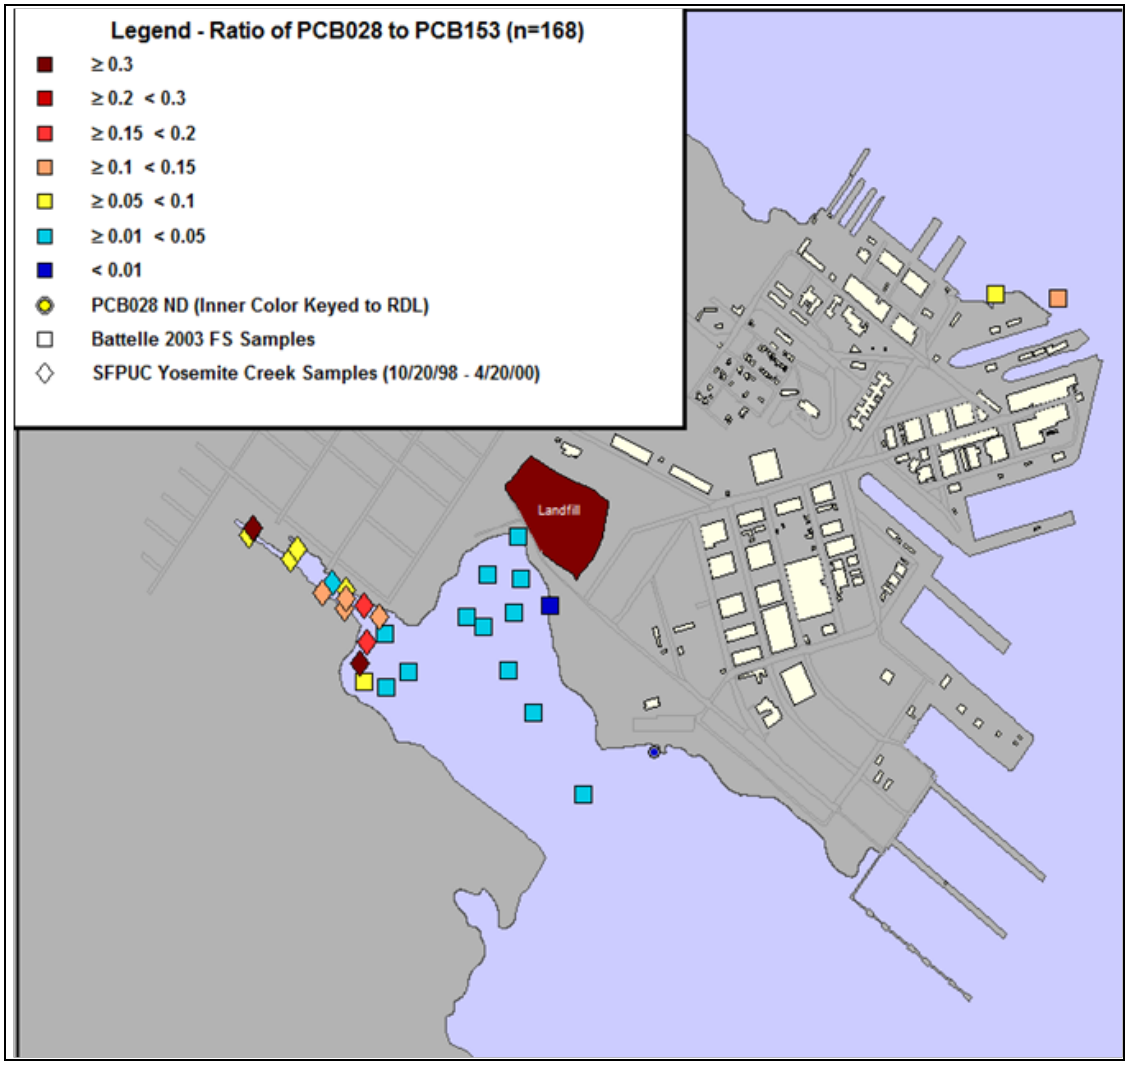

Figure 3-23. Ratio of PCB28 to PCB153 in Sediments Near Hunters Point Shipyard and Yosemite Creek, San Francisco, CA

Consideration of a Possible Fourth Source Pattern

As indicated in Section 3.1.7.5, through the statistical goodness of fit diagnostics, in conjunction with the receptor models (Figure 3-18), a minimum of three PCB compositional patterns were indicated for this data set, likely from at least two different physical sources, but some congeners still exhibited a noisy fit (see for example the PCB49 scatterplot on Figure 3-18). Therefore, the possibility of a fourth end member pattern was evaluated by applying one of the receptor model methods (PVA) to four end-members. The result was a resolution of three end-members very similar to the previous three, plus a fourth that was similar to Aroclor 1254, but with slightly higher proportions of PCB49. PCB49 is a known dechlorination product [65]. A fourth pattern

is plausible but, if present, it is not important to the source apportionment study because (1) it is a slight variant of an Aroclor 1254 weight range pattern; (2) Aroclor 1254 is already represented in the three source model; (3) to the extent that it represents a true congener pattern, there is independent evidence from the literature that suggests that is related to alteration and not a source; and (4) if this pattern does represent dechlorination, it is very subtle.

3.1.7.6 Integrated Data Analysis and Interpretation

As discussed in Section 2.5.3.6, integrated data analysis and interpretation is the process of synthesizing information from multiple lines of evidence to arrive at scientific interpretations that answer the key questions of a forensics investigation (i.e., PCB sources, alteration mechanisms, timing/history of releases). Lines of evidence typically considered include site history, published scientific literature, sediment transport/hydrodynamics, analytical chemistry which is then used to interpret total PCB concentration gradients and inspection of sample chromatograms/compositions, and chemometric analysis.

At HPS, such lines of evidence consistently support the key conclusion – that there appear to be two general physical source areas that have contributed the majority of the PCBs in the South Basin sediments – one of the source areas being the general vicinity of the landfill near the north-east shore of South Basin and the other being Yosemite Creek and, possibly also, old outfalls southwest of the mouth of Yosemite Creek (lower Figure 3-2). The PCB concentrations and compositions from these two source areas have shifted over time. In the past, sediments from deeper than 30 cm, or pre-1970s on both sides of South Basin show a similar 50/50 mix of Aroclors 1254 and 1260, but the concentrations are higher on the west side at greater depth. More recent surface sediments to the west by Yosemite Creek show much lower concentrations (indicating the source has been significantly reduced) and an increase in the relative proportion of Aroclor 1260, with smaller contributions of lower weight Aroclors (1254 and 1248). Surface and more recently deposited subsurface sediments to the east by the former landfill still have elevated concentrations, suggesting a continuing source (as of the 2003 sample collection date), with a composition that is almost entirely Aroclor 1260.

This observation is consistent with and supported by site history (Section 3.1.7.1), which indicates that PCB-contaminated material went into the landfill from 1958 to 1974, and that, in addition to leaching and erosion from the landfill, a former slough/ditch/channel in the area (which was later filled by landfill expansion) could have contributed PCBs to South Basin through runoff from other parts of the Navy property and from the landfill (Figure 3-3). Figures 3-9 through 3-12 show elevated PCB levels along the shoreline in front of the landfill, possibly from contaminated fill used to close off the former slough/channel around 1970 or illegal dumping activities noted by DTSC when HPS operated as a commercial shipyard from 1976 to 1986. The offshore sediment PCB concentration gradients (Figure 3-10) line up with the onshore elevated shoreline PCB levels (Figures 3-9 and 3-12), indicating that erosion of these shoreline materials have represented a source of PCBs to the South Basin.

The presence of numerous commercial/industrial facilities that could contribute PCBs were located up and around Yosemite Creek and could have contributed PCBs through runoff and CSO discharge. For instance, a facility operated as a 55-gallon drum recycling operation from 1948 to 1988 with noted releases of PCBs as well as other contaminants. CSO releases of mixed

stormwater/sewage were more common in the past, but after about 1970 when all CSOs were realigned into Yosemite Creek and the sewer storage capacity was increased, these releases were reduced to about one per year.

The sediment transport and hydrodynamic information for South Basin (Section 3.1.7.2) indicates that contamination entering the Basin would be expected to be relatively predictably deposited and distributed away from sources (i.e., that the geographical distribution of the PCB contamination would radiate and decline away from sources). This implies that the contour maps such as Figure 3-10 can be viewed to show two high concentration areas where PCB sources are likely to have been located. Sedimentation rates derived from the dated cores indicate a constant, steady 1 cm/yr depositional rate, so events that occurred around 1970 should be seen in these cores at about 30 cm depth. The various PCB data analyses further support the initial findings of potential sources, adding additional lines of evidence.

The PCB concentration gradients in the South Basin showed two areas of high concentration: one near the shoreline adjacent to the former landfill and another near the mouth of Yosemite Creek (Section 3.1.7.3 and Figures 3-10, 3-11, and 3-12). The preliminary PCB composition information (Section 3.1.7.4 and Figures 3-13 and 3-14) indicates at least two PCB compositional characteristics of the PCB in the sediments – one closely resembling Aroclor 1260 in the surface and near surface sediments near the former landfill, and another resembling a combination of Aroclors 1254 and 1260 in the deeper sediments near Yosemite Creek. Figures 3-15 and 3-21 show PCB data from core SB94 collected near the landfill, and illustrates a compositional shift in the PCB composition at 30 cm, which was dated at about 1970. This was the time period when the slough/channel was closed off by the landfill, the sewer capacity was increased to reduce CSO events, and the CSOs were realigned within Yosemite Creek. This suggests that the common PCB compositional signature (50/50 mix of Aroclor 1260/1254) seen deeper than 30 cm across South Basin may have been from one source or similar sources, possibly CSO outfalls located both in Yosemite Creek and at the north end of the slough/channel that was being filled by the landfill. Another possibility was that the same contaminated fill was used on both sides of the embayment and this fill served as a common source of PCBs for these deeper sediments. After the slough/channel was filled in the 1970s, the PCB composition in the sediments near the landfill shifted to closely resemble Aroclor 1260, possibly from continued erosion of the contaminated beach in front of the landfill (Figure 3-9). Sediments shallower than 30 cm in the Yosemite Creek area have much lower PCB concentrations because the CSOs (the local source of the PCB) were realigned and the sewer capacity was increased to reduce the overflow events. These PCB composition in the sediments on the west side of South Basin also show a compositional shift from the deeper sediments (Aroclor 1260 [50%]/1254 [50%]) to the shallower sediments (Aroclor 1260 [75%]/1254 [20%]/1248 [5%]).

The various chemometric analyses, which are described in more detail in Section 3.1.7.5, further support the initial findings of potential sources, adding additional lines of evidence. Much of the information from that section can be summarized in the PCA scores plot (Figure 3-22), and accompanying discussion (Section 3.1.7.5). In summary, the PCA scores plot shows the data cloud of sample points that can be enclosed by a geometric shape (triangle) with the corners (vertices) representing end-member (EM) PCB congener compositions that can be linearly mixed to provide the congener composition of all the samples at the site. The surface and near surface

sediments from the east near the former landfill plot closer to the bottom left corner marked EM2 (an Aroclor 1260 source pattern) and the surface sediment samples from Yosemite Creek plot closer to the top corner of the triangle marked EM3 (a mix of Aroclors 1260/1254/1248). Deeper samples from both sides of South Basin, and the most contaminated deep sediments from the west plot near EM1 represent a mix of Aroclors 1260 and 1254. One can easily see the change in composition with depth, where deeper samples from below 30 cm throughout South Basin generally plot close to the same 50/50 mix of Aroclors 1260 and 1254, while shallower samples have a stronger influence of Aroclor 1260.

Another way to visualize these compositional variations in a spatial representation is shown in Figure 3-21. This figure shows an east to west transect of cores to show the vertical and horizontal variations in the end member compositions across the site. On the left of each core are the depth (cm) and darkened sediment horizons that were homogenized and used for ACF congener analysis (undarkened intervals only had RSC total PCB measurements, so there is less data accuracy and the results were interpolated over these horizons). On average, there is more green (EM2) to the east (see core SB079) and more blue (EM3) to the west (see core SB105). The one fine interval dated core in this transect (SB094) shows a sharp transition at 30 cm depth (around 1970) with more red (EM1) at deeper depths. It should be noted that the error bars associated with this type of display in this case study are larger than in typical cases (usually estimated to be about 10 to 20%) because of the similarity in composition between EM2 and EM3. In fact, because Aroclor 1260 is notably present in all samples, the uncertainty in allocation among the end members is greater than in a more desirable candidate site where the different end member compositions are more unique and easy to separate.

Combining multiple lines of evidence, it appears that there are three different PCB contaminant characteristics in the sediments of the South Basin at HPS, which could have originated at two or more general areas at different times. Considering only individual lines of evidence, this might not have been at all apparent. For example, the raw concentration maps show two distinct areas of high concentration (Yosemite Creek and the HPS landfill – Section 3.1.7.3). Analyzed in isolation, this suggests two sources. It is only when one analyzes congener patterns (through direct inspection of sample composition or through chemometric analysis) that it becomes clear that there was a historical shift in congener patterns near the landfill. This suggests a change in source material emanating from the landfill area overt time. An Aroclor 1254 pattern is more dominant at depth, while an Aroclor 1260 pattern is more recent in shallow sediments. Alternatively, it is possible that sources in and around Yosemite Creek also contributed to the PCBs in the deeper, historic, South Basin sediments also closer to the Navy landfill area. However, it should be noted that the amount of PCBs (i.e., the PCB concentrations) are much lower in the deep sediments on the east side of South Basin, and, therefore, accurately identifying the origin of that contamination may be of less importance, from a sediment management perspective.

The HPS case study here has shown that these multiple lines of evidence present a consistent story. Since this case study was done with pre-existing data, it presents both advantages and limitations compared to a typical forensics study planned from the start. The obvious advantage is the cost savings, since the regulatory RI/FS project paid all the planning, sample collection, and sample analytical costs. Ideally, from a technical and defensibility perspective, it would

have been preferable to have additional samples to validate the proposed end member source compositions and sample from physical locations where the sources may have been present. This was possible for EM2, where the composition matched an Aroclor 1260 pattern and samples onshore along the beach on the east side showed the same pattern. The physical source for EM1 and EM2 seen in the deeper sediments (before 1970) is more problematic since these past sources are no longer present and contributing to recent sediments. Additional work upstream in Yosemite Creek might help to find the physical source of EM3, possibly in upstream sewer sumps. However, even without this complete validation of source locations, this case study has shown how forensics studies can be used to identify PCB sources in sediments.

3.2 Site II: Ashtabula River

3.2.1 Site Description

The second case study site is on the Ashtabula River, where the river flows into Lake Erie, east of Cleveland, Ohio (Figure 3-24). A maintenance and contaminated sediment management project was conducted at the site, in conjunction with a U.S. EPA research project of environmental dredging (e.g., investigation of dredging residuals [66]). The detailed study location is highlighted in Figure 3-24 (lower figure).

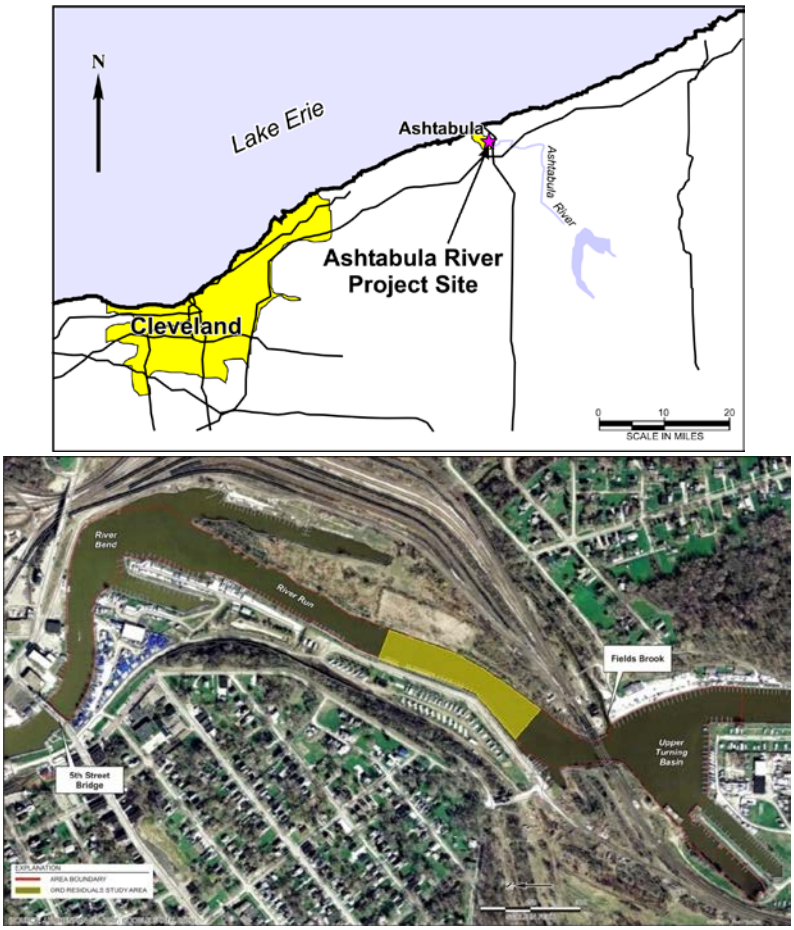

Figure 3-24. Ashtabula River with Dredge Site Study Area Highlighted

A joint partnership project was initiated in 2006 between U.S. EPA's Chicago-based Great Lakes National Program Office (GLNPO) and the U.S. EPA's Office of Research and Development (ORD), National Risk Management Research Laboratory (NRMRL), and the National Exposure Research Laboratory. GLNPO, via its Great Lakes Legacy Act (GLLA) mandate, and ORD, through its research mission, had mutual interests in evaluating the efficacy of environmental dredging. The organizations jointly initiated a monitoring effort on the Ashtabula River Dredging Project. Extensive sampling and analysis were completed before, during, and after dredging operations to measure sediment residuals and the impact of remediation.

The remediation of contamination in rivers and other water bodies often involves dredging bed sediment. Dredging, whether used alone or in conjunction with other treatment technologies like in situ capping or natural recovery, can result in the release of contaminated sediments. These residual sediments ('residuals') can be transported within dredged areas (near-field) and downstream or offsite (far-field). A number of factors can influence residual levels including: dredging equipment; operator technique; debris; dredging to bedrock; over dredging; cut lines, slopes, and depths; sediment characteristics; contaminant characteristics and distribution; and the accuracy and resolution of contaminant characterization. Residuals can be categorized as either undredged or dredge-generated. Undredged residuals are the result of missed areas and incomplete characterization. Dredge-generated residuals are released via resuspension, transport and downstream deposition; dredge mixing and immediate deposition; and sloughing.

The Ashtabula River in extreme northeast Ohio flows into Lake Erie's central basin at the City of Ashtabula (Figure 3-24). Its drainage basin covers an area of 137 square miles, with 8.9 square miles in western Pennsylvania. Major tributaries include Fields Brook, Hubbard Run, and Ashtabula Creek. The City of Ashtabula, with an estimated population of approximately 21,000 (2000 census), is the only significant urban center in the watershed, with the rest of the drainage basin being predominantly rural and agricultural. There is concentrated industrial development around Fields Brook (east of the Ashtabula River) and east of the mouth of the Ashtabula River. Sediments in portions of the Ashtabula River are contaminated with a variety of chemicals, including PCBs, the primary chemical of potential concern for this project.

Approximately 550,000 yd^3 of contaminated sediments were dredged between the Turning Basin at the mouth of Fields Brook and the Fifth Street Bridge. COPCs in this stretch of the river include PCBs, PAHs, hexachlorobenzene, hexachlorobutadiene, metals, and the radionuclides uranium, radium, and thorium. The radionuclides are above background levels but below regulatory criteria. In Phase 1 of the research project, GLNPO conducted a baseline characterization of the river that included these COPCs, while ORD focused only on the PCBs in selected areas of the river. In Phases 2 and 3 of this dredge residuals research project, ORD continued to focus on the PCB inventory in the test reach and selected areas of the river.

Historically, the PCBs are thought to have originated primarily from Fields Brook, a stream that drains into the Ashtabula River in the area of the upper Turning Basin. The Fields Brook source has been controlled and eliminated as a source of contamination (or re-contamination) of the Ashtabula River. A CERCLA cleanup of Fields Brook was completed in 2003. A post-cleanup monitoring program is in place to protect against recontamination of Fields Brook as well as the Ashtabula River.

3.2.2 Evaluate Site for Forensic Study

Potential PCB source areas at the Ashtabula River study site have been associated with upstream locations in Fields Brook (on the east side of river at Transects 185 and 186; Figures 3-25 through 3-27). Subsequent studies suggested a second much smaller source from Strong Brook where it meets the river near Jacks Marine (on the west side of the river across from Transects 187 and 188). The U.S. EPA ORD dredge study focused on identifying techniques to characterize dredge residuals and understand their sources. One technique that was evaluated was using PCB compositional information to characterize dredge residuals (the amount of sediment material that is unintentionally left behind after dredging). To support this part of the research, a large number of sediment core samples were analyzed for a detailed list of more than 100 PCB congeners. These cores were subsectioned based on elevation and sediment characteristics (sand lenses, organic matter layers, etc.). These sections were analyzed for PCB congeners and compared to the dredging information (dredge position, production, sediment slopes, etc.) to evaluate potential mechanisms for contributing to dredge residuals.

For the purposes of a case study for this document, this site resembles a typical Navy dredge site (similar dredge technology, similar deposition of contaminants, similar COPCs, etc.) and the chemical forensics data that were generated can be used to demonstrate the approach used in this document to identify multiple upstream sources of contamination. As was demonstrated in the first case study example in this document, the site history and suspected sources for Ashtabula River justify the need for a forensics study to differentiate potential contributions to the river. There appear to be at least two potential historic and/or current sources of PCBs upstream of the dredge area that may become mixed into the sediments in the downstream dredge area. If this was a Navy dredge project, it would be desirable to develop a technically defensible allocation scheme to apportion dredge costs among the upstream sources. A quantitative forensics analysis to apportion the source contributions from the Navy and other sources would be necessary. A forensics investigation would also be warranted to identify if any potential active sources continue to contaminate the river if it is unclear if all sources have been controlled. Environmental dredging or other sediment management actions should only be implemented once it has been demonstrated that all sources are controlled.

3.2.3 Develop Conceptual Site Model

Figure 3-25 shows a contour map of surface sediment PCB concentrations for the Ashtabula River dredge area to support CSM considerations at this site. Additional historic data show potential source areas up the industrial waterway, Fields Brook. The source area has had significant remediation under Superfund that was completed in the 1990s. These actions include source control to eliminate PCB discharge to Fields Brook and subsequently reduce the contaminant migration off site to Ashtabula River. As a result, the Ashtabula River recently deposited surface sediments no longer show high concentrations of PCB contamination, but the older, deeper sediments in the downstream dredge area still show contamination from these historic Fields Brook sources (Figure 3-26). However, the surface sediment contours suggest increasing concentrations across the river from Fields Brook toward Jacks Marine (and Strong Brook). As a result, additional sediment cores (JAM1-3) were later collected in this area and showed total PCB concentrations well above 1000 ppb. Therefore, this area is considered a second source area for PCBs that has more recently contributed to PCBs transported downstream to the dredge area. A forensics investigation for this area included collecting samples near the

source areas and in the comingled dredge area to compare to the two known source areas. This could be used to allocate relative contribution and apportion costs for the dredge project. Additionally, this forensic analysis provided information to ensure that all sources have been controlled before initiating sediment management activities.

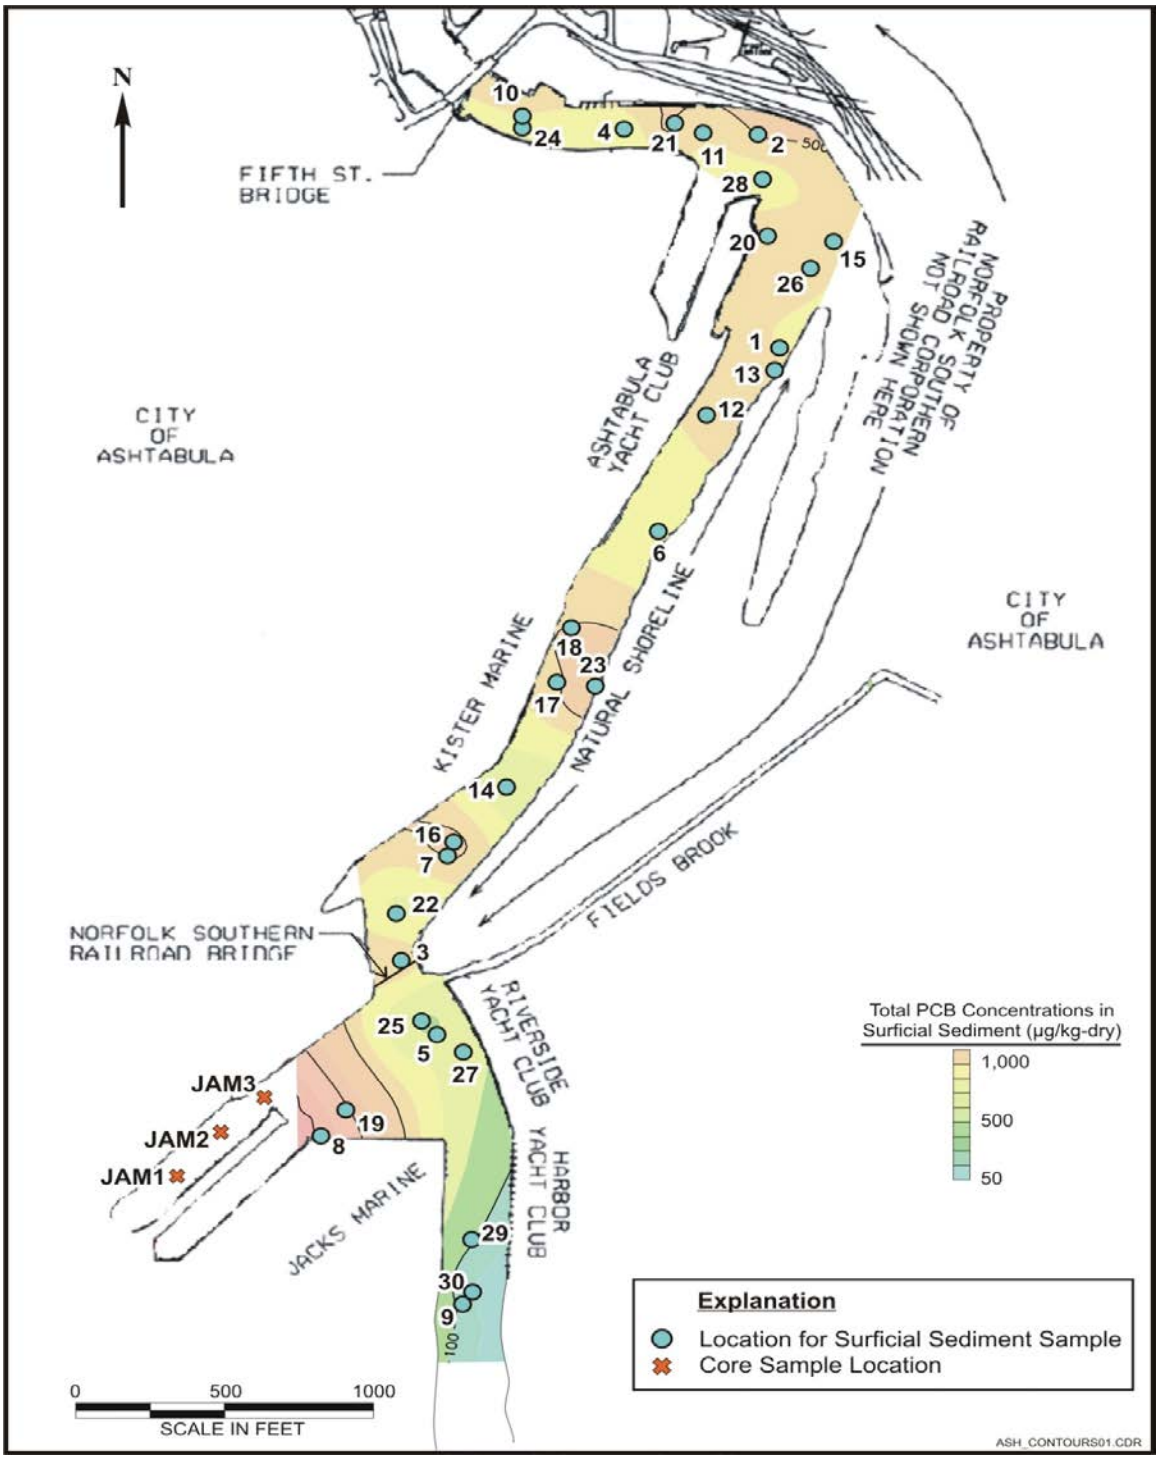

Figure 3-25. Pre-Dredge Contour Map of PCB Concentrations in Surface Sediments in the Ashtabula River Study Area

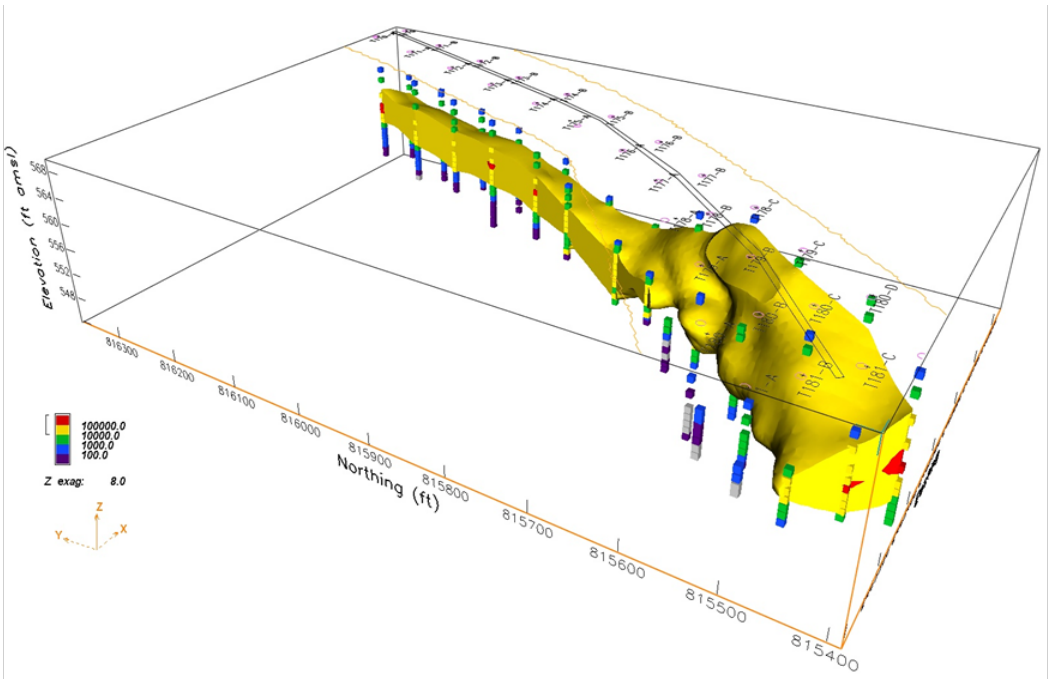

Figure 3-26. Pre-dredge Sub-surface Sediment Concentration Profiles in the Ashtabula River Study Area Indicating Sediment with Total PCB Concentration > 10,000 ppb

3.2.4 Develop and Execute a Technically Defensible Sampling Plan

Though the ORD project on Ashtabula River had significant amounts of data that were used for this case study, there were limitations to the data in terms of use for an environmental forensics investigation. The purpose of the ORD study was not to demonstrate the ACF; however, the study did provide a large portion of the data needs (at a significant cost savings) for the case study for this document. The environmental forensics demonstration made use of available data as best as possible. Figure 3-27 shows a portion of the dredge area where 30 cores were collected and segmented to produce more than 350 subsamples for both RSC and ACF analysis. Additionally, three cores (JAM1-3 in Figure 3-25) were collected in the Jacks Marine area near the confluence of Strong Brook and analyzed to identify another potential source.

To utilize these data as a case study, a data gap analysis was completed. Inconsistent sampling and analysis techniques were used for the two sets of in-river core samples (30 original cores and the JAM cores). One significant problem was the different depths of surface sediment sampling and sediment core segmenting between the two coring events. Secondly, samples were not collected at the mouth of Fields Brook, an historic source. Therefore, older and incomplete information must be relied upon to define this source. In addition, samples were not collected upstream of the confluences of the two brooks discharging to the river to ensure there were no additional sources and to identify the background PCB concentrations and composition of the river sediment. The surface sediments were generally 15 cm or more in depth in the original core samples. This depth may represent many years and even decades, depending on the rate of deposition. For ACF analysis, surface sediment samples should be no more than a few cm deep to obtain information on current or recent sources.

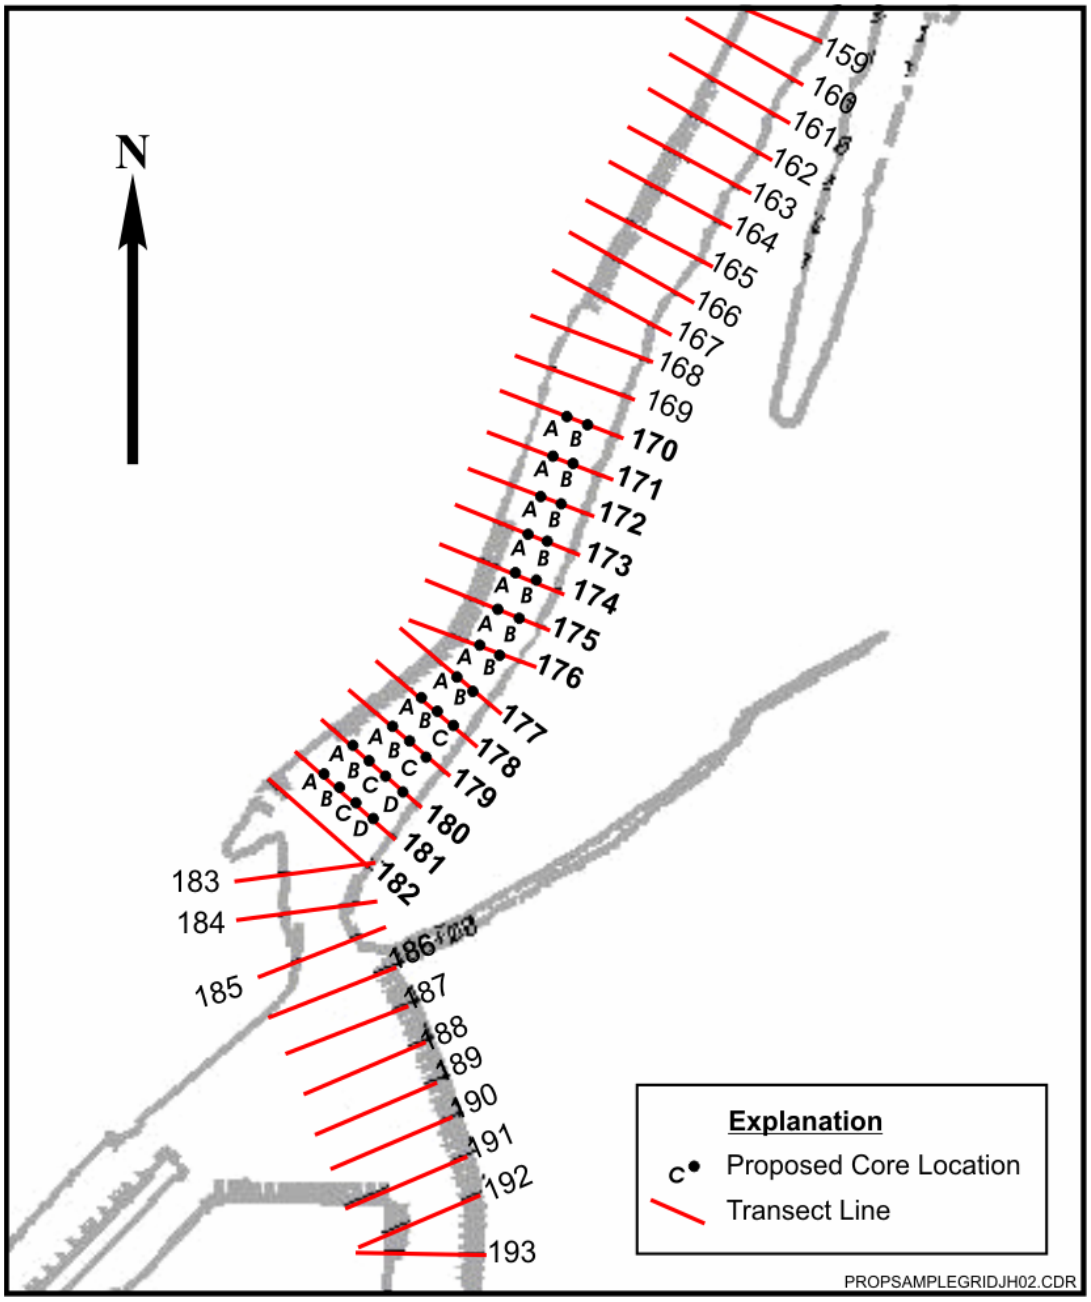

Figure 3-27. Sampling Design Map for ORD Dredge Residuals Study at Ashtabula River Transect Cores
(U.S. EPA, 2010 [67]) (These cores provided the pre-existing data used in this forensics demonstration.)

The Ashtabula River case study, like the HPS study, is based on using existing data from study designs not optimized for a forensics investigation. Clearly, there are advantages and limitations to a forensics study using only pre-existing data. Though pre-existing data provides a large cost savings, the shortcomings of a sampling design to provide information for another purpose must be accepted. As stated earlier, unexpected results are likely to occur even in the best designed forensics study. In the case of the Ashtabula study, this is why the additional JAM1-3 cores

were collected and analyzed. Initial data for this segment of the river showed surprisingly elevated concentrations with a strong Aroclor 1260 signature. This signature was different from the Aroclor 1248-dominated Fields Brook contamination. Originally, Fields Brook had been assumed to be the only source to the Ashtabula River that needed to be managed. The additional sampling in the Jacks Marine/Strong Brook confluence area identified an active source of Aroclor 1260, which subsequently was controlled shortly before dredging began. Although it may be easier to grasp a forensics study that follows a linear process (Figure 1-1), it may be more realistic to assume the process will be iterative with a need to obtain information on additional unknown sources and fill in additional information gaps as the project proceeds.

While it is cost effective and faster to use pre-existing data (no additional field or analytical costs), the limitations are that the study design may not meet all of the objectives of a well-designed forensics study. Fortunately, the study plans in the Ashtabula River case, although not intended to satisfy a forensics study, did include relatively detailed sediment sampling and rather comprehensive PCB congener analysis. Significantly more useful information was produced in the ORD research study than would be typical in a standard RI.

3.2.5 Conduct Rapid Sediment Characterization

The ELISA IA technique was also used to obtain RSC data on Ashtabula River sediment samples and the RSC data are summarized in Appendix C. The Ashtabula River research study was, like the HPS study and as described earlier, not conducted as a forensics investigation. As a result, the analyses were not tiered with the RSC analysis followed by a smaller set of ACF analyses. The PCB congener analyses were also conducted on all RSC samples.

For the Ashtabula River research study, the ELISA RSC data were not used in a tiered approach to select additional analyses. The research question was to compare the RCS to the PCB homologue data. These homologue data were also generated on the samples and provide more reliable and useful Total PCB data (Sections 2.4.1 and 2.4.3). The laboratory-based Total PCB concentrations were determined both using Method 680 to quantify individual homologues and summing those to generate the total PCB (Section 2.4.1) and by summing the 117 PCB congeners quantified during the ACF analysis; the results compared very well. The Total PCB concentrations based on the sum of the 117 PCB congeners are presented along with the individual congener data in Appendix B. As discussed earlier, those 117 congeners represent approximately 97 to 98% of the Total PCB in most environmental samples and are a good representation of the Total PCBs.

3.2.6 Conduct Advanced Chemical Fingerprinting

The ACF analysis of the Ashtabula River sediment samples consisted of determining the concentrations of 123 PCB congeners using modified Method 680/1668 (a HRGC/LRMS technique), as described in Sections 2.4.2 and 2.4.3. As for the HPS study, this work was not conducted as a forensics investigation and the ACF analysis was performed on the majority of the samples, not a subset selected by first reviewing the RSC results. However, the congeners were carefully selected to represent what could reasonably be expected in environmental PCB contamination, considering potential source material (Aroclor formulations) and environmental processes (Section 2.4.3). The Ashtabula River ACF data are summarized in Appendix B.

During the initial data review, the PCB congener set was reduced to 120 PCB congeners, because three of the congeners were consistently not detected (PCB11, PCB30, and PCB50). Those are the 120 PCB congeners reported in Appendix B. During the subsequent more detailed data review and screening (Section 2.5.2.3), about 53 of the 345 sediment samples were identified as candidates for potentially excluding from the data analysis because of lower data reliability (e.g., low overall PCB concentration [e.g., sum of congeners less that ~50 ppb], a high percentage of the PCB congeners with non-detects, or anomalous composition that cannot be explained by PCB chemistry or weathering factors). Thirty-eight of the 120 PCB congeners were also identified as potential candidates for exclusion from the data set prior to detailed data analysis because of possible lower reliability (e.g., high percent non-detect of the congener, low congener concentration, a high %RSD in the percent contribution of the congener to the Total PCB, or other data outlier issues). As discussed earlier, a stronger and more reliable data interpretation can be obtained with a high quality data for a pared down set of 80 PCB congeners than from a larger set that also includes congeners with lower reliability.

3.2.7 Data Analysis, Synthesis, and Presentation of Results

3.2.7.1 Site History and Records Research

Historical source information was lacking for the Ashtabula River case study, posing a limitation that would need to be rectified if a comprehensive forensics investigation was performed. A major tributary to the study area includes Fields Brook, a U.S. EPA Superfund site which had a high concentration of industry around it with significant runoff and drainage to Fields Brook (Figure 3-28). The site had been historically identified as a source of PCBs to the Ashtabula River; this source had been controlled (Section 3.2.1). Other locations of runoff and input to the river but with less information on historical activities include Hubbard Run, Ashtabula Creek, and Strong Brook (which flows into Jacks Marine).

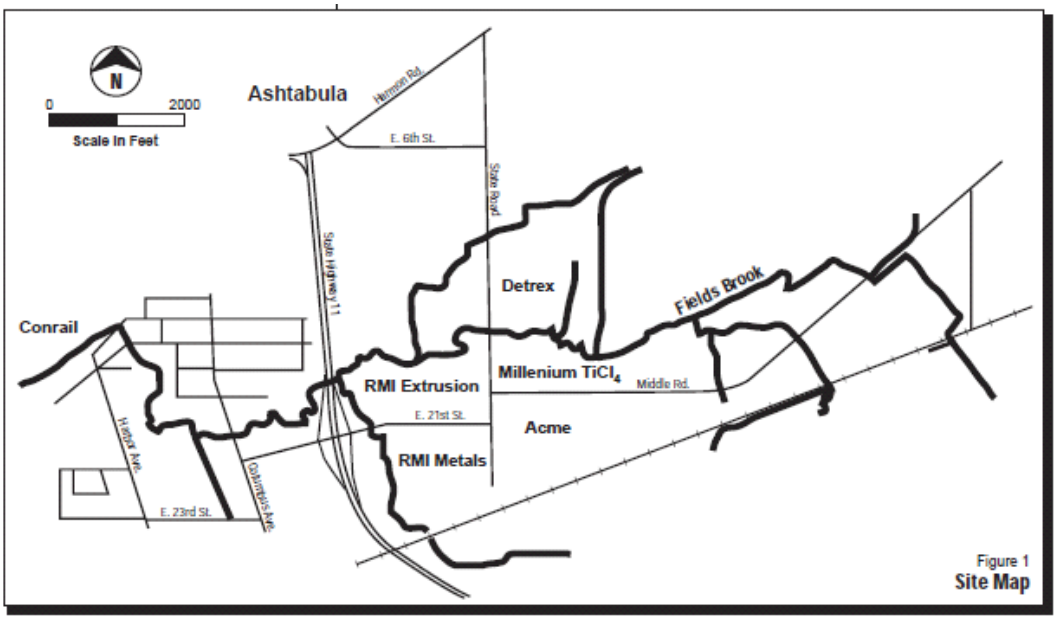

Figure 3-28. Fields Brook Drainage Showing Industrial Activities East of Ashtabula River
(Ashtabula River is located on the left side of this figure.)

3.2.7.2 Sediment Transport and Hydrodynamics

As part of the GLNPO GLLA remediation activities, sediment transport and deposition studies were conducted at Ashtabula River, but the results are not readily available. These studies indicated that an estimated 4 cm of sediment will be deposited annually. These newly deposited sediments are anticipated to be clean materials from upstream of the project area. There were no dedicated studies of hydrology or sediment stability/transport available for this Ashtabula River case study, and this was clearly a limitation that would need to be rectified if a comprehensive forensics investigation was performed. The segment of the river that was studied is upstream of tidal influence, and standard river flow considerations are all the transport information that was available.

3.2.7.3 PCB Concentrations

The PCB concentrations were relatively uniform in the Ashtabula River surface sediments for most of the ORD research study area (Figure 3-25). Figures 3-26 and 3-29 illustrate a 3D model of the sediment PCB concentration profile in the study area. Each color in the 3D figure shows a distinct isoconcentration profile that varies both horizontally and vertically. The surface sediment Total PCB concentration was between 500 and 1,000 ppb in most of the ORD research study area (Figure 3-25 and 3-27). The subsurface sediment PCB concentrations were more variable and were generally much higher than the surface concentrations. The total PCB concentration was above 10,000 ppb in much of the subsurface sediment (Figure 3-26; [66]). The most contaminated sediments were generally found at 5 to 10 ft depth, but highly contaminated sediments were found at less depth at some locations. The sediments at greater depth (below the most contaminated zone) had variable PCB concentrations that were more comparable to the surface sediment PCB concentrations. The subsurface PCB concentrations were somewhat variable within the relatively small ORD study area, but no obvious pattern of increasing or decreasing concentrations geographically was evident with the exception of the highest concentrations being measured at depth close to and immediately downstream of the mouth of Fields Brook (top, Figure 3-29).

On more careful review of the surface sediment data from the Ashtabula River, it appeared that the PCB concentrations might be elevated just outside the ORD research study area (Stations 8 and 19 in Figure 3-25), and near Jacks Marine and the confluence of Strong Brook (Figure 2-13). The PCB composition of downstream surface sediment samples indicated a composition that was slightly different from that of the primary known source (Fields Brook) and these two facts prompted additional sampling near Strong Brook's confluence area to further investigate the elevated concentrations. This was important since the area was to be dredged and it was critical that all known sources of PCBs were controlled to avoid recontamination.

The additional sampling at the confluence of Strong Brook demonstrated that the surface sediment PCB concentrations were significantly elevated (Figure 3-30); surface sediment concentrations in Jacks Marine were around 10,000 ppb (more than 10 times higher than the GLLA project area) and elevated concentrations were also measured in shallow subsurface sediment from this area.

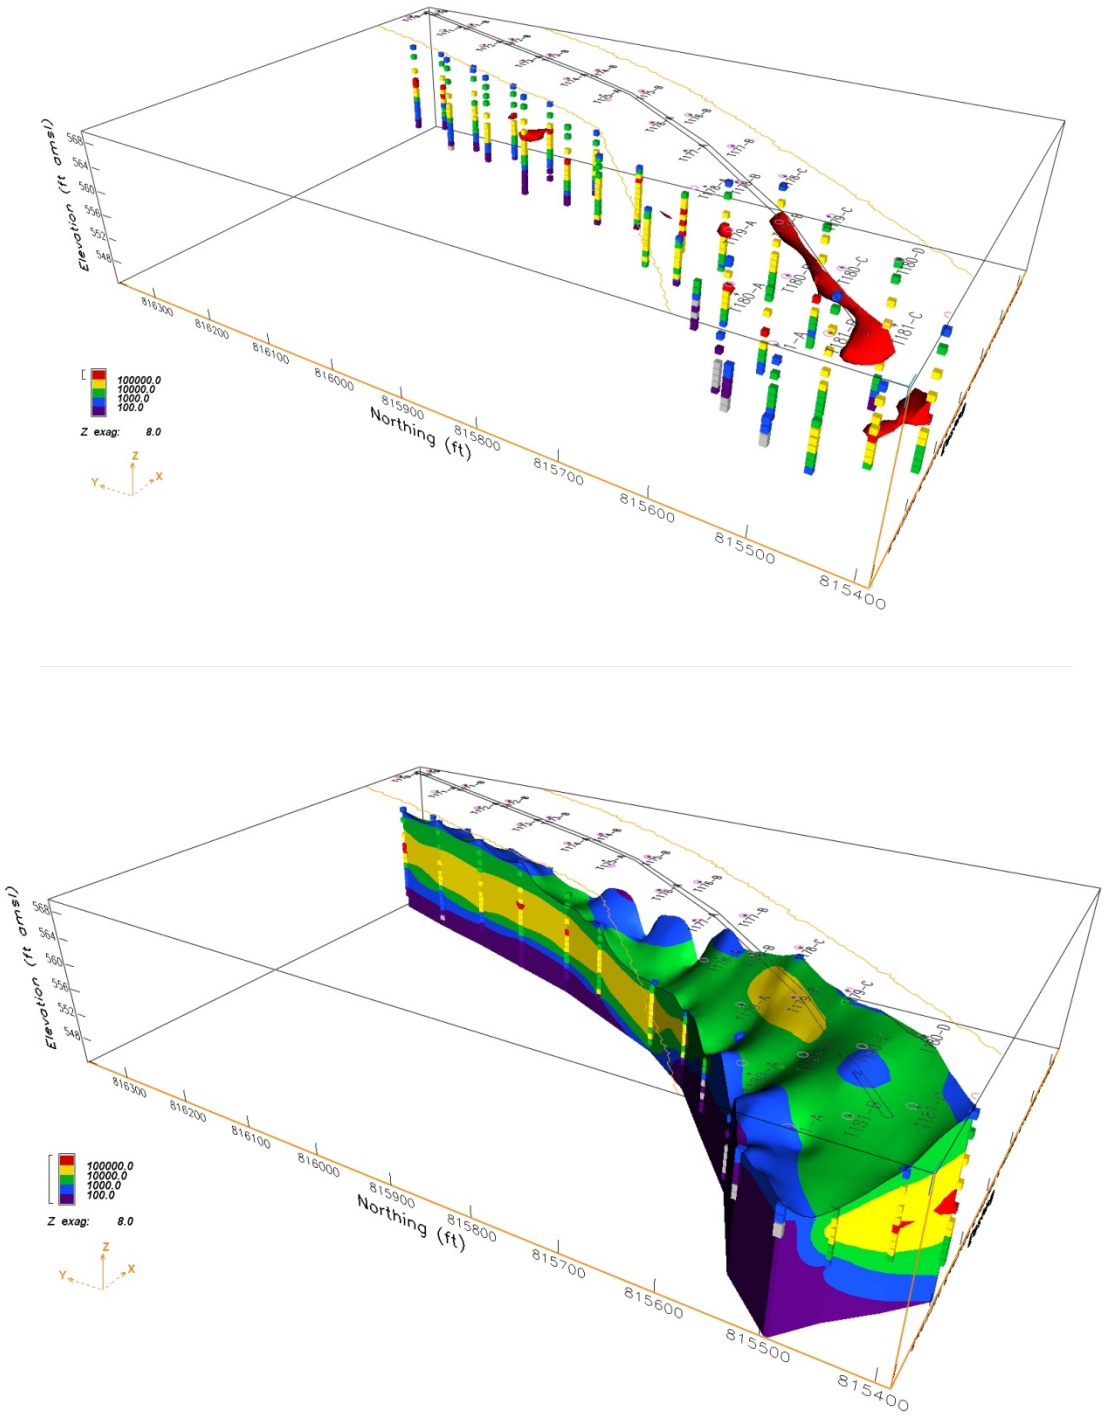

Figure 3-29. Example Ashtabula 3D Contour Maps (µg/kg or ppb total PCB): (a) >100,000 ppb Contoured Volume; (b) all contours including >100, >1000, >10,000, >100,000 ppb
(from U.S. EPA, 2010 [66])

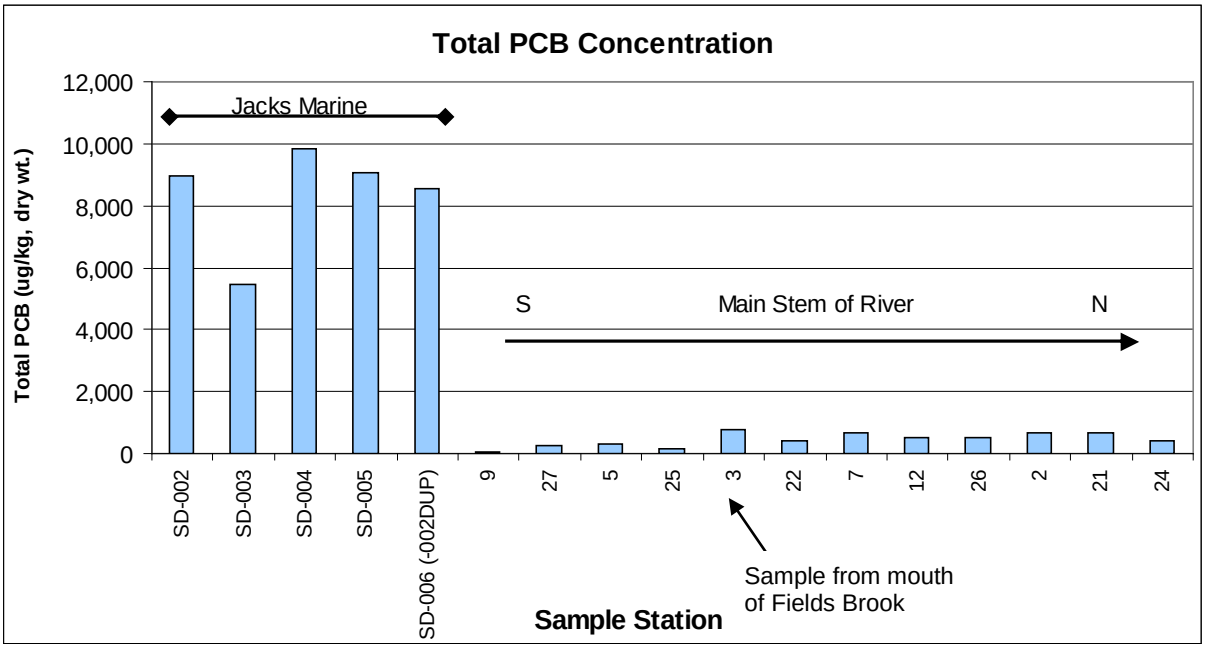

Figure 3-30. Total PCB Concentrations for Selected Ashtabula River Surface Sediment Samples, Including from Jacks Marine and the Main ORD Study Area (µg/kg, dry weight)

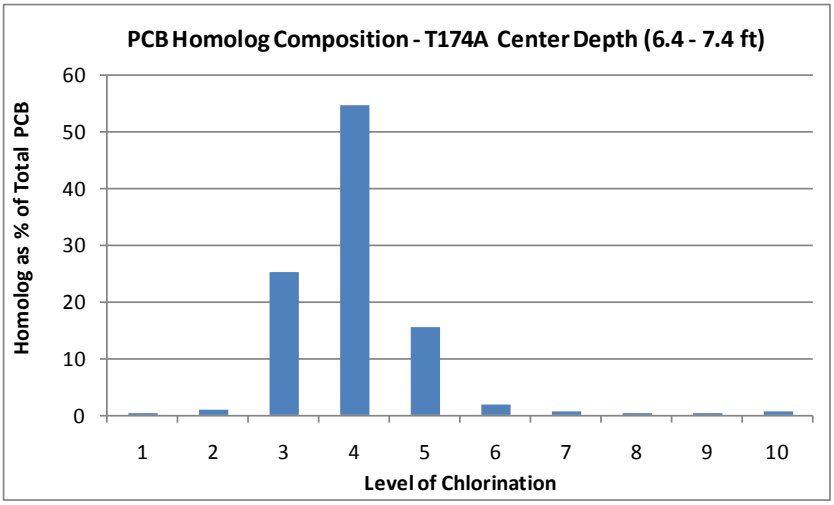
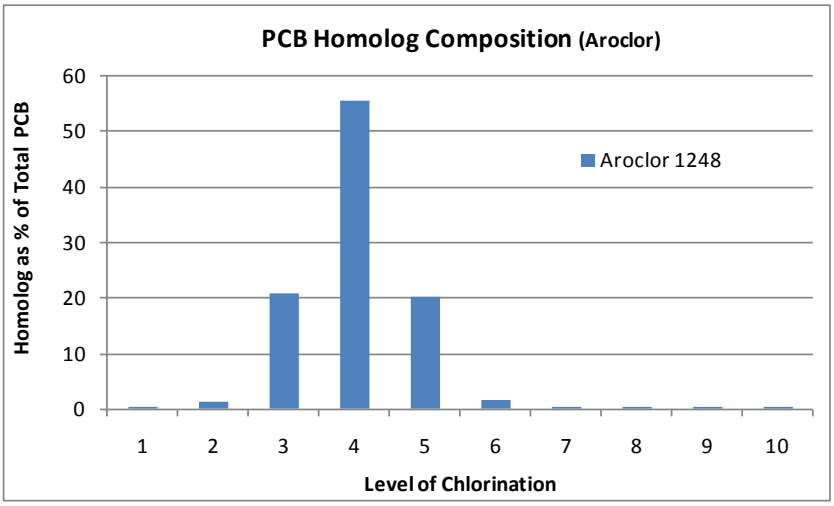
The Ashtabula River PCB concentration data indicate that most of the PCB contamination is historic and originated with the controlled Fields Brook Superfund source. This is apparent by comparing the high subsurface PCB concentrations in the main stem of the river downstream from the mouth of Fields Brook and the substantially lower surface sediment concentrations. The surface sediment PCB concentrations suggest that low levels of PCB may still be discharging from Fields Brook. This is indicated by the slightly higher PCB concentration at Station 3 (at the mouth of Fields Brook) compared to the rest of the study area, but the magnitude of elevation is small. The surface and near-surface data do, however, indicate a recent and active source of PCB to Jacks Marine (i.e., Strong Brook), likely a source of PCBs to the Ashtabula River.

3.2.7.4 PCB Composition

The Ashtabula sediment PCB composition was evaluated using both homolog and congener-specific data. Most samples from the most contaminated zone (at 5 to 10 ft depth) had a PCB composition that closely resembled Aroclor 1248-type contamination consistent with information regarding the historic Fields Brook source. This was demonstrated using both PCB homolog and PCB congener data (Figures 3-31 and 3-32); PCB homologue data can often also be very useful for compositional analysis including for multivariate analysis. This close match with Aroclor 1248 was observed throughout the ORD study area in most sediment below 1 ft in depth and in all of the most contaminated sediment. Sediment samples with a total PCB concentration above 10,000 ppb all showed a very close compositional match with Aroclor 1248.

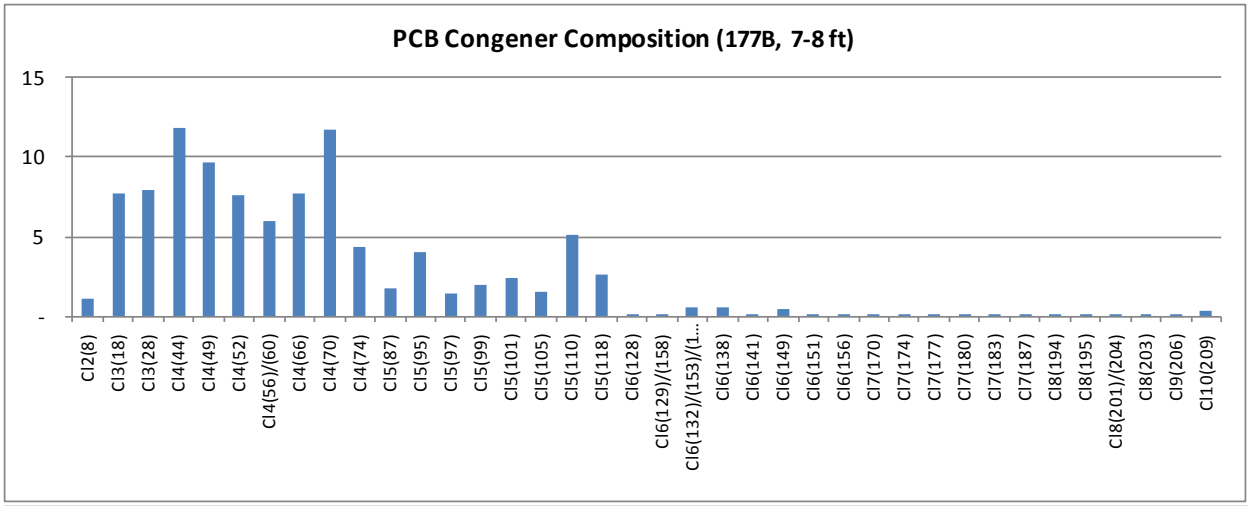


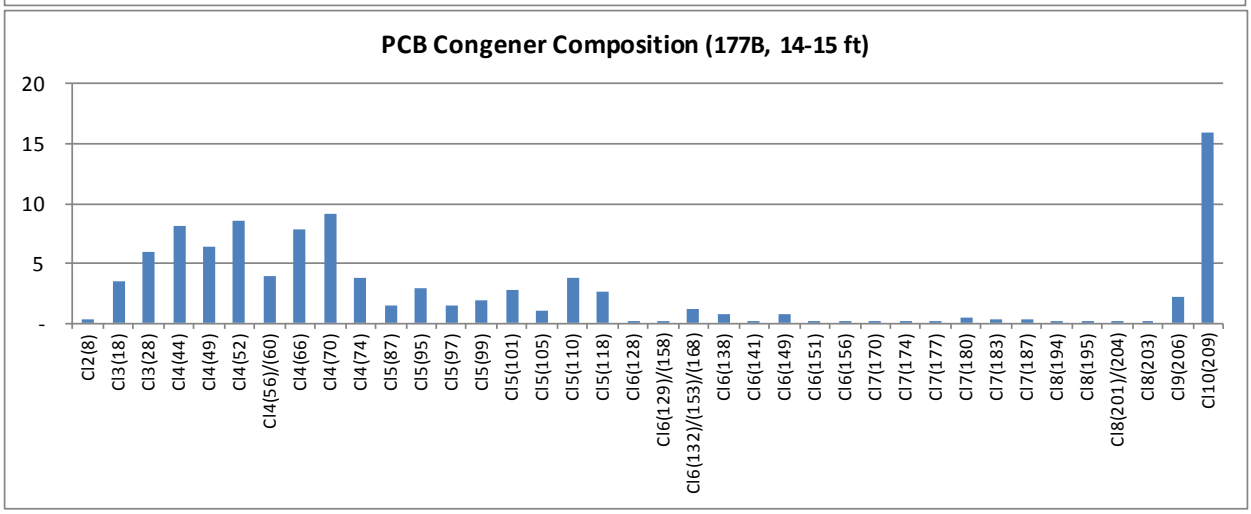
a) Pre-Dredge Core Sample T174A (from 6.4–7.4 ft sediment depth)



b) PCB Aroclor 1248

Figure 3-31. Composition Analysis Showing the Similarity in the PCB Homologue Composition of Ashtabula River: (a) Sediment Core T174A from a Depth of 6.4–7.4 ft; (b) and Aroclor 1248





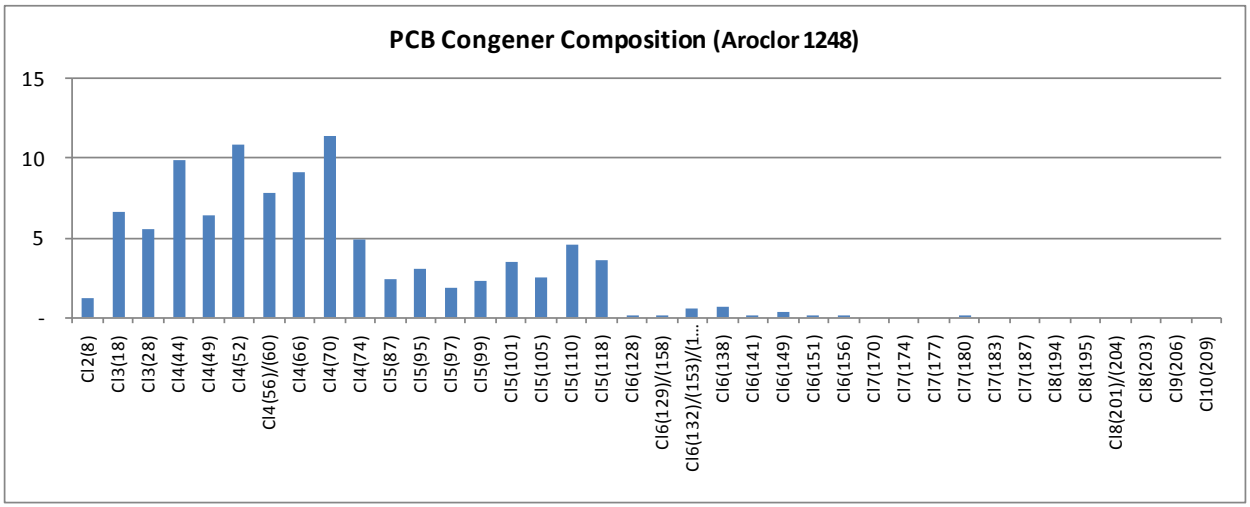


Figure 3-32. PCB Fingerprint of Sediment Samples from 7-8 ft and 14-15 ft Depth in the Center of the Ashtabula Study Area Compared to a Reference Aroclor 1248
(The primary source of the PCB was assumed to be the Fields Brook Aroclor 1248 source.)

The sediments collected from the greatest sediment depth (the lowest elevation) that were below the most contaminated zone exhibited a PCB composition that also was dominated by an Aroclor 1248 signature. However, these deeper sediments (e.g., as illustrated by the 14 to 15 ft segment in Figure 3-32), often also had a contribution by a few chlorinated PCB congeners (e.g., a few octa-, nona-, and deca-chlorobiphenyls) that do not have a clear relationship to any particular Aroclor formulation. The high relative amounts of PCB209 (deca-chlorobiphenyl) compared to the octa- and nona-chlorobiphenyls, for instance, were greater than in the highly-chlorinated Aroclor formulations (e.g., Aroclor 1268, and the rare Aroclors 1269-1271). The distribution cannot be explained by common environmental alteration processes. There are industrial processes (e.g., titanium tetrachloride production) that may selectively produce these highly-chlorinated congeners and this would warrant further investigation in a comprehensive forensics investigation. However, the sediments with this unique composition generally had low PCB concentrations compared to most samples ranging from less than 1,000 to about 3,000 ppb.

The surface and near-surface samples from the Strong Brook and Jacks Marine area did not have an Aroclor 1248-type PCB composition, but instead closely resembled Aroclor 1260 (Figure 3-33) with minor contributions from also a lower molecular weight Aroclor (possibly Aroclor 1248). The downstream surface sediment for the ORD research study area had a PCB composition that indicated contamination from both an Aroclor 1248 and Aroclor 1260 source (Figure 3-32). This was confirmed using data sets with both 38 and 80 PCB congeners (Figures 3-34 and 3-35). The Aroclor 1248 predominance was strongest near Fields Brook even in the surface sediments and the Aroclor 1260 predominance was strongest in the Strong Brook confluence. Figure 3-36 is a PCA analysis of the surface sediment PCB data (homologs and congeners) that demonstrates the association of the sample from the mouth of Fields Brook to Aroclor 1248, the association of the samples from Strong Brook confluence to Aroclor 1260 and the samples from the main study area are influenced by both the Aroclor 1248 and Aroclor 1260 source.

The observed PCB compositional match to Aroclor 1248 near Fields Brook and the sediments that were highly contaminated before the Fields Brook source was controlled. This analysis indicates that this was the source of the majority of the PCB in the ORD research study area and that, for the most part, it has been controlled. The strong Aroclor 1260 signature in the Jacks Marine sediment was evident in the surface sediments, indicating a recent and active source of PCB in this area, most likely Strong Brook which flows into Jacks Marine. The Aroclor 1260 signature and the PCB concentrations declined with depth near the confluence of Strong Brook, indicating that a source may have been active only recently.

3.2.7.5 Chemometric Statistical Analysis

As discussed in Section 2.5.2.3, the data screening process is presented in this handbook as a discrete step between data preparation (2.5.2.2) and data analysis (Section 2.5.3). In reality, it is usually an iterative process with preliminary data interpretations on numerous analyses of the data and finally arriving at data interpretation that are both robust and spatially/temporally representative of a study area. This process is well illustrated with the Ashtabula ORD research data set.

For the Ashtabula project, the PCB congener data were from two separate pre-dredge investigations: (1) the Summer 2006 GLNPO baseline surface sediment sampling (17 samples); and (2) the Fall 2006 EPA ORD Phase 1 core sampling within the proposed dredge area (328 samples). Congener-specific analyses were conducted on both data sets by the same laboratory (Battelle) using the same preparation and analytical methods. Therefore, the data from the two events could be considered comparable and subsequently combined for greater spatial representation.

The combined data were delivered in spreadsheet tables which contained the information listed in Section 2.5.2.2, including: sample ID, sample coordinates, sample depths, analyte identifiers (i.e., congener names), and laboratory results. A digital base map was received in the form of a GIS shapefile, which was used to construct a simple base map (Figure 2-13) showing key geographic features of the study area and sample/core locations.

The data set initially considered for statistical analysis was comprised of 345 samples and 123 congeners. While this represents many more samples and congeners than were available at HPS (Section 3.1), it is clear that this data set still had limitations. The vast majority of samples were a very small area (the ORD research area within the larger GLNPO GLLA project area). GLNPO collected samples across a much wider geographic area but only 17 of surface samples were collected and none at depth. In addition, samples were not collected from Fields Brook (where PCB sources are known to be located). The contribution from Strong Brook was not initially considered and samples were not collected at its confluence. This is understandable given the sampling objectives of the EPA ORD (to establish baseline conditions for evaluating dredge residuals) and EPA GLNPO programs (to evaluate pre-remediation conditions). These two sampling campaigns were designed with a PCB forensics investigation in mind for source identification and allocation.

While not ideal for purposes of source identification and apportionment, the Ashtabula case study makes for a useful and instructive example. If there are limited or no resources available for additional sampling and analysis (as is often the case), existing data may be used to effectively conduct an ACF study. An adaptation of the ideal six-step integrated forensics approach process (Section 1.2.1) that includes development of a detailed sampling plan focused on specific forensic objectives (Section 1.2.1.3) may need to be developed to use existing data with budget or time limitations.

As per Section 2.5.2.1, the Ashtabula ORD research data set underwent laboratory data quality review. Based on that review, the congener data were accompanied by recommendations for exclusion of samples and congeners. These included (1) exclusion of samples with total PCB concentrations less than 100 µg/kg; (2) exclusion of samples with greater than 20% of congeners non-detect and total PCB less than 250 µg/kg; (3) exclusion of congeners with non-detects in more than 25% of samples; and (4) exclusion of congeners that were consistently reported at low concentrations (<0.2% of total sum of all congeners). This data QA review resulted in a recommended reduced data set composed of 293 samples (down from 345) and 83 congeners (down from 123).

As was the case for the HPS case study (Section 3.1.7.5), all individual data screening decision points will not be recounted here. However, one is instructive and provides an idea of the types of considerations typically taken into account in this process. The reduced data set (based on the criteria above) considered a 293 sample/83 congener subset of the full 345 sample/123 congener data set. As per Section 2.5.2.3, these data were processed through initial multivariate analyses to assess data usability for chemometric analysis. As a result of this review, it was found that the initial 100 µg/kg sample cut off resulted in a poor fit for some key congeners, and a receptor model would not converge. As is the iterative nature of this ACF approach, it was necessary to increase the concentration cut off to 500 µg/kg. This new threshold resulted in a 252 sample 83

congener matrix and subsequently, a cleaner, better fit model was developed with more interpretable end-members.

As a means of demonstrating the data evaluation process for ACF, another data screening option is described below. The data set was also evaluated with a higher concentration threshold by increasing the total PCB concentration cut off to 1,000 µg/kg (1 ppm). This resulted in a 222 sample data matrix and an even cleaner model. However, by adopting such an aggressive concentration threshold, many GLNPO surface samples were removed from the analysis (all except those collected near Strong Brook). In addition, many of the lower concentration, deeper, samples were eliminated by the 1,000 µg/kg cut off criterion. Given this, the data set used for chemometric analyses of the Ashtabula ORD and GLNPO data set (Section 3.2.7.5) was based on the 500 µg/kg cut off. This decision was made, not because it was ideal in all respects, but because it was a good compromise between (1) a relatively clean, well fit model and (2) good spatial coverage across the study area. This example is instructive as a lesson for data screening prior to statistical analysis because the best solution is often a compromise that attempts to balance different project objectives.

The 252 sample × 83 congener matrix was analyzed using PCA as an initial exploratory tool, and was then run using all four receptor models. Goodness-of-fit diagnostics were again examined [9]. These indicated the presence of at least four congener patterns contributing to the system. The CD scatter plot array from the PVA analysis is shown in Figure 3-37. Most of the congeners show a fairly good fit, indicating that a four end-member model is a reasonable solution. Those showing a systematic lack of fit (e.g., PCB4/10 and PCB8) may provide evidence for additional source/congener patterns contributing to the system and such possibilities will be discussed in more detail in Section 3.2.7.6.

A PCA was run on these data and the resulting three component scores plot is shown in Figure 3-38. Colored symbols are used to indicate different groups of samples to illustrate the variations in PCB congener composition in the data set. Note that the data are generally not widely distributed, with the majority of the samples (around 200 of the 252) concentrated on the left side of the plot. These mid-depth core samples (green circles) show a range of chemical compositions between two distinct patterns, an Aroclor 1248 (lower left) pattern and a slightly altered Aroclor 1248 (upper left) pattern. A third distinct congener composition is shown in the deeper core samples (red circles) that plot toward the back right of the data cloud.

There is also one small group of five samples on the front right side of the plot (light blue square symbols – the one to the right labeled E2LQ3). These five samples were all collected in Jacks Marine near the confluence of Strong Brook, indicating that samples are very different from the rest of the data set. Direct inspection of chromatograms from these samples (Section 3.2.7.4) indicated that the Strong Brook area sediment samples exhibit a strong Aroclor 1260 pattern. Other surface sediment samples show a progression in congener composition from this Aroclor 1260 pattern back to more of an Aroclor 1248 pattern (bottom left samples in the data cloud). The general shape of the data cloud roughly outlines a tetrahedron in principal component space which has been drawn here using the four most mutually extreme samples as vertices. Each of these four samples are labeled with different symbols and colors on Figure 3-38.

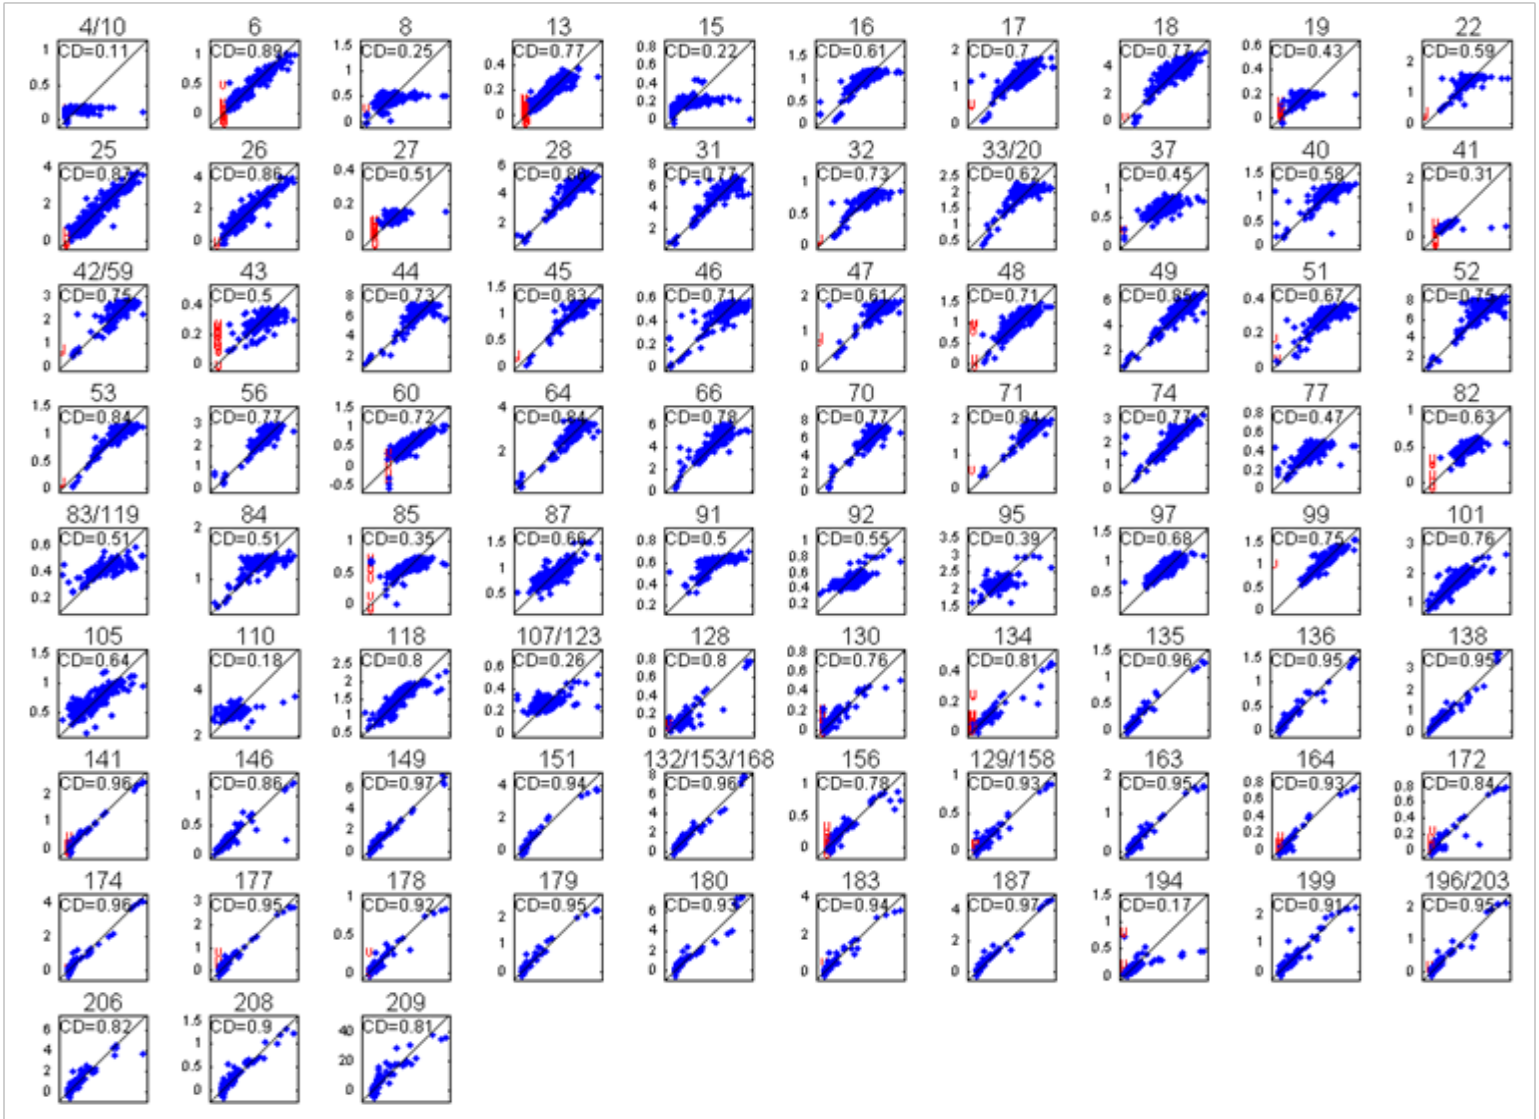

Figure 3-37. CD Scatter-plot Array for a Four Sources System, for 252 Sample 83 Analyte PCB Data Set from Ashtabula River, Ohio

(Non-detect samples are indicated as red "U".)

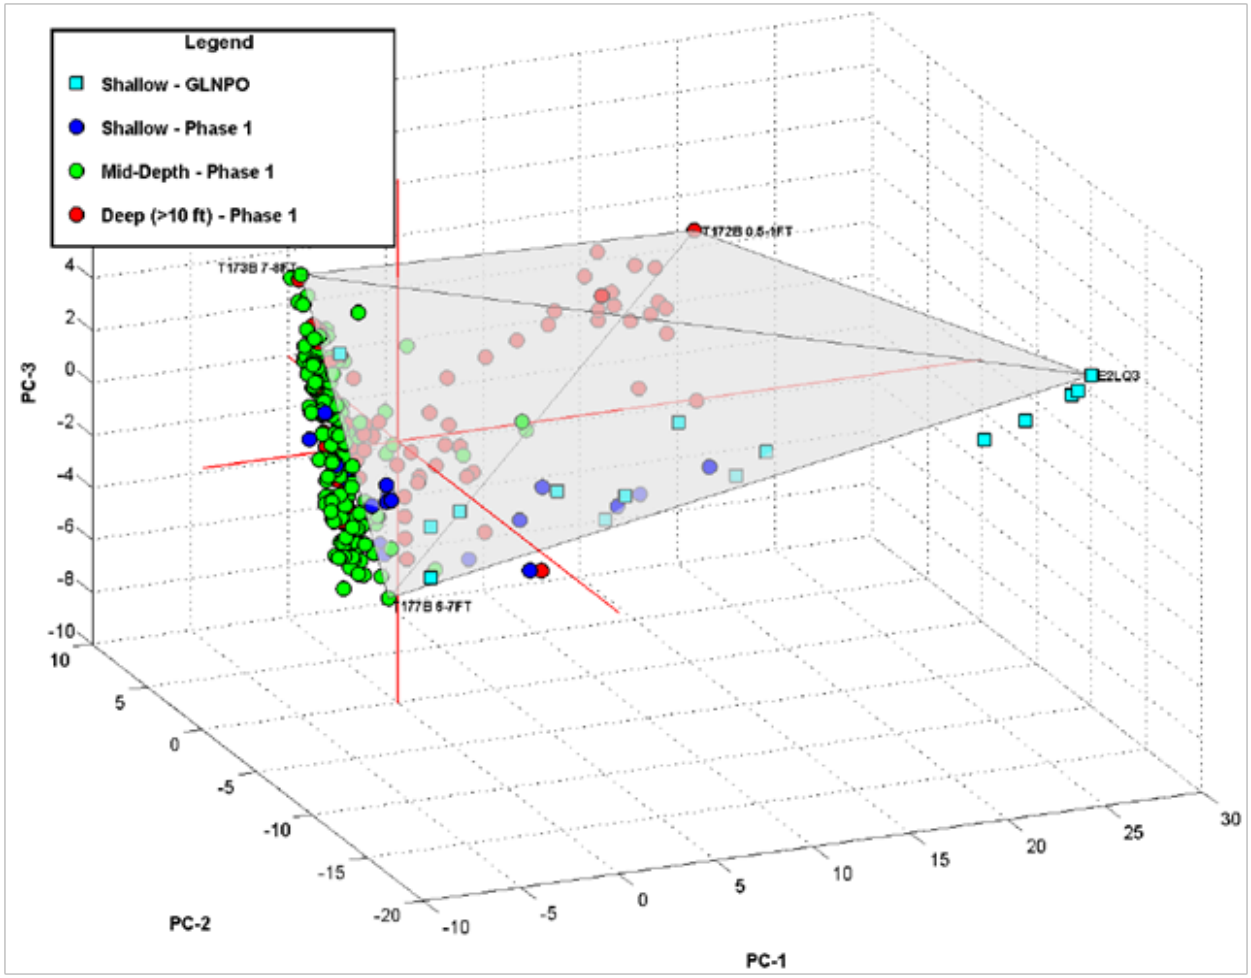

Figure 3-38. PCA Scores Plot for 252 Samples, 83 Analyte PCB Data Set from Ashtabula River

Bar graphs of these four extreme samples are shown on Figure 3-39. The tetrahedron can be thought of as a four end member mixing diagram (as opposed to the three end member triangular mixing diagram from the HPS case study), where each sample congener composition can therefore be represented by a linear mixture of these four distinct end member compositions.

The top pattern of Figure 3-39 (T177B 6-7 feet) is a high concentration sample (∑PCB = 162 ppm) and is a close pattern match to Aroclor 1248 (a source previously identified as the primary Aroclor found in Ashtabula sediments [26]). The second pattern on this figure (T173B 7-8 feet) exhibits a pattern in a similar chlorinated higher range but slightly lighter. This pattern was consistent with a PCB dechlorination pattern reported previously for the Ashtabula River [26].

The third sample (T172B 0.5-1 ft) is a low concentration sample dominated by a single congener; PCB209 (deca-chlorobiphenyl), with additional contributions from a few other highly chlorinated congeners. The bottom sample in Figure 3-39 is E2LQ3, one of the Strong Brook area surface sediment samples. This PCB pattern is primarily composed of highly chlorinated

congeners and is consistent with Aroclor 1260. It would be expected in the receptor modeling that resolved end members (congener source profiles) might be similar to these extreme samples.

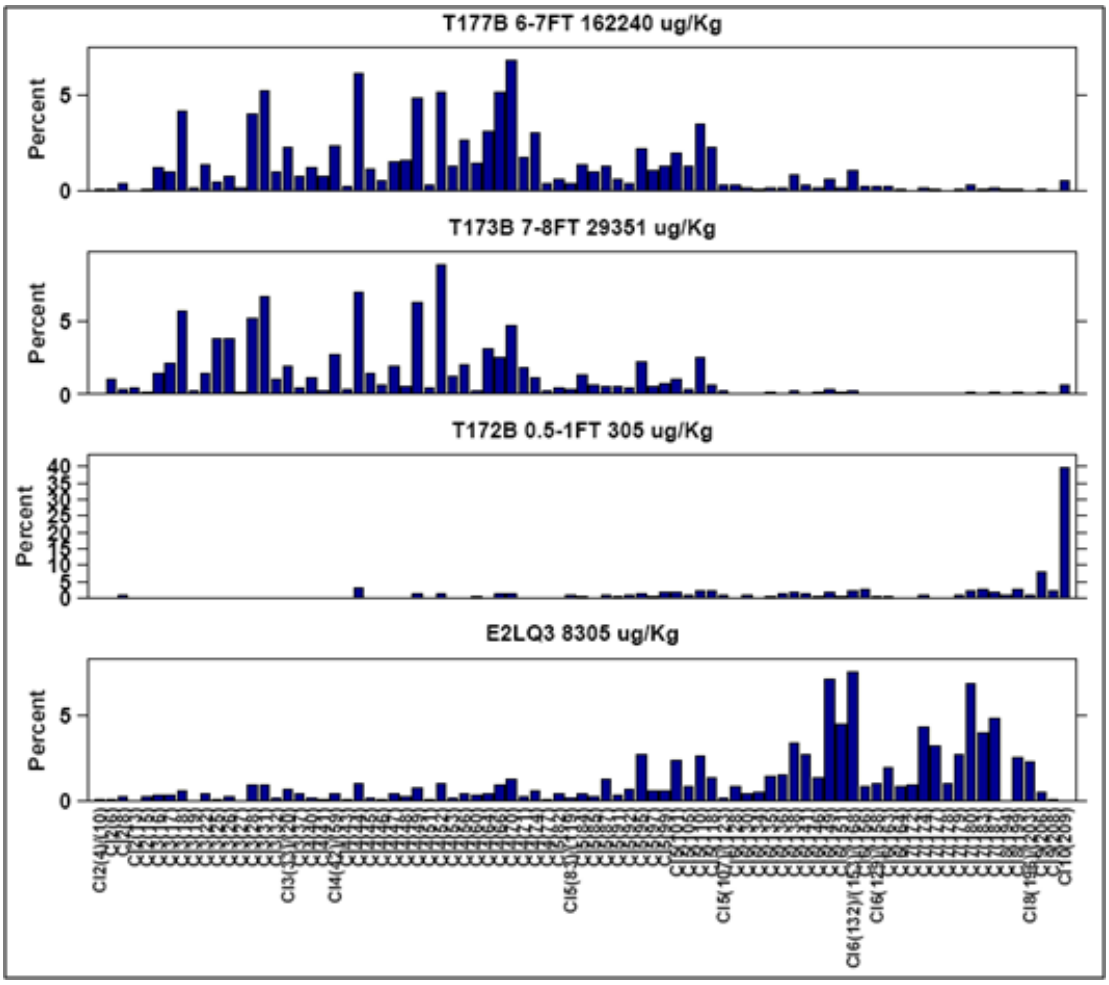

Figure 3-39. Bar Graphs of Four Extreme Samples Labeled on Figure 3-38

This data set was analyzed using the four receptor model methods described in Section 2.5.3.5. Three of the four methods were able to resolve a four compositional solution for this data set. The fourth method (Unmix) was unable to find a feasible solution. The congener profiles resolved by PVA, ALS and PMF are shown in Figure 3-40. All three methods resolved similar congener patterns as "source profiles" and those profiles generally matched those observed in the four extreme samples identified in Figures 3-38 and 3-39. Of these three models, ALS and PVA provided the best estimates. PMF resolved patterns similar to the deca-PCB and Aroclor 1260 patterns, but with notably higher proportions of lower chlorinated congeners not observed in the actual source and/or the most extreme samples in the data set.

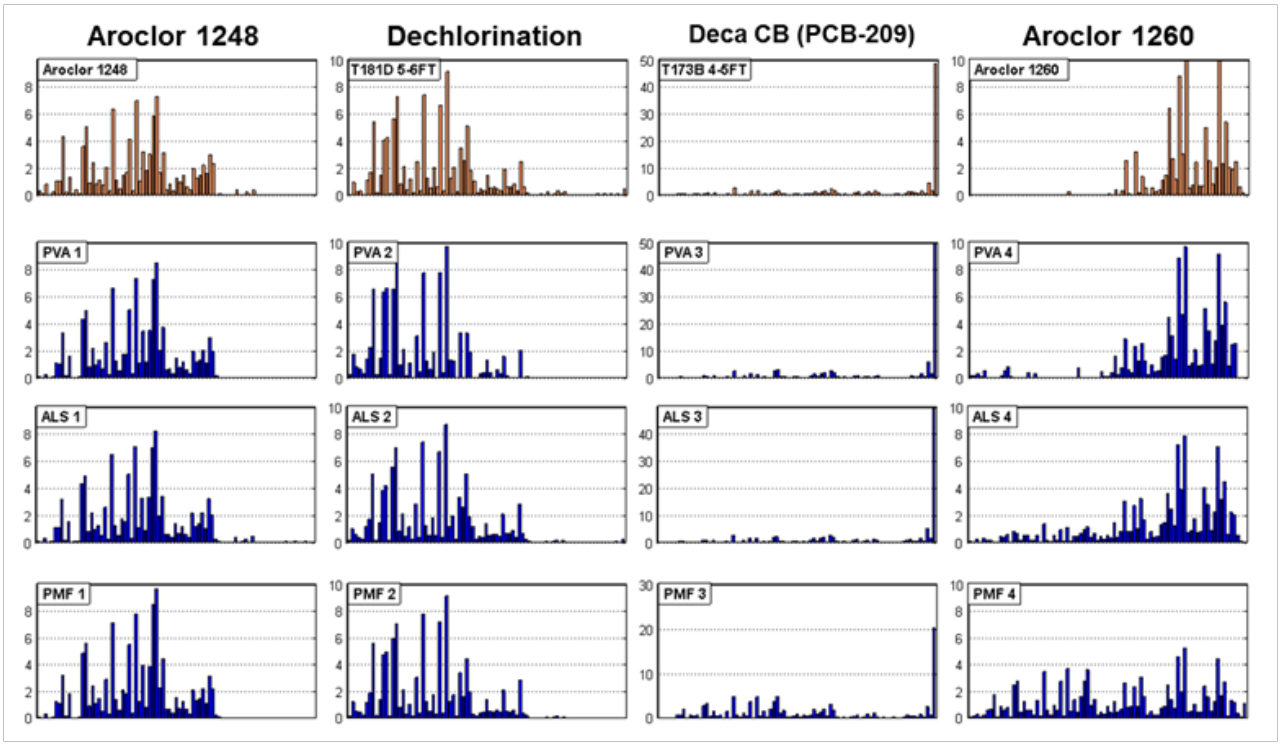

Figure 3-40. Four Congener Profiles (End Members, Source Profiles) Derived from Three Receptor Model Methods (PVA, ALS and PMF), as well as Their Reference Source Composition (e.g., Aroclors 1248 and 1260)

Unmix could not find a feasible solution for this data set. It is suspected that the Unmix method is a mathematical method of finding "edges" in multivariate space. In terms of a four source system, this process involves finding faces of a tetrahedron, which in turn requires a data set with good sample representation along faces of the tetrahedron. As is evident in the PCA scores plot (Figure 3-38), this is not the case for this data set. The data cloud is sparsely populated in the area of the Strong Brook area samples. This is a function of the sampling plan designed for other purposes and not explicitly for ACF (extremely dense sampling in the dredge area; extremely sparse sampling elsewhere) as discussed earlier in this section. Given sampling density inherited for this project, the recommendation is that the data analyst opt for PVA, ALS or PMF as preferred methods over Unmix.

Figure 3-41 shows the spatial distribution of each of the four end members as resolved from the PVA model along a north-south cross section through the dredge area. The predominance of dark and light blue patched areas confirms the observations on the PCA scores plot (Figures 3-38 and 3-39) that the predominant patterns in these cores are the Aroclor 1248 (light blue) and 1248 dechlorination patterns (dark blue). The deca/PCB209 pattern (yellow), when present, is generally observed in deeper samples in the core. Aroclor 1260 (red) is never a predominant pattern within dredge area sediments. However, when it is present, the Aroclor 1260 pattern tends to be in shallower samples. Samples that were omitted as a result of the data screening process are shown as gray patched rectangles and tend to be lower concentration samples (total PCB concentrations [mg/kg] are shown to the right of each sample).

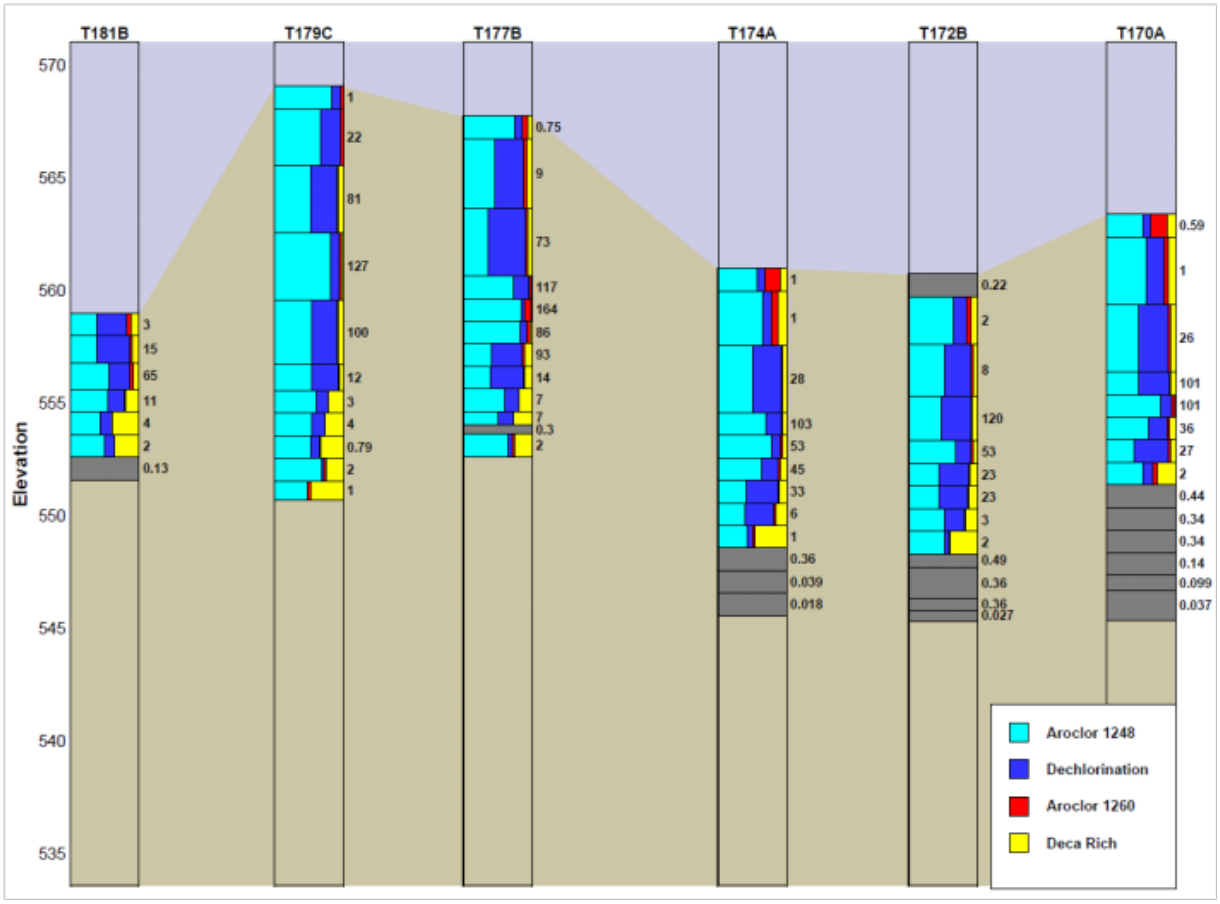

Figure 3-41. South-North Cross Section Showing Percent End-member Compositions and Total PCB Levels (ppm) in Dredge Area Sediments

Aroclor 1260 is not well represented on the sediment/depth profiles (Figure 3-41) because all cores were collected from the dredge area (Figure 2-13). As was evident in the PCA, Aroclor 1260 is predominant in the surface samples collected from the Strong Brook area (south of the dredge area and represented by surface sediment samples only). The absence of an Aroclor 1260 match in the surface sediments is likely because the top 6 inches were sampled in the dredge area, which represents not only relatively recent contamination (e.g., the top 2 cm) but also older deposition. Other work suggests that the Aroclor 1260 source may only have been active in recent years. The spatial distribution of these four patterns in surface sediments is shown on Figure 3-42. As compared to the core profile view (Figure 3-41), this surface sediment map clearly shows that the Aroclor 1260 pattern (right panel – red) is dominant in the Strong Brook area.

As was discussed in relation to HPS, one hopes to find internal consistency across all lines of evidence. However, integrated data analysis often proves most valuable when addressing lingering questions or ambiguities. The remainder of this section provides examples where further chemometric interpretation and separate lines of evidence helped answer such questions.

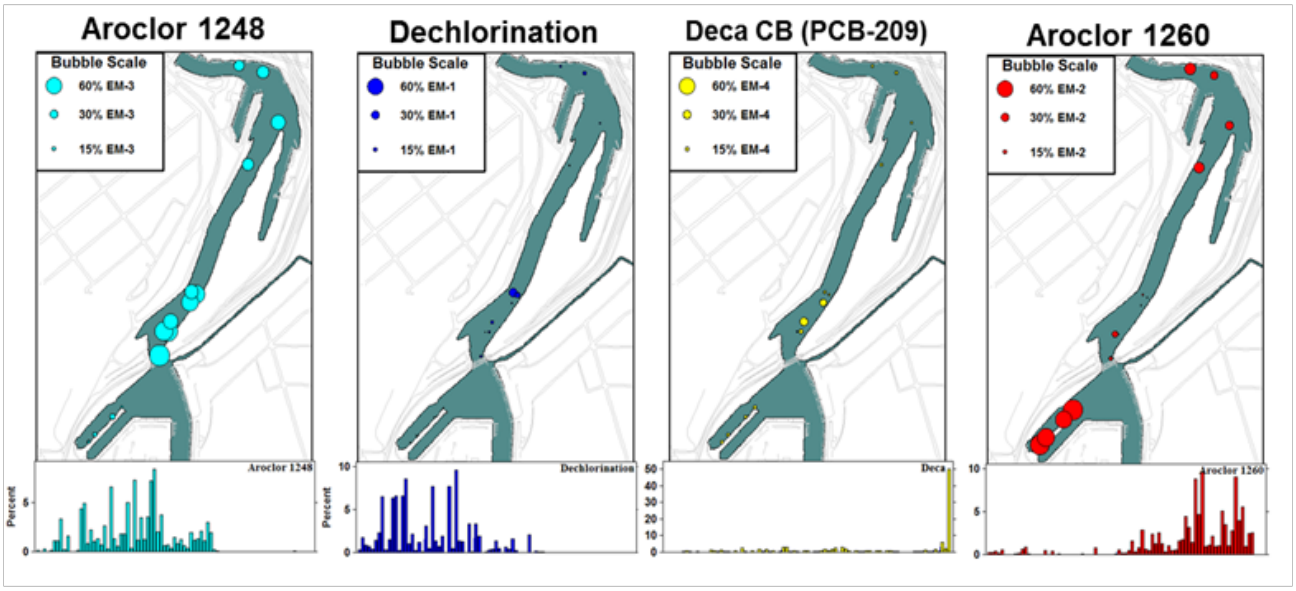

Figure 3-42. Maps of Four PVA Derived Sources in Surface Sediments of Ashtabula River

Source Explanation for Deca Source Pattern

One of the congener patterns resolved in this analysis was dominated by a single congener (deca-chlorobiphenyl; PCB209) which was preferentially observed in deeper (older) sediment taken from cores in the dredge area. This suggests an older historic source, but the specific source, industrial process and/or alteration process, could not be identified. A deca-dominated pattern is not consistent with any known, published Aroclor standard, although it had some resemblance to rarely used PCB products in the Aroclors 1269 to 1271 range. Another possibility could be the production of these highly-chlorinated congeners as part of the titanium tetrachloride manufacturing process [39]. The literature was reviewed, and several publications revealed where a similar, deca-dominated congener had been identified in other study areas [35, 39, 67]. These studies offered some possible interpretations of their version of this pattern, but nothing that could be clearly tied to known sources or alteration processes in Ashtabula. Ultimately, the choice was made to describe and map this congener pattern, but refrain from offering any speculative interpretations. The reason was that when observed in sediments, the deca pattern is usually in older samples (at great depth in sediment cores) and in samples with low relative total PCB concentration (Figure 3-41). Shallower sediment samples often exhibited total PCB concentrations that were two orders of magnitude, or more, higher. In terms of PCB mass that would require remediation, this unusual, highly chlorinated PCB pattern was not a major contributor. Given remediation/dredging concerns as the primary driver in this study, solving the mystery of this fingerprint's origin was not a priority given overall project objectives.

Consideration of a Possible Fifth Source Pattern

As indicated in Section 3.2.7.5, the statistical goodness-of-fit diagnostics performed in conjunction with PVA (Figure 3-37) indicated a minimum of four end members in this system. Some congeners, however, still exhibited a noisy fit (see for example the PCB4/10 and PCB8 scatter plots on Figure 3-37). Therefore, the efficacy of a fifth source pattern was evaluated by

running one PVA for five end members. The result was resolution of four end members very similar to the previous four, and a fifth that was similar to Aroclor 1242 (Figure 3-43).

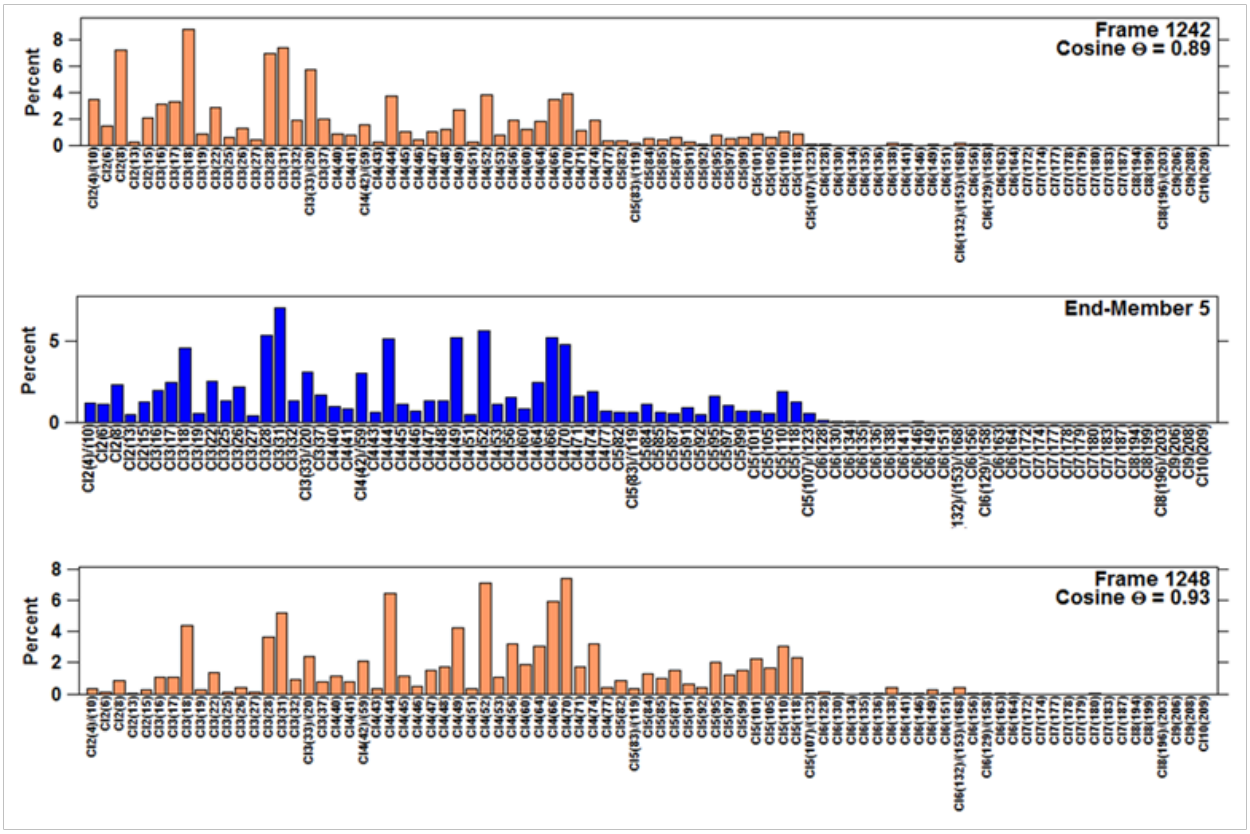

Figure 3-43. Congener Pattern Resolved as a Fifth End Member (blue bar graph) Using PVA Applied to Ashtabula Sediment Data Set
(Two Aroclors with patterns that showed similarity are plotted above and below EM-5.)

The fifth congener pattern is similar (bottom panel of Figure 3-43: cos θ = 0.93) to one of the source patterns already seen in the four end member model (Aroclor 1248). The primary difference is that this new pattern exhibits slightly higher proportions of two congeners that are more characteristic of an Aroclor with very similar chemical pattern: Aroclor 1242 (top panel of Figure 3-43 cos θ = 0.89). The new EM-5 pattern is actually intermediate in composition between Aroclors 1242 and 1248, with more lighter congeners (such as PCB4/10 and PCB8) than is present in Aroclor 1248, but not as much as is observed in Aroclor 1242. The relative contribution of this pattern is shown in Figure 3-44.

The Aroclor 1248 and the new EM-5 (altered Aroclor 1242) are very similar (cos θ = 0.89). This is an issue called "colinearity." When two resolved source patterns have very similar compositions, it increases the uncertainty of reported mixing proportions between these two end members. Ultimately, it seemed best to report the four end member model. By doing this additional exploration of a five end-member model, it is clear that Aroclor 1242 may be a more

important contributor to Ashtabula River than thought. There is clear evidence of an Aroclor 1242 source that has weathered to the point that now looks more like Aroclor 1248. This has been described elsewhere in the literature [4, 8, 30] and was discussed earlier in Section 2.5.2.3.

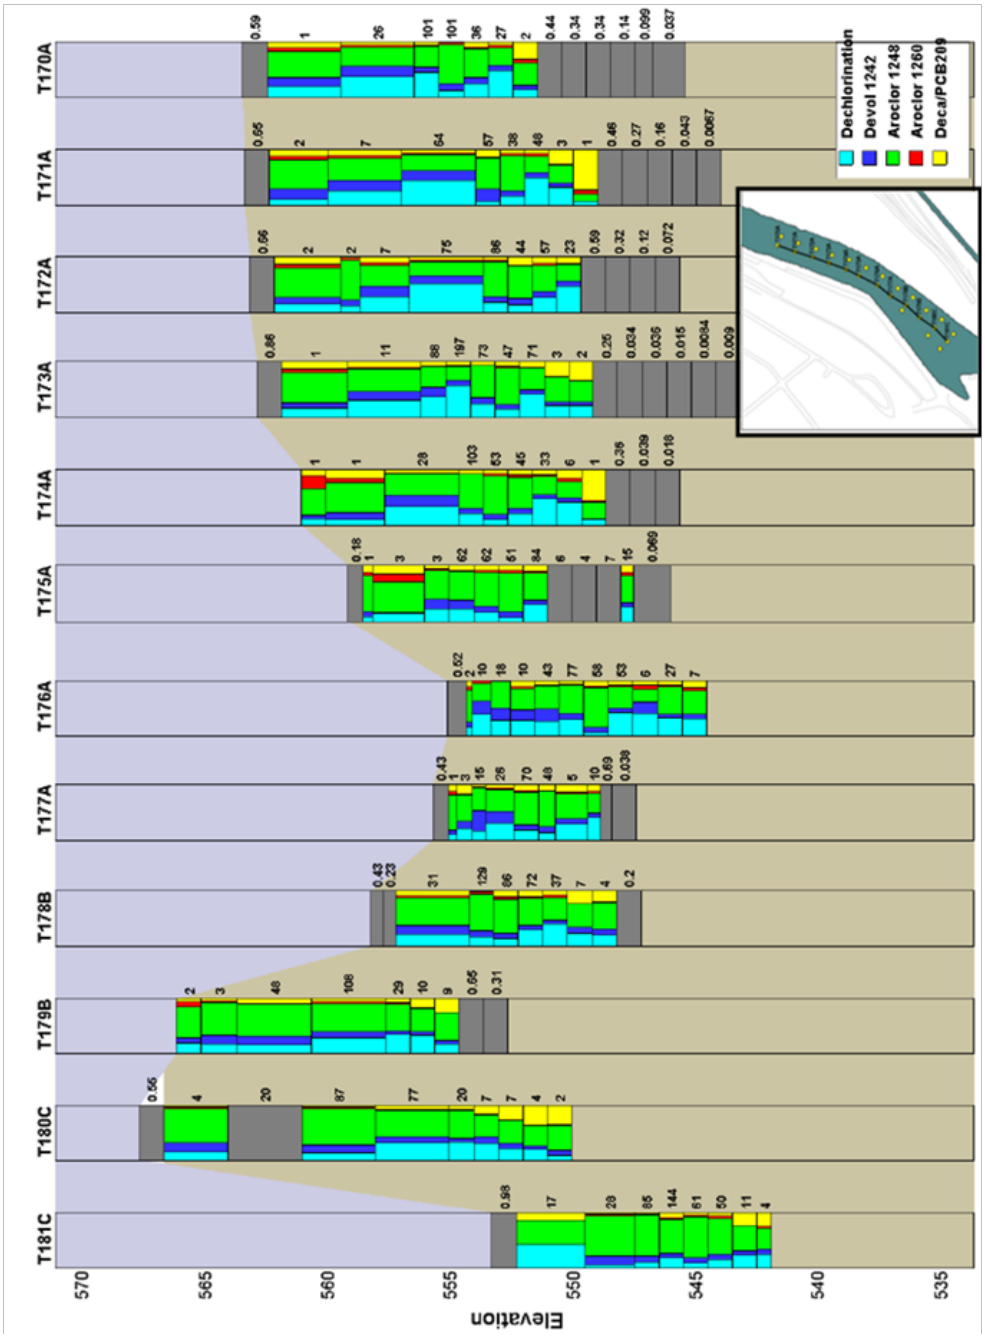

Figure 3-44. Cross-section Showing Percent Contribution of Five Chemical Fingerprints Resolved through PVA of Ashtabula Sediment Data Set

(Each pattern is color-coded. The "new" EM-5 [intermediate between A1242 and A1248] contributions are dark blue. Total PCB concentration [ppm] for each sample is indicated to the right of each sample. Gray shaded samples were omitted from the analysis because they were determined to be outliers [low concentration, or many non-detects].)

3.2.7.6 Integrated Data Analysis and Interpretation

As discussed in Section 2.5.3.6, integrated data analysis and interpretation is the process of synthesizing information from multiple lines of evidence to arrive at scientific interpretations that answer the key questions of a forensics investigation (i.e., PCB sources, alteration mechanisms, timing/history of releases). Lines of evidence typically considered include site history, published scientific literature, sediment transport/hydrodynamics, analytical chemistry which is then used to interpret total PCB concentration gradients and inspection of sample chromatograms/compositions, and chemometric analysis.

At Ashtabula, although we do not have as much data for some lines of evidence as we did for HPS (especially for site history and sediment transport), the lines of evidence consistently support several key conclusions. The analytical chemistry line of evidence may, in fact, be stronger at Ashtabula compared to HPS because of the larger number of congeners (83 versus 38) and samples (252 versus 85) for the chemometric analyses. The primary congener pattern contributing to sediments in the dredge area was consistent with an Aroclor 1248 source, and assumed to be associated with controlled sources within Fields Brook. This was confirmed by direct inspection of PCB compositions (Section 3.2.74) by four separate chemometric analyses (PCA, PVA, ALS and PMF – Section 3.2.7.5). An Aroclor 1260 source in the vicinity of Strong Brook was found to be important to the surface sediments in the study area.

This source observation is consistent with and supported by site history (Section 3.2.7.1). The sediment transport and hydrodynamic information (Section 3.2.7.2) indicates that contamination would be expected to be relatively predictably deposited and distributed away from sources (i.e., that the spatial distribution of the PCB contamination would decline downstream from sources). The PCB concentration distribution showed two general contamination profiles, one associated with historic contamination from Fields Brook and another associated with recent contamination from Strong Brook (Section 3.2.7.3 and Figures 3-25, 3-29, and 3-30). The preliminary PCB composition information (Section 3.2.7.4 and Figures 3-31 through 3-36) indicates two PCB compositional characteristics of the PCB in the sediments: one closely resembling Aroclor 1260 in the sediments near Strong Brook and another resembling Aroclor 1248 in the sediments near Fields Brook, and finally the historic, deeper sediments. The various chemometric analyses further support the initial findings of potential sources adding additional lines of evidence.

There is considerable PCB compositional alteration (e.g., through dechlorination) in some Ashtabula river sediments, suggesting dechlorination of primarily Aroclor 1248; the dechlorination compositional signature was distributed much like the Aroclor 1248 contamination. PCA, receptor models and direction inspection of raw sample compositions all identified a similar dechlorination pattern with key non-Aroclor, less chlorinated, congeners indicating dechlorination. This interpretation was further confirmed by published literature. Dechlorination had previously been reported in Ashtabula sediments [31] by looking at a completely different data set, and using two chemometric methods not used here. The Imamoglu data set [31] had far fewer congeners (24 congeners as opposed to 83). Two congeners that they did have (PCB25 and PCB26) were their primary evidence of dechlorination, and are the same two primary dechlorination indicator congeners in the current data set.

The Aroclor 1260 pattern was confirmed through direct inspection of sample compositions (Section 3.2.7.4) and by four chemometric methods (PCA, PVA, ALS, and PMF). The Aroclor 1260 was associated with sediments in and near Strong Brook, and in combination with Aroclor 1248 in downstream surface sediment. Imamoglu et al. [31] did not report an Aroclor 1260 pattern, but their study included only four cores, none of which were taken near Strong Brook. Another possibility for not observing the Aroclor 1260 pattern could be that their cores were collected in 1998, and this 1260 source appears to be relatively recent and may therefore only be observed in these 2007 cores.

The final congener patterns resolved in this analysis were dominated by a single congener (deca-chlorobiphenyl; PCB209) with lower, secondary contributions from other "heavy" congeners (e.g., PCB199 and PCB206). The deca-chlorinated PCB congener (PCB209) pattern was evident in the data set, whether the data were analyzed by direct inspection of sample congener profiles, or by chemometric analysis. This pattern was observed in deeper sections of cores collected from the dredge area. As with the Aroclor 1260 pattern, Imamoglu et al. [31] did not see the deca pattern in their analysis because PCB209 was not analyzed as part of their study and their cores were much shallower (with a maximum PCB concentration of 10 mg/kg) and never reached the deeper horizons seen in these cores. The high relative amounts of PCB209 were greater than in the highly-chlorinated Aroclor formulations (e.g., Aroclor 1268, and the rare Aroclors 1269 to 1271), and can also not be explained by common environmental alteration processes. There are industrial processes (e.g., titanium tetrachloride production) that may selectively produce these highly chlorinated congeners, and this would warrant further investigation in a comprehensive forensic investigation. This unusual PCB compositional pattern was associated with deep and less contaminated sediment, and was of limited interest from a contaminant source perspective.

Most of this information can be summarized by viewing Figures 3-38, 3-39, and 3-41. The congener compositional information is summarized in Figures 3-38 and 3-39. Most of the samples in Figure 3-38 (around 200 of the 252 samples) are from the middle of the cores and show a congener composition with a mix of Aroclor 1248 (represented at bottom left corner of tetrahedron shape) and slightly dechlorinated Aroclor 1248 (represented at the top left corner of tetrahedron shape). These two congener compositions are shown as the top two bar chart fingerprints in Figure 3-39, and appear similar since they represent the same primary Fields Brook source. The surface samples show more of the Aroclor 1260 pattern (represented at the front right of the tetrahedron) and the deeper samples show a forth compositional pattern characterized by higher levels of congener 209 and other highly chlorinated congeners (represented at the back right of the tetrahedron). The compositions of these two corners of the tetrahedron are shown by the bottom two bar chart fingerprints in Figure 3-39.

The proportion of these four compositional patterns can be better viewed in spatial displays such as the core transect diagram shown in Figure 3-41. These cores were chosen to show the general relationships between end member compositions from south (left) to north (right) in the dredge area, but multiple other transects could be constructed from other cores at the site. Core diagrams are plotted in elevation above sea level on the left, and percent end member composition along the bottom color coded to the legend. The numbers to the right of each core horizon are Total PCB concentrations in parts per million (mg/Kg). The most obvious feature of

these core diagrams is that most of the cores show (>90%) have a source of Aroclor 1248 (although some show dechlorination). Deeper sections of the cores show increasing amounts of the more chlorinated end member composition, but the majority is still Aroclor 1248 and these have lower PCB concentrations. There are only sporadic indications of the very recent additions of Aroclor 1260 in the surface sediments of some cores, ignoring the slight indications of Aroclor 1260 at depth (which is within the margin for error). Error bars on the percent end member contributions are difficult to estimate, but are likely on the order of 10 to 20% in this type of analysis. Compared to the previous HPS case, this allocation of end member compositions at Ashtabula should be more quantitative because of the more unique patterns present in the end member compositions.

In summary, it appears there was a significant source associated with Fields Brook that contributed primarily Aroclor 1248 contamination to the Ashtabula River. The majority of this contamination is several feet down in the Ashtabula River. Deeper sediments also show relatively low amount of a more chlorinated PCB pattern, which may also be from a Fields Brook source. The Fields Brook source(s) appear to have been, for the most part, controlled. It also appears that in recent years, and at the time these samples were collected, there was also a source of primarily Aroclor 1260, in the vicinity of the confluence of Strong Brook. These appear to be the two primary sources of the PCB in the Ashtabula River study area, contributing the four distinct PCB congener compositions that were observed in the Ashtabula River sediment.

Data for A1221 through A1262 condensed from: Frame, G. M., J.W. Cochran, and S.S Boewadt. J. High Res. Chromatogr., Vol. 19, pp 657-668 (1996). Lot A4 Aroclor 1254 from late production (1974-1977).
Data for A1268 from Kannan, K., K. Maryua, and S.Tanabe. Environ. Sci. Technol. 1997, 31, 1483-1488.

EXECUTIVE SUMMARY xi
1. INTRODUCTION 1
1.1. Definitions 1
1.2. After 50 Years, Advancing Beyond Hill's Considerations 2
1.3. Scope 3
1.4. Benefits and Challenges of Weight of Evidence 4
2. APPLICATIONS OF WEIGHT OF EVIDENCE 7
2.1. Contaminated Sites 8
2.2. Environmental Condition 10
2.3. Existing Pesticides and Industrial Chemicals 10
2.4. New Pesticides and Industrial Chemicals 11
2.5. Benchmark Derivation 12
2.6. Proposed Discharges 12
2.7. Special Purpose Assessments 12
3. PROCESSES FOR WEIGHING EVIDENCE 13
3.1. An Introduction to the Weight of Evidence Process 13
3.2. Planning the Assessment to Use Weight of Evidence 15
3.3. Results and Transition 19
4. ASSEMBLING EVIDENCE 20
4.1. The Process for Assembling Evidence 20
4.2. Searching Literature and Assembling Evidence 21
4.2.1. Search the literature 22
4.2.2. Screen the studies 23
4.2.3. Categorize the studies 24
4.2.4. Derive evidence from data and general knowledge 24
4.3. Design and Conduct Studies and Assemble the Evidence 25
4.4. Summary 26
4.5. Results and Transition 26
5. WEIGHTING EVIDENCE 27
5.1. The Process of Weighting Evidence 27
5.2. Scoring Systems 28
5.3. Properties to Be Weighted 29
5.4. Tables of Weights 35
5.5. Not Combining Weights for Properties of Evidence 37
5.6. Summary 37
5.7. Results and Transition 38

6. WEIGHING BODIES OF EVIDENCE 39
6.1. The Weighing Process 39
6.2. Integrating Evidence 39
6.3. Interpreting Bodies of Evidence 45
6.4. Explaining Ambiguities and Discrepancies 47
6.5. Presenting Results 49
6.6. Summary 50
7. SPECIAL CASES AND ABBREVIATED PROCESSES 51
7.1. Weighing Without Weighting 51
7.2. Weighting a Single Piece of Evidence 52
8. WEIGHT OF EVIDENCE FOR QUANTITATIVE RESULTS 53
8.1. Weight of Evidence for the Quality to Be Quantified 53
8.2. Weight of Evidence for Deriving the Quantity 54
8.2.1. Combining quantitative evidence 55
8.2.2. Choosing the best quantitative evidence 55
8.3. Weighting a Quantitative Result 56
9. WEIGHT OF EVIDENCE AND UNCERTAINTY 57
10. WEIGHT-OF-EVIDENCE SUMMARY AND THE PATH FORWARD 59

APPENDIX A. GLOSSARY OF WEIGHT-OF-EVIDENCE TERMS A-1
APPENDIX B. WEIGHT-OF-EVIDENCE METHODS FOR QUANTITATIVE RESULTS B-1
APPENDIX C. WEIGHT-OF-EVIDENCE METHODS FOR DERIVING A MODEL C-1
APPENDIX D. WEIGHT-OF-EVIDENCE APPROACHES FOR QUALITATIVE CONCLUSIONS D-1
APPENDIX E. CHARACTERISTICS OF INFERRED QUALITIES E-1

TABLES

Table 5-1. Weighting the strength of correlations (absolute value of *r*) and noting the logical implication—an example for evidence from stream biological surveys 31
Table 5-2. Table of standard scores for 3 example types of evidence out of 15 types in CADDIS....32
Table 5-3. Generic scoring table based on conventional types of evidence, with first line hypothetically completed....36
Table 5-4. Example scoring table: scoring types of evidence for sufficiency 37
Table 6-1. A generic weight-of-evidence table for *n* alternative causal hypotheses (H_1, H_2, … H_n), based on causal characteristics and collective properties of the bodies of evidence....42
Table 6-2. Partial WoE table for alternative possible causes of the decline of San Joaquin kit foxes 43
Table 6-3. Summary of evidence concerning risks to fish from a diesel spill 44
Table 6-4. Example of weighing evidence for a potential cause, major ions measured as conductivity, of the loss of macroinvertebrate genera....45
Table 6-5. Weight of evidence for causal determinations in the 2013 lead ISA....47
Table 7-1. Summary of evidence for lead as a cause of mass mortality of tundra swans in the Coeur d'Alene River Watershed 52
Table 8-1. Qualities that could be identified by qualitative WoE and the associated quantities that could be derived by the quantitative WoE process 54
Table 8-2. WoE matrix to summarize quantitative risk estimates for four evidence types or groups (numbered circles) and their weights 56

Table D-1. Inference based on the sediment quality triad.... D-3
Table D-2. Some ways in which the triad decision table might fail D-4

Table E-1. Characteristics of causal relationships E-2
Table E-2. Potential characteristics of a protective benchmark....E-2
Table E-3. Characteristics of a contaminant of concern at a contaminated site E-3
Table E-4. Potential characteristics of remediation E-4

PREFACE

The impetus for this document includes U.S. Environmental Protection Agency (EPA) policy, outside advice, and the expressed needs of EPA ecological assessors. Ensuring and maximizing the quality, objectivity, utility and integrity of information disseminated by the EPA "involves a 'weight-of-evidence' (WoE) approach that considers all relevant information and its quality, consistent with the level of effort and complexity of detail appropriate to a particular risk assessment" (U.S. EPA, 2002b). The EPA Science Advisory Board recommended that the Risk Assessment Forum's Ecological Oversight Committee consider the development of guidance for using the WoE approach a high priority (SAB, 2012). This document was prepared for EPA ecological assessors who expressed a desire for assistance in determining which WoE approaches are potentially appropriate for their assessments (U.S. EPA, 2010b).

This document has three goals. The first is to assist ecological assessors who plan to weigh multiple pieces of scientific evidence. We provide a standard framework consisting of three steps: assemble evidence, weight evidence, and weigh the body of evidence. We also present a broadly applicable system for assigning weights by evaluating and scoring the evidence and for combining the weighted evidence to determine the best-supported hypothesis. Additional material addresses how to deal with bodies of evidence that are discrepant or anomalous and how to express confidence in inferences based on the weight of evidence. Finally, we briefly address the weighing of evidence to derive quantities used in or generated by assessments.

The second goal is to make the weighing of evidence in ecological assessments more formal and defensible. Weighing evidence is best performed using pre-existing and well-described methods. The standard framework and default approach to weighing evidence presented in this document are expected to improve the practice and acceptance of weighing evidence.

The third goal is to make the logic of weighing evidence clearer and more consistent. For example, many of the EPA's weight-of-evidence analyses are based on Hill's considerations, a 50-year-old list that mixes characteristics of causal relationships, types of evidence, and properties of evidence. This document addresses those aspects of evidence separately and uses them systematically.

This document provides methods for weighing ecological evidence. Use of the methods will improve the consistency and reliability of WoE-based assessments and the defensibility of scientific input to decision making. This guidance is not meant to be prescriptive, nor does it dictate methods for specific programs and applications.

Tables, figures, and text boxes throughout the document provide examples of WoE practices. The specific methods in the examples were designed for particular statutory contexts and might need to be adapted before they are used in other contexts.

This document was prepared under the auspices of EPA's Risk Assessment Forum. The Risk Assessment Forum was established to promote scientific consensus on risk assessment issues and to incorporate this consensus into appropriate risk assessment guidance. To accomplish this purpose, the Forum assembles experts from throughout EPA in a formal process to study and report on these issues from an Agency-wide perspective.

ACRONYMS AND ABBREVIATIONS

BBN	Bayesian belief network
EPA	U.S. Environmental Protection Agency
FIFRA	Federal Insecticide, Fungicide, and Rodenticide Act
IRIS	Integrated Risk Information System
ISA	Integrated Science Assessment
LC_{50}	median lethal concentration
LOAEL	lowest-observed-adverse-effect level
MCDA	multi-criteria decision analysis
NE	No Evidence
NOAEL	no-observed-adverse-effect level
OECD	Organization for Economic Cooperation and Development
PRG	preliminary remedial goal
QA	quality assurance
QAPP	Quality Assurance Project Plan
r	correlation coefficient
RQ	risk quotient
SMAV	species mean acute value
SSD	species sensitivity distribution
TMDL	total maximum daily load
WoE	weight of evidence

EXECUTIVE SUMMARY

This document presents an approach for using weight of evidence (WoE) in ecological assessments. WoE integrates multiple pieces of evidence to infer a quality such as causality, teratogenicity, impairment, protection, or recovery. WoE can also be used to derive quantities such as a benchmark value, a magnitude of effect or a bioaccumulation factor when multiple estimates are available. WoE is essential for ecological risk assessment, because diverse laboratory and field information must be assembled, evaluated and integrated. The EPA has often employed WoE in ecological assessments, but, in the absence of guidelines, the methods are inconsistent and often informal. Advisory bodies, professional societies and the assessment science literature all encourage more and better WoE. The proper use of an explicit WoE methodology can mean the difference between an ecological risk characterization with a murky rationale and one that is persuasive and consistent with best practices. The system presented here to improve the practice and acceptance of weighing evidence is broadly applicable for evaluating and scoring evidence and combining the weighted evidence to determine the best supported risk characterization. By helping to make the logic of weighing evidence clearer and more consistent, WoE will help make ecological assessments more informative and defensible.

Ecological assessments that employ WoE have made numerous important contributions to environmental protection. The following five examples of high profile ecological assessments demonstrate the value added through incorporating a WoE methodology. 1)The Bristol Bay, Alaska watershed assessment to protect the world's best remaining wild salmon populations, and the people and wildlife that depend on them, used formal WoE analyses to integrate evidence from laboratory tests, field studies, and effects of similar mines to estimate risks to salmon of various mining activities. 2) The restoration of thousands of biologically impaired waters uses a WoE method to determine the cause of impairment (https://www3.epa.gov/caddis). 3) The assessment to support the definition of waters of the United States used WoE to show how different types of aquatic systems are connected. 4) The protection of ambient water quality depends on the ecological assessments that derive aquatic life criteria. The recent benchmark and proposed criteria method for major ions measured as conductivity are based on effects observed in the field. They depend on WoE to determine that the relationships in the field are not confounded and that the same value applies to different areas. 5) The high profile assessment of risks to pollinators from the neonicotinoid pesticide imidicloprid relies on weighing evidence from laboratory tests, semi-field tests, crop applications, and reports from bee keepers. WoE has been increasingly important to ecological assessment and Agency decisions because of the use of eco-epidemiological approaches.

Although WoE has been used in various types of assessments for programs across the U.S. Environmental Protection Agency (EPA), approaches have varied. Many of the EPA's WoE applications use a narrative approach with some guidance provided by lists of considerations, but that approach has been deemed inadequate by the National Research Council (NRC, 2014). The approach in this document is more formal. It provides a framework, a set of properties of evidence, a scoring system, tables for presenting results of weighting, and weighing evidence, a system for organizing evidence in terms of types and the characteristics they address and a means of dealing with ambiguous or discrepant results.

The framework and methods in this document also provide an integrated approach to both infer a quality of interest and estimate an associated quantitative value. For example, WoE can be used to weigh the evidence that a chemical causes malformations in fish in ambient exposures (qualitative) and to derive the best estimate of a benchmark concentration for the chemical (quantitative). Unlike qualitative WoE, quantitative WoE is not an established practice in the EPA. Therefore, quantitative methods are only briefly discussed.

The frameworks for qualitative and quantitative WoE are presented in Figure S-1 and Figure S-2. Although the qualitative processes might appear complex, the basic framework is simple: assemble the evidence, weight the evidence, and weigh the body of evidence. The document explains how to perform each step (Sections 4−6) and explains when and how the process can be adapted or abbreviated (Section 7). Figure S-2 previews Section 8, which presents the process for using WoE to estimate quantities.

The sections preceding the explanation of the process include an introduction that defines and explains WoE (Section 1), a description of the uses of WoE in the EPA's ecological assessments (Section 2), and an explanation of how to perform planning and problem formulation for assessments that includes WoE (Section 3). Sections following the process sections describe the complementary relationship between WoE and uncertainty (Section 9) and the path forward for implementing WoE in the EPA (Section 10). Section 11 presents the literature cited in support of the document.

Appendix A presents a glossary of terms, as used in this document, related to WoE. Additional appendices briefly review WoE methods for estimating quantities (Appendix B), selecting models (Appendix C), and inferring qualities (Appendix D). They provide context for the methods in this document. Appendix E explains that qualities such as causation have characteristics such as co-occurrence that can be used to organize bodies of evidence and to provide a basis for determining the completeness of the body of evidence. Characteristics of causation are established, but characteristics of other inferred qualities such as protective or impaired are new and have not been tested.

The result of the qualitative WoE process (Figure S-1) is a qualitative conclusion (e.g., the metal mixture is the most likely cause) and an overall weight that expresses confidence in the conclusion (e.g., weight of evidence for the conclusion is moderate) or multiple weights (e.g., relevance of the evidence is low, but strength and reliability are both high).

The result of the quantitative WoE process (Figure S-2) is a weighted quantitative value. In a WoE analysis, those results could consist of the value and its units (the proposed remedial goal is 2 mg/kg dry sediment), one or more expressions of weight (the overall weight of evidence is high) and the estimated statistical scatter of the value (the 95% confidence interval [CI] = ± 0.5 mg/kg dry sediment).

This document provides methods for weighing ecological evidence. Use of the methods will improve the consistency and reliability of WoE-based assessments and the defensibility of scientific input to decision making. This guidance is not meant to be prescriptive, nor does it dictate methods for specific programs and applications.

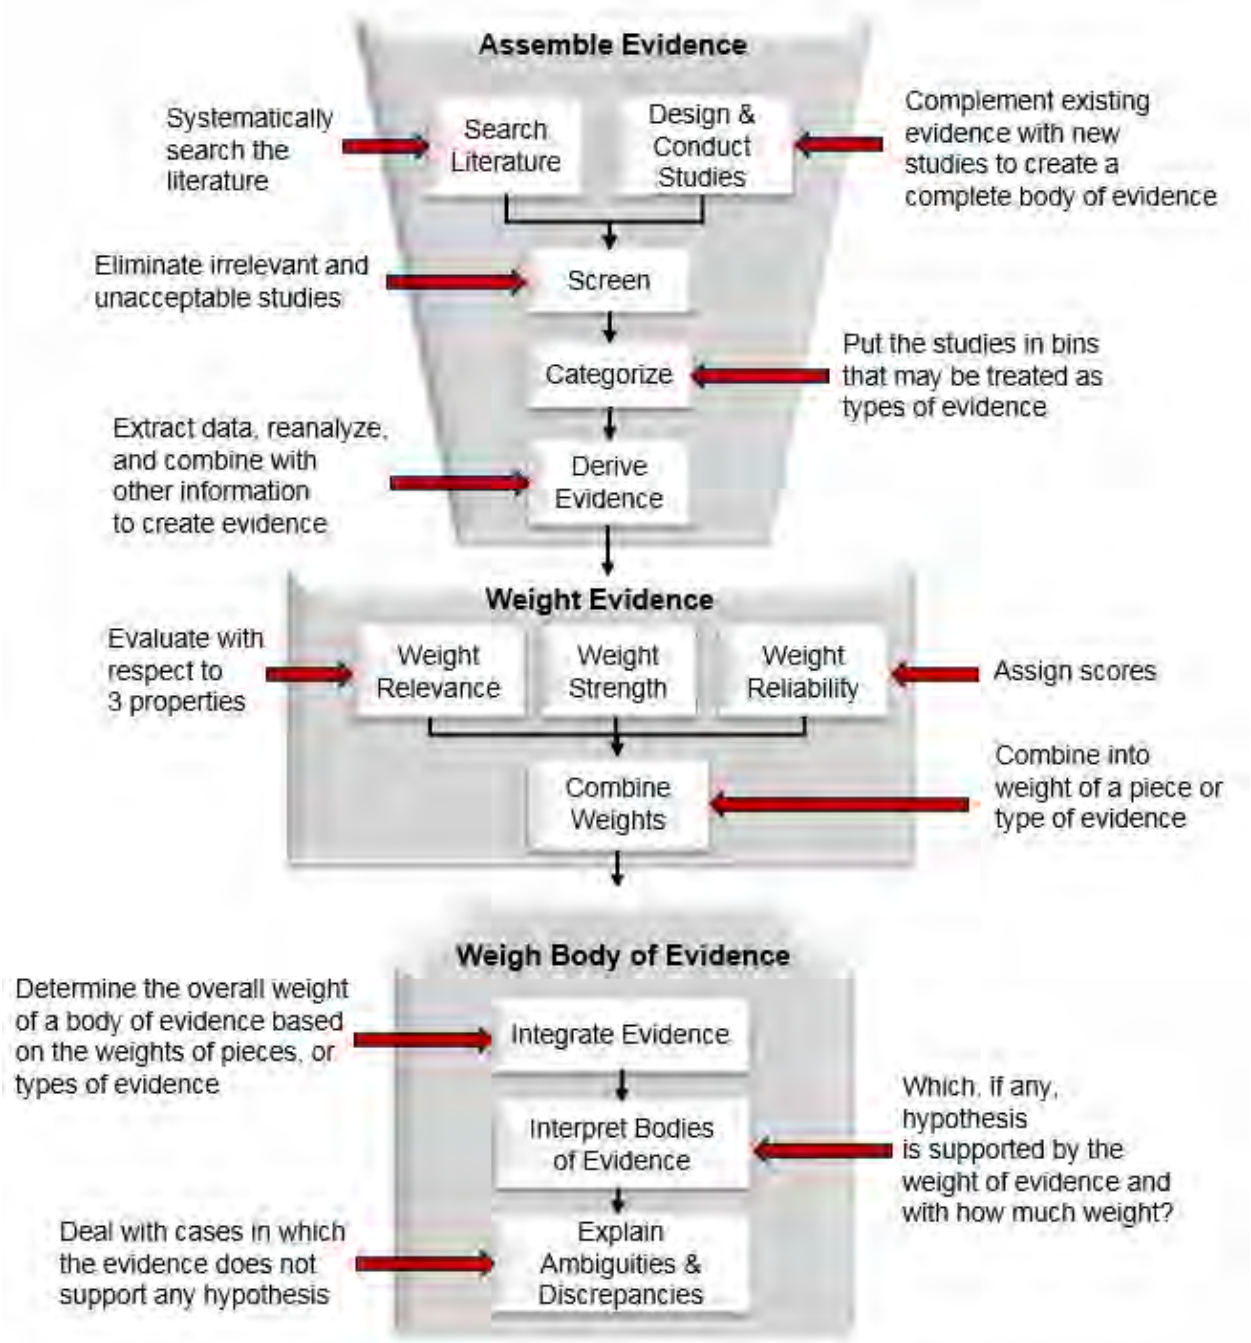

Figure S-1. An annotated diagram of the process for WoE to infer qualities by assembling evidence, weighting it, and weighing the resulting body of evidence, explained in Sections 4–7.

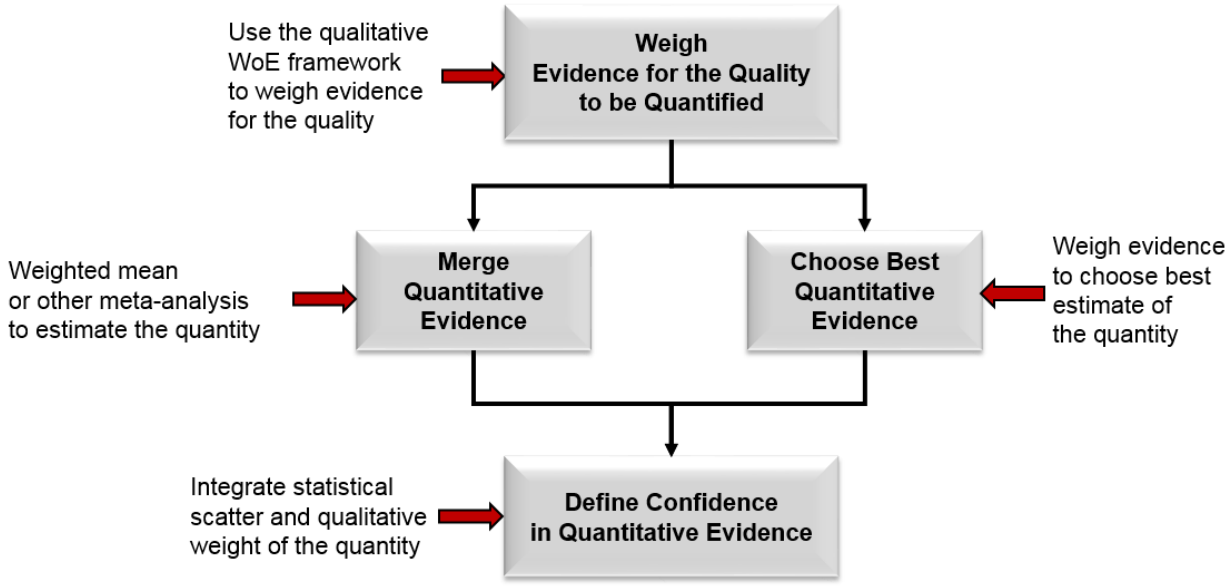

Figure S-2. An annotated diagram of the process for using WoE to estimate quantities, explained in Section 8. It begins by weighing evidence to determine the quality of interest (a qualitative WoE as depicted in Figure S-1), then uses one of two alternative methods to obtain results from multiple quantitative estimates, and finally defines the confidence in the result.

1. INTRODUCTION

The process of weighing multiple pieces of evidence is useful for judging the truth of hypotheses, identifying the best explanation of phenomena, or deriving best models or best estimates. The weight-of-evidence (WoE) process involves (1) assembling evidence, (2) weighting evidence with respect to properties, and (3) weighing the integrated body of evidence. This WoE process is embedded in larger assessment processes, which include planning, problem formulation, analysis, synthesis, and communicating results.

Scientific investigations of a topic often generate multiple pieces of evidence of various types. For that reason, WoE is inherent in medicine, engineering, and other applied sciences, including environmental assessment. Because weighing evidence is so common, the importance of the process is often overlooked and as a result, it is generally performed informally and presented as a narrative. WoE, like other scientific activities, depends on transparency for its credibility. This document encourages more explicit WoE methods, but it also encourages fitting the WoE process to the assessment to avoid processes that complicate the assessment without enhancing the results.

The *Guidelines for Ecological Risk Assessment* did not include WoE (U.S. EPA, 1998). Instead, guidance was provided for a lines-of-evidence process that is equivalent to a narrative WoE guided by considerations (see Appendix D.2). Assessment practices now have advanced sufficiently to recommend WoE for ecological assessments.

1.1. Definitions

WoE is a metaphor adapted from jurisprudence, in which multiple pieces of evidence are metaphorically placed in the pans of the scales of justice and the side with the greatest weight prevails. The metaphor is appropriate for any situation in which multiple and diverse evidence are evaluated to reach a conclusion.

In this document, WoE is defined as an inferential process that assembles, evaluates, and integrates evidence to perform a technical inference in an assessment. WoE methods have been derived to estimate a quantity (Appendix B), inform model selection (Appendix C), or reach qualitative conclusions in an assessment (Appendix D).

As part of that inferential process, WoE characterizes properties of pieces of evidence and of bodies of evidence. First, WoE determines the degree of support for a hypothesis that a piece or type of evidence provides (i.e., the weight of a piece of evidence dropped into a pan of the scales). Hence, weights indicate which pieces and types of evidence make the greatest contribution to the inference. Second, WoE determines the degree of support for a hypothesis, relative to alternatives, that the available body of evidence provides (i.e., the accumulated weight in one pan relative to the other). These cumulative weights not only inform inferences, they also indicate how much confidence assessors have in the conclusion (Section 9).

For example, “WoE was used to determine the likely cause of a bird kill” (the process). “The occurrence of carbofuran granules in the crops of dead birds is convincing evidence of exposure” (a property of a piece of evidence). “The body of evidence consistently supports carbofuran as the cause” (a property of the body of evidence). Further discussion of these terms is presented in Box 1-1. Other terms are defined in the glossary in Appendix A.

1.2. After 50 Years, Advancing Beyond Hill's Considerations

The touchstone of WoE in health and environmental assessments is Hill's considerations (Hill, 1965). Hill recognized that causal inference requires qualitative WoE because no amount of quantitative analysis of associations can suffice (i.e., correlation is not causation). He listed nine considerations to guide the process. Hill's considerations include, but do not distinguish, characteristics of causal relationships (e.g., temporality), types of evidence (e.g., experiment), properties of evidence (e.g., strength), and properties of bodies of evidence [e.g., consistency; (Cormier et al., 2010)]. EPA has adopted Hill's considerations for hazard identification in Integrated Risk Information System (IRIS) assessments and Integrated Science Assessments (ISAs).[1] Hill's considerations were designed for determining the causes of observed epidemiological effects, however, and not for applications in which effects have not been observed. In particular, Hill presumed that co-occurrence of the putative causal agent and the effect of interest (smoking and lung cancer, in his case) was clearly documented, and his goal was to demonstrate that the relationship is causal. We, however, must also address cases for which a clear real-world association has not been demonstrated.

Box 1-1. Weight versus Weigh, Weighting versus Weighing

The terms weight, weigh, weighting, and weighing, which are used throughout this document, can be confusing. This ambiguity results in part from the fact that weight is both a noun and a verb.

To *weight* a piece of evidence is to assign importance to it (a process designated by a verb). As a result of that action, the evidence has weight (a result designated by a noun). The *weighting* process formalizes the evaluation of evidence, by assigning a descriptor or score.

To *weigh* a body of evidence is to combine the weights assigned to each of the pieces (a process designated by a verb). As a result of *weighing*, the body of evidence has weight (a result designated by a noun). The weighing process formalizes the integration of evidence by determining the weight of the body of evidence.

The WoE system presented here treats explanatory implication of evidence, types of evidence, properties of evidence, and properties of bodies of evidence as separate aspects of WoE (Box 1-2). Because each serves a different function in the WoE process, they are not treated as equivalent considerations. Distinguishing them makes clear that Hill's list lacks essential characteristics, types, and properties of evidence. These aspects are the basis for weighting and weighing evidence for causation and other qualities as presented in Sections 5–7.

[1] IRIS is a program that evaluates information on health effects of environmental contaminants to determine what hazards they pose to humans and to develop benchmark values (http://www.epa.gov/iris/). ISAs assess the scientific evidence for health and welfare effects of criteria air pollutants (http://www.epa.gov/ncea/isa/).

Box 1-2. Aspects of Evidence

This approach to weighing evidence distinguishes aspects of evidence in the WoE process that may not be clearly distinguished in prior approaches. They are introduced here and explained in more detail as they appear in the WoE process.

Piece of evidence: A piece is the evidence derived from a particular experiment or observational study. A piece of evidence is the minimum unit that might be weighted.

Type of evidence: A type is a category of evidence based on the nature of the study from which the evidence is derived. Examples include single-species, laboratory toxicity tests; microcosms; mesocosms; biomarker surveys; and community surveys. Types are used to organize and combine pieces of evidence to simplify weighting and weighing.

Explanatory implication of evidence: An explanation expresses the logical relationships between evidence and inference. For example, laboratory toxicity tests may provide evidence of the sufficiency of an exposure to cause the effect, and community surveys may provide evidence of co-occurrence of the effect and putative cause.

Body of evidence: A body of evidence is all of the evidence that applies to a particular hypothesis.

Property of evidence: Properties are the aspects of evidence that determine how much weight (influence) it should have. This approach uses three general properties: relevance, strength, and reliability.

Property of bodies of evidence: Bodies of evidence are weighted with respect to collective properties including number, coherence, diversity, and absence of bias.

1.3. SCOPE

This document is intended to inform ecological assessments. Human health assessments are mentioned and cited only as background and for purposes of comparison. Weighing multiple types of evidence has been performed more widely in ecological assessments than in human health assessments (Krimsky, 2005; Suter, 1993). Although ecological and human health assessments can be performed similarly, the types of ecological assessments that have driven the development of WoE tend to differ in important respects from human health assessments. In particular, types of ecological studies that contribute evidence to Superfund and Clean Water Act assessments include effluent and ambient media toxicity tests, toxicity identification evaluation, in situ tests, biotic community surveys, and demographic models. In addition, ecological assessments must weigh evidence related to multiple endpoint species and levels of organization, which increases the need for formal WoE methods.

This document presents a framework for application of WoE in various assessment contexts. WoE is an assessment tool, just as modeling and statistical analysis are assessment tools. Therefore, the framework for WoE is not a substitute for assessment frameworks (see Section 3).

WoE can be carried through the entire assessment process or be applied to an inference that is only a component of the assessment. WoE can be limited to hazard identification (e.g., Does ozone reduce plant growth at ambient levels?), the determination of an assumption (e.g., Should a bioaccumulation factor be used?), or the estimation of a parameter (e.g., weighing field and laboratory estimates of a chemical's half-life in water). In contrast, a WoE process can carry through an entire condition or causal assessment.

This document cites literature that is directly relevant to explaining this approach to WoE but does not attempt to cover the history of WoE in environmental assessments. Reviews of WoE approaches are available elsewhere (Rhomberg et al., 2013; Linkov et al., 2009; Pope et al., 2007; Krimsky, 2005; Weed, 2005).

This document focuses on WoE for qualities such as causality and impairment (Box 1-3). WoE methods to derive quantities and to choose models are discussed in Appendix B and Appendix C, and the use of qualitative WoE to enhance the derivation of quantitative results is discussed in Section 8. Qualitative WoE is emphasized because it is more common in ecological assessments than is quantitative WoE (Appendix D).

Box 1-3. Qualities and Qualitative Weight of Evidence

Qualitative WoE: A qualitative WoE is an assessment for which the endpoint is a quality such as a condition, mode of action, source, or type of effect. It typically includes both quantitative and qualitative evidence, but the result is not a numerical quantity.

Quality of Interest: The quality for which evidence is weighed is most often causality, but it can be any quality of interest. Examples of qualities that can be or have been inferred by WoE include:

- Coxie Creek is impaired.
- Acid mine drainage causes the impairment.
- Polychlorinated biphenyls are bioaccumulative.
- Selenium is teratogenic in fish.

Quality of Evidence: This document does not recommend weighting the quality of evidence. Instead, specific properties and sub-properties of evidence are weighted. This is because the term quality has been found to be too broad to be useful in the weighing of evidence (Higgins and Green, 2011). However, quality is used in a broad sense that is consistent with U.S. government data quality policy (U.S. EPA, 2002b).

1.4. Benefits and Challenges of Weight of Evidence

Although this document recommends the use of WoE, it recognizes that WoE can have limitations in practice. We assume that assessors will consider the potential benefits and challenges of WoE (Box 1-4) relative to the requirements of their assessment before proceeding to implement the approach recommended here.

WoE techniques inevitably involve subjective expert judgments. Such judgments can cause WoE to be criticized for being biased or arbitrary. However, the objections to subjectivity can be diminished by some good practices.

1. Prior to the assessment, specify the WoE method in as much detail as is practical to minimize the need for improvised judgments about methods or assumptions during the assessment.

2. Use the standard judgments of a program expressed as standard criteria for assigning or integrating weights. For example, tests performed using an Organization for Economic Cooperation and Development (OECD) protocol with good laboratory practices might be given a standard score of +++ for reliability.

3. Be objective, in the sense of being unbiased, by self-auditing (Box 1-5).

4. Work in groups and attempt to achieve consensus concerning judgments.

5. When making judgments, try to represent the opinions that knowledgeable and unbiased members of the scientific community would have, given the evidence and the inference to be made.

6. Find assessors with sufficient relevant knowledge and experience to qualify as experts.

Box 1-4 Potential Benefits and Challenges

Inference by weighing multiple pieces of evidence has advocates who recognize its potential benefits, but challenging aspects of its application have led some assessors to oppose its use.

Potential Benefits of WoE

The primary potential benefit of WoE is the greater confidence in results obtained by considering all relevant and reliable evidence. For example, it is not uncommon for causal assessments to consider only statistical evidence of co-occurrence of an effect and its potential causes. This approach provides much less confidence than one that also considers evidence of temporal sequence, interaction, and other characteristics of causal relationships. In many cases, no single type of evidence is sufficient to reach a conclusion. Ecological assessments of polluted ecosystems commonly benefit from considering evidence from laboratory toxicity tests of chemicals, tests of effluents, or ambient media and biological surveys. This benefit of WoE occurs because the body of relevant and scientifically credible evidence provides a more complete picture than does any piece of evidence alone.

A second potential benefit is an increase in the defensibility of an assessment. An explicit WoE method demonstrates that all relevant evidence has been considered and no credible evidence, either in support of or contrary to a hypothesis, has been arbitrarily dismissed. Without an explicit process planned in advance, reviewers might criticize or even dismiss an assessment for excluding data or evidence that they believe should have been given more consideration.

Defensibility of assessments also might be increased by the transparency of the processes it uses for inference. A formal WoE method enables reviewers and readers to understand and critique the processes of assembling, weighting, and weighing the evidence.

Potential Challenges to WoE

A formal WoE process can require considerable time and effort, which could lead to performance of fewer assessments or delayed decisions. Completing and documenting a formal systematic literature review or implementing an evidence scoring system might not be resource effective if the same conclusion can be obtained with a less resource-intensive assessment. The solution to this challenge is to tailor the WoE method to the assessment.

Box 1-5. Subjectivity and Objectivity

WoE-based assessments rely on subjective professional judgments because there is no other means of weighing a diverse body of evidence from models, laboratory tests, field tests, field surveys, and other information sources to identify the best-supported hypothesis. Although inevitable, subjectivity often is considered undesirable in assessments as in other scientific contexts.

Objective properties, such as the number of fish species in a stream, are properties external to the investigator that can be confirmed by any other investigator. Subjective properties such as the reliability of biological survey results are opinions of the investigator evaluating the survey, not inherent properties. The extent to which assessors agree in their judgment of reliability is due to shared preferences, not a measurable attribute of the surveyed community.

Subjective inferences can be objective in another sense, which is defined in federal policy (U.S. EPA, 2002b): Any inference can be considered objective if it is performed in a disinterested—and therefore impartial—manner. The guidance in this document aims to create circumstances for which an inference is minimally influenced by any personal or institutional biases and in which any systematic bias can be detected.

Performing laboratory or field studies to generate data for multiple types of evidence (e.g., chemistry, toxicity, and biology) for a WoE analysis—as opposed to simply summarizing data from available literature—is more resource intensive than generating a single type of evidence (e.g., only chemistry). The value of new information to the assessment should be considered during the planning stage to obtain sufficient, but not surplus, evidence (Keilser et al., 2014).

Complex WoE methods can obscure rather than clarify the derivation of results, particularly if the method is not clearly presented. A reader is likely to dismiss the results if the assessment is incomprehensible. Clear and consistent methods can reduce this problem.

Finally, a fundamental objection to WoE is that it might mix scientifically less robust evidence with highly reliable evidence. In some cases, the body of at least minimally relevant and reliable evidence might not contribute information beyond that supplied by a single best piece of evidence. This issue is addressed by including explicit steps for screening and weighting evidence rather than treating all evidence as equal.

These objections can be minimized by careful planning and by clearly presenting the WoE process. The WoE methods should be appropriate to the assessment. The amount of detail in evaluating and scoring evidence should be appropriate to the amount and diversity of the evidence, the time and resources available, and the degree to which decision makers and stakeholders wish to engage in a WoE process. The amount of detail can also be based on the degree to which the results of an assessment are potentially contentious. If, for example, an informal review of the evidence clearly shows a site is highly toxic and the obvious decision will be to remediate, a more detailed WoE process might waste resources, prolong the contamination, and confuse the issue. In situations for which the decision is obvious and could be urgent, a protracted WoE process is counterproductive.

2. APPLICATIONS OF WEIGHT OF EVIDENCE

The uses of WoE in ecological assessments are diverse, in part because ecological assessments are conducted in diverse regulatory contexts that require different assessment methods. In addition to asking assessors for predictions of potential adverse outcomes of proposed actions (i.e., to perform risk assessments), decision makers ask assessors to determine conditions (i.e., to perform condition assessments), determine the likely causes of adverse conditions (i.e., to perform causal assessments), and determine the actual outcomes of actions [i.e., to perform outcome assessments (U.S. EPA, 2010b; Cormier and Suter, 2008)]. Each type of assessment has its own logic and methods, and therefore, weighs evidence somewhat differently. Figure 2-1 illustrates a way to organize such assessments. Assessments can be initiated by the results of a prior assessment, and WoE results from prior assessments can inform subsequent assessments. For example, if a condition assessment identifies a biological impairment, a causal assessment should follow to identify the cause and source of the causal agent, a predictive risk assessment should follow to determine the remedy, and an outcome assessment should determine whether the remedy has sufficiently improved conditions. Assessments also can be initiated by external demands. For example, a predictive risk assessment might be prompted by an application to market a new pesticide.

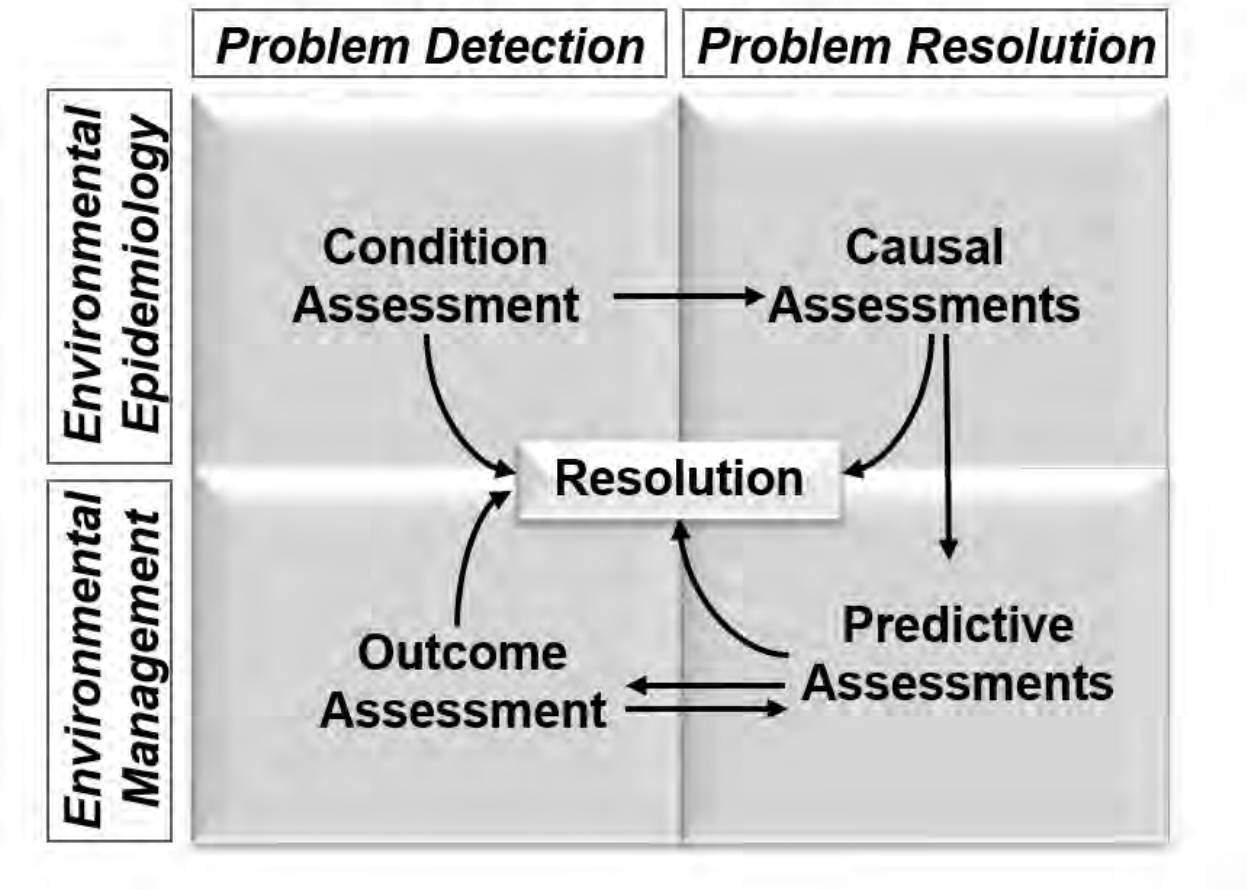

Figure 2-1. A framework depicting the relationships among types of environmental assessments. Modified from U.S. EPA (2010b); Cormier and Suter (2008).

All types of ecological assessments can weigh evidence quantitatively to combine multiple numerical values or to choose a model (see Appendix B and 11.Appendix C). This document, however, emphasizes using WoE for integrating evidence to derive a qualitative conclusion that supports a decision. Examples of qualitative conclusions are the biotic community of a stream is impaired, selenium causes cranial deformities, low pH caused the impairment, or coal ash is the source of the arsenic. To determine what qualities might require WoE, it can be helpful to consider what qualitative questions are answered by the various types of environmental assessments (Box 2-1).

Environmental problem solving often requires sequences of inferences to derive qualitative results and then quantitative results. For example, an ISA, that qualitatively weighs evidence to determine whether relevant concentrations of the pollutant cause particular effects, precedes the development of National Ambient Air Quality Standards. A qualitative weighing of evidence to determine whether the contaminated medium is causing significant adverse impacts precedes development of quantitative cleanup goals for a contaminated site. A qualitative weighing of evidence to determine whether a water pollutant is causing biological impairment might precede the development of quantitative total maximum daily load (TMDL) for the pollutant. These qualitative assessments could be treated as a separate product from the quantitative assessment (e.g., a qualitative ISA before a quantitative Welfare, Risk and Exposure Assessment). Alternatively, the qualitative assessment might be nested within the quantitative assessment as part of the problem formulation (e.g., as a hazard identification).

This section describes the various types of assessments, their application by EPA and the current and potential roles of WoE in performing the assessments.

2.1. Contaminated Sites

Contaminated sites provide a wide scope for applying WoE because the contaminated and potentially biologically impaired conditions allow for the generation of diverse evidence from observation, sampling, analysis, and testing. As a result, most of the relevant methods and literature on ecological WoE address contaminated sediments, soils, and waters (Appendix D). In the EPA, the primary venue for contaminated site assessments is Superfund sites.

The goal of contaminated site assessments is to determine whether contaminants pose an unacceptable ecological risk and, if so, what should be done to reduce it. When assessing a site, specific impaired areas can be identified without WoE by comparing contaminant concentrations to screening benchmarks. Those benchmark concentrations also could serve in some cases as the remedial goals, allowing for completion of the assessment without weighing evidence. For Superfund sites, however, multiple types of site-specific evidence are typically collected, including results of toxicity tests of contaminated media, biological surveys, or analysis of biological samples for biomarkers or body burdens of contaminants (Luftig, 1999). Such bodies of evidence can be weighed in a merged condition and causal assessment to answer the question: Is an unacceptable risk associated with the site contaminants? Such a qualitative assessment is the topic of the approaches for the sediment quality triad and the Massachusetts and Oak Ridge National Laboratory WoE methods described in Appendices D.3, 11.D.5, and D.7. Such assessments can also be performed using the approach presented in the following sections.

Box 2-1. Qualitative Questions for Which Evidence is Weighed in Different Types of Assessments

Causal Assessment

Causal assessments identify causes of observed effects and they take one of two general forms.

What causes general effect y? This is the general causal question. Examples: What causes colony collapse disorder in honeybees? What causes coral bleaching?

What causes specific effect y? This is the specific causal question. Examples: What caused low invertebrate species richness in the Coal River? What caused the 1980s decline in San Joaquin kit foxes in Elk Hills?

Risk (Predictive) Assessment

Most EPA predictive assessments are risk assessments. They begin with a problem formulation that includes a causal question regarding what hazard is associated with an agent and could be assessed.

Does agent x cause general effect y? This is a general hazard identification question for assessments like setting benchmarks or permitting use of a chemical. Examples: Does smoking cause lung cancer? Does atrazine cause deformities in frogs?

Might agent x cause effect y? This is a hazard identification question asked in risk assessments for specific actions. Examples: Might a tailings spill at the proposed mine cause a loss of salmon spawning? Might permitting a new use of atrazine result in an increase in frequency of frog deformities?

Is agent x causing effect y? This is a hazard identification question asked in risk assessments for an agent under existing conditions. Examples: Are the sediment contaminants reducing invertebrate species richness or abundance? Is acid deposition reducing forest production?

These causal questions can be answered by a separate causal assessment prior to the risk assessment or in the problem formulation for the risk assessment. Without hazard identification, defining the endpoint entity and attribute has no basis beyond using default endpoints such as fish mortality.

Other qualitative questions that might involve WoE also are answered in risk assessments. For example:

- Should dietary exposure be considered?
- Will the endangered species occur on the site in the future?
- Is the site large enough to support an assessment population of the species of concern?
- Is long-range transport a significant source?
- What are the contaminants of concern?
- Is the chemical a persistent organic pollutant?

Condition Assessment

Qualitative questions concerning conditions, such as the following, are relatively straightforward to assess when standard definitions of conditions are provided.

- Is the ecosystem impaired?
- Is the species endangered?
- Is the water contaminated?

However, framing the question could be conceptually difficult, particularly with respect to the standard of comparison: natural conditions, reference conditions, historical conditions, or defined standards.

Outcome Assessment

Qualitative questions of concerning outcome are like condition questions but include issues regarding the efficacy of remedial or regulatory actions.

- Is bioremediation sufficiently reducing exposure of endpoint species?
- Is the liner leaking?
- Is the site acceptable for recreational fishing?

Many Superfund assessments treat pieces of evidence as independent lines of evidence without weighing them (Integral Consulting Inc., 2013). Causal assessments performed by WoE for contaminated sites are illustrated by the Elk Hills and California Gulch cases (U.S. EPA, 2011c, 2009a). Such WoE assessments can be sufficient to complete the investigation, provided the decision logic is as follows: If the sediment or soil presents unacceptable risk due to waste contamination, remediate it (e.g., cap, remove, or biotreat it). For Superfund sites, however, a separate step defines chemical-specific preliminary remedial goals (PRGs). Either site-specific values or standard benchmark values might be used as PRGs for the areas identified as impaired by WoE. Site-specific PRGs can be derived from tests of site media or field exposure-response relationships used in the qualitative WoE to identify waste-impaired areas. However they are derived, PRGs represent acceptable risks, and are typically used in selecting a final remedy.

2.2. Environmental Condition

Although the condition of all ecosystems is of concern, the Clean Water Act is unique among U.S. antipollution laws in requiring that all sites (i.e., all state waters) be assessed to determine if they are impaired. The result is each state's 303(d) lists of impaired waters. Most listings are for exceedance of water quality standards, including concentrations of chemicals, levels of biological pollutants (e.g., fecal coliform counts), and physical properties (e.g., temperature). In addition, ecological properties can serve to identify impaired waters based on biological or narrative criteria. Commonly, multiple types of biological data, termed metrics, are combined into an index (Blocksom and Johnson, 2009; U.S. EPA, 1996). The regulations indicate that states should evaluate "all existing and readily available information" in developing their 303(d) lists (40 CFR §130.7(b)(5)), which suggests a WoE approach or other approaches (such as independent applicability) that consider all information (Appendix D, Box D-1).

If a water body is declared impaired based on biological effects, the cause should be identified. Guidance for using WoE to determine the cause of biological impairment was developed for the Office of Water (U.S. EPA, 2000), and a web-based support system was developed to aid in its application (http://www.epa.gov/caddis/). This system is the principal model for the WoE approach presented in this document.

Once the cause of water body impairment has been determined, the sources can be identified so that TMDLs can be developed (Clean Water Act §§ 130.2(f)-(i) and 130.7(c)). This is similar to the practice of determining sources at contaminated sites is known as environmental forensics because it often involves establishing legal liability (Murphy and Morrison, 2002). Its methods include environmental fingerprinting, isotope analyses, tracer studies, and transport modeling, and it often uses WoE. TMDLs are developed and implemented to eliminate the impairment by apportioning pollutant loading among the sources. This step typically does not involve WoE. The TMDL process often includes evaluation of the results, which can lead to removal of the stream reach from the 303(d) list. This outcome assessment can rely on biological endpoints and could involve WoE.

2.3. Existing Pesticides and Industrial Chemicals

The reregistration of pesticides provides an opportunity to collect multiple pieces and types of evidence related to pesticide use, as well as conventional laboratory data, that is generated from the registrant's data package and literature reviews by EPA. This body of evidence, which is weighed in a WoE narrative, can include results from laboratory studies of chemistry and toxicity, mesocosms, field experiments, surveys, and incident reports; pesticide monitoring and use data; and transport, fate, and exposure modeling.

Risks to animals and plants from pesticides are assessed using a tiered approach. In general, most assessments are focused on Tier 1, intended to estimate conservative environmental exposures. The risks associated with those exposures are assessed using risk quotients (RQs), which are predicted exposure levels divided by effect benchmark levels. RQs are based on the most sensitive endpoints available for survival, growth, or reproduction. When RQs exceed levels of concern, risks are characterized using a narrative WoE analysis. Although the process for deriving RQs is well established, the WoE analysis depends on the nature of the available data and the assessed chemical and its use patterns. Examples of evidence analyzed to evaluate risk conclusions include comparing estimates of exposure from models or monitoring data to available toxicity endpoints, evaluating whether laboratory fate studies are consistent with field dissipation studies, and using species sensitivity distributions to evaluate impacts of conservative assumptions on risk conclusions.

Assessments of existing chemicals under the Toxic Substances Control Act (TSCA) can weigh diverse bodies of evidence to determine whether a chemical substance presents or could present unreasonable risk of injury to health or the environment. WoE is used when conducting risk evaluations under TSCA Section 6(b) and making risk management decisions for existing chemical substances. Existing chemical assessments typically rely on a combination of predictive modeling and other computational approaches, empirical laboratory or field data specific for the chemical being assessed and empirical laboratory or field data from analogous chemicals. For example, the body of evidence can include empirical or modeled data on use and release and on transport and fate, physical/chemical properties of the chemical in question, exposure data that include field monitoring and modeled data and hazard data from laboratory toxicity tests or modeling. This information is used to assess risk and, much like the registration of pesticides, RQs are developed and the analysis depends on the available data. The assessments rely on a set of seven study quality and selection considerations (U.S. EPA, 2015b). Implementation of the new (signed June 22, 2016) Frank R. Lautenberg Chemical Safety for the 21st Century Act may change these practices. The act expressly uses the term "the weight of the scientific evidence."

2.4. New Pesticides and Industrial Chemicals

Registration of new pesticides is based on a large and diverse body of evidence (relative to other new chemicals) pursuant to the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) pesticide registration data requirements (http://www2.epa.gov/pesticide-registration/data-requirements). Similar to risk assessments for existing chemicals, a tiered approach is used. The major difference between risk assessments for new versus existing pesticides is generally the amount and types of available data. For new chemicals, the data required under FIFRA generally are available. Incident reports, monitoring data, and toxicity data for nonstandard test species, however, are rarely available for new chemicals.

The available evidence is also weighed when reviewing, assessing, and regulating new industrial chemicals under TSCA before they enter commerce. Assessments of new chemicals rely on a combination of predictive modeling and other computational approaches and empirical data from analogous substances and chemical categories and from empirical data the manufacturer submits. As with existing chemicals, the implementation of the Lautenberg act is likely to increase the importance of WoE for new chemicals.

Review of chemicals for potential endocrine-disruptive mechanisms of action is required for all pesticide active ingredients, all food-use pesticide inert ingredients, and some industrial chemicals. A WoE approach based on a set of considerations has been used for that purpose (U.S. EPA, 2012b).

2.5. Benchmark Derivation

The derivation of numerical criteria, standards, remedial goals, screening levels, and other benchmark concentrations or doses involves performing a type of risk assessment. Qualitative WoE can be applied during problem formulation to determine what hazards should be considered in the assessment. For example, ISAs—which identify hazards that may be assessed in Welfare Risk and Exposure Assessments for National Ambient Air Quality Standards—use WoE to determine what effects on welfare occur in the relevant range of air pollutant levels (U.S. EPA, 2014b, 2013). If different methods or data sets are used to derive benchmarks for different exposure routes or modes of action, WoE can be used to determine which approach to apply, as in the development of IRIS values (human health benchmarks) for carcinogens versus noncarcinogens (U.S. EPA, 2005b). Finally, if a benchmark is derived using field data, WoE can be used to determine whether the evidence suggests the relationship is causal or confounded (U.S. EPA, 2011b).

2.6. Proposed Discharges

WoE is seldom an option when assessing risks from proposed new discharges because evidence is limited to predicted release rates of constituent chemicals used in transport models, and the resulting estimated concentrations are related to benchmark concentrations. Tests of synthetic effluents or analogies to existing effluents that are expected to be similar to the proposed discharge, however, could create bodies of evidence that could be weighed.

2.7. Special Purpose Assessments

Some assessments are performed for particular nonroutine decisions. For example, the EPA performed a watershed risk assessment to inform potential decisions concerning the mining of metals in the Bristol Bay, Alaska, watershed (U.S. EPA, 2014a). The evidence used was diverse and included analogies to prior metal mines and pipelines. The evidence was therefore weighted and weighed using a method like the one in this document. Similarly, EPA borrowed from the WoE method developed for causal assessment of impaired waters to assess the connectivity of streams and wetlands to support the definition of waters of the United States (U.S. EPA, 2015a). These examples show how one-of-a-kind assessments can adapt the general approach presented in this document.

3. PROCESSES FOR WEIGHING EVIDENCE

3.1. An Introduction to the Weight of Evidence Process

The weighing of evidence is a tool that can be used for any type of assessment, at any point in an assessment process or throughout the entire assessment (Section 2; Figure 3-1). In a risk assessment, WoE is used in the problem formulation phase to identify the hazardous properties of the agent being assessed and the appropriate assessment endpoints. In particular, evidence can be weighed to determine whether it supports the hypothesis that a chemical causes some particular effect, such as failure to hatch, effects on a particular taxon, or effects by a particular route of exposure or mode of action (Meek et al., 2014). In the analysis phase, WoE can be used to select assumptions, estimate parameters, and develop models (Section 8, Appendix B, and Appendix C). In the synthesis phase, the models and parameter estimates are used to characterize risks, determine most likely causes, or determine whether an ecosystem is impaired. When multiple exposure-response relationships, spatial/temporal associations, or other relationships have been developed, WoE is used to combine them or to determine which relationship is the best (weightiest). Other types of assessments use WoE at different points in their frameworks (Section 2). In a causal assessment, WoE is carried through all analysis and synthesis phases (Norton et al., 2014).

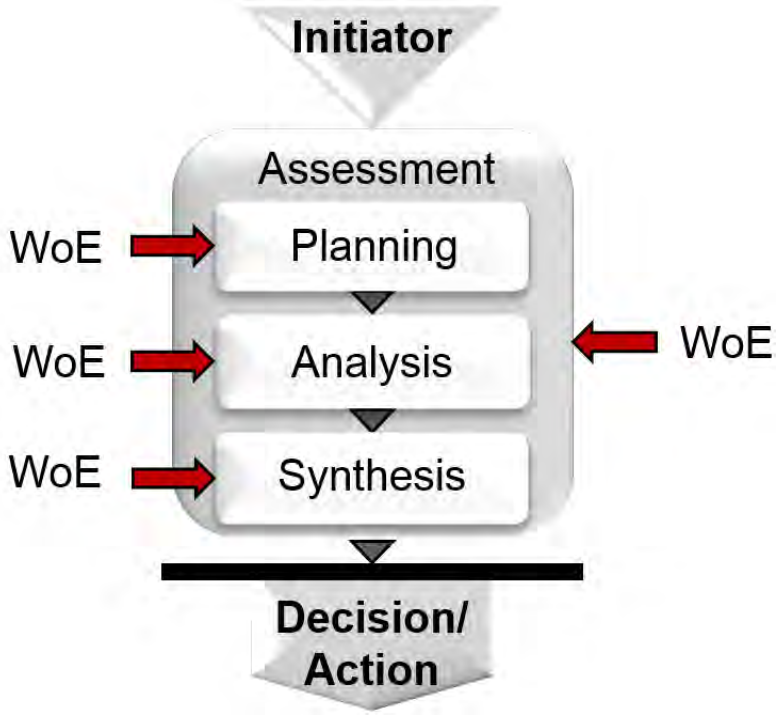

Figure 3-1. A basic framework for all types of environmental assessments (U.S. EPA, 2010b; Cormier and Suter, 2008). Weight of evidence can contribute to one or more individual steps (WoE on the left) or can be the basis for the entire assessment (WoE on the right).

However used, a formal WoE involves the same basic process (Figure 3-2). First, the evidence is assembled. This step involves finding published studies or performing new studies, determining whether their results are acceptably relevant and reliable, and extracting and analyzing data to generate useful evidence. Second, the pieces of evidence are weighted (i.e., evaluated and scored) to determine their influence on the results. Third, the body of evidence is weighed (i.e., weights are integrated and the body of evidence is interpreted) to arrive at a result.

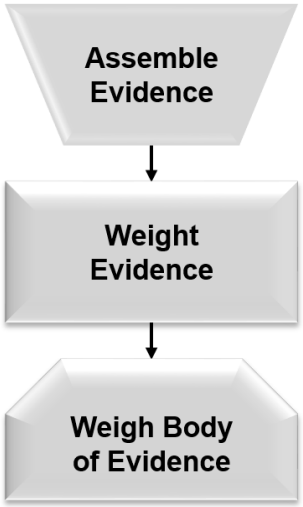

Figure 3-2. The basic WoE process (Suter and Cormier, 2011). The steps are elaborated in Sections 4–6, respectively, in this document.

WoE processes vary among applications, but these three steps are fundamental. First, you must have evidence. The final step, combining and interpreting (i.e., weighing) the evidence, is necessary to make the body of evidence inform the inference. The middle step, weighting, is also essential in that different pieces and types of evidence seldom have the same influence in an inference. However, the explicit assignment of weights is often skipped. This should be done only if the evidence is found to all be equally relevant and reliable (Section 7).

In many cases, multiple pieces of evidence are not explicitly weighed. Instead, evidence is informally weighed in a narrative (Box 3-1).

WoE can be applied to derive qualitative or quantitative results. It might be used to assess qualities such as causality, impairment, recovery, or occurrence of a specific effect or used to estimate quantitative results such as a benchmark value, a model parameter value, or the magnitude of effects. Inferences to quantities begin with quantitative evidence and apply quantitative methods (Section 8 and Appendix B). Inferences to qualities, however, use all relevant evidence (qualitative and quantitative) but apply qualitative inferential methods (Sections 5–7 and Appendix D). Even in WoE methods such as the Massachusetts system that use numerical scores, those scores are used to document qualitative judgments to reach a qualitative result (Menzie et al., 1996). The same qualitative methods can be used to make qualitative judgments about quantitative results (Section 8). For example, they might be used to judge the reliability of a quantitative effect estimate (e.g., 26 km of stream would be impaired and that result is highly reliable).

The general approach introduced in this section is intended to be flexible and broadly applicable. It is intended to provide more rigor and transparency than narrative WoE but less complexity and more flexibility than numerical systems and indices (Appendix D). The approach also is intended to merge inferences to qualitative and quantitative results in a useful manner. It can be applied to all types of environmental assessments and to both data-rich and data-poor cases.

Box 3-1. Best Practices for Narrative Weight of Evidence

Although this document explains how to use a formal method for WoE with explicit weighting and weighing, we recognize not everyone will follow this approach. Some assessors will continue to use a traditional narrative approach. In such cases, WoE narratives can benefit from some good practices.

1. When using evidence from the literature, design and carry out a literature search that will find the information needed in an unbiased manner (Section 4). Define not only the search terms but also the criteria for screening the results to obtain relevant and reliable evidence.
2. Even in a narrative approach, provide a table summarizing the selected evidence and indicate what was excluded and why.
3. Avoid narrative reviews that describes one piece of evidence after another and then present a conclusion. Instead, logically structure the narrative. At a minimum, present the evidence for a hypothesis and the evidence against it, and explain why one side has greater weight.
4. Make the narrative organization clear. Use lists and subsection headings to help the reader understand the logical structure.
5. Present the results clearly. Which hypothesis is best supported by the WoE, and how much confidence can be placed in the conclusion?
6. Express the degree of confidence in the conclusion.

3.2. Planning the Assessment to Use Weight of Evidence

All environmental assessments begin with a planning phase that defines how the assessment will be conducted. In risk assessments, this phase includes two steps termed planning and problem formulation (U.S. EPA, 1998). Assessment plans identify the evidence needs, methods that will be used to generate the evidence and methods for weighting and weighing multiple pieces and types of evidence. Specifying the WoE method in advance enhances transparency and defensibility. In particular, a previously defined system for evaluating evidence and assigning scores prevents the adjustment of weights to achieve a desired result. To the extent feasible and helpful, standard frameworks and methods should be used (Box 3-2).

In practice, there are levels of standardization. Sections 4–7 present a general WoE approach for EPA, which could reduce the burden of planning an assessment. Additional standardization can be achieved at the program level or in individual regions. The greatest specificity, however, occurs in the planning of individual assessments. Not specifying in advance how evidence will be

Box 3-2. Standardization of Weight of Evidence

Standardization of assessment practices is desirable in general. Standardization can increase efficiency by reducing the number of decisions to be made, improve assessments by setting standards of practice, and reduce bias by reducing the opportunities for assessors to make personal judgments. If the standard practices are too rigid and prescriptive given the variability in assessment problems and conditions, they can reduce efficiency, force less than optimal assessment practices, and create frustration. This conundrum is compounded when WoE approaches are used. Decisions are made concerning, among others, which inferences should be based on WoE, what evidence should be included, what properties of the evidence should be considered, and how the weights should be expressed. These decisions should be made on a program-specific basis.

weighed delays the decisions until the data are in hand and the evidence is being generated, weighted and weighed. At that point, the consequences of decisions might be apparent to the assessor. For example, if sediment toxicity tests for an area result in an average 33-percent mortality and no standard for scoring has been set, an assessor can score the evidence as 0, + or ++ (ambiguous, weak, or strong). That judgment could be biased if the assessor knows that the choice can tip the balance for or against dredging the sediment. Removing the temptation to choose a weight that gives a preferred answer by standardizing weights whenever appropriate is the better option.

Exceptions do exist. A detailed plan, on occasion, can result in nonsensical results when implemented, due to peculiarities of the case (Johnston et al., 2002). Therefore, allowing for deviations, and documenting the rationale, as Johnston et al. (2002) did, is essential.

Finally, when a decision is made to use WoE but the method was not prescribed in an analysis plan, assessors should document how they weighed the evidence and why they made their choices. Expert judgment, although essential, should be transparent.

Assessment planning should be adapted to include WoE considerations. Stakeholders and decision makers can be consulted for assurance that the weighing process is acceptable. WoE methods that are compatible with the potentially available data and evidence should be chosen. Alternatively, data needs should be specified with WoE in mind. In particular, literature reviews and new studies should be coordinated to generate complementary evidence. If a field survey will sample benthic invertebrates, literature reviews should seek toxicity studies of benthic invertebrates. Any new laboratory tests should address benthic invertebrates and preferably taxa that are sensitive or important at the site. Field sampling for different pieces of evidence (e.g., chemical concentrations, habitat characteristics, and occurrence of biological taxa) should be collocated in space and time so that the results can be used to derive relevant relationships or make comparisons.

When possible, the assessment problem to be addressed by WoE should be formulated in terms of alternative hypotheses. Identifying the hypothesis best supported by the WoE is conceptually simpler and more convincing than determining whether a single hypothesis has sufficient WoE. One hypothesis, considered alone, may appear to have sufficient evidence, but another hypothesis may have more and weightier evidence. Alternatively, a hypothesis may appear weak, but its status will be unclear until a stronger alternative is identified. For example, a study of a declining San Joaquin kit fox population began as an attempt to determine whether toxic chemicals were the cause. Its conclusion that they were not the cause became more convincing when a strongly supported alternative cause, predation, was identified (U.S. EPA, 2009a).

Because of the complexity of ecological systems and their responses to interventions, the development of conceptual models is essential to planning an ecological assessment (U.S. EPA, 1998). Conceptual models convey the processes and entities that link sources with effects on endpoints. The links can be used to guide the development of evidence for the WoE process. In risk assessments and other predictive assessments, questions can be asked such as, what sequence of events must occur following the proposed action before the endpoint effect can occur? For example, when assessing the risks from input of phosphorus to a lake, if an endpoint is fish kills due to low dissolved oxygen, the WoE should consider evidence for the occurrence of algal blooms, respiration and decomposition, and evidence against the occurrence of mixing because they all can influence dissolved oxygen (Figure 3-3). Similarly, when assessing the cause of an observed fish kill, if low dissolved oxygen is a hypothesized proximate cause, evidence of phosphorus input, algal production, decomposition, and the absence of mixing are supporting evidence that could be generated and evaluated. An approach for applying WoE to conceptual models is provided by the OECD (2013) guidance on adverse outcome pathways (Box 3-3).

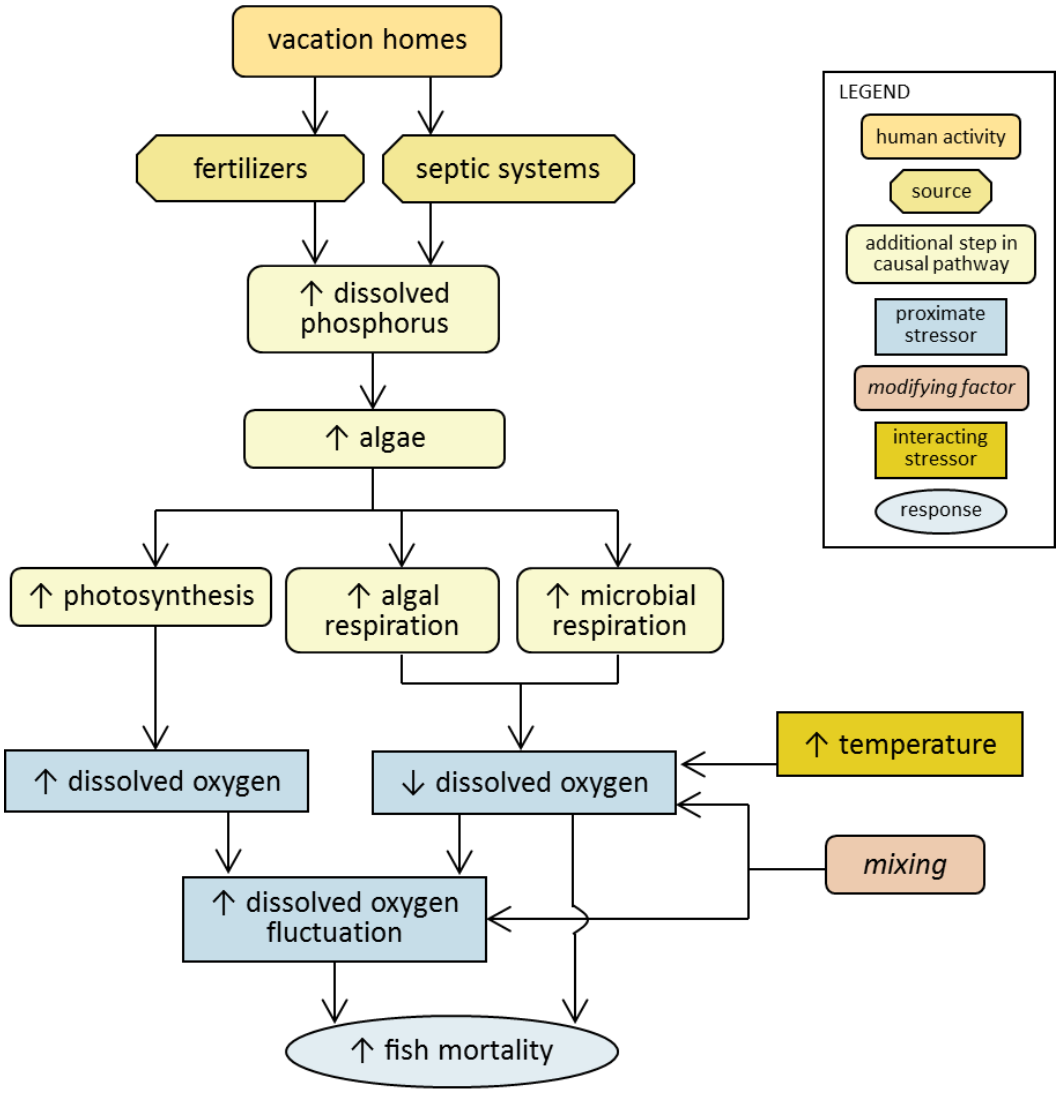

Figure 3-3. Conceptual model for a hypothetical ecological risk assessment of the relationship of phosphorous releases from a vacation home development to the risk of fish kills in a lake (graphic by Kate Schofield, using the conventions in CADDIS, at http://www3.epa.gov/caddis/).

Box 3-3. Weighing Evidence for Adverse Outcome Pathways

Adverse outcome pathways (AOPs) are representations of linkages between molecular initiating events and adverse outcomes measured at levels of biological organization considered relevant to risk assessments (Ankley et al., 2010). Although a goal of AOP development is to quantitatively implement them and predict relevant effects, currently they are primarily a form of hazard identification represented as conceptual models. For example, an AOP might link the binding of a chemical with a receptor in larval fish through a series of steps to failure of swim bladder inflation and then to reduced survival and perhaps to reduced population production (Villeneuve et al., 2014). As with other hazard identification exercises, WoE can be applied to determine the most likely hazards posed by a chemical and also to reveal gaps and weaknesses in the evidence. The OECD (2013) has recommended using Hill's considerations, tailored for AOPs, to evaluate key events, key event relationships, and overall AOPs. The tailored considerations are biological plausibility, essentiality, and empirical evidence. For each consideration, definitions of high, moderate and low confidence are provided. For example, moderate confidence in biological plausibility is defined as "the key event relationship is plausible based on analogy to accepted biological relationships but scientific understanding is not completely established." These OECD standard weights and definitions are equivalent to the standard findings and scores in Table 5-2, but types of evidence are not separately evaluated. Example cases of WoE are provided in the OECD (2013) guidance and derivative publications (Becker et al., 2015; Villeneuve et al., 2014). Subsequently, another WoE approach for AOPs was developed and demonstrated using numerical scores that were aggregated in a linear additive fashion into an overall WoE, a procedure analogous to multi-criteria decision analysis (Collier et al., 2016).

The planning of an assessment should include consideration of uncertainty. However, in the context of WoE analyses, uncertainty is one component of a set of complex issues related to confidence in the results (Section 9). As the OECD found when applying WoE to adverse outcome pathways, analysis of qualitative uncertainty is redundant with WoE (Becker et al., 2015). Conventional statistical measures such as distribution functions, standard deviations and confidence intervals are used to express the variability and uncertainty that appear as scatter in the data or scatter in modeling results. Many sources of uncertainty are unquantified or unquantifiable, however, and conventionally are simply listed. WoE can address this wider range of qualitative issues that determine confidence in the results—not just how closely the curve fits the points, but does the curve represent a causal relationship, and how relevant is the relationship to the case? A formal WoE method is a means to engage with these issues more clearly and consistently. Ideally, each quantitative result would have a conventional statistical estimate of uncertainty or variability and associated qualitative weights.

All assessments require professional judgments by assessors, but WoE makes the judgments more transparent. Clearly indicating where the assessors' judgments end and those of the decision maker begin is critical. It is clear that the decision maker, after conferring with assessors and potentially with stakeholders during the planning phase, specifies the topic and scope of the assessment and the decision to be made (U.S. EPA, 1998). It is also clear that, in the end, the decision maker determines what action will be taken. Judgments regarding the scientific evidence made between these management decisions are generally considered to be in the purview of science and are made by assessment scientists to avoid any potential political biases of decision makers (NRC, 1983). A point of potential ambiguity arrives at the conclusion of the assessment. A decision maker might request only a compilation and summary of the evidence and then decide, for example, whether the stream is impaired, which cause is the most likely or what concentration is the best benchmark value? The boundary between assessment and management, therefore, should be made clear in the planning phase because it determines the ultimate product of the assessment.

Because professional judgments play such a prominent role when weighing evidence, avoiding making the judgments in isolation is essential, particularly for less experienced assessors and for unconventional assessments. Support in professional judgment can be provided during the assessment by collaboration within the assessment team or afterwards by internal and external peer reviewers.

In the EPA, the planning of assessments includes the development and approval of a Quality Assurance Project Plan (QAPP). Although quality assurance (QA) and weighing evidence are not the same, WoE includes the screening of studies and the evaluation of evidence to weight it with respect to relevance and reliability, which encompasses evaluating the quality of input data. To avoid duplication of effort, an explicit WoE process can be used to meet the requirement for a QAPP (Box 3-4 and Section 9).

Box 3-4. Data Quality Assurance and Weight of Evidence

Quality assurance (QA) and WoE both consider the quality of scientific information and thus are related. The QA process determines whether the quality of environmental data and information supporting EPA decisions are appropriate for their intended uses (U.S. EPA, 2008). It includes documenting the process for ensuring information quality, including data generation, data analysis, and assessment methods. Thus, the development of a QAPP should encompass all aspects of the assessment planning process, including methods for WoE (U.S. EPA, 2002a). WoE contributes to QA because QA for assessments "involves a 'weight-of-evidence' approach that considers all relevant information and its quality" (U.S. EPA, 2002b). Therefore, during planning, QA should determine what WoE method is acceptable, and during the assessment, weighting determines whether the quality of information is acceptable. A formal WoE process should provide the rigor and transparency needed to meet QA requirements. Assessors should read the QA guidance and check with their organization's QA official to ensure that they properly merge QA and WoE.

3.3. Results and Transition

In this section we have dealt with determining the role of WoE in the assessment by integrating WoE considerations into the planning and problem formulation process. That is, we have identified one or more assessment problems with multiple pieces of evidence to be weighed, we have identified the WoE approach to be used, and we have determined how it relates to other aspects of the assessment. We are ready for the first step in the WoE framework, assembling the evidence.

4. ASSEMBLING EVIDENCE

4.1. The Process for Assembling Evidence

The success of WoE depends on identifying or generating useful evidence (Figure 4-1). Evidence is information that can be used to make an inference. For risk assessments and causal assessments, useful evidence principally includes information about causality (i.e., a relationship between the exposure and response and either an estimated exposure level or a response level). Exposure levels are used to solve the exposure-response relationship to estimate a future response to the potential exposure (e.g., to estimate the frequency of mortality in a conventional risk assessment) or plausible effects of the exposure (e.g., to determine whether the level of exposure was sufficient to cause the observed effect in a causal assessments; Figure 4-2). Response levels considered thresholds for unacceptability (e.g., 10-percent mortality) are used to solve the exposure-response relationship to estimate the exposure level that will protect against that unacceptable response (criteria assessments) or the exposure level that would be required to cause an observed effect (causal assessments; Figure 4-2). Exposure and response information can occur separately in a condition assessment. For example, evidence that the abundance of an endangered species is declining is sufficient for a condition assessment to prompt a causal assessment. Similarly, accumulation of a chemical in fish can be sufficient evidence of condition to prompt a risk assessment. In addition to information about exposure, response and the relationship between them, information about environmental conditions such as habitat structure or water chemistry also might be required to complete the information that constitutes a piece of evidence.

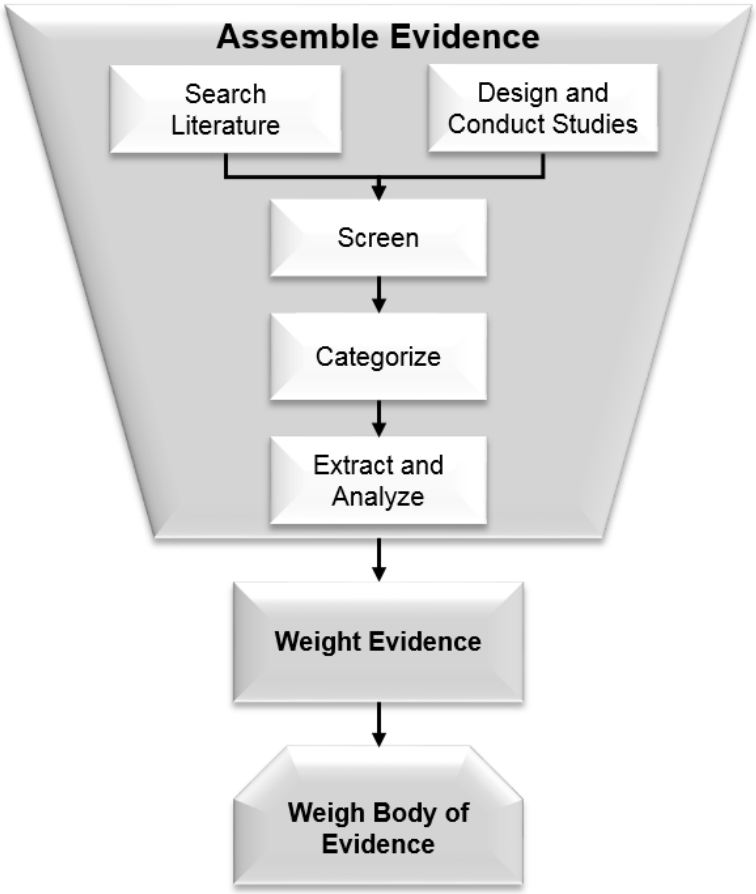

Figure 4-1. An elaboration of the process for assembling evidence, the first step in WoE.

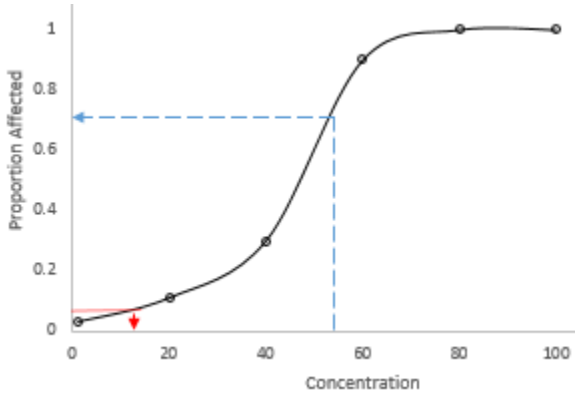

Figure 4-2. An exposure-response relationship (black curve) alone is evidence that the measured chemical can cause the effect. With a concentration, it can provide evidence of the level of effect that is expected (blue dashed arrow). With a level of effect, it can provide evidence of the concentration that would cause that level of effect or, in benchmark derivation, a concentration that would prevent greater effects (red dotted arrow).

Data alone are not evidence because evidence should indicate a hypothesized spatial, temporal, or causal relationship or the absence of a relationship. For example, contaminant concentrations are related to a particular place that has been, or potentially will be, exposed to some source and to reference concentrations from sites that are not exposed to the source. Concentrations without those relationships do not constitute evidence.

In sum, evidence usually requires more than one type of information. Recognizing this, Hope and Clarkson (2014) developed the term "evidence group" to describe the combination of an exposure-response relationship, information concerning environmental conditions that influence the relationship and either an exposure estimate or a response level. Thus, as this document discusses evidence, note that the discussion typically refers to a set of related bits of information that together constitute evidence.

4.2. Searching Literature and Assembling Evidence

A systematic literature review can provide more complete information than an informal review and can reduce the perception of bias in data selection (NRC, 2014). Recognition of the importance of performing reviews systematically has prompted development of several formal methods for systematic reviews (Box 4-1). Recent peer reviews of high-profile EPA assessments such as the stream and wetland connectivity report have called for better documented and systematic literature reviews (SAB, 2014). The method for literature review should be described in the analysis plan (U.S. EPA, 1998).

The EPA has developed the Health and Environmental Research Online (http://hero.epa.gov) database to document the literature searches and screening processes for ISAs and IRIS assessments. It provides transparency in literature searching, screening, and sorting processes and makes the results available to the public.

Box 4-1. Systematic Review

Systematic review is an approach for reviewing published scientific evidence based on a formal search protocol that provides a reasonably complete set of relevant studies that has been screened and reviewed in a consistent and replicable manner (Bilotta et al., 2014). The goal of systematic review methods is to ensure that the review is complete, unbiased, and transparent.

Systematic review was developed as a tool for integrating results of clinical trials in evidence-based medicine. The most prominent example is the Cochrane Collaboration, an organization that reviews evidence of the efficacy of medical treatments (Higgins and Green, 2011). The Campbell Collaboration (http://www.campbellcollaboration.org) extends systematic reviews to education, crime and justice, social welfare, and other issues. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) provides "an evidence-based minimum set of items for reporting in systematic reviews and meta-analyses" (http://www.prisma-statement.org/). More recently, systematic review has been adapted to mammalian toxicology, epidemiology, and human health risk assessment. Examples include the industry-funded Evidence-Based Toxicology Collaboration (http://www.ebtox.com), the foundation-funded *Navigation Guide* (Woodruff and Sutton, 2014), and the U.S. National Toxicology Program's Office of Health Assessment and Translation method (Rooney et al., 2014). Another systematic review system has been developed for environmental management (CEE, 2013). None of the specific existing methods for systematic review are directly applicable to weighing evidence in the EPA's ecological assessments. In particular, systematic review does not integrate heterogeneous evidence, which is typically necessary in ecological assessments. However, they provide methods for the assembly of information from the literature.

4.2.1. Search the literature

The two major components of a literature search are defining the topic and designing the search. The first step identifies the topic with sufficient specificity to enable assessors or information specialists to design a search strategy. Examples include the chronic toxicity of arsenic to marine teleost fish and the biodegradation rate of benzene in fresh surface waters. If the assessments performed by an organization are sufficiently consistent, developing a standard format and content for defining the search topic might be desirable. The variants of Population, Exposure, Comparator, Outcomes, and Study Design (PECOS) systems, developed for reviews of epidemiological or clinical studies, could serve as models for defining ecological search topics (Woodruff and Sutton, 2014; CRD, 2009).

Comparisons of systematic reviews to conventional literature reviews have revealed that the latter are often incomplete or biased (Egger et al., 2003). One reason is the lack of professional assistance with searches. Some useful strategies such as the use of wild cards and truncation to obtain all forms of a search term as well as procedures for using different databases and search engines might not be familiar. Although guidance on literature searching is available (Gough et al., 2012; Higgins and Green, 2011; CRD, 2009), it is not specific to ecological assessment and could soon become outdated due to advances in information science such as text mining techniques.

Multiple search strategies and tools can be employed. Some examples include:

- Electronic databases such as ECOTOX;
- Literature search engines such as PUBMED, Web of Science, or Google Scholar;
- General search engines such as Google or Bing;

- Hand searches of key journals and books;
- Citation tracking of literature cited in key papers, books, or reports;
- Citation searching for publications citing key papers, books, or reports;
- Contacts with key authors and experts;
- Solicitation of information from stakeholders; and
- Internal databases (if they are not business confidential).

One should maintain a search log of sources searched, date, terms, and syntax (i.e., the combinations of the Boolean operators: and, or, not) used. Doing so can make the search explicit, transparent, and potentially replicable. Downloading search results to reference management software such as Endnote or Reference Manager, with a distinct name for the results of each search, also can be helpful.

The inclusion of difficult-to-locate studies (i.e., not published in a journal, not in English, or not indexed in MEDLINE) influenced the results of medical meta-analyses, but the influence varied among fields (Egger et al., 2003). Such studies tended to be less comprehensive and to have lower methodological quality. Identifying relevant studies in an unbiased fashion, however, is important. Issues of study relevance and reliability should be addressed during screening or weighting of the evidence rather than during the literature search.

4.2.2. Screen the studies

Screening the search results and studies performed for the assessment identifies irrelevant or clearly unreliable studies for elimination. Elimination criteria should be defined in advance, to the extent practicable, to avoid perceived or actual bias. Defining irrelevance is relatively straightforward. If the topic is chronic toxicity of arsenic to marine teleost fish, a freshwater invertebrate study would be eliminated. Some issues of relevance might not be apparent in advance. For example, assessors might realize during the screening process that not all arsenic species are relevant, so they should also screen out studies of irrelevant arsenic species. Screening for reliability is generally more difficult than screening for relevance and might not be performed at all. That is, assessors might choose to include all relevant studies and leave differences in reliability for the evidence-weighting phase. Eliminating studies with some obviously unacceptable attribute, such as lack of replication or lack of controls in a test, however, could be efficient. If the weighting phase is skipped (Section 7), performing a more thorough screening and considering the elimination of marginally reliable studies is important.

Some criteria commonly used to screen studies are not so clearly related to relevance or reliability. They include language (English only, unless translation services are available); peer review; and use of a standard protocol or good laboratory practices. Standard protocols ensure consistent and interpretable results, and good laboratory practices improve methodological reliability. Nonstandard studies, however, could provide relevant results and might also have good QA. Entire categories of sources could be eliminated, particularly secondary sources (if possible, primary literature should be used as sources of information), unpublished reports, or abstracts.

Some EPA programs have specific data-screening criteria. For example, the Office of Pesticide Programs screens open literature publications using 14 criteria (U.S. EPA, 2011a), and the ecological soil screening levels for plants and soil invertebrates have 11 acceptance criteria (U.S. EPA, 2005a). Other screening criteria are assessment specific, such as the assessment of connectivity of U.S. waters, which used a logic diagram for screening literature (U.S. EPA, 2015a).

When very large numbers of studies are screened, a tiered process can be used. For example, in the ISAs for criteria air pollutants, publications are screened based on their titles, then on abstracts, and finally on a full reading of the text (U.S. EPA, 2013). Duplicate screeners can minimize errors by identifying and resolving differences.

The EPA has published guidance on determining whether information quality is adequate (see Box 3-3). This procedure is conceptually equivalent to the screening process described here, but it is not followed by evidence weighting and weighing. The screening and weighting processes together should be sufficient to fulfill the EPA's mandate for information quality review.

4.2.3. Categorize the studies

Sorting studies is generally desirable so that distinct categories of evidence can be weighed before they are integrated to reach a conclusion (see Section 6.2). The categorization depends on the type of assessment, amount and diversity of evidence, circumstances of the assessment, and preferences of the assessors.

The most common approach to categorization is to assign evidence to types based on the sorts of studies from which the evidence is derived. For example, the Oak Ridge National Laboratory scheme for ecological assessment of contaminated sites divided evidence into single-chemical toxicity tests, body burdens, ambient media toxicity tests, biomarkers and pathologies, and biological surveys (Suter et al., 2000; Suter, 1996). Other types of assessments would use different types of evidence. In general, field studies are separated from laboratory studies, mechanistic studies are separated from studies of overt effects, and studies of effects at different levels of organization are separated. When only toxicity benchmark values are used as measures of effects, evidence might be categorized by mode of exposure [e.g., whole sediment, pore water, or tissue concentrations (Integral Consulting Inc., 2013)]. An assessment of a specific site might separate evidence from the site from evidence derived from other locations.

Evidence could also be categorized by the characteristic it illustrates. For example, evidence in causal assessments can be organized by characteristics of causal relationships such as interaction and co-occurrence (see Appendix E). Classification in terms of characteristics serves to explain the implication of the evidence for the inference.

4.2.4. Derive evidence from data and general knowledge

Data are raw materials for generating evidence. Data are generated by observation or experimentation and must be obtained from the investigators or extracted from the published studies that pass screening. Data can include:

- Numerical data such as the median lethal concentration (LC_{50}) values or raw exposure-response data;
- Categorical data such as whether benchmark levels are exceeded; or
- Narrative data such as the appearance of a water body, the behavior of animals, or a researcher's interpretations.

In addition to data, generally accepted knowledge such as physical laws and biological principles (e.g., receptor binding of certain chemicals or the role of species competition in structuring communities) contributes to evidence generation. Such knowledge can determine the information sought for generating evidence and the way to structure that evidence. Knowledge also might be the evidence itself. For

example, evidence that a biotic community was exposed to a release from an upstream source is provided by the general knowledge that flow would carry a persistent and soluble chemical downstream. General knowledge might appear as facts (water flows downhill) or as a mathematical model (e.g., a transport and fate model for streams).

If possible, numerical data sets should be obtained from the journal's supplementary material files or directly from the investigator. Transcribing numbers from data tables is prone to error.

If the data to be extracted are sufficiently consistent (e.g., all are from laboratory toxicity tests), development of a data form can facilitate extraction and increase completeness and consistency of the extracted data. Particularly if quantitative analysis is planned, an electronic form can efficiently combine data extraction and data entry. Any form should be piloted with a subset of the studies.

Ensuring data quality by checking the entered data for consistency with the source is desirable. One way to accomplish this is to have two individuals separately extract the data and then compare their results. Discrepancies can be due to errors or to ambiguities in the source that might be variously interpreted.

Some processing of the extracted data could be required before they can be used. In the simplest cases, a summary statistic such as an annual average is calculated. If evidence will be weighed, additional processing often is required. Evidence (as opposed to data) generally involves some sort of relationship such as the impaired stream reach was channelized, but the reference reach was not. Evidence of a condition could involve simple observation. For example, the absence of a taxon (e.g., no fish) is evidence of impairment. In addition, pieces of evidence that will be numerically combined must be converted into the same form and units (e.g., LC_{50}s converted to mg/L).

Processing data to obtain evidence also might require adjusting for the conditions to which the evidence will be applied. For example, laboratory test data might not be comparable to field data until they have been adjusted for water properties such as pH, hardness, or dissolved organic matter levels. Adjusting for the occurrence of mixtures involves applying an additivity model or other combined effects model to the individual chemical test data. Adjusting for biology might require considering seasonal occurrence of sensitive life stages.

Derivation of evidence involves the consideration of variance. Different data sets might appear to be inconsistent, until it is recognized that their distributions overlap.

4.3. Design and Conduct Studies and Assemble the Evidence

In some cases, studies can be performed to provide evidence for an assessment. In such cases, the inferential process should determine the evidence needs and drive the research planning. A simple example is provided by the sediment quality triad [(Chapman, 1996); see Appendix D, Table D-1]. That WoE method includes standard inference rules that require reliable data for the sediment's chemical composition, toxicity, and biological community composition. If any of these types of evidence are missing or unreliable, the inferential method fails. Some EPA offices and programs specify data to be generated for assessments. A prime example is the Office of Pesticide Programs' FIFRA data requirements. For other purposes, such as Superfund remedial investigations, the data needs are determined for individual cases. The Data Quality Objectives Process was developed for that purpose (Bilyard et al., 1997; U.S. EPA, 1994).

Like data from the literature, data produced for the assessment should be screened for acceptability. The Office of Solid Waste and Emergency Response provided detailed guidance to determine if contaminant data are useable (U.S. EPA, 1992a, b). If data quality objectives are developed, they should specify

standards for data acceptability. The description of data to be generated is a conventional component of the analysis plan (U.S. EPA, 1998).

As with data from literature reviews, data generated for the assessment must be input to the assessment's data management system and analyzed to derive the evidence. Unlike data from the literature, the raw data from studies performed for the assessment always should be available for analysis. Results of those studies should be categorized into the same types of evidence as the results of literature reviews.

4.4. Summary

The process of assembling evidence is more complex than the simple phrase implies. When weighing evidence, ensuring the process begins with a complete search of the literature is essential. QA procedures should be applied to the processes of obtaining or extracting data or other information from the literature. Information should be screened for relevance and reliability. Finally, information should be analyzed and organized in a way that facilitates its use as evidence.

4.5. Results and Transition

The results of assembling evidence are pieces of evidence that are at least minimally relevant and reliable, and are organized and presented in a useful form. The next step in WoE is to assign weights to the evidence that have been assembled.

5. WEIGHTING EVIDENCE

5.1. The Process of Weighting Evidence

In most assessments, some pieces of evidence will be more influential than others. The evaluation of the evidence can be implicit, as in a narrative WoE. When a formal WoE method is used, however, weighting the evidence determines the appropriate degree of influence (Figure 5-1). By not only evaluating the evidence but also expressing the weights explicitly as scores, assessors transparently determine the influence that particular pieces of evidence will have when the entire body of evidence is weighed (see Section 6). Weights are usually assigned to pieces of evidence. However, if the pieces of evidence in a category (Section 4.2.3) are similar, the category may be assigned a weight (see Section 6.2).

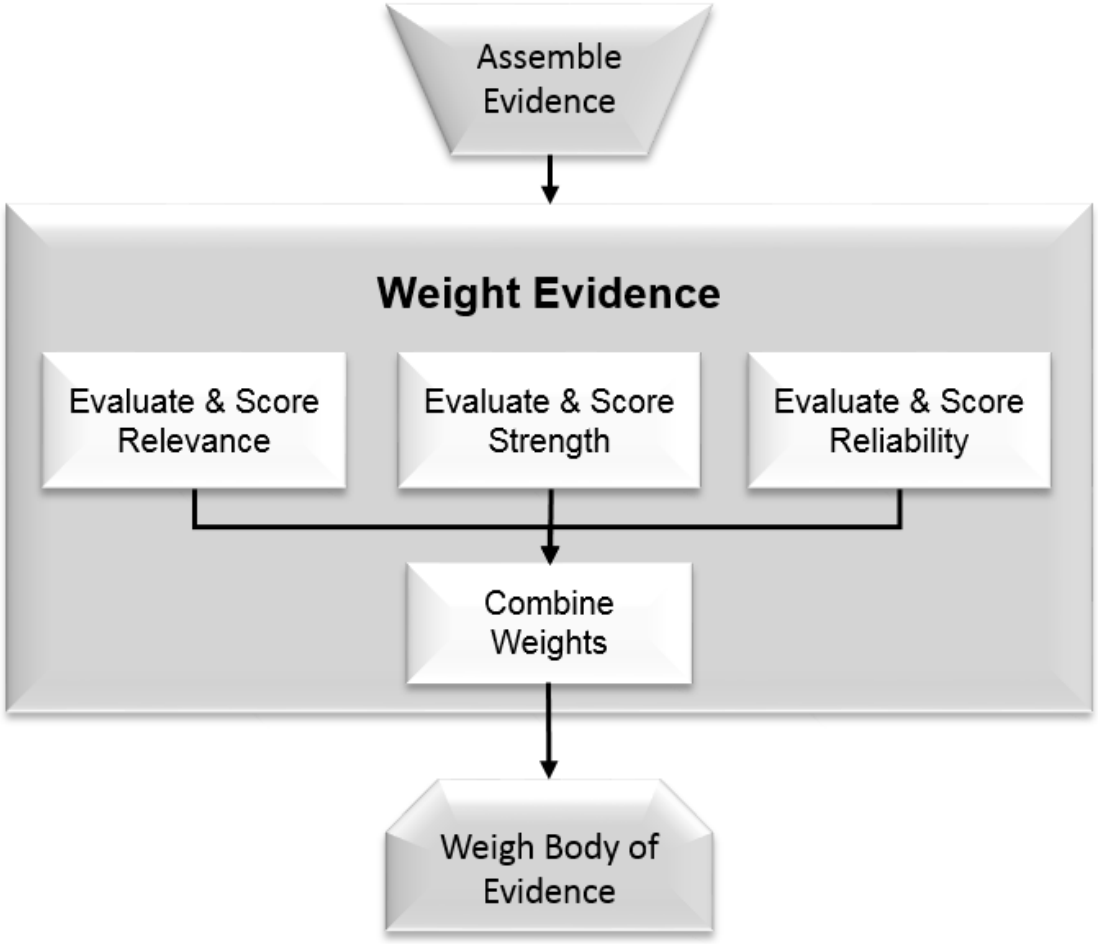

Figure 5-1. An elaboration of the process for weighting evidence, the second step in WoE.

The concept of weighting is familiar in statistics. For example, a weighted mean is the mean of study or sample values multiplied by weights, which are usually the numbers of observations. If one stream invertebrate survey of 10 sites reported a mean of 20 species and another survey of 40 sites reported a mean of 30 species, the true mean species richness across studies is found by multiplying each mean by the number of sites, adding the resulting products and dividing by 50. By weighting, the mean is shown

to be 28, not 25. Statistical weighting is an important tool of WoE for deriving quantities (see Section 8 and Appendix B) but is not considered further in this section.

The qualitative weighting of evidence has two components: evaluation and scoring. Evaluation of evidence determines the weight—how influential a piece of evidence should be, preferably based on defined properties. Scoring uses symbols to formalize the results of the evaluation. The weight is conceptual and the scores are symbolic. For example, a piece of evidence may be evaluated as moderately relevant, so the score for relevance is ++.

Many uses of WoE have not involved scoring. In these cases, either no results of evaluation are expressed or the results are expressed by descriptions. When assessors score the evidence, they are compelled to clarify the evaluation for the reader and themselves. In addition, scoring helps assessors provide clearly weighted evidence for the next step, the integration of evidence (see Section 6).

The approach presented here for qualitatively weighting evidence has been used in assessments of specific causation in the *Stressor Identification Guidance* (U.S. EPA, 2000) and in the Causal Analysis/Diagnosis Decision Information System (CADDIS, http://www3.epa.gov/caddis) and its applications. It has been used in an assessment of general causation for major ions as a cause of the impairment in stream communities (U.S. EPA, 2011b) and has been adapted to integrate evidence in a watershed risk assessment (U.S. EPA, 2014a). Below, the scoring system is presented first and then used to illustrate the evaluation of evidence.

5.2. Scoring Systems

A generally useful qualitative scoring system uses the symbols, +, − and 0, to represent evidence that, respectively, supports, weakens, or has no effect on the credibility of a hypothesis. More symbols represent greater weight. For example, the *Stressor Identification Guidance* and the CADDIS system for ecological causal assessment use the following scores.

+ + +, − − −	Convincingly supports or weakens
+ +, − −	Strongly supports or weakens
+, −	Somewhat supports or weakens
0	No effect (neutral or ambiguous)
NE	No evidence

The interpretation of plus or minus symbols is reasonably intuitive, and they have been used in other WoE systems (Rooney et al., 2014; Higgins and Green, 2011; Fox, 1991; Susser, 1986). These scoring symbols are quite general. They can be applied to a simple quantifiable property like strength of association or to a complex qualitative property like study design. Their regular use could result in clear and consist expression of WoE results. Nevertheless, other scoring systems might be more useful in particular applications.

Most other scoring systems used in environmental assessments only distinguish different degrees of support for a hypothesis. Some evidence, however, is clearly contrary to a hypothesis or has no effect. When a scoring system does not include those possibilities, a separate step must follow scoring to distinguish the logical implications of evidence [e.g., the evidence for the hypothesis is ++ for reliability and +++ for strength but it is contrary to the hypothesis (Johnston et al., 2002)]. The use of 0 and − symbols as well as + makes the logical implication of the evidence part of the weighting process rather than an afterthought.

Symbols are preferable to numerical scores because their use implies that they cannot be numerically combined. Two strongly supporting laboratory tests (++ and ++) are not equal to four somewhat supporting field tests (+, +, +, +). For a test result, a − score for study design and a + score for replication of the test do not sum to 0, because they are not commensurable. They simply signify different results for the different qualitative properties. Adding numerical scores generates a number with no units that signifies no quantity in particular.

These symbols also facilitate interpretation of bodies of evidence. When scanning a WoE table (see Section 6.2), seeing patterns in the frequencies of +, − and 0 symbols that indicate which hypotheses are supported by the weight of evidence is easier than if words or numbers are used to score evidence.

The system described above with three types of weight (positive, negative, and none) and three levels of weight (low, medium and high) has been found useful in environmental assessments, but more or less discrimination might be useful in some assessments. Binary (+/−) scores such as accept/reject and consistent/inconsistent have been recommended because more complex systems could be confusing or overwhelming (Hope and Clarkson, 2014). Alternatively, studies of survey responses have shown that people can distinguish five to seven possible response levels as in the Likert scale [e.g., very low, low, medium, high, very high (Dawes, 2008)]. Hence, the complexity of the scoring system can be adapted to the assessment and the desired degree of discrimination.

5.3. Properties to Be Weighted

Various properties of a piece or type of evidence can contribute to the degree of influence that it should exert. The specific properties fall within three general properties: relevance, strength, and reliability (defined in Box 5-1, Box 5-2, and Box 5-3).

Relevance (Box 5-1) includes biological, physical/chemical, and environmental aspects. It is at least minimally ensured when the assembled evidence is screened. Screening might be sufficient, and no further weighting of individual pieces of evidence for relevance may be necessary. For example, when assessing risk to black bears, if the only available mammalian toxicity tests are for laboratory rats and mice, the relevance of the tests cannot be distinguished because the relationships of rat and mouse sensitivities to bear sensitivity is unknown. In many cases, however, differences in study relevance are important to consider.

A strong signal is better differentiated from noise than is a weak signal, so a strong signal should be given more weight. Strong evidence shows (1) a large magnitude of difference between a treatment and control in an experiment or between exposed and reference conditions in an observational study, (2) a high degree of

Box 5-1. Relevance of a Piece or Type of Evidence

The relevance of a piece or type of evidence is the degree of correspondence between the evidence and the assessment endpoint to which it is applied.

Biological relevance—correspondence among the taxa, life stages, and processes measured or observed and the assessment endpoint (e.g., a *Daphnia* acute lethality test does not correspond well to insect life-cycle survival and fecundity, so relevance may be low).

Physical/chemical relevance—correspondence between the chemical or physical agent tested or measured at the studied site and the chemical or physical agent constituting the stressor of concern (e.g., pyrene may be used to represent a polycyclic aromatic hydrocarbon mixture, but relevance may be low).

Environmental relevance—correspondence between test conditions and conditions at the assessed site or the environmental conditions in a studied system and conditions in the region of concern (e.g., a pond mesocosm does not correspond well to a stream for many environmental parameters, so relevance may be low).

association between a putative cause and effect, or (3) a large number of elements in a set of evidence (see Box 5-2). Strength is a property of the study results, not the type of evidence or study method. The metrics for strength of evidence are familiar. Magnitude is typically represented by absolute and relative differences (e.g., body burdens were 20 times higher than at reference sites). Association is typically represented by correlation coefficients (e.g., Pearson's *r* for the correlation of emission rate and ambient concentrations was 0.8) or slopes (e.g., the regression of species richness on dissolved oxygen had a slope of 7). Number is commonly represented by the number of elements or frequency of occurrences (e.g., a fish kill has occurred at snowmelt every year for the past 6 years). Although strength occurs less frequently in WoE systems than relevance and reliability, some weight only strength (Chapman, 2007).

Box 5-2. Strength of a Piece or Type of Evidence

The strength of a piece or type of evidence is the degree of differentiation from control, reference, or randomness [modified from Norton et al. (2014)].

Magnitude—degree of difference between the amount of response at affected sites and at reference sites or in treatments and controls, between degrees of exposure or other relevant differences in the evidence, most commonly expressed as a difference between means or a ratio of means.

Association—degree to which variation in a variable representing a cause explains variation in a variable representing an effect, most commonly expressed as a correlation coefficient.

Number—the number of elements of a set of evidence (e.g., of symptoms or overt effects in a response or of steps in a causal pathway) that are reported to be observed or the number of occurrences.

Strength metrics lend themselves to standardization. For example, correlation coefficients were calculated for several associations in regional field data to determine the WoE for major ions as a cause of the extirpation of invertebrate genera and for potential confounding by other variables (U.S. EPA, 2011b). Standard scores were developed for the strength of correlations based on the authors' experience with correlations of parameters in surveys of physical, chemical, and biological properties of streams (Table 5-1). In this example, a correlation coefficient (r) between 0.25 and 0.75 is supportive but is not assigned an extra plus for strength. Because $r > 0.75$ is considered relatively strong for a correlation between a water quality measure and a biological response from a regional data set, it is given a second plus. No field correlations are believed to be convincing evidence, so none receive three + or − signs. Consistency and reasonableness of the scores are more important than the precise values chosen for the cutoffs, when they are used to compare alternative hypotheses. Documenting scoring criteria in advance also reduces the opportunities to bias the scoring relative to scoring performed without previously defined cutoff values.

Standard scores based on strength and logical implication are provided for evidence in causal assessments in the CADDIS system. The examples in Table 5-2 are based on standard alternative possible outcomes (findings) for each of 16 types of evidence and the interpretations of those outcomes in terms of the degree to which they support a potential cause. These scores show that different types of evidence have different outcomes with different implications for a hypothesis. The CADDIS table was developed for causal assessment in aquatic ecosystems. This approach to standard scoring is useful if the types of evidence and their findings are conventional. Other applications of this approach could have different types of evidence, possible outcomes, and interpretations.

Table 5-1. Weighting the strength of correlations (absolute value of *r*) and noting the logical **implication—an** example for evidence from stream biological surveys (Cormier and Suter, 2013; U.S. EPA, 2011b)

Assessment	Logical Implication and Strength	Score
The sign of the correlation coefficient depends on the relationship. For toxic relationships such as the correlation between conductivity and number of Ephemeroptera, the sign should be negative. Weak or positive correlations weaken the case for that candidate cause.	$\lvert r \rvert > 0.75$	+ +
	$0.75 \geq \lvert r \rvert \geq 0.25$	+
	$0.1 < \lvert r \rvert < 0.25$	0
	$\lvert r \rvert \leq 0.1$	−
	r has the wrong sign	− −

Table 5-2. Table of standard scores for 3 example types of evidence out of 15 types in CADDIS (http://www.epa.gov/caddis/si_step_scores.html). Each type of evidence is explained in its own CADDIS page.

Type of Evidence	Finding	Interpretation	Score
Spatial/temporal co-occurrence in site surveys	The effect occurs where or when the candidate cause occurs, OR the effect does not occur where or when the candidate cause does not occur.	This finding *somewhat supports* the case for the candidate cause, but is not strongly supportive because the association could be coincidental.	+
	Whether the candidate cause and the effect co-occur is uncertain.	This finding *neither supports nor weakens* the case for the candidate cause because the evidence is ambiguous.	0
	The effect does not occur where or when the candidate cause occurs, OR the effect occurs where or when the candidate cause does not occur.	This finding *convincingly weakens* the case for the candidate cause because causes must co-occur with their effects.	− − −
	The effect does not occur where and when the candidate cause occurs, OR the effect occurs where or when the candidate cause does not occur, and the evidence is indisputable.	This finding *refutes* the case for the candidate cause because causes must co-occur with their effects. Because the evidence is indisputable, other evidence need not be assessed.	R
Laboratory tests of site media	Laboratory tests with site media show clear biological effects that are closely related to the observed impairment.	This finding *convincingly supports* the case for the candidate cause.	+ + +
	Laboratory tests with site media show ambiguous effects, OR show clear effects that are not closely related to the observed impairment.	This finding *somewhat supports* the case for the candidate cause.	+
	Laboratory tests with site media show uncertain effects.	This finding *neither supports nor weakens* the case for the candidate cause.	0
	Laboratory tests with site media show no toxic effects that can be related to the observed impairment.	This finding *somewhat weakens* the case for the candidate cause but is not strongly weakening because test species, responses, or conditions might be inappropriate relative to field conditions.	−
Symptoms	Symptoms or species occurrences observed at the site are diagnostic of the candidate cause.	This finding is sufficient to *diagnose* the candidate cause as the cause of the impairment, even without the support of other types of evidence.	D
	Symptoms or species occurrences observed at the site include some but not all of a diagnostic set, OR symptoms or species occurrences observed at the site characterize the candidate cause and a few others.	This finding *somewhat supports* the case for the candidate cause, but is not strongly supportive because symptoms or species are indicative of multiple possible causes.	+

Type of Evidence	Finding	Interpretation	Score
	Symptoms or species occurrences observed at the site are ambiguous or occur with many causes.	This finding *neither supports nor weakens* the case for the candidate cause.	0
	Symptoms or species occurrences observed at the site are contrary to the candidate cause.	This finding *convincingly weakens* the case for the candidate cause.	−−−
	Symptoms or species occurrences observed at the site are indisputably contrary to the candidate cause.	This finding *refutes* the case for the candidate cause.	R

Properties of evidence that suggest the evidence is more reliable and should be given greater weight are listed in Box 5-3. Additional properties may be applicable in particular cases. Although scoring numerous properties for every piece of evidence could be burdensome, doing so would provide completeness and transparency for the weighting process. An alternative is to choose one or a few properties to be weighted that are judged most important or most likely to discriminate the various pieces of evidence. For example, if all evidence is consistent with prior knowledge (as is usually the case), consilience need not be scored. This approach—scoring the most important component properties of reliability—is generally useful. The least burdensome, but also least transparent, approach is to integrate the component properties of reliability implicitly for each piece of evidence and assign an overall reliability score.

Of these 11 component properties of reliability, the most attention has been devoted to study design. Developing a checklist of design features for each commonly used type of evidence is advisable. For example, Batley et al. (2002) developed a checklist of considerations for laboratory and field studies of sediment chemistry, toxicology, and community structure.

Box 5-3. Reliability of Evidence

Reliability consists of inherent properties that make evidence convincing [modified from Norton et al. (2014)].

Design and execution—evidence generated with a good study design that is well performed is more reliable.

Abundance—evidence from more numerous data is more reliable because it reflects greater replication or resolution.

Minimized confounding—evidence is more reliable when the sampling design or analysis controls extraneous correlates.

Specificity—evidence (e.g., a symptom or set of symptoms) specific to one cause or a few related causes is more reliable.

Potential for bias—evidence from a study that is not funded by an interested party, is not produced for advocacy, and is not produced by an investigator with conflicts of interest is more reliable.

Standardization—a standard method decreases the likelihood that the evidence is biased or analyses are inaccurate.

Corroboration—using models, indicators, or symptoms that have been verified by many studies and are accepted technical practice can greatly increase reliability.

Transparency—complete description of methods and inferential logic and availability of data for reanalysis provide the means to check the results and are presumed to increase reliability by reducing the likelihood of hidden faults.

Peer review—an independent peer review increases reliability of a source of information.

Consistency—the degree to which evidence does not vary in repeated instances within a study (e.g., across years, locations, sampling teams, or methods) is an indicator of reliability of a piece of evidence; when weighting types of evidence, consistency among studies of the same type is an indicator of reliability of the type.

Consilience—evidence shown to be consistent with scientific knowledge and theory, particularly with respect to underlying mechanisms, is more reliable.

Reliability is less if a study or a body of work appears biased. The potential for bias in scientific publications, although controversial, is well documented (Suter and Cormier, 2014; McGarity and Wagner, 2008). One clearly important source is publication bias, the disinclination of authors to submit and editors to accept studies with negative results (i.e., no effect is found). This bias can be detected by statistical analysis if the number of studies is sufficiently large (Ferguson and Brannick, 2012; Hunter and Schmidt, 2004). Other sources of bias can be detected only by comparing the results of studies from different sources. In particular, numerous reviews have identified different results from industry-funded studies and studies funded by neutral sources (Suter and Cormier, 2014; McGarity and Wagner, 2008). The most conspicuous example in ecological risk assessment is the difference between industry-funded and other studies and reviews concerning the teratogenicity of atrazine (Ralof, 2010). Such patterns of biases are not used to exclude data, but potential sources of bias should be identified, if possible, as they help interpret the body of evidence (NRC, 2014). For example, if results of industry-funded studies differ from government- or foundation-funded studies, they all must be carefully reviewed. If the cause of the difference cannot be determined, the reliability of the whole body of evidence may be down-weighted.

Biases may also result from personal ideologies, from a desire for publicity, or other reasons. These more personal sources are more difficult to detect but may show up in non-scientific writings.

In general, secondary sources should be screened out (Section 4.2.2), but if information from secondary sources is used, it cannot be considered highly reliable. The creation of secondary sources is an opportunity to introduce errors and biases in the extraction, analysis, and interpretation of data. Bad citing practices have been reported in the ecological literature, resulting in unsubstantiated conclusions (Sanz-Martin et al., 2016; Tood et al., 2010; Todd et al., 2007). Hence, if primary sources are unavailable, information may be taken from secondary sources but should be considered to have weak reliability. Cases in which a secondary source identifies and corrects an error in a primary source may be exceptions.

In addition to relevance, strength, and reliability, the type of evidence has sometimes been a weighting consideration. In particular, some assessors give more weight to field biological survey results than to other evidence (Chapman and Anderson, 2005). However, some field surveys have low relevance because they do not address the endpoint, do not address the sensitive taxa or other sensitive entities, or measure an irrelevant or insensitive response. In addition, field surveys might be so poorly designed or executed that the results are unreliable. For example, field data were given priority in a contaminated sediment study even though the field survey had "many limitations," including no appropriate reference sites (McPherson et al., 2008). Weighting the properties of the evidence is preferable to assuming that one type is always weightier.

Statistical analysis also has been a consideration in WoE. For example, a criterion for study evaluation in ISAs is "Are the statistical analyses appropriate, properly performed, and properly interpreted?" (U.S. EPA, 2013). However, the appropriateness of the analyses reported in a publication is immaterial if assessors perform their own analyses. Published studies should include original data or the authors should make data available for reanalysis. At least for influential evidence, assessors should consider reanalyzing the data so that results are relevant to the assessment, properly interpreted, and free of statistical errors or biases in assumptions. In such cases, evaluating the statistics the authors used is not pertinent. If original data are not available, the evidence could be given a negative score for transparency. To the extent possible, improper interpretations should be corrected (e.g., $p > 0.05$ does ***not*** mean no effect occurred), and assessors should consider down-weighting evidence that has inappropriate statistics if reanalysis is not feasible (e.g., time and resources are not available).

5.4. Tables of Weights

The primary inferential tool in weighting evidence is tabulations of pieces or categories of evidence and the weights assigned to them with respect to their properties. Because the assigned weights are expressed as scores, they are called scoring tables. Scoring tables may be aggregated to the extent that the weighting process is aggregated. Table 5-3 is a basic, generic scoring table in which both the evidence and properties are aggregated. The rows could have been individual pieces of evidence, but in this table, they are conventional types of evidence. Each of the three general properties is assigned a score based on the evaluation of the evidence each type provides. In the example, when assessing a contaminant as a potential cause of effects in the field, the results of laboratory tests of the contaminant can be positive but have low relevance to the field (+), the responses in the tests can be moderately strong (++), and the reliability of the tests can be high due to standard test designs, good laboratory practices, and regular audits (+++). In this example, the combined score (overall weight) might be + (weak supporting evidence) because the low relevance of the tests could make the strength of the results and the reliability of the method irrelevant to the inference. In other cases, a highly relevant test of the species of concern may not be sufficient to overcome very low reliability (e.g., due to absence of controls). In general, a property with very low weight will have greater influence than a moderate- or high-weight property. In

other words, a bad property of a piece of evidence tends to contaminate the whole thing. These examples illustrate why qualitative WoE is not arithmetic—you can't just add up the scores. It also illustrates why weights should be explained.

Table 5-3. Generic scoring table based on conventional types of evidence, with first line hypothetically completed. The overall weight is positive but low because the test relevance is low.

Types of Evidence	Relevance	Strength	Reliability	Overall Weight
Laboratory toxicity tests of a defined agent	+	++	+++	+
Effluent toxicity tests				
Ambient media toxicity tests				
Field biological surveys				
Field biomarkers and organ or whole-body concentrations				
Field symptoms				

Table 5-4 presents an example from a general causal assessment to determine whether dissolved major ions, measured as conductivity, cause extirpation of stream invertebrate genera. This scoring table presents three types of evidence for one characteristic of causation: the sufficiency of the observed conductivity levels to cause extirpation. Equivalent tables were presented for evidence related to each characteristic of causation. The properties of evidence were treated as binary (e.g., either the evidence is corroborated or not), so no more than one symbol was applied to a property. In this case, evidence is screened for sufficient relevance, and each relevant type of evidence is given one score designating its logical implication. Strength is scored using quantitative criteria as in Table 5-1. Corroboration is scored as the most important component of reliability in this case. Inclusion of a description of the evidence aids reader understanding.

After having assigned weights to each property of evidence (relevance, strength, and reliability), and possibly to multiple component properties of relevance, strength, or reliability, combining them into an overall weight for each piece or type of evidence might be desirable. If evidence is abundant, providing a single summary weight score can facilitate the integration step. Developing a system for combining the property weights can be relatively straightforward. The system used for the casual assessment, from which Table 5-4 was taken, is designed to provide a maximum cumulative score of three + or – units, for each of the three properties. However, as with other processes in WoE, the weights could be combined by expert judgment without defined procedures or criteria to maintain flexibility.

If evidence is scored for multiple component properties, the components should be combined before the three properties are combined. Seldom are multiple component properties of relevance or strength separately scored for a piece of evidence. Reliability has at least 11 component properties that are conceptually distinct, however, and more than one can be applied to a piece of evidence (Box 5-3). In Table 5-3, only corroboration is evaluated, but if multiple component properties of reliability were judged sufficiently important to be evaluated and scored, a separate reliability scoring table would be needed.

In any case, making the weighting convincing and transparent by explaining the reasons for the scores is desirable. This explanation could be presented in the text, but a simple statement, as in the last line of Table 5-4, might be sufficient.

Table 5-4. Example scoring table: scoring types of evidence for sufficiency (U.S. EPA, 2011b). The table is a direct copy and calls out a figure that does not appear in this document.

Type of Evidence	Description of Evidence	Log[a]	Str[b]	Cor[c]
Laboratory tests of ambient waters	A test showed acute lethality to an apparently resistant species, *Isonychia bicolor*, at conductivity levels similar to its XC_{95}.	+		
Field exposure-response relationships of biological metrics	Ephemeroptera were negatively correlated with conductivity in two data sets $r = -0.61$ and -0.72 (Figs. 2b and 4b) and $r = -0.90$ in Pond et al. (2008). This highly relevant evidence was obtained independently in two separate data sets, with moderate-to-strong correlations. Exposures were in the field with native species. Removal of sites with high levels of potential confounders had little effect on the correlation.	+		+
Field exposure-response relationships of composite indices	The field observations showed that, as conductivity increases, indices of stream condition (WVSCI and GLIMPSS) decrease [Fig. 5 and Pond et al. (2008)]. Correlations were strong [$r = -0.80$; $r = -0.90$ in Pond et al. (2008)]. Results were further corroborated by U.S. EPA (2010a). Exposures were in the field with native species.	+	+	+
Field exposure-response relationships of susceptible genera	At 500 µS/cm, the capture probabilities of more than 65% of genera began to decline. Similar results were obtained with West Virginia and Kentucky data sets.	+	+	+
Summary of sufficiency: Exposure to saline waters in Appalachia is sufficient to cause the declines of genera (+) with the salts found in the region's streams. The increases in effects of conductivity are strong even when other stressors are present (+). Different analytical approaches demonstrate that ionic strength is associated with different effect endpoints in different data sets in two states (+). The evidence is consistent. The total score is + + +.				

[a] Log = logical implication of relevant evidence, [b] Str = strength, [c] Cor = corroborated evidence.
GLIMPSS = Genus-Level Index of Most Probable Stream Status, WVSCI = West Virginia Stream Condition Index.

5.5. Not Combining Weights for Properties of Evidence

Assigning scores to each property of each piece or type of evidence might complete the weighting step. That is, separate scores for the properties, rather than a single combined weight, could be carried forward to the integration step. The advantage is that the weights assigned to each property are available to assessors while they are integrating across evidence within a hypothesis as shown in Table 6-2. In such cases, the WoE table shows which pieces of evidence are relevant, which are strong, and which are reliable. One might even score biological, physical/chemical, and environmental relevance separately if relevance is a particularly important issue in the case. The obvious disadvantage is that the integration becomes more complex because the assessor must consider weights for multiple properties while integrating multiple pieces of evidence. In addition, the relative influence of the properties might be evaluated less consistently and transparently if it is not determined in a separate step.

5.6. Summary

Once the evidence has been assembled, the WoE analysis begins in earnest with the assignment of weights to the evidence. Weights are represented by a generally useful scoring system that represents both the implication of the evidence (+, −, and 0) and the weightiness of the evidence (the number of

symbols). Three properties are scored: relevance, strength, and reliability. The evidence and associated weights are summarized in a scoring table. Weights for the three properties may be combined into an overall weight for each piece of evidence or all three may be carried forward into the next step, weighing the body of evidence.

5.7. Results and Transition

The result of the weighting step is a set of pieces or categories of evidence for each hypothesis, each of which has been assigned weights indicating how relevant, strong, and reliable it is. It is recommended that the weights be expressed as qualitative scores and organized in scoring tables. A narrative should also be provided describing the evidence and explaining the weights. This weighted set of pieces or categories of evidence are integrated and interpreted in the weighing step, which follows.

6. WEIGHING BODIES OF EVIDENCE

6.1. The Weighing Process

After weights have been assigned to pieces or categories of evidence, each resulting body of evidence is weighed to determine which, if any, hypothesis is supported. First, weighted evidence for each hypothesis is integrated to form weighed bodies of evidence for the hypotheses (Figure 6-1). Second, the bodies of evidence are interpreted to determine which hypothesis the evidence best supports. Finally, if the bodies of evidence are ambiguous or discrepant, the case should be reconsidered and additional evidence may be required.

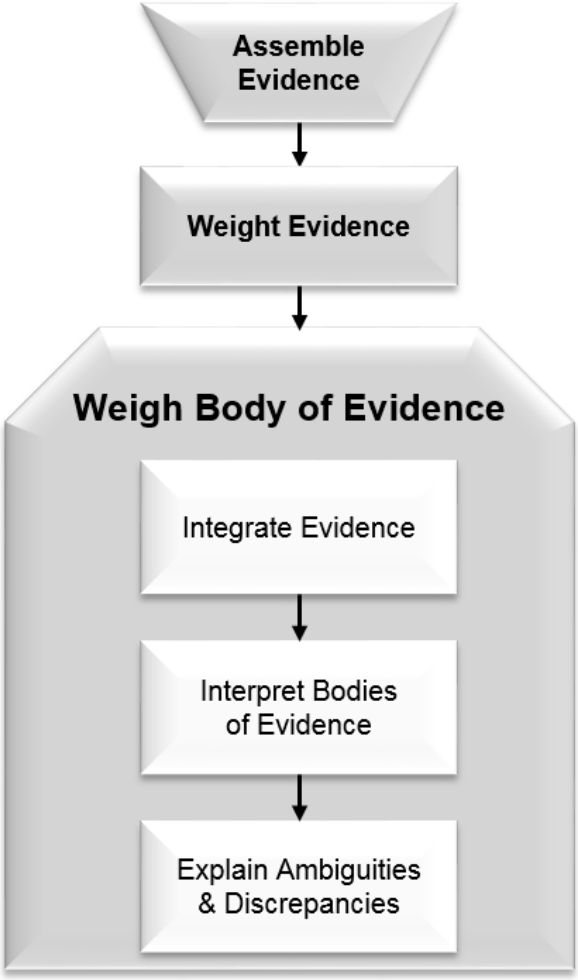

Figure 6-1. An elaboration of the process for weighing the body of evidence, the third step in weight of evidence.

6.2. Integrating Evidence

The input to the integration step is weighted pieces or categories of evidence, and the output is the weighed body of evidence for each hypothesis. The essential purpose of integration is to aggregate the evidence and associated weights into an overall weight. A secondary purpose of integration is to explain the role that the evidence serves in the inference.

1. Integration can aggregate numerous weighted pieces or categories of evidence (depending on the output of the weighting step) into a body of evidence. This purpose is typically served by deriving a combined weight for each type of evidence: evidence derived from laboratory acute tests, biomarkers, biological surveys, etc. Then, the weights are integrated across categories to weigh the body of evidence for each hypothesis.

2. Explanation can answer the question, what does the evidence do to support or weaken a hypothesis? For example, evidence from field surveys can support a hypothesized cause by showing that the cause and effect co-occur. Because WoE is often used to infer causation, the most broadly useful explanation is to associate the evidence with the characteristics of causation such as time order and interaction [Table 6-1, Table 6-4, and Table E-1 (Norton et al., 2014; Cormier et al., 2010)]. Characteristics, however, can be defined for any quality inferred by WoE such as impairment or remediation (see Appendix E). Even without defined characteristics, explanation can be performed by determining how each category of evidence relates to the hypotheses. For example, when weighing evidence for dietary bioaccumulation of a chemical in fish, concentrations in algae are evidence that the chemical occurs in the food web of the fish. If the evidence has been associated with characteristics, the sets of evidence for the characteristics can be used as categories of evidence in place of the conventional types of evidence (e.g., Table 6-4).

Evidence can be integrated in one or more steps, depending on the amount and its diversity and the circumstances of the assessment (Figure 6-2). The categories into which evidence is integrated can be types of evidence or characteristics of the quality of interest. If the pieces of evidence are few or all of one type, the body of evidence can simply be integrated after each piece of evidence is weighted (Figure 6-2a). If the differences among pieces of evidence within a category are small, weighting the pieces can be skipped and the category of evidence weighted as a whole (Figure 6-2b). When evidence is both abundant and diverse, the pieces of evidence can be weighted in each category, the categories weighed based on the weights of the pieces and the collective properties of the category (Box 6-1) and finally, the body of evidence weighed (Figure 6-2c). At the extreme, weighing a very large and diverse body of evidence can be very methodical and use multiple tiers of categories (Figure 6-2d). For example, evidence for fish acute toxicity, fish chronic toxicity, invertebrate acute toxicity, and invertebrate chronic toxicity might be separately weighted and the weights combined to weigh the evidence from all laboratory toxicity tests. Evidence from a laboratory toxicity test then could be weighed along with field tests, field surveys, and any other type of evidence to determine whether the weight of the body of evidence is sufficient to indicate that a chemical exposure is a cause of aquatic community impairment.

The degree to which the weighing of evidence is elaborated depends primarily on a tradeoff between rigor and disclosure on one hand and efficiency and simplicity on the other. The potential to confuse or overwhelm the reader with an elaborate weighing process, however, could also be a consideration. To address this problem, detailed weighting tables and text could be presented in an appendix for peer reviewers and others who need a deep understanding and a summary provided for decision makers and stakeholders.

As in the weighting step, the fundamental tool of evidence integration is a table, but this one is called a WoE table. A WoE table presents the evidence, organized in categories (types or characteristics), and the WoE scores for each evidence category and alternative hypothesis (Table 6-1). These scores come from the scoring tables created by weighting the evidence (Section 5). The same symbols are used in the weighing step as in weighting, because they express the same conceptual weights. In addition, collective properties of the body of evidence such as coherence are scored (Box 6-1). Finally, the overall weight for each hypothesis is presented. This generic table form is broadly useful, but the form of the table in any application depends on the amount of evidence, number of hypotheses, detail of the weighting, degree of

involvement of the decision maker, and other considerations. Examples of WoE tables for integrated evidence from actual assessments are presented in Table 6-2 through Table 6-4.

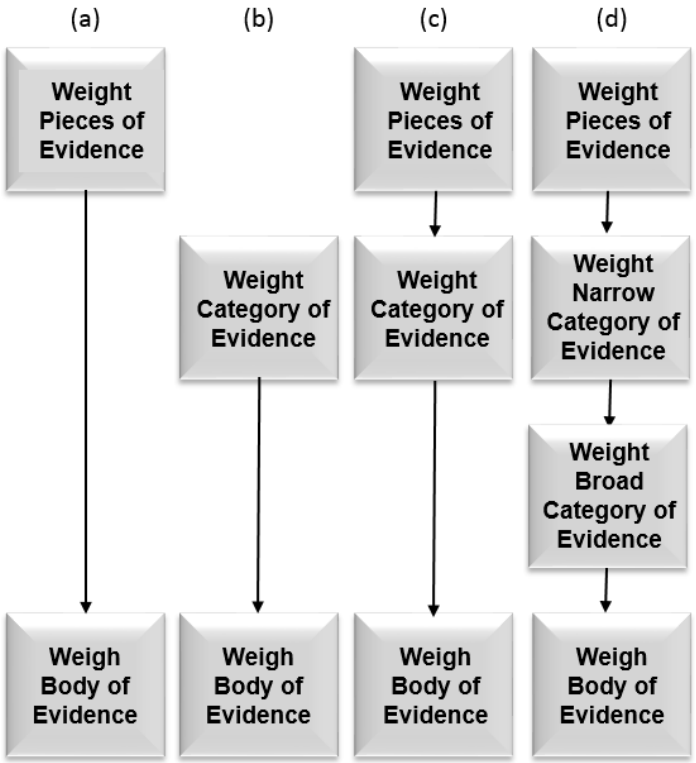

Figure 6-2. **Some alternative approaches (a–d) to weighting and weighing evidence based on different approaches to aggregating evidence.** Categories could be types of evidence or evidence for characteristics of the quality of interest. The choice depends on the amount and diversity of evidence, the circumstances of the assessment, and the judgments of the assessors. From Norton et al. (2014).

Box 6-1. Collective Properties of Bodies of Evidence. Modified from Norton et al. (2014).

The following collective properties of the body of evidence can be considered in addition to considering the relevance, strength, and reliability of the pieces or types of evidence. As with the properties of pieces or types of evidence, any of these could be used, depending on their relevance and utility for distinguishing among the hypotheses.

Number—more pieces or categories of evidence within a body of evidence increase the reliability, if they are consistent and are generated independently.

Coherence—logical consistency among types of evidence increases the reliability of a body of evidence, particularly when empirical and mechanistic evidence and evidence from a case and from elsewhere are coherent.

Absence of bias—consistent results from different funders and types of investigators (e.g., academic, industry, nongovernmental organization, government) are more reliable.

Diversity—evidence from more responses, taxa, life stages, or communities under more conditions is more likely to detect important exposures, responses, and relationships reliably.

Table 6-1. A generic weight-of-evidence table for *n* alternative causal hypotheses (H_1, H_2, ... H_n), based on causal characteristics and collective properties of the bodies of evidence

	Combined Weight		
	H_1	H_2	H_n
Characteristics of Causation

WoE for the hypothesis			

Table 6-2 presents, for illustrative purposes, a subset of the types of evidence and causal hypotheses from a WoE table for determining the cause of a precipitous decline in the abundance of San Joaquin kit foxes on the Elk Hills Naval Petroleum Reserve, California (U.S. EPA, 2009a). The full table occupies multiple pages. The evidence was scored using the types and standard scores in CADDIS, which eliminates the need to weight the evidence for relevance, strength, and reliability. However, it requires accepting the relevance of the standard weights and scores. One collective property of the body of evidence (coherence) is the primary basis for weighing the body of evidence. The conclusion was that predation by coyotes was the dominant cause of the decline and the evidence was convincing. The

coyotes appear to have increased on the site (co-occurrence), the cause of death of radio-collared foxes was known (evidence of exposure or mechanism), population modeling showed that predation was sufficient alone to account for the decline (stressor-response relationship), and coyote control coincided with an end to the decline (manipulation of exposure). Toxic chemicals were present and exposure occurred and was documented by analysis, but far too few foxes were significantly exposed to account for the decline. Accidents contributed but the contribution was relatively small. Note that the + for coherence of disease indicates that the evidence consistently fails to support that hypothesis, so that cause can be eliminated.

Table 6-2. Partial WoE table for alternative possible causes of the decline of San Joaquin kit foxes. Only 4 of 6 potential causes and 7 of 16 types of evidence are included. Adapted from U.S. EPA (2009a).

Types of Evidence	Predation	Toxics	Accidents	Disease
Spatial/temporal co-occurrence	+	+	+	−
Temporal sequence	0	0	NE	NE
Evidence of exposure or biological mechanism	++	++	++	−−
Causal pathway	+	+	+	0
Manipulation of exposure	+	NE	NE	NE
Stressor-response relationships from simulation models	+++	−	+	−−
Coherence	+++	−	+	+

Table 6-3 provides an example of a WoE table from a risk assessment. One hazard in the Bristol Bay watershed assessment was the potential failure of a diesel fuel pipeline at a stream or river crossing, so evidence was weighed for the hypothesis that a spill at a crossing would reduce salmon production (U.S. EPA, 2014a). Unlike the generic types of evidence, Table 6-2 shows types of evidence that are specific to the hypothesis. Evidence concerning the exposure-response relationship was available from laboratory tests of dissolved or dispersed diesel fuel and from eight studies of diesel spills into streams. Exposure was estimated by modeling hypothetical spills to estimate dissolved concentrations, diesel/water ratios, and total volume spilled. The results of combining the weights across properties for each type are presented as brief narratives rather than as combined scores, but the scores for each property are combined across types of evidence. This WoE table shows the consistency of results (all are supportive). It also illustrates where the weakness in the evidence lies—studies of oil spills in streams have not characterized exposure well, as indicated by ambiguous reliability.

Table 6-4 presents a table with combined scores for assessing whether major ions in streams cause extirpation of benthic invertebrates (U.S. EPA, 2011b). The evidence is categorized in terms of characteristics of causation and is derived from the results of scoring tables for each characteristic like Table 5-4. That is, the summary score from weighting evidence for sufficiency in Table 5-4 (+++) is the sufficiency score in Table 6-4 (also +++).

Table 6-4 illustrates how explanation of the pieces or types of evidence in terms of characteristics of causation elucidates the meaning of the evidence for a hypothesis. For example, elevated concentrations of a chemical in numerous streams with impaired communities mean that the chemical and community *co-occur*, and therefore, exposure is likely. If the concentration is greater than concentrations that cause relevant toxic effects, that means that the exposure believed to be *sufficient* to cause the effect. Although such explanations of the evidence might appear self-evident to assessors, it can be an important part of the inference. Although organizing evidence in terms of characteristics serves primarily to help explain the

implications of the evidence, it can also show that a study can provide evidence of multiple characteristics. For example, a laboratory toxicity test can provide evidence of sufficiency (the level of exposure required to cause effects) and of alteration (symptomatic effects of the exposure that may be observed in the field).

Table 6-3. Summary of evidence concerning risks to fish from a diesel spill (U.S. EPA, 2014a). The risk characterization is based on weighing four pieces of evidence for different routes of exposure. All evidence is qualitatively weighted on three properties: logical implication, strength, and reliability of methods. Here, all pieces of evidence have the same logical implication: all suggest a diesel spill would have adverse effects.

Route of Exposure Source of Evidence (Exposure/E-R)	Logical Implication[a]	Strength	Reliability		Result
			Exposure	E-R[b]	
Dissolved hydrocarbons: Model/laboratory acute tests	+	+	0	+	Modeled dissolved diesel concentrations are clearly lethal to invertebrates and approximately lethal to trout.
Dissolved hydrocarbons: Model/laboratory-based standard	+	++	0	++	Modeled dissolved diesel concentrations greatly exceed the state standard.
Dispersed hydrocarbons: Diesel oil:water ratio/laboratory acute tests	+	++	0	+	Diesel oil:water ratios in the spills and in tests suggest lethality to invertebrates and trout.
All routes in actual spills: Amount spilled/observed effects	+	++	+	+	Diesel spills in other streams cause acute biological effects.
Integrated weight of evidence	+	++	0	+	The effects by four types of evidence are consistent, and the observed effects are strong. The greatest uncertainty is the relation of laboratory to field exposures.

Notes:
[a] Logical implication indicates relevance and a particular direction of the evidence (supports or weakens)
[b] E-R = exposure-response relationship

Table 6-4. Example of weighing evidence for a potential cause, major ions measured as conductivity, of the loss of macroinvertebrate genera (U.S. EPA, 2011b). The evidence is organized in terms of characteristics of causation.

Characteristic	Body of Evidence	Scores
Co–occurrence	Loss of genera occurs when conductivity is high but is rare when conductivity is low.	+++
Antecedence	Sources of the ionic mixture are present and are shown to increase stream conductivity in the region.	+++
Interaction	Aquatic organisms are directly exposed to dissolved ions. Based on first principles of physics, ionic gradients in high-conductivity streams would not favor the exchange of ions across gill epithelia. Physiological studies over the past 100 years have documented the many ways that physiological functions of organisms are affected by the relative amounts and concentrations of ions (i.e., combinations of ions that some genera do not have mechanisms or the capacity to regulate).	++
Alteration	Some genera and other response metrics and assemblages are affected at sites with higher conductivity, whereas others are not. These differences are characteristic of relative sensitivity to high conductivity.	+++
Sufficiency	Laboratory analyses report results of effects for a tolerant species, but test durations and most ionic compositions are not representative of exposure in streams. Based on field observations, however, regular increases in effects on invertebrates with increased ionic exposure indicate that exposures are sufficient.	+++
Time order	Conductivity is high and extirpation has occurred after mining permits are issued, but conductivity and biological data before and after mining began are not available.	NE
Summary of body of evidence	Five characteristics are supported and none weaken the body of evidence that increases in conductivity causes extirpation of freshwater benthic invertebrates.	Very likely

6.3. Interpreting Bodies of Evidence

Interpretation is the step in which the bodies of evidence for each hypothesis are used to determine which, if any, hypothesis is supported, and therefore, is likely to be true. Depending on the case, the interpretation of evidence could be performed by comparing alternative hypotheses or by judging whether the evidence sufficiently supports a particular hypothesis. Comparison of alternatives typically occurs in specific causal assessments (e.g., What is causing the low species richness in Jones Creek?). The hypothesis with the greatest weight of evidence is the most likely of the assessed possible causes. This is not just a matter of counting the scores. In particular, the coherence of each body of evidence with respect to the associated hypothesis is considered.

Multiple hypotheses might be likely or at least well supported. For example, both a water treatment plant effluent and stream channelization might be sufficient causes of low species richness in a stream, so both hypotheses could be accepted.

Judging a single hypothesis can be conceptualized as comparing the hypothesis against its negation (e.g., WoE for teratogen versus WoE for not a teratogen) or as a comparison of the weight of evidence for the hypothesis with a standard of sufficient evidence (e.g., a sufficient WoE for teratogenicity versus insufficient evidence). One particular hypothesis can be judged in some particular types of assessments:

(1) a general causal assessment (e.g., Does selenium cause terata in frogs?), (2) specific causal assessments for which only one potential cause is considered (e.g., Does the effluent cause the observed biological impairment?), (3) a condition assessment (e.g., Is the stream impaired?), or (4) an outcome assessment (e.g., Has the wetland recovered?).

These approaches to weighing evidence are consistent with that for the conventional standard of proof in civil legal proceedings and public policy, the "preponderance of the evidence." To meet a preponderance-of-evidence standard, a hypothesis must be shown to be more likely than its negation or than the alternative hypotheses. This standard is met by comparing the weights of the bodies of evidence for a hypothesis and its alternatives.

Hume (1748), Laplace (1812), and Sagan (1980) all made the point that extraordinary claims require extraordinary evidence. This inferential rule should be kept in mind when interpreting bodies of evidence. A hypothesis is extraordinary if there is no prior evidence for it (e.g., the agent has not previously been shown to cause the effect or has been shown to be effective only at much higher levels), or it is simply not plausible. Extraordinary evidence is very weighty evidence: highly relevant, strong, and reliable.

Interpreting the evidence for hypotheses usually involves applying a three-value logic (e.g., yes, no, maybe; true, false, uncertain; or high, low, intermediate). If the interpretation is comparative, as in determining which alternative cause is best supported by the evidence, examining a summary table of the scored evidence and identifying the likely causal hypothesis are possible. Even if the best hypothesis is not clear, proposed hypotheses that clearly are not supported and can be eliminated can nearly always be identified. For example, an assessment of the cause of a precipitous decline in smallmouth bass in the Susquehanna and Juniata Rivers, Pennsylvania, using the CADDIS WoE method and existing information was inconclusive (Shull and Pulket, 2015). It did, however, classify the 18 candidate causes into three bins: 2 likely, 8 unlikely, and 8 uncertain. These results are being used to prioritize and design subsequent research and monitoring. Similarly, when judging a single hypothesis (e.g., spilled tailings would pose a substantial risk to salmon production), the hope is for a body of evidence that clearly either supports or counters the hypothesis, but the evidence might be ambiguous (U.S. EPA, 2014a).

Some WoE systems have standard categorical outcomes defined in terms of properties of the body of evidence (U.S. EPA, 2013, 2005b). A description of the potential weights of evidence used for causal determinations (i.e., categorical outcomes for general causal assessments) of criteria air pollutants is shown in Table 6-5. In such cases, interpreting the evidence involves matching the properties of the body of evidence to one of the categories. The definitions of categories, however, could be based on the scored properties rather than narratives as in this example.

Ultimately, the interpretation of evidence is a matter of logic applied to evidence and background knowledge, preferably by multiple individuals with a range of expertise. It is not simply a matter of adding or counting scores. In particular, some pieces of evidence are conclusive alone. For example, if the effect precedes a potential cause or if an aqueous effect occurs upstream of the putative source, the cause can be eliminated even if other evidence is positive. More commonly, one piece or type of evidence will influence the interpretation of other evidence. Even WoE systems that use standard scoring criteria and arithmetic integration of numerical scores rely on logic to identify and correct results that are contrary to knowledge of the system (COA Sediment Task Group, 2008; Johnston et al., 2002). As a result, applying expert judgment in any WoE is necessary to achieve an adequate, explanatory account.

At this stage, it is desirable to limit the interpretation to the hypotheses and evidence that were defined in advance. Otherwise, "ad hoc machinations" to achieve an acceptable answer can occur (Douglas, 2012). If interpreting the evidence does not identify a clear preponderance of evidence for a hypothesis, techniques that go beyond the simple weighing of evidence can be applied, as explained in the following

section. However, it should be remembered that they violate the admonition against improvised reasoning so they are less convincing than results of weighing bodies of evidence and hypotheses defined in advance.

Table 6-5. Weight of evidence for causal determinations in the 2013 lead ISA (U.S. EPA, 2013).

Causal Determination	Evidence for Ecological and Welfare Effects
Causal relationship	Evidence is sufficient to conclude a causal relationship with relevant pollutant exposures (i.e., doses or exposures generally within one to two orders of magnitude of current levels). That is, the pollutant has been shown to result in effects in studies in which chance, bias, and confounding could be ruled out with reasonable confidence. Controlled exposure studies (laboratory or small- to medium-scale field studies) provide the strongest evidence for causality, but the scope of inference could be limited. Generally, determination is based on multiple studies conducted by multiple research groups, and evidence that is considered sufficient to infer a causal relationship is usually obtained from the joint consideration of many lines of evidence that reinforce each other.
Likely to be a causal relationship	Evidence is sufficient to conclude a likely causal association with relevant pollutant exposures. That is, an association has been observed between the pollutant and the outcome in studies in which chance, bias, and confounding are minimized, but uncertainties remain. For example, field studies show a relationship, but suspected interacting factors cannot be controlled, and other lines of evidence are limited or inconsistent. Generally, determination is based on multiple studies in multiple research groups.
Suggestive of a causal relationship	Evidence is suggestive of a causal relationship with relevant pollutant exposures, but chance, bias, and confounding cannot be ruled out. For example, at least one high-quality study shows an effect, but the results of other studies are inconsistent.
Inadequate to infer a causal relationship	The available studies are of insufficient quality, consistency, or statistical power to permit a conclusion regarding the presence or absence of an effect.
Not likely to be a causal relationship	Several adequate studies, examining relationships with relevant exposures, are consistent in failing to show an effect at any level of exposure.

6.4. Explaining Ambiguities and Discrepancies

The results of weighing bodies of evidence can be ambiguous and discrepancies among pieces or types of evidence can occur. Examples include WoE results for which:

1. The bodies of evidence for all assessed hypotheses are incoherent.

2. One hypothesis has sufficient, consistently positive evidence to support acceptance, but some other hypotheses also have some relevant and reliable positive evidence.

3. No hypothesis has predominantly positive evidence.

In ambiguous, discrepant, or nonsensical cases, one can stop the assessment process and call for more data or proceed to perform follow-on analyses to resolve problems with the existing evidence. The latter course could allow successful completion of the assessment by reconsidering the evidence or by reformulating the hypotheses. Having completed the WoE analysis, some hypotheses could have been

eliminated, but the grounds for elimination might need re-examination. Also, assessors should have become deeply familiar with the evidence. That familiarity and the assessors' background knowledge could make it possible to reinterpret the data or revise the hypotheses to explain and resolve the ambiguities. Reinterpretations, however, provide opportunities to fabricate false explanations of apparent patterns in the evidence. Formulating hypotheses to accommodate the evidence is discouraged in scientific inference because it can lead to bias or self-deception. It has come to be known as HARKing (hypothesizing after results are known). As in other judgments during the assessment process, clearly articulating arguments, avoiding over interpretation, involving multiple assessors with different perspectives, and using a clear and consistent method to build the case are essential. A generally useful approach is to (1) list the discrepancies, (2) ask whether each discrepancy could be explained by a misinterpretation of the evidence or by a misspecification of the hypothesis, (3) determine whether all discrepancies can be resolved by some combination of reinterpreting evidence and respecifying hypotheses, and (4) evaluate additional evidence relevant to the explanations.

Reinterpreting the evidence is facilitated by considering ambiguities in the data and the methods used to generate them. As presented in Appendix E, Table E-3, toxicity tests might not include sensitive species, life stages, or responses; the bioavailability or form of a toxicant might be inappropriate; the exposure durations might be too long or too short, etc. Biological surveys could be conducted in the wrong season, compared to an inappropriate reference, to measured responses or taxa that are insensitive to the causal agent, etc. Measures of exposure might miss episodic events, be taken under atypical conditions, not include the causal agents, be disjunct from the biological samples, etc. Any of the evidence could be derived from studies that are biased, poorly designed, or poorly conducted in ways that were not reported or not recognized in the weighting. Inventing explanations is not difficult—the difficulty is determining which are likely to be true.

In addition to reinterpreting the evidence, assessors might explain discrepancies by changing the hypotheses or adding hypotheses in light of the evidence. At least four strategies can be applied.

Redefine the endpoint effect. Causal relationships are often unclear because the effect is unclear. For example, determining the cause of decline in peregrine falcons depended on redefining the effect as reproductive failure associated with thin eggshells. That more specific definition steered assessors away from potential causes such as habitat loss, shooting, and egg collecting and toward toxic effects. In some cases, discrepancies might be explained by defining the spatial or temporal scope of the effect more specifically. For example, defining the effect as the occurrence of fish kills in a stream as a whole will lead to discrepancies in the evidence if kills occur only in a reach below an outfall and the dead fish drift downstream.

Reconsider sources and agents. Discrepancies in evidence could be due to sources, components of emissions, or actions that were not considered, because they were overlooked or of no concern to the decision maker or stakeholders.

Integrate causal agents or networks. Rather than being alternatives, the proposed causes of an effect could be acting jointly. Also, a proposed proximate cause might actually be an indirect cause that contributes to the true proximate cause. For example, habitat disturbance did not cause the decline in San Joaquin kit foxes on the Elk Hills Petroleum Reserve, but it apparently made the foxes more susceptible to the major cause, predation (U.S. EPA, 2009a). Such possibilities can be represented in practice by rearranging the components of a conceptual model or by combining alternative conceptual models. The conceptual model can be revised by removing the box-and-arrow combinations that are not supported by evidence and examining how the remaining boxes and arrows might link within the model or among models for different causes.

Look for patterns in the evidence. Looking for properties that the pieces or categories of evidence supporting a hypothesis share, which the contrary evidence does not share, might be helpful. This examination could be facilitated by creating a matrix of evidence versus relevant attributes of the evidence. Different results might be observed, for example, in field versus laboratory studies, lotic versus lentic studies, industry-funded versus foundation-funded studies, insect versus crustacean studies, etc.

Reinterpreted evidence or revised hypotheses could explain discrepancies in a manner that seems convincing to the assessors who developed them, but explanations improvised after the analysis to account for discrepancies might not convince others without independent evidence. Independent evidence might have been available but unused in prior weighing of evidence, because it had not been relevant. For example, if the proposed resolution of a discrepancy was low bioavailability of metals, measurements of dissolved organic matter might be used to confirm that explanation. Similarly, if low dissolved oxygen is a proposed cause of a fish kill, the survival of air-breathing organisms such as frogs and turtles is supportive (Cormier et al., 2010). Ideally, confirmatory evidence would be generated by identifying a previously unmeasured or unobserved property of the system that should occur under the revised hypothesis and then taking the measurements or observations that would establish its occurrence. If the amount of evidence and the number of possible explanations of the evidence are substantial, a formal reweighing of the evidence to address the revised hypotheses might be appropriate.

6.5. Presenting Results

The results of a qualitative WoE have two parts: the conclusion and the justification. The conclusion, in the best case, is a statement of the hypothesis that is clearly supported by the WoE (e.g., the cause is the thermal effluent, the stream is biologically impaired, or the population has recovered). Ambiguous results require more explanation (e.g., hypothetical causes 1, 3, and 5 can be eliminated, but 2 and 4 are somewhat supported). Graphical presentations can be useful, such as a revised conceptual model of the identified causal relationship or a map of the areas biologically impaired by the waste. When the assessments are sufficiently standardized, a standard reporting format could be implemented as in the International Uniform Chemical Information Database (IUCLID) dossier for assessing the toxic properties of chemicals in the European Union (ECHA, 2010).

The justification of a conclusion is a summary of the evidence and logic that support the conclusion. The justification, which will vary among assessments, typically includes:

1. Statements of overall weight of evidence for the conclusion (e.g., the evidence convincingly supports, strongly supports, or somewhat supports the cause) relative to the weights for alternatives or relative to a standard of evidence.

2. Statements of consistency or coherence (e.g., all the evidence was either convincingly or strongly supportive of the cause, except for laboratory acute tests, which had low relevance).

3. Statements of the extent to which characteristics of causation or other relevant characteristics are satisfied by the evidence (e.g., evidence was available to support all characteristics of causation except time order). Alternatively, state the extent to which standard types of evidence were available (e.g., all three components of the sediment quality triad were available). In any case, state how the body of evidence provides an explanation of the credibility of the accepted hypothesis.

4. Statements explaining why the conclusion is justified despite a low weight of the body of evidence, if necessary (e.g., even if other causes could be substantially contributing, collection and treatment of the effluent is likely to improve conditions and is mandated by regulations).

6.6. Summary

Having assigned weights to the pieces of evidence, the process of weighing evidence integrates and interprets the body of evidence to determine which, if any hypothesis has sufficient weight to be accepted. Depending on the amount and types of evidence, this may include a process of aggregating the evidence into categories and integrating the weights within categories. Once the weights have been integrated, the bodies of evidence for all hypotheses should be compared and the results interpreted. Interpretation may be obvious (e.g., only one hypothesis has positive evidence) but often it requires careful logic and judgment informed by the knowledge and experience of multiple assessors. If interpretation does not provide a conclusion, an analysis of the ambiguities and discrepancies that confounded the interpretation can suggest what additional evidence or alternative hypotheses should be considered. Finally, the results should be presented in a way that make clear the results and the process that generated them.

7. SPECIAL CASES AND ABBREVIATED PROCESSES

In some circumstances, the full three-step WoE process is not necessary or practical, but a two-step process is useful. The systematic assembly of evidence is always appropriate, but weighting might be unnecessary if all evidence is equivalent (Figure 7-1a), and weighing a body of evidence is unnecessary if only one piece of evidence is available (Figure 7-1b).

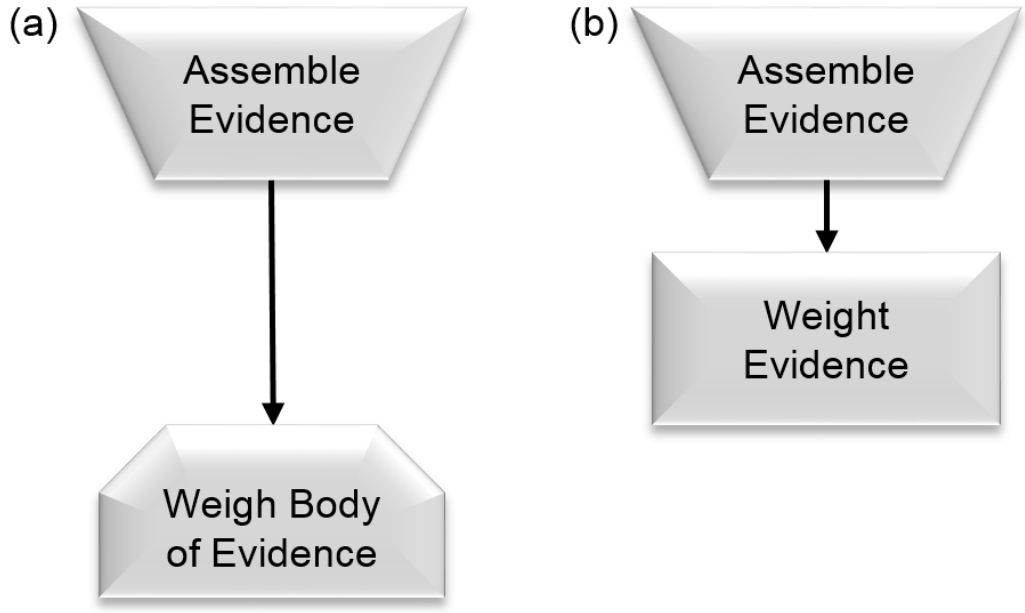

Figure 7-1. Steps in abbreviated weight-of-evidence processes: (a) skipping the weighting step when all evidence is equivalent or (b) weighting a single piece of evidence when multiple pieces are not available.

7.1. Weighing Without Weighting

Some WoE methods presume that all evidence is equal or at least that the differences are uninformative, so the weighting step (Section 5) can be skipped. For example, if all evidence is reliable and of the same type (e.g., multiple acute lethality tests performed by standard protocols), each piece of evidence will have equal influence in most cases. In practice, weighting is often skipped without determining that the relevance, strength, and reliability of the evidence are similar across pieces of evidence. Instead, if the pieces of evidence pass the screening step (see Section 3), the differences are assumed unimportant. An example of weighing evidence without weighting is the causal determination in an ISA regarding exposure to a specific air pollutant and specific effects (U.S. EPA, 2013).

A case for which distinguishing weights was unnecessary is provided by the studies used to determine that ingesting lead from lead mining and smelting caused the tundra swan kills in the Coeur d'Alene basin, Idaho (Table 7-1). The data used in the evidence were generated for the case, so they were all highly relevant; the studies were conducted by competent and reputable investigators following prescribed quality standards, so they were highly reliable; and the relationships were all strong. Because of that ideal situation, the presentation of evidence in WoE Table 7-1 is sufficient. Table 7-1 organizes the evidence in terms of characteristics of causation, rather than listing pieces or types, and briefly summarizes the evidence for each.

Table 7-1. Summary of evidence for lead as a cause of mass mortality of tundra swans in the **Coeur d'Alene** River Watershed (Norton et al., 2014). Based on evidence from URS Greiner Inc. and CH2M Hill (2011).

Causal Characteristic	Evidence
Co-occurrence	Swan kills occurred in Pb-contaminated lakes and wetlands and not elsewhere in the region.
Sufficiency	Mortality occurred in laboratory tests at Pb doses and body burdens observed in dead or moribund swans in the field. Consistent mortality in the field at blood Pb levels >0.5 µg/g.
Time order	No evidence—no pre-mining information on swan mortality.
Interaction	Dead and moribund swans had high blood and liver Pb levels. Pb-contaminated sediments were found in swan guts and excreta.
Specific alteration	Swans had pathologies characteristic of Pb toxicity, particularly, enlarged gall bladders containing viscous dark green bile.
Antecedents	Spills of Pb mine tailings and atmospheric deposition from smelters account for the high sediment Pb levels.

7.2. Weighting a Single Piece of Evidence

The concept of WoE was developed to combine multiple pieces of evidence in a way that gives each piece proper influence on the conclusion. When only one piece of evidence is available for an inference, the integration function of WoE does not apply. WoE, however, also leads assessors to consider the importance that should be assigned to a body of evidence and reveals the assessors' judgments to decision makers and stakeholders. This purpose of evaluating and interpreting a body of evidence can apply to a single piece. That is, explicitly evaluating the relevance, strength and reliability of a single piece of evidence can be informative.

Weighting a single piece of evidence also might provide consistent communication of the assessment process. That is, if many pieces of evidence are evaluated and scored for some hypotheses, the reader will expect to see scores for all hypotheses. If a hypothesis has only a single, stand-alone piece of evidence, scoring that one piece provides the expected consistency in weighing the evidence for all hypotheses.

In addition, weighting a single piece of evidence might reveal its inadequacy and lead to obtaining and weighing more evidence. For example, for the Patrick Bayou Superfund site, assessors intended to use modeling of toxicity to an amphipod as their primary approach to assessing risks to benthic invertebrates (Anchor, 2013). However, they found that the data were unreliable due to lack of reference data, confounding, poor correspondence to tests of other species, and unreliable polychlorinated biphenyl analyses. As a result, they adopted a WoE approach using the conventional triad of sediment quality evidence.

8. WEIGHT OF EVIDENCE FOR QUANTITATIVE RESULTS

Quantitative results of ecological assessments, such as benchmark concentrations, areas of habitat lost or rate constants, might be derived from multiple pieces of quantitative evidence. Commonly, these quantitative analyses follow the qualitative analyses that establish the hazard or other qualities to be quantified (Figure 8-1). Methods for deriving quantities by weighing evidence are discussed in Appendix B. They fall into two basic approaches: combine the quantitative evidence or choose the best quantitative evidence. Finally, weights can be assigned to the quantitative results to indicate how influential they should be.

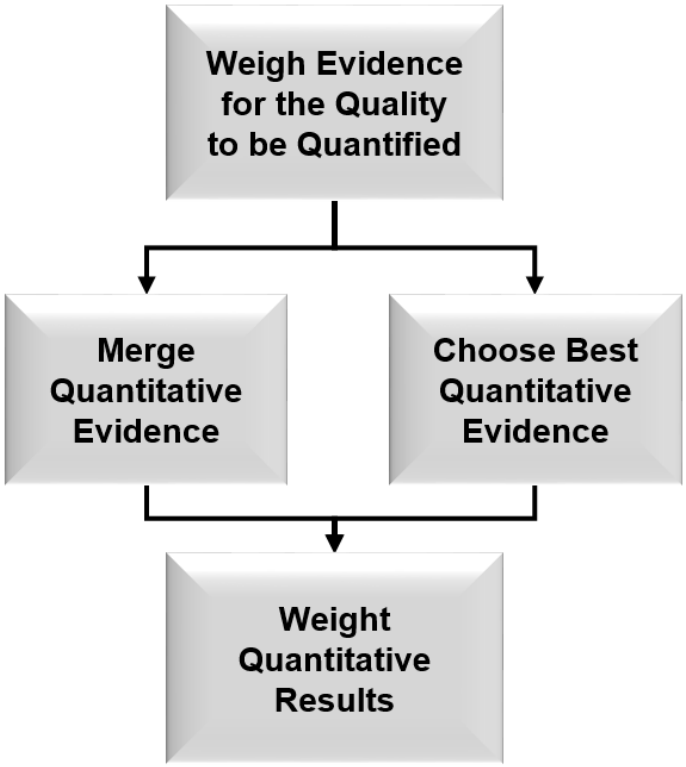

Figure 8-1. Potential steps in a process for using WoE to derive a quantitative result. Note that the top box of this process diagram encompasses the qualitative WoE process (Figure 3-2).

8.1. Weight of Evidence for the Quality to Be Quantified

Before deriving a quantity, determining what quality is to be quantified (Table 8-1) is necessary. This determination could require weighing evidence. For example, conventional risk assessments quantify, if possible, the magnitude and likelihood of a defined hazard. Environmental hazards are potential effects on an attribute of a biological entity (the assessment endpoint) resulting from exposure to an agent in particular conditions (described by the conceptual model). Similarly, criterion assessments quantify a threshold level of exposure corresponding to an unacceptable level of effect, and the effect itself is a quality that might be identified by WoE. Qualitative assessment could even precede the derivation of a model parameter. For example, a narrative WoE was used to determine whether a bioavailability adjustment factor should be used at a dioxin-contaminated site, and then the factor's value was chosen based on a prior quantitative WoE in a published review (Integral Consulting Inc., 2013). Quantitative condition assessments might determine the magnitude and spatial extent of impairment after a site has

been determined impaired by qualitative WoE applied to multiple metrics. In sum, this qualitative WoE determines whether the property to be quantified is real and significant in the context of the assessment.

Table 8-1. Qualities that could be identified by qualitative WoE and the associated quantities that could be derived by the quantitative WoE process (see Figure 3-2)

Example Quality	Example Corresponding Quantity
General cause: teratogen	Sufficient maternal body burden
General cause: carcinogen	Slope factor
Specific cause: chloride in effluent as cause of fish kills	Allowable maximum concentration
Specific cause: ammonia in stream as cause of biological impairment	Total maximum daily load
Bioaccumulative	Bioaccumulation factor
Exposure	Bioavailable concentration at point of contact
Susceptibility	Probability of responding
Alteration	Area of wetland

In some cases, assessments weigh evidence to derive a quantitative result without a prior WoE for a quality. For example, the derivation of ambient water quality criteria for aquatic life is nearly always based on a generic endpoint—protection of aquatic life from effects of direct aqueous exposures on survival, growth, or reproduction. However, for some criteria the generic endpoint is found to not be protective because an important specific effect or route of exposure is not adequately addressed. An example is the water quality criterion for selenium, which addressed a nonstandard effect (skeletal deformities in vertebrates) and route of exposure (exposure in ovo to selenium accumulated from a food web by the female parent). Such examples suggest that it may be desirable to weigh evidence for nonstandard qualities. Even if default qualities are assumed, the first step of WoE, the systematic assembly of evidence, should be performed to obtain all potentially useful quantitative estimates as well as associated information.

The place of these qualitative WoE processes in an overall assessment process depends on the type of assessment. For a conventional risk assessment, a WoE to choose the endpoints (i.e., What effects does the chemical or other agent cause in which potentially exposed organisms?) would be part of the problem formulation. The quantitative analysis and characterization phases follow to quantify the risks. In other cases, separate qualitative and quantitative assessments are performed. For example, a qualitative causal assessment to determine the cause of an observed effect may be followed by a quantitative risk assessment to derive a total maximum daily load, cleanup goal or other quantitative benchmark. In cases like the bioavailability adjustment factor example presented earlier, the qualitative and quantitative WoE processes might both be embedded in the analytical phase of an assessment.

8.2. Weight of Evidence for Deriving the Quantity

If more than one source of data with acceptable relevance and reliability is available to derive a quantitative result, the data sets should be weighed. Conventionally, the data sets would be integrated by combining the quantitative evidence or by choosing the best (i.e., weightiest) evidence. Another approach, the Rule of Five, has been useful in weighing evidence to determine a contaminated site cleanup goal (Box B-2).

8.2.1. Combining quantitative evidence

If the quantitative value can be derived from multiple data sets that are of sufficiently high relevance and reliability, the data sets can be numerically combined (Appendix B). In past EPA practices, this combining has involved taking the arithmetic or geometric mean. For example, multiple acceptable LC_{50} values are available for a species-chemical combination, their geometric mean is used when deriving national ambient water quality criteria (U.S. EPA, 1985). Geometric means of toxicity values are also used to derive soil screening levels (U.S. EPA, 2005a). Rather than treating all evidence equally, the values might be weighted before they are combined. Quantitative weighting could use a quantitative property of the study that influences its reliability such as the inverse variance.

Alternatively, quantities might be weighted based on some qualitative property. In this case, the qualitative weights are converted to numerical equivalents. For example, high, moderate, and low reliability of the study design might be converted to weights of 1, 0.7, and 0.5 or some other values, depending on how much influence study design should have and how great the variance in the study design might be.

Rather than using numerical weights to express the properties of the individual estimates, qualitative weights can be applied to the combined estimate. That is, after a combined value is derived, it might be assigned scores to express one or more qualitative aspects of its relevance or reliability. The weighted mean or other quantity derived from multiple sources should provide greater confidence than a quantity derived from any single source. Otherwise, the evidence should not have been combined.

8.2.2. Choosing the best quantitative evidence

If the range of relevance or reliability of alternative numerical values is large, choosing the best value rather than combining them is advisable. That is, the numerical values should be weighted for relevance and reliability, and the weightiest one used. (Note that in some contexts, established policy might require using the most protective acceptable value to ensure the degree of protection required by law.) Choosing the best value is particularly advisable when values can be derived from multiple types of evidence. For example, if a benchmark value of a contaminant could be derived from laboratory toxicity tests, a mesocosm test or a regional field survey, the results are likely to represent qualitatively different effects and might not be averaged, with or without weighting.

Using WoE to choose the best estimate is illustrated by Table 8-2. This table format presents the magnitude or probability of effects versus integrated weights of evidence for types or groups of evidence as recommended by Hope and Clarkson (2014). The table shows risk assessment results (probability of achieving the effect endpoint) estimated by analysis of each of four evidence groups (numbered circles) with integrated weights derived as in Section 6. In this hypothetical example, Evidence Group 3 might be chosen because it has the highest weight and is not an outlier in terms of the quantitative result (probability of effect). The result might be, Group 3 (evidence derived from stream mesocosm tests) is convincing and gives an estimate of 15% probability of reduced species richness.

Using WoE to choose the best value is not an established practice, but it is recommended for choosing among alternative test data for the same species, endpoint, duration, life stage, and testing conditions by the European Chemical Agency (ECHA, 2008). Although the European Chemical Agency does not specify a method of weighing, it indicates that various studies can provide supporting information to add weight to a particular test.

Table 8-2. WoE matrix to summarize quantitative risk estimates for four evidence types or groups (numbered circles) and their weights. Adapted from Hope and Clarkson (2014).

		Evidence Weight			
		0	+	++	+++
Probability of Achieving Effect Endpoint	>75%				
	51–75%				
	25–50%			①	
	5–24%			②	③
	<5%		④		

8.3. Weighting a Quantitative Result

Quantitative results are often accompanied by statistical expressions of variability or uncertainty, but determining how much weight the result should be given might also be useful. Weighting a quantitative result could inform decision makers and stakeholders about the result's relevance and reliability, irrespective of data scatter (Section 9). For example, an estimate of biological effects might have a small confidence interval, but it could have been generated from laboratory test data with low relevance to the case or might have been generated with poor controls or otherwise unreliable methods. As in weighting qualitative evidence, the specific properties of relevance and reliability listed in Box 5-1 and Box 5-3 and the collective properties listed in Box 6-1 could be included in the weighting of quantitative evidence if they are important.

Strength is generally not a relevant property for weighting quantitative results. For example, an exposure-response model with a high slope is strong, and therefore, lends weight to a causal hypothesis (i.e., a qualitative WoE). However, the result of a quantitative analysis to derive a benchmark exposure has whatever strength it has. An estimate of a benchmark value derived from an exposure-response relationship with a high slope is not given more weight than one derived from a relationship with a low slope.

Weighting might be used to determine the applicability of a number to particular uses. For example, at contaminated sites, weights might be used to distinguish soil benchmark values that are suitable only for screening values from those that might be suitable for cleanup goals. In any case, weights can be used along with statistical uncertainty measures to communicate confidence in results.

9. WEIGHT OF EVIDENCE AND UNCERTAINTY

The process of weighing evidence can be considered a means not only of deriving a conclusion, but also of documenting the assessors' confidence in the conclusion. That is, the weights assigned to pieces and categories of evidence are expressions of how confident the assessors are that the evidence should influence the conclusion in one direction or another. Additionally, the overall weight of the body of evidence is an expression of how much confidence the assessors have in that conclusion. If both laboratory tests and field surveys indicate that a chemical causes spinal deformities in fish, and both categories of evidence are evaluated and scored as highly relevant, strong, and reliable, we are confident that the chemical is a cause of deformities. Even if the WoE analysis is limited to a narrative, the narrative should describe the degree of confidence in the conclusion. For example, the categories of results in the ISAs and IRIS hazard assessments are explicit expressions of confidence in WoE narratives (e.g., "likely to be a causal relationship"—see Table 6-3). Such qualitative expressions of confidence are appropriate for a qualitative conclusion such as the observed relationship is likely causal, the chemical is likely a carcinogen, or the chemical is a contaminant of concern. If the standard scoring system was used to weight evidence, the resulting expression of overall confidence might be that the evidence is convincingly supportive, strongly supportive, or somewhat supportive of the conclusion. The appropriate expression of weight/confidence depends on the assessment and the decision to be supported.

The confidence concerning numerical values should include qualitative weights as well as conventional measures of scatter such as range or confidence limits[Figure 9-1 (Spiegelhalter and Riesch, 2011)].[2] For example, one would have low confidence in a benchmark value that is based on irrelevant evidence, even if it is statistically precise. Hence, presentations of quantitative results might have four parts:

1. The quality expressed—threshold for reproductive effects
2. The numerical result and units—*x* mg/L.
3. Scatter—95% CI of ±0.2*x* mg/L.
4. Weight—the body of evidence is highly relevant and moderately reliable, diverse, and coherent.

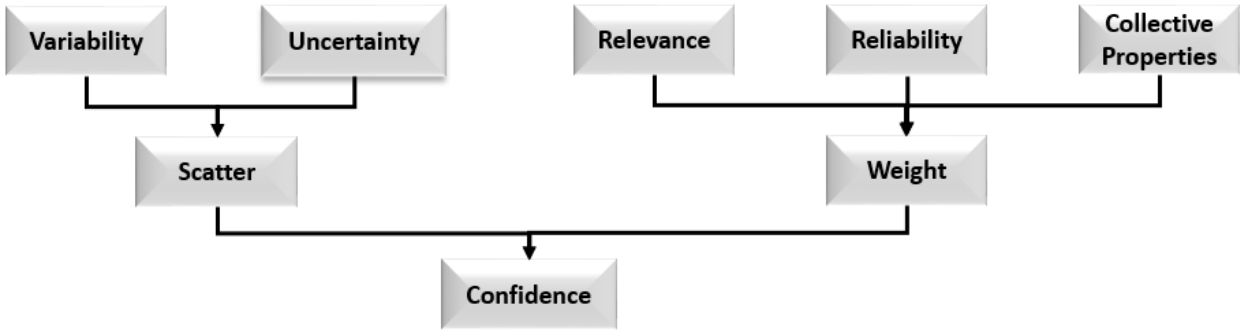

Figure 9-1. A diagram of the combination of statistical scatter and qualitative weight to define the confidence that should be afforded an assessment result.

[2] This discussion assumes an objectivist view that conceives uncertainty and variability as probabilities based on frequencies, which are distinct from qualitative judgments of weight. A subjectivist would consider all components of Figure 9-1 to be encompassed by degree of belief, and all components could be expressed as subjective probabilities.

The pieces and types of evidence that are not used to derive the numerical result could still provide information concerning the result. For example, another piece of evidence might place a limit on the possible range of effects and that information can be used to truncate the confidence limit on the estimated effect. Other evidence might inform the scope of a result. For example, a field-based benchmark value for a contaminant in streams might be based on benthic invertebrates because they provide the best data. Fish survey data that are not sufficient to derive a benchmark, however, might be sufficient to conclude that the invertebrate-based benchmark is likely also protective of the fish assemblage.

Conceivably, assessors could address the uncertainty concerning the confidence expressed by the WoE. No methods have been found for estimating or describing such meta-uncertainties. An estimate of WoE uncertainty, however, can be obtained by replicating the assessment. That is, multiple assessment teams could be engaged to assemble, weight, and weigh the evidence so that the variance among WoE results might be estimated. That implies an extraordinary effort for a routine assessment, but replication of a WoE for a condition assessment has been done experimentally (Bay et al., 2007). Six experts were provided conventional sediment quality triad data for 25 embayment sites in California. They were asked to rank the sites from best to worst and to categorize them into one of six standard categories. No instructions were provided, so the participants apparently used whatever WoE method they used in their professional practice. The rankings were highly correlated (mean Spearman rank correlation = 0.92). Differences in categorization of a site were common but mostly small and were primarily due to differences in relative weighting of the three types of evidence, so common weighting guidelines might have reduced discrepancies.

A sensitivity analysis would be more practical than replicating the assessment as a means of determining the variability in the weighting process. That is, assessors could determine the influence of changing the weights on WoE results. If the choice between alternative hypotheses could change when, for example, the reliability of a piece of evidence was scored as + rather than ++, that sensitivity would be noted. Such cases would tend to occur when few pieces of evidence are considered, when the overall weight for a body of evidence is marginal, or the bodies of evidence for alternative hypotheses have similar weights.

10. WEIGHT-OF-EVIDENCE SUMMARY AND THE PATH FORWARD

The basic framework of assembling evidence, weighting it, and weighing the body of evidence is fundamental to making inferences based on WoE (Figure 10-1). Even if a WoE is not explicitly performed using these steps, assessors should at least consider each of these processes. Adhering to an explicit framework can improve the WoE results, enhance transparency, and increase the confidence of reviewers, stakeholders, and decision makers.

The steps to implement the framework for qualitative WoE, with section numbers, include:

- Finding information (4.2.1),
- Design and conduct studies to fill information gaps (4.3)
- Screening studies (4.2.2),
- Categorizing studies (4.2.3),
- Deriving evidence from the data (4.2.4),
- Evaluating the evidence with respect to properties (5.3),
- Assigning weight scores based on the evaluation (5.3),
- Creating a scoring table to summarize the results of evidence weighting (5.4),
- Integrating the weighted evidence into bodies of evidence for each hypothesis (6.2),
- Creating a WoE table to summarize the results of evidence integration (6.2),
- Interpreting the bodies of evidence (6.3),
- Explaining ambiguities and discrepancies (6.4),
- Reiterating the process if necessary (6.4), and
- Presenting results (6.5).

In addition to the approach for applying WoE to qualities such as causality and impairment, this document briefly addresses WoE for quantities and how WoE for qualities and quantities are related (Section 8). Although WoE for quantities such as benchmark or parameter values is uncommon now, it seems likely that the use of meta-analysis and other techniques for weighting and combining quantities will gain increasing use. A combined approach to WoE for qualities and quantities is likely advantageous.

Similarly, this document briefly discusses the relationship between uncertainty and WoE (Section 9). By combining the somewhat narrow concept of uncertainty (i.e., measures of the scatter of data or of estimates) with the broader concept that some evidence and conclusions deserve more weight, it should be possible to improve the communication of confidence in assessment results.

The WoE approach in this document is based on experience in the EPA, particularly with determining the causes of impairment in ecosystems (http://www3.epa.gov/caddis/). Its application in practice will vary among programs due to differences in issues, policies, prior practices, and the amount and variety of evidence potentially available for weighing. As implementation of this approach progresses, context-specific guidance is expected to be developed in the form of exemplary applications of WoE or program-specific WoE guidance documents.

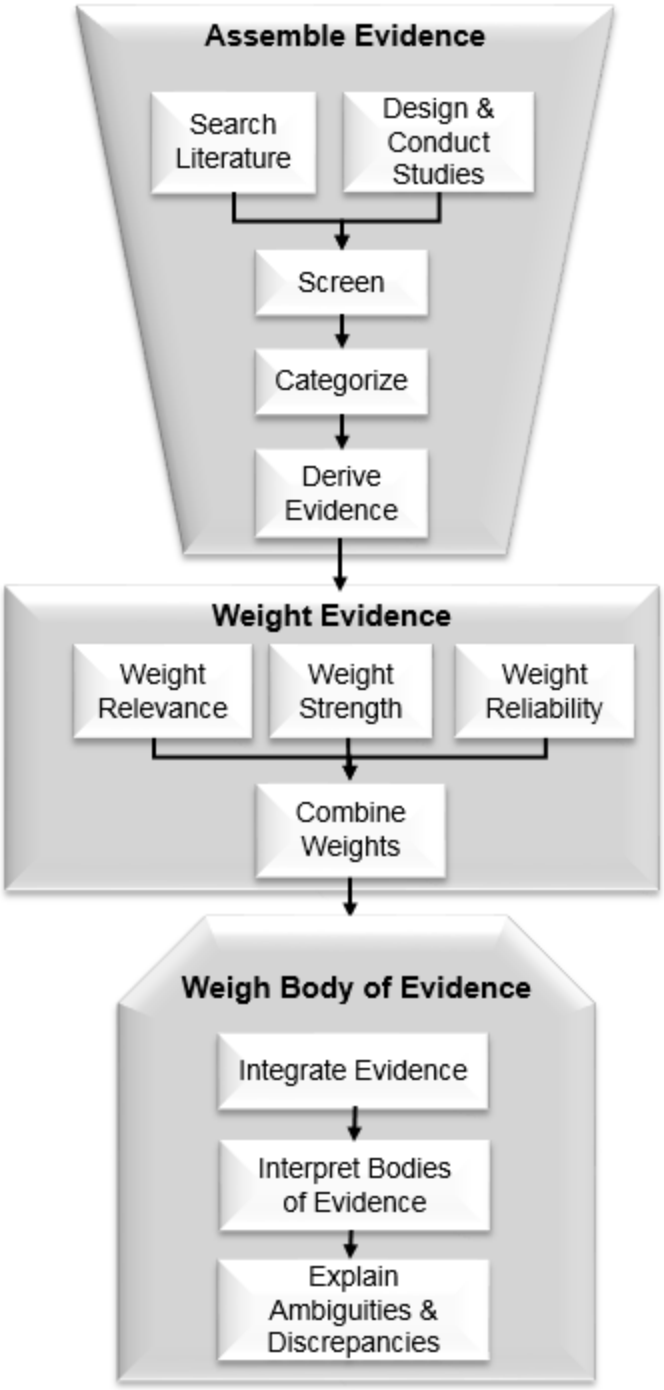

Figure 10-1. The detailed framework for qualitative WoE.

In summary, this document is intended to help ecological assessors improve the practice of WoE without imposing burdensome prescriptions. If read and applied in that spirit, this document should help advance the cause of well-informed environmental protection.

APPENDIX A. GLOSSARY OF WEIGHT-OF-EVIDENCE TERMS

The following terms are defined as used in this document. The U.S. Environmental Protection Agency (EPA) might use these terms differently in other contexts.

Alteration: (1) A characteristic of causal relationships; it specifies that the affected entity is changed by physical, chemical, or other mechanisms leading to the defined effect. (2) A change in an entity that is consistent with interaction with a cause.

Ambiguous: Evidence that has no clear meaning or more than one possible meaning. Evidence may be ambiguous because it is weak (e.g., shows no clear relationships) or unreliable (e.g., reference sites may have important extraneous differences from exposed sites).

Antecedence: A characteristic of causal relationships; it specifies that the causal interaction is itself connected to processes that precede it, potentially leading back to a source.

Assessment, environmental: (1) A process of generating and presenting scientific information to inform an environmental regulatory or management decision. (2) The product of an environmental assessment process.

Benchmark: A criterion, standard, screening value, effect threshold, or other value used to differentiate potential exposure levels that are of concern from levels that are not of concern.

Case: (1) The situation that is the subject of an environmental assessment; for example, the case may be a water body experiencing an algal bloom, a hazardous waste site or a proposed pesticide use. (2) The weighted body of evidence for an assessment hypothesis; for example, "the lack of co-occurrence weakens the case for fine sediments as the cause."

Characteristics: Properties that define a quality of interest and that could be supported by evidence. For example, when weighing evidence for causation, evidence is sought to support six characteristics of causal relationships (Table E-1).

Coherence: The property of a body of evidence that its constituent pieces are logically linked together, thus, forming a reasonable explanation.

Confidence: The credence given a conclusion. For quantitative results, confidence is determined by the scatter of estimates as well as the weight of the evidence.

Considerations: Sets of heterogeneous aspects of causation or other qualitative hypotheses that are used to structure narrative weight of evidence (WoE). They are derived from or analogous to Hill's considerations (Hill, 1965).

Co-occurrence: (1) A characteristic of causal relationships; it specifies that the cause and effect are collocated in space and time at a scale appropriate to the cause and effect. (2) An instance of collocation in space and time.

Correspondence: The similarity of a piece or type of evidence to the entity or conditions to which the evidence will be applied. Evidence is relevant if it corresponds well to all aspects of the case (biological, physical/chemical, and environmental conditions).

Corroboration: Supporting evidence for an assessment proposition from one or more independent studies providing similar results.

Data: Unanalyzed results of measurements, counts, or observations used as a basis for reasoning or calculation.

Discrepant: Evidence that is inconsistent or contrary to established facts or theory.

Endpoint, assessment: An explicit expression of the environmental values to be protected, operationally defined as an ecological entity and its attributes.

Evaluation: The determination of how much influence a piece or category of evidence should be assigned. Evaluation plus the scoring of its results constitutes the weighting of evidence.

Evidence: Information that informs inferences regarding a condition, cause, prediction, or outcome.

Evidence, body of: All the applicable evidence used to make inferences concerning a proposition.

Evidence, category of: A grouping of evidence for consistency and to facilitate weighting. In WoE for environmental assessments, evidence is categorized in terms of conventional *types of evidence*, or in terms of characteristics that the evidence supports.

Evidence, line of: (1) A complex piece of evidence including multiple causal or logical steps that establishes a line of reasoning. (2) A general term used to refer to a piece or type of evidence—this use is discouraged to reduce ambiguous terminology.

Evidence, piece of: The basic unit of evidence; examples include the results of a toxicity test or a stream survey.

Evidence, type of: A category of evidence that is based on a distinct form of study. Conventional types include biological surveys, biomarkers, ambient media toxicity tests, single-substance toxicity tests, population and ecosystem models, and quantitative structure-activity relationships.

Explanation: The process of translating pieces or types of evidence into a characteristic of causation or some other attribute that is relevant to a hypothesis. It is part of evidence integration in the weighing of the body of evidence step.

Hazard: The potentially adverse properties of an agent that, with potential exposure of a receptor, imparts a risk. Hazards are identified by a general causal assessment, such as an Integrated Science Assessment, that typically employs a qualitative WoE.

Hypothesis: A proposition proposed to be a potential explanation of a phenomenon (the fish kill may be caused by high temperatures) or a potential outcome of a phenomenon (building more rooftops and parking areas will interfere with groundwater recharge).

Inference: (1) The act of reasoning from evidence. (2) A result of such reasoning.

Information: Data or other facts used to derive evidence.

Integration: The first step in the weighing of the body of evidence in which the pieces or categories of evidence are combined to characterize the body of evidence.

Interaction: (1) A characteristic of causal relationships; it specifies that a causal agent impinges upon, enters, binds to, or initiates a response in a susceptible entity in a way that can lead to the effect of concern. (2) An instance of interaction of a causal agent on a susceptible entity that can lead to an effect.

Interpretation: The second step in the weighing of the body of evidence in which the body of evidence for each hypothesis is compared to other hypotheses or judged against a standard to determine what conclusion is best supported by the weight of evidence.

Property: A feature of evidence that determines how much weight it should be assigned. In this document, the major properties are relevance, strength, and reliability.

Property, collective: A feature of bodies of evidence that, along with the properties of the constituent pieces of evidence, determines how much weight a body of evidence should be assigned. In this document, the collective properties are number, coherence, diversity, and absence of bias.

Proposition: A condition, cause, prediction, or outcome hypothesized as a possible outcome of an assessment.

Qualitative WoE: Weight of evidence to infer a quality such as causation or impairment.

Quality of interest: A distinctive attribute of an entity, relationship, or system that should be determined to exist or not for a hypothesis in an assessment.

Quantitative WoE: Weight of evidence to estimate a quantity such as a benchmark value or a biodegredation rate.

Reasonable explanation: (1) A statement or account that coherently explains a body of evidence. (2) Informed reasons for apparent inconsistencies in a body of evidence that provide coherence.

Refutation: The logical process of demonstrating the impossibility of a condition, cause, predicted effect, or outcome.

Relevance: A property of a piece or type of evidence that expresses the degree of correspondence between the evidence and the assessment endpoint to which it is applied.

Reliability: A property of evidence determined by the degree to which it has quality or other attributes that inspire confidence**.**

Risk: The likelihood of adverse effects associated with exposure to a stressor.

Scatter: The distribution of measured or estimated values due to uncertainty, variability, or both.

Scoring: The process of formalizing the evaluation of evidence by assigning a numeral, term, or symbol. Evaluation plus scoring constitutes weighting of evidence.

Strength: A property of evidence determined by the degree of differentiation from randomness or from control, background, or reference conditions.

Sufficiency: (1) A characteristic of a causal relationship; it specifies that the causal agent or event must be adequate to induce the effect in susceptible entities. (2) An occurrence of enough of an agent or process to affect a susceptible entity.

Table, scoring: A table created in the weighting step that presents the pieces or categories of evidence and their scores with respect to relevant properties.

Table, weight of evidence: A table created in the weighing step that summarizes the bodies of evidence and their weights for one or more hypotheses.

Time order: (1) A characteristic of a causal relationship; it specifies that the cause precedes the effect. (2) The sequence, in time, of the occurrence of a candidate cause and the effect of concern. It is sometimes called temporality or temporal sequence.

Uncertainty: Lack of knowledge concerning the state of an organism or system or concerning the true value of a quantity. Uncertainty is a property of the investigator and, unlike variability, may be reduced by measurement or observation.

Variability: Heterogeneity over time, space or members of a population. Variability is a property of nature and may not be reduced by measurement or observation.

Weigh: Consider the relevance, strength, and reliability of the body of evidence to assess the likelihood of a hypothesis.

Weight: (noun) The importance to an inference of a piece or category of evidence. (verb) To assign an importance descriptor or score to a piece or category of evidence.

Weight of evidence: (1) A process of making inferences from multiple pieces of evidence, adapted from the legal metaphor of the scales of justice. (2) The relative degree of support for a conclusion provided by evidence. The result of weighing the body of evidence.

APPENDIX B. WEIGHT-OF-EVIDENCE METHODS FOR QUANTITATIVE RESULTS

Assessors are often confronted with multiple estimates of a quantitative value such as the median lethal concentration (LC_{50}) for a fish species, the half-life of a chemical in surface water, or the pH at which species richness is reduced in streams. A single estimate might be derived from multiple estimates, by weighing evidence to identify the best estimate or by using statistical techniques from meta-analysis to combine estimates (Borenstein et al., 2009; Hunter and Schmidt, 2004).

A simple method for combining values is selection of the single best (i.e., weightiest) estimate. This approach is commonly used because often one quantitative estimate is clearly superior to all others, so averaging would diminish accuracy. This approach also might be necessitated by statistical considerations, if the values cannot be combined because they do not represent independent samples from a common population of estimates (Borenstein et al., 2009). When this approach is used, a good practice is to identify in advance the properties of good estimates. Various procedures and criteria can be applied to various study properties when weighting to identify the best value (see Section 5). For example, LC_{50} values might be screened using reliability properties such as use of good laboratory practices and then the most relevant value could be chosen (e.g., the test performed in water most similar to water at the assessment site).

A common method in meta-analysis is averaging of multiple estimates. The geometric mean is often used because many environmental data sets are asymmetrical. Although weighting studies before averaging them is not common in environmental assessments, weighted averages are conventional in meta-analysis. The most common statistical model for weighting is the fixed-effects model, which weights by the inverse of the error variance (Borenstein et al., 2009). The term fixed effects is used because it implies that the estimates are all based on sampling a common variable from a common population with a set effects level (i.e., the only significant source of differences among the estimates being combined is sampling error). It has the advantage of giving more weight to larger studies and of normalizing the variance. If this assumption does not hold, a random effects model or the IVhet model can be employed (Borenstein et al., 2009).

Weighting also might be based on properties of the individual members of a higher-level entity that is being assessed. For example, in an assessment of ozone effects on forest production, estimates of reduction in timber production of individual tree species were weighted by the proportional basal trunk area before they were averaged to estimate loss of forest production (U.S. EPA, 2014b). Because of weighting, the average represented the loss of forest production and not just the averages of production losses for individuals of each species.

Although weighting in meta-analysis is usually based on statistical properties, weights based on qualitative properties also can be used (Turner et al., 2009). This approach is appropriate when studies vary significantly in terms of relevance or reliability relative to sampling variance or variance among the studied systems. For example, chronic toxicity test endpoints, even for the same species, often differ in the endpoint response, so statistical weighting would not capture the most critical differences among chronic test data. A statistical model has been developed that incorporates data quality or any other qualitative scale (Doi and Thalib, 2008). Statistical weighting models depend on variance estimates, which are not available for many environmental values such as conventional toxicity test endpoints. In those cases, weights can be assigned using improvised methods. Weighting for study quality has been common in meta-analysis, but it may introduce bias if not done appropriately (Turner et al., 2009; Greenland and O'Rourke, 2001).

Multiple quantitative estimates also can be used in regression analyses such as derivation of exposure-response relationships from multiple tests. As in averaging, the values are commonly weighted by the inverse of their error variance.

Quantitative results also can be combined into distributions. A common use is derivation of a value in environmental assessments from species sensitivity distributions (SSDs). SSDs are statistical distribution functions that, conventionally, are fit to the results of chemical toxicity tests and are generally interpreted as representing the distribution of sensitivity of species in communities. They are used to derive an exposure level that would be protective of a defined proportion of species or genera in communities or to estimate the proportion of species or genera that a defined exposure level would affect. The derivation of SSDs illustrates the issues involved in quantitative weighting of evidence (Box B-1).

Finally, rather than combining estimates, data sets from multiple studies have been combined to perform a statistical test or analysis. Some investigators combine data sets from multiple small studies with statistically insignificant results to obtain a data set large enough for the differences among treatments to be statistically significant. This practice is *not* recommended because it violates the premise of hypothesis testing that the likelihood of a data set given a null hypothesis is being determined. It is a form of *P*-hacking, which is the selection of data sets, tests, or hypotheses to achieve statistical significance. Alternatively, data sets can be combined to obtain a potentially better estimate of a mean and confidence interval than simply taking the mean of means. Also, multiple sets of exposure-response data might be combined to obtain a more accurate regression model of the relationship. As with averaging estimates, analyzing combined data sets requires attention to the statistical properties of the data.

Choosing the best estimate poses fewer technical issues than combining estimates. Combining estimates or data sets to generate an estimate introduces complications in computation and interpretation due to heterogeneity. In contrast, in a well-designed individual study, what the data and the summary statistics derived from the data represent is known. Different data sets representing the same relationship but generated at different times in different places or at different scales also might be so different due to ecological complexity and variability that they cannot or should not be combined. Further, if the studies to be combined have greatly different sample sizes and variance structures, statistically combining them might give counterintuitive results. At worst, studies that all indicate one relationship (e.g., declining species richness with increasing exposure) might give the opposite result when combined (i.e., increasing species richness with increasing exposure), a phenomenon known as Simpson's paradox (Blyth, 1972). Finally, the set of studies may be biased, particularly by the bias against publishing studies that show no effects. Thus, care should be taken when combining multiple estimates or data sets.

Despite these warnings, the benefits of combining estimates or data sets can be substantial. The combined estimate might be more accurate, particularly when sampling error is important. Inconsistencies among studies can be quantified and their sources can be analyzed. The influence on results of methodological or environmental differences among studies can be quantified. Further, some cases of combining estimates, such as averaging multiple toxicity test results for the same species following a standard protocol with moderate water chemistries, are unlikely to go astray.

Qualitative WoE may be used to derive quantitative results without combining or choosing among estimates. An example is the Rule of Five (Box B-2).

Box B-1. Combining and Weighting Data in Species Sensitivity Distributions

The combining and weighting of data in SSDs has two components. First, to derive the points in the distribution, the results of multiple tests of a species or of closely related species are combined. When deriving the species mean acute value (SMAV) for national ambient water quality criteria, multiple LC_{50}s are combined by taking the geometric mean and assigning that mean value to the species (U.S. EPA, 1985).

$$SMAV = \exp [(\sum \log LC_{50})/n]$$

The genus geometric mean value (i.e., the genus mean acute value or GMAV) is used when multiple congeneric species have been tested.

$$GMAV = \exp [(\sum \log SMAV)/n]$$

Weighting is not part of the currently accepted method for combining test results into either the species or genus means and its implications have not been investigated. However, one might weight the test results (e.g., LC_{50}s) before averaging, based on the variance, number of organisms tested, number of concentrations with partial response or some other property.

$$SMAV = \exp [(\sum(w_t \log LC_{50}))/\sum w_t]$$

Also, one might weight the species mean values before calculating the genus means based on the number of tests of each species or some other property.

$$GMAV = \exp [(\sum w_s \log SMAV)/\sum w_s]$$

(Note: Subscripts *t* and *s* indicate weights [w] for tests and species, respectively.)

Second, weighting might be involved in deriving the SSD from the species or genus mean values. If the SSD is intended to represent aquatic communities, a problem can occur with over- or under-representing particular taxa or functional groups, which might be resolved by weighting the data to achieve proportional representation (Duboudin et al., 2004; Forbes and Calow, 2002; Suter et al., 2002). This situation would require some difficult decisions. Should the weighting be based on the number of species in a higher taxon, a trophic group, or other grouping; on the relative abundance or biomass or on some measure of importance? Invertebrates would be weighted more than vertebrates for species richness, abundance, or biomass and perhaps much less for importance (depending on the measure of importance). Also, the assumption that the weighting should be based on particular categories [e.g., algae, invertebrates, and fish (Duboudin et al., 2004; Forbes and Calow, 2002)] presupposes low variance in sensitivities within those categories relative to between categories. That assumption is questionable given the large taxonomic differences within categories (e.g., cyanobacterial versus eukaryotic algae and arthropods versus mollusks, rotifers, and other invertebrates), which result in large differences in sensitivity. The communities represented by an SSD also would influence the weights. For example, stream invertebrates are predominantly benthic insects, but planktonic crustaceans and rotifers are important in lakes. Clearly, research would be required before introducing a weighting scheme for SSDs.

The derivation of weighted SSDs has been demonstrated by Semenzin et al. (2015); OECD (2013); U.S. EPA (2013). They weighted species and derived the SSD by weighted bootstrapping.

Box B-2. Cleanup Goals by Weight of Evidence Using the Rule of Five

Superfund cleanup goals for ecological risks are concentrations of contaminants that are higher than the no--observed-adverse-effect level (NOAEL) and lower than the lowest-observed-adverse-effect level (LOAEL). Because the interval between these values could be large (i.e., greater than a factor of 10) and because the measures of effect that define the bounds are not consistent, the common practice of interpolating by taking the geometric mean is often inadequate. Instead, a technique called the Rule of Five is used (Greenberg and Charters, 2007; Charters and Greenberg, 2004). The NOAEL-LOAEL interval is divided into six geometrically scaled intervals delimited by seven nodes. The node chosen as the cleanup goal depends on characteristics of the NOAEL and LOAEL, including their relevance to the assessment endpoint and their severity (e.g., Is the LOAEL defined by acute lethality or chronic reproductive effects?). The choice of node also can be influenced by measures of effects other than the LOAEL and NOAEL and by qualitative evidence concerning ecological exposure and effects on the site. The weighing of evidence to choose a node can be, at least in part, rule based. For example, a LOAEL based on mortality would move the choice one node below the middle node. The WoE also uses expert judgment. An example of applying the Rule of Five is in the Baseline Ecological Risk Assessment for the Estuary at the LCP Chemical Site in Brunswick, Georgia.

Another example of using qualitative methods to weigh evidence for quantities is the selection of surrogate values. When there are no data for a property of a chemical, the best estimate of the property may be derived from the best surrogate chemical for which the property is known. This approach, termed "read across," can be based on weighing multiple attributes of the chemicals including structure, physical/chemical properties (e.g., melting point, octanol/water partitioning coefficient) or biological properties [e.g., enzymes induced (ECHA, 2015; Wang et al., 2012)].

APPENDIX C. WEIGHT-OF-EVIDENCE METHODS FOR DERIVING A MODEL

Weight of evidence (WoE) can play three roles in the derivation of mathematical models. First, the selection of a model from a set of alternatives can be based on WoE, where WoE refers to the relative weight provided to a model by the evidence (i.e., the available data). Good (1950) defined the WoE for members of a set of alternative models as their relative likelihoods, given a data set. Models can be compared using the sum of squares or other simple goodness-of-fit statistic, Bayes's factor or Akaike's information criterion (Anderson, 2008; Hilborn and Mangel, 1997). If the models represent alternative causal hypotheses, choice of the model that best explains the data can be said to have chosen the best causal explanation of the modeled effect (Newman and Clements, 2008). This use of the term WoE is distinct from the others in this document. Rather than weighting and weighing multiple pieces or types of evidence, Good's followers weigh the alternative models against each other with respect to a common data set. That approach is included here for completeness because it has appeared in the ecological assessment literature (Linkov et al., 2009; Smith et al., 2002). Rhomberg (2015) described using relative likelihoods for selecting among human toxicological hazards. He admits, however, that it is difficult to calculate likelihoods of models of toxicological hazards, and in practice, he uses qualitative WoE.

Bayesian model averaging extends this concept to provide a more recognizable example of weighing evidence to derive a model (U.S. EPA, 2009b). That is, rather than choosing a single best model, one might combine suitable models after weighting them based on their weights in Good's sense (i.e., their consistency with the data).

A more conventional use of the concept of WoE is the weighing of evidence concerning model assumptions. For example, to determine whether certain phenomena should be included in a model, one might assemble, weight, and weigh evidence concerning their occurrence. Such phenomena might include compensatory processes in a fish population, dietary toxicity in aquatic invertebrates exposed to an aqueous contaminant, nonlinearities in exposure-response relationships, or avoidance behavior at subtoxic exposures. The methods for weighing evidence for these model assumptions would be the same as for other qualitative conclusions. For example, Hertzberg and Teuschler (2002) developed a numerical index to weigh three properties of evidence for alternative models of mixtures toxicity.

Finally, model selection can be based on weighing a mixture of statistical and biological considerations. The benchmark dose guidance recommends choosing a dose-response model based on both biological plausibility and Akaike's information criterion (U.S. EPA, 2012a). A Science Advisory Board panel has recommended broadening the statistical and nonstatistical considerations to be weighed during model selection and using a more formal and transparent weighing process (SAB, 2015). For example, for dose-response modeling, they recommended prioritizing regression models that directly use exposure data for individuals.

Because any causal hypothesis, in theory, can be represented by a mathematical model, uses of WoE for model selection could be equivalent to the approaches for deriving qualitative conclusions presented in Sections 3−7.

APPENDIX D. WEIGHT-OF-EVIDENCE APPROACHES FOR QUALITATIVE CONCLUSIONS

This appendix summarizes the diversity of weight-of-evidence (WoE) approaches that have been used in assessments to answer questions concerning environmental qualities. Each approach has been useful in some cases, and they were carefully considered during the development of the approach presented in this document.

D.1. Narrative Weight of Evidence

Traditional narrative literature reviews and the assessments that adopt their approach describe a body of evidence and reach a conclusion by methods and criteria that are not explicit. The expertise of the reviewer is assumed sufficient to ensure a correct conclusion. The WoE is the conclusion that the author reaches through reading the literature and presents to the reader by logically structuring the review's narrative. This is a common approach for weighing evidence in environmental assessments. Narrative WoE is highly flexible, but the method by which results are obtained is not as transparent or reproducible as for other methods.

D.2. Consideration-Guided Narrative Weight of Evidence

WoE narratives can be given greater structure and logical consistency by organizing the narrative in terms of a set of considerations. For example, the U.S. Environmental Protection Agency's (EPA's) Integrated Risk Information System and Integrated Science Assessment documents use modifications of Hill's considerations when weighing evidence of general causation. Also, the WoE method for Tier 1 screening of potentially endocrine-disrupting chemicals provides five considerations (U.S. EPA, 2012b), and the chemical risk assessments conducted pursuant to the Toxic Substances Control Act use seven considerations (U.S. EPA, 2015b). However, these WoE methods depend on narratives and have not explicitly weighted or tabulated the evidence for the considerations. Also, the considerations are mixtures of various types of issues to consider, not consistent sets of criteria, properties, types of evidence, or characteristics. This method is an advance over unstructured narratives and is generally accepted.

D.3. Evidence Summary and Scoring Tables

Methodological rigor and transparency can be increased by creating summary tables for the evidence concerning an inference and assigning scores. For example, a set of summary and scoring tables was developed at ORNL for contaminated site assessments (Suter et al., 2000). The authors included tables for summarizing the methods and results for each type of evidence: biological surveys, bioindicators, ambient toxicity tests, tissue analyses, and single-chemical toxicity. Another table combined the results of the types of evidence (a score and associated explanation) and presented a score for the body of evidence for an endpoint.

D.4. Criteria-Guided Scoring

Criteria for weighting evidence have been combined with evidence scoring tables in the *Stressor Identification Guidance Document* and Causal Analysis/Diagnosis Decision Information System (CADDIS) to determine the causes of specific environmental impairments (http://www3.epa.gov/caddis/). Several examples of the application of this approach can be found in the CADDIS case studies. Pieces or types of evidence were scored based on Susser's method (U.S. EPA, 2000; Susser, 1986), but scoring types of evidence has been supplemented by scoring characteristics of causation to explain the relationship of the evidence to the hypotheses (Norton et al., 2014; Cormier et al., 2010). This approach

also has been applied to a risk assessment. The Bristol Bay watershed assessment used tables of evidence and scores to clarify the WoE for risks to salmon from spills of tailings, product concentrate and diesel fuel (U.S. EPA, 2014a). Pieces of evidence were described and scored for logical implication (relevance), strength, and quality (reliability), and summary scores were derived for the bodies of evidence. A version of criteria-guided scoring is presented in this document that generalizes the approach beyond causal assessment.

D.5. Standardized Scoring and Weighting

Consistency can be increased by specifying the evidence and criteria to be considered and the scores and weights to be assigned to the possible outcomes for each type of evidence. An example is provided by the Massachusetts weight-of-evidence method for assessing ecological risks at contaminated sites (Menzie et al., 1996). The method numerically scores evidence (termed measurement endpoints) on a scale of 1 to 5 for 10 properties, weights the scores by scaling values based on the importance of the properties, normalizes the scaled scores, and sums the result to give a "measurement endpoint weight." The body of evidence is then qualitatively weighed based on concurrence of the numerical weights. The standardization of scores and weights requires consistency of the cases to which the method is applied and is facilitated by consensus of all parties.

D.6. Indices

Standardized numerical scoring and weighting of evidence has been extended to the calculation of rather complex risk indices (Benedetti et al., 2012; Dagnino et al., 2008; Semenzin et al., 2008; Bombardier and Blaise, 2000). These indices are not quantitative risk estimates, but they often contain component calculations that are part of quantitative risk assessments such as sums of toxic units, so that the index values provide estimates "of relative hazard for the sites being investigated" (Bombardier and Bermingham, 1999). Because the indices often combine evidence across pieces, types, and endpoints, many of them are computationally complex and require support systems for data entry and computations (Semenzin et al., 2009).

Indices are also used to combine multiple metrics from biological survey data into a value that can be said to represent biological integrity (Karr et al., 1986) or deviation from reference condition (Hawkins, 2006). These indices are arithmetic combinations of metrics believed to discriminate impaired and unimpaired waters. Their derivation is not normally considered to constitute a weight-of-evidence process, but they do combine multiple pieces of evidence to determine a quality—the impairment of a biotic community.

Indices are specialized and their results are difficult to relate to the input data. For example, an index of biotic integrity serves its purpose of identifying impaired waters by numerically aggregating numerous incommensurable biological metrics. To assess the cause of the impairment or risks from remedial actions, however, the individual metrics should be extracted, weighted, and weighed appropriately, as described in Sections 4–6.

D.7. Rule Based

If the potential evidence results are few and all the results are reliable, specifying an interpretation of each potential body of evidence can be possible. The decision matrix for the sediment quality triad is a commonly used example of this approach to weighing evidence [Table D-1 (Chapman, 1990)]. The triad is used to determine whether toxic contaminants are impairing a sediment community. Its elements are chemical analyses of sediments that are compared to toxicological benchmark values, toxicity tests of the sediment and surveys of the sediment biotic community. If the scores for the triad elements are, for example, −, +, +, "unmeasured toxic chemicals are causing degradation," but if it is −, −, +, "alteration is

not due to toxic chemicals." The logic of Chapman's decision matrix is correct if the evidence is reliable, but the evidence might not be sufficiently reliable to support it for many reasons (Table D-2). As a result, weighting and interpreting the evidence often is required. Thus, the standard decision matrix is an idealization that serves primarily to clarify the potential relationships among types of evidence. More recently, ambiguities in results have been recognized and new decision matrices have been developed for sediment assessments that specify a decision for only a few of the possible outcomes; for the other outcomes that include conflicting results, they direct assessors to perform additional analyses (COA Sediment Task Group, 2008; Grapentine et al., 2002). Those additional analyses could use any of the other qualitative WoE methods.

Table D-1. Inference based on the sediment quality triad (Chapman, 1990)

Situation	Chemicals Present	Toxicity	Community Alteration	Possible Conclusions
1	+	+	+	Strong evidence for pollution-induced degradation
2	−	−	−	Strong evidence for no pollution-induced degradation
3	+	−	−	Contaminants are not bioavailable, or are present at nontoxic levels.
4	−	+	−	Unmeasured chemicals or conditions exist with the potential to cause degradation.
5	−	−	+	Alteration is not due to toxic chemicals.
6	+	+	−	Toxic chemicals are stressing the system but are not sufficient to significantly modify the community.
7	−	+	+	Unmeasured toxic chemicals are causing degradation.
8	+	−	+	Chemicals are not bioavailable or alteration is not due to toxic chemicals.

Responses are shown as either positive (+) or negative (−) indicating whether measurable and potentially significant differences from control/reference conditions are determined.

Table D-2. Some ways in which the triad decision table might fail (not including errors or poor technique)

Type of Evidence	False Positive (Exaggerated Effect)	False Negative (Minimized Effect)
Single-chemical analyses/ toxicity tests	Higher bioavailability in the laboratory Site background is high Overly sensitive test organisms (sensitive test species or life stages not present at the site)	Short duration Insensitive test species or life stages Critical response not included Multiple chemicals interact Incomplete routes of exposure
Whole-medium samples/ toxicity tests	Bioavailability increased by handling Sampling below bioactive zone Overly sensitive test organisms Inappropriate reference sites	Chemical lost or altered by handling Insensitive test organisms Inappropriate reference sites Insensitive test organisms Ambient conditions (e.g., UV light) are important to effects Critical response not included Contaminated locations or times missed
Sampling locations/ biological surveys	Confounding Inappropriate reference sites	Organisms too rare Response too infrequent Sensitive organisms not sampled Critical response not included Large sample scale Contaminated locations missed Inappropriate reference sites

Another rule for weighing evidence is independent applicability. The Office of Water classifies a water body as impaired if an adequate piece of evidence demonstrates an impairment, even if other evidence did not detect the impairment. This policy takes into consideration the possibility of false negatives and that different types of evidence detect different types of impairment (Box D-1).

A two-stage rule was developed by the European Center for Ecotoxicology and Toxicology of Chemicals for weighing human and animal data in chemical risk assessments (ECETOC, 2009). The category of evidence with the highest quality for a chemical is used, but if the quality of animal and human evidence is similar, an effect is assumed to be caused by the chemical if either category of evidence shows the effect. This logic could be applied to more than two categories of evidence if equivalent quality scales could be developed for all categories.

D.8. Quantitative Alternatives

Some authors have suggested that quantitative methods are inherently superior for making qualitative inferences from multiple pieces of evidence (Linkov et al., 2009). In particular, multi-criteria decision analysis (MCDA) and Bayesian belief networks (BBNs) have been suggested to be alternatives to conventional WoE (Linkov et al., 2015; Fenton and Neil, 2013).

Box D-1. Independent Applicability and Weight of Evidence

Independent applicability of evidence of impairment has been a policy of the EPA Office of Water. That is, if a water body fails to meet water quality criteria, is toxic, or is biologically impaired, it is an impaired water body. Independent applicability can result from two possible logics.

1. All types of evidence are fallible, so any evidence can generate false negative results. Rather than weigh evidence of impairment against evidence that failed to detect impairment, the evidence of impairment is accepted. Therefore, if any type of reliable evidence detects impairment, the water body is considered impaired. This logic is defensible if the consequences of not detecting an impaired ecosystem are more serious than the consequences of failing to detect. This justification is policy based. In addition, the logic can be defended by recognizing that poor methods or poor implementation are inherently more likely to fail to detect an effect than to detect a false effect. This justification is based on the fact that poor practices introduce extraneous variance are not spatially comprehensive and otherwise tend to obscure effects. Further, it is unlikely that a type of evidence will test or measure the most sensitive conditions, taxa, life stages, responses and interactions between species and stressors. Therefore, even good studies are likely to miss real effects. This does not imply that false positives never occur (see Table D-1), but rather, poor evidence is more likely to result in false negatives and unprotective decisions.

2. Each type of evidence addresses a distinct aspect of impairment. If any one aspect is found in a water body, the water body is impaired in that way. This assumption involves no synthesis. Each type of evidence is independently evaluated with respect to its aspect of impairment. This is explicitly the case with the European Union's Water Framework Directive that distinguishes good chemical status from good ecological and good hydrological statuses (van der Ohe et al., 2014; EC, 2013). European waters should achieve all three. Equivalently, the policy of independent applicability can be interpreted as a requirement to protect three types of integrity: chemical, toxicological, and ecological. This approach is supported by the inherent differences in the types of evidence. For example, a biocriterion based on the index of biotic integrity discriminates sites on a human disturbance gradient (Blocksom and Johnson, 2009). The index responds to the multiple stressors that occur commonly on such gradients and is most responsive to those stressors that are common components of human disturbance. Many of those stressors, such as flashy flow, have no numeric criteria. On the other hand, water quality criteria are based on responses to particular chemicals or other stressors and not necessarily to common human disturbances of aquatic systems. Water quality criteria and biocriteria are criteria for different impairments.

Note that this discussion applies to integrating evidence across types. When applying independent applicability, one might weigh evidence within types. For example, multiple toxicity tests of an ambient water could be combined to determine whether the water has unacceptable toxicity. Also, once a water body is declared impaired, WoE approaches can be applied when assessing the risks associated with alternative remedial or regulatory actions.

Although WoE integrates evidence concerning some environmental quality of interest, MCDA is intended to go farther and identify the best decision, given the problem framing, decision criteria, and preferences [e.g., Which is the best option for dredge spoil disposal given costs, risks, and stakeholder preferences? (Stahl et al., 2002)]. MCDA conventionally requires that probabilities be estimated for the outcomes of a decision and that a decision maker assign utilities to attributes of the outcomes (i.e., the decision criteria) to allow calculation of the expected utility of a decision (Linkov and Moberg, 2012). Weighting is involved in conventional MCDA when combining the multiple decision criteria (cost, aquatic toxicity, public acceptance, etc.). The computational methods of MCDA, however, have been adapted for a variety of uses beyond decision making, including combining numerically weighted evidence (Linkov and Moberg, 2012). One example is weighing the evidence for adverse outcome pathways [Box 3-3, (Collier et al., 2016)]. Linkov et al. (2015) described MCDA as a suitable proxy for Bayesian analysis.

BBNs are graphical models of the uncertainties and dependencies used to calculate the probability of an outcome in a causal network (Fenton and Neil, 2013). BBNs adapted for decision analysis are termed influence diagrams (Carriger and Barron, 2011). BBNs are computationally complex and not familiar to most environmental assessors and stakeholders, but available software makes their application relatively easy. When BBNs are involved in environmental inferences, they may not have data-derived probabilities; instead expert judgment is commonly used. These networks are WoE in the sense that the probability of a variable's state can be considered as its weight and branches of the network can considered chains of evidence (Small, 2008). For example, the probabilities of fishery closure could be one weighted piece of evidence and probabilities of levels of ecological impacts might be another; these can be combined by calculating the conditional probabilities to derive levels of offshore ecosystem services impacts (Carriger and Barron, 2011). Carriger and Barron (2016) have adapted BBNs to explicitly weigh multiple types of ecological evidence. They treated the three types of evidence in the sediment quality triad as branches of a BBN, calculated probabilities that each type was indicative of effects, weighted each in terms of its importance, and then calculated an overall probability of impairment. Because this method does not use a causal network, it is no longer a BBN in the conventional sense. However, it does provide a means of computationally combining evidence rather than using qualitative logic.

Although these methods have not been used for conventional qualitative WoE tasks such as identifying causes or hazards, nothing in this document precludes using them where appropriate. An example of a relevant potential regulatory application is the use of BBNs to optimize choices of toxicity tests in European chemical regulation in place of judgment-based WoE (Jaworska et al., 2010). This case is ideal for these quantitative methods because it is a relatively simple and consistent problem with a clear decision structure. Objectively estimating constituent probabilities of, for example, a positive rat carcinogenicity test given a positive Ames assay is possible. One simply needs a sufficient database of test results.

D.9. Summarize Only

Some assessors have argued that the weighing of evidence should not determine what conclusion is best supported by the evidence (Gray, 1994). Instead, they argue that assessors should assemble, clearly summarize, and simply present the evidence to the decision maker with enough background information for them to make a decision. Although this approach takes subjective judgments concerning the integration of evidence away from assessment scientists, it confers responsibility on decision makers to interpret scientific information, which they might not be trained to do, and requires time for inferential work that they might not have.

D.10. Conclusions

This summary of WoE approaches is intended to show the range of techniques that might be used for qualitative WoE. Methods proposed or used, however, do not necessarily fit into these categories. For example, McDonald et al. (2007) translated qualitative weights to numbers that are combined algebraically and then translated into a final qualitative conclusion. This method is typical of the WoE literature, which is replete with methods developed for the individual application. The inclination to develop a new WoE method for each application might be diminished by the availability in this document of a generic WoE approach that is flexible but provides some consistency across a variety of applications.

APPENDIX E. CHARACTERISTICS OF INFERRED QUALITIES

Qualitative weight of evidence (WoE) addresses qualities, each of which is characterized by certain characteristics. For example, if the quality of interest is causation, the hypothesized relationship should have the characteristics of causation such as, the causal agent and the affected entity interact. Association of evidence with characteristics of causation, or characteristics of any other quality being addressed, can serve two purposes. First, characteristics explain what the evidence does for the hypothesis (Section 6.2). For example, aqueous concentrations of a chemical in streams can demonstrate co-occurrence but not interaction. Second, categorizing the evidence in terms of the characteristics can help to perform and justify the inference. For example, a WoE table organized in terms of causal characteristics may show that there is abundant evidence for co-occurrence but none for interaction, which would raise questions about bioavailability. Only characteristics of causation are established, but considering appropriate characteristics of other inferred qualities such as impairment or protectiveness also might be useful. Potential characteristics for five qualities are presented here.

E.1. Characteristics of Causation

In environmental assessments, WoE has been used primarily to assess causality. In fact, WoE has been equated with determining the degree of credence due a causal hypothesis (Rhomberg et al., 2013; Krimsky, 2005). WoE is particularly associated with causation because causality is a fundamental concept, and no one piece or type of evidence can prove causation (Norton et al., 2014). Rather, the relationships of evidence to characteristics of causal relationships should be considered. Six characteristics of causation, developed for ecological causal assessments, have proven useful for that purpose (Table E-1). By analogy to Hill's considerations, they have been called Cormier's causal characteristics (CCC).

Few bodies of evidence for causal assessments include evidence for all of these characteristics. Even in very well-studied cases, evidence of conditions prior to induction of the effect is seldom available to consider time order (Table 7-1). Even an incomplete WoE table based on characteristics, however, provides more insight into what is known about causation in a case than a table based only on types of evidence.

Although these characteristics were developed for causation in specific cases, they also can be relevant to general causation (i.e., Does agent *x* cause effect *y*?), if actual cases are available. The characteristics can be used to demonstrate that, at least in those actual cases, the agent could cause the effect. They can be particularly useful when the general question is framed in terms of real-world conditions. An example is the use of the characteristics to determine that, where aqueous conductivity is elevated due to major mineral ions in West Virginia and Kentucky, the ion mixture causes the extirpation of invertebrate genera (Cormier et al., 2013; Cormier and Suter, 2013; U.S. EPA, 2011b).

Although the characteristics apply to, and can be observed in actual cases, they are not observable in the same way when the general causal question is hypothetical. That is, hypothetically, can *x* cause *y* rather than, in fact, did *x* cause *y* or is *x* causing *y*? In particular, when the only evidence of effects is from toxicity tests, the co-occurrence and its antecedents are simply the design and setup of the test, and the time order is inevitable. Sufficiency in hypothetical causal assessments is not of interest because no particular effect level is identified, so no particular exposure is sufficient. Instead, we use the test data to establish an exposure-response relationship that can be applied generally. The real causal concerns are with the relevance of the co-occurrence, interaction, and alteration in the test to those in the field. Are the conditions, durations, species, and life stages in the tests relevant to the co-occurrence of interest in the

field? Are the interactions of the stressor and test organisms and the resulting alterations plausible in the field? Are others likely to be more sensitive or important?

Table E-1. Characteristics of causal relationships[a]

Causal Characteristics	Description	What Evidence of a Characteristic Shows
Time order	The cause precedes the effect.	Change in the entity after exposure to the cause and not before
Antecedence	The causal relationship is a result of a larger web of antecedent cause-and-effect relationships. Evidence includes sources and routes of transport.	Earlier events that led to the particular causal event. It demonstrates that a potential causal event is part of a network of prior causal events, which increases confidence that the potential causal event actually occurred (e.g., that it was not a result of a measurement error or hoax).
Co-occurrence	The cause co-occurs with the susceptible entity in space and time. Evidence includes contaminant concentrations in ambient media and habitat alterations.	The presence of both a causal agent and the affected entity in circumstances that create the potential for exposure
Interaction	The cause interacts with the entity in a way that can lead to the effect. Evidence includes injuries, body burdens, and biomarkers.	Signs that the entity has been exposed to the agent in such a way that changes can be initiated
Sufficiency	The intensity, frequency and duration of the cause are adequate, and the entity is sufficiently susceptible to produce the type and magnitude of the effect.	Enough of the cause and a sufficiently susceptible entity that can result in the level of the observed effect
Alteration	The entity is changed by physical, chemical, or other mechanisms leading to the defined effect. Evidence includes symptoms and related attributes of the affected entities.	Changes in the entity attributable to or at least appropriate to the cause, which can indicate that the mechanism is acting

[a] Modified from Norton et al. (2014); Cormier et al. (2010).

The characteristics of causation can be arranged in a logical sequence: *antecedent* causes lead to *co-occurrence* of the proximate cause with susceptible or affected organisms, which leads to *interaction* with the affected organisms and, if the interaction is *sufficient*, leads to *alteration* of the organisms. The characteristics also serve to prompt assessors to make full use of the evidence with respect to all characteristics of causation. For example, it is obvious that laboratory test data provide evidence concerning sufficiency, but the data also might provide evidence of alterations characteristic of organisms affected by the tested agent that might be observed in the field.

E.2. Characteristics of Protection

Criteria, standards, screening levels and other benchmarks are intended to define a limit on exposure that would be adequately protective. Protection, like causation, is a difficult concept with multiple characteristics (Table E-2). Benchmarks are usually derived using one piece or one type of evidence. WoE might be used, however, to assess the confidence provided by diverse evidence that a benchmark or a procedure for deriving benchmarks is appropriately protective. Although the U.S. Environmental Protection Agency has not explicitly used this potential application of WoE, characteristics like those Table E-2 might be useful.

Table E-2. Potential characteristics of a protective benchmark

Characteristics of Protective Benchmarks	Description
Causal relationship	The exposure-response relationship used in the derivation is likely to be causal.
Predictive model of the relationship	The model of the relationship predicts the effects of specified exposures.
Represent sensitive endpoints	Known sensitive endpoint species or other entities and responses can be represented by the relationship.
Exposure metric is relevant	The exposure metric represents the relevant exposure of the sensitive entities.
Set at an appropriately protective level	Independent data demonstrate, with sufficient confidence, a lack of effects of concern on the aquatic community and constituent taxa.
Discriminatory power	The benchmark discriminates between impaired and unimpaired communities with sufficient confidence.

E.3. Characteristics of Contaminants of Concern

Risk assessments of contaminated sites typically develop lists of contaminants of concern based on chemical analyses of site media. The contaminants of concern are then the subjects of the risk assessment. Concern may be determined by comparison to ecological benchmarks, but more often multiple characteristics of a contaminant are weighed to determine which make the list. The characteristics in Table E-3 are based on a text and a recent Superfund ecological risk assessment (Black & Veatch Special Projects Corps, 2011; Suter et al., 2000). The list may not be exhaustive.

Table E-3. Characteristics of a contaminant of concern at a contaminated site

Characteristics of Contaminants of Concern	Description
Associated with the waste or source	Chemicals that are not associated with the waste or effluent of interest could be from an extraneous local source, regional contamination, or natural background.
Frequently detected	Chemicals that are infrequently detected at the site are of lesser concern and might be artifacts.
Greater than local background	Chemicals at background levels are not of concern, unless the anthropogenic form is more bioavailable or toxic.
At potentially toxic levels	Concentrations above relevant ecotoxicological benchmarks are of concern.
Detection limits are inadequate	Chemicals that could not be detected at toxic levels are of concern, particularly if they are associated with the waste or source.
Belongs to the same class as an identified contaminant of concern	A chemical that is not of concern alone might belong to a class, such as polycyclic aromatic hydrocarbons, that could be assessed jointly.

E.4. Characteristics of Biological Impairment

Impairment of biotic populations or communities is determined under the Clean Water Act's Section 303(d) and in various other contexts. Although a population or community need be impaired in only one way to be categorized as impaired (Box D-1), multiple characteristics of impairment could increase confidence in the designation and increase support for a regulatory or remedial action. A few of

the possible characteristics of impairment include low taxonomic richness, proportion of dominant taxa, toxicity, contamination, poor physical habitat, and poor aesthetics, among others. These characteristics are familiar to ecological assessors and require no descriptions here.

E.5. Characteristics of Remediation

Assessments of the success of remedial actions are common and important examples of outcome assessments. Remediation is judged in terms of performance and effectiveness of the intervention (Table E-4). Obtaining sufficient evidence to determine whether ecological goals are attained because of the remedial action and not just natural recovery is valuable.

Table E-4. Potential characteristics of remediation

Characteristic of Remediation	Description
Performance of the Intervention	
Functions	The remedial technology functions as intended.
Reduces the agent	The technology substantially reduces the level and extent of the contaminant or other agent that causes the risk.
Achieves the physical/chemical goal	The levels of the causal agent are reduced sufficiently to achieve the goal.
Effectiveness of the Intervention	
Endpoint less exposed	The exposure of the environmental endpoint entity to the agent and their interaction are reduced as predicted.
Endpoint improved	The abundance, diversity, function, or other attributes of the endpoint entity improve within the expected time following the remediation.
Endpoint goal achieved	Reference conditions or other ecological endpoint goal are achieved in response to remediation.

E.6. Summary

Qualitative WoE is performed to support inferences concerning some qualitative property such as causality, protection, concern, or impairment. Causality has been the principal quality inferred by WoE in environmental assessments and is the only quality for which characteristics have been available. Tentative lists of characteristics are presented here as examples to demonstrate the potential use of characteristics as an organizing principle for WoE. Other qualitative properties such as recovery also might be addressed by weighing the evidence for defined characteristics. As in causal inference, weighing evidence for characteristics of these other properties could provide a better explanatory structure to WoE than simply weighing pieces or types of evidence.

U.S. EPA, Test Methods for Evaluating Solid Waste, Physical/Chemical Methods (SW-846), Abstract, https://www.epa.gov/hw-sw846SW-846/abstract-test-methods-evaluating-solid-waste-physicalchemical-methods-compendium-sw-846.

ABSTRACT

Test Methods for Evaluating Solid Waste, Physical/Chemical Methods (SW-846) provides test procedures and guidance which are recommended for use in conducting the evaluations and measurements needed to comply with the Resource Conservation and Recovery Act (RCRA), Public Law 94-580, as amended. These methods are approved by the U.S. Environmental Protection Agency for obtaining data to satisfy the requirements of 40 Code of Federal Regulations (CFR) Parts 122 through 270 promulgated under RCRA, as amended. This manual presents the state-of-the-art in routine analytical testing adapted for the RCRA program. It contains procedures for field and laboratory quality control, sampling, determining hazardous constituents in wastes, determining the hazardous characteristics of wastes (toxicity, ignitability, reactivity, and corrosivity), and for determining physical properties of wastes. It also contains guidance on how to select appropriate methods.

Several of the hazardous waste regulations under Subtitle C of RCRA require that specific testing methods described in SW-846 be employed for certain applications. Refer to 40 CFR Parts 260 through 270, for those specific requirements. Any reliable analytical method may be used to meet other requirements under Subtitle C of RCRA.

DERIVATION OF EQUATIONS DESCRIBING SOLUTE TRANSPORT IN GROUND WATER

By Leonard F. Konikow and David B. Grove

ABSTRACT

A general equation describing the three-dimensional transport and dispersion of a reacting solute in flowing ground water is derived from the principle of conservation of mass. The derivation presented in this report is more detailed but less rigorous than derivations published previously. The general solute-transport equation relates concentration changes to hydrodynamic dispersion, convective transport, fluid sources and sinks, and chemical reactions. Because both dispersion and convective transport depend on the velocity of ground-water flow, the solute-transport equation must be solved in conjunction with the ground-water flow equation.

INTRODUCTION

In recent years there has been an increased awareness of problems of ground-water contamination. Reliable predictions of contaminant movement can only be made if we understand and can quantitatively describe the physical and chemical processes that control solute transport in flowing ground water. Several reports have been published recently that develop and present solute-transport equations to compute the concentration of a dissolved chemical species in ground water as a function of space and time. Examples of these reports include Reddell and Sunada (1970), Bear (1972), and Bredehoeft and Pinder (1973). The three main processes affecting solute transport, and consequently chemical concentrations, are convective transport, hydrodynamic dispersion (including diffusion and mechanical dispersion), and chemical reactions. Because convective transport and hydrodynamic dispersion depend on the velocity of ground-water flow, the solute-transport equation must be considered in conjunction with the ground-water flow equation.

Aquifers generally have heterogeneous properties and complex boundary conditions. Therefore, the solution of the partial differential equations that describe the solute-transport processes generally require the use of a deterministic, distributed parameter, digital simulation model. Among the reports that describe or present numerical models to solve the solute-transport equations are Reddell and Sunada (1970), Bredehoeft and Pinder (1973), Pinder (1973), Ahlstrom and Baca (1974), Gupta and others (1975), Grove (1976), and Lantz and others (1976). Furthermore, several documented case histories show that where adequate hydrogeologic data are available, solute-transport models can be used to compute the rates and directions of spreading of contaminants from known or projected sources. Examples of model applications to field problems include Konikow and Bredehoeft (1974), Robertson (1974), Robson (1974), Konikow (1976), and Segol and Pinder (1976).

These models use either finite-difference methods, finite-element methods, or the method of characteristics. The selection of the "best" numerical method depends largely on the nature of the specific field problem, but also depends to some extent on the mathematical background of the analyst. Although solute-transport models are best utilized when the analyst is thoroughly familiar both with the equations and with the numerical algorithm, the increasing availability of documented and published programs affords the opportunity for the use of a model by persons with only minimal familiarity with both.

The basic purpose of this report is to derive a general form of the solute-transport equation from general principles in a more detailed, step-by-step, but less rigorous manner than has been done in previously published literature. The report is intended to serve as an introduction to quantitative modeling of solute-transport processes in ground water. It will also show how the general solute-transport equation can be modified or simplified for application to a variety of different types of field problems. Because of the interrelation between the flow equation and the solute-transport equation, the former will also be presented in some

detail although not specifically derived. It is assumed that the mathematical background of the reader includes at least a familiarity with partial differential equations.

GROUND-WATER FLOW

General flow equation

A quantitative description of ground-water flow is a prerequisite to accurately representing solute transport in aquifers. A general form of the equation describing the transient flow of a compressible fluid in a nonhomogeneous anisotropic aquifer may be derived by combining Darcy's Law with the continuity equation. By following the developments of Cooper (1966) and of Bredehoeft and Pinder (1973), the general flow equation may be written in cartesian tensor notation as:

$$\frac{\partial}{\partial x_i}\left[\frac{\rho k_{ij}}{\mu}\left(\frac{\partial P}{\partial x_j} + \rho g \frac{\partial z^*}{\partial x_j}\right)\right] = \rho\alpha \frac{\partial P}{\partial t} + \rho_o \varepsilon\beta \frac{\partial P}{\partial t}$$

$$+ \frac{\varepsilon}{v_o} \sum_{i=1}^{s} \frac{\partial m_i}{\partial t} + W^*\rho^* \qquad (1)$$

where k_{ij} is the intrinsic permeability (a second-order tensor), L^2;

ρ is the fluid density, ML^{-3};

μ is the dynamic viscosity, $ML^{-1}T^{-1}$;

P is the fluid pressure, $ML^{-1}T^{-2}$;

g is the gravitational acceleration constant, LT^{-2};

z^* is the elevation of the reference point above a standard datum, L;

W^* = $W^*(x,y,z,t)$ is the volume flux per unit volume (positive sign for outflow and negative for inflow), T^{-1};

ρ^* is the density of the source/sink fluid, ML^{-3};

α is the vertical compressibility coefficient of the medium, $LM^{-1}T^2$;

ρ_o is the fluid density at a reference pressure, temperature, and and concentration, ML^{-3};

ε is the effective porosity (dimensionless);

β is the compressibility coefficient of the fluid, $LM^{-1}T^2$;

v_o is the reference volume of the fluid, L^3;

m_i is the mass of species i in the reference volume v_o, M;

s is the number of species, (dimensionless);

x_i are the cartesian coordinates, L; and

t is time, T.

The summation convention of Cartesian tensor analysis is implied in equation 1. That is, each term is summed over the range of its subscripts. Bredehoeft and Pinder (1973) note that the derivation of equation 1 is based on the following assumptions:

1. The porous medium may only deform vertically.
2. Isothermal conditions prevail.
3. The volume of individual grains remains constant during deformation of the medium.
4. Fluid density is a linear function of pressure and concentration, as indicated by the following relationship:

$$\rho = \rho_o + \rho_o\beta\ (P-P_o) + \frac{1}{v_o} \sum_{i=1}^{s} (m_i-m_{io}) \qquad (2)$$

where P_o is the reference fluid pressure, $ML^{-1}T^{-2}$; and

m_{io} is the mass of species i in the reference volume v_o at the reference pressure, M.

5. The permeability is independent of pressure, temperature, and concentration.
6. There is no change in volume caused by mixing fluids of different ionic concentrations.
7. The proportionality constants α and β are independent of pressure and concentration.
8. Hydraulic head gradients are the only significant driving mechanism.
9. The vertical velocity of grains is negligible.

Equations of state

The density and viscosity of ground water are both related to its temperature, pressure, and chemical content. Because isothermal conditions have been assumed, temperature changes need not be considered.

Equation 2 expresses the dependence of density on both the pressure and the mass concentrations of all species. Equation 2 may be rewritten

in terms of the concentration of a single chemical species of interest as:

$$\rho = \rho_o + \rho_o\beta(P-P_o) + \gamma(C-C_o) \tag{3}$$

where C is the mass concentration per unit volume of solution for the solute species of interest, ML^{-3};
C_o is the concentration of the solute at the reference pressure and temperature, ML^{-3}; and
γ is the constant of proportionality between concentration and fluid density (dimensionless).

If the relationship indicated by equation 3 is substituted for equation 2, then equation 1 may be rewritten as:

$$\frac{\partial}{\partial x_i}\left[\frac{\rho k_{ij}}{\mu}\left(\frac{\partial P}{\partial x_j} + \rho g \frac{\partial z^*}{\partial x_j}\right)\right] = \rho\alpha \frac{\partial P}{\partial t} + \rho_o\varepsilon\beta \frac{\partial P}{\partial t} + \varepsilon\gamma \frac{\partial C}{\partial t} + W^*\rho^* \tag{4}$$

Viscosity may be similarly expressed as a linear function of concentration by the following:

$$\mu = \mu_o + \lambda(C - C_o) \tag{5}$$

where μ_o is the dynamic viscosity of the fluid at the reference pressure, temperature, and concentration, $ML^{-1}T^{-1}$; and
λ is the constant of proportionality between concentration and viscosity, L^2T^{-1}.

Flow velocity

The seepage velocity, or average interstitial velocity, of groundwater flow may be computed as:

$$V_i = \frac{q_i}{\varepsilon} \tag{6}$$

where V_i is the seepage velocity in the direction of x_i, LT^{-1}; and
q_i is the specific discharge, or specific flux, in the direction of x_i, LT^{-1}.

The specific discharge may be computed directly from Darcy's Law, which is written as:

$$q_i = \frac{-k_{ij}}{\mu}\left(\frac{\partial P}{\partial x_j} + \rho g \frac{\partial z^*}{\partial x_j}\right) \tag{7}$$

Simplifying assumptions

The general flow equation written as equation 4 can be simplified considerably if certain conditions can be satisfied. Several of these are described next.

Homogeneous fluid properties

When changes in concentrations of dissolved chemical species are relatively small, the fluid density and viscosity remain essentially constant. This assumption of homogeneous fluid properties both simplifies the flow equation and allows it to be solved independently from the solute-transport equation. If density is independent of concentration, then the third term on the right side of equation 4 can be eliminated from the flow equation.

We may aim next to express equation 4 in terms of hydraulic head rather than pressure. Following the development of Hubbert (1940), we may define the hydraulic head as:

$$h = z^* + \int_{P_a}^{P} \frac{dP}{\rho g} \tag{8}$$

where h is the hydraulic head, L; and

P_a is atmospheric pressure, $ML^{-1}T^{-2}$.

If we differentiate equation 8 with respect to x_i, for constant density we obtain:

$$\frac{\partial h}{\partial x_i} = \frac{\partial z^*}{\partial x_i} + \frac{1}{\rho g}\frac{\partial P}{\partial x_i} \tag{9}$$

Solving equation 9 for $\frac{\partial P}{\partial x_i}$ yields:

$$\frac{\partial P}{\partial x_i} = \rho g\left(\frac{\partial h}{\partial x_i} - \frac{\partial z^*}{\partial x_i}\right) \tag{10}$$

We may similarly differentiate equation 8 with respect to time to obtain:

$$\frac{\partial h}{\partial t} = \frac{\partial z^*}{\partial t} + \frac{1}{\rho g}\frac{\partial P}{\partial t} \tag{11}$$

Because $\frac{\partial z^*}{\partial t} = 0$, we can express equation 11 as:

$$\frac{\partial P}{\partial t} = \rho g \frac{\partial h}{\partial t} \tag{12}$$

If we next substitute the relations indicated by equations 10 and 12 into equation 4, and then divide both sides of the equation by the constant density, we obtain:

$$\frac{\partial}{\partial x_i}\left(\frac{\rho g}{\mu} k_{ij} \frac{\partial h}{\partial x_j}\right) = g(\rho\alpha + \rho_o \varepsilon\beta)\frac{\partial h}{\partial t} + W^* \tag{13}$$

Equation 13 may be further reduced if we consider that

$$K_{ij} = \frac{\rho g}{\mu} k_{ij} \tag{14}$$

where K_{ij} is the hydraulic conductivity tensor, LT^{-1}, and that

$$S_s = g(\rho\alpha + \rho_o \varepsilon\beta) \tag{15}$$

where S_s is the specific storage, L^{-1}.

By substituting equations 14 and 15 into equation 13, we obtain:

$$\frac{\partial}{\partial x_i}\left(K_{ij}\frac{\partial h}{\partial x_j}\right) = S_s \frac{\partial h}{\partial t} + W^* \tag{16}$$

Two-dimensional areal flow

In many ground-water studies it can be reasonably assumed that ground-water flow is areally two-dimensional. This allows the three-dimensional flow equation to be reduced to the case of two-dimensional areal flow, for which several additional simplifications are possible. The advantages of reducing the dimensionality of the equations include less stringent data requirements, smaller computer storage requirements, and shorter computer execution times to achieve a numerical solution.

An expression similar to equation 16 may be derived for the two-dimensional areal flow of a homogeneous fluid and written as:

$$\frac{\partial}{\partial x_i}\left(K_{ij} b \frac{\partial h}{\partial x_j}\right) = S_s b \frac{\partial h}{\partial t} + W^* b \tag{17}$$

where b is the saturated thickness of the aquifer, L, and it is assumed that the hydraulic conductivity, specific storage, and hydraulic head represent vertically integrated mean values (Cooley, 1974).

The transmissivity of the aquifer may be defined as:

$$T_{ij} = K_{ij} b \tag{18}$$

where T_{ij} is the transmissivity, L^2T^{-1}.

Similarly, the storage coefficient of the aquifer may be defined as:

$$S = S_s b \tag{19}$$

where S is the storage coefficient (dimensionless).

After substituting the relationships indicated by equations 18 and 19 into equation 17, we obtain:

$$\frac{\partial}{\partial x_i}\left(T_{ij} \frac{\partial h}{\partial x_j}\right) = S \frac{\partial h}{\partial t} + W \tag{20}$$

where $W = W(x,y,t) = W^*b$ is the volume flux per unit area, LT^{-1}.

Although fluid sources and sinks may vary in space and time, they have been lumped into one term (W) in the previous development. There are several possible ways to compute W. If we consider only sources and sinks such as (1) direct withdrawal or recharge, such as pumpage from a well, well injection, or evapotranspiration, and (2) steady-state leakage into or out of the aquifer through a confining layer, streambed, or lake bed, then for the case of two-dimensional horizontal flow, the source/sink terms may be specifically expressed as:

$$W(x,y,t) = Q(x,y,t) - \frac{K_z}{m}(H_s - h) \tag{21}$$

where Q is the rate of withdrawal (positive sign) or recharge (negative sign), LT^{-1};

K_z is the vertical hydraulic conductivity of the confining layer, streambed, or lake bed, LT^{-1};

m is the thickness of the confining layer, streambed, or lake bed, L; and

H_s is the hydraulic head in the source bed, stream, or lake, L.

Alignment of coordinate axes

The cross-product terms of the permeability tensor drop out when the coordinate axes are aligned with the principal axes of the tensor (Bredehoeft, 1969); that is, $k_{ij} = 0$ when $i \neq j$. Therefore, the only permeability terms with possible nonzero values are k_{xx}, k_{yy}, and k_{zz}. This assumption simplifies the general flow equation, which can now be rewritten to include all permeability terms as:

$$\frac{\partial}{\partial x}\left[\frac{\rho k_{xx}}{\mu}\left(\frac{\partial P}{\partial x} + \rho g \frac{\partial z^*}{\partial x}\right)\right] + \frac{\partial}{\partial y}\left[\frac{\rho k_{yy}}{\mu}\left(\frac{\partial P}{\partial y} + \rho g \frac{\partial z^*}{\partial y}\right)\right]$$

$$+ \frac{\partial}{\partial z}\left[\frac{\rho k_{zz}}{\mu}\left(\frac{\partial P}{\partial z} + \rho g \frac{\partial z^*}{\partial z}\right)\right] = \rho\alpha \frac{\partial P}{\partial t} + \rho_o \varepsilon\beta \frac{\partial P}{\partial t} + \varepsilon\gamma \frac{\partial C}{\partial t} + W^*\rho^* \qquad (22)$$

Darcy's Law may be written similarly for the three flow directions as:

$$q_x = -\frac{k_{xx}}{\mu}\left(\frac{\partial P}{\partial x} + \rho g \frac{\partial z^*}{\partial x}\right) \qquad (23a)$$

$$q_y = -\frac{k_{yy}}{\mu}\left(\frac{\partial P}{\partial y} + \rho g \frac{\partial z^*}{\partial y}\right) \qquad (23b)$$

$$q_z = -\frac{k_{zz}}{\mu}\left(\frac{\partial P}{\partial z} + \rho g \frac{\partial z^*}{\partial z}\right) \qquad (23c)$$

For the case of two-dimensional areal flow, if the coordinate axes are aligned with the principal directions of the transmissivity tensor, equation 20 may be written as:

$$\frac{\partial}{\partial x}\left(T_{xx} \frac{\partial h}{\partial x}\right) + \frac{\partial}{\partial y}\left(T_{yy} \frac{\partial h}{\partial y}\right) = S \frac{\partial h}{\partial t} + W \qquad (24)$$

SOLUTE-TRANSPORT EQUATION

Derivation of general transport equation

An equation describing the three-dimensional transport and dispersion of a reacting dissolved chemical in flowing ground water will be derived from the principle of conservation of mass (continuity condition). The derivation presented here is based on the developments of Reddell and Sunada (1970), Bear (1972), and Bredehoeft and Pinder (1973).

The principle of conservation of mass requires that the net mass of solute entering or leaving a specified volume of aquifer during a given time interval must equal the accumulation or loss of mass stored in that volume during the interval. This may be expressed in a verbal equation as:

(Rate of Solute Accumulation)

= (Rate of Solute Inflow) - (Rate of Solute Outflow)

+ (Rate of Chemical Production by Reactions) (25)

This relationship may then be expressed mathematically by considering all fluxes into and out of a representative elementary volume (REV), as described by Bear (1972, p. 19). The REV shown in figure 1 is centered at coordinates (x, y, z) and has dimensions (Δx, Δy, Δz).

First we will determine fluxes in the x-direction. We know that at the center of the REV the mass flux of solute in the x-direction across the y-z plane (face IJKL) is equal to ($CV_x^* \varepsilon \Delta y \Delta z$), where C is the concentration of the solute (ML^{-3}), V_x^* is the instantaneous mass velocity of the solute (LT^{-1}), and Δy and Δz are the dimensions (L) of face IJKL. Note that the term ($\varepsilon \Delta y \Delta z$) simply represents the total effective cross-sectional area through which flow is occurring.

We need expressions for the fluxes across the outer faces ABCD and EFGH. The difference between the mass flux of solute across face ABCD and face IJKL equals the rate of change of mass flux in the x-direction times the distance between these two faces. The rate of change of the mass flux of solute in the x-direction equals $\frac{\partial}{\partial x}(CV_x^* \varepsilon \Delta y \Delta z)$, and the distance from the center to face ABCD is $(-\Delta x/2)$. Thus, the mass flux through face ABCD equals

$$CV_x^* \varepsilon \Delta y \Delta z - \frac{\partial}{\partial x}(CV_x^* \varepsilon \Delta y \Delta z)\frac{\Delta x}{2}$$

Similarly, the distance from the center to face EFGH is $(+\Delta x/2)$ and the mass flux through face EFGH is given by

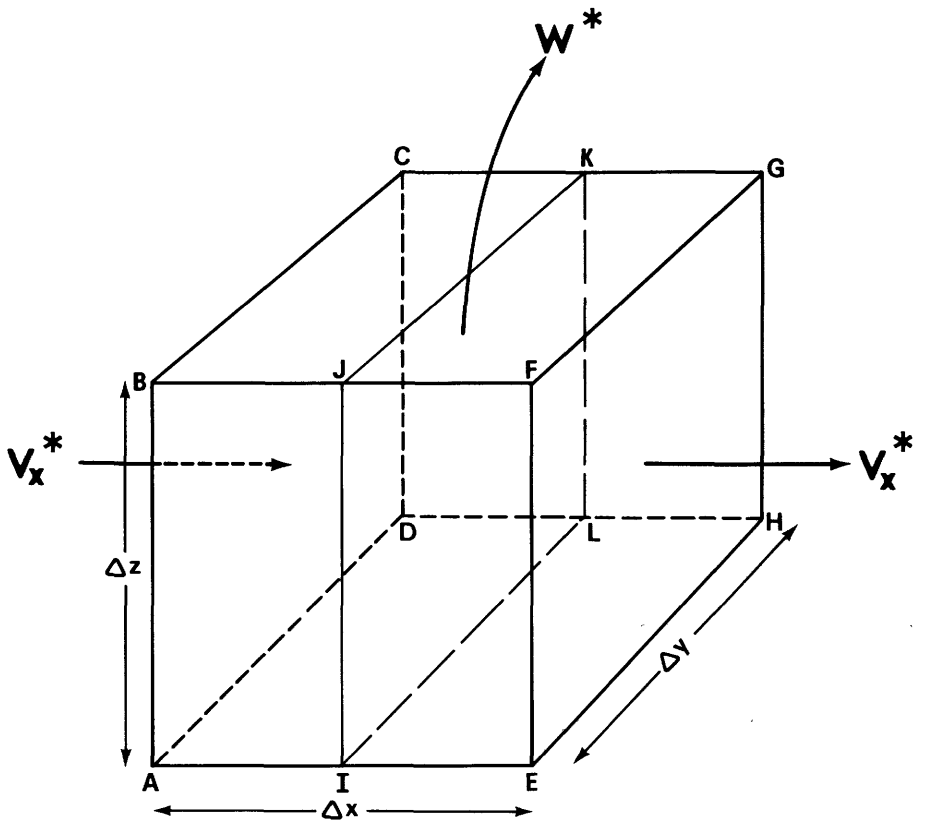

Figure 1.--Representative elementary volume (REV) of aquifer.

$$CV_x^* \varepsilon \Delta y \Delta z + \frac{\partial}{\partial x} (CV_x^* \varepsilon \Delta y \Delta z) \frac{\Delta x}{2}$$

The net mass flux of the solute entering or leaving the REV in the x-direction equals the difference (input-output) between the two previous terms:

$$(\text{Net Mass Flux})_x = \left[CV_x^* \varepsilon \Delta y \Delta z - \frac{\partial}{\partial x} (CV_x^* \varepsilon \Delta y \Delta z) \frac{\Delta x}{2} \right]$$

$$- \left[CV_x^* \varepsilon \Delta y \Delta z + \frac{\partial}{\partial x} (CV_x^* \varepsilon \Delta y \Delta z) \frac{\Delta x}{2} \right]$$

$$= - \frac{\partial}{\partial x} (CV_x^* \varepsilon \Delta y \Delta z) \Delta x \qquad (26)$$

This equation can also be derived by writing a Taylor series for the mass flux term about the point (x, y, z) (Reddell and Sunada, 1970, p. 39). Note that if the value of the derivative in the x-direction (equation 26) is negative, then the mass flux of solute entering through face ABCD is greater than the mass leaving through face EFGH. If all other fluxes balance, there will then be a positive accumulation of solute mass in the REV. Conversely, if the derivative is positive, there will be a decrease over time of solute mass stored in the REV.

It can similarly be shown that for the y-direction:

$$(\text{Net Mass Flux})_y = - \frac{\partial}{\partial y} (CV_y^* \varepsilon \Delta x \Delta z) \Delta y \qquad (27a)$$

and for the z-direction:

$$(\text{Net Mass Flux})_z = - \frac{\partial}{\partial z} (CV_z^* \varepsilon \Delta x \Delta y) \Delta z \qquad (27b)$$

Solute may also enter or leave the REV as a flux through a source or sink (W). This may be expressed mathematically as:

$$(\text{Source/Sink Mass Flux})_{REV} = C'W^* \Delta x \Delta y \Delta z \qquad (28)$$

where C' is the concentration of the solute in the source or sink fluid, ML^{-3}.

If a sink (withdrawal) is considered positive in sign and a source (recharge or injection) is considered negative in sign, then when all other fluxes balance, a positive W must be balanced by a decrease over time of solute mass stored in the REV (negative $\frac{\partial C}{\partial t}$), and vice versa. Note that for a sink C' is equivalent to the concentration in the aquifer at the location of the sink.

A particular solute may also be added to or removed from solution within the REV by the effects of chemical reactions. Examples of such reactions include radioactive decay, ion exchange, and adsorption. The amount of solute that is produced (that is, added to or removed from solution) within the REV is equal to the rate of production of the solute times the volume of solution and may be expressed as:

$$(\text{Solute Mass Produced})_{REV} = \varepsilon \Delta x \Delta y \Delta z \sum_{k=1}^{s} R_k \tag{29}$$

where R_k is the rate of production of the solute in reaction k of s different reactions (positive for addition of solute and negative for removal), $ML^{-3}T^{-1}$.

The conservation of mass for a given solute may be expressed in a continuity equation by combining the terms in equations 26, 27a, 27b, 28, and 29, resulting in:

$$\begin{aligned} \frac{\partial}{\partial t}(C\varepsilon\Delta x\Delta y\Delta z) = &- \frac{\partial}{\partial x}(CV_x^* \varepsilon\Delta y\Delta z)\Delta x \\ &- \frac{\partial}{\partial y}(CV_y^* \varepsilon\Delta x\Delta z)\Delta y - \frac{\partial}{\partial z}(CV_z^* \varepsilon\Delta x\Delta y)\Delta z \\ &- C'W^*\Delta x\Delta y\Delta z + \varepsilon\Delta x\Delta y\Delta z \sum_{k=1}^{s} R_k \end{aligned} \tag{30}$$

If we assume that changes over time in porosity of the aquifer are not significant and Δx, Δy, and Δz are constants, then their derivatives equal zero. Using an indicial notation to represent directions in which x_1, x_2, and x_3 correspond to the x-, y-, and z-directions respectively, equation 30 can be rewritten as:

$$\begin{aligned} \varepsilon\Delta x_1\Delta x_2\Delta x_3 \frac{\partial C}{\partial t} = &- \Delta x_1\Delta x_2\Delta x_3 \frac{\partial}{\partial x_i}(CV_i^* \varepsilon) - C'W^*\Delta x_1\Delta x_2\Delta x_3 \\ &+ \varepsilon\Delta x_1\Delta x_2\Delta x_3 \sum_{k=1}^{s} R_k \end{aligned} \tag{31}$$

Dividing both sides of equation 31 by $(\Delta x_1 \Delta x_2 \Delta x_3)$ to remove the common factors results in:

$$\varepsilon \frac{\partial C}{\partial t} = - \frac{\partial}{\partial x_i} (CV_i^* \varepsilon) - C'W^* + \varepsilon \sum_{k=1}^{s} R_k \qquad (32)$$

The instantaneous mass flux of the solute is given as CV_i^*. As shown by Bear (1972, p. 101), this flux can be separated into two parts:

$$CV_i^* = CV_i + \overset{\circ}{CV}_i \qquad (33)$$

where $\overset{\circ}{V}_i$ is the deviation of the mass average velocity of the solute from the average insterstitial velocity of the fluid $(\overset{\circ}{V}_i = V_i^* - V_i)$, LT^{-1}.

The term CV_i represents the convective flux of solute carried by the average fluid motion through the REV. Neglecting diffusion, the term $\overset{\circ}{CV}_i$ represents the dispersive flux resulting from velocity fluctuations.

Bear (1972, p. 101) also shows that the dispersive flux can be approximated by:

$$\overset{\circ}{CV}_i = - D_{ij} \frac{\partial C}{\partial x_j} \qquad (34)$$

where D_{ij} is the coefficient of mechanical dispersion (a second-order tensor), L^2T^{-1}.

Equation 34 indicates that the dispersive flux is directly proportional to the concentration gradient and occurs in a direction from higher concentrations towards lower concentrations. The form of equation 34 is analogous to Fick's Law describing diffusive flux, as described by Bear (1972, p. 78). In considering flowing ground water, diffusive fluxes are assumed to be negligible in comparison to dispersive fluxes. If diffusion is negligible, the coefficient of mechanical dispersion is equivalent to the coefficient of hydrodynamic dispersion described by Bear (1972, p. 606).

Coupling between forces of one type and fluxes of another type are discussed by Bear (1972, p. 85-90). By following the development of Bredehoeft and Pinder (1973), and by assuming that the only significant driving mechanism is the gradient of hydraulic head and that Darcy's Law is fully valid, we eliminate the necessity of considering coupled processes.

As a result of substituting equation 34 into equation 33, the instantaneous mass flux may be expressed in terms of the dispersion coefficient as:

$$CV_i^* = CV_i - D_{ij} \frac{\partial C}{\partial x_j} \tag{35}$$

Equation 35 can next be substituted into equation 32 to yield:

$$\varepsilon \frac{\partial C}{\partial t} = - \frac{\partial}{\partial x_i} \left[\varepsilon \left(CV_i - D_{ij} \frac{\partial C}{\partial x_j} \right) \right] - C'W^* + \varepsilon \sum_{k=1}^{s} R_k \tag{36}$$

which is equivalent to:

$$\varepsilon \frac{\partial C}{\partial t} = \frac{\partial}{\partial x_i} \left(\varepsilon D_{ij} \frac{\partial C}{\partial x_j} \right) - \frac{\partial}{\partial x_i} (\varepsilon CV_i)$$

$$- C'W^* + \varepsilon \sum_{k=1}^{s} R_k \tag{37}$$

If spatial changes in porosity are negligible, both sides of equation 37 can be divided by ε to produce:

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x_i} \left(D_{ij} \frac{\partial C}{\partial x_j} \right) - \frac{\partial}{\partial x_i} (CV_i) - \frac{C'W^*}{\varepsilon} + \sum_{k=1}^{s} R_k \tag{38}$$

which is a general equation for computing the concentration of a single dissolved chemical species in flowing ground water.

For the general case of three-dimensional transport of a single dissolved chemical species in flowing ground water, equations 4 and 38 must be solved simultaneously. This requires the use of the auxiliary equations 3, 5, 6, and 7.

At this point it is of value to consider in more detail the second term on the right side of equation 38, which describes convective transport. This term may be expanded as follows:

$$- \frac{\partial}{\partial x_i} (CV_i) = - C \frac{\partial V_i}{\partial x_i} - V_i \frac{\partial C}{\partial x_i} \tag{39}$$

It is often assumed in cases of steady-state flow that the divergence of velocity ($\partial V_i / \partial x_i$) equals zero and the first term on the right side of equation 39 can be eliminated. However, as shown by the following

development, this would be an erroneous assumption if any fluid sources are present or if fluid density varies in space.

By using the definition of V_i indicated by equation 6, we may rewrite the first term on the right side of equation 39 as:

$$-C \frac{\partial V_i}{\partial x_i} = - \frac{C}{\varepsilon} \frac{\partial q_i}{\partial x_i} \tag{40}$$

Next, substitution of the definition of q_i from equation 7 into equation 40 gives:

$$-C \frac{\partial V_i}{\partial x_i} = - \frac{C}{\varepsilon} \frac{\partial}{\partial x_i} \left[\frac{-k_{ij}}{\mu} \left(\frac{\partial P}{\partial x_j} + \rho g \frac{\partial z^*}{\partial x_j} \right) \right] \tag{41}$$

If we multiply the expression within the brackets by ρ/ρ and substitute the relationships shown in equations 4 and 7, we obtain:

$$-C \frac{\partial V_i}{\partial x_i} = \frac{C\alpha}{\varepsilon} \frac{\partial P}{\partial t} + \frac{C\rho_o \beta}{\rho} \frac{\partial P}{\partial t} + \frac{C\gamma}{\rho} \frac{\partial C}{\partial t} + \frac{CW^*\rho^*}{\varepsilon\rho} + \rho q_i \frac{\partial (1/\rho)}{\partial x_i} \tag{42}$$

If steady-state flow existed, $\frac{\partial P}{\partial t} = 0$ and the first two terms on the right side are eliminated. Although the third term may be insignificant, the fourth term, which describes sources and sinks, would have to be included in the analysis, as would the fifth term, which is related to the spatial variability of fluid density.

Two-dimensional areal solute transport

A solute-transport equation for problems involving two-dimensional areal flow may be derived in a manner analogous to the previous derivation of a general three-dimensional equation by assuming that vertical variations in head and concentration are negligible. Consider the total volume of aquifer under a representative square area, as shown in figure 2. Note that the vertical dimension is represented by the saturated thickness, b, and that b may vary within the representative area. In this case the mass flux through face ABCD is approximately equal to

$$CV_x^* \varepsilon \Delta y b - \frac{\partial}{\partial x} \left(CV_x^* \varepsilon \Delta y b \right) \frac{\Delta x}{2}$$

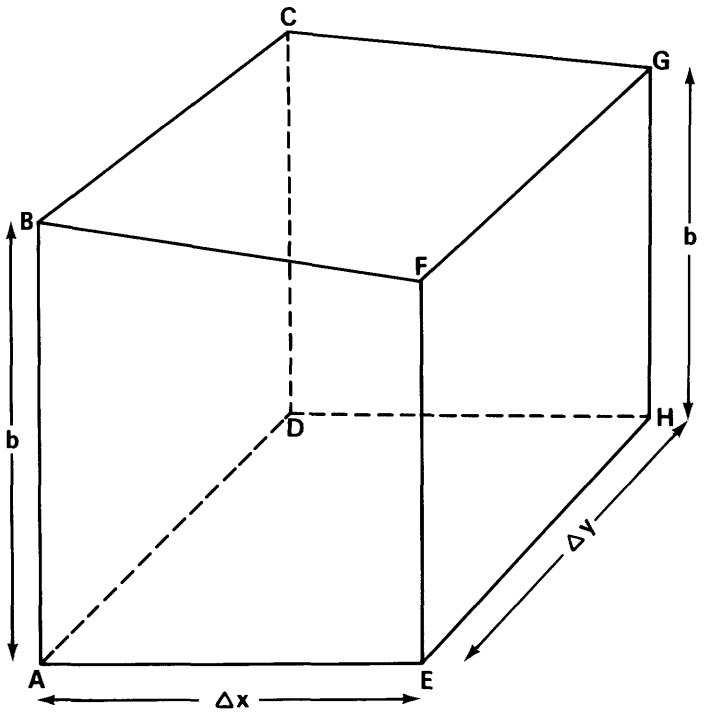

Figure 2.--Representative volume of aquifer having variable saturated thickness.

Similarly, the mass flux through face EFGH may be given by

$$CV_x^* \varepsilon \Delta yb + \frac{\partial}{\partial x}\left(CV_x^* \varepsilon \Delta yb\right)\frac{\Delta x}{2}$$

The net mass flux of the solute entering or leaving the representative volume thus equals the difference between the two previous terms:

$$(\text{Net Mass Flux})_x = -\frac{\partial}{\partial x}\left(CV_x^* \varepsilon \Delta yb\right)\Delta x \tag{43}$$

It can also be shown in the same manner that for the y-direction:

$$(\text{Net Mass Flux})_y = -\frac{\partial}{\partial y}\left(CV_y^* \varepsilon \Delta xb\right)\Delta y \tag{44}$$

In the case of two-dimensional areal flow, it is assumed that any flux across the upper or lower faces of the representative volume is included in the source/sink term. Solute entering or leaving the representative volume through a source or sink may be expressed mathematically as:

$$(\text{Source/Sink Mass Flux}) = C'W\Delta x\Delta y \tag{45}$$

Solute added to or removed from solution within the representative volume by the effects of chemical reactions may be expressed as:

$$(\text{Solute Mass Produced}) = \varepsilon \Delta x \Delta yb \sum_{k=1}^{s} R_k \tag{46}$$

The conservation of mass for a given solute may be expressed in a continuity equation by combining the terms in equations 43, 44, 45, and 46, resulting in:

$$\frac{\partial}{\partial t}\left(C\varepsilon \Delta x \Delta yb\right) = -\frac{\partial}{\partial x}\left(CV_x^* \varepsilon \Delta yb\right)\Delta x$$

$$-\frac{\partial}{\partial y}\left(CV_y^* \varepsilon \Delta xb\right)\Delta y$$

$$-C'W\Delta x\Delta y + \varepsilon \Delta x \Delta yb \sum_{k=1}^{s} R_k \tag{47}$$

If ε, Δx, and Δy are constants, equation 47 may be rewritten as:

$$\varepsilon\Delta x\Delta y \frac{\partial(Cb)}{\partial t} = - \varepsilon\Delta x\Delta y \frac{\partial}{\partial x}\left(CV_x{}^* b\right) - \varepsilon\Delta x\Delta y \frac{\partial}{\partial y}\left(CV_y{}^* b\right) - C'W\Delta x\Delta y + \varepsilon\Delta x\Delta y b \sum_{k=1}^{s} R_k \tag{48}$$

Dividing both sides of equation 48 by ($\varepsilon\Delta x\Delta y$) results in:

$$\frac{\partial(Cb)}{\partial t} = - \frac{\partial}{\partial x}\left(CV_x{}^* b\right) - \frac{\partial}{\partial y}\left(CV_y{}^* b\right) - \frac{C'W}{\varepsilon} + b \sum_{k=1}^{s} R_k \tag{49}$$

By expressing equation 49 in tensor notation and substituting equation 35, written for two dimensions, into equation 49, we obtain:

$$\frac{\partial(Cb)}{\partial t} = - \frac{\partial}{\partial x_i}\left[b\left(CV_i - D_{ij}\frac{\partial C}{\partial x_j}\right)\right] - \frac{C'W}{\varepsilon} + b \sum_{k=1}^{s} R_k \tag{50}$$

which is equivalent to:

$$\frac{\partial(Cb)}{\partial t} = \frac{\partial}{\partial x_i}\left(bD_{ij}\frac{\partial C}{\partial x_j}\right) - \frac{\partial}{\partial x_i}\left(bCV_i\right) - \frac{C'W}{\varepsilon} + b \sum_{k=1}^{s} R_k \tag{51}$$

The left side of equation 49 may be expanded as:

$$\frac{\partial(Cb)}{\partial t} = C\frac{\partial b}{\partial t} + b\frac{\partial C}{\partial t} \tag{52}$$

Substituting equation 52 into equation 51 and solving for $\partial C/\partial t$ results in:

$$\frac{\partial C}{\partial t} = \frac{1}{b}\frac{\partial}{\partial x_i}\left(bD_{ij}\frac{\partial C}{\partial x_j}\right) - \frac{1}{b}\frac{\partial}{\partial x_i}\left(bCV_i\right)$$

$$- \frac{C}{b}\frac{\partial b}{\partial t} - \frac{C'W}{\varepsilon b} + \sum_{k=1}^{s} R_k \tag{53}$$

If the saturated thickness is constant in space, the spatial derivatives of b are equal to zero. Under these conditions, equation 53 can be further simplified to:

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x_i}\left(D_{ij}\frac{\partial C}{\partial x_j}\right) - \frac{\partial}{\partial x_i}\left(CV_i\right)$$

$$- \frac{C'W}{\varepsilon b} - \frac{C}{b}\frac{\partial b}{\partial t} + \sum_{k=1}^{s} R_k \tag{54}$$

The two-dimensional solute-transport equation can be reduced further if changes in saturated thickness over time are negligible and if the solute is not affected by chemical reactions. Under these conditions equation 54 may be simplified to:

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x_i}\left(D_{ij}\frac{\partial C}{\partial x_j}\right) - \frac{\partial}{\partial x_i}\left(CV_i\right) - \frac{C'W}{\varepsilon b} \tag{55}$$

The difference between equation 53 and equation 54 can be presented more explicitly by expanding the first two terms on the right side of equation 53. After combining terms, equation 53 may then be rewritten as:

$$\frac{\partial C}{\partial t} = \frac{1}{b}\left[D_{ij}\frac{\partial C}{\partial x_j} - CV_i\right]\frac{\partial b}{\partial x_i} + \frac{\partial}{\partial x_i}\left(D_{ij}\frac{\partial C}{\partial x_j}\right)$$

$$- \frac{\partial (CV_i)}{\partial x_i} - \frac{C'W}{\varepsilon b} - \frac{C}{b}\frac{\partial b}{\partial t} + \sum_{k=1}^{s} R_k \qquad (56)$$

Thus, the difference between equations 53 and 54 is equal to:

$$\frac{1}{b}\left[D_{ij}\frac{\partial C}{\partial x_j} - CV_i\right]\frac{\partial b}{\partial x_i}$$

In other words, the error in computed concentrations caused by assuming that the saturated thickness is uniform, when it actually varies in space, is inversely proportional to the saturated thickness and directly proportional to the divergence of the saturated thickness. If the rate of change in saturated thickness is small compared to the total saturated thickness, the simpler equation 54 can be used as a reasonable approximation to equation 53.

We may also rewrite equation 53 by expanding the convective transport term, as was done by equation 39 to obtain:

$$\frac{\partial C}{\partial t} = \frac{1}{b}\frac{\partial}{\partial x_i}\left(bD_{ij}\frac{\partial C}{\partial x_j}\right) - V_i\frac{\partial C}{\partial x_i} - \frac{C}{b}\frac{\partial (V_i b)}{\partial x_i}$$

$$- \frac{C}{b}\frac{\partial b}{\partial t} - \frac{C'W}{\varepsilon b} + \sum_{k=1}^{s} R_k \qquad (57)$$

The third, fourth, and fifth terms on the right side of equation 57 may be combined into one term as follows:

$$- \frac{C}{b} \frac{\partial (V_i b)}{\partial x_i} - \frac{C}{b} \frac{\partial b}{\partial t} - \frac{C'W}{\varepsilon b}$$

$$= \frac{C\left[- \frac{\partial (\varepsilon V_i b)}{\partial x_i} - \varepsilon \frac{\partial b}{\partial t} \right] - C'W}{\varepsilon b} \tag{58}$$

It can be shown from equations 6, 7, 9, 14, and 18 that:

$$\varepsilon V_i b = - T_{ij} \frac{\partial h}{\partial x_j} \tag{59}$$

Thus, from equation 20 we can state that:

$$- \frac{\partial}{\partial x_i} \left(\varepsilon V_i b \right) = S \frac{\partial h}{\partial t} + W \tag{60}$$

By substituting equation 60 into equation 58 we can rewrite equation 57 as:

$$\frac{\partial C}{\partial t} = \frac{1}{b} \frac{\partial}{\partial x_i} \left(b D_{ij} \frac{\partial C}{\partial x_j} \right) - V_i \frac{\partial C}{\partial x_i}$$

$$+ \frac{C \left[S \frac{\partial h}{\partial t} + W - \varepsilon \frac{\partial b}{\partial t} \right] - C'W}{\varepsilon b}$$

$$+ \sum_{k=1}^{s} R_k \tag{61}$$

For the case of a water-table aquifer we may assume:

$$S = S_y \tag{62}$$

where S_y is the specific yield of the aquifer (dimensionless). We may also assume that in the case of a water-table aquifer, the Dupuit-Forchheimer assumptions hold (Bear, 1972, p. 361-366), so that:

$$\frac{\partial b}{\partial t} = \frac{\partial h}{\partial t} \tag{63}$$

For the case of an artesian aquifer we can normally assume that:

$$\frac{\partial b}{\partial t} = 0 \tag{64}$$

If changes in saturated thickness over time and space are both negligible, equation 49 may be simplified to:

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x_i}\left(D_{ij}\frac{\partial C}{\partial x_j}\right) - V_i\frac{\partial C}{\partial x_i} + \frac{C\left(S\frac{\partial h}{\partial t} + W\right) - C'W}{\varepsilon b} + \sum_{k=1}^{s} R_k \tag{65}$$

In the case of steady-state flow, the third term on the right side of equation 65 may be simplified to:

$$\frac{C\left(S\frac{\partial h}{\partial t} + W\right) - C'W}{\varepsilon b} = \frac{W(C-C')}{\varepsilon b} \tag{66}$$

It is interesting to note that when W represents withdrawal only, then C' = C and the right side of equation 66 becomes equal to zero. Therefore, withdrawals from the aquifer produce concentration changes only indirectly through the effects of the withdrawals on the velocity field, rather than by any direct effect on the mass or concentration of solutes.

If vertical variations of head or concentration are significant, then the two-dimensional equations previously derived would not precisely describe areal solute transport. Cooley (written commun., 1976) shows that when a two-dimensional solute-transport equation is derived with a more rigorous vertical integration of the three-dimensional equation, the third dimension is not actually eliminated in converting to areal coordinates but instead is transformed to boundary conditions.

Dispersion coefficient

The solution of the solute-transport equation requires consideration of the dispersion coefficient. Because of its tensorial properties, its consideration may not appear to be straightforward. Hence, we will next consider this coefficient in more detail.

Bear (1972, p. 580-581) states that hydrodynamic dispersion is the macroscopic outcome of the actual movements of individual tracer particles through the pores and that it includes two processes. One process is mechanical dispersion, which depends upon both the flow of the fluid and the nature of the pore system through which the flow takes place. The second process is molecular and ionic diffusion, which because it depends on time, is more significant at low flow velocities. Bear (1972) further states that the separation between the two processes is artificial. In developing our model we assume for flowing ground-water systems that the definable contribution of molecular and ionic diffusion to hydrodynamic dispersion is negligible.

The relationship between the dispersion coefficient, the fluid flow, and the nature of the pore system is given in tensor notation by Scheidegger (1961, p. 3275) as:

$$D_{ij} = a_{ijmn} \frac{V_m V_n}{|V|} \tag{67}$$

where a_{ijmn} is the dispersivity of the porous medium (a fourth-order tensor), L;

V_m and V_n are the components of the flow velocity of the fluid in the m and n directions, respectively, LT^{-1}; and

$|V|$ is the magnitude of the velocity vector, LT^{-1}.

Scheidegger (1961, p. 3275) states that the dispersivity tensor possesses 81 components, but that even in the case of an anisotropic medium, symmetry properties reduce the number of components to 36. Both Scheidegger (1961) and Bear (1972) show that the dispersivity of an isotropic porous medium can be defined by two constants. These are the longitudinal dispersivity of the medium, a_L, and the transverse dispersivity of the medium a_T. For an isotropic porous medium the components of the dispersivity tensor in three dimensions ($i,j = 1,2,3$) are:

$$a_{iiii} = a_L \tag{68a}$$

$$a_{iijj} = a_T \tag{68b}$$

$$a_{iiij} = a_{iiji} = a_{ijii} = a_{ijjj} = 0 \tag{68c}$$

$$a_{ijij} = a_{ijji} = \frac{1}{2}(a_L - a_T) \tag{68d}$$

The components of the dispersion coefficient for three-dimensional flow may be stated explicitly by expanding equation 67 for a range of three on i and j. After eliminating terms with coefficients that equal zero (shown by equation 68c), we obtain:

$$D_{11} = a_{1111}\frac{V_1V_1}{|V|} + a_{1122}\frac{V_2V_2}{|V|} + a_{1133}\frac{V_3V_3}{|V|} \tag{69a}$$

$$D_{22} = a_{2211}\frac{V_1V_1}{|V|} + a_{2222}\frac{V_2V_2}{|V|} + a_{2233}\frac{V_3V_3}{|V|} \tag{69b}$$

$$D_{33} = a_{3311}\frac{V_1V_1}{|V|} + a_{3322}\frac{V_2V_2}{|V|} + a_{3333}\frac{V_3V_3}{|V|} \tag{69c}$$

$$D_{12} = D_{21} = a_{1212}\frac{V_1V_2}{|V|} + a_{1221}\frac{V_2V_1}{|V|} \tag{69d}$$

$$D_{13} = D_{31} = a_{1313}\frac{V_1V_3}{|V|} + a_{1331}\frac{V_3V_1}{|V|} \tag{69e}$$

$$D_{23} = D_{32} = a_{2323}\frac{V_2V_3}{|V|} + a_{2332}\frac{V_3V_2}{|V|} \tag{69f}$$

If we substitute the identities presented in equations 68a and b into equations 69a, b, and c, we obtain directly:

$$D_{11} = a_L\frac{V_1V_1}{|V|} + a_T\frac{V_2V_2}{|V|} + a_T\frac{V_3V_3}{|V|} \tag{70a}$$

$$D_{22} = \alpha_T \frac{V_1 V_1}{|V|} + \alpha_L \frac{V_2 V_2}{|V|} + \alpha_T \frac{V_3 V_3}{|V|} \tag{70b}$$

$$D_{33} = \alpha_T \frac{V_1 V_1}{|V|} + \alpha_T \frac{V_2 V_2}{|V|} + \alpha_L \frac{V_3 V_3}{|V|} \tag{70c}$$

Next, by substituting the identities given by equation 68d into equations 69d, e, and f, we see that:

$$D_{12} = D_{21} = (\alpha_L - \alpha_T) \frac{V_1 V_2}{|V|} \tag{71a}$$

$$D_{13} = D_{31} = (\alpha_L - \alpha_T) \frac{V_1 V_3}{|V|} \tag{71b}$$

$$D_{23} = D_{32} = (\alpha_L - \alpha_T) \frac{V_2 V_3}{|V|} \tag{71c}$$

Scheidegger (1961) and Bachmat and Bear (1964) also show that for a Cartesian coordinate system x_i in which one of the axes, say x_1, coincides with the direction of the average velocity, then $V_1 = |V|$ and $V_2 = 0$. Substituting these relations into equations 70 and 71 we obtain:

$$D_{11} = \alpha_L |V| = D_L \tag{72a}$$

$$D_{22} = D_{33} = \alpha_T |V| = D_T \tag{72b}$$

$$D_{12} = D_{21} = D_{13} = D_{31} = D_{23} = D_{32} = 0 \tag{72c}$$

where D_L and D_T are respectively the longitudinal and transverse dispersion coefficients, L^2T^{-1}

Solving equations 72a and b for α_L and α_T results in:

$$\alpha_L = \frac{D_L}{|V|} \tag{73a}$$

$$\alpha_T = \frac{D_T}{|V|} \tag{73b}$$

Introducing equations 73a and b into equations 70 and 71 produces:

$$D_{11} = D_L \frac{(V_1)^2}{|V|^2} + D_T \frac{(V_2)^2}{|V|^2} + D_T \frac{(V_3)^2}{|V|^2} \tag{74a}$$

$$D_{22} = D_T \frac{(V_1)^2}{|V|^2} + D_L \frac{(V_2)^2}{|V|^2} + D_T \frac{(V_3)^2}{|V|^2} \tag{74b}$$

$$D_{33} = D_T \frac{(V_1)^2}{|V|^2} + D_T \frac{(V_2)^2}{|V|^2} + D_L \frac{(V_3)^2}{|V|^2} \tag{74c}$$

$$D_{12} = D_{21} = (D_L - D_T) \frac{V_1 V_2}{|V|^2} \tag{74d}$$

$$D_{13} = D_{31} = (D_L - D_T) \frac{V_1 V_3}{|V|^2} \tag{74e}$$

$$D_{23} = D_{32} = (D_L - D_T) \frac{V_2 V_3}{|V|^2} \tag{74f}$$

Equation 74 defines the local transformation of D_{ij} from orthogonal axes, in which x_1 is parallel to V_1, to global cartesian axes. Note that while D_{11}, D_{22}, and D_{33} must have positive values, it is possible for the cross-product terms (equations 74d, e, and f) to have negative values.

For the case of two-dimensional flow, all components and terms in equation 74 that have a subscript 3 are eliminated.

The magnitude of the velocity, $|V|$, is defined as:

$$|V| = \sqrt{V_1^2 + V_2^2 + V_3^2} \tag{75}$$

In summary, the components of the dispersion tensor that must be evaluated for three-dimensional flow in an isotropic porous medium are:

$$D_{ij} = \begin{vmatrix} D_{11} & D_{12} & D_{13} \\ D_{21} & D_{22} & D_{23} \\ D_{31} & D_{32} & D_{33} \end{vmatrix} = \begin{vmatrix} D_{xx} & D_{xy} & D_{xz} \\ D_{yx} & D_{yy} & D_{yz} \\ D_{zx} & D_{zy} & D_{zz} \end{vmatrix} \tag{76}$$

SUMMARY

A general equation describing the three-dimensional transport and dispersion of a reacting dissolved chemical in flowing ground water was derived nonrigorously from the principle of conservation of mass. The general equation relates concentration changes to hydrodynamic dispersion, convective transport, fluid sources and sinks, and chemical reactions.

Concentration changes caused by dispersion are assumed to be a function of both the dispersion coefficient and the concentration gradient. The dispersion coefficient is a second-order tensor and is related to the dispersivity of the porous medium and to the flow velocity of the ground water. If solute concentrations are affected by chemical reactions, specific mathematical expressions describing the rates of reactions must be incorporated into the general solute-transport equation.

Because both the dispersion coefficient and convective transport depend on the flow velocity, the solution of the solute-transport equation requires the definition of the velocity field, which in the general case requires that the flow and solute-transport equations be solved simultaneously. However, the solution of these equations can be considerably simplified if conditions of homogeneous fluid properties and (or) two-dimensional flow can be validly assumed.

Cover: Chunk of Texas subbituminous coal in the field. Pen for scale. Note the very thin, light-colored laminations that indicate bedding. Top-left enlargement is an example of a scanning photomicrograph showing minerals in coal. The bright-white, oval-shaped fragment is a pyrite framboid; the bright-white triangular fragment is zircon; each fragment is about 10 microns wide. The light-colored, equant blebs are quartz grains. They are set in a light-gray matrix consisting of coal macerals and a variety of clay minerals. Top-right enlargement is an example of a transmitted-light photomicrograph showing various coal macerals (organic components) such as vitrinite (dark reddish orange); liptinite (yellow and light orange); and fusinite, inertinite, and minerals (black). View is about 200 micrometers wide.

FOREWORD

During the 20th century, dramatic shifts took place in the types and sources of energy consumed in the United States. The future energy mix and the technologies used in fuel combustion will be critical in determining the economic and environmental health of the Nation as we move ahead in the 21st century. Coal was a major primary energy source within the United States for all of the last century, and, currently, coal is used to generate more than 50 percent of the Nation's electric energy. Coal supplies are adequate within the United States for this century and coal is the least expensive of the fossil fuels, making it a reliable and economical source of energy. Recent studies, however, suggest that an increased use of coal may contribute to the degradation of the environment and to global warming. A thorough understanding of coal quality will lead to the development of methods to better control the harmful effects of coal use on the environment and human health.

The U.S. Geological Survey (USGS) is actively involved in research on the quality and abundance of coal, as well as on the complex geological and geochemical factors that govern coal quality. In addition, the U.S. Geological Survey gathers information on the location, size, and nature of coal deposits, which also contributes to a basic understanding of the Nation's energy resources. This research is pertinent to discussions of future energy resources, global warming, and the dependence of the Nation on imported fossil fuels—all of which are concerns that are being faced daily at local, State, and National levels. Understanding the nature of coal quality is important for two critical issues facing our Nation—the economy and the environment.

The wise use of our Nation's resources and the careful stewardship of our public lands depend on the dissemination of accurate and timely earth science information. The U.S. Geological Survey is proud to present this report on one of the major issues to be addressed in the future use of coal.

Coal—A Complex Natural Resource

An overview of of factors affecting coal quality and use in the United States

By Stanley P. Schweinfurth

INTRODUCTION

Coal is abundant in the U.S., is relatively inexpensive, and is an excellent source of energy and byproduct raw materials. Because of these factors, domestic coal is the primary source of fuel for electric power plants in the U.S., and will continue to be well into the 21st century. In addition, other U.S. industries continue to use coal for fuel and coke production and there is a large overseas market for high-quality American coal.

Because humans have used coal for centuries, much is known about it. The usefulness of coal as a heat source and the myriad of byproducts that can be produced from coal are well understood. The continued and increasingly large-scale use of coal in the United States and in many other industrialized and developing nations has resulted in known and anticipated hazards to environmental quality and human health. As a result, there is still much to be learned about the harmful attributes of coal and how they may be removed, modified, or avoided to make coal use less harmful to humans and nature. These issues of coal quality have not been examined carefully until recently.

Some of the problems that accompany the mining and use of coal are well known. Acid mine drainage results when coal beds and surrounding strata containing medium to high amounts of sulfur, in the form of compounds known as sulfides, are disrupted by mining, thereby exposing the sulfides to air and water. Atmospheric sulfur oxides (SO_x) and subsequent acid deposition (such as acid rain) result from the burning of medium- to high-sulfur coal. The quality of surface and ground water may be affected adversely by the disposal of the ash and sludge that result from the burning of coal and cleaning of flue gases. These are some of the serious problems requiring either improved or new remedies. Other environmental problems are associated with emissions of carbon dioxide (CO_2) and nitrogen oxides (NO_x), two of the so-called "greenhouse gases." These emissions are often attributed to coal use only; however, they also result from the burning of any fossil or biomass fuel, such as wood, natural gas, gasoline, and heating oil. The greenhouse gas problem requires a broader solution than just reducing the use of coal. Research currently is being conducted in the U.S. and several other countries into the reduction and disposal of CO_2 from coal combustion. An excellent review of the results of this research and the prospects for coal can be found in a publication of IEA Coal Research (1999).

Fluidized-bed combustion (FBC) of coal, which is a new method for controlling sulfur emissions, is gaining wide acceptance. In this system, finely ground coal is mixed with finely ground limestone. Both are fed together into a furnace in a constant stream onto a horizontally moving grate. Air is forced up through the grate and the entire mass is ignited at relatively low temperatures. The forced air causes the ground coal and limestone to be mixed with the hot gases of combustion, which in turn promotes the conversion of any SO_x to gypsum as the burning mass moves along on the grate. According to the U.S. Department of Energy (2000), high-sulfur coal may be burned in this way while simultaneously capturing up to 95 percent of the SO_x and most of the NO_x emitted.

Reduction and disposal of CO_2 emissions is the subject of current research in the U.S. and several other countries.

The Clean Air Act Amendments of 1990 (Public Law 101-549) required the U.S. Environmental Protection Agency (EPA) to conduct studies of 15 trace elements released by the burning of coal to determine if they present health hazards. These 15 elements (antimony, arsenic, beryllium, cadmium, chlorine, chromium, cobalt, lead, manganese, mercury, nickel, potassium, selenium, thorium, and uranium), along with many other potentially hazardous substances released into the air by other industries, are termed "hazardous air pollutants" (HAPs).

On the basis of epidemiological studies, the EPA concluded that, with the possible exception of mercury, there is no compelling evidence to indicate that trace-element emissions from coal-burning power plants cause human health problems (U.S. Environmental Protection Agency, 1996). In December 2000, after extensive study, the EPA announced a

finding that regulation of mercury emissions from coal-fired power plants is necessary and appropriate because coal-fired power plants are the largest unregulated source of manmade emissions of mercury in the U.S. (U.S. Environmental Protection Agency, 2000).

EPA will propose regulations to limit mercury emissions in 2003 and will issue final emissions rules by 2004. Meanwhile, arsenic is still under study, not as an emissions problem from coal combustion, but for its potential role as a hazard in ground water if it is leached from coal-mining waste or from fly ash in disposal sites. Additional coal-quality research on both mercury and arsenic is being conducted at the U.S. Geological Survey (USGS) and elsewhere in order to (1) help identify their sources in coal, and (2) help resolve any remaining potential hazards issues with regard to these two elements.

In 1996, the EPA said that, of the potential HAPs from coal combustion, only mercury and arsenic needed additional study. In 2000, EPA determined that mercury emissions require regulation.

Other problems that may arise from the use of coal are not necessarily harmful to the environment or human health, but affect the use and efficiency of coal-burning equipment. For example, certain constituents in coal may cause severe erosion and corrosion of, or the buildup of mineral deposits on, furnace and boiler parts. These effects greatly reduce the efficiency and life expectancy of furnaces or boilers; as a result, costly repairs are often required.

Thus far, coal has been discussed as if it were a single homogeneous material, but this is done only for convenience in this report. In fact, a wide variety of coal types exists, depending on differing proportions and combinations of organic and inorganic (mineral) components, sulfur, and ash. For example, sulfur content may range from low (less than 1 percent), through medium (1 to 3 percent), to high (greater than 3 percent), and ash yields may range from a low of about 3 percent to a high of 49 percent (if ash yields are 50 percent or greater, the substance is no longer called coal). Coal may produce high or low amounts of energy, or contain high or low amounts of the substances that produce organic chemicals and synthetic fuels, or contain higher or lower amounts of the elements that are considered to be hazardous air pollutants (HAPs). This range in properties results from coal's diverse origins, including the long and complex geologic histories of coal deposits.

The purpose of this report is to acquaint students, non-coal scientists, and the general public with some basic information on (1) the subject of coal quality and the reasons why it is so complex, (2) methods for determining coal quality, and (3) the need for continuing studies of this complex subject. A discussion on the origins of coal is included in order to provide a framework for understanding coal's complex nature. See the section on "Further Reading" for a bibliography on coal quality and other topics (such as coal mining, uses for coal, or health effects of coal use).

ACKNOWLEDGMENTS

Grateful acknowledgment is extended to the following scientists and technicians without whose contributions and careful reviews this report would not have been possible: Philip J. Aruscavage, Linda J. Bragg, M. Devereux Carter, William A. DiMichele, Frank T. Dulong, Robert B. Finkelman, Romeo M. Flores, Harold J. Gluskoter, Joseph R. Hatch, Robert G. Johnson, Rustu S. Kalyoncu, Elizabeth D. Koozmin, Ronald J. Litwin, Paul C. Lyons, Peter J. McCabe, Eric A. Morrissey, Charles L. Oman, William H. Orem, Curtis A. Palmer, Tom A. Phillips, Eleanora I. Robbins, Leslie F. Ruppert, Ronald W. Stanton, Frank G. Walthall, Peter D. Warwick, William D. Watson, Jason C. Willett, Christopher Wnuk, and Chris J. Zygarlicke.

SPECIAL ACKNOWLEDGMENT

A special acknowledgment is included in remembrance of the late Ronald W. Stanton, a U.S. Geological Survey geologist and coal scientist. Ron's belief in the value of a report that would make the mysteries of coal quality more accessible to the public, and his encouragement and physical support during its preparation, were essential to the completion of this circular.

COAL IN THE UNITED STATES

A discussion of coal use in the U.S. and of the beneficial things that come from coal is necessary in order to provide the reader with a better understanding of the importance of coal quality and the need for continuing research on coal quality.

COAL PRODUCTION AND CONSUMPTION

Coal use in the U.S. began around two thousand years ago. Early inhabitants of this continent probably gathered coal from outcroppings, beaches, and streambeds. Coal

mining by European-Americans began in the Richmond basin of Virginia between 1720 and 1750. The Richmond area is known to have furnished coal during the American Revolution. Between 1750 and 1800, coal was discovered in many parts of the northern and southern Appalachian basin. As the population moved westward after the American Revolution, coal deposits were discovered, progressively, in the midcontinent (including Texas), the Rocky Mountains region, the Colorado Plateau, and the northern Great Plains. The first coal in the West was found along the Missouri River in 1804 by the explorers Meriwether Lewis and George Rogers Clark (Collier's Encyclopedia, 1960).

In the U.S., coal is used to produce approximately 56 percent of the annual electricity requirement; 90 percent of the coal produced is used for this purpose.

After 1830, with the beginning of the railroads, the real growth of the coal industry began. The railroads not only used coal, they also provided the means to transport coal, which encouraged the growth of energy-intensive industries. The growth of the railroads also encouraged the expansion of the iron and steel industry, which, by the 1860s, had abandoned charcoal in favor of coke for the reduction of iron ore to pig iron. In the 1880s, after the invention of electric turbines, coal soon became the principle energy source for steam-generated electricity. For a much more detailed account of the early days of coal discovery and use in the U.S., see Eavenson (1942).

By 1918, industry in the U.S. depended almost entirely on coal. During World War II, demand for coal drove coal production to record highs, but shortly thereafter, petroleum replaced coal as our chief source of energy. For about a decade following World War II, most of the decline in coal use was due to the replacement of coal-burning railroad engines with diesel engines. In the 1960s, coal production and consumption began to rise due to an increasing demand for electricity, and has risen ever since. In 1961, the U.S. produced 420.4 million tons (1 ton=2000 pounds) and used 390.4 million tons for domestic purposes; in 1998, production was 1,118.7 million tons and domestic use in 1999 was 1,045.2 million tons (figs. 1, 2) (Energy Information Administration, 2000).

The difference between the amounts of coal produced and used in the U.S. is accounted for mainly by exports. Revenue from coal exports helps reduce the deficit in the balance of payments the U.S. makes to its foreign suppliers of consumer goods. In 1998, coal exports of 78 million tons earned approximately $2.9 billion (Energy Information Administration, 1999b).

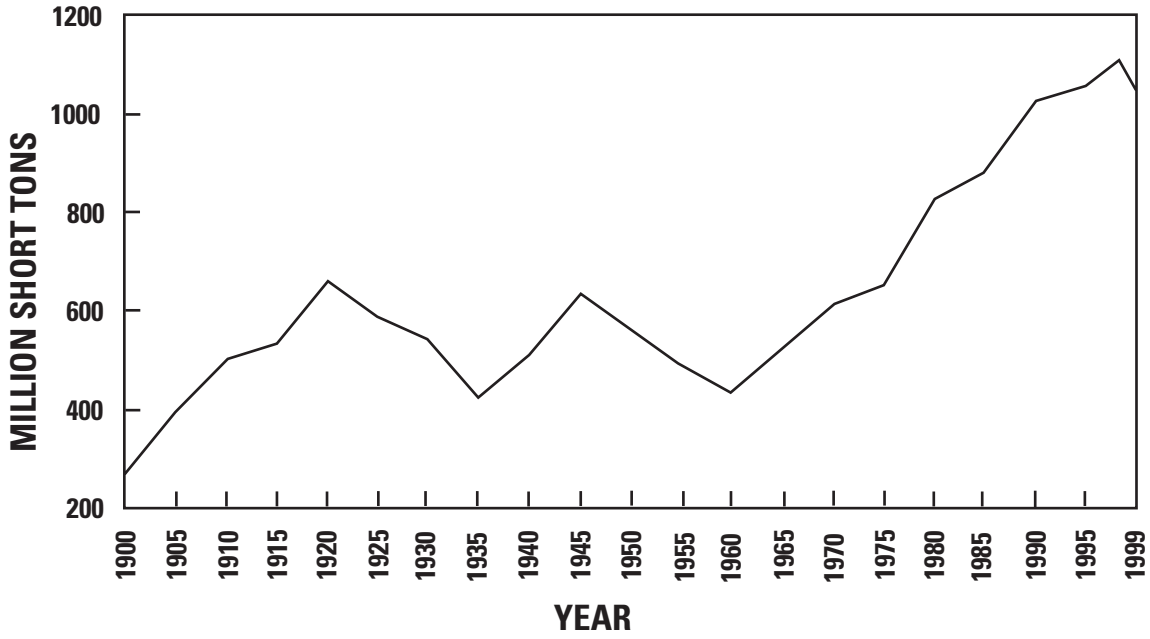

Figure 1. Graph showing trends in U.S. coal production from 1900 to 1999. The rapid growth in production after 1960 is attributed to (1) abundant reserves, (2) high productivity resulting in favorable prices for coal, and (3) the large increase in demand for electricity. Data from Energy Information Administration (2000).

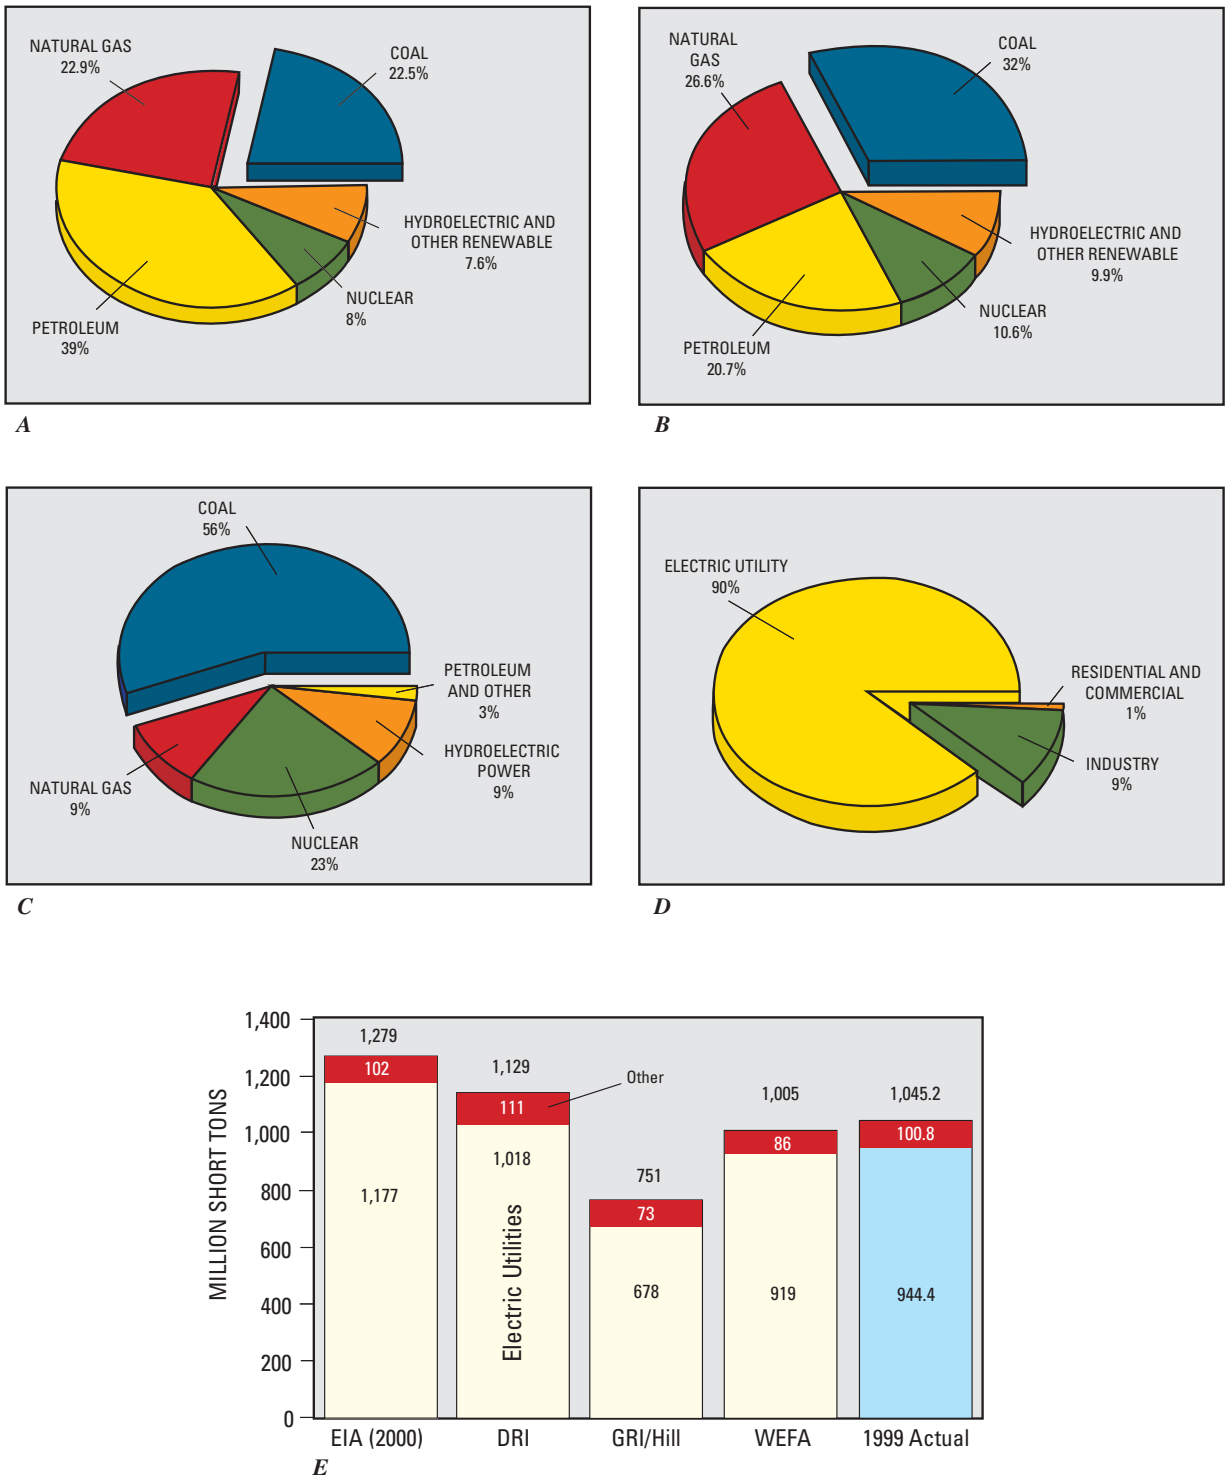

Figure 2. Diagrams showing energy consumption and production in the U.S. ***A***, Energy consumption in 1999. Of the various commodities consumed, approximately 54 percent of the oil and 16 percent of the natural gas are imported; the coal and other commodities are almost entirely domestic. ***B***, Energy production in 1999. ***C***, Electricity generated in 1999, by all commodities. ***D***, Coal consumption in 1999 by the economic sectors shown. ***E***, Forecasted coal consumption for 2020 by electric utilities (yellow) and other uses (red). The basis for comparison of commodities in diagrams *A*, *B*, and *C* is quadrillion Btu, or "quads." Total quads produced and consumed in 1999, were, respectively, 72.5 and 96.6. The basis for diagrams *D* and *E* is million short tons. EIA, Energy Information Administration; DRI, Standard & Poor's Data Resources Inc.; GRI/Hill, Gas Research Institute; WEFA, The WEFA Group. Data from Energy Information Administration (1999a, 2000).

Figure 3. Photograph of the Navajo power plant, which is a coal-fired, electric-power-generation plant near Page, Ariz. Photograph by J.C. Willett (U.S. Geological Survey).

According to the Energy Information Administration (2000), approximately 1,099.1 million tons of coal were produced in 1999 (slightly less than in 1998) and 1,045.2 million tons were used domestically (slightly more than in 1998). The differences in production and consumption between 1998 and 1999 were due to a reduction in exports of 20 million tons in 1999. Of the total coal used domestically in 1999, 90 percent (944.4 million tons) was used to fuel electric power plants (fig. 3), which produced 56 percent of the electricity in the U.S. The other 10 percent was used in industrial (coke and heating), residential, and commercial applications (fig. 2).

COAL PRICES

Steady improvements in the efficiency of coal mining in the U.S. have kept coal prices low. In 1998, the average price of a ton of coal at the mine was $17.67; the average price of a ton of coal delivered to electric utilities was $25.64 (Energy Information Administration, 2000). Prices in 1986 of $23.99 and $33.30 per ton, respectively, demonstrate this trend. Furthermore, over the last decade, coal has been the least expensive of the three main fuel sources—coal, natural gas, and petroleum—in the U.S. On the basis of a common unit of heat (million Btu) over the ten-year period, coal prices averaged about $0.91 at the mine; natural gas averaged $1.72 at the wellhead; and crude oil averaged $2.70 at the domestic first point of purchase (Energy Information Administration, 2000). Lower prices probably encourage continued high and (probably) increasing levels of coal use in the U.S.

In 1999, the Energy Information Administration (EIA) forecasted that, by the year 2020, average coal prices would decrease further to approximately $20.01 per ton delivered to electric power plants (in 1998 dollars). Coal production is forecast by the EIA (fig. 2) to grow to approximately 1,300 million tons by 2020, of which domestic use will account for 1,279 million tons; of that amount, 1,177 million tons will be used by electric power plants. These figures indicate a rate of growth of approximately one percent per year for both coal production and power plant use. Other domestic uses of coal are forecast by the EIA to remain about the same by 2020 (Energy Information Administration, 2000).

COAL SUPPLY

Although coal deposits are widely distributed throughout the U.S., the bulk of coal mining and consumption remained, until recently, in the eastern part of the country, mostly in the Appalachian basin. This was due to the concentration of population and industry in the East. Coal production recently has been moving to the Western States because the bulk of the remaining resources of low-sulfur coal are located in the Rocky Mountains and northern Great Plains regions. The demand for low-sulfur coal is based on the Clean Air Act Amendments of 1990, which began implementation in 2000. The new regulations limit SO_x emissions from coal-fired power plants to 1.2 lbs per million Btu. Power-plant managers are finding that converting their coal supplies from medium- and high-sulfur coal to low-sulfur coal, rather than installing flue-gas desulfurization (FGD) systems, generally is the least expensive option for achieving the required level of SO_x emissions (U.S. Geological Survey, 2000). There are reserves of low-sulfur coal remaining in the Appalachian basin, but most of the remaining reserves occur at depths requiring costlier underground mining methods to recover them.

Whether or not substantially more coal is used in the future than presently, coal is abundant enough in the U.S. to supply anticipated requirements for much of the 21st century. In 1999, the National Mining Association (NMA) reported that 30 of the largest coal companies in the U.S. have

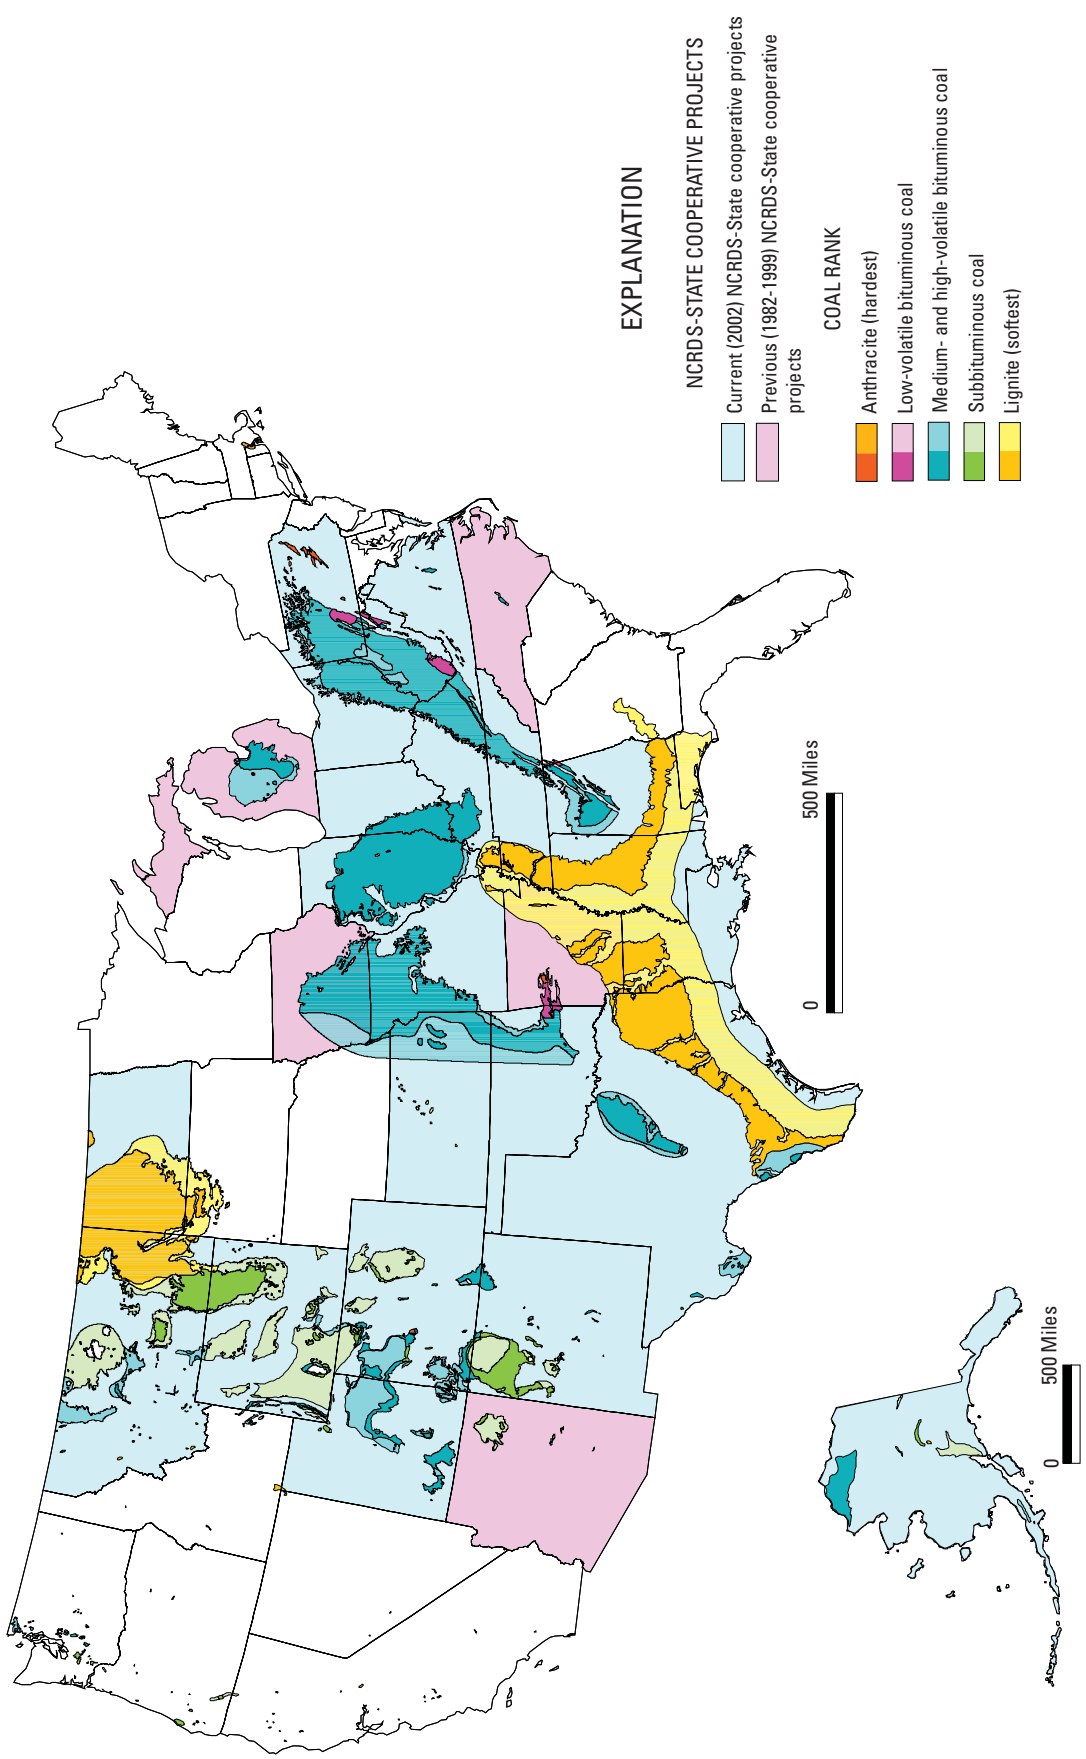

Figure 4. Map showing coal fields of the U.S. classified by coal rank and areas of cooperative study of coal resources and quality. For each category of coal rank, darker color indicates area of coal outcroppings and lighter color indicates area of subsurface coal. Also shown are States with long-term, current (light blue) or previous (light pink) cooperative relationships with the U.S. Geological Survey in the National Coal Resources Data System (NCRDS) for the long-term study of coal resources and quality. Modified from Tully (1996) and M.D. Carter (U.S. Geological Survey, written commun., 2002). (Some States contain coal fields that are too small to show rank colors.)

approximately 68 billion tons of coal in reserve (National Mining Association, 1999). In addition, numerous small coal-mining companies have reserves that are not included in the NMA's report, and there are additional coal deposits that could be mined, when and if needed.

In order to estimate the abundance of coal in beds and zones that will provide the largest percentage of the Nation's domestic energy production for the next 50 years, the USGS, in cooperation with the geological surveys of the major coal-producing States (Arizona, Colorado, Illinois, Indiana, Kentucky, Maryland, Missouri, Montana, New Mexico, North Dakota, Ohio, Pennsylvania, Tennessee, Texas, Utah, Virginia, West Virginia, and Wyoming) is in the midst of a basinwide reassessment of the coal resources of the U.S. (U.S. Geological Survey, 1996, 2000). Figure 4 shows the general distribution of coal deposits in the U.S. Results of the assessment for the Northern Rocky Mountains and Great Plains region, which includes selected coal beds of the Greater Green River, Hanna-Carbon, Powder River, and Williston basins; the Colorado Plateau; and the northern and central Appalachian Basin coal regions are available in CD-ROM format (Fort Union Coal Assessment Team, 1999; Kirschbaum and others, 2000; Northern and Central Appalachian Basin Coal Regions Assessment Team, 2001).

The USGS also is leading a cooperative program with some of the same States to assess the actual availability and recoverability of coal in areas smaller than basins. This study takes into account the many restrictions on mining imposed by environmental and land-use regulations and by the physical constraints based on geology and mining practices (Eggleston and others, 1990). For additional information on coal resources, please see the "Coal Resources" subsection of the "Further Reading" section.

COAL BYPRODUCTS

Coal—that black, dusty rock that evokes punishment of bad children at holiday times—is actually a very remarkable and rewarding material. In addition to providing heat to generate electricity (which is currently the primary use of coal), a myriad of other beneficial substances are derived from coal. Perhaps the best known of these substances is coke, which is used in the steel industry to separate iron from its ore. Coal is used in the production of other, perhaps unexpected products such as pharmaceuticals, textile dyes, food and wood preservatives, and other simple or highly complex chemicals (see centerfold). These chemicals typically are produced during the production of coke by a process called destructive distillation. In this process, coal is packed into a closed, oxygen-restricted container (retort, or coke oven) and then heated to a high temperature. This process drives off the volatile matter in the coal. The volatile matter contains the parent compounds that are used to produce the products shown in the centerfold. The lack of oxygen in the retort prevents the chemicals from completely burning.

In the past, large quantities of an impure gas containing methane and carbon monoxide (called town gas or water gas) were derived from coal in the U.S. and elsewhere. Water gas was used for heating and cooking, but has been replaced largely by natural gas in the U.S. since the 1940s. In other parts of the world, notably in Germany during World War II and in South Africa today, gasoline and heating oil have been derived from coal. Currently, research is being conducted in the U.S. to improve the techniques and economics of producing both gas and oil (called "synfuels") from coal. This work is sponsored by the U.S. Department of Energy and involves numerous private, industrial, and academic organizations (U.S. Department of Energy, 2000).

Coal is more than just a fuel source; it contains complex tars, oils, and gases that can be broken down into many useful products such as dyes,

Coal combustion products (CCPs), consisting of fly ash, bottom ash, boiler slag, and flue-gas-desulfurization (FGD) material, also have become important in the economy. As coal burns, it emits sulfur in the form of sulfur oxide. FGD is the process by which a chemical, such as calcium carbonate ($CaCO_3$), is injected into the flue-gas stream to trap the sulfur by combining with it to produce gypsum ($CaSO_4$). Gypsum is heavy and falls to the bottom of the FGD unit as sludge in a wet process, or as a powder in a dry process.

According to the USGS (Kalyoncu, 1999), approximately 57.2 million tons of fly ash, 15.2 million tons of bottom ash, 2.7 million tons of boiler slag, and 22.7 million tons of FGD material were produced in 1998. The amounts of each CCP that were used in 1998 were (in percent) 33.6, 31.3, 80.1, and 10, respectively; the rest was disposed of in landfills, settling ponds, or by other means. Coal fly ash is used mainly as an additive in concrete; fly ash may also be used as structural fill, as road base material, in waste stabilization, or in mining applications. Bottom ash is used mainly as road base and structural fill material as well as in concrete and as grit for snow and ice control. Boiler slag is used mostly in blasting grit and roofing granules. FGD gypsum is used mainly in wallboard, with small amounts being used in concrete and agricultural applications. Figure 5 shows photographs of examples of some uses for fly ash and FGD gypsum.

There are other, perhaps less well known products that can be derived from coal. For example, sulfur oxides can be captured from flue gas and used to make sulfuric acid,

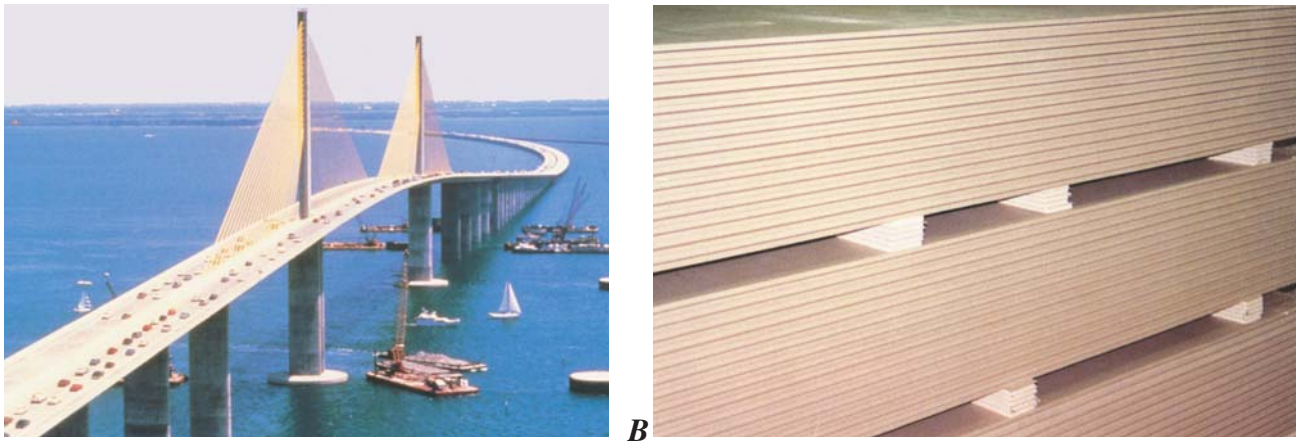

Figure 5. Photographs showing examples of the uses for coal combustion byproducts. ***A***, Fly-ash concrete was used in the decking and piers of the Sunshine Skyway bridge over Tampa Bay in Florida. ***B***, The gypsum produced by wet scrubbers was used in the manufacture of high-quality wallboard. Photographs from American Coal Ash Association (1998), used with permission.

Figure 6. Photograph of the Okefenokee Swamp, Ga., which is a modern peat-forming swamp. Modern swamps are studied as possible analogs of ancient environments in which coal beds formed. The tall trees are mostly bald cypress with some bay and black gum, the foreground is mostly sedge and reed-like plants, and the open-water areas contain water lilies. Common characteristics that modern swamps share with ancient swamps include low topography, fresh water, and varying climate. Photograph by W.H. Orem (U.S. Geological Survey).

which is an important industrial raw material. Other valuable elements, such as mercury and chlorine, also can be recovered from flue gas (Finkelman and Brown, 1991).

WHAT IS COAL?

ORIGINS

Coal begins as peat, which consists of loosely consolidated layers of various mixtures of plant and mineral matter. Peat accumulates in wetlands called "peat swamps," "bogs," or "mires." In this report, the term "peat swamp" is used to indicate a peat-forming wetland. Figure 6 is a photograph of the Okefenokee Swamp, which is a modern swamp where peat is forming. Peat swamps are wetlands that have the appropriate conditions for peat accumulation, such as abundant moisture, a stable to slowly sinking land surface, and protection from rapidly eroding forces such as rivers and ocean waves.

Over millions of years, burial, compression by overlying inorganic sediments, and the effects of heat (from depth in the earth or proximity to volcanic sources) cause peat to change to coal (fig. 7). The resultant coal is an extremely complex, mostly organic, generally well bedded sedimenta-

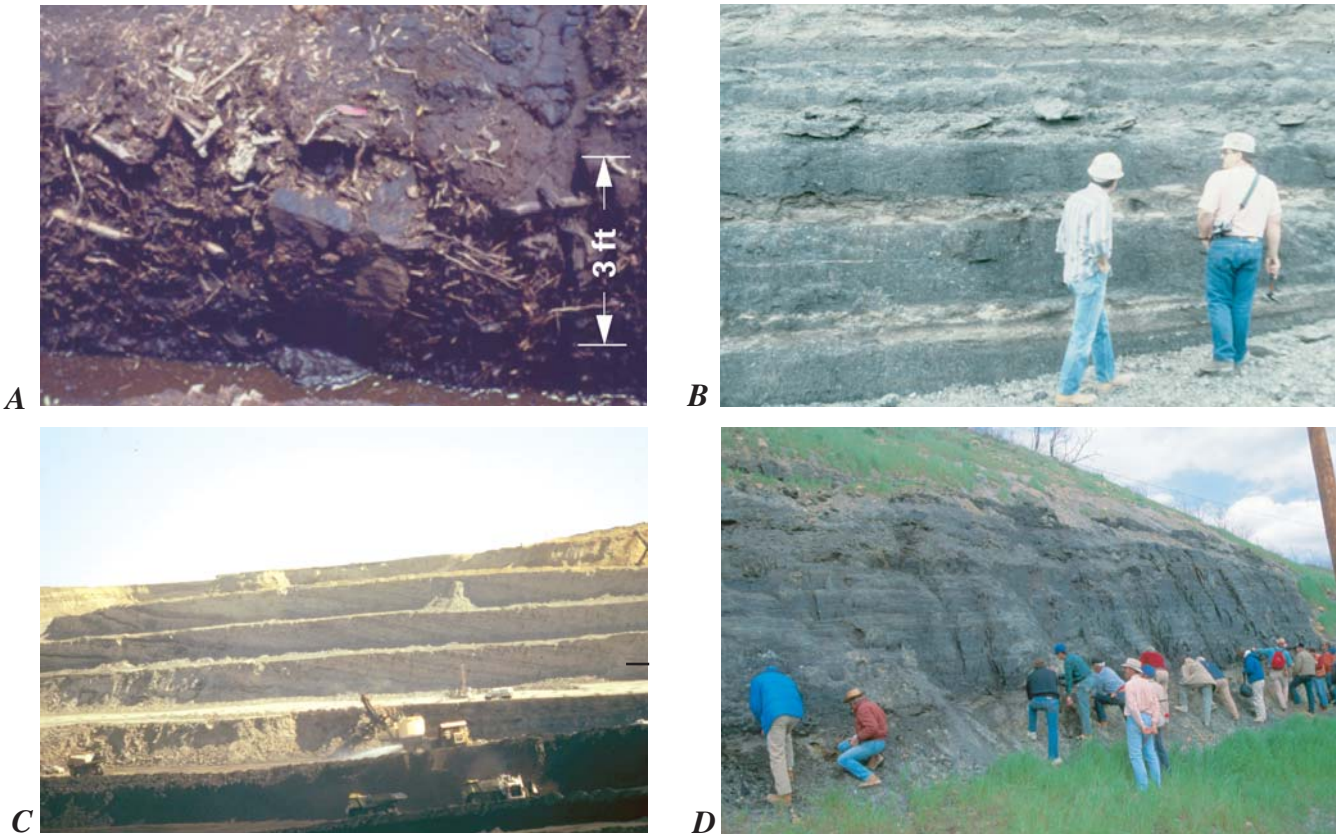

Figure 7. Photographs showing examples of peat and coal beds. ***A***, Peat bed in Indonesia. The face is approximately 3 ft high. Note heterogeneous plant material in a finer groundmass of peat. At this location, the peat bed is approximately 20 ft thick and 5,000 yrs old at the base. Photograph by S.G. Neuzil (U.S. Geological Survey). ***B***, San Miguel lignite beds of Eocene age in a coal strip mine in Texas. The individual beds of lignite (dark) are interspersed with beds of volcanic ash (lighter). The original peat has been compressed into a relatively homogeneous, evenly bedded material, but it still has a dull luster. Photograph by P.D. Warwick (U.S. Geological Survey). ***C***, Subbituminous coal strip mine in the Paleocene Anderson-Wyodak coal zone, Powder River basin, Wyoming. This bed is approximately 100 ft thick at this location, and is divided into two 50-ft-thick sections by the light-colored sedimentary rock parting above the power shovel. Photograph by P.D. Warwick (U.S. Geological Survey). ***D***, Roadcut exposing the bituminous Pennsylvanian Pittsburgh coal bed, near Morgantown, W. Va. The normal lustrous, black appearance of this coal has been dulled by exposure to the weather. Photograph by C.B. Cecil (U.S. Geological Survey).

ry rock. To be classified as coal, the rock must contain less than 50 percent ash-forming mineral matter. If it contains between 30 and 50 percent mineral matter, it is classified as impure coal.

In the U.S., individual coal beds may be as thin as a few inches or (rarely) as thick as 200 ft and may cover areas as small as a few square yards or as large as several counties or even States; for example, the Pittsburgh coal bed extends over all or parts of 25 counties in the area where Ohio, Pennsylvania, and West Virginia join (see fig. 4). Figure 8 shows two examples from the Powder River basin in Wyoming of peat deposits in relation to laterally and vertically bounding sediments deposited by rivers. The deposits were subsequently buried and coverted to lignite and coal.

COMPOSITION

Coal is composed of complex mixtures of organic and inorganic compounds. The organic compounds, inherited from the plants that live and die in the swamps, number in the millions. The approximately more than 120 inorganic compounds in coal either were introduced into the swamp from waterborne or windborne sediment, or were derived from elements in the original vegetation; for instance, inorganic compounds containing such elements as iron and zinc are needed by plants for healthy growth. After the plants decompose, the inorganic compounds remain in the resulting peat. Some of those elements combine to form discrete

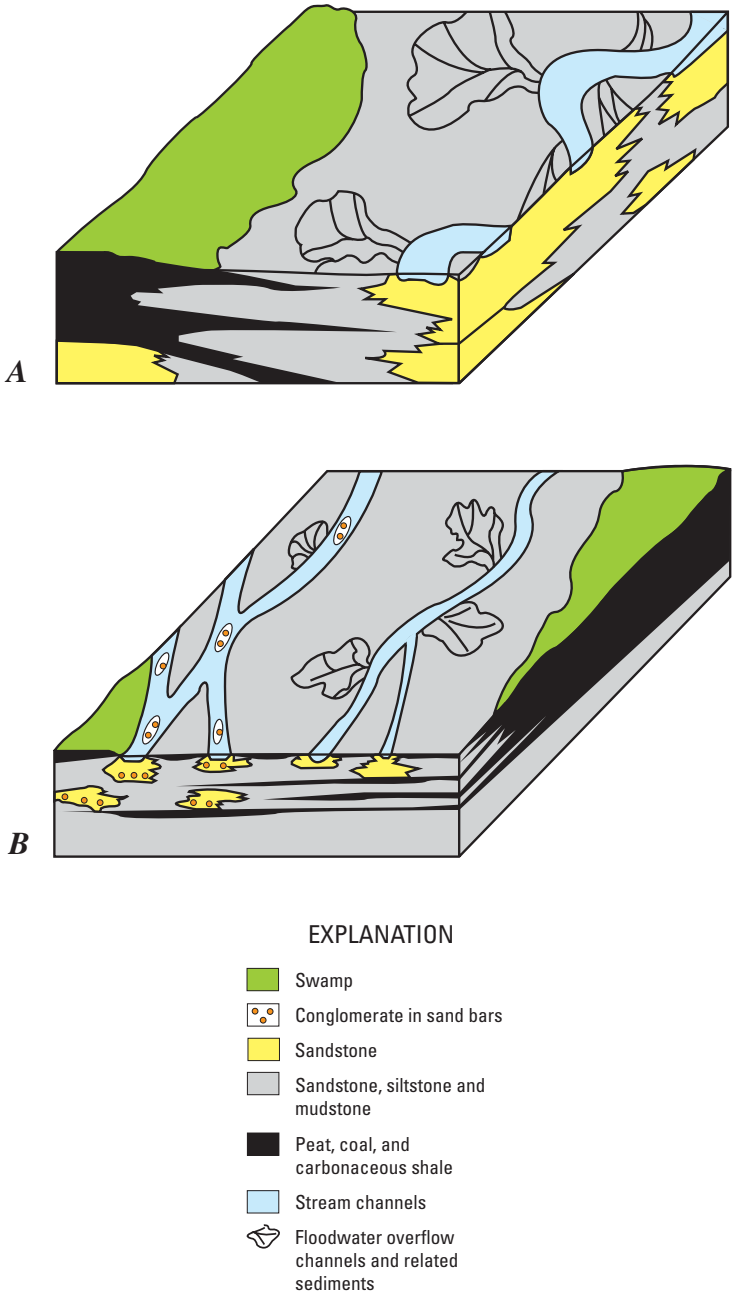

Figure 8. Block-diagram models illustrating some of the peat-sediment-climate relationships possible in the process of peat development and burial. These models explain the environments of deposition for two large coal deposits of Paleocene age in the Powder River basin of Wyoming. No specific scale implied, but the blocks represent general areas of approximately 9 to 25 mi^2, and depths of approximately 50 to 100 ft. ***A***, Decker-Tongue River area. This peat deposit developed continuously in the same place because low areas, formed by faulting or compaction of underlying sediments, may have restricted the location of a meandering stream to the edge of the peat deposit. Also, the river system may have had a somewhat restricted sediment supply, or the river system may not have been vigorous enough to invade the peat swamp except at the margin. The climate probably was wet most of the year because the peat surface in the model is shown to be higher than the surface of the stream valley. A wet climate promotes vigorous plant growth on top of the peat, which holds water like a sponge, allowing the peat to pile up above the surrounding area. The result is a large, thick, clean, coal deposit. ***B***, Kaycee-Linch area. In this case, the river system apparently had a coarser and more abundant sediment supply and was more vigorous than in part *A*, as shown by the conglomerate bars in some of the stream channels, which are a sign of stronger current flow. This river system was able to move back and forth across the peat swamps, limiting the resulting deposits, in part, to thin, discontinuous beds. This environment appears also to have been wet, but a better supply of sediment and stronger stream flows limited peat preservation. Modified from Flores and others (1989), used with permission of the American Geophysical Union.

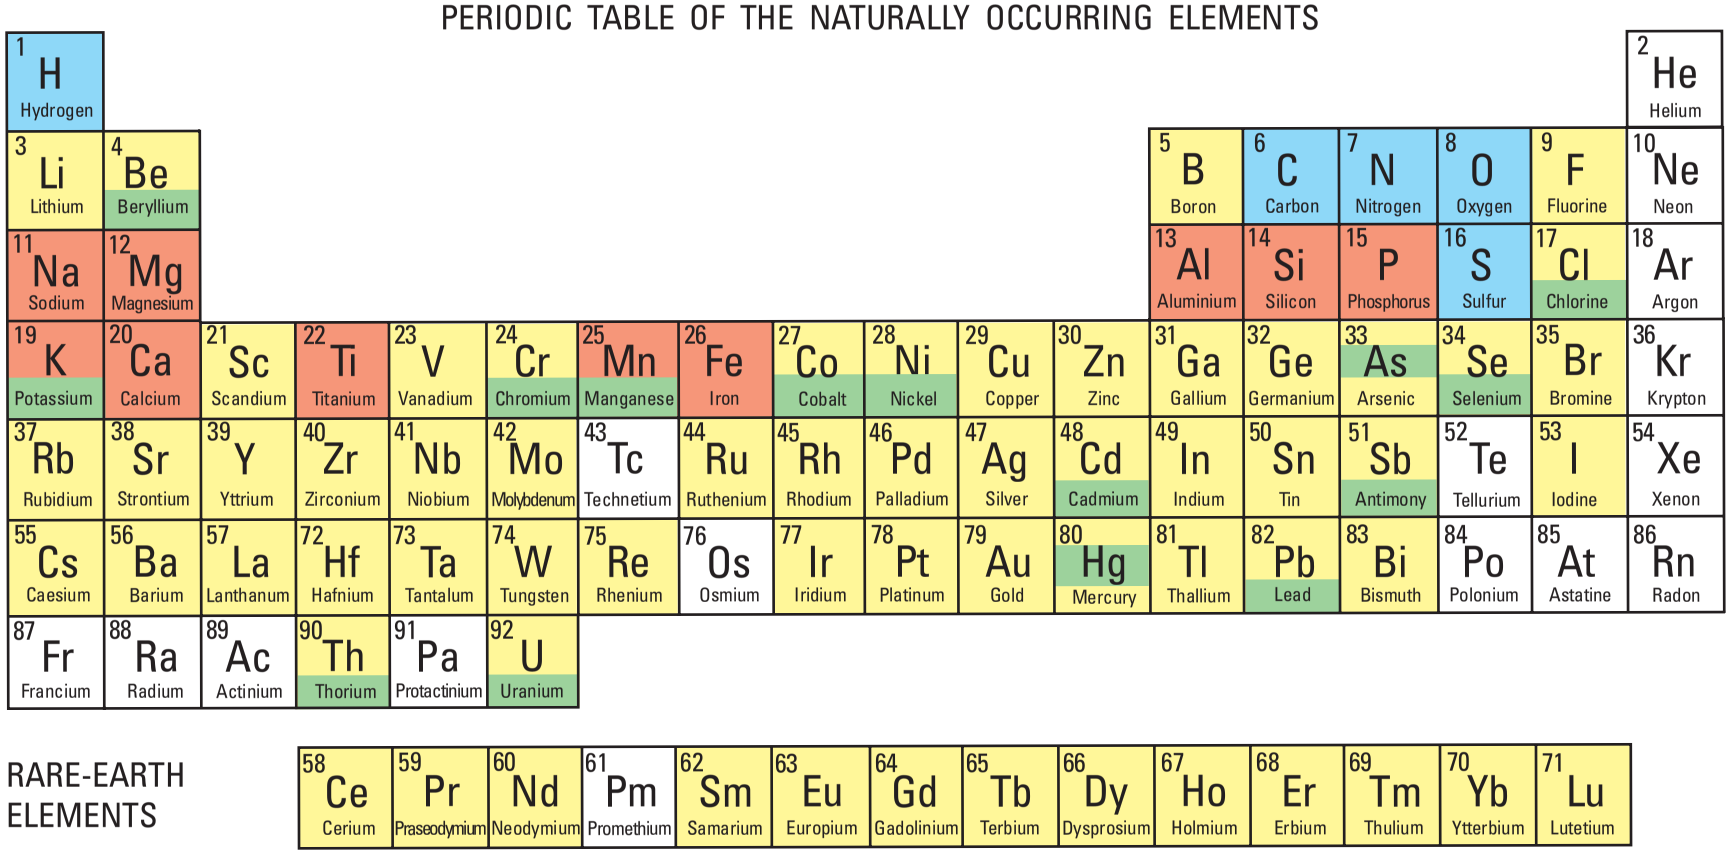

Figure 9. Periodic table of the elements. The 76 elements found in coal are highlighted by colors with regard to their general abundance in coal, as follows: blue, major elements (generally greater than 1.0 percent in abundance); red, minor elements (generally greater than or equal to 0.01 percent); and yellow, trace elements (generally less than 0.001 percent). Pursuant to the Clean Air Act Amendments of 1990 (Public Law 101-549), the U.S. Environmental Protection Agency (EPA) studied fifteen of these elements as potentially hazardous air pollutants (HAPs); green bars in their boxes indicate those fifteen elements. Thirteen of the original were cleared when the EPA found that there was no compelling evidence that they cause human health problems; a green bar across the bottom of the box indicates those elements. Two elements from the original fifteen, mercury (Hg) and arsenic (As), indicated by a green bar across the centers of their boxes, are still under study—mercury as a HAP and arsenic as a potential pollutant in ground water that flows through fly-ash and coal-mine spoil piles. Subsequently, in December 2000, EPA found that mercury emissions from coal-fired power plants require regulation; EPA will propose regulations in 2003 and issue final rules in 2004. Modified from Periodic Table of the Elements (Sargent-Welch Scientific Company, 1979), used with permission.

Table 1. Common minerals found in coal and their elemental compositions.

[Although more then 120 different minerals have been identified in coal samples, only about 33 of these occur in most coal samples; of these, only about 8 generally are abundant enough to be considered as major constituents. Data from R.B. Finkelman (U.S. Geological Survey, written commun., 2000).]

Mineral name	Chemical composition	Remarks
	Major Mineral Constituents (In general order of abundance)	
Quartz	SiO_2	
Clay Minerals:		
Kaolinite	$Al_2Si_2O_5(OH)_4$	
Illite	$KAl_4(AlSi_7O_{20})(OH)_4$	
Montmorillonite	$(\frac{1}{2}Ca,Na)_{0.7}(Al,Mg,Fe)_4[(Si,Al)_4O_{10}]_2(OH)_4 \cdot nH_2O$	
Chlorite	$(Mg,Al,Fe)_{12}[(Si,Al)_8O_{20}](OH)_{16}$	May have Mn. (Clays may also contain Be, Cr, Ni, and other trace elements.)
Pyrite	FeS_2	May contain As, Cd, Co, Hg, Ni, Sb, and Se.
Calcite	$CaCO_3$	
Siderite	$FeCO_3$	May contain Mn.
	Minor Mineral Constituents	
Analcime	$NaAlSi_2O_6 \cdot H_2O$	
Apatite	$Ca_5(PO_4)_3(OH,F,Cl)$	
Barite	$BaSO_4$	
Chalcopyrite	$CuFeS_2$	
Clausthalite	PbSe	
Crandallite Group		
Crandallite	$CaAl_3(PO_4)_2(OH)_5 \cdot H_2O$	
Florencite	$CeAl_3(PO_4)_2(OH)_6$	
Gorceixite	$BaAl_3(PO_4)_2(OH)_5 \cdot H_2O$	
Goyazite	$SrAl_3(PO_4)_2(OH)_5 \cdot H_2O$	
Dolomite	$CaMg(CO_3)_2$	
Feldspars	$(Ca,K,Na)AlSi_3O_8$	
Galena	PbS	
Marcasite	FeS_2	May contain same elements as pyrite.
Monazite	$(Ce,La,Y,Th,Nd)PO_4$	
Rutile/Anatase	TiO_2	
Sphalerite	ZnS	May contain Cd.
Xenotime	YPO_4	
Zircon	$Zr[SiO_4]$	
	Trace Mineral Constituents	
Chromite	$FeCr_2O_4$	
Gibbsite	$Al(OH)_3$	
Gold	Au	
Gypsum	$CaSO_4 \cdot 2H_2O$	
Halite	NaCl	
Magnetite	Fe_3O_4	
Muscovite	$KAl_2(AlSi_3O_{10})(OH)_2$	

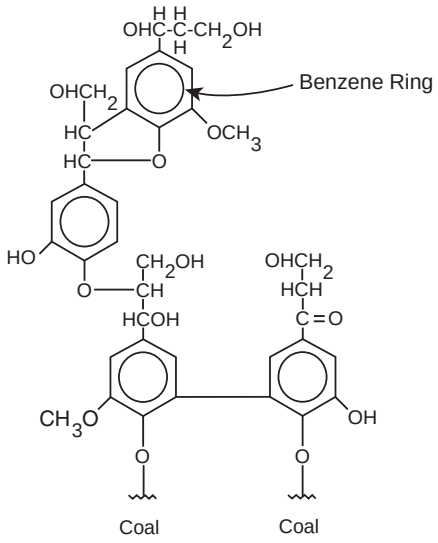

Figure 10. Diagram showing hypothetical structure of a lignin-derived organic molecule in a brown coal (lignite). This structure is based on studies using carbon-13 nuclear-magnetic-resonance (^{13}C NMR) spectroscopy and other organic-geochemical methods such as those described in table 2. Lignin is one of the constituents of woody tissue found in all vascular plants, such as trees and shrubs (W.H. Orem, U.S. Geological Survey, written commun., 1997). Studying organic matter helps provide information about the plant sources of coal and, subsequently, coal quality. See figure 9 for chemical elements.

minerals, such as pyrite. Other sources of inorganic compounds used by the plants may be either the mud that coats the bottom of the swamp, sediments introduced by drainage runoff, dissolved elements in the swamp water, windborne sand, ash, or dust.

Coals may contain as many as 76 of the 92 naturally occurring elements of the periodic table (fig. 9); however, most of those elements usually are present in only trace amounts on the order of parts per million. Occasionally, some trace elements may be concentrated in a specific coal bed, which may make that bed a valuable resource for those elements (such as silver, zinc, or germanium) (Finkelman and Brown, 1991). Some elements, however, have the potential to be hazardous (for example, cadmium or selenium), particularly if they are concentrated in more than trace amounts. Although as many as 120 different minerals have been identified in coal, only about 33 of them commonly are found in coal, and of these, only about 8 (quartz, kaolinite, illite, montmorillonite, chlorite, pyrite, calcite, and siderite) are abundant enough to be considered major constituents (table 1).

The organic compounds in coal are composed of the elements carbon, hydrogen, oxygen, nitrogen, sulfur, and trace amounts of a variety of other elements. Although only a few elements compose the organic compounds found in coal, these compounds are extremely complex and, as a result, they are not well understood; for example, an attempt to define the structure of just one organic compound in a brown coal (lignite) is shown in figure 10, but even this relatively simple structure is based on scientific conjecture. The organic compounds in coal produce heat when coal is burned; they also may be converted to synthetic fuels, or may be used to produce the organic chemicals shown in the centerfold illustration.

The affinities of trace elements for either the organic compounds or the minerals in coal affect the quality of the coal. If trace elements are organically bound, then it is difficult to remove them from the coal by cleaning processes, such as crushing and washing, which remove mineral matter from coal before it is burned. Organically bound trace elements may be released only by burning, or by deep chemical leaching, which is both very difficult and uneconomical. In contrast, trace elements associated with clays or pyrite may be largely removed from the coal by cleaning processes. The trace elements then may be disposed of in an environmentally safe manner or recovered and put to some other use. To date, however, the recovered mineral matter from coal has not been used for very many purposes, with a few major exceptions such as gypsum, the various forms of ash, and a small amount of germanium (used in semiconductors).

Coal may contain as many as 76 of the 92 naturally occurring elements of the periodic table.

MINERALS IN COAL

The most common minerals in coal (for example, illite clay, pyrite, quartz, and calcite) are made up of these most common elements (in rough order of decreasing abundance): oxygen, aluminum, silicon, iron, sulfur, and calcium. These minerals and other less common minerals usually contain the bulk of the trace elements present in coal (table 1). Minerals in coal commonly occur as single crystals or clusters of crystals that are intermixed with organic matter or that fill void spaces in the coal; sizes of mineral grains range from submicroscopic to a few inches. Some clusters of mineral grains, however, such as fracture fillings (fig. 11) or coal balls (fig. 12), may reach sizes that range from fractions of an inch up to several feet across. Coal balls result when mineral matter (such as calcite, pyrite, or siderite) infuses peat before it is compressed. Mineral grains in coal also often occur as discrete particles, such as the blebs of pyrite (framboids), which may be identified in the photomicrographs of coal in figure 13. The more finely divided the mineral grains, the higher the magnification needed to identify them (figs. 13, 14).

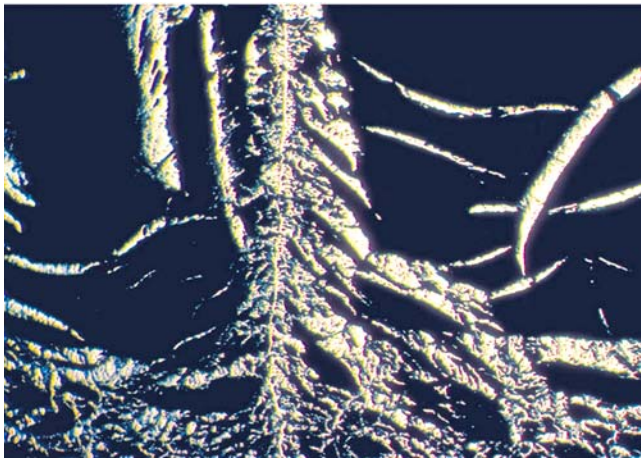

Figure 11. Photomicrograph of pyrite (yellow) filling fractures in the Upper Freeport coal bed in Pennsylvania. Magnification approximately ×4000. From Atlas of Coal Geology, American Association of Petroleum Geologists (AAPG) Studies in Geology No. 45 (Papp and others, 1998); AAPG copyright 1998, reprinted by permission of the AAPG, whose permission is required for further use.

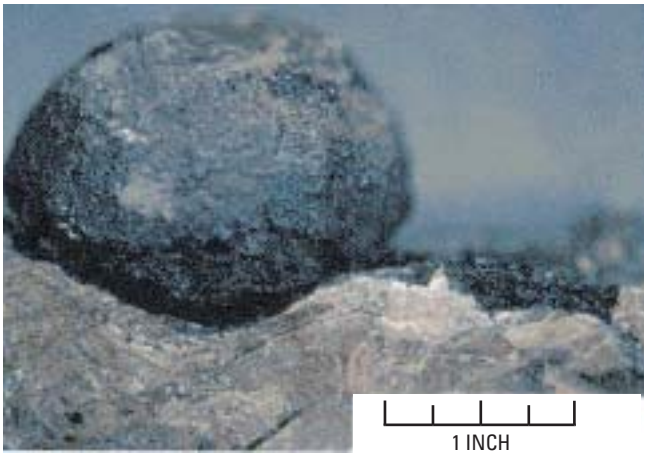

Figure 12. Photograph of small coal ball specimen from the Carbondale Formation, Illinois basin. Coal balls are concretions that occur within coal beds and are composed largely of carbonate minerals and occasionally of pyrite. Modified from a photograph by James Humphrey (Curragh Queensland Mining Ltd., Australia) in Atlas of Coal Geology, American Association of Petroleum Geologists (AAPG) Studies in Geology No. 45 (Papp and others, 1998); AAPG copyright 1998, reprinted by permission of the AAPG, whose permission is required for further use.

Although much is known about the minerals in coal, much remains to be learned about their occurrence, abundance, origin, and composition. For example, the type of clay mineral in a coal, whether montmorillonite or illite, determines how a coal will react when burned. Montmorillonite (table 1) may or may not break down (dissociate) into its constituent parts when coal is burned; if it does dissociate, then, upon cooling, it may recombine with other elements or minerals to form mineral deposits on the inside surfaces of furnaces and boilers (fig. 15). This process (called "slagging" or "fouling") produces barriers to heat exchange in the affected equipment, which can substantially reduce its efficiency and require costly repairs. Illite (table 1), however, with its simpler composition, does not cause such problems under normal furnace operating conditions. Where these two clay minerals and others occur, their relative abundances, relationships to other minerals, and exact compositions are subjects for continued research in coal quality.

The mineral content of coal determines what kind of ash will be produced, which in turn determines the design of a furnace or boiler.

When coal is burned, most of the mineral matter and trace elements generally form ash; however, some minerals break down into gaseous compounds which go out the furnace's flue. Pyrite, for example, breaks down into the individual elements iron and sulfur. Each element then combines with oxygen to become, respectively, iron oxide and SO_x. Iron oxide, a heavy solid, becomes part of the ash and SO_x, a gas, is emitted as part of the flue gas. Some trace elements also dissociate from their organic or mineral hosts when coal is burned and follow separate paths. Most become part of the ash, but a few of the more volatile elements, such as mercury and selenium, may be emitted in the flue gas.

The mineral content of coal determines what kind of ash will be produced when it is burned. The fusion temperature (melting point) of the ash dictates the design of furnaces and boilers. In general, if the fusion temperature is relatively low, then the molten ash is collected at the bottom of the furnace as bottom ash, requiring one design; however, if the fusion temperature is relatively high, then the part of the ash that doesn't melt easily, called "fly ash," is blown through the furnace or boiler with the flue gas and is collected in giant filter bags, or electrostatic precipitators, at the bottom of the flue stack, requiring a different design. Coals that are relatively rich in iron-bearing minerals (such as pyrite or siderite) have low fusion temperatures while coals relatively rich in aluminum-bearing minerals (such as kaolinite or illite) tend to have high fusion temperatures. If an electric generating or heating plant is designed to burn one type of coal, then it must continue to be supplied with a similar coal or undergo an extensive and costly redesign in order to adapt to a different type of coal. Similarly, furnaces designed to use coal that produces high amounts of heat will suffer severe losses in efficiency if they must accept coal that burns with substantially less heat.

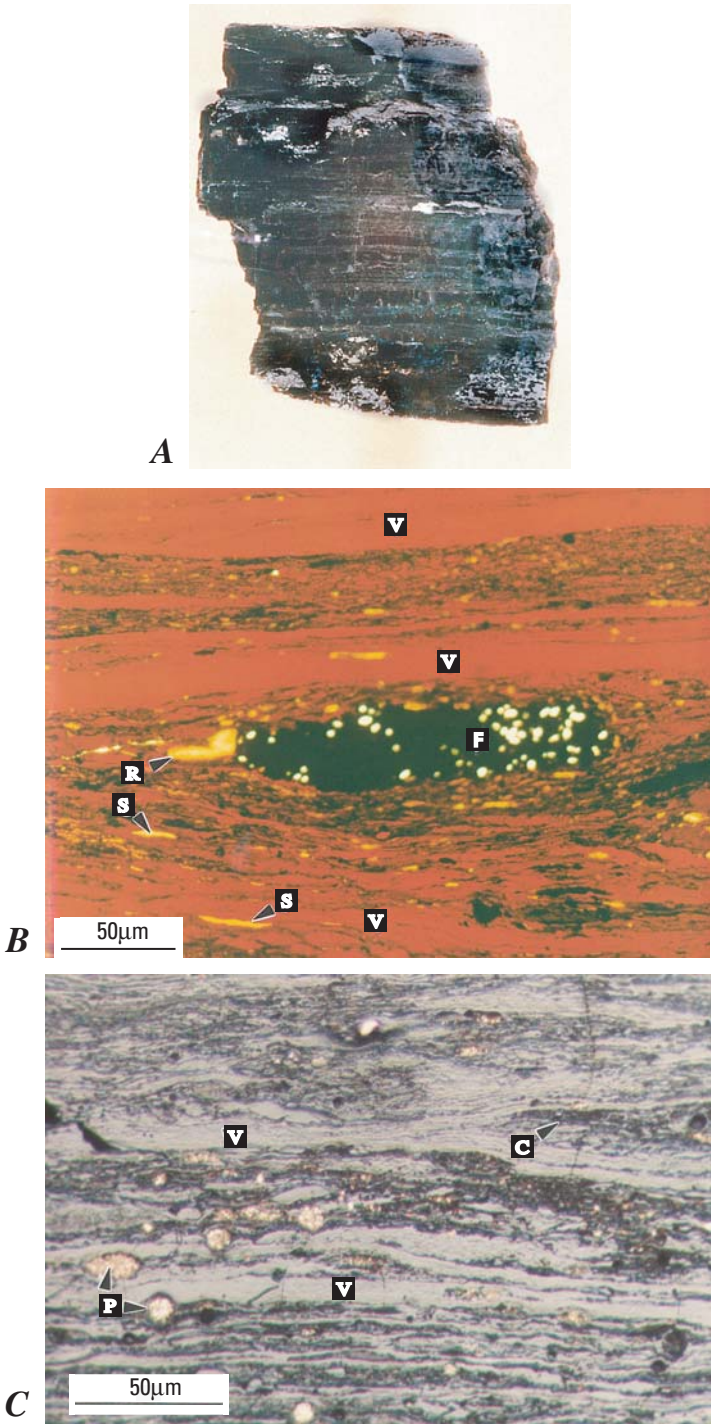

Figure 13. Photograph and photomicrographs of Pennsylvanian bituminous coal. ***A***, Photograph of a lump of bituminous coal from Pennsylvania showing typical banding caused by layering of a variety of preserved plant types as they accumulated in an ancestral peat swamp. Magnification ×0.55. ***B***, Photomicrograph of a thin section of a small piece of bituminous coal from Illinois photographed in transmitted light. Magnification approximately ×330. ***C***, Photomicrograph of a polished surface of a small piece of bituminous coal from Pennsylvania photographed in reflected light. Magnification approximately ×250. Parts *B* and *C* show some typical constituents—macerals (plant remains) and minerals—found in bituminous coals. Macerals are abbreviated as follows: V, vitrinite; F, fusinite; S, sporinite; and R, resinite. Minerals are abbreviated as follows: P, pyrite; and C, clay-sized minerals. The scale bar on parts *B* and *C* is 50 micrometers, which is equivalent to about 0.002 inch. The lump of bituminous coal is included to provide a comparison between what can be seen in a lump of coal and the wealth of detail in coal that can be seen with high magnification. The lump of coal is approximately 260 times larger than the chips of coal represented by either of the photomicrographs. Photographs and photomicrographs by R.W. Stanton (U.S. Geological Survey).

Tubes are about 1.75 inches in diameter. ***B***, Ash deposit removed from steam tubes in a coal-fired boiler at an AmerenUE plant using subbituminous coal from the Powder River Basin, Wyoming. The plant was originally designed to use bituminous coal. Ash fragment is approximately 12 inches long by 5 inches wide by 3 inches tall at its tallest point. This deposit was removed by explosive cleaning. Photographs by C.J. Zygarlicke (University of North Dakota Energy and Environmental Research Center, Grand Forks, N.D.); used with permission of Alliant Energy, Portage, Wisc. (*A*), and AmerenUE, St. Louis, Mo. (*B*).

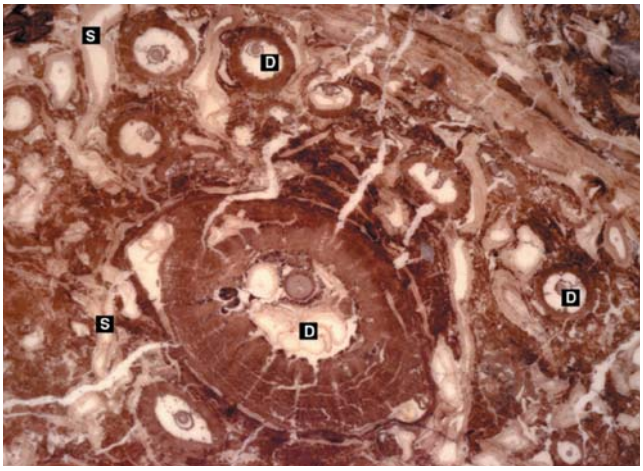

Figure 16. Photograph of a cross section of a calcareous coal ball from the Middle Pennsylvanian Murphysboro coal bed equivalent, Indiana. The coal ball contains permineralized plant material that enables scientists to identify the individual plants and the plant communities (flora) that contributed to the peat, which later became a coal bed. The coal ball contains some identifiable remains of branches and twigs of lycopsid trees (*Diaphorodendron vasculare*), labeled D on the photograph. The structures, labeled S, are sections of lycopsid rootlets, called stigmaria. Compare these structures with the shapes of the macerals in the photomicrographs of coal (fig. 13). Modified from a photograph by W.A. DiMichele (National Museum of Natural History, Smithsonian Institution, Washington, D.C.).

MACERALS

The particles of organic matter in coal, inherited from the remains of plant parts, are called "macerals." Many different types of macerals occur in coal; a few of the more common macerals are identified in the photomicrographs of a bituminous coal from Illinois (fig. 13) The identification of the original plant and its parts (such as bark, roots, spores, or seeds) that produced an individual coal maceral is helpful in determining coal quality. These connections usually are difficult to make because the original plant material has been compressed or altered beyond recognition. Coal balls (fig. 12) result when mineral matter (such as calcite, pyrite, or siderite) infuses peat before it is compressed. Coal balls often contain permineralized plant materials that have maintained their original structures because the mineral matter has prevented compression and degradation of the plants (fig. 16). Coal balls, therefore, can be used as an aid in connecting the degraded, compressed plant matter of a coal bed to the original plants.

Macerals are grouped into three main types: (1) vitrinite, (2) liptinite, and (3) inertinite. Liptinite and inertinite each contain additional maceral subtypes (American Association of Petroleum Geologists, 1998); however, in

this report, just the principal maceral types will be discussed with brief referral to some of the subtypes for illustrative purposes. Vitrinite, which is the most common maceral, results from the coalification of amorphous humic plant material (structureless plant remains). Vitrinite, sometimes called pure coal, is sensitive to heat and becomes denser, tougher, and more vitreous as it is subjected to higher heat levels, either with depth in the earth, or by proximity to an external heat source, such as a volcano. An index of vitrinite reflectance is used by coal scientists to determine the level of heat, or maturity, to which coals and other organic matter, such as petroleum, have been subjected.

Liptinite develops from waxy or oily plant parts such as spores, algae, and resin; the liptinite group contains several subgroups based on these original plant parts—sporinite, alginite, and resinite, respectively. Liptinite macerals are more enriched in hydrogen than either vitrinite or fusinite; liptinite-rich coals produce larger amounts and higher grades of liquid fuel when subjected to destructive distillation than either vitrinite- or fusinite-rich coals. Some coals, called "bog-head" or "cannel" coals consist almost entirely of oil-rich algal and plant spore material. These coals tend to yield large amounts of coal oil (kerosene) when subjected to destructive distillation because the macerals are rich in oily material. However, both cannel and bog-head coals are relatively rare.

Inertinite incorporates a group of common macerals that forms from partially oxidized or burned plant cell walls. Fusinite, or mineral charcoal, is a prominent representative of this group. Mineral charcoal is produced when, occasionally and sometimes seasonally, the surface layers of a peat swamp dry out and some surface peat either slowly oxidizes or catches fire, or some growing plants are partially charred. (The common and naturally occurring fires of the Florida Everglades are modern examples of this process.)

Coals can range in maceral composition from mostly vitrinite to mostly fusinite, depending on the original plant matter and the degree of preservation. Vitrinite-rich coals are shiny black, clean, fractured conchoidally, and often exhibit iridescence (called "peacock coal") on fresh surfaces. Fusinite-rich coals, in contrast, are similar to charcoal and are dull, black, friable, and dusty. For more information on macerals and vitrinite reflectance see the subsection on "Coal Quality" in the "Further Readings" section.

COAL RANK

A major factor in determining coal quality is coal rank. Rank refers to steps in a slow, natural process called "coalification," during which buried plant matter changes into an ever denser, drier, more carbon rich, and harder material. The major coal ranks, from lowest to highest, are lignite (also called "brown coal" in some parts of the world),

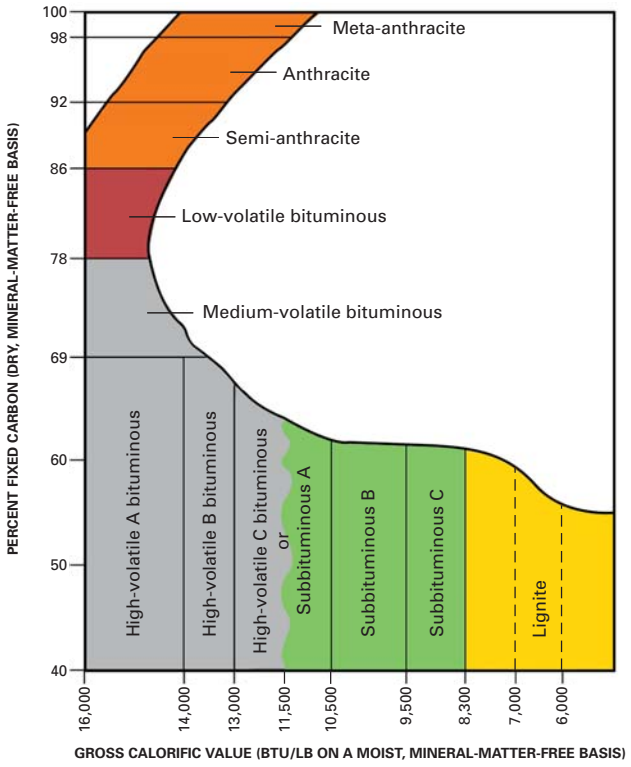

Figure 17. Diagram showing classification of coals by rank in the U.S. Rank is a measure of the progressive alteration in the series from lignite to anthracite. Higher rank coals are generally harder, contain less moisture and volatile matter, and have higher calorific values. Modified from Trumbull (1960). For a more detailed explanation of coal rank determination, see ASTM International (2002).

subbituminous coal, bituminous coal, and anthracite. Each rank may be further subdivided, as shown in figure 17. The rank of coal is determined by the percentage of fixed carbon, moisture (water), volatile matter, and calorific value in British thermal units (Btu) after the sulfur and mineral-matter content have been subtracted. Fixed carbon is solid, combustible matter left in coal after the lighter, volatile, hydrogen-rich compounds are driven off during coalification. Volatile matter is slowly removed from coal during coalification, but may be rapidly removed during destructive distillation. Volatile matter contains the raw materials from which the organic chemicals are obtained. In the U.S., the tests to determine the amounts of the above-mentioned substances and the rank of the coal are performed using standards published by ASTM International (2002).

In general, the higher the rank of a coal, the more deeply it was buried, and, therefore, the higher the temperature it was subjected to during and after burial. Older coals tend to be of higher rank because they are more likely to have been buried more deeply for longer periods of time than younger coals. To give a sense of the effects of increasing rank, the following comparison may be used: lignite is

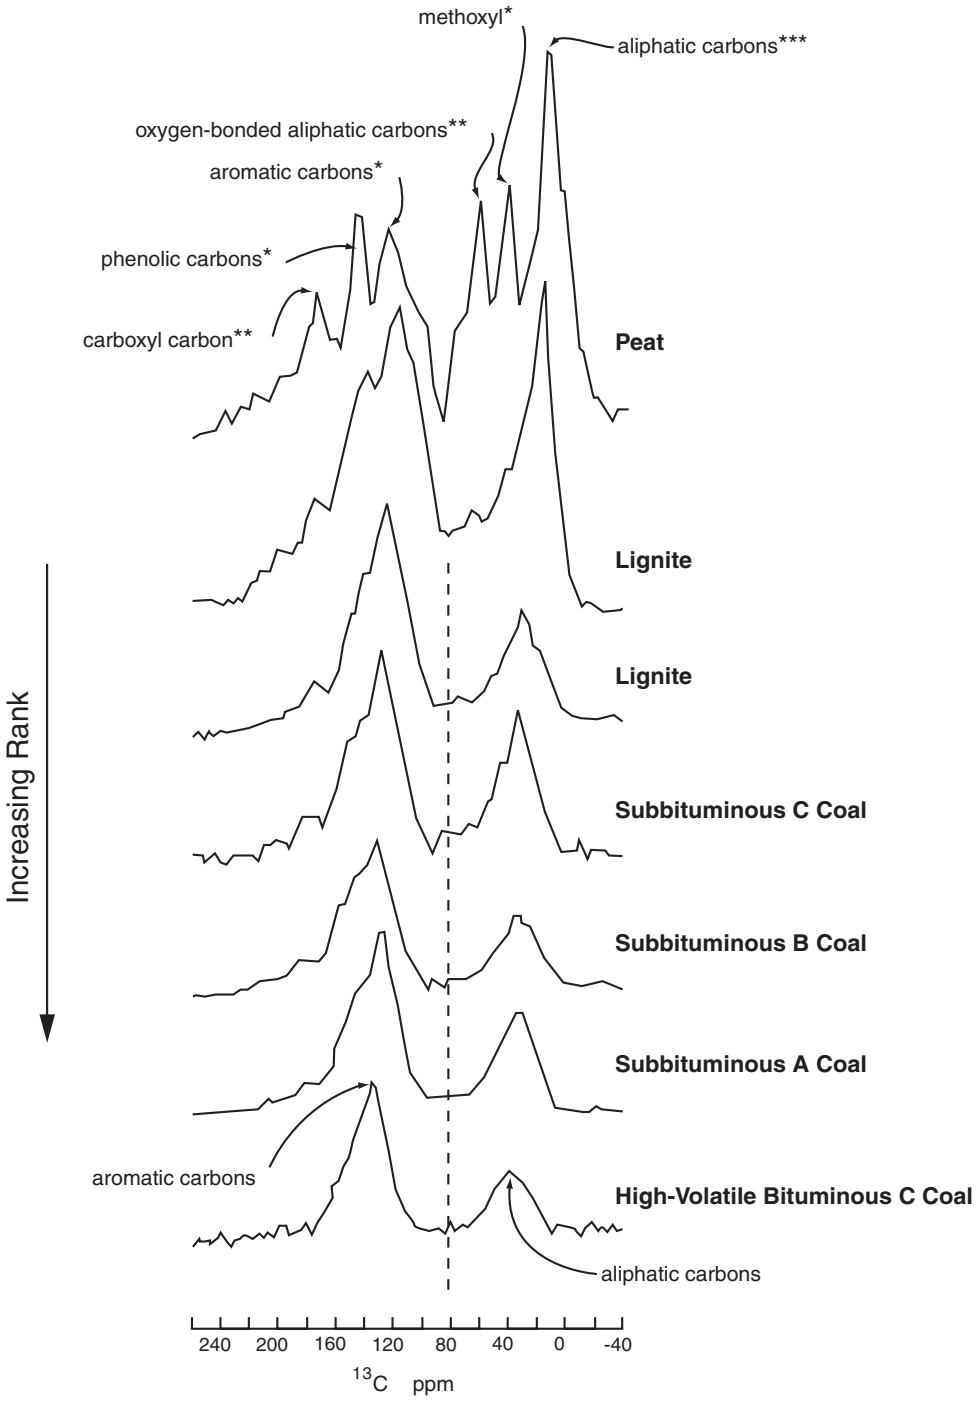

Figure 18. Carbon-13 nuclear-magnetic-resonance (^{13}C NMR) spectra of coals of increasing rank (see figure 17); ^{13}C is a stable isotope of carbon. Diagram shows changes in certain organic compounds brought about by increased coalification. The peaks represent varieties of organic compounds. As rank increases, the variety of compounds decreases and the remaining compounds become structurally tighter and denser. The compounds lost are those that are high in hydrogen and oxygen. Peaks marked with a single asterisk are lignin (woody tissue) indicators; those marked with a double asterisk represent carbohydrates (sugars); and those marked with a triple asterisk represent aliphatic substances (such as waxes and resins). The diagram shows that the carbohydrates are eliminated early in the coalification process, whereas the lignins, waxes, and resins persist to become the principal constituents of higher ranked coals. The scale at the bottom of the figure is a standard ^{13}C NMR scale in ppm (parts per million) representing distance, in frequency units, from a standard, which is assigned a position of zero on the scale. The position of peaks is used to interpret the chemical structure of the substance being analyzed, in this case coal. Data from W.H. Orem (U.S. Geological Survey).

Centerfold. Coal byproducts in tree form showing basic chemicals as branches and derivative substances as twigs and leaves. The basic chemicals may be obtained from coal through heating in a closed container (destructive distillation); the derivatives require additional processing of those basic materials. One ton of bituminous coal roasted in an airtight oven (destructive distillation) produces approximately 1,300 to 1,500 pounds of coke, 8 to 10 gallons of coal tar, 3 gallons of light oil, 5 to 6 pounds of ammonia, and 9,500 to 11,000 cubic feet of gas. Modified from an undated public domain illustration provided by the Virginia Surface Mining and Reclamation Association, Inc. Norton, Va.

Figure 19. Chart showing divisions of geologic time (ages are approximate). Since the Mississippian Period, major coal deposits have formed some place in the world except during the most recent period (Quaternary); how ever, major peat deposits formed (and are still forming) during the Quaternary and it is possible that there may be Quaternary lignite deposits as well. Periods of major coal deposits in the U.S. are shaded.

Figure 20. Photograph of an in-situ fossilized tree base and root system in the roof of an underground coal mine. The coal bed being mined is in the Cretaceous Blackhawk Formation, Wasatch Plateau coal field near Huntington, Utah. Note the radiating root network. Photograph by Alex Papp (ARCO Coal Company, Denver, Colo.) in Atlas of Coal Geology, American Association of Petroleum Geologists (AAPG) Studies in Geology No. 45 (Papp and others, 1998); AAPG copyright 1998, reprinted by permission of the AAPG, whose permission is required for further use.

soft, dusty, and can ignite spontaneously under the appropriate conditions, whereas anthracite is quite hard, clean to the touch, and must reach a temperature of about 925° F before it will ignite. Furthermore, anthracite contains about twice the calorific value of lignite (about 15,000 Btu/lb and 7,000 Btu/lb, respectively) because lignite contains more moisture and oxygen and less fixed carbon than anthracite. Subbituminous and high-volatile bituminous C coals have oxygen and moisture content and calorific values that range between those of lignite and anthracite. Bituminous coals of higher rank have calorific values that may exceed those of anthracite (fig. 17). Figure 18 shows nuclear-magnetic-resonance (^{13}C NMR) spectra of coals of increasing rank, illustrating the changes in the organic structures as coal progresses through stages of increasing rank.

WHY IS COAL SO COMPLEX?

Coal is complex because of the wide variety of factors that determine the quality of coal. These factors include the following: (1) the plants, plant remains, and other organisms (such as bacteria) in the peat swamp; (2) biological and chemical processes, and the degree of preservation of the plant matter; (3) the geometry and location of the swamp; (4) the mineral matter that accumulated with the plant material, or was introduced at some later stage; and (5) coalification. Geologic age and history will be a recurring theme throughout this discussion. Figure 19 shows the times in geologic history when coal beds formed.

THE PLANTS

Coal begins as peat, which forms in swamps having favorable conditions as explained in a previous section entitled “Origins.” These swamps, which are generally filled with standing or slowly moving water, are ideal places for prolific plant growth. When plants fall into the swamp, water covers them and slows or prevents rapid decomposition. Slow decomposition and a quiet environment allow plant matter to accumulate and form peat. The organic matter composing the peat may accumulate in place or, less commonly, may be carried by flowing water to accumulate elsewhere, but generally nearby. Most coal beds were formed from plant material that accumulated in place (fig. 20).

Coal is a complex material formed by a mix of substances and processes. The substances are plant remains and mineral matter. The processes aren’t completely understood, but involve chemical and biological reactions, heat, burial, and time.

Plant communities (flora) in peat swamps may consist of many plant types, or of only a few. Swamp flora have changed substantially through geologic time because of evolution. For instance, lycopsids and tree ferns (fig. 21) are found in older coal beds; more modern forms, such as rushes, water lilies, mangrove, and bald cypress trees (shown in figure 6) may be found in younger coal beds. Flora of the Cretaceous Period (fig. 22) included abundant species that contained relatively more resinous substances than those of the much earlier Pennsylvanian Period. Tertiary plants generally were woodier than those of either the Pennsylvanian or the Cretaceous Periods. In addition, floral communities varied from location to location even within the same time period. These changes in plant species resulted in small changes in nutrient requirements. The result is that geologically younger coals may have different mineral matter compositions than older coals.

BIOLOGICAL AND CHEMICAL PROCESSES

Once plant debris has been deposited in a peat swamp, it is subjected to degradation and decomposition by micro-

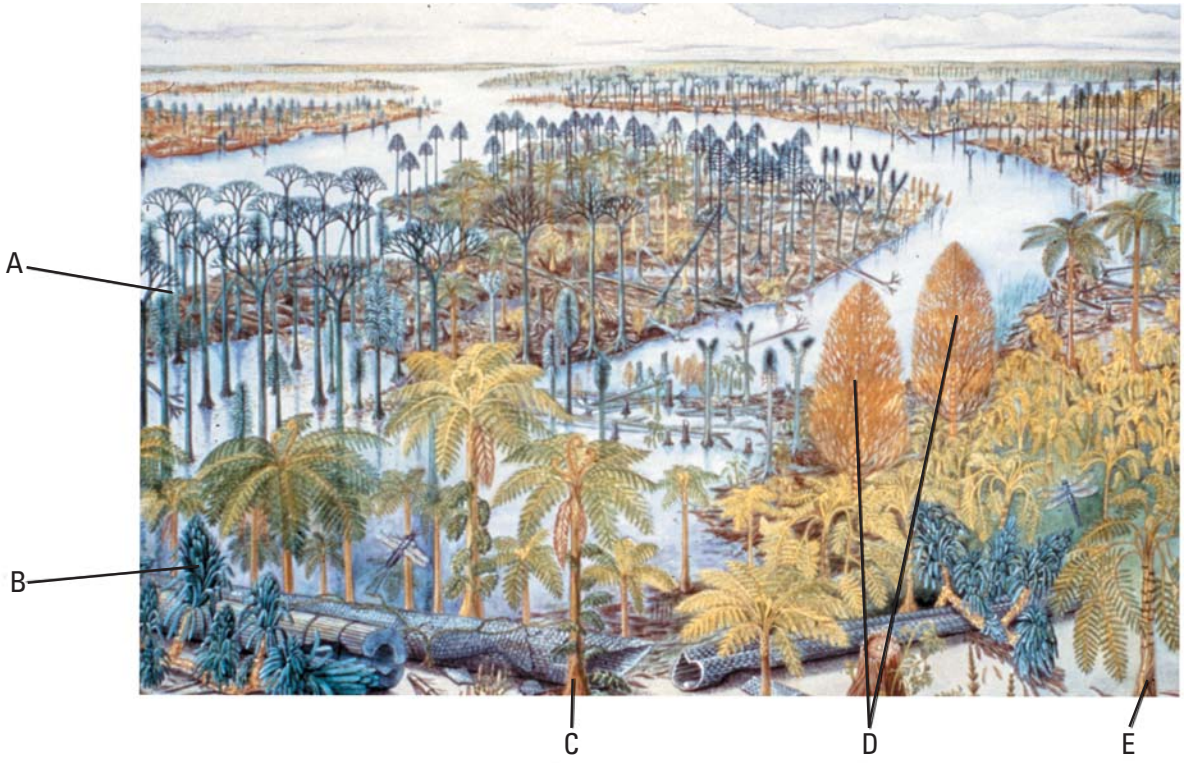

Figure 21. Reconstruction of a tropical peat swamp of Middle Pennsylvanian age (about 300 million years ago). The taller plants (A) were tree lycopsids (Lepidophloios), some of which grew to heights of 80 to 100 ft. Today, the lycopsids are represented by lowly club mosses. Other plants include cordaites (B), which were seed plants with strap-shaped leaves that are now extinct; tree ferns (C), which still live in warm, damp areas; calamites (D), which is a tree-size scouring rush; and pteridosperms (E), which were seed plants with fernlike leaves that are now extinct. The tree-like scouring rushes, which reached heights of 30 to 50 ft, are represented today by plants that grow in damp, but not necessarily warm, areas usually to only a few feet in height. From an illustration by Alice Pricket in GSA Today (Gastaldo and others, 1996, fig. 1); Geological Society of America (GSA), copyright 1996, reproduced with permission of the GSA (Boulder, Colo.), whose permission is required for further use.

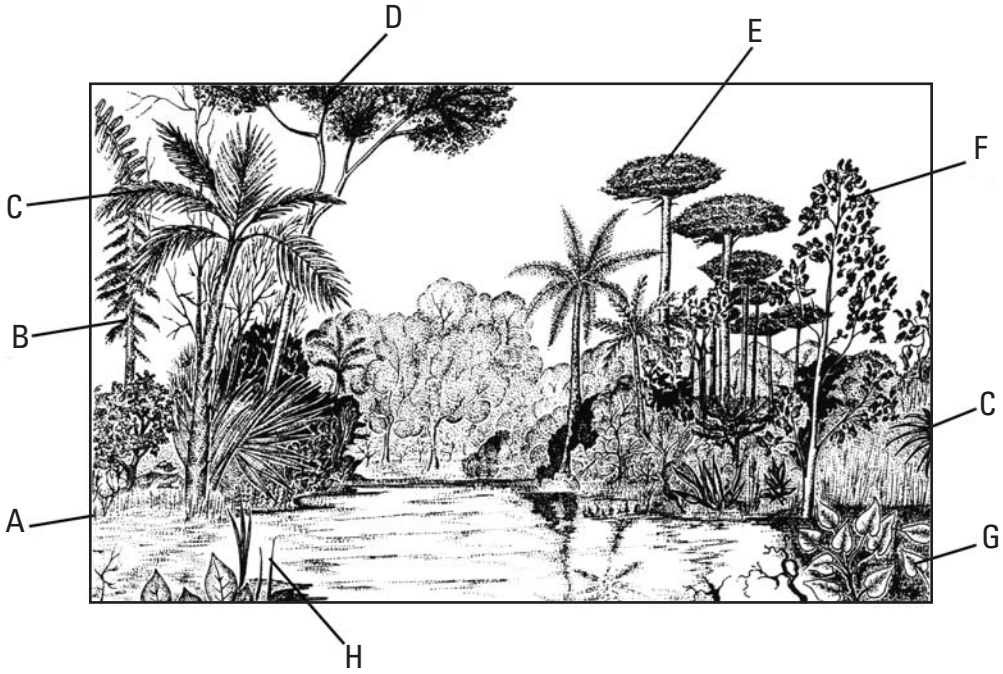

Figure 22. Reconstruction of a peat-forming, fluvial coal swamp and peripheral, bottom-land vegetation of Late Cretaceous age (about 70 million years ago) in what is now eastern Utah. Representative plants are as follows: A, horse-tail rush; B, sequoia; C, palm; D, *Rhamnites*, now extinct; E, *Araucaria*, now extinct; F, sycamore; G, fig; and H, cattail. Plants were growing on the banks of the swamp. Modified from Tidwell (1998, figure 37), used with permission of the author.

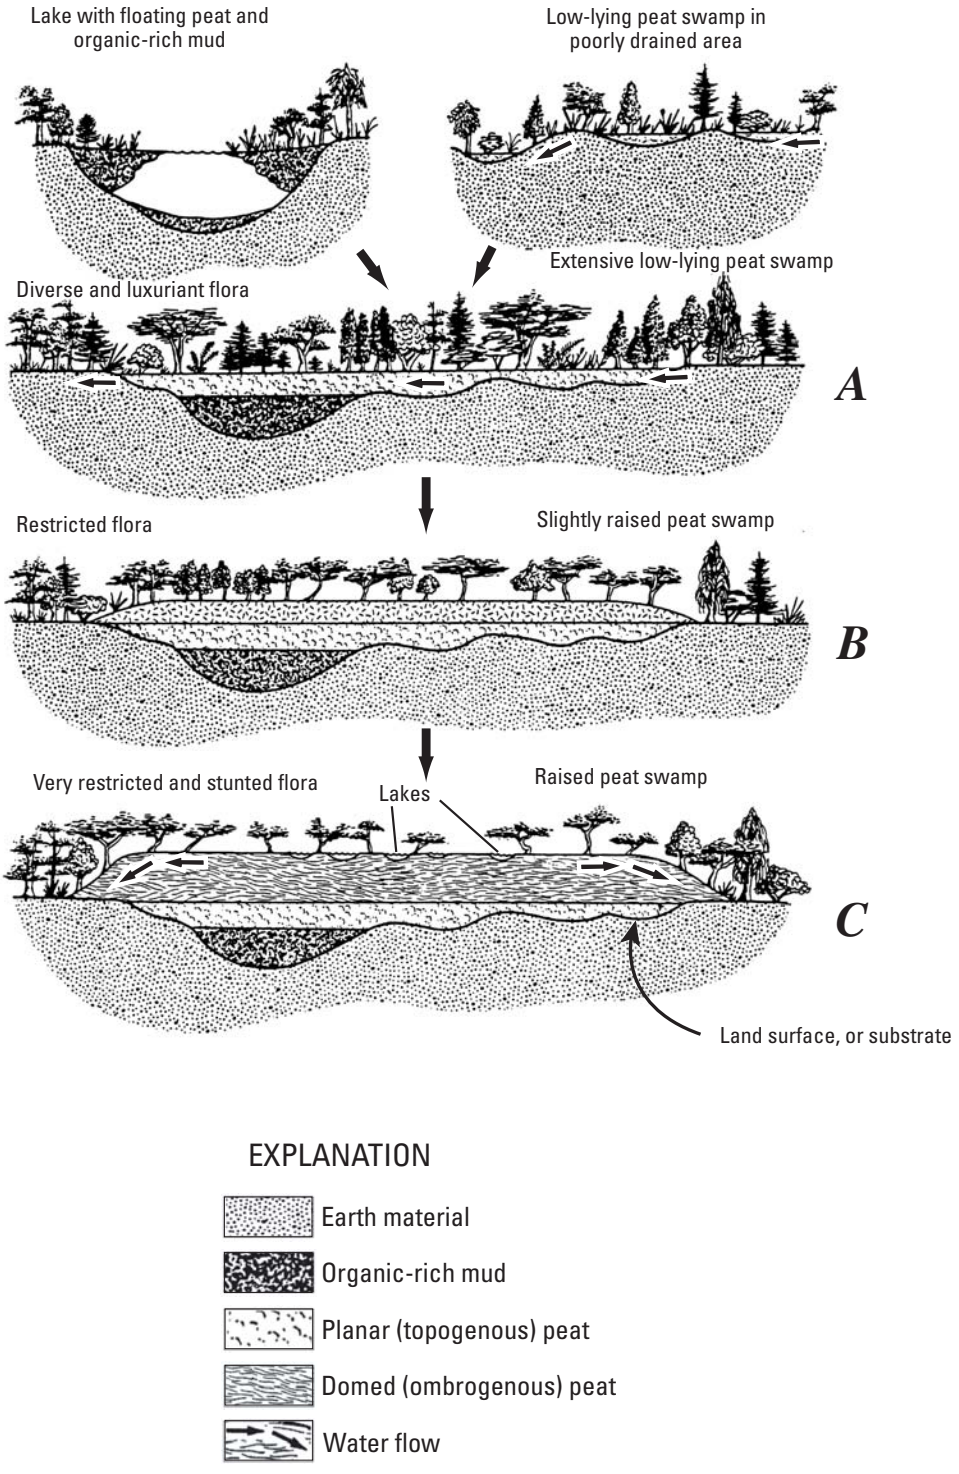

Figure 23. Sketches illustrating a possible evolution from a planar (topogenous) peat deposit to a domed (ombrogenous) peat deposit. ***A***, planar; ***B***, transitional, slightly domed; and ***C***, domed. A planar deposit may evolve into a transitional or domed deposit if climatic conditions change; the two types of peat deposits also may occur independently. No scale implied, but the horizontal dimension could be many miles and the vertical dimension could be 500 to 1,000 ft. Individual plant types were not identified in the source for this figure, but a typical flora might include cypress, magnolia, and willow trees; sassafras, sumac, and witch hazel shrubs; and ferns, reeds, and lilies as low-growing and water plants. Modified from McCabe (1987), used with permission of The Geological Society (London).

bial action, oxidation, and biogeochemical processes. These processes are pervasive and, to a large extent, determine the character of any resultant coal. The processes, which operate on microbiological and microchemical levels, are constantly changing and, therefore, are difficult to characterize. What is known is that (1) the degradation processes are carried out by oxygen from the atmosphere and various microorganisms, such as bacteria and fungi; and (2) the processes are moderated by the acidity or alkalinity of the available water. When the oxygen in the peat has been depleted, anaerobic bacteria (such as those responsible for fermentation) continue the process of degradation. Although pervasive, the process of plant decomposition is also selective in that different plant parts degrade at different rates. The most resistant parts, such as bark, cuticle, spores, lignin-rich wood, and charcoal (fusinized peat), are the parts most often retained in coal as macerals.

When standing water covers fallen plant matter, atmospheric oxidation is halted; soon thereafter, biochemical change slows to a virtual halt. Once plant matter is converted to peat and is buried, further substantial changes depend more on increases in temperature and pressure than on oxidation and biochemical processes. The acidity or alkalinity of peat swamp water may also control the rate and amount of change that takes place. Usually, the more acidic the water, the more plant matter is preserved because bacterial activity is reduced. If their work is carried to completion, bacteria and fungi produce CO_2, water, and ash; in effect, it is a slow-burning process.

SWAMP GEOMETRY, LOCATION, AND CLIMATE

From the late Paleozoic to the present, two principal types of peat swamps have existed: planar (topogenous) and domed (ombrogenous) (fig. 23). Each has unique floral characteristics that affect the quality of the resulting coal.

The planar peat swamp generally develops in areas of seasonal rainfall, mainly in low-lying areas, and depends on a high ground-water table for its continued existence. The resulting peat deposit often has an undulating bottom and a flat top. Because it forms in low-lying areas, the planar swamp is subject to periodic flooding, which results in the introduction of extraneous mineral matter such as clay, silt, and sand. This sediment brings in nutrients, but may also add impurities to any resulting coal; in extreme cases, the sediment may bury the swamp, which results in the termination of peat formation.

The domed peat swamp develops in areas that receive substantial rainfall during most of the year. In this environment, new plants grow above fallen plants, which decay very slowly because the swamp, like a sponge, remains saturated with water. This process gradually allows the top of the swamp to rise above the surrounding topography. The result is a peat deposit that has a raised, or domed, surface.

Figure 24. Photograph of a coal strip-mine highwall exposure of a thick lens-shaped parting, possibly a floodwater overflow (see fig. 9) in the Upper Freeport coal bed, central Appalachian basin. Photograph by Mark Scanlon (Canyon Fuel Co., LLC, Price, Utah) in Atlas of Coal Geology, American Association of Petroleum Geologists (AAPG) Studies in Geology No. 45 (Papp and others, 1998); AAPG copyright 1998, reprinted by permission of the AAPG, whose permission is required for further use.

The dome prevents or limits the extent of flooding of the swamp and thereby prevents the introduction of mud, silt, and sand, except around the fringes. New plants depend on dead ones for their nutrients, thus depleting the earlier deposited peat of mineral matter. The flora become stunted and restricted to plants that can survive in a mineral-poor, acidic soil. As a result, domed peat tends to contain much less mineral matter than planar peat and the resulting coals are purer.

A peat deposit may have originated as either the planar or the domed type and then, due to a change in the climate or topography or both, may transform into the other type and even back again (fig. 23). The resulting coal beds may be composites of the two types. These conditions make determining the quality of the composite coal beds difficult.

The geographic location and climate of the precursor peat swamp also affect coal quality. At present, swamps are located in tropical, temperate, and cool climates, near coastlines and inland, beside rivers and within river deltas, and in upland areas. This wide variety of geographic locations and climates in which swamps develop was most likely the case at least as far back as the Devonian Period (fig. 19).

Peat swamps located close to rivers or within river deltas suffer the possibility of periodic flooding and the introduction of large amounts of mineral matter. Swamps along coastlines, while not as easily subjected to river flooding, may be affected by offshore or coastal storms that wash sediment over offshore bars and beaches into the swamps behind them. The added mineral matter may be disseminated in the peat, may occur as layers in the peat, or may cause peat formation to stop. Discrete layers of mineral matter in coal beds are called “partings” (fig. 24).

Climate, which to some extent depends on geography, affects the growing season and the amount of rainfall that a swamp receives and, therefore, helps determine the kind of peat that will eventually form. Thick, extensive coal beds generally are thought to have originated as large peat swamps in warm, humid, and tropical to subtropical regions (Cecil, 1990). For example, extensive, thick (some up to 50 ft) peat deposits have been accumulating on the coastal areas of the islands of Indonesia (principally Sumatra; fig. 7A) and Borneo, as well as others (Neuzil and others, 1993). Those areas are in warm, ever-wet, climatic zones.

Extensive peat deposits currently are forming in the Florida Everglades, but the climate there is much more variable than that of Borneo. Southern Florida has periodic rainfall and extended dry periods that allow the surface peat to dry out and oxidize, or even burn off, resulting in a relatively thin deposit.

Other modern peat deposits form in a wide variety of climatic conditions; two additional examples are provided. The Vasjugankojev swamp in Siberian Russia, which is a notoriously cold region, is described by Cameron and others (1989) as, at an area of approximately 21,000 mi^2, the largest "peatland" in the world; however, even though the region is cold, the location of the swamp is low, flat, and wet, and part of the year is conducive to adequate plant growth while the coldness of the rest of the year serves to protect much of the plant matter from decay. No thickness of peat in this swamp was reported.

A swamp on Great Cranberry Island, Maine, also described by Cameron and others (1989), is another example of a swamp located in a cool temperate climate. This swamp formed during the recent past as sea level rose and built up a beach ridge approximately 11 to 12 ft high. A lake, which was formed behind the rising beach ridge, slowly filled with peat as the beach rose. The resultant peat deposit is relatively small (less than 250 acres) but it reaches thicknesses of as much as 27 ft. Whether either of these modern peat deposits will ever become a coal bed cannot now be determined; however, research on modern peat deposits, wherever they are located and under whatever climatic conditions they are deposited, may help in finding additional high-quality coal deposits in older rocks.

MINERAL MATTER

The living plants in a peat swamp absorb mineral matter from (1) the soil they grow in, (2) dissolved mineral matter in the water of the swamp, and (3) introduced mineral matter, such as waterborne or windborne sediment, or volcanic ash. Some of the dust and ash may be dissolved in the swamp water and serve to support plant growth, as described in the discussion of domed peat deposits, or they may occur as disseminated grains in the peat or as discrete layers called partings (fig. 24). Partings may be paper thin or they may be several feet thick. In the case of the planar swamp, dust or ash will further dilute the organic matter composing the peat, thus raising the mineral-matter content or creating partings. In the case of the domed swamp, however, these sediments may add enough new nutrients to the swamp to prolong its life and produce a thicker peat and ultimately a thicker coal bed. Volcanic ash and some types of dust are rich in the nutrients required for vigorous plant growth.

Throughout geologic time, the peat swamps that were not destroyed by erosion or oxidation were buried by sediments, which, depending on their source, affected the mineral-matter content of the resultant coal in different ways. In general, riverborne sediments tend to be richer in some elements, such as iron, whereas oceanborne sediments tend to be richer in other elements, such as sulfur.

In many coals, some of the mineral matter was introduced by epigenetic (low temperature) mineralization after the bed was formed (fig. 11). In this process, the minerals were introduced into fractures (called "cleat;" see below under "Coalification") and along bedding planes in the coal bed as ions in moving water and were deposited when the water lost its ability to maintain the mineral-forming ions in solution. This could occur when the ion-bearing water entered a different temperature and (or) chemical environment.

Epigenetic minerals commonly include pyrite, calcite, siderite, and kaolinite, and in rare cases, sphalerite and galena (see table 1 for compositions of these minerals). Epigenetic mineralization, estimated to have been introduced during the Permian Period into coal beds of older Pennsylvanian age (see fig. 19), is particularly notable in coals of the midcontinent region of the U.S. (Cobb, 1979; Brannon and others, 1997).

COALIFICATION

From the time the peat is buried, it goes through a series of chemical and physical changes called "coalification," which is the process that produces coals of increasing rank (fig. 17). Coalification is a continuing process involving increases in both temperature and pressure resulting from burial in the earth. Burial is a process that may happen very slowly or relatively rapidly depending on the speed and magnitude of the geologic forces operating on the region. Increasing temperature is considered more important than increasing pressure in promoting coalification. Higher temperatures eliminate moisture and volatile elements and, therefore, help produce coals of higher rank and higher heat (calorific) value. Higher temperatures are generally associated with deeper burial in the earth, although proximity to an unusual source of heat, such as a volcano, could produce similar effects.

Figure 25. Photograph of part of an exposed coal bed showing well-developed face cleat and poorly developed butt cleat. The coal bed is in the Cretaceous Fruitland Formation in the San Juan basin, near Durango, Colo. The compass is 2.75 in. wide. Photograph by Walter Ayers (S.A. Holditch Assoc., Inc., College Station, Tex.) in Atlas of Coal Geology, American Association of Petroleum Geologists (AAPG) Studies in Geology No 45 (Papp and others, 1998); AAPG copyright 1998, reprinted by permission of the AAPG, whose permission is required for further use.

When increases in depth of burial or temperature no longer occur, coalification slows and then ceases (unless another source of higher heat affects the coal). Thereafter, the coal will remain at the same rank even if it is raised up again (either by tectonic uplift or erosion of overlying sediments, or both) into a region of much lower temperature or pressure. Once the coal is exposed to weathering (oxidation), however, it is slowly reduced to ash.

> *Coalification is a baking process in the earth, under pressure. As it proceeds, it produces coal of increasing hardness and calorific value and results in a reduction of tar, oil and gas.*

Coalification affects not only the organic matter in coal, but the mineral matter as well. As coalification proceeds, organic matter, which is relatively rich in water, oxygen, and hydrogen, gradually loses those constituents and becomes relatively enriched in fixed carbon. Some of the hydrogen and carbon are converted to methane gas (CH_4) in the process. Changes that occur to the mineral matter during coalification are less well understood. During coalification, clay minerals may become more refractory (that is, less affected by heat and chemicals), and the elements in other minerals may become rearranged, making them more crystalline. Although deeper burial, and therefore higher temperatures, implies greater age, coals of approximately the same geologic age may exhibit a wide range in rank depending on their geologic histories. For example, Pennsylvanian coals in the eastern U.S. (figs. 4, 19) range in rank from anthracite in easternmost Pennsylvania to high-volatile C bituminous coal in western Illinois and Iowa. Coals beds in what is now eastern Pennsylvania were subjected to strong mountain-building forces during the late Paleozoic, when the Appalachian Mountains were formed. During this time, the beds were forced deep into the earth into zones of high heat, and then were compressed into tight folds. In contrast, the coals to the west, in what are now the States including western Pennsylvania, Ohio, Indiana, Illinois and Iowa, were subjected to lesser depths of burial and little or no mountain-building forces.

During the process of coalification, sets of roughly parallel, closely spaced fractures (cleat) form in the coal. Cleat tend to form in two sets at right angles to one another; one set, the face cleat, is dominant, while the other set, the butt cleat, may be only poorly developed (fig. 25). Cleat are generally well developed in bituminous coals; lignites and subbituminous coals, both less well coalified, generally exhibit only incipient cleat. Anthracite in eastern Pennsylvania generally does not exhibit cleat because strong mountain-building forces welded the coal back together into solid massive beds. (For a thorough discussion, see Damberger, 1991.)

DETERMINING THE QUALITY OF COAL

By now, it should be clear why coal is such a complex and heterogeneous material. The interplay of the many factors that affect the peat and the resulting coal affects its composition, but the composition is never quite static because it is subject to continuing change. In the past, coal was simply dug up and burned or turned into coke with little concern for its quality as long as it made a hot fire, did not have too much ash or sulfur, and would ship long distances without turning to dust. Now we know that a complete understanding of coal quality is important in order to address environmental or industrial concerns such as (1) SO_x and hazardous air pollutants (elements such as mercury and selenium in hot flue gases); (2) boiler slagging and fouling; (3) the high costs of flue-gas desulfurization; (4) the disposal of scrubber sludge, ash, and CO_2; (5) the development of clean-coal technologies; and (6) the promotion of coal as a source for synthetic oil and gas.

Many techniques currently exist for studying coal quality. Some analytical techniques (such as the ones used to determine coal rank, moisture, ash yield, sulfur content, and

Table 2. Procedures and purposes of American Society for Testing and Materials (ASTM) methods for testing coal.

Procedure	Purpose
Classification of coal by rank	Classify coal into categories indicating ranges of physical and chemical characteristics that are useful in making broad estimates of the behavior of coal in mining, preparation, and use.
Coal ash	Determine amount of ash at a given temperature.
Equilibrium moisture	Determine moisture-holding capacity of coal.
Forms of sulfur	Determine whether sulfur is in pyrite, organically bound, or in sulfates.
Free-swelling index	Determine how well a coal will form coke.
Fusibility of ash	Predict whether the coal ash will perform properly in the process for which it was chosen.
Gross calorific value	Determine potential for energy production, in kilocalories per kilogram.[1]
Hardgrove grindability	Determine resistance to grinding.
Major and minor elements	Identify major and minor elements.
Proximate analysis	Determine amount of ash, fixed carbon, moisture, and volatile matter.
Reflectance of organic matter	Determine rank and how well a coal will form coke.
Total moisture	Determine inherent water and any other water present.
Trace elements	Identify trace elements.
Ultimate analysis	Determine amount of ash, carbon, hydrogen, nitrogen, oxygen, and sulfur.
Volatile matter	Identify products given off as gases or vapors.
Maceral analysis	Determine kinds and amounts of macerals in coal.

[1] One kilocalorie per kilogram = 1.798 British thermal units (Btu) per pound.

volatile matter) are highly standardized. Coal mines, electric utilities, the coke industry, and commercial analytical labs commonly employ these tests. Many of the standards for these techniques, as well as the standards for precision in their use, are published by ASTM International (2002) and are widely followed by the coal industry in the U.S. Research scientists studying coal quality use not only the results of ASTM-based analyses in their work, but also other generally accepted techniques that have not been standardized by the ASTM; however, once research shows that a new technique is useful and accepted by the coal industry, standards may be developed for its application.

Research is currently underway to improve the existing techniques used by coal scientists for analyzing coal, to adapt some techniques used in the analysis of other materials, and to develop new analytical techniques. Procedures approved by the ASTM and their purposes are given in table 2. A list of analytical techniques currently used in coal-quality research at the USGS and their purposes is given in table 3. The two suites of analyses serve different purposes. The results of the ASTM suite of analyses allow coal-using industries to directly compare coals of differing qualities, which enables them to select a coal that is best suited to their needs. These results also allow coal research scientists to study the geologic history of a coal bed through levels of rank, and ash, sulfur, and moisture contents. The suite of analyses used by the USGS was developed to (1) aide in the search for valuable mineral byproducts, (2) develop methods to aide in determining the origins and correlations of individual coal beds, and (3) analyze for the locations, amounts, and affinities of elements that are known to, or might, pose a hazard to health. The results of both sets of analyses performed on a sample of bituminous coal from Alabama are provided in table 4 (the results of ASTM analyses are given first; the results of USGS analyses follow). The ASTM analyses were performed by the U.S. Department of Energy at the Pittsburgh, Pa., laboratory; the USGS analyses were performed at USGS laboratories at Reston, Va., and Denver, Colo.

The USGS has developed a large file of data on coal quality including the results of both ASTM and USGS procedures (Bragg and others, 1997). These data result from analyses performed on coal samples collected by USGS scientists or by cooperating agencies, such as

Table 3. Analytical methods and individual techniques used in research on coal quality and their purposes.

Method	Purpose
1. Analytical chemistry.	Determine inorganic elements and compounds.
Wet chemistry.	
Inductively coupled plasma mass spectroscopy (ICP-MS).	
Inductively coupled plasma atomic emission spectroscopy (ICP-AES).	
Neutron activation (NA).	
Atomic absorption spectroscopy (AAS).	
Molecular absorption spectroscopy (MAS).	
Optical emission spectroscopy (OES).	
Stable-isotope mass spectrometry (SINS).	
2. X-ray fluorescence.	Determine elemental composition.
3. X-ray diffraction.	Determine mineral structure.
4. Optical microscopy.	Determine distribution of coal particles and minerals and content of macerals, pollen, and spores.
5. Accelerated particle.	
Scanning-electron microscope (SEM) with energy dispersive X-ray analyzer (EDAX).	Determine shapes, sizes, and distribution of mineral grains at very high magnification and semiquantitative determination of some elements.
Transmission-electron microscope (TEM).	Similar to SEM. Also used for mineral identification.
Electron microprobe (EMP).	Determine structure and elemental composition of individual mineral and maceral grains.
Proton induced X-ray excitation (PIXE)	Similar to EMP, but more sensitive.
Laser microprobe-mass analyzer (LAMMA).	Determine trace-element presence in coal macerals.
Ion microprobe (IM).	Determine trace element presence in coal macerals.
6. Nuclear magnetic resonance (NMR).	Determine structures and structural changes of organic compounds.
7. Gas chromatography/mass spectrometry (GC/MS).	Determine organic compounds.
8. Thermoluminescence (TD) and cathodoluminescence (CD) detectors.	Infer the origin of specific minerals, whether from an igneous or sedimentary source.
9. Fourier transform infrared analysis (FTIR).	Quantitatively determine clay mineralogy and organic compounds.

Table 4. Results of standard ASTM International (ASTM) analyses and U.S. Geological Survey (USGS) research analyses of a sample (USGS 212277) of Pennsylvanian bituminous C coal from the Mary Lee coal bed, Walker County, Ala.

[1]USGS ash slightly different from ASTM ash because of different temperatures used in ashing furnaces.

State geological surveys and universities. ASTM analyses were performed by the former U.S. Bureau of Mines (USBM) and by independent testing laboratories; analyses for oxides and trace elements were performed at USGS laboratories based on USGS-developed standards.

SAMPLING TECHNIQUES

Most analyses of coal, for both standard and research purposes, are conducted on carefully collected samples of whole coal. Coal samples are taken from a variety of places—individual coal beds in place, coal-mine conveyor systems, trucks, train cars, or stockpiles—depending on the needs of the sampling and analytical programs. The goal of this process is to collect a sample that will be as representative as possible of the coal bed or other source from which it is taken. In order to produce reliable results from testing programs, sampling must be done very carefully. Samples must be taken without contamination from extraneous material, and location and orientation must be documented.

There are also a few techniques for analyzing coal beds in place. Geophysical logging is conducted in drill holes during exploration and mine planning programs. This technique measures electrical resistivity, transmissivity of sound, inherent electrical properties (such as self-potential), and the reaction of coal to bombardment by atomic particles (such as neutrons) (Wood and others, 1983). These methods accurately identify coal beds and their boundaries, and help determine whether a coal bed merits additional exploration and mining; however, they are only good for an approximate analysis of coal quality.

Channel and drill-holecore samples are two of the most common types of samples used for characterizing a coal bed. A channel sample is taken from a freshly exposed coal bed (usually in an underground or surface coal mine) by cutting a 2- to 4-in channel into the bed from top to bottom and collecting all the coal from the channel (fig. 26). Drill-hole core samples (fig. 27) are taken from subsurface coal beds where the coring bit does the cutting. If the coal bed is divided horizontally into benches (individual beds of coal separated by mineral partings), or if the bed is layered by distinct types of coal, then the benches or beds may be sampled separately, which allows for a more detailed characterization of the individual parts. The ASTM recently has published standards for the collection of channel and core coal samples (ASTM International, 2002).

The number of channel or core samples taken depends on how well the coal bed needs to be characterized. If any two samples of the same bed show considerable variation in quality between them, then more samples may be taken from the area between the two initial samples; however, cost may be a factor in the decision to collect more samples.

Figure 26. Photograph of a coal bed "face" in an underground coal mine showing personnel collecting a channel sample of fresh coal. The collecting team is standing on a floor that has been excavated below the base of the coal bed to facilitate mining. The white color in the background is limestone dust sprayed on the coal face to control coal dust. The coal sample is collected on a clean plastic sheet to minimize contamination from the floor of the mine. This sample is from the Lower Freeport coal bed, Indiana County, Pa., where the bed is about 56 in thick. Photograph by R.W. Stanton (U.S. Geological Survey).

The purpose of the analysis often determines the type of sample that is collected. If the purpose is to characterize a stock of already mined coal, then gross samples may be taken at regularly or randomly spaced intervals from the stockpile, coal car, or conveyor belt. If the purpose is to examine some specific property of a coal bed, then a sample of only a small part of the bed may be taken. If the purpose of the sample is to study some directionally controlled characteristic, such as the orientation of mineral grains, the sample must be labeled to show top and bottom and, in some cases, compass directions. For some types of analyses (for example, by either petrographic or scanning-electron microscope, figs. 11, 13B, 13C, 14), small blocks of coal are cut out of larger samples and one side is polished and examined. This technique is used when it is necessary to see the microscopic details of the types, distributions, and arrangements of the macerals and minerals in a coal sample.

When a coal sample arrives at the lab, it is crushed (unless it is to be examined in block form) and its particles are thoroughly mixed to ensure that the sample is homogeneous. The crushed sample then is divided into appropriately sized subsamples for each analytical technique to be used.

ANALYSIS

The primary reason for analyzing coal is to determine whether it will meet the needs of a specific application, or to characterize the general quality of the coal for future ref-

Photograph by P.D. Warwick (U.S. Geological Survey).

erence. For instance, coal may be analyzed to determine how much sulfur (or other element) is present, its form, and how it is distributed. If the sulfur is present in discrete pyrite grains, then much of it may be cleaned out of the coal; but, if it is organically bound, then the sulfur may be released only by burning, by using a solvent, or by employing a bacteriologic technique (although the latter two techniques are still largely experimental). If the coal has a high organic sulfur content, then it may have to be mixed or blended with a coal of lower sulfur content in order to meet sulfur emissions standards, or the sulfur may have to be cleaned out of the flue gas by flue-gas desulfurization (FGD), which is an expensive procedure. Similarly, analysis may determine whether a trace element, such as arsenic, may be eliminated from a coal by washing or whether it must be trapped in the flue gas. Finally, in extreme cases, analysis may determine that the coal cannot be used.

In general, the coal-mining and coal-consuming industries determine coal quality for immediate or near-term use, whereas Federal and State governments analyze coal to (1) characterize large areas of unmined coal (resources) for future reference, (2) to support policy decisions related to future coal use, and (3) to supply Federal and State regulatory agencies with information about the quality or special characteristics of future coal supplies, such as the presence, amounts, and modes of occurrence of sulfur and potentially toxic trace elements. Figure 28 shows a coal scientist at work identifying coal macerals and coal rank in a polished sample of coal using a high-powered, reflected-light microscope.

Coal samples may be received at the laboratory in a variety of conditions. Accordingly, analytical results may be reported in a variety of ways, depending on the condition of the samples when received and the use of the analysis. Some samples arrive in a fresh condition, not long after sampling; these may be analyzed without further processing, except grinding and mixing. The analytical results for these samples are reported on an “as-received” basis. Some samples arrive dried out due to long storage, transportation over long distances, or mishandling. The results of analyses on dried-out samples are reported on a “dry” basis. The opposite conditions may also occur if the sample arrives

wet because of excess moisture in the sample that may or may not be present in the coal bed; in this case the analyses may be reported on a "moist" basis.

Analyses also may be reported on a "mineral-matter-free" or "dry, mineral-matter-free" basis for use in calculating coal rank because rank is a function only of the maturity of the organic matter. "Mineral-matter-free" means that the amount of mineral matter in the sample has been subtracted from the total analytical results to provide only the amount that is organic. "Dry, mineral-matter-free" means that the sample was received in a dry or nearly dry state, or was dried out before an analysis was made.

An analysis on a mineral-matter-free basis also may be used for comparison with the results of an as-received analysis of "run-of-mine" coal (as it comes from the mine) if there is to be further processing, such as coal cleaning. Run-of-mine coal frequently contains (1) large amounts of mineral matter from partings in the coal bed, (2) rocks from above and below the coal bed that are mined along with the coal, (3) minerals that fill veins in the coal bed, and (4) mineral matter dispersed in the coal (such as pyrite grains). Mineral matter in run-of-mine coal may cause the coal to exceed the ash and sulfur limits set by contract requirements and environmental regulations. A mineral-matter-free analysis may indicate whether or not it will be worthwhile to clean the coal; however, the need for cleaning depends on the intended use of the coal and normal cleaning practices may not bring a coal to a completely mineral-free condition.

Most chemical analyses require the destruction of the coal sample in order to determine calorific value, volatile matter, and mineral-matter content. Destruction is achieved by burning the coal sample in a high-temperature furnace. Although that procedure is fine for determining the calorific value of coal, it is not suitable for retention of some of its volatile inorganic elements, such as mercury. Subjecting the sample to a process called "low temperature ashing," in which the sample is exposed to high-frequency radiation in a high-oxygen atmosphere, permits the organic matter to be driven off while preserving most of the mineral matter. Nevertheless, some of the very volatile inorganic elements (such as chlorine, mercury, or selenium) may be lost in this process and are best measured in whole-coal samples by X-ray fluorescence or other techniques. Most microscopic and microprobe techniques require whole-coal samples because the objective is to determine the interrelations between the constituent parts of the coal.

ORGANIC GEOCHEMISTRY

Because coal is principally an organic substance, organic geochemistry is an important factor in the study of the origin, structure, quality, and utilization of coal.

Figure 28. Photograph of a coal scientist at work identifying coal macerals and rank in a polished sample of coal using a high-powered, reflected-light microscope. Photograph by R.W. Stanton (U.S. Geological Survey).

Determining the organic matter in coal is necessary for studying (1) the organic structure and the organic sulfur compounds in coal, (2) modern peat-forming swamps as analogues of ancient peat-forming swamps, (3) the potential for coal gasification and liquefaction, and (4) the effects of coal mining and coal use on surface water, ground water, and air quality.

Recent advances in analytical instrumentation have greatly aided organic geochemical studies of coal. Most coals consist of a mechanical mixture of two principal organic components: (1) resin-like (aliphatic) organic matter of uncertain origin (that is, the specific plant structures have been destroyed during the coalification process), and (2) benzene-like (aromatic) organic matter derived from wood tissues (lignin). Using solid-state, ^{13}C nuclear-magnetic-resonance (NMR) spectroscopy, coals now are routinely classified based on their aromatic content.

Organic geochemical studies of modern peat attempt to relate processes occurring in modern environments to those that occurred in ancient peat swamps.

Other commonly used analytical techniques such as gas chromatography/mass spectrometry, the electron microscope, and the scanning electron microscope are used to study the organic sulfur concentration and distribution in coals. So far, these studies seem to indicate that most of the sulfur in organic compounds in coal is present at the edges of the organic molecules. This finding may aid the development of effective desulfurization procedures for coal containing large amounts of organically bound sulfur.

The energy produced and the reactivity of coal during burning is determined by its chemical and physical struc-

ture. Through computer-assisted molecular design, scientists can now construct two- and three-dimensional models of organic compounds in coal and determine the arrangements of the elements in various model structures.

Organic geochemical studies of modern peat deposits attempt to relate processes occurring in modern environments to those that occurred in ancient peat swamps. Such studies serve as a mechanism for a better understanding of and an ability to predict coal quality by providing insight into the early stages of coal formation; for example, a geochemical analysis of an ombrogenous peat, which is easy to sample, greatly enables the ability to predict the quality of other coal deposits that originated as ombrogenous peat deposits but that are much more difficult and costly to sample.

MINERAL-MATTER CHEMISTRY

Studies of mineral matter in coal are performed by a variety of analytical techniques. The principal techniques are analytical chemistry, X-ray spectroscopy, scanning-electron microscopy, petrography, and mineralogical studies (table 2). Two newer techniques, (1) inductively coupled plasma, atomic-emission spectrometry (ICP-AES); and (2) inductively coupled plasma, mass spectrometry (ICP-MS), have been applied to coal analysis with excellent results and are worth a brief description. Using these techniques, a sample of coal ash is first decomposed with various acids and put into solution. The solution is then aspirated into a flame (plasma), which energizes the atoms of the different elements present in the solution to generate characteristic wavelengths of radiation. The spectrum produced by the radiation is then measured in a spectrometer. The data from the spectrometer are fed into a computer where the results are compared to standard samples and the concentration of each element in the sample is calculated. The two ICP techniques simultaneously and quantitatively analyze about 50 different inorganic elements, which is a large increase in the efficiency of coal analysis. The ASTM recently has adopted ICP-AES and ICP-MS techniques as industry standard methods for analyzing coals for inorganic elements (ASTM International, 2002).

Microscopic studies of coal petrography are used to identify the constituents in coal and how they are arranged and to provide knowledge of the maceral composition and distribution. Coal petrographers may assess the rank of a coal by measuring the intensity of light reflected from the vitrinite macerals in a polished surface of a coal sample; the higher the reflectivity, the higher the rank. In some instances, however, petrographic study is not adequate to characterize all of the coal constituents. For example, if mineral matter, such as pyrite, exists as extremely small discrete grains, or if it is located inside plant cells (which are also extremely small), then identification becomes difficult with an optical microscope. In these cases, a scanning-electron microscope is used to study minute particles of mineral material. Figure 14 is a photomicrograph taken with a scanning-electron microscope of plant cells in coal containing minute grains of pyrite. In this case, chemical and mineralogic analyses had already determined the presence of pyrite, but the photomicrograph allows the pyrite to be studied in greater detail. This information could be used to determine whether the coal must be ground into a powder that is fine enough to liberate such fine-grained pyrite (an expensive process).

CONCLUSIONS

Although much is known about coal quality, much also remains to be learned. To this end, research on coal quality is being conducted in both the public and private sectors. Current studies encompass all aspects of the origin, burial history, and composition of coal in order to understand the various factors involved in determining coal quality, such as how and where to find the right coal for a specific use and how to clean coal to make its use more environmentally and industrially acceptable.

In the past, the only consideration given to coal quality was whether coal lumps held together during shipping burned easily to produce a hot fire and didn't produce too much ash. Today, however, concerns about human health, the environment, energy demands, and the supply of certain raw materials have broadened our concept of coal quality and our need to know much more about the origins, nature, and effects of coal quality. An extensive evaluation of coal quality must be central to coal use. Whatever coal is used for, whether for the direct production of energy, chemicals, synthetic fuels, or the recovery of useful minerals, and whatever problems and solutions accompany that use depend on the quality of the coal. Additional, sophisticated, multidisciplinary research on coal quality is required for the future. The results will help make it possible for society to continue to benefit from the good qualities of coal and to make progress in avoiding the undesirable affects of coal use.

In the near term, the most immediate advancements related to coal-quality research appear to be improvements in the efficiency of coal use (including more efficient production of synthetic fuels) and the development of methods to best understand, and thus control, the less desirable components in coal that have the potential to contribute to environmental degradation and adverse health effects. In the longer term, the recovery of useful substances from coal (such as iron, silver, sulfur, and zinc, as well as organic chemicals, gypsum, and ash) should be an exciting area for research related to coal quality.

COAL QUALITY AND PUBLIC HEALTH

By Robert B. Finkelman

Prior to the widespread adoption of selective mining procedures and pollution-control technology, human health had been affected by sulfur and particulates emitted from coal combustion. This section describes several examples of how organic compounds and trace elements are still affecting the health of people in Europe, Asia, and America.

The inorganic (and in some cases, organic) constituents in coal may have profound effects on the health of those people burning coal in their homes or living near coal deposits, coal mines, or coal-burning power plants. Trace elements, such as arsenic (As), emitted from coal-burning power plants in Europe and Asia have been shown to cause severe health problems. Water leaching of organic compounds from lignites may be the cause of a kidney disease that has taken the lives of more than 100,000 people in the Balkans. Widespread health problems may be caused by domestic coal combustion in developing countries. Millions of people suffer from fluorosis, thousands from arsenism. In the southwestern U.S., many members of the Navajo Nation are dependent on coal as their primary source of energy. Many Navajo suffer from chronic respiratory problems that are attributed to emissions from the burning of coal in their hogans.

A better knowledge of coal-quality parameters may help to minimize some of these health problems. Information on the concentrations and distributions of potentially toxic elements in coal may help us to avoid those parts of a coal deposit having undesirably high concentrations of these elements.

Information on the modes of occurrence of these elements and the textural relations of the minerals and macerals in which they occur may help us to anticipate the behavior of the potentially toxic components during coal cleaning, combustion, weathering, and leaching. Coal quality characterization, therefore, offers coal scientists opportunities to contribute to important societal needs such as improved public health.

POLYCYCLIC AROMATIC HYDROCARBONS (PAHS)

BALKAN ENDEMIC NEPHROPATHY

Balkan endemic nephropathy (BEN) is a potentially fatal degenerative kidney disease common in parts of former Yugoslavia, Bulgaria, and Romania. An article in a popular science magazine attributed more than 100,000 deaths to BEN since it was recognized as a distinct disease in 1956 (Zimmerman, 1983). Intensive medical research had failed to identify the cause of BEN or to explain why it occurs in clusters of villages along river valleys.

In the early 1990s, U.S. Geological Survey (USGS) researchers identified a link between the occurrence of BEN and the distribution of Pliocene lignites, which are the youngest, most chemically reactive coals in the Balkans region (Feder and others, 1991). They suggested that BEN is attributable to ingestion of organic compounds from well water that had been in contact with Pliocene lignites. Ground water in the endemic villages was found to be highly concentrated in organic chemicals such as PAHs. They also suggested that the hydrocarbons, some of which were known carcinogens, were the cause of BEN. Further evidence was found from laboratory experiments. Using distilled water to leach samples of Pliocene lignites from Yugoslavia, USGS researchers extracted a suite of PAHs similar to that found in the well water of the endemic villages (Orem and others, 1999).

BEN also may exist in Turkey and other countries. Turkey has extensive near-surface deposits of Pliocene lignites and many Turkish villagers rely solely on well water for their drinking needs. If these wells are drilled into the Pliocene lignite aquifers or into aquifers in contact with the lignites, BEN could result from drinking the water.

Information on the concentrations and distributions of potentially toxic elements in coal may help us to avoid those parts of a coal deposit that have undesirably high concentrations of those elements.

LUNG CANCER

PAHs released during unvented coal combustion in homes in Xuan Wei County, China, have been cited as the primary cause for the highly elevated incidence of lung cancer there. The PAH levels in the homes burning "smokey" coal are at industrial levels resulting in a lung cancer mortality rate five times the national average of China (Mumford and others, 1987).

TRACE ELEMENTS

Concerns have been expressed in the United States and elsewhere over the release of As, Be, Cd, Cl, Co, Cr, F, Hg, Mn, Ni, Pb, Sb, Se, and U during the burning of coal. Recent data from the U.S. Environmental Protection Agency (EPA) (1996) indicate that trace-element emissions

from coal-burning power plants that use coal with relatively low to moderate trace-element concentrations, or that have efficient pollution control devices may not present a significant health risk. Their data indicate that the risk of cancer from trace elements inhaled by humans who live or work near power plants is less than 1 in 1 million.

Elsewhere in the world, trace elements emitted from coal-burning power plants have been shown to cause severe health problems. In Czechoslovakia, children living in the vicinity of a power plant that burned high-arsenic lignite (about 1,000 parts per million (ppm) on a dry basis) suffered significant hearing loss that was attributed to arsenic poisoning from the power-plant emissions (Bencko and Symon, 1977). Perhaps the most widespread health problems are caused by domestic coal combustion in developing countries. Millions of people suffer from fluorosis and thousands suffer from arsenosis caused by coal combustion in China. Selenium and mercury poisoning also have been attributed to domestic coal combustion in China. Adsorption of fluorine by corn dried over high-fluorine (>200 ppm) coal fires is the probable cause of extensive dental and skeletal fluorosis in southwest China. The problem is compounded by the use of clay as a binder for making briquettes; that clay typically is a high-fluorine (about 900 ppm) residue from the intense leaching of the limestone substrate.

In Guizhou Province, China, the practice of drying chili peppers over high-arsenic coal fires has led to thousands of cases of arsenic poisoning (Finkelman and others, 1999). The contaminated chili peppers commonly are used for cooking and thus become the principal source of arsenic poisoning. One coal sample from this region analyzed at the U.S. Geological Survey laboratory contained 35,000 ppm arsenic on an as-received basis! Chili peppers dried over the high-arsenic coal fires contain more than 500 ppm arsenic (fresh chili peppers contain less than 1 ppm arsenic). Arsenosis, which results from ingestion of the chili peppers tainted with arsenic from the mineralized coal, also has led to severe skin cancers in the affected population (Finkelman and others, 1999).

Nearly 500 cases of human selenosis in southwest China have been attributed to the use of selenium-rich, carbonaceous shales known locally as "stone coal" (Zheng, 1992). The stone coals contain as much as 8,390 ppm selenium. The selenosis is attributed to the practice of using the combustion ash as a soil amendment. This introduces large amounts of selenium to the soil and results in selenium uptake by the crops.

Coal combustion is considered to be the largest man-made source of mercury in the environment. Although there are no confirmed reports that mercury from emissions directly impacts human health, mercury may contribute to health problems through bioaccumulation in the food chain. Mercury, a portion of which is derived from coal combustion, is deposited in lakes and rivers and can be converted to toxic methylmercury, which then accumulates and becomes enriched in fish and birds. Cases of mercury poisoning have been documented in people who eat contaminated fish for prolonged periods, both in the United States and abroad. Pregnant women and subsistence fishermen are particularly vulnerable.

A rare occurrence of chronic thallium poisoning was reported from Guizhou Province, China (Zhou and Liu, 1985). The source of the thallium poisoning appears to be from vegetables grown in soil developed over a mercury-thallium-rich mining slag. Most symptoms, such as hair loss, are typical of thallium poisoning; however, loss of vision in several patients was considered to be unique. Mineralogical analysis of coal used in the homes of the patients with visual impairment revealed abundant mercury minerals. Chemical analysis of a sample of coal being used in Guizhou Province, China, indicated the mercury concentration to be 55 ppm (Finkelman, 1999), about 200 times the average mercury concentration found in U.S. coals.

SUMMARY

Coal scientists and technologists are ideally positioned to help minimize health problems due to coal combustion by providing information on coal quality. Information on the concentrations and distributions of potentially toxic elements in coal may assist people dependent on local coal sources to avoid those areas of a coal deposit having undesirably high concentrations of toxic compounds. Information on the modes of occurrence of potentially toxic elements and the textural relations of the minerals and macerals in which they occur may help us to anticipate the behavior of the potentially toxic components during coal cleaning, combustion, weathering, and leaching.

Preface

This short course consists of material presented by Allan Kolker at Servicio Geológico Colombiano (SGC), the Geological Survey of Colombia, in Bogotá, Colombia, November 28–30, 2016, and November 27–30, 2017. The material is organized into five sessions, prepared at the invitation of the SGC as a training module for its research staff. The material presented is primarily based on studies conducted by the author and his collaborators during previous USGS investigations.

Colombia is a major coal producer, primarily of export coal, and the module provides information needed by SGC on coal quality and environmental issues related to coal production and use. Some examples given are specific to Colombian coal, but the overall principles discussed are relevant to the topic of coal geochemistry and should be useful for general application. Slide headings in English and Spanish are included in presentation slides (appendix 2).

Acknowledgments

Manuel Hernando Romero and Sonia Lucía Guerra of the Servicio Geológico Colombiano are acknowledged for helping organize the short course and for their hospitality during Dr. Kolker's time in Bogotá.

Ricardo Olea of the U.S. Geological Survey (USGS) Eastern Energy Resources Science Center (EERSC) is acknowledged for preliminary review of the accompanying slide presentation and for translating each slide heading into Spanish. USGS International Programs, notably, Dr. Victor Heilweil, Program Specialist for Latin America, provided helpful advice as the short course visit to Colombia was being planned. The USGS EERSC Director, Dan Hayba, is acknowledged for allowing Dr. Kolker to prepare and deliver this material as part of his USGS duties. USGS EERSC research staff Ricardo Olea, Mark Engle, Peter Warwick, Joe East, and Bill Orem contributed material for inclusion in the short course as did James Hower of the University of Kentucky Center for Applied Energy Research. Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

Topics in Coal Geochemistry—Short Course

By Allan Kolker

Introduction

This short course was prepared at the request of Servicio Geológico Colombiano (SGC) as a module for staff training. Prior to the short course, the SGC expressed interest in receiving training in (1) geochemistry and quality of coal; (2) geochemistry of trace elements in coal; (3) mercury and halogens in coal; (4) characterization and cycling of atmospheric mercury; (5) mercury, trace elements, and organic constituents in atmospheric fine particulate matter; (6) mercury in coal and the effect of coal quality on mercury emissions from combustion systems; (7) environmental and health effects related to coal use; and (8) related topics in coal combustion processes. A five-session short course was prepared that addressed all but the engineering aspects of coal use. In the sections that follow, topic overviews are given for the material that was presented. Brief descriptions of each slide are given in appendix 1, and the actual short course material, presented as a series of PowerPoint slides, is included in Portable Document Format (PDF) as appendix 2.

Session 1

The goal of this session is to present the larger context of coal geochemistry, before discussing specific details. World coal production is examined as well as dependence on coal for power generation. Columbia has extensive hydroelectric resources and, as a result, exports most of its coal production. Also in this session, basic parameters applicable to coal characterization are reviewed. Emerging limits for mercury and carbon dioxide (CO_2) emissions from coal-burning utility power stations are discussed from global and U.S. perspectives, updated to their status as of November 2017.

1.1 Global Coal Production and Use

In this section, available information about global coal production is discussed from Colombian and U.S. perspectives based on the most recent International Energy Agency (IEA) and U.S. Energy Information Administration (EIA) data. Colombia is highlighted as the 11th largest coal producer and the 4th largest coal exporter in the world. The United States is 1st in terms of coal reserves, and Colombia is 12th (World Energy Council, 2013). Because of its abundant hydroelectric resources, Colombia is among the lowest in the world in its dependency on coal for electric power generation (only about 10 percent). By contrast, the United States is slightly below the world average in terms of dependence on coal for power generation, but this dependence has been steadily decreasing due to the abundance of shale gas (World Bank, 2013; EIA, 2016). International Energy Agency data on coal production show increasing production of Colombian coal for nearly three decades with almost all of that produced for export (IEA, 2016; appendix 2, slide 1.1-5). The La Guajira and Cesar Departments of Colombia are the largest producers of coal relative to other parts of the country (World Coal, 2011), but smaller coal mines are present over a large part of both the eastern and western basins (Tewalt and others, 2006; appendix 2, slide 1.1-6).

In a series of slides, the U.S. energy mix for power generation is compared to that of Colombia. Coal production in the United States increased steadily for three decades up until about 2010, when it began to decline (EIA, 2016). This decline was most pronounced in the two largest U.S. coal-producing regions: the Appalachian Basin and the Powder River Basin. At the same time, coal production in the Illinois Basin was increasing, due in large part to the increased use of flue-gas desulfurization (FGD) scrubbers in the United States, because high-sulfur coal is needed to operate the scrubbers efficiently. As a result, sulfur emissions were no longer an impediment to the use of high-sulfur coal (EIA, 2016; appendix 2, slide 1.1-10). The larger trends of increasing gas-fired power generation and decreasing coal-fired power generation in the United States mirror the increase in U.S. shale gas production (EIA, 2016; appendix 2, slides 1.1-11, 1.1-14). In the current (2015) U.S. energy mix, coal and gas each account for 33 percent of net electric generation. Trends projected by the EIA show an increase in renewables and a continued increase in gas in the United States, with a corresponding decrease in the proportion of coal used for power generation. The extent of reduction in coal use depends on whether the proposed U.S. Environmental Protection Agency (EPA) Clean Power Plan (CPP; EPA, 2015) is adopted (EIA, 2016; section 1.3).

To conclude this section, U.S. Geological Survey (USGS) studies about shale gas production and its effects and about CO_2 storage capacity in U.S. saline reservoirs are discussed (USGS, 2013). Shale gas topics include studies of pore structure in shales to understand gas distribution, sampling of water produced together with gas (produced water) and testing of produced water for additives used in hydraulic fracturing. The USGS assessment of CO_2 storage capacity shows the largest capacity in the Gulf Coast, Rocky Mountains, northern Great Plains, and Alaska. The assessment of CO_2 storage capacity shows that the largest storage capacity for CO_2 is not near the greatest concentration of U.S. coal-fired power stations in the Midwestern States, requiring substantial addition of pipeline infrastructure to take advantage of this storage capacity (USGS, 2013; appendix 2, slide 1.1-16).

1.2 Review of Basic Coal Data

In this section, basic approaches to coal characterization are reviewed, and more detailed information specific to trace elements in coal and coal ash is presented later in the short course. To begin this section, basic concepts such as coal rank, heating value, moisture, and mineral matter (ash) are reviewed. Important American Society for Testing and Materials (ASTM) approaches for coal characterization are described, including how to collect coal samples and prepare them for analysis, and what is included in essential ASTM determinations such as Proximate Analysis (ASTM D3172), Ultimate Analysis (ASTM D3176), Forms of Sulfur (ASTM D2492), and Rank Classification (ASTM D388). An example of ASTM D388 Rank Classification is given in appendix 2, slide 1.2-6, for four Colombian coal samples based on proximate analyses reported by Tewalt and others (2006). Three examples of sulfur forms determinations are provided, including a freshly collected low-sulfur South African coal and a freshly collected U.S. Illinois Basin high-sulfur coal, each having different total and pyritic sulfur contents. The third example is a weathered, moderate-sulfur Ukrainian coal sample collected from an outcrop, showing characteristic sulfate formation (appendix 2, slide 1.2-10). Useful publications are highlighted, including USGS Circular 1143 (Schweinfurth, 2003), which provides an introduction to coal science and coal quality, and USGS Open-File Report 2012–1205 (East, 2013), which shows the distribution of U.S. coal basins and illustrates the ASTM D388 Rank Classification for coal.

1.3 Toward Global Emissions Standards

In this section, implications of coal use for the global environment are considered in a status report on the state of efforts to limit carbon and mercury emissions, both globally and in the United States. For carbon emissions, the global effort is the Paris Agreement on Climate Change adopted on December 12, 2015 (United Nations, 2017). In the Paris Agreement, each participating country is expected to have a plan to reduce carbon emissions. At the time of the first short course in November 2016, ratification status of the agreement had been reached. Since then, in June 2017, the United States has sought to withdraw from the agreement. Current status of the Paris Agreement on Climate Change is given at http://unfccc.int/paris_agreement/items/9485.php. The U.S. plan to limit powerplant carbon emissions is the EPA Clean Power Plan (CPP), introduced in 2015 (EPA, 2015). The CPP has a goal of a 32-percent carbon reduction relative to 2005 emissions by 2030 (appendix 2, slide 1.3-3). However, at the time of the first short course, implementation of the CPP was on hold by the U.S. Supreme Court, and more recently, the EPA has proposed to repeal it.

The Minamata Convention on Mercury (United Nations Environment Programme [UNEP], 2016) is a global effort to control the release of mercury and limit its use. The convention includes controls on air emissions of mercury as well as a ban on new mercury mines, phase-out of existing ones, and regulation of mercury used in small-scale gold mining. At the time of the first short course in November 2016, more than 100 countries had signed the convention, but it had not reached the 50 ratifications required for it to go into effect. Since then, the minimum needed for ratification has been reached, and in August 2017, the Minamata Convention entered into force. The current status of the Minamata Convention is given at http://mercuryconvention.org/.

In the United States, the EPA Mercury and Air Toxics Standards (MATS) were introduced to limit emissions of mercury [Hg], other harmful trace elements (Beryllium [Be], Chromium [Cr], Manganese [Mn], Cobalt [Co], Nickel [Ni], Arsenic [As], Selenium [Se], Antimony [Sb], and Lead [Pb]), listed in order of increasing atomic number, and acid gases (hydrofluoric acid [HF], and hydrochloric acid [HCl]; EPA, 2011a). These standards apply to all coal- and oil-fired power generating units greater than 25 megawatts, which is essentially all power generation at the utility scale. Rationale for MATS is given in a series of slides showing that (1) powerplants are the largest source of U.S. mercury emissions; (2) other toxic metals from powerplants such as arsenic, chromium, and nickel can cause cancer; (3) fish consumption advisories for mercury are in effect in every State; (4) substantial health benefits, including avoidance of premature deaths and hospitalizations for respiratory and cardiovascular diseases, are projected to result from MATS (EPA, 2011b); and (5) compared to other industrial sectors that have become regulated, the unregulated utility sector has shown minimal reduction in mercury emissions (appendix 2, slide 1.3-6, 1.3-7). Finalization of MATS in April 2016 preceded the first short course. The current status of the MATS program is given at https://www.epa.gov/mats.

Session 2

In this session, detailed information on the distribution and controls of trace elements in coal is presented. Emphasis is given to iron disulfides pyrite and marcasite (both FeS_2) because these minerals host many of the elements of environmental interest, such as As, Se, Sb, Hg, and Pb in coal. Results are presented on the basis of published determinations by the author using microanalysis and by other results from the literature. The goal of this session is to provide a better understanding of the occurrence and effect of trace elements in coal as a foundation for a later session on the behavior of trace elements in coal combustion (Session 4).

2.1 Trace Elements in Coal

This section begins by providing the rationale for understanding trace element distribution in coal. Reasons include effects on power station operation, prediction of emissions, prediction of element behavior in coal preparation, control of metals release from coal and coal combustion products to groundwater, and minimizing health consequences. This discussion is followed by an introduction to the mode of occurrence concept, which is the form that a chemical element takes within coal. The mode of occurrence of an element determines its behavior during coal combustion and its environmental impact. Mode of occurrence is a function of geologic setting and can also provide information on the geologic history of a sample. In a broad sense, elements in coal may have primary organic and inorganic associations. Among inorganic associations, minor and trace elements may substitute for major constituents, such as chromium in illite-smectite, or occur as discrete trace phases, such as lead selenide (PbSe; Finkelman, 1981; Kolker and Finkelman, 1998). Summaries of mineral matter in coal, trace phases, and modes of occurrence of potentially toxic metals in coal are given in a series of slides (appendix 2, slides 2.1-6 to 2.1-8). An overview of analytical approaches for investigating trace elements is given in this session but is expanded in Session 5. In both Session 2 and Session 5, the importance of moisture determination in accurately expressing the concentration of elements in coal is discussed.

The topic of arsenic in coal is introduced in this section by USGS Fact Sheet 2005–3152, “Arsenic in Coal” (Kolker and others, 2006a; appendix 2, slide 2.1-11). Past USGS studies used a selective chemical leaching approach to infer the mode of occurrence of elements, such as arsenic, in coal (Palmer and others, 1998; Finkelman and others, 2018). On the basis of the removal of arsenic in the nitric acid leaching step of the multi-stage leaching procedure, arsenic shows a predominant pyritic association in bituminous coals. Leaching studies also indicated a less pronounced pyritic association for arsenic in lower rank coals. The occurrence of arsenic as an abundant minor constituent in coal pyrite was confirmed by direct determinations, using electron microprobe analysis (Kolker and others, 2000; Kolker, 2012).

Using a spectroscopic approach, Huffman and others (1994) recognized that a portion of the arsenic associated with coal pyrite is converted spontaneously to arsenate, an oxidized arsenic form, over time. Huggins and others (2002) compared this spectroscopic approach to USGS selective leaching results to monitor progressive arsenic oxidation in the same coal samples. Both methods give similar proportions of arsenate if the HF and HCl leaching fractions combined are assumed to represent the arsenate fraction in coal. In a series of experiments over 18 months, Kolker and Huggins (2007) investigated the extent of arsenic substitution in pyrite on the rate of formation of arsenate in coal. Results showed similar rates of progressive arsenic oxidation under dry conditions regardless of the initial amount of pyritic arsenic. As an analogue for development of acid mine drainage in samples that were wetted, arsenic oxidation is much more rapid, leading to nearly 100 percent arsenate, a highly mobile arsenic form, by the end of the experiment (appendix 2, slide 2.1-15; Kolker and Huggins, 2007).

2.2 Trace Elements in Iron Disulfides

Iron disulfides are common components of coal and are known to contain harmful elements such as arsenic, selenium, and mercury. Studying the distribution of these constituents is especially helpful in understanding dispersion of air and water pollutants and in optimizing approaches for their reduction by coal preparation. In this section, the extents and modes of substitution of minor constituents into iron disulfides is reviewed together with the growth history of iron disulfides in coal. Divalent cations such as Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} generally substitute for Fe^{2+}, whereas monovalent anions such as As^{-}, Se^{-}, and Sb^{-} generally substitute for S^{-} (Deditius and others, 2008). Coupled substitution has been recognized most notably as a mechanism for hosting gold in pyrite as As^{3+} plus Au^{+}. Substitution of minor constituents in iron disulfides is compiled from the literature, with emphasis on the occurrence of arsenic and mercury in pyrite (appendix 2, slide 2.2-3; Kolker, 2012).

Backscattered electron (BSE) imaging and wavelength-dispersive elemental mapping reveal similar growth histories and patterns of element enrichment in iron disulfides occurring in widely dispersed coals. Framboidal pyrite is always the earliest iron disulfide generation and is almost always arsenic poor. Single framboids or composite framboid masses are commonly overgrown by a later pyrite generation that is distinguished by a subhedral texture. Overgrowths on framboids may also be

distinct compositionally, often showing enrichment in arsenic or other constituents relative to the earlier framboid as shown in appendix 2, slides 2.2-7 to 2.2-9, and in Kolker (2012). In some cases, framboids were found to have preferential nickel enrichment at or near their centers, which may indicate nickel availability in earliest diagenesis when its precursor existed in a monosulfide form (slide 2.2-10; discussed in Kolker, 2012). At the other extreme of the coal-forming sequence, cleat or vein-filling pyrite is always the last iron disulfide generation, based on crosscutting relations and, in some cases, by contrasting trace element contents.

2.3 Introduction to Mercury in Coal

In this section, common forms of mercury occurrence in coal are reviewed as an introduction to Session 3, which goes into this topic in greater detail. A brief discussion is provided about how we know that certain minerals, such as pyrite, are common hosts for mercury in bituminous coals. This section also compares available results for mercury in U.S. coals published in a USGS database (Bragg and others, 1997; updated by Palmer and others, 2015) and by the EPA, following extensive surveys of U.S. coal used in power generation conducted in 1999 (EPA, 2003) and again in 2010 (EPA, 2011c). Mean mercury contents (0.17 parts per million [ppm]) are higher in the USGS database than in the EPA databases (0.11 and 0.12 ppm, respectively) primarily because the USGS data represent coals as mined whereas the EPA databases represent delivered coals that may have undergone some degree of preparation prior to delivery (appendix 2, slide 2.3-3). This difference also reflects a greater proportion of low-mercury western coals included in the EPA databases. Mercury and arsenic in coals exported to the Netherlands are shown in appendix 2, slide 2.3-4, from the compilation by Meij and te Winkel (2009). The plots show a large range in values for each element in coal from different international sources and that coal exported from Colombia is below average for both mercury and arsenic.

Also in this section, approaches are reviewed that show how the occurrence of mercury in iron disulfides in coal is known (slide 2.3-5). In most cases, the mercury content of iron disulfides is below the detection limit of electron-beam instruments, such as an electron microprobe, but can be determined by using more sensitive instruments, such as laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS). In addition, the occurrence of mercury in pyrite is inferred in selective leaching studies of coal and in bulk elemental analysis by correlation of mercury with iron disulfide proxies such as total iron contents. Different pyrite populations can have different mercury contents, as shown in slide 2.3-6. Coals with similar pyritic sulfur contents from the U.S. Illinois Basin are compared to coals from Donets Basin of eastern Ukraine, a known mercury-enriched province. A plot showing bulk mercury content versus pyritic sulfur for coals from these locations shows strongly diverging trends despite similar pyrite contents. The trend for the Ukraine samples reflects greater substitution of mercury in pyrite compared to the Illinois Basin samples.

Session 3

This session focuses on the distribution of mercury and halogens in coal and their behavior in determining mercury emissions and promoting mercury capture in coal-fired boilers. The session also emphasizes inexpensive approaches for improving mercury capture from utility boilers on the basis of past EPA and USGS field studies and recommendations of UNEP. Past USGS studies, measuring ambient mercury contents and speciation, and using trace elements in fine particulate matter for source apportionment, are also discussed in Session 3.

3.1 Mercury and Halogens in Coal

This section begins with a review of the introductory material on mercury in coal presented in section 2.3 of the previous session. To introduce the effect of halogens in combustion systems, slide 3.1-3 shows that halogens can have positive effects by helping to improve mercury capture but can also have negative effects on boiler operation if the concentration of halogens, especially chlorine, is too high. Kolker and others (2012) reviewed the effect of halogens on mercury capture and showed how mercury, halogens, and particulates interact in the boiler. On a mass basis, bromine is more effective than chlorine in oxidizing elemental mercury in power station flue gas, thereby promoting mercury capture. On a mass basis, bromine is typically 1–4 percent of the chlorine content of U.S. coals (Vosteen and others, 2010; Kolker and others, 2012). Halogen contents of U.S. coals vary with rank and are lowest in low-rank coals and anthracite (Kolker and Quick, 2015; appendix 2, slide 3.1-6). The mode of occurrence of halogens in coal was investigated by Huggins and Huffman (1995), using spectroscopic approaches, which showed that halogens in coal are associated with the organic fraction, indicating a predominant association where halogens present in coal moisture are loosely bound to maceral surfaces or retained in pore spaces. In addition to rank variation,

halogen contents are controlled by geologic factors, including depth of burial, chemistry of associated formation waters, and proximity to geologic structures, such as fault zones, that may provide pathways for halogen-bearing fluids to interact with coal. Examples of the variation of chlorine content of U.S. coals with depth are presented for the U.S. Illinois Basin (from Gluskoter and Rees, 1964; appendix 2, slides 3.1-9, 3.1-10) and for the central Appalachian Basin (Bragg and others, 1991; appendix 2, slides 3.1-11, 3.1-12).

In the remainder of this section, a series of slides is presented from a USGS collaborative study of coals used for power generation in South Africa (Kolker and others, 2014). In this study, funded by UNEP and conducted in cooperation with Eskom, the national electric utility of South Africa, the USGS was provided with 42 samples of composite feed coals, representing all 13 operating coal-fired power stations in South Africa. A separate group of eight density separates of South African Highveld #4 coal was provided to study mercury and trace element partitioning expected during coal preparation. The mean mercury content of the South African feed coals, determined in USGS laboratories, is more than twice that of U.S. feed coals and approximately four times that of South African coal produced for export (appendix 2, slide 3.1-14). Investigation of the Highveld #4 density separates shows a strong correspondence of pyrite contents with ash and mercury. Results show that the lowest ash and mercury contents are in the lowest density separates that approximate the values of South African export coals (Kolker and others, 2017b). In situ determination of arsenic and mercury in pyrite by LA-ICP-MS confirms enrichment of these elements in pyrite relative to whole coal values and shows considerable grain-scale variation (Kolker and others, 2017b). On the basis of values for the bulk separates of the Highveld #4 coal used in South Africa, mercury contents would be expected to vary by a factor of about eight between exported coal and its discarded stone (Kolker and others, 2017b; appendix 2, slide 3.1-19).

3.2 Improving Mercury Capture

Mercury capture in coal-fired utility power stations is a function of coal quality, including rank, mercury content, and coal halogen content, as well as plant operations, including type and positioning of air pollution control devices (APCDs), the amount of unburned carbon in the particulate fraction, and whether there are specific controls for nitrogen oxides (NO_x) and (or) mercury (UNEP, 2011; Senior, 2015). For power stations with conventional APCDs, a minimum of about 300 ppm chlorine is optimal to promote mercury capture, whereas concentrations of significantly more than 1,000 ppm have a diminishing benefit and may result in corrosion of the boiler (Quick and others, 2005; Kolker and others, 2006b; appendix 2, slide 3.2-3). In the boiler, gas-phase and gas-particle reactions promote oxidation of elemental mercury to form mercury-halogen complexes or bind mercury species to particles to form particulate mercury. Each of these mercury forms is easier to capture by APCDs than elemental mercury. Low rank coals typically do not have high enough halogen contents to promote oxidation and capture of elemental mercury. In this case, activated carbon may be injected upstream from the particulate control devices, or halogen-based sorbents may be added to the coal (Kolker and others, 2012; appendix 2, slide 3.2-4). Simple ways to lower mercury emissions include (1) preparing coal to reduce input mercury by removing pyrite-associated elements such as mercury and (2) adjusting power station operating conditions to increase the amount of unburned carbon in the ash, thereby improving mercury capture from the flue gas. The latter may have unwanted effects, though, such as decreasing boiler efficiency and affecting the quality of ash for marketing. Among widely used particulate controls, fabric filters (FFs) generally capture a higher proportion of mercury from the flue gas than electrostatic precipitators (ESPs). Where regulations require reductions in powerplant sulfur dioxide (SO_2) emissions, the addition of FGD to reduce sulfur emissions should have a co-benefit of capturing a high proportion of any gaseous-oxidized mercury present.

In the remainder of this section, a case study of the Kendal and Duvha power stations in South Africa is presented. These stations were sampled in 2010 by the EPA for stack emissions, feed coal, and fly ash in each of the six boiler units for each power station (Scott, 2011; Kolker and others, 2014). Emissions measurements show lower total emissions and a higher fraction of oxidized mercury from three units in the Duvha station equipped with FFs compared to the other three units at Duvha and to all six units at the Kendal station, which are equipped with ESPs. The three Duvha units with FFs have the highest mercury capture efficiency, and USGS results show that fly ash from these units also has the highest mercury content (Kolker and others, 2014; appendix 2, slide 3.2-10). The section concludes by referring to the UNEP guidance document for reducing mercury emissions from coal combustion in powerplants. The UNEP document gives best practices for improving mercury control at a range of costs (UNEP, 2011).

3.3 Ambient Mercury and Fine Particulate Matter

This section gives a brief introduction to sampling ambient mercury and fine particulate matter, based primarily on recent USGS studies. Sampling mercury in the environment relates to coal geochemistry because coal-fired power stations are among the largest point-source emitters of ambient atmospheric mercury (EPA, 2011a, b). Measurement of ambient atmospheric mercury includes three operationally defined species: (1) reactive gaseous mercury (RGM), including all charged gaseous mercury

species; (2) particulate mercury (Hg_p), including all mercury bound to particles; and (3) elemental mercury (Hg°), the dominant form of mercury in the atmosphere. Elemental mercury has a long residence time in the atmosphere and, as a result, can be transported globally, whereas RGM is deposited locally or regionally and has a shorter residence time. Residence time of Hg_p varies depending on particle size, composition, and solubility (Kolker and others, 2007).

The USGS Mobile Mercury Laboratory (Mobile Lab) has been deployed in a variety of settings to investigate ambient mercury species and associated parameters, such as fine particulate ($PM_{2.5}$) mass, and ancillary gases, such as SO_2, NO_x, and ozone (O_3; Kolker and others, 2007, 2008, 2010; Engle and others 2008, 2010). In one such study, the Mobile Lab was deployed to Woods Hole, Massachusetts, for more than a year (Kolker and others, 2013). Mercury species in this northern coastal setting were compared to previous Mobile Lab deployments along the U.S. Gulf Coast and other southern locations to assess controls on atmospheric mercury deposition in coastal environments (Engle and others, 2008, 2010). During the Woods Hole deployment, and in previous studies (Edgerton and others, 2006; Kolker and others, 2008), transient RGM plumes were found to occur together with elevated SO_2 and NO_x, indicating these plumes have coal combustion sources.

During the Woods Hole study, fine particulate matter was collected over several months, using filter-based samplers external to the Mobile Lab (Kolker and others, 2013; appendix 2, slide 3.3-4). Trace elements in $PM_{2.5}$ were determined by extraction of particulate matter from the filters together with analysis by inductively coupled plasma-mass spectrometry (ICP-MS). Sources contributing to the observed trace element distributions were investigated by using a matrix factorization approach together with air mass back trajectories (Kolker and others, 2013). Results of the factorization analysis give weighted proportions of four probable source categories contributing to each element measured and to the total mass of $PM_{2.5}$ collected. Among sources identified, an energy generation source was determined to be the largest contributor to $PM_{2.5}$ mass with lesser contributions from crustal and marine sources and a possible metal smelting source. Elements such as vanadium (V), Cr, Ni, As, Se, molybdenum (Mo), Sb, and Hg are characteristic of coal combustion for energy generation whereas aluminum (Al), titanium (Ti), iron (Fe), yttrium (Y), zirconium (Zr), and the rare earth elements (REE) are characteristic of crustal sources (Duce and others, 1975; Pacyna and Pacyna, 2001; Song and others, 2001; appendix 2, slide 3.3-8). Surprisingly, some crustal-sourced material was contributed by air masses having offshore back trajectories. This determination supports the observed transport of Saharan dust across the Atlantic in the summer months combined with northward transport along the Atlantic coast by clockwise circulation of the summer Bermuda high (Perry and others, 1997; Kolker and others, 2013). These studies demonstrate how sampling and analysis of fine particulate matter can be used for source apportionment and to identify the contribution of energy sources to the ambient environment.

Session 4

This session emphasizes fundamentals of coal combustion products (CCPs) and recent CCP-related USGS research. A recent EPA ruling upholds the designation of CCPs as nonhazardous waste, allowing the continued beneficial use of CCPs in construction materials and in other applications, while eliminating the need for more stringent (and expensive) handling requirements if CCPs were reclassified (EPA, 2014). This session examines the mineralogy of CCPs and mineral transformations that take place during coal combustion, together with trace element variation in CCPs, and between CCPS and coal. Current beneficial use of CCPs is reviewed together with the potential for new uses, such as a source of valuable elements. In the last part of this session, the potential for mobility of coal ash and its trace constituents is considered.

4.1 Introduction to Coal Ash

Coal combustion products primarily include fly ash, bottom ash, and, in plants equipped with FGD, flue-gas desulfurization sludge. The classification of coal ash in ASTM C618 for construction purposes is based on its major element characteristics expressed as the sum of $SiO_2 + Al_2O_3 + Fe_2O_3$ compared to other major constituents. Where $SiO_2 + Al_2O_3 + Fe_2O_3$ is greater than or equal to 50 percent of the total on a weight basis, the ash is called “cementitious” and is classified as Class C. Where $SiO_2 + Al_2O_3 + Fe_2O_3$ is greater than or equal to 70 percent of the total on a weight basis, the ash is called “pozzolanic” and is classified as Class F. Each classification has specific properties for use in concrete.

Common minerals in coal, such as quartz, clays, carbonates and pyrite, either break down, react, or undergo phase transformations at boiler temperatures. Clays, such as illite-smectite and kaolinite, are either replaced in coal fly ash by aluminosilicate minerals, such as mullite ($Al_6Si_2O_{13}$), or they enter the melt, forming aluminosilicate glass upon cooling. Pyrite in coal is oxidized in the boiler to form iron oxides, whereas quartz undergoes a phase transformation to the high-temperature β form (appendix 2, slide 4.1-6). Aluminosilicate glass is the most abundant constituent of coal fly ash, making up about 70 to more than 90 percent of most samples. Unburned carbon in fly ash may be present as various forms of coke or as coal constituents, which have survived the combustion process, such as inertinite (slide 4.1-8). In slides 4.1-9 and 4.1-10, examples show the

use of electron beam methods to characterize constituents of coal ash. Methods shown include BSE and wavelength-dispersive elemental mapping. These methods are discussed further in section 5.1

4.2 Trace Elements in Coal Ash

The behavior of trace elements in pulverized-coal-fired boilers is highly dependent on relative element volatilities (Ratafia-Brown, 1994; appendix 2, slide 4.2-3). Elements such as selenium. mercury, and the halogens are extremely volatile, leading to concerns over emission of these constituents. Conversely, elements such as manganese (Mn), rubidium (Rb), Zr, and the REE, are highly retained in the ash fraction and, as a result, are considered to be potential resources if they can be effectively recovered (see the following section). Most elements have more intermediate behavior and are both emitted and retained to some degree. Elements such as Be, Cr, Ni, As, Sb, and Pb fall into this category. However, concern over their emission is sufficient for them to be included with elements whose emissions are limited under the EPA MATS regulations (EPA, 2011a). Retention or partial retention of elements of environmental interest in coal ash results in pronounced overall enrichment in these elements relative to concentrations present in coal, because the mass fraction of ash is much smaller than that of the feed coal (Deonarine and others, 2015; appendix 2, slide 4.2-5). In addition to a general enrichment of trace elements in fly ash relative to coal, fly ash trace element contents vary by location within APCDs as flue-gas temperature and particle size decrease downstream from the boiler, resulting in greater element capture. As a result, concentrations of elements such as arsenic, mercury, and lead tend to be higher in the back rows of ESPs where the finest size fractions are collected (Mardon and Hower, 2004; James Hower, unpub. data, 2004; appendix 2, slides 4.2-7, 4.2-8).

4.3 Beneficial Uses of Coal Ash

The affirmation of nonhazardous waste status by the EPA allows the continued beneficial use of CCPs, with specified procedures for proper handling, transport, and storage of these materials. In 2016, the rate of CCP re-use in the United States reached 52 percent, an all-time high (American Coal Ash Association, not dated; appendix 2, slide 4.3-3). The increased rate of re-use is important because CCPs that are not re-used must be stored in landfills or impoundments, which is costly and could release coal ash into the environment in the event of a catastrophic failure (see the following section). Primary uses of coal ash and FGD sludge include raw material in concrete products, feedstock in the production of cement, waste stabilization, and road construction. FGD sludge is a component of synthetic gypsum for use in construction and agriculture.

The U.S. Department of Energy (DOE) is supporting a range of promising research approaches to recover REE from coal and coal-related materials. These materials include coal itself, coal fly ash, and even acid mine drainage from past coal mining (DOE, 2017a, b). This effort resulted from the need for REE in a wide range of modern applications ranging from cell phones to rare earth magnets used in wind-powered electric generation (Van Gosen and others, 2014). The need for REE is also reflected in the fact that one country, China, provides much of the REE commodity supplied to the world (Gambogi, 2017; slide 4.3-5).

The USGS is currently investigating the distribution of REE in coal fly ash as an alternative source of REE to conventional mining. REE are strongly retained in the coal ash after coal combustion, leading to enrichment relative to their concentrations in coal and shale (appendix 2, slide 4.3-8). Normalization of REE concentrations to chondritic meteorites (chondrite normalization) is a convenient way to compare REE results for different samples and to compensate for the Oddo-Harkins effect, apparent in REE, in which even-numbered elements are more abundant than odd-numbered elements (appendix 2, slide 4.3-9). Although discrete REE-bearing trace mineral phases are apparent in coal (appendix 2, slides 4.3-11 and 4.3-12), these minerals are much less common in coal ash (Hower and others, 2013).

Using an ion microprobe (section 5.1; https://shrimprg.stanford.edu/), REE distribution within constituents of coal ash was investigated on a grain scale (Kolker and others, 2017a). Results indicate that glasses formed at boiler temperatures have similar REE distributions as the bulk ash samples. REE are also contained in iron oxide-glass intergrowths but are much less abundant in quartz, which constitutes a small portion of some samples. Results for bulk REE distribution in a larger group of samples (Taggart and others, 2016) show a good correlation of REE content with Al_2O_3, consistent with USGS findings on a grain scale that REE are partitioned into aluminosilicate glasses in coal fly ash (appendix 2, slide 4.3-14).

4.4 Coal Ash Environmental Issues

The continued designation of coal ash as nonhazardous waste (EPA, 2014) has allowed a wide range of beneficial uses of coal ash to continue and has eliminated the need to store a large portion of ash in U.S. landfills and impoundments. For ash that is stored, standard tests, such as the EPA Toxicity Characteristic Leaching Procedure (TCLP), help ensure that harmful elements are not readily mobilized (EPA, 1992). Recently, several large releases of stored coal ash into the environment occurred in the

United States, including ash stored at Kingston, Tennessee, in December 2008 and Eden, North Carolina, in February 2014 (appendix 2, slide 4.4-3). The Kingston spill resulted in the transport of harmful constituents, such as arsenic and mercury, from coal ash to river sediments, and these sediments continued to be affected by the spill even after concentrations of trace metals in river water returned to normal levels (Ruhl and others, 2010; Deonarine and others, 2015).

Leaching tests, such as the TCLP, assume that coal ash is stored at the land surface or in surface impoundments, under oxic conditions, where oxygen is available. This is not always the case in landfills and impoundments, especially at depth, where oxygen may be unavailable and, thus, conditions may be anoxic. Fly ash leaching experiments by Deonarine and others (2015, 2016), conducted under controlled conditions, show that leaching behavior of elements, such as chromium and arsenic, can be much different depending on the availability of oxygen. Although arsenic was leachable in all cases studied, in one sample, it was more leachable under anoxic conditions than if oxygen had been available (appendix 2, slide 4.4-6). These experiments show that additional leaching tests that more accurately reflect the conditions where coal ash is stored are needed to ascertain the potential for mobility of trace constituents from coal ash into the environment. The design of ash storage facilities is also an important factor. Lined landfills are much less likely to release constituents to the environment than unlined landfills (Deonarine and others, 2015; appendix 2, slide 4.4-5).

Session 5

In this session, analytical methods used to study trace elements in coal are reviewed, including bulk analytical methods and methods for microanalysis. Each method is discussed from the standpoint of its advantages and common pitfalls. This discussion is followed in section 5.2 by the examination of data affected by common analytical problems, especially bulk analysis by ICP-MS. The short course concludes by introducing, in section 5.3, mathematical concepts underlying compositional data analysis. The purpose of this section is to help data users avoid potential problems, such as spurious correlation and contradictory results, encountered when statistical approaches are applied to data that sum to a constant as in results expressed as a percentage and (or) parts per million. Section 5.3 describes tools needed to avoid these problems.

5.1 Laboratory Methods

This section gives methods for bulk analysis and microanalysis of coal, in large part from the authors' experience with all but transmission electron microscopy (TEM) and instrumental neutron activation analysis (INAA). Some approaches, such as X-ray diffraction (XRD), are used to identify which minerals are present in the whole (bulk) coal sample, whereas microanalysis generally provides compositional information for individual grains within a sample (slide 5.1-2). Bulk analysis is used to determine the element distribution in a whole sample. Methods for bulk chemical analysis include ICP-MS, INAA, X-ray fluorescence, and isotope dilution. Advantages and disadvantages of each method are shown in appendix 2, slide 5.1-3. ICP-MS is the most common multi-element bulk analytical method currently in use but requires that a solid sample be digested to get it into solution. Prior to sample digestion, coal samples are "ashed" in a laboratory furnace to consume the organic fraction, leaving behind all but the most volatile elements in the inorganic fraction. Volatile elements such as mercury and selenium should be run on whole coal samples rather than on laboratory ash. Care should be taken in ICP-MS analysis to avoid or correct for interferences for the elements of interest. An example is given in section 5.2 showing how one or more isotopes having the same mass as the element of interest can interfere with the determination and how to avoid or correct for these isobaric interferences. Here and previously in section 2.1, the importance of accurately determining moisture contents, especially for low-rank coals, is emphasized to express elemental concentrations in coal. To eliminate variability resulting from differences in moisture content and the proportion of ash present in coal, expression of concentrations on a moisture-free whole coal basis is recommended, requiring accurate determination of moisture in coal together with bulk analysis and knowledge of the proportion of ash present (slide 5.1-5). National Institute of Standards and Technology (NIST) standard reference material (SRM) 1632d (Trace Elements in Bituminous Coal) and SRM 1633c (Trace Elements in Coal Fly Ash) are useful for analysis of coal and coal ash. NIST SRMs are produced in batches having expiration dates, and values with three levels of certainty are given: certified, reference, and informational. Where certified values are unavailable, reference and informational values may be useful, but generally, these two values should not be used for primary instrument calibration (slide 5.1-6).

In appendix 2, slide 5.1-7, methods for bulk mercury analysis are compared. The most widely used methods are (1) thermal decomposition together with amalgamation and measurement by atomic absorption spectrophotometry, an EPA method also known as direct mercury analysis (DMA; EPA, 2007); (2) cold vapor atomic absorption (CVAA); and (3) cold vapor atomic fluorescence (CVAFS). DMA is the most common method currently in use because of its flexibility to run solid or liquid samples

and the availability of relatively inexpensive, ready-to-use analyzers. CVAA has a similar range of determination as DMA but requires solid samples to be brought into solution. CVAFS has lower detection limits than either DMA or CVAA but is used primarily in studies of low-level ambient mercury rather than mercury in coal. Portable atomic absorption units with Zeeman background corrections are useful in field applications to measure real-time vapor phase mercury, especially in areas where sources of mercury emissions are nearby.

In the next part of section 5.1, microanalysis methods used in the characterization of coal and coal combustion products are discussed, including methods that are useful in determining major constituents, such as scanning electron microscopy (SEM), electron microprobe, and TEM, and methods specific to trace element microanalysis, such as LA-ICP-MS, ion microprobe, and synchrotron-based approaches (slides 5.1-8 to 5.1-20). Examples showing laboratory setups and results generated by micro-beam instruments, such as SEM, electron microprobe, and TEM, are given in slides 5.1-9 to 5.1-13. Electron beam instruments are useful in imaging samples using secondary electrons, obtaining combined imaging and compositional data using BSE, and obtaining compositional data and element mapping using wavelength dispersive or energy dispersive analysis (slides 5.1-9 to 5.1-12). Examples illustrating trace element microanalysis using LA-ICP-MS, ion microprobe, and synchrotron-based methods are shown in slides 5.1-15 to 5.1-20. Laser ablation and ion microprobe analysis primarily offer point analyses at much lower detection limits than electron beam instruments. Both methods offer concentration and isotopic determination on the same spots. Sychrotron-based methods are primarily used for bulk sample determinations of element speciation but have been adapted to do combined concentration mapping and element speciation of the same sample areas (slides 5.1-14 and 5.1-20). TEM analysis is especially useful in revealing characteristics of particle surfaces (slide 5.1-13) and in determining sample mineralogy on a nanometer scale, which in many cases has proven to be very different than micro- or macromineralogy.

5.2 Laboratory Quality Assurance

Increasingly, laboratories such as the USGS are adopting formal quality management procedures, requiring written standard operating procedures (SOPs) for analysis methods, and enhanced review and record keeping for laboratory data. Although this process is an important aspect of laboratory operation, it is not covered in this short course. Instead, this section emphasizes common problems with bulk trace element analysis using ICP-MS and how to recognize them from ICP-MS results. As noted in section 5.1, ICP-MS is the most widely used method of bulk sample analysis, including laboratories at the SGC.

Incomplete sample digestion, especially for insoluble minerals such as zircon and monazite, is a common problem in ICP-MS if acid digestion is used. Using a sinter digestion, where sample material is mixed with sodium peroxide and sintered in a crucible at high temperature, generally gives a more complete sample digestion (appendix 2, slide 5.2-3), but acid digestion is commonly used in metals analysis, where trace phase digestion is not critical. In the example shown in appendix 2, slide 5.2-5, REE analysis of USGS standard GXR-4 after sinter digestion and acid digestion, performed by the same commercial laboratory, is compared. Results by acid digestion give much lower material recoveries for the REE, suggesting some REE-bearing phases were not dissolved. In the next example, REE analysis of NIST SRM 1633c in two sinter digestions by two laboratories is compared. Whereas there are no certified values for the REE in this SRM, it is difficult to assess the quality of the two analyses. If the results are plotted on a chondrite-normalized plot, however, the result from Lab 1 gives a smooth pattern whereas the result for Lab 2 has a kinked pattern for the heavy rare earth elements, especially ytterbium, suggesting there may be a problem with the result. Because of their low abundance, analysis of odd-numbered heavy REE such as holmium, thulium, and lutetium can often be problematic, although not in this example. Plotting results on a chondrite-normalized plot can help distinguish possible analytical problems for the REE.

In the next series of slides (appendix 2, slides 5.2-10 to 5.2-13), the problem of ICP-MS isobaric interferences is discussed and an example is given showing a correction for isobaric interferences for ^{75}As, the only isotope of arsenic. This correction uses the polyatomic species $^{37}Cl^{40}Ar$ to determine the interference of $^{35}Cl^{40}Ar$, after correcting for an interference by ^{77}Se at mass 77 with any selenium present (appendix 2, slide 5.2-13). A newer approach to arsenic and selenium determination by ICP-MS uses a collision/reaction cell to minimize spectral interferences (Li and others, 2014).

Other potential problems with ICP-MS include extrapolation of results beyond the calibrated range and carryover from a previous high-concentration sample if wash time is insufficient. Internal checks on data quality include running standards as unknowns, running total analytical blanks, and, for major elements, determining if the analysis sum is near 100 percent. For coal, sulfur is a major element and should be included in the summation. For rare earth elements, results plotted on a chondrite-normalized plot should give a smooth pattern. If not, there may be a problem. And finally, as a check, can you replicate results obtained previously or in another laboratory? The section concludes with a mercury analysis example where the same sample materials were determined at USGS laboratories in Reston, Virginia, and Denver, Colorado. Agreement generally was good, but a few samples needed multiple runs by the two laboratories for values to converge (appendix 2, slide 5.2-16; Kolker and others, 2014). This difference is a result of the concentration of mercury in pyrite contributing to variability of mercury analysis.

5.3 Introduction to Compositional Data Analysis

This section introduces basic concepts of compositional data analysis, a mathematical approach to compositional data analysis, and data interpretation. The approach is gaining acceptance in the geosciences with recognition that spurious correlations (and misinterpretation) can result from the application of conventional statistics to compositional data that are constrained to a constant sum (Aitchison and Pawlowsky-Glahn, 1997; Filzmoser and Hron, 2008; Pawlowsky-Glahn and others, 2015). Examples where compositional data are constrained to a constant sum include major element data expressed in percent and trace element data expressed in parts per million. Together, these are the primary datasets used by geochemists.

The section begins by comparing data that are mathematically limited to a constant sum, such as percent, and data that are inherently unconstrained, such as speed and molar concentrations. Closure of constrained compositional data requires that proportions of the whole must be positive or zero. This constraint sets compositional data apart from variables with absolute scales such as speed, mass, and time. In a given dataset, mathematical covariance of results can lead to spurious correlations, giving misleading or contradictory results. An example is given that is an analogue to proximate analysis of coal expressed in moisture-containing and dry states. In the moist state, there is an apparent correlation between components X_1 and X_2. However, moisture (X_4) expressed in percent is constrained to be no more than 100 percent. When this variable is removed by drying, the sign of the covariation between components X_1 and X_2 is reversed (appendix 2, slide 5.3-5). Problems with compositionally constrained data apply even where only a few of many components are measured, such as in trace element data, where values add up to be much less than the total.

To avoid problems inherent in constrained compositional data, a series of approaches is given whereby these data are converted into forms that can be used in unconstrained space where conventional statistical approaches are applicable. The first step is to compute ratios of variables and determine the logarithms of the ratios (log ratios; appendix 2, slide 5.3-8). As shown in appendix 2, slide 5.3-9, log ratios are then mathematically transformed to give calculated variables that include isometric log-ratio transformations (ilr) and centered log-ratio transformations (clr). These transformed variables can then be used to explore controlling dependencies of the dataset. One such approach is to use a two-dimensional biplot showing principal components and transformed log-ratio variables of the dataset in an unconstrained space (Otero and others, 2005; Thió-Henestrosa and Comas, 2016; appendix 2, slide 5.3-10). Log-ratio transformations can also be mapped to display transformed data in a geospatial context as shown in appendix 2, slide 5.3-11; Olea and Luppens, 2015). Both the biplot and the map show that among a range of coal parameters for the dataset examined, ash yield exerts the greatest overall control on the distribution of values obtained. Once constraints are removed, as shown in appendix 2, slide 5.1-13, compositional data can be used to test or describe processes such as variation of constituents with time, as shown, and (or) other geologically relevant processes.

Appendix 1. Short Course Slide Descriptions

Session 1

1.1 Global Coal Production and Use

1.1-1 Title slide Session 1, Topic 1: Global Coal Production and Use

1.1-2 Global Coal Production and Export. Compilation showing top ranking global coal producers and exporters based on IEA (2016) data. Colombia is highlighted as the #11 producer and the #4 coal exporter.

1.1-3 World Coal Proved Reserves. World Energy Council (2013) compilation showing the top 15 countries listed in order of proved coal reserves. The United States is #1 and Colombia is #12.

1.1-4 Electricity from Coal. Plot showing World Bank (2013) data for relative dependence on coal for electric power generation. France is lowest due to reliance on nuclear power. Poland and South Africa are among the highest. The United States is slightly below the world average coal dependence.

1.1-5 Colombian Coal Production. Plots showing increasing production of Colombian coal and coal produced for export. The two trends are nearly identical because most coal in Colombia is produced for export (IEA, 2016). Plot at right shows the proportion of coal produced in Guajira and Cesar Departments of Colombia, where the largest mines are located, relative to other parts of the country (World Coal, 2011).

1.1-6 Coal Fields of Colombia. Map at left showing the administrative Departments of Colombia and the locations of coal fields. Map at right shows simplified geologic base (from Tewalt and others, 2006).

1.1-7 Colombia—Power Generation by Source. Plot showing electric power generation in Colombia over time and that hydroelectric power generation predominates. Coal use constitutes a relatively small portion of electric power generation and this proportion has been fairly constant.

1.1-8 U.S. Coal Production (1980–2015). Graph showing declining U.S. coal production starting in about 2010. This is the first in a series of slides comparing the U.S. energy mix to that of Colombia (EIA, 2016).

1.1-9 U.S. Coal Basins. Map showing the distribution of U.S. coal basins and the location of the Appalachian Basin, Powder River Basin, and Illinois Basin discussed in slide 1.1-10 (from East, 2013).

1.1-10 U.S. Coal Production by Coal Basin. Plot showing production data, with time, of major coal producers—the Appalachian Basin, Powder River Basin, and Illinois Basin.

1.1-11 U.S. Electric Power Sector (1980–2015). Plot showing long-term U.S. trends in electric power generation by energy source. Plot shows decrease in the proportion of coal used for power generation beginning about 2010 and a corresponding increase in natural gas-fired power generation. Data are from EIA (2016).

1.1-12 U.S. Electric Power Generation (1990–2040). Plot showing current and projected trends in U.S. electric power generation by source. In current (2015) energy mix, coal- and gas-fired power generation are each 33 percent of net electric generation. Projected trends show increase in renewables and continued increase in gas-fired power generation and a decrease in the proportion of coal used for power generation. The extent of reduction in coal use depends on whether the proposed EPA Clean Power Plan (CPP) is adopted. Data are from EIA (2016).

1.1-13 U.S. Power Generation by Region. Map showing differences in the U.S. energy mix for electric power generation by region in 2015 and projected variation to 2030. Proportion of coal used for power generation is lowest in California and the Northeastern States and highest in the Northern Plains region. U.S. average from slide 1.1-13 is shown as inset in lower left. Data are from EIA (2016).

1.1-14 U.S. Shale Gas Production (2007–2014). Plot showing U.S. production of shale gas since 2007. Increasing gas production has compensated for the decline in coal production as U.S. coal-fired powerplants have increasingly adopted gas-fired power generation. Data are from EIA (2016).

1.1-15 USGS Shale Gas Studies. Summary slide listing ongoing USGS shale gas research and projection from EIA (2016) that U.S. shale gas production is expected to continue to increase between 2020 and 2040. USGS research topics include studies of pore structure in shales to understand gas distribution, sampling of produced water, and testing of produced water for constituents added in hydraulic fracturing.

1.1-16 Carbon Capture and Storage. Summary slide describing a recent USGS study of the capacity for geologic carbon dioxide (CO_2) storage in underground saline reservoirs. The largest capacity is in the Gulf Coast, Rocky Mountains, northern Great Plains, and Alaska. The study does not address how to capture and store CO_2. The study shows that the largest storage capacity for CO_2 is not near the greatest concentration of U.S. coal-fired power stations in the Midwestern States. Results are from USGS (2013).

1.1-17 Summary—Topic 1: Global Coal Production and Use. Summary of Topic 1.1 with emphasis on Colombian coal production, the energy mix in Colombia, and characteristics of Colombian coals.

1.1-18 Summary—Topic 1: Global Coal Production and Use (Continued). Summary of Topic 1.1 with emphasis on U.S. coal production, the energy mix in the United States, growth of U.S. shale gas production, and USGS work on assessing the underground storage capacity for CO_2 in the United States.

1.1-19 References—Topic 1: Global Coal Production and Use.

1.2 Review of Basic Coal Data

1.2-1 Title slide Session 1, Topic 2: Review of Basic Coal Data

1.2-2 Some Basic Points About Coal. Review slide defining basic properties of coal such as rank, heating value, moisture, and ash.

1.2-3 Coal–A Complex Natural Resource. Slide showing USGS Circular 1143 (Schweinfurth, 2003), which is an introduction to coal quality and coal science.

1.2-4 Important ASTM Methods for Coal. Summary slide showing commonly used ASTM International methods for characterizing coal, including the name for each method and what it does.

1.2-5 ASTM Coal Rank (ASTM D388). Plot showing coal rank as defined by ASTM D388, based on variation in heating (calorific) value and percent fixed carbon. Figure is from East, (2013).

1.2-6 Example of ASTM D388 Rank Classification. Example showing application of ASTM D388 formulae for fixed carbon and heating value used to determine rank classification for four Colombian coal samples using results in Tewalt and others (2006).

1.2-7 Coal Sampling. Summary slide showing ASTM methods for coal sampling and what each method is used for.

1.2-8 Sampling Coal Ash. Summary slide showing recommendations for sampling coal ash at a power station. There are no ASTM methods for geochemical sampling of coal ash.

1.2-9 Forms of Sulfur (ASTM D2492). Summary slide showing what goes into ASTM D2492 (sulfur forms), what these forms are, and how they are determined.

1.2-10 Examples of Sulfur Forms (ASTM D4239 + D2492). Slide showing three examples of sulfur forms determinations using ASTM methods. South African example is low sulfur, un-weathered; Illinois Basin example is high sulfur with corresponding sulfur reduction and increase in heating value by coal preparation. Ukraine example is moderate sulfur with sulfate fraction contributed by weathering.

1.2-11 Summary—Topic 2: Review of Basic Coal Data. Review listing of basic coal parameters and variation in coal characteristics with these parameters.

1.2-12 References—Topic 2: Review of Basic Coal Data.

1.3 Toward Global Emissions Standards

1.3-1 Title slide Session 1, Topic 3: Toward Global Emissions Standards.

1.3-2 Paris Agreement on Climate Change. Summary slide showing basic elements of the Paris Agreement to reduce carbon emissions adopted on December 12, 2015.

1.3-3 Limiting U.S. Carbon Emissions. Summary slide showing elements of the EPA CPP to limit U.S. carbon emissions.

1.3-4 Minamata Convention on Mercury. Summary slide showing elements of the United Nations Minamata Convention to limit, regulate, and phase out global mercury use, including controls on air emissions of mercury.

1.3-5 U.S. EPA Mercury and Air Toxics Standards (MATS). Slide showing basic elements of the EPA for U.S. coal- and oil-fired generating units.

1.3-6 Rationale for U.S. EPA MATS. Slide showing rationale for implementing EPA MATS in the United States and their projected health benefits. EPA estimates that 50 percent of U.S. atmospheric mercury is derived from emissions from U.S. coal-fired power stations (EPA, 2011b).

1.3-7 Rationale for U.S. EPA MATS. Further rationale for EPA MATS is shown in a map of U.S. fish consumption advisories for mercury and in a table showing reduction in mercury emissions in industrial sectors that have become regulated versus coal-fired utility powerplants, which were unregulated prior to implementation of MATS in 2016.

1.3-8 Summary—Topic 3: Global Emissions Standards.

1.3-9 References—Topic 3: Global Emissions Standards.

Session 2

2.1 Trace Elements in Coal

2.1-1 Title slide Session 2, Topic 1: Trace Elements in Coal.

2.1-2 Why Study Trace Elements in Coal? Slide summarizing rationale for understanding trace element distribution in coal. Reasons include effects on power station operation, prediction of emissions, prediction of element behavior in coal preparation, control of metals release for coal and coal combustion products to groundwater, and minimizing health consequences.

2.1-3 Effects of Inorganic Constituents on Coal Utilization. Summary slide showing inorganic constituents that affect power station operations and their effects.

2.1-4 Mode of Occurrence Concept. Introduction to the concept that the form of a chemical element in coal determines its behavior during coal combustion and other characteristics, including its environmental effect. Mode of occurrence is a function of geologic setting and can provide information on the geologic history of a sample.

2.1-5 Element Modes of Occurrence. Slide summarizing primary organic and inorganic associations of trace elements in coal.

2.1-6 Generalized Mineral Matter in Coal. Compilation of the mineral constituents of coal including major constituents such as clay minerals and trace constituents such as lead selenide. Compilation also shows trace elements substituting in major constituents, such as chromium in illite-smectite. From Finkelman, 1981; Kolker and Finkelman, 1998; Finkelman and others, 2018.

2.1-7 Minor/Trace Phases. Compilation of minor and trace mineral phases in coal and their constituents.

2.1-8 Metals in Coal. Compilation of potentially toxic metals in coal and their modes of occurrence.

2.1-9 How to Study Trace Elements in Coal. Compilation of analytical methods used to study the distribution of trace elements in coal on a bulk sample basis and in microanalysis. These methods are discussed in greater detail in section 5.1.

2.1-10 About Moisture. Slide emphasizing the importance of determining the moisture content of coal samples and the effect of moisture in determining the concentration of elements in coal.

2.1-11 Arsenic in Coal. Summary slide on the distribution and behavior of arsenic in coal, referring to Kolker and others (2006a).

2.1-12 Leaching Procedure for Coal Samples. Diagram showing selective chemical leaching of coal samples used in past USGS studies to indirectly determine the mode of occurrence of elements in coal (from Palmer and others, 1998).

2.1-13 Selective Leaching of Arsenic in U.S. Coals. Slide showing selective leaching results for arsenic in 13 U.S. coal samples, including 11 bituminous samples and 2 subbituminous coals. Plot shows a predominant pyritic (nitric-acid leached) association in the bituminous samples and a less pronounced pyritic association for arsenic in lower rank coals.

2.1-14 Arsenic Oxidation. Slide describing Kolker and Huggins (2007) study of coals with different extents of arsenic substitution in pyrite to see if this substitution affects the rate of formation of arsenate, the oxidized form of arsenic.

2.1-15 Spontaneous Arsenic Oxidation in Coal. Slide showing results of Kolker and Huggins (2007) study in which arsenic oxidation was monitored using arsenic X-ray absorption near-edge structure (XANES). Results show progressive arsenic oxidation under dry conditions regardless of starting pyritic arsenic. In samples that were wetted, arsenic oxidation was much more rapid, leading to nearly 100 percent arsenate by the end of the experiment.

2.1-16 Selective Leaching vs. X-Ray Absorption Fine Structure (XAFS) for Arsenic Species. Slide describing Huggins and others (2002) study comparing USGS selective leaching results for arsenic forms versus XANES, an XAFS approach, as a monitor for progressive arsenic oxidation in coal. Both methods give similar proportions of arsenate, but the leaching approach is indirect and requires interpretation that arsenate is removed in both the hydrochloric (HCl) and hydrofluoric (HF) acid leaching fractions.

2.1-17 Selective Leaching of Arsenic in U.S. Coals. Repeat of slide 2.2-13 included here to show combined results for the HF and HCl acid leaching fractions interpreted to represent the arsenate fraction in coal.

2.1-18 Summary—Topic 1: Trace Elements in Coal.

2.1-19 Summary—Topic 1: Trace Elements in Coal (Continued).

2.1-20 References—Topic 1: Trace Elements in Coal.

2.2 Trace Elements in Fe-Disulfides in Coal

2.2-1 Title slide Session 2, Topic 2: Trace Elements in Fe-Disulfides in Coal.

2.2-2 Why Study Fe-Disulfides (FeS_2) in Coal? Slide stating the benefits of studying pyrite and marcasite in coal. Benefits include understanding the source of air and water pollutants in coal use, reducing harmful constituents in coal preparation, showing diagenetic history, and predicting the formation of acid mine drainage (AMD).

2.2-3 Compilation of Minor Elements in Fe-disulfides in Coal. Compilation showing extents of minor and trace element substitution in pyrite and marcasite in coal. Compilation from various sources included in Kolker (2012).

2.2-4 Substitution of Minor Elements in FeS_2. Compilation from Deditius and others (2008) showing elements that substitute for iron and those that substitute for sulfur in iron disulfides (FeS_2).

2.2-5 Generations of Iron Disulfides in Coal. Slide stating that iron disulfides can be present in multiple generations in coal and that framboidal pyrite is earliest and cleat- or vein-filling pyrite is latest.

2.2-6 Framboids and their Overgrowths. Scanning electron microscope backscattered electron (BSE) images from Kolker (2012), showing framboidal pyrite overgrown by a later pyrite generation. Similar textures are found in widely dispersed coals.

2.2-7 Alabama, USA Warrior Basin Coal. Examples from Warrior Basin coal samples, showing differences in arsenic contents in different generations of pyrite in coal (Goldhaber and others, 2003).

2.2-8 Donetsk-Makeevka District, Ukraine. BSE image and wavelength-dispersive elemental maps showing arsenic-enriched pyrite overgrowths on arsenic-poor framboids in coal from Ukraine. Texture and genesis are very similar to that shown in slide

2.2-9 Arsenic and Selenium Enrichment in Iron Disulfides. Enrichment of arsenic and selenium in iron disulfides in coal, shown by wavelength-dispersive electron microprobe elemental maps for coal samples from the United States and Ukraine. From Kolker (2012).

2.2-10 Nickel Enrichment in Framboids. Wavelength-dispersive electron microprobe elemental maps for nickel in coal samples from the United States and Ukraine, showing preferential concentration of nickel at the core or mantle of pyrite framboids. From Kolker (2012).

2.2-11 Summary—Topic 2: Trace Elements in Fe-Disulfides in Coal.

2.2-12 References—Topic 2: Trace Elements in FeS_2.

2.3 Introduction to Mercury in Coal

2.3-1 Title slide Session 2, Topic 3: Introduction to Mercury in Coal.

2.3-2 Mercury in Coal. Summary slide listing the most common forms of mercury occurrence in coal and how we know that pyrite is the most common form of mercury occurrence in bituminous coals.

2.3-3 U.S. Coal Databases: Mercury Results. Comparison of mercury results in USGS and EPA U.S. coal databases. USGS COALQUAL database represents coal in the ground and has a higher mean mercury content than what is included in EPA databases, which contain data on coal delivered to power stations. This difference is a function of coal preparation prior to delivery and a greater proportion of low-mercury western coals included in the EPA databases. From Kolker and others (2012).

2.3-4 Mercury in World Export Coals. Plots of mercury and arsenic concentrations in coals imported to the Netherlands from various sources. Slide gives world averages for mercury and arsenic in coal and shows that Colombian export coals are well below the world averages for these elements. From Meij and te Winkel (2009).

2.3-5 Mercury in Iron Disulfides. Summary slide showing how it is known that mercury resides in iron disulfides in coal.

2.3-6 Mercury-Rich Coals in Ukraine versus U.S. Illinois Basin Coals. Plots of mercury and pyritic sulfur, comparing mercury-rich coals in Ukraine with U.S. Illinois Basin coals, each group having similar pyritic sulfur contents. The trend for active mines in Ukraine is shown in the upper plot (from Kolker and others, 2009). Ukraine data are shown in the lower plot together with the trend for U.S. Illinois Basin coals (Bragg and others, 1997). The lower plot shows that mercury content of the whole coal is a function of both the amount of pyrite and the mercury content of that pyrite.

2.3-7 Summary—Topic 3: Introduction to Mercury in Coal.

2.3-8 References—Topic 3: Introduction to Mercury in Coal.

Session 3

3.1 Mercury and Halogens in Coal

3.1-1 Title slide Session 3, Topic 1: Mercury and Halogens in Coal.

3.1-2 Mercury in Coal—Session 2 Review. Review of key points noted in previous session introducing the topic of mercury in coal.

3.1-3 Halogens in Coal—Cl, F, Br, I. Summary slide listing positive effects of halogens in coal to promote mercury capture and negative effects on boiler operation if the concentration of halogens, especially chlorine, is too high.

3.1-4 Mercury and Halogens in Coal. Slide listing major points about mercury and halogens in coal given in Kolker and others (2012).

3.1-5 Halogens in U.S. Coals. Plot of chlorine versus bromine contents of U.S. coals averaged by county. Plot shows that bromine content of U.S. coals typically is 1–4 percent of chlorine content on a mass basis. Plot is from Kolker and others (2012), modified from Vosteen and others (2010).

3.1-6 Rank Dependence of Halogens. Plots showing county-average distribution of chlorine and bromine contents in U.S. coals as a function of ASTM coal rank. Plots show depletion of halogens in low-rank coals. From Kolker and Quick (2015).

3.1-7 Mode of Occurrence of Halogens in Coal. Investigation by Huggins and Huffman (1995), using XANES for chlorine and bromine. Their results show association of halogens in coal with organic fraction but not bound as organohalogen complexes. Huggins and Huffman (1995) concluded that chlorine and bromine are present in coal moisture and are loosely bound to maceral surfaces or retained in pore spaces.

3.1-8 Geologic Factors Influencing Coal Halogen Contents. Summary slide listing geologic factors determining halogen content of coals. Factors include rank, depth of burial or paleodepth, chemistry of associated formation waters, and proximity to geologic structures.

3.1-9 Chlorine in U.S. Coal. Map showing the distribution of chlorine in U.S. coal by county average, used as an introduction to the case study of chlorine in coal in the U.S. Illinois Basin (example 1). Map from Quick and others (2005).

3.1-10 Example 1: U.S. Illinois Basin. Study describing the progressive increase of chlorine in formation water with depth in the Illinois Basin and a corresponding increase in the chlorine content of coal associated with those waters. From Gluskoter and Rees (1964).

3.1-11 Chlorine in U.S. Coal. Map showing distribution of chlorine in U.S. coal by county average, used as an introduction to the case study of chlorine in coal in the U.S Appalachian Basin (example 2). Map from Quick and others (2005).

3.1-12 Example 2: Chlorine Variation with Depth. Example 2 showing controls of chlorine variation in coal. Compilation from Bragg and others (1991) showing variation in chlorine content of Appalachian Basin coals with stratigraphic depth.

3.1-13 Mercury in South African Feed Coals. Introduction to the case study by Kolker and others (2014) for mercury in South African coals used in power generation.

3.1-14 Mercury Distribution by Power Station. Plot of mercury content for 13 coal-fired utility power stations operating in South Africa. The mean value for these coals is compared to U.S. feed coals from EPA databases and South African coals prepared for export. The mean mercury content of coals used for domestic power generation in South Africa is about four times the mercury content of South African export coals. From Kolker and others (2014).

3.1-15 Impact of Coal Preparation on Mercury. Summary slide showing benefits of coal preparation to improve coal quality on mercury reduction.

3.1-16 South African Highveld #4 Coal. Introduction to the case study on tests of density separates of South African Highveld #4 coal as a source of export coal (Kolker and others, 2017b).

3.1-17 Density Separates. Plots showing variation in pyritic sulfur with mercury and ash contents for density separates of South African Highveld #4 coal. Plots show correspondence of pyrite contents with ash and mercury. Results show the lowest ash and mercury contents are in the low density separates that approximate export coals (Kolker and others, 2017b).

3.1-18 Pyrite by Laser Ablation ICP-MS. In situ determination of arsenic and mercury in pyrite from density separates of South African Highveld #4 coal. Results show enrichment of both elements in pyrite relative to the whole coal and a large extent of grain-scale variation in mercury and arsenic contents within individual pyrite grains (Kolker and others, 2017b).

3.1-19 Coal Products Predicted from Density Separates. Table showing ash, mercury, arsenic, and selenium contents predicted in coal products used in South Africa, exported, or discarded, based on simple combinations of results for density separates from Highveld #4 coal. Mercury contents would be expected to vary by about a factor of 8 in these materials (Kolker and others, 2017b).

3.1-20 Summary—Topic 1: Mercury and Halogens in Coal.

3.1-21 References—Topic 1: Mercury and Halogens in Coal.

3.2 Improving Mercury Capture

3.2-1 Title Slide Session 3, Topic 2: Improving Mercury Capture.

3.2-2 Factors that Influence Mercury Capture. Summary slide listing coal quality factors and plant operation factors influencing mercury capture in coal-fired powerplants. From United Nations Environment Programme (UNEP; 2011) and Senior (2015).

3.2-3 Impact of Chlorine on Mercury Capture. Plot showing extent of mercury capture in coal-fired utility power stations equipped with various conventional air pollution control devices (APCDs). Results show the optimal range for chlorine to promote mercury capture, above which additional halogen contents are less beneficial. Results are based on U.S. county averages and available best-fit equations for each control technology. Plot is from Kolker and others (2006b), using county averages from Quick and others (2005).

3.2-4 Role of Halogens in Mercury Capture. Diagram showing gas phase and gas-particle reactions in the boiler involving mercury, halogens, and particulate matter. Halogens promote mercury oxidation to form mercury-halogen complexes or mercury bound to particles. These forms are easier to capture than gaseous elemental mercury. Diagram is from Kolker and others (2012).

3.2-5 Improving Mercury Capture. Plot showing mercury removal across an electrostatic precipitator (ESP) as a function of unburned carbon content (represented by loss on ignition [LOI]) of the ash. Results from Senior and Johnson (2005).

3.2-6 Improving Mercury Capture. Slide listing other options for improving mercury capture in coal-fired power stations equipped with conventional air pollution controls. These options include the addition of fabric filters (FFs) and the use of sorbents with an affinity for mercury.

3.2-7 Improving Mercury Capture. Slide showing addition of flue-gas desulfurization (FGD) as an option for improving mercury capture. FGD is a more expensive option, and its primary use would be to reduce sulfur emissions. If FGD is added, these devices can remove mercury in its gaseous oxidized form with high efficiency.

3.2-8 Kendal and Duvha Power Stations, South Africa. Introduction to the UNEP, Eskom, EPA, and USGS collaborative study (Scott, 2011; Kolker and others, 2014) of feed coal and fly ash from the Kendal and Duvha power stations.

3.2-9 Kendal and Duvha Power Stations, South Africa. Table showing total mercury emissions and proportion of oxidized mercury emitted from each boiler unit at Kendal and Duvha power stations. Measurements are from 2010 EPA field visit (Scott, 2011). Also shown is the concentration of mercury in fly ash as a function of the air pollution controls present. Results show that mercury oxidation is higher and more mercury is captured in the fly ash in units equipped with fabric filters (Kolker and others, 2014).

3.2-10 Kendal and Duvha Power Stations, South Africa. Plots showing that the extent of mercury capture and mercury content of fly ash is higher in Duvha boiler units equipped with fabric filters relative to Duvha and Kendal units equipped with electrostatic precipitators (ESPs). Coal and fly ash samples shown in the left plot were collected in duplicate with total sampling and analytical variation as shown (Kolker and others, 2014).

3.2-11 Kendal and Duvha Power Stations, South Africa. Summary slide showing findings with respect to variation in mercury capture in Kendal and Duvha boiler units equipped with ESPs versus FFs.

3.2-12 Improving Mercury Capture. Slide showing UNEP guidance document giving best practices for mercury emissions reduction and improving mercury capture without mercury-specific controls.

3.2-13 Summary—Topic 2: Improving Mercury Capture.

3.2-14 References—Topic 2: Improving Mercury Capture.

3.3 Measuring Ambient Mercury and Fine Particulate Matter

3.3-1 Title slide Session 3, Topic 3: Measuring Ambient Mercury and Fine Particulate Matter.

3.3-2 Speciation of Ambient Mercury. Summary slide defining measurable mercury species in the atmosphere, including elemental mercury (Hg^0), reactive gaseous mercury (RGM), and particulate mercury (Hg_p), and the characteristics of each.

3.3-3 USGS Mobile Mercury Laboratory. Slide showing USGS Mobile Mercury Laboratory and its capabilities for measuring mercury species; ancillary gases such as sulfur dioxide (SO_2), nitrous oxides (NO_x), and ozone (O_3); and fine particulate mass ($PM_{2.5}$). From Kolker and others (2007).

3.3-4 Ambient Mercury and Fine Particulate Matter. View of the interior of the USGS Mobile Mercury Laboratory showing instrument controls and view of the particulate sampler external to the Mobile Laboratory deployed to collect fine particulate matter for trace element analysis.

3.3-5 Ambient Mercury, Woods Hole, Massachusetts. Results of study by Kolker and others (2013), showing correspondence of RGM peaks with transient elevation of SO_2 and NO_x. Correspondence of all three parameters is indicative of plumes from coal-burning emission sources such as coal-fired powerplants.

3.3-6 Mercury Species and Other Gases, Woods Hole. Plots showing longer term correspondence between mercury species and ancillary gas concentrations, Woods Hole, Mass. (Kolker and others, 2013).

3.3-7 Distinguishing Sources of Ambient Mercury. Summary slide for distinguishing plumes from coal combustion versus other mercury sources such as chlor-alkali plants and the use of mercury in small-scale gold mining. Results are based on studies by Edgerton and others (2006) and by Kolker and others (2008 and 2010).

3.3-8 Trace Elements in $PM_{2.5}$. Summary slide showing generalized source categories of element groupings in fine particulate matter. From Duce and others (1975); Pacyna and Pacyna (2001); and Song and others (2001).

3.3-9 Trace Elements in $PM_{2.5}$. Results from the Kolker and others (2013) study of fine particulate matter at Woods Hole, Mass., showing crustal, marine, smelter, and energy- source categories and the calculated proportions of each.

3.3-10 Summary—Topic 3: Measuring Ambient Mercury and Fine Particulate Matter.

3.3-11 References—Topic 3: Measuring Ambient Mercury and Fine Particulate Matter.

Session 4

4.1 Introduction to Coal Ash

4.1-1 Title Slide Session 4, Topic 1: Introduction to Coal Ash.

4.1-2 Coal Combustion Products (CCPs). Summary slide with background information and definitions for coal combustion products.

4.1-3 Coal Combustion Products (CCPs). Diagram showing the range of coal combustion products produced in power generation and where in the plant they are generated. Diagram is from Deonarine and others (2015).

4.1-4 ASTM C618 Fly Ash Classification. Slide showing characteristics of ASTM Class C (“cementitious”) and Class F (“pozzolanic”) fly ash based on major element chemistry. From ASTM C618-17.

4.1-5 In the Boiler. Plot showing the range of temperature conditions in the boiler during coal combustion. From Senior (2015).

4.1-6 Mineral Transformations in Powerplants. Slide showing the mineralogical differences between coal and fly ash produced during coal combustion.

4.1-7 Examples of Fly Ash Constituents. SEM and microscopic images of coal fly ash showing constituents of the ash, including glass cenospheres, mullite ($Al_6Si_2O_{13}$), magnetite (Fe_3O_4), and partially combusted coal. Images courtesy of James Hower, University of Kentucky.

4.1-8 Fly Ash Petrography. Summary of organic and inorganic constituents of fly ash that are newly formed in the boiler (neoformed), such as glassy material, and those that are inherited from the feed coal, such as quartz and inertinite.

4.1-9 Fly Ash Microanalysis. Electron microprobe BSE images and wavelength dispersive elemental maps of iron oxide particle in glass and skeletal iron oxides with interstitial glass in fly ash. Nickel maps suggest an association of nickel with the iron oxide phase.

4.1-10 Fly Ash Microanalysis. Electron microprobe BSE and wavelength dispersive elemental maps of Fe, Ca, Al, and Si distribution in a coal fly ash sample. Images show glassy aluminosilicate cenospheres, iron oxides, and calcium-enriched zones in this sample area.

4.1-11 Summary—Topic 1: Introduction to Coal Ash.

4.1-12 References—Topic 1: Introduction to Coal Ash.

4.2 Trace Elements in Coal Ash

4.2-1 Title Slide Session 4, Topic 2: Trace Elements in Coal Ash.

4.2-2 Trace Elements in Coal Ash. Summary slide listing generalized behavior of trace elements in coal fly ash including volatile elements such as mercury that are emitted during coal combustion and refractory elements such as the rare earths that are retained in the ash fraction.

4.2-3 Behavior of Elements During Coal Combustion. Diagram showing relative volatility of elements during coal combustion. Volatile elements are emitted whereas refractory (not volatile) elements are retained in a smaller mass fraction. From Ratafia-Brown (1994).

4.2-4 From the Flue Gas. Slide summarizing the capture of volatile elements from the flue gas.

4.2-5 Element Enrichment in Coal Ash. Plot showing trace element enrichment in three U.S. coal fly ash samples relative to mean concentrations for these elements in U.S. coal from Bragg and others (1997). Plot is from Deonarine and others (2015).

4.2-6 Variation in Fly Ash Chemistry. Slide summarizing the variation in trace element content of fly ash within the ash collection system as a function of decreasing particle size and temperature.

4.2-7 Fly Ash Chemistry—Arsenic. The variation of arsenic content from front to rear in ESP hoppers in a Kentucky powerplant. From James Hower, University of Kentucky (unpub. data, 2004).

4.2-8 Fly Ash Chemistry—Mercury. The variation of mercury content from front to rear and from side to side in ESP hoppers in a Kentucky powerplant. From Mardon and Hower (2004).

4.2-9 Mercury Capture. Summary of the status of mercury capture in U.S. coal-fired utility power stations. Outline of factors that influence the process and extent of mercury capture in power stations that burn coal.

4.2-10 Summary—Topic 2: Trace Elements in Coal Ash.

4.2-11 References—Topic 2: Trace Elements in Coal Ash.

4.3 Beneficial Uses of Coal Ash

4.3-1 Title Slide Session 4, Topic 3: Beneficial Uses of Coal Ash.

4.3-2 Beneficial Use of Coal Combustion Products. Summary slide giving the status of EPA regulation of coal ash for beneficial use and the status of the use of coal combustion products in the United States. Sources: EPA (2014); American Coal Ash Association (not dated).

4.3-3 Use of U.S. Coal Combustion Products (CCPs). Plot showing amounts of CCPs produced and used by year and proportion used as a percentage. In 2016, proportion used exceeded 50 percent for the first time. Source: American Coal Ash Association (not dated).

4.3-4 Some Current Use of Coal Ash and FGD. Summary slide listing primary uses of coal ash and FGD materials. Source: American Coal Ash Association (not dated).

4.3-5 Recovery of Rare Earth Elements from Coal Ash? Summary slide listing the need for alternative sources of rare earth elements (REE), characteristics of coal ash that make it a possible source of REE, and the potential for REE recovery from coal ash.

4.3-6 Advantages of Coal Ash as a Source of REE. Summary of the advantages of coal ash as a potential source of REE, continued from previous slide.

4.3-7 Behavior of Elements During Coal Combustion. Slide emphasizing the nonvolatile behavior of REE during coal combustion. Slide is repeated from slide 4.2-3, which emphasized very volatile behavior of elements such as mercury and is the opposite of the behavior of REE during coal combustion. From Ratafia-Brown (1994).

4.3-8 REE in Coal Ash vs. Coal and Upper Continental Crust. Slide comparing REE enrichment of U.S. average coal (Bragg and others, 1997, Palmer and others, 2015; Upper Continental Crust (Taylor and McLennan, 1985), and a series of coal fly ash samples (Kolker and others, 2017a). Plot illustrates relative REE enrichment in fly ash relative to other materials. Chondrite-normalized plot, with normalizing values from from Korotev (2009).

4.3-9 Oddo-Harkins Effect. Slide illustrating the Oddo-Harkins effect in which even-numbered elements are more abundant than odd-numbered elements. Normalization to chondrites eliminates the appearance of a sawtooth abundance pattern resulting from the Oddo-Harkins effect.

4.3-10 Possible Modes of Occurrence of REE in Coal Ash. Summary slide explaining the uncertainty in mode of occurrence of REE in coal ash and giving possibilities that have been proposed for this occurrence.

4.3-11 REE-Bearing Trace Phases in Coal. Table listing REE-bearing trace phases found in coal and their melting temperatures as pure phases. These melting temperatures are similar to or exceed peak temperatures attained in coal-fired utility boilers.

4.3-12 REE-Bearing Trace Phases in Coal. Additional forms of REE occurrence in coal. Some are present only in mineralized coals.

4.3-13 Investigation of Fly Ash for REE. Outline of ongoing USGS studies of fly ash to determine the distribution of REE and preliminary results using ion microprobe analysis described in Session 5 of this short course.

4.3-14 REE in Coal Fly Ash. Results from Kolker and others (2017a) showing the distribution on a chondrite-normalized plot of REE in two bulk fly ash samples and their constituents.

4.3-15 Summary—Topic 3: Beneficial Uses of Coal Ash.

4.3-16 References—Topic 3: Beneficial Uses of Coal Ash.

4.3-17 References (Continued)—Topic 3: Beneficial Uses of Coal Ash.

4.4 Coal Ash Environmental Issues

4.4-1 Title Slide Session 4, Topic 4: Coal Ash Environmental Issues.

4.4-2 Mobility of Constituents from Coal Ash? Diagram showing possible pathways of migration of leachates from a coal ash impoundment where the impoundment is unlined. Slide also lists EPA TCLP leaching protocol used for testing potential element mobility from coal ash.

4.4-3 Mobility of Constituents From Coal Ash? Description of recent U.S. coal ash spills in Kingston, Tenn., and Eden, N.C., and the magnitudes of each spill.

4.4-4 Mobility of Constituents From Coal Ash? Photograph and map of the area affected by the 2009 Kingston, Tenn., coal ash spill. From Ruhl and others (2010), EPA (2014), and Deonarine and others (2015, 2016).

4.4-5 Potential for Mobility of Trace Elements. Slide showing USGS Fact Sheet 2015–3037 (Deonarine and others, 2015) and list of key findings: (1) Potential mobility of trace elements from coal ash differs by element; (2) Degree of oxygenation affects extent of element mobility; and (3) Standardized leaching tests only consider case where oxygen is available.

4.4-6 Leaching Experiments for Arsenic and Chromium in Fly Ash. Results from Deonarine and others (2015, 2016), showing leaching behavior of arsenic and chromium from two coal fly ash samples under oxic (with oxygen present) and anoxic (little or no oxygen present) conditions. Results show that arsenic is leachable under all conditions whereas chromium is partly leachable in one sample under oxic conditions and not leachable in the other cases.

4.4-7 Summary—Topic 4: Coal Ash Environmental Issues.

4.4-8 References—Topic 4: Coal Ash Environmental Issues.

Session 5

5.1 Laboratory Methods

5.1-1 Title Slide Session 5, Topic 1: Laboratory Methods.

5.1-2 How to Study Trace Elements in Coal. Summary slide comparing whole sample (bulk) analysis methods versus microanalysis methods for selective analysis of individual minerals or constituents in coal.

5.1-3 Common Methods for Bulk Trace Element Analysis. Table listing bulk analysis method from slide 5.2-2 and giving advantages and disadvantages of each method. Methods include inductively coupled plasma-mass spectrometry (ICP-MS), instrumental neutron activation analysis (INAA), X-ray fluorescence, and isotope dilution. Compilation is based on experience by the author with each method except for INAA.

5.1-4 About Moisture. Slide emphasizing the importance of moisture determination for coal in bulk analysis on a whole-coal basis and on a dry basis.

5.1-5 Whole Coal versus Ash Basis. Slide explaining the difference between whole-coal and ash basis for bulk analysis of coal. Slide showing sources of variation in results expressed on an ash basis and how these can be eliminated by expressing results for bulk coal samples on a dry, whole-coal basis.

5.1-6 Standards for Coal and Coal Ash Analysis. Slide listing U.S. National Institute for Standards and Technology (NIST) standard reference materials (SRMs) for coal and coal ash analysis, including SRM 1632d, Trace Elements in Bituminous Coal, and SRM 1633c, Trace Elements in Coal Fly Ash. Also, the difference between certified, reference, and informational values in NIST SRMs is explained.

5.1-7 Common Methods for Bulk Mercury Analysis. Table listing bulk analysis methods for mercury giving advantages and disadvantages of each method. Compilation is based on experience by the author with the direct mercury analysis (DMA) method.

5.1-8 Microanalysis Methods. Table listing microanalysis methods and giving advantages and disadvantages of each method, including scanning electron microscopy (SEM) with energy dispersive X-ray (EDX) analyzer, electron microprobe, and transmission electron microscopy (TEM) or high resolution (HR) TEM. Compilation is based on experience by the author with each method except for TEM.

5.1-9 Scanning Electron Microscope SEM/EDX. Photographs of an SEM equipped with EDX analyzer and an SEM image of a fly ash particle.

5.1-10 Electron Microprobe. Photograph of an electron microprobe and diagram showing the cross section of a wavelength-dispersive spectrometer used to measure characteristic X-rays of elements generated by interaction of the sample with the electron beam.

5.1-11 Electron-beam Instruments. Diagram showing interaction of sample with the electron beam and source regions for secondary electrons used in SEM, backscattered electrons used in BSE, and characteristic X-rays used for compositional analysis.

5.1-12 Microanalysis. Images showing microanalysis of a fly ash sample including wavelength-dispersive elemental maps for Fe, Ca, Al, and Si, and BSE map of the same image area.

5.1-13 Transmission Electron Microscopy (TEM). Example of high-resolution TEM image of fly ash particle surfaces showing surface coating at nanometer scale. From Deonarine and others (2015).

5.1-14 Trace Element Microanalysis Methods. Table listing microanalysis methods capable of determining trace elements and advantages and disadvantages of each method. Methods include laser ablation ICP-MS (LA-ICP-MS), ion microprobe, and synchrotron-based microprobe. Compilation is based on experience by the author with each method.

5.1-15 Laser Ablation ICP-MS. Slide showing an LA-ICP-MS instrument and its characteristics.

5.1-16 Pyrite Analysis by Laser Ablation ICP-MS. Example of LA-ICP-MS analysis of arsenic and mercury in pyrite in South Africa Highveld #4 coal density separate. From Kolker and others (2017b).

5.1-17 Ion Microprobe. Summary slide for Stanford/USGS SHRIMP-RG ion microprobe used for USGS REE studies in coal fly ash.

5.1-18 SHRIMP-RG Ion Microprobe. Photograph showing Stanford/USGS SHRIMP-RG ion microprobe and additional information on its uses. This instrument is used to determine elements present at concentrations below detection by electron beam instruments, such as the REE (Bacon and others, 2012; Stanford University, not dated).

5.1-19 Ion Microprobe Data for the REE. Preliminary REE data for selective constituents of coal fly ash determined using the SHRIMP-RG ion microprobe. Concentrations are shown on a chondrite-normalized plot together with data for bulk sample from separate bulk analysis.

5.1-20 Synchrotron Methods. Example in coal fly ash showing arsenic composition map determined by synchrotron microanalysis and corresponding arsenic species (forms of arsenic) using X-ray absorption near-edge structure (XANES). Synchrotron source has the advantage of giving bulk trace element microanalysis together with element speciation. Example is from Deonarine and others (2015).

5.1-21 Summary—Topic 1: Laboratory Methods.

5.1-22 References—Topic 1: Laboratory Methods.

5.2 Laboratory Quality Assurance

5.2-1 Title Slide Session 5, Topic 2: Laboratory Quality Assurance.

5.2-2 Common Problems in ICP-MS Analysis. Summary slide listing common problems that can affect bulk trace element analysis by ICP-MS.

5.2-3 Sample Digestion for ICP-MS. Summary slide listing approaches to digestion of solid samples for ICP-MS analysis and the requirements and limitations of each method.

5.2-4 REE-Bearing Trace Phases in Coal. Summary slide showing common REE-bearing trace phases in coal that may not be fully digested in acid digestion for REE analysis by ICP-MS.

5.2-5 Fusion Digestion vs. 4-Acid Digestion for REE. Comparison of measured and certified values for USGS standard GXR-4 in two separate ICP-MS runs by the same commercial laboratory. Using acid digestion, in most cases, recovery is only about 50 to 70 percent of the certified values. Using fusion digestion, recovery is near 100 percent.

5.2-6 Two Sinter Digestions for NIST SRM 1633c. Table showing separate ICP-MS runs for REE in NIST SRM 1633c, from two different laboratories, both using a sinter digestion procedure. Results obtained are similar in each case to available certified, reference, and informational values. Based on the values alone, it is not possible to determine which is the better analysis.

5.2-7 Chondrite Normalization. Chondrite normalization shows a smooth pattern for REE data subject to the Oddo-Harkins effect.

5.2-8 Data Comparison using Chondrite Normalization. Comparison of REE data from slide 5.2-6, using chondrite normalization. Data from Lab 1 give a smooth pattern whereas data from Lab 2 have a kinked pattern in Er and Yb, suggestive of analytical problems for the heavy REE.

5.2-9 Chondrite Normalization. Comparison of chondrite normalization approaches presented by Korotev (2009). Korotev suggests an approach using Anders and Grevesse (1989) x 1.36 to give Sm = 0.200 ppm. That approach has been adopted in this short course.

5.2-10 ICP-MS Isobaric Interferences. Summary slide showing potential isobaric interferences affecting trace element analysis by ICP-MS and ways to avoid, correct for, or eliminate them (Li and others, 2014).

5.2-11 IUPAC Periodic Table of the Isotopes. Table of the isotopes showing isotopic variation for arsenic and selenium discussed in the next slide.

5.2-12 Isotopes of Arsenic and Selenium. Table showing isotopes of arsenic and selenium needed to correct for isobaric interferences at ^{75}As, the only isotope of arsenic, in ICP-MS determination of arsenic.

5.2-13 Example of Interference Correction for ^{75}As. Example showing isobaric interferences for ^{75}As and procedure to correct for these interferences.

5.2-14 Other Common Problems with ICP-MS. Summary slide describing calibration and carryover problems inherent in ICP-MS analysis.

5.2-15 Internal Checks on Data Quality. Summary slide listing internal checks on data quality in bulk analysis. Checks include running standards, blanks, and replicates, and, for major elements, summing to near 100 percent. For REE analyses, data should define a smooth pattern on a chondrite-normalized plot. If the checks are unsatisfactory, rerun the sample.

5.2-16 Run it Over Again. Example comparing DMA mercury analyses for the same samples run in USGS laboratories in Denver, Colo., and Reston, Va. Overall, results show good agreement between the two laboratories, with a few problem samples. Rerunning the problem samples resulted in convergence of initially disparate results for the two laboratories. Results from Kolker and others (2014).

5.2-17 Summary—Topic 2: Laboratory Quality Assurance.

5.2-18 References—Topic 2: Laboratory Quality Assurance.

5.3 Introduction to Compositional Data Analysis

5.3-1 Title Slide Session 5, Topic 3: Introduction to Compositional Data Analysis.

5.3-2 Compositional Data. Common examples where compositional data are constrained to a constant sum, such as values expressed in percent and parts per million, compared to unconstrained results, such as concentrations measured in milligrams per liter, micrograms per cubic meter, or molar concentrations.

5.3-3 Closure. Closure of compositional data means that proportions of a whole must be positive or zero. This sets compositional data apart from variables using absolute scales such as speed, mass, and time.

5.3-4 Correlations. In a given sample set, mathematical covariance of results can lead to misleading or contradictory results.

5.3-5 Subcompositional Incoherence. Correlations of components are compared in case A, a sample that contains moisture, and case B, where the sample material has been dried. The sign of the covariation between components X_1 *and* X_2 is reversed by drying. This example is similar to a coal proximate analysis expressed on a moisture-containing basis and on a dry basis.

5.3-6 Simplex. This example shows a set of values in D-dimensional noncompositional space where statistical techniques are valid and a set of values in (D-1)-dimensional space (a simplex) where compositional values add to a constant. The triangular D-1 simplex is a section within D-dimensional space.

5.3-7 Warnings. Some common fallacies pertaining to compositional data are given.

5.3-8 Solutions. An approach is given whereby compositional data constrained to a constant sum can be converted for use in unconstrained space where statistical approaches are applicable. This approach includes computing rations of variables and taking the logarithms of the ratios (log ratios).

5.3-9 Log-Ratio Transformations using Geometric Means. Variable log ratios can be further transformed as shown and expressed as isometric log-ratio transformations (ilr) or centered log-ratio transformations (clr) These transformed variables can then be used to explore controlling dependencies of the dataset.

5.3-10 The Biplot: A Tool for Exploring Dependencies. Example using available software (Thió-Henestrosa and Comas, 2016) to generate plot showing principal components and variable log ratios in unconstrained space. Plot is useful in evaluating controls on data variability. Plot shows that the centered log ratio representing the ash (clr A) exerts the greatest control on the dataset.

5.3-11 Mapping. Log-ratio transformations can also be mapped to show data in a geospatial context. Here the data from the previous slide are mapped. The map also shows that where ash is highest, everything else is lower, as indicated in the previous slide.

5.3-12 Modeling of Compositional Processes. A process analogue is shown where each component has a different rate of change. This process can be applicable in cases where characterizing time series data is appropriate, such as production from different wells.

5.3-13 Summary—Topic 3: Compositional Data Analysis.

5.3-14 References—Topic 3: Compositional Data Analysis.

Reston, VA 20192

Introduction

Allan Kolker

Impact of Trace Metals

Understanding of trace-metal distribution is needed to:

- Develop models for power plant emissions.
- Predict coal behavior upon cleaning.
- Control release of metals from coal and coal combustion materials to ground water.
- Minimize health consequences of coal use in domestic settings.

Effects of Inorganic Components on Coal Utilization

Element	Effects
• Sodium	• Boiler Fouling
• Iron	• Boiler Slagging
• Chlorine	• Corrosion; Hg capture
• Si (Quartz)	• Erosion of Combustors

Trace Element Averages

Element	Mean Value (ppm)	Standard deviation	Maximum value	Number of samples
Beryllium	2.2	4.1	330	7,484
Chromium	15	15	250	7,847
Manganese	43	84	2,500	7,796
Cobalt	6.1	10	500	7,800
Nickel	14	15	340	7,900
Arsenic	24	60	2,200	7,676
Selenium	2.8	3.0	150	7,563
Cadmium	0.47	4.6	170	6,150
Antimony	1.2	1.6	35	7,473
Mercury	0.17	0.24	10	7,649
Lead	11	37	1,900	7,469
Thorium	3.2	3.0	79	6,866
Uranium	2.1	16	1,300	6,923

Average concentrations of elements of environmental interest in U. S. Coals (results from USGS COALQUAL database, Bragg et al., 1998; after Finkelman, 1993; Kolker and Finkelman, 1998).

About Moisture

- Generally, calorific value increases and moisture decreases with increasing rank. Need to know moisture content to accurately express elemental concentrations in coal.
- Moisture contents range from about 2% in bituminous coals to as much as 30% in low rank coals. Perfect analyses determined on a dry basis can be off by as much as 30% if moisture is not taken into account.

Mode of Occurrence Concept

- Definition- Understanding the chemical form of an element present in coal.
- Importance- Determines element behavior during coal combustion and potential for removal. Determines environmental impact, technological behavior and byproduct potential. Can provide information on geologic history.

Element Modes of Occurrence

Organic Association (Maceral)	Inorganic Association (Mineral)
• Ionic bound to maceral • Covalent bound to maceral • Moisture	• Solid solution (e.g As for S in pyrite; Cr in illite/smectite; Cd in sphalerite) • Essential Structural Constituent (e.g. Galena - PbS)

Results for Elements of Environmental/Human Health Interest

Element	Mode of Occurrence	Confidence*
Antimony	Pyrite; accessory sulfides	Moderate
Arsenic	Pyrite	High
Beryllium	Organic association; silicates	Low/moderate
Cadmium	Sphalerite	High
Chromium	Illlite; organic association; chromite	Moderate/high
Cobalt	Pyrite; accessory sulfides	Moderate
Lead	Galena; selenides	High
Mercury	Pyrite	Moderate/high
Manganese	Carbonates, illite	High
Nickel	Pyrite; organic; other	Moderate
Selenium	Organic; pyrite; selenides	High

* Interpretative index assigned by the authors; i.e. "High" indicates a high confidence in the results by the authors for the specified element mode of occurence.

Geologic Factors Influencing Coal Chemistry

- Burial and diagenetic changes.
- Stratigraphic and lateral variation.
- Interaction with mineralizing fluids (e.g. Alabama, China, western Washington).
- Movement of fluids along fractures.
- Cleat (fracture-filling) mineralization during coal formation.

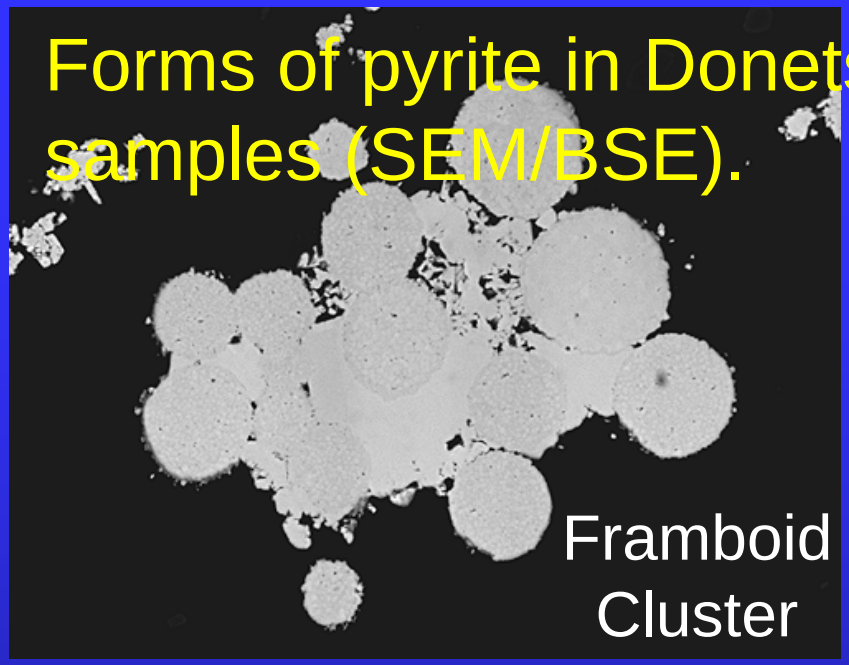
Coal Mineralogy and Mineral Chemistry

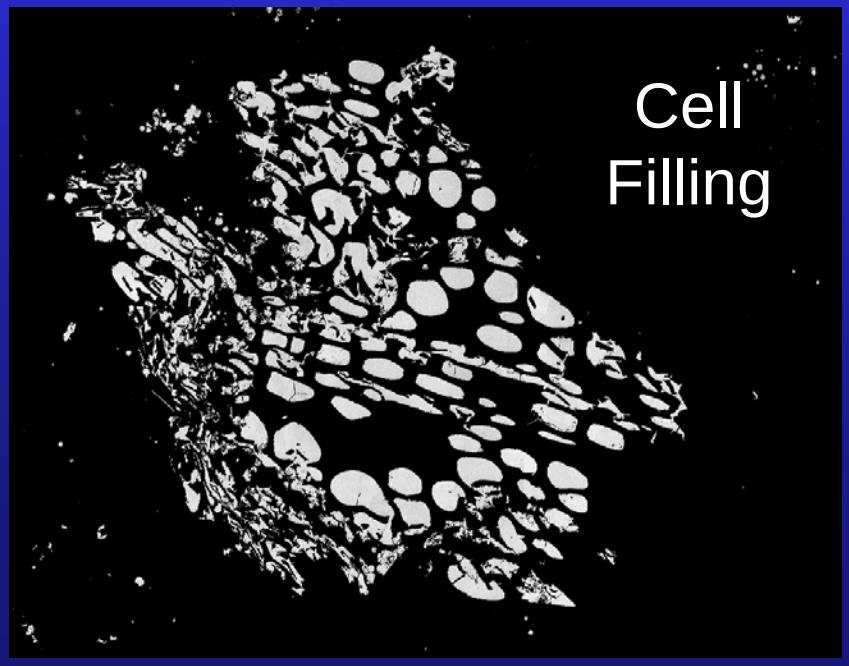
Allan Kolker

Coal Mineralogy

Mineral	Minor Elements
Quartz (SiO_2)	Negligible
Clays	
Illite/Illite-smectite	Fe,Cr,Mn,V,
Kaolinite $Al_4(Si_4O_{10})(OH_8)$	Negligible (?)
Carbonates	
Calcite ($CaCO_3$)	Sr, Mn
Siderite ($FeCO_3$)	Mn
Ankerite $Ca(Mg,Fe,Mn)(CO_3)_2$	Sr
Pyrite (Marcasite) (FeS_2)	As,Hg,Co,Ni

Forms of pyrite in Donets Basin (Ukraine) coal samples (SEM/BSE).





Minor/Trace Phases

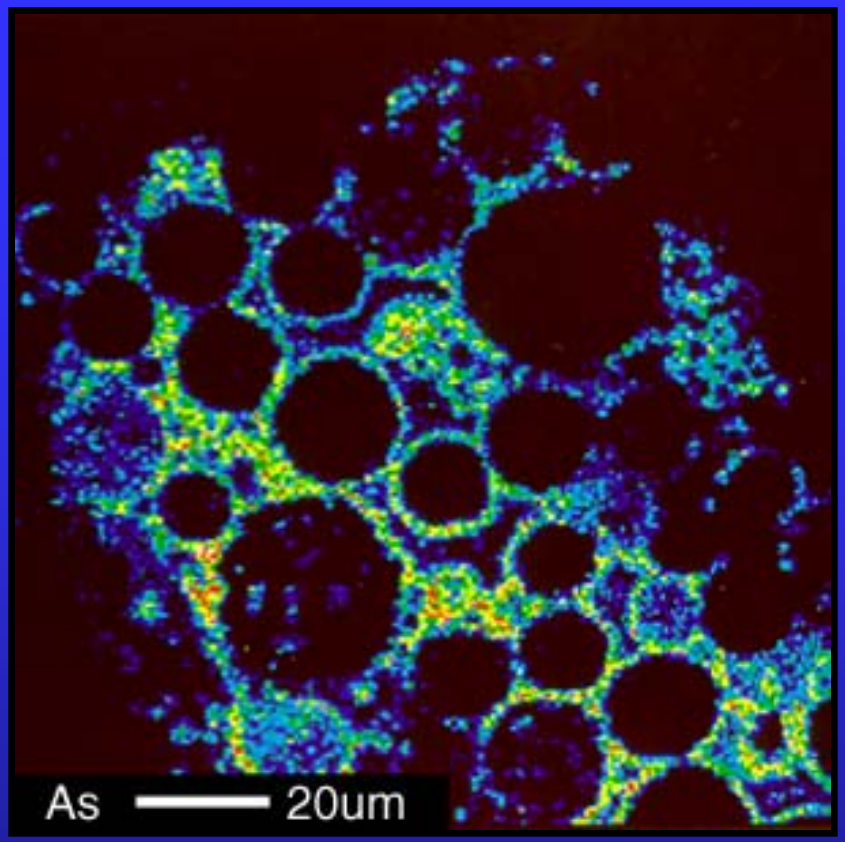
Mineral	Formula or Major Components	Minor Elements
Galena	(PbS)	
Sphalerite	(ZnS)	Cd
Chalcopyrite	($CuFeS_2$)	
Clausthalite	(PbSe)	
Crandallite Group	(Ca, Al, P)	Ba, Sr, REE
Monazite	(REE, P)	Th
Xenotime	(YPO_4)	REE
Apatite	(Ca, P)	REE
Zircon	($ZrSiO_4$)	U, Pb, Th
Rutile	(TiO_2)	
Barite	($BaSO_4$)	
Feldspars	(Ca, Na, K, Al, Si)	
Micas	(K, Fe, Mg, Ti, Al, Si)	
Zeolites	(Ca, Na, K, Al, Si)	

Low Temperature Ashing/XRD

- Method for determining coal mineralogy.
- Concentrate mineral matter by slowly consuming organic matter at 175°C.
- Mineral I.D. by X-Ray diffraction of LTA.
- Mixture of minerals solved by computer.
- Computer-controlled SEM is an alternate approach. Both techniques are semi-quantitative.

Arsenic in Coal

- Pyrite is primary host of arsenic in bituminous coals; Arsenopyrite is rare
- Arsenic contents vary widely within and between pyrite grains.
- In low rank coals, pyrite is a less important host of arsenic.



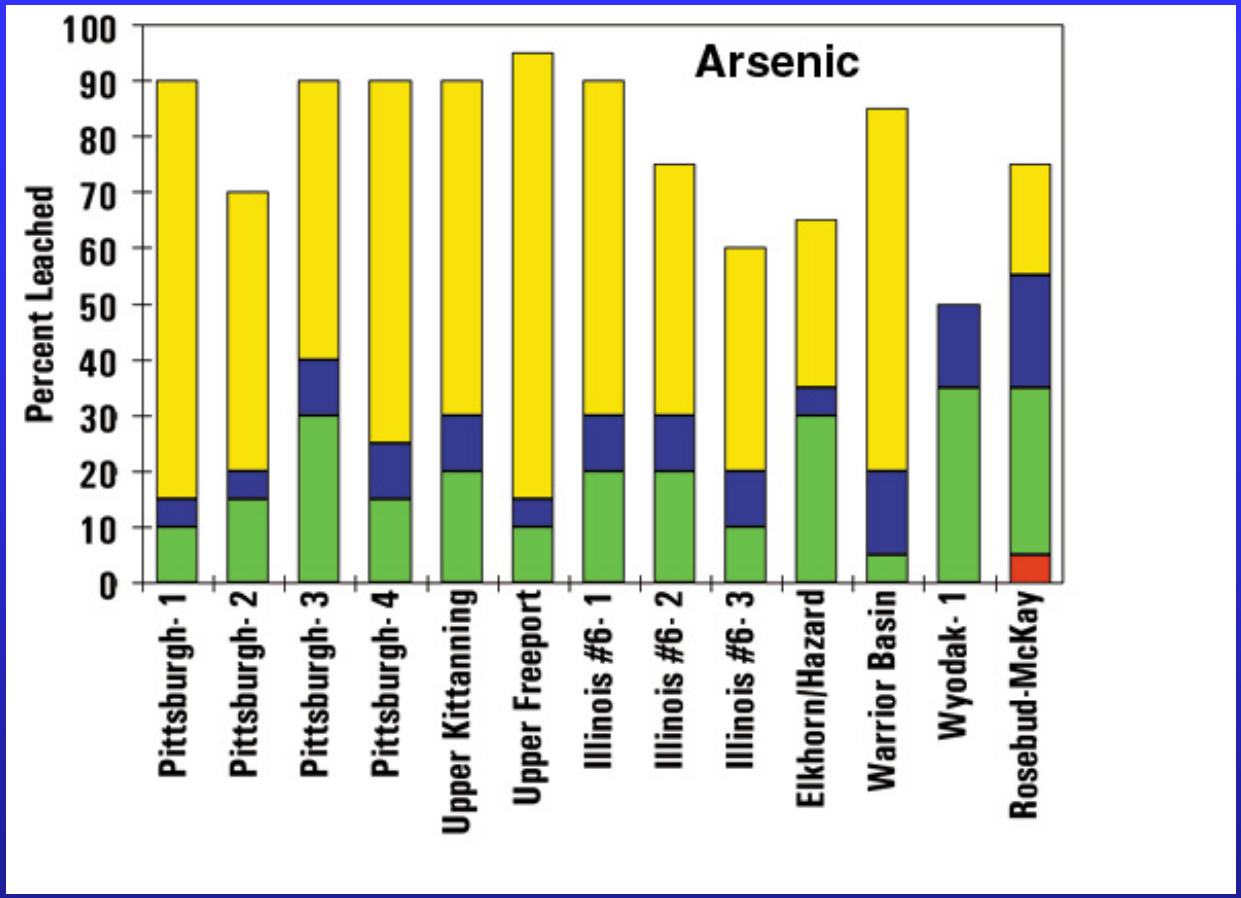
Arsenic-rich pyrite overgrowths on pyrite framboids in an Alabama bituminous coal.

Source: Goldhaber et al., 2003

Arsenic in Coal - continued

- Coal cleaning reduces pyrite content, but framboids may remain in organic fraction.
- Pyrite oxidation releases arsenic to the environment and changes arsenic oxidation state.
- Documented health effects from arsenic are rare: 1) Guizhou, Province, China: Domestic use of ultra-high-arsenic coals (up to 30,000 ppm). 2) Central Slovakia, 1970's: Arsenic toxicity from use of local coals in power plant.

Arsenic selective leaching results for 13 coal samples showing pyrite association (yellow) for 11 bituminous samples.



Source: Palmer et al., 1998

Relative Concentration of As in Pyrite

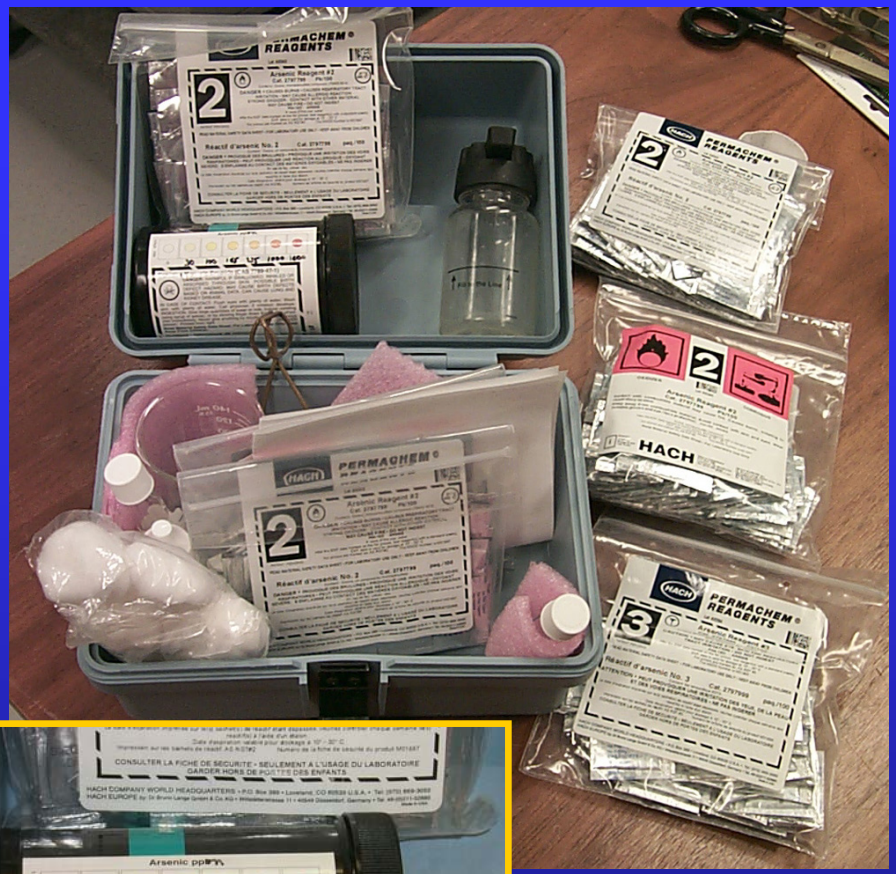
Images from Belkin et al.

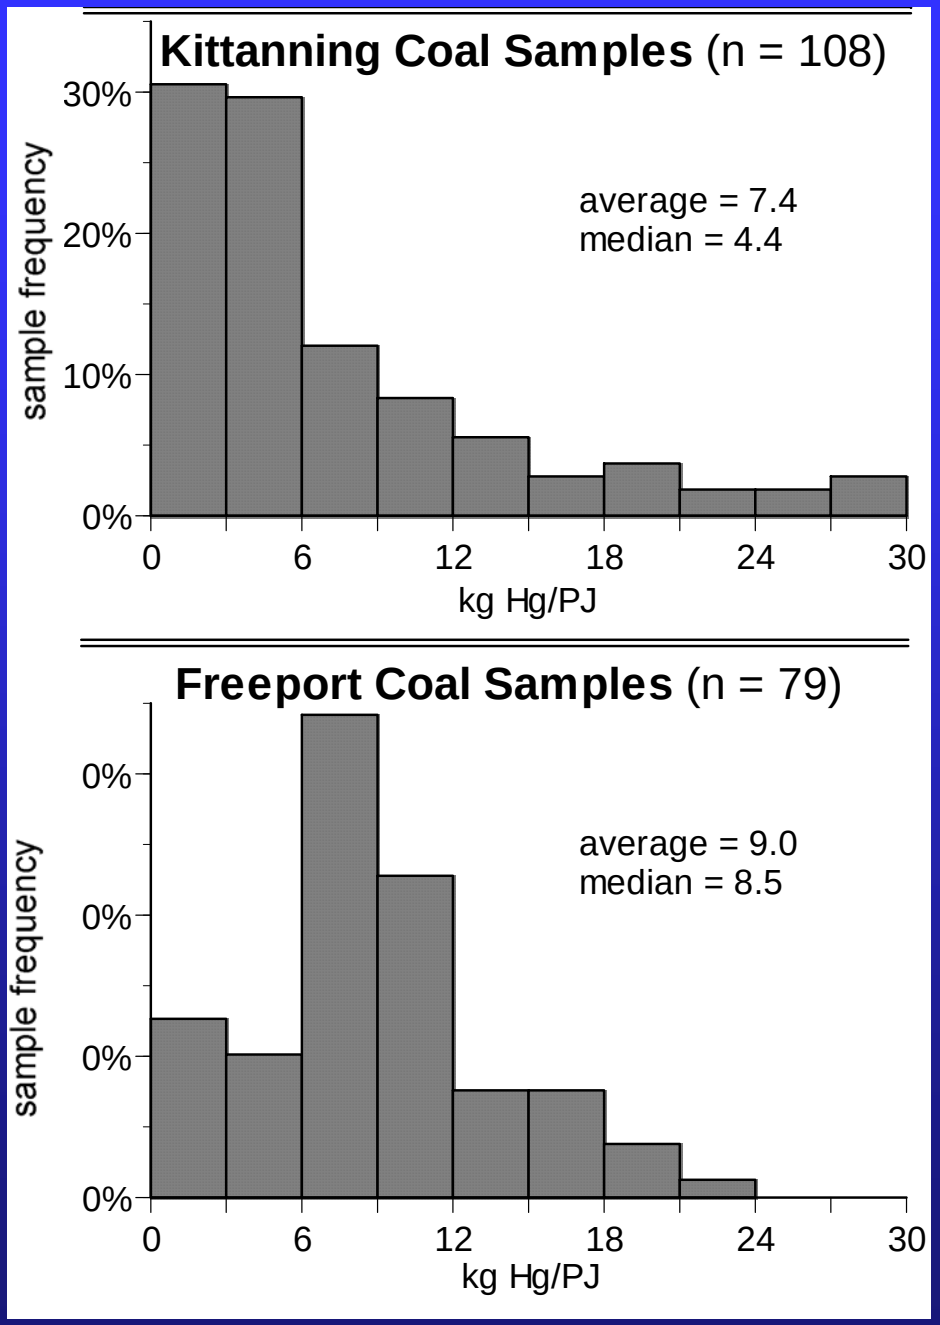
Arsenic Field Tests



- Test kit developed in China to identify arsenic-rich coals in the field.
- Commercial version (left) being introduced by U.S. manufacturer.
- Testing has resulted in closure of “mines” with highest As coal.

Mercury in Coal

- Pyrite (FeS_2) is the most common mercury association in bituminous coals.
- Mercury content of pyrite is variable and can be correlated with arsenic and other air toxics.
- In low rank coals, an organic association is common.
- In very mercury-rich coals, HgSe, HgS (cinnabar), and/or native mercury may be present.

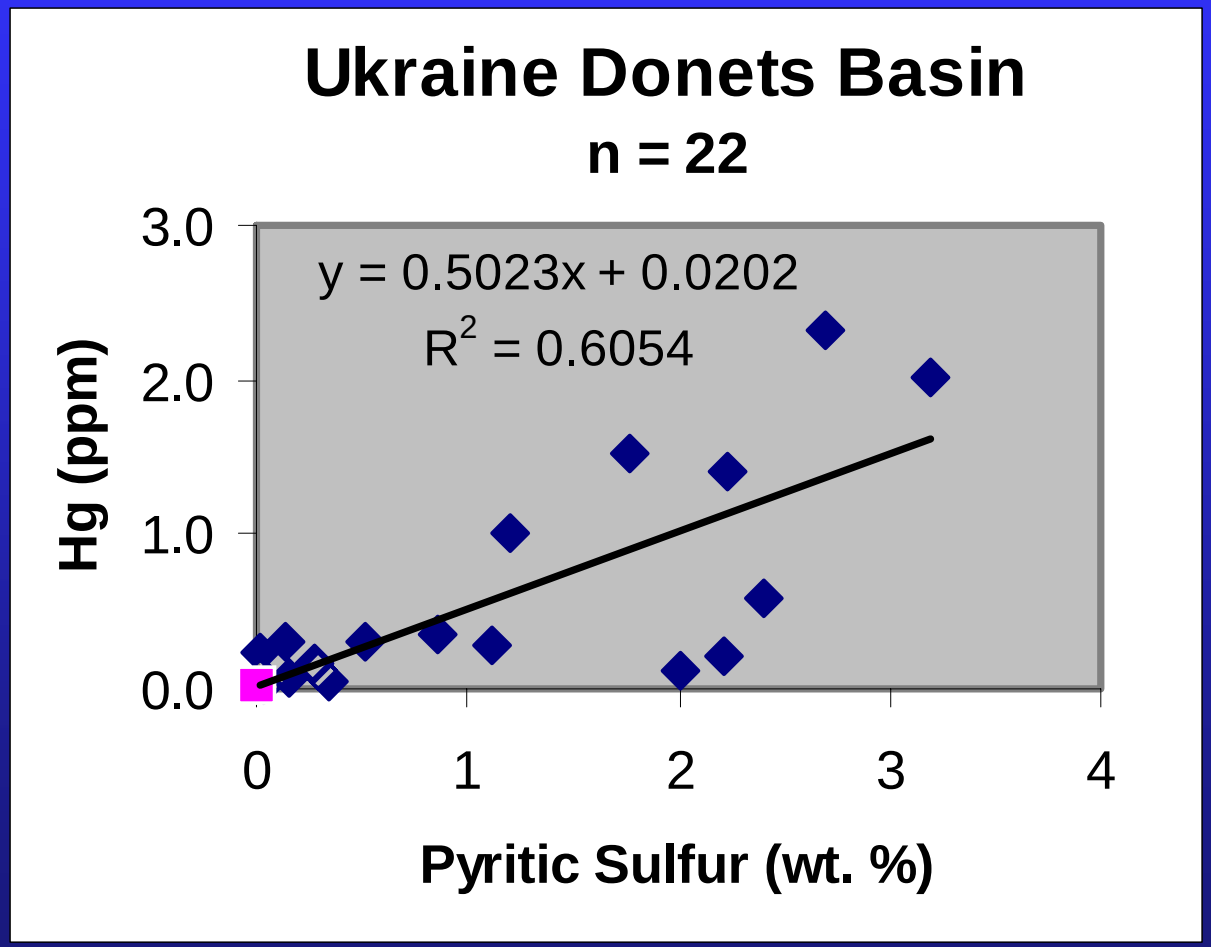


Comparison of mercury distribution in Kittanning and Freeport Coals.

From: Quick et al. , *2003, Environmental Geology*

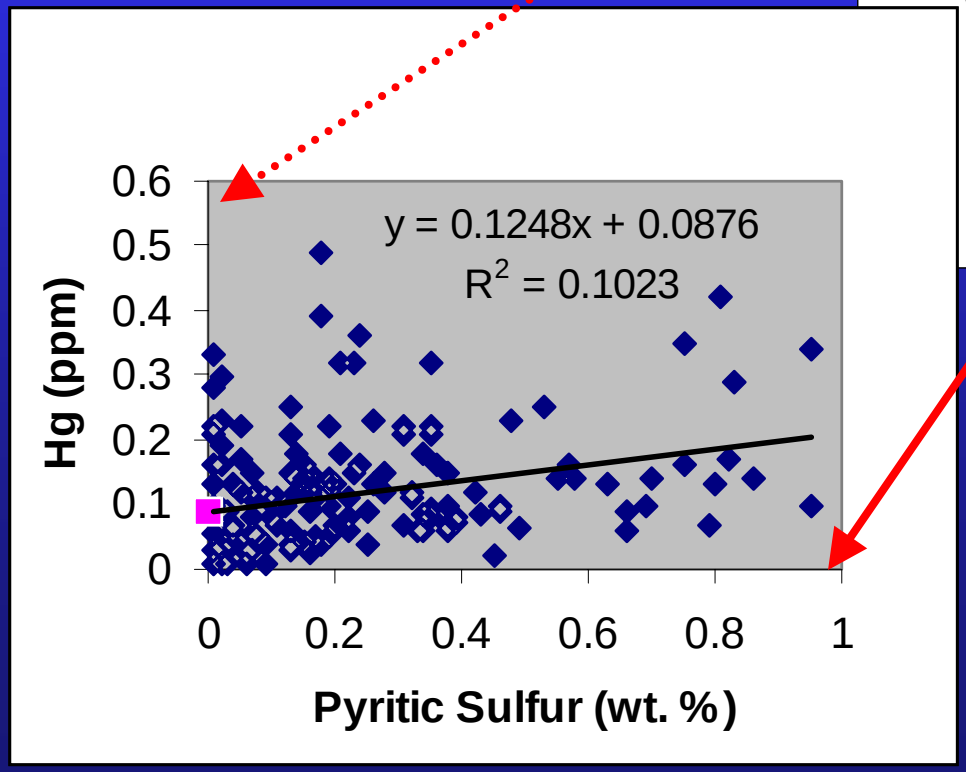
Example of Hg variation controlled by pyrite

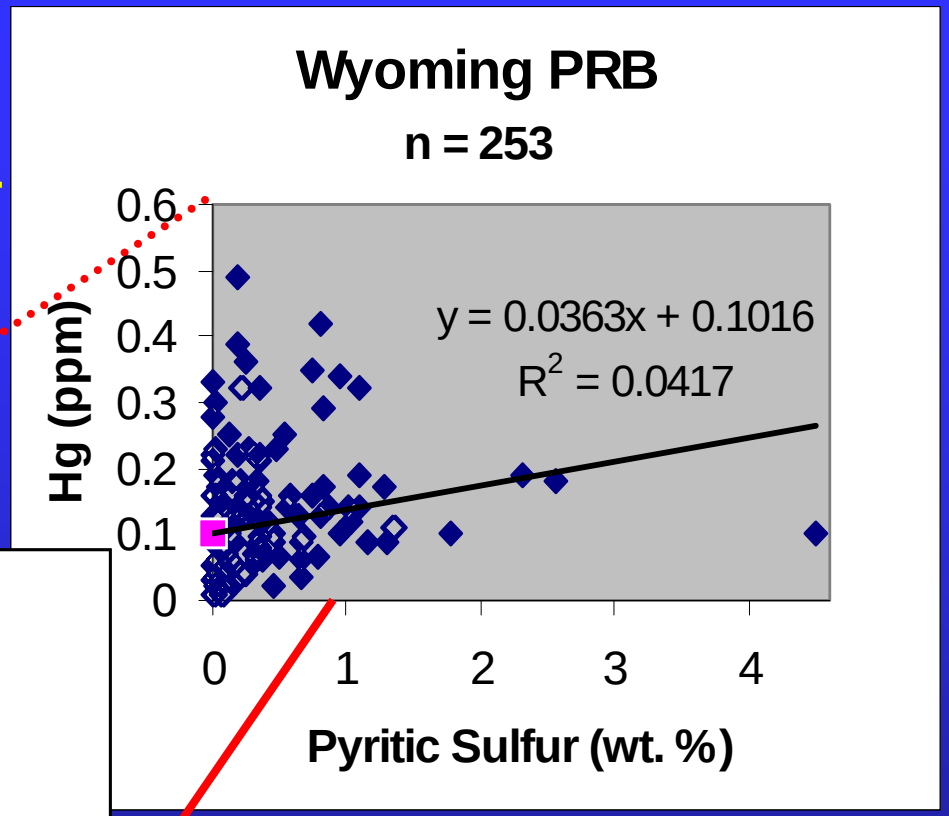
One outlier (Hg = 4.5 ppm) removed



Source: Modified from Kolker et al., 2002

Example of poor correlation between Hg and pyrite, Powder River Basin, Wyoming. Organic affinity indicated by positive Hg intercept.





Two high-Hg points excluded (1.1 and 0.74 ppm); Data from Bragg et al., 1998

Selenium in Coal

- Important organic association indicated by most studies.
- Measurable Se in some pyrite; May contribute Se to ground water upon pyrite oxidation.
- Selenides (eg. PbSe) common in coal, unlike other sediments.
- Sensitive to in-situ oxidation, but less so than As.

Chromium in Coal

- Silicate (illite) and organic-hosted forms are dominant.
- Cr may also occur in Fe-Ti-Cr oxide minerals, if present.
- Not prone to in-situ oxidation in coal, unlike Fe, As, Se.

Source: Huggins et al., 2002

Chlorine in Coal

- Chlorine content is an important parameter because of corrosive effects of HCl and Hg-Cl complexing in coal-fired power plants.
- Chlorine contents are strongly influenced by salinity or paleo-salinity.
- Salinity increases with depth or paleo-depth.

Chlorine in Appalachian Coal

Basin	Average Cl in Coal (ppm)*
Northern Appalachian	850
Central Appalachian	950
Southern Appalachian	310

*Results for Bragg et al., 1991

Chlorine Stratigraphic Variation

Age	Formation	Number of Samples	Mean Cl (ppm)
Lower Permian (?)	Dunkard Group	44	162
Upper Pennsylvanian	Monongahela Formation	73	477
Upper Pennsylvanian	Conemaugh Formation	41	828
Middle Pennsylvanian	Allegheny Formation	709	1097
Middle Pennsylvanian	Kanawha Formation	36	1408
Lower Pennsylvanian	New River Formation	56	1503

Results for Bragg et al., 1991

Trace Metals in Coal Macerals

- Limited number of determinations, in-situ or on maceral separates.
- Information on vitrinite, liptinite and inertinite groups.
- Large variation within and between coals:
  sub-ppm: Hg
  sub-ppm to few ppm: Sb, Th, U
  ppm to 10's ppm: Cr, Ni, As, V
  ppm to 100's ppm: Fe, Mn

Source: Kolker and Finkelman, 1998

Summary - Trace Metals in Coal

- Arsenic:
  - Arsenic-bearing pyrite is dominant form in fresh bituminous coals.
  - Oxidized form (arsenate) is a function of the degree of pyrite oxidation.
  - Greater organic fraction in low-rank coals.
- Chromium:
  - Illite and organic forms are dominant.
  - Oxidation state all Cr(III) in coal; rare Cr(VI) in ash.
- Mercury:
  - Pyrite is most significant host of Hg.
  - Organic fraction is greater in low-rank coals.

Trace Metals in Coal- continued

- Selenium:
  - Exhibits multiple forms; common to have a significant organic fraction, even in bituminous coals.
  - Oxidation state changes with pyrite decomposition, but less so that Fe, As.
- Chlorine:
  - Chlorine content variable; controlled by salinity or paleo-salinity.
  - Affects Hg emissions by Hg-Cl complexing.
- Macerals:
  - Largest fraction of trace elements in low-rank coals.
  - May be a significant host of transition metals.

Coal Formation and Diagenesis
Geologic Controls on Coal Chemistry
The Society for Organic Petrology
Trace Elements in Coal
September 21, 2003

Conclusions

The concentration, variation (both laterally and vertically), and modes of occurrence of trace elements are controlled by geologic and geochemical processes that begin in the peat stage of coalification and continue thru coalification and exploitation.

If we understand the processes that control elements we have a good chance of predicting: 1) where elements are; 2) how they are bound; and 3) what will happen to elements during coal utilization.

What controls coal quality?

Allogenic controls

Climate
Tectonism
Eustasy

Autogenic controls

Depositional environment
Hydrology
Sediment influx
Alteration within peat body
Diagenetic reactions
Rank
Weathering

Allogenic Control 1

Climate

Controls the type of peat, the type and rate of vegetation, and sediment input into the mire or peat swamp.

Allogenic Control 1

Domed (convex upward) peat:

- *Ever-wet, tropical climates* - domed, rain-fed (ombrogenous) peat bodies. (Sumatra foreland basin, L. Mississippian to mid-Middle Pennsylvanian Central Appalachian Basin coals: includes Pocahontas, Fire Clay, Winifred/Stockton coals.)

Doming, radial drainage, flushing.
Low in nutrients: eolian input, dissolved solids minimal.
Limited buffering capacity, rapid peat development.
Minimal degradation of organic matter.
Upland soils anchored

Allogenic Control 1

Planar (flat-lying) peats

Seasonally-wet, more temperate climates –planar, ground-water and rainwater-fed (rheotrophic) peat bodies. (U.S. coastal swamps; late Middle to U. Pennsylvanian Appalachian basin coals).

High sediment/nutrient input – eolian, fluvial, and groundwater.
Leaching can be high.
Relatively high pH (>4); organics degraded.

Allogenic Control 2

Tectonism

Controls rate of base level change – climatic fluctuations may raise or lower water table but need base level rise to build up thick peat.

Fluctuations in base level dependent on tectonic subsidence, eustasy, and compaction.

For the preservation of economic coals need a continuous rise in groundwater (subsidence) and relatively low relief of hinterlands to restrict sediment influx. These conditions occur in foreland basins.

Model for Cretaceous coals of western U.S.

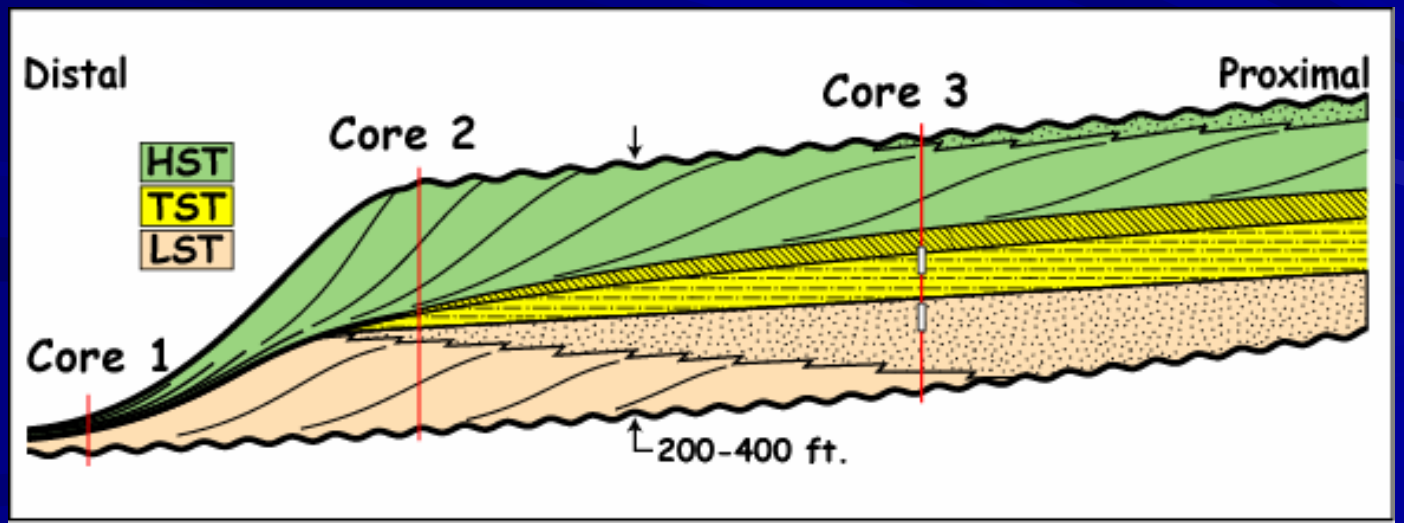
Allogenic Control 3

Eustasy

Increased water depths with marine flooding elevates water tables in non-marine and continental settings.

Elevated fresh water tables allow for plant growth, peat development, and coal preservation in the accommodation space.

Sequence stratigraphy concepts.



What controls coal chemistry?

Autogenic controls

Depositional environment
Hydrology
Sediment influx
Burial
Alteration within peat body
Diagenetic reactions
Rank
Weathering

Depositional Environment & Geologic Setting

Affects geometry, extent, and boundaries of peat bodies.

Affects bed and dissolved load of streams and peat swamp.

Controls underlying substrate.

Exerts a control on ground-water chemistry.

Hydrology

CONTROLS, TO A LARGE EXTENT, GEOMETRY

Ombrotrophic peats (rainwater-fed)

Low in ash – few dissolved solids.
Often domed – limits detrital influx.
Sediment input-eolian volcanics and dust.
Highly acidic.
Low diversity of plants, stunted in middle.

Rheotrophic peats – (groundwater-fed)

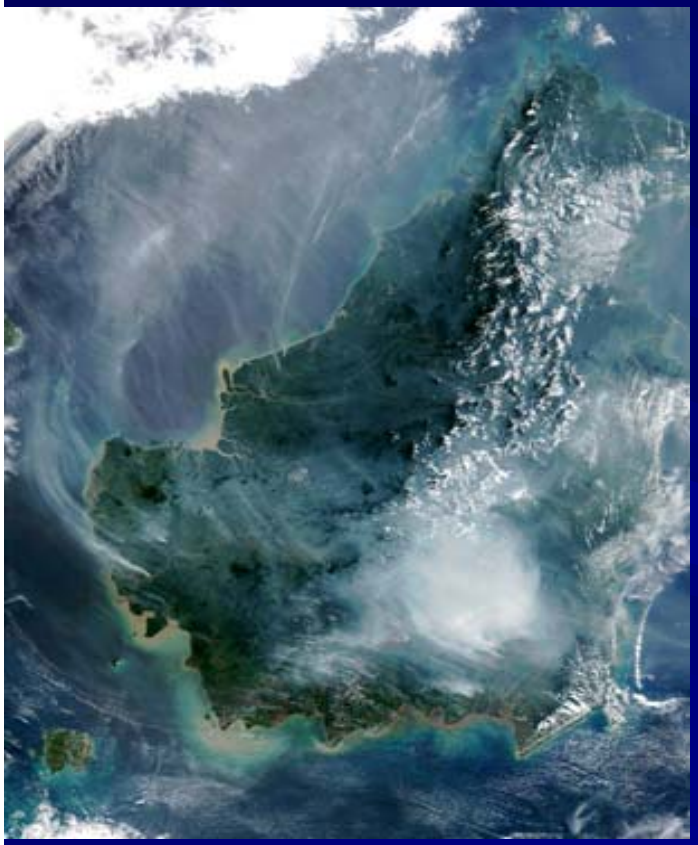
High in dissolved solids.
Often planar.
Sediment-rich.

Mesotrophic peats (ground-and rainwater)

Intermediate in ash.

Autogenic Controls

Sediment Input



www.noaa.gov

Eolian Sources (domed and planar)

Dust

Volcanic ash-fall material – amphibole, pyroxene, quartz, feldspar, glass, etc.

Cosmic dust

Sea-spray

Water-born sources (predominantly planar, edges of domes)

Dependent on geologic setting

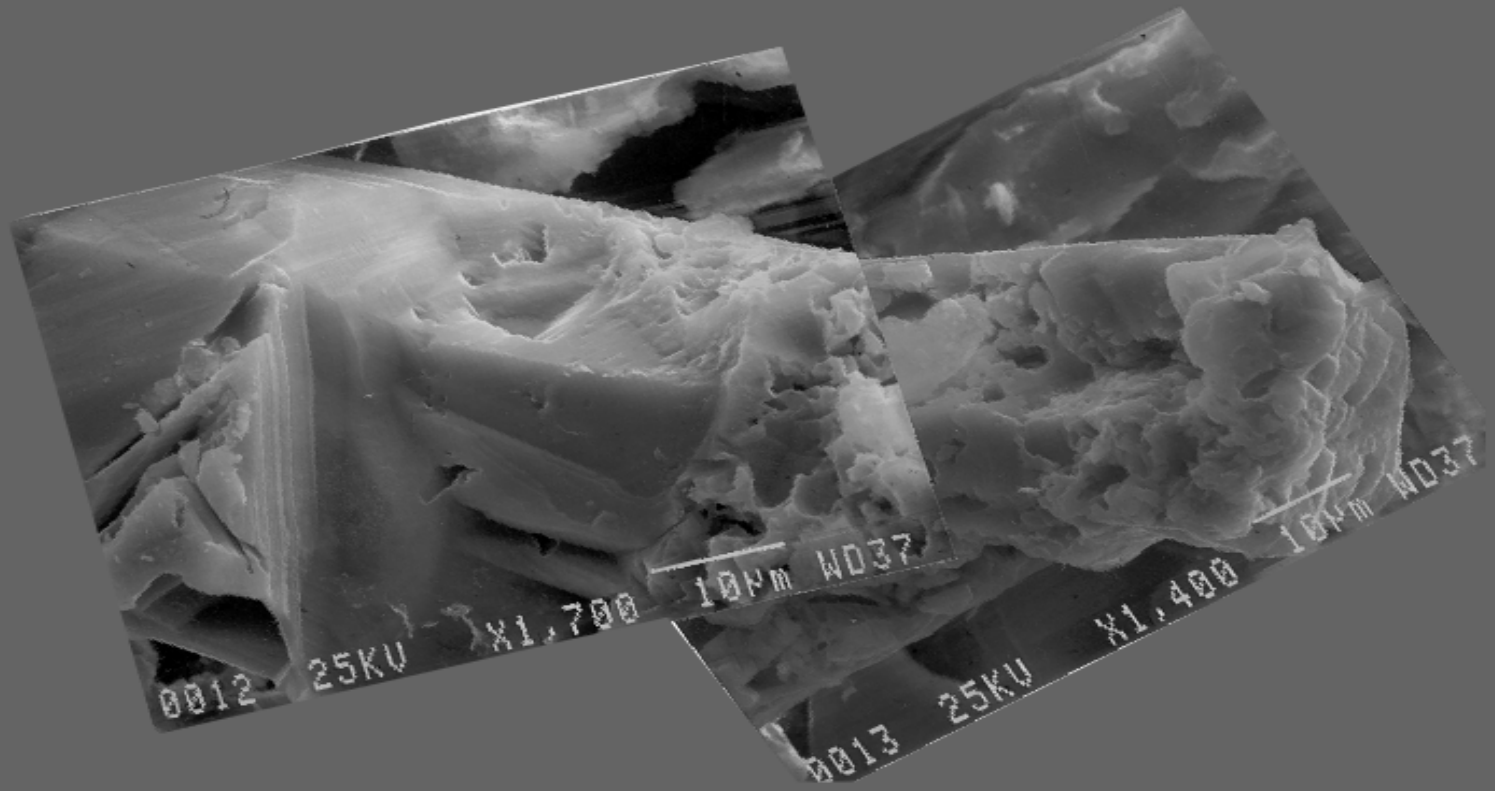
Rate and amount must be low

What gets into the peat doesn't necessarily stay there:

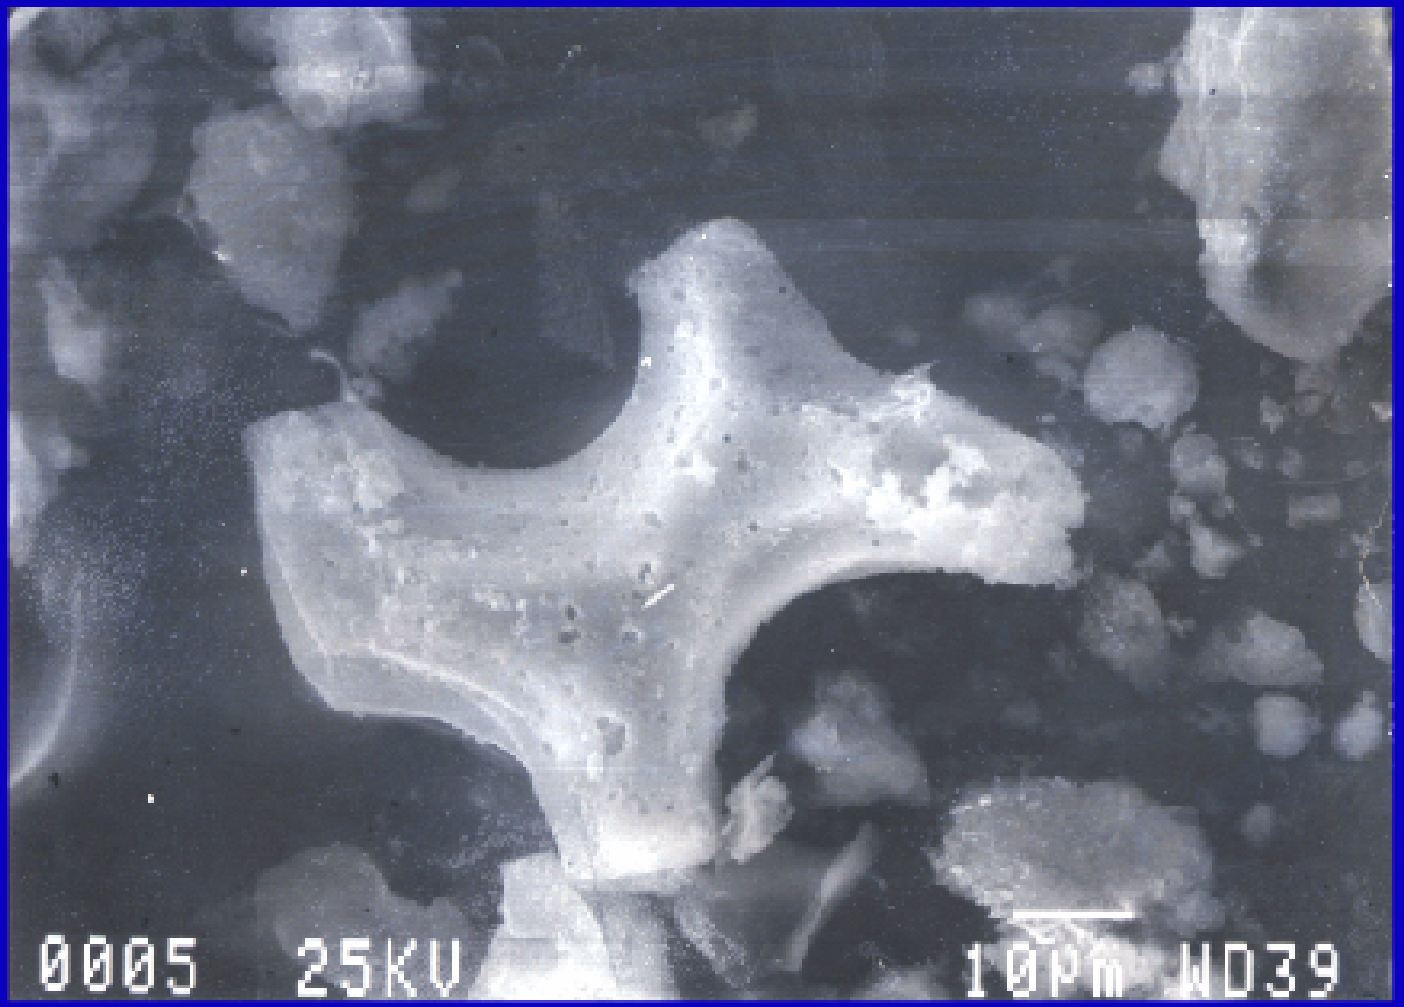
With production of multiple organic acids:

- Dissolution and alteration of mineral matter.
- Loosely bonded organic and inorganic complexes can break.
- Inorganic elements can bond with different organic complexes or become incorporated in syngenetic mineral phases.
- Ions available from ground and surface waters can be incorporated in minerals.

* Organically-associated elements are the most likely to be mobilized during diagenesis. These elements can be leached from the system or re-precipitated into epigenetic mineral phases. *



Etching of an eolian, volcanic quartz grain from a domed Indonesian peat by organic acids.



Disassociated elements can recombine into other authigenic phases, be flushed from the system, or bond to organics.

Peat Preservation and Burial

To preserve peat you need:

Anoxic conditions - control the rate and degree of humification (decay within peat profile).

Very acidic conditions - generation of humic acid from organics.

Burial must be rapid.

Subsidence must be rapid.

What gets into the peat doesn't necessarily stay there:

After burial:

As rank increases, organic bonds weaken, releasing elements.

Elements continue to be moved around.

Elements added, subtracted, and moved within the system.

Epigenetic mineral phases form.

Leaching continues.

Cleat

Two types of cleating:

1 – Moisture/volatile loss – occurs once moisture falls below about 20% (sub-bituminous range).

2 – Tectonic forces/differential compaction.

Cleats can be coated with minerals, then further infilled.

Cleat infilling – pyrite, kaolinite, sphalerite, calcite, gypsum, etc.

Multi-generational cleat infilling not uncommon.

Faults

Faults can act as conduits for fluid flow in coals and coal basins.

Example – Warrior Basin, Alabama

Weathering

Atmospheric weathering and action of ground waters effect the elemental and mineral composition of coal beds.

Development of new suites of minerals
- oxidation (pyrite to sulfate);
- inclusion of water in clay lattice – (allophane)

Removal of some remaining organically-bound minerals.

Removal of some organics concentrating inorganic elements.

Conclusions:

1 – Coal quality results from a continuum of processes that start in the peat stage and continue through coalification.

2 – Geometry of a peat body (planar vs. domed) factors heavily in the quality of the resulting coal.

The concentration, variation (both laterally and vertically), and mode of occurrence of elements are controlled by geologic and chemical processes that start during peat development and continue through coalification. Understanding those processes will allow us to predict coal quality trends before mining.

Overview of Bulk Analytical Methods and USGS Selective Leaching Procedure

Curtis Palmer

U.S. Geological Survey

Bulk Analytical Methods: Coal Quality Characterization

- ASTM Procedures
  - USGS uses contract labs such as Geochemical Testing and Wyoming Analytical Laboratories
- Major and Trace Elements
  - Uses procedures developed by USGS some of these are included in ASTM procedures and are preformed by USGS personnel

ASTM Procedures

- Ultimate analysis:
  - ASTM D3176-D3179
  - Moisture, C, H, O, N, total S
- Proximate analysis
  - ASTM D3172-D3175
  - Moisture, volatile matter, fixed carbon and ash
- Other techniques
  - Sulfur forms, calorific values,
  - Hardgrove grindability free swelling index, ash fusability,
  - Specific gravity, equilibrium moisture

Analytical Methods Overview and Relative Merits

- Methods to be covered (Elemental Analysis)
  - Routine Methods
    - Multi-Element Techniques
      - Inductively Coupled Plasma- Atomic Emission Spectroscopy (ICP-AES)
      - Inductively Coupled Plasma- Mass Spectroscopy (ICP-MS)
    - Single Element Techniques
      - Cold Vapor Atomic Absorption (CVAA; Hg)
      - Hydride Generation Atomic Absorption (HGAA; Se)
  - Non-Routine Methods
    - Instrumental Neutron Activation analysis (INAA)

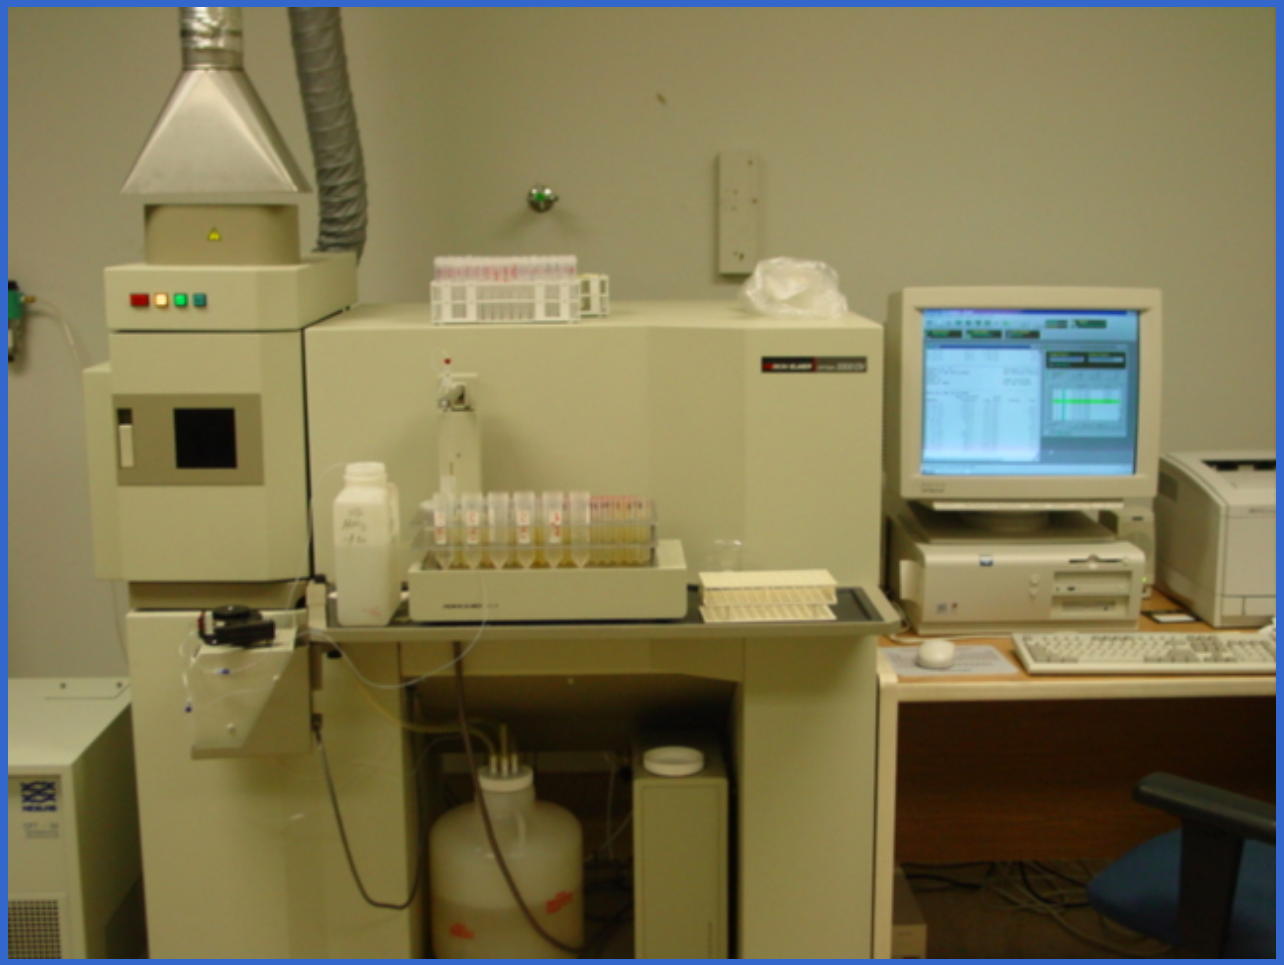
- Sample Preparation:To Ash or Not to Ash
  - Advantages of Ashing
    - Increases concentration and apparent detection limits
    - Makes it easier to place many elements into solution
    - Ash is more stable for long term storage (Archiving)
    - Can improve homogeneity

- Disadvantages of Ashing
  - Some elements may volatilize
    - Volatility may be matrix dependent
    - Amounts volatilized may be different for each sample and element
    - Occasionally elements not normally considered volatile are volatile for a given sample
    - Potential of cross-contamination of volatile components
  - Larger sample needed
  - Additional steps and time
    - Elements may need to be recalculated to a whole coal basis
    - Care must be taken to ensure ashing is complete
  - Mechanical losses can effect results

- Ashing Procedure– USGS – Similar to ASTM
  - Samples heated from 25 ^{o}C to 200 ^{o}C in about 1 hour
  - Samples heated at 200 ^{o}C for 1.5 hrs
  - Temperature increased to 350 ^{o}C and held 2 hrs
  - Temperature increased to 525 ^{o}C and held 36 hrs
  - Samples slowly cooled (1-2 hr)
  - Samples examined and re-ignited at 525 ^{o}C if necessary
  - Samples homogenized

- Methods requiring ashing
  - ICP-AES
    - Advantages
      - Rapid
      - Low Cost
      - Multi-element
    - Disadvantages
      - Requires dissolution of ash
      - Moderate sensitivity

USGS ICP-AES



- Two dissolution procedures (sinter and acid digest)
  - Sinter (Ash fused at 445 ^{o}C with Na_2O_2)
    - » Advantages
      - -- Dissolves species difficult by acid dissolution
      - -- Conserves volatile elements during acid dissolution
    - » Disadvantages
      - -- High dissolution ratio reduces sensitivity
      - -- High salt content can cause instrument problems
    - » Elements Determined
      - -- Major elements in ash except Na
      - -- Trace elements: B, Ba, Zr

- Acid Digest
  - » Advantages
    - --Low dissolution ratio--Higher sensitivity
    - --Low salt content no Na contamination
  - » Disadvantages
    - --Some elements are volatile, eg. B, Se, Cl
    - --Some elements are associated with insoluble minerals, eg. Zr, Ba
  - » Elements Determined
    - -- Major element: Na_2O
    - -- Trace elements: Be, Co Cr, Cu, Li, Mn, Ni, Sc, Sr, Th, V, Y, Zn

– ICP-MS

- Much higher sensitivity (10 to 1000 times)
- Higher cost instrument
- Some elements have interferences– poorer results than ICP-AES; Others similar results to ICP-AES
- Same dissolutions as ICP-AES but sinter dissolution is not routinely analyzed because the use of the highly ionic solution requires special setup and require additional maintenance
- Acid digest: Ag, As, Au, Bi, Cd, Cs, Ga, Ge, Mo, Nb, Pb, Rb, Sb, Sn, Te, Tl, U
- Sinter: 13 Rare earth elements, Hf, Ta and W

USGS ICP-MS

- Whole Coal Techniques
  - Cold Vapor Atomic Absorption (CVAA)
    - Single element (Hg)
    - Requires dissolution
    - 5 to 10 percent of coals below detection limit of 0.02 ppm
    - Reliable and accurate (ASTM method)
  - Ion Chromotography
    - Single element Cl
    - Requires dissolution
    - Less than 5 percent of coals below detection limit of 150 ppm
    - Reliable and acurate

USGS Ion chromotragraph

- Hydride generation atomic absorption (HGAA)
  - Single element (Se)
  - Requires dissolution
  - Several elements (especially heavy and transition metals) in high concentrations can interfere with results
- Instrumental neutron activation analysis (INAA)
  - Time consuming multi-element technique
  - Highly linear—few interferences
  - Small sample size
  - No ashing or dissolution required
  - High sensitivity
  - High cost– requires nuclear reactor
  - Elements include: Na, K, Fe, Sc, Cr, Co, Ni, Zn, As, Se, Br, Rb, Sr, Mo, Sb, Cs, Ba, La, Ce, Nd, Sm, Eu, Tb, Yb, Lu, Hf, Ta, W, Th, U
  - Other elements possible Al, Ca, Mg, Ti, S, V, Cl, I, Mn, Dy, Hg

Quality Control and Quality Assurance

- Accuracy – degree of agreement between the measured value to the “true” or proposed value
- Standard Reference Materials
  1. CLB-1 – coal
  2. NIST 1632b – coal (bituminous)
  3. NIST 1633a – coal fly ash
- Certified Calibration Standards
- Precision – degree of agreement between measured values under repetitive testing of a sample; reproducibility of results
- Duplicate samples

Summary

- Multi-element techniques provide methods to obtain a large and varied amount of data in a relatively short time.
- Cost of instruments for multi-element techniques can be very high.
- Some elements in coal can not be determined using multi-element techniques due to volatility and problem matrices.

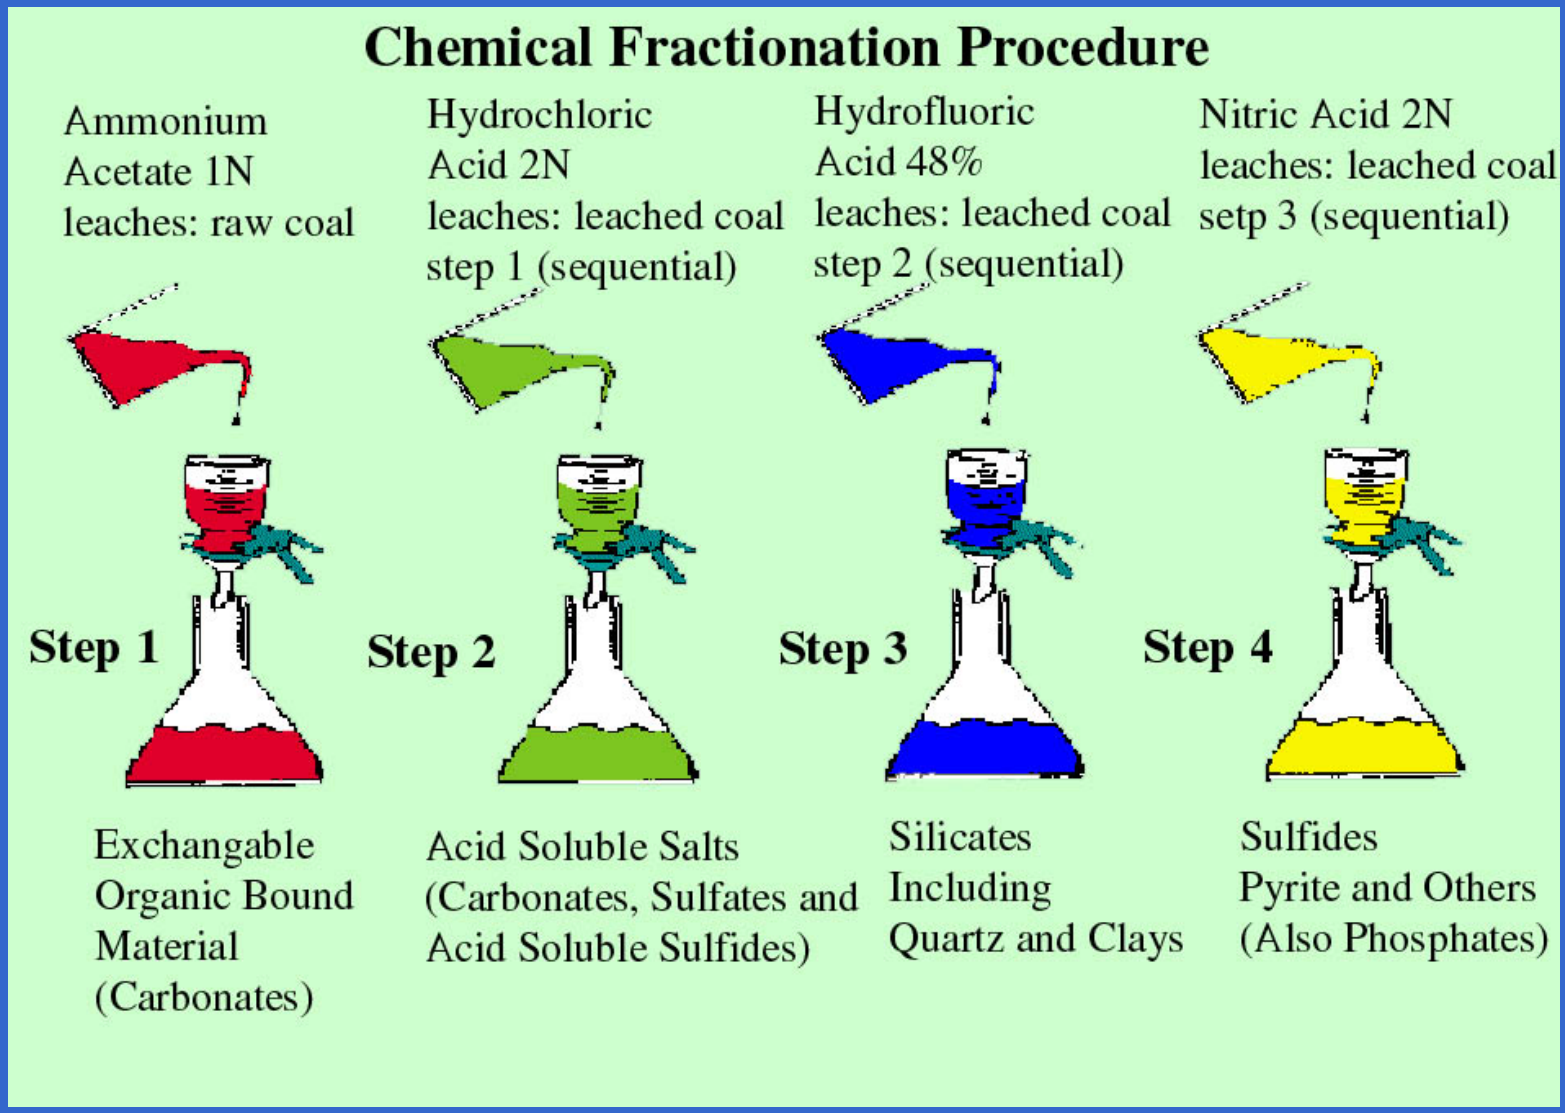
Modes of Occurrence of Elements in Coal

- Selective leaching
- Scanning electron microscopy
- Microprobe Analysis

Overview of Leaching Procedure

- A Multi-Element Semi-Quantitative Approach
  - Semi-Quantitative Leaching Results
  - Microprobe Analysis– Concentration of elements in minerals
  - Qualitative SEM– Mineral identification in whole samples and leached residues
  - Semi-quantitative XRD– Concentration of minerals in coal

Leaching Procedure



Sequential Leaching

- Duplicate, 5 gram 60 mesh samples are shaken in a centrifuge tube with 35 ml of Ammonium Acetate for 18 hrs
  - The resulting solution is saved for analysis by ICP-AES and ICP-MS
  - A 300 mg split of the resulting solid is analyzed by INAA and a 200 mg split is analyzed by CVAA for Hg. Additional splits may be taken for specialized experiments (XAFS, SEM, etc)

Sequential Leaching

- The remaining solid from each sample is leached in the same manner with hydrochloric acid (HCl) and subsequently with hydrofluoric acid (HF) with splits taken
- The remaining solid after leaching with HF is leached in a flask with nitric acid (HNO_3)
  - Procedure is similar to ASTM method for determining pyritic sulfur
  - Solutions and solid samples are analyzed as in other steps

Results

- Several Elements Are mainly associated with Pyrite as demonstrated by a large percentage of the element leached by HNO_3 (nitric acid)

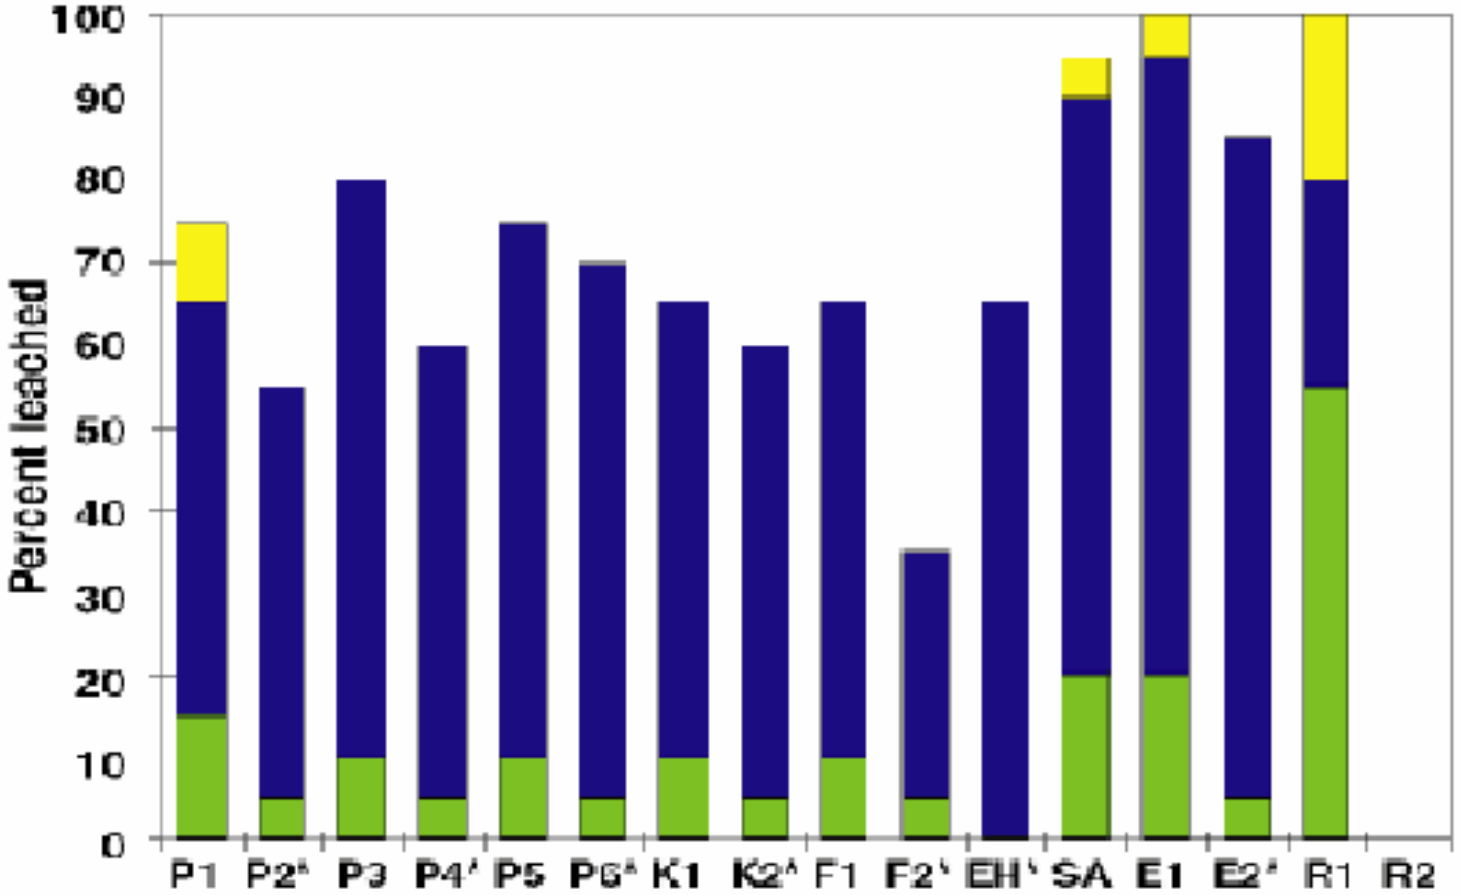
Concentrations of Hg in the original coal samples in parts per million

P1	0.09	P5	0.15	F1	0.5	E1	0.09
P2	0.09	P6	0.08	F2	0.4	E2	0.06
P3	0.13	K1	0.25	EH	0.05	R1	0.07
P4	0.06	K2	0.16	SA	0.1	R2	0.08

Results

- Other elements are mainly associated with silicates as demonstrated by a large percentage of the element leached by Hydrofluoric Acid.

Beryllium

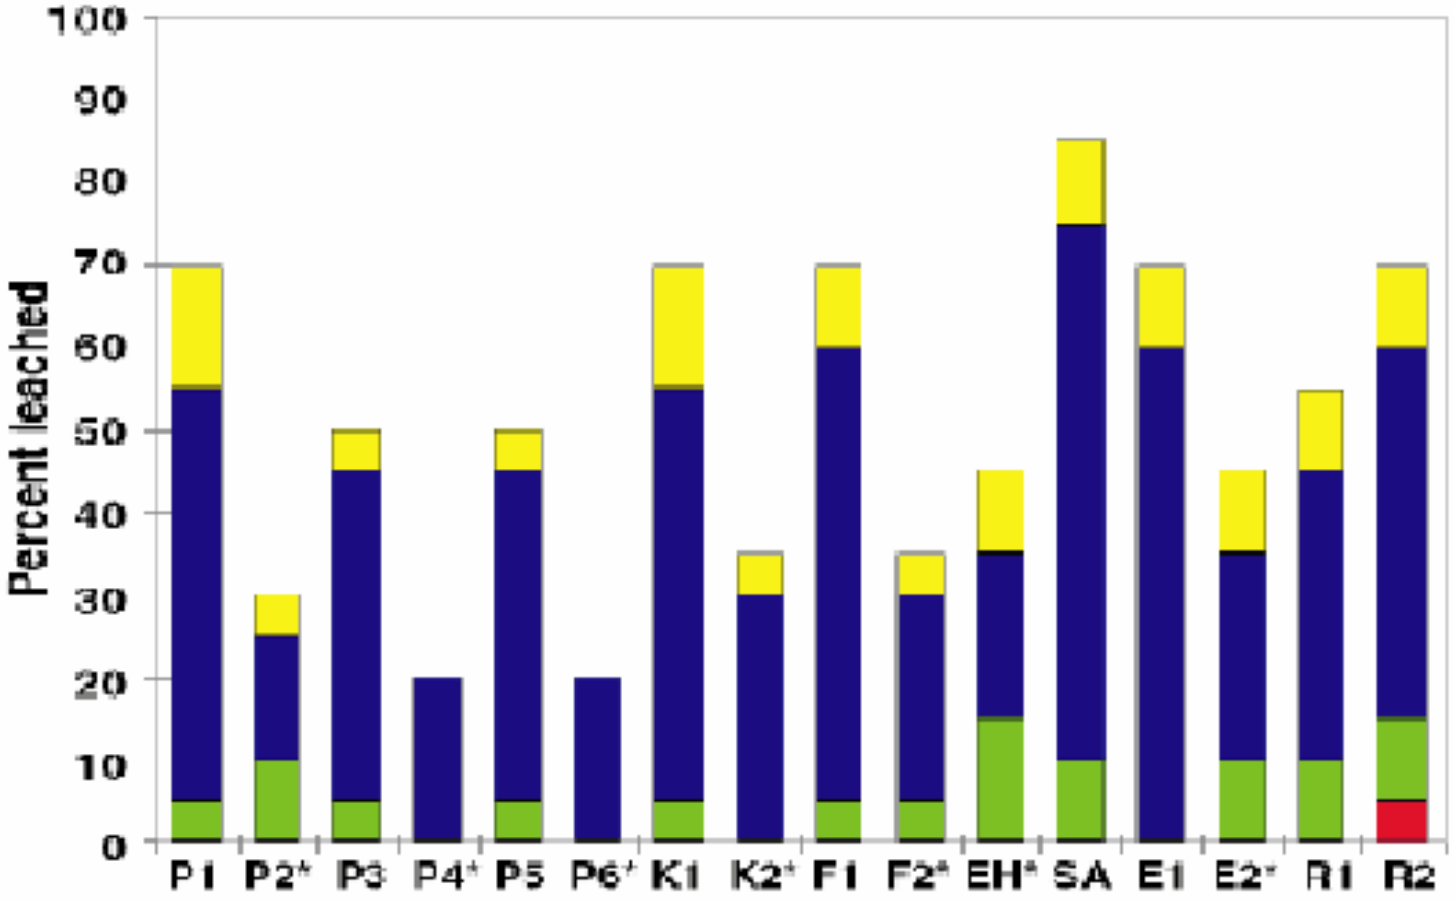


Ammonium Acetate
Hydrochloric Acid
Hydrofluoric Acid
Nitric Acid

Concentrations of Be in the original coal samples in parts per million

P1	1	P5	0.7	F1	3	E1	1
P2	0.6	P6	0.7	F2	2	E2	1
P3	0.9	K1	2	EH	12	R1	0.5
P4	0.8	K2	2	SA	31	R2	0.4

Chromium



Ammonium Acetate
Hydrochloric Acid
Hydrofluoric Acid
Nitric Acid

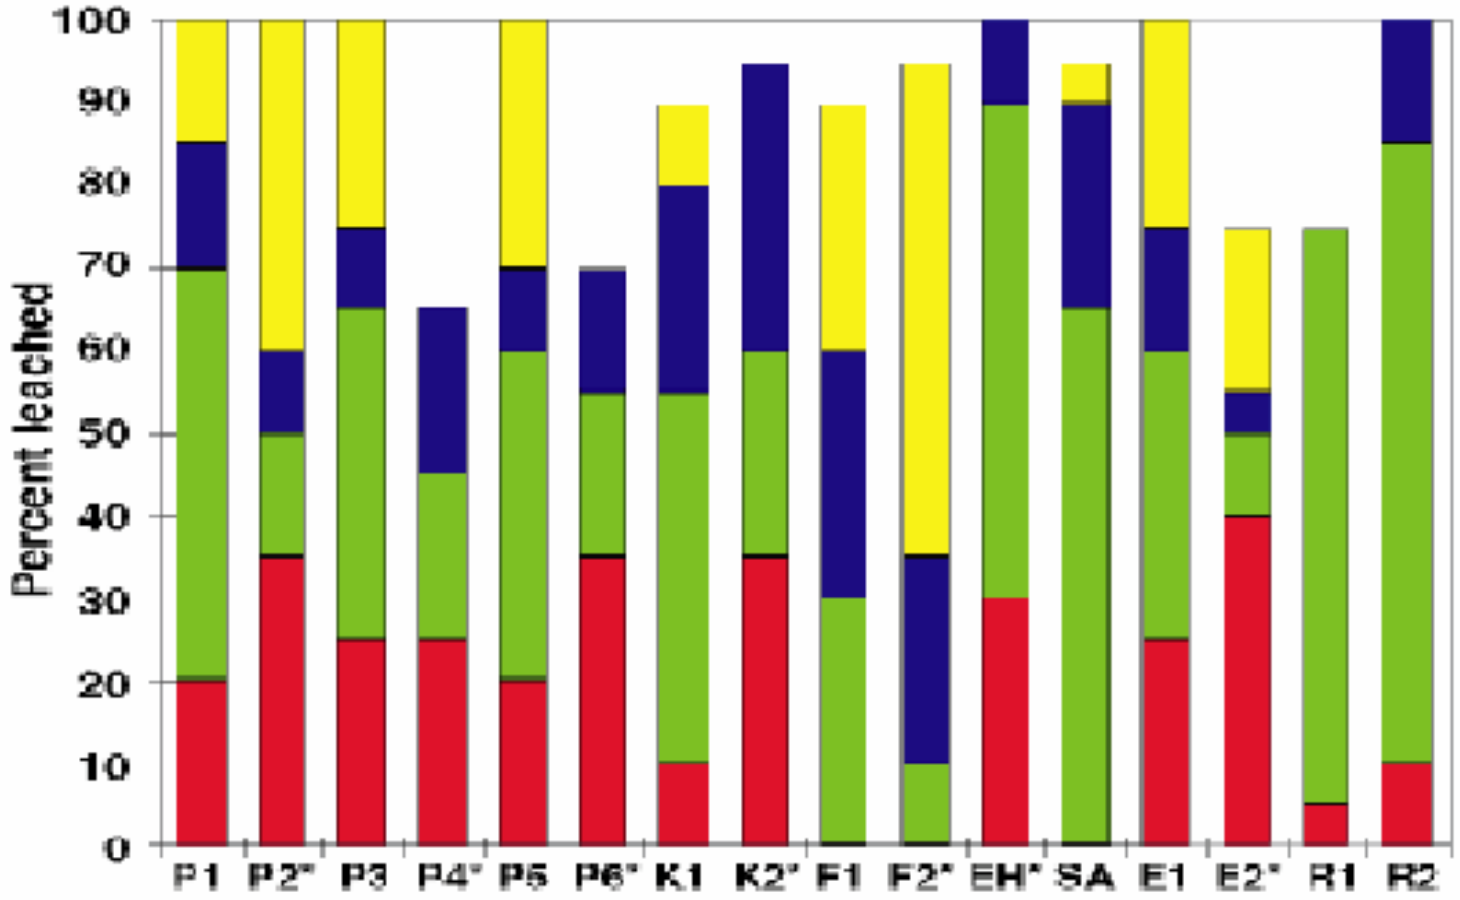
Concentrations of Cr in the original coal samples in parts per million

P1	31	P5	17	F1	33	E1	97
P2	9.7	P6	12	F2	15	E2	23
P3	20	K1	54	EH	18	R1	3.9
P4	12	K2	25	SA	62	R2	6

Results

- When the majority of a element is soluble with HCl then the element is likely associated with carbonates or monosulfides.
- Elements associated with calcite are partially soluble in ammonium acetate.

Manganese

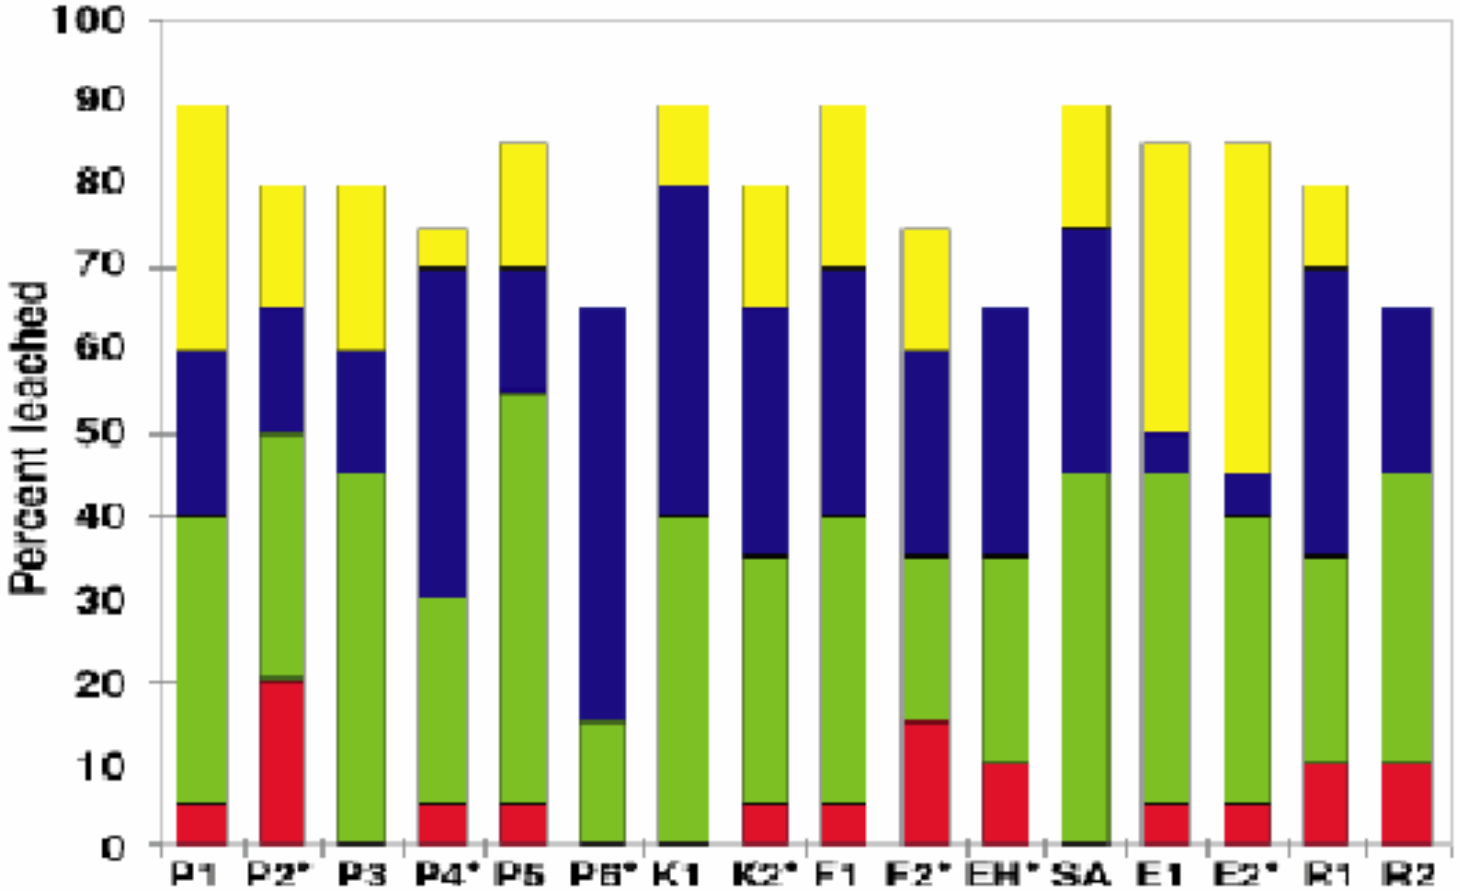


Ammonium Acetate
Hydrochloric Acid
Hydrofluoric Acid
Nitric Acid

Concentrations of Mn in the original coal samples in parts per million

P1	29	P5	35	F1	39	E1	94
P2	13	P6	16	F2	10	E2	37
P3	23	K1	57	EH	14	R1	150
P4	8.1	K2	7.4	SA	230	R2	8.7

Zinc



- Ammonium Acetate
- Hydrochloric Acid
- Hydrofluoric Acid
- Nitric Acid

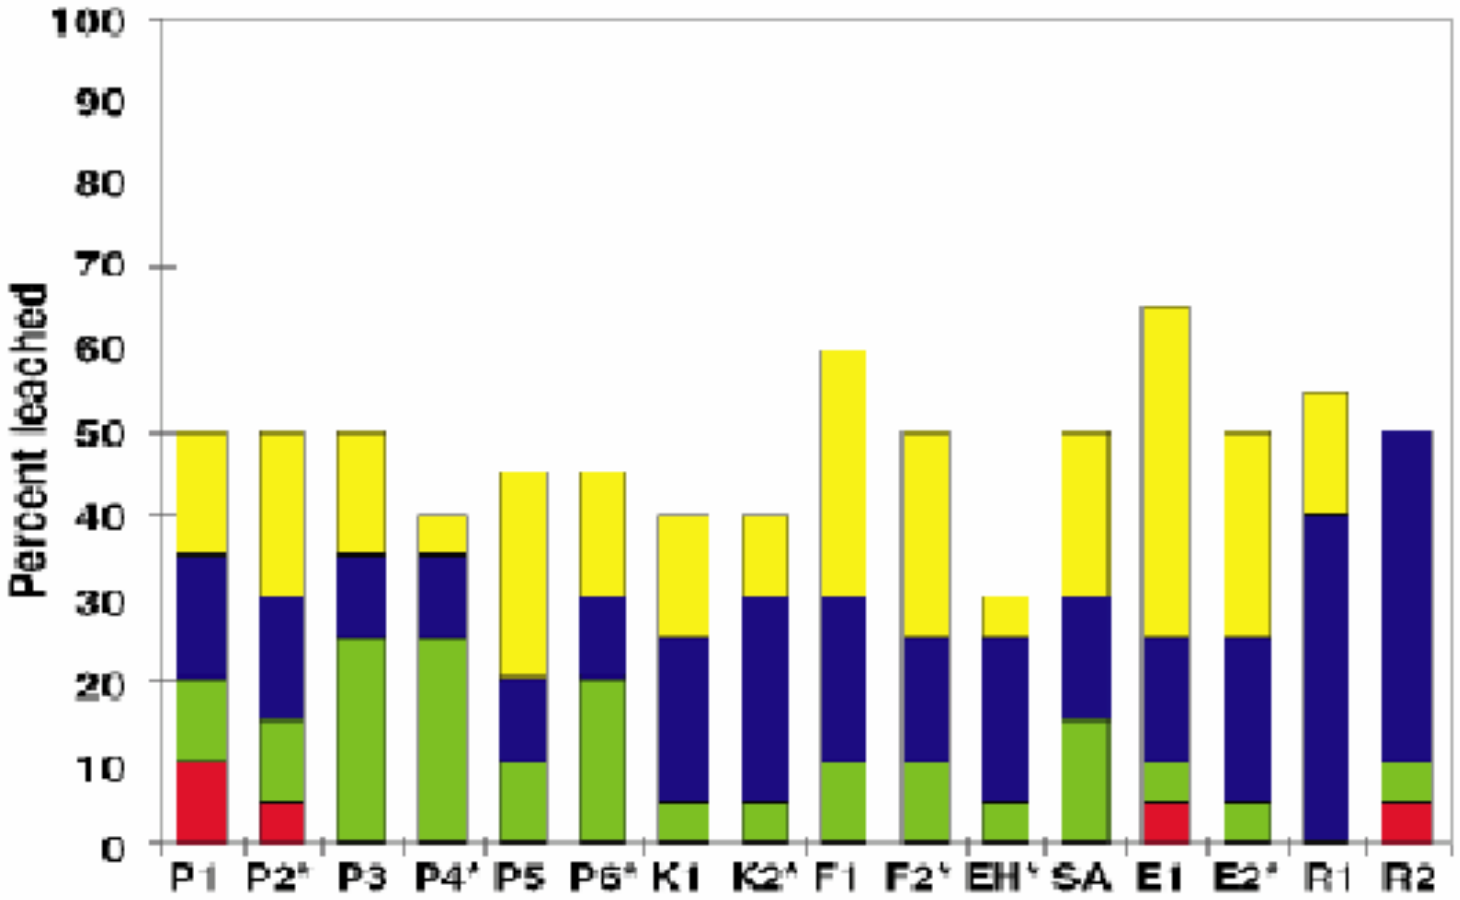
Concentrations of Zn in the original coal samples in parts per million

P1	25	P5	18	F1	34	E1	190
P2	9.3	P6	5.1	F2	13	E2	70
P3	18	K1	52	EH	6.6	R1	6.8
P4	7.6	K2	15	SA	60	R2	8.1

Results

- For some elements a significant fraction is unleached indicating that the element is organically associated
- In some cases mineral species are encapsulated or insoluble.
  - Examination by SEM can usually be used to determine encapsulated or insoluble species.

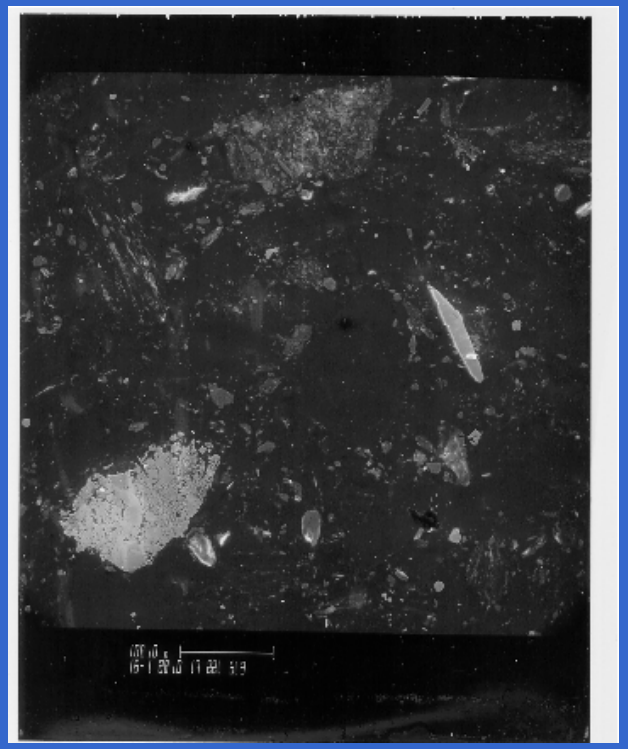
Antimony



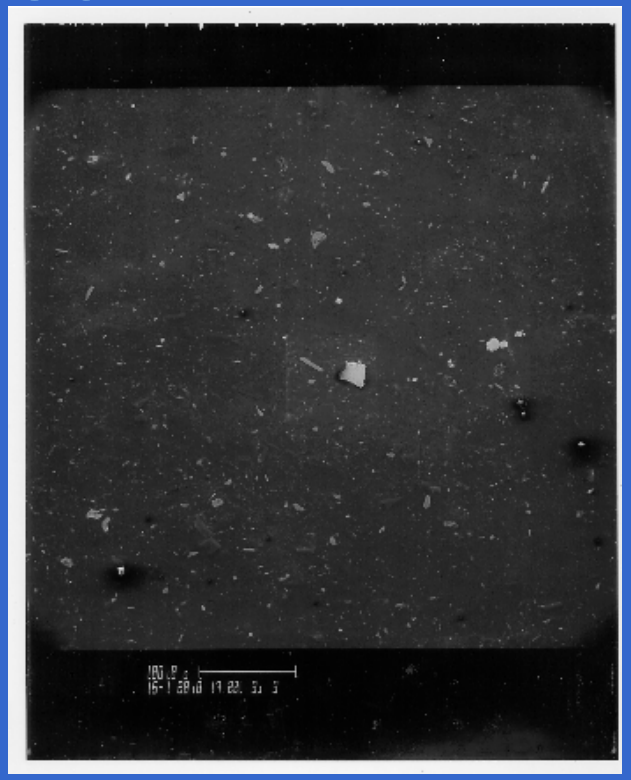
Concentrations of Sb in the original coal samples in parts per million

P1	0.72	P5	0.56	F1	0.62	E1	1.2
P2	0.29	P6	0.26	F2	0.48	E2	0.44
P3	0.49	K1	1.8	EH	1.1	R1	0.31
P4	0.31	K2	2.1	SA	1.6	R2	0.24

SEM comparison of original coal to leached coal



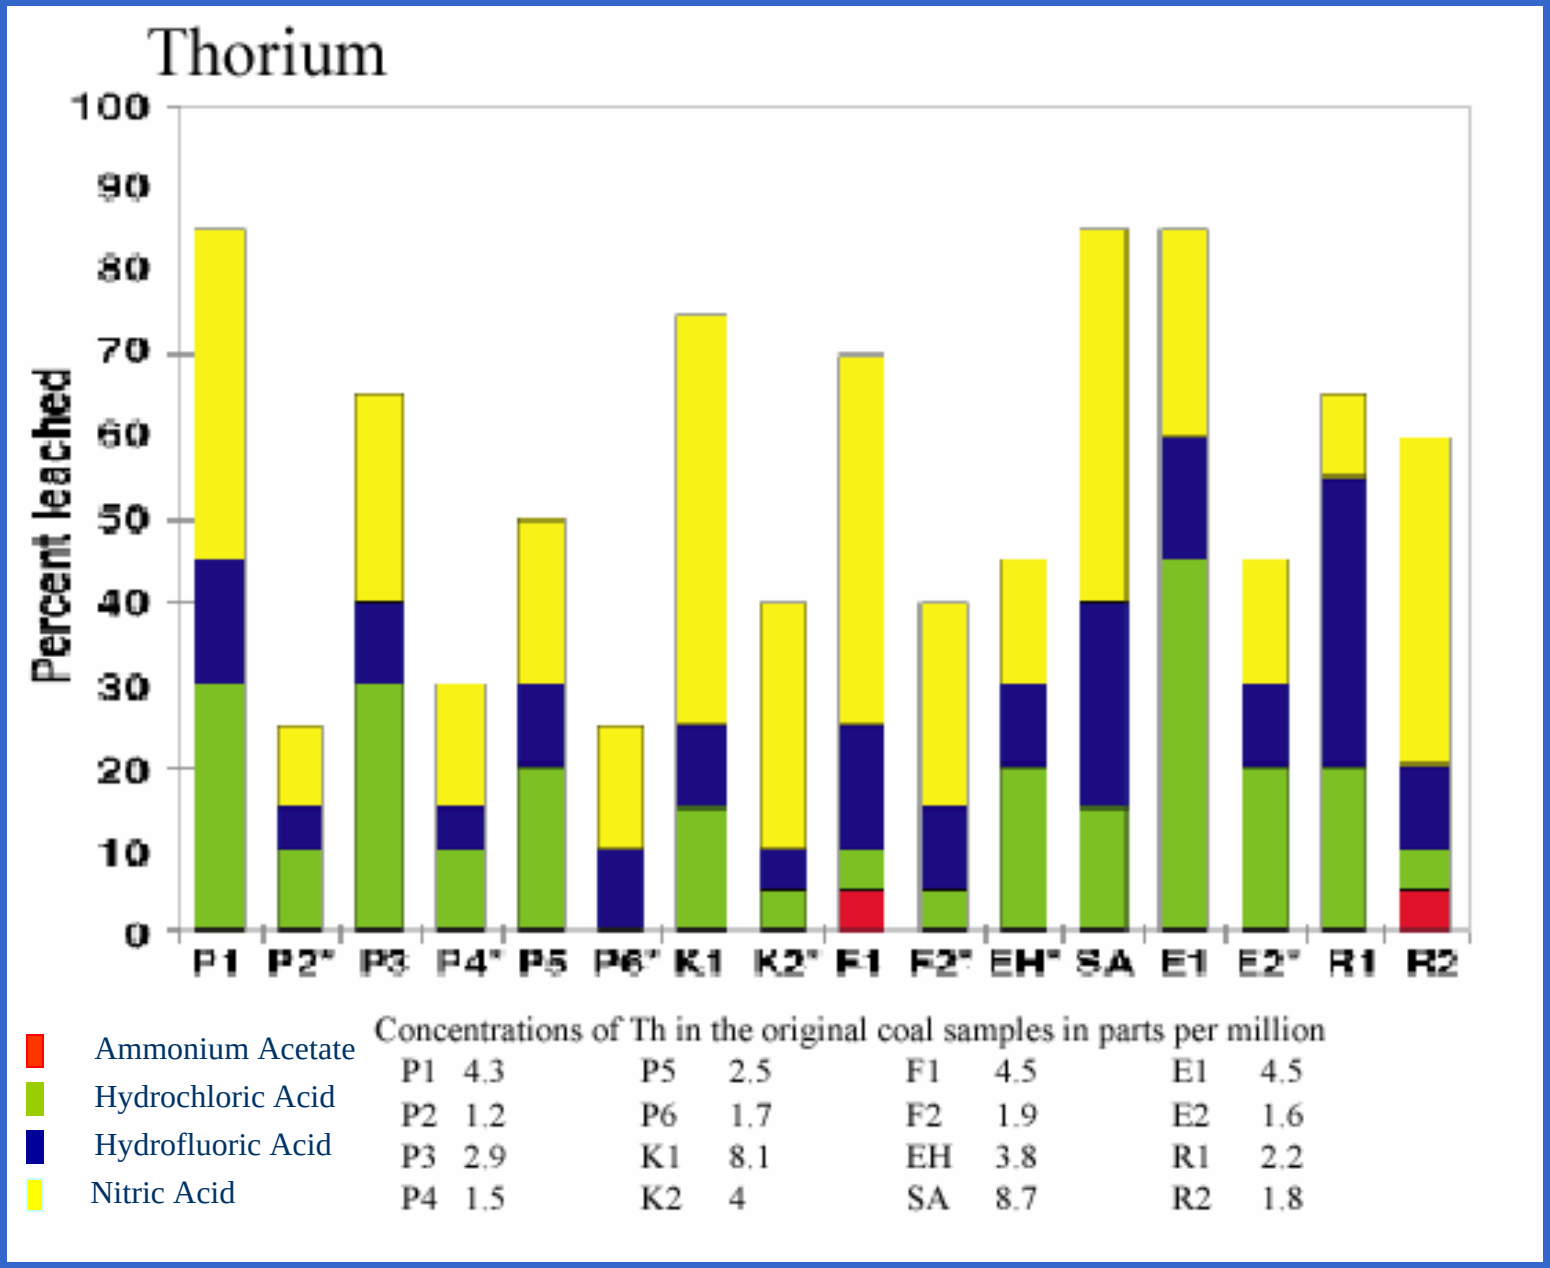
- Raw
- Minerals of all sizes



Demineralized
Small mineral grains
(mostly grinding compound)

Results

- Phosphates are also soluble in HCl
- Some elements can be in mineral forms especially phosphates encapsulated by silicates.
  - Produces significant amounts of element leached by HNO_3
  - Can be tested by leaching with HCl after HF leach

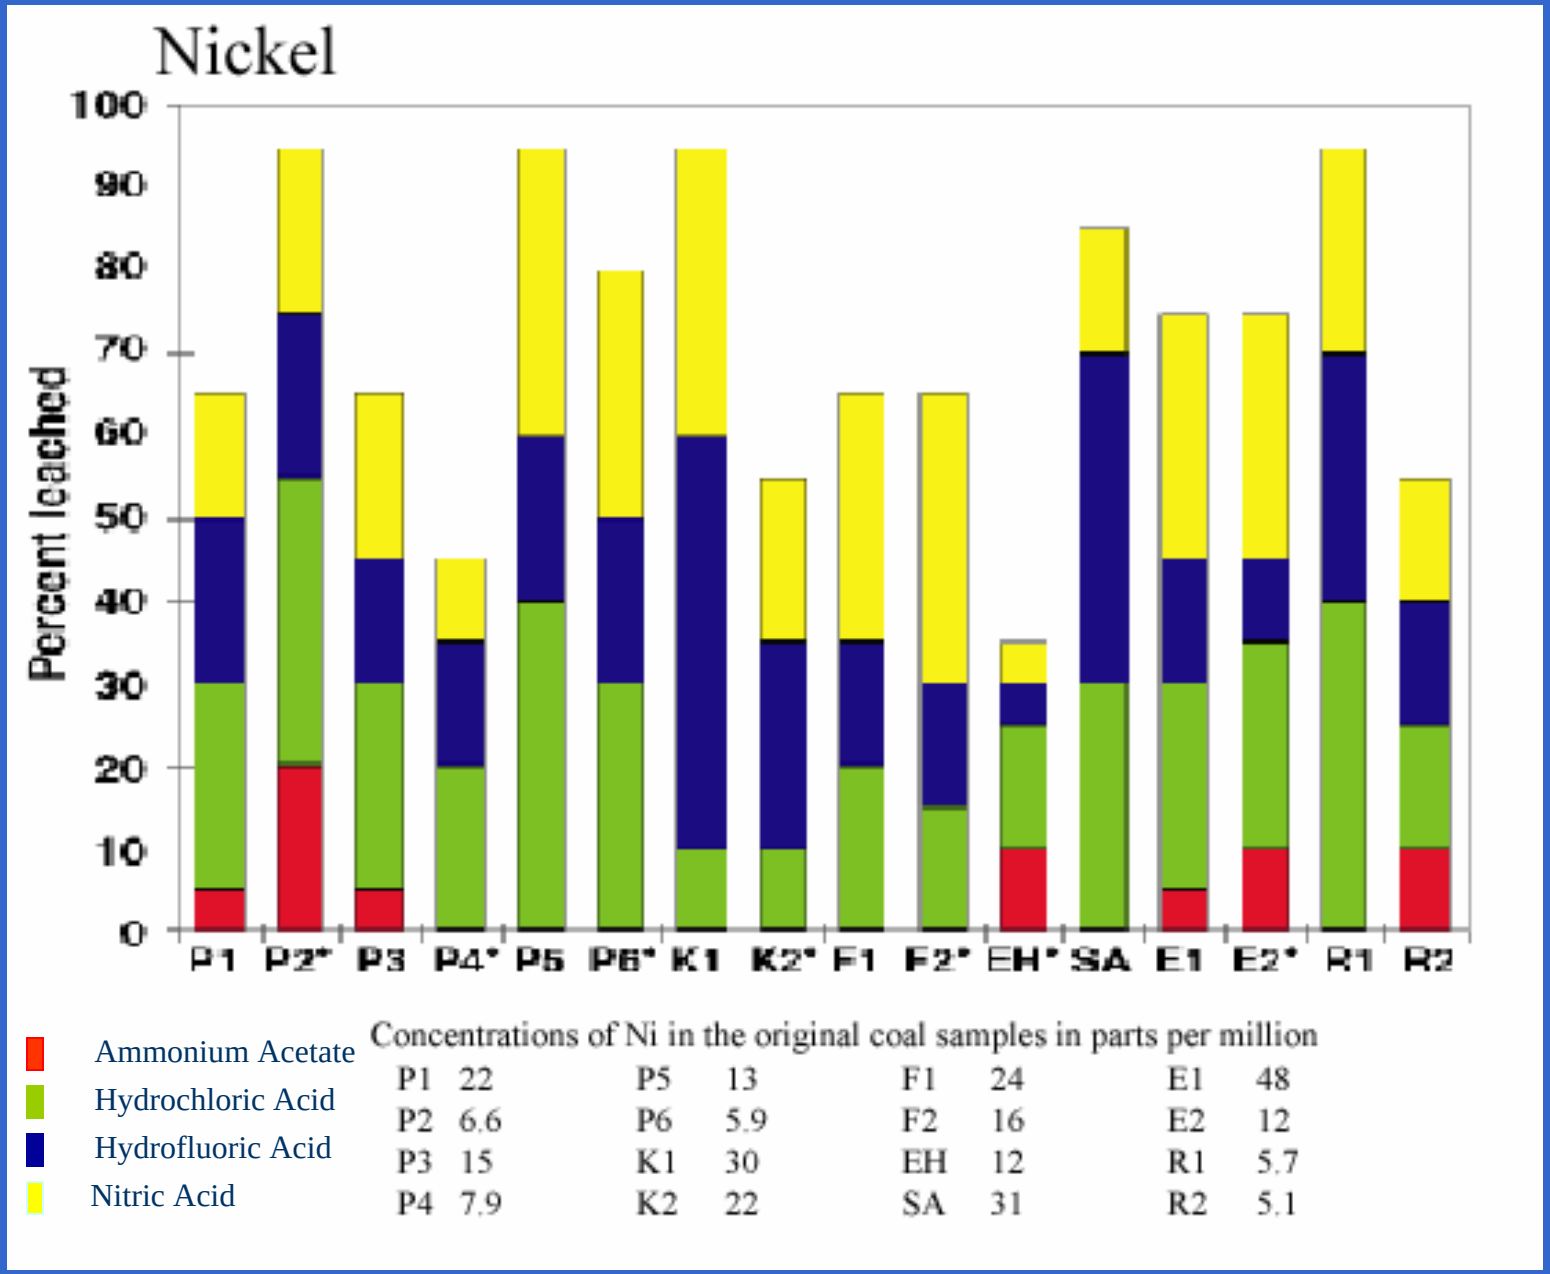


Concentrations of Th in the original coal samples in parts per million

P1	4.3	P5	2.5	F1	4.5	E1	4.5
P2	1.2	P6	1.7	F2	1.9	E2	1.6
P3	2.9	K1	8.1	EH	3.8	R1	2.2
P4	1.5	K2	4	SA	8.7	R2	1.8

Results

- Leaching of some elements are not dominated by a single solvent
  - Multiple modes of occurrence
  - Said to by mixed modes of occurrence



Concentrations of Ni in the original coal samples in parts per million

P1	22	P5	13	F1	24	E1	48
P2	6.6	P6	5.9	F2	16	E2	12
P3	15	K1	30	EH	12	R1	5.7
P4	7.9	K2	22	SA	31	R2	5.1

Conclusions

- The mode of occurrence can be semi-quantitatively determined by selective leaching
- Since each solvent dissolves more than one species supporting techniques (SEM, Microprobe etc.) are needed to determine exact mode of occurrence
- There is a great deal of consistency within a given rank of coal

Microanalysis and Spectroscopic Methods

Allan Kolker

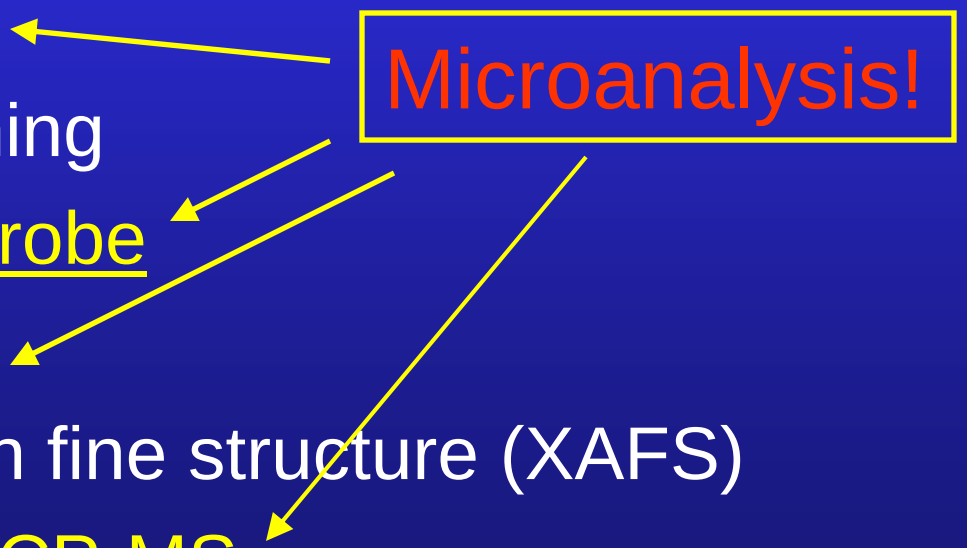
Leaching vs. Microanalysis

- Selective leaching is a bulk multi-element method.
- Interpretation is based on known or inferred leaching behavior.
- Leaching is constrained by element mass-balance.

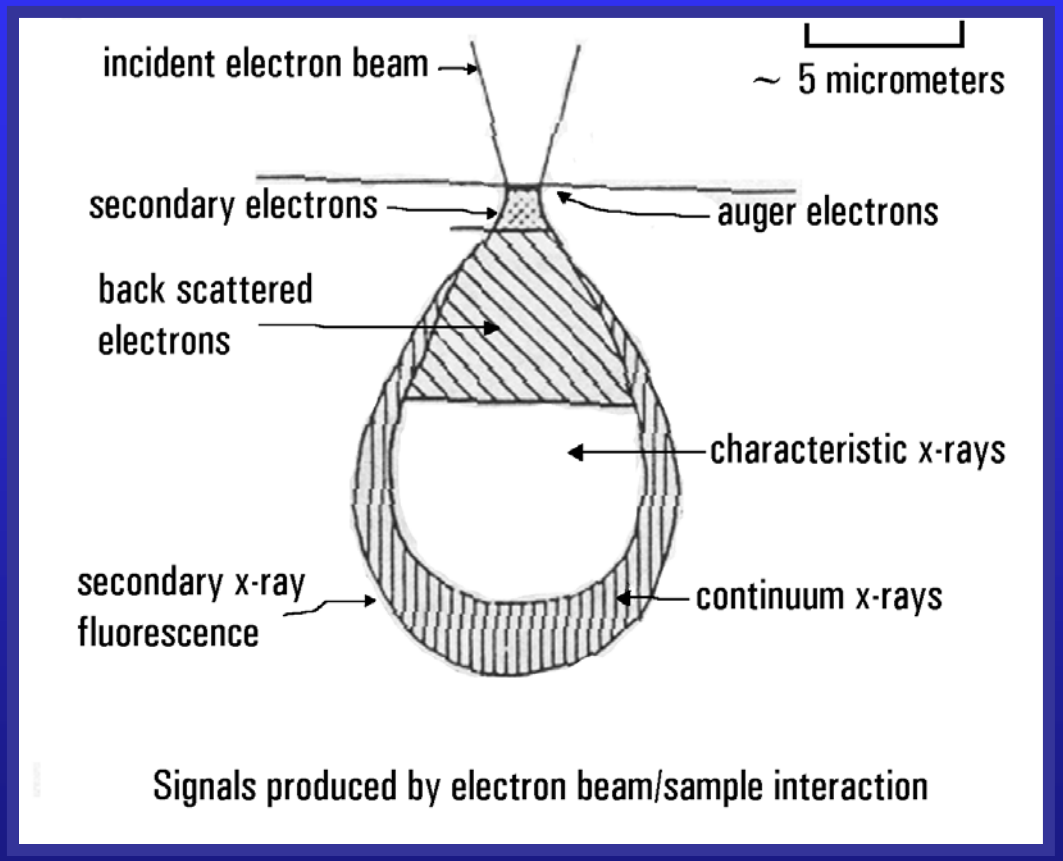
- Microanalysis selects phases of interest on a microns scale.
- Microanalysis gives a direct analysis, where an appropriate method can be found.
- Not intended to achieve a mass balance.

Methods of Determining Element Associations in Coal

- XRD Mineralogy
- Bulk Chemical Testing (INAA, ICP-AES, ICP-MS, XRF, etc.)
- SEM with BSE
- Selective Leaching
- Electron Microprobe
- Ion Microprobe
- X-ray absorption fine structure (XAFS)
- Laser Ablation ICP-MS



Electron-beam Instruments (SEM and Electron Microprobe)



Secondary Electrons

(imaging)

Back Scattered Electrons

(imaging + comp.)

Characteristic X-rays

Stanford/USGS

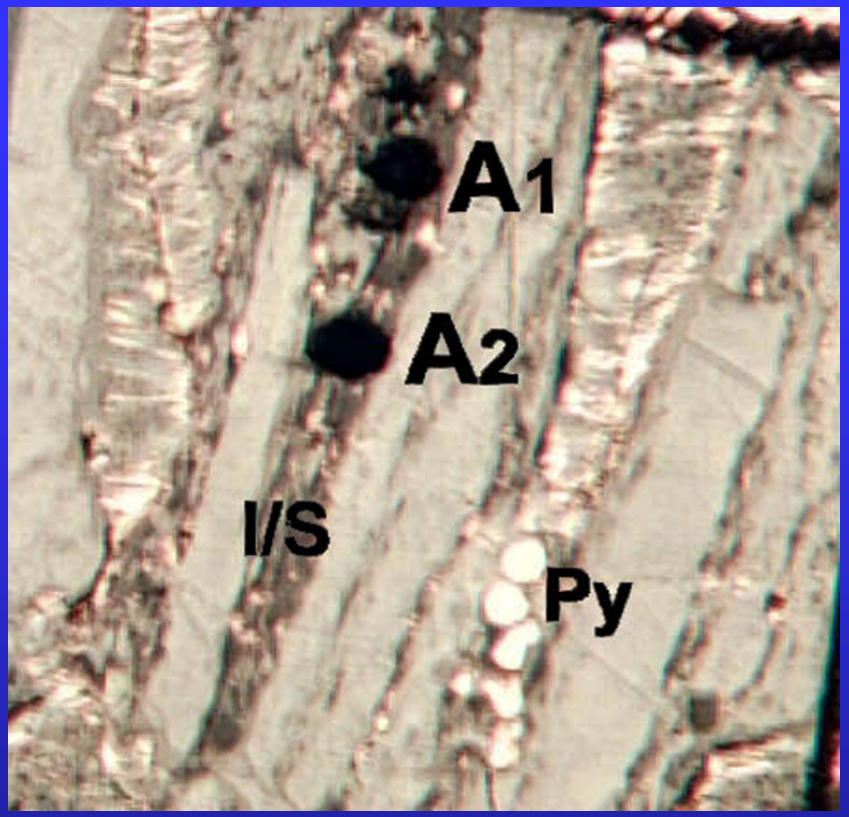
SHRIMP-RG Ion Microprobe

Sensitive High-Resolution Ion Microprobe Reverse Geometry

- Primary beam of O_2^- or Cs^+ ions
- Detection in the ppm range
- 10-15 micron spot size
- Determine isotope ratios

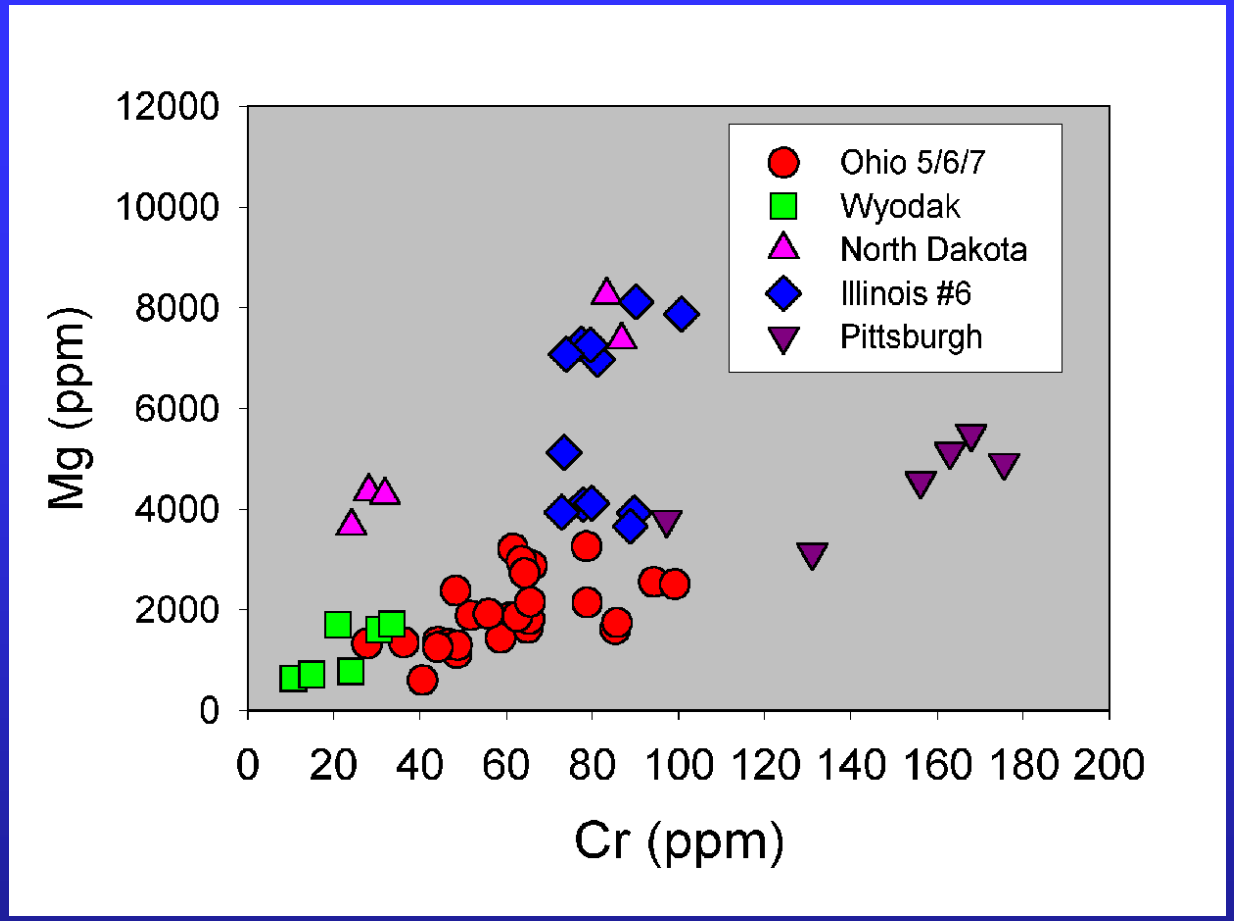
Cr in Coal

- Silicate and organic hosted forms.
- Quantitative results for illite/smectite using Stanford-USGS SHRIMP-RG ion microprobe.
- Concentrations in illite:
  Cr = 11 to 176 ppm
  Mn = 2 to 149 ppm
  V = 23 to 248 ppm
- Confirms leaching results and electron microprobe data.



Reflected-light image of illite-smectite band in Illinois coal and two 15 μm SHRIMP-RG analysis points.

SHRIMP-RG results for chromium in illite-smectite in 5 U.S. coal samples. Results confirm selective leaching studies commonly indicating a silicate association for Cr.

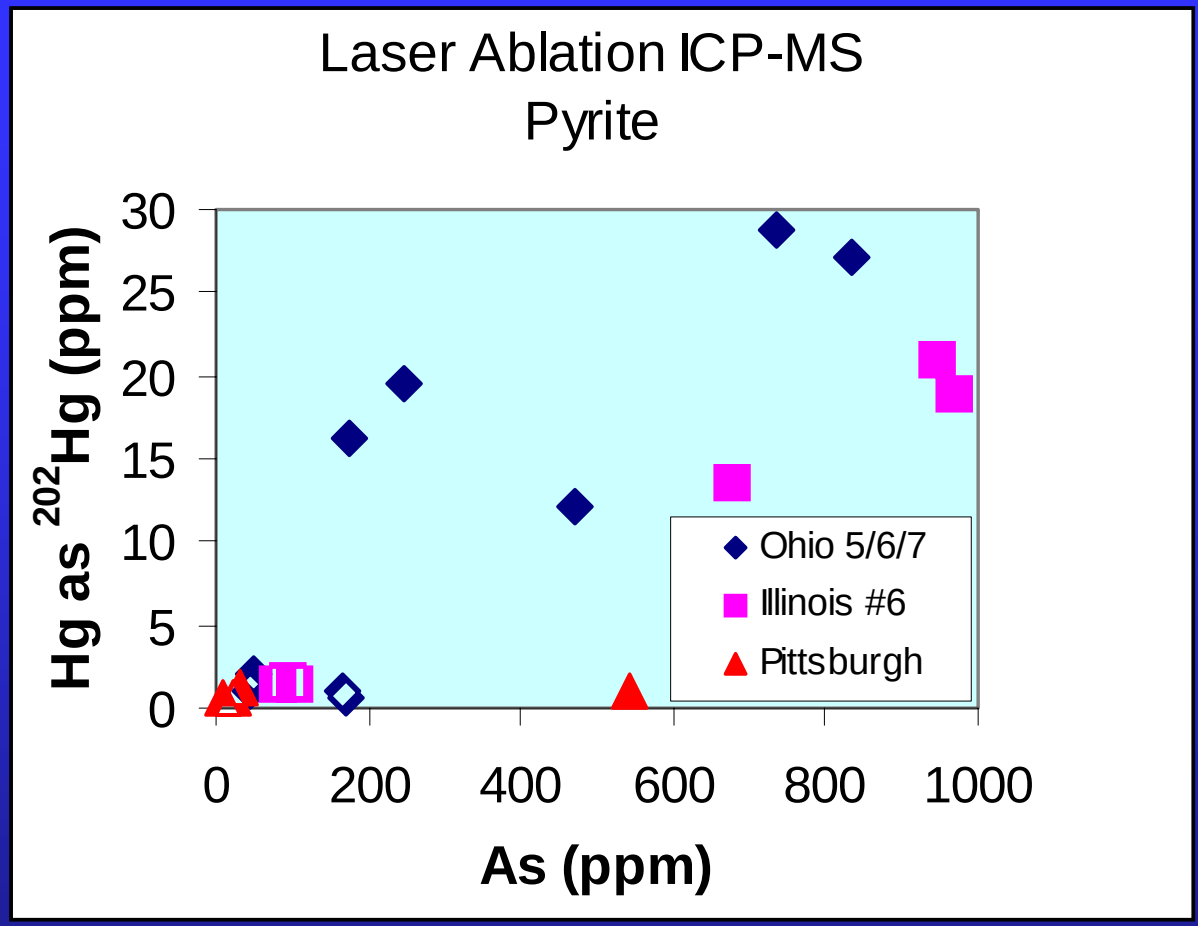


Source: Kolker et al., 2000

Laser Ablation ICP-MS

- Pulsed Nd (YAG) laser coupled to dedicated ICP-MS. Excavation rate is about 3 μm/sec.
- Results for Cr, Mn, Co, Ni, Cu, Zn, As, Se, Mo, Cd, Sb, Tl, Pb, and Hg, in pyrite.
- Sample/standard matrix match not critical as both are introduced into ICP-MS in an argon plasma.
- Best results for Hg with 50 μm beam (about 3 times that of SHRIMP-RG).

Laser ablation ICP-MS confirms mercury association with pyrite in selected bituminous coal samples.



Source: Kolker et al., 2002.

Element Speciation

- Different forms of an element can have very different behavior.

  Examples:
- Trivalent chromium is an essential nutrient; hexavalent chromium is a carcinogen.
- Trivalent arsenic (arsenite) is more toxic than pentavalent arsenic (arsenate).

Approaches to Speciation Determinations

- Classical approach using ion-exchange column chemistry.
- Spectroscopic methods such as X-ray absorption fine structure (XAFS) and ^{57}Fe Mössbauer analysis (primarily solids)
- Selective leaching, where leached form of an element corresponds to a particular species.
- Coupled ion-chromatography-ICP/MS.

XAFS

- Can determine elemental species in powdered coal samples using high-energy synchrotron radiation.
- Need samples with several ppm of an element; limited atomic number range, best for transition metals, As, Se.
- To be quantitative, need to do least-squares fitting of spectra for unknowns to spectra of calibration standards.

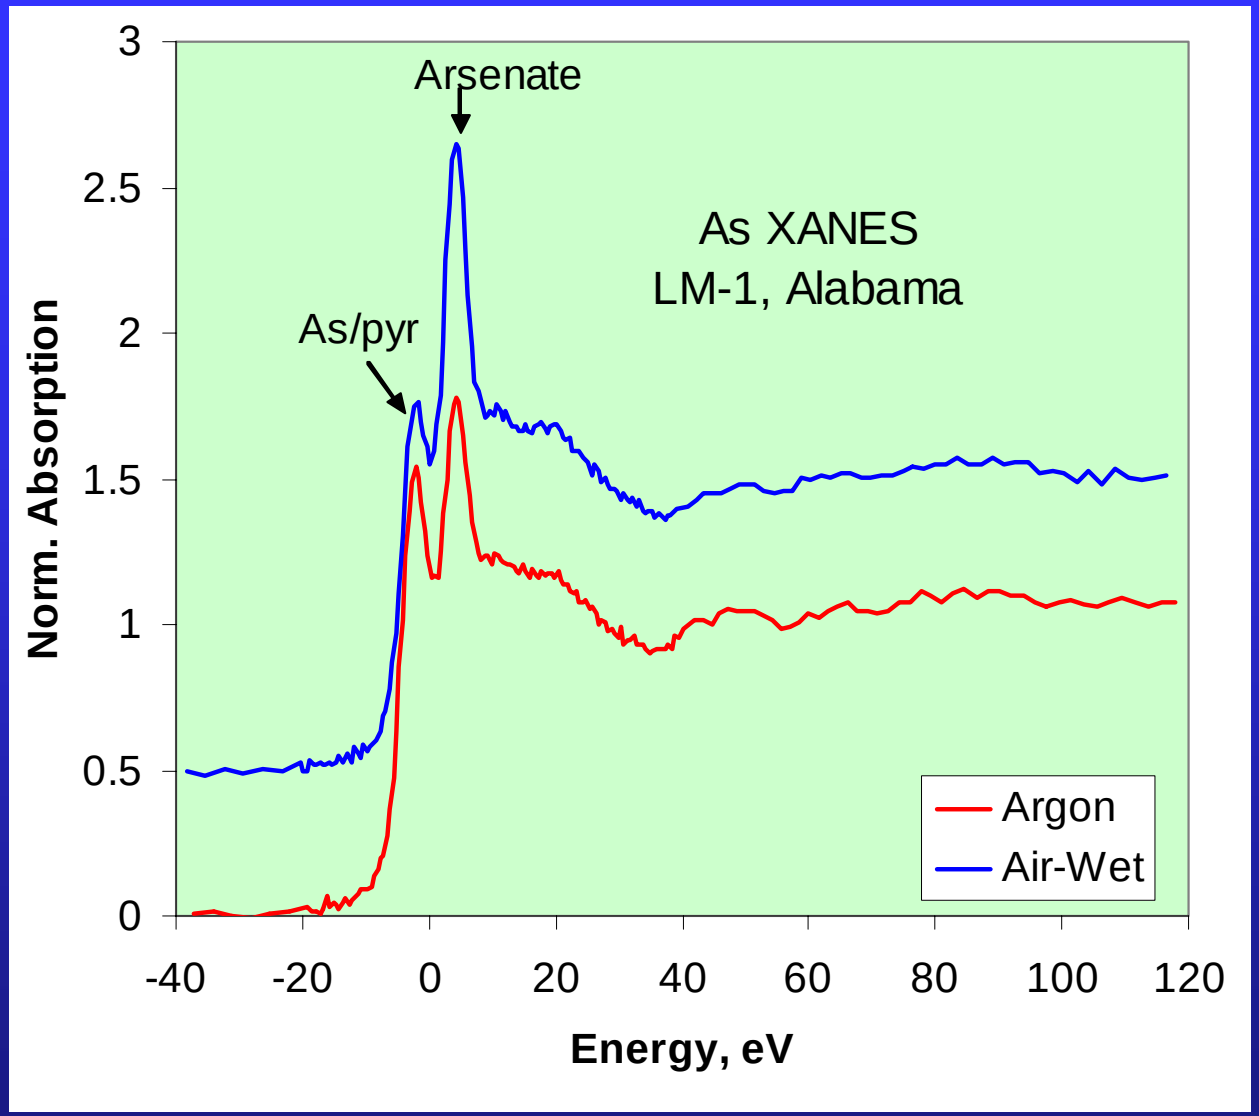
XAFS
Experiment

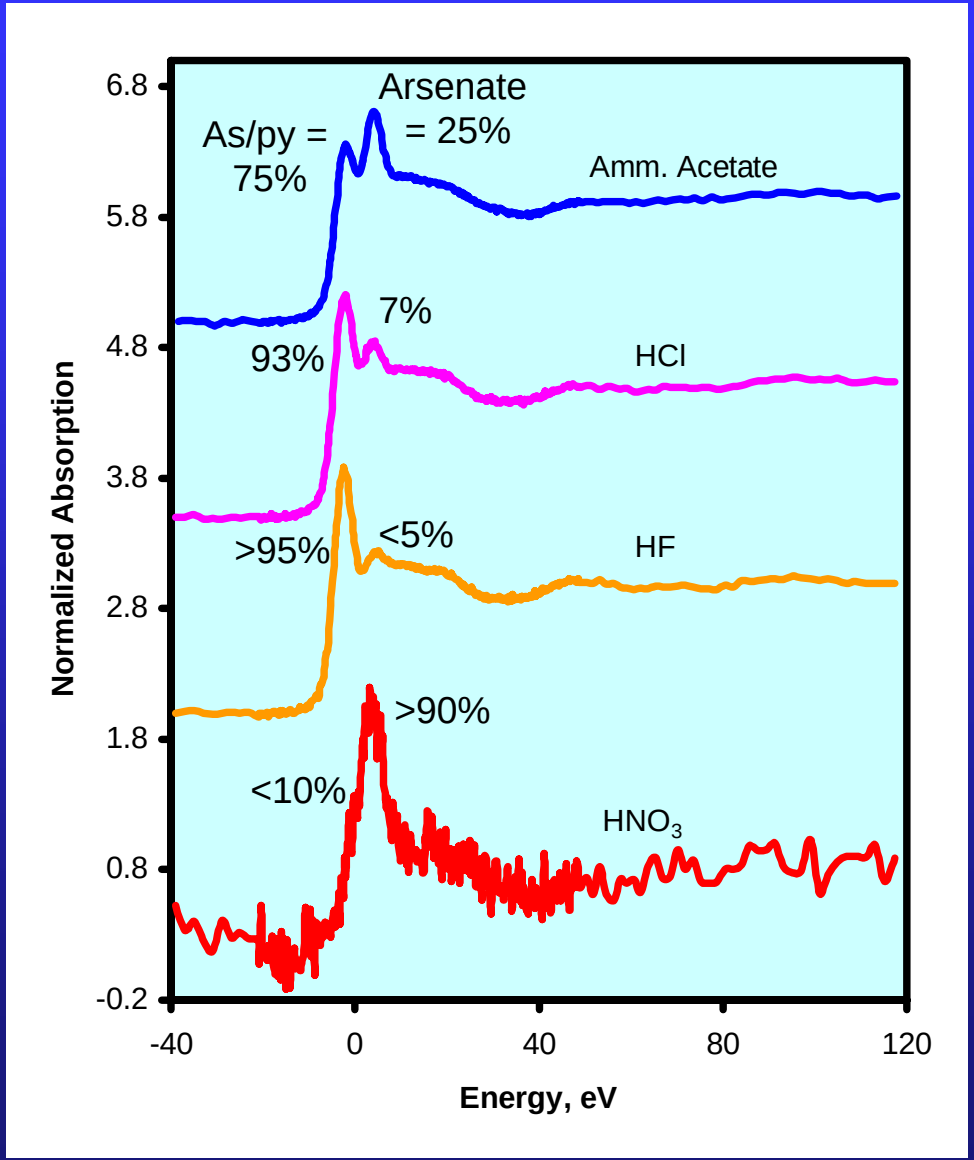
XAFS spectra of Alabama coal sample showing pyritic arsenic and arsenate forms.



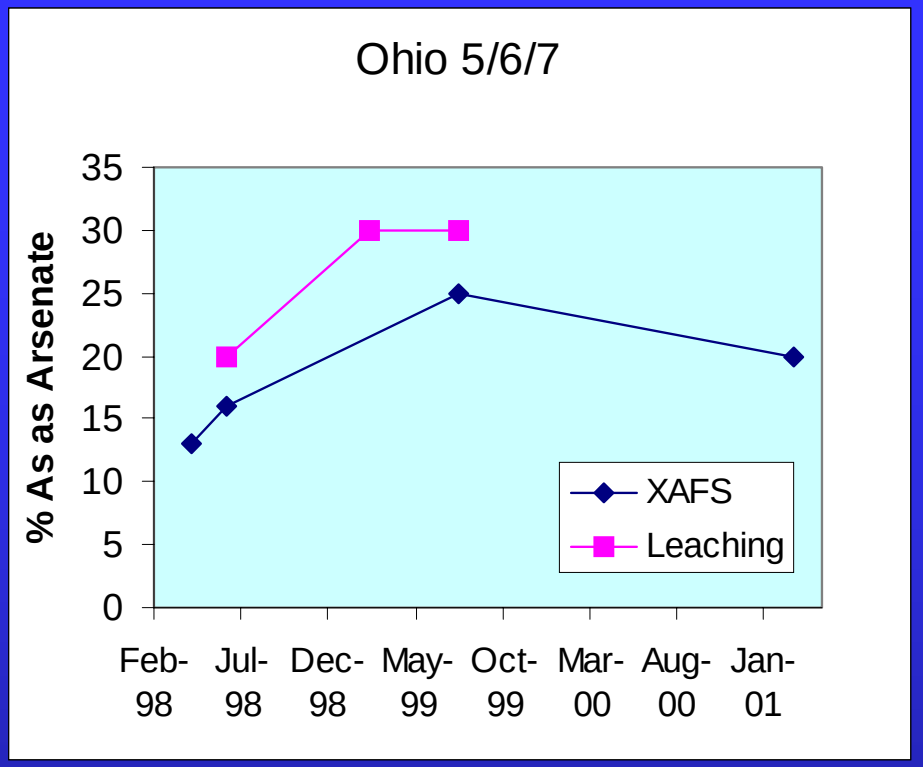
As XAFS of Leached Residues

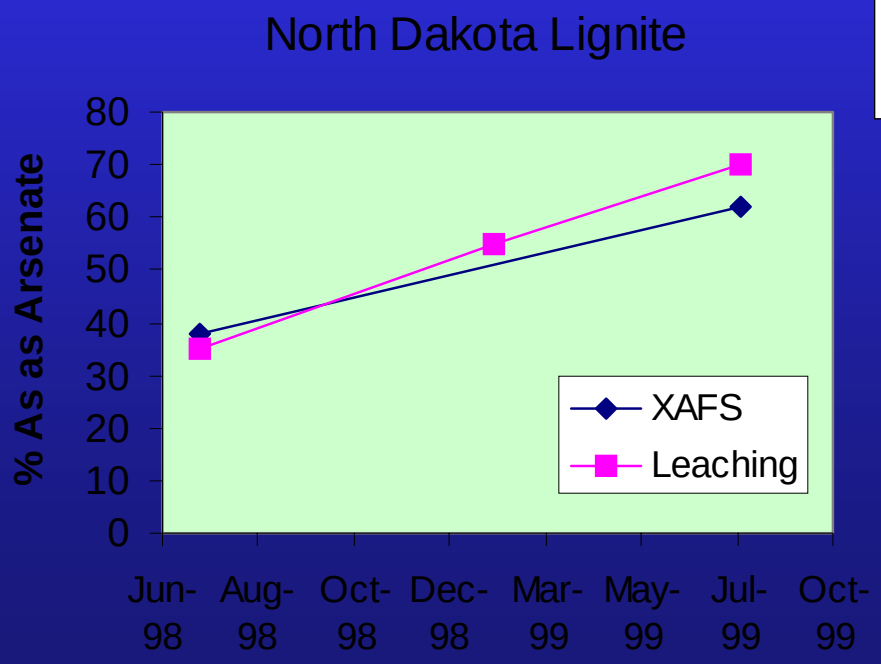
- Pyrite and arsenate are main forms of arsenic in Ohio5/6/7 (bituminous) coal.
- HCl removes arsenate but does not remove significant pyritic arsenic.
- HF removes arsenate not removed by HCl (no As-bearing silicates).
- Fraction of arsenate is primarily a function of pyrite oxidation.

Source: Huggins et al., 2002



Comparison of XAFS and leaching results for Ohio (bituminous) and North Dakota (lignite) coal samples. Determinations show formation of arsenate from As/pyrite over time.





Leaching results are sum of arsenic leached by HCl and HF. Data from Huggins et al., 2002.

XAFS Summary

Arsenic

- Pyrite and arsenate (equivalent to HCl + HF-leached As) are main forms in bituminous coals.
- Arsenate and As (III) are main forms in low rank coals.
- Fraction of arsenate is primarily a function of pyrite oxidation.

Chromium

- Two major forms identified:
  - Cr^{3+}/illite
  - Org. associated Cr (Amorph. CrOOH)
- Chromite- Common only in coals unusually rich in Cr.
- Oxidation State- Always Cr^{3+} in coal (rare Cr $^{6+}$ in some fly ash)

Coal-use Issues and Case Studies

Allan Kolker

Trace elements and coal use

- Mercury emissions balance potential health effects vs. multi-billions cost of controls.
- Fine particulate matter ($PM_{2.5}$) concentrate trace metals relative to coarser ash fractions, and are more readily inhaled.
- Water quality issues:
  - Acid mine drainage (AMD).
  - Disposal of coal preparation wastes.
  - Use of coal combustion products- considered non-hazardous under RCRA.

Pyrite Oxidation

- Oxidation of pyrite results in acid mine drainage and releases metals such as arsenic into the environment.
- Oxidation of pyrite in coal occurs spontaneously over time. Arsenic oxidation proceeds more rapidly than iron oxidation.
- Pyrite oxidation has important implications for coal transport and handling, potentially resulting in leaching of metals from coal piles.

Background- Coal Oxidation Experiments

- Huggins et al. (2002), using As XANES showed that arsenate forms from pyritic arsenic in coal samples over time.
- We use As XANES and Fe-Mössbauer analysis to monitor pyrite oxidation in coal under controlled conditions.
- Experiments test the hypothesis that arsenic-rich pyrite is more susceptible to oxidation than pyrite with little or no arsenic.

Comparison of Coal Samples Investigated

Sample	Coal Bed	Location	Arsenic Content (ppm)	Pyritic Sulfur[1] (wt. %)	Arsenic in Pyrite (wt. %)
Pitts #1	Pittsburgh	West Virginia	23.0	1.32	d.l.[2] to 0.34
Pitts #2	Pittsburgh	West Virginia	12.0	1.58	d.l to 0.14
Spfd	Springfield	Indiana	6.5	2.13	d.l. to 0.06
TP1-1.0	Warrior	Alabama	8.2	0.26	d.l. to 2.46
LM1-2.0	Warrior	Alabama	8.9	0.27	d.l. to 2.72

Air Wet	61	39	69	31	70	30	81	19	77	23

Data are %As of total As in sample that is associated with pyrite or arsenate
Estimated error ±3%

Comparison of As XANES and ^{57}Fe Mössbauer Results (Stage 1 Data)

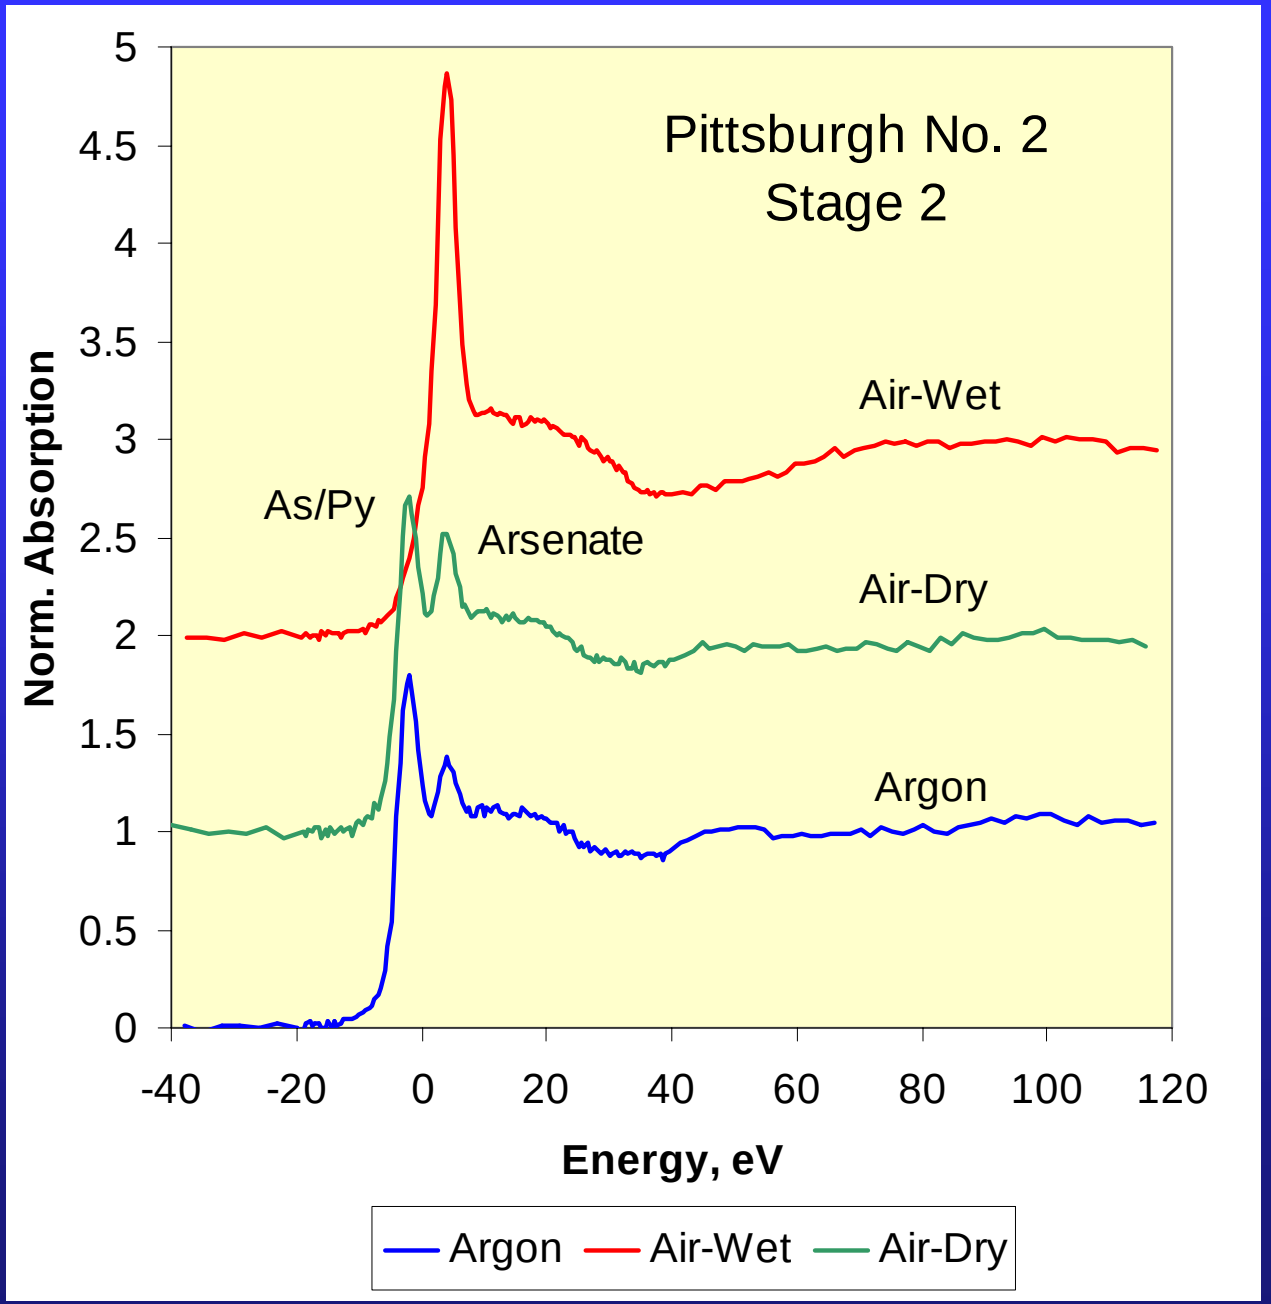
	Springfield			
	Arsenic		Iron	
	Pyrite	Arsenate	Pyrite	Jarosite
Argon	92	8	91	8
Air Wet	70	30	82	16
	Pittsburgh #1			
Argon	93	7	98	2
Air Wet	81	19	86	14

Stage 2 Experiments

- Little or no difference between samples stored under dry gasses (argon & oxygen).
- Unlike Stage 1, samples stored in air are more oxidized than those kept in dry gas.
- Air-wet samples:

  Pitts #2 and Ala TP-1 (no As/py (<5%) remaining); Ala LM-1, Springfield, Pitts #1, 10 to 50% As/py remaining (estimated).

Example of Stage 2 XAFS Results, July, 2003



Summary- Coal Oxidation Experiments

- Nearly complete range of arsenic oxidation is produced by experimental conditions. Arsenic and iron show parallel oxidation.
- Humidity and/or presence of water, and oxygen availability are most important factors controlling oxidation state.
- Complete results are needed to evaluate rates of pyrite oxidation as a function of pyrite arsenic content.

Mercury Emissions from Coal-Fired Power Plants

- December, 2000, EPA determines to limit mercury emissions from coal-fired power plants; timetable superceded by Clear Skies.
- Clear Skies*- Multi-pollutant plan links Hg, SO2 and NOx. Reduces 1999 Hg emissions (48 tons) to 26 tons by 2010 and 15 tons by 2018.
- Boiler MACT- Multi-pollutant plan for industrial/commercial boilers. Limits new boilers to 3 lbs Hg/trillion BTU and existing plants to 7 lbs/trillion BTU. Legislation sought by early 2004 and compliance in 3 years.

Health Risks from Mercury

- Exposure due to consumption of methyl-mercury in fish.
- Nervous system effects and developmental disorders. Documented effects of chronic exposure at low levels. Risk to fetuses and infants is greatest.
- Strong association with kidney damage and disease.
- Likely association with increases in lung cancer, and possible cardiovascular effects.

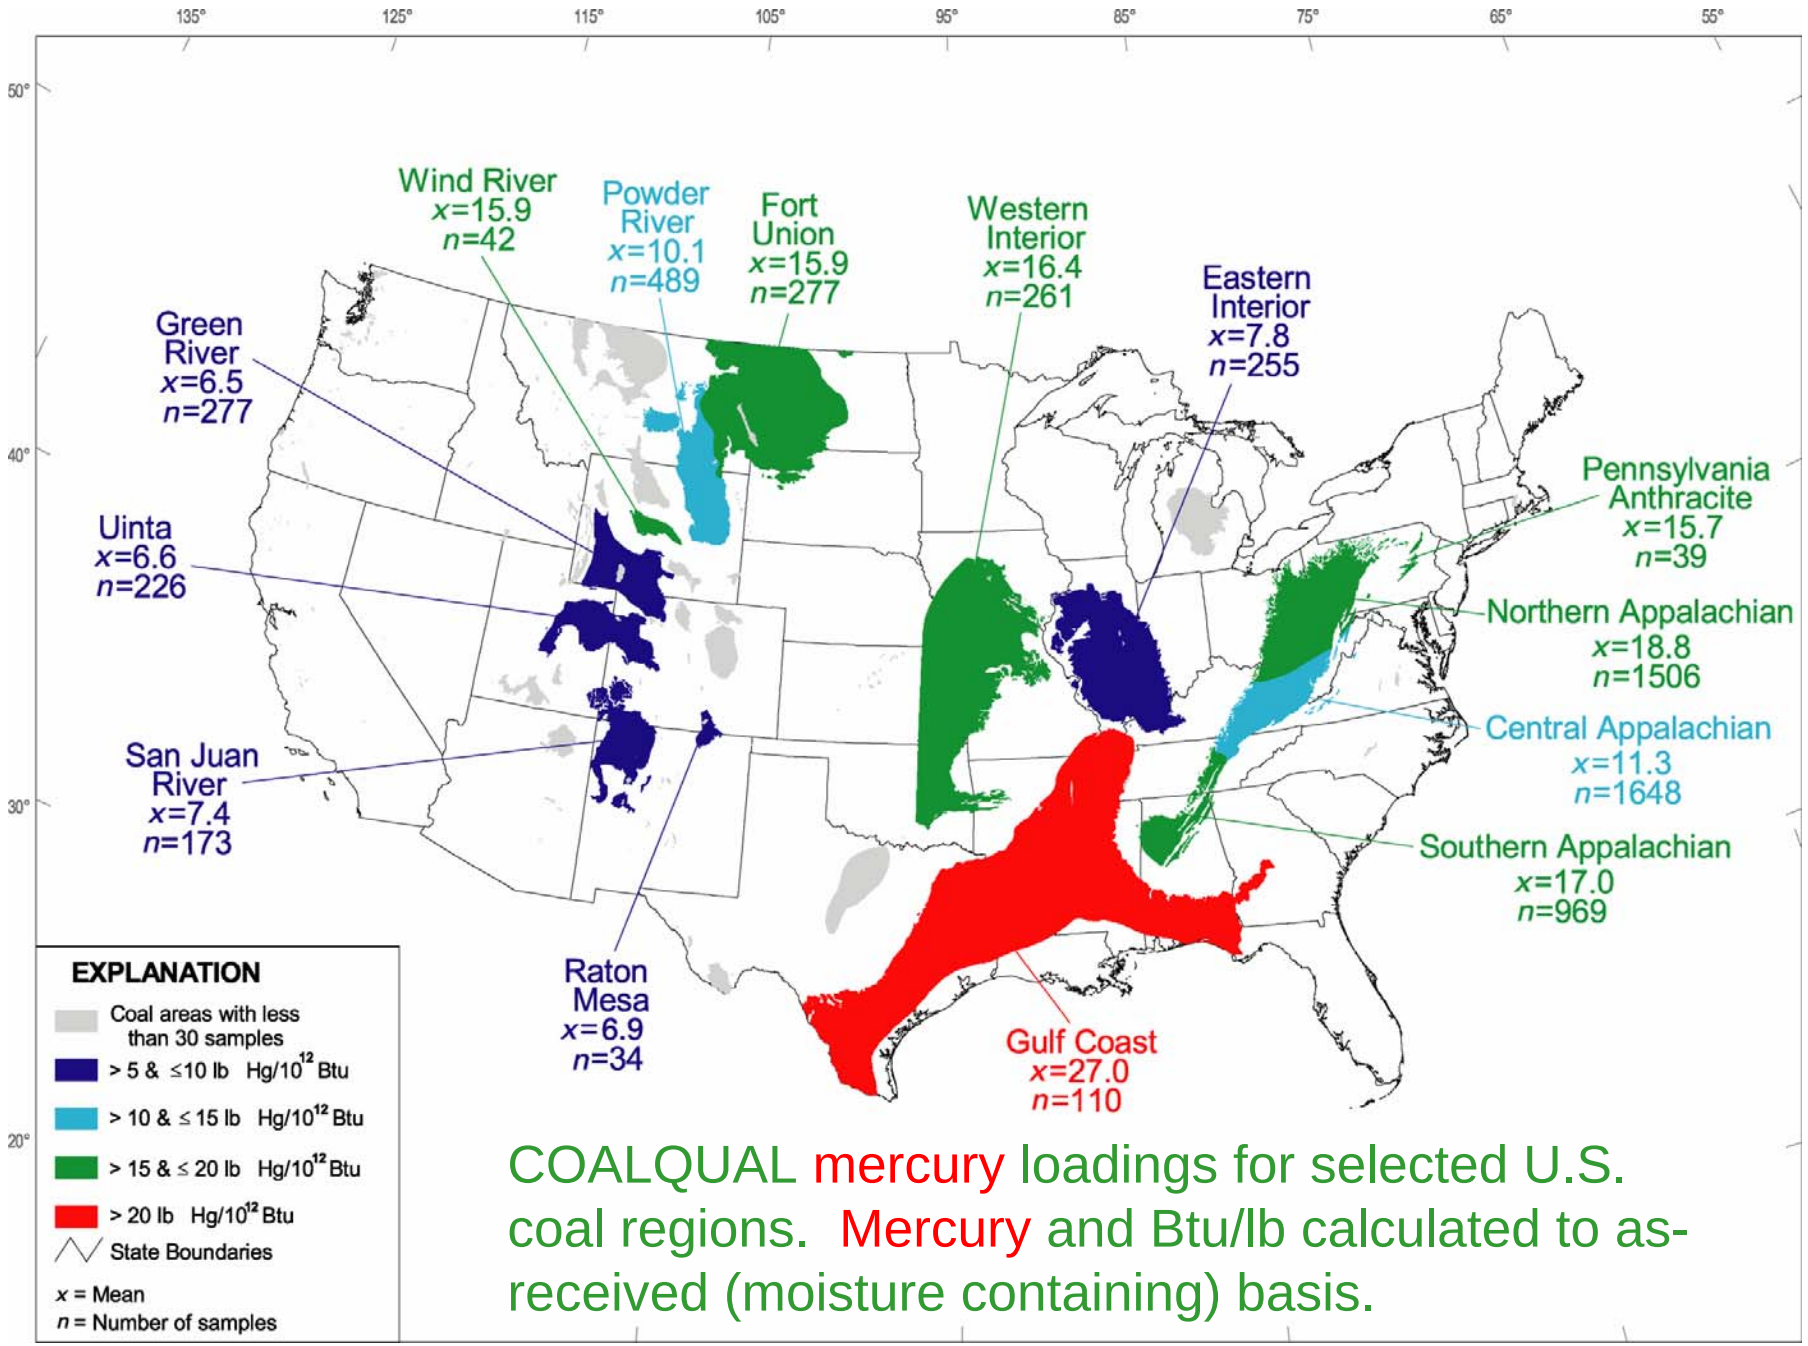
MERCURY, IN PARTS PER MILLION

Comparison of USGS and EPA ICR Data Sets

- EPA ICR database reflects mercury content of commercial coals delivered in 1999 to U.S. power plants ≥ 25 MW.
- USGS database includes data for about 40 elements and many coal-use parameters.
- Subsets[1] give averages of 0.10 ppm for ICR and 0.17 ppm for COALQUAL. Difference reflects cleaned vs. in-ground values, and increased use of low-S western coals.

[1] Quick et al. , *2003, Environmental Geology*



COALQUAL mercury loadings for selected U.S. coal regions. Mercury and Btu/lb calculated to as-received (moisture containing) basis.

Average Mercury Loadings Appalachian Coal Regions

Coal Region	**Mean Hg** (ppm)	**Mean Calorific Value** (Btu/lb)	**Mean Hg Loading*** (lbs Hg/10^{12} Btu)
Northern Appalachian	0.24	12,440	18.8
Central Appalachian	0.15	13,210	11.3
Southern Appalachian	0.21	12,760	17.0

*as-received basis

USGS Results from Tewalt et al., 2001

Calculating Mercury Loading

Example:

High-volatile B Bituminous Coal

Calorific value = 13,500 Btu/lb

Hg = 0.1 ppm Hg (equivalent basis)

$$\frac{1 \text{ lb Hg}}{10^7 \text{ lb coal}} \times \frac{1 \text{ lb coal}}{1.35 \times 10^5 \text{ Btu}} = \frac{7.4 \text{ lbs Hg}}{10^{12} \text{ Btu}}$$

Benefit of Coal Cleaning

Table shows calorific value and mercury contents for raw and cleaned coal averages for 24 eastern bituminous coal samples (dry, equal-energy basis).

Calorific value raw coal (Btu/lb)	Hg content raw coal (ppm)	Calorific value cleaned coal (Btu/lb)	Hg content cleaned coal (ppm)	Percent Hg reduction (equal energy basis)
10,704	0.23	13,730	0.16	37

Results from B. Toole-O'Neil et al., *Fuel*, v. 78, p. 47-54, 1999.

Reducing Mercury Loading

- Example- Coal Cleaning for average Central Appalachian coal:

Raw Coal (lbs $Hg/10^{12}$ Btu)	**Estimated Cleaned Coal** (37% reduction)	**MACT** (existing boilers)
11.3	7.1	7.0

Other Ways To Reduce Hg:

- Selective Mining
- Increase Hg capture with ESP, FGD, etc.
- Unburned Carbon

Eastern coal producers practice coal cleaning and selective mining; Delivered Hg contents are lower than USGS in-ground averages.

Estimating Yearly Mercury Loading to U.S. Power Plants

- Need to accurately know tonnages and moisture contents of coals having a particular mercury content.
- Estimates:

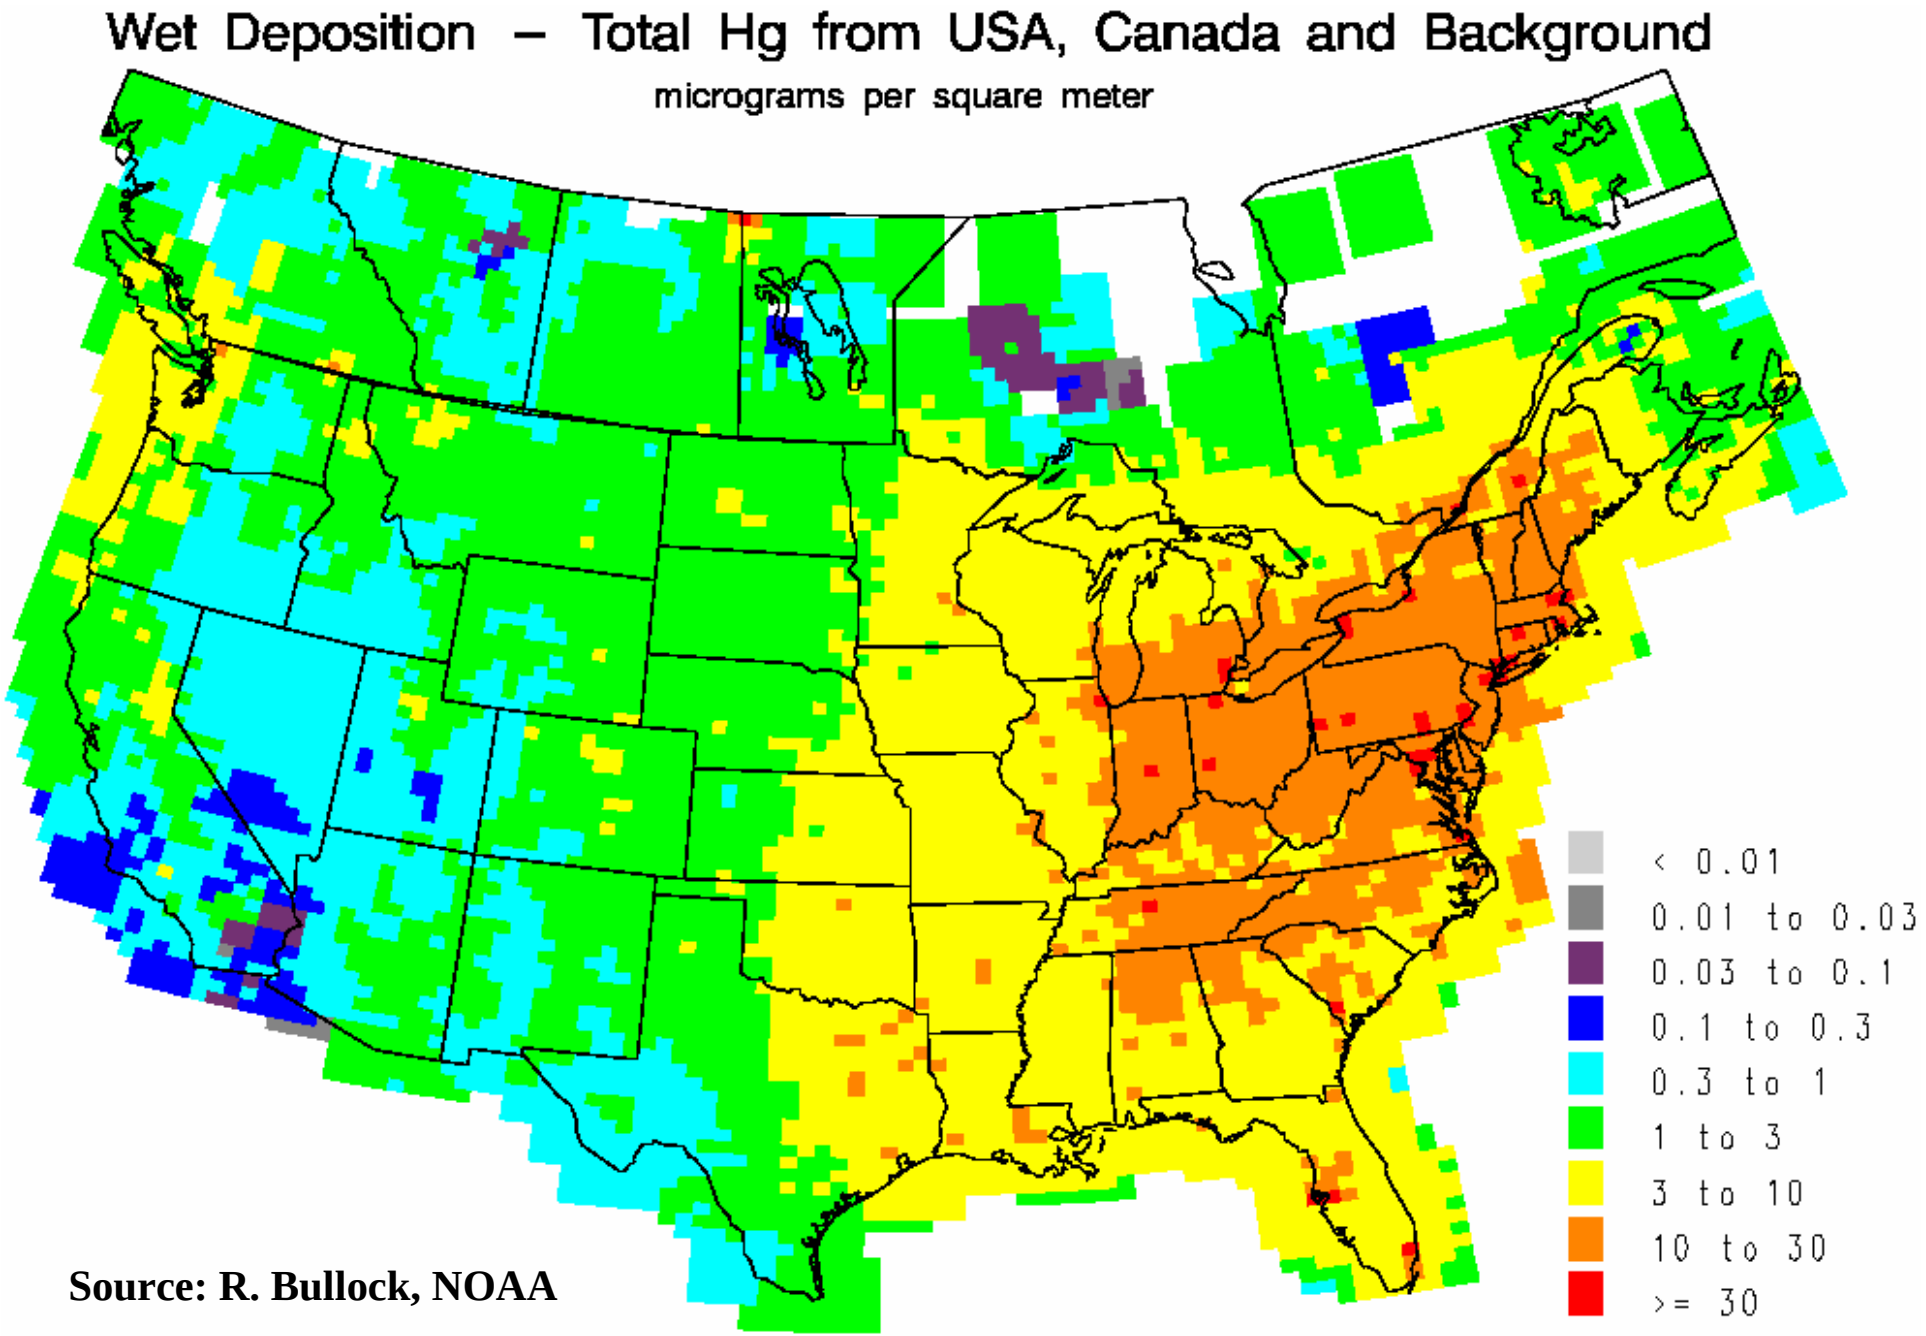
  1) 63 [1]Mg, based on ICR state averages, EIA tonnage data, for power plants ≥ 50 MW only (Quick et al.).

  2) 68 Mg, based entirely on ICR data ([2]Kilgroe et al.).

  3) 111 Mg, based on COALQUAL state averages (Quick et al.). Reduced to about 70 Mg with estimated 37% reduction by cleaning (equal energy basis).

[1]Mg is one metric ton; 1 metric ton = 1.1023 U.S. tons

[2]EPA-600/R-01-109, April 2002



Source: R. Bullock, NOAA

Mercury Deposition Network

- Subprogram of National Atmospheric Deposition Program initiated in 1995 to monitor mercury levels in precipitation.
- Current network consists of about 80 standardized sites in U.S. and Canada.
- Weekly wet deposition samples are determined by cold vapor atomic fluorescence at Frontier Geosciences, Inc.
- Data distribution and program management by Illinois State Water Survey.

Data available at: http//:nadp.sws.uiuc.edu

Background

- Highest projected rates of mercury deposition in the eastern third of U.S.
- Nonetheless, no operating MDN sites in DE, MD, VA, or WV as of 2002 (2 inactive sites).
- VA-08 Culpeper (USGS/GMU) and VA-28 SNP Big Meadows (National Park Service) started in Oct./Nov. 2002 to help fill the void.
- VA-28: Reference for ecological and water quality studies in Shenandoah National Park.
- VA-08 and VA-28: Regional background for mercury emissions prior to mandated changes.

1 INTRODUCTION

1.1 OVERVIEW

This Hydrogeologic Monitoring Plan (HMP) has been prepared by Natural Resource Technology, an OBG Company (NRT) to provide background information necessary to support the monitoring well network established for development of the Sampling and Analysis Plan (SAP) requirements of the United States Environmental Protection Agency (USEPA) Final Rule to regulate the disposal of Coal Combustion Residual (CCR) as solid waste under Subtitle D of the Resource Conservation and Recovery Act (RCRA) [40 CFR 257 Subpart D; published in 80 FR 21302-21501, April 17, 2015] for the Newton Power Station, Jasper County, Illinois. The Newton Power Station is owned by Illinois Power Generating Company (IPGC). This HMP will apply specifically to the following CCR Units: Newton Primary Ash Pond (CCR Unit ID 501) and Newton Landfill 2 (CCR Unit ID 502), as defined further below.

1.2 PREVIOUS INVESTIGATIONS AND REPORTS

Numerous hydrogeologic investigations have been performed concerning the CCR Units located at the Newton Power Station. The information presented in this HMP includes data collected in support of the monitoring well network established for development of the Sampling and Analysis Plan (SAP) and supplements comprehensive data collection and evaluations from prior hydrogeologic investigation reports (most recent to oldest), including, but not limited to, the following:

- ***Rapps Engineering and Applied Science, April 10 2013, Phase I Hydrogeological Assessment Report, Coal Combustion Product Impoundment, Ameren Energy Generating Company, Newton Energy Center, Jasper County, Illinois.*** A hydrogeologic study to assess the potential for constituent migration from this impoundment. Report includes: water well survey, development of a groundwater monitoring plan, and an initial groundwater quality assessment. This report summarizes hydrogeologic information pertinent to the site, evaluates groundwater quality data to determine if operation of the impoundment has adversely affected groundwater, and makes recommendations for future actions related to groundwater quality management.
- ***Geotechnology, Inc., February 8, 2011, Initiation of Monitoring Report, Ameren, Newton Power Station, Newton, Illinois.*** This report documents the results of the monitoring well installation and groundwater monitoring activities performed at the site. Three wells were installed, developed and sampled.
- ***Rapps Engineering and Applied Science, November 2009, Site Characterization and Groundwater Monitoring Plan for CCP Impoundment, Ameren Energy Generating Company, Newton Power Station, Jasper County, Illinois.*** Hydrogeologic study and groundwater monitoring plan to assess the potential for constituent migration from this impoundment. Includes an assessment of subsurface hydrogeologic conditions at the site, identification of private, potable water wells and oil and gas wells within 2,500 feet of the facility, public water supply (PWS) wells within 10 miles of the facility, and plans for a groundwater monitoring well network designed to characterize and monitor groundwater quality.
- ***Rapps Engineering and Applied Science, 1997, Hydrogeologic Investigation and Groundwater Monitoring Program, Newton Power Station, Jasper County, Illinois.*** Investigation presents site-specific data obtained through the completion of approximately 40 borings, 20 monitoring wells, and review of regional information and an evaluation of subsurface data from nearby residential wells. Part of Application for Landfill Permit – Rapps 1997.

The HMP supports the monitoring well network established for development of the SAP and provides the following background information:

- Site Geology and Hydrogeology
- Aquifer Properties
- Monitoring Network Placement and Rationale

1.3 SITE LOCATION AND DESCRIPTION

The Newton Power Station (NPS) is located in Jasper County in the southeastern part of central Illinois, approximately 7 miles southwest of the town of Newton (Figure 1). The plant is located on the north side of Newton Lake and has one active CCR impoundment (Newton Primary Ash Pond) located in Section 26 and the western half of Section 25, Township 6 North, Range 8 East. The site also contains the Newton Landfill 2, located in the western half of Section 26 and eastern half of Section 27, Township 6 North, Range 8 East. The area is also bounded by agricultural land and Newton Lake to the west, south, and east. Beyond the lake is additional agricultural land.

1.4 DESCRIPTION OF CCR MANAGEMENT UNITS

The CCR Units at the Newton Power Station, including the Newton Primary Ash Pond (CCR Unit ID 501) and the Newton Landfill 2 (CCR Unit ID 502), will hereafter be referred to as the 'Site'.

1.4.1 Newton Primary Ash Pond (CCR Unit ID 501)

The NPS's sole CCR impoundment, consisting of a Primary Ash Pond, was constructed in 1977 and has a design capacity of approximately 9,715 acre-feet for the primary pond. There is also a non-CCR 83.6 acre-feet Secondary Pond. The Primary Ash Pond has a surface area of 400 acres and a height of approximately 71 feet above grade. The Secondary Pond has an area of 9.3 acres and a height of approximately 29 feet above grade. The Primary Ash Pond currently receives bottom ash, fly ash, and low-volume wastewater (LVW) from the plant's two coal-fired boilers. The CCR impoundment is operated per NPDES Permit IL0049191, Outfall 001. The impoundment was not excavated during construction except for native materials used to build the containment berms.

1.4.2 Newton Landfill 2 (CCR Unit ID 502)

Newton Landfill 2 includes two cells, Phase I (west) cell and Phase II (east) cell. The Phase I cell, built around 1977, was unlined, and accepted sodium-based flue gas desulfurization (FGD) wastes. Phase I was closed in 1999 with a 40-millimeter thick geomembrane cap and currently has a Groundwater Management Zone (GMZ) established. Following a switch by the NPS to western coal in 1997, the Phase II cell began receiving coal ash that same year; a portion of the Phase II cell is still operational. The Phase II cell has a geomembrane liner with a leachate collection system.

2 GEOLOGY AND HYDROGEOLOGY

The results of the site characterization activities performed at the Site are discussed below.

2.1 GEOLOGY

Geologic units present at the Site include fill, ash generated at the site, unlithified alluvial sediments, unlithified glacial deposits, and Pennsylvanian-age bedrock.

2.1.1 Regional Setting

Illinois is situated in the south-central part of the great Central Lowland Province near the confluence of two major lines of drainage, the Mississippi and Ohio Rivers (Leighton et al., 1948). The NPS lies at the southeastern portion of the Springfield Plain of the Till Plains section, the largest physiographic division in Illinois, covering approximately four-fifths of the state. It is characterized by its flatness and shallowly entrenched drainage. Drainage systems are well developed, and the district is in a late youthful stage of dissection.

The unlithified geologic deposits in the region range from 100 to 120 feet (ft) thick and are derived from recent river deposition (alluvium), glacial outwash, and glacial till deposits. The unlithified deposits directly overly Pennsylvanian Mattoon Formation bedrock. The Mattoon Formation is the youngest formation in the Pennsylvanian System in Illinois. It is underlain by the Bond Formation, while the top is mostly an erosional surface overlain by Pleistocene glacial deposits. The Mattoon Formation has a maximum thickness of more than 600 feet in the central part of the Illinois Basin in Jasper County. It is characterized by a complex sequence of thin limestones, coals, black fissile shales, underclays, thick gray shales, and several well developed sandstones. The lateral extent of many of the named units has not been determined due to widely scattered outcrops and scarce subsurface data. However, coals and limestone units are considered to be as persistent as those in the underlying Bond Formation.

Borings advanced at the NPS as part of a hydrogeologic site investigation for a CCP landfill indicate that the elevation of the top of the bedrock surface at the site is approximately 400 to 450 ft MSL. The depth to bedrock varies widely in the area owing to the undulatory nature of the eroded upper bedrock surface and ranges from approximately 90 to 120 ft. Logs indicate that the lithology of the uppermost bedrock is mostly shale.

2.1.2 Site Geology

The geology has been evaluated during previous hydrogeologic investigations and groundwater quality assessments since the first borings and monitoring wells were installed. Quaternary deposits in the Newton area consist mainly of diamictons and outwash deposits that were deposited during Illinoian and Pre-Illinoian glaciations. The unconsolidated deposits which occur at Newton Power Station include the following units (beginning at the ground surface):

- Ash/Fill Units – CCR and fill within the various CCR Units
- Upper Confining Unit – Low permeability clays and silts, including the Peoria Silt (Loess Unit) in upland areas and the Cahokia Formation in the flood plain and channel areas to the south and east, underlain by the Sangamon Soil, and the predominantly clay diamictons of the Hagarstown (Till) Member of the Pearl Formation and the Vandalia (Till) Member of the Glasford Formation
- Uppermost Aquifer (Groundwater Monitoring Zone) – Thin to moderately thick (3 to 17 ft), moderate to high permeability sand, silty sand, and sandy silt/clay units of the Mulberry Grove Member of the Glasford Formation
- Lower Confining Unit – Thick, very low permeability silty clay diamicton of the Smithboro (Till) Member of the Glasford Formation and the silty clay diamictons of the Banner Formation
- Bedrock – Pennsylvanian-age Mattoon Formation that is mostly shale near the bedrock surface, but is characterized at depth by a complex sequence of shales, thin limestones, coals, underclays, and several

sandstones. The erosional surface of the Pennsylvanian-age Mattoon Formation bedrock ranges widely in depth in the vicinity of the site, but is typically encountered at 90 to 120 ft below ground surface (bgs).

The major unconsolidated materials present at the site are discussed in greater detail below:

2.1.2.1 Ash/Fill Units

Ash is present within the Newton Primary Ash Pond as well as the Newton Landfill 2. The majority of ash fill at the Newton Primary Ash Pond lies on top of the loess and clay.

2.1.2.2 Cahokia Formation

The Cahokia Formation of the Holocene Stage consists of deposits in floodplains and channels of modern rivers and streams and consists of mostly poorly sorted sand, silt, and clay with wood and shell fragments and local deposits of sandy gravel. The Cahokia is likely present in the Big Muddy Creek valley west of the site and along the bottom of Newton Lake to the east, which used to be the bottomland for Law Creek (Lineback, 1979; Berg and Kempton, 1987).

2.1.2.3 Peoria Silt (Loess Unit)

The Peoria Silt is a Loess Unit which extends from beneath the topsoil, derived from the loess, to the top of the Hagarstown Member. The loess, ranging in thickness from 3 to 9 ft where present, has been described as silt, clayey silt, and silty clay. The Loess Unit is generally considered unsaturated.

2.1.2.4 Sangamon Soil

The Sangamon Soil formed between the interglacial period between the Illinoian and Wisconsinan stages of glaciation as a result of weathering of the upper portion of the Illinoian drift. This layer occurs throughout the site and consists of approximately 2 to 6 ft of light brown to light gray silty clay

2.1.2.5 Hagarstown (Till) Member

The Hagarstown Member (also referred to as Hagarstown Beds) of the Pearl Formation, consists of clay till with varying amounts of sand and gravel. Where present at the site, the clay till ranges in thickness from 3 to over 24 ft. Where present, the sandy portion of the Hagarstown is generally less than 5 ft thick. The composition of the sandy portion of the Hagarstown unit varies across the site and was classified as gravelly till, poorly sorted gravel, well sorted gravel, sand and silty sand.

2.1.2.6 Vandalia (Till) Member

The Vandalia Member is a sandy/silty till with thin, discontinuous lenses of silt, sand, and gravel. The Vandalia Till was encountered in all borings advanced at the site. The Vandalia Till typically ranges in thickness from 20 to 60 ft. Results from laboratory tests completed for vertical hydraulic conductivity indicate the Vandalia unit has a very low vertical hydraulic conductivity.

2.1.2.7 Mulberry Grove Member

As described by Willman et al. (1975), the Mulberry Grove Member of the Glasford Formation typically consists of a thin, lenticular unit of gray sandy silt (Willman et al., 1975). It represents the interval between the retreat of the glacier that deposited the Smithboro Member and the advance of the glacier that deposited the Vandalia Member. At the site, the Mulberry Grove Member consists of fine to coarse sand with varying amounts of silt and small to large gravel. The portion of the Mulberry Grove Member at the site that is defined as a sand layer ranges in thickness from 3 to 17 ft with an average thickness of 8 ft. This unit generally occurs across the site at depths between 55 and 88 ft bgs.

2.1.2.8 Smithboro (Till) Member

The Smithboro Member is described as a gray, compact, silty-clay diamicton. The Smithboro Member typically ranges in thickness from 10 to 20 ft.

2.1.2.9 Banner Formation

The Banner Formation consists of pre-Illinoian undifferentiated diamictons and intercalated sand and gravel outwash that generally rest directly on bedrock. The Banner Formation is approximately 20 to 30 ft thick at the site and consist of greenish-gray silty clay with traces of sand.

Name	Age	Description
Cahokia	Holocene	poorly sorted sand, silt, and clay (alluvial)
Peoria Silt	Wisconsinan	sandy silt along bluffs to clayey silt away from bluffs; local lenses of fine to med grained sand; 3-9 ft thick
Sangamon Soil	Sangamonian	light brown to light gray silty clay; weathered upper portion of Illinoisan drift; 2.5-5.5 ft thick
Hagarstown Member	Illinoisan	gravel, sand, and gravelly diamicton; 3-24' thick where present; reddish-brown silty clay with some sand and gravel; surface at 510 to 532 ft; can also be gravelly till with poorly sorted gravel, well sorted gravel, and sand
Vandalia Member	Illinoisan	gray silty to sandy clay diamicton with traces sand and gravel; thin lenses of silt, sand, and gravel; 20-60 ft thick
Mulberry Grove	Illinoisan	fine to coarse sand with varying amounts of silt and fine to coarse gravel; 3 - 17 ft thick; may contain lenses of silt, sand and gravel
Smithboro Member	Illinoisan	gray, silty clay diamicton w/ traces sand and gravel; 10-20 ft thick
Banner Formation	pre-Illinoisan	undifferentiated diamictons; greenish-gray moist silty clay with traces of sand; 20-30 ft thick

2.2 HYDROGEOLOGY

The information used to describe the hydrogeology is based on the local geology obtained from published sources, hydrogeologic investigation data, and boring data collected during monitoring well installation.

2.2.1 Uppermost Aquifer

The uppermost aquifer is the Mulberry Grove Member, typically consisting of fine to coarse sand with varying amounts of clay, silt and fine to coarse gravel. The portion of the Mulberry Grove Member at the site that is defined as a sand layer ranges in thickness from 3 to 17 ft. with an average thickness of 8 ft and with only a few exceptions occurs between depths of 55 to 88 ft bgs.

2.2.2 Lower Limit of Aquifer

The lower hydrostratigaphic units consist of the Smithboro Member and the Banner Formation, both of which are predominantly low permeability clay diamictons with varying amounts of silt, sand and gravel. The lower unlithified confining unit is 30 to more than 50 ft thick above the underlying bedrock.

2.2.3 Hydraulic Conductivity

Hydraulic conductivity/slug tests were completed in wells screened in the unlithified material during prior site investigations and by NRT in April 2017. The hydraulic conductivity values determined from 15 individual monitoring wells (Appendix C) within the uppermost aquifer (Mulberry Grove Member) ranged from 3.9×10^{-8} to 3.6×10^{-2} centimeters per second (cm/s). The geometric mean of the hydraulic conductivity for NRT tested monitoring wells in the Uppermost Aquifer, excluding one outlier, is 2.5×10^{-4} cm/s. Monitoring wells around the Primary Ash Pond had a geometric mean hydraulic conductivity of 1.2×10^{-3} cm/s and those around Landfill 2, excluding one outlier, had a geometric mean hydraulic conductivity of 7.4×10^{-5} cm/s. Field hydraulic conductivity test results reported by Rapps (1997) for six locations near Landfill 1 ranged from 2.5×10^{-6} to 6.0×10^{-3} cm/s with a geometric mean of 9.8×10^{-4} cm/s.

The uppermost unit intercepted in the area of the Primary Ash Pond and Landfill 2 is the silty to sandy clay of the "Upper Drift", or aquitard, as identified in the Rapp's 1997 landfill investigation and consists of Peoria Silt, Sangamon Soil, and/or Hagarstown Member. The hydraulic conductivity of this unit, as tested at monitoring wells near the landfill with screen depths between 8 and 36 ft bgs (Rapps, 1997), ranged from 2.4 x 10^{-6} to 6.1 x 10^{-5} cm/s with a geometric mean of 1.7 x 10^{-5} cm/s. Three in-situ tests conducted by NRT of the uppermost materials near the Primary Ash Pond, on wells screened between 7 and 20 ft bgs, had a geometric mean hydraulic conductivity of 1.3 x 10^{-5} cm/s. Laboratory testing results for five soil samples collected from depths of 20 to 32 ft bgs in the underlying Vandalia Member (Rapps, 1997) ranged from 6.3 x 10^{-9} to 2.1 x 10^{-8} cm/s with a geometric mean hydraulic conductivity of 1.1 x 10^{-8} cm/s.

The hydraulic conductivity value determined from one field (i.e. in-situ) test of the upper part of the Lower Confining Unit by Rapps (1997), at a depth of 79 to 87 ft bgs, was 1.4 x 10^{-7} cm/s.

2.2.4 Groundwater Elevations, Flow Direction and Velocity

Seasonal variation of groundwater levels and flow direction at the Landfill is indicated in the series of 2015-2017 groundwater elevation contour maps (Appendix D). Groundwater elevations across Landfill 2 ranged from approximately 441 to 520 ft MSL (NAVD88) from 2015 to 2017. Overall groundwater flow beneath the two phases of Landfill 2 within the uppermost aquifer is southward toward Newton Lake, but with predominantly eastward flow under Phase I (west phase of Landfill 2) and an east and south component of flow under Phase II (east phase of Landfill 2). Horizontal hydraulic gradients (Table 1) were moderate at 0.016 ft/ft. Calculated groundwater flow velocity based on the January and June 2017 groundwater contour maps was 1.42 ft per day (ft/day).

Seasonal variation of groundwater levels and flow direction at the Primary Ash Pond is indicated in the series of 2015-2017 groundwater elevation contour maps (Appendix D). Groundwater elevations across the GMF Pond ranged from approximately 492 to 508 ft MSL. Groundwater flow across Primary Ash Pond within the uppermost aquifer is consistently in a south to southwest direction toward Newton Lake. Horizontal hydraulic gradients (Table 1) were low at 0.007 ft/ft. Calculated groundwater flow velocity based on the January and June 2017 groundwater contour maps was 0.12 ft/day.

Vertical hydraulic gradients as measured between shallow water table wells and uppermost aquifer monitoring wells was consistently downward at both the Landfill 2 and the Primary Ash Pond (Table 1).

3 GROUNDWATER MONITORING

In August 2015, NRT began an assessment of the existing monitoring well network(s) at the Newton Power Station with respect to the existing CCR units. Included in the assessment was a review of the current placement and number of monitoring wells with respect to individual and contiguous CCR units as well as potential locations for new monitoring wells, as appropriate. The discussion below summarizes the results of this assessment and the supplemental well installations.

3.1 CCR Monitoring Well Network

The 40 CFR Part 257 well network consists of seventeen monitoring wells installed in the uppermost aquifer and adjacent to the Newton Landfill 2 (G06D, G48MG, G201, G202, G203, G208, G217D, G220, G222, G223, G224) and the Newton Primary Ash Pond (APW5, APW6, APW7, APW8, APW9, APW10). The Site utilizes four upgradient (or background) monitoring wells (APW5, APW6, G201, and G48MG) as part of their CCR monitoring well network. The boring logs, well construction forms and other related monitoring well forms are available in the Operating Records as required by Title 40 CFR Part 257 Section 257.91 for each monitored CCR Unit. Sampling of these wells commenced December 2015. The 40 CFR Part 257 groundwater monitoring network well locations are shown on Figure 1. Details on the procedures and techniques used to fulfill the groundwater sampling and analysis program requirements are found in the SAPs for Newton Power Station. The well depths, well screen intervals, depth to groundwater and monitored units at the 40 CFR Part 257 monitoring well network locations are summarized below:

Table 3: CCR Groundwater Monitoring Well Information

Primary Ash Pond Monitoring Well Information (Unit ID: 501)					
Well Number	Well Depth (ft bgs)	Well Screen Interval (ft bgs)	Depth to Water (ft bgs)	Unit Monitored	Screened Interval Lithology
APW5	68	63-68	13.89	Upgradient Shallow Unlithified	Sand
APW6	74	68-73	19.21	Upgradient Shallow Unlithified	Sand
APW7	83	78-83	45.05	Downgradient Shallow Unlithified	Sand
APW8	82	71-81	35.29	Downgradient Shallow Unlithified	Sand
APW9	62	56-61	26.00	Downgradient Shallow Unlithified	Sand
APW10	46	41-46	16.98	Downgradient Shallow Unlithified	Sand

Landfill 2 Monitoring Well Information (Unit ID: 502)					
Well Number	Well Depth (ft bgs)	Well Screen Interval (ft bgs)	Depth to Water (ft bgs)	Unit Monitored	Screened Interval Lithology
G06D	96	74-94	30.12	Downgradient Shallow Unlithified	Clay
G48MG	77	71.5-76.5	18.59	Upgradient Shallow Unlithified	Sand
G201	69	59-69	18.54	Upgradient Shallow Unlithified	Sand
G202	74	64-74	43.21	Downgradient Shallow Unlithified	Clay/Gravel
G203	73	63-73	37.60	Downgradient Shallow Unlithified	Sand/Silt
G208	95	74-94	19.13	Downgradient Shallow Unlithified	Silty Clay
G217D	69.3	* - 69.3	16.14	Downgradient Shallow Unlithified	N/A*
G220	87	76-86	16.59	Downgradient Shallow Unlithified	Silt/Sand
G222	80	64-79	14.09	Downgradient Shallow Unlithified	Silty Clay/Sand
G223	89	79-89	33.64	Downgradient Shallow Unlithified	Silty/ Clay/Silty Sand
G224	74	63-73	41.73	Downgradient Shallow Unlithified	Silty Sand/Sand

Notes:
Groundwater depth measurements were collected June 12, 2017.
NM indicates groundwater depth was not measured.
*boring log not available for review

THERE'S A WAY

Document 37

**Lineback, J., 1979. Quaternary Deposits of Illinois:
Illinois State Geological Survey map, scale 1:500,000**

INSTITUTE OF NATURAL RESOURCES
STATE OF ILLINOIS
ILLINOIS STATE GEOLOGICAL SURVEY
Jack A. Simon, Chief
Urbana, 1979

QUATERNARY DEPOSITS OF ILLINOIS

Compiled by Jerry A. Lineback

From maps prepared in 1975 by Paul B. DuMontelle, Leon R. Follmer, David L. Gross, Alan M. Jacobs, John P. Kempton, Jerry A. Lineback, E. Donald McKay, and Philip C. Reed, with the assistance of Herbert D. Glass, W. Arthur White, and Harold B. Willman.

EXPLANATION

Because many of the areas mapped are small, the conventional symbols for Quaternary units are abbreviated. Q for Quaternary is omitted.

SYSTEM	SERIES	STAGE	SUBSTAGE
QUATERNARY	HOLOCENE	WISCONSINAN and HOLOCENE	WOODFORDIAN, TWOCREEKAN, VALDERAN, and younger
	PLEISTOCENE	WISCONSINAN	WOODFORDIAN, TWOCREEKAN, VALDERAN, and younger
			ALTONIAN, FARMDALIAN, WOODFORDIAN, TWOCREEKAN, and VALDERAN
		ILLINOIAN	LIMAN, MONICAN, and JUBILEEAN
		KANSAN	LIMAN
	PLIOCENE-PLEISTOCENE		
TERTIARY-QUATERNARY			

Surface Mines — sm

Includes coal strip mines; rock quarries; clay, sand, or gravel pits; and other excavated areas, including those where the mixed fill of bedrock or Quaternary deposits was replaced or disturbed. Also includes areas of man-made fill in areas formerly covered by Lake Michigan or Lake Calumet in northeastern Illinois and by causeways in Rend Lake and Carlyle Lake in southern Illinois. Many small areas are not shown.

Cahokia Alluvium — c

Deposits in floodplains and channels of modern rivers and streams; mostly poorly sorted sand, silt, or clay containing local deposits of sandy gravel; in many places overlies well-sorted glacial outwash of the Henry Formation.

Alluvial-fan facies of Cahokia Alluvium — c-f

Fan-shaped deposits of poorly sorted sand and silt at the mouths of tributary streams along the Illinois and Mississippi Rivers.

Lake Michigan Formation — lmr

Lacustrine sediments and beach deposits of modern lakes.

Ravinia Sand Member of Lake Michigan Formation — py

Sand on modern beaches; map shows only areas along major beaches of Lake Michigan such as those near Illinois Beach State Park.

Peyton Colluvium — pl

Narrow deposits of largely unsorted debris that resulted from creep and slopewash and accumulated on and at the base of river bluffs. May include some areas where materials were deposited by slumps or landslides (Lacon Formation).

Parkland Sand — gl

Windblown sand; well-sorted, medium-grained sand in dunes and thick sheet deposits between dunes.

Grayslake Peat

Peat, muck, and marl; dominantly organic deposits that are interbedded with silt and clay in some places. Mostly found in glacial lake basins; locally in lake basins on floodplains of major rivers.

Equality Formation — ec

Lake deposits; offshore deposits of silt and clay; sand facies near shorelines. Deposits in older lakes have a thin to medium cover of silt (Richland Loess or Peoria Loess).

Carmi Member of Equality Formation

Largely quiet-water lake sediments dominated by well-bedded silt and some clay; includes sediment of proglacial lakes and slack-water lakes in valleys tributary to major river valleys. Where thin and discontinuous, generally covers more than 25 percent of the area mapped.

Dolton Member of Equality Formation — ed

Largely shallow-water, nearshore lake sediments in beaches, bars, spits, and deltas; includes some former lakes that contain coarse-grained deposits; dominantly medium-grained sand; some gravel along beaches; contains beds of silt where gradational with the Carmi Member.

Henry Formation

Sand and gravel; generally well sorted; local minor beds of silt; glacial outwash in outwash plains, valley trains, and ice-contact deposits; generally has a thin cover of silt (Richland Loess or Peoria Loess).

Mackinaw Member of Henry Formation — hm

Sand and gravel; generally well sorted and well bedded; deposits in valleys; mostly glacial outwash in former valley trains and terrace remnants of former valley trains.

Batavia Member of Henry Formation — hb

Sand and gravel; well-sorted deposits of glacial meltwater in outwash plains and fans on uplands.

Wasco Member of Henry Formation — hw

Sand and gravel, unevenly sorted, irregularly bedded lenses of silt and till; glacial ice-contact deposits in kames, eskers, and kame terraces.

Peoria Loess and Roxana Silt — pr

Windblown silt more than 20 feet (6 m) thick on uplands; local lenses of fine-grained sand. Combined thickness of Peoria and Roxana (outside the limit of Wisconsinan glaciation) shown by 15-foot (4.5-m), 10-foot (3.0-m), and 5-foot (1.5-m) contour lines. Thicknesses are averages for undisturbed uplands. The thickness of the Peoria Loess on Altonian drift and the thickness of the Richland Loess within the areas of Woodfordian drift are also shown by the contours.

Peyton Colluvium, Peoria Loess, and Roxana Silt — ppr

A complex deposit of silt more than 20 feet (6 m) thick on steep slopes along the bluffs of the Mississippi River in the St. Louis area. A colluvial mixture of Peoria and Roxana formed by creep and slopewash.

Wedron Formation

Mostly glacial till with lenses and beds of sand, gravel, and silt; includes all tills of Woodfordian age in the Lake Michigan and Green Bay Lobes; surface often mantled with silt (Richland Loess).

Ground moraine

Solid colors indicate ground moraine, including areas of generally low relief underlain by tills that lie between the moranic ridges.

Moraine

Overprinted pattern indicates moraines associated with the till members; generally continuous curvilinear areas that have elevated hummocky topography and local deposits of sand, gravel, and peat in addition to till.

Wadsworth Till Member of Wedron Formation · Yorkville Till Member of Wedron Formation · Snider Till Member of Wedron Formation — ww wy ws

Mostly gray clayey and silty clayey till. The Wadsworth contains few pebbles and cobbles and is more clayey near Lake Michigan than till to the south and west. Local lenses of sand and silt. Where the intervening Haeger Till Member is absent, the Wadsworth is separated from the Yorkville, and the boundary is placed at the front of the Valparaiso Moranic System. The Yorkville is a gray or greenish-gray, very clayey till overlain in some places by extensive glacial lake deposits. The Snider is a gray silty clayey till that has a coarse blocky structure.

Haeger Till Member of Wedron Formation — wh

Sandy and gravelly till, commonly thin, over thick deposits of sand and gravel outwash that are included in the member; present only in northeastern Illinois.

Malden Till Member of Wedron Formation · Batestown Till Member of Wedron Formation · Piatt Till Member of Wedron Formation — wm wb wp

Gray silty till that oxidizes to olive brown; some sandy till and lenses of sand and gravel. The Malden is a gray silty till that oxidizes to olive brown; local lenses of sand and gravel. The Batestown is a gray silty till that oxidizes to olive brown; recognized in east-central Illinois only. The Piatt includes sandy and silty gray till.

Continued in next column

Tiskilwa Till Member of Wedron Formation · Ablation drift of Tiskilwa Till Member · Delavan Till Member of Wedron Formation · Fairgrange Till Member of Wedron Formation — wt wd wt-a wf

Pink, pinkish-gray, gray, brown, and reddish-brown silty and sandy till; lenses of silt, sand, and gravel in some places. The Tiskilwa is generally sandy and silty till that is pinkish- or reddish-brown; includes yellow-gray to pinkish-gray sandy ablation drift (Gilberts Drift) in a small area in northeastern Illinois. The Delavan is gray to pinkish-gray sandy to silty till. The Fairgrange is pink, reddish-brown, and brownish-gray sandy till in east-central Illinois.

Lee Center Till Member of Wedron Formation · Esmond Till Member of Wedron Formation — w/c we

Gray silty to clayey till in the Green River Sublobe of the Lake Michigan Lobe in northwestern Illinois; generally thin and discontinuous; includes some lenses of ice-contact drift. The Lee Center is a gray clayey till. The Esmond is a gray till, silty in the upper part and silty clay till in the lower part.

Trafalgar Formation (of Indiana)

Mostly till; some associated sand and gravel. An extension of Erie or Saginaw Lobe drift into Illinois; overlies part of the Yorkville Till Member of the Wedron Formation.

Unnamed till member of Trafalgar Formation (of Indiana) — tr

Mostly yellow-gray sandy and silty till; the Iroquois Drift.

Winnebago Formation

Till with interbedded silt, peat, and gravel; present at surface in northwestern and central northern Illinois; separated from the Wedron Formation by the Robein Silt and Morton Loess. Generally covered by thin to medium layers of silt (Peoria Loess).

Capron Till Member of Winnebago Formation — wic

Pink sandy till in upper part, silty in lower part; mapped in central northern Illinois only.

Argyle Till Member of Winnebago Formation — wia

A very sandy, gravelly, pinkish-tan or salmon till; may include older tills with similar composition; present in central northern Illinois.

Teneriffe Silt — t

Mostly silt and clayey silt with beds of sand or clay deposited in large proglacial lakes associated with several Illinoian glaciers; may contain some outwash, sheetwash, and eolian deposits. Generally has prominent Sangamon Soil at top of deposits and is overlain by a moderate thickness of silt (Peoria Loess and Roxana Silt).

Pearl Formation — pe

Sand, gravel, and some silt in outwash plains and valley-train deposits of Illinoian glaciers; largely preserved as small terrace remnants along major drainageways in central and western Illinois and as extensive remnants along the lower Kaskaskia River Valley in southern Illinois. Generally has prominent Sangamon Soil at top of deposits and is overlain by moderate to thick silt (Peoria Loess and Roxana Silt).

Glasford Formation

Till with interbedded sand and gravel and surficial clay, silt, sand, and gravel deposits. The Glasford is the most widespread glacial formation in Illinois. The Glasford is divided into several members; generally has prominent Sangamon Soil at top of deposits and is overlain by moderate to great thickness of silt (Peoria Loess and Roxana Silt).

Ground moraine

Solid colors indicate Illinoian ground moraine.

Moraine

Small moraines of the Illinoian present in some places are indicated by the overprint pattern. The moraines consist of subdued, rounded ridges of till and some outwash sands and gravels.

Hagarstown Member of Glasford Formation — gha

Mostly well-sorted and well-bedded sand and gravel, cemented in some places; till in places; in kames, eskers, and crevasse fillings; kames may contain large thrust blocks of older till or bedrock. Includes the Vandalia Till Member, but overlay deposits overlying older and younger tills are mapped as the Hagarstown Member also; includes the "ridged drift" of the Kaskaskia Basin, elongate sand-and-gravel-cored ridges in south-central Illinois.

Radnor Till Member of Glasford Formation · Sterling Till Member of Glasford Formation — gr gs

Mostly gray compact silty till with a little gravel, sand, and silt in some places.

Winslow Till Member of Glasford Formation · Ogle Till Member of Glasford Formation · Vandalia Till Member of Glasford Formation · Hulick Till Member of Glasford Formation — gw gv go gh

Compact, hard, silty, sandy, and clayey till and intercalated sand and gravel. The Winslow is dark-gray clayey till in northwestern Illinois, related to the Ogle, but more clayey; thin with many small outcrops of underlying bedrock included. The Ogle is thin and discontinuous, tan to grayish-brown, sandy till; many small outcrops of underlying bedrock or areas of bedrock controlled. The Hulick and Vandalia are related to the Hulick. The Hulick and Vandalia are hard, compact sandy till with sand and gravel; mapped as Hulick west of the Illinois River and Vandalia east of the Illinois River; gradational to silty till in southern Illinois.

Kellerville Till Member of Glasford Formation — gk

Brown and gray silty till with discontinuous sand and gravel beds; mineralogically intermediate between western Banner Formation tills and the Vandalia-Hulick; may include some older tills of similar composition in extreme western Illinois; mapped only west of the Illinois River; small areas of stratigraphically equivalent Smithboro Till Member in southern Illinois may be included in the Vandalia.

Banner Formation · Banner Formation outwash facies — b b-o

Mostly till, but includes small areas of outwash sands and gravels and lacustrine silt and clay. Sand and gravel facies (b-o) in terrace remnants along tributaries to the Mississippi. Mapped where not overlain by Illinoian deposits in western Illinois and in other scattered locations where it crops out from under Illinoian drift; generally has Yarmouth Soil or combined Yarmouth and Sangamon Soil at the top of deposit and is overlain by thick deposits of silt (Peoria Loess and Roxana Silt). As mapped, Banner Formation may actually include deposits of several pre-Illinoian glaciations.

Mounds Gravel — mg

Mostly gravel on uplands; brown chert pebbles; high remnants of former terrace levels believed to be of Pliocene-Pleistocene age; does not contain materials characteristic of glacial deposits; mapped only in extreme southern Illinois. Similar gravel, the Grover Gravel, is present in areas too small to map in western Illinois (Calhoun County); generally overlain by moderate to thick silt (Peoria Loess and Roxana Silt).

White areas on map indicate that rocks older than Pliocene are present at or near the surface; for bedrock units, see inset bedrock map or refer to Willman and others (1967), *Geologic Map of Illinois* (1:500,000).

5 — Thickness of loess; contour interval, 5 feet (1.5 m)

Inferred limit of glaciation

ACKNOWLEDGMENTS

We thank the following people for their assistance throughout this project.

Jeffrey S. Brown, Robert Colvin, and Thomas Capps, Velsicol Chemical Corporation, for allowing us access to their site and assistance in the completion of the field tests conducted on-site.

Frank Brookfield and Lance Perry, Hazardous Waste Research and Information Center (HWRIC), for their tireless assistance with the PRIME computer—from debugging and compiling code to not complaining when we monopolized the computer time.

Richard A. Cahill, Beverly Seyler, Robert R. Frost, Herbert Glass, and William R. Roy, Illinois State Geological Survey (ISGS), for performing various chemical and physical analyses on samples of the core, waste stream, and native formation brine. These analyses included thermodynamic modeling, x-ray fluorescence, microprobe, scanning electron microscopy, and x-ray diffraction.

Lynn R. Evans, ISGS, for compiling the data regarding the chemical and physical characteristics of the UIC wastes.

David Morganwalp, project manager for the U.S. Environmental Protection Agency, for his assistance and patience during this project.

Jackie Peden, HWRIC project manager, and Gary D. Miller, former project manager, for their assistance and patience during this project.

Adrian Visocky, Illinois State Water Survey, for his advice regarding the analysis of the data from the injection test.

Anne M. Graese, Bruce R. Hensel, Timothy H. Larson, Janis D. Treworgy, and Steven T. Whitaker, ISGS, for their insightful review of this report.

ABSTRACT

A numerical modeling study was conducted to investigate the hydraulic effects of liquid waste injection on an injection system. The site investigated was a chemical refinery with an operational Class I well and an observation well, both completed in Devonian limestone. Input data for the model were obtained from available records and field investigations.

The regional geologic investigation indicated that the injection system (defined here as the injection zone and its associated confining units) was laterally continuous. The hydraulic response of the injection system was numerically modeled under two injection scenarios: average historical injection rate and maximum average permitted rate. For both scenarios, pressure buildup from waste injection during the simulated 30-year injection and 30-year postinjection periods did not approach the pressure calculated to be necessary to initiate or propagate fractures in the injection system. Therefore, injected waste would be contained, and waste injection at this site and for the scenarios modeled would not endanger human health or the environment.

This analysis assumes that hydraulic conductivity remains constant; however, the formation of brucite within the injection zone may invalidate this assumption and the preceding analysis. Brucite formation within the injection zone requires additional study.

The model was also used to investigate the response of the injection system when a hypothetical conduit was introduced. This hypothetical conduit connected the uppermost injection zone with an overlying aquifer. Differences in head buildup were not monitorable in the injection well or in an observation well completed in the injection zone. Monitorable head differences were observed only in the overlying aquifer, when the hydraulic conductivity of the hypothetical conduit was greater than or equal to 1×10^{-10} m^2.

EXECUTIVE SUMMARY

Concern over the potential for groundwater contamination from waste injection prompted a multi-faceted research effort funded by the U.S. Environmental Protection Agency (USEPA) and industry. The research will provide the USEPA with data needed to determine if underground injection of hazardous waste endangers human health or the environment. One facet of this research effort was an investigation of the hydraulic effects of deep-well injection on the injection system.

The injection system includes the geologic units constituting the injection zone and the upper and lower confining units. The site of this investigation was a chemical refinery in Illinois that has an operational injection well and an observation well completed in Devonian limestone.

Data Collection and Analysis

Before numerical modeling could be conducted, a hydrogeologic description of the site was developed from available records and geophysical logs. Numerous records and logs were available from oil- and gas-related tests and wells within a 10-mile radius of the site. Logs and records for on-site wells were also used.

In addition, hydraulic tests and geophysical logs were run to obtain detailed hydrogeologic data on the injection system. Two hydraulic tests were run in the injection well: a continuous spinner flowmeter survey and a 15-day injection test. Sidewall cores were also retrieved from the injection well. The following geophysical logs were run in the observation well: Compensated Neutron Log, Borehole Compensated Sonic Log, Minilog, Dual Induction Spherically Focused Log, and Gamma Ray Log.

Although analyses of the data from these logs and tests yielded much information concerning the hydrogeologic character of the injection system, there was one discrepancy—the results of the spinner flowmeter indicated that the waste was flowing through different zones of the injection system than had been theorized from the results of geophysical logging. To clarify this discrepancy, we conducted additional analyses (x-ray diffraction and scanning electron microscopy). The discrepancy can be explained briefly as follows. Because of its high pH, the injected wastewater reacts with the Mg^{2+} present in the injection zones or in solution, forming brucite ($Mg[OH]_2$). Brucite accumulation reduces the permeability of the injection zone. Greater amounts of brucite apparently formed in the injection zones where the flow of fluid was greater; thus the zones with higher permeability were affected first. Additional work beyond the scope of this project is needed to verify the brucite-formation hypothesis. Also, the long-term effect of this decrease in permeability on injectivity needs to be investigated.

Numerical Modeling

Site Analysis

A description of the regional and site-specific stratigraphy, structural geology, and hydrogeology of the injection system was generated from a review of available data and the field work conducted during this project. This description formed the basis of input for the numerical model. Model input also included data on the physical and chemical characteristics of the injected wastewater and the native brine in the injection system.

These data were employed as input data for a three-dimensional groundwater flow model (HST3D). Before the effects of various injection scenarios were evaluated, HST3D was verified with respect to two analytical solutions and calibrated by the use of data collected during a 2-week injection test. Both verification and calibration were considered satisfactory.

Once calibrated, the model was used to predict the effects of various injection scenarios. The effect of long-term injection was investigated at two constant injection rates—the average historical rate (1.15×10^{-2} m^3/sec) and the maximum average rate permitted under Class I regulations (2.21×10^{-2} m^3/sec). With both scenarios, significant head buildup was observed at the injection well and radially from it. During the simulated 30-year injection period, steady state was approached but not obtained for both injection scenarios. During the subsequent 30-year postinjection period, dropoff in head buildup was fairly rapid, falling to half in less than 2,000 hours for both scenarios. The maximum hydraulic pressures at the bottom of the well and at the base of the upper confining unit were significantly lower than the pressures calculated to initiate hydraulic fracturing. A fracture gradient of 1.5×10^4 Pa/m (Pascals/meter) (0.65 psi/ft) was used to calculate the hydraulic fracture pressures.

The regional and site-specific geological analysis revealed the continuity of the stratigraphy and qualitative permeability on a regional basis. The numerical modeling indicated that injection pressures were lower than calculated pressures required to initiate hydraulic fracturing. Therefore, from a hydraulic viewpoint, waste injected into this injection system would be contained, and waste injection at this site and for the scenarios modeled would be considered protective of human health and the environment.

These results were based on an assumption that the permeability remains constant. If the hypothesis concerning the formation of brucite is correct, its formation may reduce the permeability of the injection zones and invalidate this analysis. Any reduction in permeability of the injection zones will probably increase the hydraulic pressure resulting from waste injection if the injection rate remains constant. In such a situation, hydraulic fracturing may be of concern. Because of the potential ramifications, formation of brucite within the injection zone requires additional geochemical analysis.

Effects of Hypothetical Conduit

The model was also used to investigate the hydraulic response of the injection system to the introduction of a hypothetical conduit. The conduit, a microannulus (0.01 m wide) at the injection well, hydraulically connects the uppermost injection zone and an aquifer immediately overlying the upper confining unit. To determine the impact of the microannulus, the head buildup with the microannulus present was compared with the buildup from runs with the microannulus not present. Differences in head buildup at selected positions and for certain times were computed. Differences in the head buildup were considered unmonitorable at the injection well and the observation well. The difference in head buildup in the overlying aquifer was monitorable only when the microannulus had a hydraulic conductivity greater than or equal to 1.00×10^{-10} m^2. The head buildup in the overlying aquifer is a function of its hydraulic conductivity, the hydraulic conductivity of the microannulus, and the radial distance from the microannulus. Thus for the scenario modeled, leakage via a microannulus could not be hydraulically monitored by use of the injection well or an observation well completed within the injection zone. This leakage was monitorable only through the use of an observation well in the overlying aquifer.

1. INTRODUCTION

Background

Liquid waste is disposed of through underground injection by pumping the waste into or allowing it to flow through a specially designed and monitored well. Developed by the petroleum industry in the 1930s as a method for brine disposal, the technique was adapted by other industries in the 1950s for the disposal of industrial waste streams. As regulations for the disposal of waste into landfills and surface waters became more stringent, the volume of waste disposed of by underground injection increased.

Regulatory agencies have classified injection wells according to the purpose of the wells and the proximity of injection reservoirs to the lowermost underground source of drinking water (USDW). The five classes of injection wells are:

Class I — wells used to inject hazardous and nonhazardous wastes below the lowermost USDW (this report is concerned with this class of wells).

Class II — wells associated with the production and storage of oil and gas below the lowermost USDW.

Class III — wells used in special process (mining) operations to inject fluid above, into, or below an USDW.

Class IV — wells used to inject hazardous waste into or above an USDW (this class of wells is currently banned).

Class V — wells used to inject all other wastes into or above an USDW.

According to the U.S. Environmental Protection Agency (USEPA), there were 429 Class I injection wells active in 1986 (USEPA 1986). Although the volume of waste disposed of nationwide via these wells is difficult to estimate, accurate figures are available from some states. In Illinois, nine Class I wells were used in 1984 to dispose of 310 million gallons of waste (Brower et al. 1989).

With the promulgation of the Hazardous and Solid Waste Amendments of 1984, the level of interest in underground injection increased tremendously. Provisions of the act mandated that the administrator of USEPA determine if underground injection is a threat to human health and the environment for the period the waste remains hazardous. If underground injection is found to be hazardous to human health and the environment, or if the determination is not made by the Congressionally mandated date, all underground injection will be banned. Some environmental groups want situations detailed in which underground injection has endangered or may endanger human health or the environment.

The USEPA developed an extensive research agenda to examine pertinent issues. The USEPA has funded to date one or more projects in each of the following areas: identification and classification of Class I well failures; techniques to detect abandoned wells; monitoring of various aspects of the well; flow and transport modeling of various injection scenarios; geochemical modeling of injected waste, injection formation, and brine; and hydrogeologic characterization of important injection formations and associated confining formations. Industry also has conducted research into pertinent topics of underground injection.

In this project, a numerical model was used to investigate the hydraulic effects of waste injection on the geologic reservoir. The site of the investigation is a chemical refinery located near Marshall, Illinois, in north-central Clark County (fig. 1). The chemical company used the injection well

to dispose of alkaline (pH>12) waste. An observation well, which is completed in the same formation as the injection well, is located 506 meters north of the injection well.

Purpose

The primary purpose of this project was to investigate the pressure response (flow modeling) of an actual injection formation and its associated confining formations due to waste injection via a Class I well. Modeling of solute transport was not investigated here but was addressed by other researchers sponsored by USEPA and industry. Flow modeling requires detailed characterization of the site hydrogeology, so this project bridged two areas of concern—flow modeling and hydrogeologic characterization. In addition, the effectiveness of pressure-monitoring systems to detect movement of fluid beyond the injection formation was evaluated.

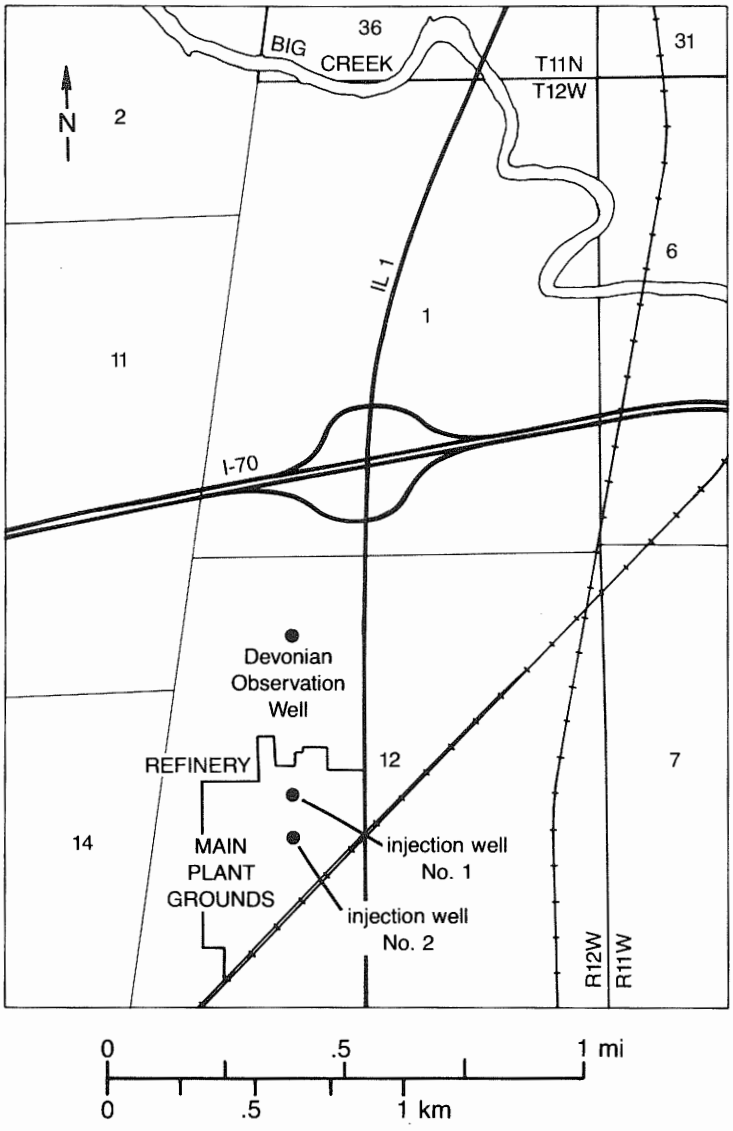

Figure 1 Location of investigation site.

2. GEOLOGY OF THE INJECTION SYSTEM

The geologic environment of an injection well site controls many aspects of the disposal operation and the fate of the injected wastes. This section includes a summary of the regional geology and hydrogeology of the units involved with the deep-well injection operation. The geologic setting is described within the context of the regional geology to show regional trends and the degree of uniformity in geologic conditions.

Only those aspects of geology pertinent to underground injection are described. The major emphasis is on the hydrogeology of the confining units and the injection interval, specifically, the hydrogeology of the upper confining unit (New Albany Group), the lower confining unit (Maquoketa Group), and the injection interval (Hunton Supergroup). The Borden Siltstone, which overlies the New Albany Group, acts as an additional confining zone.

Overview of Geologic Conditions Affecting Waste Injection

The principal geologic factors for the regional evaluation are those affecting (1) the capacity of geologic units in the injection system to accept and confine injected waste, (2) the chemical interaction of the waste with injection system components, (3) the generation of dislocations that developed during the forming of structural features or seismic events, and (4) the use of subsurface space and commercial grade resources in the area of disposal influence.

In this section we have focused on the broader regional issues that relate to local geologic conditions. Broadly defined lithologic units form a key component of the regional discussion. These units have been described in the literature, and the uniformity of their general geologic conditions and structural trends have been established by oil, gas, water, and mineral resource exploration activities in the region.

The character and trends of the regional geology have been determined from data gathered from key well records, reports, and publications. This information reveals the distribution of aquifers that meet regulatory requirements for Class I injection, i.e., aquifers that contain saline water (>10,000 mg/L total dissolved solids [TDS]) and that have confining intervals capable of protecting all USDW from contamination by injection activities. Injection is limited to selected aquifers in the southern two-thirds of Illinois, including the Hunton Supergroup and the Salem Limestone, which have been used for disposal at the study site. Injection system response to waste injection is primarily controlled by porosity and permeability characteristics, which can be directly related regionally to specific geologic units.

Porosity and permeability develop during sedimentation processes and are modified by other geologic processes. Thus porosity and permeability have a general relationship with specific lithologies. Each geologic unit in the region exhibits a range of values and areal trends. The sedimentary geologic units in east-central Illinois exhibit relatively uniform characteristics over large areas; however, both vertical and radial trends are noted within each unit. Similar patterns can also be expected within the subdivisions of each unit, but determining this would require a detailed study of subsurface records.

The lithology of the geologic units forming the injection system plays an important role in the chemical interaction between the injected waste and injection system. Chemical interaction between injected waste and the injection system can affect flow conditions (porosity and permeability) and under certain disposal conditions can compromise the integrity of the confining intervals. However, beneficial interactions may also occur that would improve flow conditions, involve retention of some waste components near the well, and provide treatment for selected, undesirable components in the waste.

This discussion focuses on the general regional characteristics of principal geologic units and relates these characteristics to hydrogeologic parameters for characterizing flow in the injection system. An effective evaluation by numerical modeling requires that the hydrogeologic character of the geologic units accepting and retaining injected waste be predictable and relatively uniform throughout the area influenced by injection. A more detailed description of the character and radial uniformity of the units in the injection system is presented in chapter 3.

General Geologic Setting

The geologic framework of Illinois in which deep-well disposal is practiced can be described as a sequence of areally extensive sedimentary rock units deposited in a large midcontinent basin known as the Illinois Basin. The study site, in the east-central part of the basin, is immediately east of the axis of the Marshall-Sidell Syncline and about 14 miles east of the La Salle Anticlinal Belt, the most dominant structural feature in the area. Figure 2 shows the generalized geology of the bedrock surface in Illinois. Generalized geologic cross sections of Illinois are depicted in figure 3. Figure 4 provides a generalized geologic column and comments on the stratigraphy, lithology, hydrogeology, and groundwater geochemistry of the geologic units associated with or protected from waste injection. Additional details on geologic units covered in this report are available in the *Handbook for Illinois Stratigraphy* (Willman et al. 1975), the *Bibliography of Illinois Geology* (Willman et al. 1968) and reports prepared by Brower et al. (1989), Cluff et al. (1981), Gray et al. (1979), and Piskin and Bergstrom (1975).

In Illinois, lithologies range from very fine- to coarse-grained clastics, a variety of carbonates, and a few evaporites and organics. Relatively uniform lithologic characteristics exist on a regional basis within individual units as a whole and within the subdivisions of each unit.

Many processes have been involved in forming, altering, and structurally readjusting these units from the time of deposition to the present day. Sedimentary deposition began early in the Paleozoic Era on the eroded surface of igneous and metamorphic rock of the Precambrian basement complex. Deposition and some erosion continued throughout the Paleozoic. Several episodes of deposition in the Mesozoic and Cenozoic Eras produced nonlithified sedimentary units. The present-day landscape has developed principally on these nonlithified sediments. Marine carbonate and clastic lithologies are dominant in the Paleozoic units, but terrestrial clastics and some organic deposits are present in the upper part of the Paleozoic (Mississippian and Pennsylvanian Systems).

The thickness of the sedimentary sequence in Illinois ranges from approximately 2,000 feet northwest of Rockford to more than 20,000 feet in the southeastern corner of the state, the deepest part of the Illinois Basin (Sargent and Buschbach 1985). In the project area, the total thickness of the sedimentary units is approximately 8,500 feet. Lithologies include dolomite, limestone, sandstone, siltstone, shale, and some coal and evaporite. The stratigraphic column in figure 4 provides a summary of the typical sedimentary sequence in the Illinois Basin. Widespread carbonate lithologies are dominant in the lower part of the Paleozoic, and a few sandstones and some shales are interbedded with these carbonates. Most of the carbonates become sandy to the north, and a few grade into sandstones in the far northern part of the state. Greater variations in regional lithology exist in the upper part of the Devonian through the middle part of the Mississippian. Cyclic deposits of fine-grained clastics (shales and siltstones), some carbonates, and some coarse-grained clastics (sandstones) accumulated in the upper part of the Mississippian and in all of the Pennsylvanian as numerous sea-level oscillations shifted shorelines across shallow-marine and flat-lowland terrestrial environments.

The study site is in the Marshall-Sidell Syncline (see fig. 5), a broad structural feature of low relief between the La Salle Anticlinal Belt, about 14 miles to the west, and the Kankakee Arch more than 90 miles to the northeast. These two structures are reflected in the distribution of the boundaries of the geologic units exposed at the bedrock surface (fig. 2). The regional dip of the units in the study area is to the southwest from the Kankakee Arch and into the Illinois Basin, but

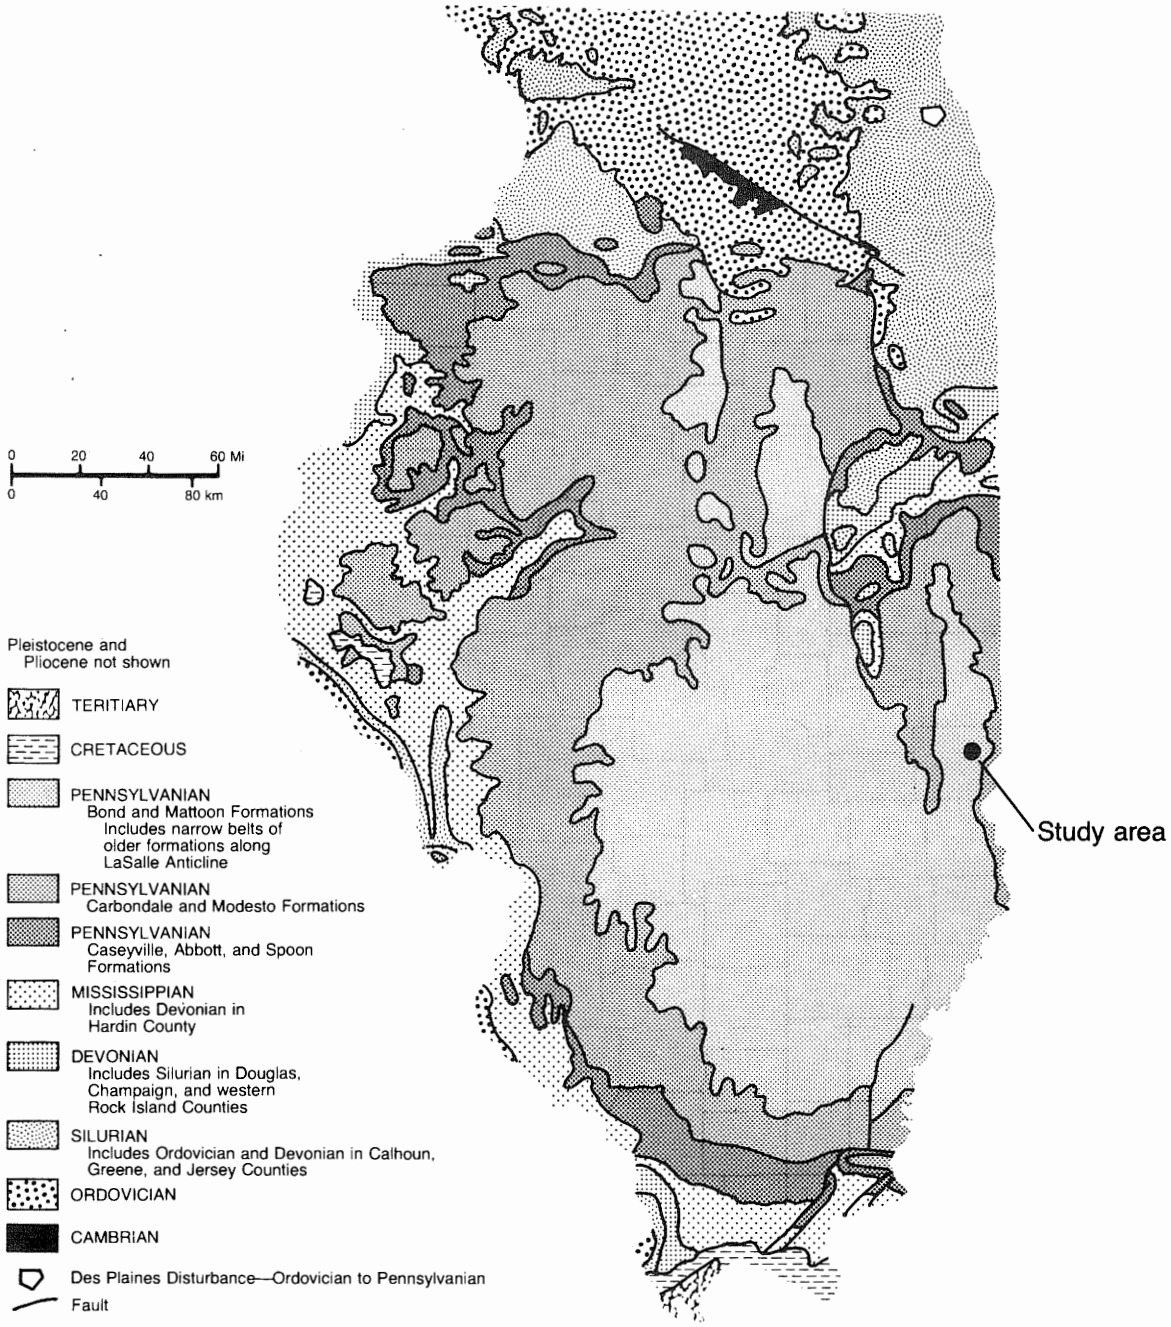

Figure 2 Generalized areal geology of the bedrock surface (from Willman and Frye 1970).

boundaries of the geologic units exposed at the bedrock surface (fig. 2). The regional dip of the units in the study area is to the southwest from the Kankakee Arch and into the Illinois Basin, but locally the units dip gently in a south-to-southwesterly direction toward the axial trend of the Marshall-Sidell Syncline.

Waste Injection Potential in Illinois

Some sequences of Paleozoic units possess sufficient porosity, permeability, and confinement to accept and retain wastes injected at moderate to high injection rates. Criteria for acceptable injec-

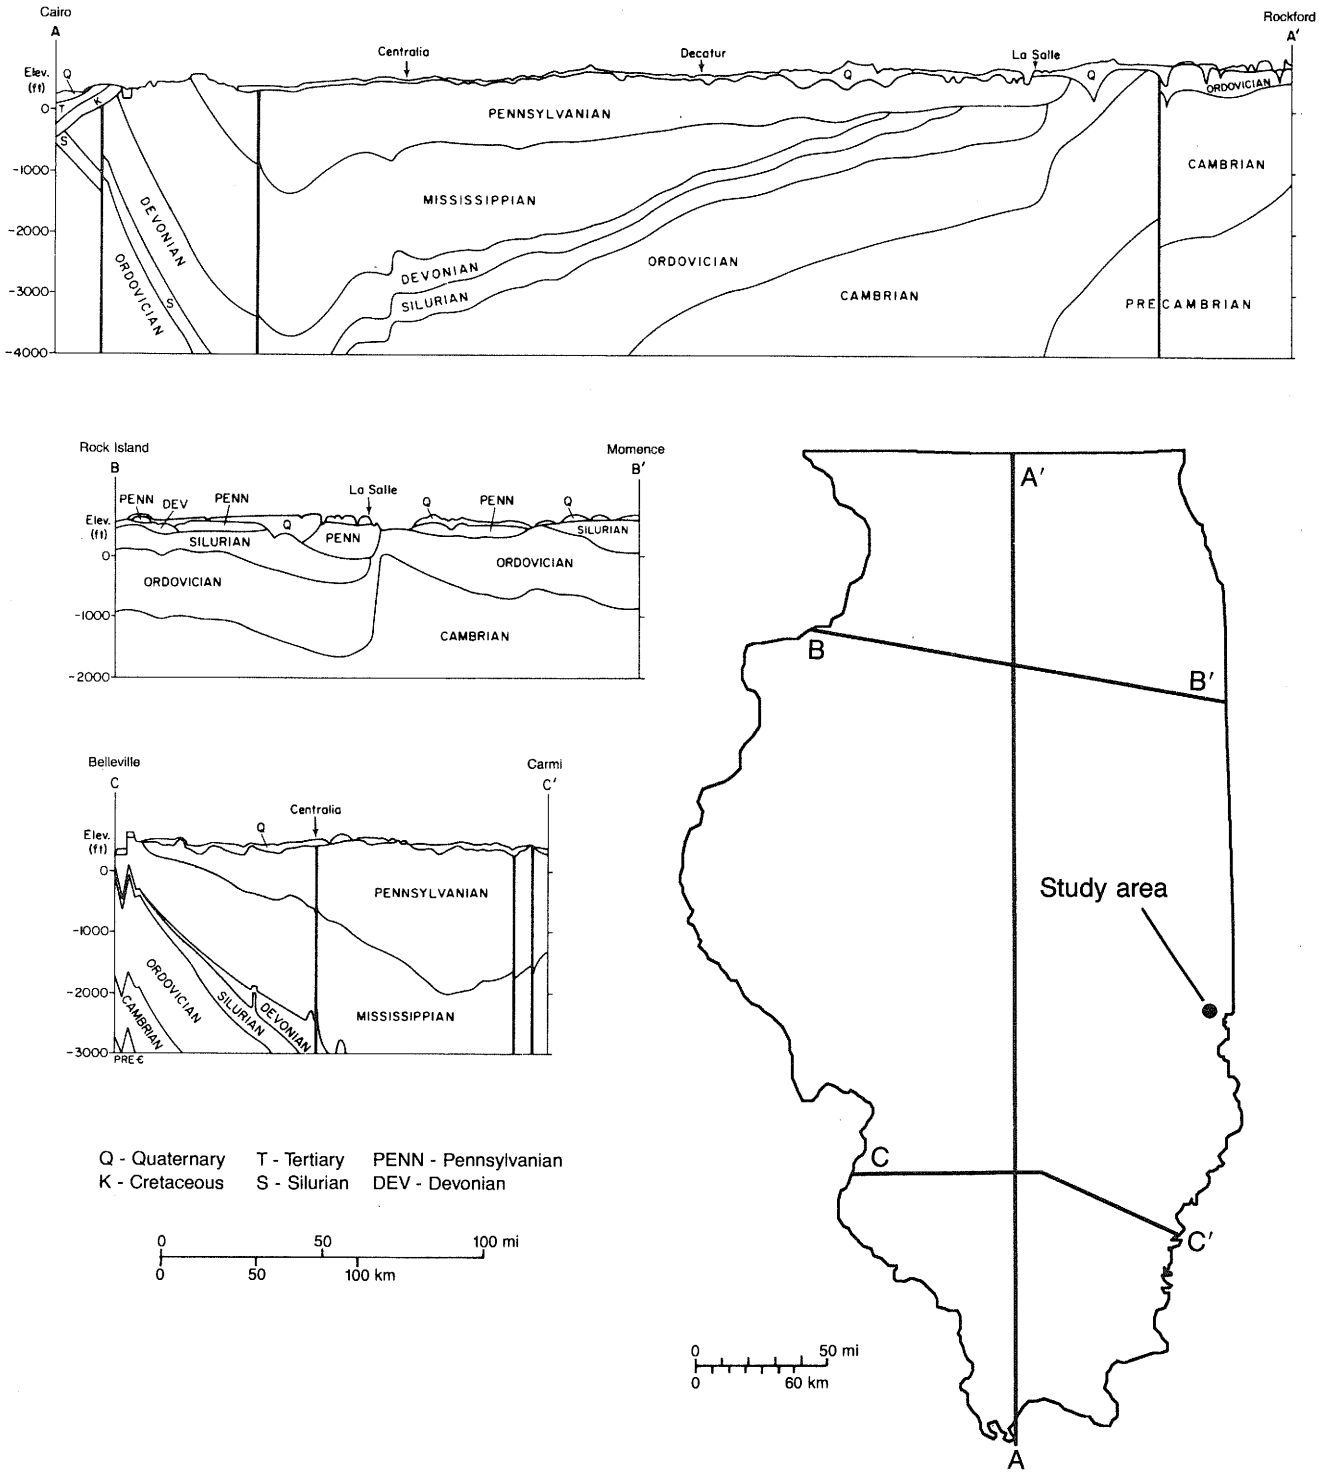

Figure 3 Generalized statewide cross sections of Illinois (from Willman et al. 1975).

Protection Act (Title 35, Illinois Administrative Code). Within Illinois, the base of the USDW ranges in depth from 500 to slightly more than 3,000 feet. All units below the lowermost USDW contain groundwater with a TDS content exceeding 10,000 mg/L (milligrams/liter). Injection is feasible only in portions of Cambrian through basal Pennsylvanian units that meet the criteria for waste injection established in the Illinois Environmental Protection Act.

In the study area, the base of the USDW has been established at a depth of about 500 feet (Piskin 1986). In the immediate vicinity of the study site, significant injection potential for the Salem and Hunton carbonate units has been proved by oil exploration and waste-injection testing conducted to a depth of 6,000 feet. Recently, injection has been limited to the Devonian portion of the Hunton. Very limited groundwater supplies have been obtained from the uppermost part of the Pennsylvanian bedrock. The City of Marshall obtains a moderate to large water supply from a shallow sand and gravel aquifer in the nearby valley of Big Creek.

Seismic Activity in Illinois

Earthquake waves traveling through earth materials can affect deep-well disposal systems. Earthquakes are infrequent in Illinois, and most have been low to moderate in magnitude and intensity (fig. 7). Several earthquakes of low-to-moderate magnitude recently occurred in the vicinity of the Wabash Valley Fault System, which extends northward into Edwards and Wabash Counties from southeastern Illinois (fig. 5). The largest earthquakes affecting Illinois in recorded history occurred near New Madrid, Missouri, in 1811 and 1812 (Heigold 1968, 1972). Although faulting is reported in other areas of Illinois, field studies and drilling records available to the Illinois State Geological Survey indicate that no faults are mapped at the surface or known to have occurred in the subsurface in the vicinity of the study area.

The greatest likelihood for major damage from earthquakes exists in 14 southern Illinois counties (figs. 6 and 7). This region of the state is in Area 3 on the Seismic Risk Map (fig. 6) compiled by Algermissen (1969). The project site is near the southern margin of Area 1, the area in which the damage expectancy from potential earthquakes is rated as minor.

Subsurface Resources

Subsurface resources in Illinois exclusive of groundwater resources include mineral deposits, hydrocarbon deposits, and subsurface storage space. Many of the geologic units containing subsurface resources also qualify as potential disposal horizons. The regulations for deep-well disposal require a review of all subsurface resources of commercial value in order to reduce the potential for conflicts between injection and resource extraction.

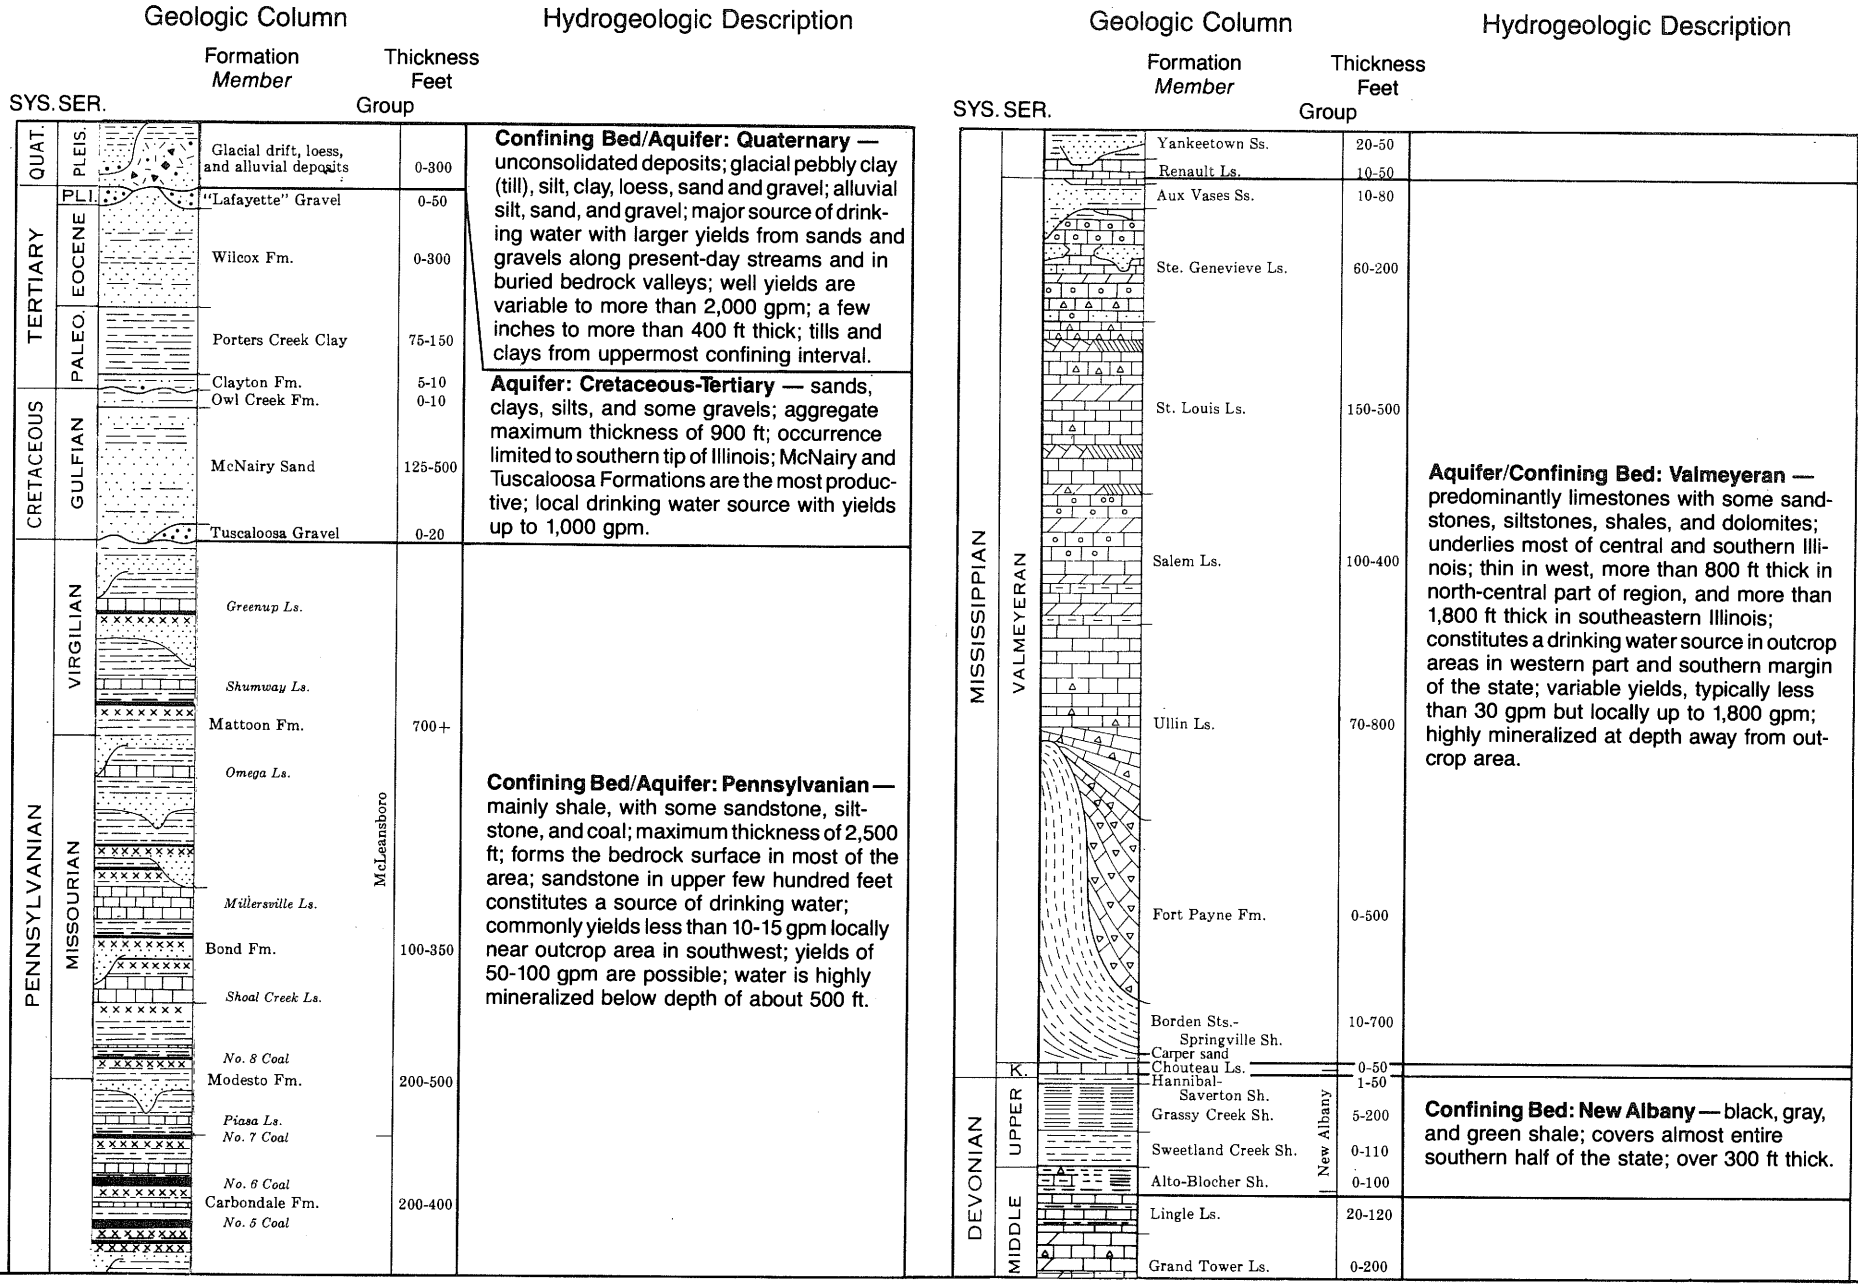
Oil and limited natural gas resources have been exploited in numerous permeable units above the St. Peter Sandstone. Oil production is mainly associated with Mississippian units; however, significant production has come from other Paleozoic units. The petroleum-producing regions in Illinois are confined to the Illinois Basin (fig. 8). Wells drilled for production provide valuable information about subsurface conditions; however, if not properly sealed, these wells can be potential avenues for fluid movement into overlying geologic units.

Oil has been produced in the Weaver Field about 9 miles to the east-southeast of the study area and in several small fields on the La Salle Anticlinal Belt, more than 14 miles to the west. Exploratory wells have been drilled throughout the vicinity of the study site; a few of these wells are within the 2.5-mile area of review of the disposal well. No commercial oil pools have been reported in the Marshall-Sidell Syncline in the vicinity of the study site.

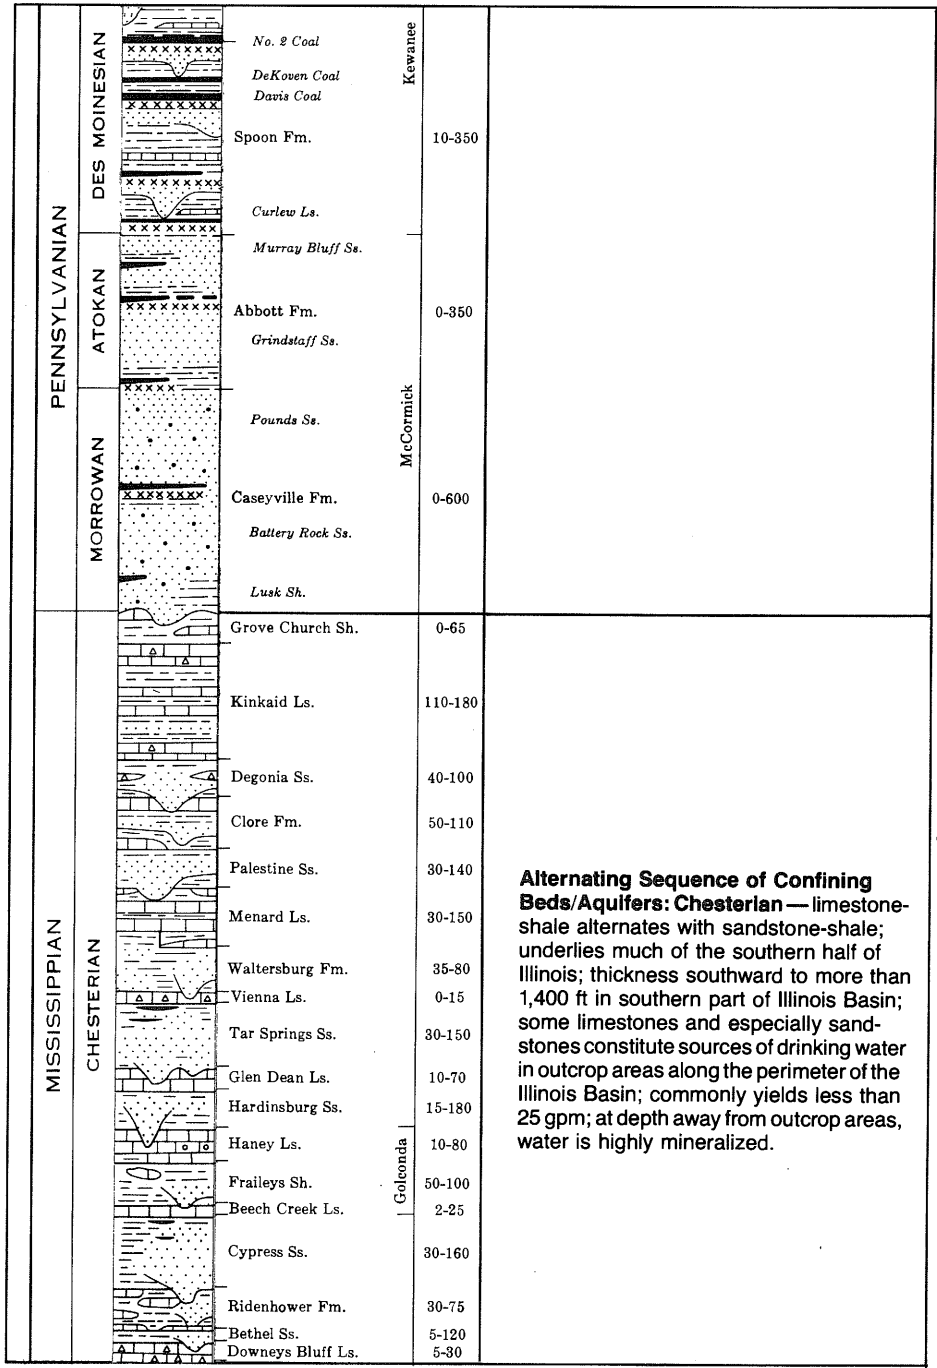
Coal deposits are more widespread than petroleum deposits in the Pennsylvanian units, and multiple coal deposits are often found where Pennsylvanian units are present. Although more than 50 potential coal horizons have been found in Illinois, only a few are thick enough for commercial development. The coals in the project area tend to be relatively thin and deeply buried. Most coal deposits mined in Illinois are shallow (less than 500 ft) and lie within units designated as USDW.

Rock Units and Their Hydrogeologic Roles

Southern Illinois



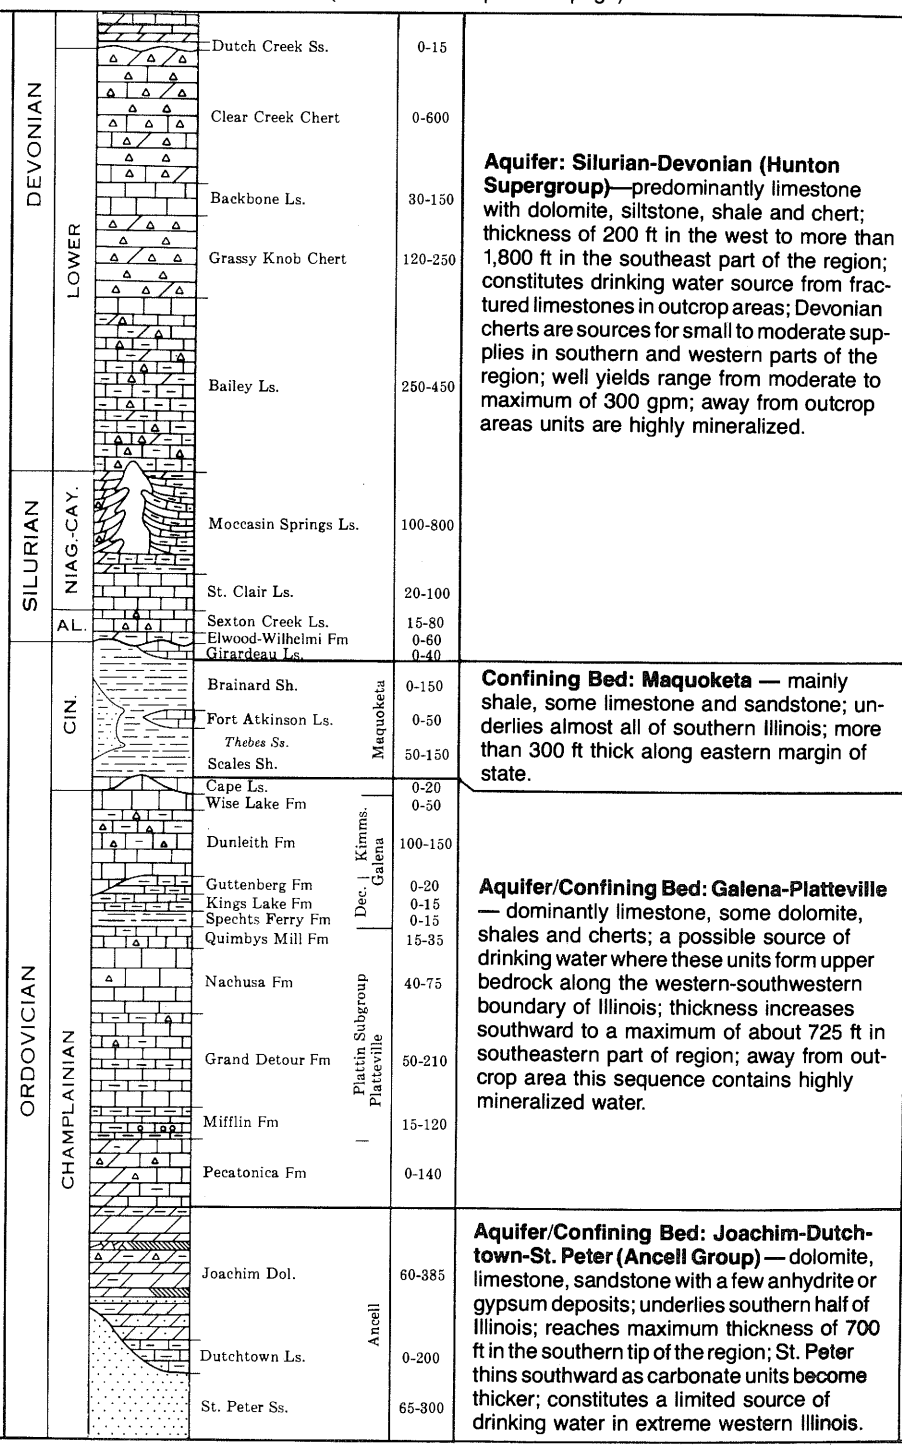
(continued from previous page)



Alternating Sequence of Confining Beds/Aquifers: Chesterian — limestone-shale alternates with sandstone-shale; underlies much of the southern half of Illinois; thickness southward to more than 1,400 ft in southern part of Illinois Basin; some limestones and especially sandstones constitute sources of drinking water in outcrop areas along the perimeter of the Illinois Basin; commonly yields less than 25 gpm; at depth away from outcrop areas, water is highly mineralized.

(continued in right column of previous page)

(continued from previous page)



Aquifer: Silurian-Devonian (Hunton Supergroup)—predominantly limestone with dolomite, siltstone, shale and chert; thickness of 200 ft in the west to more than 1,800 ft in the southeast part of the region; constitutes drinking water source from fractured limestones in outcrop areas; Devonian cherts are sources for small to moderate supplies in southern and western parts of the region; well yields range from moderate to maximum of 300 gpm; away from outcrop areas units are highly mineralized.

Confining Bed: Maquoketa — mainly shale, some limestone and sandstone; underlies almost all of southern Illinois; more than 300 ft thick along eastern margin of state.

Aquifer/Confining Bed: Galena-Platteville — dominantly limestone, some dolomite, shales and cherts; a possible source of drinking water where these units form upper bedrock along the western-southwestern boundary of Illinois; thickness increases southward to a maximum of about 725 ft in southeastern part of region; away from outcrop area this sequence contains highly mineralized water.

Aquifer/Confining Bed: Joachim-Dutchtown-St. Peter (Ancell Group) — dolomite, limestone, sandstone with a few anhydrite or gypsum deposits; underlies southern half of Illinois; reaches maximum thickness of 700 ft in the southern tip of the region; St. Peter thins southward as carbonate units become thicker; constitutes a limited source of drinking water in extreme western Illinois.

Figure 4 Description of rock units and their hydrogeologic roles (Brower et al 1989).

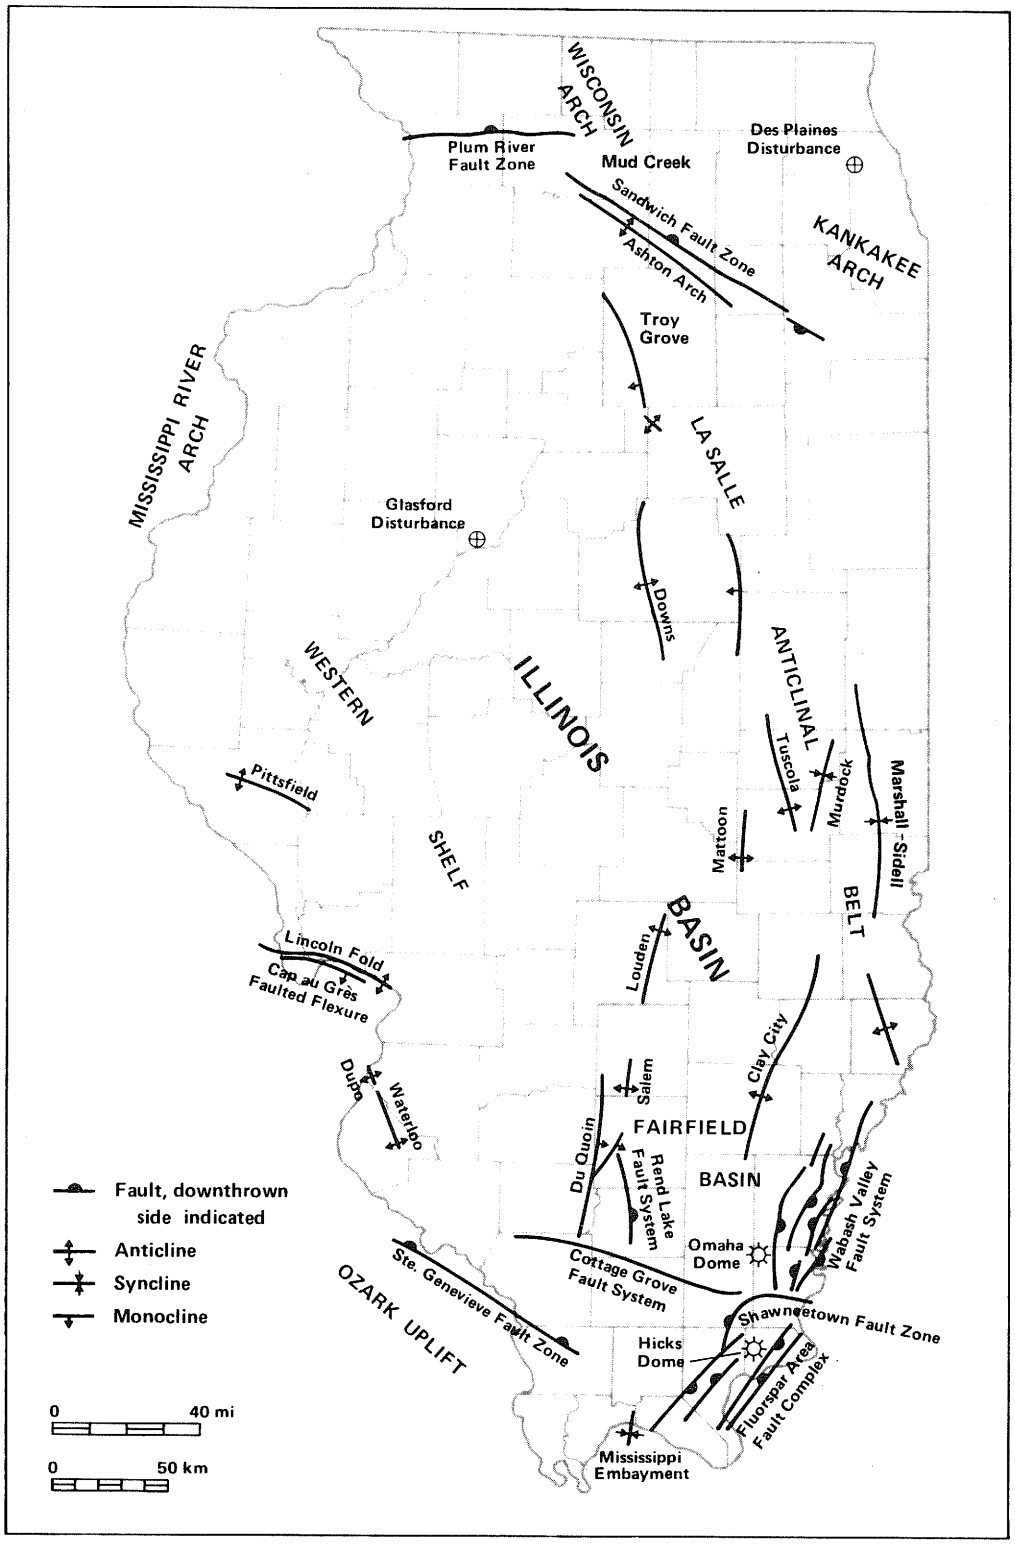


Figure 5 Geologic structures in Illinois (compiled by J. Treworgy 1979).

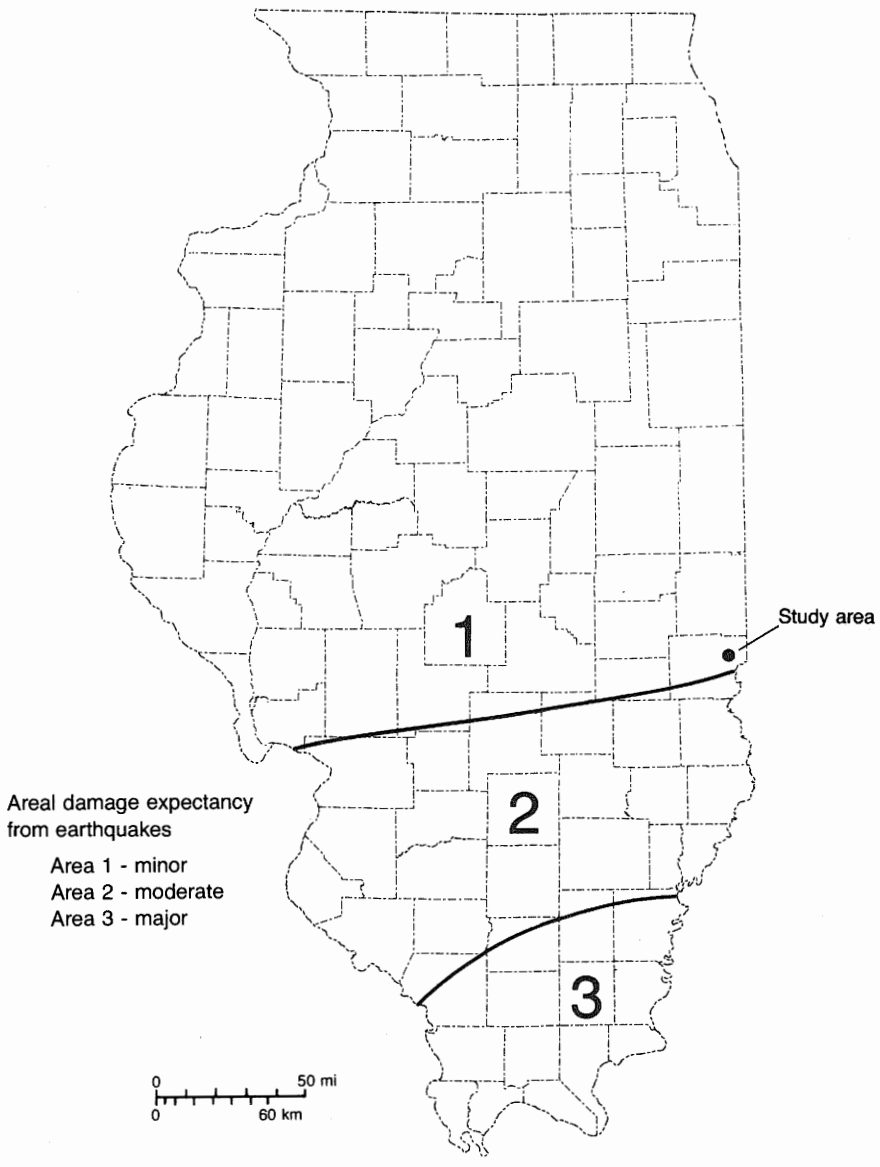

Figure 6 Seismic risk map for Illinois (after Algermissen 1969).

Other mineral resources, including building stone, agricultural lime, clay, sand, sand and gravel, metals, fluorite, barite, and tripoli, have been mined commercially throughout Illinois (Samson 1983, 1989). Most of the mining operations are at or near the land surface. Only limited surface mining (for aggregate and stone) has been done near the study area, and apparently neither the mining nor the injection operations have affected each other.

Natural gas storage fields in aquifers having localized structural closure features are scattered throughout the state. Three storage fields are located about 10 miles north and northeast of the study site (fig. 9). Aquifers of sandstone and limestone strata of Cambrian through Pennsylvanian age have been used for storage. Drilling and testing records from the Nevins, State Line, and Elbridge storage facilities have provided much useful information about subsurface geologic and

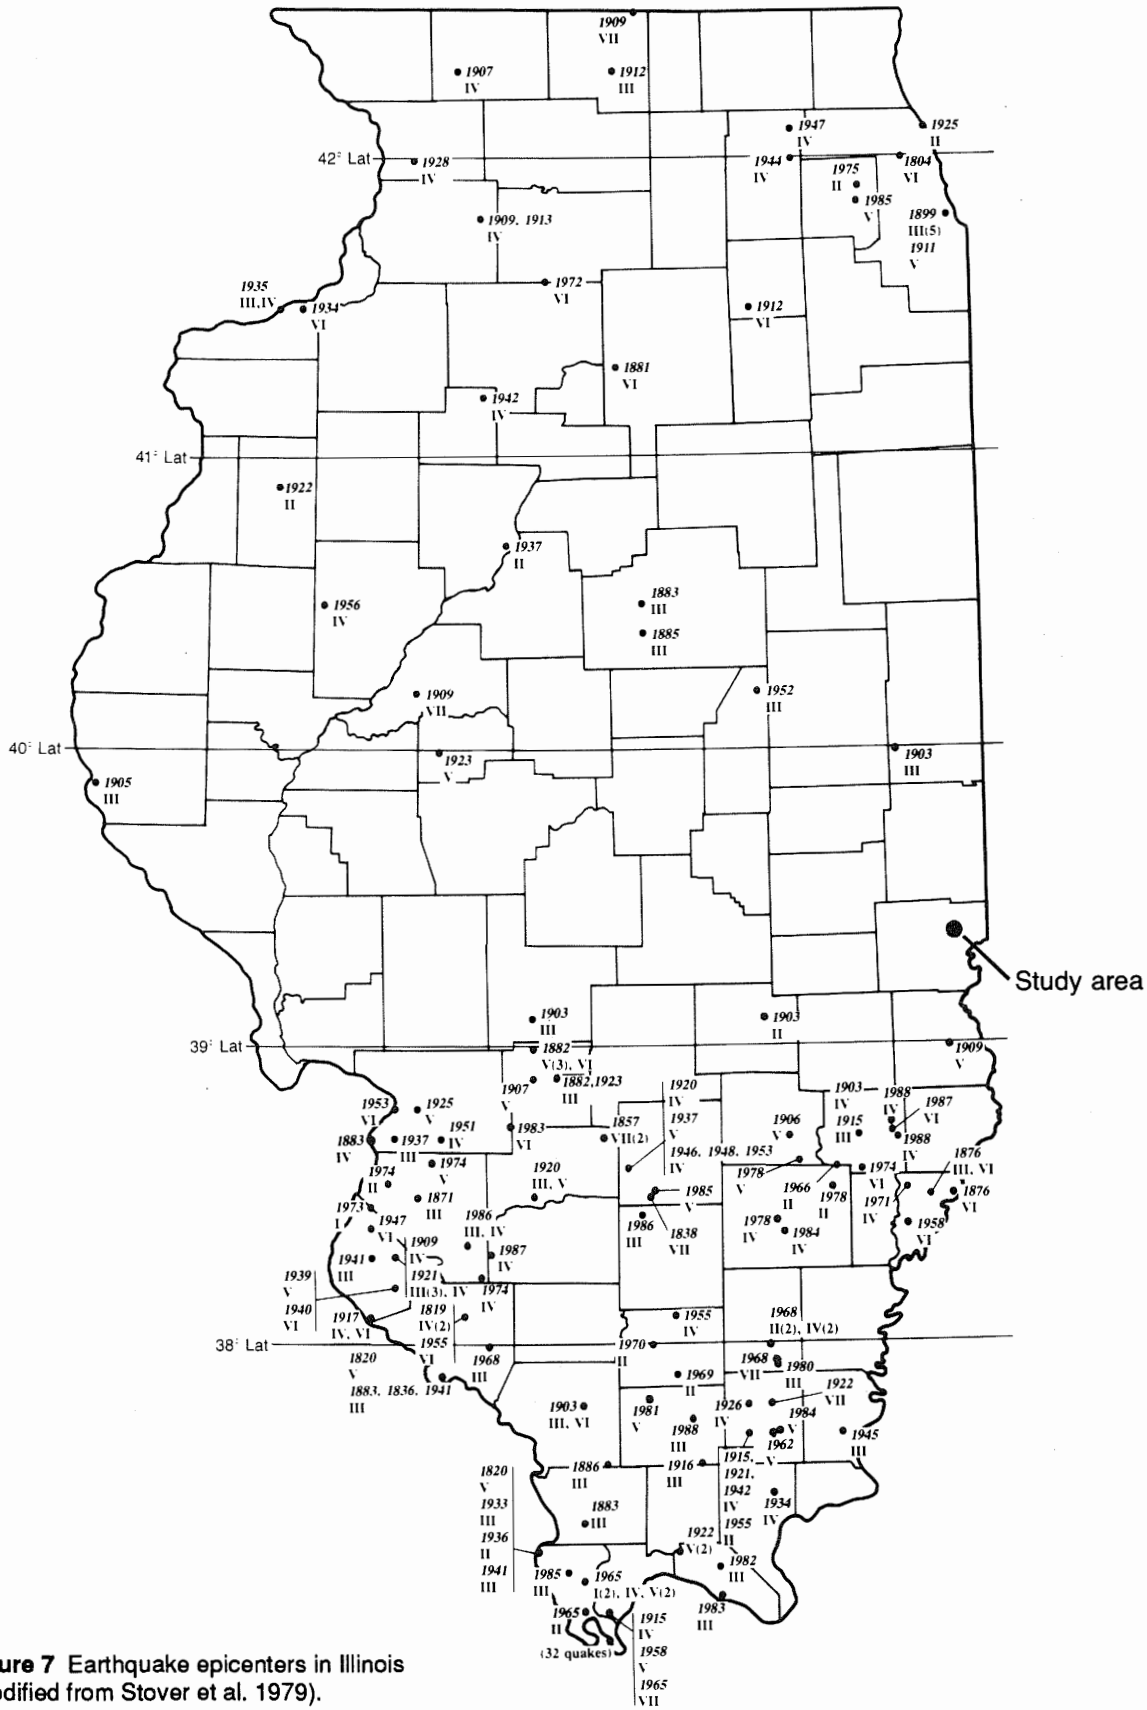

Figure 7 Earthquake epicenters in Illinois (modified from Stover et al. 1979).

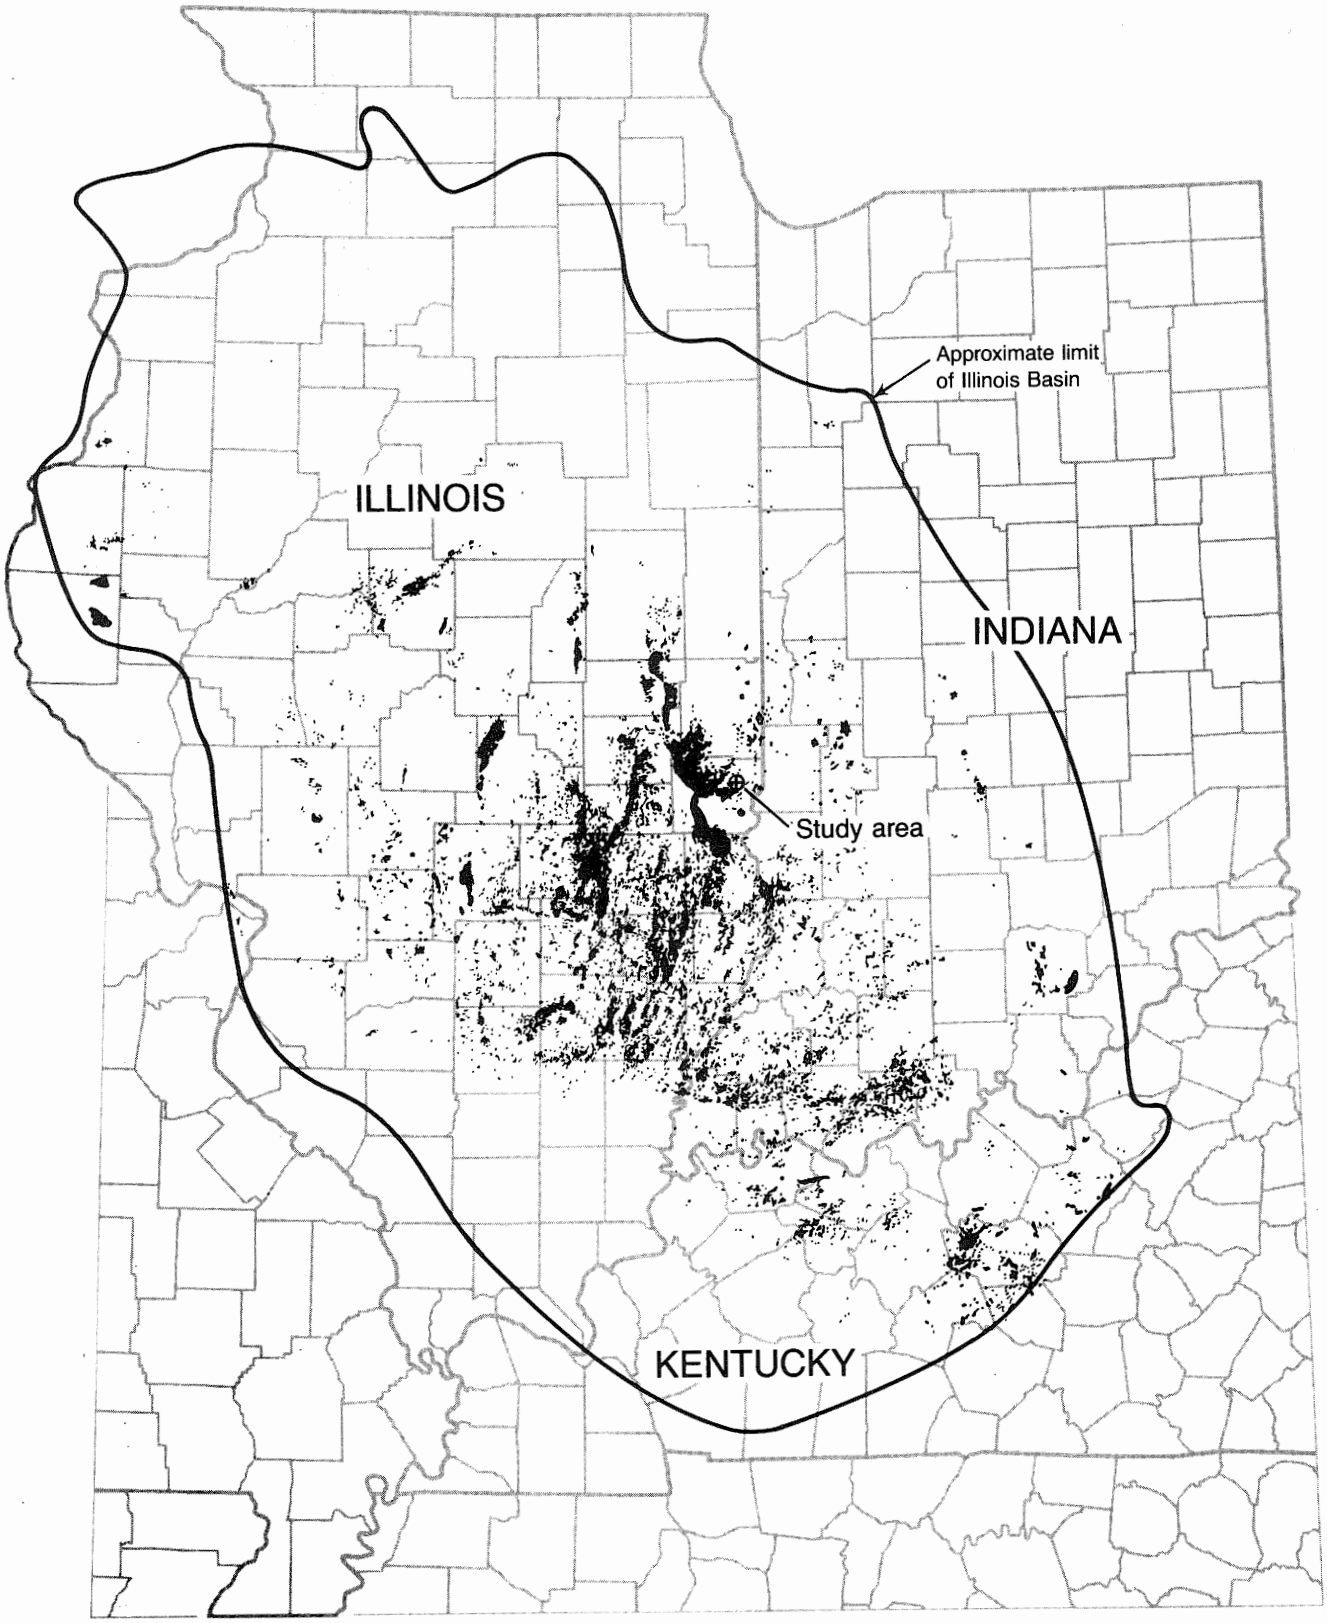

Figure 8 Oil and gas fields of the Illinois Basin (from Leighton et al. in press).

hydrogeologic conditions at the study site. Injection activities in the nearby natural gas storage fields and at the study site do not appear to affect each other significantly, although both utilize the same units of the Hunton.

Regional Geology and Hydrogeology

The units that are part of the injection system and are penetrated by the disposal well include the basal confining interval (Maquoketa Group), the injection interval (Hunton carbonate sequence), and the upper confining interval (New Albany shale sequence). Additional impermeable units and some aquifers lie between the upper confining interval and land surface. The first significant aquifer above the injection interval is the Salem Limestone.

Waste Disposal Well 2 (WDW2) was originally drilled to 6,000 feet (Eminence-Potosi Dolomites). It was plugged back into the uppermost unit of the Silurian limestone part of the Hunton because the immediately overlying Devonian limestone was the deepest, most receptive injection interval available.

Ordovician System

Ordovician strata (fig. 4) range in thickness from 700 feet (in northern Illinois) to more than 6,000 feet (in southern Illinois). The thickness increases gradually toward the south. Dolomites and limestones are the predominant lithologies; however, several distinct sandstones are found in the lower (Gunter and New Richmond Sandstones) and middle (St. Peter Sandstone) parts of the Ordovician. A thick shale-shaly carbonate sequence (Maquoketa Group) forms the upper part of the Ordovician. Many of the units below the Maquoketa are relatively impermeable and act as aquitards. The St. Peter Sandstone, a thin (50-ft), fine-grained, low-permeability sandstone in Clark County, is the first significant aquifer below the Hunton injection interval.

Maquoketa Group (Lower Confining Unit)

The Maquoketa Group (fig. 4) consists of two shale units and an interbedded shaly limestone-dolomite unit. The thickness of the Maquoketa ranges from approximately 150 feet in the western part of the state, where the top is eroded, to nearly 300 feet along the eastern edge of the state (fig. 10). In the vicinity of Marshall, the Maquoketa is less than 300 feet thick.

Hydrologic Characteristics of the Ordovician System

In northern Illinois, carbonate units of the Ordovician that are at or near land surface have moderate to relatively low permeabilities. As the burial depth of these units increases toward the south, the permeabilities of the units generally decrease. Carbonate units lying below freshwater zones (groundwater with less than 10,000 mg/L TDS) are essentially aquitards. Figure 11 shows the basal position of USDW in a north-south cross section from Rockford to Cairo. The southward-pointing tongue of USDW in the Ordovician lies in the St. Peter Sandstone. The TDS level of the St. Peter in the Marshall area is greater than 50,000 mg/L (Meents 1952).

Porosities in carbonate units in the southern half of the state are generally less than 10 percent; permeabilities in the more permeable units rarely exceed 1 to 30 millidarcys (Ford et al. 1981, Mast 1967). Porosities and permeabilities across vertical sections of the St. Peter are quite variable. The more permeable horizons measured in northern Illinois had porosities ranging from 12 to 17 percent and permeabilities ranging from 25 to 250 millidarcys. In the south, where the St. Peter is thinner, finer-grained, and more shaly, porosity and permeability values can be expected to be smaller. The shale units in the Maquoketa Group are expected to be very tight (<1 millidarcy).

Hunton Supergroup (Injection Interval)

The limestone and dolomite units of the Silurian and Devonian Systems have similar lithologic and hydrogeologic characteristics and thus are considered one large unit, the Hunton Supergroup. The thickness of the Hunton ranges from a featheredge along the Mississippi River to more than 1,800 feet near the southern tip of the state. Figure 12 shows the thickness and dis-

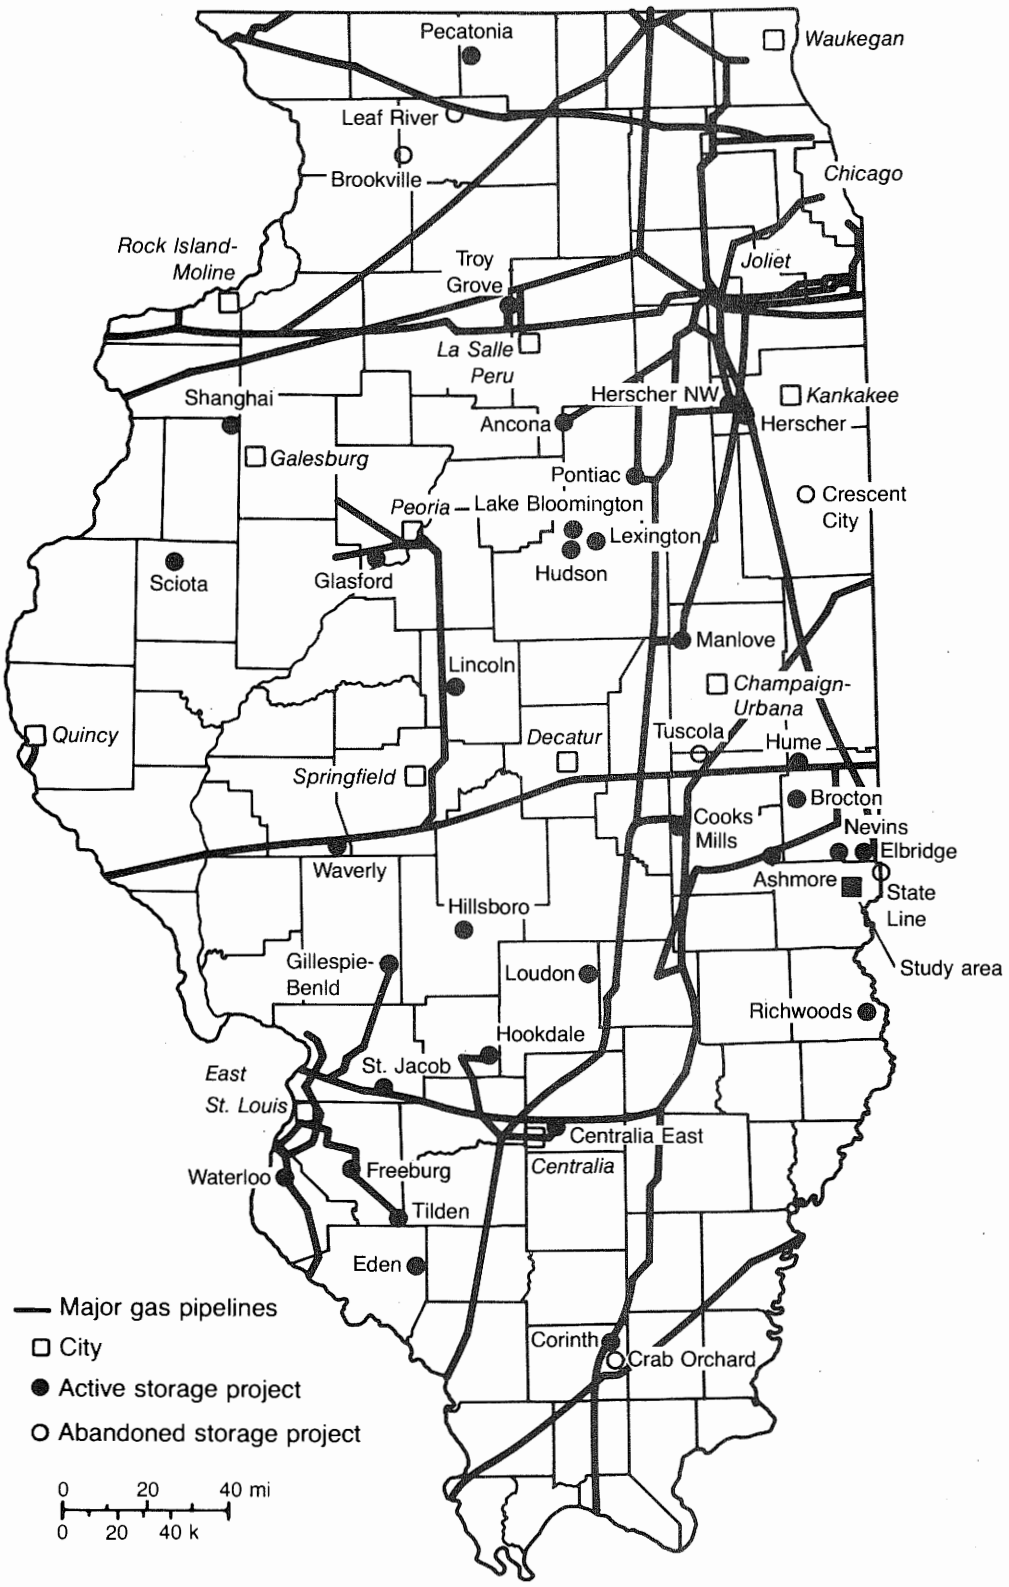

Figure 9 Location of underground gas storage projects in Illinois (after Buschbach and Bond 1974).

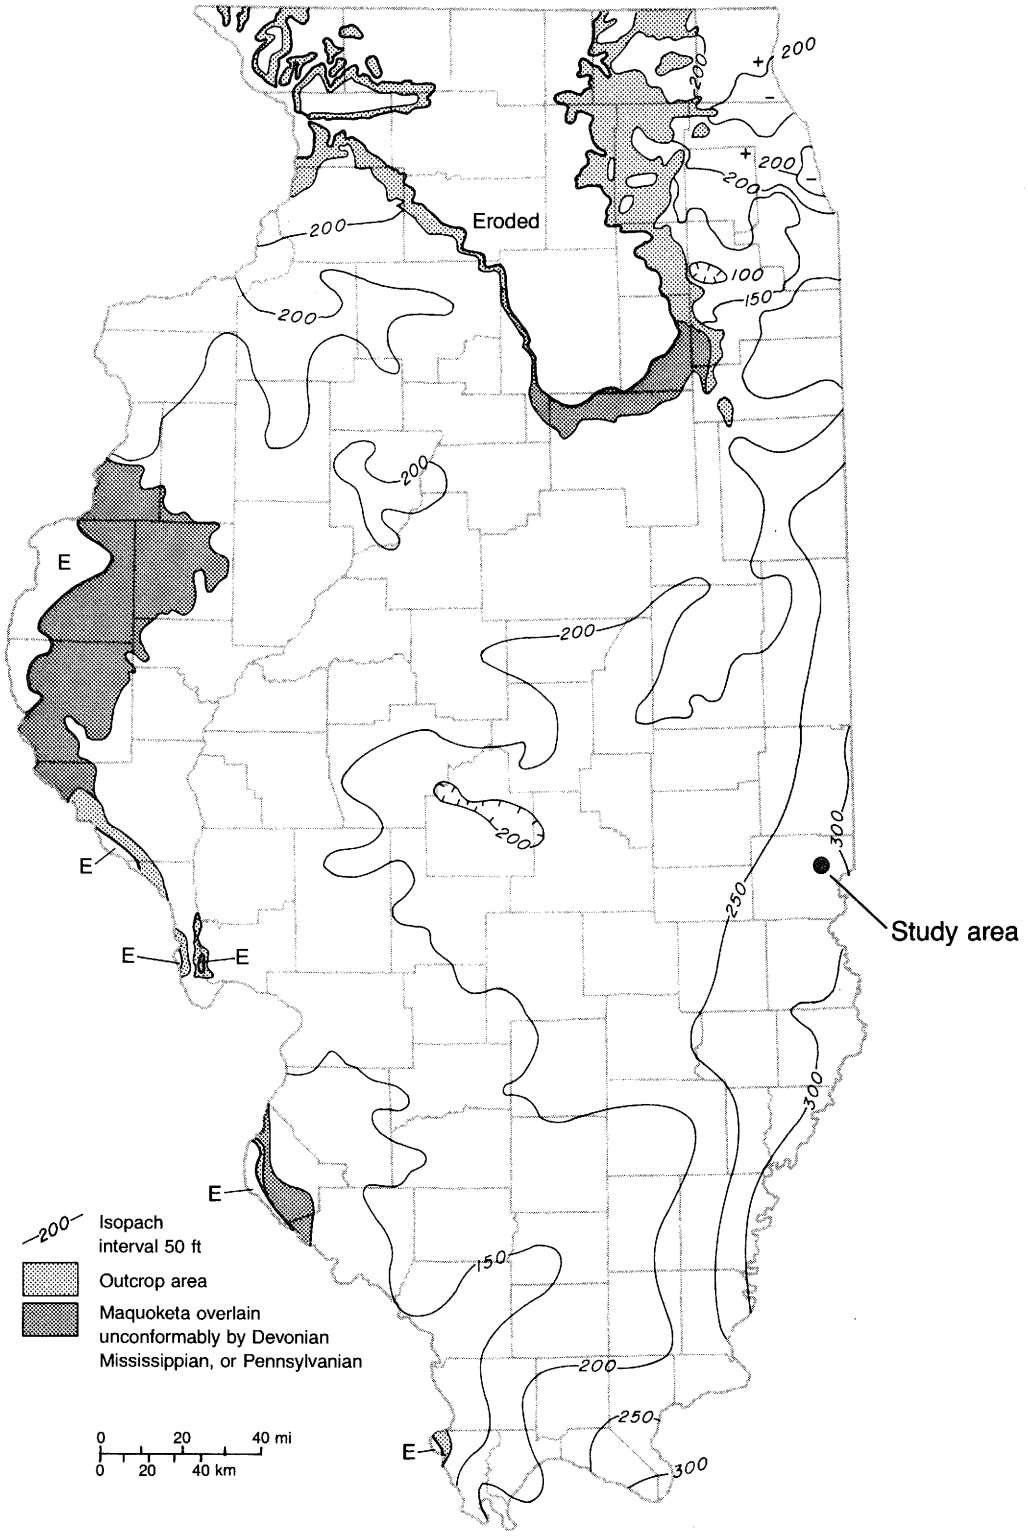

Figure 10 Generalized thickness and distribution of the Maquoketa Group (after Willman et al. 1975).

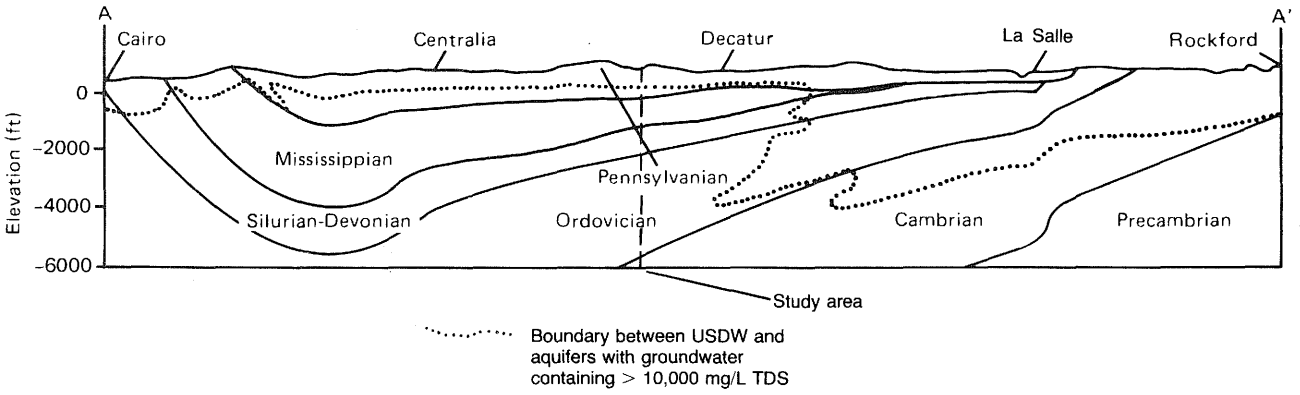

Figure 11 Cross section from Cairo to Rockford (see fig. 3) showing the position of base of the USDW (Brower et al. 1989).

tribution of this unit. Note that erosion has truncated the Hunton in a large area in the northern third of the state. Near the project site the Hunton is about 800 feet; its upper 350 feet includes units of the Devonian System.

Silurian Part of Hunton Supergroup

The Silurian consists of Alexandrian (lower part) and Niagaran (middle part) units and thickens eastward from an erosional featheredge in western Illinois to more than 700 feet in the east-central part of the state. In places, pinnacle reefs may increase the thickness to 1,000 feet. Units of the Cayugan (upper part) are thin or missing in Illinois. The Niagaran, the principal unit of the Silurian, consists of three dominant carbonate facies: shaly dolomite in the south, intermediate-purity carbonate in the north-central and northeast, and relatively high-purity carbonate in the northwest. Reefs are found throughout the Silurian units, and those in the southern part of the state (particularly in the southwestern part) may be oil-bearing (Whitaker 1988).

The uppermost Silurian unit in the study area is the Moccasin Springs Formation (fig. 4). The Moccasin Springs consists mostly of red (or red-and-gray-mottled), very silty, argillaceous limestone and calcareous siltstone; shale is common near the top. The Moccasin Springs contains numerous reefs, dominantly limestone, which have well-defined flank structures. The Moccasin Springs is commonly 160 to 200 feet thick and is more than 160 feet thick in the study area.

Devonian Part of the Hunton Supergroup

The Devonian part of the Hunton is composed of a basal sequence of four cherty limestones (including the Bailey Limestone) and an upper sequence of two limestones (the Grand Tower Limestone and the Lingle Formation). The Bailey Limestone is a silty, cherty, thin-bedded, hard limestone that begins along a southwesterly trending featheredge in central Illinois. Southeast of Marshall, additional cherty carbonate units were successively deposited above the Bailey. The combined thickness of these units reaches 1,200 feet in the southern part of the state. The Bailey is 144 feet thick in the Marshall area. The overlying Grand Tower Limestone and Lingle Formation begin along a southwesterly trending featheredge 75 miles northwest of Marshall and thicken southward to more than 400 feet in Gallatin County. Near Marshall, these two units have a total thickness of 96 feet; the Lingle is 22 feet thick.

Hydrogeology of the Hunton Supergroup

Fresh water is found at or near the surface in the Hunton in the northern half of the state and along the margins of the Illinois Basin. Well yields vary, depending mostly on the degree of fracture development. Variations in primary porosity and permeability can be related to lithology, which exerts some control on the degree of fracture development. Fracture development is greatest near the surface and generally decreases as depth of burial increases, particularly where the Hunton is overlain by impermeable shale units of the New Albany and Pennsylvanian.

The boundary marking the base of USDW in the Hunton is shown in figure 12. Typically, groundwater mineralization increases rapidly southward from this boundary. However, in Clark County the rate of increase in the TDS of the brine is relatively lower southwest of the USDW boundary, resulting in a TDS content of approximately 16,000 mg/L in the permeable Devonian units. Increased groundwater circulation in units with higher permeabilities allows less mineralized water to advance greater distances downdip (Brower et al. 1989). Other examples of this phenomenon are shown in figure 11; tongues of fresher water in the St. Peter Sandstone (Ordovician), the Ironton-Galesville Sandstone (Cambrian), and in certain shallow units (Silurian through basal Pennsylvanian near Cairo) move downdip into the Illinois Basin (Student et al. 1981). In the deeper parts of the basin, the mineral content of groundwater in the Hunton may reach from 150,000 to more than 200,000 mg/L TDS (Graf et al. 1966).

Drilling records and testing for the region show that the Lingle, portions of the Grand Tower, and a major part of the Silurian are relatively tight. The Bailey and several horizons in the Grand Tower and the Silurian have significant zones of permeability. Selected intervals of higher permeability in the Bailey have been used for disposal at the study site.

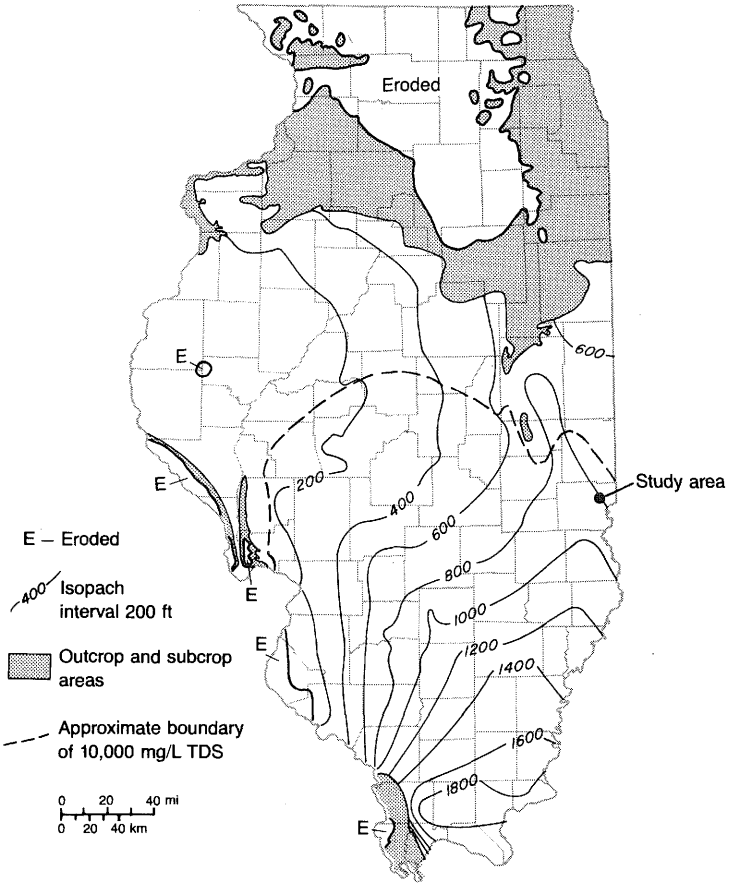

Figure 12 Generalized thickness and distribution of the Hunton Supergroup (after Willman et al. 1975) and the TDS boundary for USDW (Brower et al. 1989).

Porosity and permeability data obtained from tests run on samples collected from oil exploratory and gas storage wells scattered around the state show a mean porosity of 13 percent and a mean permeability of 40 millidarcys (Mast 1967). These data included values obtained from units in the Galena Group. Ford et al. (1981) reported porosity values of 12 to 19.5 percent and permeability values of 50 to 300 millidarcys for 269 wells completed in Devonian carbonate reservoirs of Illinois.

Evaluation of geophysical logs and sample cuttings conducted during the course of this study and for related studies of the disposal wells indicated that discrete, areally extensive horizons having high, moderate, and low permeabilities occur in the Bailey. Pore sizes range from 5 microns (μm) to over 300 (average range, 10 to 25 μm), and the pores have a fair degree of interconnection.

New Albany Group

Sedimentation during Late Devonian and Kinderhookian (Mississippian) time produced widespread accumulation of black, gray, and green shales and some limestones and siltstones. The rock units that accumulated during this time attained a total thickness of 100 to 450 feet through central and southeastern Illinois (fig. 13). Cluff et al. (1981) identified three formations present in east-central Illinois. The Blocher Shale, the basal unit, appears several miles west of the study area and thickens toward the southeast. The Blocher consists of calcareous-to-dolomitic, pyritic shale that is rich in organic matter. The Blocher is overlain with the Sweetland Creek Shale, which thickens from about 50 feet at an erosional cutoff in the central part of the state to more than 350 feet in Hardin County in southern Illinois. The Sweetland Creek is dark gray (in some places, green) and has poorly developed, laminated bedding. The unit is similar in

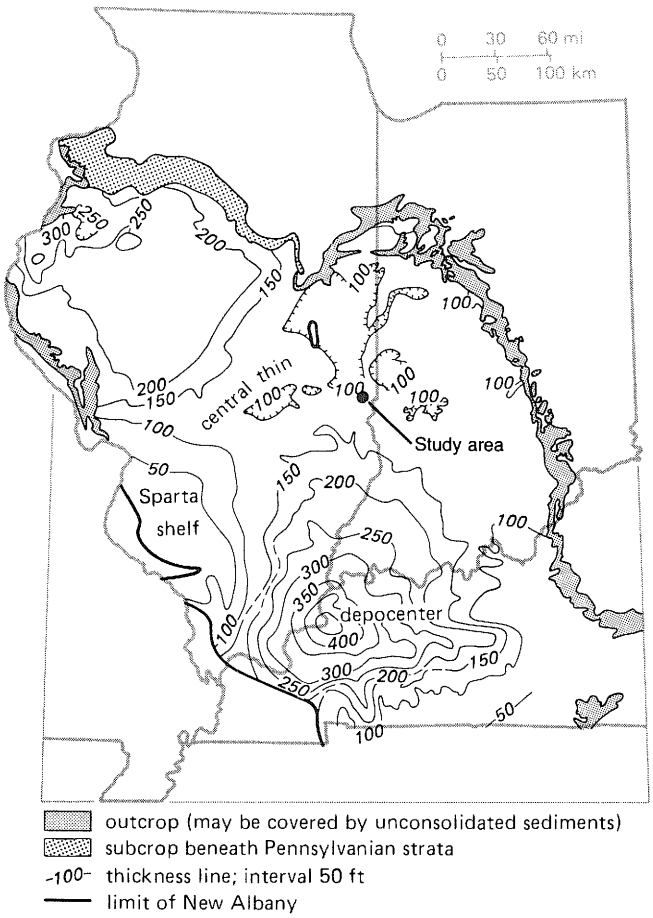

Figure 13 Generalized thickness and distribution of the New Albany Group (after Cluff et al. 1981).

appearance to both the Blocher and the overlying Hannibal Shale, but has widely traceable key beds. The overlying Hannibal Shale or its equivalent is less than 10 feet thick and indistinctly bedded. These formations are not differentiated at the study site.

Hydrogeology of the New Albany Group

The units of this group are very tight and therefore serve as an upper confining interval for the Hunton Supergroup. Natural gas storage fields completed in the Hunton utilize the low porosity and very low permeability of these units to retain gas in the underlying storage reservoirs (Buschbach and Bond 1974). The shale units in this group have essentially no water- or oil-yielding potential.

Mississippian Units

Mississippian units cover the southern two-thirds of the state and reach a maximum thickness of 3,300 feet in Williamson and Saline Counties (fig. 14). The widespread, thin, irregularly bedded Chouteau Limestone (Buschbach 1952) rests on the top of the New Albany and marks the base of three simultaneously deposited units: (1) the deltaic, tongue-shaped Borden Siltstone trending southwesterly across the state from the west-central part of Indiana; (2) the Burlington-Keokuk Limestones to the northwest; and (3) the Fort Payne Formation and Ullin Limestone to the southeast. The Borden consists of siltstone, some silty shale, and a few beds of fine sandstone and coarse siltstone. The "Carper sand" is present in places near the base of the Borden. The Ullin or its equivalent overlaps the top of the Borden with 150 feet of limestone and some shale in the Marshall area. Widespread limestone units, including the Salem, St. Louis, and Ste. Genevieve Limestones, accumulated between the Borden and the overlying alternating sequences of shale-limestone and shale-sandstone units that were deposited during Chesterian time.

The Mississippian section above the Chouteau is approximately 1,200 feet thick in the Marshall area and includes 450 feet of Borden Siltstone. The "Carper sand" is approximately 20 feet thick and lies very near the base of the Borden.

Hydrogeologic Conditions in the Mississippian

Mississippian units are used extensively for small (and some moderate) water supplies in and near outcrop areas. Most wells are finished at shallow depths, typically less than 300 to 500 feet. Groundwater mineralization increases rapidly with increasing depth of burial and in a down-dip direction toward the Illinois Basin (Meents 1952).

The Borden Siltstone is a thick unit of very low-permeability material that provides confinement in addition to the New Albany Group, the primary confining unit of the Hunton injection interval. The "Carper sand" provides the first somewhat permeable horizon above the top of the Hunton. Several thin, fine-grained sandstones also lie near the top of the Borden. Available porosity logs suggest that porosities of about 8 to 12 percent can be expected in these sandstones. At the study site, the Salem Limestone is the first overlying aquifer having significant permeability; it has been used for waste injection in the past. The measured static water level in the Salem is about 50 feet lower than the water level in the Bailey. The mineral content of the Salem and the Bailey in the Marshall area is similar (about 15,000 to 16,000 mg/L TDS). The groundwater in these units has an anomalously low mineral content, which appears to be related to the relatively high porosity and permeability of these units. Figures 12 and 14 show the location of the USDW boundary in Hunton and Mississippian units. The less permeable units of the Mississippian, particularly those in the upper part, contain groundwater with a much higher mineral content.

Pennsylvanian Units

The bedrock surface in the southern two-thirds of the state has been formed on Pennsylvanian units. Shale and clay units (more than 50% of the total thickness), sandstones and siltstones (more than 25%), limestones (less than 10%), and coals comprise more than 500 distinguishable units. Pennsylvanian strata reach a maximum thickness of 2,500 feet in the south-central part of the basin. Sandstones are interbedded with the shale throughout the Pennsylvanian but are most

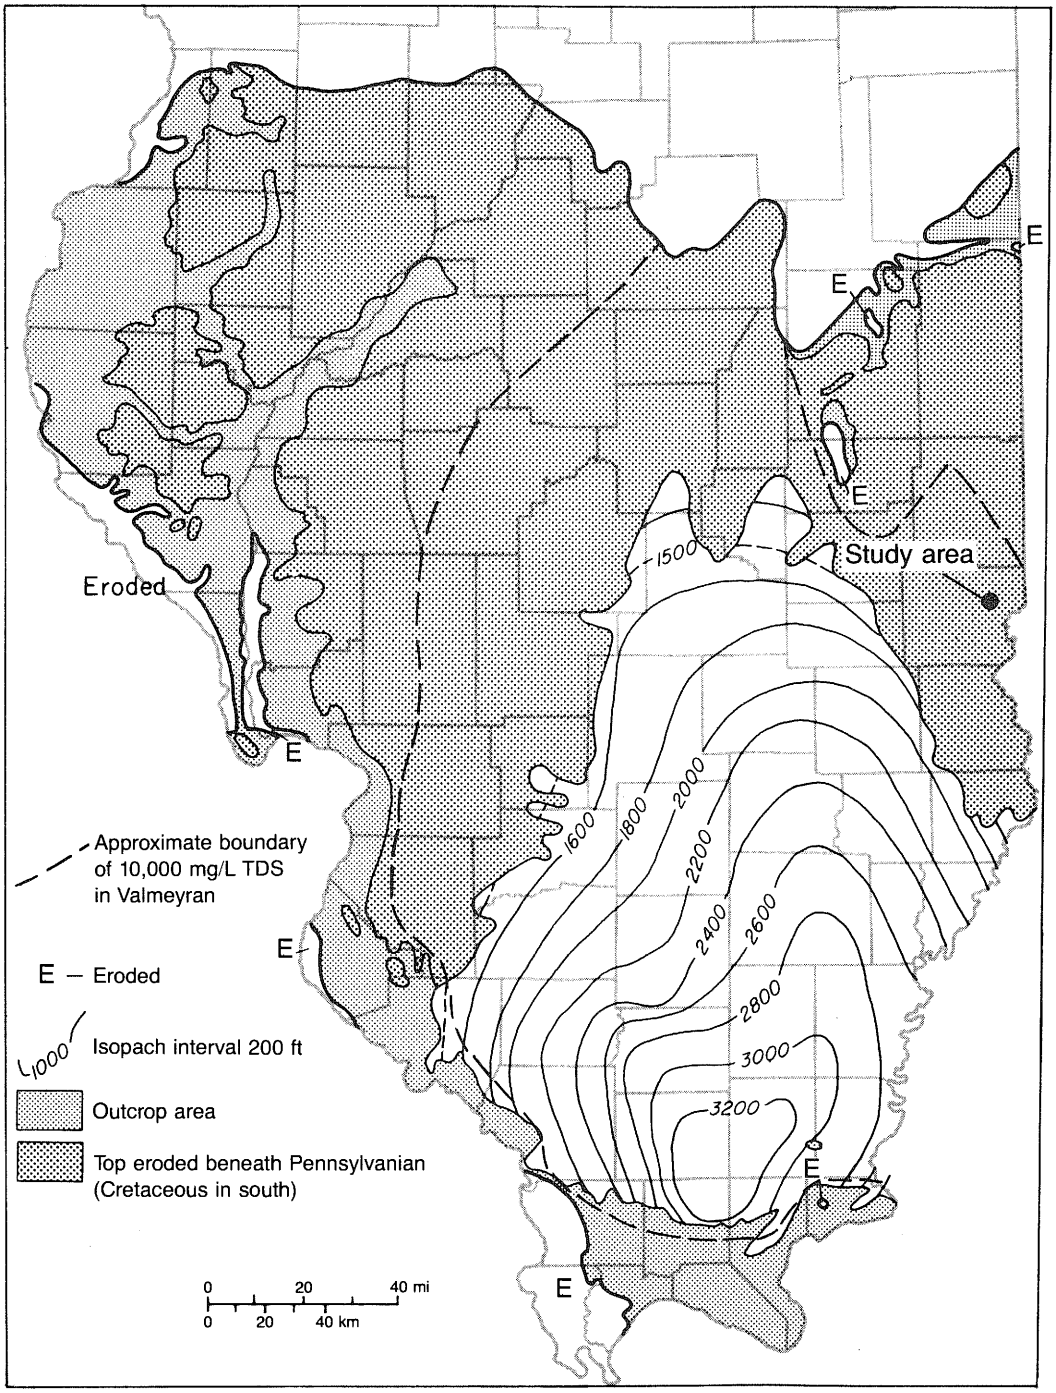

Figure 14 Generalized thickness and distribution of the Mississippian System (after Willman et al. 1975) and the TDS boundary for USDW (Brower et al. 1989).

abundant in the lower two of seven formations. Limestones are more abundant in the second formation from the top, and the most well-developed coal units are in the middle (fourth) formation.

In the Marshall area, the Pennsylvanian is about 1,050 feet thick. The thicker sandstones are found near the base of the Pennsylvanian. Coal units are present but thin. The more prominent coals occur below a depth of 400 feet.

Hydrogeologic Conditions in the Pennsylvanian Units

Fresh water exists in the upper 300 to 500 feet of the Pennsylvanian units and is a principal source for low-volume water supplies where no potential for supply exists in overlying glacial deposits. Near the margins of the basal formations, the more permeable sandstones contain fresh water to depths of more than 1,000 feet. In the Marshall area, mineralization of groundwater increases rapidly below depths of 50 to 75 feet, and water wells rarely penetrate to depths below 100 to 200 feet. The base of USDW is estimated from geophysical logs to lie about 500 feet below the surface (Piskin 1986).

Sandstones in the upper three-fourths of the Pennsylvanian are thin and widely spaced and yield very little water. The basal sandstones in the Marshall area may yield up to 20 gpm; however, water from these sandstones has a very high mineral content (38,000 mg/L TDS) (ISGS UIC files).

Porosity and permeability values measured from cores and wells collected from or finished in all types of Pennsylvanian units range from 9 to 25 percent and 10 to 10,000 millidarcys (Ford et al. 1981). Porosities measured in oil-producing sandstones are relatively uniform, averaging 17 to 20 percent (Whiting et al. 1964). Whiting also reported permeabilities of 100 to 400 millidarcys, which decrease as depth of burial increases.

Quaternary System

Glacial deposits consisting of loess, silt, clay, till, sand, and gravel cover a large part of the bedrock surface of Illinois. In the Marshall area, the drift is less than 10 to 50 feet thick in the upland areas and up to 30 to 100 feet thick in the larger stream valleys. Peoria Loess (2 to 6 ft thick) and Roxana Silt (0 to 3 ft thick) mantle the Glasford Formation (clay, sand, and till, 0 to >21 ft thick) on the upland. The Banner Formation (clay and till 0 to >20 ft) underlies Glasford Formation till where thicker drift is present in the upland areas (ISGS UIC files 1981). Cahokia Alluvium (silt, sand, and clay) overlies Henry Formation (outwash sand and gravel up to 70 ft thick) in the valley of Big Creek. Very limited to small water supplies are available from the upland glacial deposits. Moderate to large water supplies are available along some segments of Big Creek valley. Marshall obtains its water supply from the Henry Formation, about 2.25 miles east of the study site.

3. HYDROGEOLOGIC INVESTIGATION OF THE INJECTION SYSTEM

This chapter briefly discusses techniques used to collect and analyze hydrogeologic data. Details of the techniques and analyses are in appendices A and B. Specifically, stratigraphic correlations within the injection system from regional (5 to 10 miles) and local (3 miles) perspectives are discussed, along with methods used to collect additional data from the site of the injection well. These methods include geophysical logging, sidewall coring and associated analysis, and hydraulic testing. A hydrogeologic description of the injection system at the site is also given.

Stratigraphic and Structural Definition of the Injection System

The injection system consists of the geologic materials constituting the injection zone and its associated upper and lower confining units. To evaluate the confining and injection potential for the Devonian injection system, data were collected from wells in three gas storage fields (Nevins, Elbridge, and State Line), wells within 5 to 10 miles from the project site, and wells within 3 miles of the site (see figure 15 and table 1). The gas storage fields are approximately 9 miles northeast of Velsicol's Waste Disposal Well 2 (WDW2). Data from these wells were used to correlate hydrogeologic units within the injection system and to construct a structure map of the top of the Lingle Formation. The injection interval for WDW2 lies within the Devonian limestone sequence, immediately below the Lingle and Grand Tower Formations.

Each of the three gas storage fields utilizes a domal structure with closure to concentrate and store the gas. Each domal structure was formed by the deposition of Devonian- and Silurian-age shelf facies sediments over Silurian-age reef facies sediments.

Although this type of structure is not present in the area immediately surrounding the Velsicol plant, the general stratigraphic relationship of the rock units near the storage fields and those near the disposal well was shown to be consistent. Inferences were then made regarding data from the gas storage fields to the disposal well at Velsicol.

Geophysical logs from wells at a 5- to 10-mile radius from the plant were used to correlate stratigraphy and to give a regional picture of the configuration of the injection system. Geophysical logs from wells within 3 miles of the injection well were used to construct a structure map consistent with regional data.

Stratigraphic Description of the Injection System

The stratigraphy of the injection system includes the Silurian-age Moccasin Springs Formation at the base through the Grassy Creek Shale, the uppermost Devonian unit of the New Albany Group. Figure 16 is a geologic column showing the stratigraphic position and hydrogeologic characteristics of these units at the waste disposal well studied. Much of the strata information is from Willman et al. (1975). Additional data were obtained for the Middle Devonian strata from North (1969) and for the strata of the New Albany Group from Cluff et al. (1981).

The Devonian strata comprise three series—the Lower, Middle, and Upper. The Bailey Limestone, basal unit of the Lower Devonian Series, is dominantly gray to greenish gray, silty, cherty, thin-bedded, very hard limestone. Some beds are argillaceous. The chert, black to dark gray, occurs in bands up to 2 feet thick. An upper zone, 0 to 100 feet thick, is limestone that is pure, white, coarsely crystalline, and only slightly cherty.

A major unconformity occurs at the Lower and Middle Devonian interface. The basal formation of the Middle Devonian Series is the Grand Tower Limestone, which is mostly coarse-grained, light gray, medium- to thick-bedded, cross-bedded, pure, fossiliferous limestone. It also contains lithographic limestone, which becomes more abundant upward. One member differentiated at the study site is the Tioga Bentonite Bed, which is found 10 to 30 feet from the top of the Grand

Tower. The Tioga is a greenish to brownish gray shale that contains biotite flakes and an abundance of silicate minerals that distinguish it from other shales. The Tioga generally is only 1 to 2 inches thick, but it may be 6 to 8 inches thick.

The Lingle Formation overlies the Grand Tower and is more argillaceous, darker, and finer-grained than the Grand Tower. At the study site, the Lingle is composed of two members, the Howardton Limestone Member and the Tripp Limestone Member. Howardton, the basal member, is gray, fine-grained, slightly silty, argillaceous limestone, most of which has thin, shaly partings. The Tripp is heterogeneous, containing limestone, dolomite, chert, siltstone, and shale. It is largely cherty, argillaceous, silty limestone, but beds of shale are abundant near its base and top.
The New Albany Group overlies the Lingle Formation. The Devonian portion of this group includes the Blocher, Selmier (Sweetland Creek), and Grassy Creek Shales. These units were not

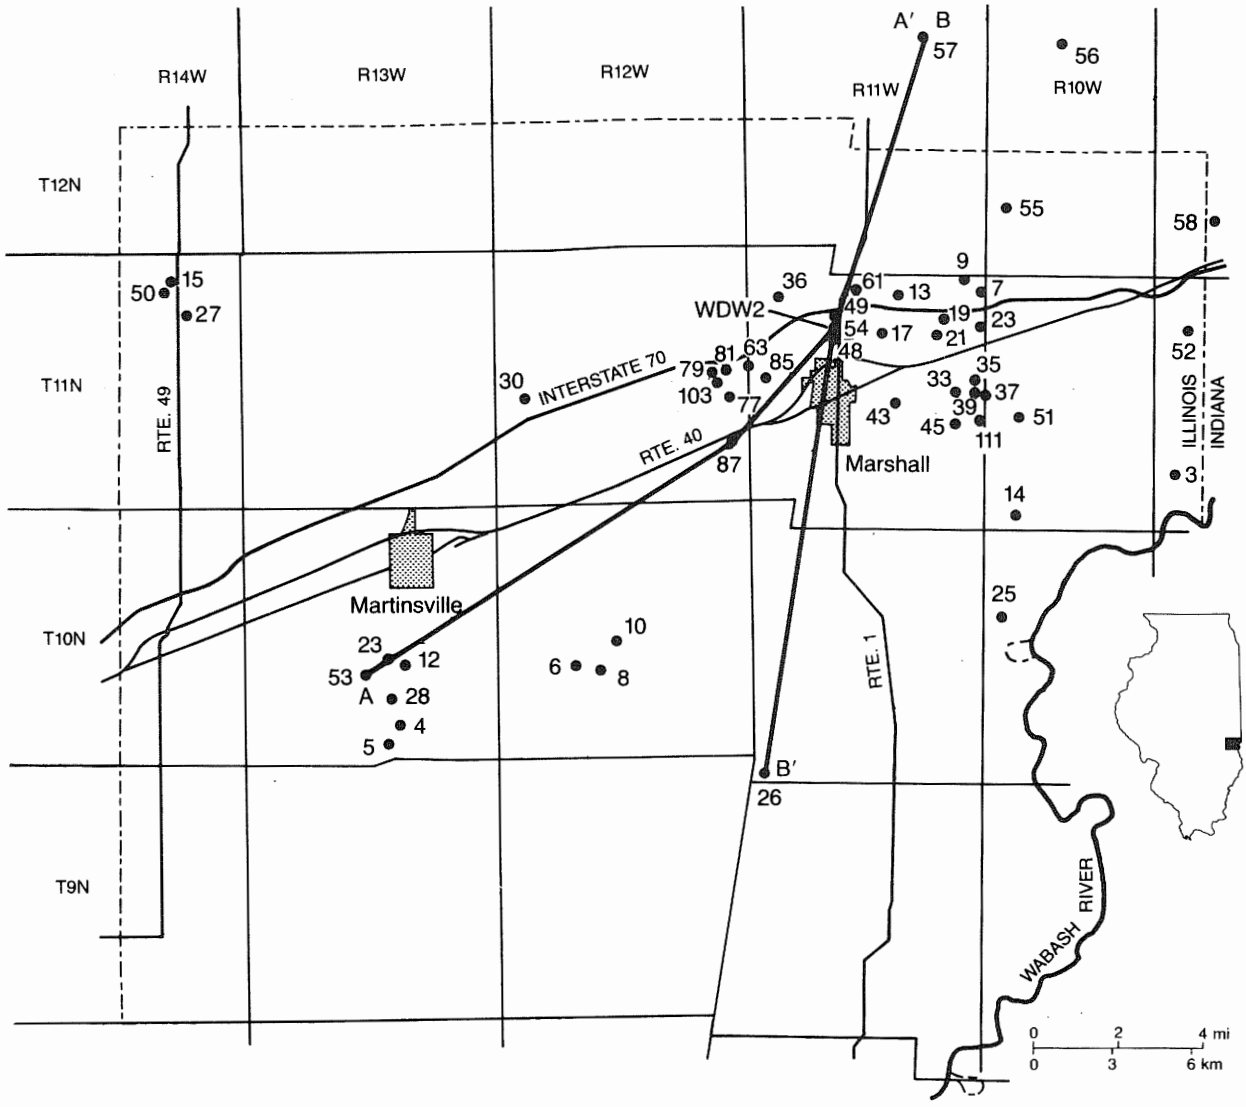

Figure 15 Well locations. Cross sections for A-A′ and B-B′ appear in figures 17, 18, and 19.

differentiated at the study site. The Blocher is the basal formation of the New Albany Group and is a calcareous or dolomitic black shale. The Blocher is the only shale in the New Albany containing much calcite.

The Selmier Shale Member overlies the Blocher and consists of greenish gray, dolomitic, bioturbated mudstone at the top that grades downward through an interbedded zone to black dolomitic laminated shale at the base. North (1969) placed these same units in the Sweetland Creek Member. The Selmier is conformably overlain by the Grassy Creek Shale Member.

The Grassy Creek is the uppermost Devonian unit of the New Albany Group and consists of brownish black to grayish black, finely laminated, pyritic, carbonaceous shale.

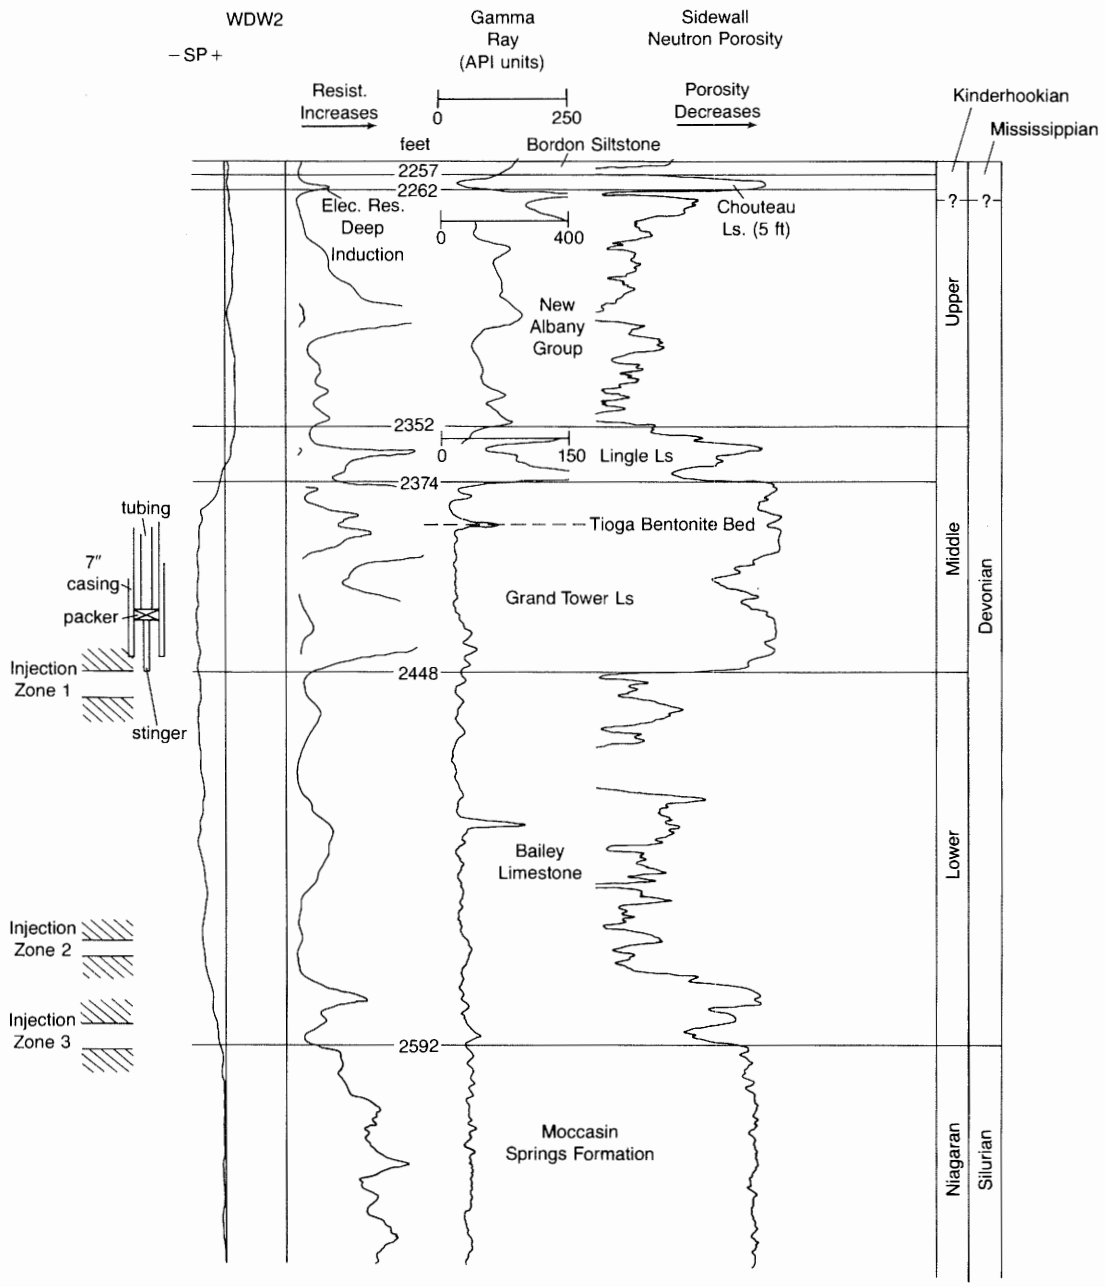

Figure 16 Geologic column for the injection system at Waste Disposal Well 2 (WDW2).

Geophysical Log Correlations

Figures 17, 18, and 19 illustrate the stratigraphic continuity of the hydrogeologic units within the injection system and the base of the New Albany Group within a 10-mile radius of WDW2. Figure 17 shows a southwest-northeast cross section based on resistivity logs, Induction Electric Logs (IEL), and Electric Logs (EL). Figure 18 is also a southwest-northeast cross section, but it is based on qualitative permeability log (Minilog) responses. Figure 19 shows a north-south cross section that is based on resistivity logs. Qualitative permeability logs were not available for all wells along this cross section.

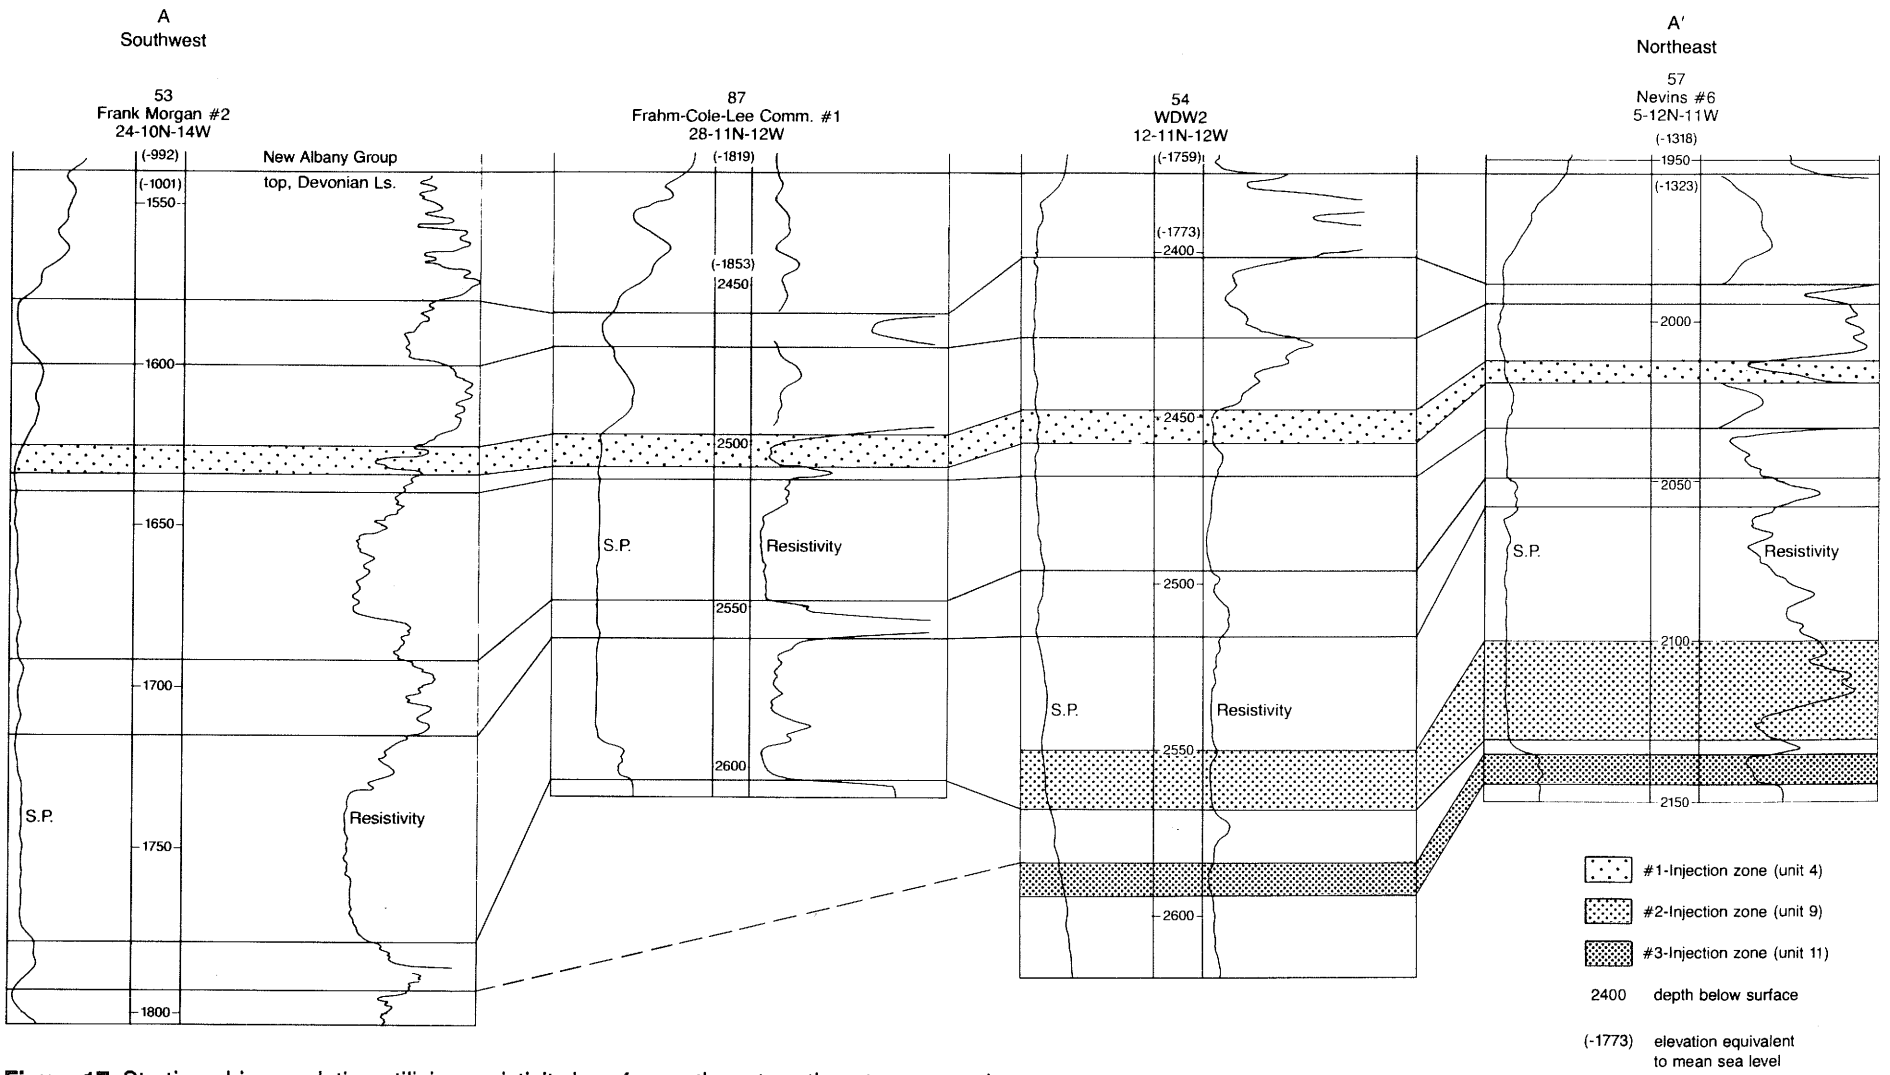

Figure 17 Stratigraphic correlation utilizing resistivity logs for southwest-northeast cross section.

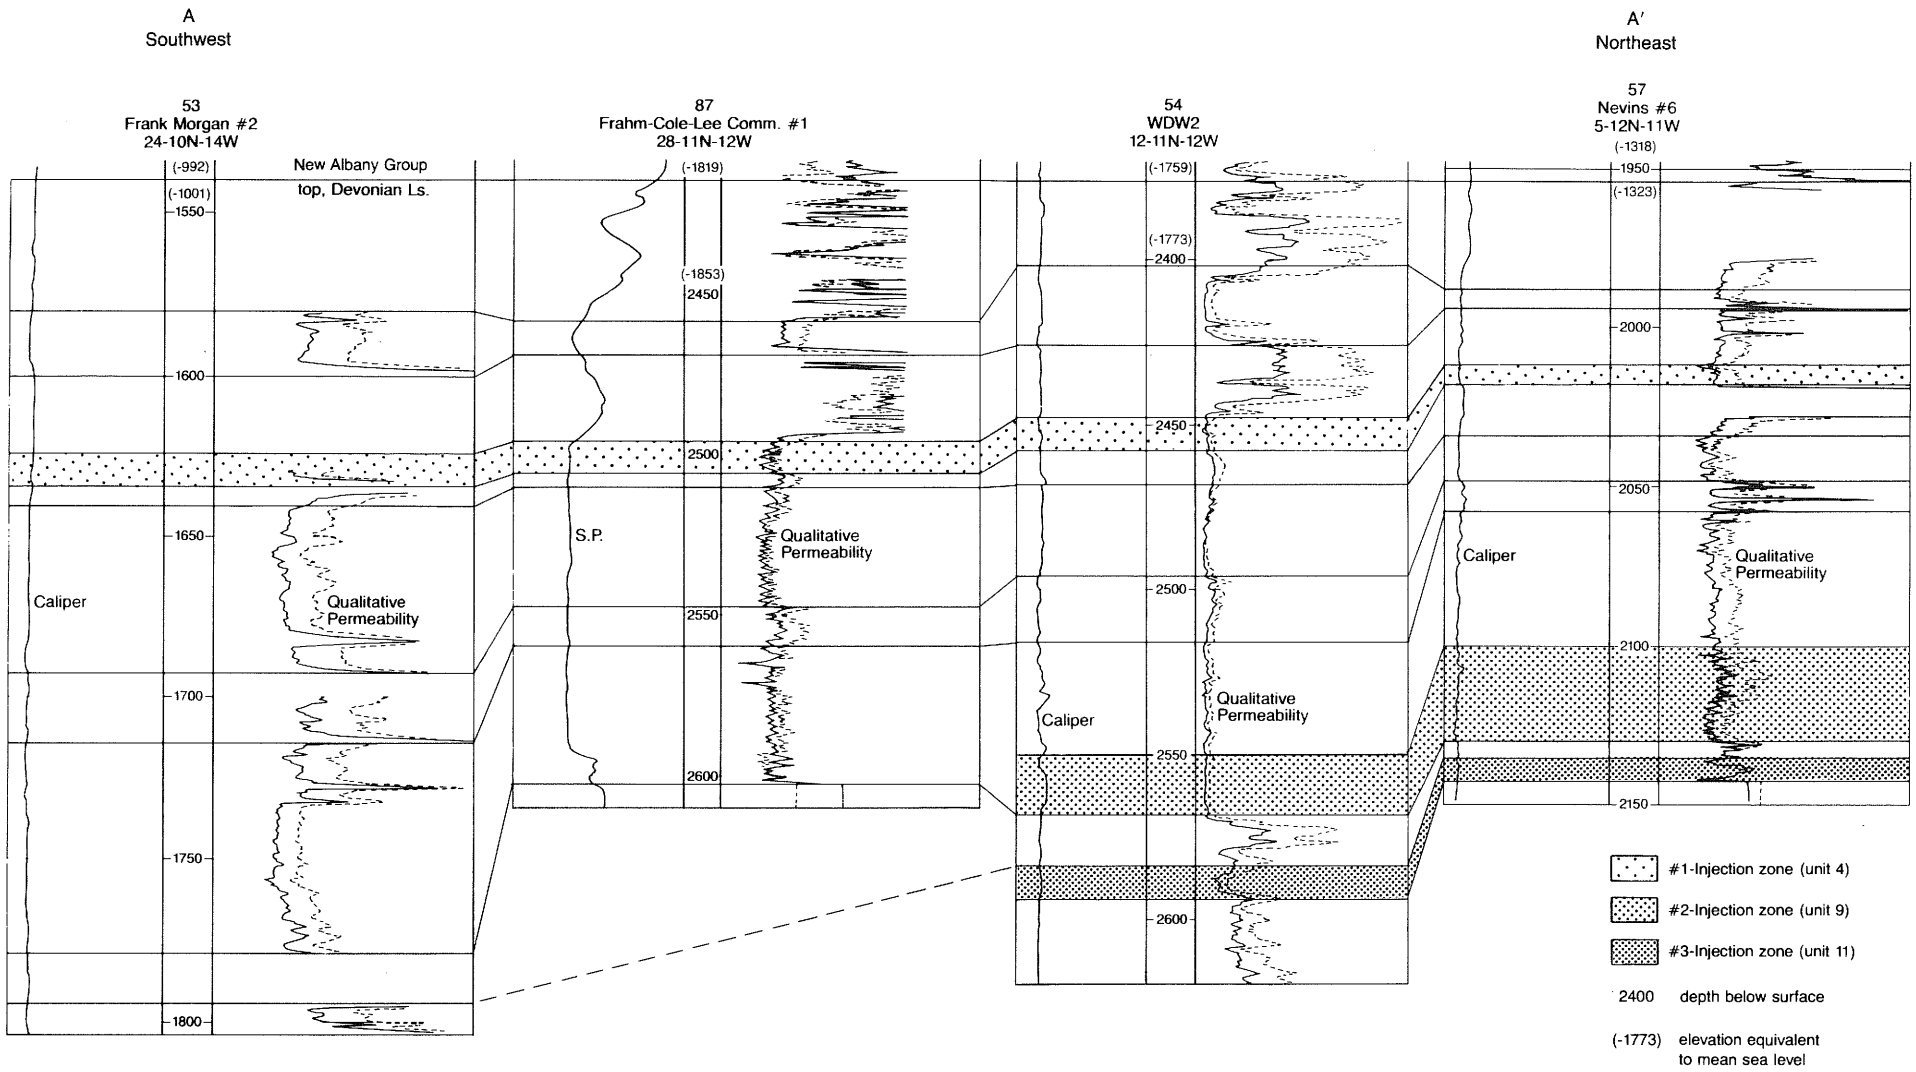

Figure 18 Qualitative permeability correlation utilizing permeability indicator logs for southwest-northeast cross section.

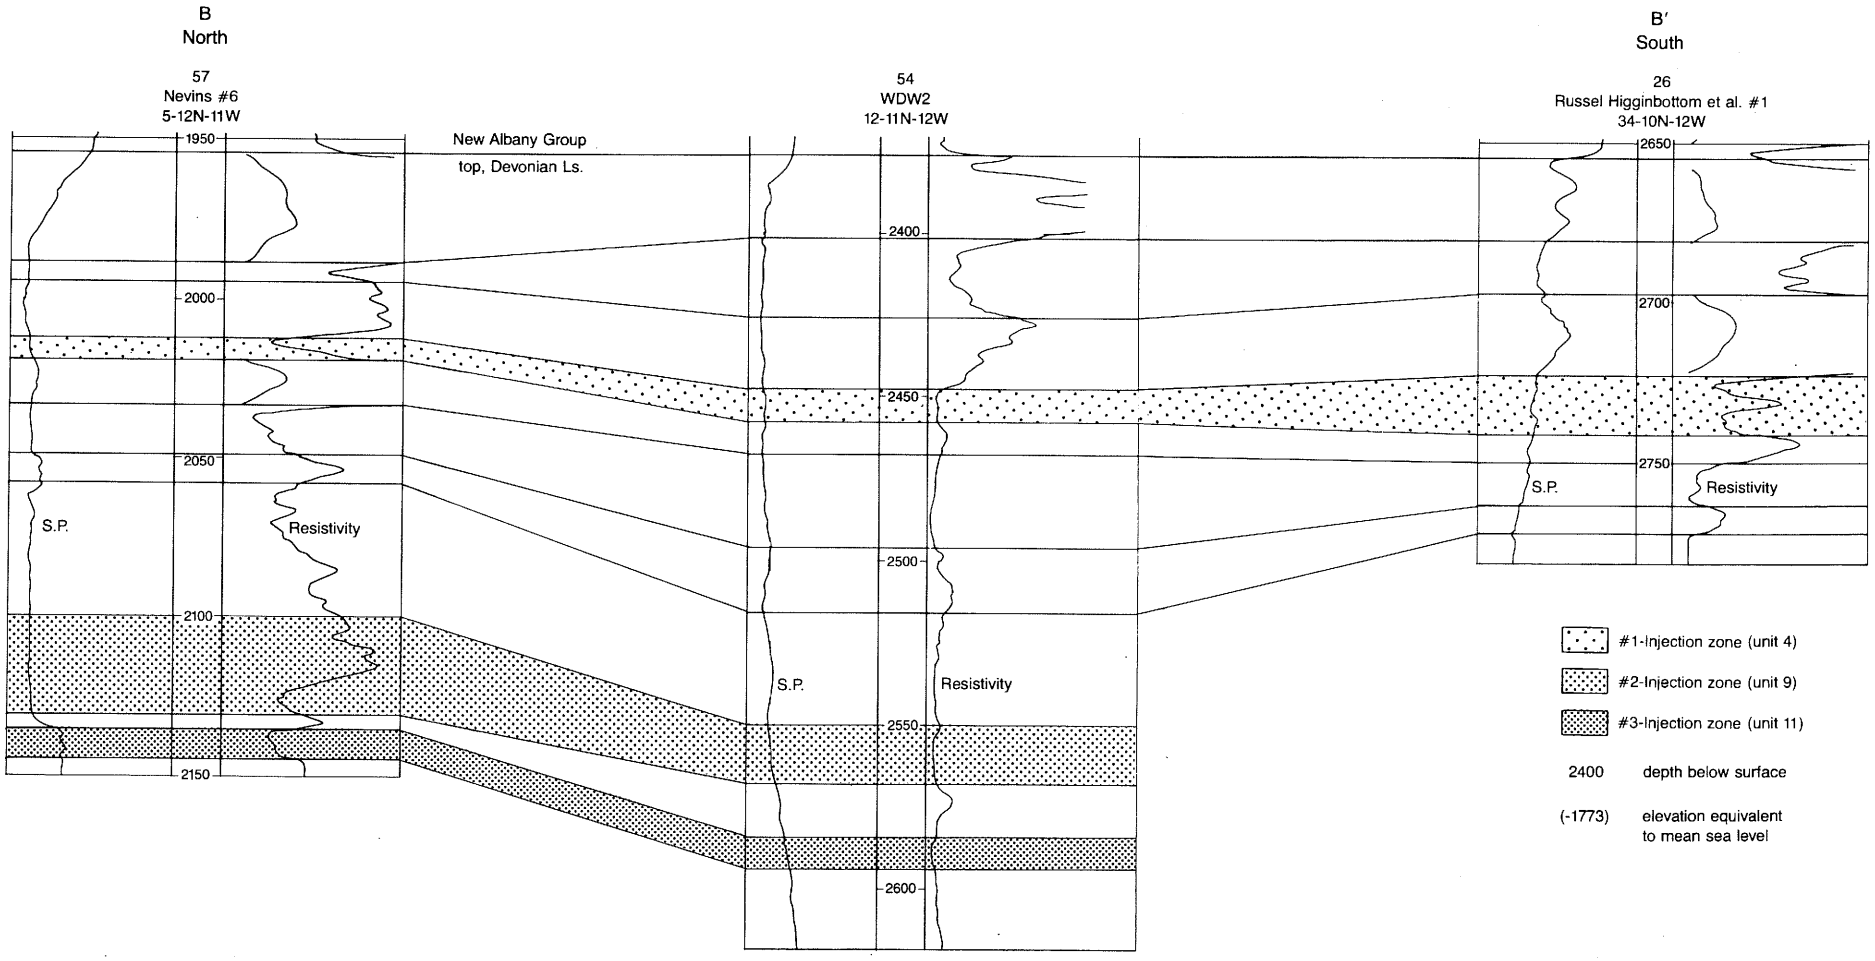

Figure 19 Stratigraphic correlation utilizing resistivity logs for north-south cross section.

The data presented in figures 17 and 19 show the hydrogeologic units within the injection system to be laterally continuous across the study area with one exception. Likewise, the continuity of the qualitative permeability of these units is inferred from figure 18. On the basis of resistivity and qualitative permeability logs, injection zone no. 2 could not be differentiated from the overlying unit in some wells in the study area. These unit designations are not included in these cross sections.

Nevertheless, the stratigraphic and qualitative permeability continuity of the Devonian limestone and the New Albany shale between the wells at Velsicol and the wells in the gas storage fields can be inferred; thus, continuity of quantitative permeability can be inferred. Analysis of core retrieved from WDW2 provided quantitative permeability data for the various hydrogeologic units. The quantitative permeability data obtained from wells at the three gas storage field wells are summarized later in this chapter (see Hydrogeology of the Site, p. 40).

A structure map of the top of the Lingle Formation was constructed (fig. 20) using information from wells within a 3-mile radius of Velsicol.

Stratigraphic and Structural Characterization

On the basis of correlations between the disposal well at Velsicol and the wells within a 5- to 10-mile radius of the plant, both the upper and lower confining units and the injection zones appear to be continuous across the study area. Although information about the thickness of the lower confining unit is limited, figures 17, 18, and 19 clearly show its stratigraphic location.

The analysis of available geophysical logs for regional hydrogeology of the injection system is summarized in figure 21. A confining unit is distinguished from an "impermeable" unit by its position with respect to the permeable units. Confining units lie directly above the uppermost perme-

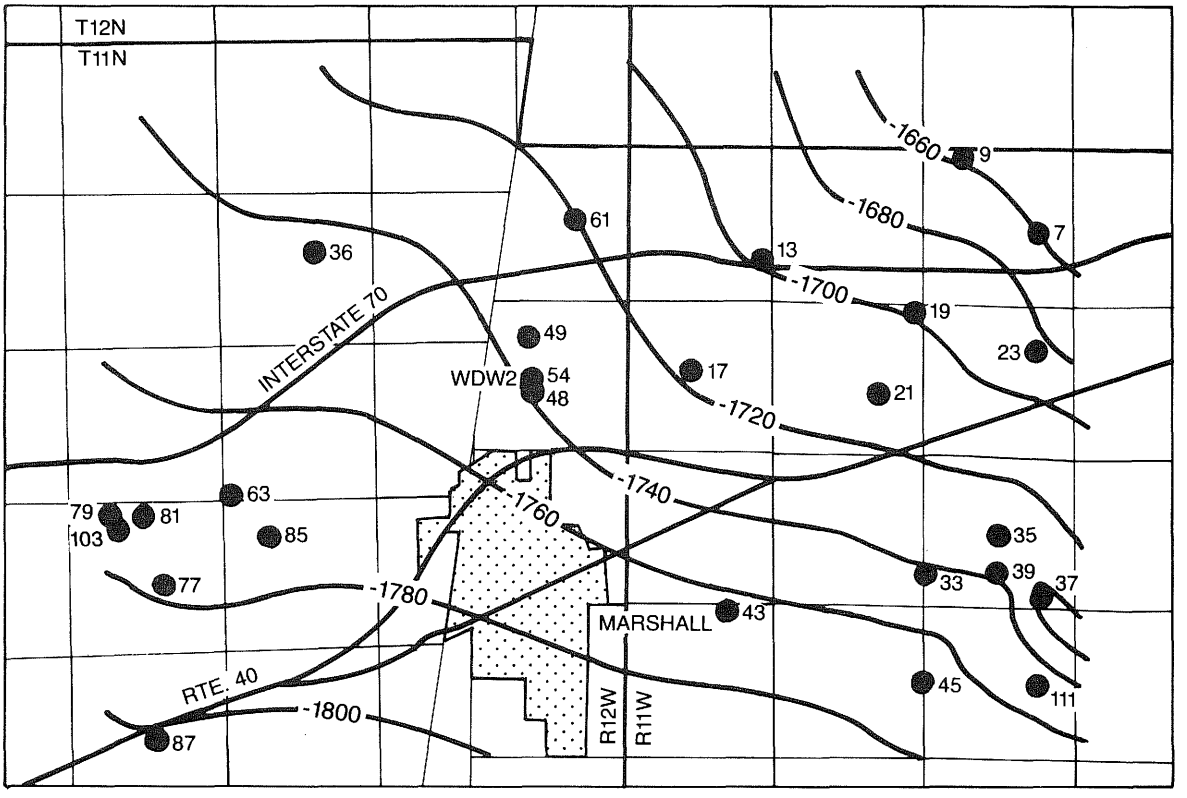

Figure 20 Structure contour map of the top of the Lingle Formation in the vicinity of the Velsicol plant.

able unit or directly below the lowermost permeable unit; impermeable units lie between permeable units. For permitting purposes, the upper confining unit includes the base of the New Albany shale and 26 feet of the Lingle Formation and Grand Tower Formation. Thickness variations for this section of the upper Devonian limestone are limited to about ±8 feet over the 10-mile region of investigation. In terms of the hydraulic confinement of the injection interval, the upper confining unit is composed of Grand Tower Limestone. Its thickness is approximately 74 feet at WDW2.

For permitting purposes, the Maquoketa shale is considered the lower confining unit. In terms of hydraulic confinement, the lower confining unit consists of the Moccasin Springs Limestone. Its total thickness could not be determined in this study because of limited data, but it is at least 160 feet thick at WDW2, based on available geophysical log data.

It is evident from figure 20 that the structure in the Velsicol plant area is generally flat with a gradual inclination of about 25 feet/mile to the northeast.

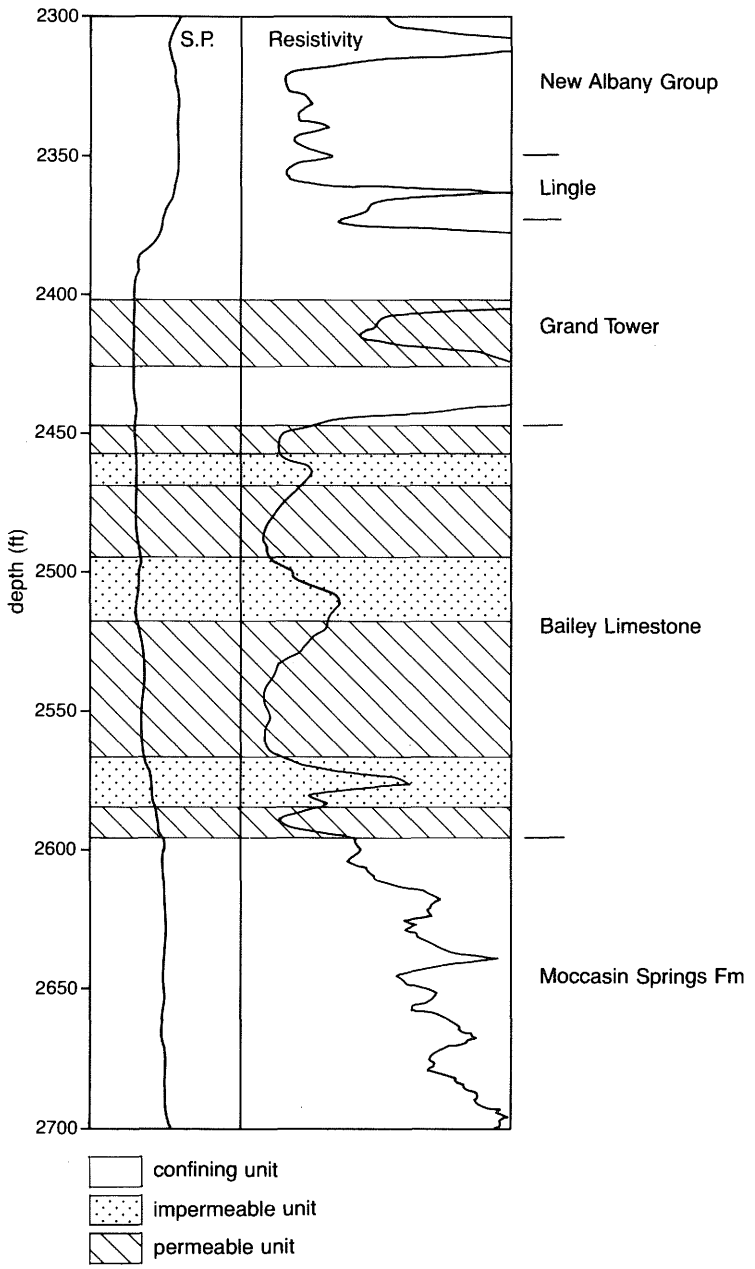

Figure 21 Injection system in WDW2 indicating permeable and impermeable zones delineated with available geophysical logging.

Determination of Horizontal Hydraulic Gradient

If the horizontal gradient is to be properly calculated, the hydraulic head within the injection system must be known for various locations. The initial reservoir pressure, obtainable from drill stem tests (DSTs), would be an excellent source of data. For initial reservoir pressure calculations, the pressure versus time chart from the DST is needed. This chart, however, was not available for wells in this area. Final flow and final closed-in pressures, as well as static water levels, were used to calculate the horizontal gradient. According to limited, high-quality data, the greatest horizontal gradient existed between wells 54 (WDW2) and 57. The hydraulic gradient (dh/dl) has a magnitude of 3.5×10^{-4} in a general direction of north to south.

Field Investigations

Two phases of geophysical logging were performed at the Velsicol site. During phase I, data on porosity and qualitative permeability, stratigraphic orientation, and the lithology of the rock units within the disposal zone were obtained from the Devonian Observation Well (DOW), Well 49. Data reduction indicated the units most favorable for fluid infiltration. Phase II was a detailed study based on information obtained from phase I. Results from phase II included quantitative data on permeability (air and water), bulk compressibility, hydraulic conductivity, specific discharge, and specific storage of the injection horizon. Those units with the greatest injection potential were further characterized for thickness, storativity, and transmissivity. In addition, hydraulic testing (flowmeter and injection testing) of the injection system was conducted.

Phase I Investigations

Records (well logs, drilling records, and other data) provided a general overview of the structure and regional continuity of stratigraphic units particularly important to waste injection and confinement. These data, however, were only one aspect of the overall integrated approach used to characterize the injection system. Additional data were needed to precisely define the character of possible confining and injection intervals. The methods and techniques used to characterize the disposal zone are discussed briefly and considered in detail in appendix A.

Existing geophysical logs. After a review of the historical records, a preliminary estimate was made of the stratigraphic location of the potential confining units (upper and lower) and the impermeable units associated with the operational waste disposal well (WDW2). These hydrogeologic units were delineated using four principal downhole geophysical logs, which were run during initial well (WDW2) construction in 1971. The logs were the Sidewall Neutron Log (SNL), Induction Electric Log (IEL), Gamma Ray Log (GRL), and Microlog (MIL). The hydrogeologic units determined from analysis of these logs are presented in figure 22. Consideration of all four logs was necessary to fully evaluate porosity, qualitative permeability, shale percentage, and lithology of the geologic materials. Interpretation methods used in the evaluation of these logs are discussed in appendix B.

Additional existing geophysical logs include the Temperature/Salinometer and GR/Neutron Logs run in the DOW in 1981 and 1973, respectively, and a Sonic Log (SL) run in WDW1 in 1965.

However, since logging instrument technology has progressed dramatically and subsequent equations and modeling of formation characteristics have advanced since these logs were run, a new suite of logs was run. Use of these geophysical logs enabled further delineation of the hydrogeologic characteristics of the injection system.

Phase I geophysical logging. A suite of logs was selected on the basis of the considerations discussed above and the physical dimensions of the casing and tubing in the three wells at Velsicol. The only well suitable for study during phase I was the DOW. Dresser Atlas performed the logging. The two types of porosity logs run were the Compensated Neutron Log (CNL) and the Borehole Compensated Sonic Log (BCS). The Minilog (MIL) was run to qualitatively determine permeability. Resistivity parameters were determined by the Dual Induction Spherically Focused

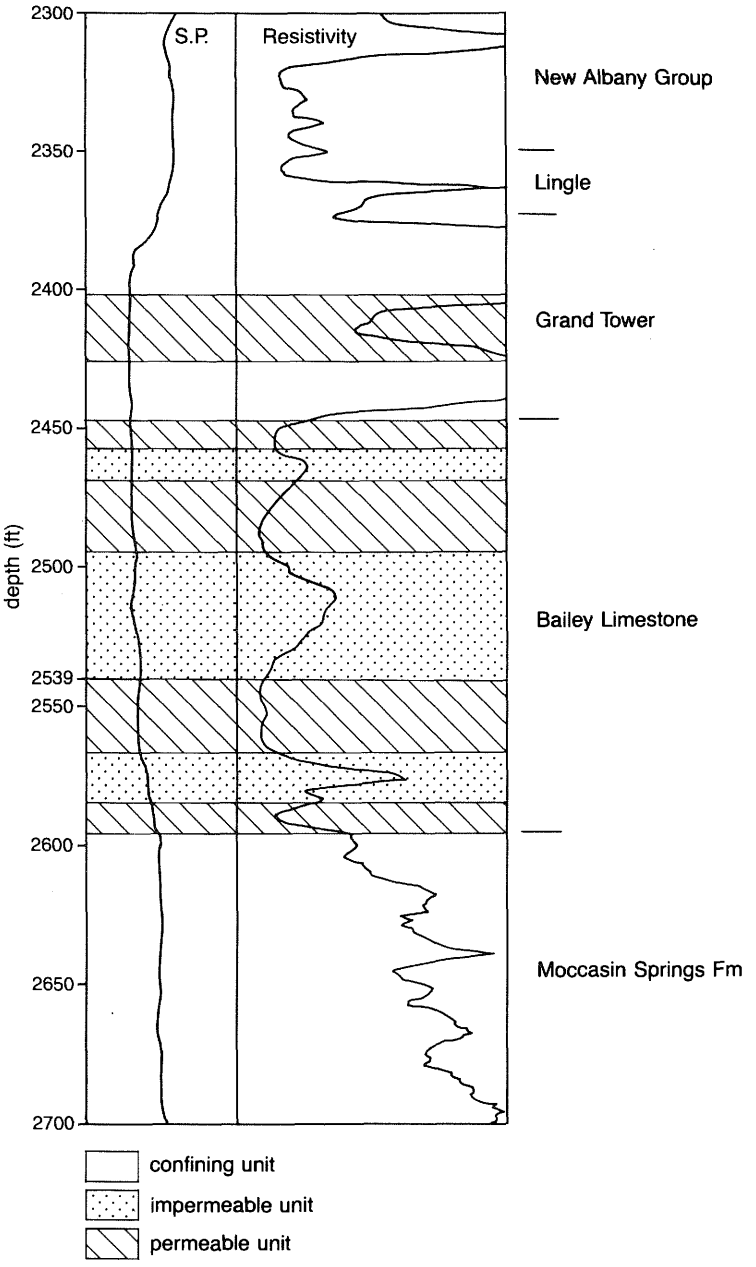

Figure 22 Injection system in WDW2 indicating permeable and impermeable zones delineated after phase I logging.

Log (DISFL). Finally, to provide the best stratigraphic correlation between the three wells at Velsicol, the Gamma Ray Log (GR) was run. (See appendix A for a discussion of the theory and general application of these logs.)

The techniques used to reduce the geophysical log data are discussed in appendix B. The data from these logs, analyzed and reported in 2-foot intervals, are presented in table 2. With the use of these modern logging tools and incorporation of improved analytical techniques, it was possible to obtain more accurate hydrogeologic data of the geologic materials constituting the injection interval. These data consisted of the formation's matrix-corrected CNL porosity ([POR]Ncor), matrix-corrected BCS porosity ([POR]BCScor), cross-plotted porosity ([POR]xp), secondary porosity ([POR]sec), true resistivity (Rt), matrix lithology (MA), water saturation (SW), shale volume (Vsh), and qualitative permeability (k). The same data were obtained from existing logs for WDW2 and are reported in table 3. Important parameters from these tables are summarized in table 4.

1 All logs used for study were from WDW2 (run during well installation), except the Sonic Log (SL), which was from WDW1 (run during well installation). The methods of analysis used were the same as above. All depths measured are from Kelly Bushing (KB), which is 12 feet above GL.

From the data (see appendix B) it appeared that the host formation, the Bailey Limestone, was composed mainly of a clean dolomite with less than 20 percent shale throughout most of the interval logged. Since the Bailey Limestone is predominantly a dolomite, secondary porosity is always a consideration. A comparison of CNL and BCSL data suggested that secondary porosity may account for up to 10 percent of the total porosity. The intervals with higher relative permeability have a slightly higher secondary porosity and, in turn, total porosity.

Also, the entire interval is primarily 100 percent water saturated with a fluid resistance of approximately 0.247 ohm-m. At a formation temperature of about 80°F and depth of 2,460 feet GL, the fluid composition was estimated to be approximately 24,000 ppm NaCl.

Phase I log analysis provided qualitative data of the disposal horizon. On the basis of this analysis, an additional section of the disposal horizon (2,518 to 2,539 ft KB [Kelly Bushing]) was eliminated as a possible injection zone (fig. 23).

Table 4 Summary of important formation characteristics

(POR)xp,ave = 16%	(POR)xp,max= 28.8	%(POR)xp, min = 8.9%
(POR)sec,ave = 1.98%	(POR)sec,max= 5.7%	
tave = $66.7x10^{-6}$ sec/ft		
tmax = $87x10^{-6}$ sec/ft		
tmin = $56x10^{-6}$ sec/ft		
Rt,ave = 8.6 ohm-m	Rt,max= 21 ohm-m	Rt,min= 3 ohm-m
Vsh,ave = 8.05%	Vsh,max= 49.2%	Vsh,min= 0.0%

Formation lithology (based on 98 feet of "higher permeability, higher porosity" unit), 61.0% dolomite, 35.0% limestone, and 4.0% sandstone.

Phase II Geophysical Logging

Phase II analysis consisted of a detailed site-specific evaluation of the injection/confining interval. Continuous Spinner Flowmeter logging (CSFL) and core analysis formed the basis of the study. Scanning Electron Microscope (SEM) analysis and formation brine/wastewater analysis were also conducted.

Continuous spinner flowmeter logging. The foregoing data were obtained exclusively from a static environment, i.e., no fluid injection into the well. For a quantitative evaluation of the response of the formation to "normal" or near-normal injection rates, a Continuous Spinner Flowmeter Log (CSFL) was run in WDW2. (An X-Y Caliper Log run prior to the CSFL provided borehole volumetric data to be used in conjunction with the CSFL data.) Again, as with the previous set of geophysical logs, borehole conditions in WDW2 restricted the interval available for logging. But work-over operations subsequent to the WDW2 logging permitted coverage of all anticipated injection zones as delineated by historical and phase I logging (fig. 23).

The CSFL data were used in two ways. First, the data enabled the delineation of specific injection zones and the calculation of the percentage of total flow into each zone. Second, the data were used to identify the lower boundary of fluid infiltration (i.e., the upper limit of the basal confining unit).

To evaluate the effect of varying injection rates, we recorded flow rates at three surficial injection rates: 75 gallons per minute (gpm), 100 gpm, and 150 gpm. The results are reported in table 5. Fluid loss is the percentage, on a volumetric basis, of fluid moving into a particular unit. For example, on average, 14 percent of the fluid flows into injection zone 1. The 150-gpm rate is the closest to the "average" waste injection rate (182 gpm) for WDW2 (see p. 58).

The repeatability of the flowmeter was verified by taking measurements as the flowmeter moved both up and down the borehole. With the flowmeter stationary, data were collected adjacent to suspected high permeability units and below the base of the anticipated injection horizon (2,594 ft KB from the other geophysical surveys). The validity of the results was checked by obtaining data with a stationary flowmeter in the 7-inch casing. At surficial injection rates of 75 gpm, 100 gpm,

Table 5 Fluid loss percentage calculated from CSFL

Injection zone no.	Depth (ft below KB)	Fluid Loss (%) injection rates (gpm)			
		75	100	150	Average
1	2448-2458	11	15	17	14
2	2552-2558	40	38	29	36
3	2584-2594	49	47	54	50

and 150 gpm, calculated flow rates in the 7-inch casing were 81 gpm, 107 gpm, and 163 gpm, respectively (margin of error less than 10%).

The effective interval of injection at the time of logging the CSFL (from the base of the 7-inch casing to the deepest depth of penetration of the logging tool) was from 2,437 to 2,614 feet KB. If conditions remain stable, fluid should infiltrate exclusively into the zones listed in table 5 and shown on figure 23. No flow was detected below 2,614 feet.

As shown on figure 23, data from the CSFL were not consistent with the interpretation of the geophysical logs. First, the interval from 2,468 to 2,496 feet was identified from both the historical and phase I logging as a potential injection zone, but the CSFL indicated an absence of flow into this interval. Second, data from the CSFL indicated that only a portion of the potential injection interval from 2,538 to 2,568 feet allowed substantial fluid infiltration. And third, on the basis solely of porosity and permeability data, zone 3 should have accepted less fluid than either zones 1 or 2;

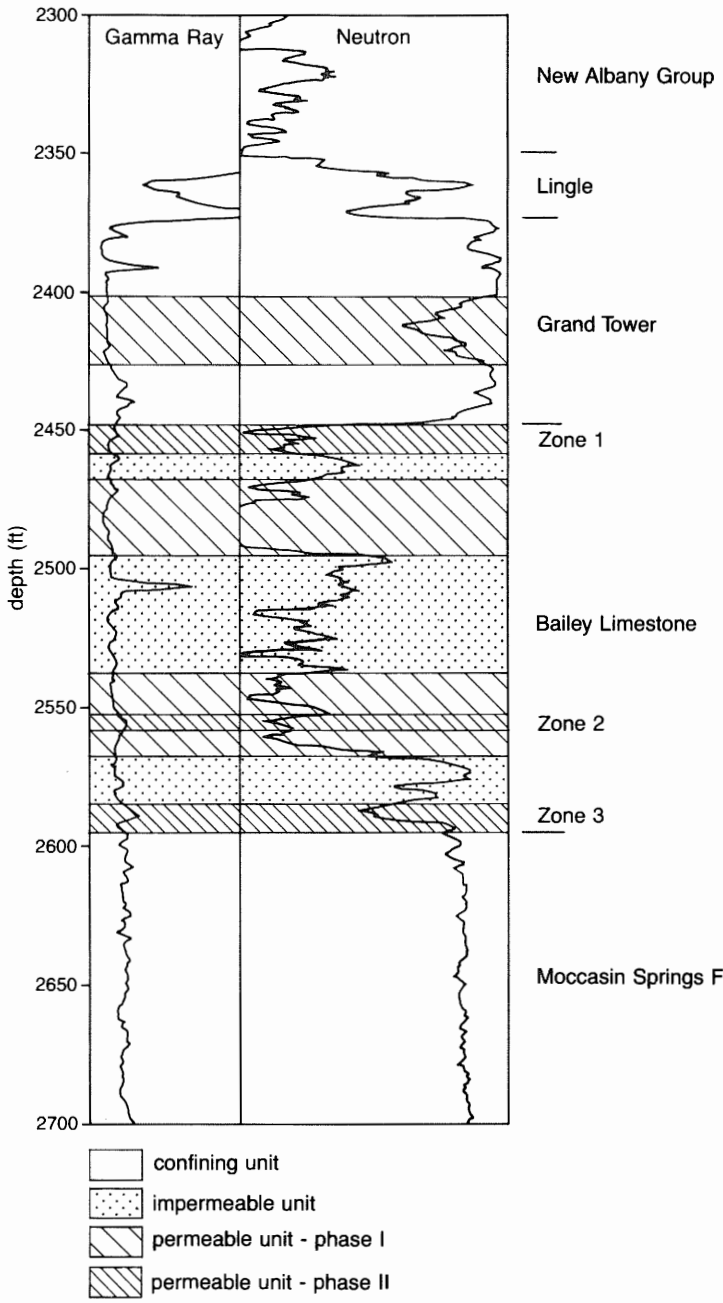

Figure 23 Injection system in WDW2 indicating permeable and impermeable units delinated after phase II logging.

however, this scenario was not supported by the CSFL data. In an effort to resolve these discrepancies and to obtain two additional parameters (quantitative permeability and bulk compressibility) essential to injection-interval evaluation, we conducted lab testing of sidewall cores.

Core retrieval and analysis. Several criteria were used to choose the coring zones. In order of decreasing priority, the selection criteria were to (1) cover all possible injection zones determined from the historical and phase I logging, (2) obtain cores from the anticipated lower confining unit indicated by logging data, and (3) cover a range of permeabilities and other physical properties present in the disposal horizon. Core depths are indicated in figure 24 and table 6.

Twenty-nine sidewall cores were retrieved with Gearhart's Hard Rock Coring tool. Gearhart Industry Inc. Corelab performed the core analysis. Additional core study was done at the ISGS. The core analysis provided data on quantitative permeability, bulk compressibility, and mineralogic composition, and provided a means to evaluate the accuracy of the downhole geophysical methods employed. The results of the core analysis are reported in table 7 and figures 25 and 26.

Table 6 Core location and analysis

1 Water permeabilities (kw) derived from air permeabilities (ka) by applying a Klinkenburg correction.
2 Separate test which yields Poisson's ratio, Young's modulus, and bulk compressibility (corrected for in situ pore and confining pressures).
3 Basic analysis and x-ray diffraction performed on all cores. Basic analysis consists of ka, total porosity, water saturation (Sw), and fluorescence. X-ray diffraction identifies all minerals that have an abundance of 1% or more by weight and the total clay percentage.

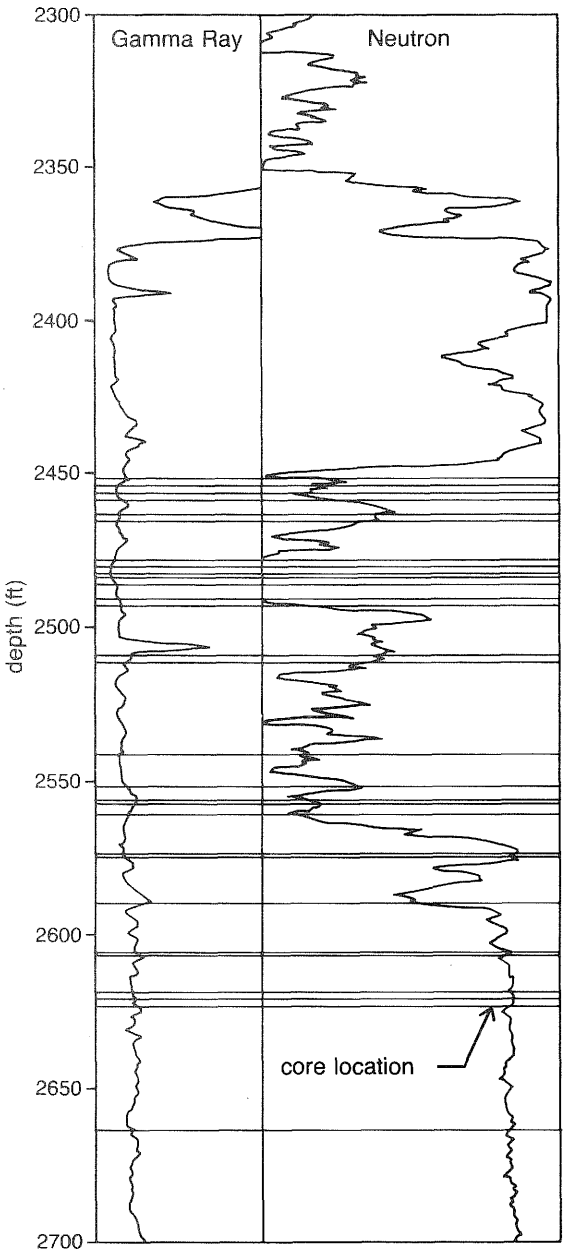

Figure 24 Core locations for WDW2.

Available data indicate that the discrepancies between the injection zones identified from phase I and phase II are due to the presence of brucite ($Mg[OH]_2$). The supporting data used to develop the brucite-formation hypothesis are summarized below and more fully described in appendix C.

Mineralogic analysis of sidewall cores identified brucite (up to 45% by weight) to be present in potential injection zones, as identified from phase I logging. Brucite, not present in the injection system prior to well operation, forms during waste injection. Brucite apparently formed in zones having the highest potential for fluid flow, as identified from phase I logging. Brucite formation does not reduce porosity (as identified from geophysical logs) but does reduce the permeability significantly. Flow rates in the different injection zones appear from CSFL results to be proportional to the brucite concentration within that zone, i.e., zones with higher brucite concentrations have lower flow rates.

The source of ions for brucite formation is not clear. The source of OH^- is the injected waste (pH > 12), but the source of Mg^{2+} is unclear. Two possible sources are the waste fluid or the dolomite within the injection zones.

Hydrogeology of the site. Having developed a hypothesis to explain brucite formation, we quantified the hydrogeologic characteristics of the injection system, which allowed the data to be used as parameter input for the numerical model. The disposal interval was divided into 12 units based on hydrogeologic characteristics (fig. 27 and table 8), using data derived from figure 23. These 12 units were used for differentiating the stratigraphic cross sections (figs. 17, 18, and 19). Local and regional stratigraphic/structural studies, presented in Stratigraphic and Structural Definition of the Injection System, page 23, were also considered to ensure that the units chosen were not localized anomalies (i.e., noncontinuous).

Table 8 lists the units and their associated characteristics. Permeability, air (ka) and water (kw), and bulk compressibility data were obtained from core analysis. Hydraulic conductivity (K) and specific storage (Ss) measurements were derived from these results. The porosity measurements (POR) were taken from table 2 (geophysical logging results) and core analysis results. Storativity (S) and transmissivity (T) data were calculated only for the three injection zones delineated previously (table 9). Units 2, 9, and 11 in table 8 correspond to injection zones 1, 2, and 3, respectively. The thicknesses (b) for units 2, 9, and 11 were determined from figure 27.

The three gas-storage field wells mentioned in Stratigraphic and Structural Definition of the Injection System, page 24, provided additional permeability data for the intervals corresponding to unit 1 and the overlying strata (above 2,402 feet KB). Values for vertical water permeabilities of

7.85×10^{-5} md (millidarcys) for the interval corresponding to unit 1 and 3.51×10^{-5} md for the overlying strata were obtained.

Long-Term Injection Test

A long-term injection test was conducted to obtain T and S values for the injection formation. An injection test is similar to a standard pump test except that water is injected into the well instead of being withdrawn from it.

The injection test started at 10 a.m., July 9, 1987, and was completed at 7 a.m., July 24, 1987. The test ended at this time because of a power outage scheduled by the power company. Velsicol

Table 9 Additional hydrogeological data for primary injection zones

Section	b (ft)	$S^c \times 10^{-6}$ (-)	$T^d \times 10^{-6}$ (cm^2 / sec)
2	10	8.14	161
8	6	2.96	3.44
10	10	5.79	1.35

Explanation for tables 8 and 9:

(a) $K = kw\rho g / \mu$

where

K = hydraulic conductivity
kw = water permeability (Klinkenburg corrected air permeability)
ρ = water density = 0.997 gm/cm^3*
g = acceleration due to gravity = 980 cm/sec^2
μ = water viscosity = 0.008705 gm/cm sec*

* temperature used to determine ρ and μ was taken to be 26°C. This came from Temperature Log run in WDW2 assuming the cooling effect due to past injection was extremely localized (see appendix A).

(b) $Ss = \rho g (\alpha + n\beta)$

where

Ss = specific storage
α = matrix bulk compressibility
β = fluid bulk compressibility* = 4.513×10^{-11} $cm\text{-}sec^2/g$
n= porosity

* temperature used to determine β was taken to be 26°C (see note above).

(c) $S = Ssb$

where

S = storativity
Ss = specific storage
b = zone thickness

(d) $T = Kb$

where

T = transmissivity
K = hydraulic conductivity
b = zone thickness

injected water from its stormwater retention ponds during the test. Table 10 shows the physical and chemical properties of the fluid injected during the in injection test (Velsicol, 1987). Table 11 shows the volume and rate of fluid injected. The average injection rate was 288.4 gpm.

Head data were collected at the DOW using a Stevens water level recorder (fig. 28). The water level recorder was set with a 1:1 gearing and an 8-day chart.

Data obtained from the DOW were analyzed by two techniques: Theis analysis and Cooper-Jacob analysis (see Todd 1980 or Freeze and Cherry 1979 for a detailed explanation of these techniques). Theis analysis is a curve-fitting technique; therefore, the T and S values obtained from this method depend on the analyst's judgment. The Cooper-Jacob technique is somewhat less subjective since the data plot is a straight line on semilog paper.

Table 10 Selected chemical and physical properties of water injected during injection test (Velsicol 1987)

Suspended solids	29 mg/L
Dissolved solids	1205 mg/L

7/23	24	424,211	294.4
7/24	24	419,352	291.0
Average		411,767	288.4

Table 12 Analysis of injection test

Method	S (-)	Transmissivity (m^2/min)
Theis	2.75×10^{-4}	0.385
Cooper-Jacob (r = 0.960)	2.47×10^{-4}	0.386

r = correlation coefficient for the linear regression

For the Cooper-Jacob technique, head buildup was plotted versus log time (fig. 29). Linear regression was used to calculate the parameters (S and t_o) for this method. An iterative approach was taken since the data used in the analysis depend on the outcome of the analysis. For the Cooper-Jacob method, u ($u = r^2S / (4Tt)$) must be less than to 0.01. From the definition of u and the value of T and S, a minimum time can be determined (i.e., only field data where $t > t_{min}$ can be used). Thus, an iterative technique was necessary to calculate T and S. Table 12 shows the results of the analyses (only the values for the final iteration of the Cooper-Jacob analysis are presented). Note the good agreement between the Theis and Cooper-Jacob analyses. The values obtained by the Cooper-Jacob technique are considered to be the more accurate since this technique is less subjective.

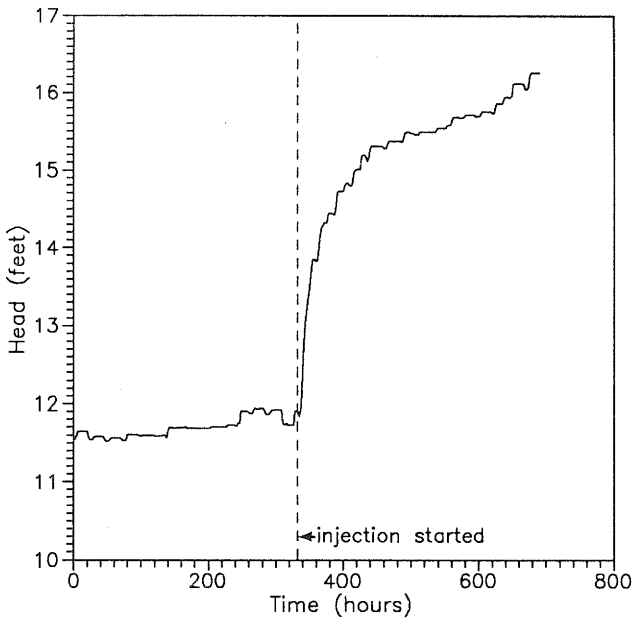

Figure 28 Water level record for DOW, including data from injection test.

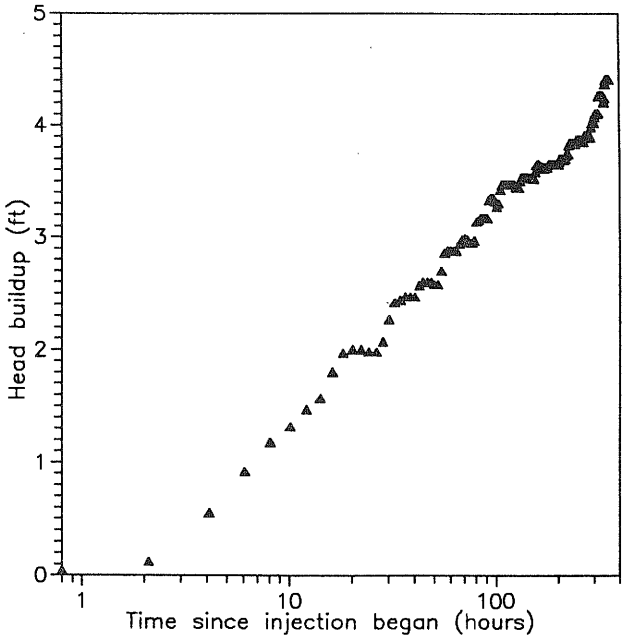

Figure 29 Plot of data used for Cooper-Jacob analysis.

4. NUMERICAL MODELING

Model Selection

Model selection is an important step in conducting a modeling investigation of a groundwater flow problem. The model should be able to handle all significant physical processes of the groundwater flow system. If the model does not incorporate these processes, it cannot be expected to simulate the field situation with any degree of accuracy.

The literature contains descriptions of many general and specialized numerical models. At the outset of this project, it was thought that a model capable of simulating three-dimensional (3D) flow and flow through complex hydrogeologic regimes would be required. Several 3D groundwater flow models have been developed, including the Sandia Waste Isolation Flow and Transport Model (SWIFT) (Reeves and Cranwell, 1981) and the Heat and Solute Transport Program (HST3D) (Kipp 1987). SWIFT and HST3D are finite difference groundwater flow and transport models that are independent modifications of SWIP (INTERCOMP, 1976). This original model, developed to model the effects of deep-well waste injection, includes sophisticated well functions rarely incorporated into other models. Although SWIFT and HST3D have a more general focus than does their predecessor, both models retain these well functions, and either model could be used for this project. Since a version of HST3D compatible with the Prime 9650 computer used in this project was available before a similar version of SWIFT (II), HST3D was selected.

Model Description

HST3D is a descendent of the Survey Waste Isolation Program (SWIP) written for the U.S. Geological Survey by INTERCOMP Resource Development and Engineering Consultants. HST3D represents a complete rewrite of SWIP with many major and minor modifications, improvements, and corrections.

Overview of Model

HST3D simulates saturated groundwater flow and associated heat and solute transport in three dimensions. The following equations are solved numerically: the saturated groundwater flow equation, formed from combining the conservation of total fluid mass and Darcy's Law for flow through porous media; the heat transport equation from the conservation of enthalpy for the fluid and porous medium; and the solute transport equation from the conservation of mass for a single solute, which may adsorb onto the porous medium and/or decay (Kipp 1987). These equations are coupled through the dependence of advective transport on the interstitial fluid velocity field, fluid viscosity on temperature and solute concentration, and fluid density on pressure, temperature, and solute concentration.

For the dependent variables of pressure, temperature, and mass fraction, numerical solutions are obtained successively using a set of modified equations that more directly link the original equations through the velocity, density, and viscosity coupling terms. Finite difference techniques are used for the spatial and temporal discretization of the equations. When supplied with appropriate boundary and initial conditions and system-parameter distributions, a wide variety of heat and solute transport simulations can be performed (Kipp 1987).

The basic source-sink term represents wells. A complex well-flow model may be used to simulate specified flow rate and pressure conditions at the land surface or within the aquifer, with or without pressure constraints. Types of boundary conditions include specified value, specified flux, leakage, heat conduction, an approximate free surface, and two types of aquifer influence functions. All boundary conditions may be functions of time (Kipp 1987).

Assumptions Incorporated into the Model

Since this project was concerned with simulation of fluid flow and not heat and/or contaminant transport, only the assumptions incorporated into the flow model will be discussed. Kipp (1987) incorporated the following assumptions into the partial differential equation describing groundwater flow:

- Groundwater fully saturates the porous medium within the region of groundwater flow.
- Groundwater flow is described by Darcy's Law.
- The porous medium and the fluid are compressible.
- The porosity and permeability are functions of space.
- The coordinate system is chosen to be aligned with the principal directions of permeability tensor so that this tensor is diagonal for anisotropic media.
- The coordinate system and the principal directions of the permeability tensor are orthogonal.
- The coordinate system is right-handed with the z-axis pointing vertically upward.
- The fluid viscosity is a function of space and time through dependence on temperature and solute concentration.
- Density-gradient diffusive fluxes of the bulk fluid are neglected relative to advective-mass fluxes.
- Dispersive-mass fluxes of the bulk fluid from spatial-velocity fluctuations are excluded.

Input Data

Input data required by HST3D for modeling fluid movement may be categorized as follows: hydrogeologic properties of the aquifer, physical dimensions of the aquifer, physical dimensions of the well(s), hydraulic properties of the well(s), and physical and chemical properties of the fluid. Additional input data are required for any attempts to model solute and/or heat transport.

Physical Configuration of the Injection System

As defined here, the injection system refers to the geologic deposits that constitute the injection zone and its associated confining units. The hydrogeology of the site is described in chapter 3. The physical dimensions and hydrogeologic properties of the injection system used as model input will be described where appropriate in each section.

Description of the Injection and Observation Wells

Waste Disposal Well 2 (WDW2) at the Velsicol Chemical Corporation's Marshall Plant was modeled. WDW2 is a packer-annulus-type well completed in Devonian limestone (fig. 30). Originally, the well was drilled to a total depth of 6,007 feet and was completed open-hole from 2,440 to 2,737 feet. Preceding the phase II field testing of the well, Velsicol completed extensive well workover procedures to remove debris, which had partially filled the well. These procedures included a high-pressure jet wash of the well bore. In addition to suspending and removing the debris in the well, the tool scoured the well bore. Thus it is assumed that the skin effect for this well would be negligible. Access for geophysical tools to total depth was blocked at 2,610 feet, presumably due to bridging of materials sloughed from the well face. However, the bridging probably did not plug the well from a hydraulic standpoint.

Located 506 meters due north of WDW2 is the Devonian Observation Well (DOW), which was completed open-hole starting near the top of the Devonian limestone (fig. 31). Total depth for this well is 2,580 feet. Water-level data were collected from this well during this project.

Physical and Chemical Properties of the Fluids

HST3D requires input of various physical properties of the fluids, including density, temperature, viscosity, and compressibility. These data are required for the fluid injected and the native fluid in the formation (brine). Fluid-compressibility data for injected wastes and/or brines were generally not available but were estimated on the basis of the chemical composition of these fluids. Much of these required input data were available from a database compiled by the ISGS.

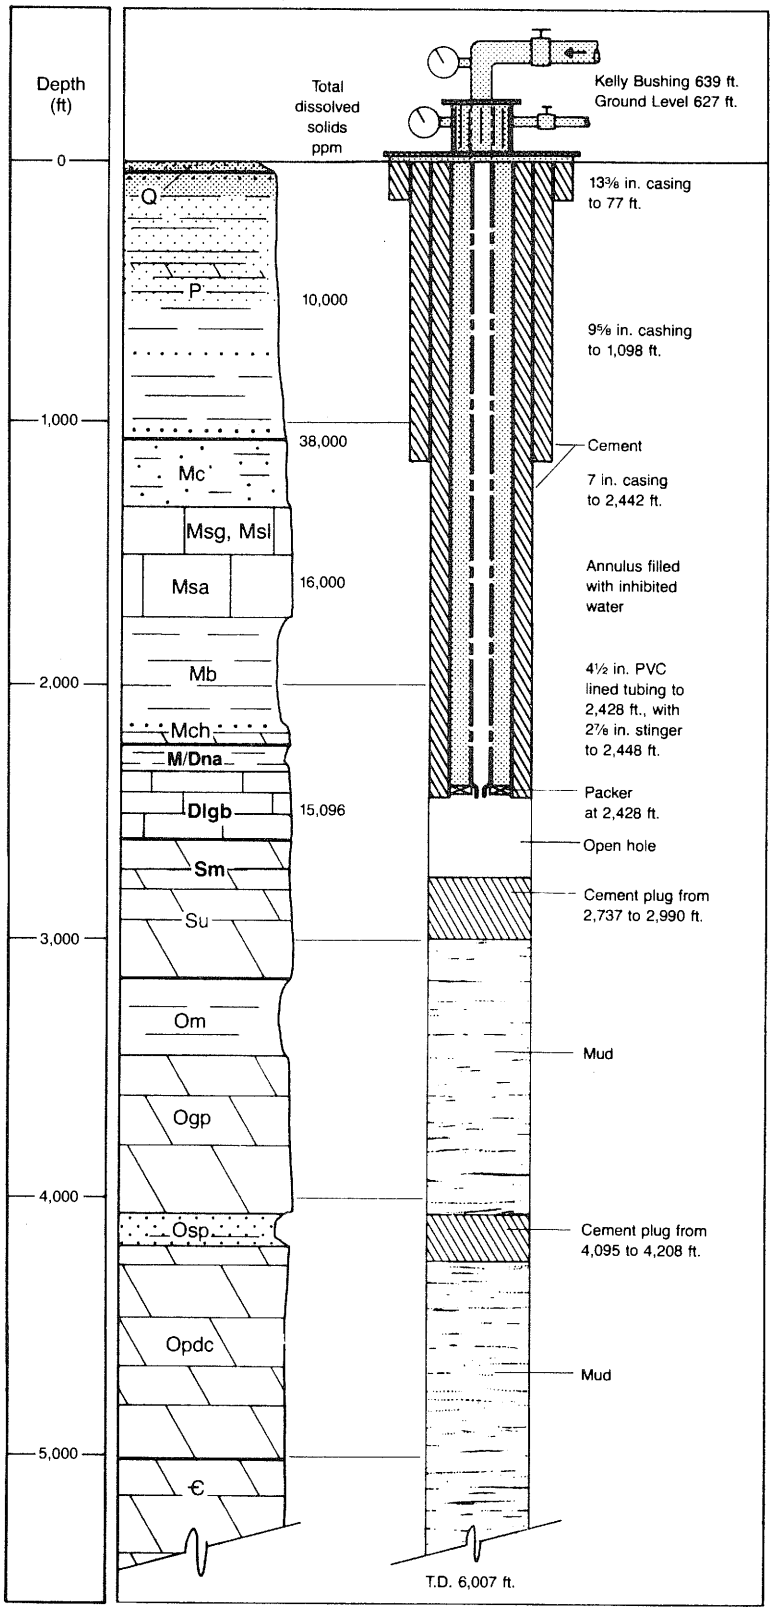

Figure 30 Schematic for WDW2 (modified from Brower et al. 1989).

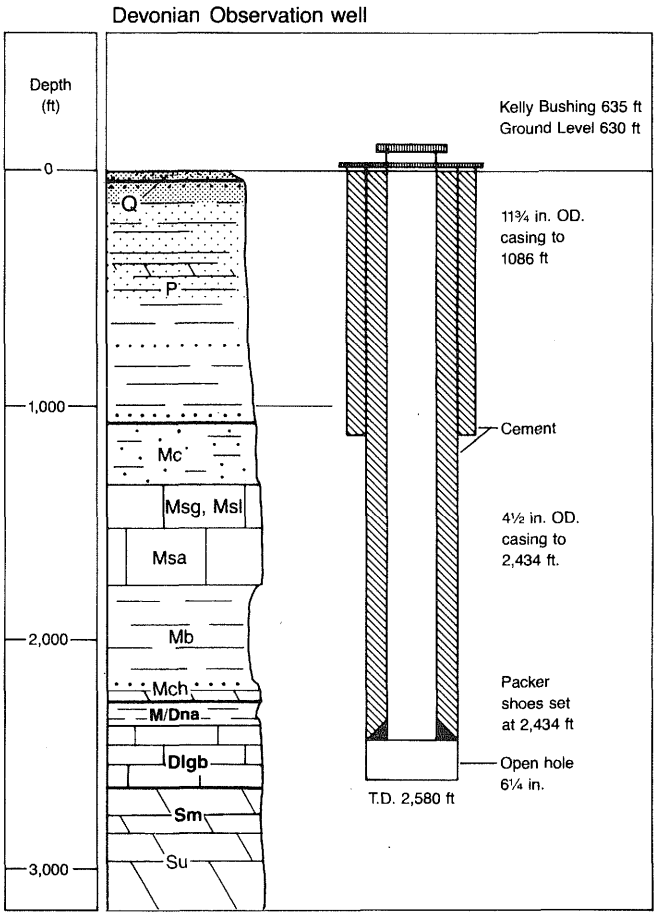

Figure 31 Schematic for DOW (Velsicol 1984).

General Parameters

Velsicol injected hazardous waste consisting of production wastewater and surface runoff water from on-site process areas. Chlorinated pesticides were produced at this site. The waste was highly alkaline (pH > 12) and contained pesticides and other chlorinated hydrocarbons. The relative concentrations of constituents in the waste were NaCl > NaOH > hexachlorocyclopentadiene (hex) > chlordane.

Velsicol has been required by permit to sample and analyze the waste injected into WDW2 and the brine from the DOW. Thus an extensive database of physical and chemical properties of the injected fluid and brine is available. This database was compiled by the ISGS and used extensively in this project. For WDW2, available data date back to early 1973, when operating reports were first required. Data for dissolved solids, specific gravity, and viscosity are presented in table 13.

Table 13 Selected parameters for fluids injected via WDW2

Parameter (unit)	Range	Average	Standard deviation	Number
Dissolved solids (mg/L)	200 - 254,000	38,346	35,388	671
Specific gravity (-)	0.9948 - 1.14	1.027	0.025	538
Viscosity (centipoise)	0.7161 - 0.9822	0.7857	0.0700	33

Data for dissolved solids in table 13 show the variability of the injected fluid, which is predominantly storm water runoff. Brower et al. (1989) attributed this variation in dissolved solids to variation of precipitation frequency and intensity.

A relationship between specific gravity and viscosity seems to exist (fig. 32). Linear regression of these variables produced a correlation coefficient of 0.873. If additional viscosity data had been available, this correlation might have improved.

The mean value for specific gravity of the waste was used as input for the numerical model. For comparison, Devonian brine sampled during construction of WDW2 had a specific gravity of 1.011. The linear relationship between viscosity and specific gravity was assumed to be valid; thus, viscosity was determined using the mean specific gravity of the waste (fig. 32).

All modeling was conducted under isothermal conditions. Although the temperature of the injected fluid varied throughout the year, it was assumed that the temperature of the formation would not change significantly from its mean temperature because of injection. The formation temperature was determined from a temperature log run down the DOW on December 18, 1986. The mean formation temperature was 34.4°C (94°F).

Compressibility of the Fluids

Lab-determined values for the compressibility of the waste and brine were not available; however, compressibility values for common saline solutions were available in the literature. Millero et al. (1974) published compressibility values for NaCl, $MgCl_2$, $NaSO_4$, and $MgSO_4$ as a function of temperature and molality. Figure 33 depicts the fluid compressibility in relation to temperature and molality for NaCl solutions.

Roy et al. (1989) characterized the brine and waste as predominantly NaCl solutions. Table 14 shows the chemical analysis of the Velsicol waste, Velsicol dilute waste, and Devonian brine. In this context, waste refers only to the fluids from the plant processes. Dilute waste, typically the fluid injected, comprises fluids from the plant processes and surface runoff. The sample of Devonian brine was obtained from the DOW in June 1987.

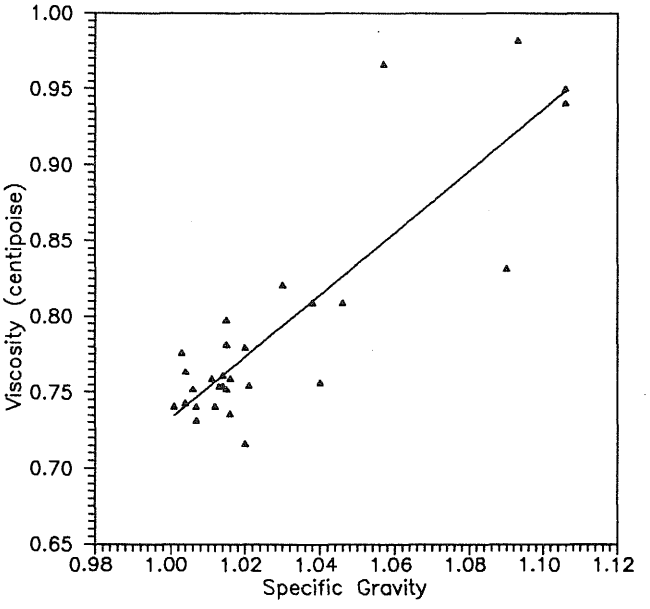

Figure 32 Relationship between waste viscosity and specific gravity.

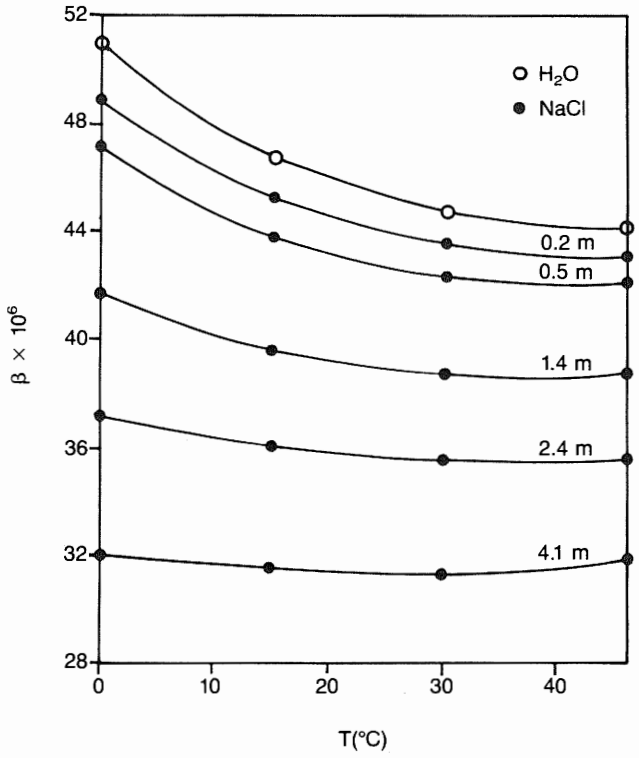

Figure 33 The compressibility of water and NaCl solutions versus temperature (Millero et al. 1974).

Table 14 Chemical analysis of waste and brine

Parameter (unit)	Waste	Dilute waste	Brine

Concentrations of the major anion and cation were used to determine the molality of each fluid. Compressibility of each fluid was determined on the basis of the molality and two assumptions: (1) that the temperature was 34.4°C and (2) that the fluids could be considered NaCl solutions. Table 15 shows the molality and compressibility of the three fluids.

Review of the TDS data for the waste and dilute waste indicated that the "average" waste injected into WDW2 (TDS = 38,346 mg/L) had a slightly higher TDS concentration than the dilute waste. Thus the compressibility of the "average" waste should be close to, but slightly lower than, the compressibility of the dilute waste. (See table 18 for the value used.)

Table 15 Compressibility of waste and brine

Fluid	Molality (moles/kg)	Compressibility (1/Pa)
Waste	3.76	3.185×10^{-10}
Dilute waste	0.799	4.105×10^{-10}
Brine	0.703	4.145×10^{-10}
Waste	—	4.46×10^{-10}

Volume of Injected Waste

Since waste injection began in March 1972, Velsicol (1987) reported that 1.4623×10^9 gallons of fluid have been injected via WDW2. Simple volumetric equations were used to determine the extent to which these fluids have moved within the injection zone.

Cross-plotted analysis of geophysical logs indicated that the thickness-averaged porosity of the injection zone is 12.5 percent. Assuming that waste has flowed through the entire thickness (174 ft) of the injection zone and radially from the well, the pore volume of the injection zone from WDW2 to the DOW (1,660 ft) is 1.406×10^9 gallons. Thus the cumulative volume of injected fluid is equivalent to 1.04 pore volumes. To account for this fact, model input of fluid data was based on the physical properties of the waste. In this project, only groundwater flow was simulated; thus, the properties of the fluid must be homogeneous throughout the injection system. To consider nonhomogeneous fluids, one would need to model solute transport.

Modeling Results

Most numerical modeling studies of groundwater flow include several modeling phases, which have also been followed in this study. First, verification of the model is conducted. In this stage, the model is used to simulate known analytical solutions. This phase is typically followed by history matching or model calibration. Here, the model was used to simulate field data, usually collected during a pump test. Sensitivity analysis generally follows model calibration. During this phase, the effect of pertinent parameters is quantified. The final stage is the prediction stage, which is an exercise in "what if." For example, what will the pressure buildup be at the well if a certain flow rate is continued for 30 years. The following discussion describes each of these phases for this project.

Model Verification

Model verification was necessary since HST3D was a new code. Verification allowed the modeler a chance to become familiar with this new model and to check the model accuracy versus analytical solutions. HST3D was verified using two analytical solutions: unsteady radial flow in a confined aquifer with constant pumping rate (Theis 1935), and unsteady radial flow in leaky systems with no storage in the semipervious layer at a constant pumping rate (Hantush 1964).

Theis Solution. Theis solution is an analytical solution for unsteady radial flow in confined aquifers. This solution is readily available in any groundwater text and is not repeated here. Input data for the analytical solution and HST3D are listed in table 16.

A radial coordinate system was used to discretize the groundwater flow domain: 50 nodes in the r-direction and 20 nodes in the z-direction. The radius of the aquifer simulated was 24,960 m. No-flow conditions were applied at all boundaries.

Figure 34 shows the drawdown at a point 100 m from the pumping well determined by numerical and analytical methods. The two solutions are identical.

Leaky Aquifer Solution . HST3D was also verified against an analytical solution for wells in leaky systems without storage in the semipervious layer (no storage in the semipervious is an as-

aquifer thickness, b = 3.05 m hydraulic conductivity, K = 3.29 x 10^{-4} m/sec porosity, n = 0.20 matrix compressibility, α = 3.34 x 10^{-8} Pa^{-1} fluid compressibility, β = 4.53 x 10^{-10} Pa^{-1} viscosity, μ = 0.001 kg/m-sec fluid density, ρ = 999.5 kg/m^3 pumping rate, q = 3.00 x 10^{-3} m^3/sec	transmissivity, T = 0.001 m^2/sec storativity, S = 0.001 pumping rate, q = 3.0 x 10^{-3} m^3/sec

sumption inherent to HST3D) (Hantush 1964). A radial coordinate system was used to discretize the aquifer: 50 nodes in the r-direction and 5 nodes in the z-direction. No-flow conditions were applied at the lower and radial boundaries. A leaky aquifer boundary condition is applied at the top boundary. The remaining input data for this simulation are listed in table 17.

The drawdown for a well 20 m from the pumping well was determined using the analytical and numerical solutions (fig. 35). The numerical solution tends to slightly underestimate the drawdown. These results are closer to the analytical solution than those reported by Ward et al. (1984) and are considered to be acceptable.

Model Calibration

Data used for model calibration (history matching) were obtained from the long-term injection test described in chapter 3 (p. 42). and plotted on figure 28. The conceptual model for the injection system was based on data presented in Long-Term Injection Test (p. 42) and is shown on figure 36. The hydraulic conductivity and physical dimensions in the vertical direction are also depicted on this figure. Other pertinent input data are listed in table 18. The injection system was discretized with radial coordinates: 60 nodes in the r-direction and 22 nodes in the z-direction.

No-flow conditions were applied at the top and bottom boundaries, while an aquifer influence was applied at the radial boundary.

Kipp (1986) describes the use of aquifer influence boundary conditions (AIF BC) as a simple, but approximate, method for embedding an inner region of groundwater simulation within a larger region where groundwater flow may be treated in an approximate fashion. The use of aquifer influence functions reduces the size of the computational grid with a corresponding reduction in computer storage and execution time.

The natural hydraulic gradient of the Devonian limestone is very low (see p. 32); thus, the hydraulics of the injection well will dominate the groundwater hydraulics in the area surrounding the well. The flow rate across an AIF boundary is a function of the potentiometric head and hydrogeologic characteristics of the aquifer. The use of the AIF BC was favored over a specified head or flow-type BC, since the AIF is a more accurate representation of the hydraulics of the injection system.

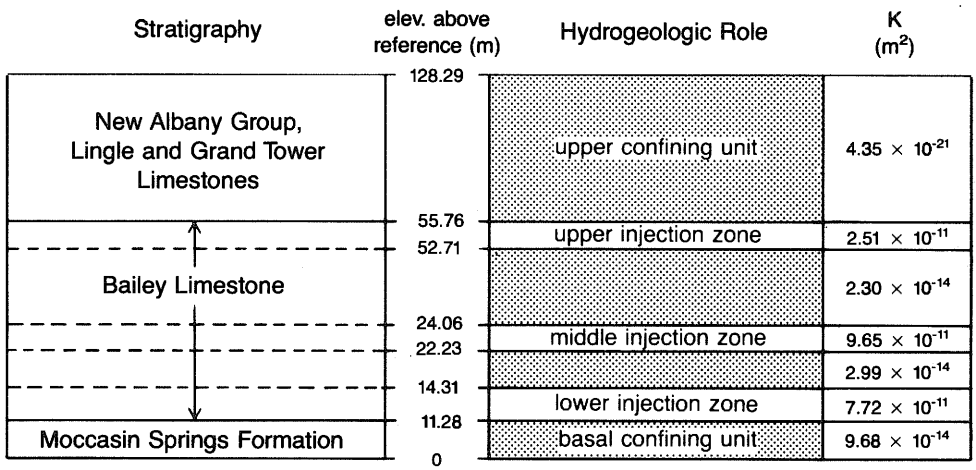

Figure 36 Conceptual model 1 of the injection system.

The T and S values calculated on the basis of input data, as well as the values determined from field testing, are presented in table 19. The input data and field data match reasonably well. Closer agreement of the field and model T and S values probably could have been obtained with minor adjustments to the input data (chiefly K, α, and β); however, the T and S values used were considered satisfactory.

The model values for T and S were even more satisfactory considering that two of the chief input parameters, α and β, are consistent with published values. Fluid compressibility (β) has been previously discussed (p. 52).

Table 19 Comparison of transmissivity (T) and storativity (S) values

	Field test	**HST3D**
T (m^2/min)	0.386	0.373
S (-)	2.47×10^{-4}	2.65×10^{-4}

Our rock compressibility (α) values also agreed with values in the literature. Birch (1966) reports that $\alpha = 1.22 \times 10^{-11}$ Pa^{-1} for dolomite. Domenico and Mifflin (1965) report α for sound rock ranges from 10^{-9} to 10^{-10} Pa^{-1}, while α for jointed rock ranges from 10^{-8} to 10^{-10} Pa^{-1}. Since secondary porosity was present in the cores retrieved, one would have expected that α for the dolomite at the study site would be slightly greater than $\alpha = 1.22 \times 10^{-11}$ Pa^{-1}. In fact, the values of the cores tested range from 1.55×10^{-10} to 3.26×10^{-11} Pa^{-1}. Thus the use of $\alpha = 4.50 \times 10^{-10}$ Pa^{-1} for model calibration seemed reasonable. As discussed in appendix C, the scanning electron microscopy (SEM) work indicated that secondary porosity was present, primarily in the form of vugginess and some localized microfractures. The microfractures were very small and tended to be interconnected. Because of the close spacing and size of the microfractures, modeling flow through this geologic material as flow through porous media was considered to be a valid assumption.

The intrinsic permeability values for the three injection zones ranged from 2.5×10^{-11} to 9.7×10^{-11} m^2 (25.4 to 97.8 darcys). Schmoker et al. (1985) summarized data for limestone and dolomite petroleum reservoirs throughout the United States. These authors report that only 11 percent of all dolomite reservoirs exceed 0.1 darcy. Freeze and Cherry (1979) list 0.2 darcy as an upper permeability limit for limestone and dolomite. Clearly, the permeability values for the injection zones seem to be quite high. The permeabilities used as model input were based on the results of the injection test and were higher than the laboratory-determined permeabilities. There appear to be two explanations for the apparent high permeability values. First, the permeability values were actually calculated from transmissivity values and thickness of "permeable" units of the aquifer. The thickness of these units could have been underestimated. Another possibility was that the cores may not be representative of the overall injection system. Greater emphasis was placed on the results of the injection test, since this is an in situ measurement of the system.

In addition to aquifer transmissivity, another control on specifying intrinsic permeability was the results of the flowmeter survey conducted during phase II of the field experiments. The intrinsic permeability of the three injection zones was adjusted so that the flow into each of these three zones matched the flow profile defined by the flowmeter. Thus in the model, 48.1 percent of the injected fluid flowed into the lower injection zone, 36.2 percent into the middle zone, and 15.7 percent into the upper zone.

Figure 37 depicts the head build-up at the DOW during the injection test and the buildup predicted by HST3D versus time. The model overpredicted the head buildup at times by less than 20 hours; however, the results at later times are very close. Oscillation of the head buildup (field data) is also evident in figure 37. This oscillation is believed to be a manifestation of earth tides and not a variation in the pumping rate.

Matching model results with the later field results was considered more important because the main use of the model was to predict long-term effects of injection. The input data were reasonable, and the predicted head buildup matched reasonably well the head buildup observed in the field; therefore, model calibration was deemed successful.

Sensitivity Analysis

A rigorous sensitivity analysis as described by Yeh (1986) was not conducted. The sensitivity analysis conducted here involved varying significant parameters and noting the effect of this variation on head buildup (Δh) at the DOW, the parameter of interest. The significance of various parameters (i.e., injection rate, hydraulic conductivity) was observed during the two previous stages of this project. Based on these observations, sensitivity analysis was conducted for the following parameters: boundary conditions, injection rate, rock compressibility, fluid compressibility, hydraulic conductivity, and anisotropy. The sensitivity analysis is summarized here and described in detail in appendix D.

Injection rate and hydraulic conductivity were the most sensitive input parameters. That is, a given change in injection rate or hydraulic conductivity would produce the largest change in Δh observed at the DOW. The type of boundary condition and the location of the boundary could also significantly affect the head buildup predicted by the model. In decreasing order, the most sensitive parameters were injection rate and hydraulic conductivity, rock compressibility, anisotropy, and fluid compressibility.

Model Projections for Long-Term Injection

Using the conceptual model developed during the model calibration phase, we investigated the effects of long-term, continuous injection at two rates: 1.150×10^{-2} and 2.208×10^{-2} m^3/sec. The first injection rate is the "average" rate at which the company injected waste during the life of the well. This was calculated by dividing the cumulative volume of waste injected by the length of operation for WDW2. The second injection rate is the maximum average injection rate permitted by the Illinois Environmental Protection Agency (IEPA 1987).

Embedded in this calculation of the "average" injection rate is the assumption that the well was operated on a continual basis; however, WDW2 was not in operation continually. A larger head buildup in the injection system would be produced by assuming continuous (24-hour) operation because pressure in the injection system would never bleed off.

HST3D was used to predict the head buildup in the injection system over a 30-year period. The decline in head was also modeled for an additional 30-year postinjection period. Thirty years was chosen since this is typically the length of service for an injection well. Because of problems experienced with HST3D, the injection rate during the postinjection period could not be set to zero. During the postinjection period, the injection rate was set as low as possible, $q = 1.82 \times 10^{-4}$ m^3/sec. Figure 38 shows the head buildup in relation to radial distance from the injection well after 10,927 days (30 years). At the DOW, Δh after this time is 0.03 m. Thus, use of $q = 1.82 \times 10^{-4}$ m^3/sec during the postinjection period did not significantly impact the pressure decline during the postinjection period.

Injection Scenario 1

Injection scenario 1 is injection for 30 years at a rate of 1.150×10^{-2} m^3/sec, followed by a postinjection period in which $q = 1.82 \times 10^{-4}$ m^3/sec. Figure 39 shows the response of the injection system during both 30-year periods (262,980 hours each). Head buildup at the DOW increases exponentially. After 30 years of injection, $\Delta h = 1.61$ m at the DOW. In terms of Δh, steady state was approached but not reached. The head buildup at the DOW also dropped exponentially. Approximately 900 hours after the change in the injection rate, the head buildup was approximately half of its maximum value. Nearly 7.5 years (66,000 hours) after the change in the injection rate,

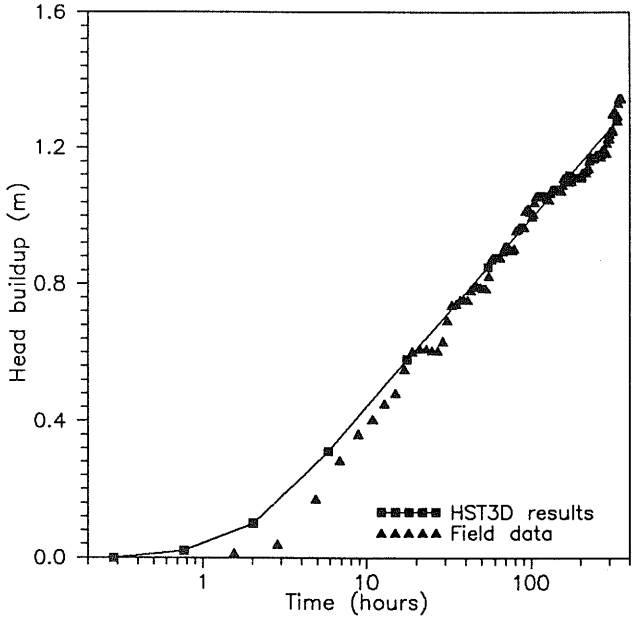

Figure 37 (left) Comparison of model-predicted Δh versus field data for DOW.

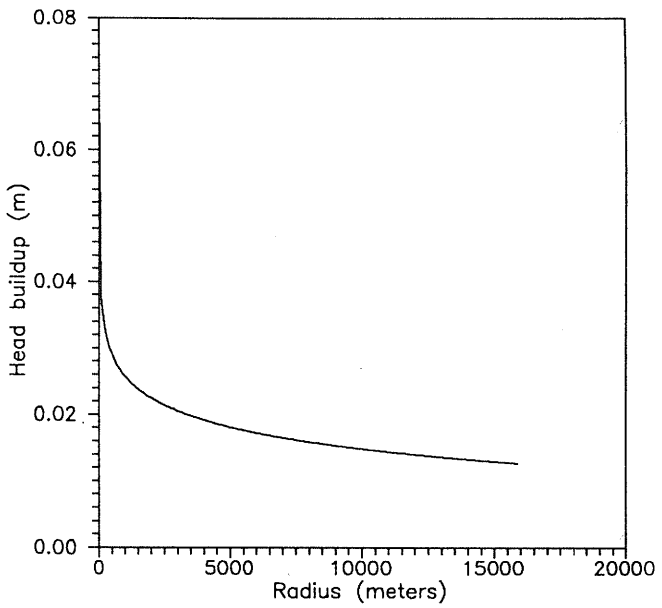

Figure 38 Head buildup versus radial distance from WDW2 $q = 1.82 \times 10^{-4}$ m^3/sec.

the head buildup was only 0.01 m, after correcting for Δh due to injection at $q = 1.82 \times 10^{-4}$ m^3/sec. During the 30-year postinjection period, the head buildup did not reduce to 0.00 m.

Injection Scenario 2

During the second injection scenario, the effects of injection for 30 years at $q = 2.208 \times 10^{-2}$ m^3/sec were investigated. A postinjection period followed during which $q = 1.82 \times 10^{-4}$ m^3/sec. Figure 40 shows the head buildup at the DOW. The results were similar to the results for injection scenario 1. The head buildup increased exponentially to a maximum Δh = 3.20 m after 30 years of injection. Also, after the injection rate was reduced, the head fell exponentially. The head buildup approached but did not go to 0.00 m during the postinjection period.

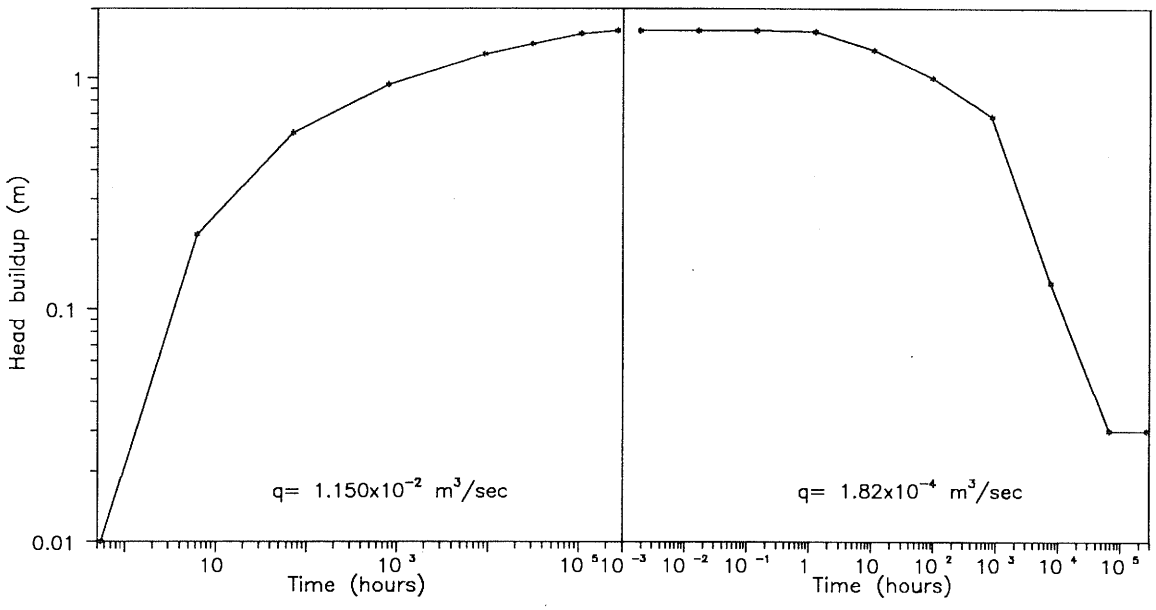

Figure 39 Injection scenario 1: head buildup and decline with time at the DOW.

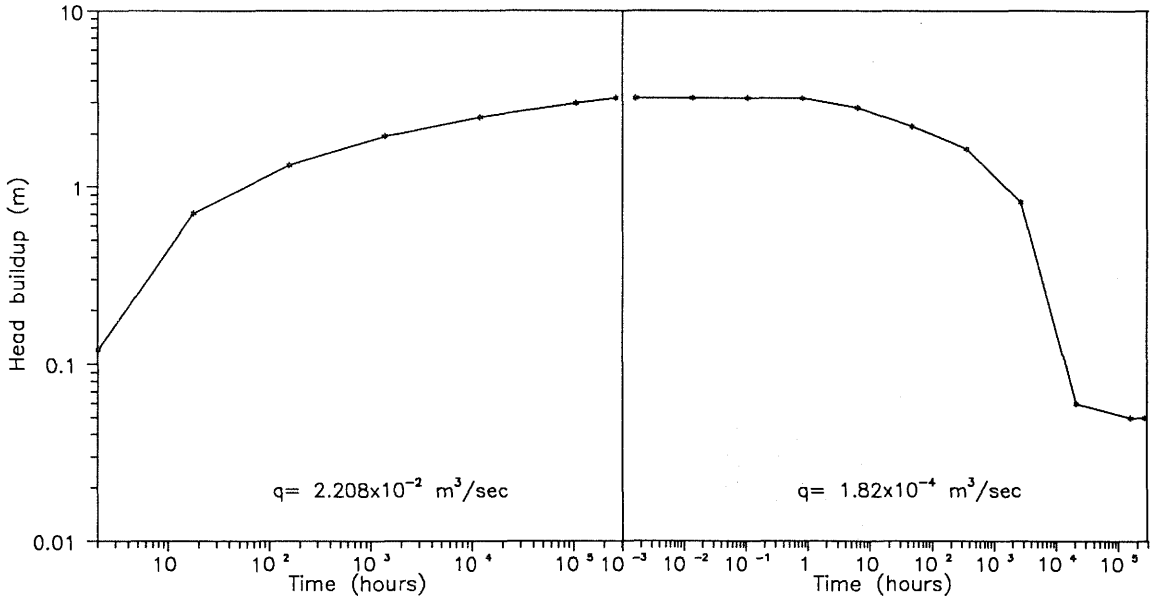

Figure 40 Injection scenario 2: head buildup and decline with time at the DOW.

Figure 41 shows the head buildup at the WDW2 during the injection and postinjection periods. The results were similar to the results shown in figure 40 except the magnitude of the head buildup was greater at the injection well. After 30 years of injection, Δh at WDW2 was 7.88 m. For comparison, Δh at WDW2 for injection scenario 1 was 4.22 m.

Maximum hydraulic pressure was 7.081x10^6 Pa (1,027 psi) and occurred at the bottom of the well after 30 years of injection under injection scenario 2. The pressure at the base of the confining layer equaled 6.687x10^6 Pa (970 psi). The pressure increase due to 30 years of injection was 7.73x10^4 and 6.69x10^4 Pa at the bottom of the well and the base of the confining unit, respectively. The pressures resulting from injection scenario 1 (q = 1.150x10^{-2} m^3/sec) were slightly lower than those listed here.

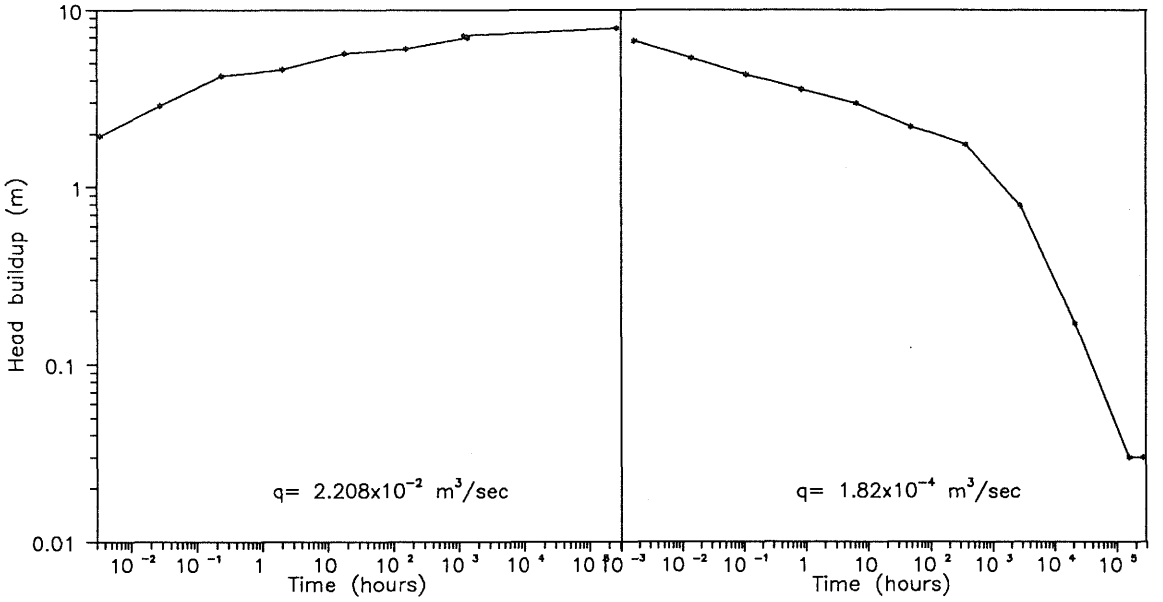

Figure 41 Injection scenario 2: head buildup and decline with time at WDW2.

In Illinois, the hydraulic fracture gradient is generally considered to be equal to $1.5x10^4$ Pa/m (0.65 psi/ft). Using this value, the hydraulic pressure necessary to initiate fractures was calculated as 1.19×10^7 Pa (1,694 psi) for the bottom of the well (depth = 794.3 m) and as $1.12x10^7$ Pa (1,591 psi) for the base of the confining unit (746.2 m). Thus pressures due to 30 years of continuous injection at the maximum permitted injection rate were much less than the pressure calculated to initiate hydraulic fracturing.

Hypothetical Conduits

During this final phase of modeling, the hydraulic response due to the presence of hypothetical conduits was investigated throughout the injection system. Jones and Haimson (1986) describe some hypothetical conduits pertinent to underground injection. These conduits, which allow fluid movement from the injection zone, include abandoned wells, microannuli at the injection well, and permeable fault zones. Time constraints restricted the investigation to the effect of a microannulus at the injection well. Accomplishing this task required numerical modeling to evaluate whether the pressure response in the injection system or in an overlying unit could be used to identify fluid movement from the injection zone. Three monitoring strategies were evaluated: monitoring at the injection well (WDW2), at the observation well (DOW), and in the overlying aquifer.

A new conceptual model of the site hydrogeology was developed for this task (fig. 42). A thicker sequence of geologic materials than that previously used included the Devonian limestones, the overlying New Albany Shale (a confining unit), the "Carper sand" (a permeable unit), and the Borden Siltstone (another confining unit). Since "Carper sand" lies near the base of Borden Siltstone, for purposes of modeling, it is considered the basal horizon of this formation. Hydrogeologic characteristics for these units appear on figure 42.

For this conceptual model, the head buildups at the injection and monitoring wells were slightly lower than the buildups used in the original model; however, the results were considered acceptable. The slight decrease (0.03 m at the DOW) was probably due to the greater thickness of compressible geologic materials for the conceptual model.

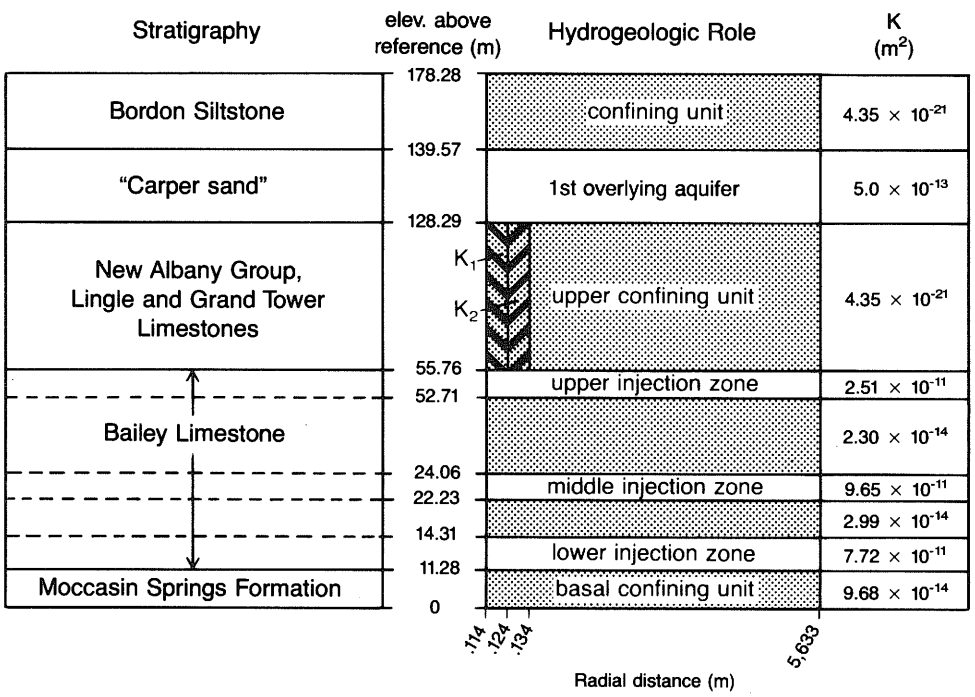

Figure 42 Conceptual model 2 of the injection system

Modeling Results: Hypothetical Conduit Scenario

In this scenario, a microannulus was assumed to have developed at the injection well. Extending from the top of the uppermost injection zone to the base of the Carper, the microannulus connected these two permeable units (fig. 42) and was input into the model as two zones. The first zone was considered the microannulus, and the second zone, a transition between the microannulus and the New Albany Shale. Both zones were 0.01 m thick and discretized using three nodes. Several runs were made, with different zone permeabilities (table 20). CT3DB1 was the baseline run used for comparison.

Table 20 Permeability (m^2) of the microannulus

Run	Microannulus (K1)	Transition zone (K2)
CT3DB1	4.35×10^{-21}	4.35×10^{-21}*
CT3DB2	1.00×10^{-12}	1.00×10^{-14}
CT3DB3	1.00×10^{-10}	1.00×10^{-12}
CT3DB5	1.00×10^{-9}	1.00×10^{-11}
CT3DB4	1.00×10^{-8}	1.00×10^{-10}

* same permeability as New Albany shale.

For this series of model runs, the maximum permitted injection rate ($q = 2.208 \times 10^{-2}$ m^3/sec) was used to maximize the pressure gradients in the injection system. Injection continued at this rate for 365 days. Because the "Carper sand" does not produce water or hydrocarbons, hydrogeologic data for this unit are rare. On the basis of interpretations of geophysical logs from wells near Marshall, which indicated that the Carper is a permeable sandstone, permeability was assumed to be 5.0×10^{-13} m^2.

For analysis of results, a head difference of 0.05 m, when compared with results of CT3DB1, was considered monitorable. Differences of less than 0.05 m were not considered sufficient to be monitored because of errors in measurement, head fluctuations due to earth and/or barometric tides, and related factors.

Head buildup in relation to time is shown for WDW2 (fig. 43), DOW (fig. 44), and the base of the Carper at WDW2 (fig. 45). As the permeability of the microannulus increased, the head buildup at WDW2 decreased slightly. For CT3DB4 ($K1 = 1.00 \times 10^{-8}$ m^2), difference in head buildup was -0.23 m after 1 year. Head buildup for the other cases were lower— for instance, Δh = -0.10 m when $K1 = 1.00 \times 10^{-10}$ m^2. A change in the head build-up of this magnitude at an operating injection well might not be monitorable because of head buildup associated with other factors, such as wellbore plugging and pipe friction increases.

For the five cases investigated, no monitorable difference in head buildup was observed at the DOW (fig. 44). For CT3DB4 ($K1 = 1.00 \times 10^{-8}$), head buildup was lower than the other cases by just 0.01 m after 365 days. Thus monitoring the DOW would not detect the leak at the microannulus. Monitorable differences in head buildup were predicted at the base of the Carper in three of the four cases. For CT3DB3, the difference after 365 days was 0.08 m. The differences after 365 days were greater for CT3DB5 (0.77 m) and CT3DB4 (3.98 m). The radial extent of head buildup at the base of the Carper varied for each of the cases. For CT3DB5, it was approximately 100 m, and for CT3DB4, more than 6,000 m (fig. 46).

In summary, monitoring the DOW would not reveal the presence of a leaky microannulus, in part because of the distance between the injection and observation wells. Monitoring the injection well might reveal a leaky microannulus, but the differences in head buildup for the cases investigated might be masked by well bore plugging, corrosion buildup in the tubing, and other related factors. Finally, monitoring in the overlying aquifer appears to be the best alternative, but it depends on the hydraulic conductivity of the microannulus. As the hydraulic conductivity of the hypothetical

conduit increases, the volume of fluid moving into the overlying aquifer and the head buildup also increases. The head buildup observed in the Carper is also a function of its hydraulic conductivity. Lower Δh would be observed if the Carper were more permeable. On the other hand, higher Δh would be observed over a smaller area if the Carper had a lower hydraulic conductivity.

5. SUMMARY AND CONCLUSIONS

Evaluation of Injection Scenarios

Available records and logs pertinent to the injection system were studied, hydraulic tests were conducted, geophysical logs were run, and other tests were conducted on-site to determine the hydrogeologic characteristics of the injection system. Regional and site-specific descriptions of the system's stratigraphy, structural geology, and hydrogeology were generated from analyses of these logs and test results. These descriptions formed the basis of input for the numerical groundwater flow model (HST3D) used to investigate the hydraulic effects of injection upon the injection system. Other input included data on the physical and chemical characteristics of the injected wastewater and the native brine in the injection system.

Before the effects of various injection scenarios were investigated, HST3D was verified with respect to two analytical solutions (figs. 34 and 35) and calibrated with respect to data collected during an injection test (fig. 37). Both verification and calibration were considered satisfactory.

Once calibrated, the model was used to predict the effects of various injection scenarios. The effect of long-term injection was investigated at two constant injection rates: the average historical rate (1.150×10^{-2} m^3/sec) and the maximum average permitted rate (2.208×10^{-2} m^3/sec). Under both scenarios, significant head buildup was observed at the injection well and radially from it. During the simulated 30-year injection period, steady state was approached but not obtained during either injection scenario. During the subsequent 30-year postinjection period, decrease in head buildup was fairly rapid—dropping to half in less than 2,000 hours for both scenarios. The maximum hydraulic pressures at the bottom of the well and at the base of the upper confining unit were significantly lower than the pressures calculated to initiate hydraulic fracturing.

The continuity of the regional stratigraphy and its qualitative permeability were determined from the regional and site-specific study. Numerical modeling indicated that the pressures resulting from waste injection were lower than pressures calculated to initiate hydraulic fracturing; thus new fractures would not be initiated. From a hydraulic viewpoint, therefore, waste injected within this injection system would be contained and would be considered protective of human health and the environment for the two injection scenarios investigated.

These results are based on an assumption that hydraulic conductivity remains constant. However, from available data it appears that the high pH of the injected wastewater causes it to react with the dolomite present in the injection zones, forming brucite ($Mg[OH]_2$), which reduces the hydraulic conductivity of the injection zone. Apparently, greater amounts of brucite formed in the zones where there was a greater flow of fluids; thus the zones with higher permeability were affected first. This hypothesis must be verified by additional work, which is beyond the scope of this project. At the study site, the long-term effect of this decrease in permeability on injectivity needs to be investigated. Any further decrease in the hydraulic conductivity of the injection zones will invalidate the results of the numerical modeling conducted for this study. In addition, any reduction in hydraulic conductivity of the injection zones will most likely cause an increase in hydraulic pressure if the injection rate remains constant. In such a case, hydraulic fracturing may be of concern.

Evaluation of Monitoring Strategies

The model was also used to investigate the hydraulic response throughout the injection system when a hypothetical conduit was introduced. In this scenario, a microannulus at the injection well was introduced, hydraulically connecting the uppermost injection zone and an aquifer immediately overlying the upper confining unit.

Model results were reported in terms of difference in head build-up when the microannulus was and was not present. At the WDW2, Δh (-0.23 m) was greatest for the scenario with the greatest microannulus permeability ($1x10^{-8}$ m^2). A difference of this magnitude at an operating well would be considered unmonitorable because of interferences such as increased Δh resulting from well bore plugging or tubing corrosion. At the DOW, Δh was considered too low to be monitorable. The difference in the overlying aquifer (Carper sand) was considered monitorable for the microannulus permeability greater than or equal to $1x10^{-10}$ m^2. The head buildup in the Carper is a function of its hydraulic conductivity, the hydraulic conductivity of the microannulus, and the radial distance from the microannulus. Thus from a practical standpoint and for the scenario modeled, the overlying aquifer is the only viable location for hydraulically monitoring leakage via the microannulus.

APPENDIX A. THEORY AND PRACTICAL APPLICATION OF GEOPHYSICAL LOGGING INSTRUMENTS

Geophysical logging was used in this study to investigate the site and regional hydrogeology, and this section briefly explains the basic operational theory and applications of the geophysical tools used. Comprehensive coverage of every aspect of tool theory or all possible applications is beyond the scope of this project. These tools and their many applications are discussed in greater detail in Bateman 1985a, Bateman 1985b, Helander 1983, Leach et al. 1974, Curtis 1966, Peebler, Hallenburg 1984, Dobrin 1976, Kovacs and Associates 1981, Pickett 1977, Hilchie 1977, Brock 1984a, Brock 1984b, Rider 1986, Gearhart, Gearhart 1983, Dresser Atlas 1981, Schlumberger 1984, Schlumberger 1985, Dresser Atlas 1985a, Dresser Atlas 1985b, Dresser Atlas 1985c, Prasada Rao 1985, Keys and MacCary 1971, and Martin 1982. The discussion below draws liberally from these references.

Caliper Log (CL)

The Caliper Log tool is a theoretically uncomplicated instrument. Most tools still rely on a single or a series of potentiometers (fig. A-1). The potentiometers respond to a number of arms (caliper arms), which transmit information about the borehole environment to the potentiometer actuator. This information is relayed as a series of pulses to the surface recording equipment, which then processes the data.

There are a number of different arm configurations with the CL tool. For the purposes of injection/confining interval evaluation, the one- and four-arm tools are appropriate.

For applications that utilize the numerical CL data, such as calculations involving the Flowmeter Log (FL), the more sensitive four-arm CL tool is employed. For other applications, such as mudcake and washout location and general borehole conditions, a one-arm CL tool (usually run in mechanical combination with another device, such as an Neutron Log, Density Log, or Permeability Log) is utilized almost invariably.

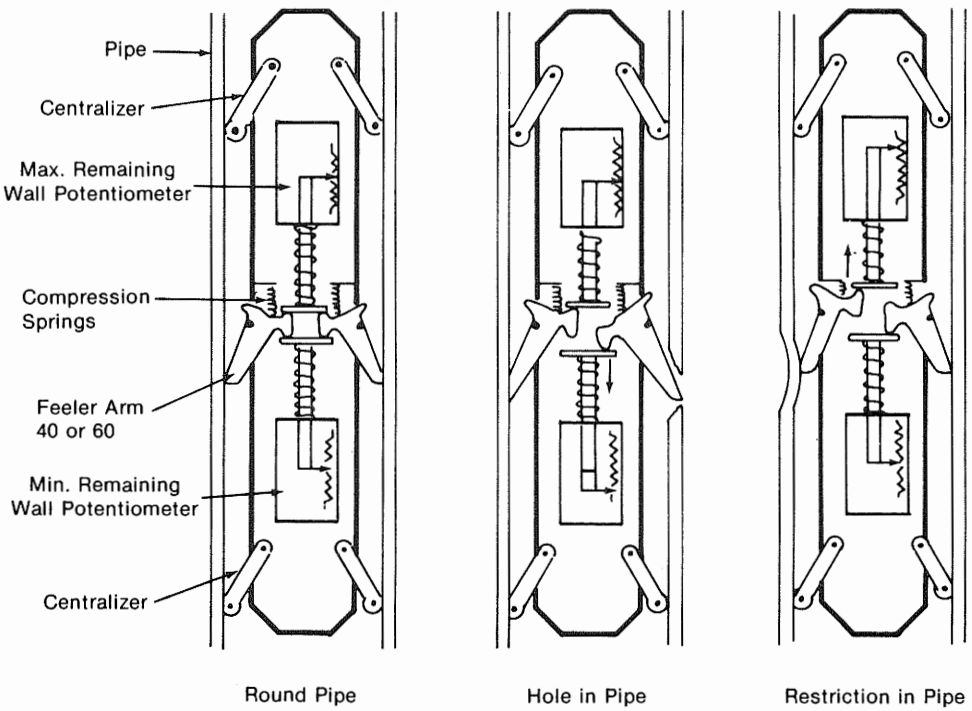

Figure A-1 Caliper Log tool that utilizes a dual potentiometer configuration (from Dresser Atlas 1985c)

Flowmeter Log (FL)

Several types of Flowmeter Log tools are available, and they all operate in a similar fashion. The tool considered in this report is the continuous variety, which would be the most appropriate at the high flow rates often encountered in waste-disposal wells.

The Continuous Spinner Flowmeter Log (CSFL) tool, shown in figure A-2, incorporates an impeller into its design. The impeller rotates in response to fluid movement. This rotation generates a series of electrical pulses that are transmitted uphole to the surface equipment for computer processing. The number of pulses generated is proportional to the number of revolutions per second of the impeller, which can be related to flow velocity. The volumetric flow rate, the measurement of most interest, can be calculated from borehole diameter data obtained from the four-arm CL tool.

The CSFL tool measures fluid velocity very satisfactorily in turbulent fluid flow. Although this flow regime is encountered most often, it nonetheless requires verification. One method of defining whether a flow regime is turbulent is to use the Reynold's Number (Re). Re is defined as

$$Re = vD\rho/\mu \qquad [A\text{-}1]$$

where ρ = fluid density, g/cm^3
v = average fluid velocity, cm/sec
D = hole diameter, cm
μ = fluid viscosity, poise

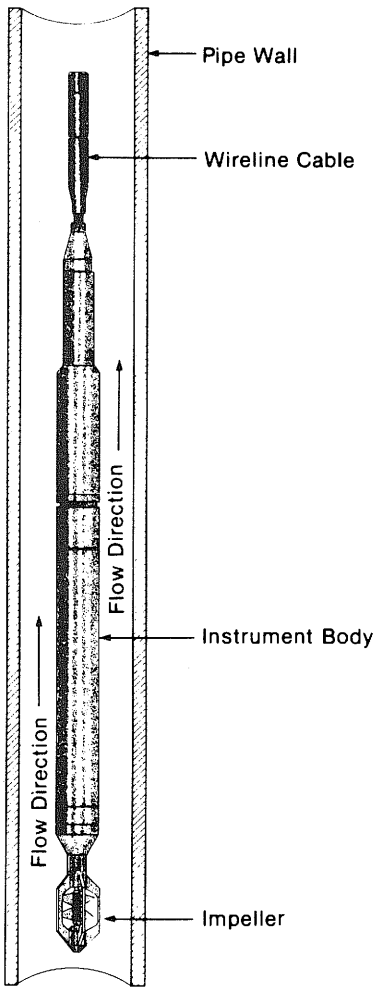

Figure A-2 Continuous Spinner Flowmeter Log tool (from Dresser Atlas 1981).

Re values of 3,000 or greater are used to represent turbulent flow in most literature dealing with fluid flow. For most applications of the CSFL tool in injection/confining interval evaluation, fluid will be injected at the surface to initiate impeller movement. A useful conversion in Re calculations is

$$v = (0.3637)Q/D^2 \qquad [A\text{-}2]$$

where v = average fluid velocity, cm/sec
D = hole diameter, cm
Q = flowrate, barrels per day

This conversion is combined with the definition of the Reynold's Number to yield

$$Re = (0.3637)Q\rho/\mu D \qquad [A\text{-}3]$$

Gamma Ray Log (GRL)

As its name suggests, the GRL detects gamma rays—random, high-energy electromagnetic waves emitted during the decay of unstable radioisotopes. The radioisotopes normally found in rocks are ^{40}K and the daughter products of the uranium and thorium decay series. The GRL discussed here is unable to differentiate the contribution of each individual radioisotope to the total intensity of gamma radiation.

The detector of the tool normally consists of a sodium iodide (NaI) crystal optically coupled to a photomultiplier tube. Atoms of the NaI crystal absorb gamma ray collision energy, which places the electrons of the atoms in a higher energy state. When the excited electrons lose this acquired energy and fall back into their original state, they give off light that is converted to a voltage pulse through the photomultiplier tube. These pulses are transmitted uphole and converted, on the appropriate scale, to a measure of the gamma ray intensity.

Because of the high natural concentration of ^{40}K in clay minerals, shales generally exhibit a high gamma ray intensity. On the other hand, sandstones and carbonates generally produce a lower gamma ray count because of their relatively low concentration of clays and other highly radioactive constituents. Because of this difference in gamma ray intensity, various lithologies can easily be identified (allowing correlation of lithologic units), and a rock unit's shale volume can be determined.

During phase I logging, a GRL that used a Geiger Mueller type of detector was run. The Geiger Mueller replaced the Scintillation type of detector employed in the previous GRL. This change results in a smoother, less fluctuating GR, which provides a better estimate of the formation's natural gamma ray activity (GR, measured in API units).

Sonic Log (SL)

The Sonic Log is an acoustic device that generates acoustic waves and measures reflected acoustic waves. The measurements taken from the SL tool are the direct result of the propagation of acoustic (elastic) waves through the borehole environment. The two important waves to the SL tool are the compressional (longitudinal) and the shear (transverse) waves.

The initial energy to produce the sound (acoustic) waves is generated by the transmitter (T) portion of the tool (fig. A-3). The velocity of a shear wave (Vs) is given by:

$$Vs = (\mu/\rho)^{0.5} \qquad [A\text{-}4]$$

where μ = modulus of shear for the medium
ρ = density of the medium

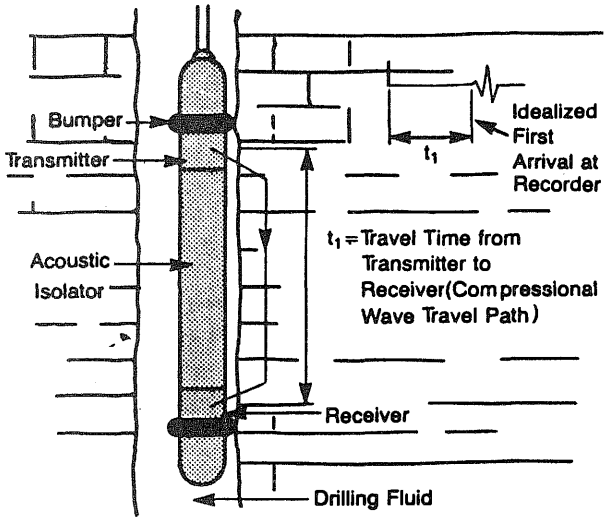

Figure A-3 (left) Generalized Sonic Log tool (from Helander 1983).

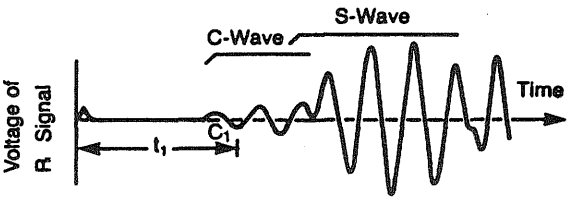

Figure A-4 Idealized schematic of receiver (R) signal (from Helander 1983).

Since the incident energy generated by the SL transmitter must first traverse a liquid medium in the borehole (where $\mu = 0$), it would appear that no shear wave would be generated, and subsequently received, by the SL tool. However, the occurrence of both shear and compressional waves in the response from the tool (fig. A-4) is a curious and useful anomaly. This apparent discrepancy can be resolved by noting that as the compressional wave strikes an interface or simply an adjacent medium with different elastic properties, a shear wave is produced. Therefore, as the compressional wave traverses from the transmitter (T) to the receiver (R) on the tool, the wave generates a shear wave that can, in this manner, be detected by the receiver circuitry. Shear waves generally are of a larger amplitude and about half as fast as compressional waves.

The transmitter-receiver array is chosen to account for abnormalities present in the borehole environment, i.e., washouts and tool tilting. The standard transmitter-receiver (T-R) arrangement is shown in figure A-5. Although other T-R configurations are available, this configuration is most nearly suited to the needs of injection/confining interval evaluation. The specific SL tool that incorporates this T-R array into its design is the Borehole Compensated Sonic Log (BCSL) tool. The main benefit of this type of T-R spacing is the compensation for washouts and tool tilting effects on travel time measurements.

Since the compressional wave has the fastest velocity of propagation, it is the one of most concern with the BCSL. If t_{fl} is the time taken to travel through the pore space (fluid travel time) and t_{ma} is the time taken to travel through the matrix, the total travel time will be t (the travel time recorded by the BCSL tool). The porosity (POR)BCS (Borehole Compensated Sonic) can be represented be the Wyllie time-average equation,

$$(POR)BCS = (t - t_{ma})/(t_{fl} - t_{ma}) \qquad [A\text{-}5]$$

The compressional wave (p-wave, also called C-wave) takes the path of least resistance. Areas of isolated (not interconnected) pockets of porosity, which would normally be found in the case of secondary porosity, will not have a pronounced effect on the travel time of the p-wave. By comparing the BCSL data with data from a tool that is influenced by the total porosity (primary and secondary), the amount of secondary porosity present can be estimated. The following equation applies to this situation,

$$(POR)tot = (POR)sec + (POR)prim \qquad [A\text{-}6]$$

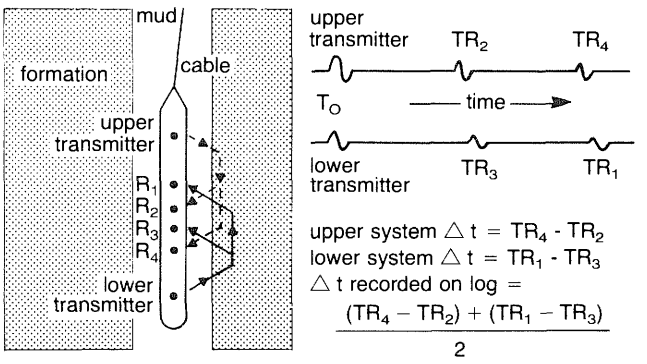

Figure A-5 Generalized Borehole Compensated Sonic Log tool (from Bateman 1985b).

During phase I logging, the BCSL was run in place of the SL. A more advanced detection system in the BCSL allows compensation for environmental factors that affect the signal transit time (t) used by the BCSL to make porosity determinations. A more accurate porosity profile results with the use of the BCSL.

One other SL tool that should be mentioned is the Long Spaced Sonic Log (LSSL) tool. It incorporates a longer T-R spacing than does the BCSL tool. In this manner, the LSSL tool is affected by a zone farther away and less disturbed by drilling operations than the zone at the borehole interface. This tool has been used for shear wave analysis, which when combined with compressional wave data results in an evaluation of some of the formation's strength characteristics, such as the pressure required to fracture the formation and the formation's elastic properties. If a hole has a large potential for washouts, this tool may be the best SL tool to use.

Neutron Log (NL)

The neutron is a fundamental particle found in the nucleus of all atoms except hydrogen, which contains only a proton. The neutron is a chargeless particle with about the same mass as the proton. The NL tool exploits these two properties of the neutron particle. The neutron source is usually a mixture of americium and beryllium, which react together to continuously emit neutrons.

Since the neutron is a small and electrically neutral particle, it passes with ease through most matter. During its passage, the neutron particle loses energy by colliding with other atoms. When the neutron's energy is reduced to a level equal to the surrounding matter (a function of absolute temperature), the neutron is called a thermal neutron. The energy of a thermal neutron is in the range of 0.025 eV.

Simple force relationships reveal that the maximum energy loss in the collision of two balls occurs when the two balls are of equal mass. Since the neutron and the hydrogen atom's proton have nearly equal masses, hydrogen dominates the behavior of neutrons and, in turn, the response of the NL tools. The thermal neutron flux is therefore controlled by the hydrogen content of the formation. Since hydrogen is found in the water molecules filling the pore space, the thermal neutron flux is a direct indication of the porosity of the formation.

Environmental factors such as hole size and mud weight influence the response of the NL tool. This influence can be corrected by taking two readings of thermal neutron flux at different spacings and using them to define the slope of the response line of the tool. This slope is relatively unaltered by environmental effects. The Compensated Neutron Log (CNL) tool utilizes this concept. The primary measurement of the CNL tool is therefore a ratio of the two count rates, far and near. Figure A-6 shows a CNL tool schematic.

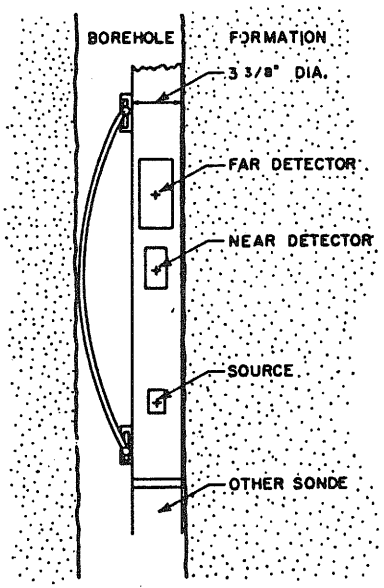

Figure A-6 Generalized Compensated Neutron Log tool (from Bateman 1985b).

The CNL displays a measurement of total porosity. Thus, it can be combined with the BCSL to provide an estimate of secondary porosity. Along with another porosity device, usually the BCSL or the Compensated Density Log (CDL), a lithologic determination may be made in addition to an accurate estimate of total porosity (cross-plotted porosity).

The CNL has replaced the Sidewall Neutron Log (SNL). The CNL utilizes a dual detector while the SNL has only one. The second detector enables the CNL to compensate effectively for environmental factors not taken into account with the SNL, such as salinity and temperature of the borehole fluid and diameter of the borehole. Accounting for these factors results in a more accurate determination of porosity with the CNL, ([POR]NIs).

Density Log (DL)

The DL utilizes a focused gamma ray source, normally cesium-137, which emits gamma rays into the formation from a pad assembly that is forced against the borehole wall via a back-up arm. The gamma rays interact with the electrons in the material opposite the focused source mainly through Compton scattering. This results in the gamma ray losing energy at each collision. The intensity of the back-scattered gamma ray is then measured by the gamma ray detectors (usually two) (fig. A-7). The measured gamma ray intensity is a function of the electron density of the formation. As the electron density of the formation increases, the probability of collision increases, resulting in reduced gamma ray intensity measured by the gamma ray detectors. The electron density, ρ_e, has been related to the bulk density, ρ_b, by the following equation,

$$\rho_e = \rho_b(2Z/A) \qquad [A\text{-}7]$$

where Z = atomic number or the number of electrons per atom
A = atomic weight

In most cases, the ratio, 2Z/A, is approximately equal to 1.0. Therefore $\rho_e = \rho_b$, and the apparent bulk density response of the tool is a response to the bulk density, ρ_b, of the formation material opposite the tool.

A two-detector DL or Compensated Density Log (CDL), which was used for phase I logging, allows for the compensation of the mudcake's effect on CDL tool response. In this way, an accurate

total porosity measurement is obtained. CDL response can be compared to BCSL porosity to estimate secondary porosity or cross-plotted with the BCSL or CNL to produce lithologic and total porosity determinations.

Resistivity Log (RL)

The property of a material that opposes the flow of an electrical current is called electrical resistance. Resistivity is a measure of the resistance of a volume of material. Several authors have noted that formation resistivity can be determined by,

$$R = KV/I \qquad [A\text{-}8]$$

where R = resistivity
K = geometric factor specific for a particular tool
V = potential across current path
I = current.

Since the RL tool measures the potential, and K and I are known, R can be calculated. The calculated resistivity is dependent on the amount of porosity and fluid contained in the pores.

RL tools have a number of applications. For this study, the resistivity device was needed for two purposes: to determine an accurate, true formation resistivity for fluid saturation calculations, cementation factor determinations, and stratigraphic correlations; and to estimate the invasion of borehole fluids into the formation, which may affect the RL tool's response.

Two appropriate resistivity logging systems are available: the Dual Laterolog Microspherically Focused Log tool and the Dual Induction Laterolog (Spherically Focused Log) tool. Although both systems will provide the necessary results, specific borehole conditions dictate which one is appropriate. The former is used when sea water or brine mud fills the borehole and the latter when fresh or oil-based mud is present. For this discussion, the Dual Induction Laterolog (DIL) tool will be considered. (The Dual Induction Spherically Focused Log [DISFL] tool is similar in principle to the DIL.)

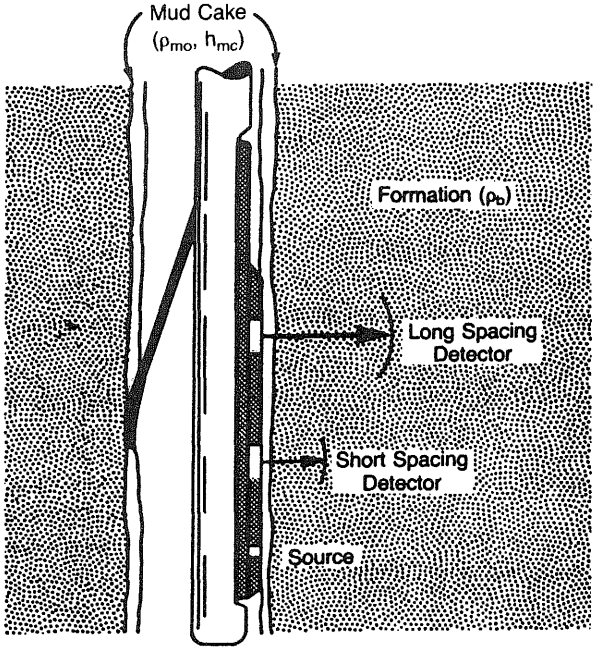

Figure A-7 Generalized two-detector Density Log tool (from Helander 1983).

The DIL tool comprises two sections: the induction and the lateral. The induction section produces two measurements, the "induction log deep" and the "induction log medium"; the lateral section yields one, the "laterolog."

The induction section, shown in schematic in figure A-8, is equipped with transmitter-receiver (T-R) coil pairs. An alternating current is applied to the transmitter, which generates a magnetic field around the tool, thereby inducing current flow in the surrounding formation. The current flow generates a magnetic field in the formation which, in turn, induces a voltage in the receiver coils. The measured voltage is proportional to the formation conductivity, which is inversely related to the formation resistivity.

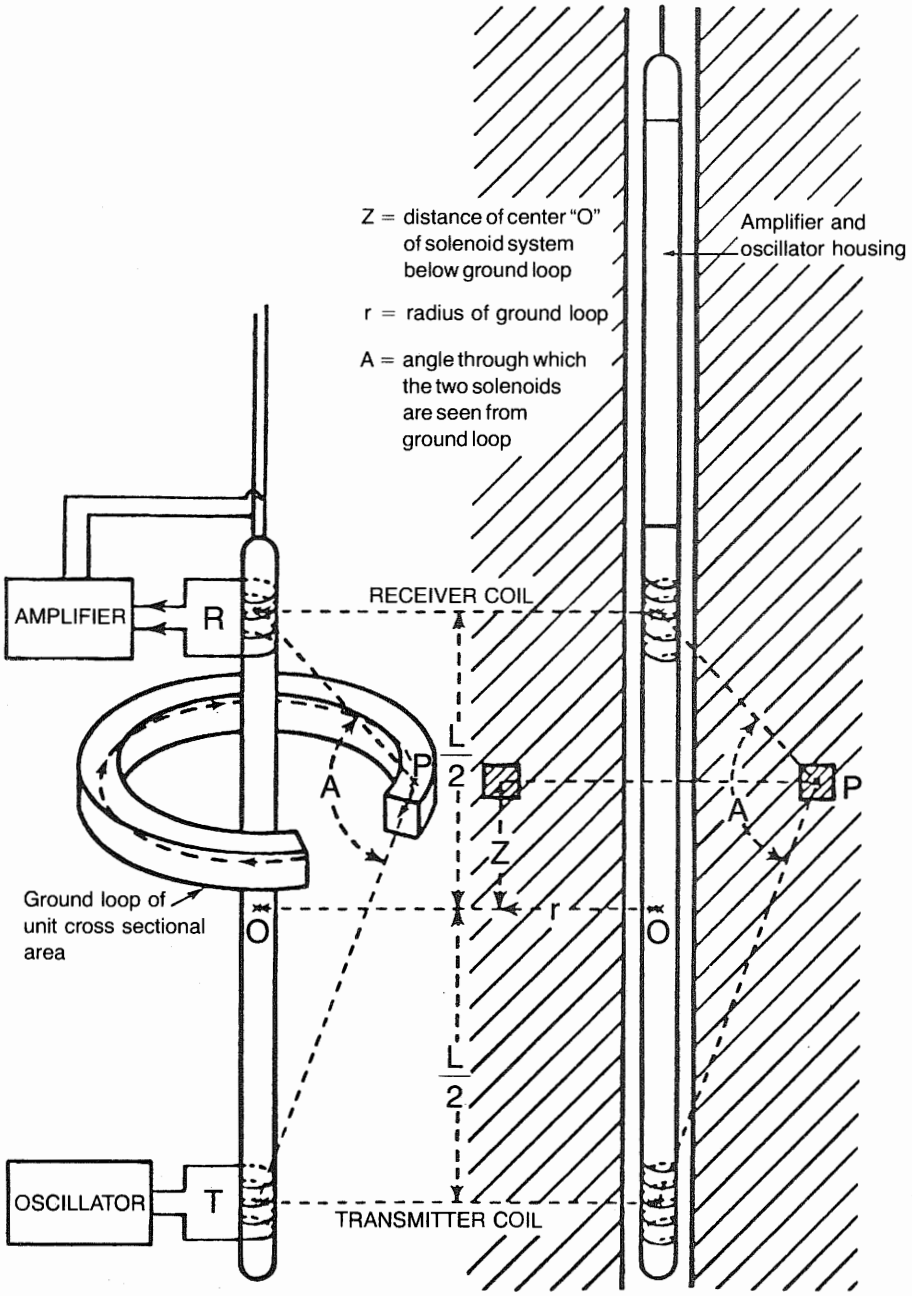

Figure A-8 Schematic diagram of induction log principles (from Hallenburg 1984).

Lateral devices pass a current of constant intensity from the tool into the formation (fig. A-9). This current flow creates equipotential spheres around the source electrode (A). Potential measuring electrodes (M, N) record the potential created by the current flow. The potential measured is then converted to formation resistivity.

The three curves generated have different depths of investigation into the formation, because of T-R spacing on the induction section and A-M,N spacing on the laterolog section. In this way, an evaluation of the amount of invasion is made, which is used to correct the deepest measurement (induction log deep) for invasion effects to produce an accurate, true formation resistivity. This resistivity can be used to obtain the cementation factor and fluid saturation of the formation.

The DISFL has replaced the Induction Electric Log (IEL). With the addition of one more resistivity curve to the output of the DISFL, the Induction Log Medium resistivity, and a deeper reading Induction Log Deep resistivity, factors that affected the resistivity response of the DISFL can be taken into account. These factors include the depth of invasion of the borehole fluids and the effect of this invasion on the determination of a true resistivity for the formation. The result is an Induction Log Deep resistivity corrected for invasion effects, which is considered more accurate than the formation's true resistivity determined by the IEL.

Permeability Log (PL)

The Permeability Log tool used most frequently today is the Minilog (MIL) tool. The MIL replaced the Microlog. Advanced electronics have increased the sensitivity of the Minilog as compared with the Microlog. Use of the Minilog results in more accurate information on permeability, mud (Rm), mud filtrate (Rmf), and mudcake (Rmc) resistivities.

The MIL, which utilizes the same resistivity theory discussed for the RL, is not discussed in detail here. The output of the MIL tool consists of two measurements: normal and lateral resistivities. The lateral configuration is described above. The normal measurement utilizes a slightly different system, shown in general schematic in figure A-10. The two arrays are housed in a nonconductive, fluid-filled rubber pad that is forced against the borehole wall by a back-up arm. This configuration is necessary to prevent the borehole fluid from short-circuiting the closely spaced current electrodes.

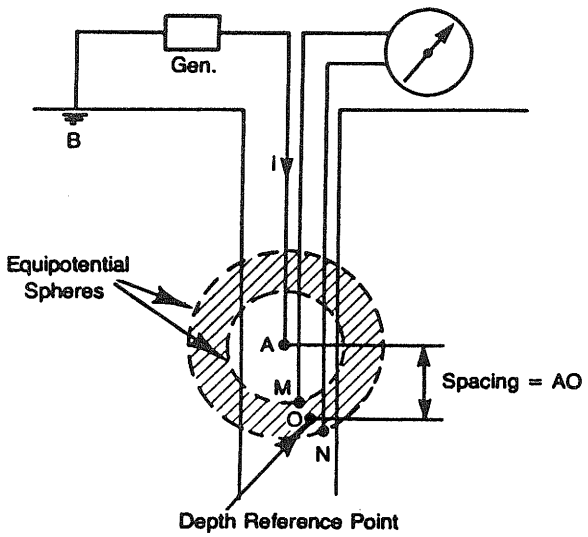

Figure A-9 (left) Schematic diagram of lateral logging system (from Helander 1983).

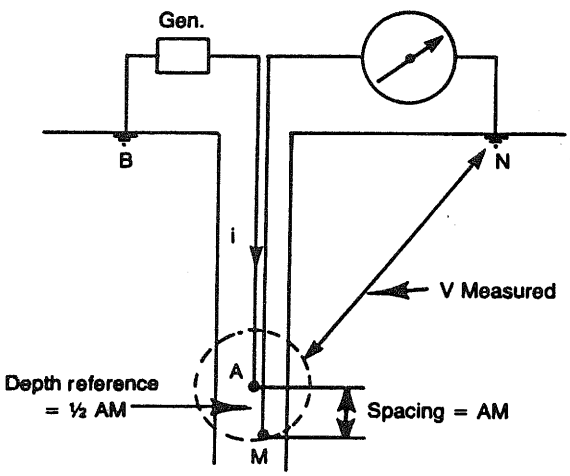

Figure A-10 Schematic diagram of normal logging system (from Helander 1983)

By utilizing two different configurations, MIL can produce varying depths of investigation. A comparison of the curves indicates the presence and magnitude of invasion of the borehole fluids into the formation. This enables a qualitative determination of the presence of permeability.

Spontaneous Potential Log (SPL)

Although the SPL system has one of the simplest physical configurations (fig. A-11), it is the result of many different factors. The SPL system records the change in naturally occurring potentials as a function of depth in the borehole. Two types of potential may contribute to the total Spontaneous Potential (E_{sp}): electrochemical (E_c) and electrokinetic (E_k). In well log analysis it is assumed that the measured SP response is due solely to the electrochemical component; therefore, $E_{sp} = E_c$.

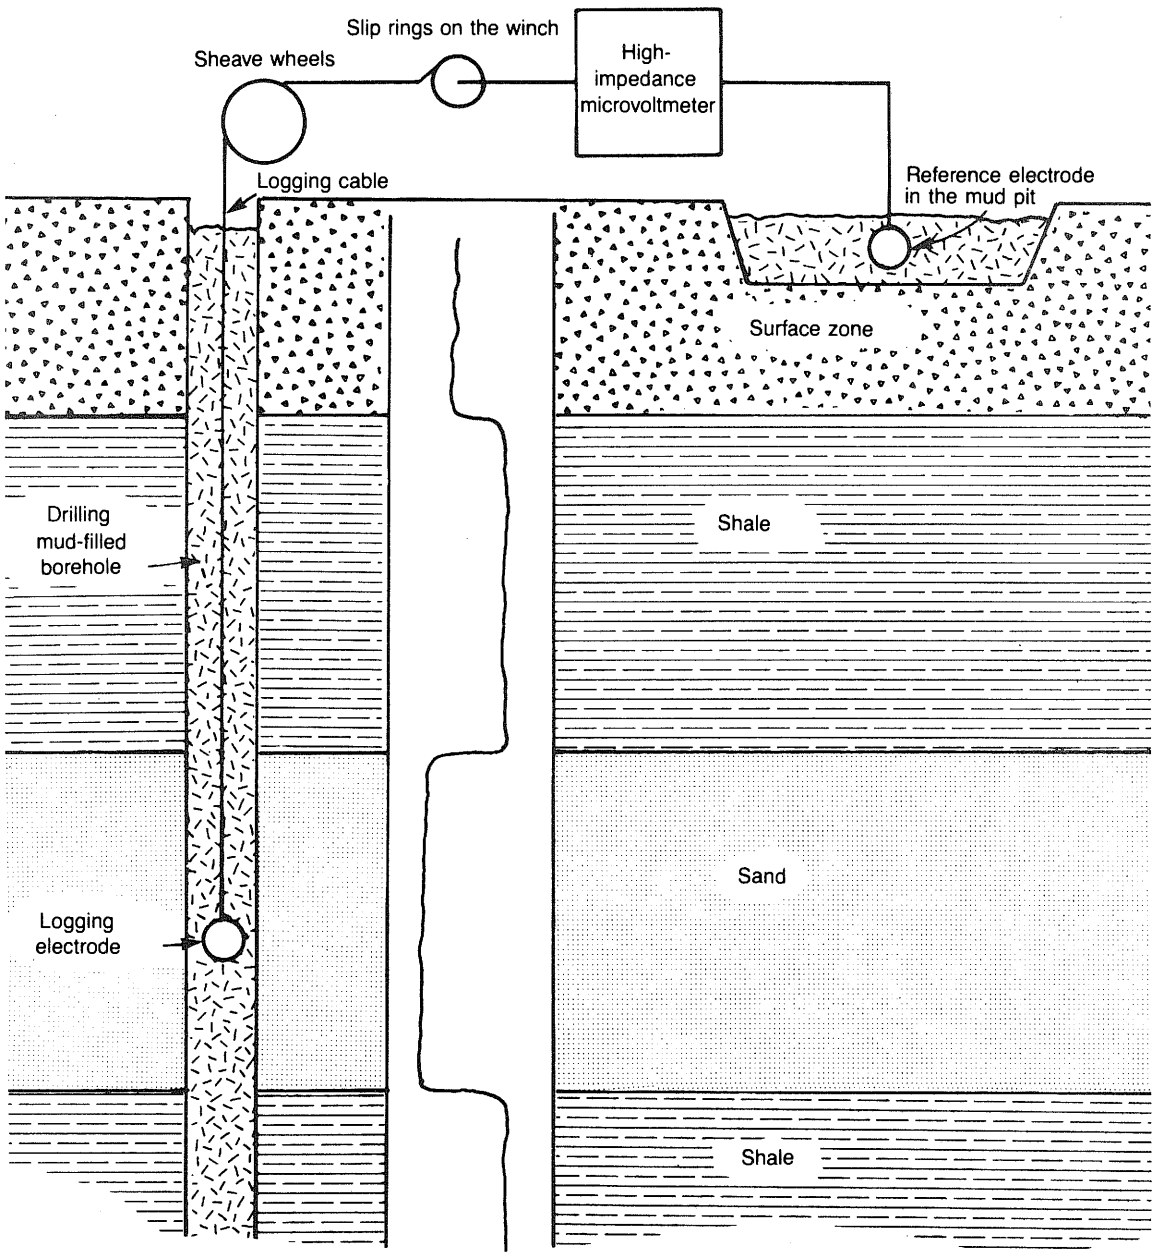

Figure A-11 Schematic diagram of spontaneous potential circuit.

The electrochemical potential is composed of the membrane potential (E_m) and the liquid junction potential (E_j). The membrane potential is caused by the separation of two fluids of different activity by a permeable, charged membrane. An analogy might be mud and formation water separated by shale. The liquid junction potential is the result of the contact of two solutions of differing activity, such as mud filtrate and formation water.

The E_{sp} is commonly written as

$$E_{sp} = -K_c \log(R_{mf}/R_w) \qquad [A\text{-}9]$$

where $K_c = 61 + 0.133T(°F)$
R_{mf} = mud filtrate resistivity
R_w = formation water resistivity.

This equation illustrates one application of the SPL system, namely R_w determination. The other applications relevant to this study are stratigraphic correlation and qualitative permeability estimation. The latter two are available through a consideration of the fluids and formation materials that give rise to the membrane and liquid junction potentials.

Temperature Log (TL)

The TL tool is simply a device that records the magnitude of the subsurface temperature. This is accomplished by incorporating into the tool's design a sensor element that provides ultrasensitive, stable readings over a suitable temperature range. A temperature probe in contact with the borehole environment transmits the thermal energy to the sensor, which converts the energy to a signal coverted by the surface equipment to absolute and differential temperature. These data can be useful to injection/confining interval evaluation in several ways. First, in many injection wells the temperature of the injection fluid is anomalously cooler than the native formation temperature. This anomaly can often be detected by the TL, providing another method, along with the CSFL, for delineating the location of fluid infiltration into a formation. Also, data from the TL provide temperature values to be used in the selection of appropriate temperature-corrected fluid and formation parameters (such as fluid density and water compressibility) necessary in many calculations.

Radioactive Tracer Log (RATL)

The Radioactive Tracer Log tool "traces" the movement of a radioactive source. This is accomplished by injecting a short-lived, radioactive isotope (usually ^{131}I) from one section of the tool and recording its movement with a detection gamma ray package housed in another section of the tool. As the radioactive isotope decays, it emits gamma rays that are detected by the gamma ray apparatus. It is in this way that the position of the radioactive "slug" can be monitored as it makes its way through the cased and uncased borehole. Thus it is another technique for delineating fluid flow within the injection zone.

APPENDIX B. REDUCTION AND ANALYSIS OF GEOPHYSICAL LOG DATA

Improved modeling techniques (correction charts) were used to interpret the advanced suite of logs run during phase I and II. Use of these charts generally improved the accuracy of data obtained from the phase I and II logs, compared with logs run during WDW2 construction. Figures B-1, B-2, and B-3 are examples of the correction charts used. By using these modern logging tools and incorporating improved analytical techniques, we were able to determine more accurately the following hydrogeologic data on geologic materials constituting the injection interval: the forma-tion's matrix-corrected CNL porosity ([POR]Ncor), matrix corrected BCS porosity ([POR]BCScor), cross-plotted porosity ([POR]xp), secondary porosity ([POR]sec), true resistivity (Rt), matrix lithology (MA), water saturation (SW), shale volume (Vsh), and qualitative permeability (k). These values, computed at 2-foot intervals throughout the injection zone, are reported in table B-1. The same parameters for geophysical logs run down WDW2 are reported in table B-2.

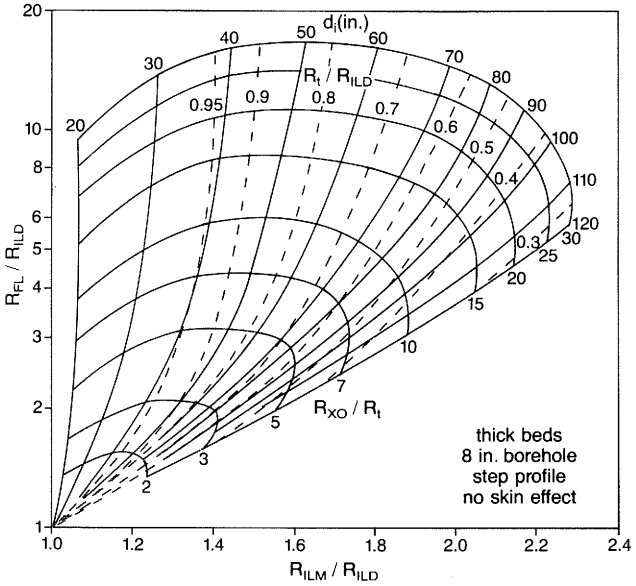

Figure B-1 (left) "Tornado" chart for Dual Induction-Focused Log analysis (Dresser Atlas 1981).

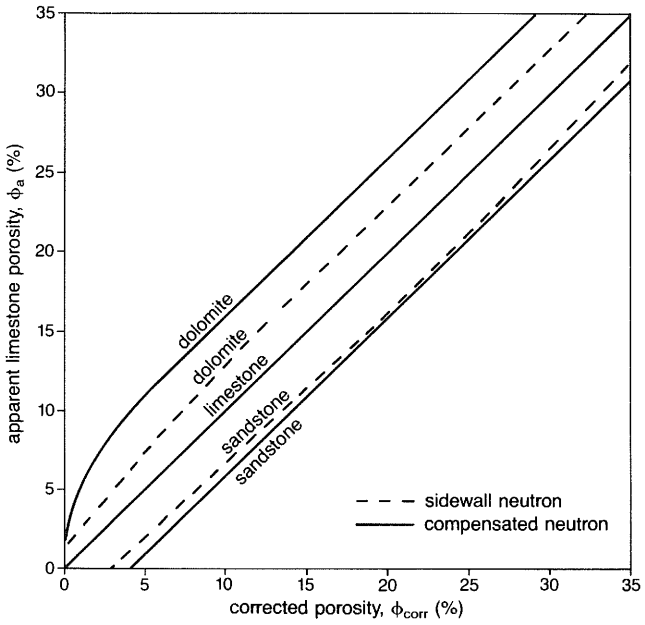

Figure B-2 Neutron porosity lithologic correction chart (Dresser Atlas 1981).

Notes for table B-1

1. Matrix corrected using figure B-2.
2. Matrix corrected using (POR)BCScor = (tlog - tma)/(tf1 - tma) x 1/Cp,
   where tma = 47.6×10^{-6} sec/ft for limestone
   tma = 43.5×10^{-6} sec/ft for dolomite
   tf1 = 189×10^{-6} sec/ft
   tlog = transit time from log
   tma = transit time of the matrix
   Cp = constant for shale correction
   assume Cp = 1, since no shale correction is needed
3. See figure B-3
4. (POR)sec = (POR)Ncor - (POR)BCScor
5. Since Rilm and Rild are approximately equal, a correction for invasion was not necessary; see figure B-1
6. Taken from (POR)N versus t crossplot, figure B-3
7. Using SW^2 = Ro/Rt = FRw/Rt = Rw/$(por)^2$Rt = Rw/(por)xp^2Rt, from this, all zones were 100% water saturated.
8. Using Vsh = (GRlog - GRc1)/(GRsh - GRc1),
   where GRlog = GR reading taken off log.
   GRcl = GR reading from the zone with the lowest GR (10 @ 2,474 ft).
   GRsh = GR reading from nearest shale zone (140 @ 2,242 ft).
9. Based on interpretation of MIL, Y denotes zone interpreted as having "significant" permeability. N denotes zone interpreted as not having "significant" permeability. MIL response is adversely affected by unevenness of borehole. A 4-arm caliper run indicated a very even borehole: 6.3-inch diameter from 2,424 to 2,524 ft, 6.2-inch diameter from 2,525 to 2,556 ft, and 5.8-inch diameter from 2,557 to 2,560 ft.

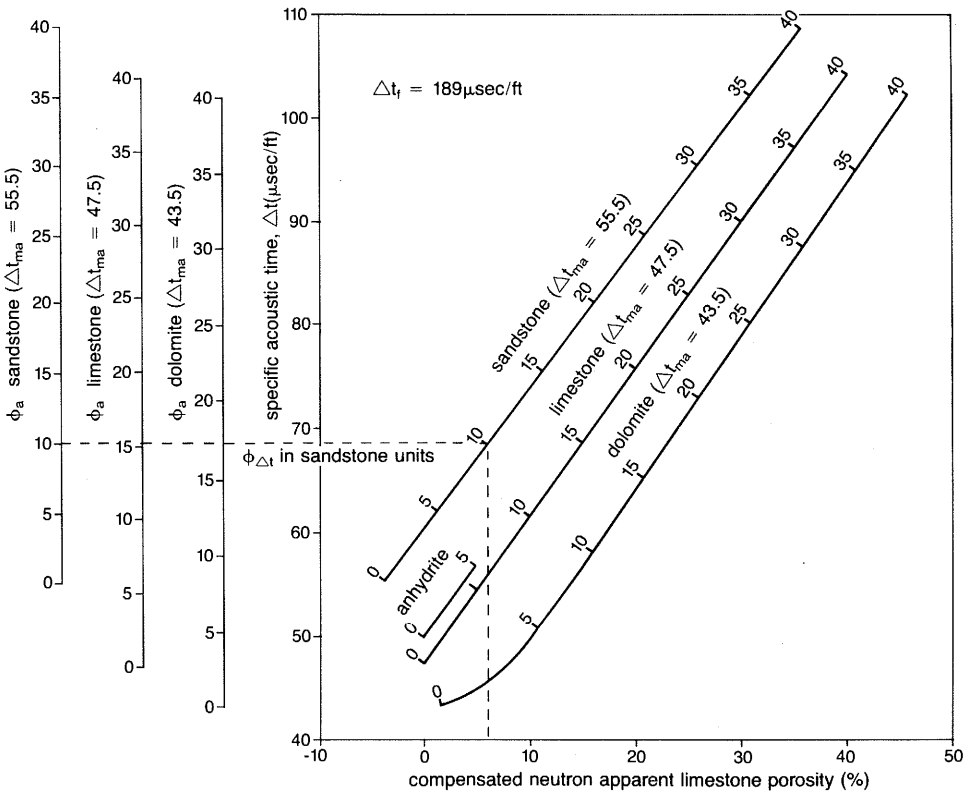

Figure B-3 Compensated Neutron Log and Borehole Compensated Acoustilog porosity crossplot (Dresser Atlas 1983).

* For explanation of column headings, see table B-1.

** All logs used for study were run during well installation, and all were from WDW2 except the sonic log (SL), which was from WDW1. Analysis methods used were those described in table B-1. All depths measured are from Kelly Bushing (KB), which is 12 ft above ground level.

A brief discussion of the computation of the correction factors and assumptions used to analyze the logging data follows. The analysis focused on data from intervals with higher relative permeabilities (as displayed by the Minilog and higher porosities from the CNL). These zones were 2,440 to 2,506 ft GL, 2,532 to 2,552 ft GL, and 2,572 to 2,582 ft GL as logged in DOW.

From figure B-4:

m = 1.54 or 1.76; this value is in close agreement with an assumed value of m = 2 for limestone (Ls) and dolomite (Dol).

From Minilog:

Rm = 0.30 ohm-m

Therefore, from figure B-5,

Rmf = 0.23 ohm-m and

Rmc= 0.41 ohm-m

From temperature log on WDW2,

Temperature @ 2,460 ft = 75.6° F.

Determine Rw:

Using Archie's Equation:

$F = a/(por)^2 = Ro/Rw$ and

$SW^n = Ro/Rt$

where F = formation factor

Ro= true resistivity of the formation at 100% water saturation (when SW = 100%)

n = saturation exponent

a = constant

For limestone and dolomite,

Assume a = 1, m = n = 2

Therefore,

$F = 1/(por)^2$

$SW^2 = Ro/Rt$

@ 2473 ft assume SW = 100%

$SW^2 = Ro/Rt$

Ro = Rt

Assume Rt = Rildcorr

Correct Rild for invasion, figure B-1
Rildcorr = 3 ohm-m
Rt = 3 ohm-m
Ro = 3 ohm-m
Ro = F x Rw = Rw/(por)^2
Rw = Ro x (por)^2
Porosity is needed; assume por = porxp of Sonic vs CNS
porxp = 28.7%

Therefore,

Rw = 0.247 ohm-m

These factors were used to analyze the logging data reported in tables B-1 and B-2. Important hydrogeologic parameters of the injection zones are summarized in table B-3.

Table B-3 Summary of important formation characteristics

(POR)xp,ave = 16%	(POR)xp,max = 28.8%	(POR)xp,min = 8.9%
(POR)sec,ave = 1.98%	(POR)sec,max = 5.7%	
tave = 66.7x10^{-6} sec/ft		
tmax = 87x10^{-6} sec/ft		
tmin = 56x10^{-6} sec/ft		
Rt,ave = 8.6 ohm-m	Rt,max = 21 ohm-m	Rt,min = 3 ohm-m
Vsh,ave = 8.05%	Vsh,max = 49.2%	Vsh,min = 0.0%

Formation lithology (based on 98 ft of "higher permeability, higher porosity" zone), 61.0% dolomite, 35.0% limestone, and 4.0% sandstone.

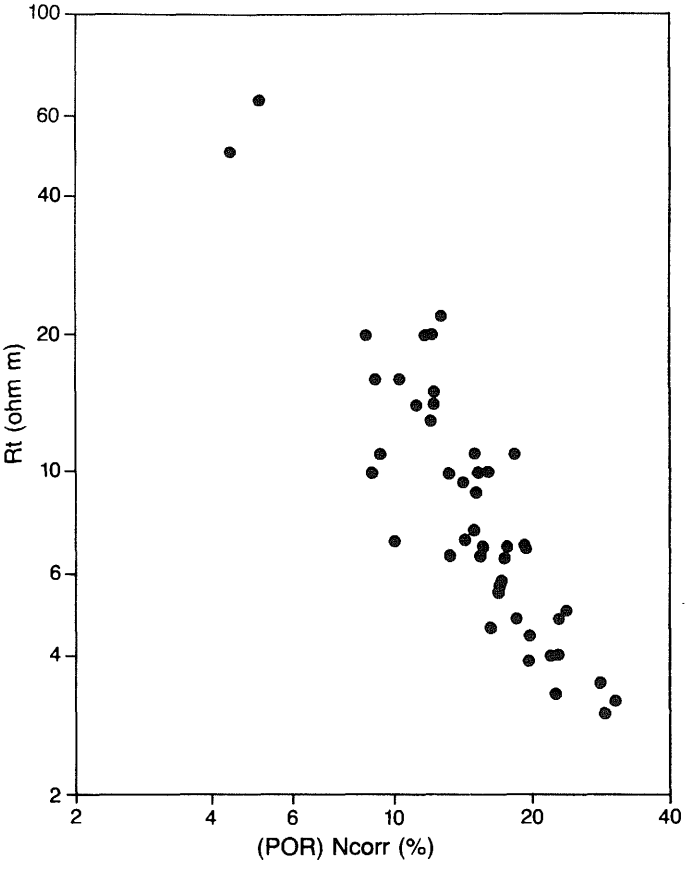

Figure B-4 Determination of the cementation factor.

After reviewing the data, we concluded that the host formation, the Bailey Limestone, is composed mainly of a clean dolomite with less than 20 percent shale throughout most of the interval logged. Since the Bailey Limestone is predominantly a dolomite, secondary porosity is always a consideration. A comparison of CNL and BCSL data suggests that secondary porosity may account for up to 10 percent of the total porosity. The intervals with higher relative permeability have a slightly higher secondary porosity and therefore a higher total porosity.

The entire interval is primarily 100 percent water saturated and has a fluid resistance of approximately 0.247 ohm-m. At a formation temperature of about 80°F and depth of 2,460 feet GL, the fluid composition is estimated to be approximately 24,000 ppm NaCl (fig. B-6).

As stated in chapter 3, one use of the core data was to verify data obtained from the geophysical logs. Figure B-7 shows good agreement between the two methods for porosity data. Figure B-8 indicates a close correlation between the two methods for true formation resistivity values (Rt); this correlation becomes more apparent when the equation used to derive water saturation (Sw) is reviewed,

$$S_w^2 = \frac{Rw}{(por) \times \frac{2}{p}} \quad (1/R_t)$$

S_w is shown to be indirectly proportional to the square root of R_t.

Figure B-7 Core porosity versus log porosity (phase I, cross-plotted porosity) for WDW2.

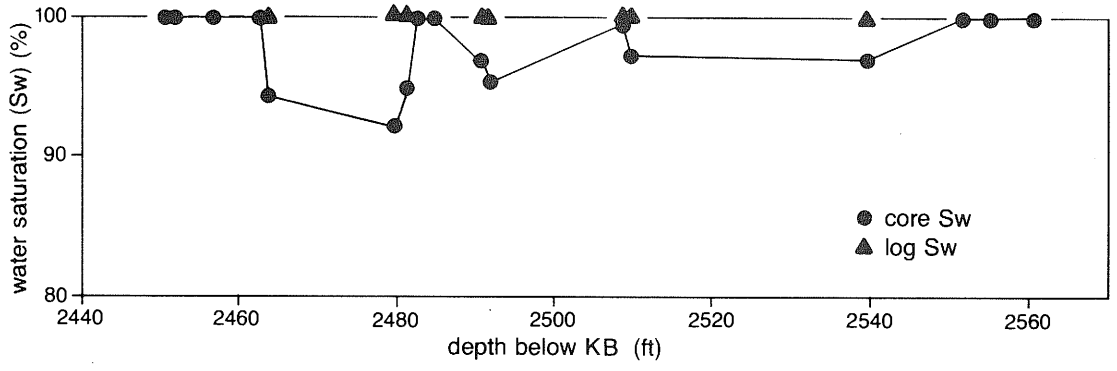

Figure B-8 Core water saturation versus log water saturation for WDW2 at designated depths. Log Sw obtained from phase I logging on the DOW.

APPENDIX C. BRUCITE FORMATION: PROPOSED MECHANISM OF FORMATION

The hydrogeologic site descriptions developed from phase I and phase II data (see chapter 3) differed from each other significantly; however, the reason for these differences was not readily apparent. To develop a hypothesis to explain the results and increase our understanding of the site hydrogeology, we conducted additional analyses.

Core Analysis

Analysis of sidewall core obtained during phase II was critical to the development of a hypothesis to explain the discrepancies described in chapter 3. Our core analysis included hydraulic testing, mineralogic analysis, and scanning electron microscope (SEM) investigation.

Hydraulic Testing

Hydraulic testing provided no hard evidence to resolve the discrepancies between phase I and phase II data. Injection zones 1, 2, and 3 (fig. C-1) had abnormally high porosities and permeabilities, but core analysis data did not agree with the results from the CSFL. First, the zone from 2,468 to 2,496 feet KB showed some injection potential. Core analysis indicated that at least some portions of this zone (e.g., 2,481.0 ft KB) were not permeable enough to allow fluid flow; however, most of this zone appeared to have sufficient permeability. Second, the core from 2539.5 feet KB seemed to have sufficient porosity and permeability to allow fluid flow, but the CSFL did not show any flow at this location. On the basis of CSFL results, zone 3 should have had the highest porosity and permeability, zone 2 the next highest, and zone 1 the lowest; however, core analysis indicated just the opposite. Therefore, the same discrepancies were encountered with core analysis as with geophysical logging.

Mineralogic Analysis

Cores were also analyzed for their mineralogical content. Brucite was found in the anomalous zones, and its presence was confirmed by x-ray diffraction (XRD) analysis. Brucite was not expected to be present in the injection system environment of WDW2. Brucite is normally found in veins in serpentine and basic rocks and as flakes scattered through some marbles (Pough 1953). Roy et al. (1989) analyzed a sample of the native formation brine taken from the DOW. The sample was vastly undersaturated with respect to brucite, $Mg(OH)_2$. The ion activity product of Mg^{2+} and OH^- (brucite) in the sample was 3 percent of that predicted by the solubility of brucite determined by thermodynamic modeling (Roy 1987).

Mineralogical analysis conducted on a few representative samples of the original well cuttings collected during the drilling of WDW2 indicated that none of these samples contained brucite. Downhole geophysical data (table 2) also confirmed the absence of brucite and indicated that prior to injection, the disposal horizon was predominantly dolomitic.

Apparently the injected waste, which consisted of a number of organics in a very alkaline (pH>12), brinelike solution, created an environment in the injection system that promoted the formation of brucite. Although the waste had a component of Mg^{2+}, dolomite (from injection zone rock) was the most likely source of Mg^{2+} for two reasons. First, an increase in the brucite concentration accompanied a corresponding decrease in the dolomite concentration (fig. C-2). Second, the porosity throughout the injection zone subsequent to brucite precipitation should have been lower than the original (pre-injection) porosity if the brine was the source of the Mg^{2+}. Data from log analysis did not indicate a decrease in porosity. Therefore, on the basis of available data, the most plausible hypothesis is that dissolution of dolomite from injection zone rock released magnesium, which then combined with the OH^- in the waste stream to form brucite.

If this hypothesis is correct, the zones that originally had the highest porosities and permeabilities would accept the greatest volume of waste fluid and thus would show the highest brucite con-

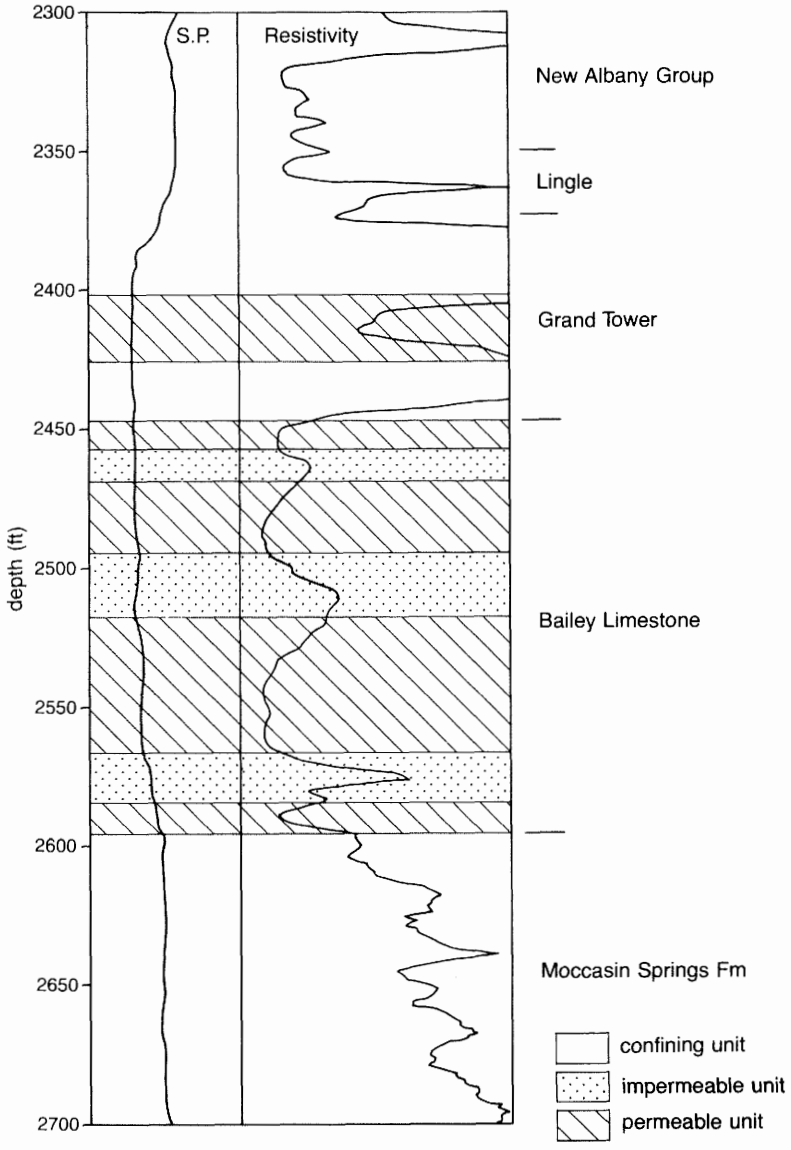

Figure C1 Injection system in WDW2 indicating permeable and nonpermeable zones delineated with the aid of geophysical logging.

centrations. Table C-1 gives porosity and brucite percentages for the cored intervals. For comparison, the Sidewall Neutron Log run during well construction was used to obtain original porosity data. Five intervals were identified and ranked on the basis of porosity characteristics. Zones with higher average porosity were given a higher porosity ranking.

Table C-2 shows the five highest ranked zones with their corresponding average brucite concentrations, air permeabilities (ka), and percentages of total flow (from the CSFL). These data indicate that the presence of brucite has a profound effect on fluid movement. However, laboratory permeability values for zones with higher brucite concentrations were greater than the values for zones with lower brucite concentrations, and laboratory porosity values for zones with higher brucite concentrations were similar to the pre-injection porosities.

In an attempt to explain this finding, we reviewed the analytical procedure used to determine permeability. Laboratory permeabilities were performed on dried samples. If the cations (Na+) that may have been lodged between the brucite layers were lost during drying, a volume reduction in brucite would occur. Therefore, in samples with high brucite concentrations, abnormally high permeability measurements could be encountered, and the cores at 2,479.5, 2,481.0, 2,490.5, 2,491.5, 2,439.5, and 2,560.5 ft KB should have higher permeabilities than expected. These depths corresponded to the zones in which discrepancies were noted between core and CSFL analysis. The anomalously high core permeabilities appeared to be the result of a volume reduction of the brucite upon drying.

Table C-1 Core porosities and brucite concentrations

Depth (KB) (ft)	Original porosity (%)	Porosity ranking	Brucite (wt %)
2450.5	23	3	9
2451.5	25	3	21
2456.5	24	3	0
2462.5	17	-	18
2463.5	19	-	22
2479.5	30+	1	45
2481	30+	1	45
2484.5	30+	1	12
2490.5	30+	1	39
2491.5	30	1	31
2508.5	18	-	26
2509.5	19	-	35
2539.5	27	2	41
2551.5	20	2	38
2555	24	4	7
2556.5	28	2	45
2560.5	28	2	45
2572.5	4	-	2

2588.5	15	5	0
2605	6	-	0
2606	6	-	0

Table C-2 Effect of brucite concentration on total flow

Porosity ranking	Brucite (wt %)	Ave ka (md)	Total Flow (vol %)
1	40	1	0
2	42.3	0.1	0
3	10	0.6	14
4	7	0.06	36
5	0	0.02	50

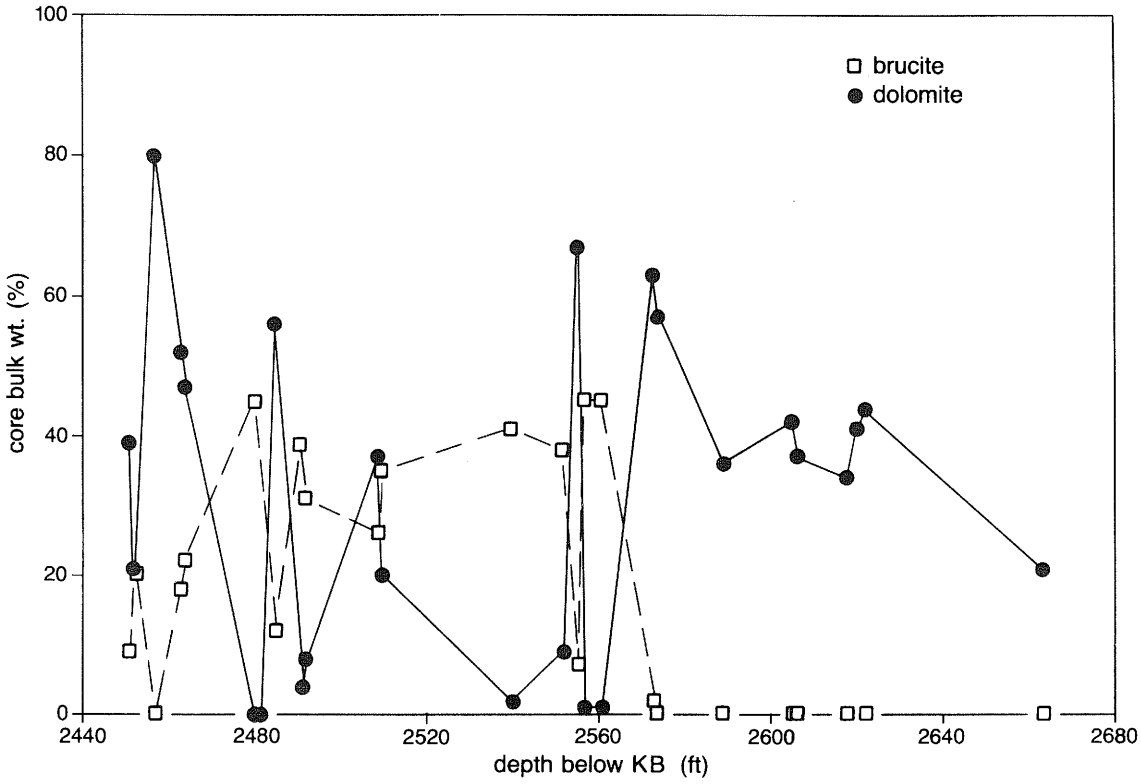

Figure C-2 Core composition: dolomite and brucite in WDW2.

On the basis of available data, this explanation appeared to be reasonable, but two problems with the results remained unresolved: (1) the cores at 2,462.5, 2,463.5, 2,508.5, and 2,509.5 ft KB showed slightly higher than expected brucite concentrations (approximately 25% brucite), and (2) the core at 2,484.5 ft KB had an extremely high core permeability (ka = 14.97 md) but a relatively low concentration of brucite (12%). Scanning Electron Microscope (SEM) analysis was performed on selected core samples in an attempt to resolve these discrepancies, gain additional information on the factors affecting fluid flow, and confirm some of the assumptions inherent in the previous discussion.

SEM Analysis

Eight cores chosen for analysis represented the three injection zones and the major areas where anomalous results were encountered by various analytical procedures (e.g., core analysis, CSFL, and standard geophysical logging). Generally, two magnifications were used per sample: approximately 100x to show the general porosity type and any large-scale features such as fracturing, and 1,000x to show the pore geometry and other small-scale features. Although a detailed discussion of SEM analysis results is beyond the scope of this project, a few generalizations can be made to help resolve the discrepancies noted.

SEM analysis was performed on dried samples; therefore, the effect of cation adsorption into the crystal lattice of brucite was assumed to be unrecognizable.

Data from historical and phase I logging indicated that the core at 2,484.5 ft KB should have had a high injection potential. When the CSFL indicated a lack of fluid flow into this zone, we reasoned—on the basis of core analysis—that the lack of flow into this zone could have been due to the presence of brucite in the sample. However, only 12 percent brucite was found in this core,

compared with an average of 40 percent in the other adjacent samples. Another explanation for the lack of flow was obviously needed. Figures C-3 and C-4 indicate that the predominant type of porosity in this sample is fracture porosity. Figure C-3 shows that the fracturing is discontinuous on a large scale. Figure C-4 is a close-up of the fracture depicted in figure C-3. The platy material on the fracture walls was interpreted to be brucite.

Another sample selected was the core at 2,479.5 feet KB, which is from the same zone as the previous sample. No fractures can be seen in figures C-5 and C-6, and the crystals and matrix of the sample are coated. Core analysis indicated that this sample was 45 percent brucite, so this coating was assumed to be brucite. With such a widespread occurrence of brucite, the decrease in permeability seems reasonable.

A sample from the uppermost injection zone (2,456.5 ft KB) (figs. C-7 and C-8) is free of the coating present in the previous samples. Core analysis indicated that this sample had no brucite, which agrees with SEM analysis and the supposition that brucite has not affected fluid flow in the uppermost injection zone.

The hypothesis used to resolve the brucite formation explains the available data and was confirmed to some extent by SEM analysis. But to evaluate this hypothesis more fully, additional work beyond the scope of this project is necessary.

Additional Research

To support the hypothesis developed regarding brucite formation, the following work should be done. A hydrogeochemical investigation of the Velsicol waste stream and the Devonian limestone, similar to that of Roy et al. (1989), should be conducted. Core from the DOW could be used in this type of investigation. This type of work would help define the conditions favorable for brucite formation.

APPENDIX D. SENSITIVITY ANALYSIS

A rigorous sensitivity analysis as described by Yeh (1986) was not conducted. The sensitivity analysis conducted for this project involves the variation of significant parameters and the effect of this variation on head buildup (Δh) at the DOW, the parameter of interest. The significance of various parameters (injection rate, hydraulic conductivity, etc.) was observed during the validation and calibration stages of modeling. On the basis of these observations, sensitivity analysis was conducted for the following parameters: boundary conditions, injection rate, rock compressibility, fluid compressibility, hydraulic conductivity, and anisotropy.

Throughout this phase of the project, the same conceptual model as depicted in figure D-1 was used unless otherwise noted. The injection system was modeled using cylindrical coordinates with 60 nodes in the r-direction and 22 nodes in the z-direction. A no-flow boundary condition was applied at the upper and lower boundaries, while an aquifer influence function (AIF) condition was applied at the radial boundary.

Boundary Conditions

Boundary conditions (BC) are the most difficult and critical issue in the development of a conceptual model for a numerical modeling study and must be selected carefully (Franke and Reilly 1987). In all cases, the upper and lower boundaries were modeled as no-flow boundaries.

The type and distance of the radial boundary from the injection well were varied. For the purposes of comparison, VELS14I was considered the baseline run. Five other runs were made in order to note the effect of the boundary condition on head buildup at various locations within the injection system. Table D-1 summarizes the types of boundary conditions and results.

The results of VELS14G2 indicate that the no-flow boundary condition did not cause an increase in head buildup at the DOW during the 14-day period investigated, but a slight increase in Δh occurred at the radial boundary. For VELS14H, the radial boundary is located farther from the injection well than in VELS14G2; no Δh was observed at the radial boundary. These two runs and the other runs of the VELS14 series show that the radial boundary exerted no real influence on the head buildup at the DOW (r = 505.95 m) during the time period investigated.

VELS14I and VELS14I2 indicate the effect of the intrinsic permeability of the aquifer influence region (k_{AIF}). A reduction in k_{AIF} may increase the Δh observed at the radial boundary. Although

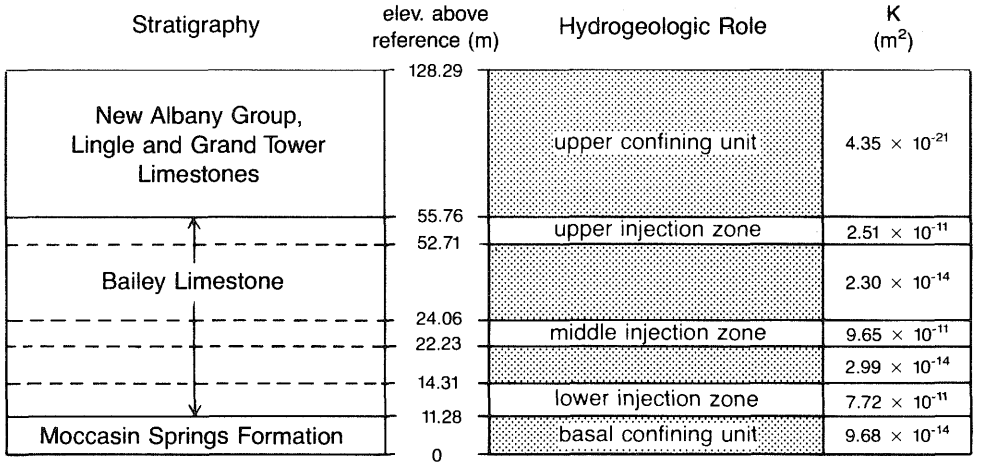

Figure D-1 Conceptual model 1 of the injection system.

Table D-1 Effect of boundary conditions on head buildup

Run	No. of r-nodes	Radius (m)	Type[1] of BC	k_{AIF}[2] (m^2)	Δh @ DOW[3] (m)	Δh @ radial boundary (m)
VELS14I	60	15870.9	AIF	1.00×10^{-11}	1.28	0.01 t = 14.0 days
VELS14G2	60	15870.9	NF	—	1.28	0.02 t = 7.16 days
VELS14H	60	35703.0	NF	—	1.28	0.00 t < 14.0 days
VELS14I2	60	15870.9	AIF	1.00×10^{-12}	1.28	0.02 t = 14.0 days
VELS18H2	60	15870.9	AIF	1.00×10^{-11}	1.25	—
VELS18J	50	2090.8	AIF	1.00×10^{-11}	0.75	—

Notes: (1) AIF = aquifer influence boundary condition; NF = no-flow boundary condition; (2) k_{AIF} = intrinsic permeability of aquifer influence region; (3) all values given at t = 14.00 days.

not shown in Table D-1, if k_{AIF} were reduced, the cumulative fluid outflow via the AIF boundary also would be reduced. In this case, the cumulative fluid outflow across the radial boundary, in terms of the total volume of fluid injected, was reduced from 3.0 percent (VELS14I) to 0.69 percent (VELS14I2) when k_{AIF} was reduced one order of magnitude.

Over longer periods, the radial boundary would certainly influence the head buildup at the DOW. Thus the use of an AIF BC appeared to be a better choice for the radial boundary, especially when the model is used as a tool to predict long-term (30-year) effects of injection upon the system. In addition, the regional hydrogeologic investigation covered a 10-mile (16,000-m) radius from the well; thus use of a radius larger than 10 miles was considered speculative.

Two runs from the VELS18 series are included to show the effect of the position of the AIF BC. The conceptual model for the VELS18 series is more complex than the VELS14 series and includes a thicker sequence of geologic materials (fig. D-2). The results from VELS18H2 are in agreement with VELS14I, allowing for a slightly lower head buildup for VELS18H2 due to the greater thickness of compressible geologic materials. For VELS18J, distance to the radial

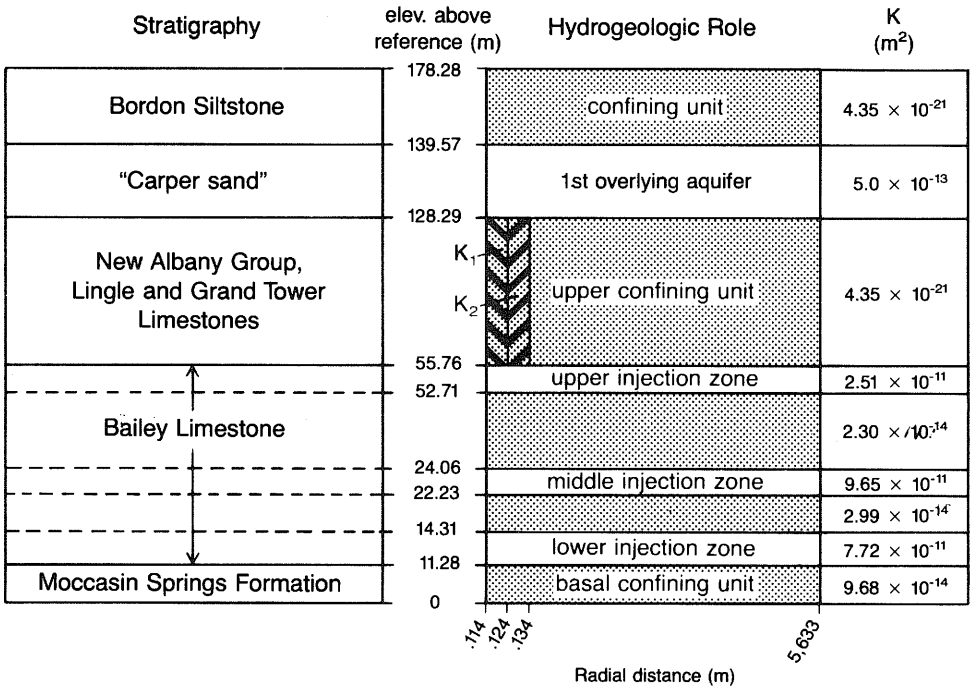

Figure D-2 Conceptual model 2 of the injection system.

boundary was much closer than for VELS18H2. In addition, the head buildup at the DOW was much lower, although k_{AIF} is the same for both runs. For both VELS18H2 and VELS18J, the AIF zone is more transmissive than the inner discretized zone; therefore, decreasing the radial distance of this zone from the injection well allows fluid to move more readily and with less head buildup. The results of VELS18H2 and VELS18J indicate the effect of the location of the boundary and the need to properly define the intrinsic permeability of the aquifer influence region.

Injection Rate

Three runs were made to investigate the effect of the injection rate upon head buildup at the DOW. VELS14I ($q = 1.820 \times 10^{-2}$ m^3/sec) is the baseline run. For VELS15A, the injection rate was increased 10 percent, $q = 2.00\ 2 \times 10^{-2}$ m^3/sec. For VELS15B, the injection rate was decreased 10 percent to 1.638×10^{-2} m^3/sec. Figure D-3 shows the Δh at the DOW with time. Increasing the q by 10 percent resulted in a 10.2-percent increase in Δh. The increase in Δh was noticeable after several hours of injection. In a similar fashion, a 10-percent reduction in the injection rate resulted in a 9.4-percent decrease in Δh. This decrease was also noticeable after several hours of injection. Round-off error for the percentage increase/decrease of Δh was responsible for these values not being equal and the deviation of these values from 10 percent as predicted by Darcy's Law.

Rock Compressibility

Storativity may be defined according to the following equation (Lohman 1972).

$$S = n\gamma b(\beta + \alpha/n) \qquad [D\text{-}1]$$

where S = storativity (-)
n = porosity (-)
γ = unit weight of fluid (kg/m^3)
b = aquifer thickness (m)
β = fluid compressibility (Pa^{-1})
α = rock compressibility (Pa^{-1})

Rock compressibility (α) is one of two major components of storativity. For HST3D, Kipp (1987) indicated that it is more convenient to use rock and fluid compressibility than a storativity term, since fluid density (i.e., unit weight) may be variable.

Three runs were used to investigate the effects of rock compressibility. VELS14I was the baseline run with $\alpha = 4.50 \times 10^{-10}$ Pa^{-1}. For VELS15C, rock compressibility was reduced 10 percent to $\alpha = 4.05 \times 10^{-10}$. For VELS15D, α was increased 10 percent, $\alpha = 4.95 \times 10^{-10}$. Figure D-4 shows the results of the runs. Decreasing α by 10 percent resulted in a 1.6-percent increase in Δh at the DOW. Similarly, a 10-percent increase in α resulted in a 1.6-percent decrease in Δh. The increase and decrease in Δh were evident after several hours of injection.

Fluid Compressibility

Fluid compressibility (β) is the other major component of storativity. VELS14I, VELS15G, and VELS15H were used to investigate the effect of varying fluid compressibility on the head buildup at the DOW. For VELS14I, $\beta = 4.00 \times 10^{-10}$ Pa^{-1}. A 10-percent reduction in β was used for VELS15G, $\beta = 3.60 \times 10^{-10}$. For VELS15H, β was increased to $\beta = 4.40 \times 10^{-10}$.

Figure D-5 shows the results from these runs. Decreasing β did not cause any change in Δh. Increasing β produced a negligible change in Δh, which was probably due to round-off error. The lack of sensitivity of Δh to β can easily be explained. Referring back to equation D-1, one can see that S is proportional to the quantity $(\beta + \alpha/n)$. For the situation investigated here, α/n was approximately 8 times larger than β; thus minor changes in β did not affect S and did not affect Δh.

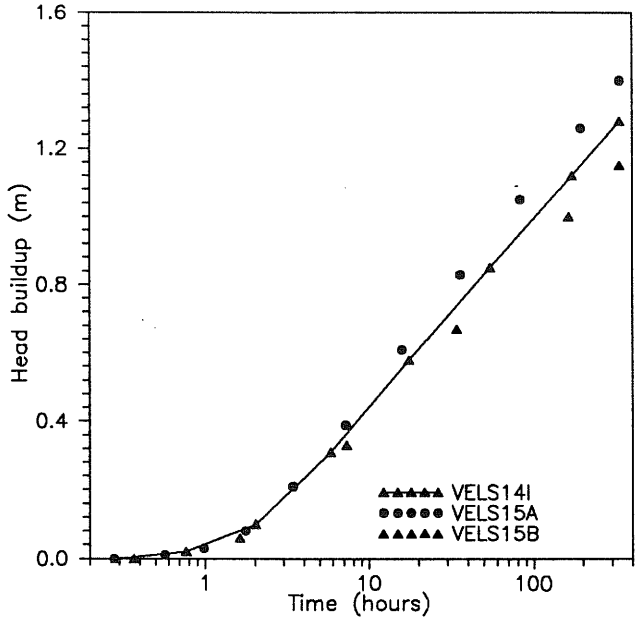

Figure D-3 (left) Sensitivity analysis: effect of injection rate.

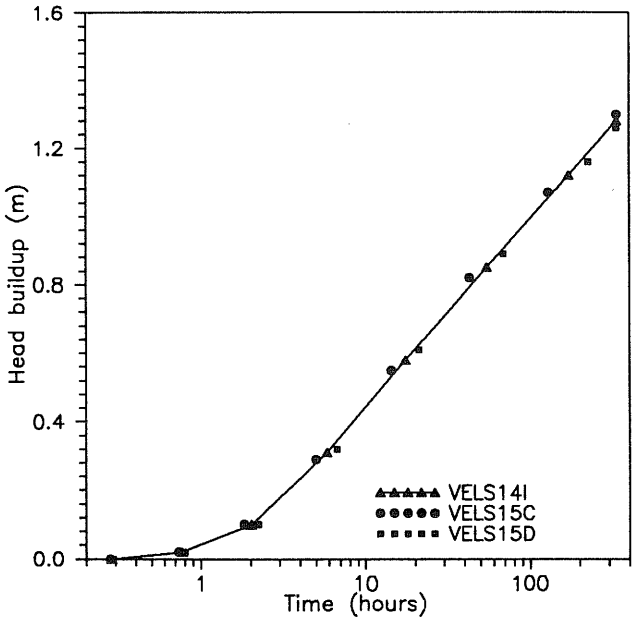

Figure D-4 Sensitivity analysis: effect of rock compressibility.

Hydraulic Conductivity

The results from VELS14I, VELS15I, and VELS15J were used to demonstrate the effect of hydraulic conductivity on Δh. For VELS15I, the hydraulic conductivity of each of the 7 layers was reduced by 10 percent, compared with the hydraulic conductivity values used for VELS14I. Similarly, the hydraulic conductivity values used in VELS15J were all increased by 10 percent.

Figure D-6 shows the results for all runs. As expected, decreasing the hydraulic conductivity resulted in an increase in Δh observed at the DOW. A 10-percent decrease in hydraulic conductivity resulted in a 9.4-percent increase (within round-off error of 10 percent) in Δh at the DOW. Increasing the hydraulic conductivity by 10 percent caused only a 7-percent decrease in Δh at the DOW. The deviation of this value from 10 percent, as predicted by Darcy's Law, is due to the K_{AIF}. The K_{AIF} for VELS15J was not increased from the value used for VELS14I, causing the head build-up within the inner aquifer region to be higher than anticipated.

Anisotropic Conditions

To this point, isotropic conditions have been assumed. On the basis of the hydrogeologic and geophysical tests conducted at the site during the project, it was not possible to establish the predominance of isotropic or anisotropic conditions. Thus, this series of runs was conducted to investigate the effect of this assumption.

Two runs were used to investigate this effect, VELS14I and VELS15K. Isotropic conditions (i.e., $k_r/k_z = 1$) were assumed for VELS14I. For VELS15K, k_z was decreased so that k was 10 times greater in the radial direction than in the vertical direction (i.e. $k_r/k_z = 10$). Figure D-7 indicates that under anisotropic conditions, Δh observed at the DOW was lower by approximately 2 percent than under isotropic conditions. Thus, if the assumption of isotropic conditions is not correct, the hydraulic conductivity of the geologic materials determined during model calibration may need to be reduced by nearly 2 percent.

Summary of Sensitivity Analysis

On the basis of the preceding sensitivity analysis, injection rate and hydraulic conductivity were the most sensitive input parameters. That is, a given change in injection rate or hydraulic conductivity produced the largest change in Δh observed at the DOW. The type of boundary condition and the location of the boundary can also have a significant effect on the head buildup predicted by the model. In decreasing order, the most sensitive parameters were injection rate and hydraulic conductivity, rock compressibility, anisotropy, and fluid compressibility.
